(c) Reduction in Ether at Reflux Temperature (Entry 3). To a vigorously stirred suspension of $LiAlH_4$ (31 mg, 0.82 mmol) in ether (0.5 ml) was added dropwise a solution of **4** (16 mg, 0.047 mmol) in ether (1.5 ml). The reaction mixture was heated under reflux for 3 h. After workup as described above, the crude product was subjected to column chromatography on silica gel [2 g, benzene–acetone (4:1→3:1)] to give **5** (7.2 mg, 44%), **6** (5.1 mg, 32%), and hemiacetal **9**[5] (2.2 mg, 13%) as a colorless oil, respectively.

9: IR ($CHCl_3$) 3600, 3450, 1480, 1385, 1085, and 1010 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz; signals for the major diastereomer) δ=1.02 (3H, d, *J*=6.9 Hz), 1.28 (3H, s), 1.56 (3H, s), 1.60 (3H, s), 1.88 (1H, ddd, *J*=15.8, 12.2, 8.2 Hz), 2.02 (1H, ddd, *J*=15.8, 8.5, 2.0 Hz), 2.08 (1H, dd, *J*=15.2, 4.9 Hz), 2.24 (1H, d, *J*=15.2 Hz), 2.20—2.35 (1H, m), 2.50—2.80 (1H, m, –OH), 3.52—3.70 (3H, m; 2H, m on addition of D_2O), 3.80 (1H, d, *J*=13.2 Hz), 3.93 (1H, d, *J*=13.2 Hz), 4.33 (1H, d, *J*=13.2 Hz), 4.58 (1H, br s), 4.65—4.80 (1H, m, –OH), 4.89 (1H, br s, –OH), and 5.13 (1H, dd, *J*=8.2, 2.0 Hz); EIMS *m/z* (rel intensity) 344 (M^+, 2), 326 (15), 311 (22), and 255 (100). HREIMS. Found: *m/z* 326.1733. Calcd for $C_{17}H_{26}O_6$: $M-H_2O$, 326.1730.

(d) Reduction in Ether at −20 °C (Entry 4). Reduction of **4** (43 mg, 0.13 mmol) with $LiAlH_4$ (1.3 mmol) was performed in ether at −20 °C for 3 h. After workup as described above, the crude product was subjected to column chromatography on silica gel [5 g, benzene–acetone (10:1→6:1→4:1)] to give **7** (4.3 mg, 10%; characterized as **8**), **9** (26 mg, 60%), and lactone **10** (9.1 mg, 21%) as a colorless oil, respectively.

10: $[\alpha]_D^{21}$ −85.4° (*c* 0.856, MeOH); IR ($CHCl_3$) 3600, 3460, 1735, 1455, 1385, and 1040 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.21 (3H, d, *J*=6.9 Hz), 1.30 (3H, s), 1.56 (3H, s), 1.63 (3H, s), 1.60—1.70 (1H, m), 1.90 (1H, dd, *J*=14.5, 6.2 Hz), 2.20 (1H, dd, *J*=11.6, 2.7 Hz), 2.28 (1H, dd, *J*=11.6, 2.7 Hz), 2.41 (1H, dq, *J*=6.2, 6.9 Hz), 2.82—2.95 (1H, m, –OH), 3.48—3.60 (1H,

m), 3.76 (1H, dd, J=2.7, 2.7 Hz), 4.33 (1H, d, J=13.2 Hz), 4.43 (1H, d, J=11.9 Hz), 4.63 (1H, d, J=11.9 Hz), 4.78 (1H, br s, -OH), and 4.98 (1H, d, J=7.9 Hz); EIMS m/z (rel intensity) 342 (M^+, 60), 327 (81), 324 (40), 298 (46), and 294 (100). HREIMS. Found: m/z 342.1661. Calcd for $C_{17}H_{26}O_7$: M, 342.1678.

Oxidation of Hemiacetal 9 to Lactone 10. A mixture of **9** (27 mg, 0.079 mmol), I_2 (209 mg, 0.83 mmol), and $CaCO_3$ (252 mg, 2.52 mmol) in 50% H_2O–MeOH (2 ml) was stirred at 50 °C for 3 d in the dark. After cooling, the reaction mixture was filtered through a pad of Celite. The filter cake was washed thoroughly with MeOH. The filtrate and washings were combined and the solution was concentrated under reduced pressure. The residue was dilute with H_2O (5 ml) and extracted with EtOAc (4×5 ml). The combined organic layers were washed with saturated $Na_2S_2O_3$ solution and saturated NaCl solution, dried, and concentrated under reduced pressure. The crude product was purified by column chromatography on silica gel [1 g, benzene–acetone (8:1→4:1→1:1)] to give **10** (21 mg, 78%) along with the recovered **9** (2.8 mg, 10%).

Conversion of Lactone 10 into Lactone 2. A mixture of **10** (45 mg, 0.13 mmol), 2-methoxypropene (15 mg, 0.21 mmol), and (+)-10-camphorsulfonic acid (3 mg, 0.013 mmol) in benzene (3.5 ml) was stirred at room temperature for 2 h. The reaction was quenched by the addition of 2 drops of pyridine and the mixture was concentrated under reduced pressure. The residue was subjected to column chromatography on silica gel [2 g, benzene–acetone (20:1→1:1)] to give **2** (45 mg, 90%) as an amorphous solid: $[\alpha]_D^{21}$ +14.5° (c 0.444, $CHCl_3$) [synthetic **2**,[3] $[\alpha]_D^{21}$ +14.8° (c 0.446, $CHCl_3$)]; IR ($CHCl_3$) 3500, 1770, 1450, and 1380 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.03 (3H, d, J=6.6 Hz), 1.32 (3H, s), 1.33 (3H, s), 1.52 (3H, s), 1.53 (3H, s), 1.56 (3H, s), 1.91 (1H, dd, J=12.8, 5.0 Hz), 2.22 (1H, dd, J=12.5, 5.3 Hz), 2.28 (1H, dd, J=12.8, 6.2 Hz), 2.32—2.47 (1H, m), 2.58 (1H, d, J=12.5 Hz), 3.25 (1H, br s, -OH), 3.55 (1H, d, J=13.2 Hz), 3.99 (1H, d, J=13.2 Hz), 3.98 (2H, s), 4.23 (1H, d, J=5.3 Hz), and 5.28 (1H, d, J=6.2 Hz); EIMS m/z (rel intensity) 382 (M^+, 1), 367 (100), 324 (87), 306 (41), and 279 (84). HRCIMS. Found: m/z 383.2069. Calcd for $C_{20}H_{31}O_7$: M+H, 383.2070.

Synopsis. Infrared NH stretching absorptions and ^{1}H NMR chemical shifts of a series of 4-(haloacetylamino)diphenylamines were reported. The halogen atoms in haloacetamido groups are shown to participate in the intramolecular NH···X hydrogen bond. The hydrogen bond tends to be strengthened in the increasing order of atomic number of the acceptor halogen atoms.

The conformations of the molecules of pharmaceutical interest are often perturbed by intramolecular hydrogen bonding. Thus the hydrogen bonding sometimes affects the biological activity. Previously the authors had determined conformations of a series of substituted salicylanilides by infrared spectroscopy and found a correlation between the preference to the hydrogen-bonded conformation and the antibacterial activities.[1] In this connection, intramolecular hydrogen bonding of a series of 4-(haloacetylamino)diphenylamines were characterized by infrared and NMR spectroscopy in search for the structure-activity correlation.

Results and Discussion

The infrared NH and C=O absorptions, as well as the chemical shifts of NH protons, are given in Table 1. Parent 4-(acetylamino)diphenylamine has two NH stretching absorptions at 3448 and 3430 cm^{-1}. These bands were assigned to the amide and diphenylamine NH groups, respectively, by comparing to the NH absorptions of several reference compounds.[2,3] ^{1}H NMR spectra in chloroform-*d* also showed to NH signals. The one at the higher field appears at around 5.5 ppm and assigned to the NH group in diphenylamine structure. The assignment was certified by showing that the signal shifts down-field when a nitro group was introduced at the ortho position.[4] The signal at the lower field (appearing at 7.25 ppm in the spectrum of 4-acetyldiphenylamine) was assigned to the NH group of secondary amide.

The low frequency shift of the amide NH stretching absorption was observed when a halogen substituent was introduced on the acetyl group, which suggests the presence of intramolecular hydrogen bonding. Formation of the five-membered hydrogen bonded chelate ring can be expected to cause a low frequency shift of the NH band to a varying degree dependent on the hydrogen accepting ability of halogen atom (X). Hydrogen bond including fluorine atom as a hydrogen acceptor is generally weak, resulting the least low

Table 2. Hydrogen Bond Shifts in The N–H···X Hydrogen Bonds

X	F	Cl	Br	I
$\Delta\nu/cm^{-1}$	17	36	45	52
$\Delta\delta$/ppm	0.59	0.87	0.78	0.41

frequency shift of amide NH band. Hydrogen bond shift ($\Delta\nu_{NH}$) increases in the increasing order of atomic number; i.e., F<Cl<Br<I (Table 2), which suggests the major contribution of polarizability effect. In other words, the $\Delta\nu$ is controlled by the strength of the N–H bond, which comes from the contribution of charge-transfer resonance structure (**2b**). The secondary amide moiety of the intramoecularly hydrogen-bonded conformer is enforced to take a trans geometry as depicted by **1**. The trans conformer usually absorbs in the frequency region higher than 3640 cm^{-1} (3480—3440 cm^{-1}) in contrast to the cis absorption in the lower frequency region (3435—3395 cm^{-1}).[5] Thus the NH absorption at 3448 cm^{-1} of 4-(acetylamino)diphenylamine showed the fact that it takes a trans conformation preferably. The carbonyl stretching absorptions at relatively high frequencies supported the trans-conformation in the *o*-haloacetyl derivatives.[6]

(Formula of the hydrogen-bonded conformation **1**)

N–H :X
(**2a**)

N:⁻ H–X⁺
(**2b**)

The ^1H NMR spectra also support the intramolecularly hydrogen-bonded conformation (**1**), showing considerable low field shifts of amide NH signals. The hydrogen bond shift ($\Delta\delta$) increases in the following order of halogen substituent: I<F<Br<Cl. The sequence of $\Delta\delta$ is quite different from that of infrared $\Delta\nu$. The hydrogen bond shifts ($\Delta\delta$) of NH proton chemical shifts should be controlled by the electron density plus charge displacement effects, which can be evaluated by the second and the first terms of Buckingham's equation ($\sigma_E=-2\times10^{-12}E_z+10^{-18}E^2$). Thus the electronegativity effect might affect the chemical shift considerably in addition to the delocalization effect. As a result of two opposite effects the NH protons of chloroacetanilides resonate at the lowest fields. In short, the two hydrogen bond shifts $\Delta\nu$ and $\Delta\delta$, some from different origins.

The strength of hydrogen bonding can be more properly evaluated by using the infrared hydrogen bond shift ($\Delta\nu$) as a measure. Since antibacterial activity can be governed by the nature of halogen atoms as is the case of hydrogen bonding, we could not conclude very definitely, but the general tendency that the strength of intramolecular hydrogen bond is in line with the inverse of minimal inhibitory concentration[7] was observed. Thus the possible contribution of the intramolecular hydrogen bonding to the activity was suggested by this research.

The authors thank Dr. Kazuhisa Sakakibara, Yokahama National University, for his valuable discussion throughout this work. This work was supported in part by the Grant-in-Aid for Scientific Research on Priority Areas No. 01648001 from the Ministry of Education, Science and Culture.

(Received May 1, 1991)

Synopsis. Various 3,3′-methylenebisazulenes were prepared in high yields upon treatment of 1-substituted azulenes with a solution of 0.1—0.2 wt% paraformaldehyde in glacial acetic acid at 25 °C for 1 h. Thus, 1-methyl-, 1-isopropyl-, 1,5-diisopropylazulene, guaiazulene, and methyl 2-hydroxy-1-azulenecarboxylate readily provided the corresponding 3,3′-methylenebisazulenes, respectively. Acetic acid which had been refluxed with 5 wt% $KMnO_4$ for 2 h and then distilled according to a purification method was found to contain 0.1—0.2 wt% formaldehyde and exert the same 3,3′-methylenebisazulene formation. 3,3′-Dideuteriomethylenebis(guaiazulene) was obtained by employing the similar distillate from acetic acid-d_4.

For the past several years, we have undertaken a systematic investigation on autoxidation of various azulenes in detail.[2)] We found that naturally originating 3,3′-methylenebis(guaiazulene) (**9**)[3)] and synthetic 3,3′-methylenebis(1,5-diisopropylazulene) (**8**), for example, gave various kinds of azulenylbenzofulvenes by autoxidation.[4,5)] Oxidation of **9** with peracetic acid has also been conducted recently, and a wide variety of azulenylbenzofulvenes and their precursors were isolated.[6)] Our interest in the physicochemical properties and biological activity of azulenylbenzofulvenes in general necessitated establishing an efficient preparative method of various 3,3′-methylenebisazulenes which in turn are expected to serve as effective intermediates for synthesis of the desired fulvenes. We wish to describe herein our results.

We employed the following 1-substituted azulenes as model substrates: 1-methylazulene (**1**), 1-isopropylazulene (**2**), 1,5-diisopropylazulene (**3**), guaiazulene (**4**), and methyl 2-hydroxy-1-azulenecarboxylate (**5**). When these compounds were treated, at 25 °C for 1 h, with a freshly prepared glacial acetic acid solution containing 0.1—0.2 wt% paraformaldehyde, we found that the corresponding 3,3′-methylenebisazulenes **6**,[7)] **7**,[8)] **8**,[5)] **9**,[9)] and **10** were best obtained (see Chart 1). Structure of the previously unknown product **10** was established on the basis of spectroscopic data (see the Experimental section). Compounds **6**—**9** had been obtained either during an attempted preparation of 3-hydroxymethylazulene derivatives or by autoxidation of the monomeric azulenes; in all cases the yields were moderate to low.

During this investigation we attempted to purify acetic acid by refluxing with 5 wt% potassium permanganate for 2 h, followed by distillation according to a standard procedure.[10)] On dissolving azulenes **1**—**5** in the above acetic acid distillate and allowing to stand at 25 °C for 1 h, we obtained 3,3′-methylenebisazulenes **6**—**10** in almost the same yields as in the case of using the paraformaldehyde solution. The analysis of the acetic acid distillate by the use of GLC and GC-MS spectrometry as well as chemical reaction with *p*-toluenesulfonohydrazide[11)] revealed that it contained 0.1—0.2 wt% formaldehyde.[12)] Commercially unavailable formaldehyde-d_2 (0.1—0.2 wt%) can therefore be prepared by the above distillation procedure with acetic acid-d_4. 3,3′-Dideuteriomethylenebis(guaiazulene) (**11**) was thus efficiently prepared in 95% yield by the present method.

The most plausible reaction pathways for the formation of formaldehyde liberated from acetic acid by the purification method[10)] and of 3,3′-methylenebisazulenes

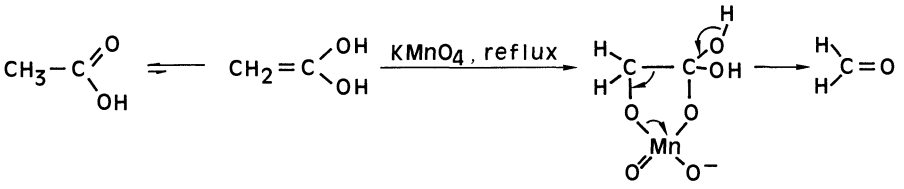
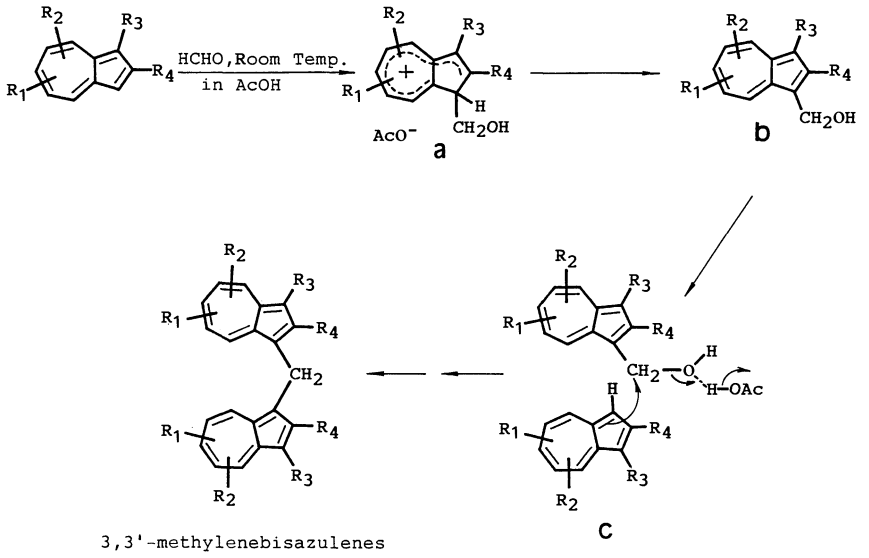


Scheme 1. A possible reaction pathway for the formation of formaldehyde present in the acetic acid distillate.



Scheme 2. A possible reaction pathway for the formation of 3,3′-methylenebisazulenes **6**—**10** from azulenes **1**-**5** and formaldehyde in acetic acid.

6—**10** from azulenes **1**—**5** are illustrated in Schemes 1 and 2, respectively. Extension of the present method to azulene itself and some other substrates is under intensive investigation.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. GLC analysis of the acetic acid distillate was conducted with a YANACO G2800 gas liquid chromatograph system equipped with a HFID (hydrogen flame ionization detector) and a PEG 20M glass-capillary column (ϕ 0.28 mm×20 m, column temp 40—180 °C/2 °C-min^{-1}).

The UV and IR spectra were taken on a Hitachi 323 spectrophotometer and a JASCO IR-A-202 Grating spectrometer, respectively. Mass spectra were taken on a JEOL JMS-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument and are given in terms of m/z (rel intensity) compared with the base peak. The ^{1}H NMR spectra were recorded in $CDCl_3$ with a JEOL FX-200 (200 MHz) cryospectrometer at 27 °C. The assignments of all singals were made by employing a first-order analysis with the aid of decoupling technique and were confirmed by a computer-assisted simulation analysis.

Preparation of 3,3′-Methylenebisazulenes (6—11). To a solution of paraformaldehyde (0.1—0.2 wt%) in acetic acid (12 ml) was added 100 mg each of 1-methylazulene (**1**), 1-isopropylazulene (**2**), 1,5-diisopropylazulene (**3**), guaiazulene (**4**), and methyl 2-hydroxy-1-azulenecarboxylate (**5**).[13] The mixture was stirred at 25 °C for 1 h under nitrogen. The precipitated 3,3′-methylenebisazulenes **6**—**10** were filtered off, washed carefully with water, and dried in a vacuum desiccator, affording pure products **6**—**10** (70—80% yields). Each of the filtrates was carefully neutralized with aq Na_2CO_3 and extracted with ether (3×30 ml). The extract was washed with water, dried (Na_2SO_4), and evaporated in vacuo, giving additional pure 3,3′-methylenebisazulenes **6**—**10** (20—25% yields). Compounds **6**—**10** were also obtained from **1**—**5** in almost the same yields by the treatment with acetic acid distillate (see later).

Previously Known Compounds: Compounds **6** (96% yield),[7] **7** (97%),[8] **8** (96%),[5] and **9** (95%)[9] were identified either by comparison of their melting points, UV-vis, ^{1}H NMR, and EI MS spectral data with those of authentic 3,3′-methylenebisazulenes.

(2H, s, OH-2,2′); EI MS *m/z* 416 (M^+; 47%), 384 (5), 352 (100), 323 (23), 307 (6), 296 (7), 268 (7), 239 (22), 215 (34), 202 (7), 183 (52), 176 (34), 170 (30), 156 (5), 142 (5), 127 (5), 119 (18), 114 (7), and 106 (4). Found: *m/z* 416.1243. Calcd for $C_{25}H_{20}O_6$: M, 416.1260.

3,3-Dideuteriomethylenebis(guaiazulene) (11). This was prepared from **4** upon treatment, at 25 °C for 1 h, with the distillate obtained from acetic acid-d_4 (see below): Dark blue prisms; 98 mg (95%); mp 186 °C; ^{1}H NMR δ=1.34 (12H, d, *J*=7.0 Hz, *i*-Pr-7,7′), 2.52 (6H, s, Me-1,1′), 2.92 (6H, s, Me-4,4′), 3.00 (2H, sept, *J*=7.0 Hz, Me_2CH-7,7′), 6.77 (2H, d, *J*=11.0 Hz, H-5,5′), 7.08 (2H, s, H-2,2′), 7.22 (2H, dd, *J*=11.0, 2.0 Hz, H-6,6′), and 8.03 (2H, d, *J*=2.0 Hz, H-8,8′); EI MS *m/z* 410 (M^+; 52%), 395 (11), 367 (3), 212 (38), 205 (10), 198 (100), 183 (27), and 167 (5). Found: *m/z* 410.2940. Calcd for $C_{31}H_{34}D_2$: M, 410.2943.

Preparation of Acetic Acid Distillate. The acetic acid distillate was obtained according to the general distillation procedures of acetic acid.[10] Namely, acetic acid (1.0 kg) was refluxed with 5 wt% potassium permanganate (50 g) for 2 h and then fractionally distilled (bp 117—118 °C). Similarly, acetic acid-d_4 (100 g) was refluxed with 5 wt% potassium permanganate (5 g) for 2 h and distilled (bp 114—115 °C).

We are grateful to Professor Masafumi Yasunami (Tohoku University) for a generous gift of 1-methyl-, 1-isopropyl-, and 1,5-diisopropylazulene and to Konan Kako Co. (Osaka) for guaiazulene.

Apparent Molal Volumes of Urea and Its Derivatives in Aqueous Alkali Chloride Solutions

Toshio OGAWA,* Kiyoshi MIZUTANI, Yukimi ANDO,† and Motoo YASUDA
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464-01
(Received March 22, 1991)

The apparent molal volumes (ϕ_v) at 25 °C have been measured for the following urea derivatives in aqueous alkali chloride solutions (from density measurements) using a digital densimeter: urea, methylurea, ethylurea, 1,1-dimethylurea, 1,3-dimethylurea, 1,1-diethylurea, and 1,3-diethylurea. The limiting values (ϕ_v°) were obtained by a linear extrapolation using the least-squares method. A notable feature of the transfer volumes found in this study was that hydrophobic urea derivatives, such as dimethylureas and diethylureas, had negative values for transfer from water to lithium chloride solutions. For the remainder, however, all transfer volumes were positive.

In a previous paper,[1] we reported on the apparent molal volumes of urea derivatives measured in several water–methanol mixtures. Due to abnormalities of the water–methanol mixtures regarding their properties, such as viscosity–composition and ultrasonic velocity–composition relationships, each plot of ϕ_v° vs. X_2, mole fraction of methanol, showed a minimum at a lower methanol concentration where the solvent is more structured than the water itself, except for unsubstituted urea which had no minimum.

The volumes of transfer from water to a more structured solvent for the more hydrophobic urea were more negative. On the other hand, the reverse order was observed for those from water to methanol, a less structured solvent than water.

Though the properties of the lithium ion are somewhat different from those of the other alkali ions, volume data measured in aqueous lithium salt solutions have been rather few. We have felt that it would be very interesting to know, particularly, the interactions between lithium ions and a hydrophobic solute. We thus determined the apparent molal volumes of urea and its derivatives in an H_2O–MCl mixed solvent (M=Li, Na, and K) from density measurements. Since the limiting values (ϕ_v°) are determined mainly by the respective intrinsic volume of the solute and the solute–solvent interactions, they can provide useful clues regarding solute–solvent interactions. In the present work the densities were measured at 25 °C for the urea (alkylurea)–alkali chloride–water ternary system at various concentrations. The alkali chloride was thought of as being a co-solvent; in other words, an aqueous alkali chloride solution was considered to be a "solvent". We used 0.5, 1, and 2 molal solutions for each of three chlorides as solvents in this study. For the 1 and 2 molal solutions, the adiabatic compressibilities of the "solvent" were determined in order to find the relationship between the adiabatic compressibility of the "solvent" and the apparent molal volume of the urea obtained in it.

† Present address: 292 Sunouchi-kou, Saijo, Ehime 793.

Experimental

The alkali chlorides used in this study were of guaranteed reagent grade from Wako Chemical Industries, Ltd., and were used without any further purification, except for lithium chloride which was used after drying for several hours at ca. 150 °C. As for urea and its alkyl derivatives, the same reagents were employed as in the previous study, some of them being recrystallized from a suitable solvent.[1]

All urea derivative solutions were prepared by weight in the concentration range 0.1—1.0 mol kg^{-1} (the number of moles of urea derivative per kg of the mixed solvent whenever the mixed solvents were used), except for the more hydrophobic urea derivatives; these urea derivatives measurements were carried out below 0.5 mol kg^{-1}, as mentioned below. The density and ultrasonic velocity measurements have been described previously.[2] The temperature control of the thermostated bath system for the densimeter was better than ±0.005 °C

Results

The apparent molal volumes of the urea derivatives were obtained by using

$$\phi_v = \frac{M}{d} + \frac{1000\,(d_o - d)}{m d_o\, d}, \quad (1)$$

where M is the molecular weight of the urea; m, its molal concentration; and d_o and d, the densities of the solvent and the solution, respectively. The data were fitted to the equation

$$\phi_v = \phi_v^\circ + S_v m, \quad (2)$$

where ϕ_v° is the infinite-dilution apparent molal volume and S_v is the experimental slope. Although the apparent molal volumes of nonelectrolytes in dilute solutions, below 1.0 mol kg^{-1} are commonly expressed as in Eq. 2, those for the more hydrophobic urea derivatives studied in alkali chloride solutions deviate from Eq. 2, even at such low concentrations as ca. 0.5 mol kg^{-1}. The limiting apparent molal volumes of 1,3-dimethylurea (1,3-DMU) and 1,3-diethylurea (1,3-DEU) were thus calculated using data for a concentration range of ca. 0.1—0.5 mol kg^{-1}. This is discussed later.

Table 1. Limiting Apparent Molal Volumes in Aqueous Alkali Chloride Solutions

Solvent	ϕ_v° / cm^3 mol^{-1}						
	U	UM	1,1-DMU	1,3-DMU	EU	1,1-DEU	1,3-DEU
H_2O	44.24	62.40	78.53	80.32	79.26	111.63	113.74
0.5m LiCl	44.52	62.46	78.55	80.27	79.29	111.92	113.66
1.0m LiCl	44.80	62.63	78.46	80.16	79.36	111.67	113.47
2.0m LiCl	45.14	62.64	78.45	80.00	79.28	111.19	112.96
0.5m NaCl	44.63	62.62	78.83	80.45	79.52	112.09	113.86
1.0m NaCl	45.08	62.90	78.86	80.59	79.80	112.31	114.02
2.0m NaCl	45.44	63.10	79.08	80.75	80.06	112.47	114.13
0.5m KCl	44.63	62.59	78.77	80.43	79.52	112.16	113.95
1.0m KCl	45.00	62.93	78.91	80.55	79.79	112.54	114.08
2.0m KCl	45.37	63.13	79.16	80.72	80.00	112.64	114.17

Table 2. Adiabatic Compressibilities of Aqueous Alkali Halide Solutions

Solution	β_s / $10^{-4}\times$bar^{-1}
H_2O	4.477
1m LiCl	4.075
2m LiCl	3.750
1m NaCl	3.979
2m NaCl	3.588
1m KCl	4.015
2m KCl	3.660

Table 1 shows the limiting values (ϕ_v°) caluculated by a linear extrapolation (Eq. 2) using the least-squares method. In this Table, U, MU, 1,1-DMU, EU, 1,1-DEU denote urea, methylurea, 1,1-dimethylurea, ethylurea, and 1,1-diethylurea, respectively. In aqueous sodium and potassium chloride solutions the values of ϕ_v° of all urea and its derivatives studied here are larger than those measured in pure water, as can be seen from Table 1. On the other hand, in aqueous lithium chloride solutions some urea derivatives have negative transfer volumes. These are well known to be hydrophobic in nature.

The adiabatic compressibilities, β_S (bar^{-1}), of the "solvent" were calculated in order to determine the correlation with ϕ_v° using Eq. 3, where u is the velocity of sound (m s^{-1}) in the solvent. The density is expressed in g cm^{-3}.

$$\beta_s=\frac{1000}{d_o\, u^2}. \tag{3}$$

The obtained values are given in Table 2; this subject will be further discussed later.

Discussion

The transfer volumes for the studied urea derivatives show that they increase in the following order:

$$Li^+ < K^+ \approx Na^+.$$

Until now, we have reported the transfer volumes of some amino acids[3] and polyalcohols[4] from water to aqueous alkali chloride solutions. The order of increasing transfer volume for these solutes was

$$Li^+ < K^+ < Na^+.$$

In the case of urea derivatives, there are no strong interactions, such as in the case of amino acids, with both the cations and anions in a mixed solvent; the absolute magnitudes of the transfer volumes are thus very small compared with those for amino acids. The lithium ion has the smallest value in each sequence; the sequence for the amino acids has been discussed by us previously.[3] While all transfer volumes were positive regarding hydrophilic solutes, such as amino acids and polyalcohols, those of the more hydrophobic urea derivatives to aqueous LiCl solutions have a negative sign.

The apparent molal volumes of tetrabuthylammonium bromide have been measured by Desrosiers and Desnoyers in aqueous solutions of NaF, NaCl, NaAc, and NH_4Ac at 25 °C[5]. Since Bu_4NBr is dilute, but not the added electrolyte, they corrected the volume data for long-range coulombic forces in order to obtain more specific noncoulombic interactions between the solute and the mixed solvent. The observed transfer volumes from water to the electrolyte solutions, corrected for the Debye-Hückel interactions, were all negative at low concentrations. The same had been observed for the sign of the transfer volume of hydrophobic nonelectrolytes, such as argon and methane,[6] from water to aqueous electrolyte solutions. They thus concluded that the noncoulombic interactions between hydrophobic and hydrophilic ions resulted in negative contributions to the volumes. In this study, since the urea derivatives were used as solute nonelectrolytes, no long-range coulombic interactions existed between the solute and alkali chloride in the "solvent"; thus, no corrections for the Debye-Hückel interactions were necessary. As mentioned above, the more hydrophobic urea derivatives have negative transfer volumes only from water to an aqueous LiCl solution; this is in contrast to the most hydrophobic solutes, for example Bu_4NBr and argon, which have negative transfer volumes from water to

aqueous NaCl and KCl solutions. Thus, the transfer volumes from water to electrolyte solutions corrected for the Debye–Hückel interactions may be used as a measure of the hydrophobicity of the solute.

The reason for the deviation in the ϕ_v data for 1,3-DMU and 1,3-DEU from Eq. 2 at low concentrations, (mentioned above) may be explained by the hydrophobicity of these solutes. In an aqueous alkali chloride solution a considerable number of water molecules are firmly combined to the alkali cations and chloride anions, so that it is likely that the concentration of the solute urea derivative virtually increases and an interaction between them (the so-called hydrophobic interaction) may result at an appreciably low solute concentration. As a result, Eq. 2 can be fitted to the data only below ca. 0.5 mol kg^{-1}. In this connection, it was reported by Wen and Saito that plots of ϕ_v *vs.* c for hydrophobic solutes, such as tetrapropylammonium and tetrabutylammonium bromides, go through a minimum at around 1 mol kg^{-1} at 15, 25, and 35 °C and then turn upward.[7] They considered this phenomenon to be related to a strong structual influence of large tetraalkylammonium salts upon water, and described by the "formation of a clathrate-like structure". Further, the such terms as the iceberg effect,[8] increase of ice-likeness,[9] and tightening of hydrogen bonds of water molecules[10] have been used to describe the structual influence.

The apparent molal volumes of urea were determined in several nonaqueous solvents as functions of the temperature by Hamilton and Stokes.[11]. They pointed out that one noteworthy feature was the large variation in the limiting apparent molal volumes with a solvent, from 37 cm^3 mol^{-1} in methanol to 45 cm^3 mol^{-1} in formamide, the latter figure being close to the molar volume of solid urea. They found that of such properties as the cohesive energy density, the dielectric constant, the molar volume and the compressibility of the solvent, which might be expected to bear some relation to ϕ_v° the last one had the only clear correlation: ϕ_v° increases as the compressibility of the solvent decreases. Since the compressibility may be regarded as being a measure of the void space in the liquid, they argued that this means that the solute molecule does not have to create a hole for itself that has the full dimentions demanded by its intrinsic size. In this connection it may be interesting to see the relation between the compressibility coefficient of the solvent shown in Table 2 and ϕ_v° of urea measured in it. In this type aqueous electrolyte "solvent", the same rule mentioned by Hamilton and Stokes has held well; ϕ_v° increases as the compressibility of the solvent decreases. This, however, does not apply to such large and hydrophobic urea derivatives as 1,3-DMU and 1,3-DEU.

As reported by us, the assumption regarding the independent solvation of both sides of the urea derivatives produced a good approximation of the molal volumes in water–methanol mixtures in the same way as in pure water and methanol.[1] An inspection of Table 1 shows that this assumption also holds to a good approximation to the apparent molal volumes in aqueous alkali chloride solutions.

In conclusion, the lithium ion shows a special behavior towards a hydrophobic solute. In order to clarify this, however, more data, especially for hydrophobic solutes in aqueous lithium salt solutions, are necessary.

Mercury(6^3P_1)- and Cadmium(5^3P_1)-Photosensitized Decompositions of Tetramethyltin

Shunzo YAMAMOTO,* Satomi INOUE, Yoshimi SUEISHI, and Norio NISHIMURA
Department of Chemistry, Faculty of Science, Okayama University, 3-1-1 Tsushima-naka, Okayama 700
(Received April 19, 1991)

The mercury(6^3P_1)-photosensitized decomposition of tetramethyltin (TMT) has been studied at 120 and 250 °C and at pressures from 10 to 20000 Pa. The gaseous products detected were ethane, methane, and hydrogen. The yields of these products increased linearly with increasing reaction time and light intensity. From the effects of O_2, NO, and H_2 on the yield of ethane, the major primary reactions of the mercury-photosensitized decomposition of TMT were concluded to be processes with an Sn–C bond cleavage. The quantum yields of these products were independent of the TMT pressure at higher pressures than 200 Pa at 120 °C. The quantum yield of ethane was also independent of the TMT pressure, while that of methane increased upon increasing the pressure at 250 °C. The cadmium (5^3P_1)-photosensitized decomposition of TMT has been studied at 280 °C. The detected products were the same as those from the mercury-photosensitized decomposition, although the yield of hydrogen was very small. The pressure dependence of the yields of ethane and methane in the cadmium-photosensitized decomposition was very similar to those in the mercury-photosensitized decomposition of TMT at 250 °C.

Organometallic compounds have been widely used for the development of microelectronic devices. There have been many quantitative studies of the thermal and photochemical decompositions of organometallic compounds in the gas phase. The major primary products of the thermal[1,2] and photochemical[3,4] decompositions of tetramethyltin (TMT) have been reported to be methane and ethane, indicating that the primary process in these decompositions is an Sn–C bond cleavage.

The mercury-photosensitized decomposition of TMT, which apparently has not been studied before, is interesting for a comparison with the mercury-photosensitized decompositions of tetramethyl compounds of other group-14 elements(neopentane (NP),[5,6] tetramethylsilane (TMS),[7,8] and tetramethylgermane (TMG)[9]) which have been quantitatively studied, and also for a comparison with the thermal decomposition and the direct photolysis of TMT. The primary processes in the mercury-photosensitized decompositions of NP, TMS, and TMG have been reported to be C–H bond cleavage; this is clearly different from that in the thermal decomposition and the direct photolysis of TMT.

The present study was undertaken in order to investigate the mercury- and cadmium-photosensitized decompositions of TMT.

Experimental

The mercury-photosensitized reaction of TMT was carried out at 120 and 250 °C in a conventional cylindrical quartz vessel (5 cm long and 4 cm in diameter) fitted with plane quartz windows at each end. Mercury vapor of constant pressure (vapor pressure at room temperature) and volume was admitted into the reaction vessel with various amounts of TMT. In this way the concentration of mercury in the vessel was kept constant irrespective of the TMT pressure and the reaction temperature ($[Hg]=9.3\times10^{-7}$ mol dm^{-3}). A low-pressure mercury lamp (Toshiba Electric Co., germicidal lamp) made of a quartz tube was used. The 184.9 nm resonance line was filtered out by a Vicor filter. The light intensity absorbed by mercury atoms at 253.7 nm was determined by means of *cis*-2-butene actinometry[10] ($I_{abs}=4.5\times10^{-9}$mol s^{-1}).

The cadmium-photosensitized reaction of TMT was carried out at 280 °C in the cylindrical quartz vessel mentioned above. A few small piecies of cadmium metal were placed within the vessel before various amounts of TMT were admitted. A home-made spiral cadmium discharge lamp (filled with about 2700 Pa Ar) made of Pyrex was used. This lamp emits only the resonance line at 326.1 nm. The absorbed light intensity at 326.1 nm was determined by *cis*-2-butene actinometry[11] ($I_{abs}=1.23\times10^{-8}$ mol s^{-1}).

Product analysis was carried out by fractionation at −196 and −89 °C, and measurements by gas buret and gas chromatography. The first portion, noncondensable at −196 °C was collected using a Toepler pump. This portion consisted of hydrogen and methane, and was analyzed by combustion over copper (II) oxide at 280 °C. Noncondensable products at −196 °C from a TMT-O_2 system were analyzed by means of gas chromatography, using a 2 m column of molecular sieve (5A) at 25 °C. The second portion, which was not condensable at −89 °C, was analyzed by means of gas chromatography, using a 6-m column of VZ-7 (Gasukuro Kogyo Co., Ltd.) at 0 °C and a 2-m column of Gasukuro-pack 55 (Gasukuro Kogyo Co., Ltd.) at 180 °C. The third portion, which was condensable at −89 °C contained a large amount of TMT; it was not analyzed.

TMT (Kanto Chemical Co., Ltd.) was dried over a molecular sieve 4A and purified by trap-to-trap distillation. *cis*-2-Butene (Nihon Tokushu Gasu K. K., pure grade), O_2, NO, N_2O, and H_2 (these inorganic gases are comercially available and all pure grade) were used as supplied.

Results

The Hg($^3P_1$)-Photosensitized Decomposition. The thermal decomposition and direct photolysis were found to be negligible under the conditions for the mercury-photosensitized reaction. The gaseous products detected in the mercury-photosensitized reaction were ethane, methane, and hydrogen. The yields of these

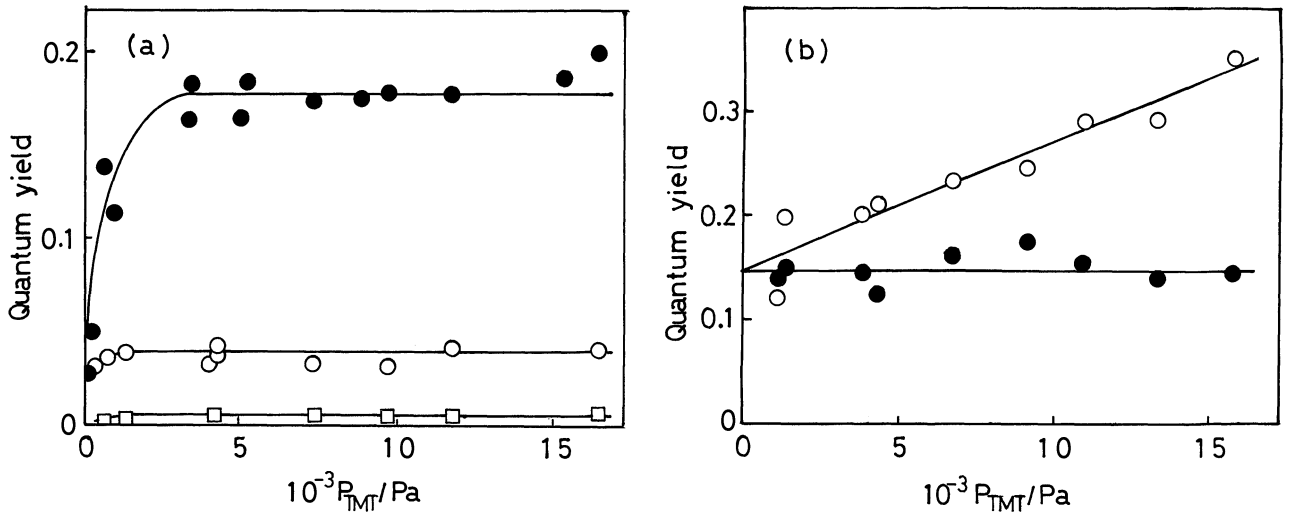

Fig. 1. Pressure dependence of the quamtum yields of ethane (●), methane (○), and hydrogen (□) in the mercury-photosensitized reaction of TMT at 120 °C (a) and 250 °C (b).

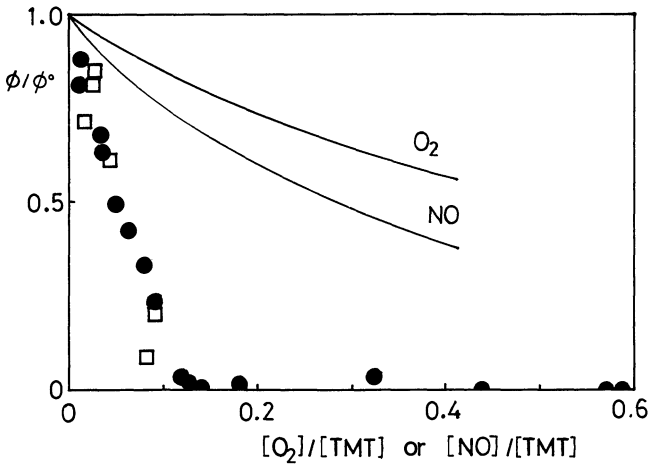

Fig. 2. Quantum yield of ethane in the mercury-photosensitized reaction of TMT at 120 °C in the presence of O_2 (●) and NO (□).

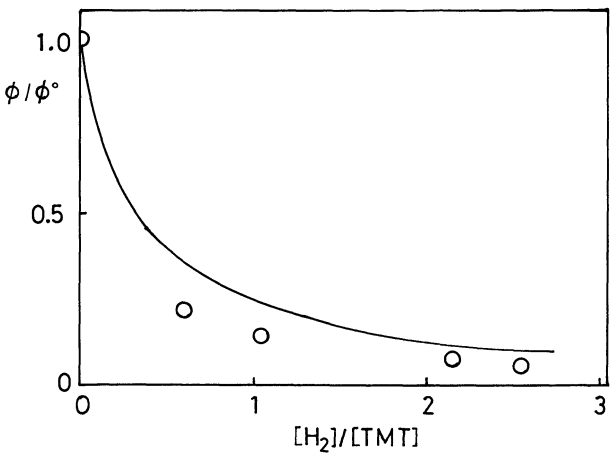

Fig. 3. Quantum yield of ethane in the mercury-photosensitized reaction of TMT at 120 °C in the presence of H_2.

products increased linearly with increasing reaction time and light intensity, showing they were primary products.

The quantum yields of these products are shown in Fig. 1 as a function of the TMT pressure (since the yield of hydrogen was very small at 250 °C, that is not shown in Fig. 1(b)). The quantum yields of all products are constant at higher pressures than 2000 Pa and decrease with decreasing TMT pressure in the low-pressure region at 120 °C (Fig. 1(a)). The quantum yield of ethane is also constant, while that of methane increases with increasing TMT pressure at 250 °C (Fig. 1(b)).

Figure 2 shows the effect of added O_2 and NO on the yield of ethane, while Fig. 3 shows the effect of added H_2 on the yield of ethane. The yield of ethane decreases with increasing the ratios of O_2 TMT, NO/TMT, and H_2/TMT.

The quenching cross section for TMT was obtained

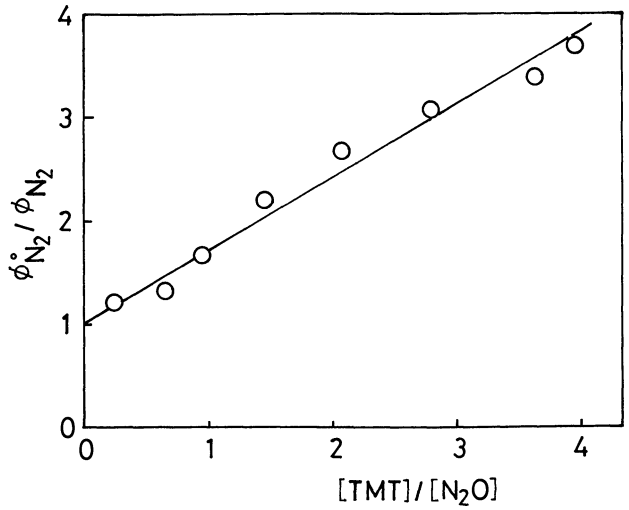

Fig. 4. Competitive quenching plot for TMT and N_2O.

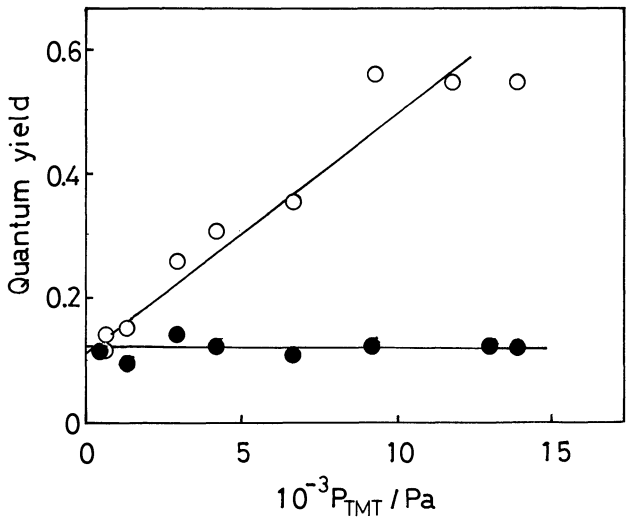

Fig. 5. Pressure dependence of the quantum yields of ethane (●) and methane (○) in the cadmium-photosensitized reaction of TMT at 280 °C.

from the competitive rates of the mercury-photosensitized reactions of TMT and N_2O. The yields of nitrogen from N_2O are expressed by

$$\frac{\phi^{\circ}_{N_2}}{\phi_{N_2}} = 1 + \beta\frac{[TMT]}{[N_2O]}, \quad (1)$$

where $\phi^{\circ}_{N_2}$ and ϕ_{N_2} are the yields of nitrogen in both the absence and presence of TMT. A β-value of 0.70 was obtained from the straight line in Fig. 4 by a least-squares method. The quenching cross section ($\sigma_Q = k_Q(8RT/\pi\mu)^{-1/2}$; k_Q is the quenching rate constant and μ is the reduced mass) for TMT can be calculated using

$$\frac{\sigma_Q(TMT)}{\sigma_Q(N_2O)} = \beta\left(\frac{1+M_{Hg}/M_{N_2O}}{1+M_{Hg}/M_{TMT}}\right)^{1/2}, \quad (2)$$

where $\sigma_Q(N_2O)$ is the cross section for N_2O; we used the value of 56.5×10^{-16} cm^2.[12] A value of 63.7×10^{-16} cm^2 for TMT was obtained. This value is considerably larger than those for NP (4.4×10^{-16} cm^2) and TMS (15.7×10^{-16} cm^2).[7]

The Cd($^3P_1$)-Photosensitized Decomposition. Primary products were the same as those from the mercury-photosensitized decomposition, with the production of ethane and methane again being linear with the reaction time. Hydrogen was a very minor product. The methane/ethane ratio of the cadmium-photosensitized decomposition was appreciably larger than that of the mercury-photosensitized decomposition at 120 °C and comparable to that at 250 °C. As Fig. 5 shows, the yield of ethane was constant and that of methane increased with increasing the TMT pressure. The effect of added H_2 on the yield of ethane was very similar to that observed in mercury-photosensitized decomposition.

Discussion

From the facts that the major products in the mercury-photosensitized reaction of TMT were ethane and methane (while hydrogen was the minor product), and that O_2 and NO in quantities of about 15% completely suppressed ethane formation (Fig. 2), the following simple sequence is indicated as being the major initial reactions:

$$Hg^* + TMT \rightarrow Hg + CH_3 + (CH_3)_3Sn, \quad (3)$$

$$CH_3 + CH_3 \rightarrow C_2H_6, \quad (4)$$

$$CH_3 + TMT \rightarrow CH_4 + CH_2Sn(CH_3)_3. \quad (5)$$

Contrary to the effect of O_2 on ethane formation,methane formation was not completely suppressed by the addition of O_2 in quantities of about 2 of O_2/TMT. The following molecular formation of methane may contribute:

$$Hg^* + TMT \rightarrow CH_4 + CH_2{=}Sn(CH_3)_2. \quad (6)$$

The primary molecular formation of methane was proposed in the direct photolysis of TMT at 185 nm.[3] Minor reactions for hydrogen formation are

$$Hg^* + TMT \rightarrow Hg + H + CH_2Sn(CH_3)_3, \quad (7)$$

and

$$H + TMT \rightarrow H_2 + CH_2Sn(CH_3)_3. \quad (8)$$

In the mercury-photosensitized rections of NP, TMS, and TMG,reactions corresponding to Reactions (7) and (8) are the major initial reactions; C–M bond cleavage (M is a central atom) as Reaction (3) was not observed.

As described above, the addition of O_2 and NO to the photosensitization system suppressed the formation of ethane (Fig. 2). As Fig. 2 shows, the yield of ethane decreases with increasing the ratios of O_2/TMT and NO/TMT. The solid lines show the relative yields calculated using the following relative quenching efficiencies for TMT, O_2, and NO:

$$k_Q(TMT)/k_Q(O_2) = 0.56$$

and

$$k_Q(TMT)/k_Q(NO) = 0.30.$$

These were obtained from the following cross sections for TMT, O_2, and NO: $\sigma_Q(TMT)=63.7\times10^{-16}$ cm^2, $\sigma_Q(O_2)=62.5\times10^{-16}$ cm^2,[12] and $\sigma_Q(NO)=111\times^{-16}$ cm^2.[12] The decreases in the yields of ethane observed in the presence of O_2 and NO are steeper than those expected by the competitive quenching of the triplet mercury atoms by TMT and O_2 or NO. This shows that O_2 and NO have an additional effect (as radical scavengers) on the formation of ethane.

The primary process in the mercury-photosensitized decompositions of NP and TMG is known to be C–H bond cleavage. It has been pointed out, however, that at high light intensities and low substrate pressures, methane is found as one of the major products, and that

atom crackings occur under these conditions.[7,9] To examine the possibility of atom cracking in the present reaction, we examined the effect of hydrogen addition to the system. If atom cracking (shown by Reactions (9) and (10)) contributes to the formation of the methyl radical, one would expect that the yield of ethane continuously increases with increasing ratio of H_2/TMT, because of the large efficiency of the formation of hydrogen atoms for H_2-triplet mercury atom system:[12]

$$H + CH_2Sn(CH_3)_3 \rightarrow TMT^* \quad (9)$$

and

$$TMT^* \rightarrow CH_3 + Sn(CH_3)_3. \quad (10)$$

As shown in Fig. 3, however, the yield of ethane decreases with increasing the ratio of H_2/ TMT. The solid line shows the relative quantum yield calculated using the following relative quenching efficiencies for H_2 and TMT ($k_Q(H_2)/k_Q(TMT)=2.90$; obtained from $\sigma_Q(H_2)=27\times10^{-16}$ cm^2 [12] and $\sigma_Q(TMT)=63.7\times10^{-16}$ cm^2). The decrease in the quantum yield can be roughly explained by a competitive quenching of the triplet mercuty by H_2 and TMT. Therefore, atom cracking can be ruled out.

The following reactions are considered to explain the pressure dependence of the yields of ethane and methane:

$$Hg^* \longrightarrow Hg + h\nu \quad k_0 \quad (11)$$

$$Hg^* + TMT \xrightarrow{\alpha_1} Hg + CH_3 + (CH_3)_3Sn \quad (3)$$

$$Hg^* + TMT \xrightarrow{\alpha_2} Hg + CH_4 + CH_2{=}Sn(CH_3)_2 \quad k_Q \quad (6)$$

$$Hg^* + TMT \xrightarrow{1-\alpha_1-\alpha_2} Hg + TMT \quad (12)$$

$$CH_3 + CH_3 \longrightarrow C_2H_6 \quad k_1 \quad (4)$$

$$CH_3 + TMT \longrightarrow CH_4 + CH_2Sn(CH_3)_3 \quad k_2 \quad (5)$$

$$CH_2Sn(CH_3)_3 \longrightarrow CH_3 + CH_2{=}Sn(CH_3)_2 \quad k_3 \quad (13)$$

Radicals → recombination reactions. (14)

From the above mechanism, the following relationship can be derived by neglecting the contribution of CH_3 and $CH_2Sn(CH_3)_3$ radicals to Reactions (14):

$$\phi(C_2H_6)=\frac{1}{2}\alpha_1 \quad (15)$$

$$\phi(CH_4)=\alpha_2+\alpha_1\frac{k_2[TMT]}{k_1[CH_3]_{ss}} \quad (16)$$

$$\frac{\phi(CH_4)}{\phi(C_2H_6)}=\frac{2\alpha_2}{\alpha_1}+\frac{2k_2}{k_1[CH_3]_{ss}}[TMT]. \quad (17)$$

Since Reaction (5) requires an activation energy, as shown by Borrell and Platt,[3] the contribution of this reaction increases with increasing temperature. If this reaction can be neglected at 120 °C, $\phi(CH_4)$ equals to α_2. Therefore, at this temperature the quantum yields of ethane and methane are independent of the pressure of TMT. This is in agreement with the experimental results shown in Fig. 1(a) (decrease in yields with decreasing TMT pressure at low pressures seem to be due to incomplete quenchlng of excited mercury atoms). At higher temperature (250 °C), however, Reaction (5) can not be neglected, and the yield of methane may depend on TMT pressure. The steady-state concentration of methyl radical can be expressed as

$$[CH_3]_{ss}=\left(\frac{\alpha_1 I_0}{2k_1}\right)^{1/2}; \quad (18)$$

this can be regarded as being independent of TMT pressure. Figure 6 shows the ratio of the yield of methane to that of ethane obtained at 120 °C and 250 °C as a function of the pressure of TMT. The ratio increases at 250 °C linearly with increasing the pressure of TMT; this is in agreement with the expectaion from Eq. 17. The slopes and intercepts of the lines in Fig. 6 are listed in Table 1.

The main products from the cadmium-photosensitized reaction of TMT were ethane and methane. The pressure dependences of the yields of these products are similar to those in the mercury-photosensitized reaction at 250 °C. The effect of H_2 on the yield of ethane is also very similar to that in the mercury-photosensitized reaction. These findings show that the reaction mechanism for the cadmium-photosensitized reaction of TMT is similar to that for the mercury-photosensitized reaction. The ratio of the yield of methane to that of ethane is shown as a function of the TMT pressure in Fig. 6. The ratio again increases linearly with increasing TMT pressure. The slope and intercept of the line for the cadmium-photosensitization are also listed in Table 1.

The values of α_2/α_1 obtained from the intercepts are listed in Table 1. The value of α_2/α_1 for the mercury-photosensitized reaction at 250 °C is very similar to that for the cadmium-photosensitized reaction. It is sensitive to temperature, and is large at high temperatures.

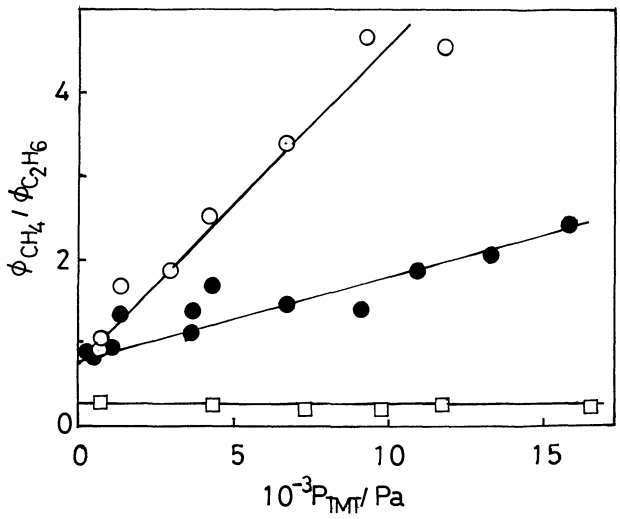

Fig. 6. Plots of $\Phi_{CH_4}/\Phi_{C_2H_6}$ against the TMT pressure for the mercury-photosensitized reaction at 120 °C (□) and 250 °C (●) and the cadmium-photosensitized reaction at 280 °C (○).

Table 1. Comparison of Various Constants for Mercury- and Cadmium-Photosensitized Reactions

	Hg		Cd
	120 °C	250 °C	280 °C
Intercept	0.12	0.89	0.80
10^5 slope/ Pa^{-1}	0	9.0	43
α_2/α_1	0.10	0.45	0.40
10^{-10} k_1/ 1 mol^{-1} s^{-1}	2.5	2.5	2.5
10^{-4} k_2/ 1 mol^{-1} s^{-1}	0.34	4.6	7.0
10^9 $[CH_3]_{ss}$/ mol l^{-1}		9.5	2.8

This shows that the ratio of the molecular formation of methane (Reaction (6)) to the formation of methyl radical (Reaction (3)) increases with increasing temperature. This molecular process for the formation of methane is known to occur in a direct photolysis of TMT vapor at 185 nm.[3] Since we have no information, however, on the temperature dependence of this process, further discussion of the temperature dependence of the α_2/α_1 seems not to be justified.

The value of the slope seems to depend on the temperature and kind of sensitizer. The k_1- and k_2-values included in the slope can be obtained from the literatures:

$$k_1/\,1\ mol^{-1}\ s^{-1} = (2.5 \pm 0.2) \times 10^{10}$$ [13]

and

$$k_2/\,1\ mol^{-1}\ s^{-1} = 1.2 \times 10^8 \exp(-4100/T).$$ [3]

These values are also listed in Table 1. The steady-state concentrations of CH_3 can be estimated from the values of the slope and those of k_1 and k_2 and are listed in Table 1. The value of $[CH_3]_{ss}$ obtained for the mercury-photosensitized reaction at 250 °C is larger than that for the cadmium-photosensitized reaction. This tendency is not apparently in agreement with the fact that the rate of the ethane formation in the mercury-photosensitized reaction of TMT is smaller than that in the cadmium-photosensitized reaction of TMT (the values of 6.7×10^{-10} and 15.7×10^{-10} mol s^{-1} for the mercury- and cadmium photosensitized reactions were obtained from the time dependences of the yield of ethane). This discrepancy may result from the difference in the volume of reaction zone, based on the differences in the cross sections of the beams of exciting light and the absorption coefficients of mercury and cadmium: that is, the mercury-photosensitized reaction occurs locally near the front window of the cell because of the large absorption coefficient of mercury (the ratio of the volumes of reaction zone ($V_{Hg}/V_{Cd} = 1/26$) is consistent with the values of $[CH_3]_{ss}$ and the apparent rate of ethane formation in the mercury- and cadmium-photosensitized reactions).

Contrary to the mercury-photosensitized decompositions of NP, TMS, and TMG, the main initial reactions of the mercury- and cadmium-photosensitized decomposition of TMT are processes with a cleavage of an Sn–C bond (the formation of CH_3 and the molecular formation of methane). In this respect, the present reactions are very similar to the direct photolysis of TMT as well as the cadmium-photosensitized reaction of acetaldehyde, which was reported to proceed through the formation of an excited complex between the Cd* and an aldehyde molecule, or after an energy transfer from Cd* to an aldehyde molecule.[14] The triplet energy of TMT is not yet known, but is probably lower than those of NP and TMS, because the absorption band of TMT shifts to a longer wavelength than do those of NP and TMS.[15] Since the quenching cross section of triplet mercury atom for TMT is larger than those for NP and TMS, as described above, the triplet energy transfer from Hg ($^3P_1$)(and Cd($^3P_1$)) to TMT to produce a triplet state of the TMT molecules seems to occur. This is the reasoning used to explain that the mechanism for TMT is different from those for NP, TMS, and TMG, and that it is rather similar to those of the cadmium-photosensitized reactions of aldehydes.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 63540342 from the Ministry of Education, Science and Culture.

(Received April 30, 1991)

The title compounds were designed and synthesized as potential inhibitors of cytochrome P-450 14α-demethylase. The antifungal activity of (4*R**,5*R**)-isomer is markedly higher than that of (4*S**,5*R**)-isomer. The crystal structures of the two diastereoisomers were determined by X-ray diffraction technique. The final *R* indices of (4*R**,5*R**)- and (4*S**,5*R**)-isomers were 0.063 and 0.070 for 2840 and 2365 reflections, respectively. The different configuration at the 4-position in the oxazolidine ring causes the differences in the ring conformation and in some torsion angles. The three-dimensional structures of the two diastereoisomers are consequently different. Among the diastereoisomers and enantiomers, the (4*R*,5*R*)-enantiomer is superimposable on lanosterol, which is a substrate of cytochrome P-450 14α-demethylase, suggesting that the 4β-methyl group plays an important role in the antifungal activity.

Compounds containing the imidazole ring or the 1,2,4-triazole ring are known to be active as antifungal agents. These compounds have been shown to inhibit biosysthesis of the cell membrane in fungi. An important step in this biosynthesis is cytochrome P-450-mediated 14α-demethylation of lanosterol to give, after several steps, ergosterol, which is an essential molecule for the formation of fungal membranes.[2] Imidazole and triazole antifungals inhibit this enzyme by a mechanism in which the heterocyclic nitrogen atom (N-3 of imidazole and N-4 of triazole) binds to the heme iron atom located in the binding site of the enzyme.[3]

In a program aimed at seeking an active agent against fungal infections, new triazolylmethyloxazolidine derivatives were designed and synthesized as potential inhibitors against fungal cytochrome P-450 14α-demethylase.[4] Among them, (4*R**,5*R**)-5-(2,4-difluorophenyl)-4-methyl-5-[(1*H*-1,2,4-triazol-1-yl)methyl]-3-[4-(trifluoromethyl)benzoyl]oxazolidine shows the excellent antifungal activity. On the other hand, the (4*S**,5*R**)-diastereoisomer exhibits significantly less activity. This paper reports the results of structural studies of the two diastereoisomers using X-ray crystallographic analysis and a structural comparison with lanosterol.

Experimental

(4*R,5*R**)-Isomer.** Colorless plates were grown by slow evaporation of a benzen–hexane solution at room temperature. Diffraction experiments were performed with a crystal, 0.1×0.3×0.8 mm, on a Rigaku AFC-5 diffractometer, using the monochromated Cu $K\alpha$ radiation. The crystal data are as follows: $C_{21}H_{17}N_4O_2F_5$, F.W.=452.4, triclinic, space group $P\bar{1}$, a=14.076(3), b=10.715(2), c=7.017(3) Å, α=95.12(3), β=96.29(4), γ=101.86(2)°, V=1022.7(4) Å^3, Z=2, D_c=1.47 g cm^{-3}, μ(Cu$K\alpha$)=11.4 cm^{-1}. The ω–2θ scanning mode was employed up to 2θ=128°. A total of 3523 reflections were measured, of which 2843 unique reflections with $F \geqslant 3\sigma(F)$ were used for the analysis. Three references measured every 200 reflections showed no significant variation in intensity. Correction was made for Lorentz and polarization factors, but not absorption. The structure was solved by the direct methods using MULTAN 78,[5] and refined by the block-diagonal least-squares technique with anisotropic thermal parameters. Hydrogen atoms were located on a difference Fourier synthesis and refined isotropically. A difference Fourier map revealed two positions of trifluoromethyl F atoms: both positions were included with population parameters of 0.7 and 0.3. Three low-angle reflections seemed to be affected by secondary extinction and were excluded from the data set. The final refinement converged at R=0.063 and R_w=0.062. The weighting scheme applied was $w=1/\sigma(F)$. Atomic scattering factors were taken from Ref. 6. Calculations were carried out with the DIRECT-SEARCH program system.[7] The final fractional coordinates and equivalent iso-

tropic thermal parameters[8] are given in Tablel 1.[9]

(4*S,5*R**)-Isomer.** Recrystallization from a benzene–ether solution gave colorless plates. The crystal used has approximate dimensions of 0.2×0.4×0.6 mm; the unit cell constants area a=18.513(3), b=6.122(2), c=19.805(1) Å, β=113.13(4)°, V=2064(2) Å^3, D_c=1.46 g cm^{-3} in space group $P2_1/a$ (Z=4), μ(Cu $K\alpha$)=11.3 cm^{-1}. Of 3432 reflections measured, 2367 were independently observed at level $F \geqslant 3\sigma(F)$. Data reduction and structure determination were carried out using the methods and procedures described for (4*R**,5*R**)-isomer. The ortho- and meta-position atoms of the trifluoromethylbenzoyl group are disordered in two orientations with weights of 0.8 and 0.2. Two low-angle reflections affected by secondary extinction were left out of the refinement. With unit weights, final residuals were R=0.070 and R_w=0.063.

Results and Discussion

The atom labelling and thermal ellipsoids are shown in Fig. 1. Bond lengths and angles are given in Table 2. Some bond lengths and angles in the two diastereoisomers, particularly in the oxazolidine rings, are significantly different from each other.

The oxazolidine ring of the (4*R**,5*R**)-isomer takes the half-chair conformation, as in the (4*S**,5*R**)-isomer. However in the (4*R**,5*R**)-isomer, the C(2) and N(3) atoms of the oxazolidine ring are displaced form the plane descried by the remaining atoms, O(1), C(4), and C(5) by −0.21(1) Å and 0.25(1) Å, while in the (4*S**,5*R**)-isomer the C(4) and C(5) atoms lie out of the plane containing the other ring atoms by 0.33(2) Å and −0.22(2) Å, respectively. This discrepancy in the ring puckering might be accounted for by the difference of the configuration at the C(4) atom in the oxazolidine ring.

Remarkable differences of some torsion angles are recognized between the two molecules, as shown in Table 3. The C(32) methyl group and the triazolylmethyl group are *trans* in the (4*R**,5*R**)-isomer, contrary to the *cis* configuration in the (4*S**,5*R**)-isomer, resulting in the C(32)–C(4)–C(5)–C(6) torsion angles of 137.2(3)° in the former and −28.1(6)° in the latter. The triazole ring of the (4*R**,5*R**)-isomer is located above the oxazolidine ring with a C(4)–C(5)–C(6)–N(7) torsion angle of 49.4(4)°. The (4*S**,5*R**)-isomer can not take

such a conformation because of the upward *cis* methyl group attached to C(4) atom.

In order to avoid the repulsion between the O(13) atom and C(32) methyl group attached to the 4-position in the oxazolidine ring, the torsion angle of C(12)–N(3)–C(4)–C(5) to take the value of 143.6(3)° in the (4*R**,5*R**)-isomer, while it is −145.3(4)° in the (4*S**,5*R**)-isomer. Consequently, the directions of the two phenyl groups in these molecules differ from each other, as shown in Fig. 1. It may be concluded that the

different configurations at the 4-position in the oxazolidine rings make the two diastereoisomers adopt the different overall structures.

Antifungal azole derivatives interfere with the microsomal P-450-dependent 14α-demethylation of lanosterol, resulting in the accumulation of 14α-methyl sterols and a decreased availability of ergosterol.[10] Oxazolidine derivatives with a (4*R**,5*R**)-configuration show markedly enhanced activities, while (4*S**,5*R**)-diastereomers possess significantly decreased activities. Of the enantiomeric pair, the activity of (4*R*,5*R*)-enantiomer is far more potent than that of (4*S*,5*S*)-enantiomer.[4] Thus, we presumed that only (4*R*,5*R*)-enantiomer, among the diastereoisomers and enantiomers, has a favorable framework to fit in the active site of the enzyme, and using it we carried out a structural comparison with lanosterol. The lanosterol model was built by use of the typical bond lengths and angles and minimized by the force-field calculation of the MM2′ program.[11]

C(4)–C(5)–C(6)–N(7)	49.4(4)	169.4(3)
C(4)–C(5)–C(24)–C(25)	69.8(5)	66.3(5)
C(5)–C(6)–N(7)–N(8)	−92.1(4)	77.0(5)

Computer graphics showed how (4*R*,5*R*)-enantiomer can be superposed on lanosterol (Fig. 2). The 5β-difluorophenyl group and the oxazolidine ring could be regarded as the B and D rings of lanosterol, and the 4β-methyl group and the methylene carbon atom of the 5α-triazolylmethyl group as the 13β-methyl and 14α-methyl group of lanosterol, respectively. The *N*-trifluoromethylbenzoyl group might correspond to the 17-alkyl side chain of lanosterol. The 4β-methyl group is expected to play an important role in antifungal potency, since a 4-demethyloxazolidine analogue exhibits an intermediate activity between (4*R**,5*R**)- and (4*S**,5*R**)-diastereoisomers.[4]

Miscibility of 2-(Octylsulfinyl)ethanol and Decylammonium Chloride in the Adsorbed Film and Micelle

Koji ABE,* Hidetsugu MATSUKIYO, Norihiro IKEDA, Makoto ARATONO, and Kinsi MOTOMURA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received May 13, 1991)

The surface tension of the aqueous solution of 2-(octylsulfinyl)ethanol (OSE) and decylammonium chloride (DeAC) mixture was measured as a function of total molality and composition of surfactants at 298.15 K under atmospheric pressure. The total surface density and compositions in the adsorbed film and micelle of the mixture were evaluated by applying thermodynamic relations to experimental results. It was found that the phase diagrams obtained for the adsorption and micelle formation of the mixture are different in shape from those of 2-(decylsulfinyl)ethanol (DeSE)–OSE and dodecylammonium chloride (DAC)–DeAC mixtures which are assumed to mix ideally in the adsorbed film and micelle. Such a nonideal behavior was attributed to the attractive interaction between OSE and DeAC molecules. Further, the interaction is concluded to be more attractive in the micelle than in the adsorbed film.

In previous papers, the surface adsorption and micelle formation of nonionic–nonionic[1–3] and cationic–cationic[4–7] surfactant mixtures have been investigated by applying the thermodynamic relations derived on the basis of excess thermodynamic quantities to measured surface tension. It has been demonstrated that the relation among the compositions of surfactants in the bulk phase, adsorbed film, and micelle provides important information about their miscibility.

There were many reports that nonionic and ionic surfactants mix nonideally in adsorbed films and micelles.[8–17] However most of them relied on the analysis using the regular solution approximation which is considered not to be appropriate to describe the mixed adsorbed films and micelles.[4,7,15,16,18]

Now it is necessary to apply our thermodynamic treatment to nonionic–ionic mixed surfactant systems. In the present study, we choose the mixture of 2-(octylsulfinyl)ethanol (OSE) and decylammonium chloride (DeAC), because we have already investigated (i) the mixed adsorbed film of OSE and DeAC[19] in a dilute concentration range and (ii) the surface adsorption and micelle formation of mixed surfactant systems which contain either OSE or DeAC as one constituent.[1–6]

Experimental

2-(Octylsulfinyl)ethanol and decylammonium chloride were synthesized and purified by the methods described previously.[2,20,21] Water was triply distilled from dilute alkaline permanganate solution.

The equilibrium surface tension was measured by the drop volume technique at 298.15 K under atmospheric pressure.[22] Surface tension values were reproducible within 0.05 mN m^{-1}.

Results and Discussion

In order to investigate the miscibility of nonionic and ionic surfactants in the adsorbed film and micelle, it is appropriate to employ the total molality $\hat{m}$ of surfactants and the mole fraction $\hat{X}_2$ of surfactant 2 in the total surfactant introduced previously[7,18] as the experimental variables. In the case of the present system, $\hat{m}$ and $\hat{X}_2$ are related to the molality m_i of surfactant i as follows:

$$\hat{m} = m_1 + 2m_2 \quad (1)$$

and

$$\hat{X}_2 = 2m_2/\hat{m}, \quad (2)$$

where the subscripts 1 and 2 express OSE and DeAC, respectively.

The surface tension γ was measured as a function of $\hat{m}$ and $\hat{X}_2$ at 298.15 K under atmospheric pressure. The γ vs. $\hat{m}$ curve obtained at constant $\hat{X}_2$ is shown in Fig. 1. It is found that the curve has a distinct break point where the micelle formation begins. The concentration of this point is referred to as the critical micelle concentration (cmc). Another break point is seen on the curve at a relatively low concentration; this point was proved to result from the phase transformation between the gaseous and expanded states of adsorbed film.[19] The γ vs. $\hat{X}_2$ curves at constant $\hat{m}$ depicted by replotting Fig. 1 are shown together with the surface tension at the cmc

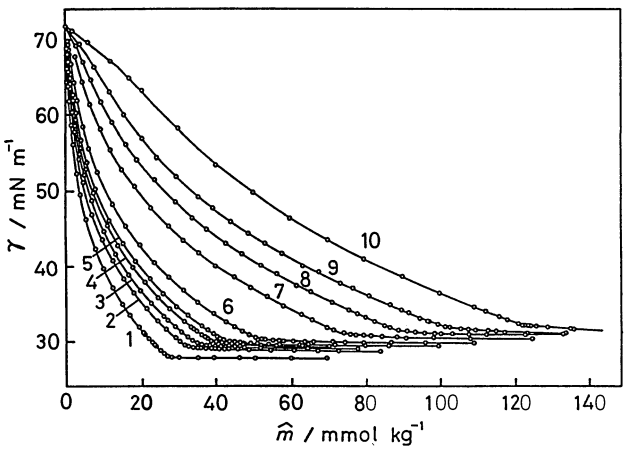

Fig. 1. Surface tension vs. total molality curves at constant composition: (1) $\hat{X}_2$=0; (2) 0.349; (3) 0.443; (4) 0.550; (5) 0.613; (6) 0.725; (7) 0.889; (8) 0.941; (9) 0.972; (10) 1.

γ^C vs. $\hat{X}_2$ curve in Fig 2. Both the γ and γ^C values increase as the composition of DeAC increases. But the curves are quite different in shape from each other; the γ^C vs. $\hat{X}_2$ curve is concave downward at a small composition and concave upward at a large composition, while the γ vs. $\hat{X}_2$ curve is concave upward over the whole range of composition. In Fig. 3, the $\hat{m}$ at constant γ and the cmc $\hat{C}$ are plotted against $\hat{X}_2$. The $\hat{m}$ and $\hat{C}$ values increase with increasing $\hat{X}_2$ and the dependence of $\hat{C}$ on $\hat{X}_2$ resembles that of $\hat{m}$.

Now let us derive the thermodynamic formulae to apply to the nonionic–uni-univalent ionic surfactant system. Adopting the two dividing planes defined so as to make the surface excess numbers of moles of water and air zero simultaneously and assuming an ideal solution, the total differential of surface tension at constant temperature and pressure is written in the form[7]

$$d\gamma = -(RT\hat{\Gamma}^{H}/\hat{m})d\hat{m} + (RT\hat{\Gamma}^{H}/\hat{X}_1\hat{X}_2)(\hat{X}_2 - \hat{X}_2^{H})d\hat{X}_2, \quad (3)$$

where $\hat{\Gamma}^{H}$ and $\hat{X}_2^{H}$ are the total surface density and composition of DeAC in the adsorbed film defined by

$$\hat{\Gamma}^{H} = \Gamma_1^{H} + \Gamma_{2+}^{H} + \Gamma_{2-}^{H} \quad (4)$$

and

$$\hat{X}_2^{H} = (\Gamma_{2+}^{H} + \Gamma_{2-}^{H})/\hat{\Gamma}^{H}, \quad (5)$$

respectively. Here Γ_1^{H}, Γ_{2+}^{H}, and Γ_{2-}^{H} are the surface excess numbers of moles of OSE, decylammonium ion, and chloride ion, respectively. Since the condition of electroneutrality holds, Γ_{2+}^{H} is equal to Γ_{2-}^{H}.

Miscibility in the Adsorbed Film at a Concentration below the cmc. First, let us examine the state of

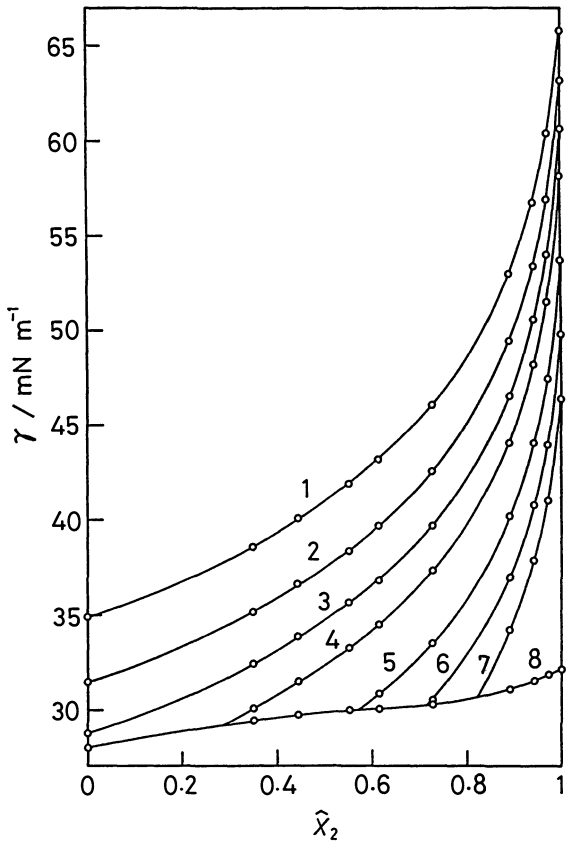

Fig. 2. Surface tension vs. composition curves at constant total molality: (1) $\hat{m}$=15 mmol kg^{-1}; (2) 20; (3) 25; (4) 30; (5) 40; (6) 50; (7) 60; (8) γ^C vs. $\hat{X}_2$.

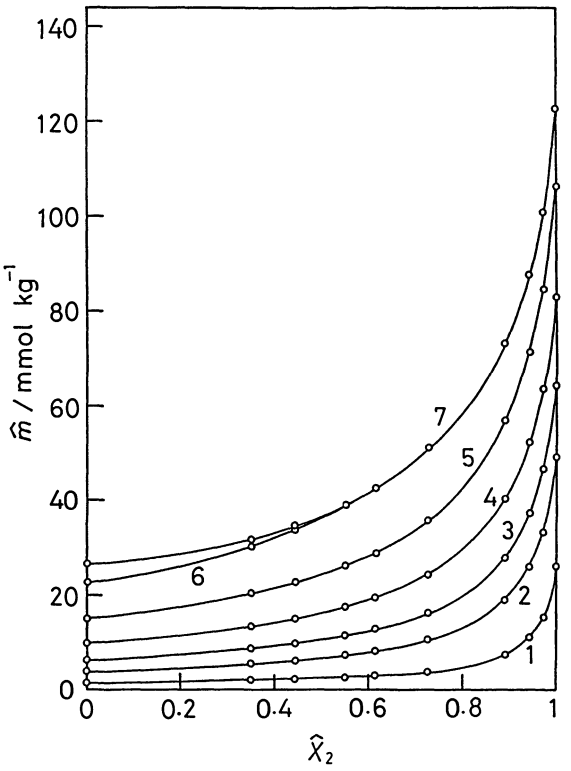

Fig. 3. Total molality vs. composition curves at constant surface tension: (1) γ=60 mN m^{-1}; (2) 50; (3) 45; (4) 40; (5) 35; (6) 30; (7) $\hat{C}$ vs. $\hat{X}_2$.

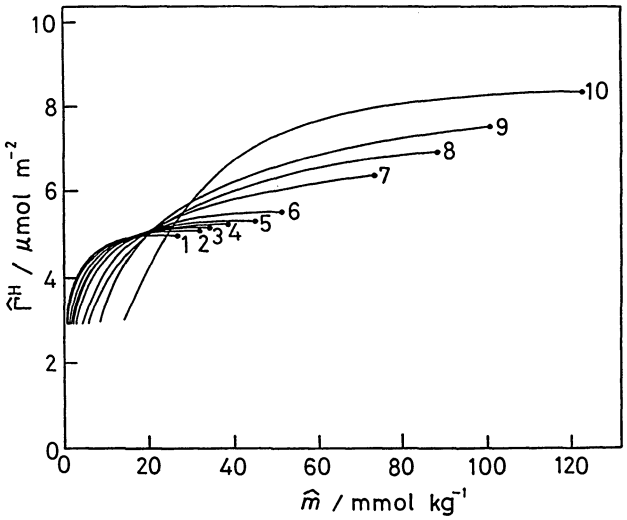

Fig. 4. Total surface density vs. total molality curves at constant composition: (1) $\hat{X}_2$=0; (2) 0.349; (3) 0.443; (4) 0.550; (5) 0.613; (6) 0.725; (7) 0.889; (8) 0.941; (9) 0.972; (10) 1; (●) total surface density at the cmc $\hat{\Gamma}^{H,C}$.

adsorbed film in terms of the total surface density $\hat{\Gamma}^{H}$. The value of $\hat{\Gamma}^{H}$ is calculated by applying the equation

$$\hat{\Gamma}^{H} = -(\hat{m}/RT)(\partial\gamma/\partial\hat{m})_{T,p,\hat{X}_2} \quad (6)$$

to the γ vs. $\hat{m}$ curve illustrated in Fig. 1; the value is plotted against $\hat{m}$ at constant $\hat{X}_2$ in Fig. 4. It is seen that the $\hat{\Gamma}^{H}$ value increases with increasing $\hat{m}$ and approaches to a saturated value at a concentration near the cmc. It is also seen that the $\hat{\Gamma}^{H}$ vs. $\hat{m}$ curve changes its shape from that of OSE to that of DeAC.

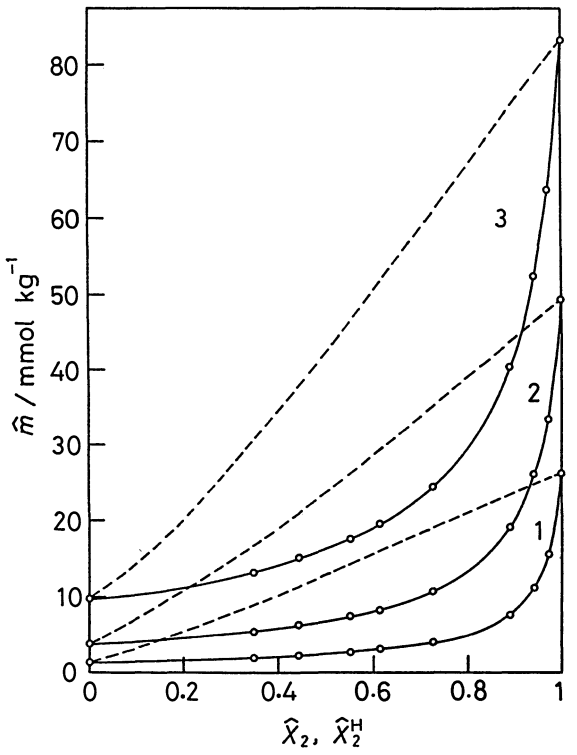

Fig. 5. Total molality vs. composition curves at constant surface tension: (1) γ=60 mN m^{-1}; (2) 50; (3) 40; (——) $\hat{X}_2$; (– – –) $\hat{X}_2^H$.

In order to clarify the miscibility of OSE and DeAC in the adsorbed film, it is useful to examine the composition in the adsorbed film. The value of $\hat{X}_2^H$ at a given γ is estimated by applying the following equation derived from Eq. 3 to the $\hat{m}$ vs. $\hat{X}_2$ curve shown in Fig. 3:

$$\hat{X}_2^H = \hat{X}_2 - (\hat{X}_1\hat{X}_2/\hat{m})(\partial\hat{m}/\partial\hat{X}_2)_{T,p,\gamma}. \quad (7)$$

The evaluated values are presented in the form of $\hat{m}$ vs. $\hat{X}_2^H$ curves at γ=60, 50, and 40 mN m^{-1} together with the corresponding $\hat{m}$ vs. $\hat{X}_2$ curves in Fig. 5. This diagram tells us that OSE and DeAC molecules are miscible with each other over the whole composition range at water/air interface and that the adsorbed film is richer in more surface active OSE molecules. Furthermore, the diagram may be said to take the shape of a distorted cigar when compared with those of 2-(decylsulfinyl)ethanol (DeSE)–OSE and dodecylammonium chloride (DAC)–DeAC systems[2,4] drawn in Fig. 6. Taking into account that the $\hat{m}$ vs. $\hat{X}_2^H$ curve deviates negatively from the straight line connecting the $\hat{m}$ values of pure OSE and DeAC, we may conclude that the OSE and DeAC molecules mix nonideally with each other in the adsorbed film.

Miscibility in the Micelle and Adsorbed Film at the cmc. Next let us proceed to see how OSE and DeAC molecules mix in the micellar state. The composition of surfactant in the micelle is defined by

$$\hat{X}_2^M = (N_{2+}^M + N_{2-}^M)/(N_1^M + N_{2+}^M + N_{2-}^M), \quad (8)$$

where N_i^M is the excess number of moles of i-species per micelle particle with reference to the dividing surface which makes the excess number of moles of water zero. Since the total molality of monomeric surfactant is

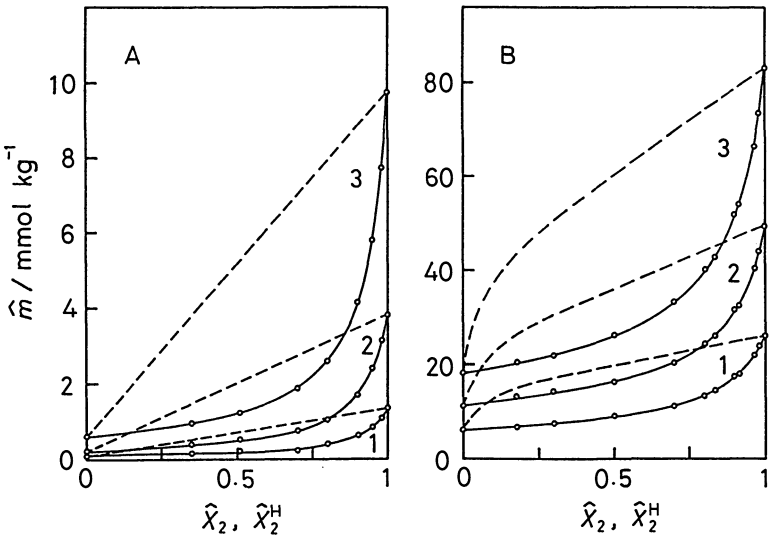

Fig. 6. Total molality vs. composition curves at constant surface tension: (A) DeSE–OSE system; (B) DAC–DeAC system; (1) γ=60 mN m^{-1}; (2) 50; (3) 40; (——) $\hat{X}_2$; (– – –) $\hat{X}_2^H$.

assumed to be equal to $\hat{C}$ in a limited concentration range near the cmc, the following relation holds at constant T and p:[7,18]

$$(RT/\hat{C})\mathrm{d}\hat{C}=(RT/\hat{X}_1\hat{X}_2)(\hat{X}_2-\hat{X}_2^{\mathrm{M}})\mathrm{d}\hat{X}_2. \quad (9)$$

Then the value of $\hat{X}_2^{\mathrm{M}}$ is immediately evaluated from the dependence of $\hat{C}$ on $\hat{X}_2$:

$$\hat{X}_2^{\mathrm{M}}=\hat{X}_2-(\hat{X}_1\hat{X}_2/\hat{C})(\partial\hat{C}/\partial\hat{X}_2)_{T,p}. \quad (10)$$

Figure 7 shows the plot of $\hat{C}$ against $\hat{X}_2^{\mathrm{M}}$ together with that of $\hat{C}$ vs. $\hat{X}_2$ curve of OSE–DeAC system deviates negatively from the straight line joining the $\hat{C}$ values of pure OSE and DeAC, although those of DeSE–OSE and DAC–DeAC systems given in Fig. 8 deviate positively. This finding indicates that OSE and DeAC molecules mix nonideally in the micelle as well as in the adsorbed film. These nonideal behavior is attributable to the attractive interaction between OSE and DeAC molecules.

On the other hand, the γ^{C} value is plotted against $\hat{X}_2$ and $\hat{X}_2^{\mathrm{M}}$ in Fig. 9. This diagram conveys some information concerning the γ vs. $\hat{m}$ curve above the cmc:[2-5] the curve of mixture is expected to increase slightly at a concentration range above the cmc. Taking into consideration that the γ values of pure OSE and DeAC decrease slightly at a concentration above the cmc, the above expectation does not contradict the results shown in Fig. 1.

Now, it is useful to inquire the relation between the compositions of micelle and adsorbed film at the cmc.

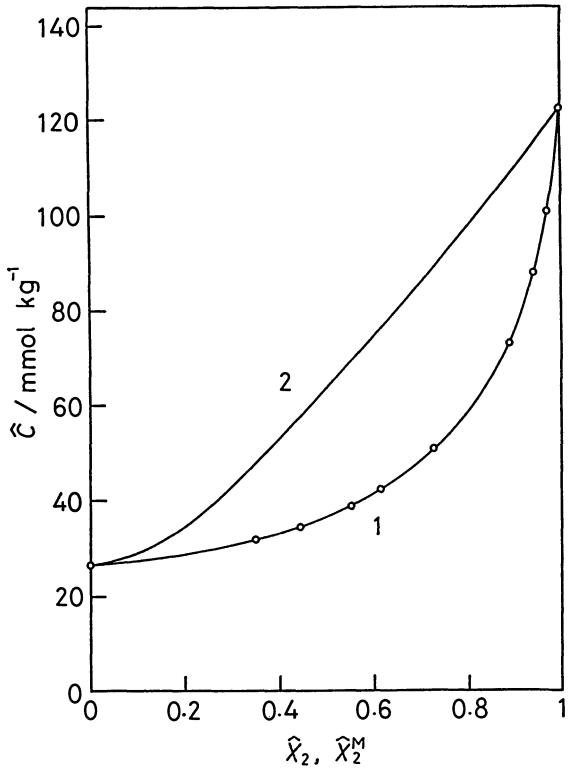

Fig. 7. Critical micelle concentration vs. composition curves: (1) $\hat{C}$ vs. $\hat{X}_2$; (2) $\hat{C}$ vs. $\hat{X}_2^{\mathrm{M}}$.

Since $\hat{m}$ is assumed to be equal to $\hat{C}$ at the cmc, Eq. 3 is rewritten as

$$\mathrm{d}\gamma^{\mathrm{C}}=-(RT\hat{\Gamma}^{\mathrm{H,C}}/\hat{C})\mathrm{d}\hat{C}+(RT\hat{\Gamma}^{\mathrm{H,C}}/\hat{X}_1\hat{X}_2)(\hat{X}_2-\hat{X}_2^{\mathrm{H,C}})\mathrm{d}\hat{X}_2, \quad (11)$$

where $\hat{\Gamma}^{\mathrm{H,C}}$ and $\hat{X}_2^{\mathrm{H,C}}$ are the total surface density and composition of adsorbed film at the cmc, respectively. Combination of Eqs. 9 and 11 leads to the equation

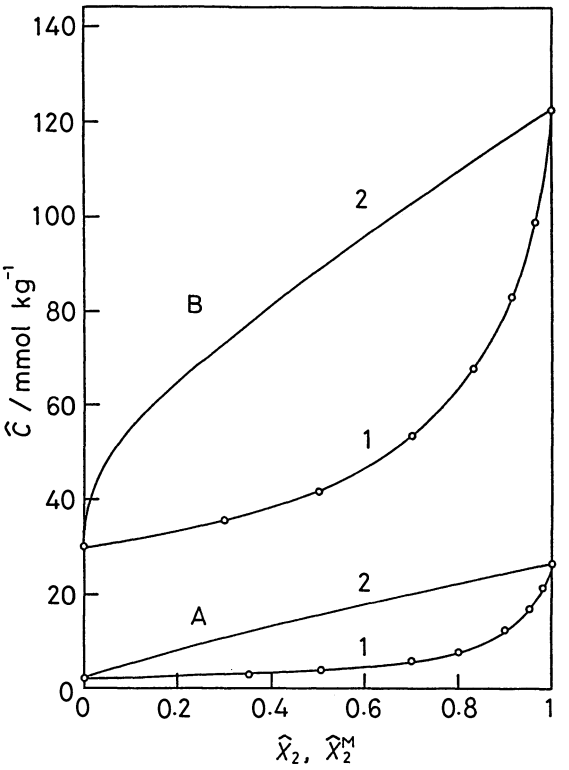

Fig. 8. Critical micelle concentration vs. composition curves: (A) DeSE–OSE system; (B) DAC–DeAC system; (1) $\hat{C}$ vs. $\hat{X}_2$; (2) $\hat{C}$ vs. $\hat{X}_2^{\mathrm{M}}$.

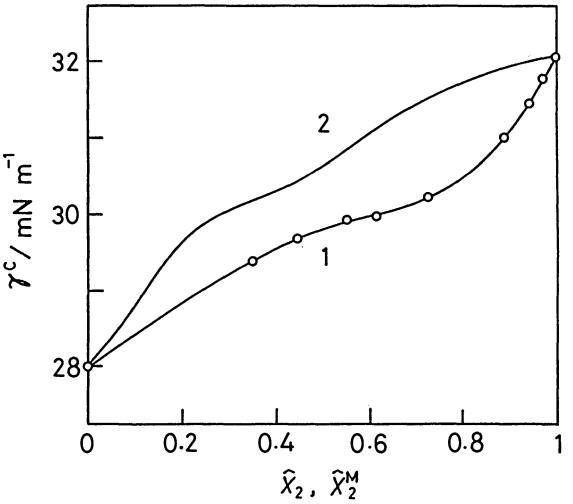

Fig. 9. Surface tension at the cmc vs. composition curves: (1) γ^{C} vs. $\hat{X}_2$; (2) γ^{C} vs. $\hat{X}_2^{\mathrm{M}}$.

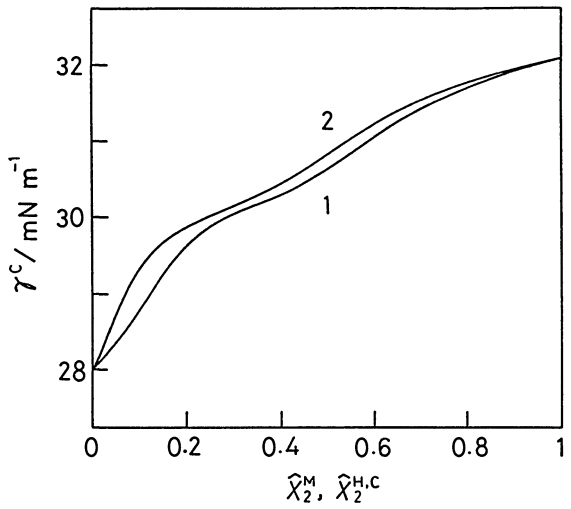

Fig. 10. Surface tension at the cmc vs. composition curves: (1) γ^C vs. $\hat{X}_2^M$; (2) γ^C vs. $\hat{X}_2^{H,C}$.

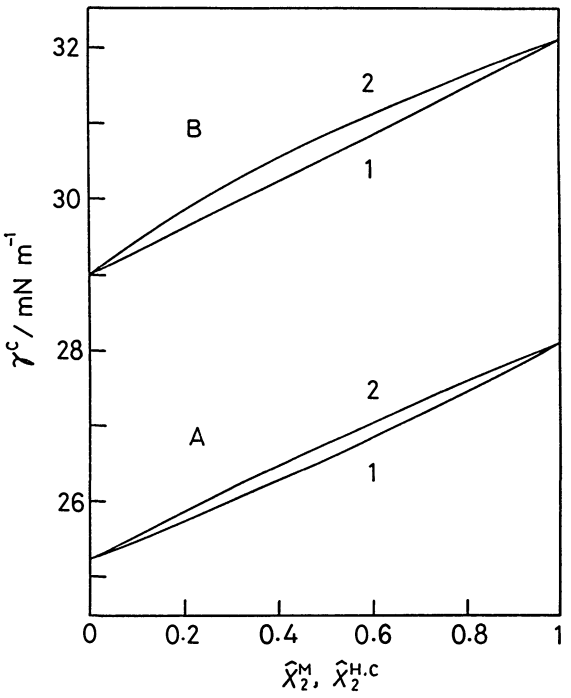

Fig. 11. Surface tension at the cmc vs. composition curves: (A) DeSE–OSE system; (B) DAC–DeAC system; (1) γ^C vs. $\hat{X}_2^M$; (2) γ^C vs. $\hat{X}_2^{H,C}$.

$$\hat{X}_2^{H,C} = \hat{X}_2^M - (\hat{X}_1\hat{X}_2/RT\hat{\Gamma}^{H,C})(\partial\gamma^C/\partial\hat{X}_2)_{T,p}. \quad (12)$$

Applying Eq. 12 to the γ^C vs. $\hat{X}_2$ curve illustrated in Fig. 2 and making use of the $\hat{\Gamma}^{H,C}$ value estimated by the extrapolation of $\hat{\Gamma}^H$ vs. $\hat{m}$ curve to the cmc in Fig. 4, we can evaluate the value of $\hat{X}_2^{H,C}$. The results are shown in Fig. 10. It is seen that the diagram has a deformed shape compared with those of the DeSE–OSE and DAC–DeAC systems given in Fig. 11. This is closely associated with the nonideal mixing of OSE and DeAC molecules in the adsorbed film and micelle. Furthermore, the γ^C vs. $\hat{X}_2^{H,C}$ curve is found to deviate more positively than the γ^C vs. $\hat{X}_2^M$ curve. Therefore, we may conclude that the interaction between OSE and DeAC molecules are more attractive in the micelle than in the adsorbed film.

It is probable from the thermodynamic viewpoint that nonionic and cationic surfactants form a negative azeotrope in the adsorbed film and micelle if their γ vs. $\hat{m}$ curves are close to each other over the whole concentration range. This will be realized for the mixture of OSE and DAC.[23]

Department of Applied Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, 2-24-16 Naka-machi, Koganei, Tokyo 184
(Received May 14, 1991)

The in situ electrochemical quartz crystal microbalance (in situ EQCM) technique has been applied to study ion and solvent transport accompanying the redox reaction of polyvinylferrocene (PVF) film coated on quartz crystal electrodes in aqueous and acetonitrile media. The dependence of apparent formal potentials $(E^{f}_{poly})_{app}$ of the F_c°/F_c^{+} redox couple (F_c° and F_c^{+} represent the reduced and oxidized sites, respectively, in the PVF film) upon the concentration of supporting electrolyte has been also examined in comparison with those of solution-phase ferrocene derivatives. The PVF film is ideally permselective to ClO_4^- anion in both aqueous and acetonitrile media. The PVF oxidation (or reduction of polyvinylferricenium ion) in aqueous media is accompanied by the ingress (or egress) of one ClO_4^- ion per redox site and some solvent (ca. one H_2O per redox site). In $LiClO_4$ acetonitrile media, during the oxidation process ClO_4^- ion with some solvent inserts into the film and the reverse phenomenon occurs during the reduction process. The results demonstrate that a combination of the in situ EQCM measurement and the measurement of the dependence of $(E^{f}_{poly})_{app}$ on the concentration of supporting electrolyte makes possible to elucidate quantitatively the ion and/or solvent transport process across the polymer film/solution interface during the redox reaction.

Charge transport in electroactive polymer films, which are coated on electrode surfaces and are well-swollen with solvent/electrolyte, has been a subject of much interest in recent years from the viewpoint of the fundamental studies on the mechanism and kinetics of charge (electron and/or ion) transport as well as the potential applications (such as electrocatalysis, optical/electronic devices, sensors and energy storage) based on their interesting properties (e.g., electron transfer catalysis, ion permselectivity, redox conductivity and electrochromic property).[1] We have also been interested in this problem and have continued to conduct the kinetic and thermodynamic study of the homogeneous charge-transport process within polymer coatings for various types of redox polymer-coated electrode systems mainly using normal pulse voltammetry, potential-step chronoamperometry (chronocoulometry), AC impedance method and hydrodynamic voltammetry based on rotating disk electrodes.[2] A fruitful information about the charge transport has been obtained.[2] However, the role of electroinactive species (e.g., solvent and counter ions) in charge-transport processes can not be directly deduced using these electrochemical techniques.

The in situ electrochemical quartz crystal microbalance technique (in situ EQCM technique), which is based on the quartz crystal microbalance used in conjunction with electrochemistry, has recently received great attention as a highly useful technique capable of quantitatively measuring small mass changes (typically of the order of 10^{-9}—10^{-6} g) of electrode surfaces which occur as a result of electrochemical processes.[3] For some electroactive polymeric films (e.g., electropolymerized polymers and polymer complexes), mass changes, which occur upon electrochemical oxidation and reduction due to insertion and expulsion, respectively, of counter ions, coions and/or solvent into and out of the film phase, have been elucidated quantitatively using the in situ EQCM technique.[3,4]

In this paper, we report on the in situ EQCM responses for the redox reaction of polyvinylferrocene (PVF) film in aqueous and acetonitrile media, together with the comparison with the data reported by other workers for PVF films.[4b,c,h–j] The variation of apparent formal potential for the F_c°/F_c^{+} redox couple in the PVF film with the concentration of supporting electrolyte will be also examined in order to gain an additional insight into the mechanism of ion and solvent transport in PVF films. An analysis of apparent formal potential shifts of electroactive polymers as a function of the electrolyte concentration enables a quantitative estimation of concomitant changes in ion populations during their redox reactions.[4i,5]

Experimental

The electrochemical quartz crystal microbalance instrumentation and the experimental procedures are essentially similar to those employed in previous studies.[4a,d,e] The experiments reported here were run on a 5 MHz AT-cut quartz crystal (diameter: 13 mm, Toyo Kurafuto Ltd.) which are driven at their resonant frequency by a feedback osillator. Each side of the crystals was coated with Au (ca. 300 nm) by vaccum deposition, using Cr (ca. 2 nm) as an adhesion layer. One side of the crystal was further coated with PVF film (thickness is typically 150 nm) and used as the working electrode. A Pt wire and a sodium chloride saturated calomel electrode

(SSCE) were used as the counter and reference electrodes, respectively. The keyhole electrode design used is similar to that described in Ref. 6, with the piezoelectrically and electrochemically active areas being 63.6 and 47.8 mm^2,respectively. The crystal was affixed to the side of the cell via Teflon O-rings (Fig. 1). The mass change (Δm in $g\,cm^{-2}$) at the electrode surface could be estimated from the frequency change observed (Δf in Hz) according to Sauerbrey's equation;[7] $\Delta f = -C_f \Delta m$, with the proportionality constant C_f of 5.67×10^7 $Hz\,cm^2\,g^{-1}$. The resonant frequency was measured using a Hewlett Packard 5334B frequency counter. EQCM data were obtained with the use of a computer-controlled apparatus.[4a]

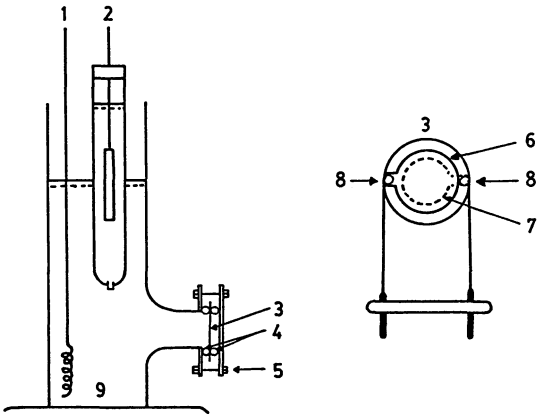

Fig. 1. A schematic depiction of the electrolyte cell and quartz crystal electrode used for in situ EQCM measurements. (1) counter electrode (Pt wire), (2) reference electrode, (3) quartz crystal (working electrode), (4) O-ring, (5) screw bolt/cap, (6) front electrode, (7) back electrode, (8) spring clip with attached lead, (9) glass cell.

The apparent formal potentials of the Fc^0/Fc^+ couple in the PVF film and the solution-phase ferrocenes in various concentrations of supporting electrolytes were obtained by cyclic voltammetry using basal-plane pyrolytic graphite (BPG, Union Carbide Co.) as a working electrode material. The reference and counter electrodes are the same as those employed in in situ EQCM experiments. The BPG disk electrodes (0.19 cm^2) were prepared and mounted into a glass tube with a heat-shrinkable polyolefin tube.

Polyvinylferrocene (PVF) was prepared according to Ref. 8. Adherent coatings of PVF were produced by transferring aliquots of a 0.1 wt% CH_2Cl_2 solution of PVF to the surface of a quartz crystal electrode and then evaporating the solvent at room temperature. The activity coefficients of ions were calculated according to the Debye–Hückel approximation.[9] All chemicals used were of reagent grade. Experiments were performed at room temperature (25±2 °C). All potentials were measured and were quoted with respect to the SSCE.

Results and Discussion

in situ EQCM Behavior of PVF Film in Aqueous Media. Figure 2 shows the typical results of in situ EQCM experiment on a PVF film-coated quartz crystal electrode in 0.26 M (1 M=1 mol dm^{-3}) $NaClO_4$ aqueous

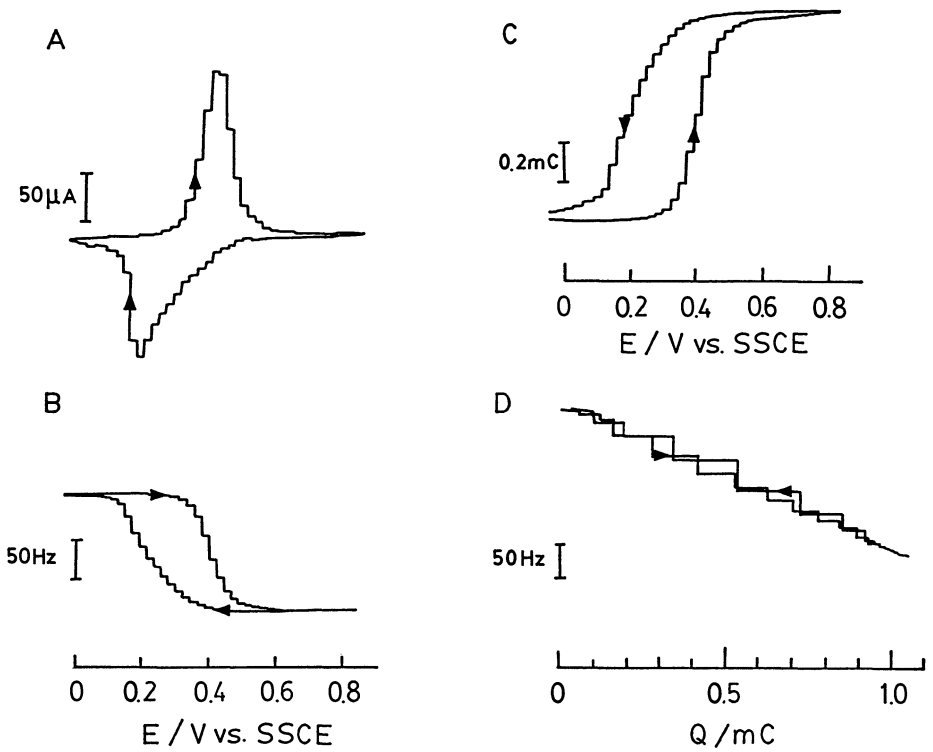

Fig. 2. (A) Current-potential, (B) frequency-potential, (C) charge-potential and (D)frequency-charge curves for a PVF film-coated quartz crystal electrode in 0.26 M $NaClO_4$ aqueous solution (pH 3.0). Amount of PVF coated on electrode: 17.3 $\mu g\,cm^{-2}$. Potential scan rate: 20 $mV\,s^{-1}$.

solution (pH 3.0). At first sight, we can see that the frequency change decreases during the oxidation process (i.e., the mass of the PVF film-coated electrode increases), while it increases during the reduction process (i.e., the mass decreases). In this case, the oscillator frequency completely returns to its initial value after the potential scan, indicating that the mass change of the PVF film accompanying its redox reaction is completely reversible on the time scale of the potential scan used (ca. 30—50 s). The half frequency change and half charge change potentials (denoted by $E_{1/2,f}$ and $E_{1/2,q}$, respectively, in this paper), at which the total frequency and charge changes, respectively, are half complete, may be used as measures of the ability of these quantities to respond to the applied potential program. At a scan rate of 20 m V s^{-1}, $E_{1/2,f}$ and $E_{1/2,q}$ are almost the same values of ca. 0.20 and 0.40 V for the negative and positive scans, respectively. This fact demonstrates that the mass transport process and electron transfer process occur simultaneously at the scan rate used, because the frequency change can be linearly correlated to the mass change according to the Sauerbrey's equation. From Fig. 2D, it is obvious that the frequency change vs. charge plots are almost linear for both anodic and cathodic processes and the slopes for both processes are almost the same (1.48×10^5 Hz C^{-1}). The increase in mass per mole of redox sites of PVF film, i.e., the molar mass equivalent (M_{eq}), could be determined to be 119 g mol^{-1} using the slopes of the Δf vs. Q plots. The physical significance of the M_{eq} obtained will be mentioned below.

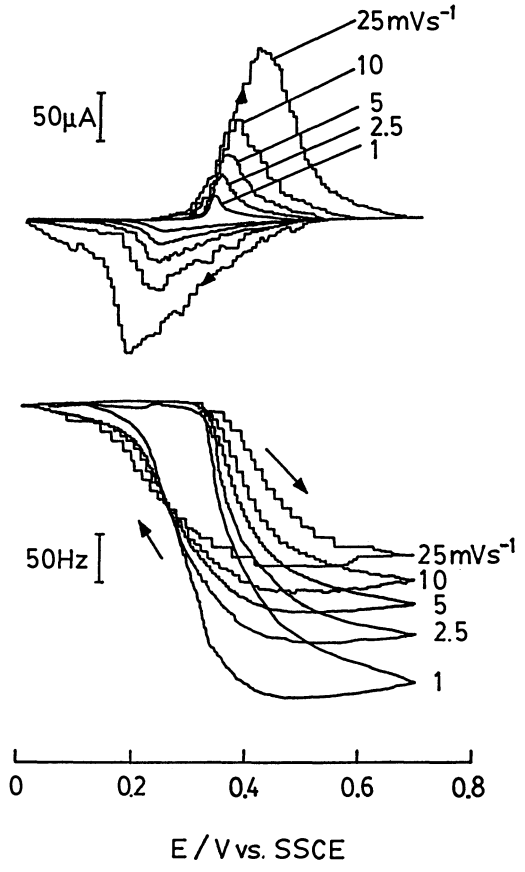

Fig. 3. Typical cyclic voltammetric and frequency-potential curves for a PVF film-coated quartz crystal electrode in 0.2 M $NaClO_4$ aqueous solution (pH 3.0) at various potential scan rates. Amount of PVF coated on electrode: 17.3 μg cm^{-2}.

Figure 3 shows typical cyclic voltammetric and frequency-potential curves for the PVF film-coated quartz crystal electrode in 0.2 M $NaClO_4$ aqueous solution (pH 3.0) at various potential scan rates of 1 to 25 m V s^{-1}. The frequency change response accompanying the redox reaction is essentially the same as that mentioned above (Fig. 2). In addition, we can see that the difference in frequency change between the oxidized and reduced states is larger at slower potential scan rate. This is qualitatively understood by considering that the number (Γ) of the redox sites in the film oxidized (or reduced) during a given potential scanning is proportional to the amount (Q) of charge passed during the period and that the oxidation (or reduction) process will require, for charge neutrality, concurrent ingress (or egress) of anion into (or out of) the film matrix. The measured values of Q, Γ, and Δf at various scan rates are summarized in Table 1, together with the calculated ones of Δm and M_{eq}. Γ and Δm increases, as expected, with decreasing potential scan rate. However, the M_{eq} values are almost constant ((123±4) g mol^{-1}). If ClO_4^- anion were the only mobile species to be transferred, the resultant value would be 99.5 g mol^{-1}. Thus, the fact that the M_{eq} obtained is larger than 99.5 g mol^{-1} may suggest the PVF oxidation (or PVF^+ reduction) is accompanied by the ingress (or egress) of one ClO_4^- ion per redox site and some solvent (ca. one H_2O per redox site), being in a qualitative agreement with the results previously reported for PVF films.[4b,h,i]

Dependence of Apparent Formal Potential on Electrolyte Concentration. When the PVF film is ideally permselective to ClO_4^- anion, the apparent formal potential ($(E^f_{poly,H_2O})_{app}$) of the F_c°/F_c^+ redox couple (F_c° and F_c^+ represent the reduced and oxidized sites, respectively, in the PVF film) in aqueous solutions could be expected to obey the following equation.

Table 1. in situ EQCM Data of PVF Film in Aqueous $NaClO_4$ Media[a)]

v[b)]	Q	$10^8\cdot\Gamma$	$-\Delta f$	$10^6\cdot\Delta m$	M_{eq}
mV s^{-1}	mC	mol cm^{-2}	Hz	g cm^{-2}	g mol^{-1}
1	1.83	3.97	286	5.03	126
2.5	1.51	3.28	235	4.13	126
5	1.36	2.95	207	3.64	123
10	1.19	2.58	181	3.18	123
25	1.06	2.30	155	2.73	119

a) Concentration of $NaClO_4$: 0.2 M. Thickness of PVF film in dry state: 150 nm. Electrochemically active area: 47.8 mm^2. See the text for the definitions of Q, Γ, Δf, Δm, and M_{eq}. b) Potential scan rate.

$$(E^{f}_{poly,H_2O})_{app} = E^{\circ}_{poly,H_2O} + E_j - \frac{RT}{F}\ln\frac{f^{F_c^{\circ}}_{poly,H_2O}}{f^{F_c^{+}}_{poly,H_2O}} - \frac{RT}{F}\ln a_{(ClO_4^-)_{soln,H_2O}}, \quad (1)$$

where $(E^{f}_{poly,H_2O})_{app}$ (vs. SSCE) was taken as the average of the anodic and cathodic peak potentials of the cyclic voltammograms for the F_c°/F_c^{+} couple obtained at the PVF film-coated BPG electrode in $NaClO_4$ aqueous solutions (0.02—2.0 M), E°_{poly,H_2O} is the standard potential of the F_c°/F_c^{+} couple in the aqueous solutions used here, E_j denotes the liquid junction potential at SSCE (aq) : $NaClO_4$ (0.02—2.0 M, aq), $f^{F_c^{+}}_{poly,H_2O}$ and $f^{F_c^{\circ}}_{poly,H_2O}$ are the activity coefficients of the F_c^{+} and F_c° redox sites, respectively and $a_{(ClO_4^-)_{soln,H_2O}}$ is the activity of ClO_4^- ion in $NaClO_4$ aqueous solutions. The last term on the right-hand side of Eq. 1 represents "Donnan potential" present at the PVF film/solution interface. On the other hand, the apparent formal potential ($(E^{f}_{soln,H_2O})_{app}$) for the monomeric ferrocene derivative (i.e., ferrocenylmethyl(trimethylammonium), F_c–N^+) dissolved in the same aqueous solutions can be written as follows:

$$(E^{f}_{soln,H_2O})_{app} = E^{\circ}_{soln,H_2O} + E_j - \frac{RT}{F}\ln\frac{f^{F_c\text{-}N^+}_{soln,H_2O}}{f^{F_c\text{-}N^{2+}}_{soln,H_2O}}, \quad (2)$$

where $(E^{f}_{soln,H_2O})_{app}$ was measured with respect to the SSCE, E°_{soln,H_2O} is the standard potential of the F_c–N^+/F_c–N^{2+} couple, and $f^{F_c\text{-}N^{2+}}_{soln,H_2O}$ and $f^{F_c\text{-}N^+}_{soln,H_2O}$ are the activity coefficients of F_c–N^+ and F_c–N^{2+}, respectively.

As can be seen from Fig. 4, the polts of $(E^{f}_{poly,H_2O})_{app}$ vs. $\log a_{(ClO_4^-)_{soln,H_2O}}$ and $(E^{f}_{soln,H_2O})_{app}$ vs. $\log a_{(ClO_4^-)_{soln,H_2O}}$ are linear in the examined range of $a_{(ClO_4^-)_{soln,H_2O}}$ with slopes of −62 and −5 mV per decade in ClO_4^- activity, respectively. Thus, the difference ($\Delta(E^{f}_{H_2O})_{app}$) between $(E^{f}_{poly,H_2O})_{app}$ and $(E^{f}_{soln,H_2O})_{app}$ can be expressed by

$$\Delta(E^{f}_{H_2O})_{app} = (E^{\circ}_{poly,H_2O} - E^{\circ}_{soln,H_2O}) - \left(\frac{RT}{F}\ln\frac{f^{F_c^{\circ}}_{poly,H_2O}}{f^{F_c^{+}}_{poly,H_2O}} - \frac{RT}{F}\ln\frac{f^{F_c\text{-}N^+}_{soln,H_2O}}{f^{F_c\text{-}N^{2+}}_{soln,H_2O}}\right) - \frac{RT}{F}\ln a_{(ClO_4^-)_{soln,H_2O}}. \quad (3)$$

This enables us to evaluate the dependence of the formal potential difference on the electrolyte activity without knowing the dependence of E_j on the electrolyte activity under the condition that the second term on the right-hand side of Eq. 3 can be assumed as a constant in the examined range of $a_{(ClO_4^-)_{soln,H_2O}}$.[11] Based on its definition, the term $(E^{\circ}_{poly,H_2O} - E^{\circ}_{soln,H_2O})$ is independent of $a_{(ClO_4^-)_{soln,H_2O}}$. If the above condition is fulfilled, the slope of $\Delta(E^{f}_{H_2O})_{app}$ vs. $\log a_{(ClO_4^-)_{soln,H_2O}}$ plot can be expected to be −59 mV per decade in ClO_4^- activity at 25 °C. The actually obtained value is −57 mV per decade. This fact strongly suggests the permselective movement of ClO_4^- anions to the PVF film in order to maintain electroneutrality in agreement with the above-mentioned in situ EQCM results. There is no evidence for cation population changes during the redox reaction under the experimental conditions employed in this study.

According to the results obtained, the following reaction mechanism can be postulated for the PVF film reaction:

$$(F_c^{\circ}, nH_2O)_{poly} + (ClO_4^-)_{soln} + m(H_2O)_{soln} \rightleftarrows (F_c^{+}\cdot ClO_4^-, (n+m)H_2O)_{poly} + e^-, \quad (4)$$

where the subscripts refer to the polymer film (poly) or supporting electrolyte solution (soln). Note that the values of the coefficients m and n are not necessarily integers, as pointed out recently.[10] The ion and solvent transport that accompanies the redox reaction of PVF film coated on the electrode is depicted schematically in Fig. 5.

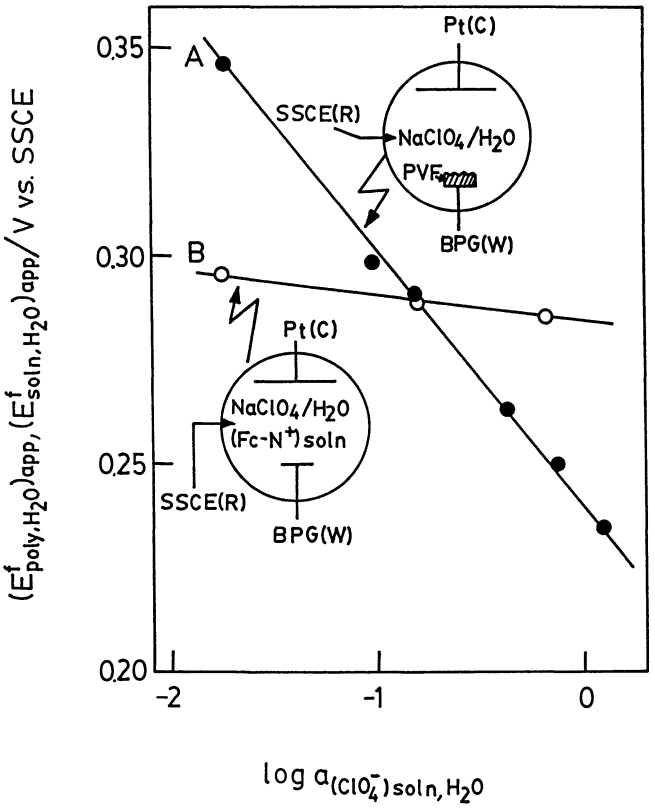

Fig. 4. Apparent formal potentials of (A) the F_c°/F_c^{+} couple in the PVF film and (B) the solution-phase F_c-N^+/F_c-N^{2+} couple as a function of the activity of the $NaClO_4$ supporting electrolyte. Amount of PVF coated on BPG electrode: 21.5 μg cm^{-2}. Concentration of F_c-N^+ in solution: 1 mM. The insets schematically represent the three-electrode systems employed to examine the dependence of $(E^{f}_{poly,H_2O})_{app}$ and $(E^{f}_{soln,H_2O})_{app}$ upon $\log a_{(ClO_4^-)_{soln,H_2O}}$.

a) Thickness of PVF film in dry state: 150 nm. Electrochemically active area: 47.8 mm^2. See the text for the definitions of Q, Γ, Δf, Δm, and M_{eq}. b) Concentration of $LiClO_4$. c) Potential scan rate.

PVF film in acetonitrile solutions containing various concentrations of $LiClO_4$. The frequency change (and so the mass change) of the film-coated electrode accompanying its redox reaction seems reversible, regardless of the concentration of $LiClO_4$. Note that the large potential difference between the anodic and cathodic peak potentials of voltammogram A, compared with those of voltammograms B and C, may originate from the significant iR drop effect due to the low concentration of the supporting electrolyte used. It was also found that for a given concentration of $LiClO_4$ $E_{1/2,f}$ and $E_{1/2,q}$ coincide within 5 mV. The mass transport process and electron transfer process are thus thought to occur simultaneously.

Table 2 contains the quantitative results concerning the charge transport, estimated from the data such as those shown in Fig. 6. The values of molar mass equivalent M_{eq} are almost the same ((109±4) g mol^{-1}), regardless of the concentration of $LiClO_4$ supporting electrolyte. However, these values are essentially larger than that (99.5 g mol^{-1}) expected when ClO_4^- is the only mobile species to be transferred. As in the case of the above-mentioned $H_2O/NaClO_4$ system, the dependence of the formal potential on the activity of ClO_4^- in acetonitrile (AN) solutions was also examined. The results are shown in Fig. 7. Here, the apparent formal potentials ($(E^f_{poly,AN})_{app}$ and $(E^f_{soln,AN})_{app}$) for the Fc°/Fc^+ couple in the PVF film and the solution-phase ferrocene/ferricinium couple in acetonitrile solutions can be represented by the Nernstian expression:

$$(E^f_{poly,AN})_{app} = E^\circ_{poly,AN} + E_j' - \frac{RT}{F}\ln\frac{f^{Fc^\circ}_{poly,AN}}{f^{Fc^+}_{poly,AN}} - \frac{RT}{F}\ln a_{(ClO_4^-)_{soln,AN}}, \quad (5)$$

$$(E^f_{soln,AN})_{app} = E^\circ_{soln,AN} + E_j' - \frac{RT}{F}\ln\frac{f^{Fc^\circ}_{soln,AN}}{f^{Fc^+}_{soln,AN}}, \quad (6)$$

where $(E^f_{poly,AN})_{app}$ and $(E^f_{soln,AN})_{app}$ were measured with respect to the SSCE, E_j' is the liquid junction potential between SSCE (aq) and $LiClO_4$ (0.02—1.0 M, AN), and the other terms correspond to those of the acetonitrile solution system in place of the aqueous solution system (Eqs. 1 and 2). The plot of $(E^f_{poly,AN})_{app}$ (or $(E^f_{soln,AN})_{app}$) vs. $\log a_{(ClO_4^-)_{soln,AN}}$ gave the straight line with slope of −136 (or −78) mV per decade in ClO_4^- activity in the examined range of $a_{(ClO_4^-)_{soln,AN}}$ (see Fig. 7). Thus, one can obtain the linear relation between $\Delta(E^f_{AN})_{app}$ ($=(E^f_{poly,AN})_{app}-(E^f_{soln,AN})_{app}$) and $a_{(ClO_4^-)_{soln,AN}}$. In this case, the slope of $\Delta(E^f_{AN})_{app}$ vs. $\log a_{(ClO_4^-)_{soln,AN}}$ plot is −58 mV per decade in $a_{(ClO_4^-)_{soln,AN}}$ which almost coincides with that (−59 mV per decade) expected for the case where the PVF film is ideally permselective to ClO_4^- anion and the dependences of the activity coefficient terms for the polymer film and solution-phase systems i.e.,

$$\frac{RT}{F}\ln\frac{f^{Fc^\circ}_{poly,AN}}{f^{Fc^+}_{poly,AN}} \quad \text{and} \quad \frac{RT}{F}\ln\frac{f^{Fc^\circ}_{soln,AN}}{f^{Fc^+}_{soln,AN}}$$

upon the activity of ClO_4^- are the same.

A probable reaction scheme, by which the in situ EQCM and potentiometric data obtained may be reasonably explained, is as follows:

$$(Fc^\circ, n'S)_{poly} + (ClO_4^-)_{soln} + m'(S)_{soln} \rightleftarrows (Fc^+\cdot ClO_4^-, (n'+m')S)_{poly} + e^-, \quad (7)$$

where S represents the solvent (CH_3CN), the coefficients m' and n' are not necessarily integers as in Eq. 4.[10] The mechanism of the ion and solvent transport accompanying the redox reaction of the PVF film in acetonitrile media may be depicted schematically in the same manner as in Fig. 5. To our knowledge, this is a first report concerning the in situ EQCM behavior of PVF film in nonaqueous media.

In conclusion, the present study strongly demonstrates that a combination of the in situ EQCM measurement and the measurement of the dependence of $(E^f_{poly})_{app}$ on the electrolyte concentration allows us to elucidate quantitatively the ion and/or solvent transport process across the polymer film/solution interface accompanying the redox reaction of thin films on electrode surfaces.

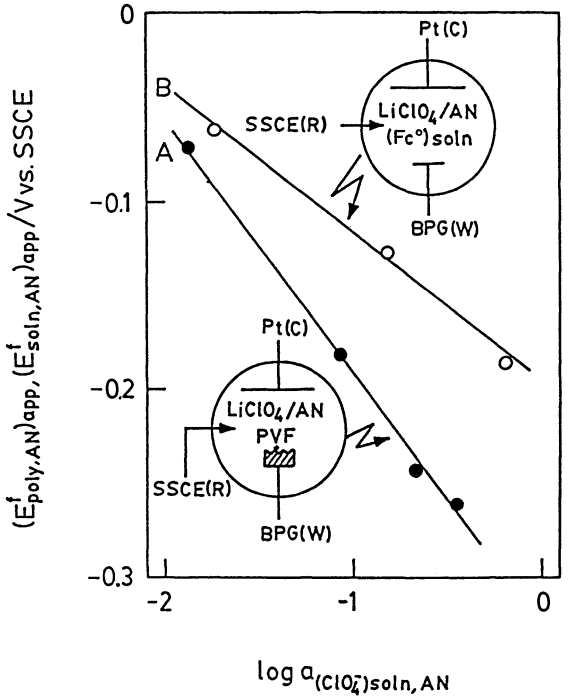

Fig. 7. Apparent formal potentials of (A) the Fc°/Fc^+ couple in the PVF film and (B) the solution-phase Fc°/Fc^+ couple as a function of the activity of the $LiClO_4$ supporting electrolyte. Amount of PVF coated on BPG electrode: 21.5 μg cm^{-2}. Concentration of ferrocene (Fc°) in solution: 1 mM. The insets schematically represent the three-electrode systems employed to examine the dependence of $(E^f_{poly,AN})_{app}$ and $(E^f_{soln,AN})_{app}$ upon $\log a_{(ClO_4^-)_{soln,AN}}$.

11) The F_c°/F_c^{+} couple in the PVF film and the $F_c\text{-}N^{+}/F_c\text{-}N^{2+}$ couple are similar in their molecular structures. It is, if possible, preferable that the charges on the oxidized and reduced forms of the PVF film are the same as those of the solution-phase ferrocene compound (as in the case of the acetonitrile solution system). However, the solubility of the reduced form of ferrocene (F_c°) in the aqueous solutions used was too low to conduct usual electrochemical experiments, so that the water-soluble ferrocene derivative (i.e., $F_c\text{-}N^{+}$) was employed in this study.

Fragmentation of Energy-Selected Fluorobenzene Ion

(Received May 15, 1991)

Dissociation of the fluorobenzene ion has been studied using threshold photoelectron–photoion coincidence (TPEPICO) mass spectrometry. The detailed breakdown curves were measured over internal energies from 0 to 9 eV. Asymmetric flight time distributions due to metastable dissociation were observed for the formations of $C_6H_5^+$ and $C_4H_3F^+$, and their absolute decay rate constants were derived from their flight time distributions. The information-theoretical approach has been employed for the analysis of kinetic energy release distribution (KERD). The results of surprisal analysis demonstrated that experimental KERDs are in good agreement with the predictions based on the statistical theory of mass spectra (QET). The heat of formation of $C_4H_3F^{\cdot+}$ has been estimated to be 222±2 kcal mol^{-1}.

The quasi-equilibrium theory (QET)[1,2] on the unimolecular dissociation of gaseous ions assumes that (1) initial vibronic excitation by ionization is converted rapidly to vibrational energy of the ground electronic state of the molecular ion, that (2) all internal modes are accessible at a given total energy and vibrational energy redistribution within an energized molecular ion is much faster than dissociation (RRKM theory);[3,4]

$$k_d \ll k_{IC} \text{ and } k_{rdt}. \tag{1}$$

Here, k_d, k_{IC}, and k_{rdt} are respectively the rate constants of dissociation, internal conversion and redistribution of initial internal energy. Furthermore, QET requires (3) an equilibrium between the molecular ion M^+ and the transition state $T^{+\neq}$:

$$M^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} T^{+\neq} \xrightarrow{k_d} \text{fragment ion} + \text{neutrals} \tag{2a}$$

and

$$k_1 \text{ and } k_{-1} \gg k_d. \tag{2b}$$

These assumptions result in the following QET expression of decay rate constant:[1]

$$k(E) = \sigma \int_0^{E_i - E_a} \rho^{\neq}(E)\, dE/h\, \rho(E_i), \tag{3}$$

where $\rho(E_i)$ is the state density of the molecular ion with internal energy of E_i, $\rho^{\neq}(E)$ that of the transition state for the dissociation process with the activation energy E_a and σ the degeneracy of reaction pathways.

Energized diatomic and triatomic molecules often relax by state-specific dissociation and/or radiative transition (fluorescence, etc.).[5–7] When the molecular ion is sufficiently large, radiative transition usually does not compete with internal conversion because of its high density of states. Therefore, a large molecular ion characterized by a large phase space should satisfy these hypothesis[1–3] which the quasi-equilibrium theory assumes.

Molecular ions containing a fluorine atom were frequently reported to dissociate nonstatistically, which include CF_4^+ and $C_2F_6^+$.[5,6] In the case of CF_4^+ fluorescent transition plays an important role prior to dissociation.[5] Here we have studied dissociation of the fluorobenzene by using threshold photoelectron–photoion coincidence (TPEPICO) mass spectrometry[8,9] since this molecule is an example of large molecular size and also contains a heteroatom fluorine. Time-dependent breakdown curves[10,11] have also been derived from absolute decay rate constants obtained experimentally and the information-theoretical approach[12] has been employed to study energy disposal in fragmentation.

Experimental

Our TPEPICO mass spectrometer has been described in detail previously.[13,14] It was used under the double-field source and space focusing condition.[15–17] A typical field strength in an ionization region was 20.0 V cm^{-1}, and the corresponding energy resolution for threshold photoelectrons was about 21 meV (FWHM) for the Ar $^2P_{3/2}$ state. The TOF mass resolution ($T/2\Delta T$) was about 50 amu (FWHM) for thermal ions.

Breakdown curves were constructed from relative ion abundances obtained from TOF peak areas. Overlapped ion peaks were deconvoluted assuming that a TOF mass peak is Gaussian. Because the m/z 95 ion was not fully separated from those of the m/z 96 ion under the ion extraction field of 20 V cm^{-1}, their relative abundances were evaluated from deconvolution results of those TOF peaks measured under the 34 V cm^{-1} field strength corresponding to the mass resolution of about 70 amu (FWHM). Ion loss due to initial kinetic energy was not taken into account for construction of breakdown curves.

Fluorobenzene was commercially obtained from Aldrich with a stated purity of 99% and was used without further purification. Both HeI photoionization and 70 eV electron-impact ionization mass spectra measured by an Extranuclear 324-9 quadrupole mass spectrometer and a Kratos AEI MS-50 DA, respectively, showed no significant impurity. All experiments were carried out at a source pressure of 3×10^{-5} Torr (1 Torr=133.322 Pa) and at room temperature.

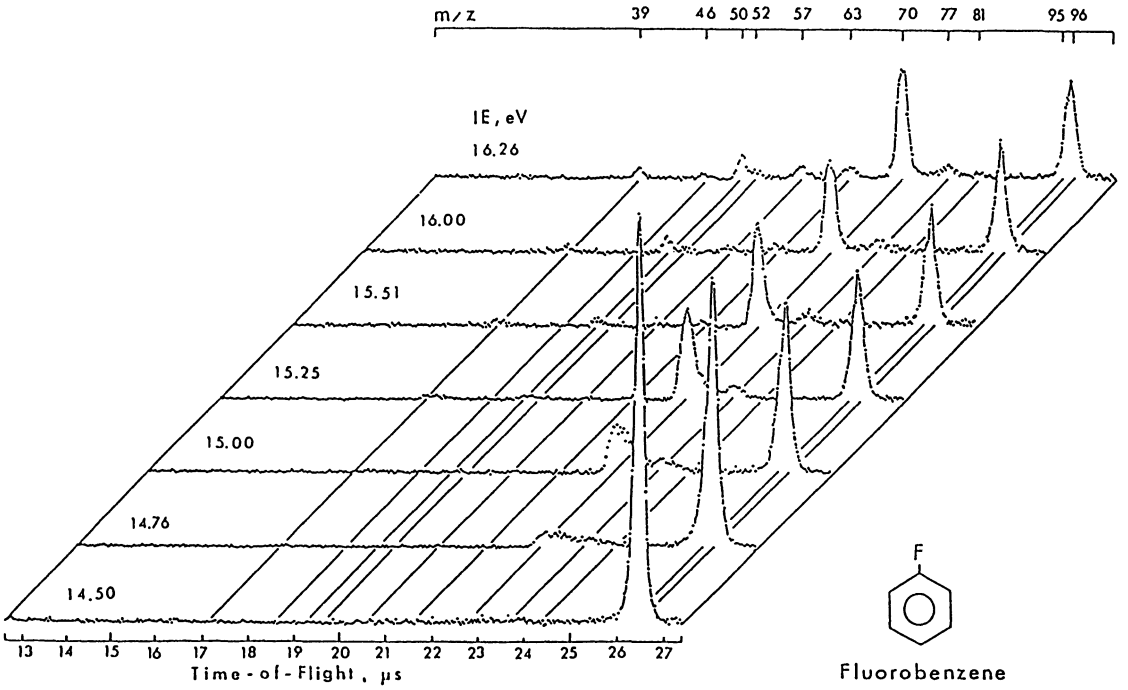

Fig. 1. Typical coincidence TOF mass spectra at several photon energies.

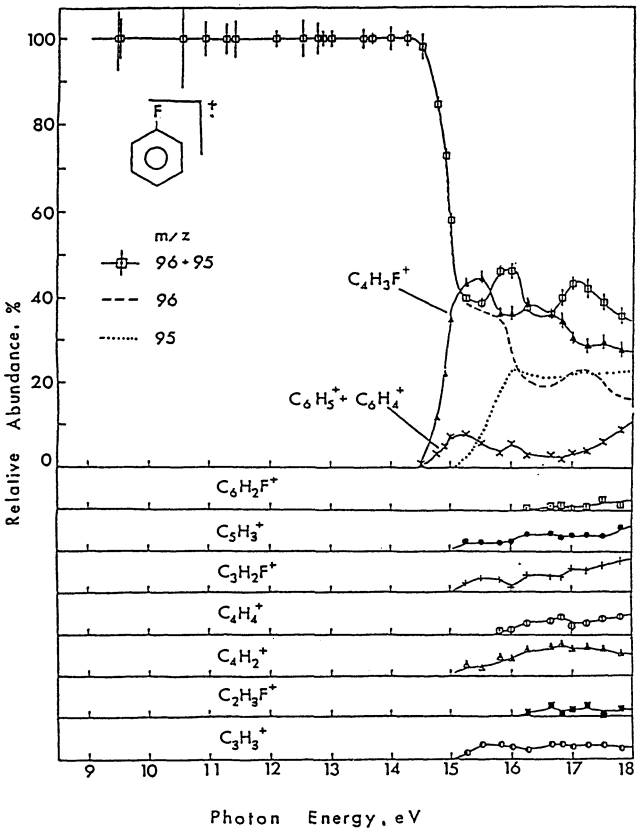

Fig. 2. The experimental breakdown curves of the fluorobenzene ion measured under an ion extraction field of 20 V cm^{-1}. The breakdown curve of $C_6H_4F^+$ was estimated from deconvolution of overlapped peaks of m/z 96 and 95 measured under the 34-V cm^{-1} extraction field, assuming the individual peaks are Gaussian.

Results and Discussion

Breakdown Curves and Fragmentation Pathways. Major products ions are $C_6H_5F^+$ (m/z 96), $C_6H_4F^+$ (m/z 95), $C_5H_2F^+$ (m/z 81), $C_6H_5^+$ (m/z 77), $C_6H_4^+$ (m/z 76), $C_4H_3F^+$ (m/z 70), $C_5H_3^+$ (m/z 63), $C_3H_2F^+$ (m/z 57), $C_4H_4^+$ (m/z 52), $C_4H_2^+$ (m/z 50), $C_2H_3F^+$ (m/z 46), and $C_3H_3^+$ (m/z 39). Fig. 1 shows typical coincidence TOF mass spectra measured at several photon energies, and the experimental breakdown curves are presented in Fig. 2. Fragmentation pathways elucidated from

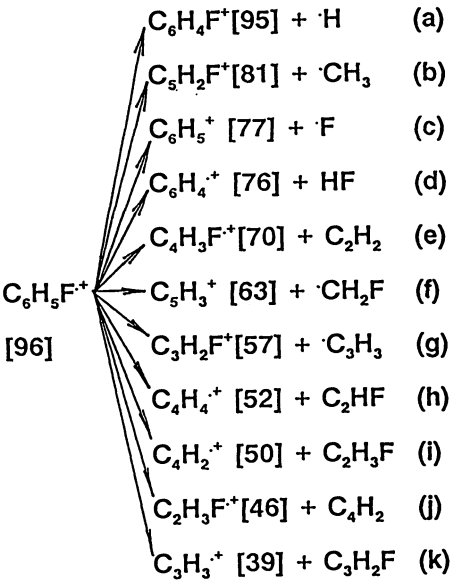

Fig. 3. Major fragmentation pathways of the fluorobenzene ion.

appearance potentials are summarized in Fig. 3. Appearance potentials obtained from breakdown curves are listed in Table 1. Among these dissociations abundant processes are (1) the C_2H_2-loss (Reaction e), (2) the hydrogen-loss (Reaction a) and (3) the fluorine elimination (Reaction c) from the molecular ion.

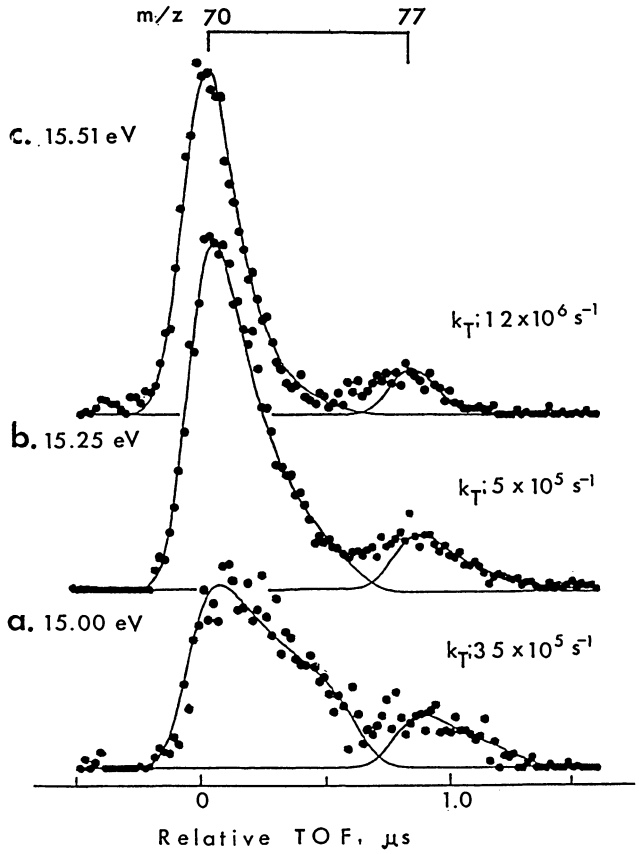

Fig. 4. The flight time distributions of m/z 70 and 77 ions (closed circles) observed at several photon energies under an ion extraction field of 34 V cm^{-1}. The solid curves are the distributions convoluted by the indicated decay rate constants.

Absolute Decay Rate Constants and Time-Dependent Breakdown Curves. A. Metastable Fragmentation. Asymmetric flight time distributions due to metastable dissociation[18] were observed for the C_2H_2- and F-eliminations from the parent ion which are formations of $C_6H_5^+$ and $C_4H_3F^+$ (Fig. 4). Total decay rate constants k_T were obtained directly from their asymmetric TOF distributions: Flight time distributions resulting from metastable fragmentation which occurs in both the first and second ion extraction fields were calculated numerically. The rate constant and initial ion kinetic energy were then adjusted until the calculated TOF distribution agrees with experiment. Experimental TOF distributions for both $C_6H_5^+$ and $C_4H_3F^+$ ions were found to be well fitted by using a single and same

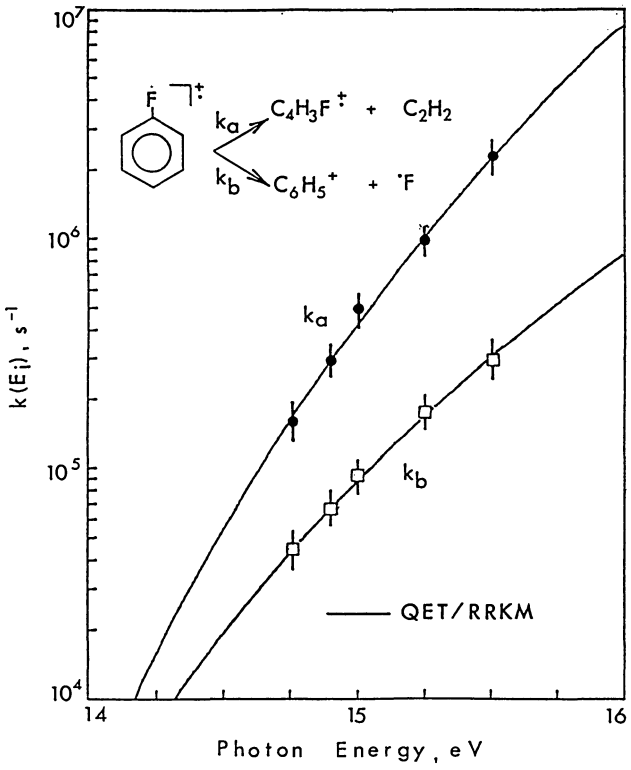

Fig. 5. Metastable decay rate constants for the formations of $C_4H_3F^+$ and $C_6H_5^+$ as a function of photon energy. Circles are the experimental decay rate constants. Solid curves are those obtained by QET calculations with the best fits to the experimental data.

rate constant (Table 2). Thus the same total rate observed suggests a competing dissociation mechanism for the fluorine and C_2H_2 loss channels. Individual rate constants for these reactions were therefore obtained from relative abundances in the breakdown diagram.

Individual decay rate constants are plotted against photon energy in Fig. 5 in comparison with those calculated by QET (the solid curves). In the QET calculation the vibrational frequencies of fluorobenzene ion were taken to be the same as those of the neutral molecule and the vibrational frequencies of the transition state were derived by multiplying those of the ion (excluding a reaction mode) by a factor F reflecting tightness ($F>1$) or looseness ($F<1$) of the transition state.[19] The frequencies and parameters used are listed in Table 3. The density of vibrational states were calculated using the Whitten–Rabinovitch approximation.[20] The activation energy E_a and factor F were used as adjustable parameters until the best fit to experiment is obtained.

Adiabatic appearance potentials were evaluated to be

respectively 13.10±0.05 eV and 13.14±0.05 eV for the formations of $C_6H_5^+$ and $C_4H_3F^+$, using the relation

$$AP_{adb} = IP + E_a, \quad (4)$$

Herein, the ionization potential IP of the fluorobenzene molecule was taken to be 9.11 eV from the literature.[27] Using these values the heat of formations $\Delta H_f(C_6H_5^+)$ and $\Delta H_f(C_4H_3F^+)$ were evaluated to be 257±2 and 222±2 kcal mol^{-1}. The heat of formation obtained in this work for the phenyl cation can be compared with the value ΔH_{f298}° ($C_6H_5^+$) of about 272 kcal mol^{-1} (1140 kJ mol^{-1}) suggested in Ref. 34 after rough correction of kinetic shift (50 kJ mol^{-1}).

B. Kinetic Shift. The experimental breakdown curves of the parent ion measured under the different field strengths of ion extraction (E_s=20 and 34 V cm^{-1}) shifted by ca. 0.1 eV. This shift results from difference in the reaction time equal to a time spending during acceleration in a TOF mass spectrometer, which are calculated to be 3.4 and 2.6 μs, respectively. The breakdown curves for these reaction times were reconstructed from the individual rate constants, and are presented in Fig. 6. In the figure a shift, about 75 meV, of crossover point between the breakdown curves of the parent ion and $C_4H_3F^+$ was consistent with experiment. The calculated breakdown curves are fairly in good agreement with the TPEPICO breakdown curves.

Such a kinetic shift leads to heat of formations higher than those derived from adiabatic potentials, and can be ascribed to a large phase space volume of the molecular ion brought about by (1) a large number of internal modes or a high density of states $\rho(E)$ and (2) a high activation energy E_a. A large phase space volume corresponds to a long lifetime of a fragmenting ion which is the average time until a given phase point crosses over the critical surface to dissociation. Our observations

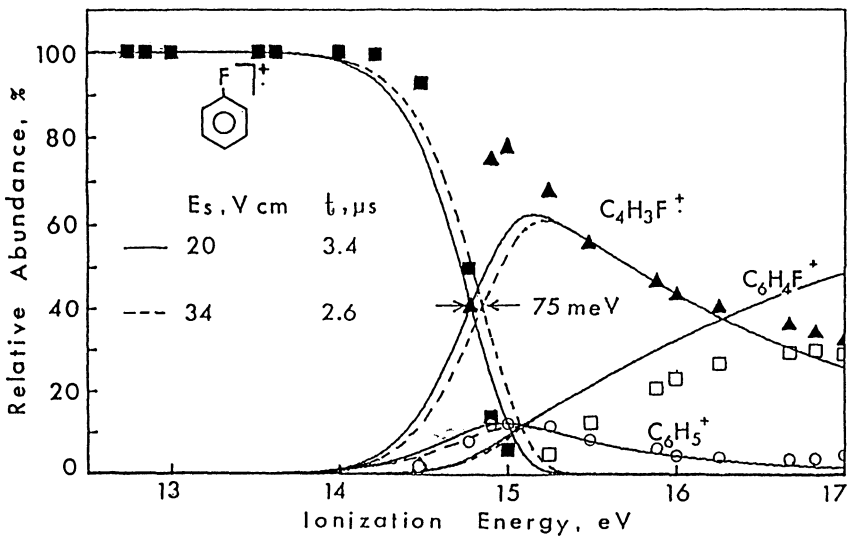

Fig. 6. The breakdown curves for the reaction times 3.4 and 2.6 μs corresponding to the extraction fields of 20 and 34 V cm^{-1}, respectively. Symbols are the corrected breakdown curves for the 20-V cm field.

are thus consistent with the prediction by QET.

Information-Theoretical Analysis of Energy Disposal in Fragmentation. A. Kinetic Energy Release Distribution (KERD). Kinetic energy release distributions for the formation of $C_4H_3F^+$ ions (m/z 70) were extracted from their flight time distributions using a linear regression method. The approach utilized here has been described previously, which follows those used by Powis et al.[21] and Baer et al.[22]

A typical deconvolution result is presented in Fig. 7. Here we used the minimum energy E_o=5.0 meV, the room temperature T=300 K and the nine discrete kinetic energy releases: $Q=(2n-1)^2 E_o$ (i=1 to 9). The experimental flight distribution $F(t)$ was convoluted by a series of calculated distributions $F(t; Q_i)$:

$$F(t)=\sum_i W(i)\, F(t; Q_i). \tag{5}$$

The KERD $P(Q_i)$ can be obtained from the coefficients $W(i)$ which give the best fit to experiment $F(t)$:

$$P(Q_i)=[W(i)/\sum_i W(i)]/[4(2n-1)E_o]. \tag{6}$$

A KERD extracted from these regression coefficients is plotted as a step graph in Fig. 8 together with the QET prediction. The QET kinetic energy release distribution $P(Q; E_i)$ to be compared to TPEPICO experiments is given to be

$$P(Q; E_i)\,dQ=\rho^{\neq}(E_i-E_a-Q)\,dQ/\,W^{\neq}(E_i-E_a). \tag{7}$$

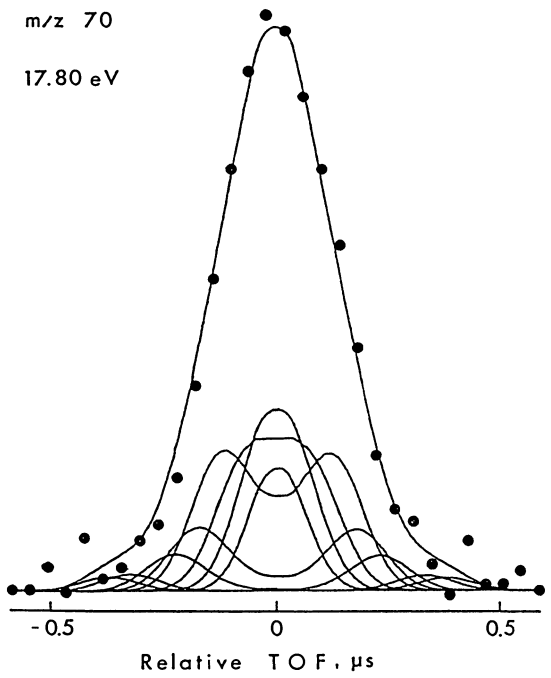

Fig. 7. An example of TOF distributions of the m/z 70 ion and a deconvolution result by the multiple linear regression method. The solid curves are the flight time distributions simulated for a series of the nine discrete kinetic energy releases and their sum to be compared with experiment.

Herein, $\rho^{\neq}(E_i-E_a-Q)$ is the state density of the transition state at internal energy of E_i-E_a-Q, and $W^{\neq}(E_i-E_a)$ is the state sum of the activated complex with excess energy E_i-E_a.

The average KERs are then obtained by

$$\langle Q\rangle_{E_i}=\int_0^{E_i-E_a} Q\, P(Q; E_i)\, dQ, \tag{8}$$

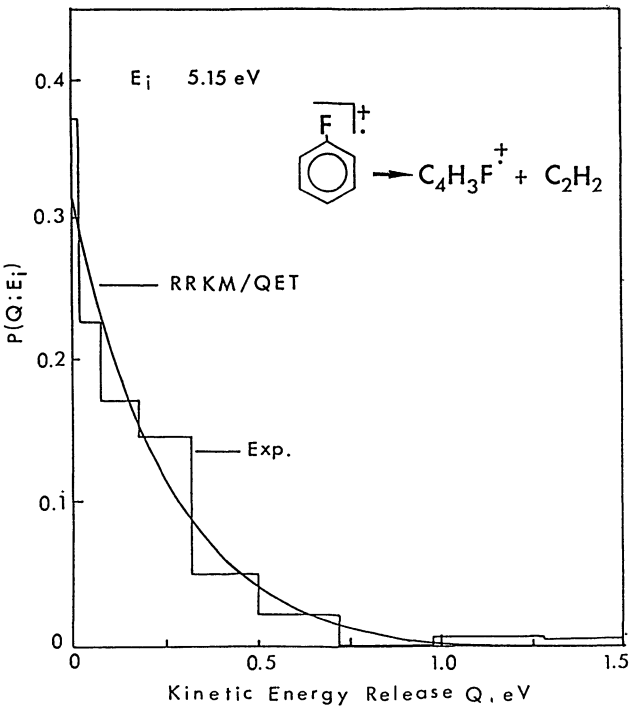

Fig. 8. A KERD for the formation of $C_4H_3F^+$ extracted from its flight time distribution is presented together with the QET prediction.

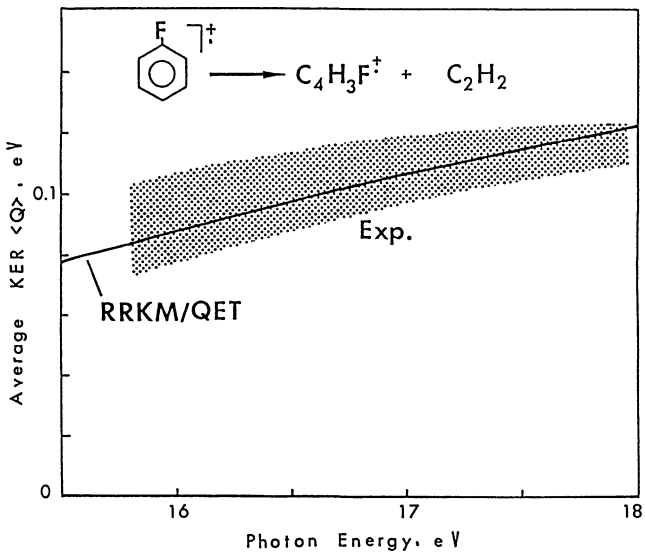

Fig. 9. Average KERs $\langle Q\rangle$ observed for the formation of $C_4H_3F^+$ (shaded area). The solid curve is the average KERs calculated by QET.

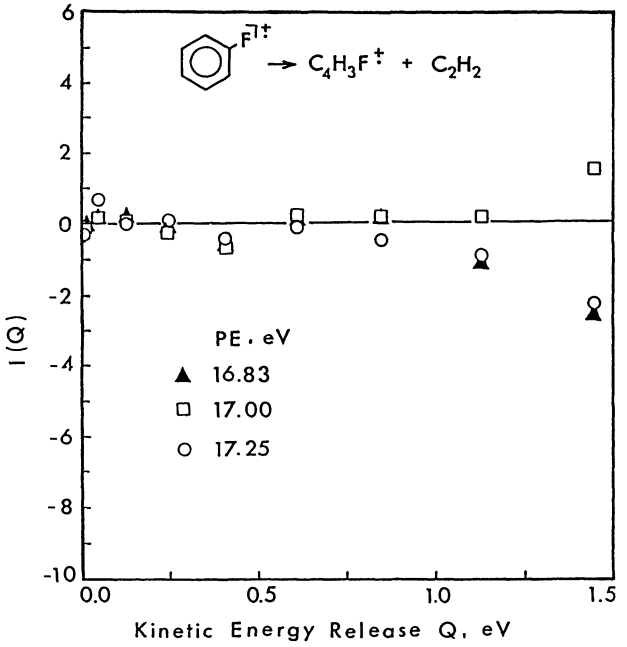

Fig. 10. Surprisal plots of KERDs observed for the $C_4H_3F^+$ formation.

and are presented in Fig. 9. Thus as seen in the figures the experimental KERDs and KERs seem to be in good agreement with the statistical expectations.

B. Surprisal Plot. Levine and Bernstein[25,26] have recently developed the thermodynamic approach to collision processes in order to bridge the gap between the equilibrium and disequilibrium on the basis of information theory. The authors[24] introduced the concept of the "surprisal" to measure how an experimental result differs from a prediction. If $P^\circ(Q)$ is the prior distribution with a kinetic energy release Q, the surprisal $I(Q)$ of an experimental distribution $P(Q)$ is defined as

$$I(Q) = -\ln[P(Q)/P^\circ(Q)]. \quad (9)$$

Here we used the QET kinetic energy release distribution as the prior distribution. The surprisal plots (Fig. 10) showed almost zero less than 0.5 eV and strongly suggest that the observed KERDs are consistent with those predicted by the statistical rate theory of mass spectra. Scattered data points over 0.5 eV corresponding to the tail of a TOF distribution are obviously due to experimental errors.

As a conclusion, whereas this molecule contains a heteroatom fluorine, statistical dissociation thus observed indicates that internal conversion controls fragmentation of the fluorobenzene ion because of its high state density.

We thank the USA Department of Energy for support of this work under Contract No. DE-AC02-76-ER02567 and the Regional Facility in Mass Spectrometry at the University of Nebraska.

(Received May 24, 1991)

The reduction of dioxygen by cytochrome oxidase has been investigated, in the time interval between 0.1 and 5.4 ms after initiation of the reaction, by using time-resolved resonance Raman spectroscopy combined with the Artificial Cardiovascular System [Ogura et al., *Biochemistry,* **28**, 8022 (1989)]. At 0.5 ms we observed a new oxygen-isotope sensitive Raman band at 356 cm^{-1} for $^{16}O_2$, which shifted down to 341 cm^{-1} for $^{18}O_2$. The temporal behavior of this band was found to be very close to that of another oxygen-isotope sensitive band at 788 cm^{-1} which had been assigned previously to the Fe(IV)=O stretching mode of the ferryloxo intermediate [Ogura et al., *J. Biol. Chem.,* **265**, 14721(1990)]. However, the fact that the 788 cm^{-1} band shifts to a higher frequency (802 cm^{-1}) in ^2H_2O, taken together with the present detection of two oxygen-isotope sensitive bands, prompts us to suggest an alternative assignment; namely, that these bands arise from the O^-–O^- (788 cm^{-1}) and Fe(III)–O^- (356 cm^{-1}) stretching modes of the Fe(III)–O^-–O^-–H intermediate. This conclusion forces a reconsideration of the currently accepted view of cytochrome oxidase catalysis.

Cytochrome oxidase is the terminal enzyme in the respiratory chain of aerobic organisms.[1,2] This enzyme is a membrane protein containing two heme A groups (Fe_a and Fe_{a3}) and two copper ions (Cu_A and Cu_B) as redox active metal centers and couples the dioxygen reduction reaction with proton translocation across the membrane. The electrochemical potential across the membrane thus generated is ultimately used to synthesize ATP. A functional unit containing the Fe_a and Cu_A ions serves as an electron transfer protein from cytochrome *c* to another functional unit containing the Fe_{a3}–Cu_B binuclear dioxygen reducing site. The Fe_{a3} and Cu_B ions are in close proximity so that they could be antiferromagnetically coupled in the oxidized state, while the Fe_a and Cu_A ions are separated and EPR active.

The reaction intermediates of this enzyme have been studied mainly with visible absorption[3–6] and EPR[7] spectroscopies. Recently, time-resolved resonance Raman spectroscopy added decisive structural information on the primary oxygenated derivative of the enzyme.[8–10] As to subsequent intermediates, a Raman band assignable to the Fe(IV)=O stretching mode of the ferryloxo heme was reported by ourselves and others.[11–13] On the basis of these results, a unified view of the catalytic cycle of cytochrome oxidase was proposed.[14] However, since the observation of the Fe(IV)=O stretching Raman band is crucial to this interpretation, if its assignment were not correct, the interpretation would lack experimental basis. In this paper we present new experimental results that are incompatible with the current interpretation of the resonance Raman spectra of the Fe(IV)=O intermediate and suggest an alternative assignment of this oxygen-isotope sensitive Raman band.

Material and Method

Cytochrome oxidase was isolated from fresh bovine hearts according to the method described elsewhere.[15] The sample solution contained cytochrome oxidase (100 μM in terms of aa_3 unit), horse heart cytochrome *c* (Sigma, 16.6 μM) and sodium ascorbate (Wako Chemicals, 50 mM) in 50 mM sodium phosphate buffer, pH 7.2. At relatively high salt concentration the cytochrome *c*-cytochrome oxidase complex formation is negligible. In order to continuously generate reaction intermediates in a flow-cell over the long time period (ca. 10 h) required for data accumulation, the "Artificial Cardiovascular System"[16] was used so as to limit the amount of enzyme needed. The quartz flow cell (cross section, 0.6×0.6 mm^2) was used in this experiment and the flow rate was held constant as 40 ml min^{-1}. Accordingly, the previously described dual-beam flow apparatus[17] was attached to the flow-cell in order to change the delay time (Δt_d) of the probe beam from the pump beam. The sample temperature in the flow-cell was maintained at 5 °C. The concentration of oxygen incorporated into the solution by the "Lung" was approximately 150 μM.

An argon ion laser (Spectra Physics, 164)-pumped dye laser (Spectra Physics, 375), employing Rhodamine 6G, was used to provide the pump beam. The output at 590 nm (100 mW), focused with a cylindrical lens to a 100 μm wide slit image, was used to photolyze carbonmonoxide from the CO-bound, fully-reduced enzyme. Photodissociation initiates the reaction of the enzyme with O_2, in the presence of O_2, but simply produces the deoxy state in the absence of O_2. Under these conditions, about 95% of the CO was photolyzed from the CO-bound enzyme, as judged from the intensity of the Fe(II)–CO stretching band. The probe beam was provided by a dye laser (Spectra Physics 375B), using stilbene 420, which was excited by another Ar^+ ion laser (Spectra Physics, 2045). The output at 423 nm (10 mW) was focused to a spot (20 μm in diameter) at various distances on the downstream side of the pump

beam. Under these conditions a given molecule is exposed to the pump and probe beams for 54 and 11 μs, respectively. The $^{16}O_2$ derivative, $^{18}O_2$ derivative and the deoxy state were measured in turn at every 5 min for the identical enzyme under identical illumination geometry. Therefore their difference spectra were very accurate. Each spectrum presented is a sum of six to nine of the individual (5 min) spectra.

The scattered light was dispersed with a double monochromator (Spex 1404) and detected with an intensified photodiode array (PAR 1421Q). Pixel-to-pixel variation of sensitivity of the photodiode array was corrected with white light; the observed Raman spectrum was divided by the spectrum of the white light. Raman shifts were calibrated with alcohol observed under the same flowing conditions and the accuracy of the peak frequency was ±2 and ±4 cm^{-1} for strong and weak Raman bands, respectively.

For a large molecule like cytochrome oxidase (M_r=200 000), the lowest frequency where any Raman band could be identified for the flowing sample was 600 cm^{-1} because of increased Rayleigh scattering, even when an optical filter (short cut filter) for removing it was placed before the monochromator. In order to lower this limit frequency, a special optical filter (referred to as a spatial filter) was designed and placed between the sample and the monochromator. This device is composed of a microscope objective lens, a rectangular slit, and a collection lens which is F-matched to the monochromator used. Although details of the device and its capability will be described separately,[18] we note here that the use of this device enabled us to measure the Raman spectrum until as low as 250 cm^{-1}.

Results

Figure 1 depicts time-resolved resonance Raman spectra of cytochrome oxidase in ^2H_2O for Δt_d=0.1 ms. Figs. 1A and 1B were observed for $^{16}O_2$ and $^{18}O_2$, respectively, and Fig. 1C shows their difference (A minus B). In both Figs. 1A and 1B porphyrin in-plane vibrational modes are seen at 750 (ν_{16}), 684 (ν_7), and 342 cm^{-1} (ν_8). Although the difference between the two spectra is small, a clear derivative-like curve is seen in Fig. 1C, indicating a frequency shift due to the oxygen isotope; a Raman band at 571 cm^{-1} for $^{16}O_2$ shifts down to 544 cm^{-1} for $^{18}O_2$. One can assign this Raman band to the Fe(II)–O_2 stretching vibration (ν_{Fe-O_2}) of the primary oxygen compound, compound A.[5] Since the intensity of the Raman band due to the heme-bound oxygen was fairly weak compared with those of porphyrin bands, hereafter we will present resonance Raman spectra of reaction intermediates as difference spectra ($^{16}O_2$ minus $^{18}O_2$).

Figures 2 and 3 display the time-resolved resonance Raman difference spectra of cytochrome oxidase in H_2O and ^2H_2O, respectively. The delay time was varied from 0.1 to 5.4 ms and is specified at the right side of each spectrum. The Raman band at 573 cm^{-1} for $^{16}O_2$ in Fig. 2A (Δt_d=0.1 ms) shows a downshift to 544 cm^{-1} for $^{18}O_2$, which well reproduced the previous observations.[8–10] This band exhibited no frequency shift in ^2H_2O within the experimental uncertainty (Fig. 3A), in agreement with the recent results by Han et al.[13]

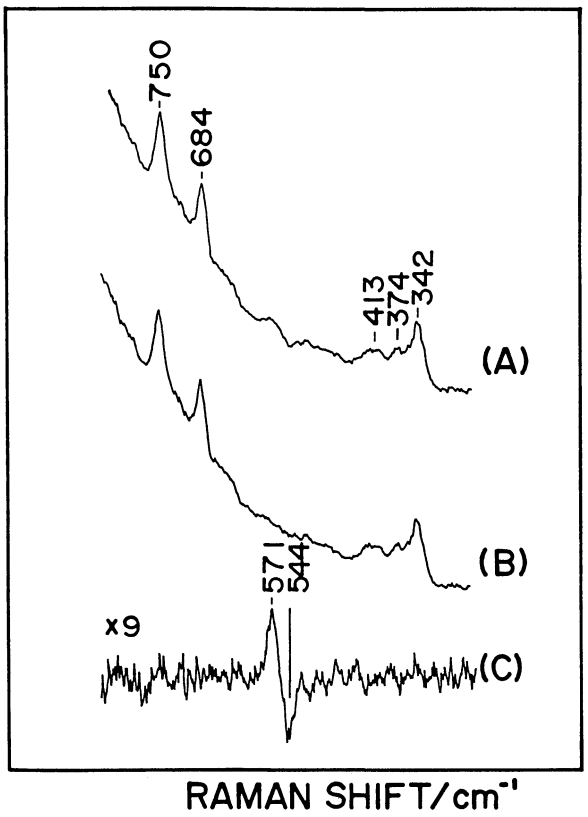

Fig. 1. Time-resolved resonance Raman spectra of cytochrome oxidase in ^2H_2O for Δt_d=0.1 ms. Spectra A and B were observed with $^{16}O_2$ and $^{18}O_2$, respectively, and trace C denotes the difference spectrum, A minus B. Accumulation time was 300 s.

In Fig. 2C, at Δt_d=0.5 ms, two new oxygen-isotope sensitive bands appeared at 788 and 356 cm^{-1} and the 573/544 cm^{-1} band apparently became weaker. The band for $^{16}O_2$ at 788 cm^{-1} exhibited a downshift to 749 cm^{-1} for $^{18}O_2$. Although it is not clear whether the 788 cm^{-1} band is actually composed of two bands or if the apparent doublet results from noise, the latter alternative appears more likely since in ^2H_2O this Raman band appeared as a singlet at 802 cm^{-1} for $^{16}O_2$ and at 766 cm^{-1} for $^{18}O_2$ as shown in Fig. 3B. The apparent upshift of the 788 cm^{-1} band is in agreement with the report by Han et al.[13] but not with that by Varotsis and Babcock.[12] This will be discussed later.

Development of the spatial filter in this study enabled us to detect another oxygen-isotope sensitive band at 356 cm^{-1} for $^{16}O_2$ which shifts to 342 cm^{-1} for $^{18}O_2$, as seen in Fig. 2C; i.e., the true positions of the 356 and 342 cm^{-1} bands might be slightly lower and higher, respectively, because those numbers were derived from the difference spectrum. This band first appears at Δt_d=0.4 ms (Fig. 2B) and persists until Δt_d=3.2 ms. In ^2H_2O the corresponding Raman band appeared at 358 and 343 cm^{-1} for $^{16}O_2$ and $^{18}O_2$, respectively. Thus, the vibrational frequency of the new band is insensitive to deuterium exchange within the experimental

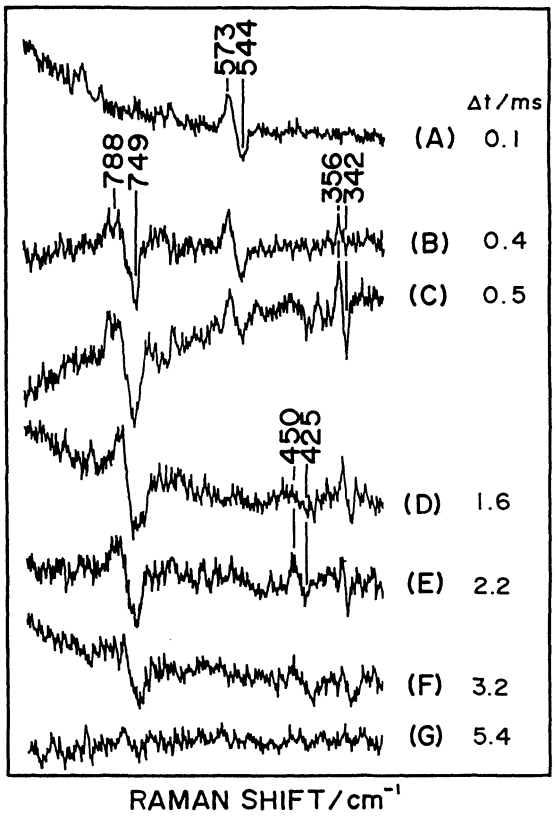

Fig. 2. Time-resolved Raman difference spectra of cytochrome oxidase in H_2O obtained by subtracting the $^{18}O_2$ spectrum from the corresponding $^{16}O_2$ spectrum. Δt_d values are specified at right side of each spectrum. The ordinate is arbitrarily scaled.

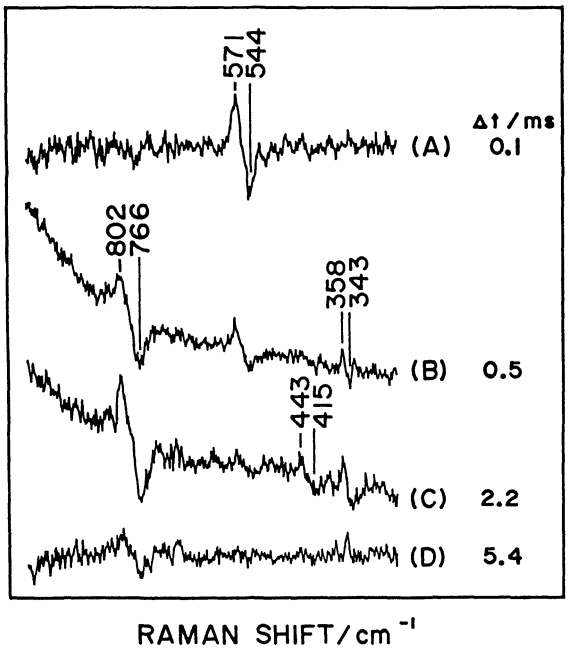

Fig. 3. Time-resolved Raman difference spectra of cytochrome oxidase in ^2H_2O obtained by subtracting the $^{18}O_2$ spectrum from the corresponding $^{16}O_2$ spectrum. Δt_d values are specified at right side of each spectrum. The ordinate is arbitrarily scaled.

uncertainty.

At Δt_d=1.6 ms the Fe(II)-O_2 stretching band at 573/544 cm^{-1} has disappeared while the other two oxygen-isotope sensitive bands remain. At Δt_d=2.2 ms (Fig. 2E) yet another oxygen-isotope sensitive Raman band is observed at 450 cm^{-1} for $^{16}O_2$, which experiences a downshift to 425 cm^{-1} for $^{18}O_2$. In ^2H_2O this Raman band appeared at 443 cm^{-1} for $^{16}O_2$ and at 415 cm^{-1} for $^{18}O_2$. This observation is consistent with the report by Han et al.[13] A simple diatomic approximation of the Fe-OH stretching mode, which is assumed to occur at 450 cm^{-1},[13] predicts a frequency shift of 19 cm^{-1} for Fe-^{18}OH and 10 cm^{-1} for Fe-O^{2}H. Accordingly, the 450 cm^{-1} band is assigned to the Fe(III)-OH stretching vibration in agreement with the reassignment by Han et al.[13] Finally, in Fig. 2G (with Δt_d=5.4 ms) no oxygen-isotope sensitive Raman band is observed, indicating that the Fe_{a3} center does not possess an oxygen ligand derived from O_2. If the Fe_{a3} had a ligand such as OH^- or H_2O group in the so-called "pulsed form",[1] the ligand

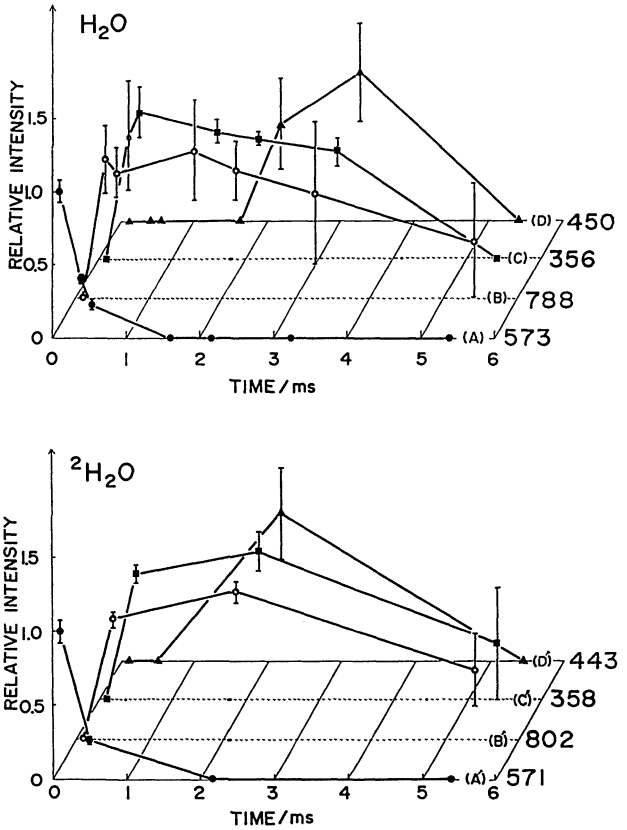

Fig. 4. Time-dependence of relatvie intensity of selected Raman bands at 573 (A, ●), 788 (B, ○), 356 (C, ■), and 450 cm^{-1} (D, ▲) for the H_2O solution and those at 571 (A′, ●), 802 (B′, ○), 358 (C′, ■) and 443 cm^{-1} (D′, ▲) in ^2H_2O solution. The trough-to-peak height of each spectrum was divided by the intensity of the porphyrin ν_7 band at 684 cm^{-1} of the original spectrum. In the plot, the highest value for individual bands is normalized to unity. Experimental uncertainty for the abscissa is smaller than the diameter of the circles.

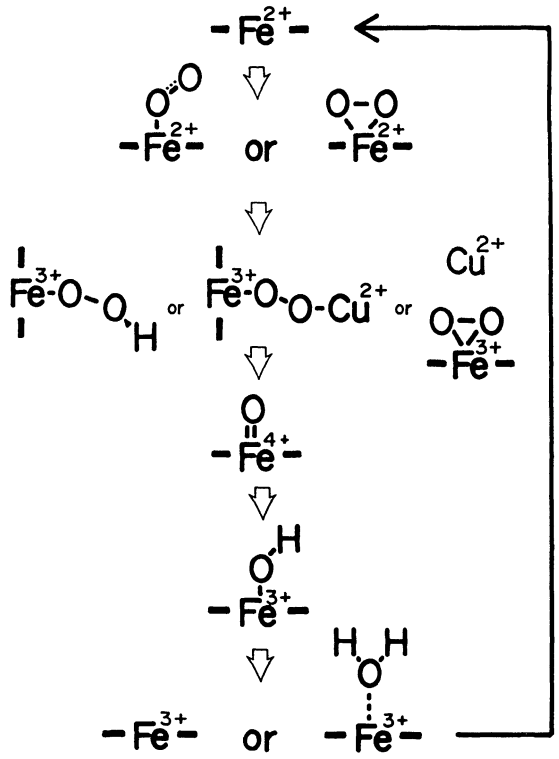
must be exchanged with bulk water.

The peak height intensities in the difference spectra shown in Figs. 2 and 3 were evaluated with regard to the intensity of the ν_7 band (684 cm^{-1} in Fig. 1) in the corresponding raw spectra of intermediates. The relative intensities are plotted against Δt_d in Fig. 4, where the upper (A—D) and lower figures (A′—D′) present the data for the H_2O and ^2H_2O solutions, respectively. For individual curves the maximum value is normalized to unity. Plots using the ν_{16} band at 750 cm^{-1} as an intensity standard gave similar curves for all the bands (not shown). Although these two porphyrin bands experience slight intensity alterations for different Δt_d, the changes were sufficiently small that they still could serve as effective intensity standards. As expected, the 571 cm^{-1} band of the primary compound quickly loses its intensity ($t_{1/2}$<400 μs). The 788 and 356 cm^{-1} bands simultaneously increase in intensity, with a concomitant decrease in intensity of the 573 cm^{-1} band. Note that the temporal behavior of the 788 and 356 cm^{-1} bands seem to proceed parallel with respect to Δt_d throughout the entire range of Δt_d (between 0.1 and 5.4 ms). The 450 cm^{-1} band arises at Δt_d=2.2 ms and has disappeared at Δt_d=5.4 ms. These features are also retained in ^2H_2O, although the number of experimental points is smaller for ^2H_2O. It is noted that the decay of the 802 (B′) and 358 cm^{-1} (C′) bands observed for the ^2H_2O solution seem somewhat slower than those of the 788 (B) and 356 cm^{-1} (C) bands of the H_2O solution, indicating that this process involves protonation to oxygen and/or couples with the proton translocation.



Scheme 1. Possible reaction intermediates.

Discussion

Assignment of the 788 and 356 cm^{-1} Raman Bands. The mechanism of oxygen reduction reaction by cytochrome oxidase has not been fully understood mainly due to the lack of decisive structural information of the reaction intermediates. Scheme 1 illustrates possible reaction intermediates involved at the Fe_{a3} site where the oxidation and ligation states of Cu_B are not included except for two cases. Resonance Raman spectroscopy is particularly well suited to determine which intermediates are actually involved, since their iron–oxygen and oxygen–oxygen stretching frequencies are expected to be distinct. For the primary intermediate (Δt_d=0.1 ms), the end-on structure for the dioxygen bound form is established from the Fe(II)–O_2 stretching frequency.[8–10] This frequency and the size of the $^{18}O_2$ isotopic shift are remarkably close to those of oxymyoglobin (569 cm^{-1})[19] and oxyhemoglobin (567[20] and 572[21] cm^{-1}), for which the X-ray crystallographic analysis has been completed.

In our previous study we assigned the Raman band at 788 cm^{-1} (748 cm^{-1} for $^{18}O_2$) to the Fe(IV)=O stretching vibration of the ferryloxo heme of the next intermediate, mainly based on the frequency value and its shift upon $^{16}O/^{18}O$ isotopic substitution.[11] Similar observations have recently been reported by two other groups,[12,13] although there was a discrepancy about the deuteration effect on this band; Varotsis and Babcock[12] reported that the 790 cm^{-1} band in H_2O exhibited no freqeuency shift in ^2H_2O, while Han et al.[13] reported that the 786 cm^{-1} band in H_2O shifted up to 801 cm^{-1} in ^2H_2O. The present result agrees with the latter observation; the 788 cm^{-1} band exhibiting a clear upshift to 802 cm^{-1} in ^2H_2O [at Δt_d=0.5 and 2.2 ms (Fig. 3)].

All groups assigned this band to the Fe(IV)=O stretching mode. In order to explain its upshift in ^2H_2O, Han et al.[13] assumed that the Fe(IV)=O oxygen is hydrogen bonded in H_2O but not in ^2H_2O. This assumption is based on the fact that the Fe(IV)=O stretching Raman band of compound II of horseradish peroxidase is shifted to a higher frequency at alkaline pH where the participating histidyl imidazole residue is deprotonated and the hydrogen bond ceases to exist.[22,23] However, the validity of that interpretation is questionable inasmuch as the pK_a of a hydrogen-bond donor residue should not be largely different between H_2O and ^2H_2O. If the hydrogen bond were disrupted in ^2H_2O while the pK_a value of the donor residue remained unaltered, we would have to postulate a large structural change of the protein between the H_2O and ^2H_2O solutions. Judging from the spectral similarity and kinetic behavior of the enzymes in H_2O and ^2H_2O, shown in Figs. 2—4, there is no evidence for such a large structural difference between the two solutions.

Moreover, the detection of another oxygen-isotope sensitive band (at 356 cm^{-1} in Figs. 2B—2D) reported here argues against the previous assignment for the

following reasons. The kinetic behavior of the 788 and 356 cm^{-1} bands in H_2O strongly suggest that these two bands arise from an identical intermediate. The same conclusion can be attained from the 802 and 358 cm^{-1} bands in ^2H_2O. In the case of an Fe(IV)=O heme, we expect only one oxygen-isotope sensitive Raman band; that is, the Fe(IV)=O stretching mode. While it may be argued that the Fe(IV)=O bending mode is also oxygen-isotope sensitive, this mode belongs to the E species of the C_{4v} point group appropriate to the Fe(IV)=O heme, and is expected to be infrared active but resonance Raman inactive. Consequently, it is quite unlikely that the 788 cm^{-1} band arises from an Fe(IV)=O heme moiety.

We suggest here that the 788 and 356 cm^{-1} bands are most appropriately assigned to the O^-–O^- and Fe(III)–O^- stretching modes of an Fe(III)–O^-–O^-–H fragment. The reasons for this assignment are as follows; 1) A simple diatomic approximation for Fe(III)–O_2H (and also for Fe(III)–$O_2{}^2H$) predicts a downshift of 12—13 cm^{-1} for ^{18}O substitution, which is close to the observed values (14—15 cm^{-1}), but a negligible downshift for its O-deuteration (3 cm^{-1}). 2) If the Fe(III)–O stretching force constant of the Fe(III)–O_2H complex is the same as that of Fe(III)–OH whose stretching frequency is located at 450 cm^{-1}, the diatomic approximation for the Fe(III)–O_2H bond predicts its stretching frequency at 355 cm^{-1}. This is satisfactorily close to the new Raman band observed in the present study. 3) The O–O stretching frequency of $^2H_2O_2$ is higher than that of H_2O_2 (by 4 cm^{-1}).[24] 4) In the case of oxyhemerythrin, for which the Fe–O–OH structure has been proposed, the O–O stretching mode is observed at 845 cm^{-1} and shifts to a higher frequency (by 4 cm^{-1}) in ^2H_2O.[25] 5) The observed ^{18}O isotopic frequency shift for the 788 cm^{-1} band (−40 cm^{-1}) is reasonably consistent with its assignment to the O–O stretching mode; using even the simple harmonic oscillator approximation, the expected shift is −45 cm^{-1} for the O–O stretching and −35 cm^{-1} for the Fe(IV)=O stretching mode.

Although the magnitude of the shift in ^2H_2O (+14 cm^{-1}) is appreciably larger than in the case of hemerythrin, it is not unreasonable because the upshift is caused by vibrational coupling between the O–O stretching and O–^2H bending modes.[24] If the frequency difference between the O–^2H bending and O–O stretching modes of the Fe(III)–O–O–H heme of cytochrome oxidase is much smaller than that of oxyhemerythrin, a larger upshift would be expected. In fact, for a porphyrin iron(III)–hydroxy compound, the Fe(III)–^{16}OH stretching Raman band at 541 cm^{-1} was observed to shift up by 13 cm^{-1} to 554 cm^{-1} upon its deuteration as a result of its interaction with the O–^2H bending mode.[26] Taking all these facts into consideration, it is most reasonable at the present stage to assign the 788 and 356 cm^{-1} bands to the O^-–O^- and Fe(III)–O^- stretching modes of the Fe(III)–O–O–H complex formed soon after the Fe–O_2 complex. A reaction mechanism involving the hydroperoxo intermediate instead of a μ-peroxo intermediate is compatible with the suggestion[27] from the infrared study of cyanide binding to this enzyme.

Alternatively the 356 cm^{-1} band could be assigned to the Fe(III)–O–OH bending mode. The Fe(III)–O–O bending mode is reported for oxyphthalocyanine iron-(II)[28] at 289 cm^{-1} but for all other oxy-iron porphyrins and oxy-hemeproteins the Fe(II)–O–O bending Raman band has not been identified. Such a band has not been observed for the primary intermediate of cytochrome oxidase shown in Fig. 2 (Δt_d=0.1 ms). The Fe–C–O bending Raman band for the CO-bound hemeproteins is usually much weaker than the Fe–CO stretching Raman band.[29,30] In contrast, the 356 cm^{-1} band of the intermediate in question has greater intensity than the Fe(II)–O_2 stretching mode. Consequently, the assignment of the 356 cm^{-1} band to the Fe(III)–O–O bending mode does not seem likely. However, definitive assignment of the 788 and 356 cm^{-1} bands will require experiments using $^{16}O^{18}O$ which will soon be undertaken in this laboratory.

On the basis of the present assignment, the 790 cm^{-1} Raman band reported by Varotsis and Babcock,[12] which showed no frequency shift upon deuteration, might be assigned to the Fe(IV)=O stretching mode of the ferryloxo complex. Since the peak power of the laser used by Varotsis and Babcock is higher by a factor of 10^5 than those used by the two other groups, it is certainly possible that the O–O bond of the Fe(III)–O–O–H complex suffered photocleavage and the Fe(IV)=O heme was generated. In fact, the O–O bond of Fe(II)–O–O–Fe(II) porphyrin complex is very photolabile even at low temperature and the photoreaction yields the Fe(IV)=O porphyrin.[31] If this is the case, the 790 cm^{-1} band should be regarded as an artifact and should not be assigned to a physiologically relevant intermediate, although this observation served as a basis for a unified view of the reaction scheme.[14]

Hydroperoxy and Ferryloxo Intermediates. The 788 and 356 cm^{-1} bands which apparently arise from a hydroperoxy intermediate, persisted (at 5 °C) at least up to 3.2 ms after initiation of the reaction (see Figs. 4B and 4C). The half-life is approximately 2.5 ms at 5 °C. The rate constant for the rate limiting step in the oxidation reaction of fully-reduced cytochrome oxidase with O_2, obtained from flash photolysis absorption studies, is ca. 1000 s^{-1} ($t_{1/2}$=700 μs) at 25 °C,[32] which is in good agreement with the value obtained in this study provided one takes into consideration the fact that the rate constant approximately doubles on every 10 °C temperature increase; $t_{1/2}$=700 μs at 25 °C should correspond to $t_{1/2}$=2.8 ms at 5 °C.

In Fig. 4 the hydroperoxy intermediate seems to be directly converted to the iron(III) hydroxide intermediate. However, this observation does not necessarily demand it. Involvement of a one electron reduced ferryloxo intermediate[7,33] in the process is possible,

although we could not clearly detect the Fe(IV)=O stretching Raman band, probably because of its short lifetime and/or weak enhancement of that intermediate. Different resonance Raman enhancement factors for two species may occur when the absorption maxima of the two are different. If the excitation wavelength of 423 nm in this study is accidentally much closer to the hydroperoxy intermediate rather than to that of ferryl-oxo intermediate, Raman bands of the hydroperoxy intermediate could dominate the resonance Raman spectra. Although the hydroperoxy-iron porphyrin[34] is generally much more reactive than the ferryloxo one, a shorter lifetime of the ferryloxo intermediate, compared with that of the hydroperoxy intermediate, is not unexpected, as was suggested by Oliveberg et al.[35]

It is useful to estimate the potential relative population of the ferryloxo intermediate during the cytochrome oxidase turnover. In order to gain an insight into this, we carried out a simple calculation for a chain reaction (A→B→C→D→E) in which each intermediate decays with rate constants of k_A, k_B, k_C, and k_D s^{-1}, respectively. The A, B, C, D, and E intermediates correspond to the Fe(II)-O_2, Fe(III)-O-O-H, Fe(IV)=O, Fe(III)-OH and the last Fe(III) species, respectively. As noted above, the final Fe(III) species might be a Fe(III)-OH compound but, if so, its axial ligand is exchangeable with bulk water. In this case, k_D represents the exchange rate. At time, t, after initiation of the reaction, the fractional population of each species can be represented by the following equations;

$$[A] = \exp(-k_A t),$$

$$[B] = k_A[\exp(-k_A t)/(k_B - k_A) + \exp(-k_B t)/(k_A - k_B)],$$

$$[C] = k_A k_B\{\exp(-k_A t)/[(k_B - k_A)(k_C - k_A)] + \exp(-k_B t)/[(k_A - k_B)(k_C - k_B)] + \exp(-k_C t)/[(k_A - k_C)(k_B - k_C)],$$

$$[D] = k_A k_B k_C\{\exp(-k_A t)/[(k_B - k_A)(k_C - k_A)(k_D - k_A)] + \exp(-k_B t)/[(k_A - k_B)(k_C - k_B)(k_D - k_B)] + \exp(-k_C t)/[(k_A - k_C)(k_B - k_C)(k_D - k_C)] + \exp(-k_D t)/[(k_A - k_D)(k_B - k_D)(k_C - k_D)],$$

$$[E] = 1 - ([A] + [B] + [C] + [D]).$$

Since the present experimental data are not sufficient for an accurate determination of rate constants, we tentatively used the following values for the rate constants; k_A=3000, k_B=250, k_C=1400, and k_D=1000. The calculated curves for the fractional population vs. time are depicted in Fig. 5. The curves satisfactorily reproduce the decay of the 571 cm^{-1} band, the rise and decay of the 788 and 356 cm^{-1} bands and the rise and decay of the 450 cm^{-1} band. We note that the mixmum population of the 450 cm^{-1} species takes place at t=3.5 ms. If k_C were smaller than k_B (for example, k_C=200), the increase in D [the Fe(III)-OH species] became noticeably slower and did not reproduce the observed curves. Consequently, it is likely that the population of the ferryloxo intermediate during turnover cannot be very large. Direct reduction of the hydroperoxy intermediate to Fe(III)-OH without forming a higher energy intermediate, that is, the Fe(IV)=O heme, is also possible for the cytochrome oxidase active site where two reductive equivalents are readily available through Fe_a and Cu_A as has been suggested by Yoshikawa and Caughey.[27] It is quite interesting to point out that if our assignment is correct, the decay rate of the hydroperoxy intermediate is close to the rate of proton release.[35]

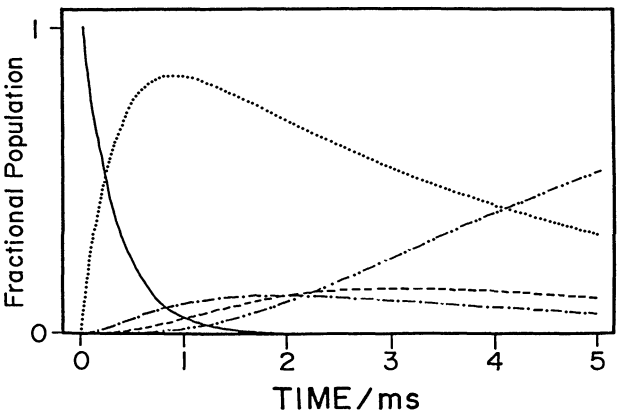


Fig. 5. Fractional population of the Fe(II)-O_2 (——), Fe(III) -O-O-H (·····), Fe(IV) =O (—·—), Fe(III) -OH (——), and the last Fe(III) compound (—··—). See text about the method of calculations, It is assumed that [Fe(II)-O_2] at time =0 is unity.

Previously Han et al.[36] reported the Fe(III)-OH stretching Raman band at 477 cm^{-1} for a compound produced under photoreduction of the resting enzyme in the presence of hexacyanoferrate(III). This compound, if correctly assigned, would be different from the Fe(III)-OH intermediate generated in the catalytic cycle. The present conclusion is consistent with another report by Han et al.[13] The iron-oxygen stretching frequency of the Fe(III)-OH compound of cytochrome oxidase is appreciably lower than those of aquametmyoglobin (490 cm^{-1}) and aquamethemoglobin (495 cm^{-1}).[37] In contrast, the iron-oxygen stretching frequency of the Fe(II)-O_2 complex of cytochrome oxidase (571 cm^{-1}) is noticeably close to those of oxymyoglobin (569 cm^{-1}) and oxyhemoglobin (567—572 cm^{-1}).[20,21] Based on these observations, it may be concluded that the distinguishing features of the cytochrome oxidase active site environment are most clearly reflected by their effects on the Fe(III)-OH stretching frequency.

The authors thank Dr. T. Egawa of IMS for his help in calculation of fractional population of intermediates and Professor Jim Kincaid of Marquett University for reading this manuscript. Chemical Analysis of Thortveitite from Oro, Mineyama-cho, Naka-gun, Kyoto Prefecture, Japan

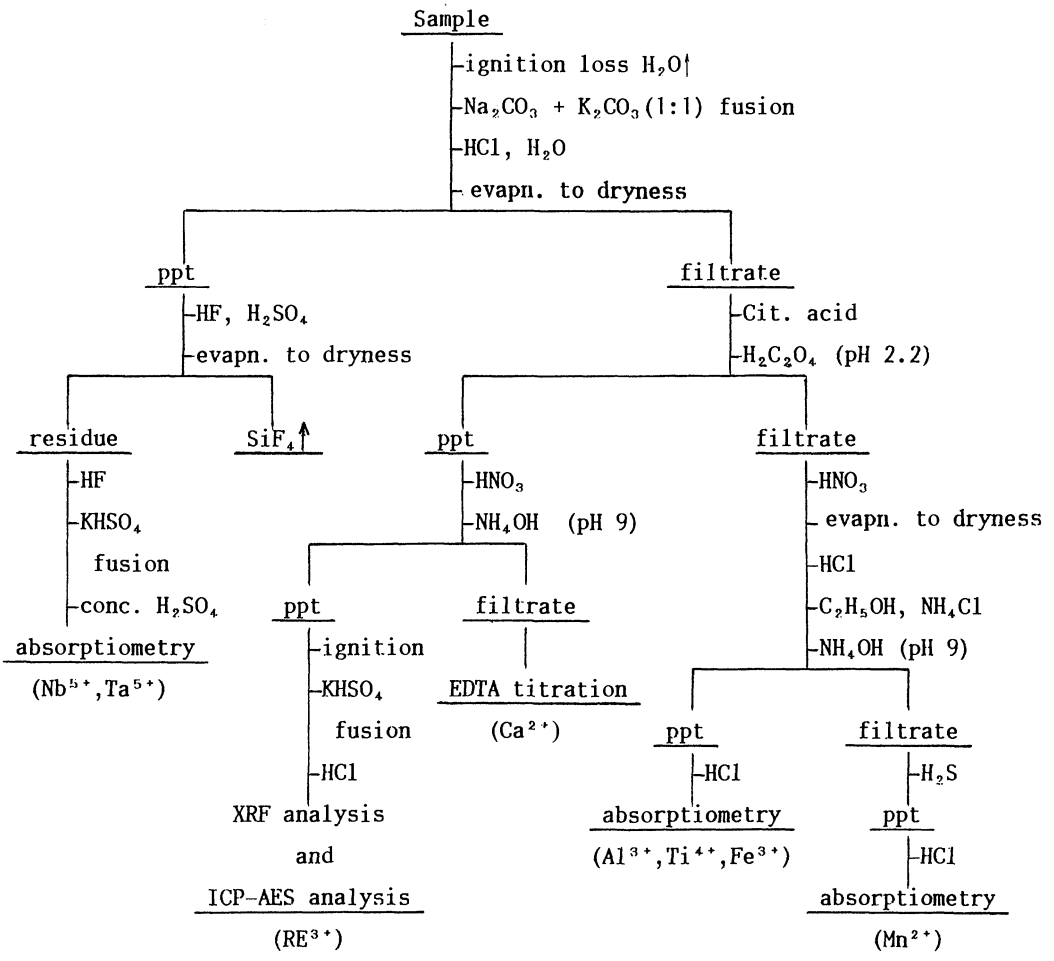
Kazuhisa MORIYASU and Yasuharu NISHIKAWA*
Department of Chemistry, Faculty of Science and Technology, Kinki University, 3-4-1, Kowakae, Higashiosaka, Osaka, 577
(Received March 2, 1991)

The geochemically interesting rare mineral, thortveitite, from Oro, Kyoto Prefecture was studied. Major constituents, scandium, yttrium, and lanthanoids, niobium, tantalum, aluminum, titanium, iron, calcium, and manganese were determined. The chemical analysis of the mineral assemblage gave Sc_2O_3 18.20, Y_2O_3 0.72, Σ Ln_2O_3 1.70, FeO 0.97, MnO 0.54, Nb_2O_5 trace, Ta_2O_5 9.96, Al_2O_3 3.02, CaO 1.72, TiO_2 0.83, SiO_2 58.31, and H_2O 4.20; total 100.17%. This sample contained tantalite 11.47, anorthite 8.37, rutile 0.83, and quartz 37.91% in addition to thortveitite 37.40%. Scandium–tantalum substitution is suggested to occur similarly to yttrium–niobium substitution in earth acid minerals.

Thortveitite, a sorosilicate mineral which has scandium and yttrium-group rare earths as its major constituents, mainly occurs in the pegmatite layer of Norway and Madagascar.[1] The crystallographic and physical properties of thortveitite are as follows: monoclinic system; space group: $C2/m$; hardness on Mohs' scale: 6—7; specific gravity: 3.58.[2]

The distribution pattern of lanthanoid elements in thortveitite, by Goldschmidt and Thomassen,[3] has been reported to be extremely specific and selective (Goldschmidts' classification: thortveitite type), with a remarkably high content of ytterbium. Other constituents of this geochemically and mineralochemically very rare mineral type are alvite and yttrotitanite.



Scheme 1. Chemical analysis of thortveitite.

In Japan, thortveitite was first collected from the Shiroishi pegmatite zone at Kobe, Omiya-cho, Naka-gun, Kyoto Prefecture, analyzed and identified by Sakurai et al.[4] In Oro, Mineyama-cho, Naka-gun, Kyoto Prefecture, granites containing pegmatite are widely distributed, and some rare element minerals such as fergusonite, zircon (yamaguchilite) and yttrofluorite have been found.[5-7] There are two ore bodies, both of which consist of graphic, feldspar, and quartz zones.[8] The feldspar zone of the ore body A contained bastnaesite, zircon, and small amounts of ilmenite, monazite, and xenotime. The feldspar zone of the ore body B had biotite and magnetite containing fergusonite, zircon, and allanite.

The thortveitite examined here was collected from the ore body A of Oro and its identity was confirmed by Yamada et al. in 1980.[8] Emission spectrochemical analysis of thortveitite from the Shiroishi pegmatite zone at Kobe has been performed in detail by Nagashima et al.[4] and the detailed distribution of lanthanoid elements in the mineral has been reported. The present paper describes the results of chemical analysis, X-ray fluorescence analysis, and ICP analysis of lanthanoids in thortveitite from the ore body A, Oro, Mineyama-cho, Naka-gun, Kyoto Prefecture.

Experimental

In order to clarify the content of thortveitite as [$(Sc,Y,Ln)_2Si_2O_7$; Ln=lanthanoids] and the contents of other minerals found together with it in the ore body A, a total chemical analysis of the thortveitite sample was performed. The analytical procedure of the mineral sample is shown in Scheme 1. A portion (0.1086 g) of the powdered sample was taken in a platinum crucible, and fused with the fusing mixture $Na_2CO_3+K_2CO_3$. The melt was treated with hydrochloric acid and water. The insoluble matter was obtained by filtration, converted to oxides by ignition and weighed as the sum of silicic anhydride and earth acid metal oxides ($Nb_2O_5+Ta_2O_5$). The oxides were treated with hydrofluoric acid and sulfuric acid to remove SiO_2 as SiF_4. After the earth acid metal oxides had been fused with potassium hydrogensulfate, the melt was treated with concentrated sulfuric acid, and niobium(V), and tantalum(V) were determined by hydrogen peroxide-absorptiometry.[9] Ten milliliters of 1 mol dm^{-3} oxalic acid was added to the filtrate, and rare earth ions and calcium ion were precipitated as oxalates at pH 2.2. The precipitates were treated with 10 cm^3 of concentrated nitric acid and heated until the oxalic acid was completely decomposed. To separate calcium ion from lanthanoid ions, the pH of the solution was adjusted to 9.0 with aqueous ammonia and the lanthanoid ions were precipitated as hydroxides. Calcium ion was determined by the EDTA titration method. Lanthanoid hydroxides were converted to the oxides and fused with potassium hydrogensulfate, and, then, the trivalent ions were collected with hydroxyiminodiacetic acid (HIDA)–chelating resin. Scandium(III), and yttrium(III), and ytterbium(III) ions on the HIDA–chelating resin were determined by X-ray fluorometry (XRF analysis) as described in previous papers.[10,11] The trace amounts of other rare earth ions were determined by the ICP-AES method.[12] Aluminum, iron, and titanium ions were determined by 2-methyl-8-quinolinol[13] and 8-quinolinol[14] absorptiometry, and manganese ion was measured by potassium permanganate absorptiometry.[15]

Analytical Results and Discussion

(1) Total Analysis of Thortveitite: The results are summarized in Table 1. With the generally accepted composition of thortveitite, $(Sc,Y,Ln)_2Si_2O_7$, the four components of thortveitite amount to Sc_2O_3 18.20%, Y_2O_3 0.72%, ΣLn_2O_3 (Ln_2O_3 0.94%+Yb_2O_3 0.76%) and SiO_2 16.78% of the total oxide. The overall content of thortveitite in this mineral sample was, then, 37.40%.

The remainder of the constituents was assigned to several minerals expected to be present in the ore body A: FeO 0.97, MnO 0.54, Nb_2O_5 trace, Ta_2O_5 9.96% →tantalite [(Fe,Mn) $(Nb,Ta)_2O_6$: 11.47%]; Al_2O_3 3.02, CaO≒1.72, SiO_2 3.63%→anorthite [$CaAl_2Si_2O_8$: 8.37%]; TiO_2 0.83%→rutile [TiO_2: 0.83%]; quartz [SiO_2: 37.91%].

The present thortveitite sample was found to be a mixture of tantalite, anorthite, rutile, and quartz. It has been reported that the zirconium content in thortveitite often varies considerably (0.1—5% ZrO_2), and the HfO_2/ZrO_2 ratio is usually high (0.5—0.02).[4,16,17] However, no detectable amounts of zirconium and hafnium were present in the present sample.

(2) Distribution of Scandium, Yttrium, and Lanthanoid Elements: The content of each rare earth element was analyzed by XRF and ICP methods. The results are listed in Table 2 with the contents of other elements in thortveitite under the assumption that the present thortveitite has the composition of $(Sc,Y,Ln)_2Si_2O_7$.

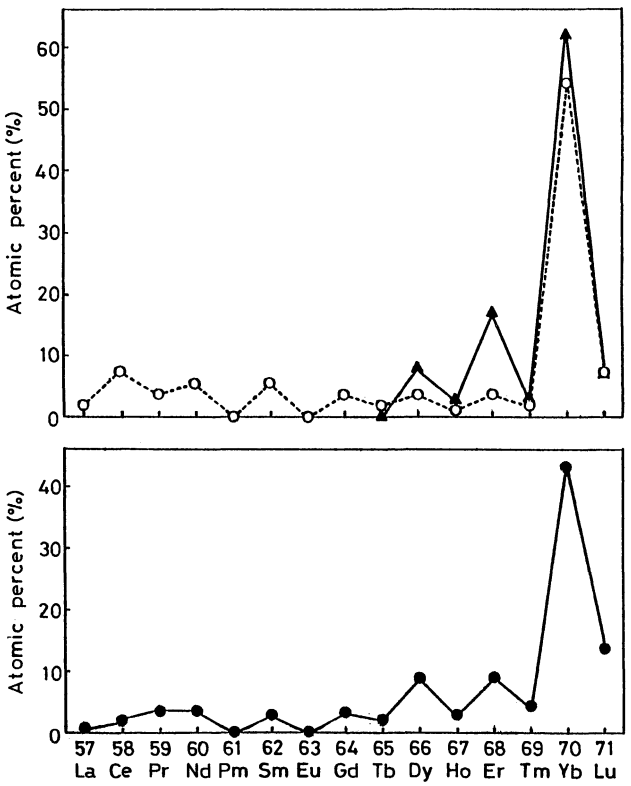

Fig. 1. Distribution of lanthanoid series elements.
---○---: Goldschmidt and Thomassen's thortveitite type (recalculated);
—▲—: Thortveitite from Kobe, Omiya-cho;
—●—: Thortveitite from Oro, Mineyama-cho (This work).

Mineyama-cho, was present in a notable amount; 48.66% as Sc_2O_3. Yttrium-group rare earths (Dy—Lu) were over 80% of the total lanthanoids.

The distribution pattern of lanthanoid elements in the thortveitite is illustrated in Fig. 1. Their amounts were compared with those of Goldschmidt.[3] and Sakurai et al.[4] for thortveitite. Although the aboundance of cerium (Z=58) and praseodymium (Z=59) are reversed, the present results on the distribution of lanthanoid elements generally conform to Oddo-Harkins' law. The ytterbium content is slightly less than that found in other studies. The abundance of an odd-numbered lutetium (Z=71) is found to be higher than those of the neighboring even-numbered dysprosium (Z=66) and erbium (Z=68). According to the Clarke number of these elements, there should be less lutetium than dysprosium and erbium.[18] But the present result may indicate that the mutual camouflage-substitution of the same valent metals in minerals is a more important factor. The camouflage-substitutions of these elements in minerals have been reported and attributed to the similarity in the ionic radius.[19] As the ionic radius of lutetium (0.99 Å) is close to that of ytterbium (1.00 Å) and scandium (0.83 Å), lutetium seems to be more selectively concentrated than other elements in thortveitite in which Yb and Sc are principal constituents.

The amount of yttrium in the present thortveitite is small, but as no detailed analytical data are available for yttrium and individual lanthanoids on thortveitite,[20–22] simple comparison of these elements with other thortveitite is difficult. The sum of yttrium oxide and heavy rare earth oxides in this thortveitite is less than that for other reported thortveitite samples as shown in Table 3.

As described in section (1), the authors have assumed that the thortveitite sample from the ore body A contains about 11% tantalite in which tantalum is more aboundant than niobium. In general, earth acid minerals such as fergusonite and columbite are constituted of large quantities of niobium and always contain yttrium as a sub-component.[5,23,24] However, the thortveitite sample analyzed in this work contains a large amount of

scandium and a little yttrium. Generally, tantalum (ionic radius: 0.64 Å) seems to be present in minerals with scandium, and niobium (0.64 Å) with yttrium. Scandium has a smaller ionic radius (0.83 Å) than yttrium (0.95 Å) and has a strong affinity for tantalum. It has been reported that Ta_2O_5 easily forms solid solutions with 2—4 mol% of Sc_2O_3 at high temperature,[25] and the crystal structure is stabilized by replacement of some Ta^{5+} by Sc^{3+}.

Financial support from the Ministry of Education, Science and Culture (Grant-in-Aid for Co-operative Research A 02303005), and Kinki University is gratefully acknowleged.

(Received March 22, 1991)

The effect of water vapor on the thermal behavior of alkaline-earth metal *cyclo*-tetraphosphates, $M_2P_4O_{12}\cdot nH_2O$ (n=7.0, 3.5, 5.5, and 4.0 for M=Mg, Ca, Sr, and Ba, respectively) (P_{4m}) was examined using DTA-TG, X-ray diffraction analysis, isothermal heating in an electric furnace, and HPLC-FIA. The calcination reaction of each P_{4m} proceeded via ring opening of P_{4m} with elimination of water of crystallization, followed by condensation of soluble oligophosphates (P_{oligo}) to insoluble polyphosphates ($P_{high\ poly}$). The rates of these reactions were faster for Mg_2P_{4m} than for other metal *cyclo*-phosphates. The decomposition of P_{4m} was appreciably faster in humid air than in dry air, because of the availability of water for hydrolysis and for breaking the P–O–P linkage. However, the effect of water vapor from the atmosphere was not conspicuous, since the atmosphere contains enough water (theor. 20 mg L^{-1}) for the hydrolysis of P_{4m}. The products of calcination of $Ba_2P_{4m}\cdot 4H_2O$ were hardly influenced by water vapor from the atmosphere, because the water of crystallization was not easily released in the Ba system compared with the other metal salts.

As is well known, phosphates hydrolyze or condense on heating to yield different types of phosphates.[1–19] Most of the previous works dealt with linear phosphates. In recent papers,[20–23] we reported that water vapor remarkably affected the dehydration and condensation of various phosphates, and that the thermal behavior of *cyclo*-phosphates were significantly influenced by water vapor in the atmosphere, as well as by the rate and temperature range of heating, etc. In this study, the thermal dehydration and condensation reactions of alkaline-earth metal *cyclo*-tetraphosphates were investigated by means of DTA-TG, X-ray diffraction analysis, isothermal heating in an electric furnace, and high-performance liquid chromatography-flow injection analysis (HPLC-FIA).

Experimental

Chemicals. Guaranteed reagents of $Mg(NO_3)_2\cdot 6H_2O$, $Ca(NO_3)_2\cdot 4H_2O$, $Sr(NO_3)_2$, $Ba(NO_3)_2$, NaCl, NaOH, Na_2S, and P_2O_5 from Wako Chemical Industries, Ltd. were used. Unless otherwise stated, other chemicals were of guaranteed grade and were used without further purification.

Preparation Methods. Sodium *cyclo*-tetraphosphate tetrahydrate ($Na_4P_{4m}\cdot 4H_2O$) was prepared by methods given in the literature.[1]

Alkaline-earth metal *cyclo*-tetraphosphates, $M_2P_{4m}\cdot nH_2O$ (n=7.0, 3.5, 5.5, and 4.0 for M=Mg, Ca, Sr, and Ba, respectively) were prepared by the method similar to those described in the literatures.[8,20] Fifteen mmol of each metal nitrate was dissolved in 150 cm^3 of water, and this solution was mixed with 100 cm^3 (7.5 mmol) of a 0.075 mol dm^{-3} sodium *cyclo*-tetraphosphate aqueous solution. The precipitate was filtered off, washed with cold water, and air-dried.

Measurements. The sample solution for HPLC-FIA was prepared as follows. A 15-mg portion of a phosphate sample was dissolved in 20 cm^3 of a 0.1 mol dm^{-3} EDTA·2Na solution, and the solution was diluted to 100 cm^3 with distilled water. A 100-μL aliquot of this solution was used for HPLC-FIA. Unless otherwise noted, the analytical procedures and apparatus were essentially the same as those used in previous work.[20,21,24]

Results and Discussion

Thermal Decomposition by DTA-TG. $Ba_2P_4O_{12}\cdot 4H_2O$ $Ba_2P_{4m}\cdot 4H_2O$: Figure 1 shows the DTA-TG curves for $Ba_2P_4O_{12}\cdot 4H_2O$ at atmospheric pressure. Two endothermic peaks at 127 and 193 °C and two exothermic peaks at 222 and 487 °C were observed. A gradual lowering of the TG curve took place over a temperature range of 200 to 500 °C. A remarkable change in the DTA and TG curves was not observed above 500 °C. To clarify the reactions occurring near the endo- and exothermic peaks, the calcination products after the peaks were removed from the DTA-TG apparatus, cooled in a silica-gel desiccator, and subjected to further analysis. Figures 2 and 3 show the X-ray diffraction patterns and the liquid chromatograms of products, respectively, heated at several tempera-

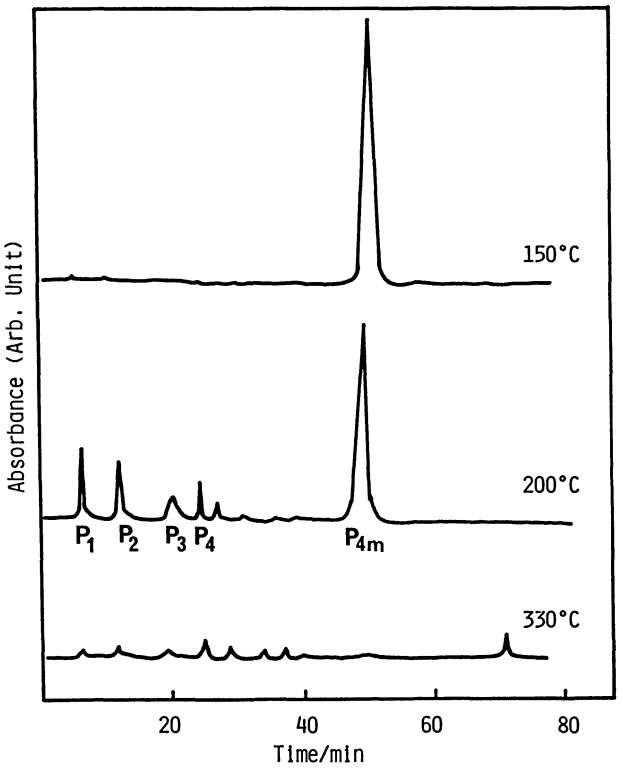

Fig. 3. Liquid chromatograms of products by heating.
Sample: $Ba_2P_4O_{12}\cdot 4.0H_2O$.

tures. In Fig. 2, the peak intensity of the anhydrous phase at 150 °C was gradually decreased with raising temperature and the product heated at 200 °C gave the X-ray difraction pattern of an amorphous phase. In view of the HPLC data at 150 °C, the P_{4m} ring structure was reserved. Therefore, the endothermic peak at 127 °C was assumed to reflect partial dehydration of the water of crystallization. The X-ray diffraction patterns of the products at a temperature range 193—330 °C were similar to that of an amorphous solid phase, as seen in Fig. 2. The HPLC trace shown in Fig. 3 suggests that decomposition of the P_{4m} ring to oligophosphates (P_{oligo}) such as ortho- (P_1), pyro- (P_2), tri- (P_3), and tetraphosphate (P_4) and the condensation of P_{oligo} to soluble polyphosphates (P_{poly}, P_5—P_{20}) occurred in the amorphous solid phase. No peak was seen in HPLC trace for product heated at 510 °C, because an insoluble polyphosphate ($P_{high\ poly}$) newly formed at this temperature. The thermal product at 510 °C showed an X-ray diffraction pattern characteristic of $Ba(PO_3)_2$. It seems that crystal growth was too slow to give one particular X-ray diffraction pattern, since under dynamic conditions the consecutive transformations of phosphates did not reach their equilibrium state, so that the X-ray diffraction pattern reflected an amorphous phase.

$Sr_2P_4O_{12}\cdot 5.5H_2O$ $Sr_2P_{4m}\cdot 5.5H_2O$: Figure 4 shows the DTA-TG curves for $Sr_2P_4O_{12}\cdot 5.5H_2O$ at atmospheric pressure. Two large endothermic peaks at about 120 and 160 °C accompanied by a weight loss are apparently due to elimination of the water of crystallization. A gradual lowering of the TG curve is noted over a temperature range of 200—400 °C. The calcinated samples were prepared in a similar manner to the barium salt and subjected to further analysis. The results of HPLC and X-ray diffraction analysis are

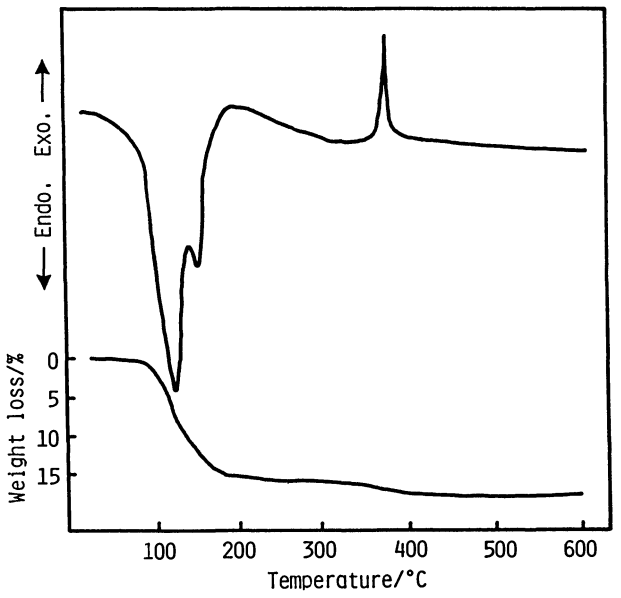

Fig. 4. DTA-TG curves for $Sr_2P_4O_{12}\cdot 5.5H_2O$.

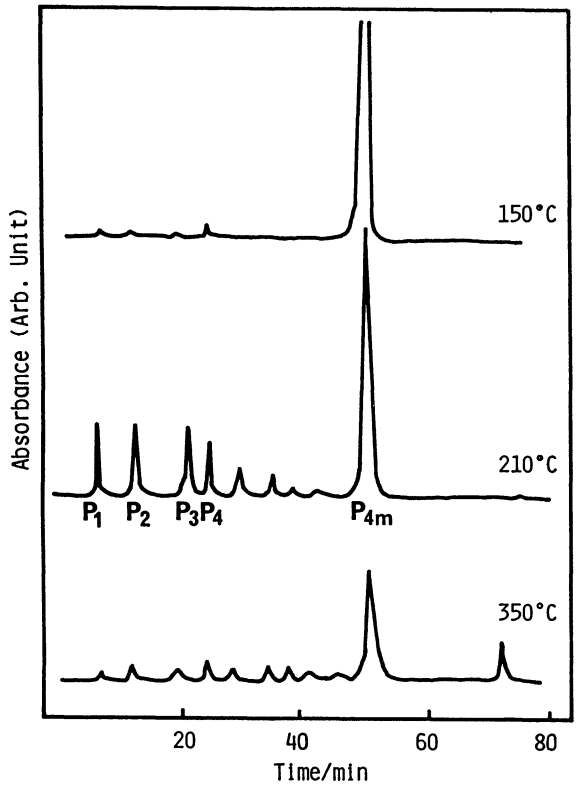

Fig. 5. Liquid chromatograms of products by heating.
Sample: $Sr_2P_4O_{12} \cdot 5.5H_2O$.

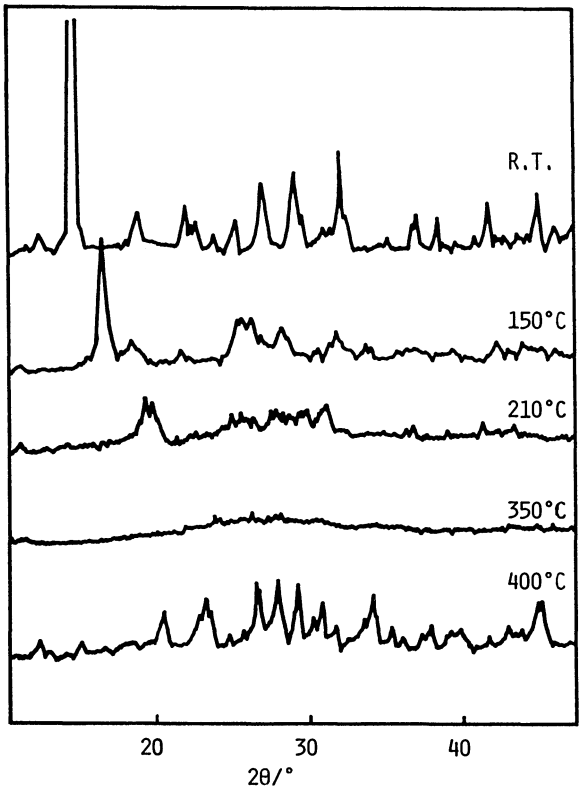

Fig. 6. X-Ray diffraction patterns of products by heating.
Sample: $Sr_2P_4O_{12} \cdot 5.5H_2O$.

shown in Figs. 5 and 6. According to the HPLC trace at 150 °C shown in Fig. 5, more than 90% of P_{4m} remained at this temperature, and the decomposition of P_{4m} to P_{oligo} was less than 10%. As seen in Fig. 6, the X-ray diffraction lines of the thermal products at temperatures from 210 to 350 °C gradually decreased by a rise in temperature and finally changed to an amorphous phase. HPLC results indicate that the decomposition of P_{4m} and the condensation of P_{oligo} to P_{poly} took place continuously. The sample heated at 400 °C did not

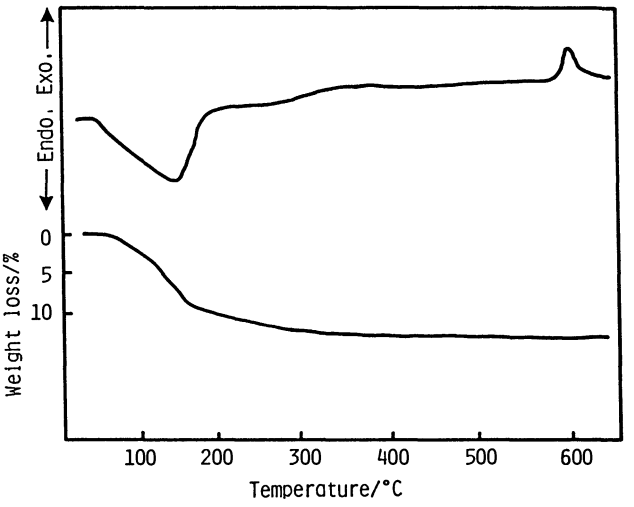

Fig. 7. DTA-TG curves for $Ca_2P_4O_{12} \cdot 3.5H_2O$.

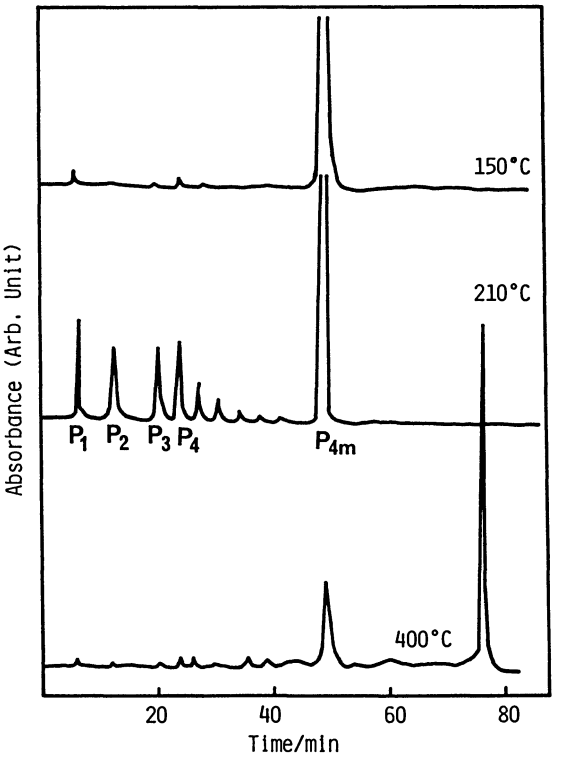

Fig. 8. Liquid chromatograms of products by heating.
Sample: $Ca_2P_4O_{12} \cdot 3.5H_2O$.

dissolve by the EDTA treatment. It seems that insoluble polyphosphates ($P_{high\ poly}$) were newly formed through dehydration and condensation reactions. The thermal product at 400 °C showed a characteristic X-ray diffraction pattern in agreement with that of $Sr(PO_3)_2$. Accordingly, the exothermic peak at 390 °C should reflect the crystallization of $Sr(PO_3)_2$.

$Ca_2P_4O_{12}\cdot 3.5H_2O$ $Ca_2P_{4m}\cdot 3.5H_2O$: Figure 7 shows the DTA-TG curves for $Ca_2P_4O_{12}\cdot 3.5H_2O$ at atmospheric pressure. The samples were prepared as described above and subjected to further analysis. The results are shown in Figs. 8 and 9. The large endothermic peak at 150 °C accompanying a weight loss may be due mainly to the release of the water of crystallization. The TG curve was gradually lowered over a temperature range of 150—350 °C. According to the HPLC data at 150 °C shown in Fig. 8, P_{4m} remained almost in an anhydride state. At 210 °C, a significant amount of P_{4m} decomposed to P_{oligo} and further condensed to P_{poly}. The sample heated at 650 °C did not dissolve by the EDTA treatment. It seems that large amounts of insoluble polyphosphates ($P_{high\ poly}$) were formed through the dehydration and condensation reactions. The X-ray diffraction patterns of products heated at 650 °C (Fig. 9) agreed with that of $Ca(PO_3)_2$. Therefore, the exothermic peak at 589 °C reflects the crystallization of $Ca(PO_3)_2$.

$Mg_2P_4O_{12}\cdot 7.0H_2O$ $Mg_2P_{4m}\cdot 7.0H_2O$: Figure 10 shows the DTA-TG curves for $Mg_2P_4O_{12}\cdot 7.0H_2O$ at atmospheric pressure. Two large endothermic peaks at 95 and 155 °C accompanying a weight loss seemed to be mainly caused by elimination of the water of crystallization. A gradual lowering of the TG curve took place over a temperature range of 200—450 °C. According to the HPLC result at 230 °C shown in Fig. 11, large

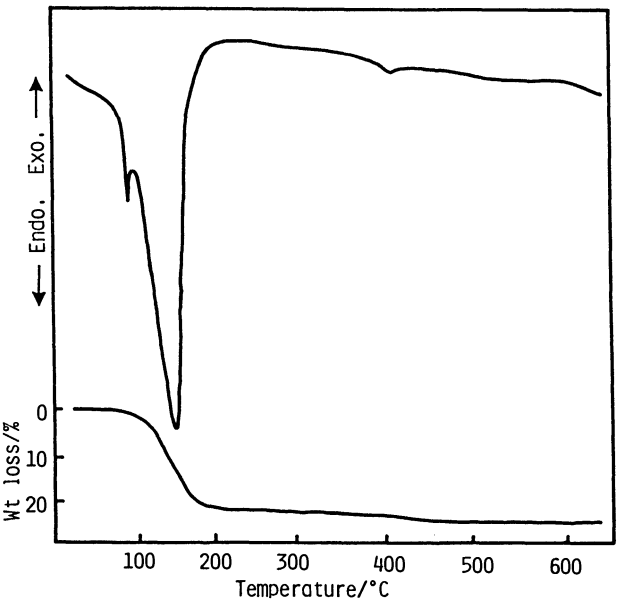

Fig. 10. DTA-TG curves for $Mg_2P_4O_{12}\cdot 7.0H_2O$.

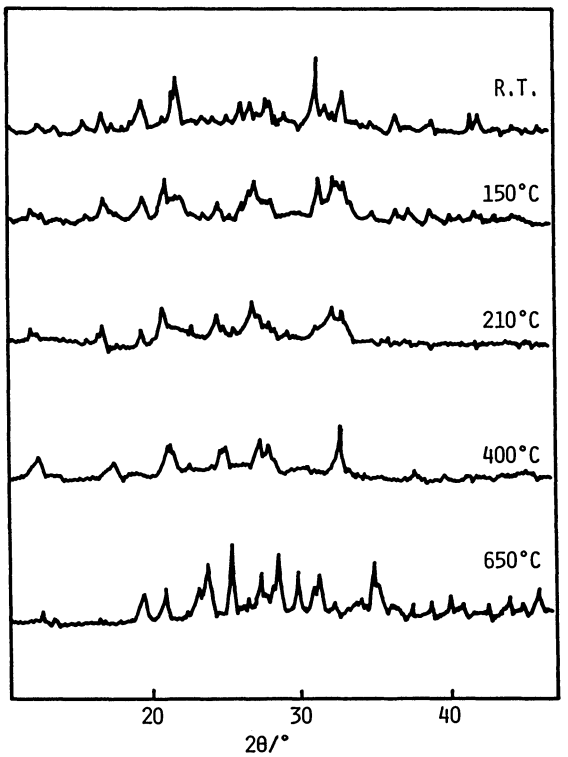

Fig. 9. X-Ray diffraction patterns of products by heating.
Sample: $Ca_2P_4O_{12}\cdot 3.5H_2O$.

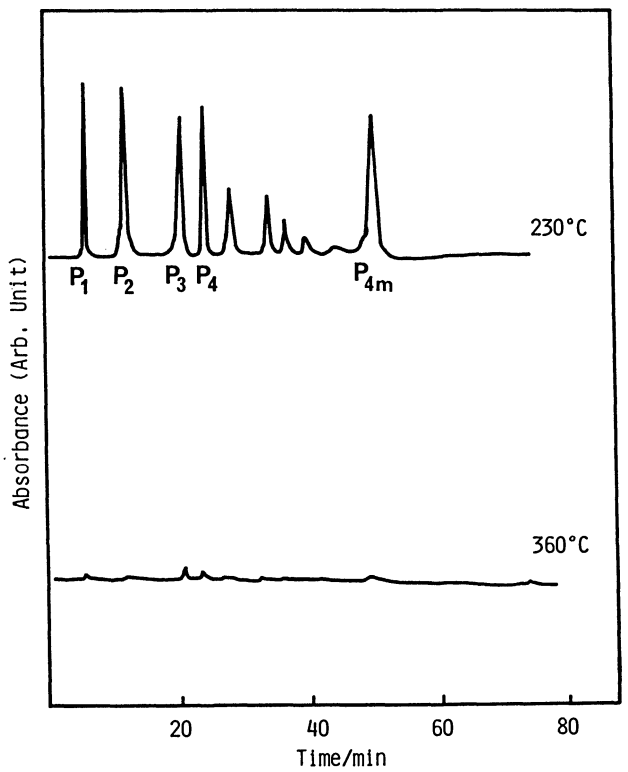

Fig. 11. Liquid chromatograms of products by heating.
Sample: $Mg_2P_4O_{12}\cdot 7.0H_2O$.

amounts of P_{4m} already decomposed to P_{oligo}. It is obvious that around this temperature the dehydration and decomposition of P_{4m} and the condensation of decomposed products of P_{4m} to P_{poly} are taking place during calcination. It is a characteristic feature of the Mg system that decomposition of P_{4m} proceeded faster than other three systems at a similar temperature. At 360 °C, no definite peaks were observed in HPLC. Therefore, it is clear that a large amount of polyphosphates ($P_{high\ poly}$) was formed through the dehydration and condensation, because the product heated at this temperature did not dissolve by the EDTA treatment. As seen in Fig. 12, the thermal products heated at 360 °C newly exhibited definite diffraction lines and they gradually increased with a rise in temperature. The X-ray diffraction lines coincided in position with those of $Mg(PO_3)_2$.

Isothermal Change. In view of the above-mentioned results, the thermal transformation of alkaline-earth metal *cyclo*-tetraphosphates, $M_2P_4O_{12}\cdot nH_2O$ (n=7.0, 3.5, 5.5, and 4.0 for M=Mg, Ca, Sr, and Ba, respectively), proceeded via dehydration, decomposition, and condensation. These reactions took place continuously, and did not reach equilibrium instantly. To examine the influence of water vapor on the thermal decomposition of $M_2P_4O_{12}\cdot nH_2O$, their isothermal decompositions were carried out in dry and humid air at various temperatures. Each $M_2P_4O_{12}\cdot nH_2O$ was heated at 200 °C for 30 min. The relationships between the amounts of various phosphates formed and the amounts of water vapor are shown in Figs. 13 through 16. P% denotes the percentage of phosphorus atoms present in these phosphate anions. The influence of the amount of water vapor on the products was not remarkable in a 20—110 mg L^{-1} range of water vapor. It is probable that there is enough water (theor. 20 mg L^{-1}) in the atmosphere for the hydrolysis of P_{4m}. However, a characteristic change was noted between the dry and the humid air. In dry air, the hydrolysis of P_{4m} was

depressed, since there was not enough water necessary for hydrolysis and for breaking the P–O–P linkage. In the Ba system shown in Fig. 1, release of the water of crystallization took place at a higher temperature than in other three systems, so that the effect of water from the atmosphere was hardly discernible. According to the present results, the thermal decomposition and condensation processes may be formulated as follows:

$$M_2P_4O_{12}\cdot nH_2O \longrightarrow M_2P_4O_{12} \quad (1)$$
(M: Ba, Sr, Ca, Mg)

$$M_2P_4O_{12} \longrightarrow P_{oligo} \quad (2)$$
$$P_{oligo} \longrightarrow P_{poly} \quad (3)$$
$$P_{poly} \longrightarrow P_{high\ poly} \quad (4)$$

The thermal reactions in the first stage proceed continuously according to Processes (1) and (2), followed by Processes (3) and (4) simultaneously. The decomposition of $M_2P_4O_{12}\cdot nH_2O$ to P_{oligo} proceeds faster in humid air than in dry air. In this work, pure anhydrides could not be obtained by heating or freeze-drying of the hydrates of *cyclo*-tetraphosphates.

The authors wish to thank Mr. Seiji Fukami for his helpful work.

The Synthesis and Thermal Reorganization of Lithium Heptasodium *cyclo*-Octaphosphate

Makoto WATANABE,* Tomohiko HONDA, and Shinsaku FURUTA
Department of Industrial Chemistry, Chubu University, Matsumoto-cho, Kasugai, Aichi 487
(Received March 25, 1991)

Lithium heptasodium *cyclo*-octaphosphate hexahydrate, $LiNa_7P_8O_{24} \cdot 6H_2O$, has been prepared by heating lead *cyclo*-tetraphosphate tetrahydrate at 340 °C for 20 min, dissolving the thermal product in a 3% aqueous solution of tetrasodium ethylenediaminetetraacetate, and then crystallizing by the addition of lithium chloride and methanol to the solution. When the *cyclo*-octaphosphate was heated above 180 °C, it decomposed to produce phosphates with chain lenghts shorter and longer than that of the *cyclo*-octaphosphate. The thermally produced phosphates were reorganized to sodium *cyclo*-triphosphate and a small amount of insoluble polyphosphates by heating at about 300 to 350 °C. The phosphates melted at about 620 °C.

Among the many kinds of polyphosphates, di-, tri-, tetra-, penta-, *cyclo*-tri-, *cyclo*-tetra, *cyclo*-penta, *cyclo*-hexa-, *cyclo*-octa, and long-chain polyphosphates have been prepared and isolated. Polyphosphates have been used for agricultural treatment, detergents, food additives, chemical manufacturing, the ceramics industry, etc.[1—3] A dry process has usually been used for the preparation of oligo- and polyphosphates. The dry process is not favorable for the preparation of unstable polyphosphates and other techniques have been developed for making phosphates.[4] Although the synthesis of *cyclo*-octaphosphate has been reported by Schülke,[5] it has been found by the present authors that the method does not give the highest yield for the preparation of *cyclo*-octaphosphate. A modified process to make *cyclo*-octaphosphate and a thermal reorganization of the *cyclo*-phosphate were studied in the present work.

Experimental

Preparation of *cyclo*-Octaphosphate. Sodium *cyclo*-tetraphosphate tetrahydrate was made by hydrolyzing α-P_2O_5 in water cooled with ice to below 15 °C, and then adding sodium chloride to the solution. This method was modified from the original, which was proposed by Bell et al.[6] Lead *cyclo*-tetraphosphate tetrahydrate was prepared by dissolving the sodium *cyclo*-tetraphosphate in water and adding an aqueous lead nitride solution to the *cyclo*-phosphate solution. According to Schülke, sodium *cyclo*-octaphosphate hexahydrate can be obtained by heating the lead *cyclo*-tetraphosphate at 150 °C for 2 h, at 300 to 350 °C for less than 30 min, dissolving the thermal product in water together with sodium sulfide, and then adding ethanol into the resulting solution. The present authors found that the thermal product obtained with the heating process by Schülke contained only about 20 P% of *cyclo*-octaphosphate and that it was necessary to study the effects of heating temperature, heating time, and atmospheric moisture on the phosphate composition of the thermal product. It was also required to improve the wet process in order to purify the *cyclo*-octaphosphate from the thermal product.

Chemical Analysis. An atomic-absorption analysis was used for the determination of sodium and lithium ions in a sample solution by using a Shimadzu atomic-absorption spectrophotometer (AA-680). Phosphorus was determined by the Molybdenum Blue method. The water of crystallization was determined by the heating loss.

High-Performance Liquid Chromatography (HPLC). An HPLC technique was employed for the separation and determination of the phosphate species in a sample solution.[7] Aqueous 0.24, 0.40, and 0.60 mol dm^{-3} solutions of potassium chloride were used as eluents at a flow rate of 1 cm^3 min^{-1}.

^{31}P NMR Measurement. ^{31}P NMR spectrum of an aqueous phosphate solution was taken by a JNM-GX270 instrument. Phosphoric acid (85%) was used as a reference with downfield positive shifts.

X-Ray Diffractometry (XRD). An X-ray diffraction diagram of a powder sample was measured with nickel-filtered Cu $K\alpha$ radiation by using a Rigaku X-ray diffractometer (RAD-1B).

Thermogravimetry (TG) and Differential Thermal Analysis (DTA). TG-DTA measurements were carried out in air using a Rigaku TG-DTA apparatus with a heating rate of 5 °C min^{-1}.

Table 1. Composition of Polyphosphates in the Thermal Products Heated at 300, 340, 360, 400, and 460 °C for 20 min

Heating temp/°C	Phosphates/P%			
	Lowpoly[a]	*cyclo*-Tetra	*cyclo*-Octa	Highpoly[b]
300	17.8	7.1	73.6	1.5
340	14.5	—	79.8	9.3
360	11.6	—	81.6	6.9
400	10.4	—	84.5	5.1
460	14.9	—	24.2	60.9

a) Polyphosphates with chain lengths shorter than that of pentaphosphate. b) Polyphosphates with chain lengths longer than that of tetraphosphate.

Results and Discussion

Heating Temperature, Heating Time, and Humidity. Lead *cyclo*-tetraphosphate tetrahydrate was heated at a temperature between 300 and 460 °C for 20 min in dry air. The dry air was prepared by passing air through glass tubes containing silica gel and phosphorus pentaoxide. The phosphate composition of the thermal product is listed in Table 1. The results show that a suitable temperature range for the formation of lead *cyclo*-octaphosphate lies between 340 and 400 °C, and that the *cyclo*-octaphosphate content is about 80 P%.

Table 2. Composition of Polyphosphates in the Thermal Products Heated at 340 °C

Heating time/min	Phosphates/P%			
	Lowpoly[a)]	*cyclo*-Tetra	*cyclo*-Octa	Highpoly[b)]
5	39.7	36.4	23.3	0.7
10	14.5	0.2	80.9	4.5
20	10.5	—	79.8	9.3
30	9.6	—	77.7	12.7

a) Polyphosphates with chain lengths shorter than that of pentaphosphate. b) Polyphosphates with chain lenghts longer than that of tetraphosphate.

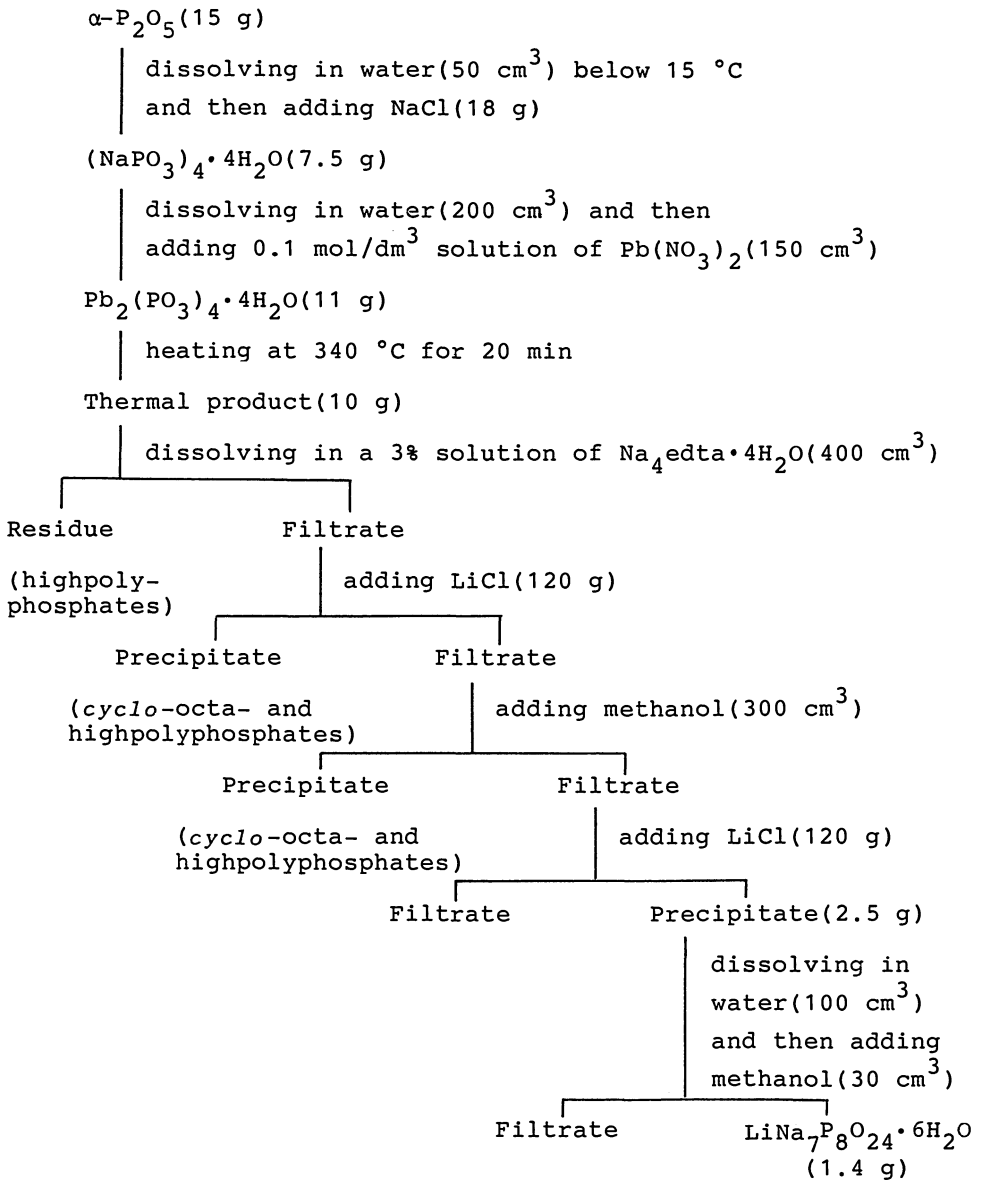

Fig. 1. Synthetic process of *cyclo*-octaphosphate.

At a lower temperature, the content of polyphosphates with shorter chain lengths increased. The content of polyphosphates with longer chain lengths increased at a higher temperature. Schülke described in his paper that the lead *cyclo*-tetraphosphate was preheated at 150 °C for 2 h, but there was not any need to heat the lead *cyclo*-tetraphosphate at that temperature. The dependence on the heating time for the phosphate composition of the thermal product at 340 °C is shown in Table 2. A heating time of 10 to 20 min seemed to be appropriate. In the case of preparation in air without drying, the content of highpolyphosphates increased at temperatures between 300 and 460 °C.

Purification of the *cyclo*-Octaphosphate. According to Schülke, the thermal product produced by heating the lead *cyclo*-tetraphosphate at between 300 and 350 °C dissolved in water. The thermal product obtained by heating the lead *cyclo*-tetraphosphate at 340 °C in this study dissolved only slightly in water and was soluble in an aqueous solution of ethylenediaminetetraacetate. The thermal product (10 g) was dissolved in 400 cm^3 of an aqueous 3% tetrasodium ethylenediaminetetraacetate tetrahydrate($Na_4edta \cdot 4H_2O$) solution, and a residue (highpolyphosphates) was filtered off. Lithium chloride (120 g) was added to the filtrate and a white precipitate (*cyclo*-octa- and highpolyphosphates) was removed by filtration. Methanol (300 cm^3) was added to the filtrate and a precipitate was filtered off. Lithium chloride (120 g) was put in the filtrate, resulting in a white precipitate (2.5 g), which was then dissolved in 100 cm^3 of water; methanol (30 cm^3) was added to the solution. About 1.4 g of a white precipitate was filtered off, washed with methanol, and dried in an air bath at 50 °C. This process is shown in Fig. 1. Found: P, 28.7; Na, 18.1; Li, 0.6; H_2O, 11.5%. Calcd for $LiNa_7P_8O_{24} \cdot 6H_2O$: P, 27.3; Na, 17.7; Li, 0.8; H_2O, 11.9%. The ^{31}P NMR spectrum of the product showed only one peak due to a middle PO_4 group at −21.5 ppm. This result indicates that the product is cyclic phosphate. The HPLC peaks of the product and several known phosphates (ortho-, di-, tri-, *cyclo*-tri-, *cyclo*-tetra-, and *cyclo*-hexaphosphates) are shown in Fig. 2. The position of the HPLC peak of the product was in accord with that of *cyclo*-octaphosphate, as shown in another paper.[8] According to these results, it was concluded that the product was lithium heptasodium *cyclo*-octaphosphate hexahydrate, $LiNa_7P_8O_{24} \cdot 6H_2O$. X-Ray diffraction data of the product are presented in Table 3, together with those of lithium *cyclo*-octaphosphate hexahydrate (JCPDS card, No. 28-0577). The *cyclo*-octaphosphate was stable at room temperature (15 to 30 °C) and had low solubility to water (about 1.9 at 20 °C).

a) AM stands for amorphous substance.

TG and DTA Measurements. TG and DTA curves of lithium heptasodium *cyclo*-octaphosphate hexahydrate are shown in Fig. 3. The thermal products (as numbered in Fig. 3) were removed from a furnace and subjected to further analysis in order to study thermal reactions within the temperature ranges. The chemical compositions of the thermal products are listed in Table 4. The first large endotherm accompanying a large weight loss seemed to be due to an elimination of the water of crystallization. The result in Table 4 shows that the decomposition of the *cyclo*-octaphosphate to phosphates with chain lengths longer and shorter than that of *cyclo*-octaphosphate occurs at the same time. The following thermal reactions can be written for the endothermic process:

$$(MPO_3)_8\cdot 8H_2O \longrightarrow (MPO_3)_8\cdot(8-x)H_2O \quad (0<x\leqslant 8) \tag{1}$$

$$(MPO_3)_8 + H_2O \longrightarrow M_8H_2P_8O_{25} \quad \text{(octaphosphate)} \tag{2}$$

$$(MPO_3)_8 + 2H_2O \longrightarrow \begin{cases} MH_2PO_4 + M_7H_2P_7O_{22} \quad \text{(ortho- and heptaphosphates)} & (3) \\ M_2H_2P_2O_7 + M_6H_2P_6O_{19} \quad \text{(di- and hexaphosphates)} & (4) \\ M_3H_2P_3O_{10} + M_5H_2P_5O_{16} \quad \text{(tri- and pentaphosphates)} & (5) \\ 2M_4H_2P_4O_{13} \quad \text{(tetraphosphate)} & (6) \end{cases}$$

$$(MPO_3)_8 \longrightarrow 4/3(MPO_3)_6 \quad \text{(}cyclo\text{-hexaphosphate)} \tag{7}$$

$$n(MPO_3)_8 \longrightarrow 8(MPO_3)_n. \quad \text{(highpolyphosphates)} \tag{8}$$

Here, M stands for sodium and/or lithium. Since the content of highpolyphosphates with chain lengths longer than that of octaphosphate was high at this step, thermal reaction 8 seemed to be preferencial. According to the successive heatings to 270 °C, the content of the highpolyphosphates increased even more. Reaction 8 was also considered to be preferable to the other degradations through heating. Thermal products 1 and 2 were X-ray diffractometrically amorphous. After a large exothermic change at about 300 °C, the *cyclo*-triphosphate content increased. The following reorganization can be responsible for the change:

$$(MPO_3)_n \longrightarrow n/3(MPO_3)_3. \tag{9}$$

A small endothermic peak accompanying a small amount of weight loss was observed at about 330 °C. Thermal product 4 gave 93.3 P% of *cyclo*-triphosphate content and all other phosphate contents decreased through the heating. Therefore, reaction 9 progressed at this step, along with a small heating loss which may have been caused by the following condensation of the phosphates with hydrogen to *cyclo*-triphosphate:

$$M_nH_2P_nO_{3n+1} \longrightarrow n/3(MPO_3)_3 + H_2O. \tag{10}$$

Thermal products 3 and 4 gave an X-ray diffraction diagram of sodium *cyclo*-triphosphate in accord with the phosphate composition given in Table 4. Since no other X-ray diffraction peaks were observed, phosphates containing lithium may be amorphous.

Preparation and Crystal Structure of a New Barium Niobium Sulfide, $Ba_9Nb_4S_{21}$

Masanobu SAEKI* and Mitsuko ONODA
National Institute for Research in Inorganic Materials, 1-1, Namiki, Tsukuba, Ibaraki 305
(Received April 11, 1991)

A new barium niobium sulfide, $Ba_9Nb_4S_{21}$, was prepared by the reaction of CS_2 with a mixture of $BaCO_3$ and Nb_2O_5. Powder X-ray diffraction peaks and electron diffraction spots for the compound were indexable on the basis of a hexagonal cell with lattice parameters of a=6.9743(6) and c=21.599(2) Å. Refinement based on powder X-ray diffraction data suggested that the crystal structure belongs to the same series with those of $Ba_{16.5}Nb_9S_{42}$ and Ba_2NbS_5 reported by Swinnea et al.[1,2]

Three compounds, $BaNbS_3$, $Ba_{16.5}Nb_9S_{42}$, and Ba_2NbS_5 have been reported in the Ba–Nb–S system. $BaNbS_3$ is isostructural with $BaNiO_3$. According to Donohue,[3] this compound has a composition of $BaNb_{0.8}S_3$ with niobium vacancies, and the Nb atom has a formal charge of +5.

The existence of $Ba_{16.5}Nb_9S_{42}$ and Ba_2NbS_5 was reported by Swinnea.[1,2] The structures of these compounds will be described later in this paper.

In the Ba–Ta–S system, six compounds are reported as listed in Table 1. (In what follows these compounds are designated **a**, **b**, **c**, **d**, **e**, and **f**, for brevity). In the Ba–Nb–S system, types **b**, **d**, and **e** ($BaNbS_3$, $Ba_{16.5}Nb_9S_{42}$, and Ba_2NbS_5) have been found so far but types **a**, **c**, and **f** have not been reported yet. From the analogy of the chemical properties of tantalum and niobium, it is suggested that there is a possibility for the existence of those types of compounds in the Ba–Nb–S system. For this reason, the preparation of new barium niobium sulfides were attempted with the result that types **a** and **f** existed but type **c** was not found. This paper aims to report the preparation and crystal structure of type **f**, $Ba_9Nb_4S_{21}$, which has been unknown until now. The compound of type **a**, the structure of which has not yet been determined, will be described elsewhere.

Experimental

Preparation. The starting materials, $BaCO_3$ (purity 99%) and Nb_2O_5 (99.9%), were mixed in a ratio of Ba/(Ba+Nb)= 0.703. The mixture was placed in a furnace and kept at 750 °C for 3 d in an atmosphere of CS_2 carried by N_2 gas. After cooling to room temperature, the specimen was sealed in an evacuated silica tube with sulfur (1.4 wt%) and kept at 900 °C for 18 h. It was quenched in water.

Chemical Analysis. Chemical analysis was performed for Ba and Nb. The details are as follows. To determine Nb and Ba contents, about 1 g of the specimen was dissolved in 0.8 equiv HCl. Hydrogen sulfide gas was evolved as the specimen dissolved. Ba was dissolved in the solution while Nb remained as solid. The resulting precipitate consisting of the Nb-compound was separated from the solution by filtration, and was then ignited in air at 1000 °C to produce Nb_2O_5. The Nb content was obtained from the weight of Nb_2O_5.

The Ba ion in the solution was precipitated as $BaSO_4$ by adding 1 equiv H_2SO_4. The $BaSO_4$ was separated from the solution and weighed to obtain the Ba content.

The sulfur content was determined from the weight of the specimen and analytical values of Ba and Nb.

Diffraction Data. Powder X-ray diffraction data were collected with a step-scan procedure on a Rigaku RAD-2B-type diffractometer using counter-side monochromatized Cu $K\alpha$ radiation. Measurements were performed from 2θ=5° to 100° with an interval of 0.02°. It took 35 seconds to measure one point. Electron diffraction patterns were taken for crushed particles using a 100 kV electron microscope (Hitachi 500-type).

Density. The density of specimen was obtained by measuring buoyancy in carbon tetrachloride. About 0.5 g of the specimen with fine particles was placed in a bottle, the volume of which was about 2 ml, and the weight of which was 1.5 g.

Table 1. Compounds in the Ba–Ta–S System

Type	**a**	**b**	**c**	**d**	**e**	**f**
Formula	$BaTa_2S_5$	$BaTaS_3$	$Ba_3Ta_2S_8$	$Ba_{16.5}Ta_9S_{39}$	Ba_2TaS_5	$Ba_9Ta_4S_{20}$
Crystal system	H	H	M	R	H	H
Lattice const. (Å)	a= 3.33 c=25.2	a=6.85 c=5.74	a=12.6 b= 6.85 c=11.9 β=108.9°	a= 6.88 c=41.8 (Hexagonal axis)	a= 6.93 c=49.4	a= 6.96 c=21.6
Electric property	Me	S	I	I	I	I
Ref.	4	3,5	6	7	8	9

H: Hexagonal, M: Monoclinic, R: Rhombohedral, Me: Metallic, S: Semiconductor, I: Insulator.

The bottle and the specimen in carbon tetrachloride were kept at reduced pressure to remove the bubbles attached on the specimen and on the surface of the bottle. The buoyancy was obtained by measuring weights in air and in carbon tetrachloride at 25±0.1 °C.

Results

The specimen obtained was of a pure single phase, and the powder X-ray diffraction pattern did not correspond to any known barium niobium sulfides. But the diffraction pattern was very close to that of type **f** in the Ba–Ta–S system, ($Ba_9Ta_4S_{20}$), with different peak intensities. This suggests that the type **f** compound also exists in the Ba–Nb–S system.

The spots of the electron diffraction patterns were indexed on the basis of a hexagonal cell.[10] The lattice parameters were calculated from the distances between two appropriate spots, resulting in a=7 Å and c=22 Å.

In the powder X ray diffraction patterns,[10] all the peaks that were detected were indexable on the basis of a hexagonal cell with lattice parameters a=6.9743(6) and c=21.599(2) Å. These values are in excellent agreement with those from the electron diffraction.

Table 2. Chemical Composition

Element	Ba/wt%	Nb/wt%	S/wt%
Experimental	54.1, 54.6, 54.6, 54.7, 54.7	15.7, 15.7, 15.8, 15.8, 15.5	
Average	54.5	15.7	29.8
Calcd for $Ba_9Nb_4S_{21}$	54.2	16.3	29.5

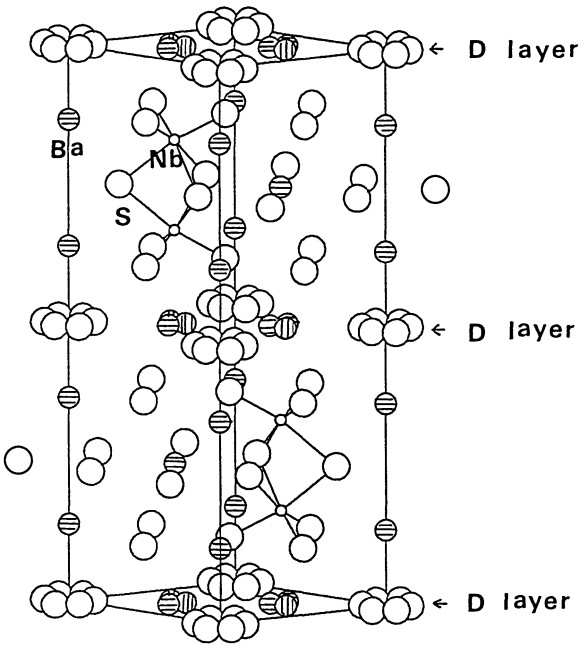

Fig. 1. Crystal structure of $Ba_9Nb_4S_{21}$.
(Niobium atoms are indicated by the small circles, barium atoms by hatched circles, and sulfur atoms by large circles.)

The results of chemical analysis of the compound are presented in Table 2. They agree with the calculated values of $Ba_9Nb_4S_{21}$ within experimental error. From the results, the compound is represented as $Ba_9Nb_4S_{21}$.

Observed densities were 4.25, 4.26 and 4.26 (g cm^{-3}), compared with the calculated one (4.16 g cm^{-3}, Z=1, V=910 Å). The specimen is an insulator, brown black in color, and generates H_2S gas by the reaction with water.

Discussion

We attempted to determine the crystal strucrure of the product ($Ba_9Nb_4S_{21}$) by refinement based on the powder X-ray diffraction pattern, which was similar to those of types **d** ($Ba_{16.5}Nb_9S_{42}$) and **e** (Ba_2NbS_5). This suggests that these three compounds belong to the same structure series.

The structures of types **d** and **e** reported by Swinnea and coworkers[1,2] are based on the stacking of BaS_3 layers in the sequence DABABDBCBCDCACA for type **d** ($Ba_{16.5}Nb_9S_{42}$) and CBDBABDBCBCDCACDCB for type **e** (Ba_2NbS_5), where the A, B, and C layers are hexagonal BaS_3 layers with Ba at (0,0,z), (2/3,1/3,z), and (1/3,2/3,z), respectively, and the D layer is a Ba-rich disordered layer in which Ba and S sites are partly occupied. The Nb atoms occupy interstices between A and B, B and C, and C and A layers, but there is no Nb atom between D and A, D, and B, and D and C layers. The structures are described in space group $R\bar{3}m$ for **d** ($Ba_{16.5}Nb_9S_{42}$) and $P6_3/mmc$ for **e** (Ba_2NbS_5).

It is assumed that the structure of $Ba_9Nb_4S_{21}$ belongs to the same series with types **d** and **e**. The structure, therefore, should have the same rule with those in stacking sequence. In addition, from the unit cell value in the c direction, it is found that 8 layers are contained in a unit cell. The chemical composition reveals that two of them are the D-layers. This information leads us to a single possible structure for $Ba_9Nb_4S_{21}$ shown in Fig. 1.

The structure refinement of the compound was attempted using a total pattern fit program RIETAN[11] based on the Rietveld method.[12] The refinement was performed for the powder X-ray diffraction pattern of $Ba_9Nb_4S_{21}$ based on the structure model given in Fig. 1, and performed for regions from d=4.4 to d=1.0 Å with 9 positional parameters, one overall temperature factor and one scaling factor. The diffraction peaks with d-values larger than 4.4 Å were ignored because it was impossible to obtain accurate intensities experimentally. The calculated pattern without the correction for the preferred orientation was in agreement with that observed (R_{wp}=16.0%, R_p=12.5%, R_I=9.1%, R_F=7.3%). See Ref. 13 for the definitions of the reliability factors R_{wp}, R_p, R_I, and R_F. Tables 3 and 4 give final values of the structure parameters and the interatomic distances.

Table 3. Crystal Data and Atomic Parameters for $Ba_9Nb_4S_{21}$

Crystal data (Hexagonal, space group $P6_3/mmc$ (No. 194)) a=6.9743(6) Å, c=21.599(2) Å, V=910 Å^3, Z=1 (According to the formula $Ba_9Nb_4S_{21}$)

Atomic parameters

Atom	Occupation	x	y	z
Nb	1.0	1/3	2/3	0.1686(8)
Ba(1)	1.0	0	0	0.1363(6)
Ba(2)	1.0	1/3	2/3	3/4
Ba(3)	0.25	0.367(2)	2x	−0.0070(6)
S(1)	1.0	0.494(3)	2x	0.120(1)
S(2)	1.0	0.159(4)	2x	1/4
S(3)	0.25	0.078(5)	2x	0.002(8)

B(Nb)=B(Ba)=B(S)=3.4(2) Å^2.

Table 4. Selected Interatomic Distances (Å) in $Ba_9Nb_4S_{21}$[a)]

Nb–S1	3×2.21(4)	S1–Nb	3×2.21(4)
–S2	3×2.75(4)	–Ba1	6×3.51(4)
Ba1–S1	6×3.51(4)	–Ba2	6×3.49(4)
–S2	3×3.12(3)	–Ba3	[1]×3.02(4)
–S3	[3]×3.08(18)	–Ba3	[2]×3.39(4)
–S3	[3]×3.10(18)	–Ba3	[1]×3.07(4)
Ba2–S1	6×3.51(4)	–Ba3	[2]×3.46(4)
–S2	6×3.49(3)		

a) Distances between Ba3 and S3 are omitted because their sites are statistically occupied.

The diffraction profile observed was compared with the calculated one.[10] The intensities calculated on the atomic parameter were compared with the integrated intensities obtained from the pattern.[10]

The structure is based on the stacking of the D- and BaS_3-layers with a sequence DABADACA. Ba and S atoms are distributed statistically at the respective sites in the D-layer. The Nb atoms occupy interstices between A and B, B and C, and C and A layers, but there is no Nb atom between D and A, D and B, and D and C layers. The structure is described in the space group $P6_3/mmc$ (No. 194) with the atomic positions given in Table 3.

$Ba_9Ta_4S_{20}$,[9] the structure of which has not yet been reported, is probably isostructural with this compound. (The refinement with the same structure model on the powder X-ray diffraction pattern of $Ba_9Ta_4S_{20}$ gave R_{wp}=12.7%, R_p=9.6%, R_I=10.8%, and R_F=6.6%).

The sulfur content in type **f** has different values in the Ba–Nb–S and Ba–Ta–S system, i.e., $Ba_9Nb_4S_{21}$ and $Ba_9Nb_4S_{20}$. They probably contain an identical amount of sulfur. The difference came from the experimental error.

From the results described above, it is concluded that there exists a previously unreported barium niobium sulfide, the chemical composition of which is $Ba_9Nb_4S_{21}$, and the refinement on the powder X-ray diffraction pattern supported the structure which belongs to the same series with the other compounds in the Ba–Nb–S system.

The authors wish to thank Dr. F. Izumi of our institute for giving us permission to use his computer program.

A Hydrogen Insertion Compound of Molybdenum Oxide Hydrate, $H_{0.12-0.22}MoO_3 \cdot H_2O$, and Its Formation Process from Hydrogen Molybdenum Bronze, H_xMoO_3

Kazuo EDA* and Noriyuki SOTANI
College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe 657
(Received April 19, 1991)

Based on XRD and chemical analysis results, the hydrogen insertion compound of molybdenum oxide hydrate (H-hydrate) was suggested to be a genotypic compound of yellow molybdenum trioxide monohydrate, $MoO_3 \cdot H_2O$. H-hydrate was obtained in a hot HCl solution and in hot water from hydrogen molybdenum bronze, H_xMoO_3. The hydrogen bronze with $x \leqslant 0.24$ and the molybdenum species formed in the solution played a role in the formation of H-hydrate. In this process, a temporary dissolution of Mo^{5+} was observed at the beginning of the formation.

Many molybdenum oxide hydrates or a similar class of materials have been known.[1] In a previous study[2] we reported on the formation of a compound identical with or similar to $Mo_8O_{15}(OH)_{16}$[3,4] by treating a hydrogen molybdenum bronze, H_xMoO_3 ($0.23<x<0.40$), with aqueous HCl at 353 K. We regarded it as a hydrogen insertion compound of molybdenum oxide hydrate (H-hydrate), or a hydrate of a hydrogen insertion of molybdenum oxide, which could be expressed as $H_{0.15}MoO_3 \cdot 0.88H_2O$. However, we could not decide whether the compound was identical with $Mo_8O_{15}(OH)_{16}$ or not. $Mo_8O_{15}(OH)_{16}$ was discovered by Glemser and Lutz.[3] These authors obtained it by heating a mixture of yellow $MoO_3 \cdot 2H_2O$ and Mo without air at 383 K. In a series of studies they also obtained $Mo_4O_{10}(OH)_2$ and $Mo_2O_4(OH)_2$ by reducing MoO_3 with Zn/HCl or $SnCl_2$ and by heating a mixture of MoO_3, Mo, and H_2O without air at 383 K.[3] (Although these compounds are formulated as fixed compositions for convenience, they are nonstoichiometric compounds with a rather wide range of homogeneity.) With respect to $Mo_4O_{10}(OH)_2$ and $Mo_2O_4(OH)_2$, they introduced the concept of genotypic compounds of MoO_3, due to the close resemblance of their X-ray diffraction (XRD) patterns to that of the starting material (MoO_3). They also obtained other members, $Mo_5O_7(OH)_8$ and $Mo_5O_5(OH)_{10}$, and finally confirmed four phases of this series.[5,6] These four phases were studied in more detail by Birtill and Dickens.[7] They have been known as hydrogen insertion compounds of MoO_3, H_xMoO_3: Type I blue orthorhombic ($0.23<x<0.4$), Type II blue monoclinic ($0.85<x<1.04$), Type III red monoclinic ($1.55<x<1.72$), and Type IV green monoclinic ($x=2.0$). On the other hand, $Mo_8O_{15}(OH)_{16}$ has been only reexamined by Rode and Lysanova[8] since Glemser and Lutz. According to TG-DTA and XRD results of yellow $MoO_3 \cdot 2H_2O$ by Sotani et al.,[9] the dihydrate decomposes to yellow monohydrate by releasing H_2O at the preparation temperature of $Mo_8O_{15}(OH)_{16}$ by Glemser and Lutz (383 K). This fact indicates that, though Glemser and Lutz used yellow dihydrate as a starting material, the true starting material of $Mo_8O_{15}(OH)_{16}$ was yellow monohydrate. (They believed that the hydration water of the dihydrate was completely released at 383 K and considered that the true starting material was MoO_3.) Moreover, Crouch-Baker and Dickens, recently, reported hydrogen insertion compounds of yellow hydrates of MoO_3, $H_1MoO_3 \cdot 2H_2O$ and $H_1MoO_3 \cdot H_2O$, obtained from yellow dihydrate and yellow monohydrate by catalytic hydrogenation (hydrogen spillover), and $H_xMoO_3 \cdot H_2O$ from $MoO_3 \cdot 2H_2O$ by reduction with acidified $SnCl_2$.[10] It is suggested that there is an intimate relation among the H-hydrates, $Mo_8O_{15}(OH)_{16}$, yellow monohydrate, $H_xMoO_3 \cdot H_2O$ and $H_1MoO_3 \cdot H_2O$; it is therefore important to discuss the relation.

In the present work, to obtain a single phase of H-hydrate, we explored its formation process, and succeeded in obtaining the single phase. The mechanism of H-hydrate formation was discussed. Based on XRD and chemical analysis results, the relation among H-hydrate, $Mo_8O_{15}(OH)_{16}$, $MoO_3 \cdot H_2O$, $H_xMoO_3 \cdot H_2O$ and $H_1MoO_3 \cdot H_2O$ was discussed briefly.

Experimental

Starting Materials. Three kinds of starting materials were used. The starting material with a maximum hydrogen content ($x=0.5$), called ST[1], was prepared by treating 30 g of MoO_3 with 6 g of Zn in 180 ml of a 2 M (1M=1 mol dm^{-3}) HCl solution. ST[1] was a mixture of Type I and Type II hydrogen molybdenum bronzes by an XRD method. The starting material with a medium hydrogen content ($x=0.3$), called ST[2], was prepared by introducing 4 g of Zn. This was Type I. A starting material with a minimum hydrogen content ($x=0.15$), called ST[3], was prepared by introducing 2 g of Zn and was a mixture of Type I and MoO_3.

Investigation of H-Hydrate Formation Process and Characterization of the Specimens. The formation process of H-hydrate from the three starting materials at 343, 353, and 363 K was followed by investigating the specimens treated for a fixed time (1, 2, 4, 7, and 14 days long). Because Type I is soluble in alkaline solutions, we chose three kinds of treating solutions: a 1 M HCl acid solution (non oxidative), a 1 M

HNO_3 acid solution (oxidative) and distilled water. Then, 3 g of the starting material was treated by 150 ml of each treating solution. After treatment the specimens were cooled to room temperature, filtrated, washed with water and vacuum-dried for one day. They were then investigated by using an XRD method and by chemical analysis. The XRD measurement was carried out using a Rigakudenki RINT 1200M diffractometer with Cu K_α radiation. The x values (i.e., hydrogen content) of the specimens were determined by Choain and Marion's method.[11] According to XRD results, most of the specimens were a mixture of the starting materials and/or H-hydrate. Because Type I, Type II, and H-hydrate completely turned to MoO_3 at 673 K in air, the x value was evaluated from the specimen weight at 673 K (Thermogravimetry). Molybdenum species dissolved in the treating solutions from the specimens were investigated by UV-visible spectroscopy.

With respect to 1 M HNO_3 treatments, all specimens were oxidized to MoO_3.

Results and Discussion

H-Hydrate. In this study, we obtained many resulting specimens which did not contain MoO_3 or H_xMoO_3. These specimens showed the XRD peaks of H-hydrate described in our previous study,[2] and were referred to as H-hydrate specimens. They were blue in color and had the composition $H_{0.14-0.22}MoO_3 \cdot 0.94—1.04H_2O$. The specimens did not release hydration water below 373 K and their compositions did not change upon a further vacuum drying. Upon standing in an air atmosphere for a long time, the x value gradually decreased; for example by standing for one year the specimens with $H_{0.21}$ and $H_{0.14}$ turned to those with $H_{0.16}$ and $H_{0.12}$, respectively. The XRD patterns of several freshly prepared specimens are shown in Fig. 1. These patterns are similar to each other, except for the pattern of the specimen with x=0.14. There are minor differences concerning the peaks at 16.9, 25.0, and 33.1°, which disappear when the peaks at 22.9 and 23.5° become broad. An inspection of Fig. 1 is likely to indicate that the disappearance of the peaks depends on the x value, but there was no change in their XRD patterns with a decrease in the x value upon standing in an air atmosphere.

The specimens show almost the same XRD pattern, although they were prepared under various conditions and their compositions cover a rather wide range ($H_{0.12-0.22}MoO_3 \cdot y\ H_2O$, y=about 1). The disappearance of the XRD peaks at 16.9, 25.0, and 33.1° does not depend on the x values and water content of the specimens, but are accompanied by a broadening of the peaks at 22.9 and 23.5°. We presume that the disappearance is related to distortion in the crystal lattice of the specimens. The x values in Fig. 1 can be regarded as being those during the formation of H-hydrate. The seeming dependence of the XRD pattern on the x value, which is observed in Fig. 1, may indicate that the x value during the formation affects the distortion. According to the Raman results,[12] there were no significant differences between the specimens with x=0.21 and x=0.14 in Fig. 1. Therefore, we believe that all H-hydrate specimens are of the same species; that is, they consist of a single phase of a nonstoichiometric compound with a rather wide range of homogeneity. We suggest that the XRD pattern with peaks at 16.9, 25.0, and 33.1° is typical of H-hydrate. Accurate d-spacings are shown in Table 1. Although we have tried to index them using an indexing program for powder XRD pattern,[13]

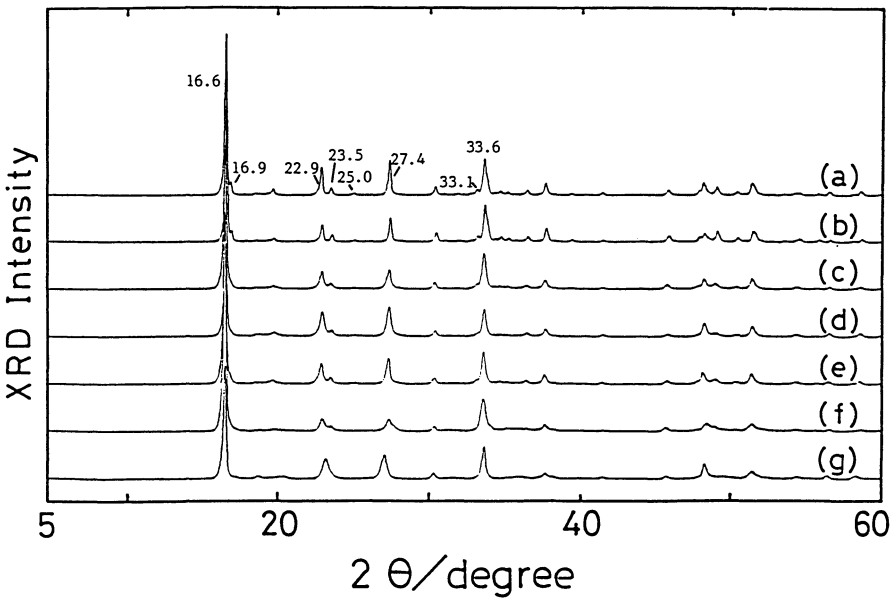

Fig. 1. Powder XRD patterns of the specimens; (a) $H_{0.22}MoO_3 \cdot 0.97H_2O$, (b) $H_{0.21}MoO_3 \cdot 1.01H_2O$, (c) $H_{0.20}MoO_3 \cdot 1.02H_2O$, (d) $H_{0.19}MoO_3 \cdot 1.02H_2O$, (e) $H_{0.18}MoO_3 \cdot 1.03H_2O$, (f) $H_{0.17}MoO_3 \cdot 1.01H_2O$, and (g) $H_{0.14}MoO_3 \cdot 0.99H_2O$.

we have not yet obtained suitable results, because the XRD pattern is too complicated.

Figure 2 shows a comparison among the XRD patterns of H-hydrate, $Mo_8O_{15}(OH)_{16}$,[3] yellow $MoO_3 \cdot H_2O$ (JCPDS 28-0666), $H_xMoO_3 \cdot H_2O$ (JCPDS 38-0066) and $H_1MoO_3 \cdot H_2O$ (JCPDS 38-0064). The XRD pattern of H-hydrate is similar to that of $Mo_8O_{15}(OH)_{16}$, except for several small peaks. According to Glemser and Lutz,[3] $Mo_8O_{15}(OH)_{16}$ was also expressed by the composition $MoO_{2.88-2.90} \cdot H_2O$. Because the composition of H-hydrate can be rewritten as $MoO_{2.89-2.94} \cdot 1.04—1.16H_2O$, H-hydrate and $Mo_8O_{15}(OH)_{16}$ are comparable to each other. On the basis of their XRD patterns and compositions, H-hydrate is identical with $Mo_8O_{15}(OH)_{16}$. The XRD pattern of $MoO_3 \cdot H_2O$ shows two strong diffraction peaks at about 16.5 and 33.0°, which are attributed to the (020) and (040) planes. This hydrate has a layer structure, and the *d*-spacing of

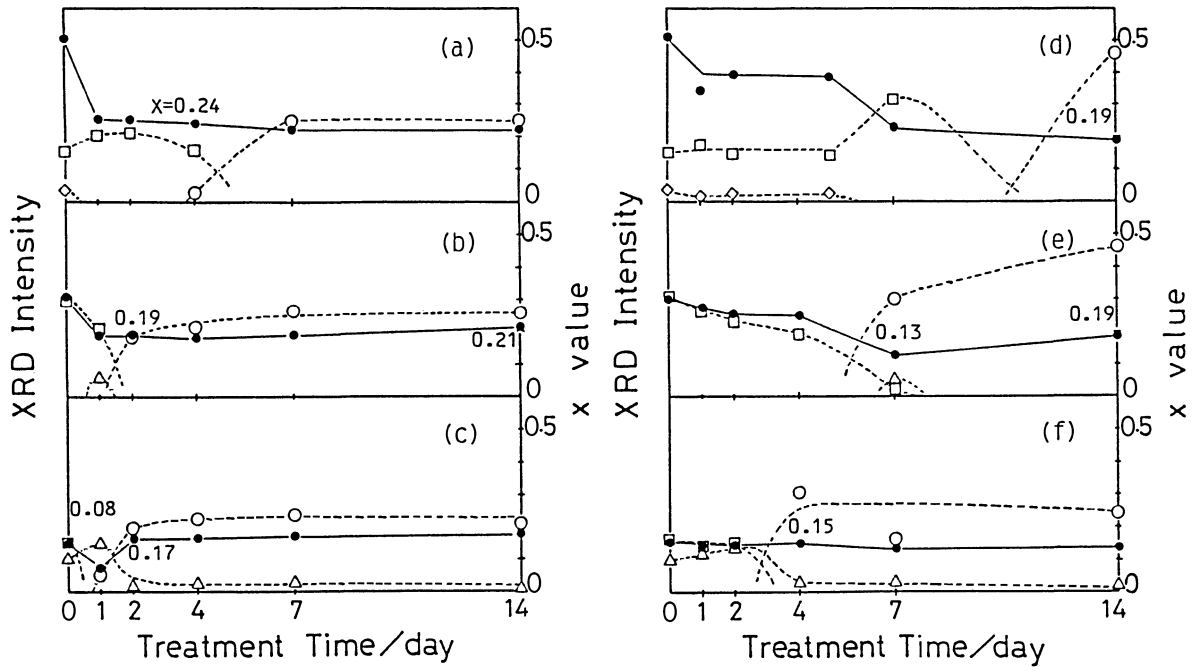

Fig. 3. Formation process of H-hydrate at 353 K by the HCl treatment from ST[1] (a), ST[2] (b), and ST[3] (c), and by the water treatment from ST[1] (d), ST[2] (e), and ST[3] (f), respectively. (□), (◇), (△), and (○) are the relative XRD intensity of the peak at 25.3° of Type I to the intensity of the peak at 28.4° of Si which was mixed with the specimens as an internal standard, that of the peak at 24.2° of Type II, that of the peak at 25.7° of MoO_3 and that of the peak at 16.6° of H-Hydrate, respectively. (●) is the *x* value of the specimen.

the (020) plane corresponds to its interlayer spacing. The XRD patterns of $H_xMoO_3 \cdot H_2O$ and $H_1MoO_3 \cdot H_2O$ also show a strong peak at about 33.0°, which is ascribed to the (040) plane. This indicates that $H_xMoO_3 \cdot H_2O$ and $H_1MoO_3 \cdot H_2O$ retain the Mo–O framework of $MoO_3 \cdot H_2O$. The two strong peaks are observed in the patterns of H-hydrate and $Mo_8O_{15}(OH)_{16}$. This fact indicates a resemblance in Mo–O framework among H-hydrate, $Mo_8O_{15}(OH)_{16}$, and yellow monohydrate. Because the starting material of $Mo_8O_{15}(OH)_{16}$ is yellow monohydrate, we suggest that $Mo_8O_{15}(OH)_{16}$, i.e., H-hydrate, is a genotypic compound of yellow monohydrate. We, thus, express H-hydrate as $H_{0.12-0.22}MoO_3 \cdot H_2O$.

The Formation Process. Figure 3 shows the formation process of H-hydrate from the three starting materials at 353 K. In the case of an HCl treatment, H-hydrate appears after 4 days of treatment for ST[1], 2 days for ST[2], and 1 day for ST[3]. In the case of a water treatment, H-hydrate formation is also observed. There is basically no difference between the results for an HCl treatment and that for a water treatment, except that H-hydrate is formed much more slowly in water than in an HCl solution. The formation of H-hydrate took place little more rapidly at 363 K, and slightly more slowly at 343 K than at 353 K. In several cases, MoO_3 temporarily appeared, or temporarily increased, just before H-hydrate appeared. This appearance or increase of MoO_3 was accompanied by a decrease in the x value. In the case of an HCl treatment at 353 K for ST[1], H-hydrate was formed without the appearance of MoO_3. In all cases, H-hydrate was formed as Type I disappeared. The formation took place when the x value of the solid phase was in the range $x \leqslant 0.24$ and Type II was not contained.

The formation of H-hydrate, followed by the disappearance of Type I, indicates that H-hydrate is formed from Type I. The maximum limit value (x=0.24) corresponds to the reduction degree [$MoO_{2.88}$]. This reduction degree is identical with that of $Mo_8O_{15}(OH)_{16}$,[3] i.e., that of H-hydrate. The temporary appearance, or temporary increase, of MoO_3 seems to be correlated with the formation of H-hydrate. However, as mentioned above, in the case of an HCl treatment of ST[1] at 353 K, formation took place without the appearance of MoO_3. To investigate whether the appearance or increase of MoO_3 is correlated with the formation, we paid much attention to specimens which contained both H-hydrate and Type I, i.e., which revealed a H-hydrate forming stage. It was then recognized that the specimens at this stage contained MoO_3 when $x<0.23$. Therefore, the appearance, or increase, of MoO_3 is not correlated with the formation of H-hydrate. It has been known that H_xMoO_3 in the range $x<0.23$ exists as a mixture of Type I and MoO_3.[7] As mentioned above, a temporary decrease in the x value was also observed just before H-hydrate formation. The temporary appearance, or temporary increase, of MoO_3 arises from a temporary decrease in the x value to less than 0.23. The temporary decrease in the x value indicates that Mo^{5+} was temporarily dissolved into the treating solution. We presume that this dissolution of Mo^{5+} takes place when the Mo–O framework based on the MoO_3 structure (H_xMoO_3) is reformed to that based on the $MoO_3 \cdot H_2O$ structure (H-hydrate).

For an HCl treatment, the supernatant solution was orange in color before H-hydrate formation took place; the color became faint as the formation proceeded. For water treatment, however, the supernatant was deep dark blue before formation, and finally the color turned to faint greenish blue. Figure 4 shows the UV-visible spectra of the supernatant solutions for ST[3]. Spectra (a) and (b) were obtained from orange (for 1 day HCl treatment at 353 K) and colorless (for 4 days HCl treatment at 353 K) supernatant solutions, respectively, while spectra (c) and (d) were obtained from deep dark blue (for 1 day water treatment at 353 K) and faint greenish blue (for 4 days water treatment at 353 K) solutions, respectively. Spectrum (a) shows a strong band below 350 nm and two weak bands at 380 and 480 nm. Spectrum (c) shows a strong band below 350 nm

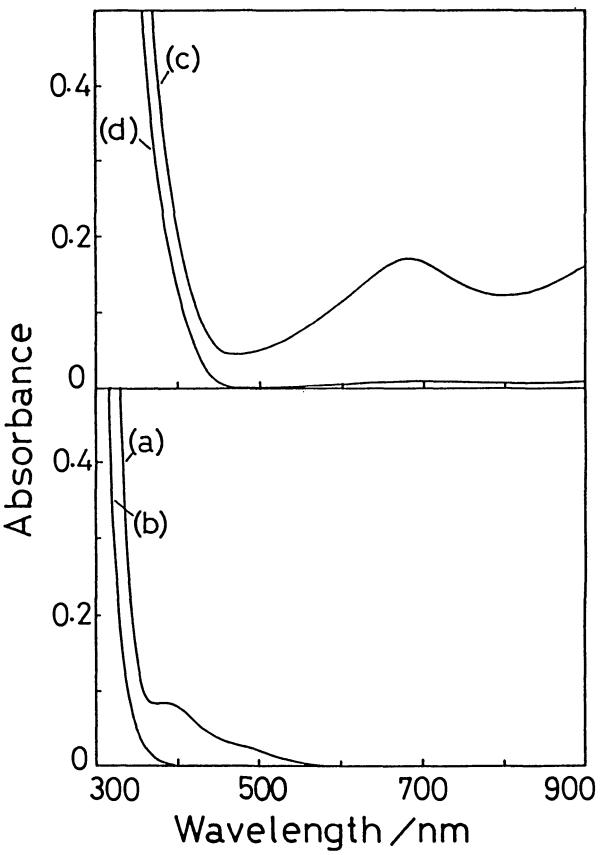

Fig. 4. Extinction spectra of supernatant solutions for HCl and water treatments of ST[3] at 353 K. The (a) and (b) spectra were obtained from the solutions for 1 day and 4 days HCl treatments, respectively, while (c) and (d), for 1 day and 4 days water treatments, respectively.

and two medium bands at 680 nm and above 900 nm. These observed bands arise from molybdenum species dissolved in the treating solutions from H_xMoO_3. The strong band below 350 nm, observed in both spectra (a) and (c), is attributed to molybdenum species consisting of Mo^{6+}. The bands at 380 and 480 nm are ascribed to mixed-valence (Mo^{6+} and Mo^{5+}) molybdenum species with a small degree of condensation, such as a dimer,[14] while the bands at 680 nm and above 900 nm are ascribed to mixed-valence molybdenum species with a large degree of condensation, which are known as isopoly-blue. The following information can be obtained from Fig. 4: (i) As the formation of H-hydrate proceeds, the amount of mixed-valence species apparently decreases. (ii) The forms of mixed-valence species depend on the treating solution; no mixed-valence molybdenum species common to both treating solutions has been observed.

This information suggests that the mixed-valence molybdenum species in the treating solution plays a role in the formation of H-hydrate. However, H-hydrate is not formed only by condensation of the molybdenum species in solution. If H-hydrate is formed only by condensation, any common mixed-valence molybdenum species with an extremely large degree of condensation should be observed in both HCl and water treating solutions during formation. As mentioned above, H-hydrate formation also depended on the x value of the solid phase (When $x \leqslant 0.24$, the formation of H-hydrate was observed). Thus, both the (mixed-valence) molybdenum species in the treating solution and H_xMoO_3, $x \leqslant 0.24$ correlate strongly with the formation of H-hydrate. There is still a question as to why these different species in an HCl solution and in water lead to the same product (H-hydrate). This question can be answered by considering that these species may also comprise of the same constituent unit, i.e., Mo–O octahedra, as H-hydrate (monohydrate of MoO_3), MoO_3, and H_xMoO_3. Mo^{5+} seems to be necessary for molybdenum species to react with the solid phase and to form H-hydrate. We conclude that H-hydrate is formed as follows:

Structure and Homogeneous Chemical Equilibria of Lithium β-Diketonates in Dimethyl Sulfoxide

Yoshinori ARAKI,† Akio IWASE, Setsuko KUDO,* Toshishige M. SUZUKI, and Toshiro YOKOYAMA
Department of Chemistry, Faculty of Science, Yamagata University, Kojirakawa-machi, Yamagata 990
† Traffic Control Materials Laboratory, Yamagata 3M Ltd., Ohaza Osanagi, Higashine 999-37
(Received April 20, 1991)

The structure and the homogeneous chemical equilibria of lithium β-diketonates (LiL), viz., Li(dbm), Li(bzac), and Li(acac), in dimethyl sulfoxide (DMSO) were studied by means of ^{13}C NMR, IR spectral measurements, and rotating disk voltammetry, where dbm^-, $bzac^-$, and $acac^-$ indicate the enolate anions of dibenzoylmethane, benzoylacetone, and acetylacetone, respectively. It was found by the ^{13}C NMR and IR spectral measurements that LiL existed mainly as Li(uni-L) in DMSO, where uni- means that the ligand coordinates to the metal as unidentate. Since it is known that LiL dissociates slightly into ions in DMSO, LiL is involved in the following homogeneous chemical equilibrium:

$$\text{Li(uni-L)} \rightleftharpoons \text{Li}^+ + \text{L}^-$$

Furthermore, the apparent dissociation constant ($\log K_{app}$) of LiL was obtained by rotating disk voltammetry in DMSO containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate (TBAP), i.e., Li(dbm): −3.0±0.1, Li(bzac): −2.7±0.1, and Li(acac): −2.0±0.1, respectively. It was noted that the homogeneous chemical equilibria shifted more to the right in 0.1 mol dm^{-3} TBAP–DMSO than in DMSO alone. The behavior can be explained mainly in terms of the interaction between the π-electron system of Li(uni-L) and the cations of TBAP.

In previous papers,[1–5] the homogeneous chemical equilibria of ten bis(β-diketonato)nickel(II) complexes in DMSO were investigated by means of conductivity, electronic spectral measurements, cryoscopy, polarography, and cyclic voltammetry. For instance, it was found polarographically that three complexes, viz., $Ni(dbm)_2$,[2] $Ni(bzac)_2$,[1] and $Ni(acac)_2$,[5] were involved in the following homogeneous chemical equilibria:

(a) $Ni(dbm)_2$ and $Ni(bzac)_2$

$$\text{Ni(bi-L)}_2 \rightleftharpoons \text{Ni(bi-L)(uni-L)} \rightleftharpoons \text{Ni(bi-L)}^+ + \text{L}^- \rightleftharpoons \text{Ni(uni-L)}^+$$

(b) $Ni(acac)_2$

$$\text{Polymeric species} \rightleftharpoons \text{NiL}_2 \rightleftharpoons \text{Ni(bi-L)}^+ + \text{L}^- \rightleftharpoons \text{Ni(uni-L)}^+$$

where bi- means that the ligand coordinates to the metal as bidentate and L^- indicates the enolate anion of the β-diketone. Because the polarographic measurements in the previous research were based on the reduction of the metal base of the complexes, they do not provide detailed information on the ligands.

The present paper deals with the structure and the homogeneous chemical equilibria of Li(dbm), Li(bzac), and Li(acac) in DMSO by use of ^{13}C NMR and IR spectral measurements, and in 0.1 mol dm^{-3} TBAP–DMSO by means of rotating disk voltammetry based on the oxidation of the ligand base. Since LiL is a simple compound, it was expected that this research would provide more direct information regarding the bond between the metal and the ligand, and more quantitative information with respect to homogeneous chemical equilibria for metal β-diketonates in DMSO.

Experimental

Reagents. Lithium dibenzoylmethanate [Li(dbm)] was prepared as follows: To 5 mmol of Aldrich Chemicals' dibenzoylmethane (98%) in 50 mL of methanol was added 5 mmol of Nakarai Chemicals' lithium hydroxide monohydrate (99%) in 150 mL of methanol. The resulting solution was evaporated and a small amount of diethyl ether was added to the concentrated solution. The solution was permitted to stand for a minimum of 2 h in an ice bath and then was filtered. The salt was recrystallized once with methanol–diethyl ether. Then, the salt was dried in vacuo at 105±5 °C for ca. 6 h. The yield of the salt was 30.5%. Found: C, 77.74; H, 5.01%. Calcd for $C_{15}H_{11}O_2Li$: C, 78.26; H, 4.82%. Lithium benzoylacetonate [Li(bzac)] and lithium acetylacetonate [Li(acac)] were synthesized by the same method as Li(dbm). Found: C, 71.11; H, 5.66%. Calcd for $C_{10}H_9O_2Li$: C, 71.43; H, 5.41%. Found: C, 55.74; H, 6.44%. Calcd for $C_5H_7O_2Li$: C, 56.62; H, 6.67%.

Tetrabutylammonium dibenzoylmethanate [*n*-Bu_4N(dbm)], tetrabutylammonium benzoylacetonate [*n*-Bu_4N(bzac)], and tetrabutylammonium acetylacetonate [*n*-Bu_4N(acac)] were obtained according to the method described by Buchta et al.[6] Found: C, 79.50; H, 10.10; N, 2.67%. Calcd for $C_{31}H_{47}O_2N$: 79.93; H, 10.19; N, 3.01%. Found: C, 76.92; H, 11.32; N, 3.00%. Calcd for $C_{26}H_{45}O_2N$: C, 77.35; H, 11.26; N, 3.47%. Found: C, 73.87; H, 13.01; N, 3.95%. Calcd for $C_{21}H_{43}O_2N$: C, 73.82; H, 12.71; N, 4.10%. These salts were stored in the dark under nitrogen.

The dimethyl sulfoxide and TBAP used in rotating disk voltammetry were the same as described previously.[7]

Apparatus and Procedures. ^{13}C NMR spectra were obtained with a Varian VXR-300 spectrometer at room temperature. Test solutions were prepared as 0.4 mol dm^{-3} LiL in methanol-d_4 (CD_3OD) and dimethyl-d_6 sulfoxide (DMSO-d_6). Chemical shifts were reported in ppm units, relative to internal tetramethylsilane.

IR spectra were recorded on a Hitachi 270-50 infrared spectrophotometer. Samples were prepared as 1% LiL dispersion in KBr pellets and 10 mmol dm^{-3} solutions in DMSO. The solutions were measured with a calcium fluoride cell of 0.5 mm optical length at room temperature.

Rotating disk voltammograms were obtained with a Nikko Keisoku DPGS-1 dual potentiogalvanostat, a Nikko Keisoku NFG-3 function generator, and a Watanabe WX 4421 X-Y plotter. A disk electrode was rotated by means of a Nikko Keisoku SC-4 motor speed controller and a Nikko Keisoku RRDE-1 rotating ring-disk electrode apparatus. Current–potential curves were measured with a three-electrode system at 25.0±0.2 °C. A platinum rotating disk electrode (surface area: 0.071 cm^2) was used as a working electrode, with a platinum wire as a counter electrode and an aqueous saturated calomel electrode (SCE) as a reference electrode. The rotation speed of the disk electrode ranged from 51 to 890 rad s^{-1}. Voltammograms were recorded at 20 mV s^{-1} scan rate. All test solutions were deaerated for ca. 30 min with nitrogen gas before measurements. As a supporting electrolyte, 0.1 mol dm^{-3} TBAP was used.

Results and Discussion

1. In DMSO. ^{13}C NMR Spectra: The data for the ^{13}C NMR chemical shift of LiL are summarized in Table 1. Each resonance was a singlet, except methylene carbon of Li(bzac) and Li(acac), measured in CD_3OD. Only one carbonyl carbon resonance was obtainted for Li(dbm) and Li(acac), while Li(bzac) gave two carbonyl carbon resonances, due to $-CH_3$ and –Ph substituents at ^{1}C and ^{3}C positions, which were assigned from the chemical shifts of acetone and acetophenone.[8] The Table shows that the carbonyl and methylene carbon resonances indicate drastic upfield shifts in DMSO-d_6, in comparison with the resonances in CD_3OD.

The differences between the chemical shifts in the two solvents used are also presented in Table 1, where

$$d_i = C_i(\text{in } CD_3OD) - C_i(\text{in DMSO-}d_6)\ (i=1\text{—}3) \quad (1)$$

The d_1 and d_3 values suggest that the structure of LiL in DMSO-d_6 is different from that in CD_3OD.

Raban et al. reported that Li(acac) existed almost completely in the chelated form in CD_3OD.[9] As described in section 2 of the present paper, Li(dbm) and Li(bzac) are more stable than Li(acac); therefore, they also tend to exist in the chelated form in CD_3OD. On the other hand, since LiL is strongly solvated in DMSO-d_6, it may be expected that the lithium-oxygen bond will tend to break in DMSO-d_6.

Shibata et al. studied ^{13}C NMR chemical shifts of various β-diketones in DMSO-d_6 and chloroform-d.[8] According to that paper, carbonyl carbon resonances indicated drastic upfield shifts in DMSO-d_6, in comparison with the resonances in chloroform-d, i.e., d=2.7—5.5 ppm. The results led to the conclusion that DMSO-d_6 broke the intramolecular hydrogen bond of the β-diketone and that the upfield shift was caused by the contribution of the free carbonyl carbon which was not influenced by the intramolecular hydrogen bond.

In addition, ^{13}C NMR chemical shifts of the carbonyl carbon for n-Bu_4NL were obtained in DMSO-d_6, viz., n-Bu_4N(dbm) showed 180.5 ppm and n-Bu_4N(bzac) indicated 190.9 and 179.8 ppm at ^{1}C and ^{3}C positions.[10] These findings suggest that the structure of LiL is analogous to that of n-Bu_4NL in DMSO-d_6. However, dissociation of Li(dbm) is negligible in DMSO-d_6 under the conditions used in this study, as discussed below.

The present research demonstrates that LiL does not take the chelated form in DMSO-d_6 (Scheme 1) because the behavior of LiL is very similar to that of the β-diketones reported by Shibata et al., and the carbonyl carbon resonances for LiL appear at the similar positions of those for n-Bu_4NL in DMSO-d_6. Therefore, it is found that the upfield shifts of LiL in DMSO-d_6 are

Table 1. ^{13}C NMR Chemical Shifts of LiL in CD_3OD and DMSO-d_6

Compound	Solvent	Chemical shift of carbonyl carbon/ppm				Chemical shift of methylene carbon/ppm	
		C_1	d_1[a]	C_3	d_3[b]	C_2	d_2[c]
Li(dbm)	CD_3OD	187.4				95.3	
	DMSO-d_6	182.5	4.9			91.1	4.2
Li(bzac)	CD_3OD	192.6		186.2		97.1[d]	
	DMSO-d_6	189.3	3.3	180.3	5.9	94.1	3.0
Li(acac)	CD_3OD	191.3				99.3[d]	
	DMSO-d_6	186.8	4.5			97.4	1.9

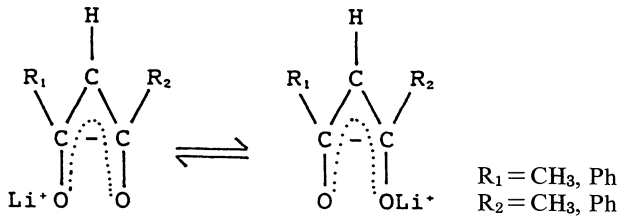

Scheme 1.

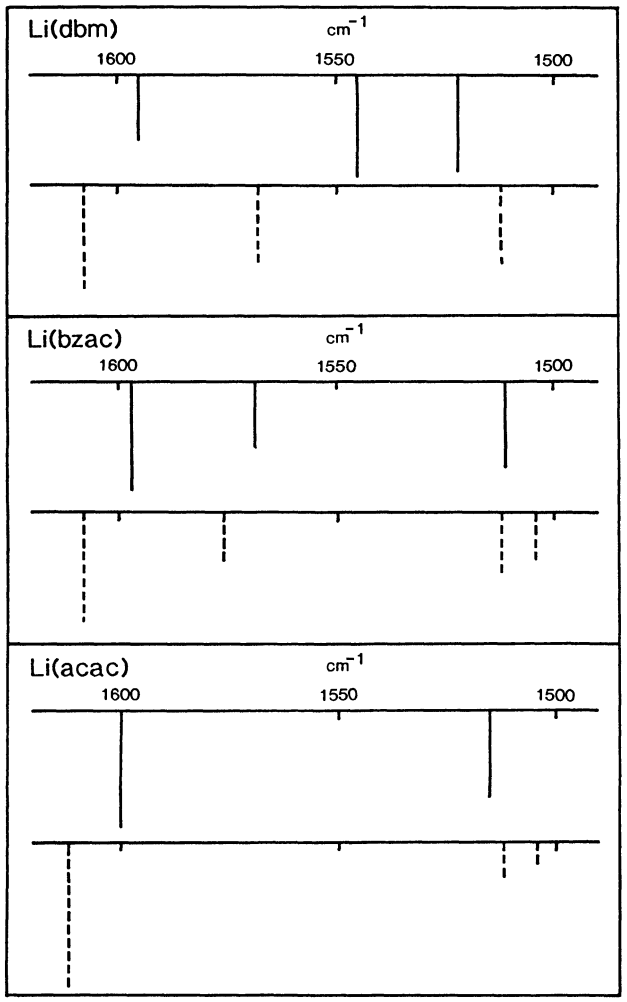

Fig. 1. IR spectra of LiL in the solid state (solid line) and in DMSO (broken line).

caused by the contribution of the free carbonyl carbon. As shown in Scheme 1, the two species contribute to the upfield shifts; however, it was not possible to separate the two species, and it was also impossible to differentiate between the free carbonyl carbon and the other within the NMR time scale. The mixture of the two species is represented as Li(uni-L) below.

IR Spectra: IR spectra of LiL in the solid state and in DMSO are diagrammed in Fig. 1. Each characteristic band of ν(C⋯O)[11,12] of Li(dbm), Li(bzac), and Li(acac) appears at 1595, 1597, and 1600 cm^{-1} in the solid state and at 1608, 1608, and 1612 cm^{-1} in DMSO, respectively. In addition, ν(C⋯O) of n-Bu_4N(dbm) was 1611 cm^{-1} in the solid state and 1612 cm^{-1} in DMSO. These findings suggest that the structure of Li(dbm) in DMSO is similar to that of n-Bu_4N(dbm). However, the degree of dissociation for Li(dbm) in DMSO is very minimal, as described below. Although it is thought that the shifts of ν(C⋯O) in DMSO are caused by the solvent effect, it is more plausible that LiL takes the unidentate structure because of the conclusion in the ^{13}C NMR study.

Chemical Equilibria: Arnett et al. reported that the dissociation constant ($\log K_D$) of Li(dbm) was -5.86 ± 0.01 in DMSO.[13] By using this datum, it is possible to calculate the degrees of dissociation for the prepared concentration in the ^{13}C NMR and IR spectral measurements. Thus, the calculated degree of dissociation is 0.2% for 0.4 mol dm^{-3} in the ^{13}C NMR study, while it is 1.2% for 10 mmol dm^{-3} in the IR study. Since these degrees of dissociation are very minimal, the dissociated species in Scheme 2, i.e., Li^+ and L^-, are negligible for the both measurements. Therefore, the main species in DMSO is Li(uni-L), and the fact is consistent with the result in ^{13}C NMR and IR studies.

2. In TBAP-DMSO. Rotating Disk Voltammetry: Typical rotating disk voltammograms of LiL and n-Bu_4NL are shown in Fig. 2. In general, a limiting current is shown by the Levich equation[14] under convective-diffusion controlled conditions, as follows:

$$i_L = 0.620nFAD^{2/3}\omega^{1/2}\nu^{-1/6}C \quad (2)$$

where i_L is the limiting current, n is the number of

$$\text{Li(uni-L)} \underset{}{\overset{K_D}{\rightleftharpoons}} \text{Li}^+ + \text{L}^-$$

Scheme 2.

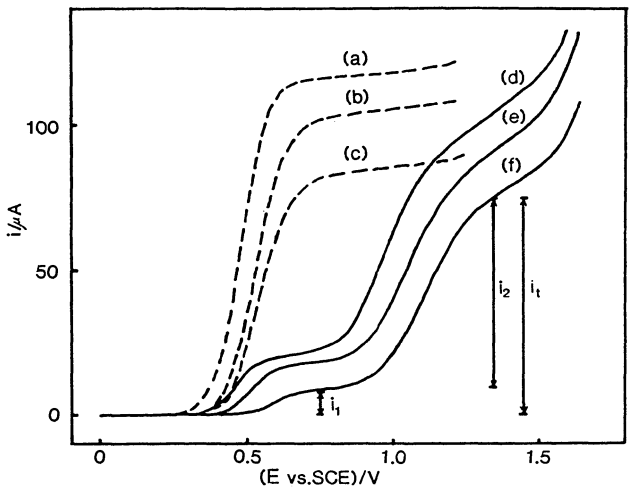

Fig. 2. Rotating disk voltammograms of 2 mmol dm^{-3} (a) n-Bu_4N(acac), (b) n-Bu_4N(bzac), (c) n-Bu_4N(dbm), (d) Li(acac), (e) Li(bzac), and (f) Li(dbm) at 775 rad s^{-1} rotation speed in 0.1 mol dm^{-3} TBAP-DMSO.

transferred electrons, F is the Faraday constant, A is the surface area of the disk electrode, D is the diffusion coefficient, ω is the rotation speed of the disk electrode, ν is the kinematic viscosity, and C is the bulk concentration. The limiting currents for LiL (i_l) and for n-Bu_4NL in Fig. 2, are proportional to the square root of ω. The plots of i_l at a constant rotation speed vs. C for LiL give a straight line in the concentration range from 1 to 10 mmol dm^{-3}.

VandenBorn et al. reported that n-Bu_4N(dbm) existed as the enolate anion in DMSO containing 0.1 mol dm^{-3} tetraethylammonium perchlorate and that controlled potential coulometry gave the n value of 0.98±0.03.[15] Therefore, the observed limiting current for n-Bu_4NL in Fig. 2 is consistent with a one-electron oxidation process; and i_l for LiL also corresponds to a totally one-electron oxidation process.

The first wave (i_1) in Fig. 2 contains a kinetic current due to a preceding chemical reaction. Figure 3 shows the correlation between i_1/i_2 and ω. As seen in Fig. 3, i_1/i_2 decreases as ω increases and it remains constant above 670 rad s^{-1}. Consequently, i_1 contains no kinetic current under the latter conditions.

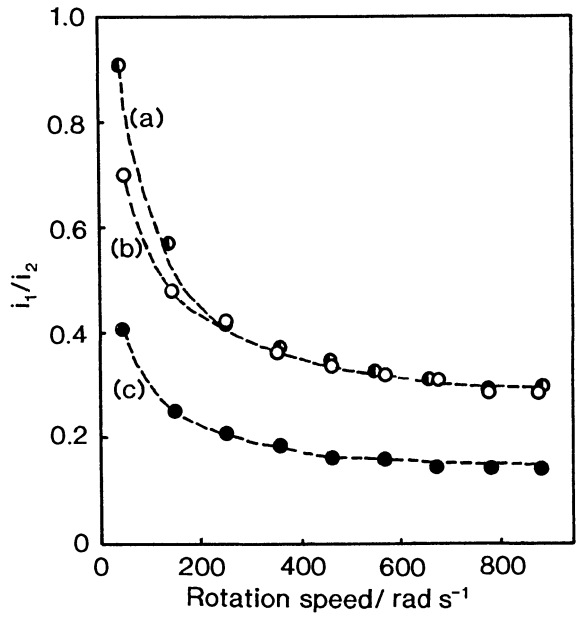

Fig. 3. Plots of i_1/i_2 vs. rotation speed for rotating disk voltammograms of 2 mmol dm^{-3} (a) Li(acac), (b) Li(bzac), and (c) Li(dbm) in 0.1 mol dm^{-3} TBAP-DMSO.

The rotating disk voltammetric data on the oxidation of LiL and n-Bu_4NL at ω=775 rad s^{-1} are summarized in Table 2. The half-wave potential and slope of i_1 for Li(bzac) and Li(acac) are almost equal to those for n-Bu_4N(bzac) and n-Bu_4N(acac) with errors of ±0.01 V and ±5 mV, respectively. While the half-wave potential of i_1 for Li(dbm) is a little different from that for n-Bu_4N(dbm), the first wave for Li(dbm) indicated the following findings:

(a) The first wave involved the kinetic current resulting from the preceding chemical reaction below ω=670 rad s^{-1}, as mentioned above.

(b) When a small amount of lithium perchlorate was added to the solution, i_1 decreased and i_2 increased under the conditions of ω=775 rad s^{-1}.

These experimental findings suggest that the first wave should be assigned to the oxidation of the enolate anion arising from the dissociative reaction; the second wave corresponds to the oxidation of Li(uni-L), on the basis of the results described in section 1 (Scheme 3).

The diffusion coefficient (D) of the enolate anion of n-Bu_4NL is calculated from the slope of the plots of limiting current vs. the square root of ω in terms of Eq. 2. The data are also presented in Table 2. The datum for n-Bu_4N(dbm) agrees with that reported VandenBorn et al.[15]

It is possible to determine the concentration of L^- (Scheme 3) in 0.1 mol dm^{-3} TBAP-DMSO in terms of Eq. 3,[14]

$$1/i_L = 1/i_K + 1/0.620nFAD^{2/3}\omega^{1/2}\nu^{-1/6}C \quad (3)$$

where i_K represents the current in the absence of any

$$\text{Li(uni-L)} \overset{K_{app}}{\rightleftharpoons} \text{Li}^+ + \text{L}^-$$
$$\downarrow -e \qquad\qquad \downarrow -e$$

Compound	C/mmol dm^{-3}	log K_{app}
Li(dbm)	1.0	—[a]
	2.0	−2.9
	5.0	−3.1
Li(bzac)	1.0	−2.7
	2.0	−2.7
	5.0	−2.6
Li(acac)	1.0	−2.0
	2.0	−2.1
	5.0	—[a]

a) It was impossible to obtain these data because of a lack of fit for the plots.

mass transfer effects. The plots of $1/i_L$ for the first wave vs. $1/\omega^{1/2}$ showed straight lines at 0.6, 0.7, and 0.8 V vs. SCE. From the slope of the line, the concentration of L^-, i.e., C, was calculated by using the D for n-Bu_4NL in Table 2 and $\nu = 0.01828$ cm^2 s^{-1}. Then, the apparent dissociation constant (log K_{app}) of LiL in 0.1 mol dm^{-3} TBAP–DMSO was obtained, as shown in Table 3.

The values decrease in the following order: Li(acac)>Li(bzac)>Li(dbm). This order agrees with that of the dissociation constants (log K_d) of β-diketones, measured in the aqueous 75 vol% dioxane, namely Hacac>Hbzac>Hdbm, which are −12.70, −12.85, and −13.75, respectively.[16] The log K_{app} of Li(dbm) is −3.0±0.1 in 0.1 mol dm^{-3} TBAP–DMSO; however, the log K_D of Li(dbm) is −5.86±0.01 in DMSO.[13] It was found that the homogeneous chemical equilibrium (Scheme 2) for Li(dbm) shifted more to the right in 0.1 mol dm^{-3} TBAP–DMSO than in DMSO alone.

The TBAP effect on the homogeneous chemical equilibrium for Li(dbm) can be considered first from the standpoint of the ionic strength of the solution. Libuś et al. reported conductometric and spectrophotometric results of copper(II) trifluoroacetate [$Cu(CF_3COO)_2$] in DMSO.[17] That paper indicated that the association constant of $CuCF_3COO^+$ in DMSO derived from the spectrophotometric results, after making activity corrections, agreed with that derived from conductometric data. If the dissociation constant of Li(dbm), after making activity corrections, is defined as K_I, the following equation is set up:

$$\log K_I = \log K_D - \log Y_{Li} - \log Y_{dbm} \quad (4)$$

where Y_{Li} and Y_{dbm} are the activity coefficients of Li^+ and dbm^-, respectively. Thus, log $K_I \approx -5.6$ is obtained by using log $K_D = -5.86$[13] and log $Y_{Li} = \log Y_{dbm} = -0.12$[18] at I (ionic strength)=0.1 in 0.1 mol dm^{-3} TBAP–DMSO. However, the log $K_I \approx -5.6$ is still different from the log $K_{app} = -3.0 \pm 0.1$.

It was described in a previous paper[19] that the dissociation of bis(benzoyltrifluoroacetonato)nickel(II), bis(2-furoyltrifluoroacetonato)nickel(II), and bis(2-thenoyltrifluoroacetonato)nickel(II) complexes in DMSO was enhanced by the presence of one of the supporting electrolytes and that it was considered that such promotion of the dissociation was caused by an interaction between the π-electron system of the complex and the cations of the electrolyte. Although it is impossible to discuss the difference between the log $K_{app} = -3.0 \pm 0.1$ and the log $K_D = -5.86 \pm 0.01$ quantitatively, the difference can be explained mainly in terms of the interaction between the π-electron system of Li(uni-dbm) and the cations of TBAP. It is thought that a similar interaction also takes place in the case of Li(bzac) and Li(acac).

The authors wish to acknowledge the useful suggestions of Professor Yuzo Nishida of Yamagata University in the field of ^{13}C NMR and IR spectroscopy.

Isomerization and Racemization of the Tris(4,4′-dimethyl-2,2′-bipyridine *N,N′*-dioxide)chromium(III) Complex

Hideaki KANNO,* Junko YAMAMOTO, Satoshi MURAHASHI, Shunji UTSUNO, and Junnosuke FUJITA†

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

†Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464-01

(Received May 1, 1991)

A new chromium(III) complex, $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ (4,4′-Me_2bpdo=4,4′-dimethyl-2,2′-bipyridine *N,N′*-dioxide) was prepared and resolved into a pair of enantiomers by an SP-Sephadex column chromatographic method using an achiral eluting agent Na_2SO_4. Both perchlorate and nitrate of the complex were found to crystallize in the *lel*$_2$·*ob*($\Delta(\lambda\lambda\delta)$, $\Lambda(\delta\delta\lambda)$) form. Upon dissolution in water, the complexes isomerized to the *lel*$_3$($\Delta(\lambda\lambda\lambda)$, $\Lambda(\delta\delta\delta)$) form with a rapid change in absorption spectra, and then racemized ($\Delta \rightleftarrows \Lambda$) slowly. The rate constants at 35.0 °C were 4.39×10^{-3} s^{-1} for the isomerization and 3.46×10^{-5} s^{-1} for the racemization. These inversion reactions including conformational change ($\delta \rightleftarrows \lambda$) and configurational change ($\Delta \rightleftarrows \Lambda$) are supposed to proceed by intramolecular mechanisms. The rates of isomerization and racemizatioin of the 4,4′-Me_2bpdo complex are ca. two and ten times slower than those of $[Cr(bpdo)_3]^{3+}$ (bpdo=2,2′-bipyridine *N,N′*-dioxide), respectively.

The skew seven-membered chelate ring of 2,2′-bipyridine *N,N′*-dioxide (bpdo) in metal complexes has been confirmed by X-ray analyses of $[La(bpdo)_4](ClO_4)_3$[1] and $[UO_2(NO_3)_2(bpdo)]$.[2] The skew conformation of bpdo can exist in a pair of enantiomers, δ and λ as shown in Fig. 1. Hence a tris(bpdo) complex has four possible racemic pairs of diastereomers, *lel*$_3$($\Delta(\lambda\lambda\lambda)$, $\Lambda(\delta\delta\delta)$), *lel*$_2$·*ob*($\Delta(\lambda\lambda\delta)$, $\Lambda(\delta\delta\lambda)$), *lel*·*ob*$_2$($\Delta(\lambda\delta\delta)$, $\Lambda(\delta\lambda\lambda)$), and *ob*$_3$($\Delta(\delta\delta\delta)$, $\Lambda(\lambda\lambda\lambda)$). Bertini et al.[3] reported that the dominant isomers of $[M(bpdo)_3](PF_6)_2$ ($M=Co^{2+}, Ni^{2+}$) in acetonitrile will be either the *lel*$_3$ or *ob*$_3$ one from ^{1}H NMR studies. They also suggested that a rapid inversion of the bpdo chelate ring ($\delta \rightleftarrows \lambda$) seems unlikely because of the anticipated high barrier to interconversion of chelating bulky bpdo.

In a previous paper,[4] we reported that both racemic and optically active $[Cr(bpdo)_3](ClO_4)_3\cdot 2H_2O$[5] crystallize in the *lel*$_2$·*ob* form, but isomerize to the *lel*$_3$ one upon dissolution in water with a rapid change in absorption spectra, and then racemize ($\Delta \rightleftarrows \Lambda$) slowly. Similar isomerization and racemization were found to occur in $[Cr(acac)(bpdo)_2](ClO_4)_2\cdot H_2O$ (acac=acetylacetonate ion).[6] The complex forms the *lel*$_2$ isomer in the solid state and the *lel*·*ob* one in an aqueous solution. These facts indicate that the bpdo chelate ring is flexible and changes its conformation ($\delta \rightleftarrows \lambda$) easily. On the other hand, its conformation can be fixed when methyl groups are introduced in the 3- and 3′-positions. Thus, $[Cr(rac\text{-}3,3'\text{-}Me_2bpdo)_3]^{3+}$ (*rac*-3,3′-Me_2bpdo=racemic 3,3′-dimethyl-2,2′-bipyridine *N,N′*-dioxide) yields three of four possible isomers, *lel*$_3$, *lel*$_2$·*ob*, and *lel*·*ob*$_2$ in the formation ratio of 4, 1, and 1, respectively.[7]

In the present paper, we have studied the stereoisomerism of a new related complex, $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ (4,4′-Me_2bpdo = 4,4′-dimethyl-2,2′-bipyridine *N,N′*-dioxide). The complex also crystallizes in the *lel*$_2$·*ob* isomer, isomerizes to the *lel*$_3$ one in water, and racemizes. However, these reactions are fairly slow compared with those of $[Cr(bpdo)_3]^{3+}$. The difference in rate between two complexes are discussed.

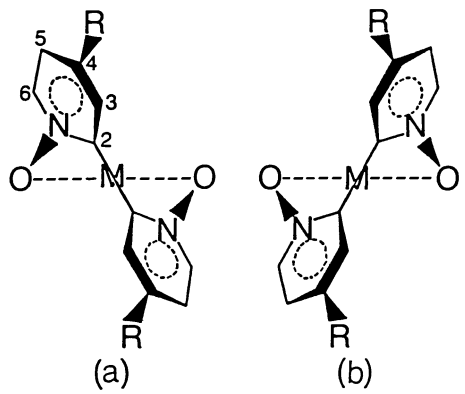

Fig. 1. Chiral conformations of bpdo (R=H) and 4,4′-Me_2bpdo ($R=CH_3$). (a) δ- and (b) λ-skew form.

Experimental

Preparation of 4,4′-Dimethyl-2,2′-bipyridine *N,N′*-Dioxide (4,4′-Me_2bpdo). An acetic acid solution (150 cm^3) of 4,4′-dimethyl-2,2′-bipyridine (25 g; Tokyo Kasei Co.) was mixed with 30% aqueous hydrogen peroxide (100 cm^3). The solution was refluxed for 4 h, then mixed with another 80 cm^3 of 30% aqueous hydrogen peroxide and refluxed for 3 h. The resulting solution was evaporated under reduced pressure to give a pale yellow oil. The residue was mixed with water (ca. 100 cm^3) and the mixture was evaporated again. This procedure was repeated twice to remove acetic acid contained in the residue. To the oily residue, 100 cm^3 of acetone was added to give pale yellow crystals. The crystals were collected by filtration, washed with acetone, and air-dried. Recrystallization from a mixture of methanol and acetone (1 : 3) gave white needles. Yield: 21 g (72%). Found: C, 66.45; H, 5.64; N, 12.76%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.95%.

IR (nujol mull) 1258, 1239 (ν_{N-O}), and 839 cm^{-1} (δ_{N-O}). ^{13}C NMR (D_2O, TMS) δ=20.5 (CH_3), 129.5 and 129.9 (C_3 and C_5), 139.5 (C_6), 141.7 (C_2), 144.4 (C_4) (see Fig. 1). ^1H NMR (D_2O, TSP) δ=2.49 (s, 6H, CH_3). The ^{13}C NMR spectrum was assigned from a comparison with those of the related compounds.[8]

Preparation and Resolution of Complexes. $[Cr(bpdo)_3](NO_3)_3\cdot 2H_2O$: The complex was prepared according to the literature method.[9] Recrystallization from a mixture of methanol and diethyl ether (2:1) gave green crystals. The complex is very soluble in water. Yield: 80%. Found: C, 43.06; H, 3.41; N, 14.85%. Calcd for $C_{30}N_{28}N_9O_{17}Cr$: C, 42.97; H, 3.37; N, 15.03%.

Resolution of $[Cr(bpdo)_3]^{3+}$: The resolution of $[Cr(bpdo)_3](ClO_4)_3$ with $(+)_{589}$-$Ag_3[Co(L\text{-}cysu)_3]$ (L-cysu=L-cysteinesulfinato(2−)-*S,N*)[10] was reported previously.[11] The nitrate was resolved in a similar manner using $(+)_{589}$-$K_3[Co(L\text{-}cysu)_3]$.[10] The resolving agent (1.9 g, 2.6 mmol) was dissolved in an aqueous solution (20 cm^3) of $[Cr(bpdo)_3](NO_3)_3\cdot 2H_2O$ (4.2 g, 5.1 mmol). The solution was cooled in an ice-bath to give yellowish green crystals, which were collected by filtration, washed with 50% ethanol and then ethanol, and air-dried. The diastereomeric salt (2.0 g) was dissolved in ice cold water (30 cm^3) and immediately $NaClO_4$ (1.0 g) was added to the solution with stirring to yield green crystals. They were collected by filtration, washed thoroughly with a 1 mol dm^{-3} $NaClO_4$ solution to remove the resolving agent, then with a small amount of cold water, finally with ethanol, and dried over P_4O_{10}. Yield: 1.6 g. The complex showed a negative rotation at 589 nm in water but rapidly lost its activity.[4,11] Found: C, 37.83; H, 2.93; N, 9.11%. Calcd for $(-)_{589}$-$[Cr(bpdo)_3](ClO_4)_3\cdot 2H_2O$=$C_{30}H_{28}N_6O_{20}Cl_3Cr$: C, 37.89; H, 2.97; N, 8.84%.

$[Cr(4,4'\text{-}Me_2bpdo)_3](ClO_4)_3\cdot 2H_2O$: An aqueous solution (50 cm^3) containing $Cr(NO_3)_3\cdot 9H_2O$ (2.0 g, 5 mmol) and 4,4′-Me_2bpdo (3.5 g, 16 mmol) was warmed at 80 °C for 2 h and then cooled to room temperature. Sodium perchlorate (3 g) was added to the resulting solution to yield green crystals, which were collected by filtration, washed with ice cold water, recrystallized from hot water, and dried over P_4O_{10}. Yield: 4 g (80%). Found: C, 41.98; H, 3.77; N, 8.21%. Calcd for $C_{36}H_{40}N_6O_{20}Cl_3Cr$: C, 41.77; H, 3.90; N, 8.12%.

$[Cr(4,4'\text{-}Me_2bpdo)_3](NO_3)_3\cdot 2H_2O$: The complex was prepared by a method similar to that for $[Cr(bpdo)_3](NO_3)_3\cdot 2H_2O$.[9] A methanol solution (50 cm^3) containing $Cr(NO_3)_3\cdot 9H_2O$ (2.0 g, 5 mmol) and 4,4′-Me_2bpdo (3.5 g, 16 mmol) was refluxed for 4 h, cooled to room temperature, and mixed with 40 cm^3 of diethyl ether. On standing the mixture in a refrigerator for 24 h, green needles were formed, collected by filtration, washed with acetone, and dried over P_4O_{10}. The complex was recrystallized from a mixture of methanol and diethyl ether (2:1). The nitrate is much more soluble in water than the perchlorate. Yield: 3.6 g (85%). Found: C, 46.93; H, 4.26; N, 13.62%. Calcd for $C_{36}H_{40}N_9O_{17}Cr$: C, 46.86; H, 4.37; N, 13.66%.

Resolution of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$: The resolution of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ was achieved by SP-Sephadex column chromatography. All the procedures were carried out in a cold room (at ca. 5 °C) because of racemization of the complex in water at ordinary temperature. An aqueous solution of the perchlorate or nitrate (0.2 g) of the complex was applied on a column (ϕ 2.2×130 cm) of SP-Sephadex C-25. By elution with a 0.3 mol dm^{-3} Na_2SO_4 solution, the column gave two completely separate bands. The faster moving band contained the $(+)_{589}$-isomer. Each eluate of the bands was collected and mixed with $NaClO_4$ to give green crystals. They were collected by filtration, washed with a small amount of ice cold water and then ethanol, and dried over P_4O_{10}. Found for the $(-)_{589}$-isomer: C, 40.52; H, 3.94; N, 7.83%. Found for the $(+)_{589}$-isomer: C, 40.44; H, 4.03; N, 7.76%. Calcd for $[Cr(4,4'\text{-}Me_2bpdo)_3](ClO_4)_3\cdot 4H_2O$=$C_{36}H_{44}N_6O_{22}Cl_3Cr$: C, 40.37; H, 4.14; N, 7.85%. Resolution of the complex by elution with a 0.3 mol dm^{-3} $Na_2[Sb_2\{(+)_{589}\text{-tartrate}\}_2]$ solution was unsuccessful to give only one band. Very small negative and positive rotations were observed at 589 nm only for the front and rear fractions of the band, respectively. In contrast to the elution with Na_2SO_4, the $(-)_{589}$-isomer was eluted faster.

Kinetic Measurements. Isomerization of the Complexes: In aqueous solutions, both perchlorate and nitrate of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ show a rapid change in absorption spectra. The change in absorbance at 620 nm was followed using a JASCO UVIDEC-320 spectrophotometer in the temperature range of 20.0—40.0 °C (±0.1 °C). The pH and ionic strength (I=0.1) of solutions were adjusted with aqueous solutions of NaCl and HCl. The complex concentrations were in the range of 8.2—12 mmol dm^{-3} for the nitrate and 2.0—2.3 mmol dm^{-3} for the perchlorate which is hardly soluble in water. In each kinetic run, the rate of change obeyed the first-order kinetic law. The observed rate constant (k_{obsd}) is expressed as $k_{obsd}=-\ln[(A_t-A_\infty)/(A_0-A_\infty)]/t$, where A's are absorbances at the time denoted by suffixes.

The rate for isomerization of the chloride and perchlorate of $[Cr(bpdo)_3]^{3+}$ in water has been reported in our previous paper.[4] In this work, the kinetic measurements for isomerization of $[Cr(bpdo)_3](NO_3)_3\cdot 2H_2O$ were carried out by a method described above in the temperature and the complex concentration ranges of 22.0—35.0 °C and 7.0—12 mmol dm^{-3}, respectively. The rate for the nitrate agreed with those for the chloride and perchlorate.

Racemization of the Complex: The decrease in optical rotation at 589 nm of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ in water was followed using a Union PM-101 digital polarimeter. The temperatures and the complex concentrations were in the range of 40.0—55.0 °C (±0.1 °C) and 1.1—2.9 mmol dm^{-3}, respectively. The complex lost the activity in two steps with different rates, the first rapid and the subsequent slow steps (vide post). In the latter step, the rate of decrease obeyed the first-order kinetic law and the observed rate constant (k_{obsd}) is also expressed by the above equation, where A's are degrees of optical rotation.

Other Measurements. Absorption and circular dichroism (CD) spectra were recorded on a Shimadzu UV-3100 spectrophotometer and a JASCO J-500 spectropolarimeter, respectively, using a cell jacket to maintain the temperature constant. ^{13}C and ^1H NMR and IR spectra were recorded on a JEOL JNM-PFT60 and a VARIAN EM-390 spectrometer, and a JASCO IR REPORT-100 spectrophotometer, respectively.

Results and Discussion

Preparation and Properties of the Complex. White crystalline 4,4′-Me_2bpdo was obtained by a method similar to that for bpdo[12] from 4,4′-dimethyl-2,2′-bipyridine and hydrogen peroxide. The $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ complex was prepared by a method similar to that for $[Cr(bpdo)_3]^{3+}$[9,11,13] from $Cr(NO_3)_3\cdot 9H_2O$ and the ligand. As shown later, both perchlorate

and nitrate of the complex crystallized in the *lel*$_2$·*ob* isomer. This isomer isomerized fairly rapidly to the *lel*$_3$ form upon dissolution in water. The complex was completely resolved into a pair of enantiomers by SP-Sephadex column chromatography carried out at 5 °C using an achiral eluting reagent, an aqueous Na_2SO_4 solution. The same chromatography at 20 °C was unsuccessful to give only one band on the column because of racemization of the complex. The $[Cr(bpdo)_3]^{3+}$ complex racemizes too fast to be resolved by a column chromatographic method.[4,11]

The achievement in resolution using Na_2SO_4 indicates that the enantiomers of the complex are discriminated by chiral SP-Sephadex resin composed of D-glucose.[14] On the contrary, elution with $Na_2[Sb_2\{(+)_{589}\text{-tartrate}\}_2]$, which is known as an effective eluting reagent for chromatographic resolution of metal complexes,[14,15] resulted in very poor resolution. The $(-)_{589}$-isomer was eluted faster in the chromatography with this chiral eluent, while the $(+)_{589}$-isomer was eluted faster with Na_2SO_4. That is to say, opposed effects were observed between the discrimination by the resin and that by $[Sb_2\{(+)_{589}\text{-tartrate}\}_2]^{2-}$. A similar behavior in chromatographic resolution was observed for the complexes, $[Cr(acac)(bpy)(bpdo \text{ and } 3,3'\text{-}Me_2bpdo)]^{2+}$ (bpy=2,2'-bipyridine).[16]

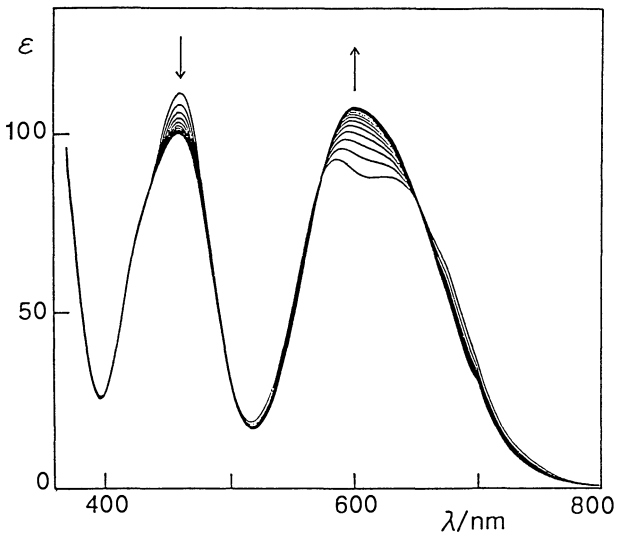

Fig. 2. Absorption spectral change with time of $[Cr(4,4'\text{-}Me_2bpdo)_3](NO_3)_3 \cdot 2H_2O$ in water at 25.0 °C. Spectra were recorded at 1—156 min after dissolution in water at regular time intervals (5 min). Trends of the spectral change are shown by arrows.

Figure 2 shows the absorption spectra of racemic $[Cr(4,4'\text{-}Me_2bpdo)_3]X_3$ ($X=NO_3^-$, ClO_4^-) in water which change rapidly with isosbestic points at 653, 575, and 437 nm. The optically active isomer behaves in the same way. Since the complex is stable in water as confirmed by column chromatography of the reaction product, the spectral change is attributable to the isomerization between two isomers of the complex. The spectrum immediately after dissolution in water closely resembles that of the *lel*$_2$·*ob* isomer of $[Cr\{(R \text{ or } S)\text{-}3,3'\text{-}Me_2bpdo\}_3]^{3+}$, while the final spectrum resembles that of the *lel*$_3$ isomer of the same complex.[7] Thus it is concluded that the nitrate and perchlorate of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ crystallize in the *lel*$_2$·*ob* isomer, but isomerize to the *lel*$_3$ one in water, and the complex exists in an equilibrium, *lel*$_2$·*ob* $\rightleftarrows$ *lel*$_3$ with a great preference for the latter (vide post). The same isomerization from *lel*$_2$·*ob* to *lel*$_3$ was observed for $[Cr(bpdo)_3]^{3+}$,[4] of which the spectral change was faster than that of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$. Figure 3 shows the structures by Dreiding molecular models of the *lel*$_3$ and *lel*$_2$·*ob* isomers of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$. The complex has a crowded structure, but the isomerization between the *lel*$_3$ and *lel*$_2$·*ob* isomers, a conformational inversion of one che-

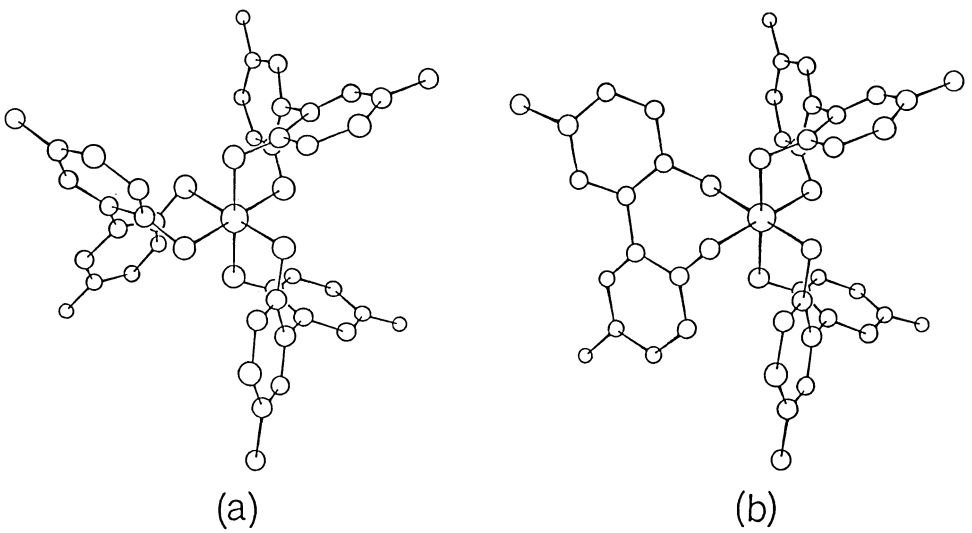

Fig. 3. Schematic drawing of the two conformational isomers of Δ-$[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$; (a) $\Delta(\lambda\lambda\lambda)(lel_3)$, (b) $\Delta(\lambda\lambda\delta)(lel_2 \cdot ob)$.

late ring, seems to occur easily. However, the inversion is much slower than those of diamine chelate rings in [Fe(CN)4(1,2- or 1,3-diamine)]$^-$ (10^4—10^8 s^{-1} at 25 °C), the kinetics of which were studied by ^{1}H NMR spectroscopy.[17]

The two absorption bands in Fig. 2 correspond to the two d-d transitions of Cr(III), $^4T_{2g}\leftarrow{}^4A_{2g}$ and $^4T_{1g}\leftarrow{}^4A_{2g}$. The *lel*$_2$ · *ob* isomer has lower symmetry (C_2) than the *lel*$_3$ isomer (D_3) and shows the split band due to the first spin-allowed transition around 600 nm. The splitting disappears and the band becomes single and sharp with passage of time. Figure 4 shows the absorption spectra

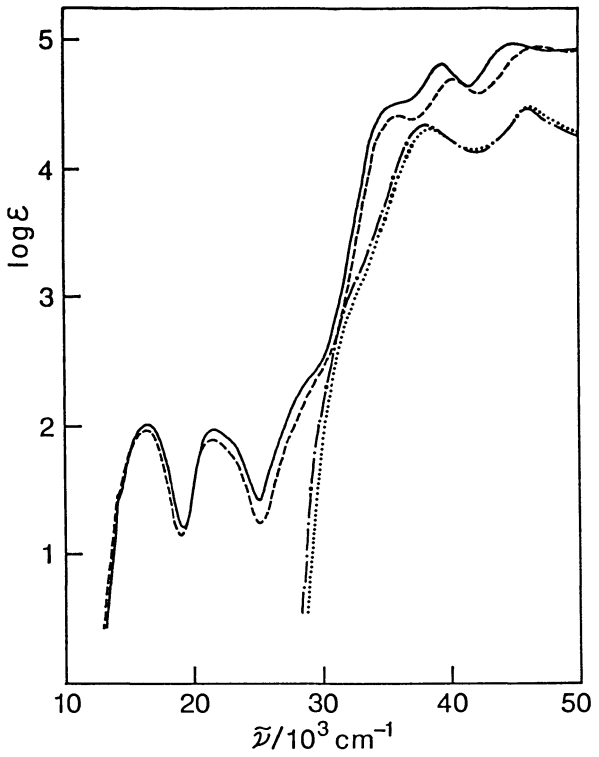

Fig. 4. Absorption spectra of [Cr(4,4'-Me2bpdo)3]3+ (——), [Cr(bpdo)3]3+ (——), 4,4'-Me2bpdo (— · —), and bpdo (·····) in water. The spectra were recorded after an equilibrium of *lel*$_2$ · *ob* ⇄ *lel*$_3$ had been reached.

Table 1. Absorption Spectral Data in Water[a]

Compound	$\tilde{\nu}$ / 10^3 cm^{-1} (log ε)
bpdo[b]	38.55 (4.32), 46.08 (4.48)
4,4'-Me2bpdo	38.20 (4.35), 46.04 (4.47)
[Cr(bpdo)3]3+ [b]	14.3 (1.5)sh, 16.41 (1.97), 21.39 (1.90), 22.7 (1.8)sh, 30.3 (2.5)sh, 35.96 (4.40), 40.26 (4.69), 46.73 (4.94)
[Cr(4,4'-Me2bpdo)3]3+	14.3 (1.5)sh, 16.56 (2.01), 21.72 (1.98), 22.7 (1.9)sh, 29.4 (2.4)sh, 36.4 (4.5)sh, 39.39 (4.81), 45.23 (4.97)

a) The data for the complexes are those for an equilibrium mixture of *lel*$_3$ and *lel*$_2$ · *ob* isomers. b) This work. sh: Shoulder.

of [Cr(4,4'-Me2bpdo)3]3+ and [Cr(bpdo)3]3+ in water at 25 °C after an equilibrium was reached between the two isomers. The spectra of free 4,4'-Me2bpdo and bpdo ligands are also given in Fig. 4. The spectral data are listed in Table 1. The spectra of these two complexes are very similar over the whole region. The first d-d band of the 4,4'-Me2bpdo complex (16560 cm^{-1}) is at higher energy by 150 cm^{-1} than that of the bpdo complex (16410 cm^{-1}). Whyman et al.[18] reported that the ligand field strength (10 Dq) of [Cr(4-Rpyo)6]3+ (4-Rpyo=4-substituted pyridine *N*-oxide) increases in the order of R=Cl<H<CH_3<CH_3O, and the Dq value increases with an increase in electron-releasing ability of the substituent at the 4-position of pyridine. The 10 Dq value of [Cr(4-CH_3pyo)6]3+ (16000 cm^{-1}) is larger by 130 cm^{-1} than that of [Cr(pyo)6]3+ (15870 cm^{-1}).[18] The shift of the band of [Cr(4,4'-Me2bpdo)3]3+ to higher energy from that of [Cr(bpdo)3]3+ is attributable to the same electron-releasing effect of two 4-methyl groups on bpdo. The [Cr(4,4'-(MeO)2bpdo)3]3+ (4,4'-(MeO)2bpdo=4,4'-dimethoxy-2,2'-bipyridine *N,N'*-dioxide) complex shows the first d-d band at 16720 cm^{-1} higher in energy by 160 cm^{-1} than that of the 4,4'-Me2bpdo complex.[19]

Figure 5 shows that (−)$_{589}$-[Cr(4,4'-Me2bpdo)3]-(ClO_4)3 · 4H_2O in aqueous solution loses optical activity in two steps with different rates. In the first rapid step (A), the decrease in activity accompanied the change of absorption spectra shown in Fig. 2, while no change of the spectra was observed in the subsequent slow step (B). Figure 6 shows the CD spectral change of the same (−)$_{589}$-isomer. In the first rapid step (Fig. 6(A)), the spectra change with isodichroic points at 596 and 510 nm, while in the second slow step (Fig. 6(B)), the spectra simply decrease the magnitude. These results support the previous conclusion that the first rapid step

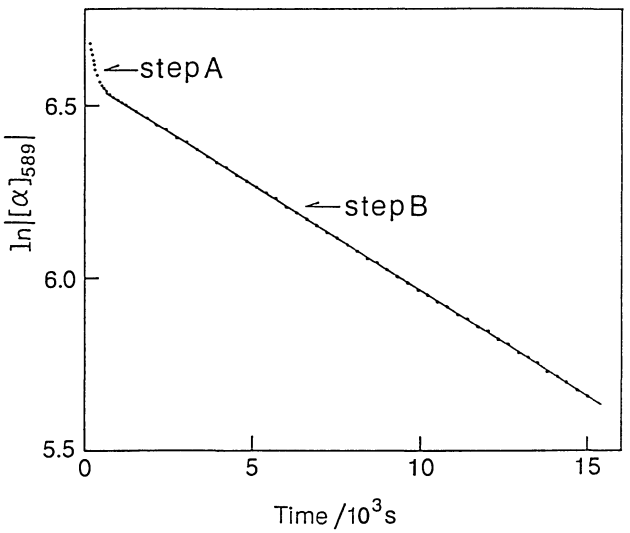

Fig. 5. Decrease in optical rotation with time of (−)$_{589}$-[Cr(4,4'-Me2bpdo)3](ClO_4)3 · 4H_2O in water at 40.0 °C. [Complex]=1.09 mmol dm^{-3}; *I*=0.1.

involves the isomerization of the *lel*$_2$·*ob* to *lel*$_3$ isomers, and the second slow step the racemization of the complex. The CD pattern of the $(-)_{589}$-isomer in the slow step (B) resembles that of $\Delta(\lambda\lambda\lambda)$-*lel*$_3$-[Cr{(*R*)-3,3'-Me$_2$bpdo}$_3$]$^{3+}$,[7] and the complex can be assigned to the Δ configuration. Thus it is concluded that $(-)_{589}$-[Cr(4,4'-Me$_2$bpdo)$_3$](ClO$_4$)$_3$·4H$_2$O crystallizes in the $\Delta(\lambda\lambda\delta)$ (*lel*$_2$·*ob*) isomer, but upon dissolution in water it isomerizes rapidly to the $\Delta(\lambda\lambda\lambda)$ (*lel*$_3$) isomer and then racemizes slowly, $\Delta(\lambda\lambda\lambda)$ (*lel*$_3$) $\rightleftarrows$ $\Lambda(\delta\delta\delta)$ (*lel*$_3$).

Kinetics of Isomerization and Racemization of [Cr(4,4'-Me$_2$bpdo)$_3$]$^{3+}$. The isomerization of [Cr(4,4'-Me$_2$bpdo)$_3$] (NO$_3$)$_3$·2H$_2$O in water, *lel*$_2$·*ob* $\rightleftarrows$ *lel*$_3$, was followed by monitoring the change in absorbance at 620 nm under the conditions described in Experimental part. The rate of spectral change obeyed the first-order kinetic law and the observed rate constant (k_{obsd}) was obtained from the slope of log ($A_\infty - A_t$) vs. time, where A's are absorbances at the time denoted by suffixes. The values of k_{obsd} are listed in Table 2, and the activation parameters in Table 3. The values for [Cr(bpdo)$_3$](NO$_3$)$_3$·2H$_2$O studied in this work are also given in the tables for comparison. The data of the nitrate of bpdo complex agreed well with those of the chloride and perchlorate reported previously.[4] The rates of both 4,4'-Me$_2$bpdo and bpdo complexes were independent of concentrations of H$^+$ and the free ligand, indicating an intramolecular reaction. The small nega-

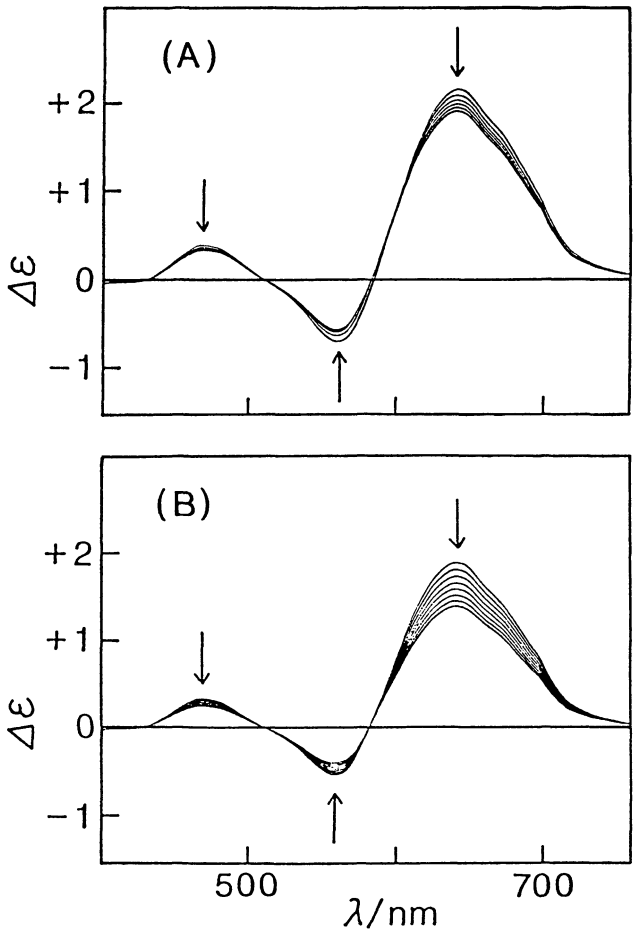

Fig. 6. CD spectral change with time of $(-)_{589}$-[Cr(4,4'-Me$_2$bpdo)$_3$](ClO$_4$)$_3$·4H$_2$O in water at 35.0 °C. Trends of the spectral change are shown by arrows. Reaction time (min): (A): 5, 10, 20, 30, 40, 50; (B): 60, 80, 100, 120, 140, 160, 180, 200 after dissolution in water.

tive values for the activation entropy would also indicate that the reactions proceed by an intramolecular mechanism. The activation enthalpy of 4,4'-Me_2bpdo complex is a little larger than that of the bpdo complex, and the complex isomerizes about two times slower than does the bpdo complex. The effect of two 4-methyl substituents is not clear on the conformational inversion of the 4,4'-Me_2bpdo chelate ring. The rate of racemization of the 4,4'-Me_2bpdo complex is also reduced by a factor of 10 compared with that of the bpdo complex as stated below.

Racemization of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ in water was studied by monitoring the change in optical rotation at 589 nm under the conditions described in Experimental part. The rate in step (B) in Fig. 5 obeyed the first-order kinetic law and the rate constant (k_{obsd}) was obtained from the slope of $\log|\alpha_t|$ vs. time, where α is degrees of optical rotation. The k_{obsd} values are given in Table 4, and the activation parameters in Table 5 together with those of the bpdo complexes. The rate was independent of concentrations of H^+ and the free ligand. The kinetic parameters for the 4,4'-Me_2bpdo and bpdo complexes in Table 5 are similar to those for the racemization of such complexes as $[Cr(bpy)_3]^{3+}$ or $[Cr(1,10\text{-phenanthroline})_3]^{3+}$, for which the reactions are suggested to proceed via an intramolecular twist mechanism.[20] The present dioxide complexes are supposed to racemize by such a mechanism, but the details remain unknown.

As Table 5 shows, the racemization of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ is about ten times as slow as that of $[Cr(bpdo)_3]^{3+}$. If it is assumed that these racemizations proceed by an intramolecular twist mechanism, the reactions involve both configurational ($\Delta \rightleftarrows \Lambda$) and conformational ($\delta \rightleftarrows \lambda$) inversions of three chelate rings in the complex. Studies with molecular models suggest that introduction of two methyl groups at the 4,4'-positions of bpdo scarcely exerts a steric effect on these inversions. As stated previously, the electron-releasing methyl groups on bpdo would increase the electron density of oxygen donor atoms and strengthen the Cr–O bonds to stabilize the complex. The rates of $[Cr(4,4'\text{-}Me_2bpdo)_3]^{3+}$ slower than those of $[Cr(bpdo)_3]^{3+}$ are supposed to result from such an electronic effect of the methyl substituent.

Preparation and Characterization of Cobalt(III), Nickel(II), and Copper(I) Complexes Containing 5,8-Diphenyl-5,8-diphospha-2,11-dithiadodecane (L), $CH_3SCH_2CH_2P(C_6H_5)CH_2CH_2P(C_6H_5)CH_2CH_2SCH_3$, and Molecular Structure of $[Ni(rac(P)\text{-}L)_2](BF_4)_2$

Δ-RR,Λ-SS-$[Co(acac)_2(rac(P)\text{-}L)]^+$ and $[Co(acac)_2(meso(P)\text{-}L)]^+$ were obtained by reaction of $[Co(acac)_3]$ (acac=2,4-pentanedionate ion) with 5,8-diphenyl-5,8-diphospha-2,11-dithiadodecane (L) in 1:1 molar ratio in dichloromethane in the presence of active charcoal, no *Δ-SS,Λ-RR* isomer of the *rac(P)*-L complex being formed. Five-coordinate $[Ni(rac(P)\text{-}L)_2]^{2+}$ and $[Ni(meso(P)\text{-}L)_2]^{2+}$ were yielded by reaction of Ni(II) and L in 1:2 molar ratio in methanol, and the molecular structure of less soluble $[Ni(rac(P)\text{-}L)_2](BF_4)_2$ was determined by X-ray analysis. Crystal data: monoclinic, space group $P2_1/n$, a=17.136(3), b=20.134(5), c=14.106(3) Å, β=93.30(2)°, V=4859(2) Å^3, Z=4, R=0.089 for 8001 reflections. The Ni atom is surrounded square pyramidally by four P atoms in the basal plane and one S atom at the apical position with distances of the Ni–P: 2.214(2)—2.234(2) Å and the Ni–S: 2.603(2) Å. Both $[Ni(rac(P)\text{-}L)_2]^{2+}$ and $[Ni(meso(P)\text{-}L)_2]^{2+}$ in CH_2Cl_2 solutions exchange four $-SCH_3$ groups at the apical positin on the NMR time scale. White $[Cu(rac(P)\text{-}L)]BF_4$ was precipitated selectively by reaction of $Cu(BF_4)_2\cdot 6H_2O$ and L in 1:1 molar ratio in ethanol.

In our previous papers, we have reported the preparation and stereochemistry of octahedral cobalt(III) complexes with linear quadridentate phosphine ligands of the PNNP[1–4] and NPPN[5–7] types for donor atoms. The ligand of the latter type has two chiral phosphorus donor atoms and forms various stereoisomers depending on the chirality. This paper reports the preparation and characterization of cobalt(III), nickel(II), and copper(I) complexes of 5,8-diphenyl-5,8-diphospha-2,11-dithiadodecane, $CH_3SCH_2CH_2P(C_6H_5)CH_2CH_2P(C_6H_5)CH_2CH_2SCH_3$ (L), together with the X-ray crystal structure of $[Ni(rac(P)\text{-}L)_2](BF_4)_2$. The ligand is also a linear quadridentate ligand with two chiral phosphorus and two sulfur donor atoms. However, ligand L was found to act as a bidentate in Co(III), a bidentate and a terdentate in Ni(II), and a quadridentate in Cu(I) complexes.

To our knowledge, only two papers have appeared for metal complexes of the SPPS-type ligand. Issleib and Gans[8] prepared $[MX(NH_3)(SCH_2CH_2PHCH_2CH_2PHCH_2CH_2S)]$ (M=Co, X=Br; M=Rh, X=Cl) and $[M\{SCH(R)CH_2PHCH_2CH_2PHCH_2CH(R)S\}]$ (M=Ni, Pd, Pt; R=H, CH_3). However, detailed stereochemistry for Co(III) and Rh(III) complexes was not reported. Schmelzer and Schwarzenbach[9] reported the X-ray crystal structures of *rac(P)*- and *meso(P)*-isomers of $[Ni(SCH_2CH_2P(C_6H_5)CH_2CH_2CH_2P(C_6H_5)CH_2CH_2S)]$, but experimental details and chemical properties were not described.

Experimental

The phosphine ligand was handled under an atmosphere of nitrogen until it formed metal complexes. All solvents used for the preparation of the ligand and complexes were made oxygen-free by bubbling nitrogen for 20 min immediately before use. Absorption and ^1H and ^{13}C NMR spectra were recorded on a Hitachi U3400 and a R-90H spectrometer, respectively.

Preparation of 5,8-Diphenyl-5,8-diphospha-2,11-dithiadodecane (L). A 15% hexane solution of butyl lithium (53 cm^3, 0.086 mol) was added dropwise with stirring to a dry tetrahydrofuran solution (600 cm^3) of 1,2-bis(phenylphosphino)ethane[10] (8.3 g, 0.034 mol). The solution changed from red to orange in color and gave yellow precipitate of $C_6H_5P(Li)CH_2CH_2P(Li)C_6H_5$. The precipitate was dissolved by warming at 50 °C. To the solution was added 2-chloroethyl methyl sulfide (7.5 g, 0.067 mol). The mixture was stirred at 50 °C for 5 h, and cooled to room temperature. Water (800 cm^3) was added to the solution dropwise with stirring. The ethereal layer was separated, dried over $MgSO_4$ (5 g) overnight, filtered, and the filtrate was evaporated to leave an oily product. This was used for the preparation of metal complexes without further purification. Yield: 13.2 g (98%).

Preparation of Metal Complexes. $[Co(acac)_2(meso(P)\text{-}L)]SbF_6$ (A-I) and *Δ-RR,Λ-SS*-$[Co(acac)_2(rac(P)\text{-}L)]SbF_6$ (A-II). A mixture of $[Co(acac)_3]$[11] (0.19 g, 0.53 mmol), L (0.21 g, 0.53 mmol) and active charcoal (0.03 g) in dichloromethane (20 cm^3) was stirred for 10 h. Active charcoal was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The residue was dissolved in a mixture of water and methanol (2:1, 50 cm^3), and the solution was applied on a column (ϕ3 cm×120 cm) of SP-Sephadex C-25. By elution with a 0.1 mol dm^{-3} NaCl aqueous solution two large dark-red bands (**A-I** and **A-II** in the order of elution) and several small bands appeared. Each eluate of the two large bands was shaken with chloroform to extract the complex. The extract was evaporated to dryness and the residue was dissolved in water. On addition of excess $NaSbF_6$ the solution yielded orange brown crystals, which were collected by filtration and recrystallized from a hot mixture of water and methanol (1:1). Yield: 93 mg (19%) for **A-I** and 99 mg (21%) for **A-II**. Found for **A-I**: C, 40.61; H, 4.83%. Found for **A-II**: C, 40.89; H, 4.81%. Calcd for $[Co(acac)_2L]SbF_6=C_{30}H_{42}O_4S_2P_2SbF_6Co$: C, 40.61; H, 4.77%. The complexes are soluble in methanol, ethanol, chloroform, and acetone, and

slightly soluble in water and diethyl ether.

[Ni(*rac*(*P*)-L)$_2$](BF$_4$)$_2$ (B-I) and [Ni(*meso*(*P*)-L)$_2$](BF$_4$)$_2$ (B-II). Ni(BF$_4$)$_2$·6H$_2$O (0.54 g, 1.6 mmol) and L (1.2 g, 3.1 mmol) were mixed in methanol (15 cm^3) with stirring at room temperature, and then the mixture was cooled at 0 °C. After 30 min a red-brown precipitate (**B-I**) which appeared was collected by filtration and recrystallized from hot methanol. Yield: 0.43 g (27%). The filtrate was allowed to stand to evaporate slowly, yielding red-brown crystals (**B-II**). They were recrystallized from hot methanol. Yield: 0.23 g (15%). Found for **B-I**: C, 47.03; H, 5.56%. Found for **B-II**: C, 47.15; H, 5.64%. Calcd for [Ni(L)$_2$](BF$_4$)$_2$=C$_{40}$H$_{56}$P$_4$S$_4$B$_2$F$_8$Ni: C, 47.04; H, 5.53%. The complexes are soluble in chloroform and methanol, and insoluble in water and diethyl ether.

[Cu(*rac*(*P*)-L)]BF$_4$. Mixing of Cu(BF$_4$)$_2$·6H$_2$O (0.13 g, 0.53 mmol) and L (0.21 g, 0.53 mmol) in methanol (10 cm^3) with stirring resulted in immediate formation of a white precipitate. It was collected by filtration and washed with water. Yield: 0.09 g (31%). Found: C, 44.03; H,5.16%. Calcd for [Cu(L)]BF$_4$=C$_{20}$H$_{28}$P$_2$S$_2$BF$_4$Cu: C, 44.10; H, 5.18%. The complex is soluble in chloroform, but insoluble in water, methanol, and diethyl ether.

X-Ray Analysis. A reddish brown crystal of [Ni(*rac*(*P*)-L)$_2$](BF$_4$)$_2$with approximate dimensions, 0.30×0.28×0.25 mm^3 was used for the data collection. Crystal data: monoclinic, $P2_1/n$, a=17.136(3), b=20.134(5), c=14.106(3) Å, β=93.30(2)°, V=4859(2) Å^3, D_X=1.40, D_m=1.39 g cm^{-3}, Z=4, and μ(Mo $K\alpha$)=7.53 cm^{-1}. Diffraction data were collected on a Rigaku AFC-5R diffractometer with graphite Mo $K\alpha$ radiation (λ=0.71069 Å). Within the range $2\theta<60°$, 8001 independent reflections with $|F_o|>3\sigma(|F_o|)$ were obtained. Absorption corrections were made by using the DABEX program.[12] The calculations were carried out on a HITAC M-680H computer at the Computer Center of the Institute for Molecular Science with the program system UNICS III.[12]. The structure was solved by the usual heavy-atom method; the position of Ni was deduced by means of the Patterson synthesis, and all the non-hydrogen atoms were located by the subsequent Fourier synthesis. The positions of 16 among 56 hydrogen atoms were identified in the subsequent difference-Fourier maps. The structure was refined by block-diagonal least squares methods with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogen atoms. The function minimized was $\sum w||F_o|-|F_c||^2$. Final R was 0.089 for 8001 observed unique reflections, and the atomic parameters of non-hydrogen atoms are listed in Table 1. Complete lists of observed and calculated structure factors, hydrogen atomic parameters, and anisotropic thermal parameters for non-hydrogen atoms are deposited as Document No. 8964 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

Cobalt(III) Complexes. Two isomers (**A-I** and **A-II**) of [Co(acac)$_2$(L)]$^+$ were obtained by reaction of [Co(acac)$_3$] with L in dichloromethane in the presence of active charcoal. The two isomers show absorption spectra very similar to each other, and give the first d-d band at 21300 (**A-I**) and 21200 cm^{-1} (**A-II**) (Fig. 1). These band positions are similar to those of [Co(acac)$_2$-{(C$_6$H$_5$)$_2$PCH$_2$CH$_2$P(C$_6$H$_5$)$_2$}]$^+$ (20200 cm^{-1})[13] and [Co(acac)$_2${(CH$_3$)$_2$PCH$_2$CH$_2$P(CH$_3$)$_2$}]$^+$ (23400 cm^{-1}),[14] indicating the coordination of two phosphorus atoms of L in these isomers. For [Co(acac)$_2$L)]$^+$, there are three

possible isomers, *Λ-RR,Λ-SS*- and *Λ-RR,Λ-SS*-[Co(acac)$_2$(*rac*(*P*)-L)]$^+$ and [Co(acac)$_2$(*meso*(*P*)-L)]$^+$. The *rac*(*P*)- and *meso*(*P*)-L complexes have C_2 and C_1 symmetries, respectively. In the ^{1}H NMR spectra isomer **A-I** exhibits six singlets for the methyl group (δ=0.96, 1.94, 2.03, 2.06, 2.16, 2.17, in $CDCl_3$) and two singlets for the methine group (δ=4.74, 5.51). Thus isomer **A-I** was assigned to the *meso*(*P*)-L complex. For isomer **A-II**, three singlet methyl signals (δ=1.04, 2.06, 2.12) and one singlet methine signal (δ=4.93) are observed, and the isomer can be assigned to the *rac*(*P*)-L complex. The assignment of either the *Λ-RR,Λ-SS* or *Λ-RR,Λ-SS* isomer was made on the basis of the chemical shift of methine proton of acac. Molecular models show that the phenyl groups of L in the *Λ-RR, Λ-SS* isomer are located over the acac chelate rings, while those in the *Λ-RR,Λ-SS* isomer are disposed away from the acac chelate rings. The methine protons of isomer **A-II** resonate at a remarkably high field (δ=4.93) compared with that (δ=5.51) of [Co(acac)$_3$]. The high field shift is attributable to the shielding effect of the phenyl group located over the acac chelate ring as has been often observed for related complexes.[3,6,7,13–15]

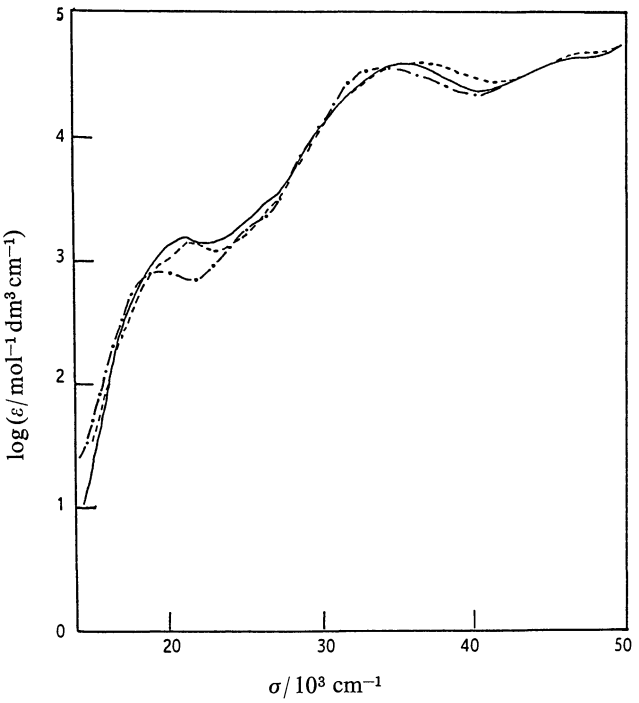

Fig. 1. Electronic spectra of [Co(acac)$_2$(X)]SbF$_6$ in CH_3CN solution; X=*rac*(*P*)-L (——), X=*meso*(*P*)-L (– – –), and [Co(acac)$_2${(C$_6$H$_5$)$_2$PCH$_2$CH$_2$P(C$_6$H$_5$)$_2$}]PF$_6$ (— · —) in ethanol.

Thus **A-II** was assigned to the *Λ-RR,Λ-SS*-L isomer. Two methine proton signals with a large chemical shift difference in the *meso*(*P*)-L complex (**A-I**) are consistent with molecular model considerations.

The formation of the other *Λ-RR,Λ-SS* isomer of the *rac*(*P*)-L complex was not observed. In this isomer the $-CH_2CH_2SCH_3$ group is disposed over the acac chelate ring, and the structure is supposed to be less stable than that of the *Λ-RR,Λ-SS* isomer with the phenyl group over the acac chelate ring. No acac complex containing quadridentate L, [Co(acac)(L)]$^{2+}$ was formed under the experimental conditions, in contrast to $NH_2(CH_2)_2P(C_6H_5)(CH_2)_nP(C_6H_5)(CH_2)_2NH_2$ (=NPPN, n=2[5,6], 3[6]) which formed only quadridentate ligand complexes, [Co(acac)(NPPN)]$^{2+}$ by similar reactions. The coordination ability of the $-SCH_3$ group would be weaker than that of acac toward Co(III).

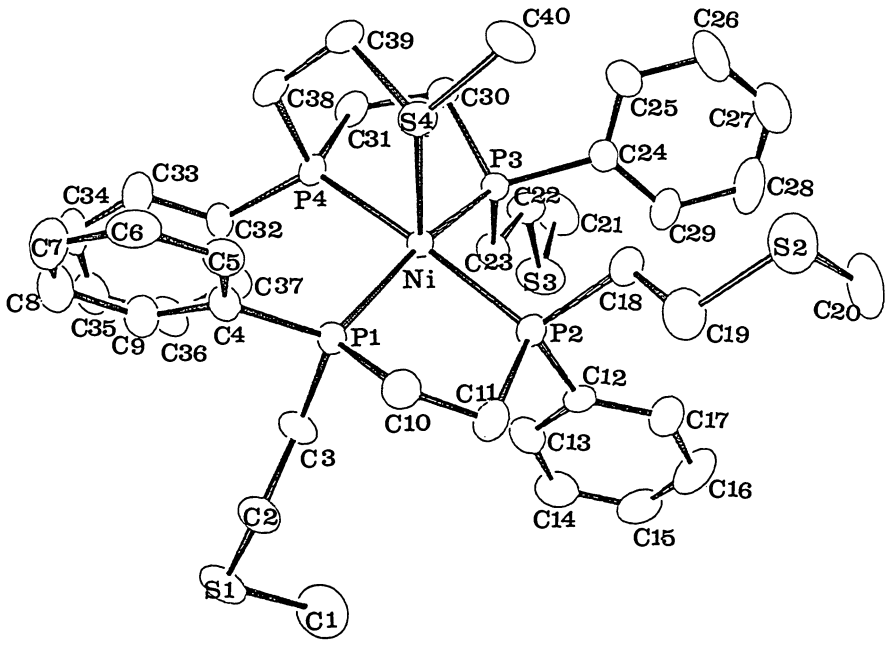

Fig. 2. A perspective view of [Ni(*rac*(*P*)-L)$_2$]$^{2+}$.

Nickel(II) Complexes. Two isomers (**B-I** and **B-II**) of $[Ni(L)_2](BF_4)_2$ were obtained by fractional crystallization from a methanol solution containing $Ni(BF_4)_2 \cdot 6H_2O$ and L in 1 : 2 molar ratio. The structure of the less soluble isomer (**B-I**) was determined by an X-ray diffraction method. A perspective view of the complex cation is shown in Fig. 2. The selected bond distances and angles are given in Table 2. The complex is a racemate consisting of $[Ni(RR(P)\text{-}L)_2]^{2+}$ and $[Ni(SS(P)\text{-}L)_2]^{2+}$. The chirality of the coordinating sulfur atom is *S* for the *RR*(*P*)-L and *R* for the *SS*(*P*)-L complexes. The Ni(II) ion forms a slightly distorted square pyramid with four phosphorus atoms in the basal plane and the sulfur atom at the apical position. The average Ni–P distance of 2.226(2) Å is very similar to those reported for square pyramidal diphosphine–Ni(II) complexes, $[NiBr(HQ)(H_2Q)] \cdot H_2O$ (av. 2.227(2) Å, H_2Q=$HO_2CCH_2P(C_6H_5)(CH_2)_2P(C_6H_5)CH_2CO_2H$, Br^- at the apical position)[16] and [NiI(depe)$_2$]I (av. 2.224(5) Å, depe =$(C_2H_5)_2P(CH_2)_2P(C_2H_5)_2$, I^- at the apical position).[17] The Ni–S distance (2.603(2) Å) is longer than those found in both square planar (2.22 Å) and octahedral (2.43 Å) Ni(II) complexes.[18] It is known that the apical Ni-ligand bond distance in a square pyramidal complex is, in general, fairly long compared with those in the basal plane.[19] For example, the apical Ni–S bond distance in the square pyramidal [NiI_2{bis(*o*-methylthiophenyl)phenylphosphine}] complex is 2.789(10) Å, while that at the basal position is 2.189(9) Å.[20]

The deviations from the mean plane formed by four phosphorus atoms are −0.111(2), 0.126(2), 0.113(2), and −0.143(2) Å for P(1), P(2), P(3), and P(4), respectively, 0.204(1) Å for the Ni(II) and 2.753(2) Å for the S atom. The two P–P chelate rings take a nearly δ gauche conformation in $[Ni(RR(P)\text{-}L)_2]^{2+}$, while the P–S chelate ring forms a λ gauche one. The dihedral angles are 45.1(5)° for P(1)–C(10)–C(11)–P(2), 41.9(4)° for P(3)–C(30)–C(31)–P(4), and 54.7(5)° for S(4)–C(38)–C(39)–P(4). Four skeletal atoms of each uncoordinated P–C–C–S group are almost in a plane (dihedral angles: 5.7(7), 7.8(7), 13.5(5)°).

The ^1H and ^{13}C NMR spectra of $[Ni(rac(P)\text{-}L)_2]^{2+}$ in CD_2Cl_2 at 30 °C show a singlet signal at δ=2.16 and 16.8, respectively, for the $-SCH_3$ groups. These results indicate that the coordinating $-SCH_3$ group in the solid state dissociates or exchanges rapidly with free $-SCH_3$ groups on the NMR time scale in solution. In Fig. 3 is compared the absorption spectrum in CH_2Cl_2 solution with the reflection spectrum in the solid state. These spectra are very similar in pattern, and the band around 25000 cm^{-1} is the one characteristic of a square pyrami-

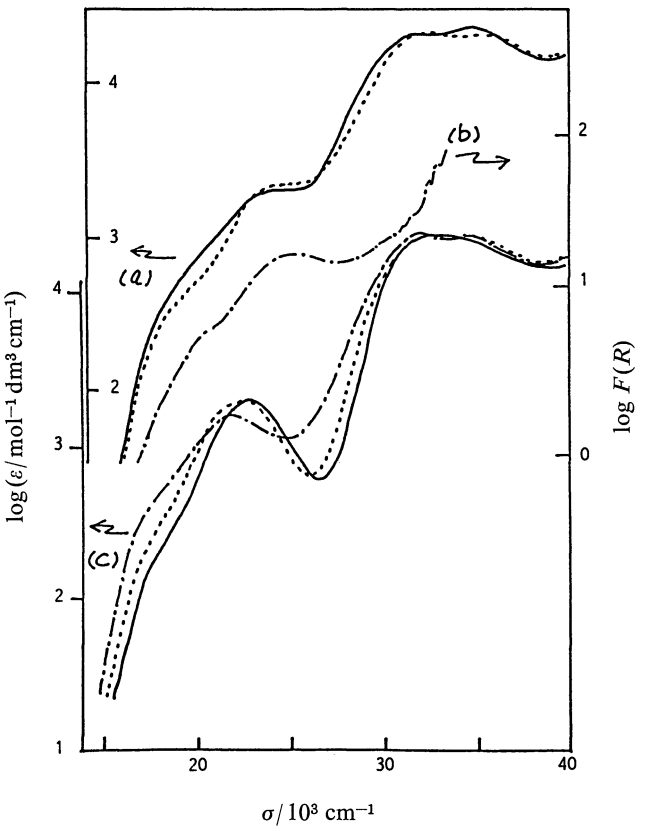

Fig. 3. Electronic spectra of Ni(II) complexes: (a) [Ni(*rac*(*P*)-L)$_2$](BF$_4$)$_2$ in CH_2Cl_2 (——), [Ni(*meso*(*P*)-L)$_2$](BF$_4$)$_2$ in CH_2Cl_2 (– – –), (b) [Ni(*rac*(*P*)-L)$_2$](BF$_4$)$_2$ in the solid state (—·—), (c) [Ni(*rac*(*P*)-L)$_2$](BF$_4$)$_2$ in CH_2Cl_2 in the presence of LiCl (——), LiBr (– – –), and KI (—·—).

dal Ni(II) complex with C_{4v} symmetry.[21] Thus it is concluded that the complex in CH_2Cl_2 solution retains the square pyramidal structure with P_4S donor atoms, but the coordinating $-SCH_3$ group exchanges with free $-SCH_3$ groups on the NMR time scale. The ligand field bands (20000—25000 cm^{-1}) of [Ni(*rac*(*P*)-L)$_2$]$^{2+}$ in CH_2Cl_2 are shifted to lower energy in the presence of excess halide ions (X^-) as shown in Fig. 3(c). The peak positions are shifted in accordance with the spectrochemical series, 29000 cm^{-1} (LiCl), 22700 cm^{-1} (LiBr), and 22000 cm^{-1} (KI). A similar spectral change was reported for square pyramidal [NiX{*o*-C_6H_4(As(CH$_3$)$_2$}$_2$]$^+$.[21] Thus [Ni(*rac*(*P*)-L)$_2$]$^{2+}$ in CH_2Cl_2 in the presence of excess halide ions would form square pyramidal [NiX(*rac*(*P*)-L)$_2$]$^+$ in which the $-SCH_3$ group is replaced by the X^- ion.

To assign the more soluble isomer **B-II**, the L ligand in this isomer was liberated from the Ni(II) ion in CH_2Cl_2 by mixing with an excess aqueous KCN solution. The [Co(acac)$_2$(L)]$^+$ complex prepared with this ligand was only the *meso*(*P*)-L complex **A-I**. Thus isomer **B-II** was assigned to [Ni(*meso*(*P*)-L)$_2$]$^{2+}$. For the arrangement of chiral phosphorus atoms in [Ni(*meso*(*P*)-L)$_2$]$^{2+}$, there are two possible isomers, *trans-RS* and *trans-RR,SS*. The ^{1}H and ^{13}C NMR spectra of isomer **B-II** in CD_2Cl_2 indicate the isomer to be a single species, but the structure could not be assigned. The absorption spectrum of isomer **B-II** in CH_2Cl_2 is very similar to that of **B-I** (Fig. 3(a)), and behaves in a similar manner to isomer **B-I** when added excess halide ions. The NMR spectra in CD_2Cl_2 show only one kind of $-SCH_3$ signal. These results indicate that isomer **B-II** is also a square pyramidal complex with the $-SCH_3$ group at the apical position, and the $-SCH_3$ group exchanges with free $-SCH_3$ groups on the NMR time scale in solution. The [Ni(*rac*(*P*)-L)(*meso*(*P*)-L)]$^{2+}$ isomer was not obtained under the experimental conditions.

Copper(I) Complex. White air-stable [Cu(L)]BF$_4$ was immediately precipitated by reaction of L and Cu(BF$_4$)$_2$·6H$_2$O in methanol. The molar conductivity of 150 S cm^2 mol^{-1} in acetonitrile shows a 1:1 electrolyte for this complex.[22] The complex exhibits a singlet $-SCH_3$ signal in the ^{1}H (δ=2.16) and ^{13}C (δ=19.1) NMR spectra in CD_2Cl_2, indicating a single species. The assignment of L, *rac*(*P*) or *meso*(*P*) in the complex was made by the same method as for [Ni(*meso*(*P*)-L)$_2$]$^{2+}$. The L ligand obtained from the copper complex gave only [Co(acac)$_2$(*rac*(*P*)-L)]$^+$. Thus the copper complex is assigned as [Cu(*rac*(*P*)-L)]$^+$, and the coordination geometry should be tetrahedral. Molecular models show that *rac*(*P*)-L can coordinate to a metal ion tetrahedrally as a quadridentate ligand without strain, while one of the two $-SCH_3$ groups of *meso*(*P*)-L can not bind to the metal ion in a tetrahedral complex. The *meso*(*P*)-L complex would remain in the reaction mixture, but was not isolated in this study. The reduction mechanism of Cu(II) to Cu(I) is not clear. In general, phosphines tend to form stable complexes with Cu(I), and only a few complexes with Cu(II) are reported.[23]

We wish to thank the Institute for Molecular Science (Okazaki) for the use of X-ray and computation facilities.

A Novel and Efficient Method for the Preparation of α-Hydroxyimino Carbonyl Compounds from α,β-Unsaturated Carbonyl Compounds with Butyl Nitrite and Phenylsilane Catalyzed by a Cobalt(II) Complex

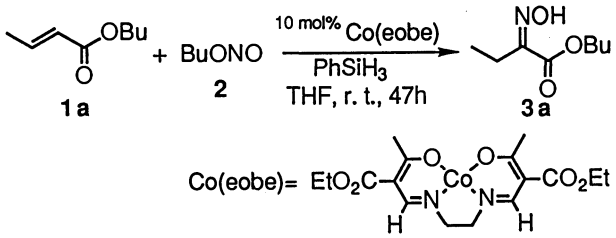
Koji KATO* and Teruaki MUKAIYAMA†
Basic Research Laboratories for Organic Synthesis, Mitsui Petrochemical Industries, Ltd., Nagaura, Sodegaura, Chiba 299-02
†Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 22, 1991)

Various α,β-unsaturated carbonyl compounds, such as α,β-unsaturated esters, α,β-unsaturated ketones, α,β-unsaturated nitriles, and α,β-unsaturated amides, were directly converted to the corresponding α-hydroxyimino carbonyl compounds in high yields on treatment with butyl nitrite and phenylsilane in the presence of a catalytic amount of *N,N'*-bis(2-ethoxycarbonyl-3-oxobutylidene)ethylenediaminatocobalt(II) complex under mild conditions.

The introduction of a nitrogen atom into organic compounds is one of the most important reactions in organic synthesis, and several methods using various amines, nitrogen monoxide, azide, etc. with transition-metal complexes as a catalyst have been extensively investigated.[1] For example, concerning the introduction of a nitrogen atom into olefinic compounds, K. B. Sharpless and co-workers reported a method for the preparation of *cis*-2-aminocyclohexanol from cyclohexene with chloramine T (TsNClNa) catalyzed by osmium tetraoxide in *t*-butyl alcohol, followed by the reduction with sodium in liquid ammonia.[2] A method for the addition of *N*-chloro amines to olefins by using a redox catalyst, such as Cu(I)/Cu(II) or Fe(II)/Fe(III), was also presented.[3] We recently reported the α-nitrosation of α,β-unsaturated amides yielding the corresponding 2-nitroso amides with nitrogen monoxide and triethylsilane in the presence of a catalytic amount of *N,N'*-bis(2-ethoxycarbonyl-3-oxobutylidene)ethylenediaminatocobalt(II) (Co(eobe)) at room temperature.[4] However, the above-mentioned reaction is limited to α,β-unsaturated amides, and no practical methods for the direct introduction of a nitrogen atom at the α-position of α,β-unsaturated esters and α,β-unsaturated ketones catalyzed by transition-metal complexes have been reported at all.

We have considered the possibility of the employment of alkyl nitrites, which are commercially available reagents and are employed in various reactions, to introduce a nitrogen atom into organic compounds. For example, oximes of α-keto esters were prepared by the reaction of saturated esters with alkyl nitrite by a metal alkoxide.[5] Recently, the titanium chloride-promoted reaction of ketene alkyl silyl acetals with isopentyl nitrite affording oximes of α-keto esters was reported.[6]

In a previous communication,[7] we reported the α-oximation of various α,β-unsaturated esters with butyl nitrite and a silane affording the 2-hydroxyimino esters, the useful intermediates,[8] catalyzed by Co(eobe) under mild conditions. For example, when butyl crotonate (**1a**) was treated with butyl nitrite (**2**) and phenylsilane ($PhSiH_3$) in tetrahydrofuran (THF) in the presence of 10 mol% of Co(eobe) at room temperature, the corresponding oxime, butyl 2-(hydroxyimino)butyrate (**3a**), was obtained in an 89% yield (Scheme 1).



Scheme 1.

Here, we would like to discuss in detail the α-oximation of various α,β-unsaturated carbonyl compounds, such as α,β-unsaturated esters, α,β-unsaturated ketones, α,β-unsaturated nitriles, and α,β-unsaturated amides with butyl nitrite and a silane using a cobalt(II) complex as a catalyst.

Results and Discussion

α-Oximation of Butyl Crotonate (1a) with Butyl Nitrite (2). First, the reaction of butyl crotonate (**1a**) with butyl nitrite (**2**) and triethylsilane (Et_3SiH) in the presence of 10 mol% of Co(eobe) in 1,2-dichloroethane (DCE) was attempted at room temperature. It was found that butyl crotonate (**1a**) was consumed after 62 h, and butyl 2-(hydroxyimino)butyrate (**3a**) was obtained in a 28% yield (Entry 1 in Table 1). The effect of solvents on the yield of the oxime compound was studied by taking the reaction of butyl crotonate (**1a**) with butyl nitrite (**2**) and Et_3SiH catalyzed by Co(eobe) as a model. As shown in Table 1, a change in the

Table 1. α-Oximation of Butyl Crotonate (**1a**) in Various Solvents[a]

Entry	Solvent	Conversion[b]/%	Yield[c]/%
1	DCE	—	28
2	Benzene	85	39
3	AcOEt	100	55
4	THF	100	79

a) Reaction conditions; butyl crotonate (**1a**) 0.5 mmol, butyl nitrite (**2**) 1.5 mmol, Co(eobe) 0.05 mmol, Et_3SiH 1.5 mmol, solvent 2.5 ml, room temperature, under argon atmosphere. b) Determined by GC analysis. c) Isolated yield.

Table 2. α-Oximation of Butyl Crotonate (**1a**) Catalyzed by Various Cobalt(II) Complexes[a]

Entry	Co(II) complex	Conversion[b]/%	Yield[c]/%
1	Co(eobe)	100	79
2	Co(acacen)[d]	5	4
3	$Co(acac)_2$[e]	10	2
4	$Co(ecbo)_2$[f]	51	5

a) Reaction conditions; butyl crotonate (**1a**) 0.5 mmol, butyl nitrite (**2**) 1.5 mmol, Co(II) complex 0.05 mmol, Et_3SiH 1.5 mmol, THF 2.5 ml, room temperature, under argon atmosphere. b) Determined by GC analysis. c) Isolated yield. d) *N,N'*-Bis(1-methyl-3-oxobutylidene)ethylenediaminatocobalt(II). e) Bis(acetylacetonato)cobalt(II). f) Bis(2-ethoxycarbonyl-3-oxobutanalato)cobalt(II).

reaction medium from DCE to more polar solvents, such as ethyl acetate (EtOAc) and THF, improved the yield of oxime **3a**, especially in the case of THF, where oxime **3a** was obtained in a 79% yield (Entry 4).

Next, several cobalt(II) complexes were screened in the α-oximation of butyl crotonate (**1a**) in THF (See Table 2), and it was shown that Co(eobe) was the most effective catalyst for the present α-oximation of butyl crotonate (**1a**) (Entry 1). The catalytic activity of *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediaminatocobalt (II) (Co(acacen)) was very low (Entry 2), and in the cases of cobalt(II) complexes having 1,3-diketone-type ligands, the yields of oxime **3a** were low and reduction of **1a** to butyl butyrate with Et_3SiH proceeded exclusively (Entries 3 and 4).

Considering that a silane would be another important factor in the present reaction, the effect of various kinds of silanes on the α-oximation was examined by taking the reaction of butyl crotonate (**1a**) with butyl nitrite (**2**) in THF catalyzed by Co(eobe) as a model (See Table 3). Consequently, the yield of oxime **3a** increased in accordance with the reduction capability of the silane, and oxime **3a** was obtained in an 89% yield when $PhSiH_3$ was used (Entry 4). The influences of the amounts of butyl nitrite (**2**) and silane were also checked, and the oxime **3a** was produced in a 79% yield by using nearly one equivalent of $PhSiH_3$ to **1a** (Entry 5). On the other hand, the amount of butyl nitrite (**2**) influenced the reaction rate; that is, when one and a half equivalents of **2** to **1a** were used, the conversion of **1a** was reduced to 64% (Entry 6). This suggested that the step involving butyl nitrite (**2**) seemed to be the rate-determining step in the present reaction.

α-Oximation of Various α,β-Unsaturated Carbonyl Compounds with Butyl Nitrite and $PhSiH_3$ Catalyzed by Co(eobe). The above procedure was successfully applied to the α-oximation of various α,β-unsaturated carbonyl compounds such as α,β-unsaturated esters, α,β-unsaturated ketones, α,β-unsaturated nitriles, and α,β-unsaturated amides (See Table 4). First, the reactions of various α,β-unsaturated esters (**1b—i**) with butyl nitrite (**2**) and $PhSiH_3$ in the presence of 10 mol% of Co(eobe) in THF at room temperature were examined. As a result, acrylic esters (**1b** and **c**) and β-monosubstituted α,β-unsaturated esters (**1d—f**) were converted to the corresponding oximes (**3b—f**) in high yields (Entries 1—5). It was noted that the α-oximation of *p*-tolyl crotonate (**1g**) gave *p*-tolyl 2-(hydroxyimino)butyrate (**3g**) in a 78% yield accompanied without the decomposition of the *p*-tolyl ester moiety which was frequently observed when saturated esters were treated with alkyl nitrite in alcohol under basic conditions according to the conventional procedure[5] (Entry 6). The α-oximation of a functionalized α,β-unsaturated ester such as diethyl fumarate (**1h**) took place readily and the corresponding oxime **3h** was obtained in an 89% yield (Entry 7). In the case of a β,β-disubstituted α,β-unsaturated ester, such as benzyl 3-methylcrotonate (**1i**) hindered at the β-position, no reaction took place at all and the starting material was recovered (Entry 8).

Next, the α-oximation of α,β-unsaturated ketones

Table 3. α-Oximation of Butyl Crotonate (**1a**) with Various Silanes and Butyl Nitrite (**2**)[a]

Entry	Silane	Amount of silane[b]	Amount of **2**[b]	Conversion[c]/%	Time/h	Yield[d]/%

16		**8a**	48		**9a**	78
17		**8b**	60		**9b**	80

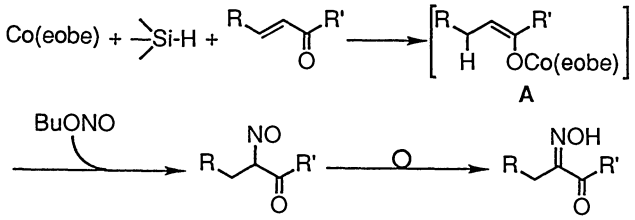
a) Reaction conditions; substrate 0.5 mmol, Co(eobe) 0.05 mmol, butyl nitrite (**2**) 1.5 mmol, $PhSiH_3$ 1.5 mmol, THF 2.5 ml, room temperature, under argon atmosphere. b) Isolated yield. c) Butyl nitrite (**2**) 3.0 mmol and $PhSiH_3$ 3.0 mmol were used at 60 °C.

under the above-mentioned conditions was investigated. It was found that vinyl ketones (**4a** and **b**) and β-monosubstituted α,β-unsaturated ketones (**4c** and **d**) also reacted with butyl nitrite (**2**) and $PhSiH_3$ to afford the monooximes (**5a**—**d**) of 1,2-diketones in high yields (Entries 9—12). The present method was effective for the selective preparation of monooximes of unsymmetrical 1,2-diketones, whereas the control of the chemoselectivity was difficult in the reaction of 1,2-diketones with hydroxylamine[9] or the α-oximation of saturated

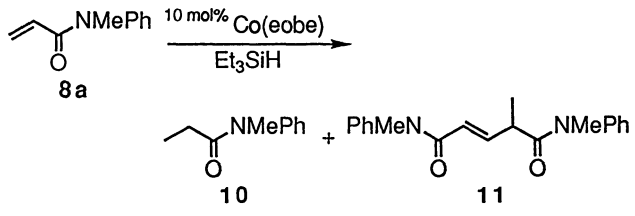
ketones having hydrogen atoms at both α-positions with alkyl nitrite under acidic conditions.[10] In the cases of α,β-unsaturated ketones, it should be pointed out that when a β,β-disubstituted α,β-unsaturated ketone such as mesityl oxide (**4e**) was treated with butyl nitrite (**2**) and $PhSiH_3$ in the presence of a catalytic amount of Co(eobe) at 60 °C, the corresponding oxime **5e** was obtained in a 67% yield, while in the case of benzyl 3-methylcrotonate (**1i**), no reaction took place at all under the same conditions (Entry 13).

The present procedure could also be applied to the α-oximation of α,β-unsaturated nitriles and α,β-unsaturated amides; for example, acrylonitrile (**6a**) and 2-pentenenitrile (**6b**) were converted to the corresponding oximes **7a** and **7b** in 82% and 70% yields, respectively (Entries 14 and 15), and acrylamide **8a** and crotonamide **8b**, respectively, afforded the 2-hydroxyimino amides **9a** and **9b** in good yields (Entries 16 and 17).

Even though the pathway of the present α-oximation has not yet been made clear, it can be assumed that the intermediate **A** shown in Scheme 2 is initially generated from α,β-unsaturated carbonyl compounds, Co(eobe), and a silane. The successive reaction of this intermediate **A** with butyl nitrite affords the corresponding oximes. This explanation is supported by the result that when acrylamide **8a** was treated with Et_3SiH and Co(eobe) in the absence of butyl nitrite (**2**), propionamide **10** (a reduced product) and a coupling product **11** of acrylamide were produced instead of the oxime as shown in Scheme 3. The difference in the reactivity



Scheme 2.



Scheme 3.

between β,β-disubstituted α,β-unsaturated ester **1i** and ketone **4e** suggests that a nucleophilic attack of the bulky active species, such as a cobalt hydride, on the β-position of α,β-unsaturated carbonyl compounds occurs first to generate the intermediate **A**.

It is concluded that butyl nitrite is an effective reagent for the α-oximation of α,β-unsaturated carbonyl compounds, such as α,β-unsaturated esters, α,β-unsaturated ketones, α,β-unsaturated nitriles, and α,β-unsaturated amides, in the presence of a silane and a catalytic amount of Co(eobe) to afford the corresponding oximes. The catalyst, Co(eobe), has the highest activity for α-oximation, and the combined use of phenylsilane in tetrahydrofuran improves the yield of the α-oximation of α,β-unsaturated carbonyl compounds. The present procedure thus provides a novel and useful method for the preparation of α-hydroxyimino carbonyl compounds directly from α,β-unsaturated carbonyl compounds under mild conditions.

Experimental

General: Melting points were measured on a Mettler FP62 apparatus and are uncorrected.

(a) Spectrometers: IR spectra were obtained by using a JASCO Model IR-700 infrared spectrometer on KBr pellets or liquid film on NaCl. ^1H NMR spectra were recorded with a JEOL Model FX270 spectrometer using $CDCl_3$ as the solvent and tetramethylsilane as an internal standard.

(b) Chromatography: Column chromatography was conducted using silica gel (Daiso gel IR-60). Preparative TLC was carried out on silica gel (E. Merck, 13895). GC-analyses were performed on a Shimadzu GC-15A chromatograph using a column packed with PEG 20M(20%) supporting Chromosorb W (3 mm×2 m), and the peak areas were obtained with a Shimadzu chromatopack CR-5A.

(c) Solvents and Reagents: 1,2-Dichloroethane and tetrahydrofuran were HPLC-grade and stored over molecular sieves. Toluene, benzene, and ethyl acetate were purified by distillation and stored over molecular sieves. Butyl nitrite (**2**) was purchased from TCI Co., Ltd. and stored in a cooled room after purification by distillation under reduced pressure. Triethylsilane, diethylsilane, diphenylsilane, and phenylsilane were purchased from Shin-Etsu Chemicals Co. and used without further purification.

(d) α,β-Unsaturated Carbonyl Compounds: Butyl acrylate (**1b**), *t*-butyl acrylate (**1c**), butyl crotonate (**1a**), *p*-tolyl crotonate (**1g**), and diethyl fumarate (**1h**) were purchased from TCI Co., Ltd. and purified by distillation. The other α,β-unsaturated esters were prepared from the corresponding acid chlorides and benzyl alcohol. Ethyl vinyl ketone (**4b**), 1-phenyl-2-buten-1-one (**4c**), 3-decen-2-one (**4d**), and mesityl oxide (**4e**) were purchased from Aldrich Chemical Company, Inc. or TCI Co., Ltd. and purified by distillation. 1-Phenyl-2-propen-1-one (**4a**) was prepared according to the reported method.[11] Acrylonitrile (**6a**) and 2-pentenenitrile (**6b**) were purchased from TCI Co., Ltd. and purified by distillation. *N*-Methylacrylanilide (**8a**) and *N*-methylcrotonanilide (**8b**) were prepared from the corresponding acid chlorides and *N*-methylaniline.

Preparation of Cobalt(II) Complexes. Bis(acetylacetonato)cobalt(II) ($Co(acac)_2$) was purchased from TCI Co., Ltd. and dried under reduced pressure (1 mmHg, 1 mmHg= 133.322 Pa) at 70 °C. *N,N'*-Bis(1-methyl-3-oxobutylidene)-ethylenediaminatocobalt(II) (Co(acacen))[12] and bis(2-ethoxycarbonyl-3-oxobutanalato)cobalt (II) ($Co(ecbo)_2$)[13] were prepared according to the reported methods, respectively. *N,N'*-Bis(2-ethoxycarbonyl-3-oxobutylidene)ethylenediaminato-

cobalt(II) (Co(eobe)) was prepared by a modified procedure of Kida's method:[14] An aqueous solution of sodium hydroxide (23.2 mmol, 11.6 ml) was added at 50 °C under an argon atmosphere to a solution of *N,N'*-bis(2-ethoxycarbonyl-3-oxobutylidene)ethylenediamine[15] (3.95 g, 11.6 mmol) in *N,N*-dimethylformamide (100 ml). After stirring for 0.5 h at 50 °C, a solution of cobalt(II) chloride hexahydrate (2.76 g, 11.6 mmol) in water (20 ml) was added, and the mixture was stirred for 0.5 h at 50 °C. After cooling at 0 °C, the orange precipitates were collected by filtration, washed with water (50 ml), and dried in vacuo at room temperature for 16 h. They were recrystallized from toluene to afford pure Co(eobe) (3.04 g, 66% yield). Mp 287—289 °C; IR(KBr) 1695 and 1585 cm^{-1} Found: C, 48.55; H, 5.71; N, 7.02%. Calcd for $C_{16}H_{22}N_2O_6Co$: C, 48.37; H, 5.58; N, 7.05%.

α-Oximation of Butyl Crotonate (1a) (*A Typical Procedure*, see Entry 4 in Table 3). Phenylsilane (162 mg, 1.5 mmol) and butyl nitrite (**2**) (159 mg, 1.5 mmol) were successively added to a solution of butyl crotonate (**1a**) (79 mg, 0.5 mmol) and Co(eobe) (20 mg, 0.05 mmol) in THF (2.5 ml). After stirring for 47 h at room temperature under an argon atmosphere, MeOH (1.5 ml) and concentrated HCl (3 drops) were added to the reaction mixture. After stirring for 30 min, water (20 ml) was added to the reaction mixture, which was then neutralized with a saturated aqueous $NaHCO_3$ solution. Organic materials were extracted with dichloromethane and the organic layer was washed with brine and dried over anhydrous magnesium sulfate. After evaporation of the solvent and purification by silica gel TLC (hexane–EtOAc, 3:1), butyl 2-(hydroxyimino)butyrate (**3a**)[16] was obtained (77 mg, 89% yield). ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, *J*=7 Hz), 1.13 (3H, t, *J*=7 Hz), 1.43 (2H, sextet, *J*=7 Hz), 1.72 (2H, quintet, *J*=7 Hz), 2.64 (2H, q, *J*=7 Hz), and 4.26 (2H, t, *J*=7 Hz); IR ($CHCl_3$) 3278, 2962, and 1726 cm^{-1}.

Analytical Data of the Oximes (in Table 4). Butyl 2-(Hydroxyimino)propionate (3b): Mp 51—53 °C; ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, *J*=7 Hz), 1.41 (2H, sextet, *J*=7 Hz), 1.70 (2H, quintet, *J*=7 Hz), and 4.23 (2H, t, *J*=7 Hz); IR ($CHCl_3$) 3284 and 1721 cm^{-1}. Found: C, 52.43; H, 8.26; N, 8.48%. Calcd for $C_7H_{13}NO_3$: C, 52.82; H, 8.23; N, 8.80%.

Substituent Effects in the Solvolysis of *p*-(2-Substituted Cyclopropyl)-α-Methylbenzyl Chlorides[1)]

(Received March 28, 1991)

The solvolysis rates of *p*-(*cis*- or *trans*-2-substituted cyclopropyl)-α-methylbenzyl chlorides including electron-donating and electron-attracting substituents relative to a hydrogen substituent were measured in 80% aqueous acetone. The trans isomers were more reactive than the corresponding cis derivatives where cyclopropyl and phenyl groups could not get a most favorable "bisected" conformation for the cyclopropyl group to release electrons to the benzene ring. The relative rates of the trans isomers at 45 °C were best correlated by means of σ_m values with a ρ value of −3.14 and a correlation coefficient of 0.97, indicating that the cyclopropane ring was a poor transmitter of a resonance effect. The substituent effects were analyzed by means of the LSFE equation.

The C–C bonds of the cyclopropane ring have, to a greater or lesser degree, the characteristics of C–C double bonds, including more *p*-orbital character than expected for saturated C–C bonds.[2)] The cyclopropyl group can enter into conjugated systems[3,4)] and can become a strong electron donor when it is directly attached to the electron-deficient center.[5)] The superior electron-donating ability of the cyclopropyl group is evidenced quantitatively by the more negative σ^+ value (−0.41—−0.54)[6–8)] than that of isopropyl (−0.28) and other alkyl groups (−0.25 to −0.32).[9)]

In a previous paper,[6)] we reported the kinetics of the solvolysis of *p*-substituted α-methylbenzyl chlorides in 80% aqueous acetone; the *p*-cyclopropyl derivative reacted 353 times faster than the parent chloride, indicating the strong contribution of a resonance effect in the transition state. However, the relative rate of the *p*-(2,2-dichlorocyclopropyl) derivative to the unsubstituted α-methylbenzyl chloride was only 1.24. The σ^+ value for the 2,2-dichlorocyclopropyl group estimated from the solvolysis of *p*-(2,2-dichlorocyclopropyl)-α-methylbenzyl chloride and the dissociation of *p*-(2,2-dichlorocyclopropyl)phenylacetic acid in 50% ethanol by means of the LArSR equation[10)] presented by Yukawa and Tsuno, was only −0.02.[6)] Moreover, the parameter $\Delta\bar{\sigma}_R^+$ values which measure the capacities of the substituents to supply electrons by a resonance effect in the LArSR equation were −0.35 and −0.07 for the cyclopropyl and the 2,2-dichlorocyclopropyl groups, respectively. Thus, the replacement of the two hydrogens at the 2-position of cyclopropyl with two chloro substituents caused a remarkable reduction of the resonance exaltation of the cyclopropyl group. Two factors may be responsible for this reduction of the resonance effect. One is the decreasing of the polarizability of C_1–C_2 bonds due to the strongly electronegative chloro substituent. The other is the conformational change from the most favorable "bisected" conformation in order to release electrons from cyclopropyl to phenyl, due to the repulsion between the cis chlorine atom and the hydrogen atom at the ortho position of the benzene ring.[11,12)]

In order to evaluate the relative contribution of these two factors and to clarify the electronic characteristics of 2-substituted cyclopropyl groups, we have studied the solvolysis of *p*-(*cis*- and *trans*-2-substituted cyclopropyl)-α-methylbenzyl chlorides. The mechanism of this solvolysis reaction was well studied by Tsuno and co-workers.[10b)]

Results and Discussion

The solvolysis rates of *p*-(2-substituted cyclopropyl)-α-methylbenzyl chlorides in 80% aqueous acetone were determined by conductometric measurements at the initial concentrations of 10^{-5} mol dm^{-3}. The reproducibilities of the rate constants were within an accuracy of 2%. The rate constants for the bromo and the chloro

a) Ref. 6. b) E. Berliner and N. Shieh, *J. Am. Chem. Soc.*, **79**, 3849 (1957).

derivatives thus obtained were identical to those obtained by the acid-base titration method.[6] The obtained rate constants are summarized in Table 1 together with those of the 1-methylcyclopropyl and 2,2-dichlorocyclopropyl derivatives and the parent α-methylbenzyl chloride. The relative rates of solvolysis of *p*-(2-substituted cyclopropyl)-α-methylbenzyl chloride and the activation parameters at 45 °C are listed in Table 2. The ^{1}H NMR observation revealed that the product of this solvolysis was the corresponding alcohol.

For all compounds measured, the trans isomers reacted faster than the corresponding geometrical isomers, the cis derivatives (Table 2). k_{trans}/k_{cis} values were in the range of 1.05—3.69 and increased as the van der waals radii of the substituents increased, indicating that these rate differences were caused by the repulsion between the substituent and the hydrogen atom at the ortho position in the phenyl group in the cis derivative. Our results obtained here are consistent with the solvolysis of the geometrical isomers of 2-[*p*-(2-chlorocyclopropyl)phenyl]-2-chloropropane and 2-[*p*-(2-bromocyclopropyl)phenyl]-2-chloropropane in 90% aqueous acetone reported by Kulinkovich and co-workers.[8] Thus, the cis isomers had an energetically less-favorable conformation and could not get a maximum overlap between cyclopropyl C_1–C_2 bonds and the p-orbital of the benzene ring, leading to the rate depression relative to the trans isomer. The rate deceleration effect of the 1-methyl group for the cyclopropyl group supported this explanation. The k_{trans}/k_{cis} values for a chlorine was 1.93, while k_{trans}/k_H=0.065 and k_{cis}/k_H=0.034. The rate depression by two chlorine atoms observed for the 2,2-dichlorocyclopropyl group[6] was ascribed mainly to the decreased polarizability of C_1–C_2 bonds of the cyclopropyl group, due to the electronegative behavior of the chlorine atom. These effects of the chlorine substituent obtained here were similar to those observed in the solvolysis of 2-[*p*-(2-chlorocyclopropyl)phenyl]-2-chloropropanes.[8]

It was very interesting that the methoxyl group (trans),[13] a strong electron-donating substituent by a resonance effect, retarded the reaction rate by a factor of 0.63. The phenyl group (trans) also decreased the reaction rate by a factor of 0.48. The $\log k/k_0$—$\log k/k_0$ plot of the relative rates of solvolysis between the *m*-, *p*-substituted α-methylbenzyl chlorides and the *p*-(*trans*-2-substituted cyclopropyl)-α-methylbenzyl chlorides under the same conditions showed a linear relation for the *m*-derivatives but not for the *p*-derivatives as illustrated in Fig 1. Indeed, $\log k_X/k_H$ values for *p*-(*trans*-2-substituted cyclopropyl)-α-methylbenzyl chlorides were best correlated linearly by σ_m (ρ value: −3.14, *r*:[14] 0.972) rather than σ_p and σ^+. This correlation confirmed that the cyclopropane ring was a poor transmitter of a resonance effect. There have been some experimental observations that the transmission of the conjugation through the cyclopropane ring is smaller than that through carbon-carbon double bonds.[5,15]

In a previous study, we succeeded in the estimation of the relative importance of an inductive effect and a resonance effect contributing to the dissociation of the 2-substituted 1-cyclopropanecarboxylic acids by means of Yukawa and Tsuno's treatment.[15b] A linear substituent free energy (LSFE) equation presented by Yukawa and Tsuno is considered the most useful for the estimation of the relative contribution of an inductive effect as well as a resonance effect in an extended pi-system beyond the original phenyl system.[16–18]

$$\log(k_X/k_H) = \rho_i\sigma_i + \rho_\pi^+\sigma_\pi^+$$

Here, σ_i is the inductive substituent constant and σ_π^+ is a substituent constant which measures the capability of substituents to donate electrons through electronic delo-

a) Ref. 6.

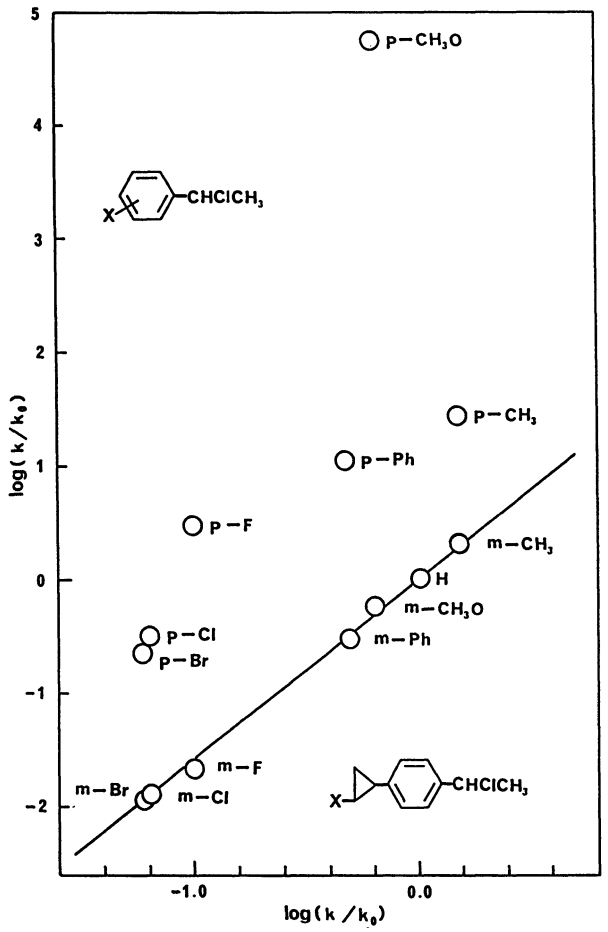

Fig. 1. Log–Log plot of relative rates of solvolysis of *m*- and *p*-substituted α-methylbenzyl chlorides against solvolysis of *p*-(*trans*-2-substituted cyclopropyl)-α-methylbenzyl chlorides in 80% aqueous acetone at 45 °C.

calization. The results of the application of the LSFE equation to the present reactivities are expressed as follows;

$$\log(k_X/k_H) = -3.52\,\sigma_i - 1.89\,\sigma_\pi^+ - 0.08 \text{ (\textit{trans}), } r = 0.996,^{14)}$$

$$\log(k_X/k_H) = -3.12\,\sigma_i - 1.30\,\sigma_\pi^+ - 0.33 \text{ (\textit{cis}), } r = 0.913.^{14)}$$

The ratios of the coefficients of σ_i and σ_π^+ (f_i and f_r, respectively) for the solvolysis of *p*-substituted α-methylbenzyl chlorides, *p*-(2-substituted cyclopropyl)-α-methylbenzyl chlorides, 1-(4′-substituted 4-biphenylyl)-ethyl chlorides,[17] and 1-(7-substituted 2-fluorenyl)ethyl chlorides[18] under the same conditions are summarized in Table 3. It appeared that the relative effectiveness of a transmitting resonance effect could be evaluated from f_r values. The intervention of the cyclopropane ring led to the deceleration of the resonance effect by a factor of 0.1. The transmitting resonance effect of the *trans*-1,2-cyclopropanediyl group was about a third that of *p*-phenylene. These results were predicted from the CNDO calculation for (2-substituted cyclopropyl) methyl cations where the LUMO of the cyclopropyl cation had small coefficients at C_2 and C_3 so the π-interaction by substituents at these positions was small.[15c] The transmitting inductive effect through the 1,2-cyclopropanediyl group was, however, larger than that through the *p*-phenylene group.

Experimental

All melting points were measured on a YANACO mp hot-stage melting-point apparatus and were uncorrected. The boiling points were also uncorrected. GLC analyses of liquid materials were performed on a YANACO GL80 gas chromatograph. High-performance liquid chromatography was carried out with a JASCO TRIROTOR-V by means of a Finepak SIL column with a Shodex RI SE-51 detector. Preparative-scale LC separations were carried out on a Shodex LC PR100 packed with a MERCK Lichroprep Si60 gel. A mixture of hexane and ethyl acetate was used as an eluent. The geometrical isomers were conveniently separated by this method. The mass spectra were determined at 70 eV using a JEOL D300 instrument. The IR spectra were measured using a JASCO A100 spectrometer. The NMR spectra were determined as a solution in $CDCl_3$ unless otherwise stated, with TMS as an internal standard on a JEOL EX90 spectrometer (90 MHz for ^1H and 22.4 MHz for ^{13}C) and a JEOL FX60 spectrometer (60 MHz for ^1H and 15 MHz for ^{13}C). The assignment of the structure for the geometrical isomers of substituted cyclopropanes was made from the ^{13}C NMR spectra, where the cis isomer always resonated at higher fields than did the corresponding trans isomer.[4,19]

All the *p*-(2-substituted cyclopropyl)-α-methylbenzyl chlorides were prepared from the corresponding substituted benzyl alcohols by chlorination with hydrogen chloride in dichloromethane at 3 °C. The obtained chlorides were used for the kinetic measurements without further purification after the removal of dichloromethane under reduced pressure. All the *p*-(2-substituted cyclopropyl)-α-methylbenzyl alcohols were prepared from the corresponding ketones by reduction with $NaBH_4$ in 2-propanol at room temperature or with $LiAlH_4$ in ether at 3 °C.

(2-Bromo-2-fluorocyclopropyl)benzene: Sodium *t*-butoxide (100 g) was added over 2 h to a solution of dibromofluoro-

methane (50 g, 0.26 mol) and styrene (52 g, 0.5 mol) in 150 ml of hexane cooled to 3 °C. After the addition had been completed, the mixture was stirred at room temperature for 1 h. The reaction was quenched with 500 ml of water. The reaction mixture was extracted with hexane, washed, dried ($MgSO_4$) and filtered. After the removal of hexane under reduced pressure, the remaining styrene was distilled through a Widmer column fitted with a glass spiral core and the product was distilled carefully through a short column (10 cm): yield 18.5 g (33%); bp 88 °C (7 mmHg, 1 mmHg=133.322 Pa),[20] lit,[21] 71—72 °C (5 mmHg);[20] ^{1}H NMR (CCl_4) δ=1.52—2.3 (m, 2H, CH_2), 2.35—3.1 (m, 1H, CH), and 6.9—7.4 (s, 5H).

(2-Fluorocyclopropyl)benzene: This was obtained by the reduction of (2-bromo-2-fluorocyclopropyl)benzene with $LiAlH_4$ in THF.[22] Yield 77%; bp 96—104 °C (40 mmHg).[20] Fractional distillation through a Hempel column gave a geometrical isomer of 80% purity by GC measurements. *Cis:* bp 55—58 °C (10 mmHg),[20] *trans*: bp 96—104 °C (26 mmHg).[20]

***p*-(2-Fluorocyclopropyl)acetophenone:** Iron(III) chloride (1.62 g, 0.01 mol) was added at 10 °C over 10 minutes to a mixture of (2-fluorocyclopropyl)benzene [(1.36 g, 0.01 mol), isomer ratio (4 : 1)], acetyl chloride (0.79 g, 0.01 mol), and carbon disulfide (15 ml). After the addition had been completed, the mixture was stirred at room temperature for an additional hour. The produced complex was hydrolyzed by adding diluted hydrochloric acid. The usual work-up gave *p*-(2-fluorocyclopropyl)acetophenone. Yield 0.86 g (48%). Bp 120—140 °C (6 mmHg).[20] *Cis* isomer: mp 42 °C; ^{1}H NMR δ=0.9—2.8 (m, 3H, cyclopropyl), 2.6 (s, 3H, CH_3), 4.15—4.5 and 5.15—5.60 (m, 1H, CHF), 7.38 (d, *J*=10 Hz, 2H, PhH), and 7.98 (d, *J*=10 Hz, 2H, PhH); ^{13}C NMR δ=12.53 (d, ^2J=10.28 Hz), 21.65 (d, ^2J=11 Hz), 26.54, 72.59 (d, *J*=223.1 Hz), 128.15, 128.40, 142.05, and 197.59. *Trans* isomer: Oil; ^{1}H NMR δ=0.9—2.8 (m, 3H, cyclopropyl), 2.60 (s, 3H, CH_3), 4.1—4.4 and 5.0—5.4 (m, 1H, CHF), 7.1 (d, *J*=10 Hz, 2H, PhH), and 7.9 (d, *J*=10 Hz, 2H, PhH); ^{13}C NMR δ=15.65 (d, ^2J=9.8 Hz), 22.68 (d, ^2J=11.5 Hz), 26.48 (CH_3), 75.34 (d, *J*=228.7 Hz), 126.05 (CH), 128.49 (CH), 135.21, 144.98, and 197.36.

***p*-(*cis*-2-Fluorocyclopropyl)-α-methylbenzyl Alcohol:** Bp 118 °C (3 mmHg).[20] ^{1}H NMR δ=0.8—1.3 (m, 2H, CH_2), 1.4 (d, *J*=8 Hz, 3H, CH_3), 1.6—2.3 (m, 1H, cyclopropyl), 2.43 (s, 1H, OH), 3.9—4.3 and 5.1—5.41 (m, 1H, CHF), 4.5—6.0 (q, *J*=8 Hz, 1H, CH–O), and 7.1 (s, 4H, PhH); ^{13}C NMR δ=11.62 (d, ^2J=10.3 Hz, CH_2), 21.13 (d, ^2J=11.1 Hz, CH), 24.97 (CH_3), 69.90 (CH–O), 72.34 (d, *J*=247.7 Hz, CF), 125.16 (CH), 128.45 (d, ^3J=1.3 Hz), 134.97 (d, ^3J=3.0 Hz), and 143.84.

Kinetic Measurement. 80% aqueous acetone was prepared by mixing corresponding volumes of two components at room temperature. The solvolysis rates were followed in the usual manner according to a conductometric method. Conductivity readings were taken by using a conductivity meter (Model CM-50AT equipped with time interval unit and printer, TOA Electric Ltd.). Solvolysis was followed by taking at least 30 points at appropriate intervals for 2.5 half-lives, and an infinity reading was taken after 10 half-lives. Temperatures of the thermostat bath for the reaction rate experiments were within ±0.03 °C. The rate determination by titration was done by the same procedure as previously published.[6]

The rate constants were obtained graphically. Rate constants from repeated runs were reproducible with an accuracy of 2%.

The present work was partially supported by a Grant-in-Aid (1990) for Special Research from the Ministry of Education, Science and Culture.

Ozone Fading of 2,2′-Dihydro Azo Copper Complex Dyes

Masaki MATSUI,* Kenjiro TSUBOTA, Katsuyoshi SHIBATA,
and Hiroshige MURAMATSU
Department of Chemistry, Faculty of Engineering, Gifu University, Yanagido 1-1, Gifu 501-11
(Received April 18, 1991)

The reactivities of dyes with ozone were in the following order, Acid Blue 74>disodium 1-(2-hydroxyphenylazo)-2-naphthol-3,6-disulfonate>Direct Yellow 12>Acid Orange 7>disodium 1-phenylazonaphthalene-3,6-disulfonate-2,2′-diolatocopper(II)>Mordant Red 3>Basic Green 4. The reaction of disodium 1-phenylazonaphthalene-3,6-disulfonate-2,2′-diolatocopper(II) with ozone was retarded by the introduction of electron-withdrawing groups and 8-sulfonato group. The potassium sulfonate dye was less reactive than the sodium one. Ozonization of 1-phenylazonaphthalene-2,2′-diolatocopper(II) gave phenol, 2-naphthol, and phthalic anhydride.

Reaction of dyes with ozone is of interest from the viewpoint of ozone fading of coloring matter and ozone treatment of dye wastewater.[1] It is important to evaluate the factors which affect the ozone fading of dyes. In our continuing series of studies on the reaction of ozone with dyes, ozone fading mechanism of several dyes have been proposed.[2–6] This report describes the reactivity and products in ozone fading of 2,2′-dihydro azo copper complex dyes.

Results and Discussion

Figure 1 shows dyes used in this study. 2-Hydroxybenzenediazonium chloride, prepared from 2-aminophenol, sodium nitrite, and hydrochloric acid, was reacted with 1- and 2-naphthol derivatives to afford metal free **1** and **2**, which were treated with copper sulfate to give **1** and **2**.

It is of interest to compare the reactivity of metal complex dyes with those of the other dyes whose ozone fading mechanisms have been reported.[2–6] In order to estimate the reactivity, the reaction in the initial stage was applied to first-order rate kinetics. For example, Fig. 2 shows the plots of logarism of A_0/A_t vs. time, where A_0 and A_t are absorbance at 0 and t sec at maximum wavelength, respectively. The plots of **1a** were linear and the rate constant (k) was calculated to be 0.0057 s^{-1}.

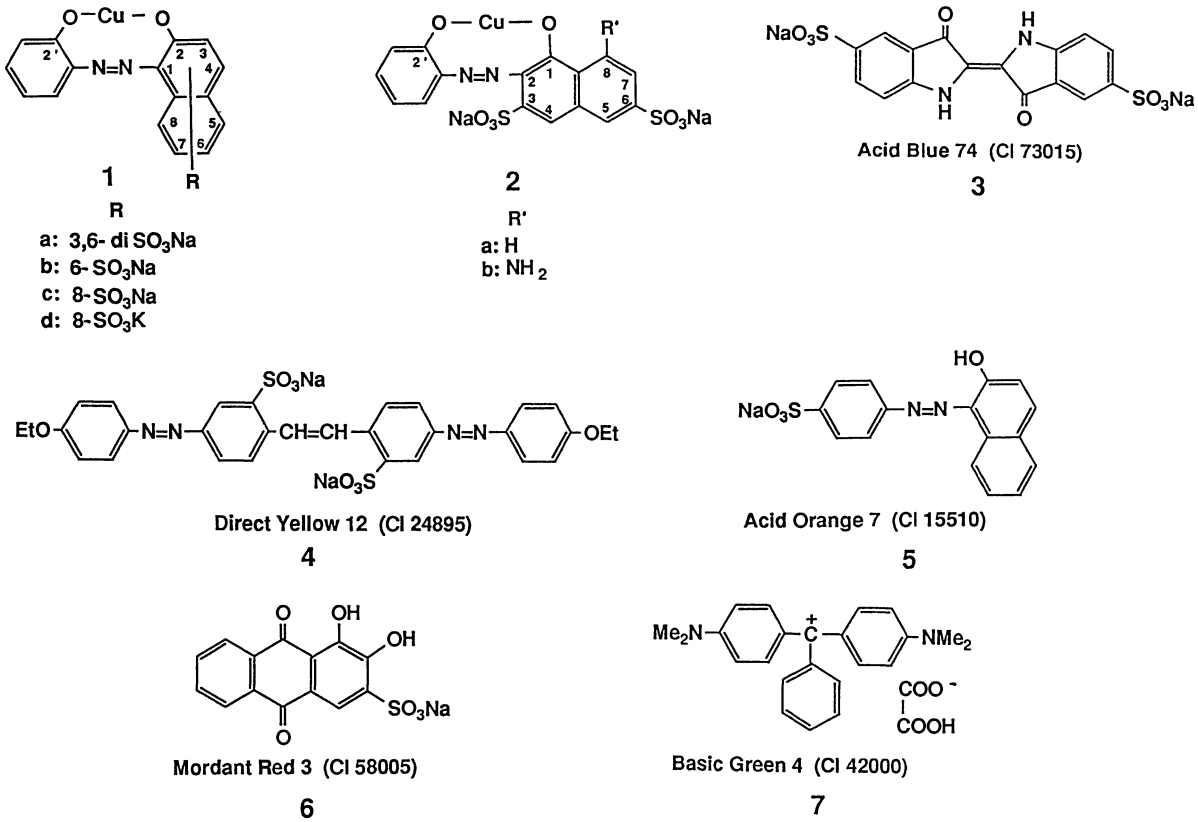

Fig. 1. Materials.

Table 1. Reactivities of Dyes with Ozone

Run	Dyes	$k\times10^3$ (s^{-1})
1	**3**	13.0±0.3
2	Metal free **1a**	12.3±0.3
3	**4**	9.6±0.0
4	**5**	6.6±0.1
5	**1a**	5.7±0.1
6	**6**	5.2±0.6
7	**7**	4.6±0.4
8	**1b**	6.8±0.1
9	**1c**	5.5±0.3
10	**1d**	4.0±0.2

12	**2b**	6.0±0.1

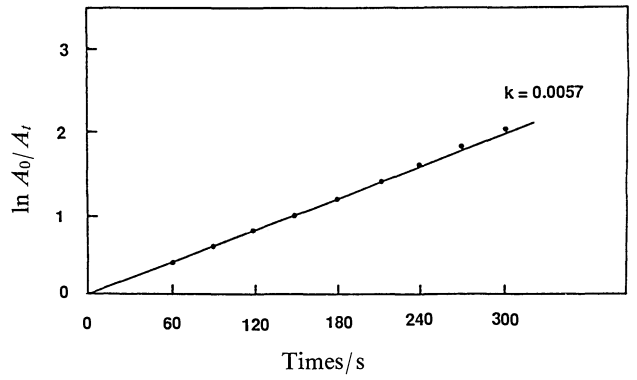

Fig. 2. Reactivity of disodium 1-phenylazonaphthalene-3,6-disulfonate-2,2′-diolatocopper(II) with ozone.

Table 1 shows the reactivities of dyes with ozone. The rate constants of dyes were in the following order, Acid Blue 74 (**3**)>metal free **1a**>Direct Yellow 12 (**4**) >Acid Orange 7 (**5**)>**1a**>Mordant Red 3 (**6**)>Basic Green 4 (**7**) (Runs 1—7). Ozone reacts easily with double bonds such as C=C and C=N. Ozonolyses of central olefinic bonds of 2-(1,3-dihydro-3-oxo-2*H*-indol-2-ylidene)-1,2-dihydro-3*H*-indol-3-one (Vat Blue 1, CI 73000) and Direct Yellow 12 (**4**) have been reported to give carbonyl compounds.[2,3] Ozone fading of 2-hydroxyazo dyes have been reported to proceed via the hydrazone isomers on the basis of substituent and solvent effects.[4] It has been reported that 1,2-dihydroxyanthraquinone (Pigment Red 83, CI 58000) was ozonized to give phthalic anhydride.[5] Although ozone attacked both the dimethylamino and olefinic moieties of aminotriphenylmethane dyes, it attacked mainly the dimethylamino moiety in the case of Basic Green 4 to give the formylmethylamino derivative.[6] Since the product is still colored, the rate constant of ozone fading is apparentely small. Aromatic azo compounds are fairly stable for ozone.[7,8] Since **1a** has bulky and electron-withdrawing copper atom in a molecule, the rate constant was smaller than the metal free **1a**.

Figure 3 shows the substituent effect on ozone fading of **1a**. The plots of logarism (k_R/k_H) vs. Hammett's σ constants, where k_R and k_H are rate constants of substituted and unsubstituted dyes respectively, were linear, whose slope (ρ) was calculated to be −0.22 (r=0.95). This result suggested that ozone attacked electrophilically the substrate and that introduction of electron-withdrawing groups into diazo component improved stability of dyes for ozone.

The reaction rates of some 2,2′-dihydro azo copper complex dyes, whose couplers consisted of 1- and 2-naphthol derivatives are summarized in Table 1. The results indicated that 1) electron-withdrawing sulfonato group (σ: 0.09 (p), 0.05 (m)) inhibited the reaction (Runs 5, 8); 2) bulky sulfonato group at the 8 position retarded the reaction (Runs 8, 9); 3) greater potassium ion (ionic radius, K=1.38 Å, Na=1.02 Å) inhibited the reaction (Runs 9, 10); and 4) electron-releasing amino group of the coupler accelerated the reaction (Runs 11, 12).

Ozonization of 1-phenylazonaphthalene-2,2′-diolatocopper(II) (**8**) gave phenol (**9**), 2-naphthol (**10**), and

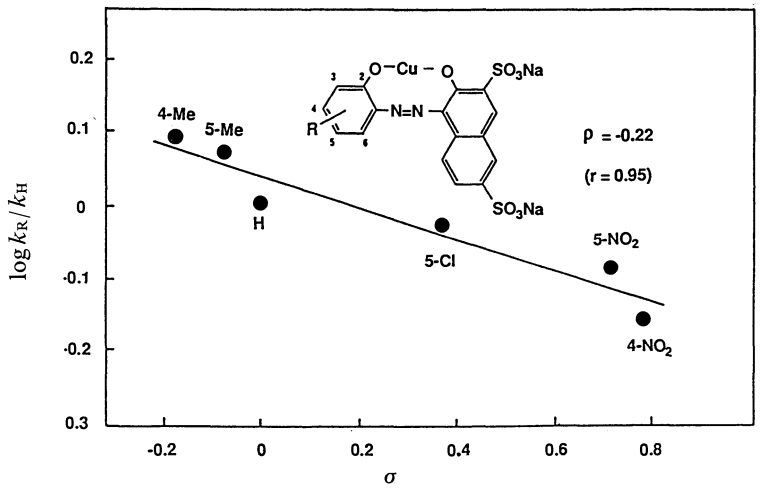

Fig. 3. Hammett's plots for the ozone fading of disodium 1-phenylazonaphthalene-3,6-disulfonate-2,2′-diolatocopper(II).

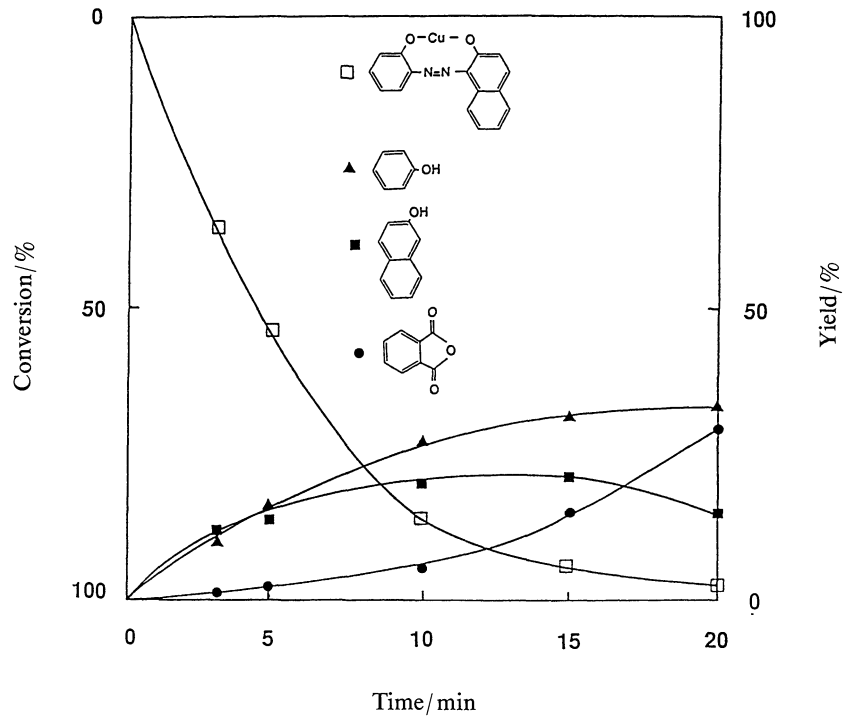

Fig. 4. Ozonization of 1-phenylazonaphthalene-2,2'-diolatocopper(II). Ozonization was carried out with an ozone–oxygen mixture (O_3: 0.068 mmol min^{-1}, O_2: 200 ml min^{-1}) on 1-phenylazonaphthalene-2,2'-diolatocopper(II) (1.6 mmol) in DMSO (2 ml) at 30 °C.

phthalic anhydride (**11**). Figure 4 shows the time-dependence of products. The ozonization of **8** gave **9** and **10**, which was further ozonized to afford **11**. Ozonization of phenol has been reported to give formic acid as a main product.[9] The reaction of 2-naphthol with ozone gave phthalic anhydride. Ozone attacked the azo linkage of **8** to give unstable azoxy intermediates which is followed by the hydrolysis of Cu–O bond to give **9** and **10**. Ozone could attack also the C=N bond of the hydrazone isomer of **8** to give the products.

Experimental

Instruments. Ozone was generated with a Nihon Ozon 0-1-2 type ozonizer. Melting points were measured with a Yanagimoto micro melting point apparatus and uncorrected. NMR, UV, and mass spectra were obtained with JEOL JUM GX 270, JASCO 410, and Shimadzu QP-1000 spectrometers, respectively. Gas chromatography was performed on a Shimadzu 4C-PF gas chromatograph.

Materials. Acid Blue 74 (**3**), Direct Yellow 12 (**4**), Acid Orange 7 (**5**), and Basic Green 4 (**7**) were purchased from Tokyo Kasei Co., Ltd. Mordant Red 3 (**6**) was obtained from Aldrich Chemical Co., Ltd. They were used without further purification.

2,2'-Dihydro azo compounds were prepared as follows; to 50% hydrochloric acid solution of 2-aminophenol (3.2 g, 29 mmol) was added 30% aqueous solution (8 ml) of sodium nitrite at 0 °C. The mixture was stirred for 1 h. To the diazotized solution was added 20% aqueous sodium hydroxide solution (35 ml) of a coupler (30 mmol). The mixture was stirred at 0 °C for 1 h. The product was obtained by salting-out techniques. Physical and spectral data of 1-(2-hydroxyphenylazo)-2-naphthol are shown below. Mp 194.0—195.0 °C (lit,[10] 193 °C); ^{1}H NMR ($CDCl_3$) δ=7.0—8.2 (m, 10H), 12.4 (s, 1H), and 14.5 (s, 1H); EIMS (70 eV) m/z (rel intensity) 264 (M^+, 100).

2,2'-Dihydro azo copper complex dyes were synthesized as follows; in the case of **1** and **2**, to an aqueous solution (150 ml) of 2,2'-dihydro azo compound (10 mmol) was added an aqueous solution of copper sulfate penta hydrate (10 mmol). The mixture was stirred at room temperature. In the case of **8**, the reaction was carried out in an acetone solution. The resulting precipitate was collected and washed with water or acetone. Found: C, 54.19; H, 3.26; N, 7.89%. Calcd for $C_{16}H_{10}N_2O_2Cu \cdot H_2O$: C, 55.89; H, 3.52; N, 8.15%.

Reactivity of Dyes with Ozone. Ozonization was carried out with an ozone–oxygen mixture (O_3: 0.068 mmol min^{-1}, O_2: 200 ml min^{-1}) on dye (0.1 mmol) in phosphate buffer solution (pH=6.8, 500 ml) at 30 °C. The rate constants were calculated on the basis of the changes of the absorbance at λ_{max} of the solution during the reaction.

Ozonization of 1-Phenylazonaphthalene-2,2'-diolatocopper-(II). Ozonization was carried out with an ozone–oxygen mixture (O_3: 0.068 mmol min^{-1}, O_2: 200 ml min^{-1}) on 1-phenylazonaphthalene-2,2'-diolatocopper(II) (1.6 mmol) in DMSO (2.0 ml) at 30 °C. After the reaction, the mixture was allowed to stand overnight. The disappearance of peroxide activity was checked by a KI test. Products were identified by GC-mass analysis and determined by gas chromatography. The conditions of gas chromatography are shown below. GLC 1: column 2% OV-1 on Gaschrom Q (60—80 mesh), 3 mm×1 m; column temperature 80—240 °C (10 °C min^{-1});

injection temperature 250 °C; detector temperature 250 °C; detection FID. GLC 2: column 2% FFAP on Gaschrom Q (80—100 mesh), 3 mm×1 m; column temperature 80—210 °C (10 °C min^{-1}); injection temperature 220 °C; detector temperature 220 °C; detection FID.

Authors would like to express their gratitude to Mr. Hiroshi Takimoto of Mitsubishi Kasei Co. for his valuable discussion.

Preparation and Reactivities of (η^3-1- and 2-Trimethylsiloxyallyl)$Fe(CO)_2NO$ Complexes. Intermediates Functioning as Equivalents of β- and α-Acyl Carbocations and Acyl Carbanions

(Received April 22, 1991)

(η^3-1- and 2-Trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes were prepared by the reaction of the corresponding siloxyallylic halides with $Bu_4N[Fe(CO)_3NO]$. These complexes reacted with both of carbon nucleophiles and carbon electrophiles preferentially at the less hindered sites of the allylic ligands. In these reactions, (η^3-1-trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes served as synthetically equivalent synthons for both of β-acyl carbocations and β-acyl carbanions and (η^3-2-trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes as both of α-acyl carbocations and α-acyl carbanions. The stereochemical courses of the reactions are described.

π-Allyl transition metal complexes have been shown to be useful intermediates in organic synthesis.[1] In most cases, these complexes have been used as a synthetically equivalent synthon for allylic carbocations. An exceptional case is π-allyl nickel complexes. They react with carbon electrophiles such as organic halides in polar media to produce alkylated allyl compounds.[2] However, the synthetic applicability of π-allyl iron complexes has been less explored, compared with the other transition metal complexes such as π-allyl nickel and palladium complexes. Nicholas et al. have reported that cationic π-allyl iron complexes of the type, (η^3-allyl)$Fe(CO)_4BF_4$, react with carbon nucleophiles preferentially at the less hindered site of the allylic ligands to produce alkylated allyl compounds.[3] Roustan et al. have shown that allylic acetates and halides couple with carbon nucleophiles in the presence of a catalytic amount of $Na[Fe(CO)_3NO]$ also to produce alkylated allyl compounds.[4] In this catalytic reaction, the attack of nucleophiles occurs preferentially at the leaving group-bearing carbons of the allylic ligands. They proposed that this reaction proceeds via (η^3-allyl)$Fe(CO)_2NO$ complexes. Xu and Zhou have reported a similar type of coupling reactions using n-$Bu_4N[Fe(CO)_3NO]$ as catalyst, but they proposed σ-allyl iron complexes as a key intermediate in this catalytic reaction.[5] However, no systematic studies have so far been made for the reactivities of (η^3-allyl)$Fe(CO)_2NO$ complexes. Previously, we reported a convenient procedure for preparation of the tetrabutylammonium ferrate, n-$Bu_4N^+[Fe(CO)_3NO]^-$ (TBAFe), and have shown that this ferrate complex can be utilized as a useful reagent for the synthesis of a variety of (η^3-allyl)$Fe(CO)_2NO$ complexes.[6] We also found that (η^3-allyl)$Fe(CO)_2NO$ complexes derived from allylic halides react with carbon electrophiles such as allyl, acyl and alkoxycarbonyl halides to give 1,5-dienes and β,γ-unsaturated carbonyl compounds, respectively.[6] In our previous communications,[7] we showed that (η^3-1-trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes react with both of carbon nucleophiles and electrophiles at the same position of the allylic ligands. Therefore, these iron complexes are envisaged to serve as a synthetically equivalent synthon for both of β-acyl carbocations and β-acyl carbanions. Since then, we have extensively investigated the chemical reactivities of iron complexes of this sort. In this paper, we report the preparation of (η^3-1- and 2-trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes and their reactivity features. These complexes have a dual reactivity and react with both of carbon nucleophiles and electrophiles at the same position of the allylic ligands of the complexes, preferentially at the less hindered sites. The stereochemical courses of the reactions are also discussed.

Results and Discussion

Preparation of (η^3-Trimethylsiloxyallyl)$Fe(CO)_2NO$ Complexes. The reaction of 3-halo-2-trimethylsiloxy-1-propenes **1a**—**d** with one equiv of TBAFe in CH_2Cl_2 at room temperature gave (η^3-2-trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes **2a**—**d** with evolution of one equiv of CO. The results are given in Scheme 1 and Table 1. The complexes were fairly stable to air and moisture, and they could be isolated by column chromatography on slica gel.

The structures of **2a**—**d** were established from their spectral data. The IR spectra showed characteristic absorption due to two CO ligands and one NO ligand in 1950—2050 and 1720—1730 cm^{-1} regions, respectively. The ^1H NMR spectra exhibited signals assignable to the allylic ligands. The ^1H NMR spectrum of **2c** revealed that this complex is actually a 1:1 mixture of two isomers in which the allylic ligand has a different configuration; i,e. the one isomer has the *syn*-methyl and *anti*-ethyl configuration and the other isomer has the *syn*-ethyl and *anti*-methyl configuration. The methyl proton signal of the former isomer appeared at a lower field (δ=2.07) than that of the later isomer (δ=1.51). In the case of **2d**, chlorine atom on the allylic ligand was found to be oriented to the anti-direction.

(η^3-1-Trimethylsiloxyallyl)$Fe(CO)_2NO$ complexes

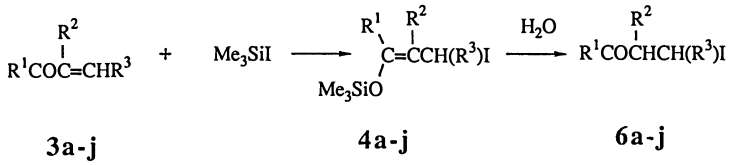

Scheme 2.

5a—**j** were synthesized by the reaction of TBAFe in CH_2Cl_2 at room temperature with one molar equiv of 3-iodo-1-trimethylsiloxy-1-propenes **4a**—**j**, which had been prepared in situ from α,β-unsaturated carbonyl compounds **3a**—**j** and Me_3SiI. Complexes **5a**—**j** were unable to isolate in pure forms because of their sensitivity to air and moisture. However, formation of the iron complexes was supported by their chemical properties and spectral data.

The reaction of **3a**—**j** with Me_3SiI in CH_2Cl_2, followed by acid hydrolysis, gave the β-iodo ketones and esters **6a**—**j**. This reaction is likely to proceed via silyl enol ethers **4a**—**j**.[8)] In separate experiments, **4a**—**j**, which were prepared from **3a**—**j** and Me_3SiI, were first treated with TBAFe, and then hydrolyzed with 4 M (1 M=1 mol dm^{-3}) HCl. This treatment gave quantitatively the starting ketones and esters **3a**—**j**. All of these results can be explained in terms of the reaction pathways shown in Scheme 2. A more direct support for the formation of **5a**—**j** was secured from the IR spectra of the reaction mixtures. The IR spectrum of the reaction mixture obtained from **3a**, Me_3SiI and TBAFe showed the characteristic bands for **5a** at 2060 and 1980 cm^{-1} due to two CO ligands, 1745 cm^{-1} due to the NO ligand, and 870 cm^{-1} due to the O–Si bond of the allylic ligand. Similar spectral data were obtained for **5b**—**j** which were prepared in a similar manner.

Reactions of (η^3-Trimethylsiloxyallyl)Fe(CO)$_2$NO Complexes. Ligand Exchange. The reactions of (η^3-trimethylsiloxyallyl)Fe(CO)$_2$NO complexes **2b** and **5b** with one equiv of allylic halides, acetates, and carbonates **7a**—**h** in CH_2Cl_2 resulted in the ligand exchange to give (η^3-allyl)Fe(CO)$_2$NO complexes **8a**—**d**. In these reactions, small amounts of ketones **9** and **3b**, which were obtained by hydrolysis of the trimethylsiloxyallylic ligands, were produced as by-products. The results are summarized in Scheme 3 and Table 2. Noteworthy is that allylic acetates and carbonates have little reactivity toward TBAFe, but they react with (η^3-trimethylsiloxyallyl)Fe(CO)$_2$NO complexes to form (η^3-allyl)-Fe(CO)$_2$NO complexes via the ligand exchange reaction. The reactivity in the ligand-exchange reaction

implies that the stability of (η^3-allyl)$Fe(CO)_2NO$ complexes depends upon substituents on the allylic ligands and decreases in the order: alkyl, aryl>2-trimethylsiloxy>1-trimethylsiloxy.

Reactions with Carbon Nucleophiles. The iron complexes **2a**—**d** reacted with carbon nucleophiles such as $NaCH(CO_2Et)_2$, $NaCH(COMe)CO_2Et$ and $NaCH(CN)_2$ in THF at room temperature to give α-alkylated ketones **10a**—**h** along with small amounts of the regioisomers **11a**—**h** (**10a**=**11a**, **10b**=**11b**) after acid hydrolysis of the reaction mixtures. The results are shown in Scheme 4 and Table 3. In these reactions, the attack of carbon nucleophiles occurred predominantly at the less hindered sites of the allylic ligands. In the cases of **2d**, the reductive elimination of chlorine atom occurred concurrently to give the corresponding α-alkylated products. Consequently, the iron complexes **2a**—**d** can be regarded as a synthetically equivalent synthon for α-acyl carbocations.

The iron complexes **5a,d,e,h** also reacted with carbon nucleophiles in THF at room temperature to give β-alkylated ketones **12a,d,e,h** after acid hydrolysis of the reaction mixtures. The results are shown in Scheme 5 and Table 4. The regioselectivity in these reactions was extremely high, so that the nucleophiles reacted only at the less hindered sites of the allylic ligands, giving a single product in every case. Thus, the iron complexes **5a,d,e,h** can be regarded as a synthetically equivalent synthon for β-acyl carbocations.

Reactions with Carbon Electrophiles. Iron complexes **2a**—**c** reacted with 2-propynyl bromide in *N,N*-dimethylformamide (DMF) or *N*-methyl-2-pyrrolidinone (NMP) at 80 °C. In these reactions, the attack of 2-propynyl bromide occurred regioselectively also at the less hindered sites of the allylic ligands of the iron complexes. The acid hydrolysis of the reaction mixtures gave 3-butynyl ketones **13a**—**c** as sole isolable products. The results are given in Scheme 6 and Table 5.

Treatment of 3-halo-2-trimethylsiloxy-1-propenes **1a**—**c** with a half molar equiv of TBAFe in toluene at 110 °C, followed by acid hydrolysis of the reaction mixtures, gave two regioisomeric mixtures of 1,4-diketones, **14a**—**c** and **15a**—**c** (**14a**=**15a**). The results

a) Isolated yields based on the substrates **1** used.

are shown in Scheme 7 and Table 6.

This reaction probably proceeds via an electrophilic attack of **1a—c** toward the intermediary produced iron complexes **2a—c**. With **1b,c**, the formation of **14b,c** predominated, indicating that a coupling at the less hindered sites of both of **1a—c** and **2a—c** is favored. Mechanistically, this reaction may involve an oxidative addition of the C–X bonds of **1a—c** on the Fe atom of the iron complexes **2a—c** as a key step. The detailed mechanistic feature of the reaction of the allylic iron complexes with allylic halides will be discussed later.

The above results strongly imply that the iron complexes **2a—c** serve as a synthetically equivalent synthon for α-acyl carbanions. Previously, Hegedus and Stiverson have demonstrated that η^3-2-methoxyallyl nickel complexes also serve as a synthetically equivalent synthon for α-acyl carbanions.[9]

The iron complexes **5a—g,i,j**, which were prepared in situ from **3a—g,i,j**, Me_3SiI and TBAFe, reacted regioselectively with 2-propynyl bromides in DMF or NMP at 80 °C to give β-propynylated ketones and esters **16a—g,i,j**, after acid hydrolysis of the reaction mixtures. The results are given in Scheme 8 and Table 7. The yields of the products were appreciably improved by pretreating **5a—g,i,j** with one equiv of triphenyl phos-

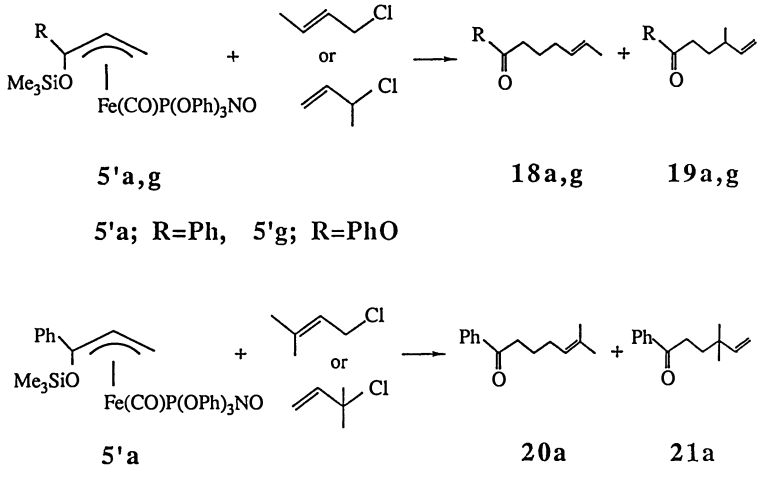
5j:	C_6H_5O	CH_3	H	**17j**	42

a) Reaction conditions: **5**; 2 mmol, CH_2=$CHCH_2Br$; 4 mmol, P(OPh)$_3$; 2 mmol, Temp; 80 °C, Time; 15 h. b) NMP was used as solvent.

The iron complexes **5a—d,f,g,i,j** also reacted in DMF or NMP with allyl bromide after treating the complexes with triphenyl phosphite to give β-allylated ketones and esters **17a—d,f,g,i,j**. In the absence of triphenyl phosphite, the complexes did not react with allyl bromide at room temperature, but the ligand-exchange reaction occurred to give (η^3-allyl)Fe(CO)$_2$NO complex **8a**. The results are shown in Scheme 9 and Table 8. When the reaction was carried out at 80 °C, 1,5-hexadiene was obtained by the coupling of the allyl ligand of the complex **8a**.

All the above results strongly support the assumption that the actual reactive complexes in the reactions of the iron complexes **5** in the presence of triphenyl phosphite are **5′**, and indicate that the nucleophilic reactivity of the iron complexes **5** is increased by converting the electron-withdrawing CO ligand in the complexes to the electron-donating P(OPh)$_3$ ligand. A more detailed mechanistic feature for the reaction of the iron complexes with allylic halides was obtained from the following experiments.



Scheme 10.

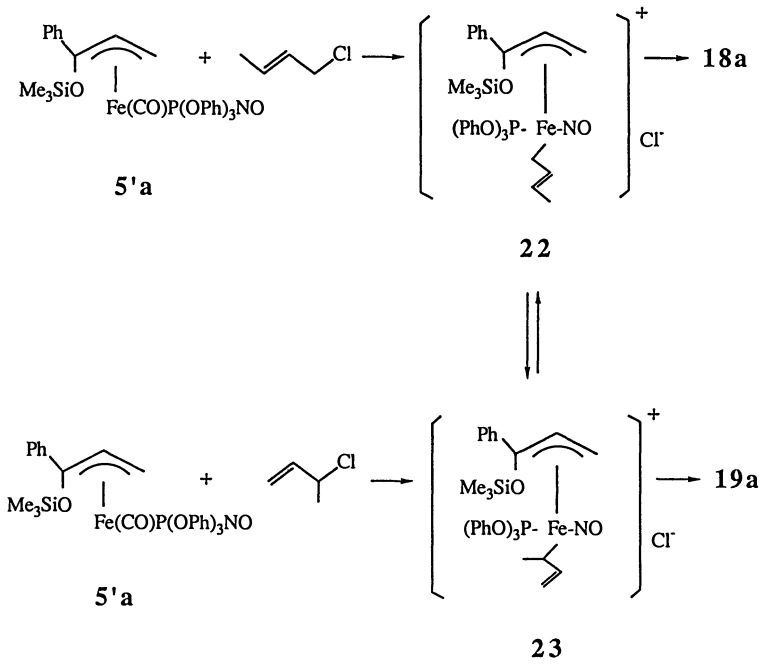
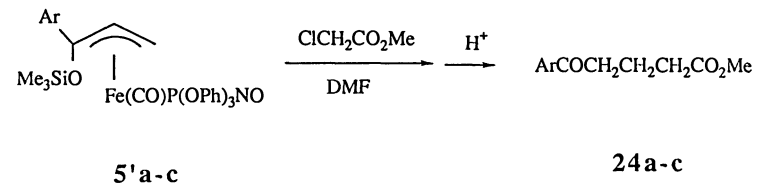


Scheme 11.



Scheme 12.

The reaction of **5'a** and **5'g** with 1-chloro-2-butene and 3-chloro-1-butene in DMF afforded a mixture of δ,ε-unsaturated ketones **18a** and **19a** and a mixture of **18g** and **19g**, respectively, essentially in the same ratio from both of the allylic halides. The reaction of **5'a** with 1-chloro-3-methyl-2-butene and 3-chloro-3-methyl-1-butene also afforded a mixture of two unsaturated ketones **20a** and **21a** almost in the same ratio. The results are given in Scheme 10 and Table 9. These results can be accounted for in terms of the reaction pathway shown in Scheme 11. The first step is the oxidative addition of allylic halides on the Fe atom of the iron complexes to form iron complexes **22** and **23** which are in equilibrium with each other. The reductive elimination of two allylic moieties gives the products.

The other example for the electrophilic addition on the iron complexes is the reaction of methyl chloroacetate with **5'a—c** in DMF. This reaction gave δ-keto esters **24a—c** in moderate yields. The results are given in Scheme 12 and Table 10.

All the above results indicate that the iron complexes **5** and **5'** serve as a synthetically equivalent synthon for β-acyl carbanions. Since β-acyl carbanions are useful intermediates in organic synthesis, several methods have already been developed for the generation of these inter-

Table 10. Reaction of (η^3-1-Trimethylsiloxyallyl)-Fe(CO)[P(OPh)$_3$]NO Complexes with Methyl Chloroacetate in DMF

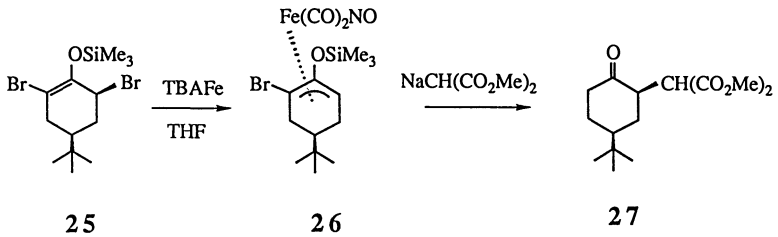
Complex		Product	Yield/%
5'a:	Ar=C_6H_5	**24a**	32
5'b:	Ar=*p*-$CH_3C_6H_4$	**24b**	48
5'c:	Ar=*p*-ClC_6H_4	**24c**	28

Reaction conditions: **5'**; 2 mmol, $ClCH_2CO_2Me$; 4 mmol, Temp; 80 °C, Time 15 h.

mediates.[10–14] An approach is the desilylative ring cleavage of siloxycyclopropanes with metal salts.[12] The other approach is based on the preparation of heteroatom-substituted allylic carbanions.[13,14] By utilizing our method, carbon electrophiles can be introduced at β-position of α,β-unsaturated ketones and esters with high regioselectivity via (η^3-1-trimethylsiloxyallyl)Fe(CO)[P(OPh)$_3$]NO complexes in a one-pot manner.

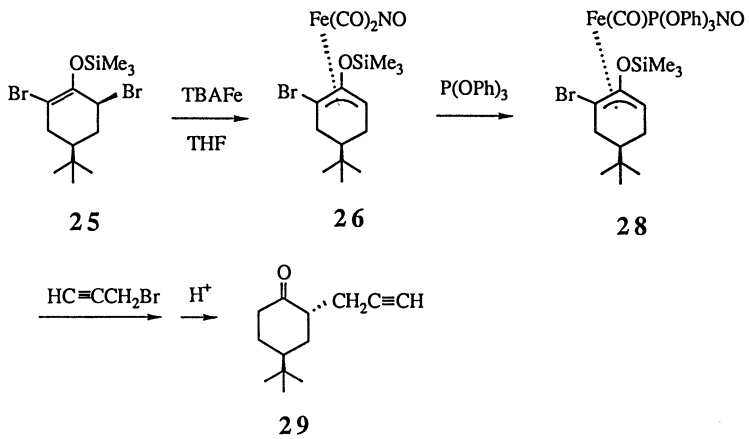
Stereoselectivities. 2,6-Dibromo-4-(*t*-butyl)-1-trimethylsiloxycyclohexene (**25**) was converted to the iron complex **26** by treating with TBAFe in THF. This complex reacted smoothly with $NaCH(CO_2Me)_2$ in THF at room temperature to give exclusively *cis*-4-*t*-butyl-2-[bis(methoxycarbonyl)methyl]cyclohexanone (**27**) in a 76% yield (Scheme 13). The ^{1}H NMR spectrum of **25** showed that the hydrogen atom on C-6 was oriented to the axial direction; its proton appeared as a double doublet centered at δ=4.72 (*J*=12.01 and 5.24 Hz). The ^{1}H NMR spectrum of the final product showed that the $CH(CO_2Me)_2$ group on C-2 of **27** was oriented to the equatorial direction and the hydrogen atom on the same carbon to the axial direction; the proton signal on C-2 appeared as a triple doublet centered at δ=3.22 (*J*=13.29, 9.26, and 5.23 Hz). This result suggests that 1) the ferrate ion of TBAFe attacks the C-6 carbon of **25** via a SN_2 like process with inversion of configuration at the reaction center to form iron complex **26**, and 2) the attack of the nucleophile on the allylic ligand of **26** occurs from the opposite side of the coordinated Fe atom and causes inversion of the configuration at the reaction center. During this reaction, the reductive elimination of bromine atom occurs to produce **27**. Trost et al. have proposed a similar stereochemical course for the Pd-catalyzed reaction of *cis*-3-acetoxy-5-(methoxycarbonyl)cyclohexene with carbon nucleophiles.[2,15]

The reaction of the iron complex **26** with 2-propynyl bromide gave *trans*-4-(*t*-butyl)-2-(2-propynyl)cyclohexanone (**29**) in a 36% yield when the reaction was carried out in DMF at 75 °C after treating **26** with triphenyl phosphite (Scheme 14). The ^{1}H NMR spectrum showed that the propynyl group on C-2 of **29** was oriented to the axial direction and the hydrogen atom on the same carbon to the equatorial direction; the proton signal of the hydrogen on C-2 appeared as a qd pattern centered at δ=2.45 (*J*=7.66 and 4.42 Hz). In this reaction, **26** produced from **25** is first converted to the triphenyl phosphite complex **28**, and then react with



25 **26** **27**

Scheme 13.



25 **26** **28**

Scheme 14.

2-propynyl bromide to produce **29**. The final step occurs via the oxidative addition of 2-propynyl bromide on Fe atom of **28** and subsequent reductive elimination of the organic moieties.[1] As a result, the configuration of C-2 of **25** is inverted.

Experimental

General. IR spectra were taken on a Shimadzu IR 24 spectrometer. NMR spectra were recorded with a Hitachi 24B or a JEOL FT-270 in $CDCl_3$ using tetramethylsilane as an internal standsard. Column chromatography was carried out with a Wako-gel C-200 (Wako Pure Chemical Industries). GLC analyses were performed on a Shimadzu GC 4CPF chromatograph using a column packed with SE 30 (10%) (3 mm×1 m). Elemental analyses were carried out on a Yanaco MT-3 elemental analyzer.

Materials. Tetrabutylammonium tricarbonylnitrosylferrate (TBAFe), $Bu_4N[Fe(CO)_3NO]$, was prepared by modification of the method previously reported.[6]

A solution of $Fe(CO)_5$ (60 mmol) in CH_2Cl_2 (20 cm^3) was added to a mixture of $NaNO_2$ (60 mmol) and Bu_4NBr (60 mmol) in water (20 cm^3). The resulting mixture was stirred under argon at room temperature for 2 h. The organic layer was separated, washed with water, and dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure gave $Bu_4N[Fe(CO)_3NO]$ (TBAFe) as yellow crystals in 86% yield; mp 56—56.5 °C; IR (KBr) 1980, 1850 cm^{-1} (CO), 1630 cm^{-1} (NO). Found: C, 55.60; H, 8.96; N 6.58%. Calcd for $C_{19}H_{36}N_2O_4Fe$: C, 55.35; H, 8.80; N, 6.79%.

1-Penten-3-one, 2-cyclohexen-1-one, 3-bromo-1-phenyl-1-propene, methyl acrylate, methyl cinnamate, 1-chloro-2-butene, 3-chloro-1-butene, and 1-chloro-3-methyl-2-butene were commercial products and purified before use.

3-Chloro-2-trimethylsiloxy-1-propene (**1a**),[16] 3-bromo-3-methyl-2-trimethylsiloxy-1-butene (**1b**),[17] 3-bromo-3-methyl-2-trimethylsiloxy-1-pentene (**1c**),[17] 1,3-dichloro-2-trimethylsiloxy-1-propene (**1d**),[18] *cis*-2,6-dibromo-4-*t*-butyl-1-(trimethylsiloxy)cyclohexene (**25**),[18] and 3-chloro-3-methyl-1-butene[19] were prepared by the literature methods.

1a: Bp 61—63 °C/35 mmHg (1 mmHg=133.322 Pa); IR (neat) 2960, 2900, 1635, 1315, 1260, 1225, 1160, 1030, 915, 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.40 (9H, s), 3.92 (2H, t, J=0.9 Hz), 4.28 (1H, dt, J=2.0, 0.9 Hz), 4.50 (1H, dt J=2.0, 0.9 Hz).

1b: Bp 79 °C/22 mmHg; IR(neat) 1620, 1060, and 875 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.40 (9H, s), 1.95 (6H, s), 4.10 (1H, d, J=2.0 Hz), 4.60 (1H, d, J=2.0 Hz).

1c: Bp 80—82 °C/15 mmHg; IR (neat) 1620, 1060, and 875 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.40 (9H, s), 1.04 (3H, t J=7.0 Hz), 1.95 (3H, s), 2.17 (2H, q, J=7.0 Hz), 4.20 (1H, d, J=2.0 Hz), 4.53 (1H, d, J=2.0 Hz).

1d: Bp 55—56 °C/5 mmHg; IR (neat) 1620, 1310, 1246, 1212, 980, 841 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.34 (9H, s), 3.89 (2H, s), 5.70 (1H, s).

25: Bp 98—100 °C/2 mmHg; IR (neat) 1620, and 868 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.25 (9H, s), 0.87 (9H, s), 1.74 (1H, m), 1.92 (1H, m), 2.14 (1H, m), 2.38 (1H, dd, J=16.92, 11.28 Hz), 2.52 (1H, dd, J=16.92, 6.64 Hz), 4.61 (1H, dd, J=12.02, 5.04 Hz). ^{13}C NMR ($CDCl_3$) δ=0.98, 27.1, 34.3, 36.2, 40.8, 52.0, 108.9, 145.9. The proton signal of CHBr at C-6 appeared at δ=4.61 (dd, J=12.02, 5.04 Hz), confirming that this material has the assigned configuration.

Phenyl vinyl ketone (**3a**),[20] *p*-tolyl vinyl ketone (**3b**),[20] *p*-chlorophenyl vinyl ketone (**3c**),[20] 2-methyl-1-phenyl-2-propen-1-one (**3i**),[20] Phenyl acrylate (**3f**),[21] and phenyl methacrylate (**3j**)[21] were also prepared by the method of the literatures.

3a: IR(neat) 1670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.72 (1H, dd, J=3.0, 10.3 Hz), 6.25 (1H, dd, J=3.0, 17.2 Hz), 7.06 (1H, dd, J=10.3, 17.2 Hz), 7.33 (3H, m), 7.76 (2H, m).

3b: IR (neat) 1676 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.31 (3H, s), 5.72 (1H, dd, J=2.7, 10.3 Hz), 6.27 (1H, dd, J=2.7, 17.1 Hz), 7.00 (1H, dd, J=10.3, 17.1 Hz), 7.08 (2H, d, J=7.9 Hz), 7.67 (2H, d, J=7.9 Hz).

3c: IR (neat) 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.73 (1H, dd, J=2.4, 10.8 Hz), 6.23 (1H, dd, J=2.4, 17.3 Hz), 6.98 (1H, dd, J=10.8, 17.3 Hz), 7.28 (2H, d, J=8.3 Hz), 7.73 (2H, d J=8.3 Hz).

3f: IR (neat) 1726 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.88 (1H, m), 6.29 (2H, m), 7.02 (5H, m).

3i: IR (neat) 3030, 2940, 1646 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.01 (3H, s), 5.52 (1H, d, J=1.0 Hz), 5.78 (1H, d, J=1.0 Hz), 7.28 (3H, m), 7.58 (2H, m).

3j: IR (neat) 1724 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.95 (3H, s), 5.57 (1H, d, J=1.0 Hz), 6.10 (1H, d, J=1.0 Hz), 7.02 (5H, m).

Preparation of (η^3-Trimethylsiloxyallyl)Fe(CO)$_2$NO Complexes. General Procedure. A mixture of one of 3-halo-2-trimethylsiloxy-1-propenes (**1**) (2 mmol) and $Bu_4N[Fe(CO)_3NO]$ (TBAFe, 2 mmol) in CH_2Cl_2(5 cm^3) was stirred at room temperature for 2 h. During this period, one molar equiv of CO to TBAFe evolved. The solvent was removed under reduced pressure. Chromatography of the residue on silica gel with pentane solvent gave the corresponding (η^3-2-trimethylsiloxyallyl)Fe(CO)$_2$NO complex.

2a: IR (neat) 2020 and 1955 cm^{-1} (CO), 1720 cm^{-1} (NO), 835 cm^{-1} (OSi); ^{1}H NMR ($CDCl_3$) δ=0.18 (9H, s, $SiMe_3$), 3.47 (2H, d, J=4.0 Hz, *anti*-H), 3.90 (2H, d, J=4.0 Hz, *syn*-H). ^{13}C NMR ($CDCl_3$) δ=0.0, 51.0, 136, 218.

2b: IR (neat) 2010 and 1945 cm^{-1} (CO), 1725 cm^{-1} (NO), 845 cm^{-1} (OSi); ^{1}H NMR ($CDCl_3$) δ=0.17 (9H, s, $SiMe_3$), 1.53 (3H, s, *anti*-Me), 2.07 (3H, s, *syn*-Me), 3.51 (1H, d, J=4.2 Hz, *anti*-H), 3.98 (1H, d, J=4.2 Hz, *syn*-H). ^{13}C NMR ($CDCl_3$) δ=0.0, 24.1 (*anti*-CH_3), 28.3 (*syn*-CH_3), 46.8, 86.9, 136, 220.

2c: IR (neat) 2030 and 1950 cm^{-1} (CO), 1720 cm^{-1} (NO), 845 cm^{-1} (OSi). The ^{1}H NMR spectrum showed that this complex contains two isomers with respect to the configuration of the alkyl substituents on the allylic ligand in a 1 : 1 ratio. For the *anti*-methyl and *syn*-ethyl isomer; ^{1}H NMR ($CDCl_3$) δ=0.19 (9H, s, $SiMe_3$), 1.33 (3H, t, J=7.0 Hz, *syn*-$CH_2\underline{CH_3}$), 1.51 (3H, s, *anti*-CH_3), 2.53 (2H, q, J=7.0 Hz, *syn*-$\underline{CH_2}CH_3$), 3.47 (1H, d, J=4.2 Hz, *anti*-H), 4.00 (1H, d, J=4.2 Hz, *syn*-H). ^{13}C NMR, ($CDCl_3$) δ=0.0 ($OSi\underline{Me_3}$), 16.8 (*syn*-CH_2 $\underline{CH_3}$), 23.9 (*anti*-$\underline{CH_3}$), 33.6 (*syn*-$\underline{CH_2}CH_3$), 46.8, 87.2, 137, 219. For the *syn*-methyl and *anti*-ethyl isomer; ^{1}H NMR($CDCl_3$) δ=0.19 (9H, s, $SiMe_3$), 1.19 (3H, t, J=7.0 Hz, *anti*-$CH_2\underline{CH_3}$), 1.75 (2H, q, J=7.0 Hz, *anti*-$\underline{CH_2}CH_3$), 2.09 (3H, s, *syn*-CH_3) 3.61 (1H, d, J=4.2 Hz, *anti*-H), 4.10 (1H, d, J=4.2 Hz, *syn*-H). ^{13}C NMR($CDCl_3$) δ=0.0 ($OSi\underline{Me_3}$), 15.0 (*anti*-$CH_2\underline{CH_3}$), 28.5 (*syn*-$\underline{CH_3}$), 31.5 (*anti*-$\underline{CH_2}CH_3$), 46.8, 87.2, 137, 219.

2d: IR (neat) 2030 and 1965 cm^{-1} (CO), 1725 cm^{-1} (NO), 840 cm^{-1} (OSi); ^{1}H NMR ($CDCl_3$) δ=0.30 (9H, s, $SiMe_3$), 3.84 (1H, d, J=2.5 Hz, *anti*-H), 3.92 (1H, d, J=2.5 Hz, *syn*-H), 5.60 (1H, s, *syn*-C$\underline{H}$Cl). ^{13}C NMR ($CDCl_3$). δ=2.0, 48.5, 60.6, 128, 224.

Preparation of (η^3-1-Trimethylsiloxyallyl)Fe(CO)$_2$NO Com-

plexes. General Procedure. A mixture of one of vinyl ketones **3**, (2 mmol) with Me_3SiI (2.2 mmol) in CH_2Cl_2 (5 cm^3) was stirred at room temperature for 2 h. This reaction gave one of the corresponding 3-iodo-1-trimethylsiloxy-1-propenes (**4**). Without isolating the siloxypropenes, a solution of TBAFe (2 mmol) in CH_2Cl_2 (2.5 cm^3) was added to each of the above reaction mixtures, and the resulting mixtures were stirred under argon atmosphere at room temperature for 2 h. During this period, one equiv of CO to TBAFe evolved.

The iron complexes **5a**—**j** thus produced were unable to isolate in pure forms because of their high sensitivity to moisture and air. But, support for the formation of **5a**—**j** was furnished by IR spectra of the reaction mixtures and their chemical transformation as described in text.

Ligand Exchange of (η^3-Allyl)Fe(CO)$_2$NO Complexes. A Typical Procedure. A mixture of (η^3-2-trimethylsiloxyallyl)-Fe(CO)$_2$NO complex **2b** (2 mmol) prepared in situ and allyl bromide **7a** (2 mmol) in CH_2Cl_2 (5 cm^3) was refluxed with stirring for 2 h. After cooling, the reaction mixture was chromatographed on silica gel. Elution with hexane gave the iron complex **8a** and subsequent elution with hexane–ethyl acetate (95/5) gave 3-methyl-2-butanone (**9**).

8a: IR (neat) 2030, 1980, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.12 (2H, d, J=12.0 Hz), 3.96 (2H, d, J=6.0 Hz), 5.72 (1H, m).

8b: IR (neat) 2030, 1970, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.91 (1H, d, J=11 Hz), 3.85 (1H, d, J=6.0 Hz), 4.90 (2H, m), 7.20 (5H, m).

8c: IR (neat) 2030, 1970, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.95 (3H, d, J=5.0 Hz), 2.76 (1H, d, J=12.0 Hz), 3.68 (1H, d, J=6.0 Hz), 4.1 (2H, m).

8d: IR (neat) 2030, 1970, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.6—2.7 (m, 6H), 4.5—5.7 (m, 3H).

These spectral data of the iron complexes were essentially identical with those of the same complexes previously reported.[6]

Reaction of (η^3-Trimethylsiloxyallyl)Fe(CO)$_2$NO Complexes with Carbon Nucleophiles. General Procedure. Iron complexes **2a**—**d** (2 mmol) were prepared from 3-halo-2-trimethylsiloxy-1-propenes and TBAFe by the procedure described above. These complexes were used without isolation for the following reactions.

A mixture of an iron complex and one equiv of a carbon nucleophile in THF was stirred at room temperature for 15 h. The resulting mixture was extracted with ether. The extract was washed successively with 4 M hydrochloric acid and water, and then dried over Na_2SO_4. The solvent was removed under reduced pressure. Chromatography of the residue with hexane–ethyl acetate (9/1) gave the corresponding mixture of each one of α-alkylated ketone **10a**—**h** and **11c**—**h**.

Similarly, treatment of mixtures of (η^3-1-trimethylsiloxyallyl)Fe(CO)$_2$NO complexes **5** and carbon nucleophiles gave the corresponding β-alkylated ketones and esters **12a**—**h**.

10a: IR (neat) 1745, 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.27 (6H, t, J=7.0 Hz), 2.16 (3H, s), 2.91 (2H, d, J=7.0 Hz), 3.72 (1H, t, J=7.0 Hz), 4.17 (4H, q, J=7.0 Hz). Found: C, 55.32; H, 7.46%. Anal. Calcd for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46%.

Reaction of (η^3-2-Trimethylsiloxyallyl)Fe(CO)$_2$NO Complexes with 2-Propynyl Bromide. A Typical Procedure. A mixture of 3-chloro-2-trimethylsiloxy-1-propene (**1a**, 2 mmol) and TBAFe (2 mmol) in DMF (or NMP, 10 cm^3) was stirred at room temperature for 2 h, and 2-propynyl bromide (4 mmol) was then added. The resulting mixture was heated at 80 °C for 15 h. The mixture was hydrolyzed with 4 M hydrochloric acid and extracted with ether. The extract was washed with water, dried over Na_2SO_4, and the solvent was evaporated under reduced pressure. The residue was chromatographed on silica gel with hexane–ethyl acetate (95/5) to give α-alkynyl ketones **13a**. Similar treatments of **1b,c** gave **13b,c**.

13a: IR (neat) 3300, 2100, 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.89 (1H, t, J=2.0 Hz), 1.98 (2H, td, J=7.0, 2.0 Hz), 2.09 (3H, s), 2.52 (2H, t, J=7.0 Hz). Found: C, 74.72; H, 8.50%. Calcd for C_6H_8O: C, 74.97; H, 8.39%.

13b: IR (neat) 3300, 2120, 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.07 (6H, d, J=7.0 Hz), 1.88 (1H, t, J=2.0 Hz), 1.98 (2H, td, J=7.0, 2.0 Hz), 2.54 (1H, m), 2.68 (2H, t, J=7.0 Hz). Found: C, 77.28; H, 9.66%. Calcd for $C_8H_{12}O$: C, 77.38; H, 9.74%.

13c: IR (neat) 3300, 2120, 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.02 (3H, t, J=7.0 Hz), 1.09 (3H, d, 17.0 Hz), 1.24 (2H, m), 1.89 (1H, t, J=2.0 Hz), 1.98 (2H, td, J=7.0, 2.0 Hz), 2.54 (1H, m), 2.60 (2H, t, J=7.0 Hz). Found: C,78.01; H, 10.05%. Calcd for $C_9H_{14}O$: C,78.21; H, 10.21%.

Formation of 1,4-Diketones via (η^3-1-Trimethylsiloxyallyl)-Fe(CO)$_2$NO Complexes. General Procedure. A mixture of 3-halo-2-trimethylsiloxy-1-propenes **1a—c** (4 mmol) and a half equiv of TBAFe (2 mmol) in toluene (10 cm^3) was heated at 110 °C for 15 h. The mixture was hydrolyzed with 4 M hydrochloric acid and then extracted with ether. The extract was washed with water, dried over Na_2SO_4 and the solvent was evaporated under reduced pressure. 1,4-Diketones **14a—c** and **15a—c** were isolated by chromatography of the residue on silica gel with hexane–ethyl acetate (95/5).

14a: IR (neat) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2. 22 (6H, s), 2.71 (4H, s). Found: C, 63.21; H, 8.78%. Calcd for $C_6H_{10}O_2$: C, 63.14; H, 8.83%.

14b: IR (neat) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (12H, d, J=7.0 Hz), 2.52 (2H, m), 2.62 (4H, s). Found: C, 70.48; H, 10.48%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

14c: IR (neat) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92—1.24 (16H, m), 2.52 (2H, m), 2.62 (4H, s). Found: C, 72.63; H, 11.05%. Calcd for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

15b: IR (neat) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (6H, d, J=7.0 Hz), 1.12 (6H, s), 2.08 (3H, s), 2.52 (1H, m), 2.64 (2H, s). Found: C, 70.44; H, 10.57%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

15c: IR (neat) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90—1.24 (16H, m), 2.08 (3H, s), 2.52 (1H, m), 2.64 (2H, s). Found: C, 72.70; H, 11.15%. Calcd for $C_{12}H_{22}O_2$: C, 72.68, H, 11.18%.

Reaction of (η^3-1-Trimethylsiloxyally1)Fe(CO)$_2$NO Complexes with Organic Halides. General Procedure. A mixture of one of α,β-unsaturated ketones or esters (**3a—g,i,j**, 2 mmol) and Me_3SiI (2.2 mmol) in CH_2Cl_2 (10 cm^3) was stirred at room temperature for 2 h. A solution of TBAFe (2 mmol) in CH_2Cl_2 (2.5 cm^3) was added, and the resulting mixture was stirred at the same temperature for 2 h. After removal of the solvent under reduced pressure, DMF or NMP (10 cm^3) was added as a new solvent, and an organic halide (4 mmol), 2-propynyl bromide, was added to this solution. The resulting mixture was heated at 80 °C for 15 h, cooled, and extracted with ether (30 cm^3). The extract was washed successively with 4 M hydrochloric acid, aqueous $NaHSO_3$ and water, and then dried over Na_2SO_4. The solvent was removed and the residue was chromatographed on silica gel. Elution with hexane–ethyl acetate (97.5/2.5) gave the β-alkylated ketone or ester, **16a—g,i,j**.

A Typical Procedure of the Reaction in the Presence of P(OPh)$_3$. A mixture of phenyl vinyl ketone (**3a**, 2 mmol) and Me_3SiI (2.2 mmol) in CH_2Cl_2 (10 cm^3) was stirred at room temperature for 2 h. A solution of TBAFe (2 mmol) in CH_2Cl_2 (2.5 cm^3) was added, and the resulting mixture was stirred at the same temperature for 2 h. $P(OPh)_3$ (2.0 mmol) was then added, and the mixture was heated at 50 °C for 1 h. After removal of the solvent under reduced pressure, DMF (10 cm^3) was added as a new solvent, and 2-propynyl bromide (4 mmol) was added to the DMF solution. The mixture was heated at 80 °C for 15 h, cooled, and extracted with ether (30 cm^3). The extract was washed successively with 4 M hydrochloric acid, aqueous $NaHSO_3$ and water, and then dried over Na_2SO_4. The solvent was removed, and the residue was chromatographed on silica gel. Elution with hexane–ethyl acetate (97.5/2.5) gave the β-alkylated ketone **16a** in good yield. In a similar manner, **3a—g,i,j** were converted to the corresponding β-alkylated ketones and esters, **16b—g,i,j**, **17a—d,f,g,i,j**, **18a,g**, **19a,g**, **20a**, **21a**, and **24a—c** via the reactions of the iron complexes **5′** with organic halides, such as 2-propynyl bromide, allyl bromide, and methyl chloroacetate.

16a: Oil; IR (neat) 3300, 2100, 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.84—2.00 (3H, m), 2.14—2.40 (2H, m), 3.04 (2H, t, J=6.9 Hz), 7.30—7.38 (3H, m), 7.74—7.88 (2H, m). ^{13}C NMR ($CDCl_3$) δ=17.9, 22.7, 37.0, 69.1, 83.7, 127.9, 128.0, 128.6, 136.9, 199.5. 17f: Oil; IR (neat) 1708, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.97 (2H, m), 2.17 (2H, q, J=7.0 Hz), 2.72 (2H, t, J=7.0 Hz), 5.04 (2H, m), 5.81 (1H, m), 7.22 (5H, m); ^{13}C NMR ($CDCl_3$) δ=17.8, 23.6, 33.0, 115.7, 121.5, 121.6, 125.7, 125.8, 150.7, 171.6. Found: C, 75.41; H, 7.02%. Calcd for $C_{12}H_{14}O$: C, 75.76; H, 7.42%.

17g: Oil; IR (neat) 1746, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.37 (2H, m), 2.89 (1H, m), 3.39 (2H, d, J=7.0 Hz), 3.81 (3H, s), 5.13 (2H, m), 5.95 (1H, m), 7.38 (5H, m); ^{13}C NMR ($CDCl_3$) δ=31.8, 48.0, 51.8, 63.5, 116.1, 127.2, 128.0, 128.8, 135.7, 140.4, 168.4. Found: C, 76.45; H, 7.81%. Calcd for $C_{13}H_{16}O_2$: C, 76.45; H 7.81%.

17i: Oil; IR (neat) 1676, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, d, J=7.0 Hz), 1.97 (2H, q, J=7.0 Hz), 2.09 (2H, qt, J=7.0, 1.21 Hz), 3.50 (1H, m), 4.94 (2H, m), 5.85 (1H, ddt, J=15.0, 10,2, 7.0 Hz), 7.47 (3H, m), 7.93 (2H, m); ^{13}C NMR ($CDCl_3$) δ=17.3, 31.5, 32.6, 39.8, 115.2, 128.3, 128.6, 132.8, 136.7, 138.1, 204.5. Found: C, 82.56; H, 8.57%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

17j: Oil; IR (neat) 1712, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.29 (3H, d, J=7.0 Hz), 1.96 (2H, q, J=7.0 Hz), 2.16 (2H, q, J=7.0 Hz), 2.71 (1H, m), 5.12 (2H, m), 5.83 (1H, m), 7.12 (5H, m); ^{13}C NMR ($CDCl_3$) δ=18.4, 32.8, 38.2, 43.5, 114.9, 121.5, 121.6, 125.7, 127.1, 129.4, 171.2. Found: C, 76.33; H, 7.78%. Calcd for $C_{13}H_{16}O_2$: C,76.43; H, 7.90%.

18a: Oil; IR (neat) 1686, 960 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.56 (3H, br d, J=7.0 Hz), 1.72—2.10 (4H, m), 2.81 (2H, t, J=7.0 Hz), 5.31 (2H, m), 7.30 (3H, m), 7.75 (2H, m); ^{13}C NMR ($CDCl_3$) δ=20.2, 24.8, 32.3, 37.6, 121.0, 121.6, 128.6, 132.8, 136.7, 138.4, 202.0. Found: C, 82.72; H, 8.61%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

19a: Oil; IR (neat) 1684, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.98 (3H, d J=7.0 Hz), 1.70—2.15 (3H, m), 2.81 (2H, t, 7.0 Hz), 4.98 (2H, m), 5.60 (1H, m), 7.30 (3H, m), 7.75 (2H, m); ^{13}C NMR ($CDCl_3$) δ=17.9, 24.7, 30.9, 33.7, 115.7, 125.6, 128.5, 129.0, 136.0, 138.4, 203.0. Found: C, 82.69; H, 8.46%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

18g: Oil; IR (neat) 1708, 965 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.68 (3H, d, J=7.0 Hz), 1.84 (2H, m), 2.12 (2H, q, J=7.0 Hz), 2.57 (2H, t J=7.0 Hz), 5.47 (2H, m), 7.36 (5H, m); ^{13}C NMR($CDCl_3$) δ=20.2, 31.4. 32.3, 37.6, 113.9, 121.6, 125.8, 129.4, 129.7, 143.3, 172.3. Found: C, 76.42; H, 7.79%. Calcd for $C_{13}H_{16}O_2$; C,76.43; H, 7.90%.

19g: Oil; IR (neat) 1708, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.10 (3H, d J=7.0 Hz), 1.73 (2H, q, J=7.0 Hz), 2.20 (1H, m), 2.55 (2H, t, J=7.0 Hz), 5.07 (2H, m), 5.69 (1H, m), 7.25 (5H, m); ^{13}C NMR ($CDCl_3$) δ=17.9, 24.7, 30.9, 33.7, 121.6, 125.2, 125.7, 126.2, 129.2, 129.4, 172.3. Found: C, 76.21; H, 7.92%. Calcd for $C_{13}H_{16}O_2$: C, 76.43; H, 7.90%.

20a: Oil; IR (neat) 1685 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.66 (6H, br s), 1.78—2.27 (4H, m), 2.79 (2H, t, J=7.0 Hz), 5.30 (1H, m), 7.20 (3H, m), 7.75 (2H, m); ^{13}C NMR ($CDCl_3$) δ=23.4, 26.1, 28.3, 29.8, 41.6, 119.8, 128.0, 128.3, 128.5, 128.6, 132.8, 203.7. Found: C, 83.05; H, 8.89%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

21a: Oil; IR (neat) 1682, 990, 910 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.12 (6H, s), 1.70 (2H, t, J=7.0 Hz), 2.80 (2H, t, J=7.0 Hz), 5.08 (2H, m), 5.70 (1H, dd, J=16.2, 10.6 Hz), 7.21 (3H, m), 7.75 (2H, m); ^{13}C NMR ($CDCl_3$) δ=17.6, 26.2, 33.2, 41.2, 115.4, 125.2, 128.0, 128.6, 132.8, 202.4. Found: C, 82.88; H, 8.78%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

24a: Oil; 1726, 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.12 (2H, quintet, J=7.0 Hz), 2.46 (2H, t, J=7.0 Hz), 3.07 (2H, t, J=7.0 Hz), 3.70 (3H, s), 7.52 (3H, m), 7.92 (2H, m); ^{13}C NMR ($CDCl_3$) δ=23.3, 32.9, 37.0, 51.6, 127, 128, 133, 141, 174, 200. Found: C, 69.67; H, 6.74%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%.

24b: Oil; IR (neat) 1746, 1678 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.07 (2H, quintet, J=7.2 Hz), 2.41 (3H, s), 2.44 (2H, t, J=7.25 Hz), 3.03 (2H, t, J=7.25 Hz), 3.68 (3H, s), 7.27 (2H, d, J=8.02 Hz), 7.85 (2H, d, J=8.02 Hz); ^{13}C NMR ($CDCl_3$) δ=19.5, 21.6, 33.2, 37.3, 51.6, 120.1, 128.2, 129.9, 138.4, 173.8, 199.1. Found: C, 70.77; H, 7.16%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

24c: Oil; IR (neat) 1730, 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.02 (2H, m), 2.46 (2H, t, J=7.0 Hz), 3.63 (2H, t, J=7.0 Hz), 3.70 (3H, s), 7.18 (2H, d, J=8.3 Hz); 8.02 (2H, d, J=8.3 Hz); ^{13}C NMR ($CDCl_3$) δ=22.6, 33.0, 37.8, 51.6, 129, 130, 138, 140, 172, 206. Found: C, 59.77, H, 5.42%. Calcd for $C_{12}H_{13}ClO_3$: C, 59.88; H, 5.44%.

Stereoselectivity in the Reaction of (η^3-Allyl)Fe(CO)$_2$NO Complexes with a Carbon Nucleophile. A mixture of *cis*-2,6-dibromo-4-*t*-butyl-1-(trimethylsiloxy)cyclohexene (**25**, 3 mmol) and TBAFe (4 mmol) in THF (10 cm^3) was stirred at room temperature for 3 h and then $NaCH(CO_2Me)_2$ (6 mmol) in THF (5 cm^3) was added. The resulting mixture was stirred at the same temperature for 15 h, hydrolyzed with 4 M hydrochloric acid, and extracted with ether. The extract was washed with water and dried over Na_2SO_4. After removal of the solvent under reduced pressure, the residue was chromatographed on silica gel. Elution with hexane–ethyl acetate (9/1) gave the alkylated product, **27**: Oil; IR (neat) 1746, 1724, 1280, 1060 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (9H, s), 1.30—1.50 (2H, m), 1.65 (1H, tt, J=2 84, 12.1 Hz), 2.00—2.42 (4H, m), 3.22 (1H, ddd, J=5.24, 9.26, 13.29 Hz), 3.68 (1H, d, J=9.26 Hz), 3.74 (3H, s), 3.75 (3H, s); ^{13}C NMR ($CDCl_3$) δ=27.3, 27.6, 28.5, 32.0, 32.5, 41.1, 46.8, 49.7, 52.6, 52.7, 168.8, 168.9, 210.0. Found: C, 63.35; H, 8.33%. Calcd for $C_{15}H_{24}O_5$: C, 63.36; H, 8.50%.

A mixture of *cis*-2,6-dibromo-4-*t*-butyl-1-(trimethylsiloxy)-cyclohexene (**25**, 3 mmol) and TBAFe (4 mmol) in DMF (10 cm^3) was stirred at room temperature. To the mixture, triphenyl phosphite (3 mmol) was added and then the mixture was heated at 50 °C for 1 h. To the resulting mixture, the carbon electrophile, 2-propynyl bromide (6 mmol), was added and then the mixture was heated at 75 °C for 15 h. The mixture was hydrolyzed with 4 M hydrochloric acid, and extracted with ether. The extract was washed with 4 M NaOH aqueous solution and then water, dried over Na_2SO_4. After removal of the solvent under reduced pressure, the residue was chromatographed on silica gel. Elution with hexane–ethyl acetate (97.5/2.5) gave the alkylated product, **29**: Oil; IR (neat) 3200, 2100, 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$)δ=0.94 (9H, s), 1.47 (1H, m), 1.58 (1H, m), 1.65 (1H, tt, J=12.10, 2.82 Hz) 1.97 (1H,t, J=2.82 Hz), 2.10 (1H, ddd, J=16.52, 12.10, 4.42 Hz), 2.18 (1H, ddd, J=16.52, 7.66, 2.82 Hz), 2.42 (2H, dd, J=7.66, 2.82 Hz), 2.45 (1H, qd, J=7.66, 4.42 Hz), 2.50 (1H, m), 2.65 (1H, ddd, J=16.52, 4.43, 2.42 Hz); ^{13}C NMR ($CDCl_3$) δ=18.9 (t), 27.7 (q), 28.6 (t), 32.6 (s), 34.3 (d), 41.3 (t), 46.9 (t), 48.7 (d), 69.5 (d), 82.7 (s), 211.1 (s). Found: C, 81.06; H, 10.31%. Calcd for $C_{12}H_{20}O$: C, 81.20; H, 10.48%.

Isolation of Iron Complex 26. A mixture of **25** (2 mmol) and TBAFe (2 mmol) in CH_2Cl_2 (5 cm^3) was stirred at room temperature for 3 h. The resulting mixture was chromatographed on silica gel. Complex **26** was isolated from the fraction eluted with hexane; IR (neat) 2020, 1960 cm^{-1} (CO), 1725 cm^{-1} (NO), 850 cm^{-1} (OSi); ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s), 0.92 (9H, s), 1.93 (1H, m), 2.22 (1H, m), 2.52—2.80 (3H, m), 5.30 (1H, m); ^{13}C NMR ($CDCl_3$) δ=1.8, 27.2, 31.6, 34.2, 36.2, 40.8, 47.1, 52.0, 129, 214.

Effect of Unpaired Terminal Nucleotides of Substrate RNAs on the RNA Ligation with T4 RNA Ligase

Naoki SUGIMOTO,* Akiko MATSUMURA, Keiko HASEGAWA, and Muneo SASAKI
Department of Chemistry, Faculty of Science, Konan University, Okamoto, Higashinada-ku, Kobe 658
(Received May 27, 1991)

The effect of double-helix formations and unpaired terminal nucleotides of RNA oligomer substrates on a RNA ligation with T4 RNA ligase has been investigated by using high-performance liquid chromatography (HPLC), UV absorbance, and circular dichroism (CD) measurements, and the energy calculation for the double-helix stability of RNAs. In the 1-hour reaction of single-stranded RNA acceptors, the yield of the product increased in the order of pyrimidine donors pCp>pUp and purine donors pAp>pGp. In the reaction of a double-stranded RNA acceptor, UGCGCA, the yield also increased in the same order of the donors. On the other hand, in the reaction of double-stranded RNA acceptors containing unpaired terminal nucleotides (dangling ends), pUp and pGp donors gave the largest yields of the products in the reactions of AUGCGCA and CAUGCAU acceptors, respectively. Furthermore, the yield of the product is the largest for CAUGCAU acceptor within the acceptors having A, C, G, and U dangling ends in the reaction of pGp donor. These results sugggest that the formation of the terminal base pairs of the donors and the dangling ends may affect the RNA ligation with T4 RNA ligase.

Unpaired terminal nucleotides (dangling ends) play very important roles in the structure and interaction of ribonucleic acids (RNAs). It is well-known that the dangling ends determine the stability of codon–anticodon associations[1,2] and are responsible for some codon context effects.[3] It is also known that the nucleotides determine important tertiary structures of a transfer RNA (tRNA)[4] and a catalytic core of *Tetrahymena* ribozyme.[5,6] Recently, the effect of the dangling ends on the stability of RNA duplexes has been studied energetically.[7,8] The result showed that both 3′ and 5′ terminal nucleotides stabilized the core duplexes. However, little is known about the effect of the unpaired terminal nucleotides on biochemical reactions such as ligase and nuclease reactions.

In this work, we have investigated the effect of the unpaired terminal nucleotides of substrate RNAs on the RNA ligation with T4 RNA ligase of which the overall reaction is shown in Scheme 1. The study can provide insight into the contribution of the formation of a substrate double-helix and terminal base-pair to the RNA ligation.

Scheme 1.

Experimental

Materials. UGCGCA, AUGC, AUGCA, AUGCG, and XAUGCAU (X=A, U, G, C) were synthesized chemically on a solid support with phosphoramidite procedures[9] and purified with high-performance liquid chromatography (HPLC) after deblocking. AUG was purchased from Sigma Chemical Co. These oligomers were further purified and desalted with a C-18 Sep-Pak cartridge. Final purity of the oligomers was checked by HPLC and was greater than at least 95%. The concentration of the oligomers was determined as described previously.[10]

Nucleotides 3′,5′-bisphosphates (pZp), albumin from bovine serum (BSA), and T4 RNA ligase were purchased from Pharmacia, Sigma Chem. Co., and BRL Inc., respectively. Adenosine 5′-triphosphate (ATP) and dithiothreitol (DTT) were products of Wako Chem. Ind.

T4 RNA Ligase Reaction. The RNA ligase reaction mixture contained 2×10^{-1} mol dm^{-3} Tris-HCl (pH 7.5), 2×10^{-2} mol dm^{-3} $MgCl_2$, 7.5×10^{-3} mol dm^{-3} ATP, 5×10^{-3} mol dm^{-3} DTT, 25×10^{-9} g dm^{-3} BSA, 1×10^{-3} mol dm^{-3} acceptor RNA oligomer, and 25 to 90 unit/ml (U/ml) of the enzyme. At the assay for the reaction, 4×10^{-3} mol dm^{-3} donor pZp was also present in the reaction mixture. After incubation for adequate times, mainly for 1 h at 37 °C, the reaction mixture was heated for 2 min at 100 °C and treated with alkaline phosphatase for 20 min at 65 °C.[11]

The analysis was performed by HPLC using a Tosoh LC System and a Cosmosil Packed Column 5C18-AR onto which aliquots from the reaction mixtures were injected. The analysis was done at a flow rate of 1 ml min^{-1} with a 50-min linear gradient from 0 to 25% methanol containing 10^{-1} mol dm^{-3} NaH_2PO_4. The peaks at 254 nm corresponding to the substrates, intermediates, and products were integrated using a Tosoh Sic Chromatocorder 12. The extent of reaction was determined by the ratio of the peak area of the product to that of the substrate. The HPLC analysis indicated no significant loss of the substrate due to contaminating nucleases.

Spectroscopy. UV absorbance spectra of the RNA oligomers were measured on a Tosoh UV 8011 spectrophotometer. Their UV melting curves (absorbance vs. temperature curves) were measured on a Hitachi U-3200 programmable spectrophotometer equipped with a Hitachi SPR-7 temperature controller. The heating rate was 0.5 or 1 °C min^{-1}. A melting temperature, T_m, at each oligomer concentration of 10^{-3} mol dm^{-3} was determined by Eq. 1:[12]

$$T_m = \Delta H^\circ / (\Delta S^\circ + R \ln(C_t)), \quad (1)$$

where ΔH° and ΔS° were the enthalpy and entropy changes for the double-helix formation of the oligomer,[7] R was the gas constant, and C_t was 10^{-3} mol dm^{-3}. Circular dichroism (CD) spectra of the oligomers were measured on a JASCO J-600 spectropolarimeter equipped with the temperature controller.

Stability Calculation of RNA Duplexes. The stability energy of the oligomer duplexes was obtained from nearest-neighbor thermodynamic parameters[7,12] as described previously.[13] For example, the entropy change ΔS° for the formation of the self-complementary UGCGCA duplex was calculated as follows:

$$\begin{aligned}\Delta S^\circ &= \Delta S^\circ(\text{initi}) + \Delta S^\circ(\text{sym}) + \Delta S^\circ(\text{UG/AC}) \\ &\quad + \Delta S^\circ(\text{GC/CG}) + \Delta S^\circ(\text{CG/GC}) \\ &\quad + \Delta S^\circ(\text{GC/CG}) + \Delta S^\circ(\text{CA/GU}) \\ &= (-10.8) + (-1.4) + (-27.8) + (-34.9) + (-19.4) \\ &\quad + (-34.9) + (-17.8) \\ &= -157.0 \text{ cal K}^{-1} \text{ mol}^{-1},\end{aligned}$$

where ΔS°(initi) was an entropy change for the initiation of making the first base pair in the region, ΔS°(sym) was the correction entropy-factor for the self-complementary sequence, and ΔS°(UG/AC), ΔS°(GC/CG), ΔS°(CG/GC), ΔS°(GC/CG), and ΔS°(CA/GU) were propagation entropy-changes for making each subsequent base pair. Similarly, the enthalpy change

$$\Delta H^\circ = -57.4 \text{ kcal mol}^{-1}.$$

Therefore, the free-energy change at 37 °C, ΔG°_{37}, which was the stability energy of the UGCGCA duplex, was obtained as follows:

$$\begin{aligned}\Delta G^\circ_{37} &= \Delta H^\circ - T\Delta S^\circ \\ &= (-57.4) - (273 + 37) \times (-157.0 \times 10^{-3}) \\ &= -8.7 \text{ kcal mol}^{-1}.\end{aligned}$$

The value of ΔG°_{37} gives the equilibrium constant, K, of the transition of the single-stranded RNA to the double-helix 1.4×10^6 mol^{-1} dm^3 at 37 °C in Eq. 2:

$$K = \exp(-\Delta G^\circ_{37}/RT) = 1.4 \times 10^6 \text{ mol}^{-1} \text{ dm}^3. \quad (2)$$

Results and Discussion

HPLC Chromatograms of Substrate and Product at Each Reaction Time. The ligations as shown in Scheme 1 were performed under the standard conditions of an 1-hour to 20-hour incubation at 37 °C with an acceptor : donor ratio of 1 : 4. Figure 1 shows the HPLC chromatograms of the ligation mixture of AAUGCAU to pUp at several reaction times. As shown in Fig. 1, only two peaks which are due to the substrate AAUGCAU and the product AAUGCAUUp can be detected after a 40-min flow, although the peaks of pUp, ATP, ADP, and AMP are observed before a 30-min flow. The yields of the product were 51, 90, and 100% at 1, 4, and 8 h, respectively.

Ligation of Single-Stranded Acceptors to Pyrimidine and Purine Donors. The yields of the products in the reaction of single-stranded RNA acceptors to pyrimidine and purine donors are listed in Table 1 with the results of Romaniuk et al.[14] The melting temperatures of AAU and AUGCA which have the possibility of the formation of the self-complementary double-helix are calculated to be less than 0 and 29 °C, respectively, suggesting these oligomers are mainly single-stranded at 37 °C. In the case of pyrimidine donors in the ligation of AUG acceptor, the yield of the product for pCp donor is larger than that for pUp donor. The same tendency for the pyrimidine donors is observed in the reaction of AAU acceptor. In the reaction of the acceptors containing a different sequence and a different strand length (Entry Nos. 5—8 in Table 1), pCp donor also gives the larger yield than pUp.

In the case of purine donors in the ligation of AUGC acceptor, pAp donor gives the larger yield than pGp. The same tendency for the donors is detected in the reaction of AAU acceptor having a different sequence and a different strand length (Nos. 11 and 12 in Table 1).

a) Conditions: acceptor, 0.5 mM; donor, 1.0 mM; ATP, 3.3 mM; incubated at 37 °C in Ref. 14.

Ligation of Double-Stranded Acceptor to Pyrimidine and Purine Donors. Table 2 shows the stabilization energies at 37 °C, ΔG°_{37}, the melting temperatures, T_m, and the equilibrium constants, K, for the self-complementary double helices of UGCGCA, AUGCGCA, AUGCAU, and XAUGCAU (X=A, U, G, C). In Table 2, the calculated and observed T_m value for UGCGCA of 62.6 and 63.1 °C, respectively, suggests that the acceptor forms the self-complementary duplex at 37 °C which is the temperarure of the ligation in this work. The ΔG°_{37} value of −8.7 kcal mol^{-1} and the K value of 1.4×10^6 mol^{-1} dm^3 indicate that the oligomer exists almost as the duplex at 37 °C. In addition, the duplex of the oligomer may form an A-type double helix,[15] because, in Table 2, the T_m value calculated using A-type nearest-neighbor parameters[7,12] is consistent with the observed value. Therefore, all the results support the UGCGCA acceptor is not single-stranded but double-stranded at the reaction temperature.

The yields of the products in the reaction of double-stranded UGCGCA acceptor to pyrimidine and purine donors are listed in Table 3. In the case of pyrimidine donors, the yield of the product for pCp donor is larger than that for pUp donor. On the other hand, in the case of purine donors, pAp donor gives the larger yield than pGp. These are the same results observed in the case of the single-stranded RNA acceptor as shown in Table 1. Therefore, whether the acceptor is single-stranded or double-stranded does not affect the efficiency of the RNA ligation.

Ligation of Double-Stranded Acceptors Containing Dangling Ends to pZp Donors. In Table 2, the values of ΔG°_{37}, T_m, and K for AUGCGCA and XAUGCAU (X=A, C, G, U) show that these oligomers exist almost as the self-complementary duplexes at 37 °C as well as UGCGCA and AUGCAU. CD spectra of these oligomers support the above consideration: Figure 2 shows a typical CD spectrum of 10^{-3} mol dm^{-3} AAUGCAU in a 2×10^{-1} mol dm^{-3} Tris-HCl (pH 7.5), 2×10^{-2} mol dm^{-3} $MgCl_2$ buffer at 37 °C. The CD spectrum indicates a large positive peak at 278 nm and a small negative peak at 237 nm which are well-known to be due to a A-type RNA double helix.

In Table 2, the T_m value of AUGCGCA is 3.6 °C higher than that of UGCGCA. Also, in the case of the dangling ends on AUGCAU in the same table, the T_m values of XAUGCAU are about 4—6 °C higher than that of AUGCAU. The values of ΔG°_{37} in Table 2 show that the double helix having each dangling end is about 0.2 or 0.3 kcal mol^{-1} more stable than the core double helix of UGCGCA or AUGCAU. These results suggest the dangling nucleotide stabilizes the core double helix with its stacking interaction.[7]

In the ligation of purine donors to the AUGCGCA double-stranded acceptors having the A dangling end, the yield of the product for pAp donor is higher than that for pGp donor as shown in Entry Nos. 3 and 4 in Table 4. The result is the same in the cases of the single-stranded RNA acceptors and the double-stranded UGCGCA acceptor. In contrast, in the case of pyrimidine donors, pUp donor gives the yield of 12% higher than pCp, even under the lower enzyme unit of 25 U/ml, in Nos. 1 and 2 in Table 4, which is the opposite tendency as observed in the above cases, that is, the cases of the single-stranded and double-stranded accep-

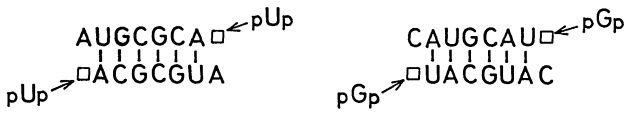

Fig. 3. The schematic illustrations of pUp and pGp donors approaching the dangling **A** and **C** nucleotide on AUGCGCA and CAUGCAU self-complementary duplexes, respectively.

tors. Even in comparison with pyrimidine donors, the pUp donor gives the highest yield of the product for 1 h. The result leads to the consideration that the pUp donors can approach most easily the dangling **A** nucleotide with a base-pair interaction[15] between the U and A nucleotides as shown in Fig. 3.

In the reaction of the double-stranded CAUGCAU acceptor having the **C** dangling end, pyrimidine donors show the same tendency observed in the single-stranded and double-stranded acceptors having no dangling end, but purine donors indicate the opposite tendency, that is, pGp gives the yield of the product 27% higher than pAp (Nos. 5—8 in Table 4). The yield of the product for pGp is the highest value for all the donors. The result supports the consideration that a base-pair interaction between the **G** and **C** nucleotides in Fig. 3 has a large effect on the ligation. Therefore, the base-pair interaction in the case of the **A** and **C** dangling ends accelerates the RNA ligation.

It follows that the base-pair formation in the reaction of the acceptors having different dangling ends to the same donor should accelerate the reaction rate more than the mismatch interactions such as GA, GU, and GG interactions.[16] In order to examine the above idea, the ligation of the pGp donor to the double stranded XAUGCAU (X=A, C, G, U) acceptors were

Table 5. The Yield of the Product in the Reaction of Double-Stranded RNA Acceptors Having Dangling Ends with pGp

Entry No.	Acceptor X···Y	Donor pZp	Enzyme concn U/ml	Time h	Yield %
1	AAUGCAU / UACGUAA	G	50	1	50
2	CAUGCAU / UACGUAC	G	50	1	100
3	GAUGCAU / UACGUAG	G	50	1	37
4	UAUGCAU / UACGUAU	G	50	1	41

studied. In Table 5, the 100% yield of the product for CAUGCAU is the largest value in comparison with the 50, 37, and 41% yield for AAUGCAU, GAUGCAU, and UAUGCAU, respectively. The result suggests the base-pair interaction between the dangling X nucleotide on the core double helix and the pZp donor, in general, accelarate the rate of the RNA ligation by its making the donor approaching easily the ligation site of the acceptor. Therefore, the study in this paper suggests that the interaction between the substrates such as the base-pair interaction between the unpaired terminal nucleotide on the double helix of the RNA acceptor and the donor as well as the interaction of the substrates with the enzyme,[17] plays a very important role in the RNA ligation with T4 RNA ligase.

The authors thank Professor D. H. Turner and Dr. S. M. Freier, University of Rochester, for their help in getting started. This work was partly supported by a Grant-in-Aid for Scientific Research on Priority Areas from the Ministry of Education, Science and Culture.

Synthesis of 14,14-Difluoro-4-demethoxydaunorubicin[1)]

Fuyuhiko MATSUDA, Teruyo MATSUMOTO, Masako OHSAKI, and Shiro TERASHIMA*
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229
(Received May 29, 1991)

The title compound, (+)-14,14-difluoro-4-demethoxydaunorubicin hydrochloride (**9**), was prepared starting from the readily available (−)-hydroxy ester (**10**). This synthesis featured the efficient synthetic route to (−)-14,14-difluoro-4-demethoxy-7-deoxydaunomycinone (**20**) employing the Reformatsky reaction of ethyl bromodifluoroacetate with the (−)-siloxy aldehyde (**14**) and previously developed glycosylation method in which trimethylsilyl trifluoromethanesulfonate was used as an activator. In P388 *in vitro* test, **9** was found to be fifty times more active than adriamycin (**1**). Prominent antitumor activity was also observed for **9** in P388 *in vivo* test.

The anthracyclines, represented by adriamycin (**1**) and daunorubicin (**2**), are important anticancer agents exhibiting clinical effectiveness against leukemia and solid tumors.[2,3)] However, their utility for cancer chemotherapy is seriously restricted by various undesired side effects, the most notable of which is dose-related cardiotoxicity. Thus, numerous attempts have been made to prepare various structural types of congeners by chemical synthesis with an aim to overcome these disadvantages. Among synthetically elaborated analogues of **1** and **2**, unnatural 4-demethoxyadriamycin (**3**) and 4-demethoxydaunorubicin (**4**) have been reported to show better therapeutic indices than natural **1** and **2**.[2–4)]

On the other hand, a large number of the fluorinated biologically active compounds have been synthesized in the last decade to improve therapeutic property of the parent compounds or to explore novel pharmacological activity.[5)] In the field of anthracyclines, some derivatives possessing fluorinated sugar[6)] or D-ring[7)] have been synthesized. In conjunction with our program directed toward the development of novel synthetic anthracycline congeners as anticancer agents, we achieved the first synthesis of the 14-fluoroanthracyclines (**5**—**8**) which had a fluoroacetyl group as their C-9 side chain. Furthermore, these novel anthracyclines showed potent antitumor activity against P388 murine leukemia *in vitro* and *in vivo*.[8)] Thus, taking into account of these results, we are interested in evaluating the antitumor activity of 14,14-difluoro-4-demethoxydaunorubicin (**9**), the most representative member of 14,14-difluoroanthracyclines. Recently, the first synthesis of **9** has been accomplished by employing the Reformatsky reaction of ethyl bromodifluoroacetate as a key step. Moreover, **9** was found to exhibit prominent *in vitro* cytotoxicity and *in vivo* antitumor activity against P388 murine leukemia.[1)] This report deals with full details of the synthesis and antitumor activity of the novel 14,14-difluoroanthracycline (**9**).

Results and Discussion

Preparation of 14,14-Difluoro-4-demethoxydaunomycinone. Numerous preliminary experimentations were carried out using racemic anthracyclinone derivatives to construct a difluoroacetyl side chain at the C-9 position. At the outset of this work, introduction of fluorine atom into the C-14 position of racemic 14-fluoro-4-demethoxy-7-deoxydaunomycinone (*dl*-**15**) was examined according to the fluorination method previously explored for 7-deoxydaunomycinones.[8)] However, attempted bromination of *dl*-**15** always produced complex mixtures of reaction products. Accordingly, the Reformatsky reaction of ethyl bromodifluoroacetate[9)] was next studied, which had been frequently used to introduce a difluorinated carbon chain.[10)] Although the Reformatsky reaction with the hydroxy aldehyde (*dl*-**13**) or the acylimidazole derivative generated from the hydroxy acid (*dl*-**16**)[11)] resulted in decomposition or recovery of the starting material respectively, it was finally uncovered that the reaction with the siloxy aldehyde (*dl*-**14**) successfully produced the addition product, β-hydroxy ester (*dl*-**17**). In contrast, *dl*-**17** could not be obtained from *dl*-**14** when methyl difluoroiodoacetate[12)] was employed instead of ethyl bromodifluoroacetate probably due to instability of the zinc enolate generated *in situ*. The racemic aldehydes (*dl*-**13** and *dl*-**14**) could be prepared from the hydroxy ester (*dl*-**10**)[11)] according to the same procedures as described for optically active compounds (vide infra). On the basis of these results, an efficient synthetic method of 14,14-difluoro-4-demethoxy-7-deoxydaunomycinone (**20**) as described below was eventu-

ally explored employing the Reformatsky reaction of ethyl bromodifluoroacetate with **14** as a key step.

The synthesis of optically pure **14** was carried out by utilizing the readily available optically pure (−)-hydroxy ester (**10**),[11] mp 214—215 °C, $[\alpha]_D^{20}$ −63.6° (*c* 0.110, $CHCl_3$), as the starting material. Reduction of **10** with sodium borohydride in the presence of cerium(III) chloride heptahydrate yielded the (−)-diol (**11**). The reduction product (**11**) was purified by silica-gel chromatography in a form of the corresponding (−)-acetonide (**12**), mp 220—223 °C, $[\alpha]_D^{20}$ −51.0° (*c* 0.050, $CHCl_3$), because of its sparing solubility in usual organic solvents. According to this procedure, **12** could be obtained in a higher yield (78% from **10**) than that previously reported for the reduction of **10** with lithium tri-*t*-butoxyaluminum hydride (55% from **10**).[11] Acidic hydrolysis of **12** yielded a pure sample of **11**, mp 260—263 °C, $[\alpha]_D^{20}$ −50.0° (*c* 0.060, dioxane). The (−)-siloxy aldehyde (**14**), mp 251—252 °C, $[\alpha]_D^{20}$ −76.9° (*c* 0.104, $CHCl_3$), was derived from **11** by sequential oxidation and silylation of the resulting (−)-hydroxy aldehyde (**13**), mp 248—249 °C, $[\alpha]_D^{20}$ −54.5° (*c* 0.110, dioxane).

The Reformatsky reaction of ethyl bromodifluoroacetate with **14** took place cleanly under the usual conditions,[9] giving rise to the β-hydroxy ester (**17**) as an epimeric mixture. The ratio of two epimers estimated by the ^1H NMR spectra of the mixture was 2 : 1. Without separation of the epimers, **17** was oxidized to the (−)-β-keto ester (**18**), mp 119—121 °C, $[\alpha]_D^{20}$ −91.8° (*c* 0.098, $CHCl_3$), using the Dess–Martin periodinane[13] as an oxidizing reagent. The oxidation of **17** appeared to be exceptionally difficult. Oxidants other than the Dess–Martin reagent resulted in complete recovery of **17**.[14] Sequential hydrolysis of the ethyl ester and decarboxylation of the formed β-keto acid (**19**) afforded (−)-14,14-difluoro-4-demethoxy-7-deoxydaunomycinone (**20**),[16] mp 225—228 °C, $[\alpha]_D^{20}$ −26.1° (*c* 0.153, dioxane).

Next, preparation of 14,14-difluoro-4-demethoxydaunomycinone (**21**) from **20** was examined. Since all the attempts to protect the ketonic function of **20** in a form of acetal met with failure probably due to the adjacent two fluorine atoms, direct introduction of the C_7-hydroxyl group was studied. Bromination of **20** with bromine under irradiation followed by immediate treatment of the resulting unstable C_7-bromide with aqueous alkali gave (+)-14,14-difluoro-4-demethoxydaunomycinone (**21**),[16] mp 210—213 °C, $[\alpha]_D^{20}$ +44.2° (*c*

0.113, dioxane), along with its $C_{7\beta}$-epimer in a form of the (−)-hemiacetal (**22**), mp 253—255 °C, $[\alpha]_D^{20}$ −153° (*c* 0.157 dioxane). The mixture of **21** and **22** could be separated by preparative TLC on silica gel. The stereochemistry of the C_7-position of **21** was established by the ^{1}H NMR spectrum ($CDCl_3$) which showed a W_H value of 8.0 Hz for the signal of the $C_{7\beta}$-H [δ=5.36—5.45 (m)]. On the other hand, in the ^{1}H NMR spectrum ($CDCl_3$) of **22**, a single triplet assignable to the C_{14}-methine proton appeared at δ=5.58 (J=54 Hz). Thus, it becomes apparent that **22** consists of a single hemiacetal whose stereostructure at the hemiacetal carbon could not be determined. All the attempts to epimerize **22** under acidic conditions[17] resulted in simple recovery of the starting material. Additionally, 14,14-difluoro-7-deoxydaunomycinone (**20**) could be obtained only in low yield (32%) by hydrogenolysis of **22** following the reported procedure (H_2, Pd–$BaSO_4$, MeOH, rt, 2 h).[18] These phenomena might originate from the electron-withdrawing effect accumulated by the two fluorine atoms making the hemiacetal form highly stable.

Preparation of 14,14-Difluoro-4-demethoxydaunorubicin. With **21** in hand, glycosylation was attempted using the L-daunosamine derivative according to the procedure previously reported by us.[19] Thus, **21** was allowed to react with 3-*N*-trifluoroacetyl-1,4-bis-*O*-(*p*-nitrobenzoyl)-L-daunosamine[19] in the presence of trimethylsllyl trifluoromethanesulfonate. The formed glycoside was treated with dilute alkali to effect hydrolysis of the 4′-*O*-*p*-nitrobenzoyl group, affording (+)-3′-*N*-trifluoroacetyl-14,14-difluoro-4-demethoxydaunorubicin (**23**),[16] $[\alpha]_D^{20}$ +117° (*c* 0.163, dioxane), as a sole product. The α-glycoside structure of **23** could be readily confirmed by the coupling pattern of the $C_{1'}$-H [δ=5.53 (d, J=4.2 Hz)] in the ^{1}H NMR spectrum ($CDCl_3$) of **23**. The assigned structure was further supported by comparison of the ^{1}H NMR spectrum with that of 3′-*N*-trifluoroacetyl-4-demethoxydaunorubicin.[19] Further alkaline hydrolysis of the 3′-*N*-trifluoroacetyl group followed by salt formation furnished (+)-14,14-difluoro-4-demethoxydaunorubicin hydrochloride (**9**), mp 168—171 °C, $[\alpha]_D^{20}$ +111° (*c* 0.090, MeOH). The ^{1}H NMR and ^{19}F NMR spectra (DMSO-d_6+D_2O) of **9** proved that this compound was composed of a mixture of the ketonic and the hydrate forms (3:1 by ^{1}H NMR).[16] Representative NMR spectral data are as follows; **9**: ^{1}H NMR δ=6.04 (t, J=55.8 Hz, CHF_2, hydrate), 6.85 (t, J=52.9 Hz, CHF_2, ketone); ^{19}F NMR δ=−128.0 (d, J=52.9 Hz, ketone), −131.2 (d, J=55.8 Hz, hydrate).

Antitumor Activity of 14,14-Difluoro-4-demethoxydaunorubicin. 14,14-Difluoro-4-demethoxydaunorubicin (**9**) was subjected to P388 murine leukemia *in vitro* assay along with its 3′-*N*-trifluoroacetyl derivative (**23**). While **23** showed comparable cytotoxicity (IC_{50}= 1.1×10^{-3} μg ml^{-1})[20] to that of adriamycin (**1**) (IC_{50}= 2.5×10^{-3} μg ml^{-1}), **9** was found to be at least fifty-fold more active (IC_{50}=4.6×10^{-5} μg ml^{-1}) than **1**. Since cytotoxicity of 14-fluoro-4-demethoxydaunorubicin (**6**) has already been disclosed to be compared well with that of **1**,[8] it appeared that **9** was obviously more cytotoxic than **6**. Furthermore, in P388 *in vivo* test,[21] it turned out that **9** exhibited potent inhibitory activity [T/C=161% (1.0 mg kg^{-1})].[22]

Further investigations aimed at characterizing antitumor activity of **9** are in progress and will be reported shortly.

Experimental

General. All melting points were determined with a Yamato MP-21 melting point apparatus and are uncorrected. Measurements of optical rotations were carried out by using a Horiba SEPA-200 automatic digital polarimeter. IR spectral measurements were performed with a JASCO A-202 IR spectrometer. ^{1}H NMR spectra were measured with a Hitachi R-90H spectrometer (90 MHz) and a Bruker AM-400 spectrometer (400 MHz). Measurement of ^{19}F NMR spectra were carried out with a Varian XL-100 spectrometer (94 MHz). All ^{1}H and ^{19}F-signals were expressed as ppm downfield from tetramethylsilane ($SiMe_4$) and trichlorofluoromethane ($CFCl_3$), respectively, used as an internal standard (δ-value). The following abbreviations are used: singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broad (br). Assignments of peaks are indicated according to the numbering of IUPAC nomenclature. Mass spectra (MS) were taken with a Hitachi RMU-6MG mass spectrometer (EI-MS) and a Hitachi M-80A mass spectrometer (SI-MS). Wako Gel C-200 and Merck Silica Gel $60F_{254}$ were used for column chromatography and preparative thin-layer chromatography (TLC), respectively. All reactions were performed by using anhydrous solvents. In particular, tetrahydrofuran and ether freshly distilled from sodium benzophenone ketyl, and commercially available dichloromethane stabilized with 2-methyl-2-butene were used. The following abbreviations are used for solvents; acetic acid (AcOH), carbon tetrachloride (CCl_4), chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), ethyl acetate (AcOEt), methanol (MeOH), tetrahydrofuran (THF), toluene (PhMe).

(*R*)-6,8,11-Trihydroxy-8-hydroxymethyl-7,8,9,10-tetrahydro-5,12-naphthacenedione (11). $NaBH_4$ (8.11 g, 214 mmol) was added in small portions to a stirred solution of (*R*)-6,8,11-trihydroxy-8-methoxycarbonyl-7,8,9,10-tetrahydro-5,12-naphthacenedione (**10**),[11] mp 214—215 °C, $[\alpha]_D^{20}$ −63.6° (*c* 0.110, $CHCl_3$), (7.89 g, 21.4 mmol) and $CeCl_3\cdot7H_2O$ (40.0 g, 107 mmol) in a mixture of $CHCl_3$ (400 ml) and MeOH (160 ml) cooled at 0 °C. The reaction mixture was allowed to warm up to ambient temperature and stirring was continued at the same temperature for 3 h. After further amounts of $CeCl_3\cdot7H_2O$ (40.0 g, 107 mmol) and $NaBH_4$ (8.11 g, 214 mmol) were successively added at room temperature, the reaction mixture was further stirred at the same temperature for 4 h. The mixture was poured into 1 mol dm^{-3} HCl, and extracted with a mixture of AcOEt and THF. The combined organic extracts were washed with H_2O, and dried over anhydrous $MgSO_4$. Filtration and concentration in vacuo gave crude **11**, which was dissolved in a mixture of THF (420 ml) and acetone (210 ml). After 2,2-dimethoxypropane (830 ml) and *d*-10-camphorsulfonic acid (800 mg, 3.44 mmol) were successively added to the solution at ambient temperature, the mixture was stirred at the same temperature for 4 h, poured

into saturated $NaHCO_3$, and extracted with $CHCl_3$. The organic layers were combined, washed successively with H_2O and brine, dried over anhydrous $MgSO_4$, filtered, then concentrated in vacuo. The residue was purified by column chromatography (SiO_2, PhMe–AcOEt 200:1) to give (*R*)-5′,12′-dihyroxy-2,2-dimethyl-3′,4′-dihydrospiro[1,3-dioxolane-4,2′(1′*H*)-naphthacene]-6′,11′-dione (**12**) as a red solid (6.37 g, 78%), mp 220—223 °C, $[\alpha]_D^{20}$ −51.0° (*c* 0.050, $CHCl_3$) [lit,[11] mp 222—223 °C, $[\alpha]_D^{20}$ −52.0° (*c* 0.050, $CHCl_3$)]. Spectral and chromatographic comparison showed that **12** was identical with an authentic sample.[11]

Twelve mol dm^{-3} hydrochloric acid (160 ml) was added to a suspension of **12** (6.37 g, 16.9 mmol) in THF (640 ml) at room temperature. After stirring at the same temperature for 4 h, the mixture was poured into ice-water, and extracted with a mixture of AcOEt and THF. The combined extracts were washed successively with H_2O and saturated $NaHCO_3$. dried over anhydrous $MgSO_4$, filtered, then concentrated in vacuo. Trituration of the residue with ether gave pure **11** as a dark orange solid (5.12 g, 90%), mp 260—263 °C, $[\alpha]_D^{20}$ −50.0° (*c* 0.060, dioxane) [lit,[11] mp 265—267 °C, $[\alpha]_D^{20}$ −52.0° (*c* 0.050, dioxane)]. The spectra and chromatographic behaviors of this sample were identical with those of an authentic sample.[11]

(*R*)-8-Formyl-6,8,11-trihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (13). A suspension of sulfur trioxide pyridine complex (467 mg, 2.93 mmol) in DMSO (1.0 ml) was added with stirring under an Ar atmosphere to a solution of **11** (49.8 mg, 0.146 mmol) and triethylamine (0.61 ml, 4.38 mmol) in DMSO (3.0 ml) at ambient temperature. After stirring at the same temperature for 10 min, the mixture was poured into 1 mol dm^{-3} HCl, and extracted with AcOEt. The combined organic layers were washed successively with H_2O and brine, and dried over anhydrous Na_2SO_4. Filtration and concentration in vacuo gave the crude product, which was purified by column chromatography (SiO_2, PhMe–AcOEt 20:1→10:1), affording pure **13** as a red powder (39.0 mg, 79%). This was recrystallized from PhMe, giving an analytical sample of **13** as red crystals, mp 248—249 °C, $[\alpha]_D^{20}$ −54.5° (*c* 0.110, dioxane). IR (KBr) 3500, 1730, 1620, 1580 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.80—2.00 (2H, m, C_9–H_2), 2.50 (1H, s, C_8–OH), 2.97—3.20 (4H, m, C_7–H_2, C_{10}–H_2), 7.77—7.93, 8.30—8.50 (each 2H, m, ArH×4), 9.75 (1H, s, CHO), 13.50 (2H, s, ArOH×2). EI-MS *m*/*z* 338 (M^+), 309 (M^+ −CHO), 291. Anal. Calcd for $C_{19}H_{14}O_6$: C, 67.45; H, 4.17%. Found: C, 67.18; H, 4.22%. The racemic hydroxy aldehyde (*dl*-**13**) prepared by the same procedure as described above, showed mp 251—253 °C. The ^{1}H NMR spectrum ($CDCl_3$) of *dl*-**13** was identical with that of the optically active compound.

(*R*)-8-*t*-Butyldimethylsilyloxy-8-formyl-6,11-dihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (14). 2,6-Lutidine (25.2 ml, 216 mmol) and *t*-butyldimethylsilyl trifluoromethanesulfonate (50.5 ml, 220 mmol) was successively added under an Ar atmosphere to a stirred suspension of **13** (3.69 g, 10.9 mmol) in CH_2Cl_2 (80 ml) at 0 °C. After stirring was continued at the same temperature for 30 min, the reaction mixture was allowed to warm up to room temperature, then stirred at the same temperature for 5 h. The mixture was poured into saturated $NaHCO_3$, and extracted with $CHCl_3$. The extracts were combined, washed successively with H_2O and brine, dried over anhydrous Na_2SO_4, filtered, then concentrated in vacuo. Recrystallization of the residue from PhMe gave pure **14** as orange crystals (4.23 g, 86%), mp 251—252 °C, $[\alpha]_D^{20}$ −76.9° (*c* 0.104, $CHCl_3$). IR (KBr) 3450, 2880, 1730, 1620, 1590 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=−0.10, 0.15 (each 3H, s, $SiMe_2$), 0.83 (9H, s, ^{t}Bu), 1.63—2.20 (2H, m, C_9–H_2), 2.83—3.20 (4H, m, C_7–H_2, C_{10}–H_2), 7.70—7.90, 8.23—8.47 (each 2H, m, ArH×4), 9.30 (1H, s, CHO), 12.95, 12.98 (each 1H, s, ArOH×2). EI-MS *m*/*z* 452 (M^+), 437 (M^+ −Me) 395 (M^+ −^{t}Bu). Anal. Calcd for $C_{25}H_{28}O_6Si$: C, 66.35; H, 6.24%. Found: 66.57; H, 6.25%. The racemic siloxy aldehyde (*dl*-**14**) prepared by the same procedure as described above, showed mp 255—257 °C. The ^{1}H NMR spectrum ($CDCl_3$) of *dl*-**14** was identical with that of the optically active compound.

(*R*)-8-*t*-Butyldimethylsilyloxy-8-(2-ethoxycarbonyl-2,2-difluoro-1-hydroxyethyl)-6,11-dihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (17). A mixture of Zn (1.28 g, 19.5 mmol) and ethyl bromodifluoroacetate[9] (4.22 g, 20.8 mmol) in THF (60 ml) was heated at reflux under an Ar atmosphere for 1 min. After a solution of **14** (588 mg, 1.30 mmol) in THF (60 ml) was added under reflux to the reaction mixture, stirring was continued under reflux for 30 min. After cooling, the mixture was poured into 1 mol dm^{-3} $KHSO_4$ cooled in an ice bath, and extracted with AcOEt. The combined extracts were washed with brine, and dried over anhydrous Na_2SO_4. Filtration and concentration in vacuo gave the crude product, which was chromatographed (SiO_2, PhMe–AcOEt 50:1→30:1) to give pure **17** (a 2:1 mixture of the diastereomers by ^{1}H NMR) as a red amorphous powder (313 mg, 42%). IR (KBr) 3500, 1760, 1620, 1580 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.00, 0.20 (each 3H, s, $SiMe_2$), 0.90, 0.92 (total 9H, each s, ^{t}Bu), 1.33 (3H, t, *J*=6.0 Hz, CH_2*Me*), 1.80—2.50 (2H, m, C_9–H_2), 2.60—3.67 (4H, m, C_7–H_2, C_{10}–H_2), 3.70—4.20 (1H, m, $C_{1'}$–H), 4.35 (2H, q, *J*=6.0 Hz, CH_2Me), 7.60—7.93, 8.20—8.40 (each 2H, m, ArH×4), 13.40, 13.46, 13.44 (total 2H, each s, ArOH×2). ^{19}F NMR ($CDCl_3$) δ=−106.4 (d, *J*=260.0 Hz), −106.7 (d, *J*=257.0 Hz), −124.3 (dd, *J*=260.0, 20.0 Hz), −125.9 (dd, *J*=257.0, 22.5 Hz). EI-MS *m*/*z* 577 (M^+ +H), 519 (M^+ −^{t}Bu).

(*R*)-8-*t*-Butyldimethylsilyloxy-8-ethoxycarbonyldifluoroacetyl-6,11-dihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (18). Dess–Martin reagent (428 mg, 1.01 mmol) was added under an Ar atmosphere to a stirred solution of **17** (116 mg, 0.202 mmol) in CH_2Cl_2 (20 ml) at 0 °C. The reaction mixture was allowed to warm up to room temperature, stirred at the same temperature for 20 min, poured into saturated $NaHCO_3$ containing excess $Na_2S_2O_3$, and extracted with ether. The organic layers were combined, washed successively with saturated $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, filtered, then concentrated in vacuo. The residue was purified by column chromatography (SiO_2, PhMe–AcOEt 30;1), giving pure **18** as an orange solid (52.0 mg, 45%). This was recrystallized from hexane–PhMe to afford an analytical sample of **18** as orange crystals, mp 119—121 °C, $[\alpha]_D^{20}$ −91.8° (*c* 0.098, $CHCl_3$). IR (KBr) 3450, 1790, 1740, 1620, 1600 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.01, 0.19 (each 3H, s, $SiMe_2$), 0.85 (9H, s, ^{t}Bu), 1.36 (3H, t, *J*=7.2 Hz, CH_2*Me*), 2.19 (1H, dt, *J*=13.2, 6.2 Hz, $C_{9\text{-ax}}$–H), 2.33 (1H, dt, *J*=13.2, 6.2 Hz, $C_{9\text{-eq}}$–H), 2.88 (1H, ddd, *J*=19.2, 7.4, 6.2 Hz, $C_{10\text{-ax}}$–H), 3.00 (1H, d, *J*=18.6 Hz, $C_{7\text{-aq}}$–H), 3.09 (1H, dt, *J*=19.2, 6.2 Hz, $C_{10\text{-eq}}$–H), 3.44 (1H, d, *J*=18.6 Hz, $C_{7\text{-eq}}$–H), 4.38 (2H, q, *J*=7.2 Hz, CH_2Me), 7.80—7.85, 8.34—8.38 (each 2H, m, ArH×4), 13.44, 13.50 (each 1H, s, ArOH×2). ^{19}F NMR ($CDCl_3$) δ=−109.1 (s). EI-MS *m*/*z* 575 (M^+ +H), 559 (M^+ −Me), 517 (M^+ −^{t}Bu). Anal. Calcd for $C_{29}H_{32}O_8F_2Si$: C, 60.61; H, 5.61%. Found: C, 60.57; H, 5.69%.

(*R*)-8-Difluoroacetyl-6,8,11-trihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione(14,14-difluoro-4-demethoxy-7-deoxydaunomycinone) (20). A 0.53 mol dm^{-3} solution of KOH (0.74 ml, 0.392 mmol) was added to a solution of **18** (102 mg, 0.177 mmol) in a mixture of THF (5.0 ml) and MeOH (5.0 ml) cooled in an ice bath. After stirring at 0 °C for 30 min, the mixture was neutralized with 1 mol dm^{-3} HCl (pH 7), diluted with brine, and extracted with AcOEt. The combined organic layers were washed with brine, and dried over anhydrous Na_2SO_4. Filtration and concentration in vacuo gave crude (*R*)-8-carboxydifluoroacetyl-6,8,11-trihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (**19**), which was dissolved in DMF (10 ml). The solution was heated at 60 °C for 35 min, poured into brine, extracted with AcOEt. The combined extracts were washed with brine, dried over anhydrous Na_2SO_4, filtered, then concentrated in vacuo. The residue was purified by preparative TLC (SiO_2, PhMe–AcOEt 1 : 1) and successive azeotropic removal of H_2O using PhMe[16] to afford pure **20** as a red powder (50.5 mg, 73%). Recrystalllzation from PhMe gave an analytical sample of **20** as red crystals, mp 225—228 °C, $[\alpha]_D^{20}$ −26.1° (*c* 0.153, dioxane). IR (KBr) 3500, 1750, 1620, 1590 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.00—2.30 (2H, m, C_9–H_2), 2.72 (1H, s, C_8–OH), 2.57—3.55 (4H, m, C_7–H_2, C_{10}–H_2), 6.40 (1H, t, *J*=4.3 Hz, CHF_2), 7.67—8.06, 8.20—8.57 (each 2H, m, ArH×4), 13.41 (2H, s, ArOH×2). ^{19}F NMR ($CDCl_3$) δ=−127.1 (d, *J*=54.3 Hz). EI-MS *m/z* 388 (M^+), 309,291. Anal. Calcd for $C_{20}H_{14}O_6F_2$: C, 61.86; H, 3.63%. Found: C, 61.67; H, 3.54%.

(8*S*,10*S*)-8-Difluoroacetyl-6,8,10,11-tetrahydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (14,14-Difluoro-4-demethoxydaunomycinone) (21) and (1*R*,3*S*)-13—Difluoromethyl-3,5,12,13-tetrahydroxy-1,2,3,4-tetrahydro-1,3-(epoxymethano)-6,11-naphthacenedione (22). A 0.083 mol dm^{-3} solution of Br_2 in CCl_4 (0.57 ml) was added with stirring to a mixture of **20** (30.5 mg, 0.0785 mmol) in a two-layer mixture of CCl_4 (3.1 ml), $CHCl_3$ (6.1 ml), and H_2O (4.6 ml) at ambient temperature, then the reaction mixture was stirred under irradiation with a 60 W tungsten lamp at the same temperature for 2.5 h. Further amounts of 0.083 mol dm^{-3} solution of Br_2 in CCl_4 (0.19 ml×7, total 1.90 ml, 0.158 mmol) were added after 15, 20, 25, 30, 35, 40, and 45 min. After cooling in an ice bath, 2.5 mol dm^{-3} NaOH (0.19 ml, 0.475 mmol) was added, and stirring was continued at 0 °C for 15 min. The mixture was neutralized with 1 mol dm^{-3} HCl (pH 7), and extracted with AcOEt. The combined organic layers were washed successively with H_2O and brine, dried over anhydrous Na_2SO_4, filtered, then concentrated in vacuo. The residue was separated by preparative TLC (SiO_2, $CHCl_3$–MeOH 10 : 1), affording pure **21** (containing a small amount of the hydrate form by ^{1}H NMR)[16] as a red powder (8.3 mg, 26%) and pure **22** as a red powder (9.8 mg, 31%). Recrystallizations of these from PhMe gave analytical samples of **21** and **22** as red crystals, respectively.

21: Mp 210—213 °C, $[\alpha]_D^{20}$ +44.2° (*c* 0.113, dioxane). IR (KBr) 3450, 1750, 1620, 1590 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.18 (1H, dd, *J*=14.8, 4.8 Hz, $C_{9\text{-aq}}$–H), 2.60 (1H, d, *J*=14.8 Hz, $C_{9\text{-eq}}$–H), 3.03 (1H, d, *J*=18.8 Hz, $C_{7\text{-ax}}$–H), 3.34 (1H, brs, C_{10}–OH), 3.40 (1H, dd, *J*=18.8, 2.3 Hz, $C_{7\text{-eq}}$–H), 4.76 (1H, s, C_8–OH), 5.36—5.45 (1H, m, C_{10}–H), 6.60 (1H, t, *J*=53.1 Hz, CHF_2), 7.79—7.94, 8.30—8.43 (each 2H, m, ArH×4), 13.27, 13.58 (each 1H, s, ArOH×2). ^{19}F NMR ($CDCl_3$) δ=−129.5, −130.0 (each dd, *J*=315.0, 53.1 Hz). EI-MS *m/z* 404 (M^+), 386, 368, 317, 307, 289. High-resolution MS, Found: *m/z* 404.0706. Calcd for $C_{20}H_{14}O_7F_2$: M, 404.0706.

22: Mp 253—255 °C, $[\alpha]_D^{20}$ −153° (*c* 0.157, dioxane). IR (KBr) 3500, 1625, 1590 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.04 (1H, dd, *J*=11.2, 1.8 Hz, $C_{2\text{-ax}}$–H), 2.78 (1H, ddd, *J*=11.2, 5.7, 1.8 Hz, $C_{2\text{-eq}}$–H), 3.24 (1H, d, *J*=19.5 Hz, $C_{4\text{-ax}}$–H), 3.40 (1H, d, *J*=19.5 Hz, $C_{4\text{-eq}}$–H), 5.58 (1H, t, *J*=54.5 Hz, CHF_2), 5.74 (1H, dd, *J*=5.7, 1.0 Hz, C_1–H), 7.82—7.88, 8.32—8.39 (each 2H, m, ArH×4), 13.15, 13.23 (each 1H, s, ArOH×2). ^{19}F NMR ($CDCl_3$) δ=−1287, −136.3 (each dd, *J*=347.0, 54.5 Hz). EI-MS *m/z* 404 (M^+), 368, 308, 290. High-resolution MS, Found: *m/z* 404.0703. Calcd for $C_{20}H_{14}O_7F_2$: M, 404.0706.

Preparation off 20 from 22. A mixture of **22** (9.8 mg, 0.0243 mmol) and 10% Pd–$BaSO_4$ (11.2 mg) in MeOH (2.5 ml) was stirred under a H_2 atmosphere at room temperature for 2 h. The catalyst was filtered off and washed with MeOH. The combined filtrates were concentrated in vacuo. Purification of the residue by preparative TLC (SiO_2, PhMe–AcOEt, 1 : 1) afforded pure **20** as a red powder (3.0 mg, 32%). Spectral and chromatographic comparisons revealed that this was identical with an authentic sample synthesized as described above.

(8*S*,10*S*)-10-*O*-(2,3,6-Trideoxy-3-trifluoroacetoamido-α-L-*lyxo*-hexopyranosyl)-8-difluoroscetyl-6,8,11-trihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione (3′-*N*-Trifluoroacetyl-14,14-difluoro-4-demethoxydaunorubicin) (23). A 1.0 mol dm^{-3} solution of trimethylsilyl trifluoromethanesulfonate in CH_2Cl_2 (0.17 ml, 0.170 mmol) was added under an Ar atmosphere to a mixture of 1,4-bis-*O*-(*p*-nitrobenzoyl)-3-*N*-trifluoroacetyl-L-daunosamine[19] (46.0 mg, 0.0850 mmol) and molecular sieves 4A (257 mg) in a mixture of ether (3.7 ml) and CH_2Cl_2 (4.6 ml) at −40 °C. The mixture was stirred at 0 °C for 40 min, then cooled to −20 °C. After a solution of **21** (9.2 mg, 0.0228 mmol) in THF (4.0 ml) was added to the reaction mixture, stirring was continued at −10 °C for 5.5 h. The mixture was poured into a two-layer mixture of AcOEt and saturated $NaHCO_3$, and extracted with AcOEt. The combined extracts were washed successively with H_2O and brine, dried over Na_2SO_4, filtered, and concentrated in vacuo. The residue was dissolved in MeOH (20 ml), and 0.1 mol dm^{-3} NaOH (0.2 ml) was added to the solution cooled in an ice bath. After stirring at the same temperature for 20 min, the mixture was neutralized with 2 mol dm^{-3} AcOH, diluted with H_2O, and extracted with AcOEt. The organic layers were combined, washed successively with H_2O and brine, dried over Na_2SO_4, filtered, then concentrated in vacuo. The crude residue was purified by column chromatography (SiO_2, $CHCl_3$→$CHCl_3$–acetone 10 : 1) followed by trituration with ether and azeotropic removal of H_2O using PhMe,[16] giving pure **23** as a red amorphous powder (12.8 mg, 89%), $[\alpha]_D^{20}$ +117° (*c* 0.163, dioxane). IR (KBr) 3450, 1750, 1720, 1625, 1590 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.31 (3H, d, *J*=6.6 Hz, $C_{5'}$–Me), 1.86 (1H, dt, *J*=13.2, 4.2 Hz, $C_{2'\text{-ax}}$–H), 1.93—1.98 (1H, m, $C_{4'}$–OH), 2.03 (1H, dd, *J*=13.2, 5.3 Hz, $C_{2'\text{-eq}}$–H), 2.12 (1H, dd, *J*=14.7, 4.0 Hz, $C_{9\text{-ax}}$–H), 2.63 (1H, d, *J*=14.7 Hz, $C_{9\text{-eq}}$–H), 3.16 (1H, d, *J*=19.1 Hz, $C_{7\text{-ax}}$–H), 3.40 (1H, dd, *J*=19.1, 1.9 Hz, $C_{7\text{-eq}}$–H), 3.65—3.72 (1H, m, $C_{4'}$–H), 4.16—4.26 (1H, m, $C_{3'}$–H), 4.25 (1H, q, *J*=6.6 Hz, $C_{5'}$–H), 4.67 (1H, s, C_8–OH), 5.28 (1H, dd, *J*=4.0, 1.9 Hz, C_{10}–H), 5.53 (1H, d, *J*=4.2 Hz, $C_{1'}$–H), 6.60 (1H, t, *J*=54.6 Hz, CHF_2), 6.67 (1H, brd, *J*=8.5 Hz, NH), 7.80—7.90, 8.32—8.41 (each 2H, m, ArH×4), 13.32, 13.59 (each 1H, s, ArOH×2). EI-MS *m/z* 629 (M^+), 404, 386, 368, 317, 307. High-resolution MS, Found: *m/z* 629.1334. Calcd for $C_{28}H_{24}NO_{10}F_5$: M, 629.1318.

(8*S*,10*S*)-10-*O*-(3-Amino-2,3,6-trideoxy-α-L-*lyxo*-hexopyranosyl)-8-difluoracetyl-6,8,11-trihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione Hydrochloride and (8*S*,10*S*)-10-*O*-(3-Amino-2,3,6-trideoxy-α-L-*lyxo*-hexopyranosyl)-8-(2,2-difluoro-1,1-dihydroxyethyl)-6,8,11-trihydroxy-7,8,9,10-tetrahydro-5,12-naphthacenedione Hydrochloride [14,14-Difluoro-4-demethoxydaunorubicin Hydrochloride] (9). A 0.05 mol dm^{-3} solution of NaOH (4.3 ml) was added to a solution of **23** (22.5 mg, 0.0357 mmol) in THF (0.9 ml) at ambient temperature. After stirring was continued at the same temperature for 50 min, the mixture was neutralized (pH 9) with 1 mol dm^{-3} HCl, and extracted with $CHCl_3$. The combined extracts were washed with H_2O, dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo to ca. 0.5 ml in volume. When 0.25 mol dm^{-3} HCl in MeOH (0.7 ml) and ether (ca. 20 ml) was successively added to the concentrated solution, a red powder separated. This was collected by decantation and triturated with ether. The upper ethereal layer was removed, and the precipitation was dried over KOH in vacuo, giving pure **9** (a 3 : 1 mixture of ketonic and hydrate forms by ^{1}H NMR) as a red powder (8.1 mg, 40%), mp 168—171 °C, $[\alpha]_D^{20}$ +111° (*c* 0.090, MeOH). IR (KBr) 3450, 1620, 1590 cm^{-1}. ^{1}H NMR (DMSO-d_6+D_2O) δ=1.15 (3H, d, *J*=6.6 Hz, $C_{5'}$–Me), 1.62—2.24 (3H, m, $C_{2'}$–H_2, $C_{9\text{-ax}}$–H), 2.36 (0.75H, d, *J*=14.9 Hz, $C_{9\text{-eq}}$–H, ketone), 2.43 (0.25H, d, *J*=14.9 Hz, $C_{9\text{-eq}}$–H, hydrate), 2.86 (0.25H, d, *J*=18.8 Hz, $C_{7\text{-ax}}$–H, hydrate), 3.05 (0.75H, d, *J*=18.8 Hz, $C_{7\text{-ax}}$–H, ketone), 4.11—4.23 (1H, m, $C_{5'}$–H), 4.96—5.04 (1H, m, C_{10}–H), 5.29—5.35 (1H, m, $C_{1'}$–H), 6.04 (0.25H, t, *J*=55.8 Hz, CHF_2, hydrate), 6.85 (0.75H, t, *J*=52.9 Hz, CHF_2, ketone), 7.96—8.04, 8.26—8.35 (each 2H, m, ArH×4). ^{19}F NMR (DMSO-d_6 +D_2O) δ=−128.0 (d, *J*=52.9 Hz, ketone), −131.2, (d, *J*=55.8 Hz, hydrate). SI-MS *m*/*z* 552 (M^+ +H−HCl+H_2O), 534 (M^+ +H−HCl), 495, 405, 387, 369, 308.

We are grateful to Drs. Kunikazu Sakai and Kaoru Yamada, Sagami Chemical Research Center, Drs., Shigeru Tsukagoshi, Takashi Tsuruo, and Tazuko Tashiro, Cancer Chemotherapy Center, Japanese Foundation for Cancer Research, for evaluation of *in vitro* cytotoxicity and *in vivo* antitumor activity against P388 murine leukemia. Thanks are given to Professors Takeo Taguchi and Yoshiro Kobayashi, Tokyo College of Pharmacy, for providing us with a sample of methyl difluoroiodoacetate.

(Received April 30, 1991)

The Michael addition of lithium 1,3-dien-2-olates with α,β-unsaturated carbonyl compounds is described. With α,β-unsaturated esters the reaction was reversible even at −78°C, while kinetically controlled with α,β-unsaturated ketones or alkylidenemalonates. At room temperature, the initially formed Michael adducts undergo subsequent intramolecular Michael addition to give substituted cyclohexanone derivatives in a highly stereoselective manner. Mostly *anti*-selectivity has been observed for the initial Michael addition, and the intramolecular cyclization was *cis*-selective.

1,3-Dien-1-olates, generated by the deprotonation of α,β-unsaturated carbonyl compounds, have enjoyed wide synthetic applications in alkylation,[1,2] acylation,[2c] aldol addition,[1d] Michael addition,[3,4] and other fields of organic synthesis.[5] Limited papers have been reported, however, about the reaction of 1,3-dien-2-olates; alkylation,[2,6a,b] aldol addition,[6c] and Michael addition[7] are among them. One exception is the cyclization reaction of cyclic 1,3-dien-2-olates with α,β-unsaturated esters or ketones. Since such reaction proceeds stereoselectively under mild reaction conditions to produce Diels–Alder type cyclization products, wide applications to natural product synthesis have been studied.[8]

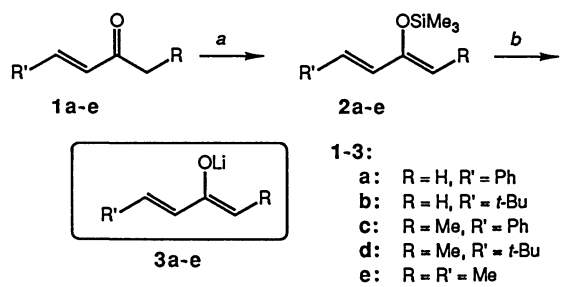
The *endo*-selectivities observed in these six-membered ring-forming reactions[7a,8,9] were the same as those of the *endo*-selective Diels–Alder reactions of related dienes such as cyclic 2-silyloxy-1,3-dienes.[10] This is why anion-accelerated Diels–Alder reaction is taken into account as a possible mechanism for the sequential double Michael reaction.[7a,8] Although there is known an example in which the Michael reaction between cyclic 1,3-dien-2-olates and α,β-unsaturated lactones resulted in a different stereoselectivity,[7b,c] high *endo*-selectivity is usually observed in the Michael addition of cyclic 1,3-dien-2-olates.

We assumed that the high stereoselectivity observed in the cyclization reaction of cyclic 1,3-dien-2-olates could be due to the attractive secondary orbital interaction just like the *endo*-selective Diels–Alder reaction. If this is true, such interaction would be generally utilized in the stereocontrol of Michael addition employing acyclic 1,3-dien-2-olates and α,β-unsaturated carbonyl compounds. In contrast with the many reported examples of *endo*-selective Diels–Alder type cyclization of cyclic 1,3-dien-2-olates, it is very surprising that few example is known for the Michael reaction of acyclic 1,3-dien-2-olates.[11]

Results and Discussion

Preparation of Lithium 1,3-Dien-2-olates. Lithium (1*Z*,3*E*)-1,3-dien-2-olates **3a**—**e** were generated from enones **1a**—**e** via 2-silyloxy-1,3-dienes **2a**—**e** as follows: Horner–Emmons olefination of 2-oxoalkylphosphonates using lithium bromide/triethylamine in tetrahydrofuran (THF) gave (*E*)-enones **1b**—**d** as single isomers (Scheme 1, **1b**: 71%, **1c**: 91%, **1d**: 78%); other enones **1a**,**e** were commercially available. Attempted lithiation of enones **1a**,**b** with lithium diisopropylamide (LDA) at −78 °C in THF produced the formal dimer[12] of **1** along with a complex mixture of many products,[13] indicating that the indirect generation method should be applied. Accordingly, enones **1a**—**e** were first silylated with chlorotrimethylsilane and 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU)[14] to give **2a**—**e** (**2a**: 71%, **2b**: 87%, **2c**: 64%, **2d**: 92%, **2e**: 78%) after vacuum distillation, among which **2c**—**e** were obtained as single isomers. Treatment of these 2-silyloxy-1,3-dienes **2a**—**e** with butyllithium,[3a] at room temperature for 30 min in THF generated lithium 1,3-dien-2-olates **3a**—**e** in excellent yields.

To determine the structure of **2d** by comparison with its stereoisomer **2d′**, silylation of **1d** was performed according to the Danishefsky's method[15] using chrolotrimethylsilane, triethylamine, and zinc chloride in benzene to produce an 89 : 11 mixture (GLC) of **2d** and **2d′** (Scheme 2); the major isomer **2d** was assigned the *Z*,*E*-isomer on the basis of NOE spectrum in which the



Scheme 1.

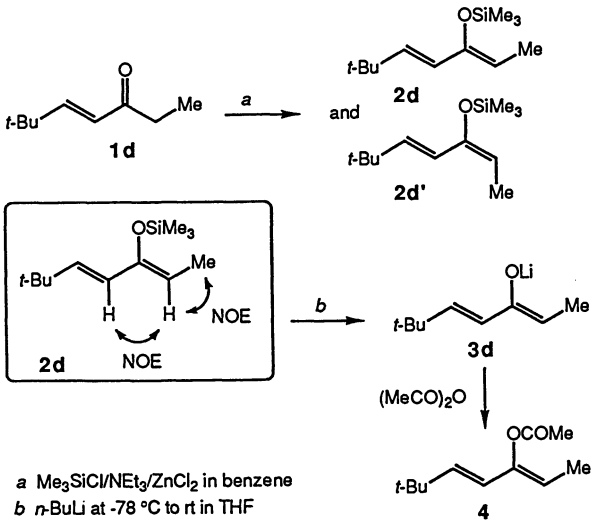
notable signal enhancement was observed between H-2 and H-4. Other 2-silyloxy-1,3-dienes **2c,e** were assigned also as the *Z,E*-structures by analogy.

Acetylation of **3d**, generated from **2d** and butyllithium by the method described above, with acetic anhydride gave acetate **4** in 85% yield as the sole *Z,E*-isomer, indicating the full retention of the *Z,E*-stereochemistry during the lithiation of **2d**. The use of THF containing hexamethylphosphoric triamide (HMPA, 10 vol%) as co-solvent in the above procedure provided essentially the equivalent result (**4**: 87%, single), confirming that the *Z*-isomer of **3d** is thermodynamically more stable.[16]

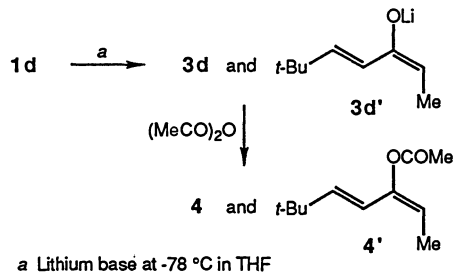
Direct lithiation of ethyl ketone **1d** with various lithium amides provided a mixture of isomeric lithium enolates, lithium *Z,E*-**3d** and *E,E*-enolate **3d'**. The *Z*/*E* ratios **3d**/**3d'** were determined after the mixtures of the lithium enolates **3d** and **3d'** were acetylated with acetic anhydride, while the yields of **4** were not always satisfactory (Scheme 3 and Table 1). The use of bulky lithium amides such as lithium hexamethyldisilylamide (LHMDS) and lithium 2,2,6,6-tetramethylpiperidide (LTMP), which are in general known to favor the formation of *E*-enolates, did not effect the selective generation of *E,E*-enolate **3d'**. The *Z,E*-isomer **3d** was still the major isomer (Table 1, Entries 6—9).[17]

Michael Reactions of Lithium 1,3-Dien-2-olates. Michael Addition to α,β-Unsaturated Esters. The reaction of lithium (2*Z*,4*E*)-6,6-dimethyl-2,4-heptadien-3-olate (**3d**) with methyl crotonate in THF was monitored on thin-layer chromatography (TLC). Within the reaction for 48 h at −78 °C, one clear new spot appeared and grew up along with the spot of **3d**, showing the occurrence of a clean reaction at a low temperature. Although this new spot was expected to correspond to the Michael adduct **6**, actually no trace of **6** was isolated after the usual hydrolytic quench of the reaction mixture. The starting enone **1d** was recovered quantitatively. Use of some other quenching agents such as saturated aqueous ammonium chloride, solid ammonium chloride, wet silica gel, methanol, *p*-toluenesulfonic acid, acetic acid, chlorotrimethylsilane, and iodomethane also resulted in the quantitative recovery of **1d**.

However, the cyclohexanone derivative **5a** was obtained in 49% yield as a single stereoisomer when the reaction temperature was raised to room temperature and continued for 26 h (Scheme 4 and Table 2, Entry 3). Assignment of the structure of **5a** will be discussed below. The stereoselective formation of **5a** seemed to



Scheme 2.



Scheme 3.

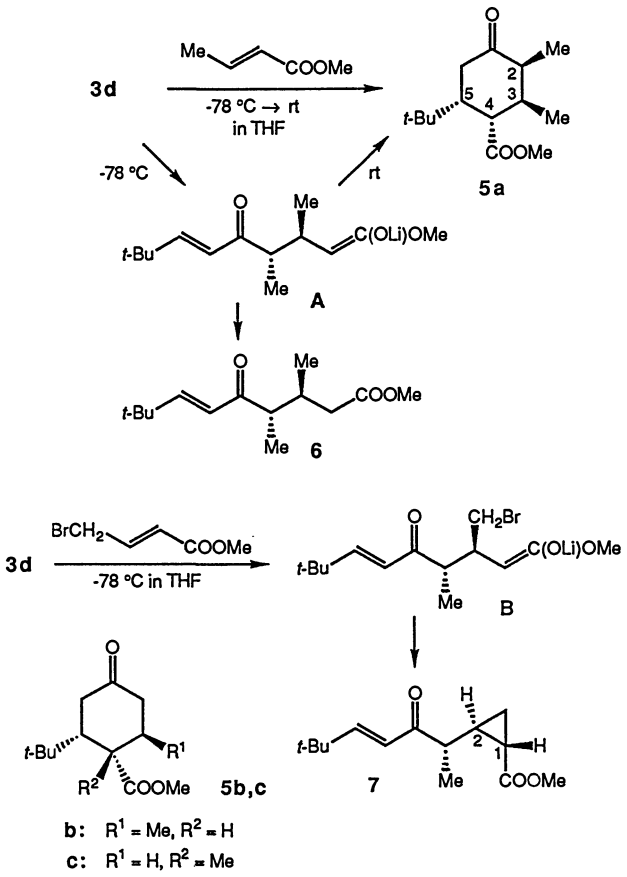
8	**1d**		LHMDS	**3d**	88:12[e]	55
9	**1d**		LTMP	**3d**	67:33[e]	32

a) Determined by ^{1}H NMR spectrum after the *O*-acetylation with acetic anhydride. b) Isolated yield based on **2d** (Entry 4) or **1d** (Entries 6—9). c) The exclusive formation of (1*Z*,3*E*)-1,3-dien-2-olates was assumed on the basis of the observed full retention of *Z,E*-stereochemistry of the starting 2-silyloxy-1,3-diene **2d**. d) Pure (1*Z*,3*E*)-1,3-dien-2-olate. e) To the freshly prepared lithium bases in THF was added **1d** in a period of 25 min at −78 °C.

be deeply related with the appearance of a single spot on TLC during the aforementioned reaction at −78 °C. Employment of methyl (*E*)-4-bromo-2-butenoate, instead of methyl crotonate, in the reaction with **3d** at −78 °C in THF produced cyclopropane **7** as a single stereoisomer in 50% yield. It is clear that the formation of **7** took place through the intramolecular alkylation of the stereoselectively formed Michael adduct enolate **B**.

The following points are clear on the basis of these results: (1) the Michael addition of **3d** with methyl crotonate is a reversible process,[18] (2) As readily anticipated from the decreased length of conjugation, the Michael adduct enolate **A** is less stabilized than the starting enolate **3d** so that the equilibrium lies in favor for **3d**, (3) the adduct enolate **A** rapidly decomposes into each components on quenching, (4) the irreversible cyclization of the minor contributor **A** takes place around room temperature to produce the cyclized product **5a**, and (5) the reversible process and the irreversible cyclization are both stereoselective.



Scheme 4.

To stabilize the Michael adduct enolate **A**, the lithium enolate **3d** was first treated with zinc(II) chloride[19] at −20 to −30 °C and then allowed to react with methyl crotonate at room temperature[20] to give the Michael adduct **6** as a single diastereomer, albeit in a low yield (18%). Based on the reversible nature of the reported aldol reaction of zinc enolates with carbonyl compounds,[21] it is likely that the Michael reactions of lithium enolate **3d** and its zinc derivative are both reversible. The *anti*-configuration of **6** was tentatively assigned on the basis of the structure of **5a** which was derived from **A** presumably under thermodynamic control.

Similar reactions of lithium (1*Z*,3*E*)-5,5-dimethyl-1,3-hexadien-2-olate (**3d**) with methyl crotonate (4 h) and methacrylate (15 h) at room temperature produced cyclohexanone derivatives **5b** (87%) and **5c** (20%), respectively, both as single stereoisomers again (Scheme 4 and Table 2, Entries 1, 2).

The skeletons of **5a**—**c** correspond to the formal Diels–Alder cycloadducts of lithium 1,3-butadien-2-olates **3b,d** with methyl crotonate and methacrylate.[10] With an expectation to obtain the corresponding Diels–Alder cycloadduct, whose stereostructure may be readily assigned on the basis of the well-established stereochemical dignity of Diels–Alder reaction, enone **2d** was heated with methyl crotonate in benzene at 130 °C in a sealed tube for 6 d. However, the quantitative recovery of **2d** resulted, and the stereostructures of **5a**—**c** were assigned only on the spectroscopic basis.

The most bulky *t*-butyl substituent of **5a** must occupy the equatorial position in its stable chair conformation. That the axial H-5 showed only one big vicinal coupling with H-6$_{ax}$ (J_{5-6ax}=14.3 Hz) and the other two couplings were small (J_{5-6eq}=4.0 and J_{5-4}=3.8 Hz) indicates the 4,5-*cis* relationship. Notable NOEs were observed between H-6$_{ax}$/H-2 and H-2/H-3, showing the axial and equatorial positions of H-2 and H-3, respectively. Thus, **5a** was determined as *r*-2,*c*-3,*t*-4,*t*-5-configuration. Similar structural analysis was applied to **5b** (Scheme 4).

Table 2. Reiterative Michael Addition of Lithium 1,3-Dien-2-olates **3** with α,β-Unsaturated Esters

Entry	Enolate	α,β-Unsaturated ester	Solvent	Temp/°C[a]	Time/h[a]	Product	Yield/%[b]	Isomer ratio[c]
1	**3b**	Methyl crotonate	THF	−78→rt	2.3→1.5	**5b**	87	Single
2	**3b**	Methyl methacrylate	THF	−78→rt	2.5→22	**5c**	20	Single
3	**3d**	Methyl crotonate	THF	−78→rt	1.5→26	**5a**	49	Single
4	**3d**[d]	Methyl crotonate	THF	−78→rt	20→52	**6**	18	Single
5	**3d**	Methyl 4-bromocrotonate	THF	−78	17	**7**	50	Single

a) Each reaction time corresponds to each reaction temperature. b) Isolated yield based on **2**. c) Based on ^{1}H NMR spectrum. d) The lithium enolate **3d** was treated with zinc(II) chloride (1 equiv) at −20 to −30 °C for 20 min before methyl crotonate was added.

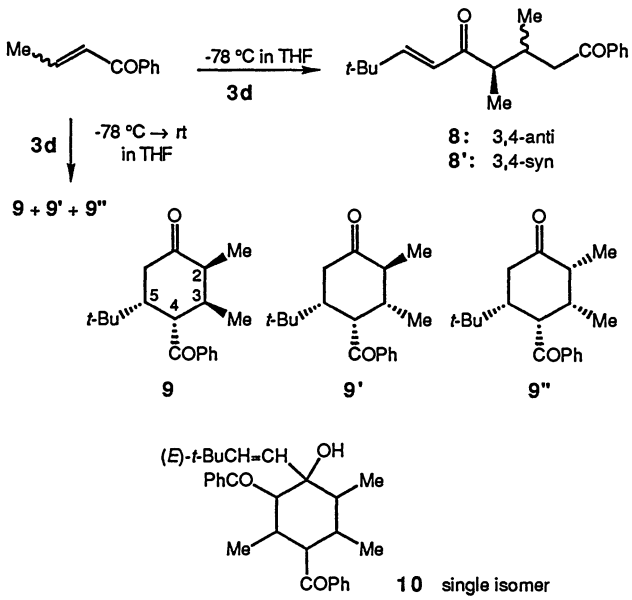
Structure assignment of **5c** was mainly based on the analogy of reaction mode to that of the above two cases.

As a result, the reaction of (1*Z*,3*E*)-1,3-dien-2-olate **3d** with methyl crotonate led to the stereoselective formation of *anti*-adduct enolate **A**, which was in an equilibrium with the starting components, **3d** and methyl crotonate. Stereoselectivity in the retro-Michael reaction process is not important because thermodynamically more stable *Z*-enolate **3d** and methyl crotonate are released from **A** in this retro process, and hence the retro Michael reaction process would not affect the stereoselectivity of the whole reaction. The 4,5-*cis*-selective intramolecular Michael addition pathway from the initially formed *anti*-Michael adduct enolates **A** leading to **5a—c** corresponds to that observed previously in the second cyclization step of the Michael addition of cyclic 1,3-dien-2-olates.[8] Probably the role of metal chelation is important.[9,22]

Although the *trans*-substitution of the cyclopropane ring of **7** was determined by its small vicinal coupling constant between H-1/H-2 (J_{1-2}=4.4 Hz), the configuration at the third chiral center could not be assigned only on the spectroscopic basis. Since *anti*-adduct enolate **A** was confirmed to be the intermediate involved in the reaction of **3d** with methyl crotonate, a similar *anti*-adduct enolate **B** was proposed as the intermediate involved in this reaction. Stereochemistry of **7** was tentatively assigned as shown in Scheme 4.

Michael Addition to 1-Phenyl-2-buten-1-one, (*E*)-3-Penten-2-one, or (*E*)-4-Phenyl-3-buten-2-one. To suppress the retro-Michael reaction pathway, α,β-unsaturated ketones were employed as Michael acceptors in the reactions with 1,3-dien-2-olate **3d**. Stabilization of a carbanionic center by the attaching α-acyl substituent is much higher than the stabilization by the α-ester moiety. As expected, a smooth Michael reaction took place between **3d** and 1-phenyl-2-buten-1-one (*Z*:*E*=10:90 by ^{1}H NMR) in THF; this reaction was completed in 1 h at −78 °C. An 87:13 mixture (^{1}H NMR) of Michael adducts **8** and **8′** was obtained in 73% of combined yield, after quenching with *p*-toluenesulfonic acid (Scheme 5, Table 3, Entry 1).

It was clear by the following observation that no retro-Michael reaction took place in the stage of



Scheme 5.

Michael adduct formation at −78 °C as confirmed. Thus, when the Michael adduct enolate derived from **3d** and 1-phenyl-2-buten-1-one was treated with dimethyl ethylidenemalonate, no corresponding Michael adduct to the ethylidenemalonate acceptor was detected. The details of the reaction of **3d** with alkylidenemalonates will be described below. The Michael reaction of **3d** with 1-phenyl-2-buten-1-one (*Z*: *E*=1 : 99 to 9 : 91) in the presence of HMPA or 18-crown-6 showed satisfactorily high *anti*-selectivity (Table 3, Entries 2, 3, 5).

Next examined was the Michael reaction of (*E*)-1-phenyl-2-buten-1-one (99% pure) with the lithium 1,3-dien-2-olate with several **3d**/**3d′** ratios. As shown in Table 3 (Entries 10—13), the stereoselectivity **8**/**8′** was related with the enolate ratio **3d**/**3d′**, *anti*- **8** and *syn*-adduct **8′** being formed mainly from the *E*- and *Z*-enolate, respectively. Addition of HMPA increased the *anti*-selectivity, but only by 5% (Entry 14), making a striking contrast with the highly *anti*-selective Micahel addition of **3d** (Entries 2,5).

On the other hand, (*Z*)-1-phenyl-2-buten-1-one[23] was found to be much less reactive toward **3d**. No formation of the Michael adduct was detected on TLC after 1 h at −78 °C (Entry 6); addition of HMPA to activate the enolate **3d** was also totally ineffective (90 min at −78 °C, Entry 7). Finally, (*E*)-1-phenyl-2-buten-1-one was added to this reaction mixture and allowed to react for additional 1 h to give an 83 : 17 mixture of **8** and **8′** (65%) along with the single stereoisomer of the cyclized product **10** (28%), whose stereochemistry remained unsolved. Thus, the diastereomer ratio **8**/**8′** was independent of the *Z*/*E* ratio of the acceptor molecule, 1-phenyl-2-buten-1-one (Table 3, Entries 1—5). This is because (*E*)-1-phenyl-2-buten-1-one was the only reactive isomer. The lack of full conjugation between the carbon–carbon double bond and the carbonyl moiety may be the major reason for the decreased reactivity of (*Z*)-1-phenyl-2-buten-1-one.

When the reaction time was prolonged, (*Z*)-1-phenyl-2-buten-1-one reacted with **3d** at −78 °C to give a mixture of **8** and **8′** albeit in a poor isomer ratio (**8** : **8′**=62 : 38, Entry 8); essentially the equivalent result (**8** : **8′**=59 : 41, Entry 9) was obtained in a similar reaction in the presence of HMPA. The low *anti*-selectivity in the presence of HMPA and no dramatic change of the isomer ratio were again surprising. Although the products obtained were in cyclized forms, high stereoselectivity and satisfactory yield were observed when the same reaction was carried out at room temperature (Entry 17, 91 : 9). The poor *anti*/*syn*-selectivity observed in the reactions at −78 °C would be due to the slow Michael addition of (*Z*)-1-phenyl-2-buten-1-one. This *Z*-isomer presumably underwent partial isomerization to (*E*)-1-phenyl-2-buten-1-one in the course of Michael addition through the retro-Michael addition pathway.

At room temperature, three isomers of the cyclized products **9**, **9′**, and **9″** were obtained in the reaction of **3d** with (*Z*)-1-phenyl-2-buten-1-one (Entry 17). Since these products were assigned, mainly on the basis of NOE spectra, *r*-2,*c*-3,*t*-4,*t*-5- for **9**, *r*-2,*t*-3,*t*-4,*t*-5- for **9′**, and *r*-2,*c*-3,*c*-4,*c*-5-isomer for **9″**, the stereoselectivity of the intermolecular Michael addition was calculated to be *anti*/*syn*=91 : 9. The reactions with (*E*)-1-phenyl-2-buten-1-one at room temperature afforded the comparable results (Entries 15, 16). The equally high *anti*-selectivities observed in these reactions (Entry 17 and Entries 15, 16), regardless of the *Z*/*E* ratio of the acceptor molecules employed, would be due to the ready isomerization of (*Z*)-1-phenyl-2-buten-1-one to the (*E*)-1-phenyl-2-buten-1-one at room temperature.

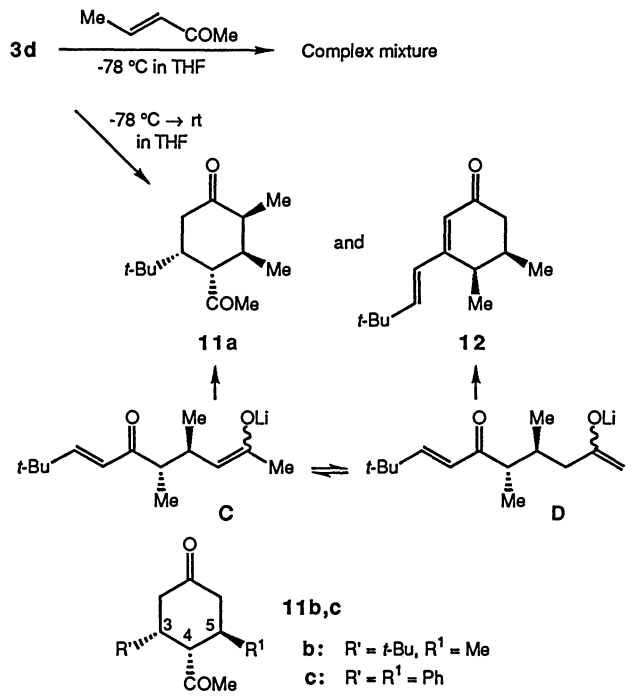
Stereostructures of the cyclized products, **9** and **9′**, were determined on the basis of ^{1}H NMR spectra: Based on the small couplings for J_{5-4}(4.0 Hz) and J_{2-3}(6.2 Hz) as well as the notable NOEs between H-2/H-3, H-2/H-6$_{ax}$, and H-5/3-Me, the major stereoisomer **9** was confirmed to be the 2,3-*cis*-3,4-*trans*-4,5-*cis* structure. On the other hand, the small coupling for J_{5-4}(3.7 Hz) and big coupling for J_{2-3}(12.4 Hz) indicated the axial positions of H-2, H-3, and H-5 and the equatorial position of H-4, minor isomer **9′** being assigned the 2,3-*trans*-3,4-*cis*-4,5-*cis* structure.

The points to be noteworthy are: (1) at a low temperature (−78 °C) *anti*-**8** and *syn*-Michael adduct **8′** are mainly formed from (2*Z*,4*E*)-**3d** and (2*E*,4*E*)-1,3-dien-2-olate **3d′**, respectively, (2) the stereospecific cyclization of the resulting Michael adduct enolates leads to the cyclization products **9** and **9′** at room temperature, (3) the Michael addition at a low temperature is kinetically controlled, (4) (*Z*)-1-phenyl-2-buten-1-one is much less reactive than the (*E*)-1-phenyl-2-buten-1-one in the reaction with **3d**, (5) the presence of HMPA does not alter the transition state, (6) the fast retro process is involved in the reaction at room temperature, while this process is less important at −78 °C.

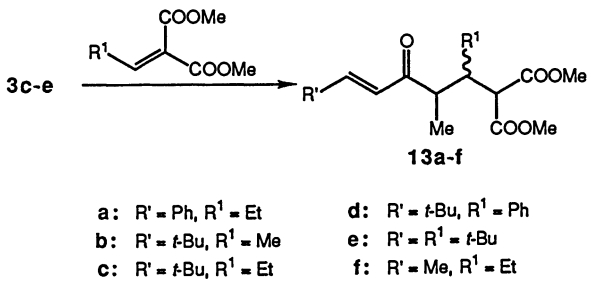
The reaction of lithium (1*Z*,3*E*)-1,3-dien-2-olate **3d** with (*E*)-3-penten-2-one at room temperature produced two cyclized products **11a** and **12** in 5 and 49% yields, respectively, while the same reaction at −78 °C resulted in the formation of complex products (Scheme 6). The structures of **11a** and **12** were determined on the basis of spectral data and also of the assumed reaction mode, and the 4,5-*cis*-configuration of **12** was confirmed by the small J_{4-5} value (3.7 Hz). The initial *anti*-Michael adduct enolate **C** went to the equilibration with the terminal enolate **D** whose irreversible aldol condensation produced **12**. Slow cyclization of enolate **C** into **11a**, even at room temperature, probably allowed the equilibration with **D**.

Similarly, reactions of **3b** and **3a** with (*E*)-3-penten-2-one and (*E*)-4-Phenyl-3-buten-2-one at room temperature gave stereoselectively cyclized products **11b** (31%) and **11c** (31%), respectively.

Michael Addition to Alkylidenemalonates. As discussed above, the reactions of lithium 1,3-dien-2-olates **3** with α,β-unsaturated esters were thermodynamically



Scheme 6.



Scheme 7.

controlled even at −78 °C, no Michael adducts having been isolated on quenching. Although α,β-unsaturated ketones and **3** formed stable adducts at a low temperature (−78 °C), they underwent ready equilibration with the starting substrates at room temperature. On the other hand, alkylidenemalonates bear two electron-withdrawing ester groups at the same sp^2 carbon so that high stabilization of the adduct enolates is expected. Therefore their Michael addition should be kinetically controlled.

One of two ester moieties of alkylidenemalonates is cis to the β-substituent R^1 and the other trans, and therefore the study of Michael addition of **3** with alkylidenemalonates would provide some useful informations to solve the transition state. The question on the aforementioned rate difference of Michael additions to the *Z*- and *E*-enone acceptors, e.g. (*Z*)- and (*E*)-1-phenyl-2-buten-1-one and that on the kinetic stereoselectivity of the *Z*- and *E*-isomers of α,β-unsaturated carbonyl acceptors would be also answered.

The reactions of **3c—e** with alkylidenemalonates went to full completion within 30 min at −78 °C to give, after usual hydrolytic workup, the corresponding Michael adducts **13a—f** in excellent yields (Scheme 7 and Table 4). One exception was the reaction with dimethyl (2,2-dimethylpropylidene)malonate bearing a bulky *t*-butyl β-substituent. A higher reaction temperature and a longer reaction time were required (11 days at room temperature) and the Michael adduct **13e** was obtained only in 36% yield (Entry 9). When the β-substituent R^1 of the alkylidenemalonates was small, e.g. R^1=Me or Et, the diastereomer ratios were extremely poor (70 : 30 to 52 : 48) regardless of the nature of the terminal substituent R′ of the donor molecules **3** (Entries 1—6, 10). On the other hand, selectivities better than 90% were achieved when a bulky β-substituent R^1 such as Ph or *t*-Bu was attached at the β-position (Entries 7—9). Improvement of the stereoselectivity by adding HMPA was observed, but again only a little (Entries 2, 4, 6, 8).

It was found that the reactions with alkylidenemalonates were all kinetically controlled on the basis of the following cross reaction. Treatment of the Micahel adduct enolate between **3d** and dimethyl propylidenemalonate with dimethyl ethylidenemalonate produced no adduct to the latter acceptor.

Stereochemistry of the major isomer of **13d** was determined by its chemical conversion shown in Scheme 8

Table 4. Reaction of Enolates **3** with Dimethyl Alkylidenemalonates

Entry	Dienolate **3**	Alkylidenemalonate R^1	Solvent/additive[a]	Temp/°C	Time/h	Product	Yield/%[b]	Isomer ratio *anti*/*syn*[c]
1	**3c**	Et	THF	−78	0.5	**13a**	85	55 : 45
2	**3c**	Et	THF/HMPA	−78	0.5	**13a**	83	62 : 38
3	**3d**	Me	THF	−78	0.5	**13b**	83	52 : 48
4	**3d**	Me	THF/HMPA	−78	0.5	**13b**	87	60 : 40
5	**3d**	Et	THF	−78	0.5	**13c**	80	60 : 40
6	**3d**	Et	THF/HMPA	−78	0.5	**13c**	82	70 : 30
7	**3d**	Ph	THF	−78	0.5	**13d**	64	92 : 8
8	**3d**	Ph	THF/HMPA	−78	0.5	**13d**	89	95 : 5
9	**3d**	*t*-Bu	THF	rt	11d	**13e**	36	93 : 7
10	**3e**	Et	THF	−78	0.5	**13f**	60	64 : 36

a) HMPA (12 vol% to THF) was added as an additive. b) Isolated yield based on **2**. c) Determined by HPLC or ^{1}H NMR.

and also on the basis of spectral analysis of the derivatives. The 95:5 mixture of **13d** was purified through column chromatography to give pure sample of the major isomer of **13d**. Catalytic reduction of **13d** over palladium/carbon was followed by the carbonyl reduction with zinc borohydride in ether to give the expected lactone **15** (41%, 85:15) along with hemilactal **16** (37%, 76:24) as an overreduction product. Although these products **15** and **16** were derived from the diastereomeric alcohols produced from **14**, their different reactivity toward the zinc borohydride reduction is uncertain. It was clear that **15** consisted of two 3-epimers and **16** was a mixture of the 2- or 3-epimers, because they were converted into **17** and **18**, respectively, as single stereoisomers by the followed demethoxycarbonylation and oxidative demethoxycarbonylation. Thus, **15** and **16** were treated with aqueous sodium hydroxide in methanol at room temperature to give **17** (66%, single isomer) and **18** (94%, single isomer), respectively.

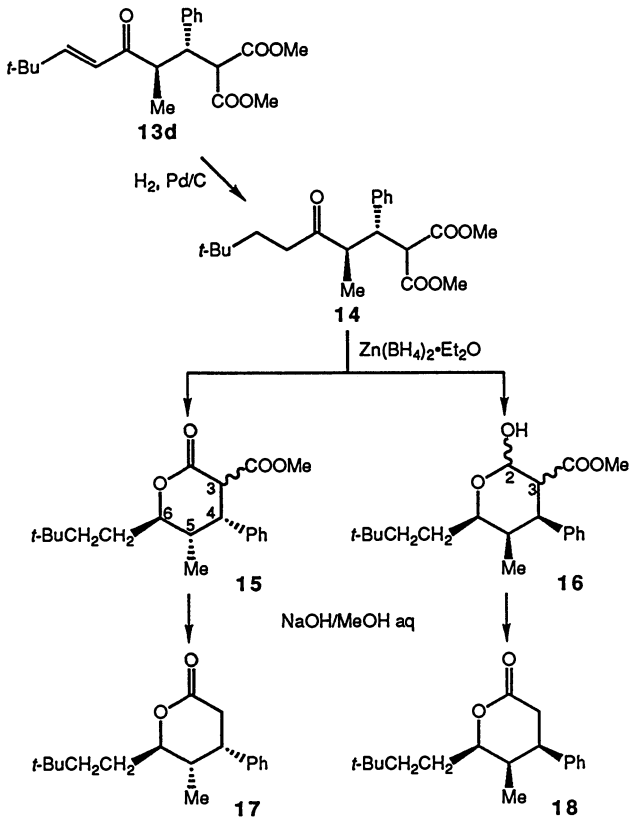
Structures of **17** and **18** were easily distinguished from each other on the basis of the observed NOE spectra (**17**: H-4/H-5, 4-Ph/5-Me, and 4-Ph/H-6; **18**: H-3_{ax}/Ph, H-3_{eq}/H-4, H-4/H-5, H-4/H-6, and H-5/H-6). Thus, the major isomer of **13d** was determined to be the *anti*-configuraion, and therefore the other major diastereoisomers **13a**—**f** obtained in the reactions of **3c**—**e** with alkylidenemalonates were assigned *anti*-stereochemistry by analogy.

Nature of Transition State. After the transition state model recently proposed by Heathcock and co-workers for the Michael addition of amide and thioamide enolates,[24] transition states **E**, **F**, **E′** and **F′** were drawn in Fig. 1. The reaction between **3d** and (*E*)-1-phenyl-2-buten-1-one was chosen as the representative example for the Michael addition of lithium 1,3-dien-2-olates to α,β-unsaturated carbonyl compounds.

From the viewpoint of stabilization of the chelating bond, the chelation between the lithium atom of **3d** and the carbonyl oxygen of the acceptor molecule should be most favorably built with the nonbonding orbital of the oxygen (models **E′** and **F′**). However, **E′** and **F′** were not the transition states actually involved in the reactions because there are serious steric repulsions between the *t*-butyl and the phenyl substituents (**F′**) or between the eclipsed three substituents (**E′**). The second favorable models were constructed with the pai orbital of the carbonyl moiety (models **E** and **F**).

The transition state **F** leading to the *syn*-adduct **8′** is nearly identical with **F′** where the only difference is the location of the lithium atom, and so **F** is also suffering from the serious steric repulsion. Without such steric repulsion between the *t*-butyl and phenyl substituents, **F** and **F′** should have been highly stabilized by chelate formation as well as the secondary orbital interaction that is often very important in the *endo*-transition state of Diels–Alder reaction. It was finally concluded that the anticipated transition state **F** or **F′** was not included in the Michael additions of lithium 1,3-dien-2-olates **3** to α,β-unsaturated carbonyl compounds. The participation of the sterically most favored transition state **E** led to the *anti*-adduct **8** as major diastereomers.

In the reaction of **3d** with alkylidenemalonates bearing a small β-substituent R^1, there are two possible



Scheme 8.

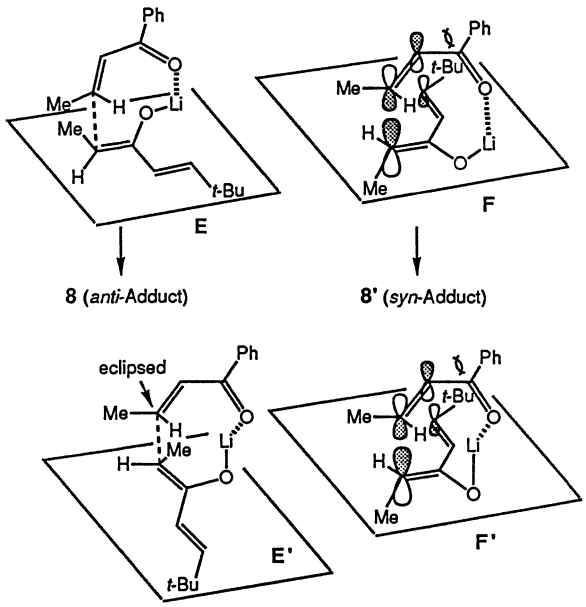


Fig. 1. Chelated treansition state for the Michael addition of lithium 1,3-dien-2-olate **3d** to (*E*)-1-phenyl-2-buten-1-one.

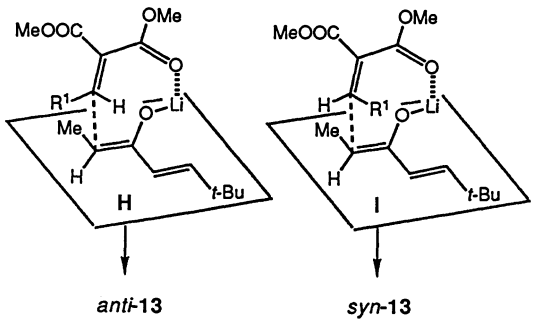

Fig. 2. Chelated transition state for the Michael addition of lithium 1,3-dien-2-olate **3d** to dimethyl alkylidenemalonates.

chelated transition states **H** and **I** with comparable stabilization energies (Fig. 2). When R^1 becomes bulky, the transition state model **I** becomes less favored sterically. Thus, it is now understood that poor stereoselectivities were observed in the reaction with the alkylidenemalonates bearing a small β-substituent R^1.

We assume that the role of chelate formation would be quite important in the Michael addition of lithium enolates to α,β-unsaturated carbonyl compounds. Little change of stereoselectivity by adding HMPA to the reaction system was observed throughout the present work. Although this seems to be inconsistent with the importance of chelation, an increased reactivity of the chelated acceptor molecule may be a key clue. The metal atom of the enolates would work as a Lewis acid catalyst to lower the LUMO (lowest unoccupied molecular orbital) level of the acceptor molecule when they come into chelation so that only the chelated acceptors are activated. The addition of a polar additive like HMPA to the reaction system does decrease the concentration of chelating molecules, but the chelating acceptors are preferentially allowed to undergo the Michael addition. There is no doubt that the reaction was chelation-controlled.

Experimental

General. Melting points were recorded on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with JASCO IRA-1 and A-702 spectrometers. ^{1}H and ^{13}C NMR spectra were measured with Hitachi R-40 (^{1}H NMR: 90 MHz) and JEOL GSX-270 (270 MHz for ^{1}H NMR and 67.94 MHz for ^{13}C NMR) instruments. Chemical shifts are recorded in parts per million downfield from internal tetramethylsilane. Mass spectra and high-resolution mass spectra (HRMS) were taken with a JEOL-01SG-2 spectrometer at an ionization energy of 70 eV. Elemental analyses were performed with a Hitachi 026 CHN analyzer. For preparative column chromatography, Wakogel C-200, C-300, and Merck silica gel 60 were employed. Flash chromatography was performed with an Eyera EF-10 apparatus with a 20×180 mm column packed with silica gel 60 (0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished with a Yanaco G-2800 gaschromatograph with an ionization flame detector using a 3×2000 mm glass column (SE-30) or a 0.25×50000 mm glass capillary column (Silicone GE, SE-30). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus.

Materials. Enones **1a** and **1e** are commercially available, and **1b**[25] and **1c,d**[26] were prepared according to the reported procedures. Zinc borohydride was prepared as follows: A solution of $ZnCl_2$ (2 g, 14.7 mmol) in dry diethyl ether (25 ml) was refluxed under nitrogen for 3 h. After cooling to room temperature, the solution was separated by decantation. This solution was added to a solution of $NaBH_4$ (1.31 g, 34.5 mmol) in ether (75 ml) and the solution was stirred under nitrogen for 18 h. The solution separated by decantation contains $Zn(BH_4)_2$ in the concentration of 0.36 M (1 M=1 mol dm^{-3}).

General Procedure for the Preparation of 2-Silyloxy-1,3-dienes 2a—e. Silylation of **1d** is described as a typical procedure. A mixture of **1d** (3.31 g, 23.6 mmol), Me_3SiCl (3.6 ml, 28.3 mmol), and DBU (4.59 ml, 30.7 mmol) in dry CH_2Cl_2 (10 ml) was refluxed for 2 h under nitrogen. After cooled to room temperature, the mixture was poured into hexane (450 ml). The colorless solid (DBU · HCl) precipitated was filtered off, the filtrate was quickly washed with ice water, and dried over magnesium sulfate. The solvent was evaporated in vacuo and the residue (5.93 g) was distilled under reduced pressure to give **2d** (4.63 g, 92%) as pale yellow liquid.

The other 2-silyloxy-1,3-dienes **2a**—**c** and **2e** were similarly prepared in the yields shown in Table 1.

(*E*)-1-Phenyl-3-(trimethylsilyloxy)-1,3-butadiene (2a): Prepared according to the reported method.[14]

(*E*)-5,5-Dimethyl-2-(trimethylsilyloxy)-1,3-hexadiene (2b): Pale yellow liquid; bp 108 °C/60 mmHg (1 mmHg=133.322 Pa) (bulb-to-bulb); IR (neat) 2950, 1600, 1460, 1310, 1260, 1030, and 900 cm^{-1}; ^{1}H NMR (C_6D_6) δ=0.19 (9H, s, $SiMe_3$), 0.99 (9H, s, *t*-Bu), 4.32, 4.35 (each 1H, each br s, H-1), 5.93 (1H, d, J_{3-4}=15.4 Hz, H-3), and 6.25 (1H, d, J_{4-3}=15.4 Hz, H-4); ^{13}C NMR (C_6D_6) δ=0.10 ($SiMe_3$), 29.59 (*t*-Bu), 32.79 (*t*-Bu), 94.55 (C-1), 123.50 (C-3), 142.30 (C-4), and 155.78 (C-2); MS *m/z* (rel intensity, %) 199 (M^++1, 10), 198 (M^+, 57), 183 (63), 155 (23), 141 (base peak), 93 (22), 75 (51), and 73 (80). HRMS Found: *m/z* 198.1440. Calcd for $C_{11}H_{22}OSi$: M, 198.1439.

(1*E*,3*Z*)-1-Phenyl-3-(trimethylsilyloxy)-1,3-pentadiene (2c): Pale yellow liquid; bp 140 °C/27 mmHg (bulb-to-bulb); IR (neat) 2950, 1620, 1400, 1370, 1320, 1240, 1190, 1020, 930, 820, 740, and 680 cm^{-1}; ^{1}H NMR (C_6D_6) δ=0.23 (9H, s, $SiMe_3$), 1.67 (3H, d, J_{5-4}=7.0 Hz, H-5), 4.89 (1H, q, J_{4-5}=7.0 Hz, H-4), 6.58 (1H, d, J_{2-1}=15.8 Hz, H-2), 6.84 (1H, d, J_{1-2}=15.8 Hz, H-1), and 7.01—7.30 (5H, m, Ph); ^{13}C NMR (C_6D_6) δ=0.73 ($SiMe_3$), 12.15 (C-5), 110.98 (C-4), 126.84, 127.12, 127.47, 127.92, 128.88, 137.65 (C-2, C-3, and Ph), and 150.45 (C-1); MS *m/z* (rel intensity, %) 233 (M^++1, 21), 232 (M^+, base peak), 231 (28), 217 (46), 203 (39), 75 (36), and 73 (68). Found: C, 72.47; H, 8.33%. Calcd for $C_{14}H_{20}OSi$: C, 72.34; H, 8.68%.

(2*Z*,4*E*)-6,6-Dimethyl-3-(trimethylsilyloxy)-2,4-heptadiene (2d): Pale yellow liquid; bp 150 °C/40 mmHg (bulb-to-bulb); IR (neat) 2950, 1620, 1450, 1330, 1240, 1200, 1030, 840, and 750 cm^{-1}; ^{1}H NMR (C_6D_6) δ=0.23 (9H, s, $SiMe_3$), 1.01 (9H, s, *t*-Bu), 1.65 (3H, d, J_{1-2}=7.0 Hz, H-1), 4.75 (1H, q, J_{2-1}=7.0 Hz, H-2), 5.89 (1H, d, J_{4-5}=15.8 Hz, H-4), and 5.98 (1H, d, J_{5-4}=15.8 Hz, H-5); NOE: H-2/H-4; ^{13}C NMR (C_6D_6) δ=0.85 ($SiMe_3$), 11.84 (C-1), 29.79 (*t*-Bu), 32.80 (*t*-Bu), 107.70 (C-2), 124.34 (C-4), 139.59 (C-5), and 150.26 (C-3); MS *m/z* (rel

intensity, %) 213 (M^++1, 20), 212 (M^+, base peak), 197 (53), 183 (39), 169 (21), 155 (51), 107 (32), 75 (34), and 73 (91). HRMS Found: m/z 212.1597. Calcd for $C_{12}H_{24}OSi$: M, 212.1595.

(2*Z*,4*E*)-3-(Trimethylsilyloxy)-2,4-hexadiene (2e); Pale yellow liquid; bp 100 °C/18 mmHg; IR (neat) 2950, 1620, 1430, 1360, 1330, 1250, 1200, 1030, 910, 830, and 740 cm^{-1}; ^1H NMR (C_6D_6) δ=0.19 (9H, s, $SiMe_3$), 1.61—1.64 (6H, m, H-1 and H-6), 4.69 (1H, q, J_{2-1}=7.0 Hz, H-2), and 5.84—5.88 (2H, m, H-4 and H-5); ^{13}C NMR (C_6D_6) δ=0.75 ($SiMe_3$), 11.76 (C-1), 17.62 (C-6), 107.14 (C-2), 123.08 (C-4), 130.81 (C-5), and 150.07 (C-3); MS m/z (rel intensity, %) 171 (M^++1, 11), 170 (M^+, 65), 155 (base peak), 141 (57), 75 (98), and 73 (93); HRMS Found: m/z 170.1132. Calcd for $C_9H_{18}OSi$: M, 170.1126.

Generation of 1,3-Dien-2-olates 3a—e and 3d′. A) From 2a—e and Butyllithium: As a typical procedure the generation of **3d** from **2d** is described: To a solution of **2d** (0.212 g, 1 mmol) in dry THF (2 ml) was added, at −78 °C under nitrogen, *n*-BuLi (1.6 M in hexane, 0.63 ml, 1 mmol). The mixture was stirred at −78 °C for 30 min and the stirring was continued for additional 30 min at room temperature to provide the THF solution of **3d**. We refer to the solution thus prepared as the standard solution of **3d**, and also the standard solutions of **3a**—**c** and **3e** were prepared by similar methods.

B) From 1d and LDA: To a solution of diisopropylamine (0.168 ml, 0.121 g, 1.2 mmol) in THF (3 ml) was added, at −78 °C under nitrogen, *n*-BuLi (1.6 M in hexane, 0.75 ml, 1.1 mmol). After stirring for 20 min, **1d** (0.14 g, 1 mmol) in THF (5 ml) was slowly added (in a period of 25 min by the aid of a Micro Feeder) and the stirring was continued at −78 °C for additional 15 min to give a solution of **3d** and **3d′** (67 : 33).

C) From 1d and LHMDS: To a solution of 1,1,1,3,3,3-hexamethyldisilazane (0.232 ml, 0.177 g, 1.1 mmol) in THF (3 ml) was added, at −78 °C under nitrogen, *n*-BuLi (0.66 ml, 1.05 mmol). After stirring for 20 min, **1d** (0.14 g, 1 mmol) in THF (5 ml) was slowly added (in a period of 25 min by the aid of a Micro Feeder) and the stirring was continued at −78 °C for additional 15 min to give a solution of **3d** and **3d′** (88 : 12).

D) From 1d and LTMP: To a solution of 2,2,6,6-tetramethylpiperidine (0.186 ml, 0.155 g, 1.1 mmol) in THF (3 ml) was added, at −78 °C under nitrogen, *n*-BuLi (0.66 ml, 1.05 mmol). After stirring for 20 min, **1d** (0.14 g, 1 mmol) in THF (5 ml) was slowly added (in a period of 25 min by the aid of a Micro Feeder) and the stirring was continued at −78 °C for additional 15 min to give a solution of **3d** and **3d′** (67 : 33).

Generation of 3d Followed by Acetylation Leading (2*Z*,4*E*)-3-Acetoxy-6,6-dimethyl-2,4-heptadiene (4). To a solution of **2d** (0.106 g, 0.5 mmol) in THF (I ml) was added, at −78 °C under nitrogen, *n*-BuLi (1.6 M in hexane, 0.32 ml, 0.5 mmol). After 30 min at −78 °C, the stirring was continued for additional 30 min at room temperature, and then cooled to −78 °C. Acetic anhydride (0.057 ml, 0.6 mmol) was added and the mixture was stirred for 40 min. The resulting mixture was poured into saturated aqueous NH_4Cl and extracted with CH_2Cl_2 (15 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.091 g) was chromatographed on silica gel using hexane–EtOAc (15 : 1) to give **4** (0.077 g, 85%). Pale yellow liquid; IR (neat) 2950, 1750, 1430, 1360, 1190, 1010, 950, 900, and 770 cm^{-1}; ^1H NMR (C_6D_6) δ=0.97 (9H, s, *t*-Bu), 1.49 (3H, d, J_{1-2}=7.0 Hz, H-1), 1.80 (3H, s, OCOMe), 5.07 (1H, q, J_{2-1}=7.0 Hz, H-2), 5.79, and 5.89 (each 1H, each d, J_{4-5}=15.8 Hz, H-4 and H-5); ^{13}C NMR (C_6D_6) δ=11.40 (C-1), 19.91 (OCOMe), 29.60 (C-7), 32.86 (*t*-Bu), 114.57 (C-2), 121.13 (C-4), 139.55 (C-5), 147.53 (C-3), and 166.89 (OCOMe); MS m/z (rel intensity, %) 183 (M^++1, 4), 182 (M^+, 31), 140 (89), 125 (31), 111 (base peak), and 43 (33). HRMS Found: m/z 182.1308. Calcd for $C_{11}H_{18}O_2$: M, 182.1306.

General Procedure for the Reactions of Lithium 1,3-Dien-2-olates 3 with α,β-Unsaturated Esters Leading to 5a—c. The reaction of **3d** with methyl crotonate is described as a typical example: To the standard solution of **3d** generated from **2d** (0.425 g, 2 mmol) was added, at −78 °C under nitrogen, methyl crotonate (0.2 g, 2 mmol) in THF (1 ml). After stirring at −78 °C for 1.5 h and then at room temperature for 26 h, the mixture was poured into saturated aqueous NH_4Cl and then extracted with CH_2Cl_2 (20 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.546 g) was chromatographed on silica gel with hexane–EtOAc (30 : 1, v/v) to give **5a** (0.235 g, 49%).

***c*-5-*t*-Butyl-*t*-4-(methoxycarbonyl)-*r*-2,*c*-3-dimethylcyclohexanone (5a):** Pale yellow liquid; IR (neat) 2950, 1730, 1705, 1440, 1360, 1300, 1160, and 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (3H, d, J_{Me-3}=7.3 Hz, 3-Me), 0.90 (9H, s, *t*-Bu), 0.96 (3H, d, J_{Me-2}=7.0 Hz, 2-Me), 1.89 (1H, ddd, J_{5-4}=3.8, J_{5-6eq}=4.0, and J_{5-6ax}=14.3 Hz, H-5), 2.26—2.39 (2H, m, H-3 and H-6_{eq}), 2.81 (1H, dd, J_{4-3}=3.3 and J_{4-5}=3.8 Hz, H-4), 2.99 (1H, dd, J_{gem}=13.2 and J_{6ax-5}=14.3 Hz, H-6_{ax}), 3.33 (1H, dq, J_{2-Me}=J_{2-3}=7.0 Hz, H-2), and 3.72 (3H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=11.63 (3-Me), 15.55 (2-Me), 27.96 (*t*-Bu), 33.00 (C-3), 39.65, 39.81 (C-5 and *t*-Bu), 43.45 (C-6), 45.76, 46.68 (C-2 and C-4), 51.56 (COOMe), 175.42 (COOMe), and 213.63 (C-1); MS m/z (rel intensity, %) 241 (M^++1, 8), 240 (M^+, 31), 184 (21), 183 (base peak), 127 (44), and 126 (15). Found: C, 69.94; H, 10.00%. Calcd for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07%.

***r*-3-*t*-Butyl-*c*-4-(methoxycarbonyl)-*t*-5-methylcyclohexanone (5b):** Similar procedure using **2b** (0.397 g, 2 mmol), *n*-BuLi (2 mmol), and methyl crotonate (0.2 g, 2 mmol) under stirring at −78 °C for 2.3 h and then at room temperature for 1.5 h followed by silica-gel column chromatography with hexane–EtOAc (6 : 1, v/v) gave **5b** (0.392 g, 87%): Pale yellow liquid; IR (neat) 2950, 2900, 1700, and 1400 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (9H, s, *t*-Bu), 1.06 (3H, d, J_{Me-5}=7.3 Hz, 5-Me), 1.93 (1H, dt, J_{3-2eq}=J_{3-4}=3.8 and J_{3-2ax}=13.9 Hz, H-3), 2.03 (1H, br dd, J_{6eq-5}=2.2 and J_{gem}=14.3 Hz, H-6_{eq}), 2.27 (1H, br dd, J_{2eq-3}=3.8 and J_{gem}=13.9 Hz, H-2_{eq}), 2.43 (1H, dtq, J_{5-6eq}=J_{5-4}=2.2 Hz, J_{5-6ax}=6.6, and J_{5-Me}=7.3 Hz, H-5), 2.77 (1H, br dd, J_{4-5}=2.2 and J_{4-3}=3.8 Hz, H-4), 2.93 (1H, t, J_{gem}=J_{2ax-3}=13.9 Hz, H-2_{ax}), 3.04 (1H, dd, J_{6ax-5}=6.6 and J_{gem}=14.3 Hz, H-6_{ax}), and 3.70 (3H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=20.65 (5-Me), 27.83 (*t*-Bu), 32.92 (C-5), 33.30 (C-3), 39.39 (*t*-Bu), 43.84, 44.71, 44.88 (C-2, C-4, and C-6), 51.40 (COOMe), 175.19 (COOMe), and 211.27 (C-1); MS m/z (rel intensity, %) 227 (M^++1, 8), 226 (M^+, 15), 170 (23), 169 (base peak), 127 (10), and 110 (23). HRMS Found: m/z 226. 1575. Calcd for $C_{13}H_{22}O_3$: M, 226.1568.

***r*-3-*t*-Butyl-*c*-4-(methoxycarbonyl)-*t*-4-methylcyclohexanone (5c):** Similar procedure using **2b** (0.397 g, 2 mmol), *n*-BuLi (2 mmol), and methyl methacrylate (0.2 g, 2 mmol) under stirring at −78 °C for 2.5 h and then at room temperature for 22 h followed by silica-gel column chromatography with hexane–EtOAc (7 : 1, v/v) gave **5c** (0.045 g, 20%): Pale yellow liquid; IR (neat) 2950, 1720, 1450, 1200, and 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (9H, s, *t*-Bu), 1.45 (3H, s, 4-Me),

1.74—1.86 (2H, m, H-3_{eq} and H-5), 2.16—2.88 (5H, m, H-2, H-6, and H-3_{ax}), and 3.72 (3H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=27.33 (4-Me), 29.62 (*t*-Bu), 35.10 (C-5), 35.85 (C-3), 36.92 (*t*-Bu), 40.72 (C-2), 44.28 (C-6), 51.62 (COOMe), 53.46 (C-4), 176.83 (COOMe), and 212.72 (C-1); MS *m/z* (rel intensity, %) 227 (M^++1, 5), 226 (M^+, 1), 171 (17), 170 (57), 169 (47), 138 (15), 111 (40), and 110 (base peak). Found: C, 69.14; H, 9.65%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

Reaction of 3d with Methyl Crotonate in the Presence of $ZnCl_2$ Leading to Methyl (3*RS*,4*RS*,6*E*)-3,4,8,8-Tetramethyl-5-oxo-6-nonenoate (6). To a solution of **2d** (0.425 g, 2 mmol) in THF (1 ml) was added, at −78 °C under nitrogen, *n*-BuLi (1.6 M in hexane, 1.25 ml, 2 mmol). After stirring at −78 °C for 20 min and at room temperature for additional 30 min, the mixture was cooled down to −20 to −30 °C and a solution of $ZnCl_2$ (0.273 g, 2 mmol) in THF (1.5 ml) was added. After 20 min, the mixture was cooled down to −78 °C and methyl crotonate (0.2 g, 2 mmol) in THF (1 ml) was added. Stirring was continued at −78 °C for 20 h and at room temperature for 52 h. The mixture was poured into saturated aqueous NH_4Cl and extracted with CH_2Cl_2 (15 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.366 g) was chromatographed on silica gel using hexane–EtOAc (15 : 1) to give **6** (0.087 g, 18%): Pale yellow liquid; IR (neat) 2950, 1740, 1630, and 1460 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97 (3H, d, J_{Me-3}=6.2 Hz, 3-Me), 1.07 (3H, d, J_{Me-4}=7.0 Hz, 4-Me), 1.09 (9H, s, *t*-Bu), 2.12 (1H, dd, J_{2-3}=8.8 and J_{gem}=14.7 Hz, one of H-2), 2.29—2.46 (2H, m, H-3 and the other of H-2), 2.74 (1H, quint, J_{4-3}=J_{4-Me}=7.0 Hz, H-4), 3.67 (3H, s, COOMe), 6.08 (1H, d, J_{6-7}=16.1 Hz, H-6), and 6.87 (1H, d, J_{7-6}=16.1 Hz, H-7); ^{13}C NMR ($CDCl_3$) δ=13.36 (3-Me), 18.33 (4-Me), 28.74 (*t*-Bu), 29.62 (C-3), 32.41 (C-2), 33.79 (*t*-Bu), 37.75 (C-4), 51.46 (COOMe), 124.32 (C-6), 157.42 (C-7), 173.36 (COOMe), and 203.52 (C-5); MS *m/z* (rel intensity, %) 241 (M^++1, 3), 240 (M^+, 5), 140 (17), and 111 (base peak). HRMS Found *m/z* 240.1723. Calcd for $C_{14}H_{24}O_3$: M, 240.1724.

Reaction of 3d with Methyl (*E*)-4-Bromo-2-butenoate Leading to Methyl (1*RS*,2*SR*)-2-[(1*RS*,3*E*)-1,5,5-Trimethyl-2-oxo-3-hexenyl]-1-cyclopropanecarboxylate (7). To a solution of **2d** (0.212 g, 1 mmol) in THF (1 ml) was added, at −78 °C under nitrogen, *n*-BuLi (1.6 M in hexane, 0.63 ml, 1 mmol). After 20 min at −78 °C, stirring was continued for additional 20 min at room temperature, and then cooled to −78 °C. To this mixture was added a solution of methyl (*E*)-4-bromo-2-butenoate (0.179 g, 1 mmol) in THF (1 ml). The mixture was stirred at −78 °C for 17 h, poured into saturated aqueous NH_4Cl, and then extracted with CH_2Cl_2 (15 ml×3). The combined extracts were dried over $MgSO_4$ and evaporated in vacuo. The residue (0.205 g) was chromatographed on silica gel with hexane–EtOAc (15 : 1) to give **7** (0.118 g, 50%): Pale yellow liquid; IR (neat) 2950, 1730, 1700, 1660, 1620, 1450, 1210, 1170, 990, and 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.86 (1H, ddd, J_{3-1}=4.4, J_{3-2}=6.2, and J_{gem}=8.4 Hz, one of H-3), 1.10 (9H, s, *t*-Bu), 1.13—1.28 (1H, m, the other of H-3), 1.20 (3H, d $J_{Me-1'}$=7.0 Hz, Me), 1.49 (1H, dt, J_{1-2}=J_{1-3}=4.4, and J_{1-3}=8.4 Hz, H-1), 1.60 (1H, dddd, J_{2-1}=4.4, J_{2-3}=6.2, $J_{2-1'}$=9.2, and J_{2-3}=10.6 Hz, H-2), 2.20 (1H, dq, $J_{1'-Me}$=7.0 and $J_{1'-2}$=9.2 Hz, H-1′), 3.70 (3H, s, COOMe), 6.12 (1H, d, $J_{3'-4'}$=15.8 Hz, H-3′), and 6.88 (1H, d, $J_{4'-3'}$=15.8 Hz, H-4′); ^{13}C NMR ($CDCl_3$) δ=14.85 (Me), 16.27 (C-3), 18.98 (C-2), 25.20 (C-1), 28.70 (*t*-Bu), 33.87 (*t*-Bu), 47.62 (C-1′), 51.78 (COOMe), 123.18 (C-3′), 157.89 (C-4′), 174.23 (COOMe), and 201.91 (C-2′); MS *m/z* (rel intensity, %) 239 (M^++1, 2), 238 (M^+, 12), and 111 (base peak). HRMS Found: *m/z* 238.1571. Calcd for $C_{14}H_{22}O_3$: M, 238.1568.

Reaction of 3d with 1-Phenyl-2-buten-1-one Leading to 8 and 8′. A) To the standard solution of **3d** prepared from **2d** (0.106 g, 0.5 mmol) was added under nitrogen at −78 °C a solution of 1-phenyl-2-buten-1-one (0.073 g, 0.5 mmol, *Z*: *E*=10 : 90). After stirring at −78 °C for 1 h, the mixture was poured into saturated aqueous NH_4Cl and extracted with CH_2Cl_2 (10 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.16 g) was chromatographed on silica gel with hexane–EtOAc (10 : 1, v/v) to give an inseparable mixture of **8** and **8′** (0.104 g, 73%, **8** : **8′**=87 : 13 by ^{1}H NMR).

B) To a solution of **2d** (0.212 g, 1 mmol) in dry THF/HMPA (4 ml/0.5 ml) was added under nitrogen at −78 °C *n*-BuLi (1.6 M in hexane, 0.63 ml, 1 mmol). After 20 min, a solution of 1-phenyl-2-buten-1-one (0.146 g, 1 mmol, *Z*: *E*=9 : 91) was added, and the reaction was continued for 30 min. Similar workup and chromatographic purification gave **8** and **8′** (0.239 g, 84%, **8** : **8′**=95 : 5 by ^{1}H NMR).

C) To the standard solution of **3d** prepared from **2d** (0.212 g, 1 mmol) was added under nitrogen 18-Crown-6 (0.264 g, 1 mmol) in dry THF (2 ml). After 15 min, a solution of 1-phenyl-2-buten-1-one (0.146 g, 1 mmol, *Z*: *E*=9 : 91) was added, and the reaction was continued for 2.5 h. Similar workup and chromatographic purification gave **8** and **8′** (0.233 g, 81%, **8** : **8′**=95 : 5 by ^{1}H NMR).

3,4,8,8-Tetramethyl-1-phenyl-6-nonene-1,5-dione (8+8′): Isomer 8: Pale yellow liquid; IR (neat) 2950, 1660, 1610, 1450, 1360, 1260, 1200, and 980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.01 (3H, d, J_{Me-3}=6.6 Hz, 3-Me), 1.07 (9H, s, *t*-Bu), 1.13 (3H, d, J_{Me-4}=7.0 Hz, 4-Me), 2.51—2.66 (1H, m, H-3), 2.71 (1H, dd, J_{2-3}=9.3 and J_{gem}=15.8 Hz, one of H-2), 2.86 (1H, dq, J_{4-3}=5.1 and J_{4-Me}=7.0 Hz, H-4), 3.08 (1H, dd, J_{2-3}=3.3 and J_{gem}=15.8 Hz, the other of H-2), 6.11 (1H, d, J_{6-7}=16.1 Hz, H-6), 6.89 (1H, d, J_{7-6}=16.1 Hz, H-7), 7.41—7.58, and 7.91—8.00 (3H and 2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=12.60 (3-Me), 18.40 (4-Me), 28.71 (*t*-Bu), 31.46 (C-3), 33.78 (*t*-Bu), 41.55 (C-4), 48.67 (C-2), 124.23 (C-6), 128.10, 128.56, 132.98, 137.14 (each Ph), 157.40 (C-7), 199.76 (C-5), and 203.69 (C-1); MS *m/z* (rel intensity, %) 287 (M^++1, 8), 286 (M^+, 36), 230 (12), 167 (40), 140 (34), 111 (base peak), and 105 (25). Found: C, 79.46; H, 9.08%. Calcd for $C_{19}H_{26}O_2$: C, 79.67; H, 9.16%.

Isomer 8′: Its formation was deduced on the basis of ^{1}H and ^{13}C NMR spectra of the crude reaction mixture because **8′** could not be separated from the mixture with **8**: Partial ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, d, J_{Me-3}=6.6 Hz, 3-Me), 1.07 (3H, d, J_{Me-4}=7.0 Hz, 4-Me), 1.09 (9H, s, *t*-Bu), 6.13 (1H, d, J_{trans}=15.8 Hz, H-6), 6.94 (1H, d, J_{trans}=15.8 Hz, H-7), 7.41—7.60, and 7.92—8.00 (5H, m, Ph). Other signals are overlapping with those of **8**. Partial ^{13}C NMR ($CDCl_3$) δ=12.08 (3-Me), 16.08 (4-Me), 28.71 (C-9), 31.42 (C-3), 33.79 (C-8), 43.67 (C-4), 47.86 (C-2), 124.14 (C-6), 128.16, 128.62, 133.07, 137.06 (each Ph), 157.56 (C-7), 199.69 (C-5), and 203.90 (C-1).

Reaction of 3d with 1-Phenyl-2-buten-1-one Leading to 9+9′+9″. To the standard solution of **3d** prepared from **2d** (0.106 g, 0.5 mmol) was added, under nitrogen at −78 °C, 1-phenyl-2-buten-1-one (0.074 g, 0.5 mmol, *Z*: *E*=10 : 90 by ^{1}H NMR) in THF (1 ml). After stirring at −78 °C for 30 min and then at room temperature for 42 h, the mixture was poured into saturated NH_4Cl and extracted with CH_2Cl_2 (10 ml×3). The combined extracts were dried ($MgSO_4$) and

evaporated in vacuo. The residue (0.137 g) was chromatographed on silica gel with hexane–EtOAc (20 : 1, v/v) to give a mixture of **9**, **9′**, and **9″** (0.101 g, 71%, 62 : 16 : 22 by GLC), which were separated from each other by careful chromatographic operation.

General Procedure for the Reactions of 3 with Dimethyl Alkylidenemalonates Leading to 13a—f. As a typical procedure the reaction of **3d** with dimethyl ethylidenemalonate is described: To the standard solution of **3d** prepared from **2d** (0.212 g, 1 mmol) was added under nitrogen at −78 °C dimethyl ethylidenemalonate (0.158 g, 1 mmol) in THF (0.5 ml). After stirring for 30 min at −78 °C, the mixture was poured into saturated aqueous NH_4Cl and extracted with CH_2Cl_2 (10 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue was chromatographed on silica gel with hexane–EtOAc (15:1, v/v) to give **13c** (0.25 g, 80%, *anti*/*syn*=60:40 by ^{1}H NMR). These isomers were separated and purified by careful chromatographic operation.

Dimethyl [(*E*)-1-Ethyl-2-methyl-3-oxo-5-phenyl-4-pentenylidene]malonate (13a): Two isomeric adducts were separated and purified through column chromatography on silica gel with hexane–EtOAc (15:1, v/v).

anti-**13a:** Pale yellow liquid; IR (neat) 2950, 1720, 1680, 1600, 1420, 1190, 1140, and 1020 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.96 (3H, t, *J*=7.3 Hz, Me of Et), 1.17 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.50 (2H, dq, $J_{CH2-1'}$=5.9 and *J*=7.3 Hz, CH_2 of Et), 2.66 (1H, ddt, $J_{1'-CH2}$=$J_{1'-2}$=5.9 and $J_{1'-2'}$=7.0 Hz, H-1′), 3.10 (1H, dq, $J_{2'-Me}$=$J_{2'-1'}$=7.0 Hz, H-2′), 3.62 (1H, d, $J_{2-1'}$=5.9 Hz, H-2), 3.70, 3.75 (each 3H, each s, COOMe), 6.83 (1H, d, J_{trans}=15.8 Hz, H-4′), 7.37—7.65 (5H, m, Ph), and 7.60 (1H, d, J_{trans}=15.8 Hz, H-5′); ^{13}C NMR ($CDCl_3$) δ=12.74 (Et), 13.23 (2′-Me), 23.93 (Et), 41.99 (C-1′), 46.10 (C-2′), 52.34, 52.37, 52.48 (COOMe and C-2), 125.01 (C-4′), 128.40, 128.92, 130.49, 134.55, 142.72 (Ph and C-5′), 169.31, 169.54 (each COOMe), and 202.25 (C-3′); MS *m/z* (rel intensity, %) 333 (M^++1, 2), 332 (M^+, 8), 201 (21), 200 (43), 160 (76), and 131 (base peak); Found: C, 68.83; H, 7.41%. Calcd for $C_{19}H_{24}O_5$: C, 68.64; H, 7.28%.

syn-**13a:** Pale yellow liquid; IR (neat) 2950, 1720, 1690, 1430, 1200, and 1140 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.84 (3H, t, *J*=7.3 Hz, Me of Et), 1.09 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.26—1.58 (2H, m, CH_2 of Et), 2.68—2.77 (1H, m, H-1′), 3.03 (1H, dq, $J_{2'-Me}$=4.4 and $J_{2'-1'}$=7.0 Hz, H-2′), 3.54 (1H, d, $J_{2-1'}$=8.1 Hz, H-2), 3.73, 3.78 (each 3H, each s, COOMe), 7.00 (1H, d, J_{trans}=15.8 Hz, H-4′), 7.39—7.64 (5H, m, Ph), and 7.69 (1H, d, J_{trans}=15.8 Hz, H-5′); ^{13}C NMR ($CDCl_3$) δ=10.99 (Et), 12.80 (2′-Me), 21.43 (Et), 41.01 (C-1′), 46.20 (C-2′), 52.48, 52.57 (each COOMe), 54.53 (C-2), 124.76 (C-4′), 128.48, 128.91, 130.42, 134.68, 142.86 (Ph and C-5′), 169.25, 169.41 (each COOMe), and 202.04 (C-3′); MS *m/z* (rel intensity, %) 333 (M^++1, 4), 332 (M^+, 21), 201 (21), 200 (26), 160 (84), and 131 (base peak). Found: C, 68.28; H, 7.42%. Calcd for $C_{19}H_{24}O_5$: C, 68.64; H, 7.28%.

Dimethyl [(*E*)-1,2,6,6-Tetramethyl-3-oxo-4-heptenylidene]malonate (13b): Obtained as a 52:48 inseparable mixture of *anti*-**13b** and *syn*-**13b** (by ^{1}H NMR) after column chromatography on silica gel using hexane–EtOAc (15:1, v/v). Colorless liquid; IR (neat) 2950, 1750, 1740, 1620, 1440, and 1200 cm^{-1}; ^{1}H NMR ($CDCl_3$) *anti*-isomer δ=1.01 (3H, d, $J_{Me-1'}$=7.0 Hz, 1′-Me), 1.09 (9H, s, *t*-Bu), 1.12 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 2.50—2.63 (1H, m, H-1′), 2.85—2.97 (1H, m, H-2′), 3.59 (1H, d, $J_{2-1'}$=6.2 Hz, H-2), 3.75, 3.76 (each 3H, each s, COOMe), 6.06 (1H, d, J_{trans}=15.8 Hz, H-4′), and 6.86 (1H, d, J_{trans}=15.8 Hz, H-5′); *syn*-isomer δ=0.88 (3H, d, $J_{Me-1'}$=7.0 Hz, 1′-Me), 1.00 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.11 (9H, s, *t*-Bu), 2.68—2.81 (1H, m, H-1′), 2.85—2.97 (1H, m, H-2′), 3.41 (1H, d, $J_{2-1'}$=8.4 Hz, H-2), 3.73, 3.74 (each 3H, each s, COOMe), 6.12 (1H, d, J_{trans}=16.1 Hz, H-4′), and 6.94 (1H, d, J_{trans}=16.1 Hz, H-5′); ^{13}C NMR ($CDCl_3$) *anti*-isomer δ=12.44 (1′-Me), 14.86 (2′-Me), 28.73 (*t*-Bu), 33.84 (*t*-Bu), 36.11 (C-1′), 46.55 (C-2′), 52.24, 52.41 (each COOMe), 53.66 (C-2), 124.60 (C-4′), 157.68 (C-5′), 169.01, 169.08 (each COOMe), and 202.69 (C-3′); *syn*-isomer δ=11.00 (1′-Me), 15.36 (2′-Me), 28.73 (*t*-Bu), 33.84 (*t*-Bu), 34.34 (C-1′), 45.59 (C-2′), 52.34, 52.50 (each COOMe), 55.20 (C-2), 123.77 (C-4′), 157.89 (C-5′), 168.92, 169.45 (each COOMe), and 203.09 (C-3′); MS *m/z* (rel intensity, %) 299 (M^++1, 2), 298 (M^+, 8), 167 (21), 140 (30), and 111 (base peak). HRMS Found: *m/z* 298.1782. Calcd for $C_{16}H_{26}O_5$: M, 298.1779.

Dimethyl [(*E*)-1-Ethyl-2,6,6-trimethyl-3-oxo-4-heptenylidene]malonate (13c): *anti*-**13c:** Colorless liquid; IR (neat) 2980, 1755, 1735, 1620, and 1460 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, t, *J*=7.3 Hz, Me of Et), 1.07 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.10 (9H, s, *t*-Bu), 1.38—1.58 (2H, m, CH_2 of Et), 2.53—2.62 (1H, ddt, $J_{1'-2}$=5.9 and $J_{1'-2'}$=$J_{1'-CH_2}$=7.0 Hz, H-1′), 3.01 (1H, dq, $J_{2'-1'}$=7.0 and $J_{2'-Me}$=7.0 Hz, H-2′), 3.58 (1H, d, $J_{2-1'}$=5.9 Hz, H-2), 3.70, 3.74 (each 3H, each s, COOMe), 6.08 (1H, d, J_{trans}=16.1 Hz, H-4′), and 6.86 (1H, d, J_{trans}=16.1 Hz, H-5′); ^{13}C NMR ($CDCl_3$) δ=12.74 (Et), 13.33 (2′-Me), 23.86 (Et), 28.74 (*t*-Bu), 33.79 (*t*-Bu), 41.96 (C-1′), 45.54 (C-2′), 52.25, 52.30 (each COOMe), 52.44 (C-2), 124.11 (C-4′), 157.24 (C-5′), 169.35, 169.57 (each COOMe), and 203.06 (C-3′); MS *m/z* (rel intensity, %) 313 (M^++1, 2), 312 (M^+, 4), 180 (10), 140 (base peak), and 111 (89). Found: C, 65.55; H, 9.02%. Calcd for $C_{17}H_{28}O_5$: C, 65.34; H, 9.04%.

syn-**13c:** Colorless liquid; IR (neat) 2950, 1750, 1730, 1620, 1455, and 1430 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.83 (3H, t, *J*=7.3 Hz, Me of Et), 1.03 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.11 (9H, s,

t-Bu), 1.23—1.54 (2H, m, CH_2 of Et), 2.57—2.67 (1H, m, H-1′), 2.92 (1H, dq, $J_{2'-1'}$=4.8 and $J_{2'-Me}$=7.0 Hz, H-2′), 3.49 (1H, d, $J_{2-1'}$=8.1 Hz, H-2), 3.73, 3.75 (each 3H, each s, COOMe), 6.21 (1H, d, J_{trans}=16.1 Hz, H-4′), and 6.93 (1H, d, J_{trans}=16.1 Hz, H-5′); ^{13}C NMR ($CDCl_3$) δ=11.46 (Et), 12.90 (2′-Me), 21.48 (Et), 28.74 (*t*-Bu), 33.81 (*t*-Bu), 41.08 (C-1′), 45.73 (C-2′), 52.38, 52.48 (each COOMe), 54.44 (C-2), 123.71 (C-4′), 157.52 (C-5′), 169.27, 169.35 (each COOMe), and 202.87 (C-3′); MS *m/z* (rel intensity, %) 313 (M^++1, 2), 312 (M^+, 7), 181 (12), 140 (91), and 111 (base peak). Dimethyl [(*E*)-1-Ethyl-2-methyl-3-oxo-4-hexenylidene]malonate (13f): Obtained as a 64 : 36 inseparable mixture of *anti*-**13f** and *syn*-**13f** (by ^{1}H NMR) after column chromatography on silica gel using hexane–EtOAc (10 : 1 to 15 : 1, v/v). Pale yellow liquid: IR (neat) 2900, 1720, 1690, 1620, 1420, 1190, and 1140 cm^{-1}; ^{1}H NMR ($CDCl_3$) *anti*-isomer δ=0.92 (3H, t, *J*=7.3 Hz, 1′-Et), 1.06 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.24—1.58 (2H, m, 1′-Et), 1.91 (3H, dd, $J_{6'-4'}$=1.8 and $J_{6'-5'}$=7.0 Hz, H-6′), 2.53—2.68 (1H, m, H-1′), 2.99 (1H, dq, $J_{2'-1'}$=$J_{2'-Me}$=7.0 Hz, H-2′), 3.56 (1H, d, $J_{2-1'}$=6.2 Hz, H-2), 3.69, 3.73 (each 3H, each s, COOMe), 6.21 (1H, dq, $J_{4'-6'}$=1.8 and J_{trans}=15.8 Hz, H-4′), and 6.89 (1H, dq, $J_{5'-6'}$=7.8 and J_{trans}=15.8 Hz, H-5′); *syn*-isomer δ=0.82 (3H, t, *J*=7.3 Hz, 1′-Et), 1.02 (3H, d, $J_{Me-2'}$=7.0 Hz, 2′-Me), 1.24—1.58 (2H, m, 1′-Et), 1.92 (3H, dd, $J_{6'-4'}$=1.8 and $J_{6'-5'}$=7.0 Hz, H-6′), 2.53—2.68 (1H, m, H-1′), 2.89 (1H, dq, $J_{2'-1'}$=4.4 and $J_{2'-Me}$=7.0 Hz, H-2′), 3.49 (1H, d, $J_{2-1'}$=8.1 Hz, H-2), 3.73, 3.76 (each 3H, each s, COOMe), 6.34 (1H, dq, $J_{4'-6'}$=1.8 and J_{trans}=15.8 Hz, H-4′), and 6.96 (1H, dq, $J_{5'-6'}$=7.0 and J_{trans}=15.8 Hz, H-5′); ^{13}C NMR ($CDCl_3$) *anti*-isomer δ=12.69 (Et), 12.96 (2′-Me), 18.30 (C-6′), 23.90 (Et), 41.83 (C-1′), 45.08 (C-2′), 52.31, 52.35, 52.40 (COOMe and C-2), 130.68 (C-4′), 142.73 (C-5′), 169.32, 169.56 (each COOMe), and 202.30 (C-3′); *syn*-isomer δ=11.07 (Et), 12.80 (2′-Me), 18.30 (C-6′), 21.44 (Et), 40.95 (C-1′), 45.43 (C-2′), 52.45, 52.54 (each COOMe), 54.53 (C-2), 130.25 (C-4′), 142.95 (C-5′), 169.28, 169.40 (each COOMe), and 201.97 (C-3′); MS *m/z* (rel intensity, %) 271 (M^++1, 3), 270 (M^+, 15), 139 (27), 98 (base peak), and 69 (41). HRMS Found: *m/z* 270.1467. Calcd for $C_{14}H_{22}O_5$: M, 270.1466.

Catalytic Hydrogenation Followed by $Zn(BH_4)_2$ Reduction of 13d Leading to 15 and 16. A solution of **13d** (0.67 g, 1.86 mmol) in EtOH (10 ml) in the presence of palladium/carbon (10 wt%) was stirred under hydrogen at room temperature for 12 h. The catalyst was filtered off through cerite and the filtrate was evaporated in vacuo to give **14** (0.679 g, 100%) as colorless oil [**14:** IR (neat) 2950, 1710, 1430, 1230, 1150, and 1010 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.74 (9H, s, *t*-Bu), 1.14 (3H, d, $J_{Me-2'}$=7.3 Hz, 2′-Me), 1.12—1.26 (2H, m, H-5′), 1.97—2.21 (2H, m, H-4′), 3.15 (1H, dq, $J_{2'-Me}$=7.3 and $J_{2'-1'}$=7.7 Hz, H-2′), 3.47, 3.71 (each 3H, each s, COOMe), 3.73 (1H, dd, $J_{1'-2'}$=7.7 and $J_{1'-2}$=9.2 Hz, H-1′), 4.03 (1H, d, $J_{2-1'}$=9.2 Hz, H-2), and 7.15—7.29 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.92 (3-Me), 29.01 (*t*-Bu), 29.63 (*t*-Bu), 36.66 (C-5′), 37.87 (C-4′), 47.79, 49.70 (C-1′ and C-2′), 52.31, 52.61 (each COOMe), 54.56 (C-2), 127.31, 128.29, 128.95, 139.16 (each Ph), 168.36, and 168.91 (each COOMe), and 213.43 (C-3′), MS *m/z* (rel intensity, %) 363 (M^++1, 24), 362 (M^+, base peak), 231 (79), 221 (59), and 113 (68). HRMS Found: *m/z* 362.2094. Calcd for $C_{21}H_{30}O_5$: M, 362.2092]. An ethereal solution of freshly prepared $Zn(BH_4)_2$ (0.36 M in diethyl ether, 8.3 ml, 3 mmol) was added to **14** (0.13 g, 0.375 mmol) in ether (1 ml) and the mixture was stirred at 0 °C for 21.5 h. The reaction was quenched with aqueous HCl (1 equiv) and extracted with CH_2Cl_2 (15 ml×2). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.12 g) was chromatographed on silica gel with hexane–EtOAc (10 : 1 to 4 : 1, v/v) to give **15** (0.046 g, 37%, 85 : 15 by ^{13}C NMR) and then **16** (0.046 g, 37%, 78 : 22 by ^{13}C NMR).

Methyl *c*-5-Methyl-*t*-6-(3,3-dimethylbutyl)-*r*-4-phenyl-2-oxoperhydropyran-3-carboxylate (15): Only the major isomer was isolated from the mixture. Colorless solid; mp 74—77 °C; IR (KBr) 2950, 1720, 1430, 1150, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.80 (3H, d, J_{Me-5}=7.3 Hz, 5-Me), 0.91 (9H, s, *t*-Bu), 1.12—1.29 (2H, m, two of H-1′ and H-2′), 1.49—1.80 (2H, m, the other of H-1′ and H-2′), 2.26 (1H, ddq, J_{5-6}=4.8, J_{5-4}=5.5, and J_{5-Me}=7.3 Hz, H-5), 3.67 (1H, dd, J_{4-5}=5.5 and J_{4-3}=7.0 Hz, H-4), 3.93 (1H, d, J_{3-4}=7.0 Hz, H-3), 4.17 (1H, dt, J_{6-5}=4.8, $J_{6-1'}$=4.8, and 7.3 Hz, H-6), and 7.12—7.38 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.34 (5-Me), 28.75 (C-2′), 29.24 (*t*-Bu), 30.06 (*t*-Bu), 34.34 (C-1′), 38.62 (C-5), 43.86 (C-4), 51.10, 52.94 (C-3 and COOMe), 84.33 (C-6), 127.53, 128.19, 128.72, 138.09 (each Ph), 167.64, and 169.21 (C-2 and COOMe); MS *m/z* (rel intensity, %) 332 (M^+, 75), 288 (50), 287 (39), 273 (base peak), 214 (35), 199 (37), 190 (25), 189 (23), 162 (23), 143 (41), 131 (63), 129 (29), 118 (53), 117 (25), 103 (24), 91 (44), 69 (29), 57 (54), and 41 (33). Found: C, 72.48; H, 8.43%. Calcd for $C_{20}H_{28}O_4$: C, 72.25; H, 8.49%.

Methyl 2-Hydroxy-*c*-5-methyl-*c*-6-(3,3-dimethylbutyl)-*r*-4-phenylperhydropyran-3-carboxylate (16): Only the major isomer was isolated from the mixture. Colorless solid; mp

132—134 °C; IR (KBr) 3300, 2850, 1680, 1420, 1250, 1060, and 1000 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.68 (3H, d, J_{Me-5}=7.0 Hz, 5-Me), 0.89 (9H, s, *t*-Bu), 1.08—1.81 (5H, m, H-1′, H-2′, and H-5), 3.05 (1H, dd, J_{3-2}=8.1 and J_{3-4}=12.5 Hz, H-3), 3.37 (1H, dd, J_{4-5}=4.0 and J_{4-3}=12.5 Hz, H-4), 3.53 (3H, s, COOMe), 3.69—3.75 (1H, m, H-6), 4.96 (1H, d, J_{2-3}=8.1 Hz, H-2), and 7.10—7.33 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=6.41 (5-Me), 27.63 (C-2′), 29.30 (*t*-Bu), 30.14 (C-1′), 37.02 (*t*-Bu), 39.86 (C-5), 48.34 (C-3 and C-4), 51.86 (COOMe), 80.11 (C-6), 97.79 (C-2), 126.69, 128.06, 128.29, 140.14 (each Ph), and 172.98 (COOMe); MS *m/z* (rel intensity, %) 334 (M^+, 2), 288 (29), 209 (15), 164 (16), 163 (base peak), 162 (34), and 118 (13). Found: C, 71.77; H, 8.88%. Calcd for $C_{20}H_{30}O_4$: C, 71.81; H, 9.05%.

Demethoxycarbonylation of 15 (or 16) Leading to 17 (or 18). To a solution of **15** (0.046 g, 0.138 mmol) in MeOH (1.5 ml) was added dropwise at room temperature aqueous NaOH (3%, 1 ml). This solution was stirred for 2 h, poured into aqueous HCl (1N), and extracted with dichloromethane (10 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue was chromatographed on silica gel with hexane–EtOAc (3 : 1, v/v) to give **17** (0.025 g, 66%). A similar procedure using **16** (0.046 g, 0.137 mmol) gave **18** (0.041 g, 93%).

***c*-5-Methyl-*t*-6-(3,3-dimethylbutyl)-*r*-4-phenyl-2-oxoperhydropyran (17):** Pale yellow liquid; IR (neat) 2900, 1710, 1450, 1360, 1210, 990, 750, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82 (3H, d, J_{Me-5}=7.0 Hz, 5-Me), 0.89 (9H, s, *t*-Bu), 1.12—1.80 (4H, m, H-1′ and H-2′), 2.14 (1H, ddq, J_{5-4}=4.8, J_{5-6}=7.0, and J_{5-Me}=7.0 Hz, H-5), 2.79—2.92 (2H, m, H-3), 3.29 (1H, m, H-4), 4.07 (1H, ddd, $J_{6-1'}$=4.0, 7.8, and J_{6-5}=7.0 Hz, H-6), and 7.11—7.38 (5H, m, Ph); NOE: H-4/H-5, 4-Ph/5-Me, and 4-Ph/H-6; ^{13}C NMR ($CDCl_3$) δ=14.53 (5-Me), 28.74 (C-2′), 29.26 (*t*-Bu), 30.05 (*t*-Bu), 34.50 (C-1′) 35.61 (C-5), 38.56 (C-4), 40.53 (C-3), 83.24 (C-6), 127.15, 128.15, 128.52, 139.59 (each Ph), and 171.57 (C-2); MS *m/z* (rel intensity, %) 275 (M^++1, 7), 274 (M^+, 32), 142 (22), 131 (27), 118 (base peak), 104 (28), and 91 (22). Synthesis and Fluorescence Properties of Selectively Metallated Diporphyrins with Electron-Accepting Moieties

Toshi NAGATA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received May 29, 1991)

Synthesis of selectively metallated diporphyrins with electron-accepting moieties is described. Steady-state fluorescence spectra of these compounds showed substantial quenching of the fluorescence of the free-base porphyrin. A possible "superexchange" mechanism of long-range electron transfer is discussed.

At the initial stage of photosynthesis, an electron travels from the photoexcited (bacterio-)chlorophylls to the acceptor quinone producing a high-energy charge-separation state[1] which is utilized in the following dark processes. In the case of purple bacteria, the primary charge separation process consists of two (or three, as argued in recent reports[2]) consecutive electron transfer processes, with a bacteriopheophytin as an intermediate acceptor. The X-ray structures of bacterial photosynthetic reaction centers have been reported for several species,[3] and spatial arrangement of the chromophores is now known. However, it is still unclear what structural features are critically important for the complexes to function properly.

Many artificial chlorophyll- (or porphyrin-) quinone model compounds are being studied in order to relate

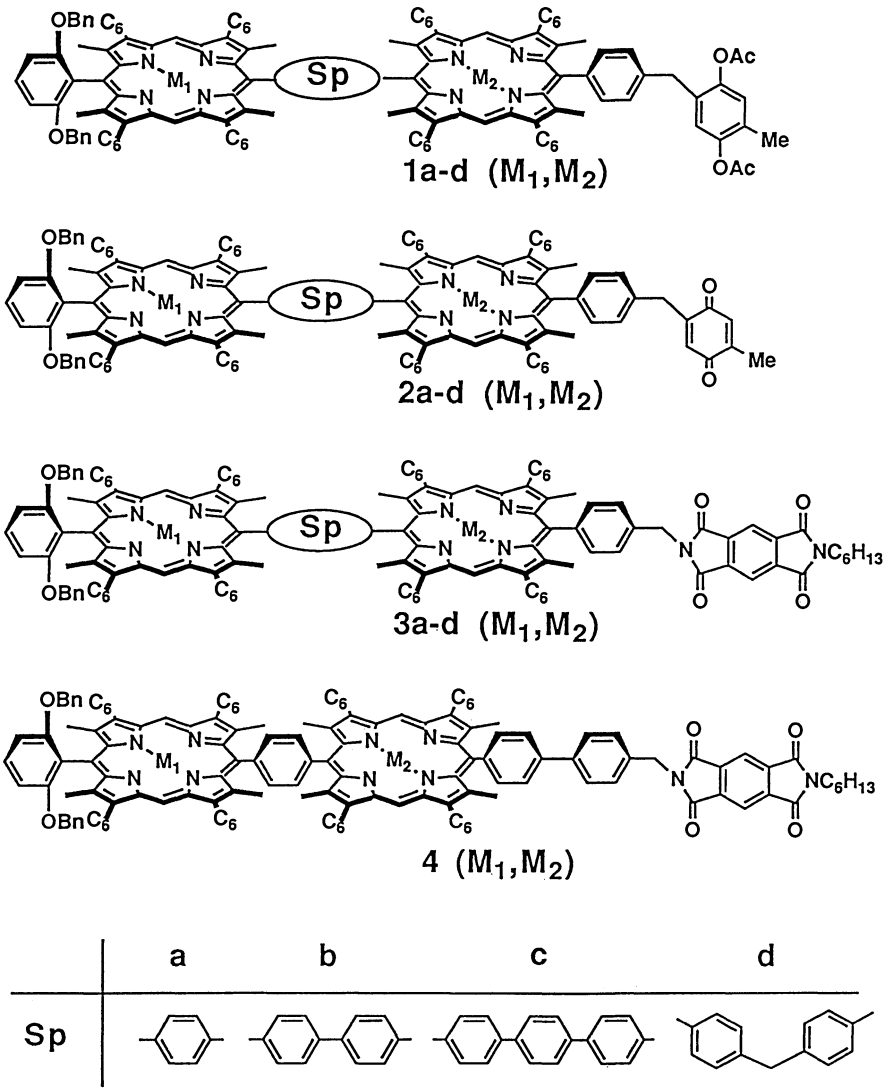

Chart 1.

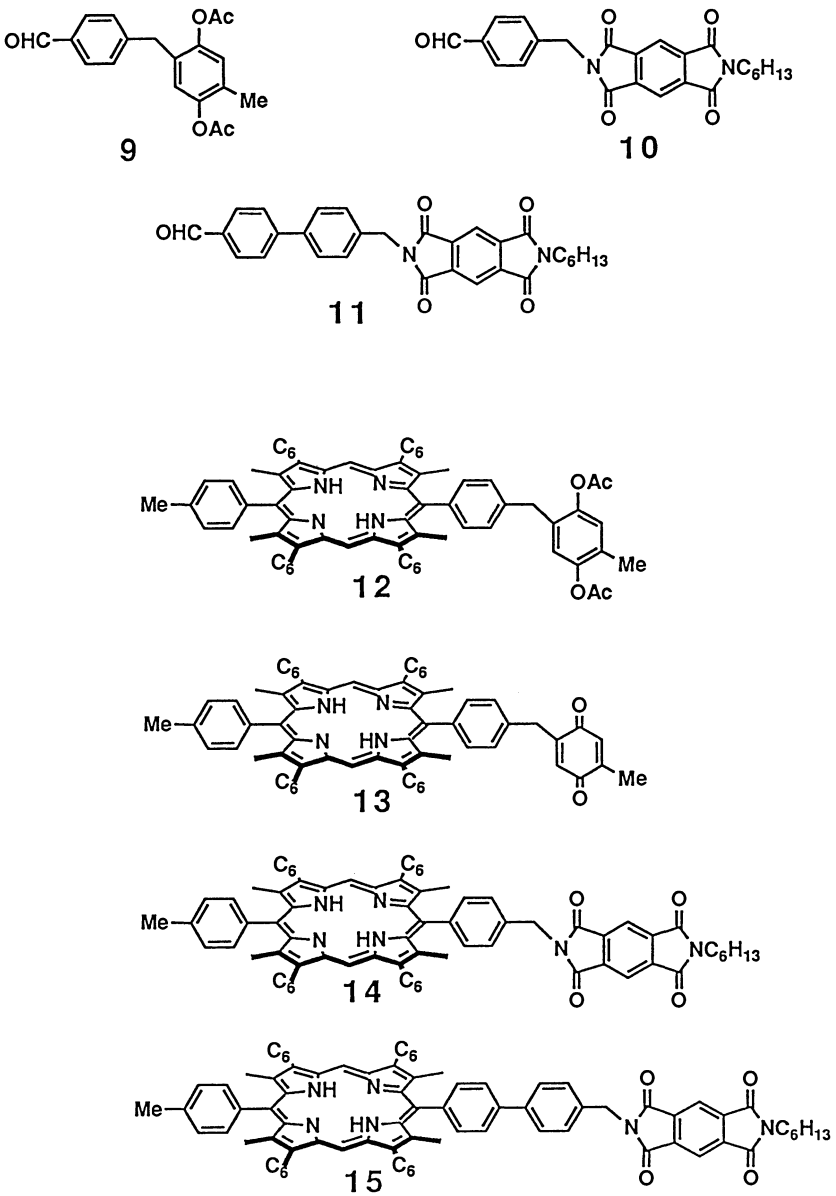

Chart 2.

the photophysical properties to the structural parameters.[4] In the course of our study on new photosynthetic model systems,[5] we designed partially metallated functionalized diporphyrins **1a**—**d** (H_2, Zn), **2a**—**d** (H_2, Zn), and **3a**—**d** (H_2, Zn) (Chart 1), as models for studying long-range electron-transfer reactions. The compounds **2a**—**d** and **3a**—**d** have the electron-accepting benzoquinone and 1,2:4,5-benzenebis (dicarboximide) (pyromellitic diimide) moieties, while the compounds **1a**—**d** are the reference compounds with the non-electron-accepting 1,4-diacetoxybenzene (hydroquinone diacetate) moiety. For each of these series, four compounds were prepared (**a**—**d**) with different types of bridging groups between the two porphyrins; 1,4-phenylene, 4,4′-biphenylylene, 4,4″-terphenylylene, and methylenebis(1,4-phenylene). The compound **4** was also prepared, in which the distance between the diimide moiety and the "distant" porphyrin (i.e. the one which is not directly bound to the diimide moiety) is the same as that in **3b** but the distances between the neighboring chromophores are different from those in **3b**. In these systems, it was expected that the photoinduced electron transfer would occur from the free-base porphyrin to the terminal acceptor, and that the intervening zinc porphyrin might play an important role during this electron transfer, as the "accessory" bacteriochlorophyll in the natural photosynthetic system might do.[6]

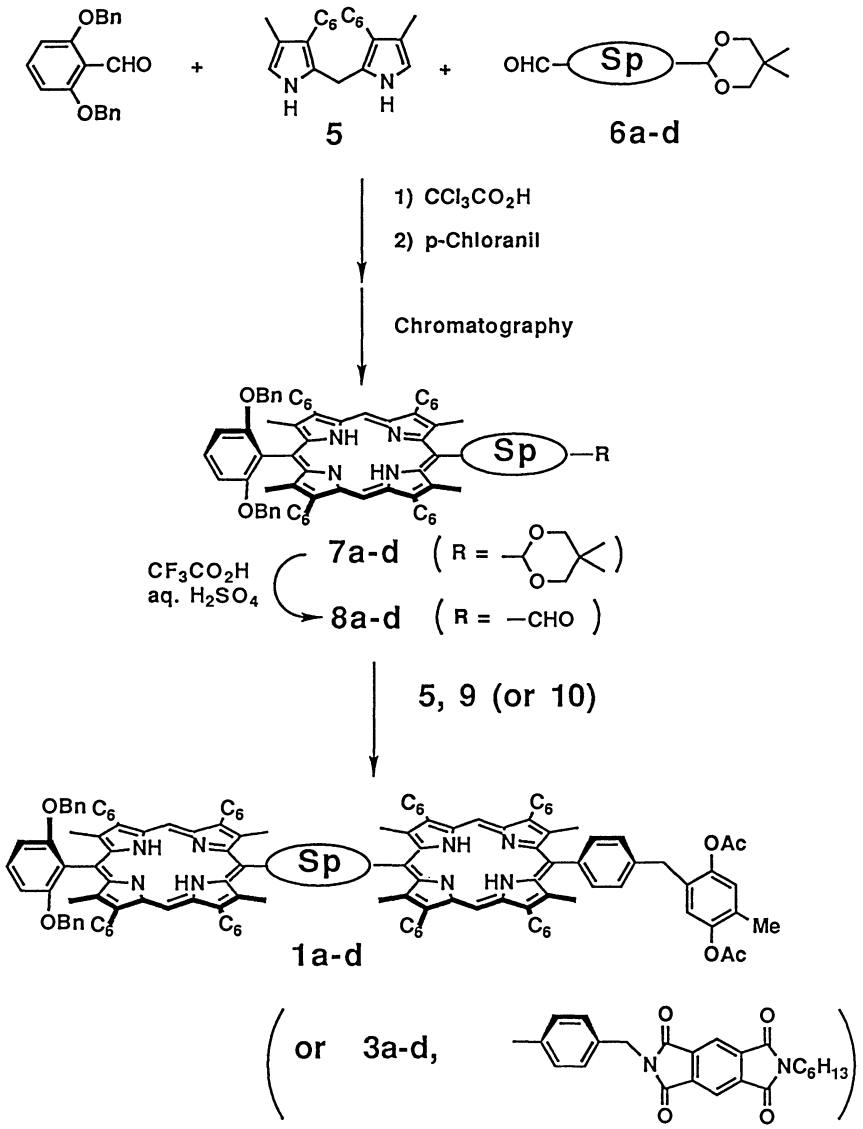
In this paper, the synthesis and steady-state fluorescence spectra of these compounds are reported and discussed. The keypoint in the synthetic strategy is to introduce a bulky 2,6-bis(benzyloxy)phenyl group on one end of the diporphyrin core. This group offered some regioselectivity of metal insertion which prefers the less hindered porphyrin ring. The steady-state

fluorescence spectra showed that the singlet excited state of the free-base porphyrin was quenched by the electron-accepting group. A possible "superexchange" mechanism of long-range electron transfer is also discussed.

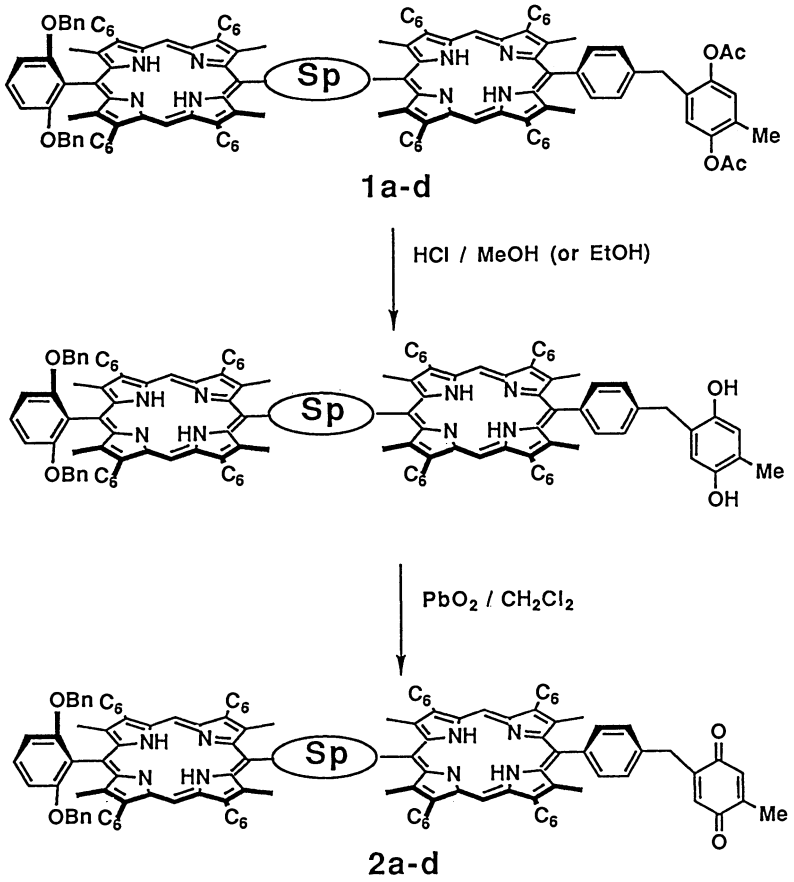
Results and Discussion

Synthesis of Selectively Metallated Diporphyrins. The synthesis of functionalized free-base diporphyrins **1**, **2**, and **3** is shown in Scheme 1. Acid-catalyzed condensation[5e] of dipyrrolylmethane **5** with 2,6-bis(benzyloxy)-benzaldehyde and monoprotected aromatic dialdehyde **6** gave a mixture of three porphyrins. The cross-coupling product **7** was separated by column chromatography. The acetal **7** was hydrolyzed to give the corresponding aldehyde **8**, which was allowed to condense with dipyrrolylmethane **5** and functionalized aldehyde **9** (or **10**, **11**). The 1,4-diacetoxybenzene-linked diporphyrin **1** (or the diimide-linked diporphyrins **3**, **4**) was separated by column chromatography. The quinone-linked diporphyrin **2** was derived from **1**, by acidic hydrolysis of phenolic esters followed by oxidation with lead dioxide (Scheme 2). The functionalized monomeric porphyrins **12**, **14**, and **15** were synthesized by condensation of **5** with *p*-tolualdehyde and appropriate functionalized aldehyde, and separated and purified by column chromatography. The quinone-linked porphyrin **13** was derived from **12** in a similar manner as **1**.

Selectively metallated diporphyrins were synthesized by partial metallation followed by chromatographic separation. Treatment of free base of **1**, **2**, or **3** with a limited amount of zinc acetate (molar ratio $Zn(OAc)_2$/diporphyrin=0.5—1.0) in dichloromethane gave a mixture of four species, (Zn, Zn), (H_2, Zn), (Zn, H_2), and (H_2, H_2), which could be separated by flash column chromatography. The dizinc complex and the starting



Scheme 1.



Scheme 2.

metal-free material were easily characterized using UV-visible spectroscopy. The remaining two species were characterized as monozinc complexes. Typical UV-spectra of dizinc complex, monozinc complex and metal-free diporphyrin are shown in Fig. 1. The Q-band (460 to 650 nm) absorption spectra of the free-base and dizinc diporphyrins showed the characteristic features of the monomeric free-base and zinc porphyrins, respectively (Fig. 1, A). On the other hand, the Q-band spectra of the monozinc complex was identical to the sum of those of monomeric free-base and zinc porphyrins (Fig. 1, B). The FAB (fast atom bombardment) mass spectra of these diporphyrins also showed the correct molecular weights of dizinc, monozinc, and free-base species.

Identification of the two monozinc species was a more subtle problem. In every experiment, one species (which moves slower on TLC than the other) was obtained in larger amount than the other (about 2.5 : 1). This major species was identified as the (H_2, Zn) complex based on the ^{1}H NMR spectral patterns of the porphyrin-NH protons. Figure 2 shows the high-field regions of ^{1}H NMR Spectra of metal-free **3d**, two monometallated **3d**'s (major and minor species), and monomeric porphyrins **8d** and **14**. The NH signals of **8d** appeared in lower field than those of **14**, probably due to the substituent effect of the 2,6-bis(benzyloxy)-phenyl group. The metal-free **3d** showed four signals in the NH region. The two signals in the lower field were assigned to the NH-protons of the bis(benzyloxy)-phenyl substituted ring, and the two signals in the higher field to those of the other ring. Comparison of the spectra of the two monozinc species with that of the free-base led to the conclusion that the "major" one is the (H_2, Zn) complex.

Sessler et al. reported synthesis of quinone-substituted monometallated diporphyrins.[4h] They observed complete regioselectivity in metallation of their systems, but this was not the case in the systems described here. Partial zinc insertion of **1**, **2**, and **3** always gave mixtures of all the four possible products, which were separated by column chromatography. Among the two monometallated species, one species was always obtained in higher yield, and this was identified as the (H_2, Zn) complex. Apparently, the porphyrin ring on the right side (in the drawings in Chart 1) was preferentially metallated over the ring on the left side. When the 2,6-bis(benzyloxy)phenyl group is replaced by a 2,6-dimethoxyphenyl group, the selectivity of metallation was much lower, and when the group is replaced by a hydrogen atom, essentially no selectivity was observed (data not shown). It is likely that the regioselectivity in metallation of **1**, **2**, and **3** (although not very high) is due to the bulkiness of the 2,6-bis(benzyloxy)phenyl group.

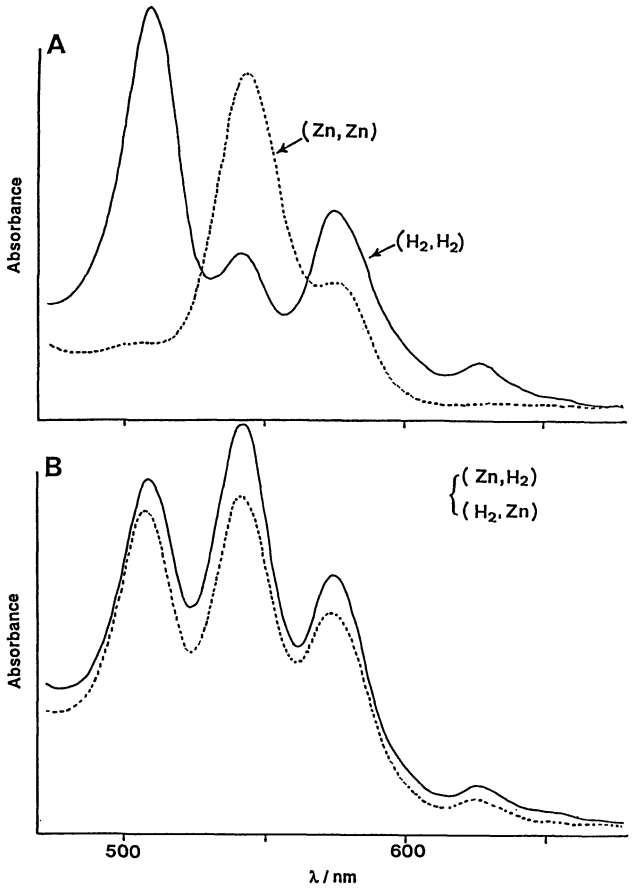


Fig. 1. Visible absorption spectra of metallated diporphyrins in THF. (A) **3d** (H_2, H_2) and **3d** (Zn, Zn). (B) Two isomeric monozinc complexes of **3d**. Solid line is the "major" complex, i.e. **3d** (H_2, Zn).

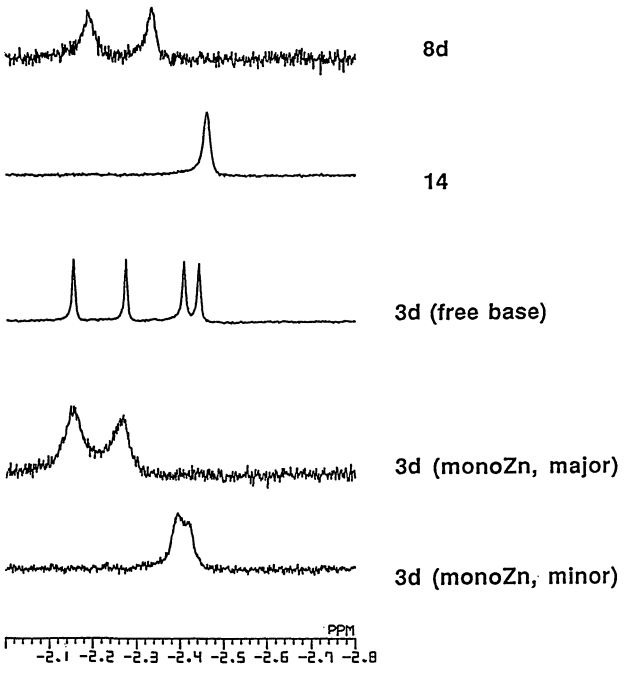

Fig. 2. ^{1}H NMR spectra of monomeric porphyrins and partially metallated diporphyrins in the high-field region.

Steady-State Fluorescence Spectra. In order to investigate the photophysical properties of monometallated diporphyrins, the fluorescence emission spectra were measured under steady-state conditions. The (H_2, Zn) compounds with attached acceptor moieties are of particular interest because of the possible long-range electron transfer from the free-base porphyrin to the acceptor.

When a THF solution of an (H_2, Zn) complex was irradiated by the 507 nm light (or 510 nm light in the case of **1a**, **2a**, and **3a**),[7] which was mainly absorbed by the free-base porphyrin moiety, characteristic emission spectrum of the free-base porphyrins was observed. Figure 3 shows the typical fluorescence spectra of the (H_2, Zn) diporphyrins with the diacetoxybenzene, quinone, and diimide moieties. The spectral shapes were essentially invariant with the various bridging groups and acceptor moieties, while the relative fluorescence intensities varied significantly. Table 1 shows the relative fluorescence intensities of these compounds (the

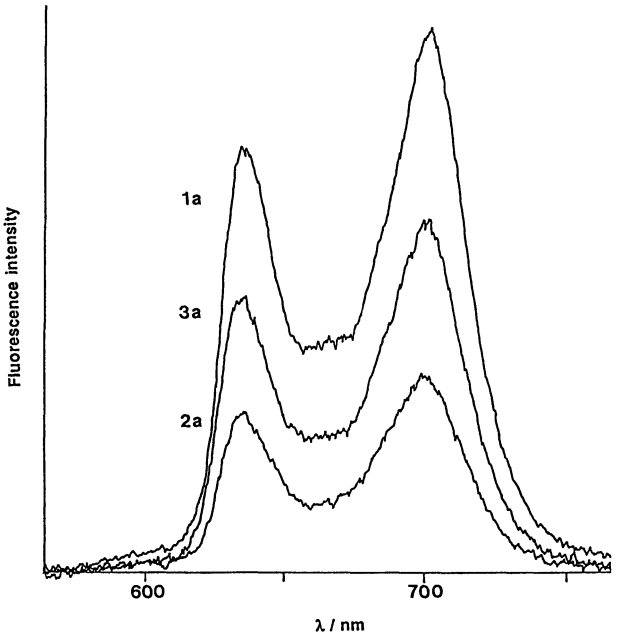

Fig. 3. Steady-state fluorescence spectra of **1a** (H_2, Zn), **2a** (H_2, Zn) and **3a** (H_2, Zn) in THF at 25 °C. Excitation at 510 nm.

Table 1. Relative Fluorescence Intensities of (H_2, Zn) Diporphyrins. Excitation at 507 nm (or 510 nm, Where Indicated). Emission at 700 nm. In THF, at 25 °C

a) Excitation at 510 nm.

corresponding 1,4-diacetoxybenzene-linked diporphyrins **1a**—**d** (H_2, Zn) were chosen as the references).[8] Two points should be noticed: (1) the fluorescence intensity is decreased when an acceptor moiety is present; the quinone moiety has a greater effect than the diimide moiety, and (2) the effect of the acceptor moiety is increased as the bridging group between the two porphyrin rings varies in the order 4,4″-terphenylylene< 4,4′-biphenylylene<methylenebis(1,4-phenylene)<1,4-phenylene.

It is reasonable to assume that the fluorescence of the free-base porphyrin is quenched through the electron transfer (ET) from the excited porphyrin to the acceptor quinone or diimide. A number of studies about porphyrin-quinone systems have confirmed that quinones readily accept an electron from excited molecules of porphyrins.[9] Recent transient-absorption studies have shown that quenching of porphyrin excited states by a diimide moiety also proceeds through an ET process.[10] Considering an ET quenching in the systems described here, one can explain why the quinone moiety worked as a more efficient quencher than the diimide moiety, as the ET reaction is more exothermic for the quinone than the diimide.[11] However, it is curious that the rate of "electron transfer" is unusually large for the very long donor-to-acceptor distance; k_{ET} was estimated to be 1.4×10^8 s^{-1} for **2a** (center-to-center distance 21 Å), while a rate constant less than 10^7 s^{-1} was reported for the bis(bicyclooctane) linked porphyrin-quinone system (center-to-center distance 18.8 Å).[12] It is very likely that a "superexchange" mechanism is working, in which the intervening zinc porphyrin acts as a mediator.[13]

The quenching efficiency clearly depends on the bridging group between the two porphyrins. As a general, the quenching becomes less efficient as the donor-to-acceptor distance becomes larger. However, the compound **4** offers a problem; although **4** has the same donor-to-acceptor distance as **3b**, **4** showed practically no quenching while **3b** showed quenching of 12% efficiency. The theory of superexchange can explain such a difference. It has been shown[12] that the rate of superexchange electron transfer in a D–I–A system (D, I, and A denote donor, intermediate, and acceptor) depends on the product of two transfer integrals V_{DI} and V_{IA}. In the present case, D is the free-base porphyrin, I is the zinc porphyrin, and A is the acceptor. The compound **3b** has a shorter distance between D and I and a longer distance between I and A than the compound **4**. Although there is no estimation for the values of V_{DI} and V_{IA} from the experimental data at present, the reported rates of electron transfer between two chromophores with similar geometries may be suggestive. Osuka et al. reported the rates of electron transfer in zinc–iron(III) hybrid diporphyrins;[14] 7.4×10^{10} s^{-1} for the 1,4-phenylene bridged diporphyrin and 1.6×10^{10} s^{-1} for the 4,4′-biphenylylene bridged one. The same authors also reported the rates of energy transfer in zinc–(free base) hybrid diporphyrins;[15] 6.6×10^{10} s^{-1} for the 1,4-phenylene bridged one and 7.8×10^9 s^{-1} for the 4,4′-biphenylylene bridged one. Insertion of one additional 1,4-phenylene group resulted in the decrease of the rate by a factor of 4.6 (electron transfer) or 8.5 (energy transfer). On the other hand, the fluorescence quantum yields of the two imide-linked (mono)porphyrins **14**-Zn and **15**-Zn were measured (relative values to **12**-Zn), and it was found that the fluorescence quenching in the latter was 100 times slower than in the former. These results show that, when one additional phenyl group is inserted between the two chromophores, the effect of this insertion upon the rates of electron (or energy) transfer is greater for the porphyrin–imide systems than for the porphyrin–porphyrin systems. Thus it may be possible that V_{IA} drops more severely in **4** than V_{DI} rises and hence the rate of electron transfer is smaller in **4** than in **3b**, only if it can be generally stated that the porphyrin–imide interaction is more sensitive to the distance than the porphyrin–porphyrin interaction.

Conclusion

A new series of selectively metallated diporphyrin-acceptor systems **1**, **2**, and **3** were synthesized. Introduction of a bulky substituent at one end of the diporphyrin led to preferential formation of the (H_2, Zn) isomer over the (Zn, H_2) isomer, when metallated with a limited amount of zinc acetate. Although the selectivity was not complete, the (H_2, Zn) isomers of **1**—**3** were readily purified by column chromatography, with sufficient purity for spectroscopic studies.

The (H_2, Zn) complexes of **2** and **3** showed substantial quenching of the fluorescence of the free-base porphyrin moiety. It is likely that a long-distance, superexchange electron transfer is responsible for this quenching. Synthesis and spectroscopic studies of other "partially metallated" functionalized oligoporphyrins are currently under way.

Experimental

General. For synthetic use, tetrahydrofuran (THF), dichloromethane, acetonitrile, and acetone were refluxed over and distilled from sodium benzophenone ketyl, P_2O_5, CaH_2, and $CaSO_4$, respectively. *N,N*-Dimethylformamide (DMF) was distilled under reduced pressure and stored over molecular sieves. Other solvents and reagents were reagent grade. Melting points were measured on a Yanagimoto micro melting point apparatus and are uncorrected. Preparative separations were usually performed by flash column chromatography on silica gel (Merck, Kieselgel 60H, Art. 7736).

UV-visible spectra were obtained with a Shimadzu UV-3000 spectrometer. Steady-state fluorescence spectra were taken on a Shimadzu RF-502A spectrofluorimeter. ^1H NMR spectra were recorded on a JEOL GX-400 spectrometer (operating at 400 MHz), chemical shifts being reported in the delta scale (ppm) relative to Me_4Si. Mass spectra were recorded on JEOL DX-300 and HX-110 spectrometers. For porphyrin

compounds, the positive-FAB (fast atom bombardment) ionization method was used (accelerating voltage 1.5 kV and 10 kV, Xe atom as the primary ion source). The FAB matrix was 3-nitrobenzyl alcohol/chloroform.

2,6-Bis(benzyloxy)benzaldehyde. Synthesized from 2,6-dihydroxybenzoic acid by the following sequence: (1) conversion to the methyl ester (diazomethane in THF, r.t., 98%), (2) conversion to the bis(benzyloxy) derivative by treatment with benzyl bromide (2.2 equiv) in the presence of K_2CO_3 (2.5 equiv) in acetone (reflux overnight, 71%), (3) reduction to the primary alcohol ($LiAlH_4$ in THF, r.t., 96%), and finally (4) oxidation to the aldehyde (1.2 equiv of PCC (pyridinium chlorochromate) in CH_2Cl_2, r.t., 5.5 h, 98%). Pale yellow needles, mp 76—77 °C (EtOH). ^{1}H NMR δ=10.66 (1H, s), 7.47 (4H, d, J=7.0 Hz), 7.40 (5H, m), 7.32 (2H, m), 6.63 (2H, d, J=8.5 Hz), 5.19 (4H, s). Found: H, 5.63; C, 79.16%. Calcd. for $C_{21}H_{18}O_3$: H, 5.70; C, 79.23%.

Bis(3-hexyl-4-methyl-2-pyrrolyl)methane (5). The compound **5** was synthesized from ethyl 3,5-dimethyl-4-hexyl-2-pyrrolecarboxylate[16] by the following sequence: (1) conversion to bis(5-ethoxycarbonyl-3-hexyl-4-methyl-2-pyrrolyl)-methane, via 5-acetoxymethyl derivative of the starting pyrrole,[17] (2) alkaline hydrolysis of the ester groups and decarboxylation.[18] The compound **5** was purified by passing its solution in CH_2Cl_2 through a short column of silica gel. Dark brown oil, which can be stored for about a month in the freezer. Purity was checked by ^{1}H NMR before use. ^{1}H NMR δ=7.39 (2H, br), 6.37 (2H, s), 3.81 (2H, s), 2.40 (4H, t, J=7.8 Hz), 2.04 (6H, s), 1.46 (4H, m), 1.30 (12H, m), 0.89 (6H, t, J=6.9 Hz).

4-(5,5-Dimethyl-1,3-dioxan-2-yl)benzaldehyde (6a). This aldehyde was synthesized from methyl 4-formylbenzoate by the following sequence: (1) protection of the formyl group by 2,2-dimethyl-1,3-propanediol (1.1 equiv, 0.1 equiv of *p*-toluenesulfonic acid, benzene, reflux, 2 h, 100%), (2) reduction to the primary alcohol (2 equiv of $LiAlH_4$, THF, 0 °C to r.t., 4 h, 75%), (3) oxidation to the aldehyde (1.5 equiv of PCC, 0.4 equiv of anhydrous sodium acetate, CH_2Cl_2, r.t., 3 h, 92%). Mp 60—63 °C (lit,[19] 59—62 °C).

4′-(5,5-Dimethyl-1,3-dioxan-2-yl)-[1,1′-biphenyl]-4-carbaldehyde (6b). [1,1′-Biphenyl]-4,4′-dicarbaldehyde (2.0 g, 9.5 mmol) was treated with 2,2-dimethyl-1,3-propanediol (1.0 g, 9.5 mmol) in the presence of *p*-toluenesulfonic acid (0.19 g, 1.0 mmol) in 150 ml of benzene (reflux, 2 h). The reaction mixture was cooled and shaken with saturated aqueous solution of $NaHCO_3$ (30 ml). The orange solution turned colorless and white precipitates appeared. The precipitates (bis-acetal compound) were removed by filtration and the filtrate was washed with water, dried and evaporated. The mixture was then treated with $LiAlH_4$ (360 mg, 9.5 mmol) in THF. After usual workup, the mixture was separated by column chromatography (eluted with CH_2Cl_2/Et_2O). The second fraction was collected (380 mg) and treated with PCC (388 mg, 1.8 mmol) in the presence of sodium acetate (40 mg). The monoprotected aldehyde **6b** was obtained (329 mg, 12%). ^{1}H NMR δ=10.06 (1H, s), 7.95 (2H, d, J=8.5 Hz), 7.74 (2H, d, J=8.2 Hz), 7.63 (4H, ABq), 5.46 (1H, s), 3.80 (2H, d, J=9.9 Hz), 3.68 (2H, d, J=10.7 Hz), 1.32 (3H, s), 0.82 (3H, s).

The compound **6c** and **6d** was synthesized in a similar manner as **6b**. The compound data are listed below:

6c: ^{1}H NMR δ=10.04 (1H, s), 7.94 (2H, d, J=8.6 Hz), 7.77 (2H, d, J=8.2 Hz), 7.68 (4H, s), 7.60 (4H, ABq), 5.43 (1H, s), 3.78 (2H, d, J=11.3 Hz), 3.66 (2H, d, J=10.6 Hz), 1.30 (3H, s), 0.80 (3H, s).

6d: ^{1}H NMR δ=9.96 (1H, s), 7.77 (2H, d, J=7.8 Hz), 7.45 (2H, d, J=7.8 Hz), 7.31 (2H, d, J=7.8 Hz), 7.19 (2H, d, J=8.0 Hz), 5.37 (1H, s), 4.05 (2H, s), 3.76 (2H, d, J=10.8 Hz), 3.64 (2H, d, J=11.0 Hz), 1.29 (3H, s), 0.79 (3H, s).

Methyl 4-[(2,5-Dimethoxy-4-methylphenyl)methyl]benzoate. The precursor ketone, methyl 4-(2,5-dimethoxy-4-methylbenzoyl)benzoate, was prepared from 4-methoxycarbonylbenzoyl chloride and 2,5-dimethoxytoluene ($SnCl_4$, CH_2Cl_2, reflux). A mixture of this ketone (2.04 g, 6.49 mmol), KOH (1.82 g, 32 mmol), hydrazine monohydrate (4.87 g, 97 mmol), and diethylene glycol (50 ml) was heated to 200 °C. The color of the solution changed from yellow via red-orange to colorless. After 5.5 h, the reaction mixture was poured into ice water, and acidified by hydrochloric acid. The white precipitates were collected, washed with water, dissolved again in aqueous NaOH solution, and precipitated again by adding dilute hydrochloric acid. The precipitates were filtered and washed with water, and dissolved in chloroform. The solution was dried over Na_2SO_4 and evaporated, to give 4-[(2,5-dimethoxy-4-methylphenyl)methyl]benzoic acid (1.77 g, 6.18 mmol, 95%). This was converted to the methyl ester by treatment with methyl iodide (1.6 equiv) and potassium carbonate (2.5 equiv) in acetone (reflux, overnight). The inorganic substance was removed by filtration, and acetone and excess MeI were removed by rotary evaporation. The residue was dissolved in CH_2Cl_2, washed with water, dried, and evaporated. The residual yellow oil crystallized on standing. Yield: 96%. Mp 79—80 °C (EtOH). ^{1}H NMR δ=7.92 (2H, d, J=8.2 Hz), 7.25 (2H, d, J=7.9 Hz), 6.70 (1H, s), 6.57 (1H, s), 3.98 (2H, s), 3.89 (3H, s), 3.73 (3H, s), 3.72 (3H, s). Found: H, 6.70; C, 71.79%. Calcd for $C_{18}H_{20}O_4$: H, 6.71; C, 71.98%.

4-[(2,5-Diacetoxy-4-methylphenyl)methyl]benzaldehyde (9). The methyl ester derivative (see above) was converted to the corresponding aldehyde in two steps ($LiAlH_4$ in THF, 0 °C to r.t., 6.5 h, 89%; PCC in CH_2Cl_2, r.t., 3 h, 89%). This aldehyde (1.25 g, 4.6 mmol) was dissolved in 50 ml of acetonitrile (reagent grade), and a solution of cerium(IV) ammonium nitrate (5.5 g, 10.1 mmol) in 20 ml of water was dropwise added over 30 min. After 2 h, water (50 ml) was added to the bright yellow solution, and the mixture was extracted with CH_2Cl_2. The extract was washed with water and evaporated. The residual orange oil was purified by flash column chromatography (R_f=0.5, CH_2Cl_2). This product (826 mg, 3.4 mmol) was dissolved in 15 ml of acetic anhydride, and this solution was added dropwise to a suspension of zinc dust (530 mg, 8 mmol) and anhydrous sodium acetate (290 mg) in acetic anhydride (5 ml) at 0 °C (under N_2). The mixture was stirred overnight, filtered to remove inorganic salts. The solvent was removed in vacuo, and the residual white solid was dissolved in ethyl acetate, washed with water and brine, dried, and evaporated. Yield: 1.06 g (3.2 mmol, 96%). Mp 107—108 °C (EtOH). ^{1}H NMR δ=9.97 (1H, s), 7.79 (2H, d, J=8.3 Hz), 7.31 (2H, d, J=8.3 Hz), 6.96 (1H, s), 6.80 (1H, s), 3.92 (2H, s), 2.28 (3H, s) 2.17 (3H, s), 2.15 (3H, s). Found: H, 5.48; C, 69.31%. Calcd for $C_{19}H_{18}O_5$: H, 5.56; C, 69.93%.

***N*-Hexyl-*N*′-[(4-formylphenyl)methyl]-1,2 : 4,5-benzenebis(dicarboximide) (10).** A precursor of this compound, 4-(5,5-dimethyl-1,3-dioxan-2-yl)benzylamine was synthesized in 2 steps from 4-cyanobenzaldehyde: (1) protection of the formyl group (1.1 equiv of 2,2-dimethyl-1,3-propanediol, 0.1 equiv of *p*-toluenesulfonic acid, benzene, reflux 1.5 h, 98%), (2) reduc-

tion to the primary amine ($LiAlH_4$, ether/THF, 0 °C, 5 h, 96%). This amine (6.6 g, 30 mmol) and hexylamine (9.1 g, 90 mmol) was dissolved in 150 ml of DMF, and a solution of 1,2:4,5-benzenetetracarboxylic dianhydride (13.1 g, 60 mmol) in 80 ml of DMF was added. The mixture was heated to reflux overnight and cooled. The precipitates were collected by filtration. TLC showed three products (CH_2Cl_2), and the second one was collected by column chromatography. This product (2.2 g, 4.4 mmol, 15%) was treated with acid to hydrolyze the acetal protecting group ($CHCl_3$ 50 ml, trifluoroacetic acid 20 ml, 5% aqueous H_2SO_4 15 ml, r.t., overnight). The mixture was poured into water and the organic layer was separated, washed with $NaHCO_3$ solution and water, dried and evaporated. Yield: 1.4 g (3.2 mmol, 73%). Mp>300 °C (benzene). ^1H NMR δ=9.99 (1H, s), 8.28 (2H, m), 7.86 (2H, d, J=8.3 Hz), 7.59 (2H, d, J=8.0 Hz), 4.96 (2H, s), 3.73 (2H, t, J=7.4 Hz), 1.69 (2H, m), 1.31 (6H, m), 0.87 (3H, m). Found: H, 5.05; C, 68.86; N, 6.72%. Calcd for $C_{24}H_{22}N_2O_5$: H, 5.30; C, 68.89; N, 6.69%.

4′-(5,5-Dimethyl-1,3-dioxan-2-yl)-[1,1′-biphenyl]-4-methanamine. To a solution of the monoprotected aldehyde **6b** (445 mg, 1.5 mmol) in a mixture of ethanol (50 ml) and CH_2Cl_2 (10 ml) was added a solution of hydroxylamine hydrochloride (118 mg, 1.7 mmol) and sodium carbonate (95 mg, 0.9 mmol) in 2.5 ml of water. The solution became opaque and white precipitates appeared. The mixture was stirred overnight at room temperature, then poured into 100 ml of water, extracted with CH_2Cl_2, washed with water, dried, and evaporated. The white solid was washed with hexane and dried in vacuo to give an oxime (346 mg, 1.1 mmol, 74%). This oxime (1 mmol) was treated with $LiAlH_4$ (2 mmol) in 17 ml of THF (70 °C, 6 h). After cooling, 1 ml of water and 1 ml of 10% NaOH solution was added, the solid was removed by filtration (washed by ether), and the filtrate was washed with brine, dried, and evaporated. Yield: 240 mg (0.81 mmol, 81%). ^1H NMR δ=7.58 (6H, m), 7.37 (2H, d, J=8.3 Hz), 5.44 (1H, s), 3.90 (2H, s), 3.79 (2H, d, J=11.3 Hz), 3.67 (2H, d, J=10.7 Hz), 1.31 (3H, s), 0.81 (3H, s).

***N*-Hexyl-*N*′-[[4′-formyl-[1,1′-biphenyl]-4-yl]methyl]-1,2:4,5-benzenebis(dicarboximide) (11).** This compound was synthesized from the above-described amine (0.67 mmol), hexylamine (6.0 mmol) and 1,2:4,5-benzenetetracarboxylic dianhydride (6.7 mmol) in a similar manner as **10**. Yield: 144 mg (0.29 mmol, 43%). ^1H NMR δ=10.05 (1H, s), 8.28 (2H, s), 7.93 (2H, d, J=8.2 Hz), 7.71 (2H, d, J=8.5 Hz), 7.61 (2H, d, J=8.5 Hz), 7.56 (2H, d, J=8.3 Hz), 4.95 (2H, s), 3.73 (2H, t, J=7.3 Hz), 1.69 (2H, m), 1.31 (6H, m), 0.88 (3H, m).

Synthesis of Formyl Porphyrins. 5-[2,6-Bis(benzyloxy)-phenyl]-15-(4-formylphenyl)-2,8,12,18-tetrahexyl-3,7,13,17-tetramethylporphine (8a). 2,6-Bis(benzyloxy)benzaldehyde (425 mg, 1.33 mmol), 4-(5,5-dimethyl-1,3-dioxan-2-yl)benzaldehyde **6a** (294 mg, 1.33 mmol), and bis(3-hexyl-4-methyl-2-pyrrolyl)methane **5** (913 mg, 2.67 mmol) were dissolved in 35 ml of acetonitrile. Trichloroacetic acid (131 mg, 0.80 mmol) was added, and the mixture was stirred overnight (room temperature, under nitrogen, in the dark). A solution of *p*-chloranil (1.0 g, 4.1 mmol) in a minimum amount of tetrahydrofuran was added, and the mixture was stirred for 5 h. The solvent was evaporated and the residue was taken up in chloroform, washed with saturated $NaHCO_3$ solution and water, and dried over Na_2SO_4. To this chloroform solution was added 5 ml of saturated solution of zinc acetate in methanol, and the mixture was heated to reflux for 2 h. After cooling, the reaction mixture was washed with water, dried over Na_2SO_4 and evaporated. TLC showed three products (R_f=0.8, 0.5, and 0.3, benzene) and the second was separated by column chromatography (benzene). Yield of **7a** (zinc complex): 612 mg (0.492 mmol, 37%).

The compound **7a** zinc complex (419 mg, 0.337 mmol) was dissolved in a mixture of trifluoroacetic acid (10 ml), acetic acid (20 ml) and 5% aqueous sulfuric acid (5 ml). After being heated at 100 °C for 1.5 hours, the mixture was poured into 150 ml of water and extracted with CH_2Cl_2. The organic phase was washed with saturated $NaHCO_3$ solution (effervescence!), dried over Na_2SO_4, and evaporated. The residue was triturated and washed in methanol and dried in vacuo. Yield of **8a**: 303 mg (0.277 mmol, 82%). Mp 163—167 °C. ^1H NMR δ=10.40 (1H, s, CHO), 10.22 (2H, s, meso), 3.97 (8H, m, hexyl-1), 2.57 (6H, s, Me), 2.46 (6H, s, Me), 2.19 (8H, m, hexyl-2), 1.73 (8H, m, hexyl-3), 1.46 (8H, m, hexyl-4), 1.37 (8H, m, hexyl-5), 0.90 (12H, m, hexyl-6), −2.2 (2H, br, NH); 5-Ph: 7.62 (1H, t, J=8.5 Hz), 7.00 (2H, d, J=8.8 Hz); 15-Ph: 8.28 (4H, AB quartet); benzyloxy: 6.85 (2H, t, J=7.3 Hz), 6.72 (4H, t, J=7.9 Hz), 6.58 (4H, d, J=7.3 Hz), 4.94 (4H, s).

The compounds **8b**, **8c**, and **8d** was prepared in the similar manner as **8a**. The compound data are listed below:

8b: Yield (2 steps) 24%. Mp. 195—200 °C. ^1H NMR δ=10.22 (2H, s, meso), 10.18 (1H, s, CHO), 3.99 (8H, m, hex-1), 2.57 (6H, s, Me), 2.56 (6H, s, Me), 2.20 (8H, m, hex-2), 1.74 (8H, m, hex-3), 1.48 (8H, m, hex-4), 1.35 (8H, m, hex-5), 0.90 (12H, m, hex-6), −2.3 to −2.5 (2H, br, NH); 5-Ph: 7.62 (1H, t, J=8.3 Hz), 7.01 (2H, d, J=8.8 Hz); biphenylylene: 8.20 (2H, d, J=8.3 Hz), 8.13 (4H, s), 7.61 (2H, d, J=8.3 Hz) benzyloxy: 6.85 (2H, t, J=7.8 Hz), 6.72 (4H, t, J=7.6 Hz), 6.58 (4H, d, J=7.3 Hz), 4.94 (4H, s).

8c: Yield (2 steps) 20%. Mp 181—185 °C. ^1H NMR δ=10.22 (2H, s, meso), 10.12 (1H, s, CHO), 4.00 (8H, m, hex-1), 2.58 (6H, s, Me), 2.57 (6H, s, Me), 2.21 (8H, m, hex-2), 1.74 (8H, m, hex-3), 1.48 (8H, m, hex-4), 1.38 (8H, m, hex-5), 0.90 (12H, m, hex-6), −2.15 (1H, s, NH), −2.26 (1H, s, NH); 5-Ph: 7.62 (1H, t, J=8.3 Hz), 7.01 (2H, d, J=8.3 Hz); terphenyl: 8.18 (2H, d, J=8.3 Hz), 8.10 (2H, d, J=8.3 Hz), 8.07 to 8.03 (4H, 2 doublets), 7.92 (2H, d, J=8.3 Hz), 7.90 (2H, d, J=8.3 Hz); benzyloxy: 6.85 (2H, t, J=7.3 Hz), 6.72 (4H, t, J=7.9 Hz), 6.58 (4H, d, J=7.3 Hz), 4.94 (4H, s).

8d: Yield (2 steps) 32%. Mp 52—58 °C. ^1H NMR δ=10.20 (2H, s, meso), 10.10 (1H, s, CHO), 3.98 (8H, m, hex-1), 2.57 (6H, s, Me), 2.51 (6H, s, Me), 2.19 (8H, m, hex-2), 1.74 (8H, m, hex-3), 1.46 (8H, m, hex-4), 1.36 (8H, m, hex-5), 0.90 12H, m, hex-6), −2.2 (2H, NH); 5-Ph: 7.62 (1H, t), 7.00 (2H, d, J=8.3 Hz); $PhCH_2Ph$: 8.02 (2H, d, J=7.8 Hz), 7.98 (2H, d, J=7.8 Hz), 7.62 (2H, d), 7.55 (2H, d, J=7.3 Hz), 4.44 (2H, s); benzyloxy: 6.84 (2H, t, J=7.3 Hz), 6.71 (4H, t, J=7.6 Hz), 6.57 (4H, d, J=7.8 Hz), 4.93 (4H, s).

Synthesis of Free-Base Diporphyrins. 15-[2,6-Bis(benzyloxy)phenyl]-15′-[4-[(2,5-diacetoxy-4-methylphenyl)methyl]-phenyl]-5,5′-(1,4-phenylene)bis[2,8,12,18-tetrahexyl-3,7,13,17-tetramethylporphine] (1a). The formylporphyrin **8a** (147 mg, 0.13 mmol) was dissolved in 15 ml of acetonitrile containing 57 mg (0.35 mmol) of trichloroacetic acid. The aldehyde **9** (261 mg, 0.80 mmol) in 5 ml of CH_3CN and **5** (319 mg, 0.93 mmol) in 5 ml of CH_3CN were added, and the mixture was stirred overnight (room temperature, under N_2, dark). A solution of *p*-chloranil (344 mg, 1.4 mmol) in a minimum amount of tetrahydrofuran was added, and the mixture was stirred for additional 3 h. The reaction mixture was poured into 100 ml

of water, extracted with CH_2Cl_2, washed with $NaHCO_3$ solution and dried over Na_2SO_4. This dichloromethane solution was treated with a saturated solution of zinc acetate in methanol (5 ml, 2 h reflux), washed with water, dried and evaporated. At this stage, all porphyrinic products were separated from tarry materials by column chromatography (CH_2Cl_2, R_f=0.8 to 1.0). This mixture of zinc porphyrins were dissolved in dichloromethane and shaken with two portions of 4 M (1 M=1 mol dm^{-3}) hydrochloric acid, neutralized with $NaHCO_3$ solution, dried and evaporated, to give a mixture of free-base porphyrins. The mixture was separated by column chromatography (CH_2Cl_2+Et_2O) to give two products (R_f=0.6 and 0.3, CH_2Cl_2/Et_2O (v/v)=100/5). The second fraction was the diporphyrin **1a**. Yield: 116 mg (56 mmol, 43%). Mp 134—140 °C. ^{1}H NMR δ=10.34 (2H, s, meso), 10.32 (2H, s, meso), 4.15 (8H, m, hex-1), 4.04 (8H, m, hex-1), 3.20 (12H, s, Me), 2.61 (6H, s, Me), 2.54 (6H, s, Me), 2.32 (8H, m, hex-2), 2.25 (8H, m, hex-2), 1.86 (8H, m, hex-3), 1.78 (8H, m, hex-3), 1.6—1.4 (m, hex-4 and hex-5), 1.0—0.9 (24H, m, hex-6); bridging phenylene: 8.58 (4H, s); 15-phenyl: 7.64 (1H, t, J=8.3 Hz), 7.03 (2H, d, J=8.8 Hz); benzyloxy: 6.88 (2H, t, J=7.3 Hz), 6.76 (4H, t, J=7.6 Hz), 6.62 (4H, d, J=7.3 Hz), 4.98 (4H, s); 15′-substituent: 8.02 (2H, d, J=8.3 Hz), 7.55 (2H, d, J=7.8 Hz), 7.12 (1H, s), 7.10 (1H, s), 4.24 (2H, s, benzylic), 2.44 (3H, s, acetyl), 2.43 (3H, s, acetyl), 2.27 (3H, s). MS m/z 2065 ($M+H^+$), 1032 (doubly charged ion).

The compounds **1b**, **1c**, and **1d** were prepared in the similar manner as **1a**. The compound data are listed below:

1b: Yield 69%. Mp 279—283 °C. ^{1}H NMR δ=10.29 (2H, s, meso), 10.27 (2H, s, meso), 4.0 (16H, m, hex-1), 2.75 (12H, s, Me), 2.60 (6H, s, Me), 2.53 (6H, s, Me), 2.24 (16H, m, hex-2), 1.77 (16H, m, hex-3), 1.5 (m, hex-4), 1.40 (m, hex-5), 0.93 (m, hex-6), −2.12 (1H, br, NH), −2.18 (1H, br, NH), −2.29 (1H, br, NH), −2.35 (1H, br, NH); bridging biphenylylene: 8.34 (8H, m); 15-phenyl: 7.64 (1H, t), 7.02 (2H, d, J=8.3 Hz); benzyloxy: 6.87 (2H, t, J=6.8 Hz), 6.74 (4H, t, J=7.8 Hz), 6.61 (4H, d, J=7.3 Hz), 4.96 (4H, s); 15′-substituent: 8.02 (2H, d, J=7.8 Hz), 7.54 (2H, d, J=7.8 Hz), 7.11 (1H, s), 7.09 (1H, s), 4.23 (2H, s, benzylic), 2.44 (3H, s, acetyl), 2.43 (3H, s, acetyl), 2.26 (3H, s). 15-[2,6-Bis(benzyloxy)phenyl]-15′-[4-[(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)methyl]phenyl]-5,5′-(1,4-phenylene)-bis-[2,8,12,18-tetrahexyl-3,7,13,17-tetramethylporphine] (2a). The diporphyrin **1a** (43 mg, 0.020 mmol) was dissolved in a mixture of 20 ml of methanol and 3 ml of concentrated hydrochloric acid. The mixture was heated under gentle reflux for 2.5 h (under N_2), poured into aqueous $NaHCO_3$ solution, extracted with CH_2Cl_2, dried and evaporated. The residue was dissolved again in CH_2Cl_2 (10 ml) and treated with 90 mg (0.38 mmol) of PbO_2 at room temperature for 2 h. The mixture was filtered through Celite to remove the inorganic material and evaporated. The crude product was purified as the dizinc complex (treatment with large excess of $Zn(OAc)_2$) by column chromatography (benzene). The free-base **2a** was recovered from the dizinc complex by treatment of the dichloromethane solution with 4 M hydrochloric acid. Yield: 30 mg (0.015 mmol, 75%). ^{1}H NMR δ=10.35 (2H, s, meso), 10.32 (2H, s, meso), 4.13 (8H, m, hex-1), 4.04 (8H, m, hex-1), 3.21 (12H, s, Me), 2.61 (6H, s, Me), 2.55 (6H, s, Me), 2.33 (8H, m, hex-2), 2.24 (8H, m, hex-2), 1.87 (8H, m, hex-3), 1.78 (8H, m, hex-3), 1.6 to 1.3 (m, hex-4 and hex-5), 0.98 to 0.90 (m, hex-6), −1.5 to −2.2 (br, NH); bridging phenylene: 8.57 (4H, s); 15-phenyl: 7.64 (1H, t), 7.03 (2H, d, J=8.3 Hz); benzyloxy: 6.88 (2H, t, J=7.8 Hz), 6.76 (4H, t, J=7.6 Hz), 6.62 (4H, d, J=7.3 Hz), 4.98 (4H, s); 15′-substituent: 8.08 (2H, d, J=7.8 Hz), 7.58 (2H, d, J=7.8 Hz), 6.79 (1H, s), 6.66 (1H, s), 4.13 (2H, s, benzylic), 2.17 (3H, s, Me). J=8.3 Hz), 6.78 (1H, m, J<2 Hz), 6.65 (1H, m, J<2 Hz), 4.11 (2H, s, benzylic), 2.16 (3H, m, J<2 Hz, Me). MS m/z 2071 ($[M+3H]^+$).

15-[2,6-Bis(benzyloxy)phenyl]-15′-[4-(6-hexyl-1,3,5,7-tetrahydro-1,3,5,7-tetraoxobenzo[1,2-*c*:4,5-*c*′]dipyrrol-2-yl)phenyl]-5,5′-(1,4-phenylene)bis[2,8,12,18-tetrahexyl-3,7,13,17-tetramethylporphine] (3a). The formyl porphyrin **8a** (60 mg, 0.055 mmol) and the *N*-(formylphenyl)diimide **10** (161 mg, 0.385 mmol) were dissolved in a mixture of 10 ml of dry acetonitrile and 10 ml of dry benzene containing 33 mg (0.2 mmol) of trichloroacetic acid. To this solution, bis(3-hexyl-4-methyl-2-pyrrolyl)methane **5** (151 mg, 0.44 mmol) in 10 ml of acetonitrile was added, and the mixture was stirred for 5 h (dark, under N_2, room temperature). A solution of *p*-chloranil (162 mg, 0.66 mmol) in THF was added, and stirring was continued for 2 h. The solvent was removed by rotary evaporation, and the residue was taken up in dichloromethane and washed with aqueous $NaHCO_3$ solution. At this point, red precipitates appeared from the organic phase. Methanol was added to complete precipitation, and the solids were collected by filtration and washed with methanol. The red-violet solids were dissolved again in dichloromethane and treated with excess zinc acetate to give a mixture of zinc porphyrins, which was separated by column chromatography to give two products (R=0.6 and 0.4, CH_2Cl_2). The second fraction was the dizinc complex of **3a**, from which the free-base **3a** was obtained by successive treatment with 4 M hydrochloric acid and aqueous $NaHCO_3$. Yield 79 mg (0.036 mmol, 67%). ^{1}H NMR δ=10.33 (4H, s, meso), 4.17 (8H, m, hex-1), 4.03 (8H, m, hex-1), 3.21 (12H, s, Me), 2.62 (6H, s, Me), 2.46 (6H, s, Me), 2.34 (8H, m, hex-2), 2.25 (8H, m, hex-2), 1.88 (8H, m, hex-3), 1.60 (8H, m, hex-3), 1.6 to 1.3 (m, hex-4 and hex-5), 1.0 to 0.9 (m, hex-6), −1.82 (2H, br, NH), −1.91 (1H, br, NH), −2.09 (1H, br, NH); bridging phenylene: 8.59 (4H, s); 15-phenyl: 7.65 (1H, t), 7.04 (2H, d, J=8.8 Hz); benzyloxy: 6.89 (2H, t, J=7.3 Hz), 6.77 (4H, t, J=7.6 Hz), 6.64 (4H, d, J=6.8 Hz), 4.99 (4H, s); 15′-substituent: 8.2 (2H, br, imide-aromatic H), 8.08 (2H, d, J=7.8 Hz), 7.76 (2H, d, J=7.8 Hz), 5.21 (2H, s, benzylic), 3.74 (2H, t, hex-1), 1.7 (2H, m, hex-2), 1.3 (m, hex-3, 4, 5), 1.0 to 0.9 (m, hex-6). 5-(4-Methylphenyl)-15-[4-[(2,5-diacetoxy-4-methylphenyl)-methyl]phenyl]-2,8,12,18-tetrahexyl-3,7,13,17-tetramethylporphine (12). Synthesized from the aldehyde **9**, *p*-tolualdehyde and **5** in a similar manner as **7a** (see the synthesis of **8a**). The zinc porphyrin was converted to the free-base **12** by treatment with 4 M hydrochloric acid. Yield: 32%. Mp 140—142 °C. ^{1}H NMR δ=10.22 (2H, s), 7.98 (2H, d, J=8.3 Hz), 7.92 (2H, d, J=7.8 Hz), 7.53 (2H, d, J=7.8 Hz), 7.52 (2H, d, J=7.8 Hz), 7.10 (1H, s), 7.07 (1H, s), 4.21 (2H, s), 3.97 (8H, t, J=7.8 Hz), 2.72 (3H, s), 2.503 (6H, s), 2.498 (6H, s), 2.42 (3H, s), 2.41 (3H, s), 2.25 (3H, s), 2.18 (8H, quint, J=7.4 Hz), 1.72 (8H, quint, J=7.5 Hz), 1.47 (8H, quint, J=7.2 Hz), 1.36 (8H, sext, J=7.3 Hz), 0.90 (12H, t, J=7.4 Hz), −2.41 (2H, s). MS m/z 1090.

The compound **14** (or **15**) was also synthesized from the aldehyde **10** (or **11**), *p*-tolualdehyde and **5** in a similar manner as **12**. The compound data are shown below:

14: Yield: 39% (solvent: CH_3CN+C_6H_6=2 : 1). Mp 120—124 °C. ^{1}H NMR δ=10.20 (2H, s), 8.31 (2H, s), 8.04 (2H, d, J=7.8 Hz), 7.92 (2H, d, J=7.8 Hz), 7.74 (2H, d, J=7.8 Hz), 7.54 (2H, d, J=7.8 Hz), 5.24 (2H, s), 3.95 (8H, m) 3.76 (2H, t, J=7.3 Hz), 2.72 (3H, s), 2.50 (6H, s), 2.41 (6H, s), 2.17 (8H, m), 1.72 (10H, m), 1.47 (8H, m), 1.35 (14H, m), 0.89 (15H, m), −2.46 (2H, s). MS m/z 1181.

15: Yield: 30% (solvent: $CH_3CN+CH_2Cl_2=4:3$). Mp 275—278 °C. ^1H NMR δ=10.22 (2H, s), 8.22 (2H, s), 8.12 (2H, d, J=7.8 Hz), 7.94 (6H, m), 7.68 (2H, d, J=8.3 Hz), 7.54 (2H, d, J=7.8 Hz), 5.01 (2H, s), 3.97 (8H, m), 3.73 (2H, t), 2.72 (3H, s), 2.52 (6H, s), 2.51 (6H, s), 2.17 (8H, m), 1.72 (10H, m), 1.53 (8H, m), 1.36 (14H, m), 0.89 (15H, m), −2.43 (2H, s). MS m/z 1257.

5-(4-Methylphenyl)-15-[4-[(3,6-dioxo-4-methyl-1,4-cyclohexadienyl)methyl]phenyl]-2,8,12,18-tetrahexyl-3,7,13,17-tetramethylporphine (13). Synthesized from the diacetoxyphenyl porphyrin **12** in a similar manner as **2a**. Yield: 91%. Mp 190—193 °C. ^1H NMR δ=10.27 (1H, s), 8.03 (2H, d, J=7.8 Hz), 7.96 (2H, d, J=7.3 Hz), 7.57 (2H, d, J=7.8 Hz), 7.50 (2H, d, J=7.8 Hz), 6.75 (1H, s), 6.59 (1H, s), 4.02 (10H, m, benzylic and hex-1), 2.76 (3H, s), 2.55 (6H, s), 2.52 (6H, s), 2.23 (8H, m), 2.15 (3H, s), 1.78 (8H, m), 1.53 (8H, m), 1.42 (m), 0.96 (12H, m), −2.35 (2H, s). MS m/z 1006 ($[M+3H]^+$).

Procedure for Selective Metallation. The free-base diporphyrin (0.015 mmol) was dissolved in 20 ml of CH_2Cl_2, and a 30 mM solution of zinc acetate in $MeOH/CH_2Cl_2$ (0.4 ml, 0.012 mmol) was added. The mixture was stirred at room temperature for 15 min, and washed with water and dilute $NaHCO_3$ solution, dried and evaporated. The residue was separated by column chromatography ($CH_2Cl_2+Et_2O$) to four fractions, and each was checked by UV-visible, MS and ^1H NMR spectra (see text). The (H_2, Zn) complex was obtained in 12—33% yield. Purity was checked by TLC and ^1H NMR spectra.

The author expresses heartful thanks to Professor Kazuhiro Maruyama and Dr. Atsuhiro Osuka of Kyoto University for their encouragement and helpful discussion. The author is also grateful to Professor Ikuo Yamashina of Kyoto Industrial University for his kind permission to use the JEOL HX-110 mass spectrometer.

7) In the case of the 1,4-phenylene bridged diporphyrins, the UV-visible absorption spectra were slightly (about 3 nm) red-shifted due to the exciton interaction between the two porphyrins.

8) The photophysics of the (H_2, Zn) diporphyrins are somewhat complicated because of the singlet energy transfer from the zinc porphyrin to the free-base porphyrin. When the acceptor moiety is present, the excited state of the zinc porphyrin (which is formed by absorption of the incident light; ε(free-base):ε(zinc)=6.3:1 at 507—510 nm) should be also quenched by the acceptor. Therefore, decrease of the fluorescence intensity of the free-base porphyrin can be partly attributed to the quenching of the zinc porphyrin. Analysis of the photo-steady state led to the estimation that the free-base fluorescence would be decreased through this effect by a factor of $(\varepsilon_H+k_{EN}\varepsilon_Z/(k_{EN}+k_0+k_q))/(\varepsilon_H+k_{EN}\varepsilon_Z/(k_{EN}+k_0))$, where ε_H, ε_Z are extinction coefficients of free-base and zinc porphyrins, k_{EN} is the rate of energy transfer, k_0 is the decay rate constant of the zinc porphyrin, and k_q is the rate of electron transfer from the zinc porphyrin to the acceptor. Using the values of $k_0=6.3\times10^8$ s^{-1}, $k_q=7.1\times10^{10}$ s^{-1} (for **2**), 1.3×10^{10} s^{-1} (for **3**), 8.5×10^7 s^{-1} (for **4**), and the reported values of k_{EN} (Ref. 15), the factor was estimated to be in the range of 0.89 to 1.0. The values shown in Table 1 have been compensated by these factors, thus their deviation from unity can be ascribed simply to the interaction of the free-base and the acceptor moiety.

Photochemical Hydroformylation of Olefins in the Cobalt-Phosphine Catalyst System

Sadayuki MORI,* Shunji TATSUMI, Masaki YASUDA, Kiyoshi KUDO, and Nobuyuki SUGITA
Institute for Chemical Research, Kyoto University, Gokanosho, Uji 611
(Received April 19, 1991)

Cobalt-catalyzed hydroformylation of olefins was found to proceed even at ambient temperature under UV irradiation in the presence of phosphine. Extremely high selectivity toward straight-chain aldehyde (99% in case of 1-hexene) was obtained by lowering the partial pressure of carbon monoxide at ambient temperature. A catalytic species different from the well-known species under high pressure of carbon monoxide and high temperature contributed to the highly selective formation of straight-chain aldehydes. Two photochemical processes were suggested to be involved in the photochemical hydroformylation reaction, that is, the formation of $HCo(CO)_3PBu_3$ from the cationic cobalt species, $[Co(CO)_3(PBu_3)_2]^+$, and then the formation of the coordinatively unsaturated hydride, $HCo(CO)_2PBu_3$.

Organometallic photochemistry is an area of growing interest in homogeneous transition-metal catalysis.[1] Photochemical hydroformylation of olefins was first reported by Mirbach and co-workers[2] They have examined the effects of UV irradiation on hydroformylation in some different cobalt catalyst systems. With $Co(OAc)_2$ or $Co_2(CO)_8$ as catalyst precursor in the presence of excess tributylphosphine, olefin hydroformylation proceeds photochemically under the conditions where no reaction could take place thermally (85 °C), and yields linear aldehydes in a relatively high selectivity.

$$\text{1-octene} \xrightarrow[Co(OAc)_2/PBu_3]{h\nu,\ CO/H_2,\ 85\,^\circ C} \underset{79\%}{\text{nonanal}} + \underset{9\%}{\text{2-methyloctanal}} + \underset{12\%}{\text{octane}}$$

In the absence of phosphine the thermal reaction with $Co(OAc)_2$ catalyst at 85 °C has a long induction period of 15 h, whereas the reaction under UV irradiation is initiated within 1 h. Based on the observed high pressure IR and UV absorption spectra, they have suggested the photogeneration of active catalytic species, $HCo(CO)_3PBu_3$ or $HCo(CO)_4$ in the presence or absence of phosphine, respectively.

Later, they found rhodium catalysts to be also photochemically active for the hydroformylation of olefins in the presence of norbornadiene.[3]

Recently E. M. Gordon and R. Eisenberg reported that Ru(0) complexes such as $Ru(CO)_3(PPh_3)_2$, $Ru(CO)_4PPh_3$ and $Ru_3(CO)_{12}$ are effective for the photochemical hydroformylation of ethylene and propene under mild conditions.[4]

We found the cobalt-catalyzed photochemical hydroformylation proceeds even at ambient temperature, and extremely high selectivity toward linear aldehyde is achieved at low CO partial pressure. Here we report the influence of reaction temperature and CO partial pressure on the reaction rate and selectivity toward straight-chain products, and discuss the photochemical processes and catalytic species.

Experimental

Photochemical Experiments. The photochemical reactions were performed in a 10 mL home-made UV autoclave as shown in Fig. 1. Inside of the autoclave is coated with Teflon to avoid the contact of the solution with stainless steel. If necessary, this can be used as a high-pressure UV cell for UV spectroscopy. Mixing of the liquid and gases was achieved by a magnetically driven up-and-down stirrer. The reaction solution in the autoclave was irradiated with an external high-pressure mercury lamp (500 W, Ushio USH500D) through a

a; gas inlet, b; magnet, c; solenoid, d; spring, e; up-and-down stirrer, f; thermocouple hole, g; heater or coolant, h; Teflon packing, i; quartz window, j; sample outlet.

quartz lens and a cooled water filter (2 cm thickness).

In a typical run, methanol solution (5 mL) of olefin (3.2 mol dm^{-3}), $Co(OAc)_2 \cdot 4H_2O$ (0.016 mol dm^{-3}), and PBu_3 (0.16 mol dm^{-3}) was introduced into the autoclave. The autoclave was flushed with synthesis gas (CO/H_2=1/1) three times and then pressurized to a desired pressure. The reaction mixture was stirred and then irradiated after the autoclave had been thermostated to a desired temperature. When the gas mixture of low CO content was employed, the fresh gas mixture was introduced continuously into the solution through the sample outlet portion (j in Fig. 1), and released from the gas inlet valve (a in Fig. 1) with keeping a constant pressure. The product solution was taken out through the sample outlet valve to a cooled bottle. Product analysis was performed by GLC with internal standards (Shimadzu GC-5A). A back flush system fitted with tandem column of PEG 20M and *n*-Octane/Poracil C was used for a concurrent analysis of hydrocarbons and hydroformylation products. GC-MS (NEVA TE-600) was also used to identify the products. UV absorption spectra of cobalt species such as Co^{2+}, $[Co(CO)_3(PBu_3)_2]^+$, and $Co_2(CO)_6(PBu_3)_2$ were measured by JASCO UVDEC-1 spectrometer.

Thermal Reaction with $HCo(CO)_3PBu_3$. $HCo(CO)_3PBu_3$ was prepared according to Piacenti and co-workers,[5] except for the addition of free phosphine which can avoid the concomitant formation of $HCo(CO)_4$.[6] Without isolating $HCo(CO)_3PBu_3$, a solution containing the hydride was used for the reaction, that is, $Co_2(CO)_6(PBu_3)_2$ (0.35 mmol), PBu_3 (0.35 mmol) and pentane (15 mL) were placed in a 50 mL rocking type autoclave and pressurized with 7 atm of CO and 22 atm of H_2. The autoclave was heated at 120 °C for 2 h, then cooled immediately at −70 °C. Two milliliter (16 mmol) of 1-hexene was injected into the autoclave by means of a plunger pump under −70 °C. The autoclave was rapidly heated to a desired temperature, and the reaction was started.

Materials. Commercially available $Co(OAc)_2 \cdot 4H_2O$, olefins and methanol were used without further purification. Tributylphosphine was distilled under vacuum. Hydrogen was obtained commercially. Carbon monoxide was prepared by decomposing formic acid in hot sulfuric acid. Its purity was above 98%, and impurity was mainly hydrogen. $Co_2(CO)_6(PBu_3)_2$ and $HCo(CO)_2(PBu_3)_2$ were prepared according to the procedures described in literatures.[7,8]

Results and Discussion

The results of the photochemical hydroformylation of 1-hexene with cobalt acetate and tributylphosphine in methanol are summarized in Table 1. The reaction proceeds even at ambient temperature and surprisingly the rate of hydroformylation at 30 °C is nearly the same at 80 °C and 120 °C. Heptanal via CO addition to the terminal carbon atom of 1-hexene is a principal product, and total of branched aldehydes (2-methylhexanal and 2-ethylpentanal) is about 1/10 of normal aldehyde (n/i=10, the ratio of straight-chain product to branched products is expressed by n/i hereafter). 2-Ethylpentanal is still less than 1/6 of 2-methylhexanal. The n/i ratio in isomeric aldehydes decreases slightly at 120 °C. Alcohols are minor products under these conditions, though a conventional hydroformylation with the phosphine-modified cobalt catalysts at higher temperature leads to the alcohol formation due to the highly reductive character of $HCo(CO)_3PBu_3$. Hydrogenation of olefinic substrate occurs in small extent and isomerization becomes significant only at higher temperature.

Total yield of hydroformylation products increases with the period of irradiation such as 13.6% for 18 h, 24% for 40 h, and 34% for 68 h at 30 °C, but the reaction ceases completely when the light is turned off. Thus the reaction is photocatalytic. Reactions of 1-pentene, 1-hexene, and 1-octene give almost the same results in the yield and the distribution of the corresponding

Table 1. Photochemical Hydroformylation of 1-Hexene[a]

Temp	Product yield[b]/%							
°C	*n*-Ald[c]	*i*-Ald[d]	*n*-Alc[e]	*i*-Alc[f]	Acetal[g]	Ester[h]	Hexane	2- and 3-Hexenes
30	11.9	1.12	0.17	0.03	0.01	0.35	1.3	0.1
80	13.4	1.27	0.78	0.07	0.11	0.32	1.6	2.3

a) Reaction conditions: $Co(OAc)_2 \cdot 4H_2O$, 0.0164 mol dm^{-3}; PBu_3, 0.163 mol dm^{-3}; 1-hexene, 3.20 mol dm^{-3}; solvent, methanol; total pressure, 80 atm (CO/H_2=1/1); reaction time, 18 h. b) Based on starting 1-hexene. c) Heptanal. d) Branched aldehyde: total of 2-methylhexanal and 2-ethylpentanal. e) 1-Heptanol. f) Branched alcohol: 2-methyl-1-hexanol. g) Heptanal dimethyl acetal. h) Methyl heptanoate.

Table 2. Photochemical Hydroformylation of Hexene Isomers[a]

Hexene	Product yield/%				
	Heptanal	2-Methylhexanal	2-Ethylpentanal	*n*-Alc[b]	*i*-Alc[b]
1-Hexene	23.6	1.96	0.31	0.39	0.08
trans-2-Hexene	18.4	2.18	0.58	0.53	0.23
trans-3-Hexene	17.4	1.86	1.41	0.61	0.31

a) Reaction conditions: Hexene, 1.60 mol dm^{-3}; temperature, 30 °C; others are the same as in Table 1. b) See footnotes in Table 1.

hydroformylation products.

In the hydroformylation of hexene isomers, the formyl group preferentially adds to the terminal carbon atom of each olefin, though the position of double bond in starting olefins affects slightly on the isomeric distribution of produced aldehydes as seen in Table 2. These results are similar to those in the conventional cobalt-catalyzed hydroformylation at higher temperature.[9] It has been assumed that fast isomerization of π-olefin complex via σ-π interconversion takes place without releasing isomerized olefins.

$$\underset{\mathrm{HCo(CO)}_m\mathrm{L}_n}{\mathrm{RCH{=}CH{-}CH_3}} \rightleftarrows \underset{\mathrm{H}\quad\mathrm{Co(CO)}_m\mathrm{L}_n}{\mathrm{RCH{-}CH{-}CH_3}} \rightleftarrows \underset{\mathrm{HCo(CO)}_m\mathrm{L}_n}{\mathrm{RCH_2{-}CH{=}CH_2}}$$

(L=phosphine)

On steric grounds, the preferable π-olefin complex is that involving the terminal olefins, thus the production of straight-chain aldehydes predominates. It is rather interesting that 2-propylhexanal was reported as the main product in the photochemical hydroformylation of 4-octene with $Co_2(CO)_8$ catalyst at 80 °C, CO/H_2=40 atm/40 atm,[10] though the thermal hydroformylation of 4-octene preferentially afforded nonanal (150 °C, CO/H_2=100 atm/100 atm).[9]

Influence of Phosphine Ligand. The influence of phosphine on the hydroformylation of 1-hexene is summarized in Table 3. At 30 °C both the presence of phosphine and UV irradiation are essential to initiate the hydroformylation reaction, and even at higher temperature (80 °C) the reaction in the presence of phosphine is still photochemical. The photochemical reaction in the absence of phosphine is faster than that in the presence of phosphine, but the n/i value is low ($n/i \approx 2$). This value is similar to that in a typical $Co_2(CO)_8$ catalyzed hydroformylation. In the absence of phosphine, aldehydes are obtained mainly as dimethyl acetals. $HCo(CO)_4$, a well-known active species in a $Co_2(CO)_8$ catalyzed hydroformylation, dissociates to H^+ and $Co(CO)_4^-$ in methanol solvent, and high acidity of the solution promotes the acetal formation. On the other hand, $HCo(CO)_3L$ (L=phosphine) in a cobalt-phosphine catalyst system is a very weak acid (K_a=1×10^{-7} for L=PBu_3[11]), thus aldehydes cannot be converted into acetals. The thermal reaction without phosphine scarcely occurs under these conditions due to a long induction period as reported previously.[2] The thermal reaction in cobalt-phosphine catalyst system at 120 °C is still very slow, whereas the photochemical reaction proceeds with a similar rate to that at 30 °C. In the absence of phosphine the reaction proceeds thermally as well as photochemically, and the n/i ratios in both thermal and photochemical reactions are low.

Table 3. Influence of Phosphine on Hydroformylation[a]

Temp	PBu_3	Product yield[b]/%	
°C	mol dm^{-3}	Photochemical	Thermal
30	0.163	13.6 (10.5)[c]	0
30	0	0	0
80	0.163	16.0 (10.6)	0
80	0	59.3[d] (2.2)	0.75[d] (2.0)
120	0.163	15.5 (8.0)	3.3 (7.8)
120	0	94.3[d] (1.8)	97.6[d] (1.8)

a) Conditions as in Table 1. b) Total yield of hydroformylated products (Aldehydes, alcohols, acetals, and ester). c) Values in parentheses indicate the n/i ratio in (aldehydes+acetals). d) Obtained mostly as dimethyl acetals.

Consequently, the characteristic of the photochemical hydroformylation is that the reaction proceeds at ambient temperature when phosphine-modified cobalt catalysts are employed.

Photochemical Process. Reductive carbonylation of $Co(ClO_4)_2\cdot6H_2O$ in the presence of phosphines affords $[Co(CO)_3L_2]^+$ (L=PBu_3) in alcoholic media under ambient conditions.[12] On the basis of UV and IR absorption spectra from the reaction of $Co(OAc)_2$ with PBu_3 under the elevated pressure of synthesis gas, Mirbach and co-workers ascertained the formation of $[Co(CO)_3(PBu_3)_2]^+$ at room temperature.[2]

$$Co^{2+} + 2PBu_3 \xrightarrow[20\,^\circ C,\ \text{in MeOH}]{H_2/CO,\ 80\ \text{atm}} [Co(CO)_3(PBu_3)_2]^+$$

As the cation $[Co(CO)_3(PBu_3)_2]^+$ has a large absorption coefficient in UV region (λ_{max}=245 nm, ε=80000), they believed that this cation is a sole photoactive species and is converted into a phosphine-coordinated hydridocarbonylcobalt under the photochemically hydroformylating conditions (Eq. 1). They assumed that the hydride initiates *thermally* the hydroformylation reaction in a similar manner proposed in a conventional hydroformylation reaction (Eqs. 2—4).

$$[Co(CO)_3(PBu_3)_2]^+ \xrightarrow[+H_2,\ -H^+,\ -PBu_3]{h\nu} HCo(CO)_3PBu_3 \quad (1)$$

$$HCo(CO)_3PBu_3 \rightleftarrows HCo(CO)_2PBu_3 + CO \quad (2)$$

$$HCo(CO)_2PBu_3 + \text{olefin} \xrightarrow{CO} RCOCo(CO)_2PBu_3 \quad (3)$$

$$RCOCo(CO)_2PBu_3 + H_2 \longrightarrow RCHO + HCo(CO)_2PBu_3 \quad (4)$$

We also observed immediate appearance of UV absorption maximum at 245 nm when a methanol solution of $Co(OAc)_2$ and PBu_3 was pressurized with 80 atm of synthesis gas. Upon irradiation to the solution the absorption at 370 nm, which can be assigned to $Co_2(CO)_6(PBu_3)_2$, appeared as a shoulder. It is probable that $HCo(CO)_3PBu_3$ was generated photochemically under the conditions employed. However, it is doubtful whether the phosphine-coordinated hydridocarbonylcobalt *thermally* initiates the hydroformylation reaction under Mirbach's conditions (85 °C) and especially under our conditions (30 °C). Because $HCo(CO)_3PBu_3$ is known to react with olefins only above 100—120 °C, in contrast to the behavior of $HCo(CO)_4$ which is active at room temperature.[5,13] Thermal reaction of $HCo(CO)_3PBu_3$ with 1-hexene was examined, and the

80	4	0.8	0.1	0.2	0
80	15	1.0	0.1	0.4	0
100	4	24.7	2.3	5.0	0.6
100[d]	4	2.3	0.2	0.3	0
120	4	142.7	19.8	27.3	3.3

a) Conditions and procedure: See Experimental in the text. b) Based on $Co_2(CO)_6(PBu_3)_2$. c) See footnotes in Table 1. d) Without pretreatment at 120 °C for 2 h.

results are shown in Table 4. The thermal hydroformylation of 1-hexene by $HCo(CO)_3PBu_3$ catalyst occurs only above 100 °C, and scarcely below 80 °C. No increase in the yield with prolonged reaction time (15 h) at 80 °C implies that $HCo(CO)_3PBu_3$ decomposes rather than reacts with olefin as reported earlier (Eq. 5).[5]

$$2HCo(CO)_3PBu_3 \longrightarrow Co_2(CO)_6(PBu_3)_2 + H_2 \quad (5)$$

In these experiments the formation of $HCo(CO)_3PBu_3$ is confirmed by no reaction taking place at 100 °C without the pretreatment at 120 °C for 2 h (see experimental section). Thus, absorption of light by the hydride should be required for the initiation of the reaction below 80 °C, though its steady concentration will be low.

$$HCo(CO)_3PBu_3 \xrightarrow{h\nu} HCo(CO)_2PBu_3 + CO \quad (6)$$

The photochemistry and UV spectral feature of the hydride have not been investigated. With respect to $HCo(CO)_4$, its photolysis in a matrix isolation system has been studied, in which the major process was the liberation of CO,

$$HCo(CO)_4 \xrightarrow[\text{Ar matrix}]{h\nu(254\text{ nm})} HCo(CO)_3 + CO$$

and $HCo(CO)_4$ had a absorption maximum at 227 nm with a large absorption coefficient (ε=ca. 55000).[14] A similar spectral feature may be expected for $HCo(CO)_3PBu_3$.

Consequently, two photochemical processes must be included in the photochemical hydroformylation reaction below 80 °C: First, the formation of $HCo(CO)_3PBu_3$ from the ionic species $[Co(CO)_3(PBu_3)_2]^+$ (Eq. 1), and second, the formation of the coordinatively unsaturated cobalt hydride $HCo(CO)_2PBu_3$ (Eq. 6).

Temperature Dependence. The reaction with $Co(OAc)_2/PBu_3$ catalyst affords the hydroformylation products almost in the same yield at different temperatures of 30, 80, and 120 °C as seen in Table 1. It seems to be rather unusual that the reaction rate does not change with temperature. Detailed temperature dependence on the product yield (or the reaction rate) was examined in the range of 0 °C and 140 °C, and shown in Fig. 2. The reaction proceeds slowly even at

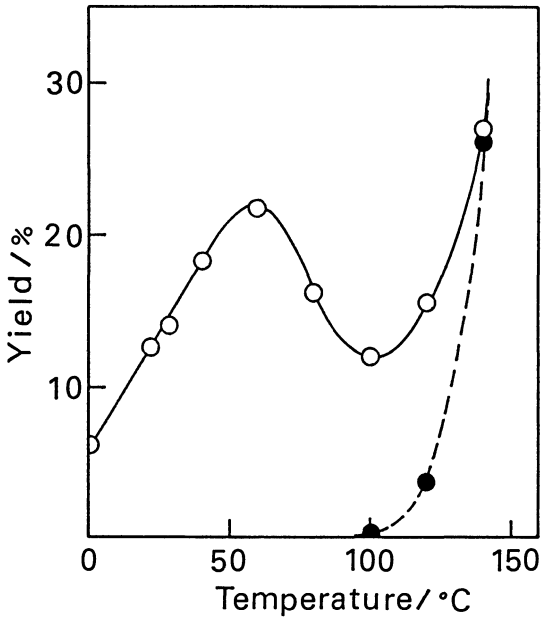

Fig. 2. Influence of reaction temperature on the hydroformylation of 1-hexene.
Reaction conditions as in Table 1, ○; photochemical, ●; thermal.

0 °C. The yield increases with temperature up to 60 °C, then decreases and again begins to increase at 100 °C. It can be seen that the yields at 30, 80, and 120 °C happened to lie on a similar value in the curve. Similar temperature dependence was found in the reactions of other substrates such as 1-pentene, 2- and 3-hexene, and 1-octene. The yield curve obtained in the thermal reaction is shown together in dotted line in Fig. 2. Thermal hydroformylation occurs above 120 °C, and at 140 °C no enhancement by irradiation is found. Thus, the reaction can be classified in two temperature regions of the photocatalytic reaction below 100 °C and the thermal reaction above 120 °C. In the photocatalytic region, the reaction is retarded above 60 °C. No detailed mechanistic consideration can be made here, but a most probable assumption is as follows: Photochemically generated $HCo(CO)_3PBu_3$ mostly decomposes to $Co_2(CO)_6(PBu_3)_2$ (Eq. 5), and regeneration of the hydride by the reverse reaction of Eq. 5 does not occur over the photocatalytic temperature range. If the photochemical generation of $HCo(CO)_3PBu_3$ has little temperature effect, then the steady concentration of the hydride will be lower at higher temperature. Although $Co_2(CO)_6(PBu_3)_2$ formed in Eq. 5 is consumed by the disproportionation in a polar solvent such as methanol,[15]

$$Co_2(CO)_6(PBu_3)_2 \xrightarrow{CO} [Co(CO)_3(PBu_3)_2]^+[Co(CO)_4]^- \quad (7)$$

small amounts of $Co_2(CO)_6(PBu_3)_2$ prevent largely the photochemical hydroformylation reaction due to its large absorption coefficient (ε=21500 at 370 nm).[16] The disappearance of the dicobalt species by disproportionation is more facile at higher temperature, then the

expected photochemical reactions become more favorable with increasing temperature.

Unsaturated hydride species $HCo(CO)_2PBu_3$, which is probably generated photochemically as described before (Eq. 6), reacts with olefins to lead to hydroformylation, or reacts with CO or phosphine to return to the saturated species.

$$HCo(CO)_2PBu_3 \xrightarrow{\text{olefin}} HCo(CO)_2(PBu_3)(\text{olefin}) \quad (8)$$

$$\xrightarrow{CO} HCo(CO)_3PBu_3 \quad (9)$$

$$\xrightarrow{PBu_3} HCo(CO)_2(PBu_3)_2 \quad (10)$$

These reactions may have different temperature dependence. Hydroformylation cycle (Eqs. 3 and 4) will have positive temperature effects, though the activation energies in each step may be low as the alkyl and acyl cobalt complexes readily react with CO and H_2, respectively, at room temperature.[5] Complex sequence of these reactions under applied conditions would result in the observed yield curve.

Thermal generation of $HCo(CO)_3PBu_3$ by the reverse reaction of Eq. 5 will become substantial above 120 °C, and thermal equilibrium (Eq. 2) has been assumed under the hydroformylating conditions. Then the irradiation becomes less effective, and at 140 °C the light has little effect on the hydroformylation reaction.

Effect of CO Partial Pressure. In conventional hydroformylation reactions, it is known that both the reaction rate and the n/i ratio in the products increase with lowering the CO partial pressure.[13,17] The former has been explained by the equilibria (Eqs. 2 and 11),

$$HCo(CO)_4 \rightleftarrows HCo(CO)_3 + CO \quad (11)$$

and the latter by the equilibrium between the phosphine substituted and unsubstituted hydride (Eq. 12), respectively.

$$HCo(CO)_3PBu_3 + CO \rightleftarrows HCo(CO)_4 + PBu_3 \quad (12)$$

In the photochemical hydroformylation of 1-hexene, similar dependence of CO partial pressure was observed as shown in Table 5. The yields of aldehydes and alcohols, and the selectivities toward normal products increased with lowering CO partial pressure. Here, following characteristic aspects are found: a) At 80 °C, the n/i ratio obtained under low CO pressure is only 1.5 times larger than that under high CO pressure. On the other hand, at 30 °C, it shows a extremely high value of 77, which corresponds to 98.7% of normal aldehyde and 1.3% of branched aldehydes. Such high selectivity has never been reported with cobalt catalysts except for the case of propene in the photochemical hydroformylation.[2] b) When high CO pressure is employed, lowering the temperature causes no increase in the n/i ratio (n/i=10 at 30 and 80 °C). c) Considerable hydrogenation of olefinic substrate is accompanied under low CO pressure, especially at 30 °C.

Thus, the high selectivity is achieved only at low pressure and low temperature. This can not be ascribed to only the above equilibrium (Eq. 12), since its equilibrium constant has been reported to have negative temperature dependence.[18] Existence of other catalytic species besides $HCo(CO)_3PBu_3$ can be expected under the conditions of low CO pressure and low temperature. Bis(phosphine) species $HCo(CO)_2(PBu_3)_2$ is most probable as the formation of about 1 : 1 mixture of $HCo(CO)_3PBu_3$ and $HCo(CO)_2(PBu_3)_2$ has been suggested in the photolysis of the cationic cobalt(I) complex $[Co(CO)_3(PBu_3)_2]^+$ under 50 atm of hydrogen.[19]

In order to ensure the contribution of $HCo(CO)_2(PBu_3)_2$ in the photochemical hydroformylation in the $Co(OAc)_2/PBu_3$ system, the hydroformylation of 1-hexene with $HCo(CO)_2(PBu_3)_2$ was carried out, and the results are summarized in Table 6. In the photochemical reaction, surprisingly high value of the n/i ratio was obtained at 30 °C and CO/H_2=1.5 atm/40 atm (n/i =215). However, when the temperature was raised to 80 °C, the n/i ratio largely decreased (n/i=25) to

40/40	80	Dark	<0.1	0	0	0

a) Conditions: $HCo(CO)_2(PBu_3)_2$, 0.022 mol dm^{-3}; PBu_3, 0.21 mol dm^{-3}; 1-hexene, 0.80 mol dm^{-3}; solvent, methanol; reaction time, 6 h. b) Based on 1-hexene. c) See footnotes in Table 1. d) 1-Heptanol (2-methyl-1-hexanol was not detected). e) Values in parentheses indicate the *n*/*i* ratio in produced aldehydes.

approach to the value obtained in the $Co(OAc)_2/PBu_3$ catalyst system (*n*/*i*=15 in Table 5). Similar situation is found at high CO pressure and low temperature. Hydrogenation of olefin is remarkable only at low CO pressure and low temperature. No reaction occurs without irradiation under the conditions employed.

Predominant photochemical reaction of $HCo(CO)_2(PBu_3)_2$ is perhaps ligand dissociation, mainly of CO.

$$HCo(CO)_2(PBu_3)_2 \xrightarrow{h\nu} HCo(CO)(PBu_3)_2 + CO$$

This coordinatively unsaturated hydride will afford exclusively normal aldehyde owing to its highly steric crowding. Decrease in the *n*/*i* ratio with increasing CO pressure is due to the known equilibrium (Eq. 13).[8]

$$HCo(CO)_2(PBu_3)_2 + CO \rightleftarrows HCo(CO)_3PBu_3 + PBu_3 \quad (13)$$

Low *n*/*i* value obtained at 80 °C under much low CO pressure suggests that the above equilibrium shifts to the right-hand side at higher temperature. Lower hydrogenation activity at higher temperature also suggests the conversion of $HCo(CO)_3(PBu_3)_2$ to $HCo(CO)_3PBu_3$ under these conditions, because the hydrogenation activity of phosphine-coordinated cobalt hydrides increases with increasing the number of phosphine coordinated to the hydride.[8]

The results obtained in the reaction of $HCo(CO)_2(PBu_3)_2$ under various conditions are in accord with those in the reaction with $Co(OAc)_2/PBu_3$ catalyst. Thus, $HCo(CO)_2(PBu_3)_2$ will largely contribute to the high selectivity toward normal aldehyde as observed in the photochemical hydroformylation reaction with $Co(OAc)_2/PBu_3$ catalyst under low CO pressure and low temperature. $HCo(CO)_2(PBu_3)_2$ is known to be fairly stable up to 140 °C in various organic solvents,[8] then it can not contribute to the thermal hydroformylation reaction because higher temperature must be required to initiate the reaction and under such conditions $HCo(CO)_2(PBu_3)_2$ will be readily converted into $HCo(CO)_3PBu_3$ even under much low CO pressure. Consequently, the highly selective hydroformylation can be achieved only by the photochemical reaction which is able to proceed readily at low temperature.

Hydrates of Organic Compounds. XVI. Determination of the Melting Points and Hydration Numbers of the Hydrates of Tetrabutyl(or Tetraisopentyl)ammonium Alkanesulfonates

Haruo NAKAYAMA,* Masashi YAMANOBE, and Kei BABA
Division of Materials Science and Chemical Engineering, Faculty of Engineering,
Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received May 23, 1991)

The solid-liquid phase diagrams of binary mixtures of water with tetraisopentylammonium alkanesulfonates, $[(i\text{-}C_5H_{11})_4N][n\text{-}C_nH_{2n+1}SO_3]$ (n=1—8), bis(tetrabutylammonium) alkanedisulfonates, $[(n\text{-}C_4H_9)_4N]_2[O_3S(CH_2)_nSO_3]$ (n=2—5), and with bis(tetraisopentylammonium) alkanedisulfonates, $[(i\text{-}C_5H_{11})_4N]_2[O_3S(CH_2)_nSO_3]$ (n=2—5), were examined in order to confirm the formation of hydrates. For all of the sulfonates examined the formation of hydrates has been newly confirmed. The hydrates of the tetraisopentylammonium alkanesulfonates have hydration numbers of around 37—40 and fairly high melting points (lie between 13 and 19 °C). The typical hydrates formed by the bis(tetrabutylammonium) alkanedisulfonates have hydration numbers of around 52 and those by the bis(tetraisopentylammonium) alkanedisulfonates around 76. The former disulfonate hydrates have low melting points (between 1.0 and 10 °C). However, the latter disulfonate hydrates have fairly high melting points (between 13 and 18 °C). A salt with n=4 forms the most stable hydrate for both series of alkanedisulfonates. Judging from the hydration numbers and melting points, these hydrates seem to be clathrate-like.

It is well-known that some tetrabutylammonium and tetraisopentylammonium salts, such as $(n\text{-}C_4H_9)_4NF$ and $(i\text{-}C_5H_{11})_4NF$, can form unusual hydrates which have a large number of water molecules per one ammonium ion (hydration numbers) as well as fairly high melting points between 0 °C and room temperature.[1-3] According to a single-crystal X-ray examination by Jeffrey and co-workers[2-5] these hydrates were semi-clathrate hydrates, similar to the so-called gas hydrates:[4] The water structure is a hydrogen-bonded framework, and is essentially a regular arrangement of polyhedra, such as pentagonal dodecahedra and tetrakaidecahedra; each alkyl group of an ammonium cation is incorporated into one of the polyhedra.[2-3]

The formation of similar types of hydrates has also been known for various tetrabutylammonium (or tetraisopentylammonium) salts which have organic anions like alkanoates[5-11] and dialkanoates.[11,12] These hydrates are of special interest, since their atability and structure are affected not only by the type of tetraalkylammonium cation, but also by the hydrocarbon portion of the anion. Recently, from the fact that tetrabutylammonium alkanedioates, $[(n\text{-}C_4H_9)_4N]_2[OOC(CH_2)_n\text{-}COO]$, can form a stable clathrate-like hydrate when n=3,[12] the possibility to form a hydrate of tetrabutylammonium polyacrylate was both anticipated and verified.[13] The formation of a hydrate of such a polymeric salt has never been known before.

Another polyanion which is expected to possibly form a similar type hydrate is a polysulfonate anion, such as the poly(ethenesulfonate) anion and the poly(styrenesulfonate) anion. However, there is no basic information about the formation of hydrates of tetraalkylammonium alkanesulfonates and alkanedisulfonates, except for a series of tetrabutylammonium alkanesulfonates.[14] Thus, in this work, phase-diagrammatic studies regarding binary mixtures of water with tetraisopentylammonium alkanesulfonates, bis(tetrabutylammonium)alkanedisulfonates, or bis(tetraisopentylammonium) alkanedisulfonates were carried out in order to confirm the formation of clathrate-like hydrates and, when formed, to determine the effect of the hydrocarbon portion of the anion on the melting points and hydration numbers.

Experimental

Aqueous solutions of tetraisopentylammonium alkanesulfonates, $[(i\text{-}C_5H_{11})_4N][n\text{-}C_nH_{2n+1}SO_3]$ (n=1—6, and 8), bis(tetrabutylammonium) alkanedisulfonates, $[(n\text{-}C_4H_9)_4N]_2[O_3S(CH_2)_nSO_3]$ (n=2—5), and of bis(tetraisopentylammonium) alkanedisulfonates, $[(i\text{-}C_5H_{11})_4N]_2[O_3S(CH_2)_nSO_3]$ (n=2—5), were prepared by neutralization of either an aqueous tetrabutylammonium hydroxide solution or an aqueous tetraisopentylammonium hydroxide solution with the corresponding sulfonic acid solutions. The hydroxide solutions were obtained by treating either tetrabutylammonium iodide or tetraisopentylammonium iodide with freshly prepared silver(I) oxide in water followed by filtration of the AgI precipitate. Tetrabutylammonium iodide was prepared by precipitation from an aqueous solution of tetrabutylammonium bromide (purchased from Tokyo Kasei Kogyo Co., Ltd.) with the addition of sodium iodide, followed by washing with water and air-drying in a desiccator. The iodide was purified by repeated recrystallization from ethyl acetate. Tetraisopentylammonium iodide was synthesized and purified in the same manner as described in a previous paper.[11] All of the sulfonic acid solutions, except for CH_3SO_3H and $C_2H_5SO_3H$, were obtained by passing each sodium salt solution through a column of cation-exchange resin (Amberlite IR-120B) converted, in advance, into the acid form by about a 2 mol dm^{-3} hydrochloric acid solution. Two acids, CH_3SO_3H and $C_2H_5SO_3H$, and the sodium salts $n\text{-}C_nH_{2n+1}SO_3Na$ with n=5, 6, and 8, were purchased either from Tokyo Kasei Kogyo Co., Ltd. or Aldrich Chemical Co., Inc.. Two sodium salts, $n\text{-}C_nH_{2n+1}SO_3Na$ with n=3 and 4, were synthesized in the manner reported by Reed et al.[15] A half mole of the corre-

sponding alkyl iodide was slowly added to a hot saturated aqueous solution of one mole of sodium sulfite. The mixture was refluxed for a few days. After the water had been evaporated under reduced pressure, the reaction product was extracted with hot ethanol. The sodium salt was purified by repeated recrystallization from ethanol. Two sodium alkanedisulfonates, $NaO_3S(CH_2)_nSO_3Na$ with n=2 and 4, were purchased from Tokyo Kasei Kogyo Co., Ltd., and two other sodium salts with n=3 and 5 were synthesized using the corresponding dibromide, $Br(CH_2)_nBr$ (n=3 or 5), by a similar manner as discribed above.[16] All of the synthesized disodium salts were confirmed by their NMR and IR spectra.

The solid-liquid phase diagrams for the binary systems of water-each sulfonate mentioned above were determined in the same manner as described in previous papers.[8-11] The concentration of each mother solution was determined by measuring the amount of either tetrabutylammonium cation or tetraisopentylammonium cation by titration with a sodium tetraphenylborate solution standardized by pure $(n\text{-}C_4H_9)_4NI$ solid.

Results and Discussion

(1) The Formation of Hydrates of Tetraisopentylammonium Alkanesulfonates. The solid-liquid phase diagrams for the binary systems, water-$[(i\text{-}C_5H_{11})_4N][n\text{-}C_nH_{2n+1}SO_3]$, where n=1—3, are shown in Fig. 1. The

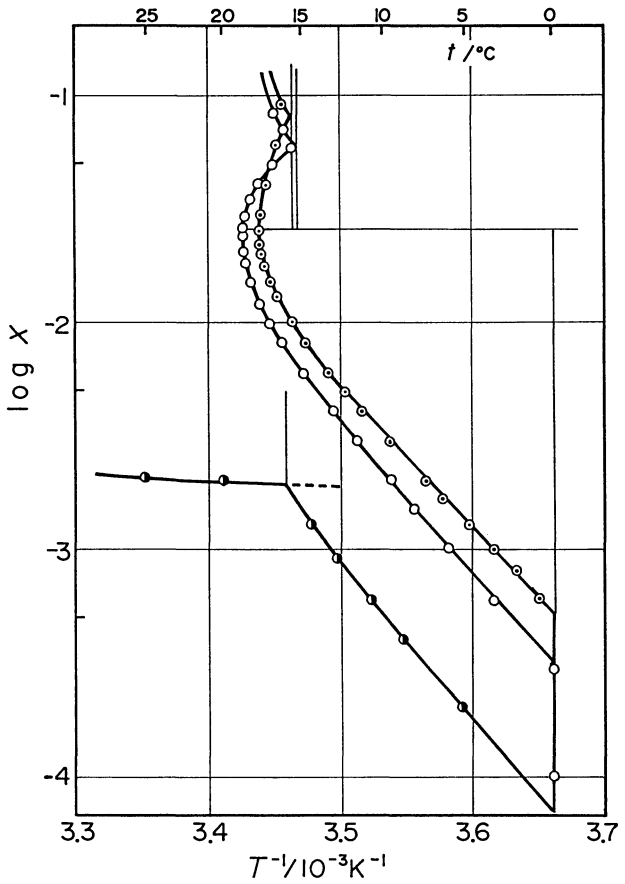

Fig. 1. Solid-liquid phase diagrams for the water-$[(i\text{-}C_5H_{11})_4N][n\text{-}C_nH_{2n+1}SO_3]$ systems. ○: n=1; ⊙: n=2; ◑: n=3.

logarithm of the concentration, expressed as the mole fraction, X, is plotted against the reciprocal of the absolute temperature. The phase diagrams of the salts with n=1 and 2 exhibit congruent melting points at concentrations near X=0.025, indicating that these two salts form a hydrate with hydration numbers around 39. These hydrates are fairly stable: The melting points are 18.7 °C (n=1) and 17.6 °C (n=2), respectively. It is interesting to note that the formation of these hydrates occurs in very dilute solutions (around $X=5\times10^{-4}$), just as found for other tetraisopentylammonium salt hydrates.[11,17]

In the n=3 system, two kinds of solid-liquid equilibrium lines intersect each other at around X=0.002 and 16.1 °C. The line at temperatures below 16.1 °C may be regarded as being an equilibrium line between a hydrate solid and an aqueous solution, just as in the case of the other two salts with n=1 and 2, since the slopes $-\partial \log X/\partial(1/T)$ are almost the same for these three systems: It has been verified that this slope is approximately proportional to the hydration numbers of the hydrate.[18] Thus, it can be concluded that the salt with n=3 forms a hydrate with hydration numbers around 39 at temperatures below 16.1 °C. Its melting point is estimated to be 22—23 °C if the hydrate were stable above 16.1 °C. The line at temperatures above 16.1 °C seems to exhibit an equilibrium between an anhydrous $[(i\text{-}C_5H_{11})_4N][n\text{-}C_3H_7SO_3]$ solid and a saturated solution. It is interesting to note that although the salt with n=3 can form a fairly stable hydrate, its anhydrous salt is more stable at temperatures above 16.1 °C.

The phase diagrams for the salts with n=4 and 5 are essentially the same as those of n=1 and 2 shown in Fig. 1, except that for the salt with n=5; in this case a region in which two liquid phases are in equilibrium appears above 20.9 °C. The critical concentration is almost the same as the congruent composition of its hydrate (X=0.025).

The phase diagrams for the salts with n=6 and 8 are shown in Fig. 2. For these two systems, the liquid-liquid equilibrium region extends towards the wide-concentration range and the low-temperature region. The solid-liquid phase diagram for the n=6 system intersects with its liquid-liquid phase diagram at X=0.067, which is greater than its congruent composition (X=0.024). However, for the n=8 system these two lines intersect at a concentration (X=0.01) before the solid-liquid line reaches its congruent composition. As a result of this, the melting point and hydration numbers for the hydrate of the n=8 salt cannot be determined exactly, though a similar hydrate to that of the n=6 salt is undoubtedly formed at concentrations below X=0.01 for the same reason as mentioned regarding the n=3 system. Its melting point is estimated to be 14—15 °C.

All of the melting points and hydration numbers, determined from each congruent melting point and congruent composition, are summarized in Table 1,

together with estimated melting points for the hydrates of the salts with n=3 and 8. The existence of these hydrates has been newly confirmed in this study. From Table 1 it is clear that all of the hydrates have hydration numbers around 39. As mentioned above, the hydrates formed by the salts with n=3 and 8 presumably have similar hydration numbers. It is interesting to note that the same type of hydrate is formed regardless of the chain length of the alkyl group in the alkanesulfonate anion. The melting points of these hydrates are fairly high (higher than 17 °C, except for the hydrates of n=6 and 8) and the effect of the chain length of the $C_nH_{2n+1}SO_3^-$ anion on the melting points of these hydrates is not so marked. Judging from the values of the hydration numbers and the melting points, these hydrates seem to be an isostructural clathrate-like hydrate with a well-known (i-C_5H_{11})$_4$NF·39H_2O hydrate, whose structure has been examined in detail by Jeffrey and his co-worker.[3)]

In Fig.3 the relationships between the melting points (t_m) of the hydrates and the number of carbon atoms of the alkyl group in the anion (n) is shown (A), together with those of two related salts of [(n-C_4H_9)$_4$N][n-$C_nH_{2n+1}SO_3$] (B)[14)] and [(i-C_5H_{11})$_4$N][n-C_nH_{2n+1}COO] (C).[11)] A comparison of line A with line B clearly indicates that the hydrates of tetraisopentylammonium alkanesulfonates are more stable than those of tetrabutylammonium alkanesulfonates: The melting points of the former hydrates are more than 15 degrees higher than those of the latter hydrates when n is larger than 3. This fact suggests that a hydrogen-bonded framework of water molecules surrounding an (i-C_5H_{11})$_4$N$^+$ cation is fairly stable, compared with that around an (n-C_4H_9)$_4$N$^+$ cation, as has been pointed out in other studies.[11,18)] It is interesting to note that when n=1 and 2 the melting points of a series of tetraisopentylammonium alkanesulfonates (A) are 6—10 °C lower than those of a series of tetraisopentylammonium alkanoates (C). As discussed

in an earlier paper,[11] the highest melting point of the [(i-C_5H_{11})$_4$N][C_2H_5COO] hydrate is explained by the best fit of the $C_2H_5COO^-$ anion to a pentagonal dodecahedron, which exists in a gap between the arrangement of larger polyhedra filled by one of the isopentyl groups of a tetraisopentylammonium cation. For the sulfonate hydrates with n=1 and 2, however, the distortion of the hydrogen-bonded water network which incorporates sulfonate anions, like $CH_3SO_3^-$ and $C_2H_5SO_3^-$, will be greater than when incorporates such alkanoate anions as CH_3COO^- and $C_2H_5COO^-$ because of the bulkiness of the SO_3^- group, compared with the COO^- group. This leads to a lowering of the melting points of the hydrates of [(i-C_5H_{11})$_4$N][CH_3SO_3] and [(i-C_5H_{11})$_4$N]-[$C_2H_5SO_3$].

Another feature which can be seen from a comparison of lines A and C in Fig.3 is the fact that when n is larger than 3 the melting points of both series of hydrates decrease with increasing n, and the difference between them become less than 4 degrees. This behavior may be explained, at least partly, as follows: When n is larger than 3, both the $C_nH_{2n+1}SO_3^-$ anion and the $C_nH_{2n+1}COO^-$ anion can no longer be accommodated in a small cage, like a single pentagonal dodecahedron, because of their increased ionic volume. As a result, they must be accommodated in a larger polyhedron. For such a large polyhedron the distortion of the water network due to the SO_3^- group and COO^- group does not play an important role concerning the stability of the hydrates.

(2) The Formation of Hydrates of Bis(tetrabutylammonium) Alkanedisulfonates and of Bis(tetraisopentylammonium) Alkanedisulfonates. Solid-liquid phase diagrams for the binary systems, water-[(n-C_4H_9)$_4$N]$_2$-[$O_3S(CH_2)_nSO_3$], where n=2—5, are shown in Fig. 4 in the same manner as in Figs. 1 and 2. Three systems with n=2—4 exhibit congruent melting points at concentrations of around X=0.019, indicating that these three salts form a hydrate with hydration numbers of about 52. The melting points of these hydrates, however, are fairly low: they lie between 5.7 and 9.9 °C. The system with n=5 shows two congruent melting points at 1.0 and 1.4 °C at concentrations of around X=0.016 and 0.032, indicating that two kinds of hydrates with hydration numbers of around 61 and 30 are formed. The latter hydrate is also formed by a salt with n=4. In addition, in systems with n=2—4 there are incongruent melting points at concentrations of around X=0.014—0.015; the hydration numbers of the hydrates formed at concentrations below the incongruent compositions seem to be the same as that formed for the n=5 salt, around 61, because of a similarity in the slope ($\partial \log X/\partial(1/T)$) in all systems with n=2—5.

All of the melting points, hydration numbers, which are determined from each congruent composition and the congruent melting point, are summarized in Table 2. As mentioned above, three types of hydrates with hydration numbers of around 30, 52, and 61 are formed. The existence of these hydrates has been newly confirmed in this study. No information about the structure of these hydrates is present at this stage. However, hydrates with hydration numbers of about 61 seem to be isostructural with a well-known (n-C_4H_9)$_4$NF·30H_2O hydrate,[2] since the number of the water molecules per one (n-C_4H_9)$_4$N$^+$ cation is almost the same in both hydrates. Although the formation of several types of tetrabutylammonium salt hydrates which have hydration numbers less than 30 per one (n-C_4H_9)$_4$N$^+$ cation and fairly high melting points (higher than 10 °C) is known at pres-

ent,[10] the correlation between these hydrates and those found in this study with hydration numbers of 30 and 52 is uncertain. Another interesting feature of Table 2 is the fact that the melting points of the hydrates of the salt with a short methylene chain of n=2 and with a somewhat long methylene chain of n=4 are higher than those of the n=3 and 5 hydrates. This may be explained by assuming that the n=2 hydrate comprises a sequence of $[(n\text{-}C_4H_9)_4N^+ \cdots {}^-O_3S(CH_2)_2SO_3^-]+[(n\text{-}C_4H_9)_4N^+]$, and that the n=4 hydrate $[(n\text{-}C_4H_9)_4N^+ \cdots {}^-O_3S(CH_2)_4SO_3^- \cdots (n\text{-}C_4H_9)_4N^+]$ in which the central ${}^-O_3S(CH_2)_4SO_3^-$ anion is surrounded by a large polyhedron made of hydrogen-bonded water networks; in the n=3 hydrate the distortion effect of the ${}^-O_3S(CH_2)_3SO_3^-$ anion on the hydrogen-bonded water network surrounding an $(n\text{-}C_4H_9)_4N^+$ cation will increase compared with that of the ${}^-O_3S(CH_2)_2SO_3^-$ anion in the n=2 hydrate; in the n=5 hydrate the distortion effect of the ${}^-O_3S(CH_2)_5SO_3^-$ anion become larger than that of the ${}^-O_3S(CH_2)_4SO_3^-$ anion in the n=4 hydrate.

The solid–liquid phase diagrams for the binary systems, water–$[(i\text{-}C_5H_{11})_4N]_2[O_3S(CH_2)_nSO_3]$, where n=2—5, are shown in Fig. 5. The phase diagram of the system with n=2 is shown by a broken line because of the similarity of data with those of the n=3 salt. It is clear from this figure that all four systems exhibit congruent melting points at around X=0.013, indicating that these four salts form a hydrate with hydration numbers around 76. Furthermore, the two systems with n=2 and 4 exhibit other congruent melting points around X=0.042—0.043, corresponding to hydrates with hydration numbers of 22—23. All of the melting points and hydration numbers determined are summarized in Table 3, together with some incongruent melting points. These hydrates were newly confirmed in this study. The hydrates with hydration numbers of around 76 seem to be isostructural with a well-known $(i\text{-}C_5H_{11})_4NF \cdot 39H_2O$ hydrate,[3] since the number of water molecules per one $(i\text{-}C_5H_{11})_4N^+$ cation is almost the same in both hydrates. The interesting features of Table 3 are summarized as follows: (1) The melting points of hydrates with hydration numbers of around 76 are 7—12 °C higher than those of the hydrates formed by a series of bis(tetrabutylammonium) alkanedisulfonates (shown in Table 2), suggesting that a hydrogen-bonded framework of water molecules around an $(i\text{-}C_5H_{11})_4N^+$ cation is more stable than that around an $(n\text{-}C_4H_9)_4N^+$ cation, as is often pointed out;[11,18] (2) The order of the melting points with respect to n is 4>2>3>5, which is the same as in the case of bis(tetrabutylammonium) alkanedisulfonate hydrates (shown in Table 2). The reason for this can be explained in the same manner as mentioned above; and (3) For the n=2 and 4 salts hydrates with hydration numbers of 22—23 are slightly stable compared with those of around 76.

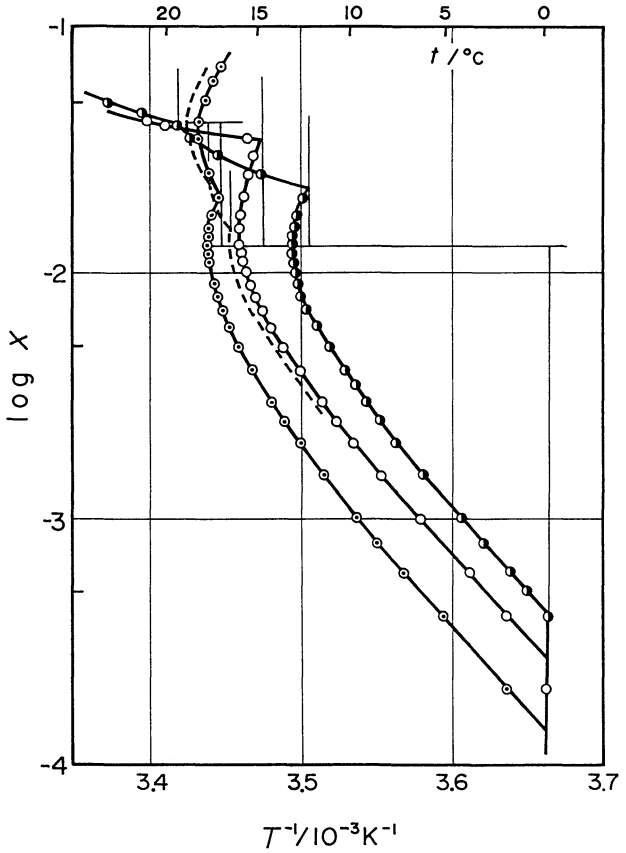

Fig. 5. Solid–liquid phase diagrams for the water–$[(i\text{-}C_5H_{11})_4N]_2[O_3S(CH_2)_nSO_3]$ systems. ○: n=3; ⊙: n=4; ◑: n=5; broken line: n=2.

Finally, in Fig. 6 the melting points of the two series of hydrates of alkanedisulfonates, $[(n\text{-}C_4H_9)_4N]_2[O_3S(CH_2)_nSO_3]$ and $[(i\text{-}C_5H_{11})_4N]_2[O_3S(CH_2)_nSO_3]$, are compared with those of the hydrates of the corresponding alkanedioates,[11] $[(n\text{-}C_4H_9)_4N]_2[OOC(CH_2)_nCOO]$ and $[(i\text{-}C_5H_{11})_4N]_2[OOC(CH_2)_nCOO]$, respectively. The dependence of the melting points on the number of n for the latter two series of hydrates has been discussed in a previous paper.[11] It is obvious from this figure that when the kind of cation is the same, either $(n\text{-}C_4H_9)_4N^+$ or $(i\text{-}C_5H_{11})_4N^+$, the melting points of the alkanedioate hydrates are fairly high compared with those of the alkanedisulfonate hydrates: The melting-

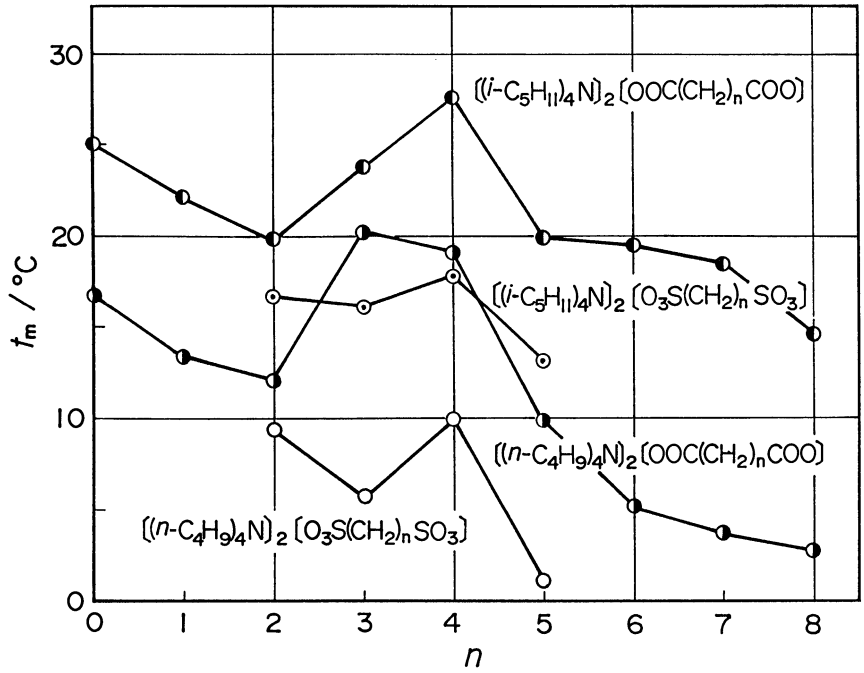

Fig. 6. Relationships between the melting points, t_m, of the hydrates of four series of salts and of the number of carbon atoms, n, of the methylene chain of the anion. ○: $[(n\text{-}C_4H_9)_4N]_2[O_3S(CH_2)_nSO_3]$; ⊙: $[(i\text{-}C_5H_{11})_4N]_2[O_3S(CH_2)_nSO_3]$; ◑: $[(n\text{-}C_4H_9)_4N]_2[OOC(CH_2)_nCOO]$; ◐: $[(i\text{-}C_5H_{11})_4N]_2[OOC(CH_2)_nCOO]$.

point differences are 9—14 °C for the tetrabutylammonium salt hydrates and 7—10 °C for the tetraisopentylammonium salt hydrates for n=3—5, although when n=2 the difference is somewhat slight (about 3 °C) for both hydrates. The high stability of the alkanedioate hydrates probably indicates that a distortion effect of the bulky alkanedisulfonate anion $[O_3S(CH_2)_nSO_3]^{2-}$ on the hydrogen-bonded water networks is larger than that of the alkanedioate anion $[OOC(CH_2)_nCOO]^{2-}$, just as discussed concerning the difference in curves A and C when n=1 and 2 in Fig. 3.

Coated Wire Electrodes Sensitive to Local Anesthetic Cations and Their Application to Potentiometric Determination

Hiromu SATAKE,* Takahiro MIYATA, and Shoji KANESHINA
Department of Biological Science and Technology, Faculty of Engineering,
The University of Tokushima, Minamijosanjima-cho, Tokushima 770
(Received February 6, 1991)

Coated wire electrodes sensitive to procaine(PC), tetracaine(TC), lidocaine(LC), dibucaine(DC), mepivacaine(MC), and bupivacaine(BC), based on ion-pair formation between tetraphenylborate ions and the corresponding local anesthetic cations in a plasticized poly(vinyl chloride) membrane were prepared. The electrodes showed linear responses with Nernstian slopes (55—58 mV/decade) over concentration ranges of 4×10^{-5}—10^{-2}, 4×10^{-5}—10^{-2}, 10^{-4}—10^{-2}, 4×10^{-5}—10^{-2}, 5×10^{-5}—10^{-2}, and 2×10^{-4}—10^{-2} mol dm^{-3} for PC, TC, LC, DC, MC, and BC, respectively. The change in pH did not affect the electrode performance within ranges of 3.2—7.4, 3.2—7.4, 2.1—7.7, 2.5—7.4, 3.5—7.0, and 2.4—5.6 for PC, TC, LC, DC, MC, and BC, respectively. The reproducibility, stability, response time, and selectivity were also investigated. The electrodes were applied satisfactorily to the determination of local anesthetics by potentiometry.

Many local anesthetics in clinical use are basically tertiary amine compounds, and are classified as being of the ester type [procaine (PC), tetracaine (TC), benzocaine etc.] and amide type [lidocaine (LC), dibucaine (DC), mepivacaine (MC), bupivacaine (BC) etc.]. These drugs exist in both positively charged and uncharged forms under normal in vivo conditions.[1] Both species apparently have different biological activities. The establishment of analytical methods for both species will provide useful information concerning the molecular mechanism of local anesthetic action.[2,3]

Although many methods[4-10] (including polarography, spectrophotometry, HPLC, and fluorometry) have been reported for the determination of local anesthetics, these are generally used for measuring the total concentration of local anesthetics. Potentiometry[11-17] using an ion-selective electrode has an advantage in that the electrode enables estimates of free cationic anesthetics. An ion-selective electrode comprising a poly(vinyl chloride) (PVC) membrane is the most suitable type for use as a sensor in the potentiometric determination of organic cations like local anesthetics. So far reported have been a liquid-membrane electrode[12] incorporating PC–tetraphenylborate (TPB^-) and a PVC membrane electrode with a PC–TPB ion pair[11,16] and crown ether[15] used as the sensor elements; these electrodes have complicated structures and electrodes preparation is time consuming. On the other hand, a coated wire electrode based on a PVC membrane can easily be prepared in various shapes and miniaturized. Coated wire electrodes have been used as sensors in the potentiometric titration of PC by K. Vytras et al;[13,14] other local anesthetics were not studied.

This paper discusses the preparation of PVC-membrane coated wire electrodes sensitive to PC, TC, LC, DC, MC, and BC, as well as some of the properties of the resulting electrodes. The concerned electrodes were used successfully as sensors in direct potentiometry and potentiometric titration of local anesthetics.

Experimental

Reagents. All of the reagents used in the preparation of the electrode and solution were of analytical grade. The hydrochloride salts of local anesthetics used were purchased from Sigma Chemical Co., except for lidocaine hydrochloride (Fujisawa Yakuhin Co.). The chemical structures of the local anesthetics used are shown in Fig. 1. Sodium tetraphenylborate (NaTPB) (Aldrich), dioctyl phthalate (DOP) (Tokyo Kasei), PVC (Wako) of high molecular weight, and tetrahydrofuran (THF) (Wako) were used; the THF solvent was dehydrated with molecular sieves (Wako). Ion-pairs of PC–TPB, TC–TPB, LC–TPB, DC–TPB, MC–TPB, and BC–TPB were prepared according to the same method described previously for an ion pair of tetraphenylphosphonium–tetraphenylborate,[18] and were identified by elemental analysis. Water was purified by triple distillation, once from an alkaline potassium permanganate solution.

Construction of Electrode. A coated wire electrode sensitive to local anesthetic cations was prepared by the same method described previously.[18] The copper wire (0.8 mm diameter) was coated with a PVC-membrane of ca. 0.4 mm thickness. The solution used for the PVC-membrane usually included ion pairs, DOP, PVC, and THF with various compositions. The electrode was allowed to stand for at least ten hours in contact with air; it was then conditioned by soaking in 10^{-3} mol dm^{-3} of a local anesthetic drug solution or water prior to measurements.

Potential Measurement. The electrochemical system was as follows: A local anesthetic coated wire electrode/test solution/1 mol dm^{-3} sodium nitrate agar-bridge/saturated potassium chloride/Ag–AgCl electrode.

The electromotive force (EMF) was measured at 25 °C with a multi-ion monitor (Yamashita Giken) in a constantly stirred solution. The temperature of the test solution was controlled by circulating water from a thermostatic bath (Komatu Yamato) through a double-wall beaker.

Calibration curves of the EMF vs. the logarithm of the anesthetic concentration were made as follows: The EMF values were recorded after suitable increments of standard local anesthetic solution was added to 50 cm^3 of water, so as to cover the concentration range 10^{-6}—10^{-2} mol dm^{-3}. The

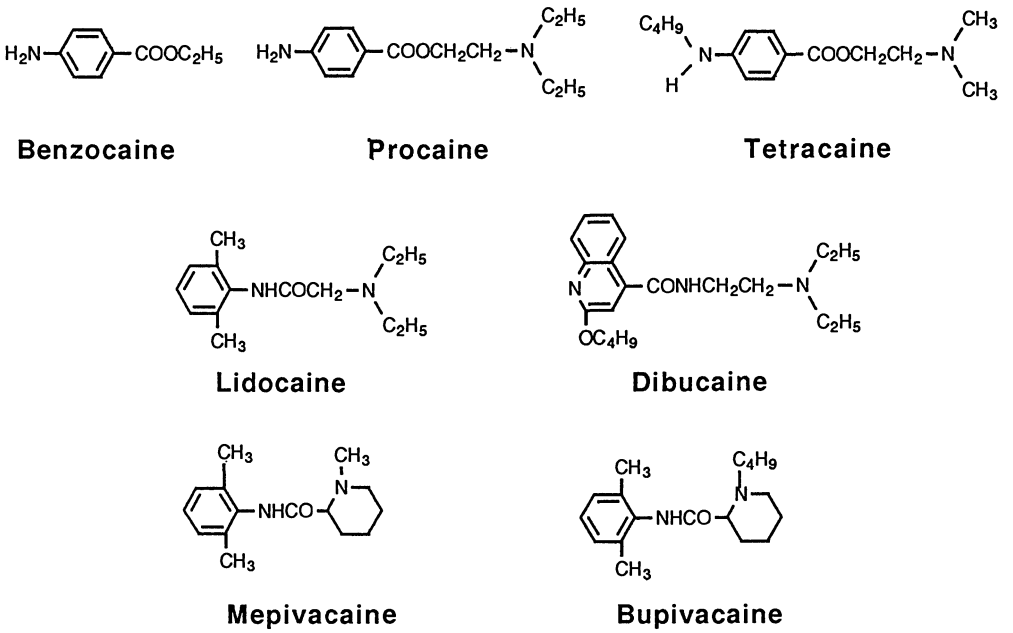

Fig. 1. Chemical structure of local anesthetics.

local anesthetic coated wire electrode and the sodium nitrate agar-bridge connected to a reference electrode was immersed in each test solution; the EMF values were recorded after each addition.

Potentiometric Titration. The anesthetic solutions for potentiometric titration were prepared in three ways. Ten cm^3 of test solution was transferred into a 100 cm^3 beaker; distilled water was added until obtaining a total volume of 50 cm^3. The resulting solution was titrated with 10^{-2} mol dm^{-3} standard NaTPB solution using the respective electrode as the sensor.

Results and Discussion

Response of the Electrode. Since the potential response of the coated wire electrode is considered to be similar to that of a liquid-membrane electrode,[19,20] the membrane potential of the electrodes depends on the ion-exchange process at the membrane/solution interface, the mobilities of anesthetic cations in the membrane, and the potentials at the membrane/electrode copper interface. Provided that both the potential at the copper/PVC membrane interface and the diffusion potential in the PVC membrane are constant, and the anesthetic cations (A^+) and TPB^- (X^-) in the membrane are in chemical equilibrium with the anesthetic-TPB ion pairs (AX) in the membrane, the membrane potential of the electrode (E_M) can be represented by

$$E_M = \text{Const} + \frac{RT}{Z_A F} \ln \frac{a_{A^+}}{\bar{C}_{A^+}}$$
$$= \text{Const} + \frac{RT}{Z_A F} \ln a_{A^+} + \frac{RT}{Z_A F} \ln K_{AX} \cdot \bar{C}_{X^-}$$
$$- \frac{RT}{Z_A F} \ln \bar{C}_{AX}, \quad (1)$$

where a_{A^+} is the activity of the anesthetic cation in the test solution, and Z_A is the charge of anesthetic cation. $\bar{C}_{A^+}$, C_{X^-} and $\bar{C}_{AX}$ represent the concentrations of the anesthetic cation, TPB^- and ion pairs in the membrane, respectively. K_{AX} is the association constant of the ion pair. F, R, and T are the Faraday constant, gas con-

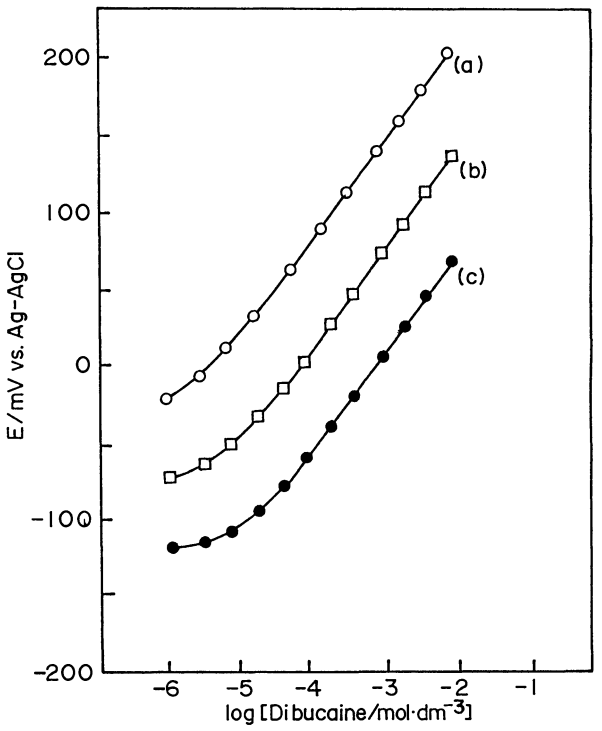

Fig. 2. Effect of the number of ion pairs in a PVC membrane on the potential of a dibucaine electrode. (a) Ion pair 1 mg+PVC 110 mg+DOP 100 mg, (b) Ion pair 5 mg+PVC 110 mg+DOP 100 mg, (c) Ion pair 50 mg+PVC 110 mg+DOP 100 mg.

stant and absolute temperature, respectively.

Equation 1 means that the higher is the concentration of the anesthetic–TPB ion pairs in PVC membrane, the lower is the membrane potential. Figure 2 shows the response curve for a dibucaine electrode containing various amounts of the dibucaine–TPB ion pairs in the PVC membrane. The potential response curve shifts to the negative side with increasing number of ion pairs in the PVC membrane, as expected from Eq. 1. Consequently, the membrane potential was defined as the activity of the anesthetic cations in solution in the case of a constant concentration of anesthetic–TPB ion pairs in the PVC membrane.

If interfering ions (B^+) exist, when the concentration of anesthetic–TPB ion pairs in the PVC membrane is kept constant, the membrane potential of the electrode is empirically given by

$$E_M = \text{Const} + \frac{RT}{Z_A F} \ln (a_{A^+} + K_{AB} \cdot a_{B^+}^{\frac{Z_A}{Z_B}}), \quad (2)$$

where K_{AB} is the selectivity coefficient of the B^+ ions for the anesthetic electrode, and a_{B^+} and Z_B are the activity and charge of a B^+ ion.

Composition of Electrode Membrane. Coated wire electrodes sensitive to local anesthetics with various membrane compositions were prepared, and the effect of the membrane composition on both the response time of the electrode and the slope of the EMF vs. concentration curve was investigated. A suitable PVC-membrane composition is shown in Table 1. The best results were obtained with an electrode membrane prepared from mixtures of local anesthetic–TPB ion pairs (5 mg), DOP (100 mg), PVC (110 mg) and 1.5 cm^3 of THF. Typical calibration curves of PC, TC, LC, DC, MC, and BC are shown in Fig. 3. The usable concentration range determined by the linear region of the calibration curves was 4×10^{-5}—10^{-2}, 4×10^{-5}—10^{-2}, 10^{-4}—10^{-2}, 4×10^{-5}—10^{-2}, 5×10^{-5}—10^{-2}, and 2×10^{-4}—10^{-2} mol dm^{-3} for PC, TC, LC, DC, MC, and BC, respectively. The response of the concerned electrodes was Nernstian (57.7, 56.6, 55.9, 58.6, 54.8, and 58.2 mV/decade for PC, TC, LC, DC, MC, and BC, respectively) and the standard relative deviation (%) of the slopes was less than 1%. The electrode can be used to determine the concentration of local anesthetic cations over a period of one month. When the contents of DOP (<50 mg) and ion-pairs (<1 mg) decreased, the electrode potential became unstable because of the high resistance of the membrane. A large excess of DOP and ion pairs in the membrane caused the surface of the copper wire to gradually become black, thus shortening the electrode lifetime and decreasing the slope of the potential curves.

Response Time and Reproducibility. The response time of the local anesthetic electrode was less than 30 seconds for a local anesthetic concentration range of 10^{-2} to 10^{-5} mol dm^{-3} and 2 min for 10^{-6} mol dm^{-3}. The reproducibility of the electrode potential was checked by either increasing or decreasing the local anesthetic concentration. The fluctuation of the electrode potentials was within a 1% standard relative deviation, with a concentration range from 10^{-4} to 10^{-2} mol dm^{-3} or from 10^{-2} to 10^{-4} mol dm^{-3}. Even after a

0.167	55.9	69.1	−4.2—−2.2	0.9999

a) NaCl added.

continuous measurement of the electrode potential over a period of eight hours, the change of the electrode potential was within 3 mV.

Effect of Ionic Strength. The performance characteristics of the PC electrode at various ionic strengths were examined by adding sodium chloride as the supporting electrolyte. The results are given in Table 2. The slope was almost independent of the ionic strength. The usable range of the calibration curve became slightly narrow.

Effect of pH. The effect of the pH on the electrode potential was examined for 10^{-3} mol dm^{-3} test solutions of local anesthetics, except for dibucaine (10^{-4} mol dm^{-3}). Figure 4 shows the variation in the electrode potential with changes in the pH by the addition of 10^{-1} mol dm^{-3} hydrochloric acid and/or sodium hydroxide solutions which included a corresponding local anesthetic of 10^{-3} mol dm^{-3}. The results indicate that the change in the pH did not affect the potential reading within the pH ranges 3.2—7.4, 3.2—7.4, 2.1—7.7, 2.5—7.4, 3.5—7.0, and 2.4—5.6 for PC, TC, LC, DC, MC, and BC, respectively. In acidic media of lower pH than these ranges, the electrode potential decreased as the pH value decreased. This may be attributed to a disappearance of the protonated local anesthetic, since they transformed to a diprotonated species.[11] The negative shift of the electrode potential at pH higher than about 7.5[11] may be due to a decrease in the concentration of the protonated species as a result of the precipitation of uncharged species of the local anesthetic.[11,21] In the case of the BC electrode, positive shifts of the electrode potential were observed at pH higher than 5.6. This phenomenon needs further clarification.

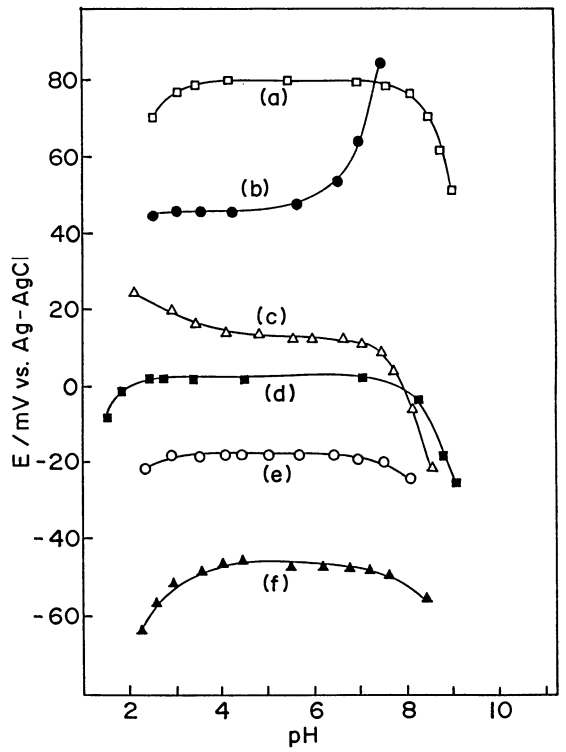

Fig. 4. Effect of pH on the response of a local-anesthetic coated wire electrode: (a) Tetracaine (9.92×10^{-4} mol dm^{-3}); (b) Bupivacaine (9.92×10^{-4} mol dm^{-3}); (c) Mepivacaine (9.92×10^{-4} mol dm^{-3}); (d) Lidocaine (9.92×10^{-4} mol dm^{-3}); (e) Dibucaine (9.98×10^{-5} mol dm^{-3}); (f) Procaine (10^{-3} mol dm^{-3}).

Selectivity of Electrodes. The selectivity of a membrane electrode based on ion-pair formation depends on the selectivity of ion-exchange at the membrane-test solution interface, the mobilities of the respective ions in the membrane, and hydrophobic interactions between the anesthetic cation and the organic membrane. The influence of some inorganic and organic cations, as well as the various substances contained in a tablet or injection solution of the local anesthetic drug, on the electrodes were investigated. The selectivity coefficients determined by a separate solution method[22,23] using 10^{-2} mol dm^{-3} of local anesthetic and interferent solution are summarized in Table 3. None of the investigated species (in Table 3) were found to interfere, as shown by the very small values of the selectivity coefficients, except for atropine, to the PC electrode. It is known that an atropine reacts with TPB^- to form an atropine-TPB ion pair.[24] The low selectivity of the PC electrode toward atropine is attributable to the partial ion-exchange of PC in a PC-TPB ion pair with atropine. The selectivity coefficients of each electrode toward other anesthetic cations was determined (summarized in Table 4). None of the electrodes were interfered with benzocaine. The DC electrode was found to have the most significant selectivity toward other local anesthetics, and the selectivity coefficients decreased in the order TC=BC>MC=LC>PC>benzocaine. The PC electrode has the lowest selectivity toward other local anesthetics. The PC electrode can therefore be used to measure the PC, TC, LC, DC, and BC concentration, as is shown in Fig. 5, even though its response is very slow. The difference in the hydrophobic property of local anesthetic molecules seems to be responsible for the difference in the electrode potential and the selectivity

coefficients among the anesthetics appearing in Fig. 5 and Table 4. The distribution coefficients between 1-octanol and a buffer solution (pH 7.4), which reflect the hydrophobicity of anesthetic molecules, are known to be 1.7 for PC, 221 for TC, 43 for LC, 21 for MC, and 346 for BC.[21] The hydrophobicity of anesthetic molecules was closely related to the binding affinity of anesthetics with protein.[1] The binding affinity increased in the order PC<LC<MC<TC<BC. The larger is the distribution coefficient of the anesthetic, the higher is the electrode potential and selectivity to other anesthetics. As can be seen from Table 4, the high selectivity of the DC electrode toward other anesthetics accurately reflects differences in the distribution constant or ion-exchange ability between anesthetics. The difference in the selectivity of each electrode toward various local anesthetic can therefore be closely related to the hydrophobicity of local anesthetic molecules and the stability of anesthetic–TPB ion pair.

Analytical Application. It was proved by both potentiometric titration and direct potentiometry that PC, TC, and DC electrodes are useful sensors for the potentiometric determination of local anesthetic drugs in either pure forms or in pharmaceutical preparation. The results are shown in Tables 5 and 6. Potentiometric titration, which offers higher precision and accuracy than does a direct method, was applied to determining the purity of DC, PC, and TC reagents. PC, TC, and DC were quantitatively analyzed at a standard relative

deviation (%) less than 0.5% by potentiometric titration using the respective electrode as the sensor, and NaTPB as a titrant (Table 5). The determination of PC in a tablet (sample I) and two aqueous injection solutions (samples II and III)[12] was carried out by potentiometric analysis. The preparation of pharmaceutical solutions and the results of analysis are shown in Table 6. It was found that PC in pharmaceutical drugs can be determined with good precision without the influence of added ingredients.

A Further Modification of the Born Equation

Takehiro ABE
College of General Education, Tohoku University, Kawauchi, Aoba-ku, Sendai 980
(Received May 9, 1991)

By considering the distance-dependent relative permittivity of a solvent, the Born equation has been modified for a diatomic ion in which the charge is located on an atom deviating from the center of a spherical cavity. The new equation has been successfully applied to the diatomic ions of OH^-, SH^-, and CN^-.

The Born equation[1] has long been widely applied in many fields regarding the solvation free energies of ions. The Born equation is written for 1 mol of ions of point charge Ze (where Z is the formal charge and e the charge of proton) located in a spherical cavity embedded in a continuous dielectric medium of solvent as

$$\Delta G_m^\circ = \frac{e^2LZ^2}{2a} \times \left(\frac{1}{\varepsilon_r} - 1\right), \quad (1)$$

where ΔG_m° is the increase in the standard molar Gibbs function due to electrostatic interactions when one transfers the ions from a vacuum to a solution at infinite dilution of the ionic species. Here, L is the Avogadro constant, ε_r the relative permittivity of the solvent, and a the radius of the spherical cavity. In the Born model, the charge is located in the center of the spherical cavity and the local relative permittivity in the immediate neighborhood of the ion is assumed to be equal to the bulk relative permittivity (ε_r) of the solvent. The latter defect was overcome by Abe[2] by considering a distance-dependent relative permittivity of the solvent. In Abe's model, the point charge is still assumed to be located in the center of the spherical cavity, as in the case of the Born equation. This model is certainly valid for a monoatomic ion but is not valid for a polyatomic ion in which the charge located on an atom is not necessarily in the center of the cavity. In the case of a polyatomic ion, such as a diatomic ion, the point charge usually deviates from the center. Recently, Rashin and Namboodiri[3] have presented a general method for calculating the hydration enthalpy for a single charged molecule of arbitrary shape, using the Born equation and the boundary element technique. They obtained excellent results. However, applying the boundary element technique employed to obtain a numerical solution of the Poisson equation is not easy. Recently, Zhou and Stell[4] have obtained analytical equations for the pair correlation functions in the mean spherical approximation for the case of two hard-sphere ions in a model solvent of dipolar dumbbells and an expression for a single ion by letting the number density of the ionic species be infinitesimally small. The expression is similar to an empirical formula used for fitting experimental data to Eq. 1, and is currently not applicable to the present problem. In this paper, therefore, an attempt has been made to derive a simple equation that is easily applicable to a single diatomic ion in which the point charge deviates from the center of the spherical cavity, by considering the distance-dependent relative permittivity of the solvent.

Theory

As shown in Fig. 1, the point charge of Ze is located at position O in a spherical cavity (of radius a) embedded in a continuous dielectric medium of solvent whose bulk relative permittivity is ε_r. Inside the cavity, the relative permittivity is assumed to be equal to that of a vacuum. Let the origin be at position O, which deviates from the center (C) of the cavity by r_0. The z-axis is taken in the direction of line $\overline{CO}$. The distance of an arbitrary point (P) from O is denoted by r. The point at which line of $\overline{OP}$ crosses the cavity surface is denoted by Q. The angle between $\overline{OP}$ and the z-axis is denoted by θ. Then, one can write line $\overline{OQ}$ as

$$\overline{OQ} = \frac{-2r_0\cos\theta \pm \{(2r_0\cos\theta)^2 + 4(a^2 - r_0^2)\}^{1/2}}{2}, \quad (2)$$

since $a^2 = r_0^2 + \overline{OQ}^2 - 2r_0\overline{OQ}\cos(\pi - \theta)$. Here, $\overline{OQ}$ should be positive. From Eq. 2, therefore, one obtains

$$\overline{OQ} = -r_0\cos\theta + (a^2 - r_0^2\sin^2\theta)^{1/2}. \quad (3)$$

The electric field caused by Ze within the cavity is

$$E = \frac{Ze}{r^2}, \quad (4)$$

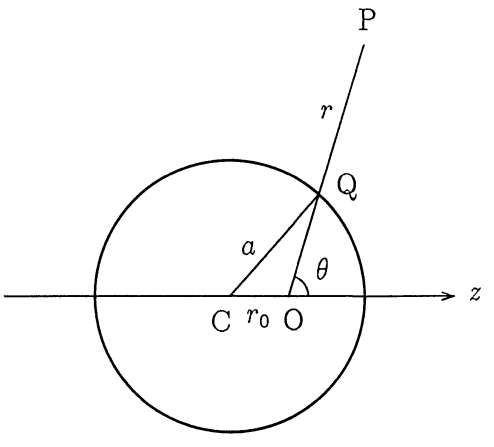

Fig. 1. Model.

while the electric field in the medium is written as

$$E_s=\frac{Ze}{\varepsilon(r)r^2}, \tag{5}$$

where $\varepsilon(r)$ is the distance-dependent relative permittivity. Here, the same formula for $\varepsilon(r)$ as was used in a previous paper[2] is adopted,

$$\varepsilon(r)=e_r\exp(-\kappa/r), \tag{6}$$

where κ is determined under the condition $\varepsilon(r)=1$ for $r=\overline{OQ}$, i.e., $1=\varepsilon_r\exp(-\kappa/\overline{OQ})$ as

$$\kappa=\overline{OQ}\ln\varepsilon_r. \tag{7}$$

When $\varepsilon(r)$ is written as $\varepsilon(r)=\varepsilon_r\exp\{-(\overline{OQ}\ln\varepsilon_r)/r\}$, the potential Φ_i (due to Ze) inside the cavity can be written simply as Ze/r, which is the same expression as in a vacuum. The potential (Φ_o) outside the cavity is $Ze/\varepsilon(r)r$. These potentials obviously satisfy the two boundary conditions of $\Phi_i=\Phi_o$ and $(\partial\Phi_i/\partial r)\cos\theta'=\varepsilon(r)(\partial\Phi_o/\partial r)\cos\theta'$ (for the normal line ($\overline{CQ}$) components, where $\theta'=\angle CQO$) for $r=\overline{OQ}$, since $\varepsilon(r)=1$ for $r=\overline{OQ}$. This simple expression for Φ_i may be due to the fact that the polarization (P) given by $P=\{\varepsilon(r)-1\}\times E_s/4\pi$ is zero for $r=\overline{OQ}$ (i.e. on the cavity surface) in this case.

By following the same procedure that Slater and Frank[5] used to calculate the total energy of an electron using a Poynting vector, the Born equation will be further modified. The infinitesimal area of the cavity surface contained in the solid angle between θ and $(\theta+d\theta)$ is given by $2\pi(a\sin\theta)(ad\theta)$. As in a previous paper,[2] therefore, one can write the solvation free energy of 1 mol of ions with the charge Ze by using a Poynting vector as follows:

$$\Delta G_m^\circ=\frac{L}{8\pi}\int_0^\pi\int_Q^\infty\{\varepsilon(r)E_s^2-E^2\}\times 2\pi(r\sin\theta)(rd\theta)dr$$
$$=\frac{L}{4}\int_0^\pi d\theta\sin\theta\int_Q^\infty\{\varepsilon(r)E_s^2-E^2\}r^2dr. \tag{8}$$

Using Eqs. 4, 5, 6, and 7, one obtains the following integral calculation:

$$\int_Q^\infty\{\varepsilon(r)E_s^2-E^2\}r^2dr=-\frac{Z^2e^2}{\varepsilon_r\kappa}\times\{1-\exp(\kappa/\overline{OQ})\}-\frac{Z^2e^2}{\overline{OQ}}$$
$$=-Z^2e^2\times\left(\frac{1-\varepsilon_r}{\varepsilon_r\ln\varepsilon_r}+1\right)\times\frac{1}{\overline{OQ}}. \tag{9}$$

Using Eqs. 3 and 9, one can rewrite Eq. 8 as follows:

$$\Delta G_m^\circ=-\frac{Z^2Le^2}{4}\times\left(\frac{1-\varepsilon_r}{\varepsilon_r\ln\varepsilon_r}+1\right)\times\int_0^\pi\frac{\sin\theta d\theta}{(a^2-r_0^2\sin^2\theta)^{1/2}-r_0\cos\theta}$$
$$=\frac{Z^2Le^2}{4a}\times\left(\frac{1}{\ln\varepsilon_r}-\frac{1}{\varepsilon_r\ln\varepsilon_r}-1\right)$$
$$\times\left\{\frac{1}{1-(r_0/a)^2}+\frac{1}{2(r_0/a)}\ln\frac{1+(r_0/a)}{1-(r_0/a)}\right\}, \tag{10}$$

where $e^2L/2=69.45$ nm kJ mol^{-1}.

Discussion

When $r_0=0$ is put into Eq. 10, one should obtain the modified equation given in a previous paper.[2] However, some modification of Eq. 10 is necessary for obtaining the ΔG_m° value for $r_0=0$, because it is impossible to put $r_0=0$ directly into Eq. 10. Expanding the terms of $1/\{1-(r_0/a)^2\}$ and $\ln\{1+(r_0/a)\}/\{1-(r_0/a)\}$ in Eq. 10 in series, one finally obtains

$$\Delta=\frac{1}{2}\times\left\{\frac{1}{1-(r_0/a)^2}+\frac{1}{2(r_0/a)}\ln\frac{1+(r_0/a)}{1-(r_0/a)}\right\}$$
$$=1+\frac{1}{2}\sum_{n=1}^{\infty}\left(1+\frac{1}{2n+1}\right)\left(\frac{r_0}{a}\right)^{2n}. \tag{11}$$

This is obviously convergent, since $a>r_0$. Thus, one can write Eq. 10 as

$$\Delta G_m^\circ=\frac{Z^2Le^2}{2a}\times\left(\frac{1}{\ln\varepsilon_r}-\frac{1}{\varepsilon_r\ln\varepsilon_r}-1\right)$$
$$\times\left\{1+\frac{1}{2}\sum_{n=1}^{\infty}\left(1+\frac{1}{2n+1}\right)\left(\frac{r_0}{a}\right)^{2n}\right\}. \tag{12}$$

When $r_0=0$, Eq. 12 is reduced to

$$\Delta G_m^\circ=\frac{Z^2Le^2}{2a}\times\left(\frac{1}{\ln\varepsilon_r}-\frac{1}{\varepsilon_r\ln\varepsilon_r}-1\right). \tag{13}$$

This is a modified equation given in a previous paper.[2] Ehrenson[6] has shown that the solvent parameter of $\{1/\ln\varepsilon_r-1/(\varepsilon_r\ln\varepsilon_r)-1\}$ in Eq 13 is the best in the inverse exponential radial dielectric function family of the modified Born equations for correcting the free energies of solvation. In a comparison of Eq. 12 with Eq. 13, Δ (Eq. 11) is a factor which indicates the degree of deviation of the position of the charge from the center of the spherical cavity for ΔG_m°.

A plot of the Δ values vs. the r_0/a values is given in Fig. 2. This figure shows that the Δ value is approximately unity over the range of r_0/a values smaller than

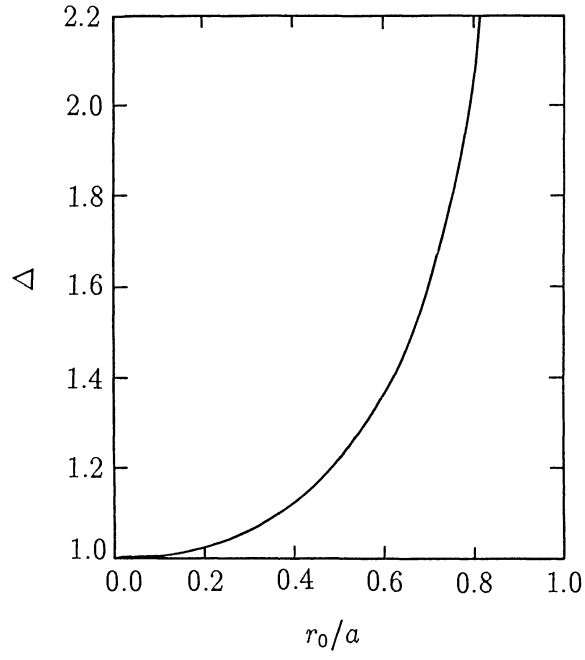

Fig. 2. Plot of Δ vs. r_0/a.

0.2. Therefore, Eq. 13 may be approximately used for an r_0/a value smaller than 0.2. However, Fig. 2 shows that the deviation of the Δ value from unity can not be ignored for r_0/a values larger than ca. 0.25. In this case, therefore, Eq. 10 should be used instead of Eq. 13.

When the constant bulk relative permittivity of ε_r is used instead of $\varepsilon(r)$, one can easily obtain the following expression for ΔG_m° in the same way as in the derivation of Eq. 10:

$$\Delta G_m^\circ = \frac{e^2LZ^2}{2a} \times \left(\frac{1}{\varepsilon_r} - 1\right) \times \Delta. \tag{14}$$

This corresponds to a modified equation of Eq. 1 for the case of a deviation of the charge from the center of the cavity by r_0. In this case, the charges are induced on the cavity surface, since $P=(\varepsilon_r-1)E_s/4\pi \neq 0$ for $r=\overline{OQ}$, where $E_s=Ze/\varepsilon_r r^2$. From the continuity of potentials at Q, the potential inside the cavity may be written as $\Phi_i=Ze/r+(1/\varepsilon_r-1)Ze/\overline{OQ}$. The second term of $(1/\varepsilon_r-1)Ze/\overline{OQ}$ (the reaction field) does not contribute to the electric field ($E=-\partial\Phi_i/\partial r=Ze/r^2$), since the term does not contain r, according to Eq. 3.

On the assumptions that only the electrostatic contribution is dominant and that a does not depend on the temperature, one can easily derive the following equations for the increase of standard molar entropy of solvation of a diatomic ion from Eqs. 1, 13, 14, and 10 according to $\Delta S_m^\circ = -(\partial \Delta G_m^\circ/\partial T)_p$ (where sufffix p denotes the constant pressure and T is the thermodynamic temperature (K)):

$$\Delta S_m^\circ = \frac{e^2LZ^2}{2a} \times \frac{1}{\varepsilon_r^2} \times \frac{d\varepsilon_r}{dT}, \tag{15}$$

$$\Delta S_m^\circ = \frac{e^2LZ^2}{2a} \times \frac{\varepsilon_r - \ln\varepsilon_r - 1}{\varepsilon_r^2(\ln\varepsilon_r)^2} \times \frac{d\varepsilon_r}{dT}, \tag{16}$$

$$\Delta S_m^\circ = \frac{e^2LZ^2}{2a} \times \frac{1}{\varepsilon_r^2} \times \frac{d\varepsilon_r}{dT} \times \Delta, \tag{17}$$

and

$$\Delta S_m^\circ = \frac{e^2LZ^2}{2a} \times \frac{\varepsilon_r - \ln\varepsilon_r - 1}{\varepsilon_r^2(\ln\varepsilon_r)^2} \times \frac{d\varepsilon_r}{dT} \times \Delta, \tag{18}$$

respectively, since the Δ factor is independent of the temperature.

Applications

The present equations have been applied to the hydration of OH^-, SH^-, and CN^-, in order to compare with the experimental ΔG_m° values (298.15 K) for the hydration of these ions reported by Marcus,[7] as shown in Table 1. In these diatomic ions the negative charges are probably located on the atoms of O, S, and N, because the electronegativities of these atoms are larger than those of the corresponding bonding atoms and the negative charge of each ion may be located at one atom according to the adjacent charge rule of Pauling.[8]

In applying Eqs. 1, 10, 13, and 14, the reported data for a (Table 1)[7] and $\varepsilon_r=78.46$ (298.15 K)[7] were used and the r_0 values were approximated by the half values of the bond lengths of these diatomic ions, based on the assumption that the center of the bond length for each diatomic ion is located at the center of the spherical cavity. The values used for the bond lengths of OH^-, SH^-, and CN^- were 0.0970, 0.1336, and 0.11718 nm,[9] respectively. The results of calculations are listed in Table 1. The table clearly shows that the values calculated by both the Born equation (Eq. 1) and its modified equation (Eq. 14) derived by considering the deviation of r_0 are in worse agreement with the experimental values than those calculated by the modified equation (Eq. 13) derived by considering only the distance-dependent relative permittivity of the solvent; it also shows that a further modified equation (Eq. 10) derived by considering both the distance-dependent relative permittivity of a solvent and the deviation of r_0 best reproduces the experimental values among the 4 equations. Thus, Eq. 10 should be used instead of Eq. 13 for an ion in which the charge is located on one atom considerably deviating from the center of the spherical cavity.

Table 1. ΔG_m° Values

Ion	a[a]/nm	ΔG_m°/kJ mol^{-1}				
		Eq. 1	Eq. 13	Eq. 14	Eq. 10	Exp.[a]
OH^-	0.140	−490	−384	−534	−418	−439
SH^-	0.195	−352	−276	−382	−300	−303
CN^-	0.191	−359	−281	−384	−301	−305

a) Ref. 7.

Table 2. ΔS_m° Values

Ion	ΔS_m°/J K^{-1} mol^{-1}				
	Eq. 15	Eq. 16	Eq. 17	Eq. 18	Exp.[a]
OH^-	−29	−111	−32	−121	−161
SH^-	−21	−80	−23	−87	−101
CN^-	−21	−82	−23	−87	−80

a) Ref. 7.

The experimental ΔS_m° values (298.15 K) for the hydration of these ions are reported also by Marcus,[7] as shown in Table 2. In applying Eqs. 15—18, the $d\varepsilon_r/dT$ value[10] of −0.3595 K^{-1} for water was used. The results calculated for ΔS_m° are shown in Table 2. The table shows that Eq. 18 best reproduces the experimental values among the 4 equations.

Syntheses and Spectral Properties of New Nitrosyl-[poly(1-pyrazolyl)borato]ruthenium Complexes†

Masayoshi ONISHI
Department of Industrial Chemistry, Faculty of Engineering,
Nagasaki University, Bunkyo-machi, Nagasaki 852
(Received February 4, 1991)

Trichloro(nitrosyl)ruthenium(III) was treated with alkali-metal or thallium poly(1-pyrazolyl)borates $M(BRPz_3)$ (Pz=1-pyrazolyl) to give new nitrosyl[poly(1-pyrazolyl)borato]ruthenium(III) complexes $[RuCl_2(BRPz_3)(NO)]$ (**1**, R=Pz; **2**, R=H). A similar reaction with thallium tris(3,5-dimethyl-1-pyrazolyl)hydroborate $TlBH(3,5\text{-}Me_2Pz)_3$ (3,5-Me_2Pz=3,5-dimethyl-1-pyrazolyl) afforded the complex $[RuCl_2\{BH(3,5\text{-}Me_2Pz)_3\}(NO)]$ (**3**) as the minor product and the 3,5-dimethylpyrazole complex $[RuCl_3(NO)(3,5\text{-}Me_2PzH)_2]$ as the major one. The observation of ν(NO) bands over the range 1870 to 1900 cm^{-1} determined the NO^+ linear coordination mode in these complexes, rather than NO^- bent one. The ν(NO) values of **1**—**3** were larger than those of the corresponding known π-cyclopentadienyl analogues by ca. 90 cm^{-1}, indicating a smaller degree of π-back donation of metal–NO bonds in the former complexes. ^1H, ^{13}C, and ^{11}B NMR data of the new complexes are described. In ^1H NOE measurements of **1**, irradiation at a chemical shift of 5-H protons in the coordinated pyrazolyl groups induced a positive NOE on the 5-H proton in the uncoordinated group, and individual assignments of the pyrazolyl protons were carried out with the help of ^1H–^1H and ^{13}C–^1H COSY.

The utility of poly(1-pyrazolyl)borato ligands $BH_nPz_{(4-n)}^-$ (Pz=1-pyrazolyl),[1-3] which were first discovered by Trofimenko,[2] has been demonstrated in synthesizing a variety of transition-metal complexes. The ligands, especially in the tripodal coordination mode, have been shown to confer considerable stability on organometallic complexes and novel fluxionality in NMR spectroscopy, and have been compared to π-cyclopentadienyl ligands from the standpoint that both types of ligands are uninegative and can occupy three facial coordination sites on a metal ion. Moreover, it has been generally accepted that substituent introduction on boron and pyrazolyl carbons can significantly change the chemical reactivities, as well as other properties of their transition-metal complexes.[1-3]

In addition to the early studies concerning first-row transition-metal and molybdenum complexes, many papers have been published concerning various second- and third-row complexes in recent years,[1] regarding ruthenium, however, only a handful of poly(1-pyrazolyl)borato complexes are known,[3] in spite of the well-known potentiality of ruthenium for affording highly efficient catalytic species in a variety of homogeneous catalytic reactions. As part of our objectives in developing their catalytic reaction systems, the present author has prepared some new nitrosyl[poly(1-pyrazolyl)borato]ruthenium(III) as catalyst precursors. The dual nature of the nitrosyl ligands as NO^- and NO^+ coordination modes in transition-metal complexes is well-known, and the catalytic potential has been expected, which this duality provides.[4] For some nitrosyl complexes effective as catalysts in such reactions as olefin disproportionation and hydrogenation, their catalytic activities have been assumed to result from a facile redox process between metal and the nitrosyl ligand, which causes favorable stereochemical or structural changes about the metals.[4]

Concerning the NMR assignment of 3- and 5-H protons in the poly(1-pyrazolyl)borato ligands, there have been some arguments about uncertainty.[5] Therefore, ^1H NOE (Nuclear Overhauser Effect) measurements were carried out for the first time in order to prevent any obscurity in the assignment.

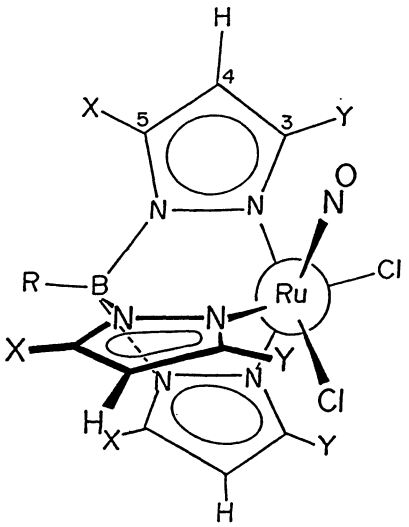

Fig. 1. New (nitrosyl) [poly(1-pyrazolyl)borato]ruthenium complexes.
1, R=1-pyrazolyl, X=Y=H; **2**, R=X=Y=H; **3**, R=H, X=Y=CH_3.

† Following the publication of "Nomenclature of Inorganic Chemistry" by IUPAC, the nitrosyl ligand is considered as being neutral in counting the formal oxidation number of ruthenium for the representation of its complexes in this paper. However, as described later, the nitrosyl ligand in the present new ruthenium(III) complexes was found to be in a NO^+ linear coordination mode, indicating an actual second-valent state of ruthenium.

Results and Discussion

Syntheses of New Ruthenium Complexes. Sodium tetrakis(1-pyrazolyl)borate $NaBPz_4$ was added to an ethanol solution of trichloro(nitrosyl)ruthenium(III). Recrystallization of the resulting precipitates from dichloromethane and benzene gave brown microcrystals of $[RuCl_2(BPz_4)(NO)]$ (**1**) in 26% yield. The microcrystals were soluble in dichloromethane, chloroform, and THF, but were sparingly soluble in benzene, diethyl ether, and ethanol.

In the case of hydrotris(1-pyrazolyl)borate anion $BHPz_3^-$, its potassium salt was treated with the trichloro(nitrosyl)ruthenium in THF to afford a mixture of some reaction products. Only brown microcrystals of $[RuCl_2(BHPz_3)(NO)]$ (**2**) were isolated after silica-gel column chromatographic separation. The yield was only 14%. The use of the thallium(I) salt of this anion increased the yield to 27%.

Thallium tris(3,5-dimethyl-1-pyrazolyl)hydroborate $TlBH(3,5\text{-}Me_2Pz)_3$ (3,5-Me_2Pz=3,5-dimethyl-1-pyrazolyl) gave the complex $[RuCl_2\{BH(3,5\text{-}Me_2Pz)_3\}(NO)]$ (**3**) as the minor product. The major one was found to be a 3,5-dimethylpyrazole complex of $[RuCl_3(NO)(3,5\text{-}Me_2PzH)_2]$ (**4**). Only the latter complex was isolated from a similar reaction of the potassium analogue. These findings indicated that bond cleavage between boron and pyrazolyl-nitrogen atoms in the tris(3,5-dimethyl-1-pyrazolyl)hydroborate anion occurred to a considerable extent in the course of the reaction with trichloro(nitrosyl)ruthenium, affording the boron-free pyrazole complex **4**. Fairly low yields of **1**—**3** were possibly due to the occurrence of the analogous cleavage of the respective poly(1-pyrazolyl)borate anions. King and Bond described similar cleavage of the poly(1-pyrazolyl)borato ligands in reactions with $[Fe(\pi\text{-}C_3H_5)I(CO)_3]$ and $[Co(\pi\text{-}C_5H_5)R_fI(CO)]$ (R_f=perfluoroalkyl).[6] From the analogous reaction of thallium tetrakis(3-*t*-butyl-1-pyrazolyl)borate, no distinguishable products were isolated.

Spectroscopic equivalence of the two 3,5-dimethylpyrazole ligands in **4** was observed in its ^1H and ^{13}C NMR spectra (vide infra, Tables 4 and 5). Figure 2 shows two probable configurations, i.e. *mer*, *trans*-configuration A and *facial*, *cis* one B. For a comparison, the complex $[RuCl_3(NO)(Pz_2CMe_2)]$ (**5**) {Pz_2CMe_2= 2,2-bis(1-pyrazolyl)propane} was prepared, where two neutral pyrazole-subunits form a *cis*-bidentate chelate to ruthenium. In contrast to **4**, this complex was insoluble in common organic solvents, and NMR observation was not possible. Although configuration determination of **4** should be deferred until X-ray analyses elucidate the molecular structure, it is tempting to suggest the *mer*, *trans*-configuration A for **4**. Among the known complexes $[RuCl_3(NO)L_2]$ (L=monodentate neutral ligands),[7] only the *mer*, *trans*-configurations of phosphine, sulfide, and selenide complexes have been determined by means of detailed spectroscopic and single crystal X-ray studies.

Spectroscopic Studies of the New Ruthenium Complexes. As summarized in Table 2, these complexes showed IR ν(NO) bands in the range 1870 to 1900 cm^{-1}. The ν(NO) bands have been reported to be in 2000—1600 and 1725—1525 cm^{-1} for the NO^+ coordination mode with linear metal–N–O bonds and the NO^- mode with bent ones, respectively.[4a,4c,8] The ν(NO) values given in Table 2 determine the NO^+ linear coordination mode in these complexes.

Similarly to the case of ν(CO) bands in metal carbon-

yls, the values ν(NO) have been correlated to the extent to which π-back donation from metals occurs in nitrosyl complexes.[4,8] The complexes $[Ru(\pi\text{-}C_5R_5)Cl_2(NO)]$, i.e. π-cyclopentadienyl analogues to the poly(1-pyrazolyl)boratoruthenium **1**—**3**, have been described to show ν(NO) bands at 1809 and 1790 cm^{-1} for H and CH_3 as R, respectively.[9] The ν(NO) values of the present poly(1-pyrazolyl)borato complexes are larger than those of the π-cyclopentadienyl analogues by ca. 90 cm^{-1}, indicating a smaller degree of π-back donation of metal–NO bonds in **1**—**3**. Similar phenomena were noticed in the series of (carbonyl)ruthenium(II)[3b,3c] (Table 3) and (nitrosyl)molybdenum(III)[10] complexes reported previously.

On the contrary, it has also been described that Bruce's (carbonyl)[poly(1-pyrazolyl)borato]copper(I) complexes[11] show ν(CO) bands at lower wavenumbers than those of their π-cyclopentadienyl analogues, for example, 2083 cm^{-1} for $[Cu(BHPz_3)(CO)]$ vs. 2093 cm^{-1} for $[Cu(\pi\text{-}C_5H_5)(CO)]$,[11a] and considerable stability of the Bruce's carbonyls has been recognized to result primarily from the strong σ-donor character of the poly(1-pyrazolyl)borato ligands. The copper complexes have an essentially sp^3-hybrid four-coordinate structure with a d^{10}-electron configuration, free of unoccupied d-orbitals, whereas the ruthenium complexes have an essentially d^2sp^3-hybrid six-coordinate structure with a d^6-electron configuration.

Accordingly, delocalization of the π-electron system extended to the CO or NO ligand in the ruthenium complexes was expected to occur to a more significant extent than that in the copper complexes, and the π-donor ability of the poly(1-pyrazolyl)borato ligands was revealed to be not as large as that of the π-cyclopentadienyl ligands.[12,13].

Tables 4 and 5 summarize the NMR spectral data of the new complexes observed in $CDCl_3$.[14] Complexes **2** and **3** showed ^{13}C NMR resonances of three pyrazolyl groups,[14] which are classified into two groups in a 2 : 1 ratio. The classification was readily interpretable by

zolyl group, in addition to those of the three coordinated ones.

The ^{1}H NMR spectrum of the BPz_4 complex **1** is shown in Fig. 3-A. Four pyrazolyl groups were classified into three by a 2 : 1 : 1 ratio, similar to the ^{13}C NMR data, with the help of ^{1}H–^{1}H COSY (Correlation Spectroscopy) (Fig. 4) and a ^{1}H–^{1}H selective decoupling technique. Two stereochemically equivalent coordinated pyrazolyl groups (Fig. 1) gave the signal set X at δ=6.45 (2H), 7.87 (2H, overlapping), and 8.00 (2H). The remaining two unique groups were associated with a set Y of the signals at δ=6.33 (1H), 7.87 (1H, overlapping), and 8.28 (1H), and the other set Z at δ=6.68 (1H), 7.95 (1H), and 7.98 (1H).

Signals in the range δ=5.8 to 6.8 were obviously 4-H protons in the respective sets of the pyrazolyl groups. In order to prevent any obscurity in the NMR assignment of the 3- and 5-H protons, NOE measurements of **1** were carried out in this study. No similar work has so far been described concerning known poly(1-pyrazolyl)borato complexes. The NOE difference-spectra (B and C in Fig. 3) were obtained by saturating signals at δ=8.00 and 7.87, respectively. The irradiation at δ=8.00 (set X) accompanied unavoidably some simultaneous partial irradiation of the signal at δ=7.98 (set Z) owing to their close chemical shifts, and did not give any positive NOE signals except for the neighboring 4-H protons attached to the same pyrazolyl rings.[15] On the contrary, irradiation at δ=7.87 in the set(s) of X (and Y)[16] brought about a positive NOE signal at δ=7.95, belonging to the set Z. NOE value is defined as the percent variation of the intensity of a signal when another signal is saturated, and the value obtained at δ=7.95 was +5.4%. This finding clearly revealed the stereochemically close positions of the protons for the signals at δ=7.87 and 7.95. These protons were assigned to 5-H, and the set Z, which includes the signal at δ=7.95, was determined for the uncoordinated pyrazolyl group (Fig. 1).[16] The remaining set Y was attributed to the coordinated but also unique group. The signal at δ=8.00 was associated with the 3-H protons in the set X. Other NMR signals of **1** were assigned readily,[17] and the results are listed in Table 5. The ^{1}H NMR assignment was consistent with the above-described ^{13}C NMR data, as can be seen from ^{13}C–^{1}H COSY in Fig. 5. Thus, the present work demonstrated for the first time the utility of ^{1}H NOE measurements with the help of ^{1}H–^{1}H and ^{13}C–^{1}H COSY, in the assignment of 3- and 5-H protons of the poly(1-pyrazolyl)borato complexes. NMR data of **1** were helpful in analogous assignments of the other complexes, **2**—**4**.

As for the NMR fluxionality of the poly(1-pyrazolyl)borato ligands,[1c,2b,2e] the ^{1}H NMR spectra of **1** and **2** did not show any significant temperature-dependent change from −60 to 55 °C. The lack of fluxionality was in sharp contrast to the case of Trofimenko's complexes of $[Mo(\pi\text{-allyl})(BRPz_3)(CO)_2]$ with temperature-dependent trigonal-twist-rotation around the B–Mo axis.[2b,2e]

Further studies are currently in progress to apply these poly(1-pyrazolyl)boratoruthenium complexes as catalyst precursors to some homogeneous catalytic reactions, and results will be published elsewhere.

Experimental

General Procedures. Alkali-metal poly(1-pyrazolyl)-borates[2a,2c,2f] and 2,2-bis(1-pyrazolyl)propane[18] were prepared according to methods described in the literature. Trichloro-(nitrosyl)ruthenium monohydrate is commercially available or its pentahydrate was obtained by reported methods.[19] Wakogel C-200 was used for silica-gel column chromatography. Preparative operations were performed under nitrogen.

IR spectra were obtained by a JASCO A-100 spectrometer. ^1H, ^{13}C, and ^{11}B NMR spectra were recorded on a JEOL model JNM GX-400 spectrometer operating at 399.7, 100.4, and 128.2 MHz, respectively, by use of tetramethylsilane as an internal standard for the former two nuclei and trimethyl borate as an external standard for the third. The chemical shifts δ are reported in parts per million from these standards, and downfield shifts are noted as positive in all cases. Melting points were determined on a Yanagimoto MP-S3 micro-stage apparatus and are uncorrected.

Conversion of Potassium Poly(1-pyrazolyl)borates to Thallium Analogues. The conversion of the $BHPz_3$ salt has been performed using thallium formate and water as a solvent,[3b] and this procedure was also applicable to the BPz_4 salt. On the other hand, the solubility properties of the $BH(3,5\text{-}Me_2Pz)_3$ and $B(3\text{-}t\text{-}BuPz)_4$ (3-*t*-BuPz=3-*t*-butyl-1-pyrazolyl) salts are slightly different, and it thus seems to be noteworthy to describe their conversion procedures in more detail.[2c,2f]

Potassium tris(3,5-dimethyl-1-pyrazolyl)hydroborate (520 mg, 1.55 mmol), washed well with hexane to remove any free 3,5-dimethylpyrazole impurity, was dissolved in methanol and mixed with thallium formate (390 mg, 1.55 mmol) in methanol. After stirring for 2 h, the solvent was evaporated under reduced pressure, and the dichloromethane extract of the residue was washed with methanol to give white microcrystals of thallium tris(3,5-dimethyl-1-pyrazolyl)hydroborate (410 mg, 0.82 mmol) in 53% yield. Mp 273 °C (melt with sublimation).

The reaction of potassium tetrakis(3-*t*-butyl-1-pyrazolyl)-borate was performed in methanol in a manner similar to that of the $BH(3,5\text{-}Me_2Pz)_3$ salt. At the working-up stage, hexane extract was collected to afford a white powder of thallium tetrakis(3-*t*-butyl-1-pyrazolyl)borate in 56% yield. Mp 174—175 °C.

Reaction of the BPz_4 Anion with $RuCl_3(NO)$. Sodium tetrakis(1-pyrazolyl)borate (150 mg, 0.50 mmol) was added to an ethanol solution (10 ml) of trichloro(nitrosyl)ruthenium (120 mg, 0.50 mmol). After stirring overnight at room temperature, the resulting precipitates were recrystallized from dichloromethane and benzene to give brown microcrystals (63 mg, 0.13 mmol) of $[RuCl_2(BPz_4)(NO)]$ in 26% yield. For further purification, silica-gel column chromatographic separation was effective by elution with dichloromethane. The reaction of the potassium salt showed similar results.

Reaction of the $BHPz_3$ Anion with $RuCl_3(NO)$. Thallium hydrotris(1-pyrazolyl)borate (190 mg, 0.46 mmol) was mixed with trichloro(nitrosyl)ruthenium (104 mg, 0.44 mmol) in THF (20 ml). The mixture was stirred for 4 h. After removing the solvent under reduced pressure, a dichloromethane extract of the residue was chromatographed on a silica-gel column, eluting with dichloromethane to give a brown solid upon evaporation. Recrystallization from THF and diethyl ether afforded brown microcrystals (60 mg, 0.12 mmol) of $[RuCl_2(BHPz_3)(NO)]\cdot THF$ in 27% yield. A similar reaction of the potassium salt gave the same product in 14% yield.

Reaction of the $BH(3,5\text{-}Me_2Pz)_3$ Anion with $RuCl_3(NO)$. Trichloro(nitrosyl)ruthenium (130 mg, 0.55 mmol) in THF (15 ml) was treated with thallium tris(3,5-dimethyl-1-pyrazolyl)-hydroborate (280 mg, 0.56 mmol) and the mixture was stirred for 3 h at ambient temperature. Silica-gel column chromatographic separation was performed for the dichloromethane extract from the reaction mixture. A brown band upon elution with benzene and dichloromethane (1/1) gave green-tinged brown microcrystals (26 mg, 0.050 mmol) of $[RuCl_2\{BH(3,5\text{-}Me_2Pz)_3\}(NO)]\cdot 0.25C_6H_6$ in 9% yield. The dichloromethane eluate of the ensuing reddish-pink band was evaporated, and recrystallization of the residue from THF and hexane afforded reddish-brown microcrystals (39 mg, 0.078 mmol), which were characterized as $[RuCl_3(NO)(3,5\text{-}Me_2PzH)_2]\cdot THF$ (14% yield).

Reaction of 2,2-Bis(1-pyrazolyl)propane. Trichloro(nitrosyl)ruthenium (74 mg, 0.31 mmol) was allowed to react with 2,2-bis(1-pyrazolyl)propane (70 mg, 0.40 mmol) in ethanol (15 ml). The mixture was stirred overnight and the resulting precipitates were collected and washed with diethyl ether. Pale-yellow microcrystals (81 mg, 0.19 mmol) were obtained and assigned to the complex $[RuCl_3(NO)(Pz_2CMe_2)]\cdot 0.5H_2O$ (62% yield).

The present work was partially supported by the Asahi Glass Foundation. Special thanks are due to Professor Katsuma Hiraki, Mr. Yushichiro Ohama, and Mr. Kazuto Ikemoto in this Department for helpful discussions.

12) R. H. Crabtree, "The Organometallic Chemistry of the Transition Metals," John Wiley & Sons, New York (1988), p. 104.

13) The complexes $[RuCl_2(BHPz_3)(NO)]$ and $[RuCl(BHPz_3)(CO)_2]$[3c] in C_6D_6 showed ^{11}B NMR resonances at $\delta=-22.6$ {J(BH)=111 Hz} and $\delta=-22.3$ {J(BH)=113 Hz}, respectively, which were a little higher fields than that of $[Cu(BHPz_3)(CO)]$[11a] at $\delta=-20.3$ {J(BH)=103 Hz]. The present author suggests some negative charge was retained on boron in **1**—**3**, at the expense of the electron delocalization to the nitrosylruthenium moiety, and was associable with the above-mentioned easy cleavage of the poly(1-pyrazolyl)borate anions in the reactions with trichloro(nitrosyl)ruthenium. Alkali-metal salts of poly(alkyl-substituted 1-pyrazolyl)borate, where alkyl substituents increase electron density on boron, were hydrolyzed gradually upon exposure to moist air with release of some alkyl-substituted pyrazoles.

14) For ruthenium and some other transition-metal complexes with tridentate poly(1-pyrazolyl)borates, ^{13}C NMR signals of 3-C were observed usually at lower fields than those of 5-C. A subsequent paper is in preparation concerning a reinvestigation of the ^1H and ^{13}C NMR assignment of known poly(1-pyrazolyl)borato complexes. A similar short description has appeared concerning alkali-metal poly(1-pyrazolyl)borates.[5b]

15) Negative NOE signals were observed for some interrelations between the 3- and 5-H protons on the same pyrazolyl rings.

16) In the case where the uncoordinated pyrazolyl group does not rotate around the axis through the 1-nitrogen atom of the group and the boron atom, two 5-H protons in the coordinated pyrazolyl groups are conceivably located at the close positions to the 5-H proton in the uncoordinated group under consideration (Fig. 1), and are thought to be responsible for the positive NOE signal of the latter proton. However, the present author presumed the other case, in which the uncoordinated pyrazolyl group rotates freely around the axis, since the ^1H NMR spectra of **1** did not show any significant temperature-dependent change from −60 to 55 °C. In this case, all three 5-H protons in the coordinated pyrazolyl groups are responsible on the average, for the positive NOE observed. Similar free rotation of the terminal uncoordinated pyrazolyl group was described for some BPz_4 complexes.[2e]

17) By considering ^{13}C–^1H COSY in Fig. 5, the present author distinguished between 3- and 5-H proton signals in the set Y.

(Received March 11, 1991)

The synthesis and characterization of three copper(II) triphenylacetate–pyridine complexes are reported along with their magnetic and spectral properties: $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**), $[Cu_2(O_2CCPh_3)_4(py)_2]$ (**2**), and $Cu(O_2CCPh_3)_2\cdot 2py$ (**3**). Crystal structure analyses of **1** and **3** have revealed unusual geometries around copper: **1**, triclinic, space group $P\bar{1}$ with a=19.558(7) b=16.605(6), c=14.997(5) Å, α=114.55(2)°, β=97.11(2)°, γ=111.65(2)°, and Z=2; **3**, monoclinic, space group $P2_1/c$ with a=8.931(1), b=12.602(1), c=19.578(1) Å, β=118.17(0.4)°, and Z=2. The coordination sphere around each copper in the dimeric complex **1** is a highly distorted trigonal bipyramid with bridging triphenylacetato ligands spanning the apical and equatorial positions, resulting in a long Cu–Cu distance of 3.086(1) Å. Temperature-dependent magntic susceptibility measurements on **1** indicate that the two coppers are antiferromagnetically coupled with $-2J$=187 cm^{-1}. The structure of the monomeric complex **3** is unusual in that the out-of-plane carboxylate oxygen is twisted 12° from the normal. Two solid modifications are observed for **2**. The magnetic and spectral properties of **2a** ($-2J$=173 cm^{-1}) resemble those of **1**, and **2b** ($-2J$=321 cm^{-1}) those of copper(II) acetate monohydrate. Magneto-structural correlations are presented. The novel structural features of these complexes are suggested to arise from steric effects resulting from the spatial relationships both between and within the molecules in the crystal environment.

The structures of a large number of dimeric copper(II) complexes with the formula $[Cu_2(O_2CR)_4(L)_2]$, where R is an organic group and L is a Lewis base, have been determined.[2–6)] Almost all of these complexes have the classical copper(II) acetate monohydrate-type structure in which the ligand atoms in the coordination sphere around copper(II) are located near the corners of a square pyramid. Recently, some members of two families of these complexes have been observed to have a variation of this structure, in which the arrangement of the ligands around copper(II) can best be described as being distorted trigonal bipyramidal: complexes with bridging triphenylacetato ligands[7–10)] and complexes with bridging trichloroacetato ligands.[10–16)]

In this paper we report on the first complete structural analysis of a complex from the family containing triphenylacetato ligands, [tetrakis(μ-triphenylacetato-*O,O'*)bis(pyridine)dicopper(II)]–benzene(1/1), $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**). In **1**, the coordination geometry around each of the two copper atoms is that of a highly distorted trigonal bipyramid. The factors which cause the unusual geometry around copper(II) in this binuclear complex are attributed to steric effects resulting from the spatial relationships both between and within the molecules in the crystal environment, the former being of prime importance.

Two different solid modifications of the dimeric complex, [tetrakis(μ-triphenylacetato-*O,O'*)bis(pyridine)dicopper(II)], $[Cu_2(O_2CCPh_3)_4(py)_2]$ (**2a** and **2b**), have been prepared and found to exhibit different magnetic and spectral properties. We report on the first study concerning the effect of the ligand arrangement around copper, distorted trigonal bipyramidal and square pyramidal, on the magnetic and spectral properties of these binulear conformers.

The conversion of **1** to *trans*-bis(triphenylacetato-*O,O'*)bis(pyridine)copper(II), $Cu(O_2CCPh_3)_2\cdot 2py$ (**3**), in the crystalline state is discussed. The crystal structure of the monomeric complex **3** reveals a structural modification from the reported structures for complexes of the type $Cu(O_2CR)_2\cdot 2L$, where L represents a nitrogeneous base, resulting from steric effects in which the out-of-plane carboxylate oxygen is twisted 12° from the normal. The so-called "dimer spectral band", which is observed for the complexes **1**, **2a**, and **2b**, is not observed for **3**.

Experimetal

General Procedures. All calculations for copper(II) carboxylates are based on formula weights, unless indicated otherwise. Analyses were performed by Analytische Laboratorien, Elbach, West Germany, with the exception of some copper analyses that were performed in our laboratories by atomic absorption and EDTA titration.

Materials. The starting materials (and sources) are as follows: triphenylacetic acid, benzene-d_6, ethanol-*d* (Aldrich Chemical Co.); copper(II) acetate monohydrate, pyridine (Fisher Scientific Co.).

Preparation of the Complexes. (a) $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (1) Crystals. A Büchner funnel with a fritted disk (30 mL-30 M) was placed in a beaker (100 mL). A melting-point tube open at both ends was bent and then inserted so that the air pocket which formed under the filter could be minimized. Into the beaker was added a solution of absolute ethanol–pyridine (50 : 1 v/v). $Cu(O_2CCPh_3)_2\cdot 2H_2O$ (0.3 g, 0.4 mmol), prepared by the method of Steward et al.,[17] was dissolved in hot benzene (25 mL) and poured into the Büchner funnel. The solution developed the characteristic green color of $Cu(O_2CCPh_3)_2\cdot py$ at this time. The height of the outer solution was then adjusted to ca. 1 cm above the level of the inner solution. The entire apparatus was placed in a desiccator. After four days, blue-green crystals of **1** had formed on the fritted disk in the filter. Anal. Calcd for $C_{48}H_{38}O_4CuN$: C, 76.22; H, 5.06; Cu, 8.40; N, 1.85%. Found: C, 76.15; H, 5.00; Cu, 8.45; N, 1.88%.

(b) $Cu(O_2CCPh_3)_2\cdot py$ (2a): Procedure 1. $Cu(O_2CCPh_3)_2\cdot 2H_2O$ (1.29 g, 1.91 mmol) was dissolved in benzene (150 mL). Warming on the steam bath reduces the time required for the complex to dissolve. Pyridine (0.59 g, 7.46 mmol) was added, resulting in a color change from blue to green. After filtering, the complex was precipitated by adding petroleum ether, bp 30—60 °C (700 mL). The light-green precipitate was collected in a Büchner funnel with a fritted disk (reduced-pressure filtration). The precipitate was washed with a benzene–petroleum ether mixture (1 : 9 v/v, 100 mL) and allowed to dry in air for several days, yielding 1.16 g, 1.62 mmol, (84.8% yield) of **2a**. Anal. Calcd for $C_{45}H_{35}O_4CuN$: C, 75.35; H, 4.92; Cu, 8.86; N, 1.95%. Found: C, 75.46; H, 5.00; Cu, 8.94 (EDTA titration), 8.52 (atomic absorption); N, 1.86%.[18]

Procedure 2. A mixture of $Cu(O_2CCPh_3)_2\cdot 2H_2O$ (0.67 g, 1.0 mmol) and pyridine (87 mg, 1.1 mmol) in chloroform (60 mL) was stirred on a hot plate for 0.5 h. The chloroform solution was then filtered, and the filtrate was concentrated to one-third of its volume. After standing overnight at ca. 5 °C, the concentrated solution afforded yellow-green crystals of **2a**. The crystals were washed with petroleum ether and dried in vacuo. Anal. Calcd for $C_{45}H_{35}O_4CuN$: C, 75.35; H, 4.92; Cu, 8.86; N, 1.95%. Found: C, 75.15; H, 4.65; Cu, 8.59; N, 2.12%.

(c) $Cu(O_2CCPh_3)_2\cdot py$ (2b). A mixture of $Cu(O_2CCPh_3)_2\cdot 2H_2O$ (0.67 g, 1.0 mmol) and pyridine (0.12 g, 1.5 mmol) in ethanol (50 mL) was heated with stirring on a hot plate for ca. 2 h. The resulting yellow-green precipitate was collected, washed repeatedly with ethanol and dried in vacuo. Anal. Calcd for $C_{45}H_{35}O_4CuN$: C, 75.35; H, 4.92; Cu, 8.86; N, 1.95%. Found: C, 74.62; H, 4.92; Cu, 9.11; N, 1.84%.

(d) $Cu(O_2CCPh_3)_2\cdot 2py$ (3), Crystals. Crystals of **1** were placed in a screw-capped vial containing an absolute ethanol–pyridine (50 : 1 v/v) solution. After one day, mixed crystals containing both blue-green and dark blue areas had formed. After three days, the blue-green crystals had been completely transformed into dark-blue crystals of **3**. Anal. Calcd for $C_{50}H_{40}O_4CuN_2$: C, 75.42; H, 5.06; Cu, 7.97; N, 3.51%. Found: C, 75.28; H, 4.99; Cu, 8.08; N, 3.50%.

Preparation of Triphenylacetic Acid-*d*. A small amount of triphenylacetic acid was dissolved with warming in ethanol-*d* (99.5+ atom % D). The solvent was removed by evaporation under a stream of dry nitrogen. The resulting solid was dried in a desiccator under reduced pressure.

X-Ray Procedure. (a) Collection and Reduction of the Data. The crystal of **1** selected was mounted on a glass fiber and coated with an epoxy resin. A crystal of **3** having the dimensions 0.15×0.19×0.32 mm was similarly mounted. Refined cell constants were obtained by a least-squares fit to the observed 2θ angles of 110 high-angle reflections. Data concerning the crystals are given in Table 1. The intensity data were collected using a Picker FACS-1 four-circle diffractometer to a 2θ limit of 90° for **1** and 125° for **3** using graphite-monochromated Cu $K\alpha$ radiation; a $\theta : 2\theta$ scanning technique over the range 2.5° for **1** and 2.2° for **3**; a scan rate of 1° min^{-1} was used. The background was counted for 20 s at each end of the scan range. For **1**, three standard reflections were monitored after each 100 reflections; their intensities decreased by ca. 9%. For **3**, three standard reflections were monitored after each 50 reflections; their intensities showed no fluctuations greater than ±2%. The intensities for **1** were scaled and assigned variances, $\sigma^2(I)$, according to the statistics of the scan and background counts plus the correctional term, $(0.03\ S)^2$, S being the scan count. The intensities and their variance were corrected for both Lorentz and polarization factors. For **3**, corrections were made for both absorbance and secondary extinction.[19]

Table 1. Crystallographic Data for $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (1) and $Cu(O_2CCPh_3)_2\cdot 2py$ (3)

Solution and Refinement of the Structures. (a) $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (1). The triclinic unit cell was first determined from Weissenberg photographs and the $P\bar{1}$ space group was confirmed by the subsequent structure solution and refinement. The phase problem was solved by direct methods using the MULTAN program.[20] Two copper and 34 non-hydrogen atoms were located from the most probable E map. The corresponding Cu–Cu vectors were confirmed on an E^2-1 Patterson synthesis. After two difference Fourier syntheses, 102 atoms had been located. The 102 atom model, assumed to be complete, was subjected to full-matrix least-squares refinement using a program called QWKREF.[21] On the difference Fourier map, the benzene of solvation was revealed. Two more difference Fourier syntheses revealed all 71 hydrogen atoms bonded to the molecule. The hydrogen positions for the solvent ring were generated by a program called GENATM.[22] The atomic positional parameters and iso-

tropic thermal parameters for hydrogen (3.7 Å) were included in the structure factor calculations, but were not refined. Four more cycles of refinement with anisotropic thermal parameters for all of the nonhydrogen atoms converged to R=0.045. The atomic scattering factors (Cu, C,·N, and O) and the anomalous dispersion corrections (Cu and O) were taken from Ref. 23a. The scattering factors for hydrogen were taken from Stewart et al.[23b] The observed and calculated structure factors are included in the supplementary material.[24]

(b) $Cu(O_2CCPh_3)_2 \cdot 2py$ (3). The structure was solved by the multi-solution tangent-refinement method.[20] The best E map with 350 reflections (E>1.45) and 5000 phase relationships gave all of the nonhydrogen atom positions. The copper atom was located and the position confirmed by an origin removed Patterson synthesis. The positional parameters and isotropic thermal parameters of the nonhydrogen atoms were refined by several cycles of full-matrix least-squares using QWKREF program,[21] yielding R=0.115. After conversion to anisotropic thermal paramters, several further cycles reduced R to 0.069. At this point, the hydrogen atoms were located and included in the refinement. After changing the weighting scheme from counting statistics to a scheme based on an analysis of the variance,[25] the extinction correction was applied. Further refinement with the new weights converged to R=0.030. The atomic-scattering factors and anomalous-dispersion corrections employed are the same as those described in part (a). The observed and calculated structure factors are included in the supplementary material.[24]

Physical Measurements. IR spectra were recorded on a Perkin-Elmer 1430 ratio recording spectrophotometer, polystyrene standard. Reflectance spectra were obtained on a Hitachi recording spectrophotometer (323). ESR spectra were obtained from polycrystalline samples in quartz tubes, DPPH standard, as described previously,[17] except for samples of **2a**[26] and **2b**.[27]

Magnetic moments were determined in solution by the Evans method, as described previously.[17] Magnetic susceptibilities over the temperature range of 80 to 300 K were determined by the Faraday method. Corrections for the diamagnetic contributions were made using Pascal's constants.[28] The cryomagnetic data of complexes **1**, **2a**, and **2b** were fitted to the Bleaney-Bowers equation allowing for the presence of paramagnetic impurities,[29]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\left(\frac{1}{3}\right)\exp\left(\frac{-2J}{kT}\right)\right]^{-1}(1-P)+\frac{Ng_i^2\beta^2}{4kT}P+N\alpha, \quad (1)$$

where P is the mole fraction of the noncoupled copper(II) impurity and g_i is the average g factor for the impurity. The values of g_i=2.2 and $N\alpha$=60×10^{-6} emu (1 cgs emu=4π×10^{-6} m^3) were used throughout this study. The other symbols have their usual meanings. The best-fit parameters (−2J, g, and P) were obtained by using a nonlinear least-squares program[30] on a FACOM M-200 computer at the Nagoya University Computation Center. As a convenient statistical indicator of the quality of the least-squares fit, the discrepancy index, σ_{dis}, was employed,

$$\sigma_{dis} = \left[\frac{\sum(\chi_{obsd}-\chi_{calcd})^2}{\sum\chi_{obsd}^2}\right]^{1/2}. \quad (2)$$

The Curie law was employed to correlate the cryomagnetic data for **3** assuming no monomeric impurities and $N\alpha$= 60×10^{-6} emu.

Results and Discussion

Structures. Single-crystal X-ray structures have been determined for $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**), Figs. 1a and 1b, and $Cu(O_2CCPh_3)_2\cdot 2py$ (**3**), Fig. 2. The atomic positional and isotropic thermal parameters for all atoms, except hydrogen, in the complexes are

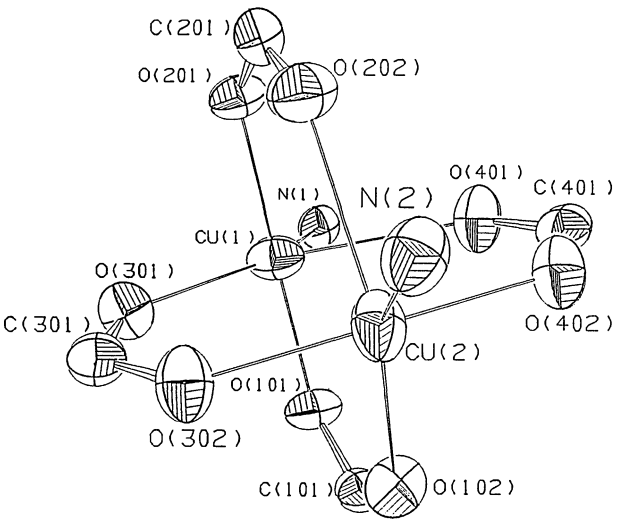

Fig. 1a. View of the cage structure of $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**). N(1) and N(2) are in py(P11) and py(P21) respectively. Thermal ellipsoids are drawn to the 50% probability level.

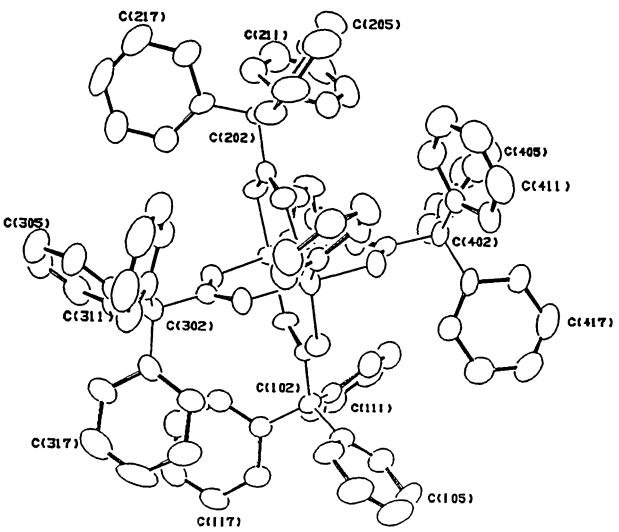

Fig. 1b. View of the structure of $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**). The orientation of the cage is the same as that shown in Figure 1a. For clarity, only a few atoms in the triphenylmethyl groups have been numbered, and the hydrogen atoms and the benzene of crystallization are omitted. Thermal ellipsoids are drawn to the 50% probability level.

listed in Tables 2 and 3; listings of the positional parameters for the hydrogen atoms are included in the supplementary material (Tables 1S and 7S). Selected bond distances and bond angles are given in Tables 4 and 5; complete tables are included in the supplementary material (Tables 3S and 9S).

The structure of **1** contains two crystallographically independent copper atoms and is novel in that the five atoms in the coordination sphere around copper(II) are arranged near neither the corners of a square pyramid nor the corners of a trigonal bipyramid. Each copper atom is coplanar with two oxygen atoms and a nitrogen

a) B_{eq} equals one-third of the trace of the orthogonalized B_{ij} matrix.

atom: Cu(1), O(301), O(401), N(1) and Cu(2), O(102), O(202), N(2).[31] The O–Cu–X angles, where X is N or O, between coplanar atoms for Cu(1) and Cu(2) are 82°, 136°, 142° and 84°, 136°, 139° respectively. There are six O–Cu–X angles for each copper in the range 88—92° and one large O–Cu–O angle between 178—179°. The Cu–O bond distances for each copper vary over a considerable range, Cu(1) 1.90—2.46 Å and Cu(2) 1.88—2.35 Å.[32] The out-of-plane Cu–O bonds are very short, Cu(1) 1.90—1.91 Å and Cu(2) 1.88—1.90 Å respectively. One in-plane Cu–O bond to each copper is unusually long, 2.46 and 2.35 Å for Cu(1) and Cu(2) respectively. These Cu–O bonds are the longest that have been observed for a bridging carboxylato ligand in a dimeric copper(II) complex.[5] The Cu–N bonds are somewhat shorter than those previously observed for apical ligands in dimeric copper(II) carboxylates.

In **1**, where the ligands bonded to copper(II) do not assume a configuration which coincides with or is closely related to one of the usual five-coordinate geometries, square pyramidal or trigonal bipyramidal, one cannot readily decide by inspection whether to describe the arrangement of the ligands as distorted square pyramidal or distorted trigonal bipyramidal. Zemann[33] has described a test which allows one to make a rational choice between these two alternatives by considering the sum of the deviations of the angles between the ligands and the central metal atom in the complex from the angles in the idealized structures. Based on this test, the arrangement of the ligands in **1** is best described as distorted trigonal bipyramidal.

The cage structure of **1** is very unusual as a result of the ligand arrangement around each copper(II). The structure of the cage is depicted in Fig. 1a. The two distorted trigonal bipyramids formed by the ligands around each copper(II) are linked through the four bridging carboxylato ligands, spanning the apical and equatorial positions, to form a cage in which the dihedral angle between the equatorial planes is 88.8°. There are two adjacent short and long bridge distances in the cage: 6.48, 6.49, 6.78, and 6.86 Å. While the two short bridge distances are in the range reported for the complexes with copper(II) acetate monohydrate-type structures,[3,4] the distances of the other two bridges are the longest observed to date. The long bridge distances are primarily the result of the long Cu–O bonds, one to each copper(II). A considerable variation in the Cu–O–C angles is observed, 116—140°, with the two largest angles encompassing the long Cu–O bonds. However, there is no corresponding opening of the O–C–O angle; the mean value is 125°. As a result of the two long bridge distances, the Cu–Cu distance (3.086 Å) across the cage is much longer than that encountered in complexes where the four carboxylate bridges are of approximately the same length.[5]

The spatial relationships between the two pyridine rings which lie within the molecule, py(P11) and py(P21), and the corresponding two pyridine rings in

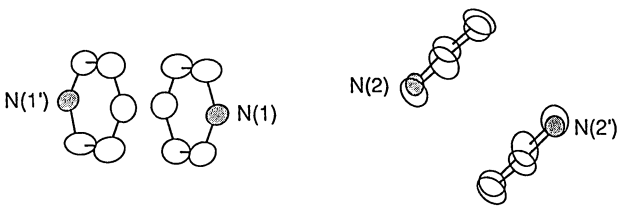

Fig. 3. View of the two intramolecular pyridine rings, py(P11) and py(P21), and the adjacent intermolecular pyridine rings, py(P11′) and py(P21′), along the *a* crystal axis of $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**). N(1), (N1′), N(2), and N(2′) are in py(P11), py(P11′), py(P21), and py(P21′) respectively.

adjacent molecules, py(P11′) and py(P21′), along the *a* crystal axis, are shown in Fig. 3. The two intramolecular pyridine rings are tilted with respect to the Cu–Cu axes [Cu(2)–Cu(1)–N(1), 144.5°; Cu(1)–Cu(2)–N(2), 146.3°] toward the long Cu–O bonds, and the dihedral angles between the planes of the pyridine rings and the planes of the long bridging carboxyl groups are: py(P11)–carboxyl[O(401)C(401)O(402)], 81° and py(P21)–carboxyl[O(202)C(201)O(201)], 72°. The dihedral angle between the pyridine rings is 49.1°. The pyridine rings on adjacent molecules abut these rings resulting in parallel alignments (required by symmetry), as shown in Fig. 3. The intermolecular distances between the least-squares planes of the two intramolecular pyridine rings and the atoms of the adjacent rings are given in Table 6.

The conformations of the triphenylacetato ligands are of interest since intergroup repulsions could, in part, account for the unusual geometry around copper(II). The C–CO_2^- bond lengths (mean of 1.570 Å) are unusually long for an sp^3–sp^2 C–C bond. The triphenylmethyl groups C(101)–C(120) and C(301)–C(320) have left-

handed twist propeller conformations while the twists for the groups C(201)–C(220) and C(401)–C(420) are right-handed. Jeffery et al.[34] has reported the simultaneous occurrence of two conformations in one molecule in bis(triphenylmethyl) sulfide. The angles between the phenyl rings exhibit a better threefold symmetry in the left-handed conformations than in the right-handed ones. All of the phenyl rings are coplanar with a maximum deviation of 0.142 Å. The torsion angles for defining these groups are given in Table 5S. The intramolecular distances between the ligands in **1** of < 3.7 Å are listed in Table 6S.

The benzene of crystallization is held in the crystal structure by van der Waals interactions and is lost when the crystal is allowed to stand in an open container. The ring shows considerable thermal motion.

The structure of the complex, $[Cu_2(O_2CCPh_3)_4(py)_2]$, can vary, depending on the method of preparation (see Experimental Section). The crystal structures of the two forms of $[Cu_2(O_2CCPh_3)_4(py)_2]$ (**2a**, **2b**) have not been determined; however, some conclusions concerning their molecular structures can be formulated based on their magnetic and spectral properties, vide infra. The molecular structures of **2a** and **1** must be closely related since both complexes give similar magnetic and spectral data; therefore, **2a** is assigned a distorted trigonal bipyramidal structure similar to that of **1**. The method of preparation of **2a** (Procedure 1 or 2) may result in small structural differences. The molecular structure of **2b** is more closely akin to the classical copper(II) acetate monohydrate-type structure. The magnetic and spectral data observed for **2b** are in agreement with this assignment.

The structure of $Cu(O_2CCPh_3)_2\cdot 2py$ (**3**), Fig. 2, is a variation of the *trans*-bis(acetato-*O,O′*)diamminecopper(II) type.[35] In this structure, the two triphenylacetato and two pyridine ligands are bonded to copper(II); the copper(II) lies at a center of symmetry. The coordination plane around copper(II) consists of two triphenylacetate oxygen atoms, O(1) and O′(1) and two nitrogen atoms N and N′ in a nearly square planar arrangement. The second carboxyl oxygens, O(2) and O(2′), are weakly bonded to copper(II) above and below the plane: the weak Cu–O bond distance is 2.673 Å, the O(1)–Cu–O(2) angle is 54.1°, and the N–Cu–O(2) angle is 81.0°. The dihedral angle between the coordination plane around copper(II) and the plane of the carboxyl group is 78.0°. The coordination geometry around copper(II) is best described as distorted octahedral.

In the triphenylacetato ligands, the carboxyl O(1)–C(1)–O(2) angle is 123.2°. The C–O bond lengths are significantly different: C(1)–O(1), 1.284 Å and C(1)–O(2), 1.220 Å, which suggests that the shorter C–O bond has considerably more double-bond character. The dihedral angle between the plane of the pyridine ring and carboxyl group is 80.6°. As in **1**, the $C-CO_2^-$ bond length (1.570 Å) is unusually long for an sp^3–sp^2 C–C bond. The triphenylmethyl group has a non-propeller conformation and a pseudo bisector plane passing through the atoms, C(1), C(2), C(15), and C(18).

The molecules of **3** are packed only by van der Waals forces. A stereoscopic ORTEP packing diagram is included in the supplementary material (Fig. 1S) along with the following tables: least-squared planes (Table 10S), torsion angles (Table 11S), and intramolecular nonbonded distances <3.26 Å (Table 12S).

Magnetic Susceptibility. The magnetic susceptibility data of the dimeric complexes **1**, **2a**, and **2b** were correlated using Eq. 1 (see Fig. 4). The best-fit parame-

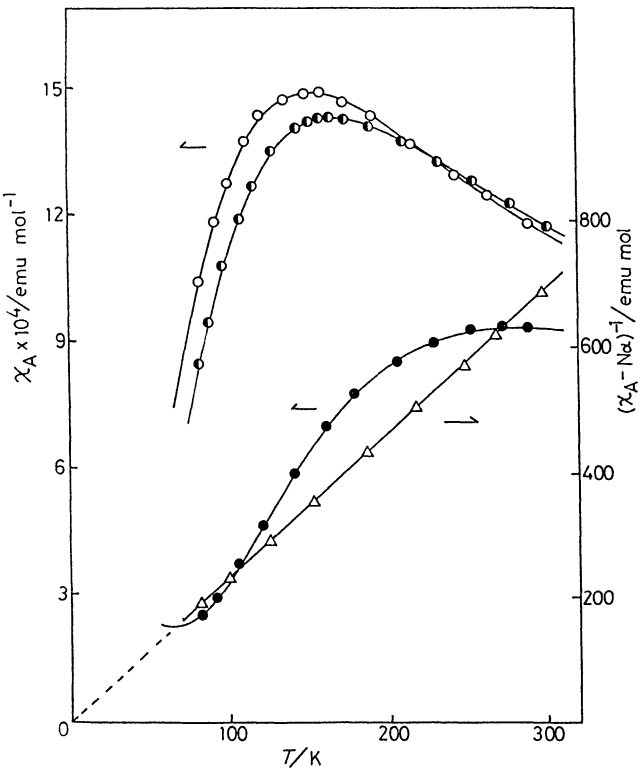

Fig. 4. Variation of the magnetic susceptibilities of the complexes with temperature: $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**) (◐); $[Cu_2(O_2CCPh_3)_4(py)_2]$ (**2a**) (○), (**2b**) (●); $Cu(O_2CCPh_3)_2\cdot 2py$ (**3**) (△).

ters are given in Table 7 along with the discrepancy index (Eq. 2). The $-2J$ values of complexes **1** and **2a** are considerably smaller than the values reported for a large number of copper(II) carboxylates with a square pyramidal metal geometry, ca. 300 cm^{-1}.[5] The anomalously small $-2J$ values observed for these dimeric complexes are undoubtedly related to the novel geometry around copper, distorted trigonal bipyramidal. The small singlet-triplet separation in these complexes may be interpreted in terms of their unusual cage structure. In a bridged structure similar to that observed for **1**, in which each copper has a distorted trigonal bipyramidal metal geometry, the two ends of a Cu–O–C–O–Cu exchange pathway would connect with different metal d orbitals: one end with the $d_{x^2-y^2}$, d_{xy} orbitals having paired electrons and the other with the d_{z^2} orbital having an unpaired electron.[36]. The copper(II) carboxylates with a square pyramidal metal geometry are known to have $-2J$ values of ca. 300 cm^{-1}, as observed for copper(II) acetate monohydrate, while theoretically, those with a regular trigonal bipyramidal metal geometry should have $-2J$ values close to zero (ferromagnetic). Thus, complexes **1** and **2a**, which have intermediate $-2J$ values, are expected to have a metal geometry in between a regular square pyramidal and a regular trigonal bipyramidal arrangement. The $-2J$ value determined for **2b** is consistent with a structure for this complex, which is closely related to the classical copper(II) acetate monohydrate type.

The magnetic behavior of **3** is consistent with the monomeric structure determined in the present study (see Figs. 2 and 4, Table 7).

Electron Spin Resonance. The X-band ESR spectra of polycrystalline samples of the $Cu(O_2CCPh_3)_2 \cdot n$py complexes have been recorded. The ESR data for these complexes at ambient temperature are given in Table 8.

3[f]	2.28	2.06	2.14	

a) Ambient temperature. b) H_{dq}=2777 G and H_m=3150 G at 9.06 GHz. c) Prepared by Procedure 1. d) H_{dq}=2910 G at 9.34 GHz. e) H_m=3300 G at 9.46 GHz; $A_{\parallel}$=0.0070 cm^{-1}. f) $A_{\parallel}$=0.0175 cm^{-1}.

The X-band ESR spectrum of **1** is different from the spectra reported for dimeric copper(II) carboxylates in which the metal geometry is square pyramidal. The difference arises as a result of the small zero-field splitting, D, in **1** which is less than the microwave energy ($h\nu$); whereas, $D>h\nu$ for dimeric copper(II) carboxylates with approximately square pyramidal geometry. The ESR spectrum of **1** at ambient temperature (9.05 GHz) is shown in Fig. 5. The spectrum consists of two $H_{\parallel}$ lines (927, 4790 G) and two $H_{\perp}$ lines (1780, 4050 G) as well as a line resulting from a double quantum transition (2780 G) and a weak line from a monomeric impurity (3150 G). The number and positions of the lines are consistent with theoretical calculations for randomly oriented molecules in the triplet state.[37] The isotropic double quantum absorption is observed when $1/2\ h\nu<D<h\nu$.[38] The ESR spectrum of **1** at 133 K is essentially the same as at ambient temperature, except for the relative intensities of the monomer and dimer lines. Since our initial report,[8] two other copper(II) carboxylates have been observed to have similar ESR spectra.[10,13]

The small zero-field splitting parameter (D) undoubtedly is the result of the novel geometry of **1**. This parameter consists of a dipolar term (D_{dip}) which is a function of the Cu–Cu distance, and a pseudo-dipolar term (D_{ex}) which results from an exchange coupling via the orbitals of the cage.[38,39] For **1**, the smaller D parameter can be related to the geometry of the cage in which the long Cu–Cu distance and the two very long bridging distances are contributing factors.

The ESR spectrum of **2a** at ambient temperature is similar to the spectrum of **1** with nearly identical ESR parameters. The spectral similarity between **1** and **2a** suggests that removing the benzene of crystallization from **1** has little effect on the dimer structure. These

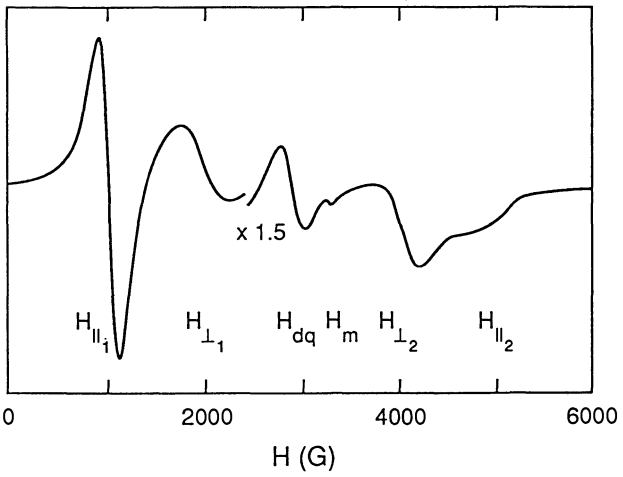

Fig. 5. The ESR spectrum (X-band, 9.05 GHz) of polycrystalline $[Cu_2(O_2CCPh_3)_4(py)_2] \cdot C_6H_6$ (**1**) at ambient temperature.

data suggest that the crystal structures of **1** and **2a** are similar, except for the benzene of crystallization.

The ESR spectrum of **2b** at 130 K shows three absorption lines which are typical of a dimeric copper(II) carboxylate when $D>h\nu$[3,4] and a line attributed to a monomer impurity. The hyperfine splitting of the low-field absorption line yields a seven-line pattern. The spectrum at ambient temperature is essentially the same, except that the hyperfine structure is not as well resolved. These data, along with the magnetic susceptibility data, suggest that the structure of **2b** is more closely aligned with the copper(II) acetate monohydrate-type structure than **1** and **2a**.

The ESR spectra of **3** at 133 K and ambient temperatures are quite typical of a monomeric copper(II) complex with a distorted octahedral geometry, showing two spectral lines resulting from the parallel and perpendicular alignments of the complex with the field;[40] the hyperfine coupling splits the low-field absorption, yielding a four-line pattern, of which only three are resolved.

Electronic Spectra. The reflectance spectra of the four copper(II) triphenylacetate-pyridine complexes are shown in Fig. 6, and the spectral data are reported in Table 9.

The most striking difference in the spectral features of the three dimeric complexes (**1**, **2a**, and **2b**) is the separation of the two peaks in the d–d band region. The peak separations in **1** and **2a**, which have a distorted trigonal bipyramidal metal geometry, are about 2000 cm^{-1}, while this separation in **2b** is 5000 cm^{-1}, a value observed for copper(II) carboxylates with the common square pyramidal geometry.[10,13] Thus, the electronic spectral data augments the proposal that complex **2b** has a structure which is closely aligned with the classical copper(II) acetate monohydrate type.

Another salient feature of the electronic spectra of the dimeric complexes **1**, **2a**, and **2b** is that the d–d band energies are about the same, **1** and **2a** having only slightly higher band energies, in spite of the structural differences. This same type of behavior has been reported for the copper(II) trichloroacetate adducts.[10–13] The d–d band energy of copper(II) complexes with trigonal bipyramidal metal geometry is reported to be lower than the band energy of the corresponding complexes with square pyramidal metal geometry.[36] The anomalously high d–d band energy observed for complexes **1** and **2a** may be ascribed to the short Cu–O bonds in the axial coordination sites which raise the energy of the d_{z^2} orbital.

The d–d band of **3**, ca. 17×10^3 cm^{-1}, occurs at higher energy than that observed for **1**, **2a**, and **2b** (ca. 13×10^3 cm^{-1}), indicating that the ligand field in complex **3** is stronger than in the latter complexes. This shift to higher energy of the d–d band of **3** undoubtedly reflects the difference in the number of coordinating atoms and the metal geometry, distorted octahedral.[41]

The so-called "dimer band" is observed as a shoulder in the near-ultraviolet region for complexes **1**, **2a**, and **2b**. This band has been reported for a large number of dimeric copper(II) carboxylates and other dimeric copper(II) systems.[42–44] The spectrum of the monomeric complex **3** does not show an absorption band in this region.

Infrared Spectra. The carbon–oxygen stretching frequencies of the copper(II) triphenylacetate–pyridine complexes are given in Table 10. The splitting of the RCO_2^- stretching frequencies, $\Delta\bar{\nu}=\bar{\nu}_{asym}-\bar{\nu}_{sym}$, is related to the symmetry of the carboxylato group: the greater the deviation from C_{2v} symmetry, the larger the $\Delta\bar{\nu}$

values.[45–47] The order observed for $\Delta\bar{\nu}$ for the copper(II) triphenylacetate-pyridine complexes is **3**>**1**, **2a**>**2b**. This is the order expected from symmetry considerations for the carboxylato ligands in these complexes based on the structural, magnetic, and spectral properties given above. The C–O bond distance data (Tables 4 and 5) for complexes **1** and **3** show that there is a greater difference in the C–O bond lengths in the carboxylato ligands in **3** than in **1**. In complex **2b**, which is proposed to have a structure more closely aligned with the copper(II) acetate monohydrate type than **1**, the bridging carboxylato groups are expected to be more symmetrical than in **1**, where there is a considerable variation in the C–O bond lengths in each bridging group.

Discussion of Structures. The first reports of dimeric copper(II) carboxylates with a distorted trigonal bipyramidal geometry around copper are for $[Cu_2(O_2CCPh_3)_4(py)_2]\cdot C_6H_6$ (**1**)[7,8] and $[Cu_2(O_2CCCl_3)_4(L)_2]$, where L=tempo and proxyl.[11,12] The main structural differences between **1** and the above-mentioned trichloroacetate complexes are: in **1**, the carboxylato bridging distances are longer and the equatorial angles show larger deviations from the ideal trigonal bipyramidal geometry. Thus, in **1**, there is considerably more distortion of the geometry around copper. Recently, preliminary reports of additional dimeric complexes with distorted trigonal bipyramidal metal geometry have appeared: $[Cu_2(O_2CCPh_3)_4(\gamma\text{-picoline})_2]\cdot$2toluene,[9] $[Cu_2(O_2CCPh_3)_4(\gamma\text{-picoline})_2]\cdot$2benzene,[9] $[Cu_2(O_2CCCl_3)_4(caffeine)_2]$,[14,16] $[Cu_2(O_2CCCl_3)_4(2,5\text{-}Cl_2\text{-py})_2]\cdot$benzene,[16] $[Cu_2(O_2CCCl_3)_4(3,5\text{-}Cl_2\text{-py})_2]\cdot$toluene.[16]

The structural transformation of **1** from the usual square pyramidal arrangement of ligands around copper(II), as observed in the classical copper(II) acetate-type structure, to a distorted trigonal bipyramidal arrangement, can best be explained in terms of steric effects in the crystal environment which can arise from both inter- and intramolecular forces. The crystal-structure data for **1** suggest that crystal-packing forces play an important role in this transformation. Along the *a* crystal axis, the pyridine rings at the opposite ends of the molecule form a dihedral angle of 49.1°. The pyridine rings on adjacent molecules abut these rings resulting in a parallel alignment (cf. Fig. 3 and Table 6). The intermolecular distances between the pyridine rings and the atoms of the adjacent rings are ca. 3.41 Å for py(P11)–py(P11′) and 3.47 Å for py(P21)–py(P21′) respectively. These distances approach the value reported by Pauling[48] for the effective thickness of an aromatic ring, 3.4 Å. Cu(1) which shows the largest distortion from a square pyramidal structure, N(1)–Cu(1)–O(401), 82.0°; Cu(2)–Cu(1)–N(1), 144.50°; Cu(1)–O(401), 2.458 Å, is bonded to the py(P11) with the smallest intermolecular distance, while Cu(2) which is bonded to py(P21) shows less distortion, N(2)–Cu(2)–O(202), 84.2°; Cu(1)–Cu(2)–N(2), 146.3°; Cu(2)–O(202), 2.349 Å. These data indicate that crystal packing forces are an important factor in determining the geometry around copper(II).

The complex, $[Cu_2(O_2CCPh_3)_4(py)_2]$, exists in two crystalline modifications which exhibit different magnetic and spectral properties. Form **2a** was prepared by allowing **1** to lose the benzene of crystallization upon standing in an open container (Procedure 1) or by crystallizing the complex from a chloroform solution (Procedure 2). The magnetic and spectral properties of **2a** are nearly identical to those of **1**, suggesting that the crystal structures are similar with or without the benzene of crystallization. Form **2b** was prepared by crystallization of $[Cu_2(O_2CCPh_3)_4(py)_2]$ from an ethanol solution. The magnetic and spectral properties of **2b** are similar to those of the copper(II) carboxylates which have the classical copper(II) acetate-type structure.[5] While the crystal structure of **2b** has not been determined, the structure is certainly more closely related to complexes with a square pyramidal metal geometry than **1** and **2a**.

Further evidence which supports the above conclusion, that crystal packing forces play an important role in determining the geometry around copper(II) in **1** and **2a**, is provided by magnetic-moment data (see Table 11). Crystalline **1** and powder **2a** have the same magnetic moments at 308 K, 1.68 μ_B, both of which have similar magnetic properties that are consistent with a distorted trigonal bipyramidal structure around each copper(II) in which there is one very long Cu–O bond (2.3—2.5 Å), vide supra. The magnetic moments of these complexes in benzene solution at the same temperature are 1.56 μ_B and 1.53 μ_B, respectively. This decrease in the magnetic moments towards the value obtained for crystalline **2b** (1.51 μ_B), for which magnetic measurements are consistent with a cage structure more closely aligned with the copper(II) acetate type, suggests that on dissolution in benzene the forces which cause the molecular distortion are diminished.

The question arises as to what is structurally different

Table 11. Comparison of the Magnetic Properties of $Cu(O_2CCPh_3)_2\cdot n$ py Complexes at 308 K

Complex	$\chi_A\times10^6$ / emu mol^{-1}	μ_{eff} / μ_B	Form
1	1150[a,b]	1.68	Cryst
	1047[c]	1.56	Soln, C_6H_6
2a[d]	1150[a,b]	1.68	Powder
	1011[c]	1.53	Soln, C_6H_6
2b	930[a,b]	1.51	Cryst
3	1390[b,e]	1.85	Cryst

a) Corrected for constituent atom diamagnetism and temperature independent paramagnetism, 60×10^{-6} emu mol^{-1} of Cu(II). b) Calculated from variable temperature data, Faraday method. c) Evans method; not corrected for paramagnetic impurities. d) Prepared by Procedure 1. e) Corrected for temperature independent paramagnetism of Cu(II).

about the bridging triphenylacetato ligand which leads to the structural transformation. The triphenylacetato ligand is bulkier than other carboxylato ligands in complexes $[Cu_2(O_2CR)_4(py)_2]$ of known structure.[5] An examination of a model of **1** based on crystal-structure data, reveals that there is an area of space around each of the pyridine rings which is void of atoms. Thus, more efficient crystal packing can be obtained if the pyridine rings are angled away from the apical positions to make room for the pyridine rings on adjacent dimer units.

At the same time, the intramolecular forces between the bulky bridging triphenylacetato ligands may also have some effect on the structure. Steric repulsions between the bridging ligands could be reduced by staggering two adjacent triphenylacetato ligands with respect to the horizontal plane in D_{4h} symmetry. The out-of-plane ligands, i.e., the ligands which form the long bridges (which have right-handed conformations of the phenyl groups) show the largest deviations from threefold symmetry. These observations suggest that intramolecular steric forces could be responsible for some of the staggering of the ligands, as well as for the larger deviations from threefold symmetry. Porter et al.[12] have suggested that intramolecular steric crowding is responsible for determining the copper coordination geometry in the copper(II) trichloroacetate complexes. However, intramolecular steric crowding cannot be the major factor which controls the geometry of the dimeric copper(II) triphenylacetate–pyridine complexes, since all indications are that the structure of complex **2b** is closely akin to the classical copper(II) acetate monohydrate type.

Recently, crystal structures have been reported for the complexes, $[Cu_2(O_2CMPh_3)_4(L)_2]$ (where M=Si, L=α-picoline; M=Ge, L=quinoline), both of which have carboxylato ligands with three α-phenyl groups.[49] It is interesting to note that these complexes, while maintaining the square pyramidal metal geometry, show considerably more variation in the Cu–O bond distances than observed for complexes in which the carboxylato ligand has fewer than three α-phenyl groups. On inspection, their structures show a slight distortion of the type observed for **1**, resulting in one slightly longer Cu–O bonds to each copper in the adjacent bridging groups. One would expect less distortion by intramolecular forces in silicon and germanium complexes than in **1** as a result of the longer C–M distances in the carboxylato ligands.

The 1:2 dark blue crystalline complex, $Cu(O_2CCPh_3)_2 \cdot 2py$ (**3**), is formed from **1** by placing the blue-green crystals of **1** in an ethanol–pyridine solution and allowing the reaction to proceed for several days. The interesting aspect of this conversion is that it appears to occur in the solid phase. After one day, mixed crystals are obtained which contain both blue-green and dark-blue areas.[50] Apparently, pyridine molecules are able to diffuse into the crystal, perhaps replacing the benzene of crystallization, where the reaction occurs. Crystal-packing maps of **1** indicate that there is considerable space between molecular units. It is interesting to note that the volume of the unit cell for **3** is about one-half the volume of **1** with the *a* unit-cell distance in **3** being about one-half the *b* distance in **1**, while the other unit cell distances are comparable.

The structure of $Cu(O_2CCPh_3)_2 \cdot 2py$ (**3**) is a variation of the *trans*-bis(acetato-*O,O'*)diamminecopper(II) type.[35] Several other structures of this type, $Cu(O_2CR)_2 \cdot 2L$, where L is a nitrogeneous base, have been reported.[51–54] In comparing **3** with these structures, one observes that the Cu–O(2) distance (2.673 Å) is the shortest and the N–Cu–O(2) angle (81.0°) is the smallest so far reported. Also, the N–Cu–O(1) angle (91.5°) is greater than 90°, indicating a small deviation from a square planar arrangement of the atoms around copper in the coordination plane. In the other complexes of this type, the angles corresponding to the N–Cu–O(2) angle are close to 90° except for $Cu(O_2CCH_3)_2$-(imidazole)$_2$ (86°) where intermolecular hydrogen bonding occurs between imidazole and O(2).[12] These data indicate that in **3** the steric effects resulting from the bulky triphenylmethyl groups cause a twisting of the carboxyl groups relative to the coordination plane around copper.[55] The dihedral angle between the carboxyl ligand and the coordination plane is 78.0°.

Davey and Stephens[56] have reported the crystal structure for $Cu(O_2CCHCl_2)_2(\alpha\text{-picoline})_2$. In this complex, the *cis* conformation of the α-picoline ligands results in an asymmetric arrangement of the chelating dichloroacetato ligands. The geometry around copper(II) is distorted from a square planar arrangement, the angles formed by the out-of-plane Cu–O bonds with the plane are different, and the out-of-plane Cu–O distances vary.

In conclusion, the geometry of the coordination sphere around copper in monomeric and dimeric copper(II) carboxylates can vary considerably, depending on the size and shape of the ligands. Crystal packing forces and intramolecular repulsion forces are responsible for these structural changes. The flexibility of the coordination sphere around copper(II) has been noted.[12,36,40] Thus, one would expect to find other variations from the classical copper(II) acetate monohydrate-type and the *trans*-bis(acetato-*O,O'*)diamminecopper(II)-type structures as the spatial relationships both within and between the molecules are changed.

We greatfully acknowledge the contributions of Professor Y. Saito and Dr. S. Ohba, Keio University, for their fruitful discussions and suggestions in the preparation of this paper. We also wish to thank Professor D. W. Pratt, University of Pittsburgh, for the use of his ESR facilities, Drs. I. B. Goldberg and T. M. McKinney, Rockwell International, for running the ESR spectra of **2b**, and Professor J. W. Whittaker, Carnegie-Mellon University, for running an ESR spec-

trum of **2a**. The authors also wish to acknowledge Dr. C. E. Taylor's (formerly of our group) contribution in determining the magnetic moments by the Evans method.

Chromium(VI) Complexation with Triisooctylamine in Organic Solvents

Yaou-Huei HUANG, Chuh-Yung CHEN, and Jen-Feng KUO*
Department of Chemical Engineering, National Cheng Kung University, Tainan, Taiwan 70107, R.O.C.
(Received November 26, 1990)

Liquid–liquid extraction of chromium(VI) from chromic acid solutions with triisooctylamine (tris(6-methylheptyl)amine, abbrev. to TIOA) dissolving in various organic solutions has been studied. The reaction between chromium(VI) and TIOA in *o*-xylene has been discussed in detail. It has been found that dichromate ion and hydrogen chromate ion coexist in the system, based on the extraction data and the IR and UV-visible spectra of the TIOA-chromium salt. The chromium extraction equilibria can be expressed as:

$$\overline{\text{TIOA}} + \text{H}^+ + \text{HCrO}_4^- \rightleftarrows \overline{(\text{TIOAH})\text{HCrO}_4}$$

$$2\overline{\text{TIOA}} + 2\text{H}^+ + \text{Cr}_2\text{O}_7^{2-} \rightleftarrows \overline{(\text{TIOAH})_2\text{Cr}_2\text{O}_7}$$

The extraction constants are obtained.

It is well-known that chromate and dichromate ions can be extracted using TBP or an amine as an extractant. Many workers used tertiary amines to extract chromium(VI) from various acid solutions.[1–16] The extraction mechanism proposed by them is confusing. for example, Fedorov et al.[11] reported that trioctylamine extracts chromium(VI) as CrO_4^{2-} from H_2SO_4 solutions. Depula[12] reported that trioctylamine extracts chromium(VI) as $Cr_2O_7^{2-}$ from H_3PO_4 solutions and it probably involves $HCr_2O_7^-$ from $HClO_4$ and concentrated HNO_3 solutions in addition to $Cr_2O_7^{2-}$. Recently Takahashi et al.[16] used 3-(4-pyridyl)-1,5-dipheylpentane (a tertiary amine) to extract chromium(VI) from sulfuric acid solutions. They reported that $HCrO_4^-$ was extracted into organic phase. Henkel corporation[9] indicated that tertiary amines may extract chromium(VI) by solvating:

$$2\overline{\text{R}_3\text{N}} + 2\text{H}^+ + \text{Cr}_2\text{O}_7^{2-} \rightleftarrows \overline{(\text{R}_3\text{NH})_2\text{Cr}_2\text{O}_7},$$

or by ion exchange:

$$\overline{(\text{R}_3\text{NH})_2\text{X}} + 2\text{H}^+ + \text{Cr}_2\text{O}_7^{2-} \rightleftarrows \overline{(\text{R}_3\text{NH})_2\text{Cr}_2\text{O}_7},$$

$X=SO_4^{2-}$ or $2Cl^-$.

In order to realize the behavior of chromium(VI) extracted by amines from various acid solutions, it is necessary to extract chromium(VI) from chromic acid at first. In the study, it was decided to identify amine–chromium(VI) species and determine extraction constants for triisooctylamine–chromic acid extraction system.

Experimental

Reagents: 1.92×10^{-2} M (M=mol dm^{-3}) stock solutions (1000 ppm chromium) were prepared by dissolving 1.923 g of chromium trioxide (99.0%) in distilled deionized water and diluting to volume in a 1 dm^3 standard flask. Appropriate amouuts of TIOA (98%) were diluted with organic solvents (E.P. grade) to obtain the desired TIOA concentrations.

Procedure: Both aguecus and organic phases were vigorously mixed in a 50 cm^3 dark centrifugal tube more than six minutes at 24±1 °C. After centrifuging, the tube was settled in a water bath at 25±0.1 °C for more than three hours. The pH value of the aqueous phase was measured by a PHM 85 precision pH meter (Radiometer & Copehagen Co.). Chromium concentrations in the aqueous phase were determined using an IL-551 type atomic absorption spectrophotometeter (Instrumentation Laboratory Inc.). The concentration of chromium in the organic phase was calculated from the difference in chromium content in the aqueous phase before and after extraction multiplied by the phase A/O ratio (volume ratio of aqueous and organic phases). The free TIOA concentration was calculated by the subtraction of chromium concentration in the organic phase from initial TIOA concentration used.

Results and Discussion

Extraction Equilibrium of Chromium(VI): Figure 1 shows the log–log plots of $[\overline{\text{Cr}}]$ vs. $[\overline{\text{TIOA}}](\text{H}^+)(\text{HCrO}_4^-)$ in *o*-xylene. The initial chromium concentration is varied from 2.5×10^{-4} M to 4.0×10^{-2} M. The

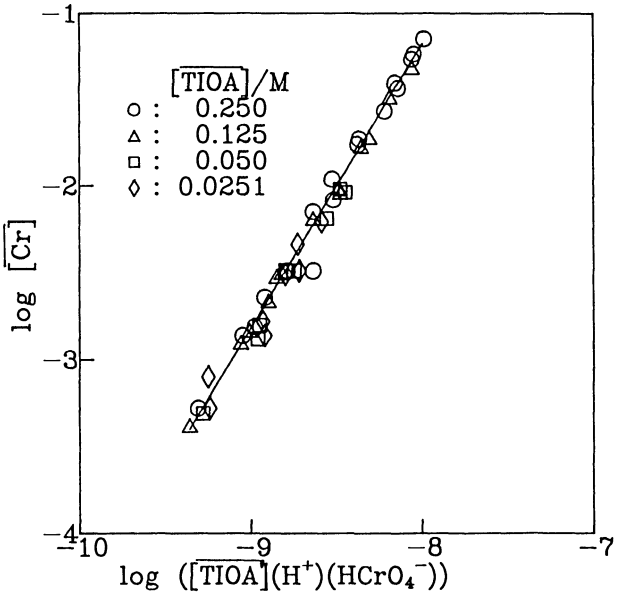

Fig. 1. Plots of $\log[\overline{\text{Cr}}]$ vs. $\log([\overline{\text{TIOA}}](\text{H}^+)(\text{HCrO}_4^-))$ for TIOA in *o*-xylene.

bar overhead in the equations denotes organic phase. It is seen from Fig. 1 that a straight line of the slope 1.6 was obtained. The result indicates that the extraction mechanism can not be described just using a single species either $HCrO_4^-$ or $Cr_2O_7^{2-}$. It is plausible that both $HCrO_4^-$ and $Cr_2O_7^{2-}$ were extracted by TIOA into the organic phase. An extraction model for the equilibria with the two components is proposed. The model involves dissociation and association of Cr(VI) species (Eqs. 1—5) in the aqueous phase, and chromium(VI) extraction equilibria (Eqs. 6 and 7) by TIOA. The values of the dissociation constants of chromic acid in Eqs. 1—5 were obtained by Neuss and Rieman,[22] Davis and Prue,[21] Takahashi et al.,[16] Hala et al.,[8] and Deptula.[2]

$$H_2Cr_2O_7 \rightleftarrows H^+ + HCr_2O_7^-, \quad (1)$$

$$K_1 = (H^+)(HCr_2O_7^-)/(H_2Cr_2O_7), \quad K_1 = 1\times10^6$$

$$HCr_2O_7^- \rightleftarrows H^+ + Cr_2O_7^{2-}, \quad (2)$$

$$K_2 = (H^+)(Cr_2O_7^{2-})/(HCr_2O_7^{2-}), \quad K_2 = 0.85$$

$$H_2CrO_4 \rightleftarrows H^+ + HCrO_4^-, \quad (3)$$

$$K_3 = (H^+)(HCrO_4^-)/(H_2CrO_4), \quad K_3 = 1.21$$

$$HCrO_4^- \rightleftarrows H^+ + CrO_4^{2-}, \quad (4)$$

$$K_4 = (H^+)(CrO_4^{2-})/(HCrO_4^-), \quad K_4 = 3.2\times10^{-7}$$

$$2HCrO_4^- \rightleftarrows Cr_2O_7^{2-} + H_2O, \quad (5)$$

$$K_5 = (Cr_2O_7^{2-})/(HCrO_4^-)^2, \quad K_5 = 98$$

$$2\overline{TIOA} + 2H^+ + Cr_2O_7^{2-} \rightleftarrows \overline{(TIOAH)_2Cr_2O_7}, \quad (6)$$

$$K_6 = [\overline{(TIOAH)_2Cr_2O_7}]/[\overline{TIOA}]^2(H^+)^2(Cr_2O_7^{2-}),$$

$$\overline{TIOA} + H^+ + HCrO_4^- \rightleftarrows \overline{(TIOAH)HCrO_4}, \quad (7)$$

$$K_7 = [\overline{(TIOAH)HCrO_4}]/[\overline{TIOA}](H^+)(HCrO_4^-).$$

The symbols [ ] and ( ) represent the molar concentration and molar activity, respectively. The activity coefficient in the organic phase is assumed to be unity for convenience. Combining the constant of Eq. 5 with that of Eq. 6 gives:

$$K_8 = [\overline{(TIOAH)_2Cr_2O_7}]/[\overline{TIOA}]^2(H^+)^2(HCrO_4^-)^2. \quad (8)$$

The total concentration of chromium in the organic phase can be expressed as:

$$[\overline{Cr}] = [\overline{(TIOAH)HCrO_4}] + 2[\overline{(TIOAH)_2Cr_2O_7}]. \quad (9)$$

Substituting Eqs. 7 and 8 into Eq. 9 and rearranging gives:

$$[\overline{Cr}]/\{[\overline{TIOA}](H^+)(HCrO_4^-)\} = K_7 + 2K_8[\overline{TIOA}](H^+)(HCrO_4^-). \quad (10)$$

Equation 10 indicates that the plot of $[\overline{Cr}]/\{[\overline{TIOA}](H^+)(HCrO_4^-)\}$ vs. $[\overline{TIOA}](H^+)(HCrO_4^-)$ will give a linear line. The slope of it is $2K_8$ and the intercept is K_7.

Figure 2 shows the plots of $[\overline{Cr}]/\{[\overline{TIOA}](H^+)(HCrO_4^-)\}$ vs. $\{[\overline{TIOA}](H^+)(HCrO_4^-)\}$. The activity coefficient of chromium in the aqueous phase was calculated by Guntelberg expression.[19] The total activity of chromium in aqueous phase ($(Cr)_{aq,total}$) is as follows:

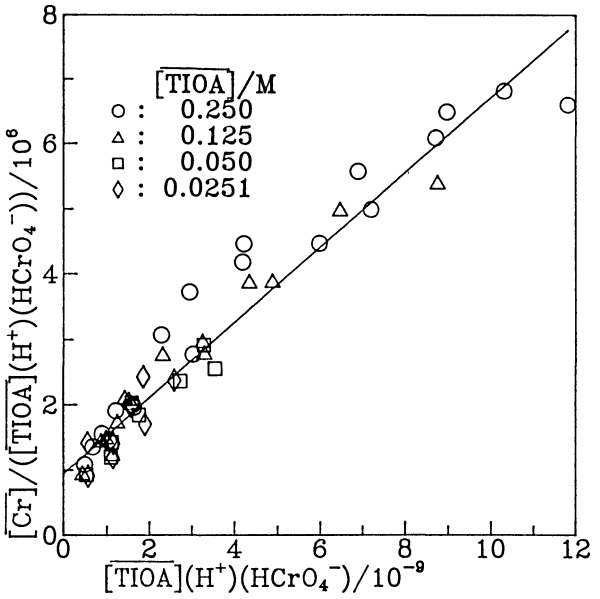

Fig. 2. Plots of $[\overline{Cr}]/([\overline{TIOA}](H^+)(HCrO_4^-))$ vs. $[\overline{TIOA}](H^+)(HCrO_4^-)$ for TIOA in *o*-xylene.

$$(Cr)_{aq,total} = 2(H_2Cr_2O_7) + 2(HCr_2O_7^-) + 2(Cr_2O_7^{2-}) + (H_2CrO_4) + (HCrO_4^-) + (CrO_4^{2-}). \quad (11)$$

Then, from Eqs. 1—5, $(Cr)_{aq,total}$ can be expressed in terms of $(HCrO_4^-)$ as well as the appropriate equilibrium constants involved.

$$\begin{aligned}(Cr)_{aq,total} &= 2\{(H^+)^2/K_1K_2 + (H^+)/K_2 + 1\}(Cr_2O_7^{2-}) \\ &\quad + \{(H^+)/K_3 + 1 + K_4/(H^+)\}(HCrO_4^-) \\ &= \{2K_5/K_1K_2\}\{(H^+)^2 + K_1(H^+) + K_1K_2\}(HCrO_4^-)^2 \\ &\quad + \{1/K_3(H^+)\}\{(H^+)^2 + K_3(H^+) + K_3K_4\}(HCrO_4^-). \quad (12)\end{aligned}$$

The activity of $HCrO_4^-$ in the aqueous phase was calculated from Eq. 12. As shown in Fig. 2, a linear line confirms the extraction model suggested. The values of $\log K_7 = 6.01$ and $\log K_8 = 14.5$ were obtained in *o*-xylene, and those in other solvents are shown in Table 1.

Table 1. Extraction Constants of Triisooctylamine-Chromium System in Various Organic Diluents

Diluent	$\log K_7$[a]	$\log K_8$[b]	ε[c]	δ[d]
Chloroform	7.73	17.1	4.90	9.3
Benzene	6.62	15.6	2.28	9.15
Toluene	6.49	14.7	2.24	8.9
o-Xylene	6.01	14.5	2.56	9.0
Carbon tetrachloride	5.62	13.7	2.21	8.6
Hexadecane	5.35	12.9	2.10	—
Hexane	4.59	12.7	1.89	7.3

a) $K_7 = [\overline{(TIOAH)HCrO_4}]/[\overline{TIOA}](H^+)(HCrO_4^-)$. b) $K_8 = [\overline{(TIOAH)_2Cr_2O_7}]/[\overline{TIOA}]^2(H^+)^2(HCrO_4^-)^2$. c) From Ref. 23. d) From Ref. 24.

Using these two equilibrium values, we can obtain the concentrations of $(TIOAH)HCrO_4$ and $(TIOAH)_2Cr_2O_7$ in the organic phase. The molar ratio of $(TIOAH)HCrO_4$ to $(TIOAH)_2Cr_2O_7$ in the organic phase can be expressed as:

$$[\overline{(TIOAH)HCrO_4}]/[\overline{(TIOAH)_2Cr_2O_7}] = K_7/\{K_8[\overline{TIOA}](H^+)(HCrO_4^-)\}, \quad (13)$$

which indicates that increasing value of $[\overline{TIOA}](H^+)(HCrO_4^-)$ will increase the molar fraction of $(TIOAH)_2Cr_2O_7$ in the organic phase.

IR and UV-visible Absorption Spectra Studies: It has been reported that the UV absorption spectra of $HCrO_4^-$ and $Cr_2O_7^{2-}$ anions show the maximum at 350 and 370 nm, respectively.[8,17] Figure 3 shows absorption spectra of TIOA-chromium salt solutions in *o*-xylene. As shown in Fig. 3, the absorption maxima of solutions 1 to 4 appear at 352.0, 353.5, 364.5, and 366.0 nm, respectively, suggesting the presence of $HCrO_4^-$ ion in solutions 1 and 2, and $Cr_2O_7^{2-}$ ion in solutions 3 and 4 as main species. Indeed, the values of $[\overline{TIOA}](H^+)(HCrO_4^-)$ in solutions 1 to 4 are estimated as $10^{-9.52}$, $10^{-9.25}$, $10^{-8.16}$ to $10^{-7.93}$, respectively, and by substituting these values into Eq. 13, we obtained the molar ratios of $(TIOAH)HCrO_4$ to $(TIOAH)_2Cr_2O_7$ to be 10.7, 5.6, 0.46, and 0.27, respectively. Consequently, the coexistence of both $HCrO_4^-$ and $Cr_2O_7^{2-}$ in the organic phase may be concluded.

The vibration spectrum of the dichromate ion had been studied. According to Stammreich et al.,[18] a weak symmetric stretching Cr–O–Cr vibration appears at 567 cm^{-1} and antisymmetric Cr–O–Cr vibrations appears at 762 cm^{-1} (strong) and 795 cm^{-1} (weak). Figure 4 shows the IR spectrum for solution 4 in Fig. 3. For comparison, the IR spectrum of pure TIOA was also shown in Fig. 4. The peaks appearing at 562, 762, and 800 cm^{-1} make sure that $(TIOAH)_2Cr_2O_7$ exits in the organic phase.

Solvent Effect: The extraction of chromium by TIOA was examined in various diluents, toluene, benzene, chloroform, carbon tetrachloride, hexane, and hexadecane. For the former four extraction systems, linear lines are obtained in the plots of $[\overline{Cr}]/$

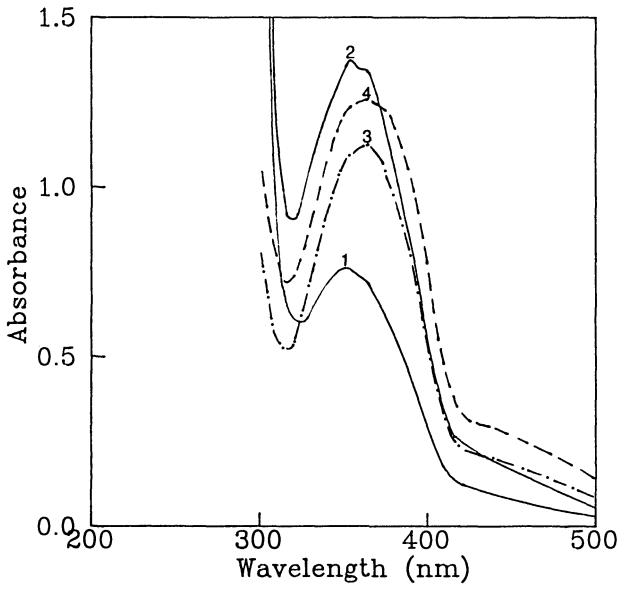

Fig. 3. UV/vis absorption spectra of Cr(VI) in the organic phase.
1 and 2: $[Cr]_i$=0.00192 M; [TIOA]=0.025 M; V_A/V_O=0.25 and 0.5 respectively.
3 and 4: $[Cr]_i$=0.0192 M; [TIOA]=0.25 M; V_A/V_O=2 and 4, respectively.

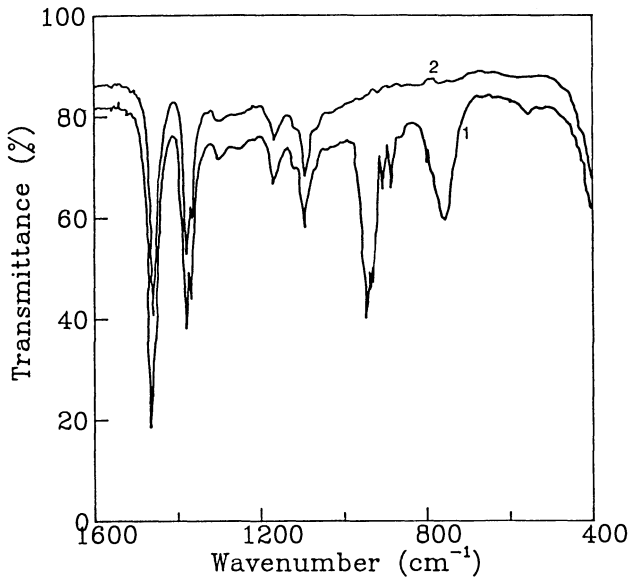

Fig. 4. IR absorption spectra of Cr(VI) in the organic phase.
Curve 1: TIOA-chromate salt. Curve 2: pure TIOA.

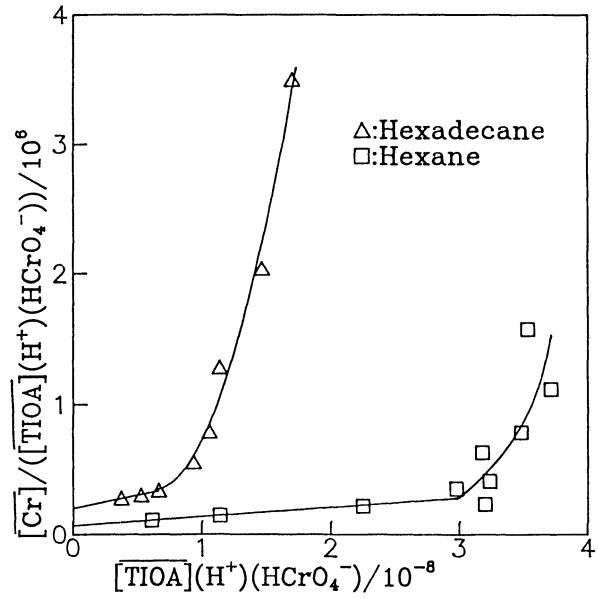

Fig. 5. Plots of $[\overline{Cr}]/([\overline{TIOA}](H^+)(HCrO_4^-))$ vs. $[\overline{TIOA}](H^+)(HCrO_4^-)$ for 0.25 M TIOA in hexane and hexadecane.

$\{[\overline{TIOA}](H^+)(HCrO_4^-)\}$ vs. $\{[\overline{TIOA}](H^+)(HCrO_4^-)\}$. However, for the latter two diluents, as shown in Fig. 5, the linear line only suits for a limited range. Beyond the linear range the slope of the lines tremendously increases. The phenomenon may be attributed to the aggregation of TIOA–chromium salt in the high chromium concentration in the organic phase. The aggregation may be caused from the low dielectric constant or low solubility parameter of hexane and hexadecane. The values of log K_7 and log K_8 for the reaction between chromium(VI) and TIOA in the diluents studied are shown in Table 1. Diamond[20] used trilaurylamine to extract HBr from aqueous phase. He found that in general, the higher the dielectric constant of the organic solvent, the better the extraction. For comparison, the dielectric constants of the solvents are also shown in Table 1. It is seen that except for the *o*-xylene system, the values of K_7 and K_8 obtained decrease with the decrease of the dielectric constant of the solvent, i.e.: chloroform>benzene>toluene>carbon tetrachloride> hexadecane>hexane. This tendency is in good agreement with that indicated by Diamond.[20] In this work, we also attempt to correlate extraction constant with the solubility parameter of solvent. As shown in the last column of Table 1, obviously a similar result as the dielectric constant was obtained.

Extraction-Spectrophotometric Determination of Osmium Using 4-(2-Pyridylazo)resorcinol

Shayessteh DADFARNIA and Mojtaba SHAMSIPUR*
Department of Chemistry, Shiraz University, Shiraz, Iran
(Received January 5, 1991)

An extraction-spectrophotometric method for the determination of trace amounts of osmium(VIII) is described. Osmium is quantitatively extracted from aqueous solutions at pH 3.0—3.5 into a 10:1 chloroform–methyl isobutyl ketone mixture with tetrabutylammonium bromide, followed by spectrophotometric determination, using 4-(2-pyridylazo)resorcinol as a metallochromic indicator. The orange-red mixed complex of osmium absorbs light at λ_{max}=530 nm with a molar absorptivity of 2.5×10^4 $dm^3\,mol^{-1}\,cm^{-1}$. Beer's law is obeyed over the range 0.5—18 $\mu g\,cm^{-3}$. The method has a wide range and is sensitive and free from interferences from many anions and cations, including some platinum metals.

Because of the increasing use of osmium oxides as popular oxidizing agents in organic chemistry, and as effective catalysts for a wide variety of chemical reactions,[1–5] the separation and determination of osmium in trace levels are of special interest. Thiocyanate,[6,7] Bismuthiol II,[8] 9,10-phenanthrenequinone monoxime,[9] 1-(2-pyridylazo)-2-phenanthrol(II),[10] and 7-amino-1-hydroxynaphthalene-3,6-disulfonic acid[11] are among the spectrophotometric reagents used for the extraction and determination of osmium. However, there are some difficulties associated with the presence of interfering ions, especially platinum metals, which cannot be eliminated uisng the direct methods. On the other hand, although the catalytic methods seem to be more sensitive than extraction-spectrophotometric procedures, there is a need for rigid control of temperature, acidity, reagent, impurities, etc.[12,13]

4-(2-Pyridylazo)resorcinol (PAR) has also been used for the determination of osmium, but it suffers from the poor selectivity for osmium over the several commonly associated interfering ions.[14] In this paper we report a sensitive method for the selective extraction of Os(VIII) with tetrabutylammonium bromide (TBAB) from acidic aqueous solutions into a 10:1 chloroform–methyl isobutyl ketone mixture, which is followed by spectrophotometric determination of osmium in organic phase using PAR as a chromogenic indicator.

Experimental

Reagents. All of the chemicals used were of the highest purity available and were used without further purification.

Tetrabutylammonium bromide (TBAB, Merck) solution, 1.5% w/v. Prepared with triply distilled water.

Organic Phase. Prepared by mixing appropriate amounts of methyl isobutyl ketone (MIBK, Merck) and chloroform (Merck) to form a 1 to 10 v/v mixture.

Osmium Stock Solution. A 1 g sealed ampul of osmium tetraoxide (Fluka) dissolved in about 100 cm^3 of 0.20 M (1 M=1 $mol\,dm^{-3}$) sodium hydroxide solution and then diluted to 1 dm^3 with triply distilled water.[15] The solution was then standardized by the Klobbie's method[16] as follows: 15 cm^3 of 6 M sulfuric acid and 2 g of potassium iodide were added to 25 cm^3 of the solution and the liberated iodine was titrated against a 0.250 normal solution of sodium thiosulfate. The end-point was determined using starch paper externally as indicator. Working solutions were prepared by suitable dilution of the stock solution.

4-(2-Pyridylazo)resorcinol (PAR, Merck) solution, 0.1% w/v. Prepared with absolute methanol (Merck).

Potassium chloride (Merck) solution, 3.5 M. Prepared with triply distilled water.

Apparatus. All spectra were obtained with a Beckman DK-2A ratio recording spectrophotometer and the absorbance measurements were made with a Perkin–Elmer 35 spectrophotometer. The pH values were determined with a Corning 125 pH meter using a combined electrode.

Procedure. An aliquot of the sample solution containing 5—180 μg of Os(VIII) was placed in a 10-cm^3 flask. One cm^3 of 1.5% TBAB and 3 cm^3 of 3.5 M KCl solution were added and pH was adjusted between 3.0 and 3.5 with dilute HCl. The solution was diluted to the mark with triply distilled water. Next, the solution was transferred into a 60-cm^3 separatory funnel, 10 cm^3 of 1:10 MIBK–chloroform solvent was added and the mixture was shaken vigorously for 10 min. The phases were allowed to separate and the organic layer was collected in a 25-cm^3 flask. To ensure the complete extraction of osmium, the aqueous layer was treated with another 5-cm^3 protion of fresh organic solvent. To the combined organic extracts 1 cm^3 of 0.1% PAR solution and 3 cm^3 of methanol were added and the mixture was diluted to the mark with chloroform. For complete color development, the solution was heated in a thermostated water-bath at 50 °C for 2 h. The absorbance of the orange-red solution was measured at 530 nm against a reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of the mixed complex of osmium with PAR and blank reagent are shown in Fig. 1. As it is seen, the orange-red complex shows a maximum at 530 nm with a molar absorptivity of 2.5×10^4 $dm^3\,mol^{-1}\,cm^{-1}$, whereas the reagent blank shows a negligible absorbance at this wavelength.

Effect of pH. The extraction of Os(VIII) with TBAB was carried out over the pH range 0.8—12.6 and the results are given in Fig. 2. It is seen that the extraction is quantitative at pH range of about 1—4, the percent of

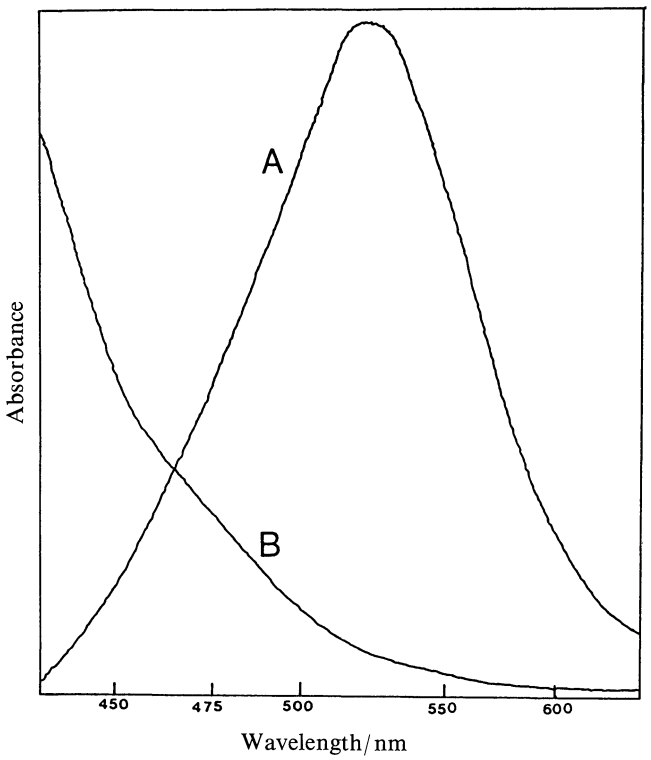

Fig. 1. Absorption spectra of the mixed complex of Os(VIII) with PAR (A) and the reagent blank (B) in organic phase.

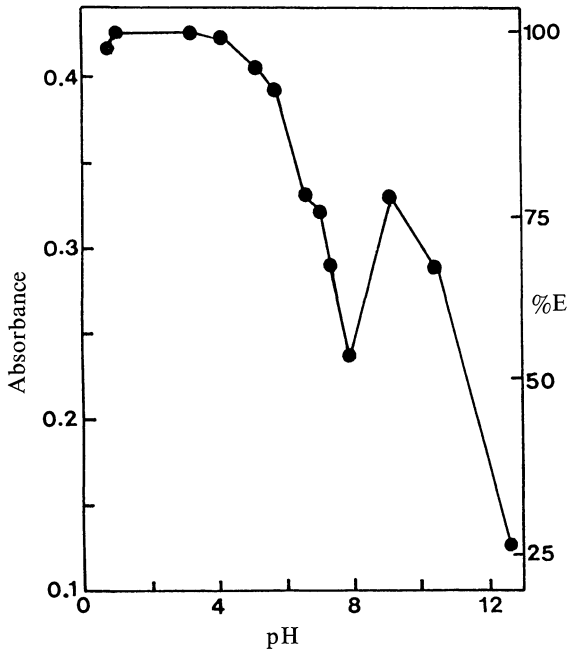

Fig. 2. Effect of pH on the extraction of Os(VIII). Conditions: Os, 10.24 μg cm^{-3}; TBAB, 3 cm^3 of 0.5% in H_2O; PAR, 1 cm^3 of 0.1% in CH_3OH; λ_{max}, 530 nm; color, orange-red.

extraction (%E) decreases drastically by an increase in pH from 4 to 12.6.

Effect of TBAB Concentration. The influence of the

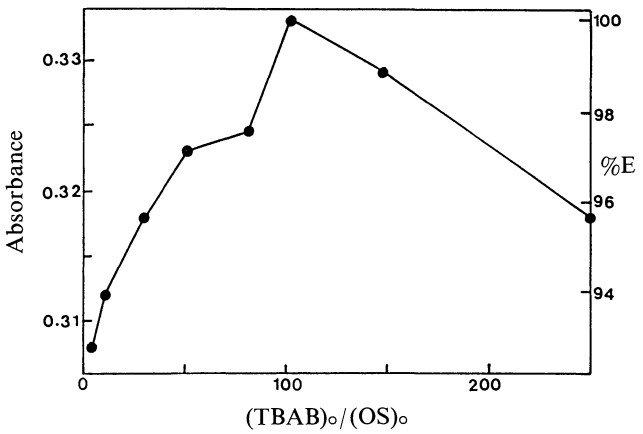

Fig. 3. Effect of TBAB concentration on the extraction of Os(VIII). Conditions: Os, 8.0 μg cm^{-3}; PAR, 1 cm^3 of 0.1% in CH_3OH; pH, 3.2; λ_{max}, 530 nm.

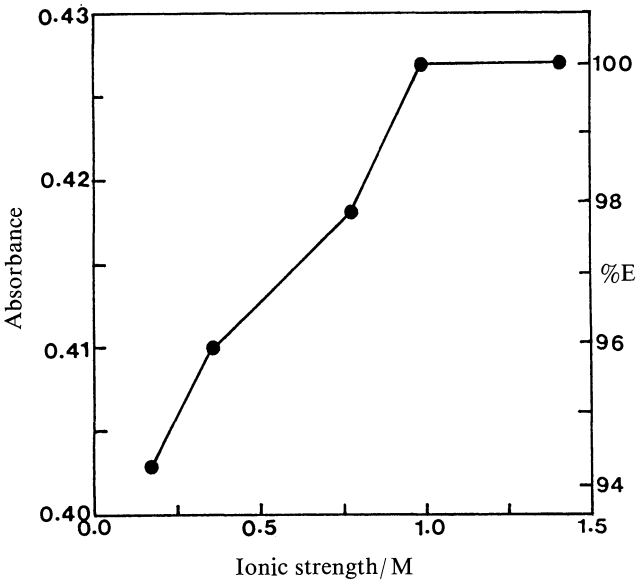

Fig. 4. Effect of ionic strength on the extraction of Os(VIII). Conditions: Os, 10.24 μg cm^{-3}, TBAB, 1 cm^3 of 0.1% in CH_3OH; pH, 3.2; λ_{max}, 530 nm.

TBAB concentration on the extraction of osmium is shown in Fig. 3. The extraction was found to be quantitative when the TBAB to osmium mole ratio is about 100. A further excess of TBAB would cause a decrease in %E, probably due to a change in the extent of ion pairing.

Effect of Ionic Strength. The ionic strength of aqueous solution was found to influence the extraction process (Fig. 4). There is an increase in %E with ionic strength of the solution, maintained by addition of KCl; quantitative extraction results at ionic strength 0.99 M. No change in %E was observed upon further addition of the KCl solution.

Effect of Organic Solvent. The extraction process was performed in a single stage at optimal condition with pure MIBK and pure chloroform. The amount of

remaining osmium in aqueous phase was checked by the reported catalytic methods.[12,13] It was found that the exctraction was more complete with MIBK, but the color intensity of the resulting complex with PAR was much higher in chloroform. However, a 1 : 10 MIBK–chloroform mixture was chosen in this study in which the effect of MIBK on the color intensity was negligible, while in a single stage process the %E was found to be >97.

Effect of Shaking Time. The extraction of osmium(VIII) under the conditions recommended in the procedure is rapid. A shaking time of 8—12 min was found sufficient for the complete extraction.

Effect of PAR Concentration. Addition of methanolic solution of PAR to the chloroform extract of osmium forms a turbid red adduct. In order to overcome the turbidity, absolute methanol was added to the solution until a 5 : 1 v/v ratio of chloroform to CH_3OH is reached and a completely clear solution was obtained. Studies with various concentration of PAR showed that 1.0 cm^3 of a 0.1% (w/v) of PAR in methanol was adequate for the complete color development (Fig. 5). A further excess of PAR increased the absorbance of reagent blank.

Effect of Temperature and Time. The influence of temperature on the color development of osmium–PAR system was studied. There is an increase in the rate of complex formation, and hence in the color development, with temperature. However, 50 °C was chosen in the procedure because of the considerable evaporation of the solvent at higher temperatures. Measurements of absorbance against time at 50 °C showed that, a duration of about 2 h is needed for complete color development. Absorbance of the resulting colored solution was found to remain unchanged for 48 h, if it was protected from the direct sunlight.

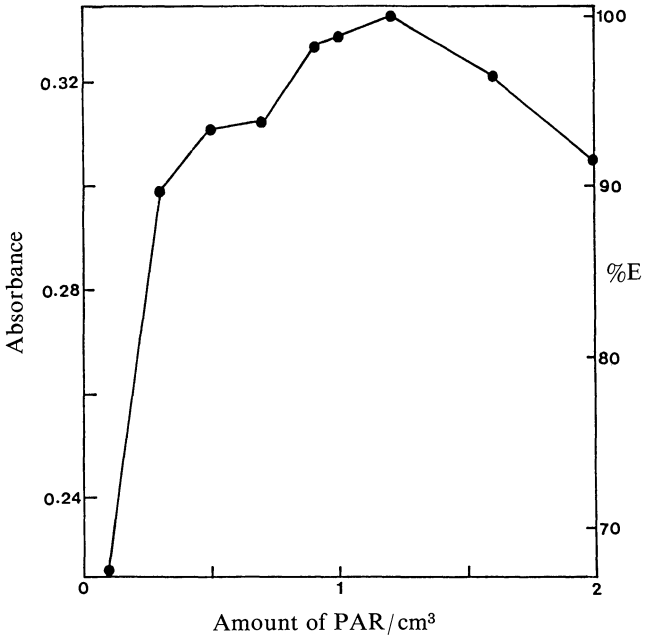

Fig. 5. Effect of PAR concentration on the absorbance of Os–PAR complex. Conditions: Os, 8.0 μg cm^{-3}; TBAB, 1 cm^3 of 1.5% in H_2O; pH, 3.2; λ_{max}, 530 nm.

Beer's Law Study. A calibration graph for osmium was obtained under the recommended conditions in procedure. Beer's law was obeyed over the concentration range 0.5—18 μg cm^{-3} of Os(VIII) and Sandell's sensitivity[17] for 0.001 absorbance was 0.0076 μg cm^{-2}. The relative error (95% confidence level) for 10.24 μg cm^{-3} of osmium was ±1.3% (12 replicates).

Stoichiometry of the Complex. The ratio of osmium to PAR in the resulting complex in organic phase was studied by continuous variations method,[18] and found to be 1 : 2.

Effect of Diverse Ions. Osmium(VIII) was extracted according to the recommended procedure in the presence of several other ions to determine the sensitivity and validity of the method. The results are shown in Table 1. An error of ±2% in the absorbance reading was considered tolerable. As it is seen, most of the common anions and cations associated with osmium did not interfere in the extraction of Os(VIII), except Ag^+, Cd^{2+}, Hg^{2+}, Zn^{2+}, and Pd^{2+}. Interferences form these cations were eliminated by either in situ masking or preseparation using appropriate methods indicated in Table 1.

Conclusion. The method described provides a reliable means of determining trace amounts of osmium. It has a wide range and is free from interferences from many anions and cations, including some platinum

Spectrophotometric Determination of Trace Amounts of Selenium Based on Catalytic Reduction of Toluidine Blue by Sulfide Ion

Hooshang PARHAM and Mojtaba SHAMSIPUR*
Department of Chemistry, Shiraz University, Shiraz, Iran
(Received January 16, 1991)

A simple, rapid, and sensitive kinetic method for the determination of trace selenium (0.03—1.5 $\mu g\,cm^{-3}$) based on its catalytic effect on the reduction reaction of toluidine blue and sodium sulfide is reported. The reaction is monitored spectrophotometrically by measuring the decreasing absorbance of toluidine blue at 605 nm by the variable time method. The detection limit is 8 $ng\,cm^{-3}$ and the relative standard deviation for 1 $\mu g\,cm^{-3}$ selenium is 1.4%. The procedure was successfully applied to the determination of selenium in real samples.

Because of the increasing industrial use of selenium,[1,2] in one hand, and its serious toxicity and cumulative effect in body,[3,4] in the other, the separation and determination of the metal ion in trace levels is of special interest. Several extraction-spectrophotometric,[5,6] and spectrophotometric catalytic[7,8] methods for the determination of selenium have been reported recently. Despite the need for rigid control of experimental parameters in the catalytic methods, they have shown very promissing features for the determination of metal ion in ultratrace levels.

In this paper we wish to report a simple, rapid, and sensitive spectrophotometric method for the determination of Se(IV) based on its catalysis of the reduction of toluidine blue by sodium sulfide in neutral solutions.

Experimental

Reagents. All chemicals were of the highest purity available and used without further purification except for vacuum drying over P_2O_5. Triply distilled deionized water was used throughout.

Selenium (IV) stock standard solution (1000 $\mu g\,cm^{-3}$) was prepared by dissolving 3.3308 g of $Na_2SeO_3 \cdot 5H_2O$ (Merck) in water and diluting to 1 dm^3 in a volumetric flask. The solution was standardized iodometrically.[9] Working solutions were prepared by appropriate dilution of the stock solution with water.

Sodium sulfide solution (1000 $\mu g\,cm^{-3}$) was prepared by dissolving 1.8750 g of $Na_2S \cdot 9H_2O$ (Hopkin and Williams) in water and diluting to 250 cm^3 in a volumetric flask. This solution was prepared daily and standardized.[9]

A 3.27×10^{-4} M (1 M=1 $mol\,dm^{-3}$) stock solution of toluidine blue (Merck) was prepared by dissolving the dyestuff in water.

Apparatus. Absorption spectra were recorded on a Beckman DK-2A ratio recording spectrophotometer and the absorbance measurements were made on a Perkin-Elmer model 35 spectrophotometer. Measurements of pH was made using a corning 125 pH-meter. A Gallen Kamp BJH-400-010D thermostirrer in which the temperature could be fixed to ±0.1 °C was used.

Procedure. The catalyzed reaction was monitored spectrophotometrically by measuring the change in absorbance at 605 nm. An appropriate amount of sample solution containing 0.30 to 1.50 $\mu g\,cm^{-3}$ of Se(IV) was transferred into a 10 cm^3 flask. Then 1 cm^3 of a 100 $\mu g\,cm^{-3}$ solution of sodium sulfide and 0.3 cm^3 of 0.01 M HCl solution (to adjust pH between 6.5—7.5) and enough water for diluting the solution to ca. 8 cm^3 were added. The solution was kept in water bath at 25 °C for 20 min. Then, 2 cm^3 of 3.27×10^{-4} M solution of toluidine blue was added when diluted to the mark and time was measured from just after the addition of toluidine blue. A portion of solution was transferred into a glass cell immediately for the absorbance measurements. The time required for the absorbance to decrease to A=0.500 was then measured.

Results and Discussion

Catalytic Reduction of Toluidine Blue by Sulfide Ion. It was found that sulfide ion at neutral pH, where it is mostly in hydrogen sulfide form HS^-, reduces toluidine blue only slowly. The half-reaction for the reduction of the dyestuff is as follows:

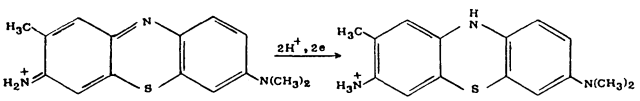

Figure 1 shows the change in the absorption spectrum of toluidine blue in the presence of sulfide ion at pH=7. However, trace amounts of Se(IV) catalyzes the reaction so that it will proceed much faster.

The catalytic effect of selenium(IV) has been explained by the formation of SeS^{2-}, after the initial reduction of Se(IV) to its elemental state.[10] This compound can then reduce the dye molecule and reform Se(IV).

Effect of Variables on the Catalyzed Reaction. The rate of the reduction reaction both in the presence and absence of Se(IV) was found to increase by increasing temperature. A temperature of 25 °C was used as the most suitable.

The rate of the catalyzed reaction was investigated over the pH range of 4—12 and the results are shown in Fig. 2. It is seen that the largest difference between the

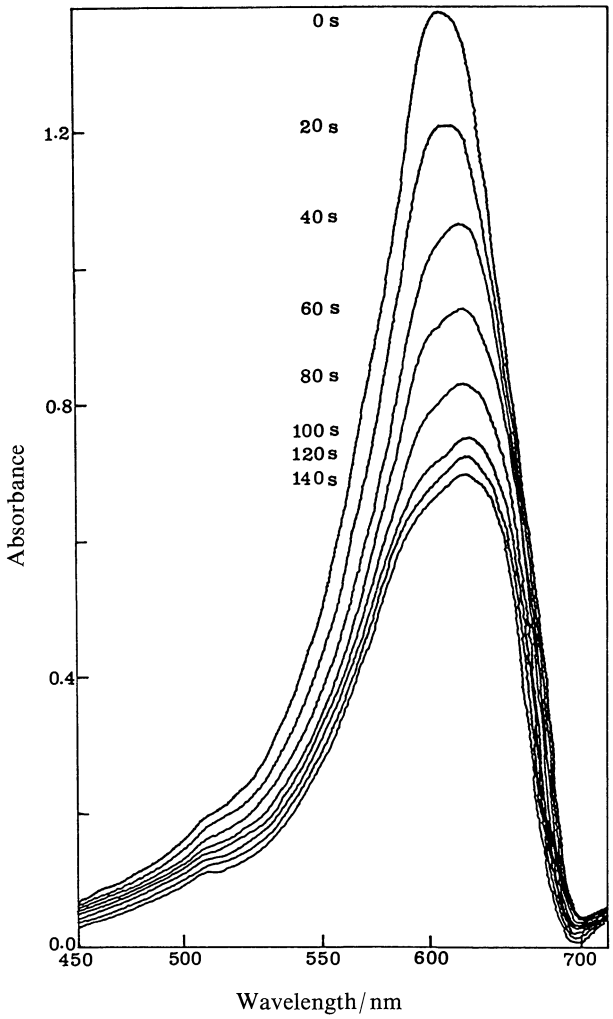

Fig. 1. Absorption spectra of 6.5×10^{-5} M toluidine blue in the presence of 3.1×10^{-4} M sodium sulfide at pH=7. Time intervals 20 s.

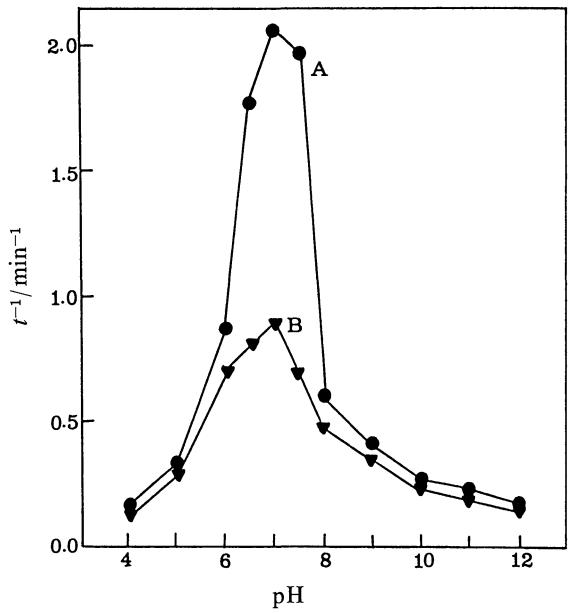

Fig. 2. Effect of pH on the reaction rate. A, sample; B, blank. Conditions: sodium sulfide, 3.13×10^{-4} M; Selenium (IV), 1 μg cm^{-3}; toluidine blue, 6.54×10^{-5} M. The letter t denotes the time required for absorbance to decrease to 0.500.

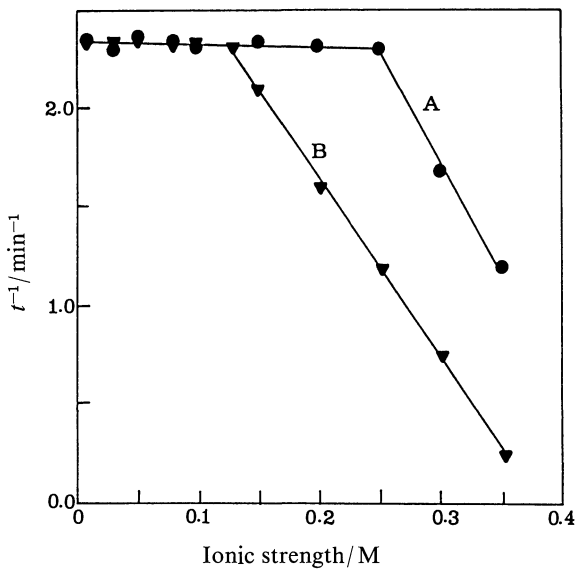

Fig. 3. Effect of ionic strength on the reaction rate. A, NaCl; B, $NaClO_4$. Conditions: Sodium sulfide, 3.13×10^{-4} M; Selenium (IV), 1 μg cm^{-3}; pH, 7; toluidine blue, 6.54×10^{-5} M.

reaction rate of the catalyzed reaction and blank occurs at pH 6.5—7.5.

Effect of ionic strength on the rate of catalyzed reaction was studied (Fig. 3). The ionic strength of solution varied from 0.01 to 0.35 M using NaCl and $NaClO_4$ solutions. As it is seen, change in the ionic strength of solution has no considerable effect on the reaction rate up to a value of about 0.15 M of $NaClO_4$ and 0.25 M NaCl. A further increase in the ionic strength would cause a drastic decrease in the reaction rate.

The influence of the concentration of sulfide ion and toluidine blue was also studied. The best results were obtained at about 3.13×10^{-4} M of sulfide ion and 6.45×10^{-5} M of the dyestuff.

Calibration. Under the optimum conditions described above, in the concentration range of 0.03—1.50 μg cm^{-3} the following regression equation is obtained:

$$1/t\ (\text{min}^{-1}) = 0.9685 + 1.2045\ \ \text{Se(IV)}$$
$$(r = 0.99968)$$

The limit of detection obtained from $Y_{DL}=Y_B+3s_B$[11] is 8 ng cm^{-3}, where Y_B is the average blank signal (0.9623 min^{-1} for ten replicate determinations) and s_B is the standard deviation of the blank signal (0.00520). The relative standard deviation of eight replicate determinations is 1.4% for a 1 μg cm^{-3} selenium(IV) solution.

Effect of Diverse Ions. In order to study the effect of various anions and cations on the determination of Se(IV), a fixed amount of selenium (1 μg cm^{-3}) was

Table 1. Tolerance Limits of Diverse Ions on the Determination of 1 μg cm^{-3} Selenium

Ion	Tolerated radio of foreign ion to Se(IV)

Table 2. Determination of Selenium in Kjeldal Tablets

Sample taken	Se/μg cm^{-3}		Recovery/%
cm^3	Contained	Found	
0.5	0.250	0.261	104.3
1.0	0.500	0.524	104.8
1.0	0.500	0.489	97.9
1.5	0.750	0.750	100.0
2.5	1.000	0.975	97.5

taken with different amounts of foreign ions and the recommended procedure was followed. A relative error of 3% was considered tolarable. The results are summarized in Table 1. As it is seen, all the anions and a large number of cations used have no considerable effect on the determination of Se(IV). However, as it is expected, the presense of cations which can form insoluble precipitates with sulfide ion would interfere the selenium determination. These cations were successfully removed from the solution by passing it from a column containing a strongly acidic cation exchanger of H^+ form (Merck, R-SO_3^- type).

It is interesting to note that, by this method Se(IV) can be determined in the presence of Se(VI), which has no catalytic effect on the reduction reaction of toluidine blue by sulfide ion. However, determination of total selenium in different samples would also be possible by the recommended procedure after the conversion of Se(VI) fo Se(IV), which can easily be done by using hydrochloric acid. It is interesting to note that, Se(VI) showed no catalytic effect on the reduction reaction of toluidine blue and sulfide ion.

Application. In order to evaluate the applicability of the method to the real samples, it was applied to the determination of selenium in Kjeldal tablets. One tablet (1.1142 g) containing 0.05 g selenium was dissolved, using a suitable procedure[12] and diluted with water to 1 dm^3 in a volumetric flask. It should be noticed that the final stage of the dissolution process involves the boiling of sample in 4 M HCl, which completely converts Se(VI) to Se(IV).[13] Then 10 cm^3 of this solution was diluted to 100 cm^3 with water and selenium content in different portions of the resulting solution was determined by the recommended procedure. The results are given in Table 2.

The support of this work by the Shiraz University Research Council is gratefully acknowledged.

Thermodynamic Studies of Copper(II) Sulfate in Aqueous Mannitol from Electromotive Force Measurements

Ratan L. BLOKHRA* and Anil K. SHARMA
Department of Chemistry, Himachal Pradesh University, Summer Hill, Shimla 171005, India
(Received February 18, 1991)

Electromotive force measurements of the cell Cu-Hg/$CuSO_4$(m)/Hg_2SO_4(s)/Hg have been made at 288, 298, 308, and 318 K for mannitol composition X=5, 15, and 25% (w/w) in water. The standard emf values of the cell at different temperatures and at different composition of mannitol+water mixtures have been determined by an extrapolation method. These have been utilized to evaluate the mean activity coefficient of copper(II) sulfate. The standard free energy for the cell reaction, and the primary medium effects upon $CuSO_4$ have been evaluated. The standard thermodynamic quantities for the process of transfer of $CuSO_4$ from water to the mannitol solution have been calculated from the values of the standard potential. The transfer parameters have been split into the electrostatic and chemical contributions and the results have been explained in the light of ion-solvent interactions and structural contributions to solvents.

The behavior of electrolytes in aqueous carbohydrate solutions has recently been a subject of interest.[1-6] The study of electrolytes in carbohydrate solutions is of great importance in the understanding of the physiological and biological processes associated with life. Blokhra et al.[7-9] have reported the transfer energetics of copper(II) sulfate in diethylene glycol-water, ethylene glycol-water, dioxane-water mixtures, and urea-water solutions. In continuation with the previous study, the present investigations have been carried out by using copper(II) sulfate in different mannitol+water mixtures. By setting a suitable cell, we carried out electromotive force measurements. The temperature variation of the standard potential was used to calculate different thermodynamic quantities. From these quantities and transfer energetics, we can obtain information about the thermodynamic properties of $CuSO_4$ in these solvents and about the properties and structure of the solvents. The activity coefficients of copper(II) sulfate in various mannitol+water mixtures have also been calculated.

Experimental

Mannitol and copper(II) sulfate were of analytical grade and were used without further purification. Water used was triply distilled having specific conductance of the order of 10^{-14} $m^{-1}\,\Omega^{-1}$. Solvents of various compositions were made by weight.

The emf cell used for the present study was as previously described.[7-9] Copper amalgam was prepared by electrolyzing a copper(II) perchlorate solution with a mercury pool as cathode, as described elsewhere.[10] At room temperature, a two-phase amalgam is formed between 0.0032 and 24.1% copper (w/w).[11,12] Within this range the potential will be independent of composition, and the exact composition of copper is therefore unimportant.[13] All precautions taken earlier[7] were observed in the present investigation as well.

The emf measurements were made with a digital potentiometer (Equip Tronics, Bombay) having precision of ±0.1 mV. All measurements were made in water thermostat having fluctuation of $<\pm 0.1$ °C. The cell attained equilibrium after about one hour in all the solvent mixtures. The concentrations of the solutions were occassionally checked with a conductivity bridge and no significant change was detected.

Results and Discussion

The emf (E) values of the cell are reported in Table 1.

Assuming copper(II) sulfate to be dissociated in the solutions studied, the standard molal potentials, $E^{\ominus}_{m}$, of the cell:

$$\text{Cu–Hg/CuSO}_4\text{(m), mannitol + water mixtures/Hg}_2\text{SO}_4\text{(s)/Hg}$$

in different solutions have been estimated satisfactorily from the Hitchcock[14] type equation because concentration of solutions is <0.1 m.

$$E'_{o} = E + k\log m - k\left(\frac{AZ^{+}Z^{-}I^{1/2}}{1+Ba_{o}I^{1/2}}\right) = E^{\ominus}_{m} - kB'I, \quad (1)$$

where I is the ionic strength of the solution, m is the molal concentration of the solution, A and B are the Debye–Hückel constants, a_o is the ion-size parameter, Z^+ and Z^- are the valencies of the cation and anion, respectively, and k equals 2.3026 RT/F. B' is a constant quantity and it is a measurement of the interaction energy.[14] For each solvent at any temperature $E^{\ominus}_{m}$ was obtained by the usual extrapolation technique and the procedure is essentially the same as that used in our previous determinations.[7–9]

The dielectric constant (D_s) for the various mannitol + water mixtures were taken from the literature.[15] The densities (ρ_o) and the Debye parameters were determined experimentally[16] and from the expressions given in standard electrochemistry book.[17] The parameters A, B, and D_s are given in Table 2.

The values of activity coefficients, $\lambda_{\pm}$, can be evaluated from the relation.[18]

$$E = E^{\ominus}_{m} - k\log m\lambda_{\pm}. \quad (2)$$

From Eq. 1 it is expected that E'_o should be linear function of I when a suitable value of the ion-size parameter is chosen. The intercept of the plot at I=0 gives the value of $E^{\ominus}_{m}$. The a_o values for the various solvent mixtures at different temperatures are chosen in such a way that the deviation from linearity of the plot of E'_o against I is minimum. The following a_o values were selected for the different mannitol + water mixtures:

Mannitol (wt%)	5	15	25
a_o/Å	5.0	5.1	5.2

The values of $E^{\ominus}_{m}$ have average standard deviation of ±0.3 mV, these values at different temperatures for various mannitol + water mixtures are given in Table 3. The values of $E^{\ominus}_{m}$ could be expressed as a function of temperature in the following form:

$$E^{\ominus}_{m} = a - b(T-298.15) - c(T-298.15)^2, \quad (3)$$

where T is the temperature in K. The constants a, b, and c are given in Table 4.

The mean activity coefficient $\lambda_{\pm}$ of copper(II) sulfate

5	0.2655 (0.2665)	0.2615 (0.2615)	0.2540 (0.2533)	0.2470 (0.2449)
15	0.2620 (0.2620)	0.2560 (0.2560)	0.2490 (0.2490)	0.2405 (0.2419)
25	—	0.2505 (0.2505)	0.2435 (0.2434)	0.2350 (0.2358)

in different solvent was calculated with the help of Eq. 2 and these values at 298 K are listed in Table 5. An error of ±0.1 mV in emf values results in an error of ±0.002 in the value of $\lambda_{\pm}$.

The values of the activity coefficient in water (0% mannitol) are comparable with the literature values[23,24] at 298 K e.g. it is 0.153[23] and 0.150[24] for 0.1 m $CuSO_4$, 0.438[23] for 0.01 m $CuSO_4$, showing thereby that there is consistency in the measurements and the estimation of the molal activity coefficient of copper(II) sulfate. The values of the activity coefficient at a particular molality have been found to decrease with increasing mannitol content in the medium except 4.00, 6.00, and 8.00 m solutions in water. The decrease in the values may be attributed to the lowering of the dielectric constant of the medium and the abnormal lower values at lower concentration in water may be attributed to the increase in the ion-ion interactions or partial hydrolysis of the copper sulfate solution.

The standard thermodynamic function $\Delta G^{\ominus}$ for the cell reaction:

$$Hg_2SO_4(s) + Cu\text{-}Hg(s) \rightleftarrows 3\ Hg(s) + CuSO_4\ (solvated)$$

has been calculated from the temperature variation of the standard molal potential in mannitol + water solvent using

$$\Delta G^{\circ} = -nFE^{\ominus}_{m} = -2F[a - b\,(T-298.15) - c(T-298.15)^2]. \quad (4)$$

The calculated thermodynamic functions of the cell at 288—318 K in 0, 5, 15, and 25% (w/w) of mannitol + water solvents are recorded in Table 6. It is evident from Table 6 that all the thermodynamic functions are negative. The magnitude of the standard free energy changes increases with an increase in either the mannitol content in the solvent mixture or the temperature of the solvent system which may be attributed to the decrease in the dielectric constant of the medium. As the dielectric constant decreases, more work is required to keep the ions apart, and therefore, less work is produced by the electrode reaction and more positive free energy changes results. There is less spontaneity, because of decrease dissociation at lower dielectric constants.

Table 6. Standard Molal Free Energy of the Cell Reaction in Various Mannitol + Water Solvents at 288—318 K

T/K	Mannitol/wt%			
	0	5	15	25
	$-\Delta G^{\circ}$/kJ mol^{-1}±0.020			
288	52.69	51.24	50.57	—
298	51.24	50.47	49.41	48.35
308	49.89	49.02	48.06	46.99
318	48.54	47.67	46.42	45.36

The primary medium effect represents the difference in ion solvent interaction for copper(II) sulfate at the standard state in the particular solvent and in water. It is a measure of the change of Gibbs free energy which accompanies the transfer of one mole of copper(II) sulfate from the standard state in water to the standard state in respective solvent. Thus the primary medium effect measures the change in escaping tendency of copper(II) sulfate in the transfer from a standard state in one solvent to a standard state in another solvent. The primary medium effect, $\log {}^{s}_{w}\gamma^{\ominus}_{\pm}$ (mole fraction scale), of the mannitol + water solvents upon $CuSO_4$ were computed by the usual relation[19,20] at 288—318 K. The results are given in Table 7. It is seen from Table 7 that addition of mannitol changes the behavior of the medium upon the ions and the effect upon the ions is greater at higher concentrations of mannitol. Further it shows a decreasing tendency with increasing temperature. This suggests that the escaping tendency of $CuSO_4$ is greater in mannitol + water solvents than in water.

The standard thermodynamic quantities for the transfer of one mole of copper(II) sulfate from the standard state in water (w) to the standard state of respective solvents (s) were evaluated at 288—318 K with the help of usual relations.[19,20]

$$-2F[(E_m)_s - (E_m)_w] - 2\times 2.3026RT\log(M_s/M_w) = \Delta G^{\ominus}_{t} = O - PT + QT^2 \quad (5)$$

and the corresponding values for solutions of copper(II) sulfate in the various solvent media at 288—318 K are given in Table 8.

It is quite evident from Table 8 that the standard Gibbs free energy of transfer, $\Delta G^{\ominus}_{t}$, becomes more and more positive with the increase of mannitol content in the medium. The positive $\Delta G^{\ominus}_{t}$ values suggest that the elactrolyte is in higher free energy state in mannitol + water mixtures than in water so that copper(II) sulfate has more affinity for water than mannitol + water mixtures. The transfer of copper(II) sul-

fate from water to mannitol + water mixture is, therefore, not a spontaneous process with the solute in standard state in either medium. Ahluwalia and Sharma[21] suggested that the transfer of structure breaking solutes should be accompanied by a positive free energy change thereby making the transfer of there solutes from water to the mixed solvents thermodynamically unfavorable. The positive $\Delta G_t^\ominus$ values, therefore suggests that copper(II) sulfate behaves as a structure breaker in water. The positive $\Delta G_t^\ominus$ values also suggest that water is more basic than mannitol + water solvents and basicity decreases with increasing the mannitol concentration in the solvents. This view is also consistant with the fact that the escaping tendency of copper(II) sulfate is greater in mannitol + water solvent than in the pure aqueous solutions (Table 7, medium effect). The effect of temperature on $\Delta G_t^\ominus$ shows decrease in the contribution for the effects of the ions on the structure of the solvents.

The values of the transfer entropy and enthalpy reflect the complicated nature with regard to the contributions from the effects of the ions on the structure of the solvents. The values of $\Delta H_t^\ominus$ and $\Delta S_t^\ominus$ are negative at 318 K and at 15% and 25% mannitol at 308 K, while values at other temperatures and concentration are positive. The negative values suggest that the tendency of order created by copper(II) sulfate in 15% and 25% mannitol + water mixtures at 308 K and 5%, 15%, and 25% mannitol + water mixtures at 318 K is more than in pure water. However this tendency is less in 5% (w/w) mannitol + water mixture at 308 K and in all the solvents at 288 and 298 K in comparison with pure water. This shows reintroduction of some order in mannitol + water mixtures at higher temperatures. Copper(II) sulfate thus breaks more structure in water than in mannitol + water solvent at higher temperatures.

The process of transfer is associated with the transfer of charged species i.e. Cu^{2+} and SO_4^{2-} ions from water to the aqueous mannitol medium. It may, therefore, be possible to split the $\Delta G_t^\ominus$ values into two parts as suggested earlier[22] an electrostatic part, $\Delta G_{t,el}^\ominus$ corresponding to a change in dielectric constant of the medium, and a nonelectrostatic or chemical part, $\Delta G_{t,ch}^\ominus$, arising from specific chemical interactions between the ions and the solvent. Thus

$$\Delta G_t^\ominus = \Delta G_{t,el}^\ominus + \Delta G_{t,ch}^\ominus. \quad (6)$$

The electrostatic contribution $\Delta G_{t,el}^\ominus$, $\Delta H_{t,el}^\ominus$, $\Delta S_{t,el}^\ominus$, and the chemical contributions $\Delta G_{t,ch}^\ominus$, $\Delta H_{t,ch}^\ominus$, $\Delta S_{t,ch}^\ominus$ have been calculated as described earlier.[7-9] These values so calculated at 298 K are presented in Table 9. It is obvious from Table 9 that $\Delta G_{t,ch}^\ominus$ and $\Delta G_{t,el}^\ominus$ are increasingly positive in all mannitol + water mixtures. This indicates that transfer of $CuSO_4$ from water to mannitol + water mixtures is not favored as far as chemical interactions are concerned. This suggests that all mannitol + water mixtures are less basic than pure water and this enhances with increasing mannitol concentration. The electrostatic contribution of enthalpy and entropy of transfer goes on decreasing with increase in mannitol concentration. Same is the trend for chemical contribution. Taking an overall view it can be inferred that the chemical contribution or solvation predominates over electrostatic factor, resulting in an overall unfavorable effect on the transfer process from water to mannitol + water mixtures. The negative values of these parameters may be due to the introduction of order in mannitol + water mixtures.

Table 9. Electrical and the Chemical Parts of the Thermodynamic Quantities Accompanying the Transfer of Copper(II) Sulfate from Water to Mannitol + Water Mixtures at 298 K

Mannitol	$\Delta G_{t,el}^\ominus$	$\Delta G_{t,ch}^\ominus$	$\Delta H_{t,el}^\ominus$	$\Delta H_{t,ch}^\ominus$	$\Delta S_{t,el}^\ominus$	$\Delta S_{t,ch}^\ominus$

Spectrophotometric Determination of Palladium Using 2-(2-Hydroxyimino-1-oxoethyl)thiophene

Anoop Kumar CHHAKKAR and Lajpat Rai KAKKAR*
Department of Chemistry, Kurukshetra University, Kurukshetra 132119 (Haryana State), India
(Received February 28, 1991)

A highly sensitive and selective method for the determination of palladium in trace amounts is developed by complexation of Pd(II) with 2-(2-hydroxyimino-1-oxoethyl)thiophene (INAT) at pH 2.8—6.5, adjusted with diluted acetic acid. The colored species is quantitatively extracted into chloroform, whose absorbance is measured at 425 nm. The method is free from the interference of a large number of elements of great analytical importance. The usefulness of the method is further tested by analyzing different samples and the results obtained are quite satisfactory.

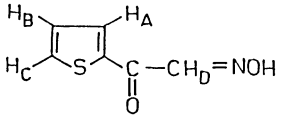
Though a number of methods using organic reagents[1-4] have been developed for the spectrophotometric determination of palladium, but most of them suffer from disadvantages[3,4] particularly due to the serious interferences from several elements of interest and poor sensitivities. Complexes potentially useful for the solvent extraction of palladium are those formed with 8-quinolinethiol[5,6] and thiocyanate.[7] There are also methods available where complexes are formed with hydroxyimino-substituted ketones[8-11] and some of their derivatives.[12] The efficiency of these extractions as separatory methods in the presence of other platinum and associated base metals has received relatively little attention. In many instances, the problem of coextraction has been related to the degree of interference with the colorimetric measurements. Taking into account all these factors, modern analytical techniques for the determination of trace amount of noble metals are growing in demand to the extent that one can deal effectively with a few μg of metals so as to achieve very acceptable results.

Consequently, it has been found while working that Pd(II), in microgram amounts, forms a yellow complex with 2-(2-hydroxyimino-1-oxoethyl)thiophene [(2-[α-(hydroxyimino)acetyl]thiophene, abbrev. to INAT] in diluted acid solutions (pH 2.8—6.5) which is extractable into chloroform whose absorbance is measured at 425 nm, where the absorbance of the reagent blank is minimal.

Experimental

Reagents. A stock solution of palladium containing 1 mg Pd ml^{-1} is prepared by dissolving an accurately weighed amount of $PdCl_2$ (Johnson Metthey & Co,, London) in a minimum volume of hydrochloric acid and is standardized gravimetrically.[13] Stock solutions with lower concentrations of the metal ion at the μg ml^{-1} level are prepared by suitable dilutions therefrom.

Preparation of 2-(2-Hydroxyimino-1-oxoethyl)thiophene:



Sodium metal (1.15 g) is dissolved in 23 ml absolute ethanol and to the solution 6.7 ml of isopentyl nitrite are added slowly under cooling and stirring at the same time. This is followed by the addition of 5.4 ml of 2-acetylthiophene. The mixture is kept overnight at 0 °C. The brown sodium salt thus obtained is washed well with diethyl ether and dried in air. It is then dissolved in ice-water and neutralized with glacial acetic acid. The creamish solid is filtered, dried and crystallized from ethanol, (70% yield): Mp 115 °C; IR (Nujol) 3186 (ν_{O-H}, intramolecular hydrogen bonding), 1592 ($\nu_{C=O}$, intramolecular hydrogen bonding) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.00—7.18 (1H, m, H_B), 7.65 (1H, d, $J_{C,B}$=5.4 Hz, H_C), 7.89 (1H, s, H_D), 8.03 (1H, d, $J_{A,B}$=3.6 Hz, H_A); Found: C, 46.23; H, 3.13; N, 8.95%. Calcd for $C_6H_5NO_2S$: C, 46.45; H, 3.22; N, 9.03%. 0.1% solution of INAT in ethanol is used.

Buffer solution is prepared with sodium acetate–acetic acid (1 mol dm^{-3}).

Sample solutions are obtained by mixing the solutions of palladium(II) and other metal ions in a suitable proportion as shown in Table 2.

Pd-Charcoal Catalyst (Aldrich 20, 568-0): A weighed amount of the sample is brought into solution by heating with HCl and HNO_3 (3:1). Charcoal is filtered off from the solution and the excess of HNO_3 is decomposed completely by evaporating it to dryness. The residue is treated with water and diluted HCl and processed for the determination of palladium as described below in the procedure.

Procedure for the Determination of Palladium. To the sample solution containing 50 μg Pd(II) and/or other ions in a 100 ml separatory funnel, add 1 ml of the 0.1% INAT, 5 ml of buffer solution and the volume is made to 20 ml with distilled water (pH 4.75—4.78). The contents are gently mixed and equilibrated once with an equal volume of chloroform for one min. The two phases are allowed to separate. The organic phase is filtered through a Whatman's filter paper (No. 41) into a 25 ml volumetric flask which is then filled upto the mark with the pure chloroform. The absorbance of the yellow complex is measured at 425 nm against reagent blank on UV-visible 140-02 spectrophotometer (Shimadzu, Japan) using 1 cm cells and the amount of the metal ion is determined from the standard curve obtained by plotting different concentrations of Pd(II) and the corresponding absorbance values.

Results and Discussion

The extractability of the palladium(II)–INAT complex is affected by the kind of acid. The extractability

Table 1. Effect of Various Parameters on the Absorbance of Palladium-INAT Complex

pH[a]	2.10	2.5	2.8—6.5	7.5	8.6	9.6	10.1	10.65

a) Figure in brackets indicates the amount of the metal ion in mg. b) Sample Nos. 13, 14, 15, 16, and 17 are analogous to palladium-silver, palau, jewellery alloys, cooperite, and braggite ores, respectively. c) Reported value.

at constant acidity decreases in the following order $CH_3COOH > H_2SO_4 > HNO_3 > HClO_4 > H_3PO_4 > HCl$. Therefore, acetic acid is preferred for adjustment of pH of the solution.

The effect of various parameters namely, pH, reagent concentration and equilibration time on the absorbance of Pd(II) complex is depicted in Table 1. It is evident from the study of these variables, that for getting optimal absorbance for 50 μg Pd, pH 2.8—6.50, 0.7—5.0 ml (0.1% INAT in ethanol), 0.5—5 min shaking time are the necessary conditions to transfer quantitatively the colored species into chloroform, whose λ_{max} lies at 425 nm. The absorbance shows a downward trend if 1,2-dichloroethane, ethyl acetate, benzene, toluene, carbon tetrachloride, dichloromethane, and 1-pentanol, respectively, are used as extractant in place of chloroform.

Effect of Diverse Ion. Under the optimum conditions as given in the procedure, Os(VIII), Re(VII), Mo(VI), W(VI), Cr(III,VI), V(V), Ce(IV), Ti(IV), Se(IV), Pt(IV), Rh(III), As(III), Fe(II,III), Ni(II), Cu(II), Co(II), Mn(II), Zn(II), Cd(II), Hg(II), Be(II), Sr(II), Ba(II), Ca(II), Ag(I), each 1 mg ml^{-1}; in 20 ml aqueous volume, do not show any absorbance and hence are noninterfering.

Chloride (150), sulfate (400), nitrate (500), phosphate (100), acetate (100), citrate (150), tartrate (200), fluoride (75), oxalate (10), added initially to the aqueous phase, do not affect the absorbance of the Pd(II)-INAT complex. The figure in parentheses indicates the amount of sodium salt of the anion in milligram.

Spectral Studies and Stoichiometry of the Complex. The spectrum of the Pd(II)-INAT complex shows absorption maxima at 425 nm. Beer's law is obeyed in the range 0—4 μg Pd ml^{-1} with molar absorptivity of 3.27×10^4 $dm^3\,mol^{-1}\,cm^{-1}$ and Sandell's sensitivity is 0.003 μg Pd cm^{-2}. The ratio of metal to INAT in the extracted species is determined by Job's method of continuous variations[14] as modified by Vosburgh and Cooper[15] by taking equimolar solutions (1.8793×10^{-4} M, 1 M=1 mol dm^{-3}) of both Pd and INAT at three different wavelengths, namely, 400, 425, and 450 nm. The sharp break in the three curves obtained indicates that metal and INAT are present in the ratio of 1:2 in the complex. This is further confirmed by mole ratio method.[16]

Back Extraction. The metal ion of the Pd(II)-INAT complex in the organic phase can be easily stripped by shaking the organic phase with an equal volume of 0.5 M HCl.

Applications. The proposed method for the

Since only C.A. is available, detailed information about the work could not be obtained.	4
5.	42 μg Pd, 3 ml of 1 M HCl, in 10 ml volume	1×10^{-3} M 2-Thiazolecarbaldehyde 2-quinolylhydrazone in C_6H_6 (10 ml), 625 nm	i) upto 4.2 μg Pd ml^{-1} ii) 1.93×10^4 $dm^3\ mol^{-1}\ cm^{-1}$ iii) 0.0055 μg Pd cm^{-2}	I^-, SCN^-, EDTA, Hg(II), Au(III), Re(VII), Ir(III), W(VI); low tolerance limits for Hg(II), Au(III), Re(VII), Ir(III), W(VI) which give yellow insoluble precipitates.	Pt(II) forms blue complex, behavior of Os(VIII), Rh(III), Ru(III) are not studied.	20
6.	50 μg Pd, 1 ml 0.1% INAT in ethanol, 5 ml buffer solution (Sodium acetate–acetic acid) pH (4.75—4.78), in 20 ml volume (PROPOSED METHOD)	$CHCl_3$ (20 ml), 425 nm	i) 0—4 μg Pd ml^{-1} ii) 3.27×10^4 $dm^3\ mol^{-1}\ cm^{-1}$ iii) 0.003 μg Pd cm^{-2}	26 Cations and 9 anions do not show any effect on the absorbance of Pd complex.	High sensitivity and selectivity, good tolerance limits, easy back extraction of the metal ion from the solvent.	(PROPOSED METHOD)

microdetermination of palladium is highly accurate and is free from the interference of a large number of elements especially the other platinum metals. The results are quite reproducible with a standard deviation of ±0.002. It compares favorably with the existing methods in terms of its sensitivity and selectivity (Table 3). Moreover, the recovery of Pd(II) from the organic solvent can be easily effected by simple back extraction. The validity of the method is further tested by analyzing satisfactorily several samples of varying complexity (Table 2).

Our sincere thanks are due to the Chairman, Department of Chemistry, Kurukshetra University, Kurukshetra for providing laboratory facilities and to UGC, New Delhi for financial support to one of us (AKC).

Unusual Solvent Effect on the Cycloadditions of Aromatic Nitrile *N*-Oxide with Alkyl Substituted *p*-Benzoquinones in Ethanol-Water Systems

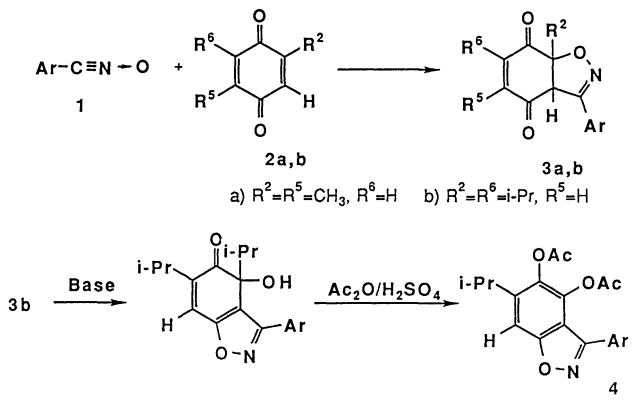
Yukihiko INOUE, Koji ARAKI, and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo, Roppongi 7-22-1, Minato-ku, Tokyo 106
(Received March 18, 1991)

The second-order rate constants of 1,3-dipolar cycloaddition reactions of 2,6-dichlorobenzonitrile *N*-oxide (**1**) with 2,5-dimethyl-*p*-benzoquinone (**2a**) or 2,6-diisopropyl-*p*-benzoquinone in various solvents at 20 °C were determined by spectrophotometric method. The rate of **1** and **2a** in ethanol : water=60 : 40 solution was 5.55×10^{-2} $dm^3\,mol^{-1}\,s^{-1}$, which was fourteen folds of that in chloroform (3.9×10^{-3} $dm^3\,mol^{-1}\,s^{-1}$). This solvent effect and the low solubility of the cycloadduct in aqueous ethanol were successfully applied to the cycloadduct synthesis.

Aromatic nitrile *N*-oxides undergo 1,3-dipolar cycloaddition with alkyl di-substituted *p*-benzoquinones (**2**) at their C=C double bond to give cyclohexenedione-fused 2-isoxazoline derivatives (**3**) in good yields.[1] Some of the cycloadducts were isomerized into isoxazole derivatives by base-induced ring system transformation,[2] and subsequently by dienone–phenol rearrangement-like reaction into isoxazole-fused catechol derivatives (**4**), which exhibit barnaclecide activity.[3]

In the synthetic pathway to the potentially useful compounds, the step of the nitrile *N*-oxide cycloaddition is desirable to enhance the reaction rate and to simplify workup processes involved. In benzene solution, the reaction had to be carried out for a day to complete the reaction. The product could be obtained after chromatographic separation and subsequent recrystallization to remove unreacted quinone. The rate constants of nitrile *N*-oxide cycloaddition in various solvents were reported mostly in the early seventies.[4] In general, there is little or only a little solvent effect on the rate, and an increase of solvent polarity causes slight decrease of the rate in the cycloaddition. Chang et al. reported[5] that the rate constant of cycloaddition of 2,4,6-trimethylbenzonitrile *N*-oxide with 1,2-bis(trifluoromethyl)fumaronitrile in acetone-d_6 was fourteen times smaller than that in benzene-d_6. This is the only report of solvent effect on the cycloaddition of nitrile *N*-oxide to a C=C double bond exhibiting over ten folds difference. Recently, Breslow and Rideout reported remarkable rate acceleration for the Diels–Alder reaction in aqueous media.[6] Therefore, it is of interest to investigate the cycloaddition reactivity of nitrile *N*-oxide in aqueous solution. As far as we know, the reactions of nitrile *N*-oxides with bases or other nucleophiles in aqueous dioxane solution were the only report of the reaction of nitrile *N*-oxides in aqueous solution[7] and no report has appeared to date as to the 1,3-dipolar cycloaddition of nitrile *N*-oxides in aqueous media.

In the present research, we have examined the cycloaddition reaction of nitrile *N*-oxide with substituted *p*-benzoquinones in aqueous ethanol or other organic solvents in order to optimize the cycloaddition conditions.



Scheme 1. Cycloaddition reaction of nitrile *N*-oxide with alkyl substituted *p*-benzoquinones (**2a**—**b**) and subsequent ring conversion reaction of the cycloadduct **3b**.

Experimental

Electronic spectra were recorded with JASCO Ubest-50 spectrometer. IR spectra of the nitrile *N*-oxide solutions were recorded with JASCO IR-700 spectrometer in KRS cell (cell length 0.1 mm). Liquid chromatography was performed with ODS column (Cica-Merck LiChrospher 100 RP-18, acetonitrile : water=70 : 30, UV 254 nm). All the reactions and measurement were carried out at 20 °C.

Reagents and Solvents. 2,6-Dichlorobenzonitrile *N*-oxide (**1**) was prepared from corresponding benzaldehyde oxime by Grundmann's method[8] and recrystallized from aqueous ethanol. All the procedures were carried out keeping temperature below 40 °C to avoid isomerization. 2,5-Dimethyl-*p*-benzoquinone (**2a**) and 2,6-diisopropyl-*p*-benzoquinone (**2b**) were synthesized from corresponding alkyl-substituted phenols by oxidation using sodium dichromate–sulfuric acid.[9] Recrystallization from hexane and vacuum distillation were used for the purification of **2a** and **2b**, respectively. Organic solvents were obtained commercially and used after distillation with desiccants. Ion-exchanged water was further purified by ultrafiltration. Composition of the water-ethanol mixture was reported in volume per cent.

The Reactions of 1 with 2a; Kinetic Study. A sample solution containing **1** and **2a** (1.00×10^{-2} mol dm^{-3} for each of the reactant) was prepared freshly, and the progress of the reaction was monitored by spectrometer at 20 °C. Amounts

of the product (**3a**) were calculated from the absorbance around 380 nm, where n–π^* absorption of **3a** was observed. The rate constants k_2 were determined according to the second-order rate equation. The same procedure was applied for determination of rate constants of **1** and **2b**.

The Reactions of 1 with 2b; Syntheses of 7-(2,6-Dichlorophenyl)-1,3-diisopropyl-8-aza-9-oxa-[4.3.0]bicyclonona-3,7-diene-2,5-dione (3b). The reactions were carried out with 1.00 mmol for each of the reactant. Stirring conditions were kept at constant throughout all experiments. The progress of the reaction was followed by HPLC analyses. In all experiments, only the formation of **3b** was observed up to 60 min. The conversions were calculated from the peak intensity of unreacted **2b**. After the reaction, precipitated **3b**, if existed, was collected by filtration, dried in vacuo, and weighed.

Results and Discussion

The Kinetic Investigation of the Cycloaddition Reaction of 1 with 2a. The reactions of **1** with **2a** were carried out in various solvents. Figure 1 represents the typical spectral change during the reaction in ethanol. In all cases, isosbestic points were observed throughout the spectral change, and the time course of the reaction followed the second-order rate equation. Therefore, contribution of side reactions such as nitrile *N*-oxide isomerization or dimerization was thought negligible under these reaction conditions. IR spectra of the product isolated from the reaction mixture was identical with that of an authentic sample of **3a**. The rate constants of these reactions were summarized in Table 1.

In the case of organic solution, the reaction was slowest in chloroform and only four folds differences were observed for the solvents examined. But in ethanol : water=60 : 40 solution, over fourteen folds of acceleration compared to that in chloroform was observed. Further increase of water content resulted in precipitation of the product (**3a**) during the reaction, and the rate constants in aqueous ethanol containing more than 60 vol% could not be determined. Logarithmic plot of the rate constants vs. solvent polarity parameters, dielectric constants (ε),[10] and E_T values,[11] are shown in Fig 2.

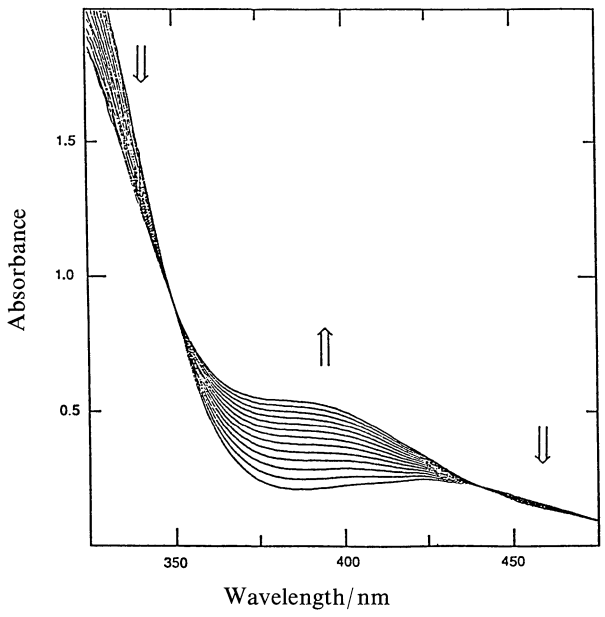


Fig. 1. Electronic spectra of **1** and **2a** in ethanol from 4 min to 64 min after the reaction was started. Substrate concentration; 1.00×10^{-2} mol dm^{-3}, Reaction temperature 20 °C.

Both curves have concave shapes, suggesting that the mode of solvent effect on the reaction is different in lower and higher region of the solvent polarity. At the lower side of the solvent polarity from cyclohexane to chloroform, the rate constants decreased as the polarity increased. In this region, rate constants exhibited normal correlation with solvent polarity.[4] But in the solvents of higher polarity, the rate constants increased as the polarity increased. Furthermore, the rate constant in ethanol : water=60 : 40 solution was fourteen times larger than that in chloroform. This solvent-induced rate acceleration is fairly large as the solvent effect on 1,3-dipolar cycloaddition reaction to C=C double bond. It is reported that the reaction of 2,4,6-trimethylbenzonitrile *N*-oxide and 1,2-bis(trifluoromethyl)fumaronitrile exhibits similar extent of solvent effect.[5] This reaction in acetone-d_6 containing water is fourteen times slower than that in benzene-d_6. In this reaction, the increase of solvent polarity caused the decrease of the rate constant. This is therefore still within the category of the normal solvent effect on 1,3-dipolar cycloaddition. However, the reaction of **1** and **2a** was accelerated in highly-polarized aqueous ethanol solvent. No other report of solvent effect exhibiting over ten folds of rate constants difference has appeared as nitrile *N*-oxide cycloaddition to C=C double or C≡C triple bond, and the results presented here are the unusual type of solvent effect on the nitrile *N*-oxide cycloaddition.

To understand this solvent effect, we tested the effect of solvation to the substrates (**1** and **2a**) and to the

Ethanol : water=60 : 40	424(1.46)	322(2.43)	254(4.32)

a) Could not be determined due to the absorption of solvent.

product (**3a**) by spectroscopic method. Peak positions of C≡N stretching band of **1** ($\nu_{C\equiv N}$) in several solvents are summarized in Table 2, which might reflect the solvation to the nitrile *N*-oxide moiety of **1**. The $\nu_{C\equiv N}$ increase monotonously as the solvent polarity increased (except for chloroform), and the direct relationship between $\nu_{C\equiv N}$ and rate constants was not observed.

Absorption maxima of **2a** in different solvents are shown in Table 3. The band above 400 nm is assigned to be an n–π^* transition band and the stronger two bands are due to π–π^* transitions.[12] These three bands exhibited ordinary solvatochromic shifts, i.e., hypsochromic shift for n–π^* and smaller bathochromic shift for π–π^* as solvent polarity increased.

Table 4. Absorption Maxima of the n–π^* Band of **3a** in Various Solvents at 20 °C

Solvents	λ_{max}/nm (log ε)
Cyclohexane	390 (2.10)
Benzene	389 (2.11)
Chloroform	388 (2.10)
Ethyl acetate	385 (2.10)
Ethanol	384 (2.10)
Ethanol : water=80 : 20	384 (2.07)
Ethanol : water=60 : 40	383 (2.07)

The effect of solvation to the product (**3a**) was examined by electronic spectroscopy. Table 4 shows the absorption maxima of n–π^* transition of **3a**. The band exhibited hypsochromic shift monotonously and the molar extinction coefficient of the absorption slightly decreased as solvent polarity increased. These results did not reproduce the different mode of solvent effect,

and the observed rate difference could not be explained from the solvation of substrates or product. Therefore, other reasons, such as cage effect of the solvent or solvophobic effect[6] of the substrates, may play a role in this unusual solvent effect.

Synthetic Application of Unusual Solvent Effect in Aqueous Ethanol Solutions. The Reaction of 1 with 2b. In an ethanol: water=50: 50 solution, the precipitate of cycloadduct **3a** was formed soon after the solutions of **1** and **2a** were mixed, and the measurement of the time course of the reaction by electronic spectrum was unsuccessful. But this fact indicated that aqueous ethanol system offered two advantage over organic solvent systems from synthetic point of view. One is acceleration of the reaction rate and the other convenient isolation of the product. Therefore, we applied this solvent system to the cycloadduct synthesis.

For this purpose, 2,6-diisopropyl-*p*-benzoquinone (**2b**) was employed as a quinone reactant because the cycloadduct **3b** can be converted to isoxazole-fused catechol derivatives by base-catalyzed rearrangement.

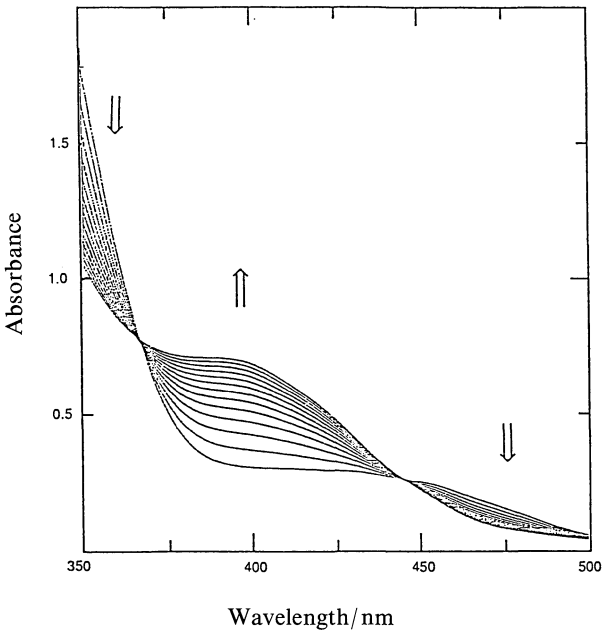

Fig. 3. Electronic spectra of **1** and **2b** in ethanol from 4 min to 64 min after the reaction was started. Substrate concentration; 1.00×10^{-2} mol dm^{-3}, Reaction temperature 20 °C.

Second order rate constants of **1** and **2b** in homogeneous media were determined by spectrophotometric method. Electronic spectra showed isosbestic points throughout the reaction, indicating the reaction proceeded without any side reactions (Fig. 3). The results are shown in Table 5. The rate constants are about twice as large as those of **1** and **2a**, and solvent effect on the rate is essentially the same as that on the reaction of **1** and **2a**. It was reported in the previous papers[13] that the reactions of **1** and **2a** or **2b** were mainly controlled by HOMO(quinone)–LUMO(nitrile *N*-oxide) interaction. Therefore, the difference between the rate constants of **1** and **2a** and those of **1** and **2b** could be ascribed to the electron donating effect of isopropyl substituents of **2b**.

In this reaction, the formation of a precipitate of **3b** was observed in ethanol: water=60: 40 system. The reaction in millimolar scale was carried out in this solvent system, and the results were shown in Table 6. Conversions determined from unreacted **2b** showed good correlation with the rate constants shown in Table 5. In the case of benzene which is frequently used as a solvent for cycloaddition of nitrile *N*-oxide, 69% of unreacted **2b** remained in the reaction mixture after 30 min. But in ethanol: water=60: 40 solvent, the reaction almost completed within 30 min and 77% of **3b** could be isolated as a precipitate by simple filtration. The filtrate was pure **3b** containing neither unreacted quinone nor nitrile *N*-oxide, and this filtrate could be used directly for the subsequent base-induced rearrangement without further purification.

In conclusion, cycloaddition reactions of nitrile *N*-oxide with quinones exhibited unusual solvent effect and were accelerated in aqueous ethanol. In this reaction, the cycloadduct could be isolated as a precipitate in pure form. Therefore the synthesis of cycloadduct was successfully optimized.

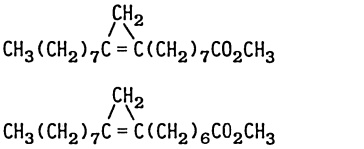
Absolute Stereochemistry and Novel Ring-Opening Oxidation of Methyl (*R*)-2-Hydroxysterculate

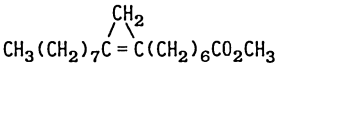
Munehiro NAKATANI and Tsunao HASE
Department of Chemistry, Faculty of Science, Kagoshima University, 1-21-35 Korimoto, Kagoshima 890
(Received March 22, 1991)

A cyclopropene-ring-containing fatty acid ester, methyl (*R*)-2-hydroxysterculate, was isolated from *Hibiscus rosa-sinensis* along with methyl sterculate and malvalate. The stereochemistry of the asymmetric carbon at C-2 was determined as *R* by applying a dibenzoate chirality method, and a mild air oxidation afforded two conjugated enone isomers accompanying a ring opening.

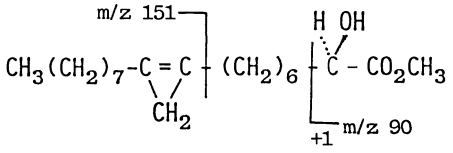
In continuous study on the seed germination inhibitors from *Hibiscus rosa-sinensis* (Malvaceae),[1,2] we isolated a third cyclopropene-ring-containing fatty acid ester, methyl (*R*)-2-hydroxysterculate (**1**), from the methanol extract of the root bark along with two known cyclopropenoids, methyl sterculate (**2**)[3] and malvalate (**3**).[4] Although these compounds **1**—**3** may be present as free acids or glycerides in the plant, they also showed inhibitory activites to lettuce seed germination.



2



3



1

Compounds containing cyclopropane or cyclopropene ring in a fatty acid chain have been known to affect strongly insect metabolism.[5–9] The cyclopropenoids of sterculic acid, malvalic acid and their methyl esters (**2** and **3**), when fed to some noxious insects, sterilized their females[5,6] and reduced pupation and pupal weight of their larvae.[7,8] Therefore, 2-hydroxysterculate (**1**) is also expected to have similar activities against insects.

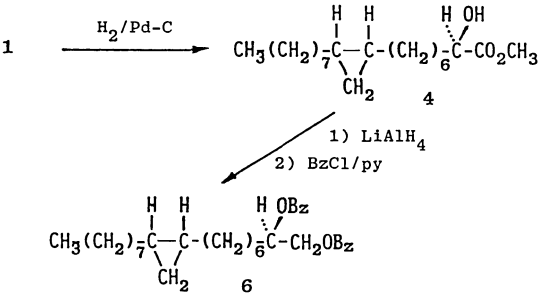
2-Hydroxysterculic acid was first isolated from alkaline hydrolysis products of glycerides from *Pachra* and *Bombacopsis* oil, and the stereochemistry at C-2 of the methyl ester **1** was inferred as *R* from the specific rotation ($[\alpha]_D$ −5.1°) by analogy with some α-hydroxy acid methyl esters.[10] We have now confirmed it unambiguously from the CD spectrum of a 1,2-*O*-dibenzoyl derivative **6** by applying the dibenzoate chirality method of Harada and Nakanishi.[11]

Some cyclopropenoids were known to be sensitive to air and to give polymerized mixtures.[12] A mild oxidation of **1** with air afforded a pair of conjugated enone isomers, methyl 2-hydroxy-10-methylene-9-oxooctadecanoate (**7**) and methyl 2-hydroxy-9-methylene-10-oxooctadecanoate (**8**). We also describe this novel ring opening oxidation.

Results and Discussion

Compound **1** ($C_{20}H_{36}O_3$; $[\alpha]_D$ −10°), 2.8 mg, was isolated from the root bark (1.5 kg) and identified as methyl 2-hydroxysterculate by spectrometry. It showed the presence of hydroxyl (3500 cm^{-1}) and methoxycarbonyl (1740 cm^{-1}) groups and a 1,2-disubstituted cyclopropene ring [^{1}H NMR: δ=0.77 (2H, s) and ^{13}C NMR: δ=7.4 (t), 109.2 (s), and 109.5 (s)]. The presence of the hydroxyl group on 2-position was deduced from the ^{1}H NMR and MS spectra (see Experimental). The position of the cyclopropene ring in the chain was determined by a prominent peak at *m/z* 151, corresponding to fission α to the cyclopropene ring, which was also observed (see Experimental) in the MS of methyl sterculate (**2**) and malvalate (**3**).

Stereochemistry at C-2. Several approaches to determine the configuration of chiral alcohols have been reported,[13–15] in which CD method provides better means to determine the absolute configuration of a small amount of chiral compound having suitable UV chromophores which give Cotton effects reflecting the absolute stereochemistry. We prepared a 1,2-dibenzoate **6** from **1** according to Scheme 1 and applied the dibenzoate chirality method of Harada and Nakanishi[11] for the determination of the stereochemistry of the asymmetric carbon at C-2.



Scheme 1.

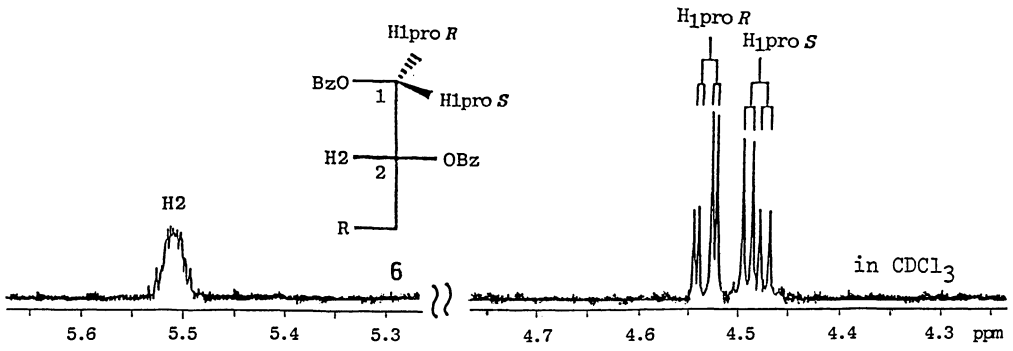


Fig. 1. The 400 MHz ^{1}H NMR spectrum of compound **6**.

The cyclopropenoid **1** was hydrogenated over palladium catalyst to give a saturated ester **4**, which should be a diastereoisomeric mixture but it showed one spot on TLC. Signals of a 1,2-disubstituted cyclopropane ring were observed at δ=−0.33 and 0.56 (1H each, $\underline{CH}_2$ / \ -CH-CH-) and 0.65 (2H, -C$\underline{H}$-C$\underline{H}$-) in the ^{1}H NMR and at δ=11.2, 16.3, and 16.3 in the ^{13}C NMR. The ester **4** was in turn reduced with lithium aluminium hydride to give a 1,2-diol **5** [^{1}H NMR: δ=3.46 and 3.65 (1H each, -CH(OH)C$\underline{H}_2$OH) and 3.72 (1H, -C$\underline{H}$(OH)-CH_2OH)]. The 1,2-dibenzoate **6** was prepared by acylation of **5** with benzoyl chloride in pyridine in the presence of a catalytic amount of 4-dimethylaminopyridine.

The ^{1}H NMR spectrum of the dibenzoate **6** showed two geminal protons due to the benzoyloxymethylene group at δ=4.48 (1H, dd, J=11.7 and 6.8 Hz) and 4.53 (1H, dd, J=11.7 and 3.4 Hz) (Fig. 1). The proton at higher field and with larger vicinal coupling constant was assigned to the H_1-pro-*S* in the case having 2*R* configuration and to the H_1-pro-*R* in 2*S*.[16] The assignment of the two prochiral protons at C_1 and an application of the Karplus type equation proposed by Haasnoot et al.[17,18] revealed that **6** existed predominantly in a *gt* conformer in the solution (see Fig. 2) and its population was 58% in $CDCl_3$ and 62% in CD_3OD (Table 1).

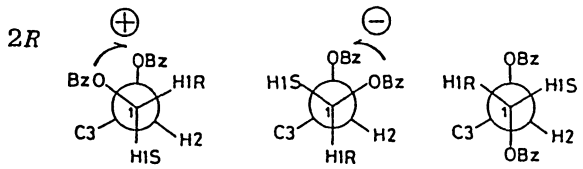

Fig. 2. Three possible conformers, *gg*, *gt*, and *tg*, in 2*R* about the C_1–C_2 bond.

The CD spectrum (Fig. 3) of **6** gave a negative exciton coupled CD having the first band at 237 nm with a negative sign and the second band at 224 nm with a positive one. The CD peaks can be attributed to the interaction between the di-*O*-benzoyl chromophores at C_1 and C_2, and the negative sign of the Cotton effect indicates that C_1–O and C_2–O bonds adopt a negative helicity, namely, *gt* conformation in 2*R* and *gg* in 2*S* (Fig. 2): there exist three kinds of staggered conformations in each case of 2*R* and 2*S*, namely, *gg*, *gt*, and *tg* about C_1–C_2 axis. In 2*R*, conformer *gt* of the C_1–C_2 bond should have a negative contribution, while conformer *gg* should have a positive contribution to the exciton coupling. On the other hand, the reverse contributions should be predictable in 2*S*. Here, the contribution of conformers *tg* with the antiperiplanar disposition of the two benzoyloxy groups will be negligible.

The results of the conformational analysis by NMR spectroscopy and the CD study revealed the absolute

Table 1. ^{1}H NMR Data of 1,2-Dibenzoate **6** (400 MHz)

configuration of C-2 to be *R*.

Ring-Opening Air Oxidation. Without the bubbling air, compound **1** was slowly oxidized by air at room temperature and, after 2 weeks, completely changed to give a 1 : 1 mixture of isomers **7** and **8** (Scheme 2).

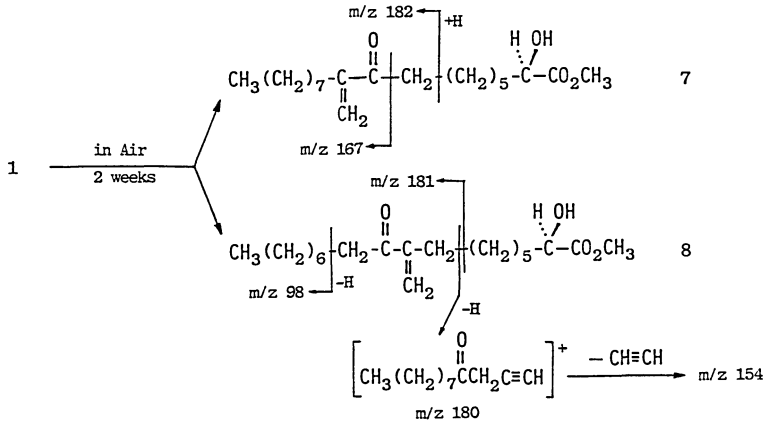
The MS spectra of **7** and **8** both indicated the same molecular formula of $C_{20}H_{36}O_4$ and their UV spectra also resembled each other to show the presence of a conjugated enone system at λ_{max} 228 nm. Signals in the ^1H and ^{13}C NMR spectra of **7** suggested the presence of a 1,1-disubstituted ethylene double bond [δ=5.70 (1H, s) and 5.97 (1H, s), and δ=124.1 and 149.2] and two carbonyl groups [δ=175.9 and 202.6] as well as a methine bearing an OH group [δ=4.21 (1H, m) and 70.4]. These data suggested that **7** had a conjugated enone system containing a side-chain methylene group instead of the cyclopropene ring in **1**. A comparison of the ^1H and ^{13}C NMR of **8** with those of **7** indicated that the two compounds had nearly identical structures and differed from one another only in the location of the enone system, and they were similar type isomers with the air-oxidation products from methyl sterculate (**2**) and malvalate (**3**) reported recently by us.[19]

Unequivocal support for their structures were obtained from their MS fragmentations. The position of the CO group in **7** has been assigned to C-9 since the significant α- and β-fission ions were obtained at m/z 167 and 182, respectively. On the other hand, **8** showed a different fragmentation to give a characteristic rearranged peak at m/z 180 and a peak at m/z 154 due to a successive loss of HC≡CH, along with a β-cleaved ion peak to the CO group at m/z 98.

These enone isomers would have been produced by a singlet oxygen attack to either of the two olefinic carbons of cyclopropene ring in **1**. Compounds **7** and **8** were also sensitive to air to give gradually a complex mixture at room temperature.

Cyclopropenoid fatty acids, sterculic acid and malvalic acid, are constituents of the seed oils of many species of the natural order Malvales and have been recognized to occur generally together, one or other being predominant according to species. The structures of these cyclopropenoid acids suggest that malvalic acid may be derived from sterculic acid by a biological α-oxidation mechanism. Evidence for this suggestion has been obtained from an incubation experiment using radioactivity labelled acetate[20] so that, if malvalic acid was derived from sterculic acid in this way, 2-hydroxysterculate (**1**) would be an intermediate to malvalate (**3**).

The occurrence of the oxidation products, **7** and **8**, in *Hibiscus* has not been observed yet, but the possibility is present at least on compound **7** because two analogs, methyl 10-methylene-9-oxooctadecanoate and 9-meth-



Scheme 2.

ylene-8-oxoheptadecanoate, respectively derived by air oxidation from sterculate (**2**) and malvalate (**3**), have been isolated from it.[2] The isolation study of **7** is now in progress.

Experimental

IR and UV spectra were recorded on Shimadzu IR-408 and UV-210A spectrophotometers, respectively. ^{1}H and ^{13}C NMR spectra were measured in $CDCl_3$ at 400 and 100 MHz using a JEOL FX-400 spectrometer. Mass spectra were recorded on a JEOL D-300 spectrometer. Optical rotation and circular dichroism (CD) were measured using a JASCO J-20A spectropolarimeter.

Plant Material. The root bark of *H. rosa-sinensis* was collected at Amami-Oshima (Amami Islands) in August 1988.

Isolation. The fresh root bark (1.5 kg) was extracted with MeOH. The acetone-soluble part afforded an oil containing a viscous material (Fraction A) to be separated, each of which was fractionated twice by flash chromatography on SiO_2 with CH_2Cl_2–hexane. Final purification by repeated passage through an HPLC, Waters μ-bondasphere semiprep column, using a solvent system of MeCN–H_2O gave 2.8 mg of **1** and two known cyclopropene esters **2**[3] (54.2 mg) and **3**[4] (81.6 mg). The solvent evaporation was performed at 40 °C under reduced pressure under nitrogen and the resulting products were also stored under nitrogen atmosphere.

Methyl 2-Hydroxysterculate (1). A colorless sirup; $[\alpha]_D^{24}$ −10° (*c* 0.083, $CHCl_3$); IR (liq. film) 3500, 1740, 1200 cm^{-1}; UV (MeCN) 212 nm (ε 2700); ^{1}H NMR δ=0.77 (2H, s, C$\underline{H}_2$ of cyclopropene ring), 0.88 (3H, t, *J*=6.6 Hz, 18-H), 1.25—1.37 (16H, m), 1.54 (4H, m, 7- and 12-H), 1.65 (1H, m, 3-H), 1.80 (1H, m, 3-H), 2.37 (4H, t, *J*=7.0 Hz, 8- and 11-H), 2.67 (1H, d, *J*=5.9 Hz, O$\underline{H}$, exchangeable with D_2O), 3.79 (3H, s, OC$\underline{H}_3$), 4.20 (1H, dt, *J*=4.4 and 7.0 Hz, 2-H); ^{13}C NMR δ=7.4 (C$\underline{H}_2$ of cyclopropene ring), 14.1 (C-18), 22.7 (C-17), 24.7 (C-4), 2×26.0 (C-8 and 11), 27.3 (C-7), 27.4 (C-12), 29.1, 29.3, 2×29.4, 31.9 (C-16), 34.4 (C-3), 52.5 (O$\underline{C}$H$_3$), 70.5 (C-2), 109.2 (C-9), 109.5 (C-10), 175.8 (C-1); EIMS *m/z* 324 (4, M$^+$), 265 (5), 165 (11), 151 (14), 149 (12), 109 (34), 95 (81), 90 (54), 81 (base peak), 68 (73), 67 (59), 55 (52), 42 (75). Found: *m/z* 324.2612. Calcd for $C_{20}H_{36}O_3$: M, 324.2613.

Methyl Sterculate (2). ^{13}C NMR δ=7.4, 14.1, 22.7, 25.0, 26.0, 26.1, 27.3, 27.4, 29.0, 29.1, 29.2, 29.3, 2×29.4, 31.9, 34.1, 51.5, 109.2, 109.5, 174.3; EIMS *m/z* 308 (M)$^+$, 277, 151, 109, 95, 81, 68, 55, 42.

Methyl Malvalate (3). ^{13}C NMR δ=7.4, 14.1, 22.7, 24.9, 26.0, 27.3, 27.4, 29.0, 29.1, 29.2, 29.3, 2×29.4, 31.9, 34.1, 51.4, 109.2, 109.5, 174.3; EIMS *m/z* 294 (M)$^+$, 263, 196, 151, 122, 95, 81, 68, 67, 55, 42.

Cyclopropaneoctanoic Ester 4. Cyclopropenoid **1** (1.2 mg) was hydrogenated over Pd–C in EtOH for 12 h. After removal of catalyst, the filtrate was purified by prep. TLC using ether–hexane (1:1) to give **4**. ^{1}H NMR δ=−0.33 (1H, dt, *J*=3.6 and 4.5 Hz, of cyclopropane ring), 0.56 (1H, ddd, *J*=3.6, 8.1 and 8.2 Hz,  of cyclopropane ring), 0.65 (2H, m, 9- and 10-H), 0.89 (3H, t, *J*=6.7 Hz, 18-H), 1.13 (4H, m, 8- and 11-H), 1.23—1.55 (20H, m), 1.65 (1H, m), 1.79 (1H, m), 2.67 (1H, d, *J*=6.1 Hz, O$\underline{H}$), 3.79 (3H, s, OC$\underline{H}_3$, 4.20 (1H, m, 2-H); ^{13}C NMR δ=11.2 (C$\underline{H}_2$ of cyclopropane ring), 14.5 (C-18), 2×16.3 (C-9 and 10), 23.1 (C-17), 25.2 (C-4), 2×29.1, 2×29.7, 29.8, 2×30.0, 2×30.6, 32.2 (C-16), 34.9 (C-3), 53.0 (O$\underline{C}$H$_3$), 71.0 (C-2), 175.0 (C-1). Found: *m/z* 326.2815. Calcd for $C_{20}H_{38}O_3$: M, 326.2821.

8-Cyclopropyl-1,2-octanediol (5). The cyclopropane ester **4** was reduced with $LiAlH_4$ in ether to give the diol **5**. ^{1}H NMR δ=−0.32 (1H, dt, *J*=4.3 and 5.4 Hz), 0.58 (1H, dt, *J*=4.3 and 8.1 Hz), 0.66 (2H, m), 0.89 (3H, t, *J*=6.8 Hz), 1.1—1.8 (26H, m), 3.46 (1H, m, 1-H), 3.65 (1H, m, 1-H), 3.72 (1H, m, 2-H); EIMS *m/z* 298 (M)$^+$.

8-Cyclopropyl-1,2-octanediol Dibenzoate (6). A mixture of the diol **5** and 4-dimethylaminopyridine (0.3 mg) in pyridine (0.2 ml) was stirred for 0.5 h at room temperature. To the solution was added benzoyl chloride (0.2 ml), and the mixture was stirred for 12 h. TLC separation of the product using hexane–AcOEt (3:1) gave the dibenzoate **6**. ^{1}H NMR δ=−0.34 (1H, dt, *J*=4.2 and 5.5 Hz), 0.57 (1H, dt, *J*=4.1 and 8.3 Hz), 0.64 (2H, m), 0.89 (3H, t, *J*=6.7 Hz), 1.12 (4H, m), 4.48 (1H, dd, *J*=11.7 and 6.8 Hz, 1-H-pro-*S*), 4.53 (1H, dd, *J*=11.7 and 3.4 Hz, 1-H-pro-*R*), 5.51 (1H, m, 2-H), 7.34 (2H, t, *J*=8.2 Hz), 7.37 (2H, t, *J*=8.2 Hz), 7.47 (2H, dd, *J*=8.2 and 7.5 Hz), 7.93 (2H, dd, *J*=7.5 and 0.8 Hz), 7.98 (2H, dd, *J*=7.5 and 0.8 Hz); ^{1}H NMR (CD_3OD) δ=−0.35 (1H, dt, *J*=4.1 and 5.5 Hz), 0.58 (1H, ddd, *J*=4.2, 8.1, and 8.2 Hz), 0.66 (2H, m), 0.90 (3H, t, *J*=6.7 Hz), 1.15 (4H, m), 4.46 (1H, dd, *J*=12.1 and 6.8 Hz, 1-H-pro-*S*), 4.62 (1H, dd, *J*=12.1 and 3.2 Hz, 1-H-pro-*R*), 5.50 (1H, m, 2-H), 7.43 (2H, t, *J*=7.7 Hz), 7.46 (2H, t, *J*=7.7 Hz), 7.58 (1H, t, *J*=7.7 Hz), 7.60 (1H, t, *J*=7.7 Hz), 7.95 (2H, d, *J*=7.7 Hz), 8.01 (2H, d, *J*=7.7 Hz). Found: *m/z* 506.3412. Calcd for $C_{33}H_{46}O_4$: M, 506.3397.

Air Oxidation of 1. i) When air was bubbled into a CH_2Cl_2 solution of **1** (0.2 mg) for 30 min, the product was a complex mixture on HPLC. ii) Compound **1** (0.9 mg) changed to a mixture of two compounds when exposed to air at room temperature for two weeks. The products were separated by HPLC using MeCN containing 10% H_2O to give **7** (0.4 mg) and **8** (0.4 mg).

7; ^{1}H NMR δ=0.91 (3H, t, *J*=6.7 Hz, 18-H), 1.67 (1H, m, 3-H), 1.80 (1H, m, 3-H), 2.23 (2H, t, *J*=7.7 Hz, 11-H), 2.66 (2H, t, *J*=7.4 Hz, 8-H), 3.79 (3H, s, OC$\underline{H}_3$), 4.21 (1H, m, 2-H), 5.70 (1H, s,), 5.97 (1H, s,); ^{13}C NMR δ=14.1 (C-18), 22.7 (C-17), 24.6 (C-7), 28.5 (C-11), 29.0, 2×29.1, 29.3, 2×29.4, 30.9, 31.9, 34.3 (C-3), 37.8 (C-8), 52.3 (O$\underline{C}$H$_3$), 70.4 (C-2), 124.1 (=C$\underline{H}_2$), 149.2 (C-10), 175.9 (C-1), 202.6 (C-9); EIMS *m/z* 340 (5, M$^+$), 324 (6), 195 (8), 182 (36), 167 (28), 139 (7), 125 (12), 111 (47), 97 (32), 90 (2), 83 (52), 69 (75), 55 (base peak).

8; ^{1}H NMR δ=0.90 (3H, t, *J*=6.6 Hz, 18-H), 1.66 (1H, m, 3-H), 1.80 (1H, m, 3-H), 2.24 (2H, t, *J*=7.6 Hz, 8-H), 2.66 (2H, t, *J*=7.5 Hz, 11-H), 3.71 (3H, s, OC$\underline{H}_3$), 4.21 (1H, m, 2-H), 5.70 (1H, s,), 5.96 (1H, s,); ^{13}C NMR δ=14.1 (C-18), 22.7 (C-17), 24.7 (C-12), 28.4 (C-8), 2×29.1, 29.2, 29.3, 2×29.4, 30.9, 31.8, 34.1 (C-3), 37.9 (C-11), 51.6 (O$\underline{C}$H$_3$), 70.5 (C-2), 123.4 (=C$\underline{H}_2$), 149.1 (C-9), 176.6 (C-1), 202.5 (C-10); EIMS *m/z* 340 (3, M$^+$), 181 (30), 180 (33), 154 (38), 151 (44), 137 (10), 123 (30), 109 (28), 98 (26), 95 (31), 90 (3), 81 (48), 67

(59), 42 (base peak).

Seed Germination Test. Twenty seeds of lettuce (*Lactuca sativa* L.) were placed on a filter paper in a 9-cm Petri dish containing 2 ml of test solution. The dish was incubated at 23 °C in the dark room. After 3 d, the percentage germination was determined; **1**: 55% (*c* 1.5 mM), **2**: 20% (*c* 2.3 mM), and **3**: 15% (*c* 2.3 mM).

Catalytic Oxidation of Naphthalene on Palladium in Cooperation with Copper(I)/(II) Redox Couple

Yasushi KURODA,* Atsutaka KUNAI, Michiyuki HAMADA, Tomoyuki KITANO, Sotaro ITO, and Kazuo SASAKI

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Kagamiyama, Higashi-Hiroshima 724

(Received May 24, 1991)

Catalytic oxidation of naphthalene in moist acetic acid solutions has been studied. The catalyst used was a silica-supported palladium which works in cooperation with the Cu^{+}/Cu^{2+} redox couple. Products were 1-naphthol, 1,4-naphthoquinone and (*E*)-2-formylcinnamaldehyde with a total yield of more than 78% in which naphthoquinone shared 40%. Reaction mechanism has been discussed in comparison with that of benzene.

Among many unit processes of organic synthesis, aromatic hydroxylation reaction is one of the most difficult reactions. In recent years, we have developed a new catalytic oxidation process which works efficiently under ambient conditions and proceeds in a single batch reactor without any cumbersome treatment.[1,2] Our attention to date was, however, limited to the reaction of benzene. Since the process is expected to be applied to many aromatics other than benzene, the reaction of naphthalene has been studied tentatively. A similar study regarding the reaction of benzoic acid will appear separately.[3]

Experimental

Catalyst. For preparing catalysts, a mixture of metal salts ($CuSO_4$ and/or $PdCl_2$) and powdery silica (Merck, No. 9385, 230—400 mesh) dispersed in water was first exposed to ultrasonic wave for 90 min to homogenize the mixture. This process is necessary for achieving a high catalytic activity.[2] The mixture was then heated to dryness on a steam bath with gentle agitation. Two catalysts of different composition were prepared in this manner. They are shown as Catalyst A (1000 $CuSO_4$–50 $PdCl_2$) and B (100 $PdCl_2$), respectively, where numbers in the parentheses indicate μmol of respective metal salt per gram of silica support. In case of Catalyst B that contains no copper salt, a preliminary activation (reduction of Pd^{2+} to Pd^{0}) of the catalyst with hydrogen was done separately in benzene.

Reaction. All reactions were carried out at 25 °C under the atmospheric pressure. When catalyst A was used, the catalyst (1 g) and a mixture (20 cm^3) of benzene with a solvent given in Tables 1 and 2 were placed into an Erlenmeyer flask (100 cm^3 in volume). After replacing air in the flask with hydrogen, the flask was shaken (30 mm stroke, 140 cycle/min) or stirred magnetically for 2 h to activate the catalyst. Upon this treatment the catalyst color gets black indicating that Pd^{2+} is reduced to its metallic state. Cu^{2+} ion is also believed to be reduced to its lower valence states, at least partly. Control of the stirring rate (800 rpm) is required for attaining reproducible results. Hydrogen was then replaced by air or pure oxygen to begin the oxidation reaction.

For reactions in acetic acid, copper(II) acetate (1 mmol) and naphthalene were dissolved into the solution (25 cm^3). Reaction was performed by using Catalyst B (1 g) that contains Pd species alone and by introducing hydrogen and oxygen into the reactor flask either alternately or simultaneously.

The reaction mixture was filtered to remove the catalyst, and the solvent was removed using a rotary evaporator. Hexane was added to the residue and copper acetate was filtered off. The filtrate was concentrated, and (*E*)-2-formylcinnamaldehyde was isolated by thin-layer chromatography on silica gel: MS *m/z* 131 (M^{+} −29); ^{1}H NMR ($CDCl_3$) δ=6.67 (1H, dd, *J*=16.1, 7.8 Hz), 7.6—8.0 (4H, m), 8.58 (1H, d, *J*=16.1 Hz), 9.81 (1H, d, *J*=7.8 Hz), 10.23 (1H, s); ^{13}C NMR ($CDCl_3$) δ=128.0, 130.7, 132.3, 133.6, 133.9, 134.6, 135.4, 149.2, 192.7, 193.7.

Product Analysis. Product analysis was made by use of a high-performance liquid chromatograph equipped with a Merck Hibar column (Lichrosorb RP-18, 10×250 mm). Eluent used was a mixture of acetonitrile and a phosphate buffer solution of pH 3.5, of which the mixing ratio was varied depending on the nature of compounds to be analyzed.

Results and Discussion

1. Examination of Catalyst and Solvent. We have already demonstrated that Catalyst A shows excellent activity for producing phenol even in benzene itself.[2] We thus tried to use this catalyst for the oxidation of naphthalene. In contrast to benzene, however, naphthalene is solid at room temperature and thus needs some appropriate solvents.

We have first studied the effect of several organic solvents given in Table 1 in the reaction of benzene. The reaction was performed by using Catalyst A (1 g) in a mixture (20 cm^3) of benzene with a given solvent at several different ratio. After shaking the mixture under hydrogen for 2 h, the oxidation reaction was started and continued for 1 h by introducing air to the reactor flask. Yields of phenol are listed in Table 1. As is expected, the presence of any of the solvent hinders the oxidation of benzene appreciably. However, the hindering effect is minor in cyclohexane and this prompted us to study the oxidation of naphthalene in this solvent. Unfortunately, however, the reactivity of naphthalene in cyclohexane was unexpectedly low and produced only 0.5 μmol of 1-naphthol.

As has been reported in a previous paper,[2] the catalyst containing copper acetate was not effective when it

Table 1. Yield of Phenol (μmol) in the Oxidation of Benzene in Several Solvents

Exp.	Solvent	Volume fraction of organic solvent/%			
		80	50	20	0
1	Cyclohexane	10.5	19.3	22.0	
2	Ethyl acetate	6.9	12.5	12.2	
3	Propylene carbonate	1.1	5.1	14.7	25.9±4.3[a]
4	Acetic acid	3.2	3.8	6.8	
5	95% Acetic acid	2.4	3.6	—	

Catalyst: A (1 g), Solution volume: 20 cm^3, Gas feeding: H_2 (2 h) followed by Air (1 h).
a) Mean value of ten measurements using catalysts from five different lots. Rather a big deviation is due to the use of different lots of catalyst. Values for a given solvent were determine using a single lot of catalyst and the error was less than a few %.

Table 2. Oxidation of Benzene in Acetic Acid

Exp.	Solvent component / v/v			Product yield/μmol				Formal potential[f] (Cu^+/Cu^{2+}) /mV vs. SCE
	AN[a]	H_2O	AcOH[b]	PhOH[c]	HQ[d]	BQ[e]	Total	
1	0	0	100	4.3	0.2	1.0	5.5	—

Catatalyst: B (1 g), Solution: $Cu(OAc)_2$ (40 mM) was dissolved in AcOH (25 cm^3) containing both AN and H_2O at 4% in volume.
a) H_2 (15 min) followed by air (2 h), b) H_2 (15 min) followed by O_2 (2 h), c) H_2 (15 min) follow by O_2 (15 min), cycle repeated 4 times, d) simultaneous (7.5 $cm^3\,min^{-1}$ for both H_2 and O_2, 2h), e) simultaneous (7.5 $cm^3\,min^{-1}$ for both H_2 and O_2, 20 h), f) CH_3COONa (50 mM) was added. g) Values in the parentheses indicate selectivity (%) based on the amount of naphthalene consumed, h) 1-naphthol, i) 1,4-naphthoquinone, j) (*E*)-2-formylcinnamaldehyde. k) Based on Pd.

was used in neat benzene. However, the catalyst became effective when a small amount of acetic acid was added to benzene. Accordingly, we next studied the reaction in acetic acid using Catalyst B that contains Pd species alone. In this case, copper(II) acetate was dissolved in the solution phase. The use of neat acetic acid resulted, however, in a poor product yield (Table 2, exp. 1). This can be attributed to the slow redox rates of the Cu(I)/Cu(II) couple in acetic acid. It is known that hydrated Cu(I) ions are oxidized readily to Cu(II) ions with dioxygen[4-7] and also that they can be stabilized with acetonitrile (AN).[4,8] We hence added both AN and water as the cosolvents. As is seen in Table 2, the presence of both the two cosolvents increased markedly the oxidation efficiency (exp. 4). Electrochemical measurements also proved that the presence of water favors the oxidation of Cu(I) to Cu(II) while AN favors the reverse reaction. The effect of water and AN is counteracting and the use of 4—7% in volume ratio for both the cosolvents seems to be optimal.

It is worth noting that under the conditions in experiment 4, nearly equal amounts of hydroquinone and phenol are produced. This is in accordance with our previous observations. In the reaction in aqueous $CuSO_4$ solutions, phenol was formed as the main product at pH 1 while hydroquinone dominated at pH 3.5.[7] Even in the reaction in neat benzene under a pressurized oxygen atmosphere, the use of the Pd–Cu composite catalyst resulted in a predominant formation of *p*-benzoquinone.[2] The present result is consistent with those and the presence of copper acetate favors the formation of hydroquinone.

2. Reaction of Naphthalene. Basic knowledges obtained for the oxidation of benzene were applied to the reaction of naphthalene by using 1 g of Catalyst B in a solution (25 cm^3) of 40 mM $Cu(OAc)_2$ (1 M=1 mol dm^{-3}) in acetic acid containing water and acetonitrile (4.0% for each). Results obtained are shown in Table 3. In experiments 1—7, the reaction was continued for 2 h. Products obtained are 1-naphthol, 1,4-naphthoquinone and (*E*)-2-formylcinnamaldehyde (which will be abbreviated as dialdehyde hereafter). A trace amount of 2-naphthol was detected among some other minor products.

The first three experiments, in which hydrogen was first supplied to the reactor for 15 min and then air followed for 2 h, indicate that the concentration of naphthalene has no remarkable effect on the yield (exps. 1—3). Replacement of air by pure oxygen results in the increase in the yield of naphthoquinone and thus total products (exp. 4).

In experiment 5, the supply of hydrogen and oxygen was alternated every 15 min and the cycle was repeated 4 times (total oxygen feeding: 1 h). The frequent alternation of gas feeding results in a marked increase of the product yield indicating that 1 h of oxidation time is unnecessarily long. The selectivity of each product remains almost unchanged. Experiment 6 was conducted under the conditions of simultaneous gas feeding i.e., both hydrogen and oxygen were supplied with an equal feed rate (7.5 $cm^3\,min^{-1}$). In comparison with the foregoing (exps. 4 and 5), the total yield increased still more by keeping the product distribution unchanged. A deliberate addition of sodium acetate increases the product yield and so that the turnover frequency (exp. 7).

In order to determine the material balance, a prolonged experiment was carried out (exp. 8), and the total selectivity with regard to the sum of the three products was found to be 78.4% and naphthoquinone shared 39.9% in it. The rest 21.4% was left undetermined. The prolonged reaction time (exp. 8) seems to increase the relative yield of dialdehyde.

Under the condition of alternate gas feeding, the product accumulation during the oxidation of naphthalene was studied. A typical example is shown in Fig. 1. It is interesting that the yield of naphthol first increases but after a short period of time it decreases gradually

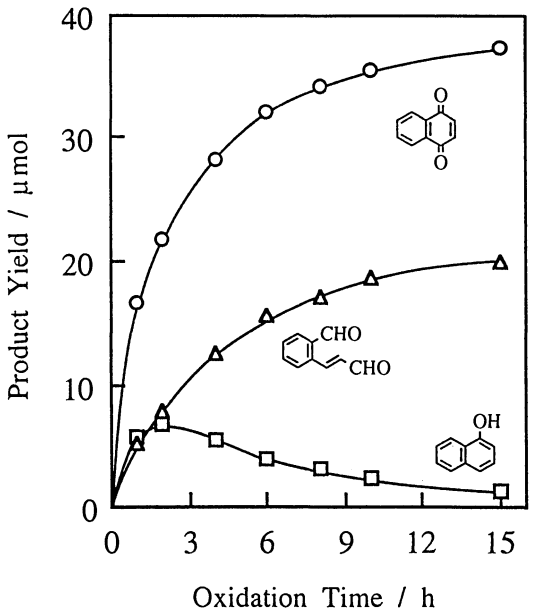

Fig. 1. Accumulation of the products during oxidation of naphthalene in acetic acid. Catalyst: B (1 g). Solution: 0.3 M Naphthalene and 40 mM $Cu(OAc)_2$ in AcOH (25 cm^3) containing both AN and H_2O at 6.5% in volume. Gas feeding: H_2 (15 min) followed by O_2.

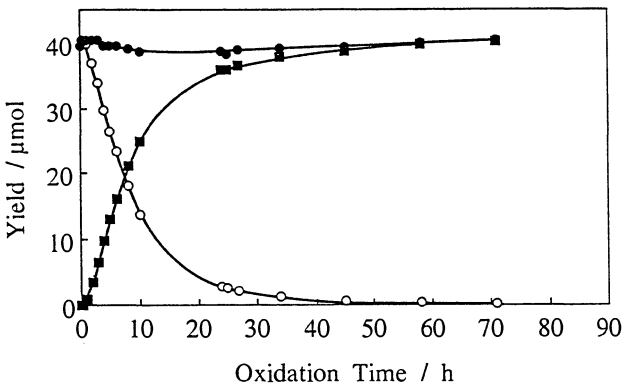

Fig. 2. Aerial oxidation of 1-naphthol to 1,4-naphthoquinone in the presence of Pd-catalyst and copper salt.
Catalyst: B (1 g). Solution: 2 mM 1-Naphthol and 10 mM $Cu(OAc)_2$ in AcOH (20 cm^3) containing both AN and H_2O at 6.5% in volume. Gas feeding: H_2 (15 min) followed by O_2.

while other two products increases monotonously. Undoubtedly, this suggests that 1-naphthol is converted secondarily to some other product(s). In order to confirm what the final product was, the reaction of 1-naphthol was studied separately under similar reaction conditions as in Fig. 1. Further details are indicated in the caption of Fig. 2. As this figure indicates, 1-naphthol is converted quantitatively to 1,4-naphthoquinone. Fig. 3 shows results of another experiment in which Pd catalyst was not used but naphthol was

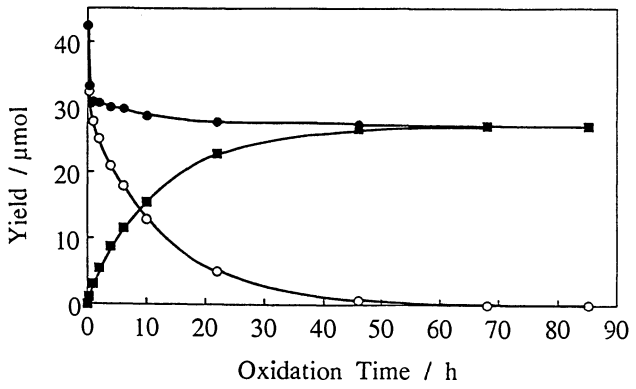

Fig. 3. Aerial oxidation of 1-naphthol in the absence of Pd-catalyst.
Solution: 2 mM 1-Naphthol and 10 mM $Cu(OAc)_2$ in AcOH (20 cm^3) containing both AN and H_2O at 6.5% in volume. The solution was kept under O_2 atmosphere with use of neither Pd-catalyst nor Cu^+ salt.

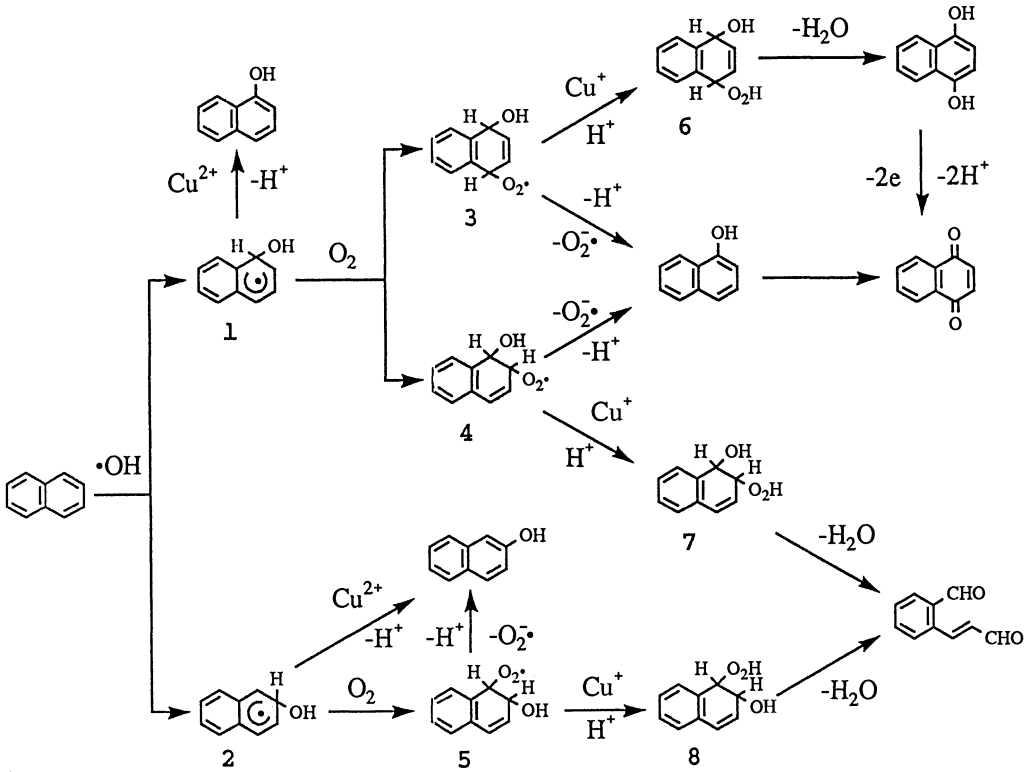
simply dissolved in an acetic acid solution containing copper(II) acetate. In this case too, 1-naphthol was oxidized under the oxygen atmosphere to give 1,4-naphthoquinone although 35% of starting material was missed from detection by some unknown reason. In any case, it is clear that the primary product, 1-naphthol, is converted to the corresponding quinone under the conditions of the present experiments.

3. Reaction Mechanism. We have already demonstrated in the aqueous phase reactions that Cu(I) ions activate dioxygen to produce hydrogen peroxide.[5–7] Hydrogen peroxide is then reduced with Cu(I) ions to water via transient formation of hydroxyl radical. Of course, there still remain several uncertainties regarding detailed points. For instance, transient formation of a copper–oxygen complex was suggested by Zuberbuehler[9] and it might be involved in the reaction sequence. These, however, do not affect the following discussion. According to our view, the basic mechanism in the oxidation of benzene involves the formation of hydroxyl radical as the reactive species as described in our previous papers[5–7] as well as the work of several authors.[10,11] The recent publication of Okunowski[12] is in consistent with our view, particularly.

The primary intermediate is hydroxycyclohexadienyl radical, an adduct of hydroxyl radical to benzene. Under the oxygen atmosphere, the cyclohexadienyl radical readily transforms to its peroxyl radicals by adding dioxygen.[13] The peroxyl radicals are converted, depending upon the conditions of the surroundings, to either phenol or hydroquinone. We have also demonstrated that copper ions have an ability of converting efficiently a peroxyl intermediate, 4-hydroxy-2,5-cyclohexadienylperoxyl radical, to hydroquinone via, presumably, the corresponding hydroperoxyl intermediate.[5–7] These mechanisms may also be applied to the reaction of other aromatic compounds regardless of reaction media.

Generally speaking, addition of hydroxyl radical to



Scheme 1.

naphthalene has a possibility of occurring at either 1- or 2-position of the ring (see, Scheme 1). Considering the electrophilic nature of the reaction, however, one may conclude the preference for the 1-position, since the electron density is 0.362 at 1-position while it is 0.138 at 2-position.[14] The relative ratio of the 1- and 2-isomers will indicate the relative rate of forming 1- and 2-hydroxylated cyclohexadienyl radicals (radicals **1** and **2**, respectively), to which dioxygen adds to give peroxyl radicals (radicals **3**, **4**, and **5**). It should be noted that 1-naphthol is derived from either radical **3** or **4** by eliminating HO_2 radical (Dorfman's path[10]). Experimental results shown in Table 3 agree with this expectation and 1-naphthol is produced as the dominant product while 2-naphthol is minor. By analogy of the reaction of benzene,[5-7] direct formation of naphthols from the cyclohexadienyl radicals through the oxidative elimination of proton can be ruled out when sufficient amount of oxygen is present in the reaction medium, where radical **3** or **4** prevails.

We have shown that 1,4-naphthoquinone is certainly produced from 1-naphthol. However, this route seems to be of secondary importance in the reaction, because 1,4-naphthoquinone is produced and increases steadily from the initial stage of oxidation (see Fig. 1). The main route to lead to 1,4-naphthoquinone is believed to pass through radical **3**.

Dialdehyde may be produced through the formation of either peroxyl radical **4** or **5** derived from radical **1** or **2**, respectively. Of these, the route via radical **5** and thus hydroperoxide **8** is ruled out since radical **2** is believed to have a minor contribution. Hydroperoxide **7** derived from **4** will result in a carbon-carbon bond cleavage upon elimination of water because of the steric hindrance between hydroxyl and hydroperoxyl groups. In the oxidation of benzene, a trace amount of 2,4-hexadienedial was found in the products. In contrast, naphthalene produces dialdehyde as the second main product following to the main product, 1,4-naphthoquinone. This is due to increased stability resulted from the conjugation of an unsaturated bond in peroxyl radical **4** with a fused benzenoid system. As a result, contribution of the Dorfman's path[10] decreases and the amount of dialdehyde increases appreciably.

1,4-Naphthoquinone is formed not only by the competing reaction but also by oxidation of 1-naphthol, particularly, after the latter compound has been accumulated. As a result, the selectivity of naphthoquinone becomes more than 52% (Table 3, exp. 8). In addition, an appreciable formation of the dialdehyde from naphthalene contrasts to the negligible production of 2,4-hexadienedial from benzene. This is attributed to the difference in relative stability of oxygenated cyclohexadienyl radicals derived from benzene and naphthalene.

This work was supported financially by a Grant-in-Aid for Scientific Research on Priority Area No. 62607001 from the Ministry of Education, Science and Culture. Thanks are also due to Tokuyama Soda Co., Ltd. and Toso Co., Ltd. for their support in many respects.

Anionic Surfactants with Divalent Counterions of Separate Electric Charge. III. Proton NMR Study

Yoshikiyo MOROI,* Ryohei MATUURA, and Tadashi YONEMITSU†
Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
†Department of Industrial Chemistry, Faculty of Engineering, Kyushu Sangyo University, Higashi-ku, Fukuoka 813
(Received March 22, 1991)

The proton NMR spectra of 1-tetradecanesulfonates whose cationic counterion, the 1,1′-polymethylenedipyridinium ion (with even-numbered methylene groups up to 14), is divalent with separate electric charge, were measured. From the chemical shifts the pyridine rings were found to move about in quite hydrophilic environment of micellar surface region, leading to a downfield shift of methylene groups next to head group of surfactant ion. The chemical shifts of methylene groups of micellized counterions with more than eight methylene groups are different from those of corresponding counterions in aqueous environment and are similar to those of methylene group in hydrophobic micellar interior. These results strongly support the previous conclusion that the polymethylene group with more than eight methylene groups folds and penetrates micellar interior in their micellized state.

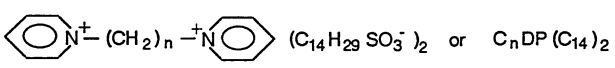
The properties of aggregates or micelles of ionic surfactants are strongly influenced by the kind of surfactant ion and counterion. Counterions of conventional anionic surfactants so far investigated have been alkali or alkaline earth metal ions, their electrical charge being localized within a very small volume. The electrical potential of such ions seems to be energetically stabilized by coulombic interaction. This leads to smaller aqueous solubility of surfactants, resulting in higher micelle temperature range[1] or higher Krafft point.[2–4] As for organic counterions, on the other hand, the counterion binding to micelles increases with its increasing hydrophobicity and promotes a micelle formation, where the size and shape of micelles are radically affected.[5–10] Surfactants with divalent counterions whose electric charge is diffuse[11] or separate,[12,13] in particular, have physicochemical properties much different from those of conventional surfactants.

In our preceding papers on anionic surfactants with divalent counterions of separate electric charge (1,1′-polymethylenedipyridinium ion, C_nDP^{2+}), the solubility and micelle formation[14] and the micellar size and surface activity[15] have been systematically studied. The conclusion was that the polymethylene chain with eight or more methylene groups folds and penetrates the hydrophobic micellar interior. However, the questions as to how deep the penetration is and where the location of pyridinium ion is still remain unsolved. One of the promising approaches to counterion binding is to employ the NMR technique.[16–18] This technique can also indicate the solubilization site of molecules in micelle in the case where they carry the π-electrons, like the couterions of ionic surfactants used in the present study.[19–24]

This paper, then, aims to solve the above two questions using the proton NMR technique and to confirm the conclusion from the preceding works by another experimental evidence.

Experimental

Materials. Anionic surfactants with divalent cationic counterions of separate electric charge, 1,1′-polymethylenedipyridinium tetradecane-1-sulfonate were the same as those used in the previous papers,[14,15] in which the surfactants were



n = 2, 4, 6, 8, 10, 12, 14

named as 1,1′-(1,ω-alkanediyl)bispyridinium tetradecane-1-sulfonate or $C_nBP(C_{14})_2$. C_nDPX_2 (X=Cl, Br) were kind gifts from Prof. Kuwamura's laboratory of Gunma University and were used without further purification except those which were purified by recrystallization from acetone–ethanol mixture. Water used as a solvent is D_2O from Merck Co., Ltd.

NMR Measurement. The concentration of $C_nDP(C_{14})_2$ is 0.01 mol dm^{-3} which is about 50 times cmc for three surfactants of n=2, 4, and 6, while that of C_nDPX_2 is 0.02 mol dm^{-3}. The sample solutions were sonicated for 30 min after apparent sample dissolution. As for solutions of $C_2DP(C_{14})_2$ and $C_{14}DP(C_{14})_2$ whose Krafft points are higher than the measurement temperature the recording was made before their precipitation. The chemical shift of residual HDO signal, δ=4.5, was used as the standard of the chemical shifts, because the molar ratio of water to the divalent ion of more than 2700 is so large that the effect of the divalent ion on bulk water structure can be negligible. The NMR spectra were recorded with a JEOL GX-400 p-FT NMR spectrometer at room temperature.

Results and Discussion

The proton NMR spectra of $C_nDP(C_{14})_2$ are shown in Fig 1. The NMR spectra of C_nDPX_2 are very helpful to analysing the spectra of $C_nDP(C_{14})_2$, because C_nDP are the counterions of the latter micelles and do not form micelles by themselves at the concentration of 0.02 mol dm^{-3}: The most hydrophobic counterion $C_{14}PPCl_2$ was found to form micelles around 0.02 mol dm^{-3}.[25] In other words, their chemical shifts of every ^{1}H bound to

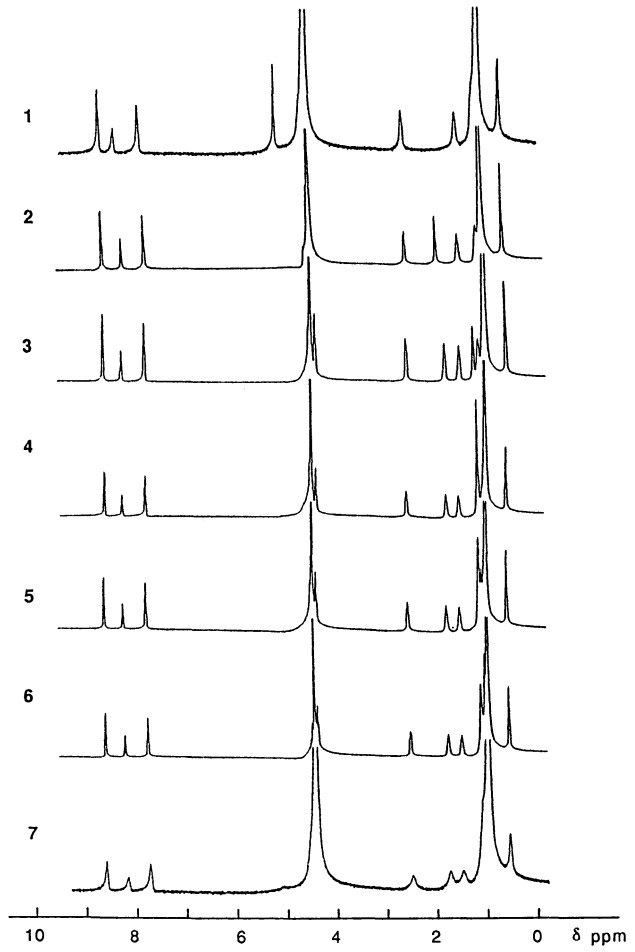


Fig. 1. ^{1}H NMR spectra of $C_nDP(C_{14})_2$: **1** n=2, **2** n=4, **3** n=6, **4** n=8, **5** n=10, **6** n=12, **7** n=14.

carbon atom are those in a very hydrophilic or an aqueous environment. The chemical shifts of C_nDPX_2 are analyzed from their intensity and position, and assigned as shown in Table 1. The chemical shifts of the ^{1}H atoms in pyridine ring are spread in the lower field as expected from the effect of π-electrons, and those of the hydrogen atoms of methylenes near the pyridine ring are found also to be influenced by the electrons as is clear from the lower chemical shifts of $=N-CH_2-$ and adjacent $-CH_2-$. The chemical shifts of ^{1}H of methylene chain in aqueous environment are 0.88—0.99 ppm.

The chemical shifts of the surfactants are also analyzed on the same ground as those of C_nDPX_2. The results are given in Table 2. More than 90% of the couterions are supposed to be bound to micelles[15] and, therefore, the spectra can be said to represent their bound state. As far as ^{1}H atoms in pyridine ring are concerned, their chemical shifts are almost the same as those of C_nDPX_2, which suggests that the cationized rings remain in an aqueous environment in micellized state. These are quite different from the chemical shifts in hydrophobic environment, for example, 8.95, 8.58, and 8.13 ppm for the α-, γ-, and β-H atoms in cyclohexane.[26] The rings connected by the longer methylene chain have been expected to be drawn toward less hydrophilic region of inner micelle, but it has turned out from the results that this is not the case. In other words, the region of micellar surface where the rings are located is very hydrophilic aqueous environment. In Fig. 2 are illustrated the difference in the chemical shifts by deducting the chemical shifts in Table 1 from those in Table 2. It is worth to mention that the down-field shift in the pyridine ring increases in the order $\alpha>\gamma>\beta$. At the same time, the enhanced down-field shift of every methylene group in polymethylene chain clearly results from concentration of pyridine rings due to micelle formation. As for PM_1, its variation is quite similar to the variation of micelle aggregation number,[15] which indicates that methylene protons of PM_1 are very sensitive to a manner of packing of surfactant ions.

The proton chemical shifts of terminal methyl and other methylenes of surfactant ion, which are referred to M_1, M_2, M_3, M_4, and M_5, change quite gradually from ca. 0.5 to 2.5 ppm. The classification of methylene groups of the alkyl chain as M_1, M_2, M_3, M_4, and M_5 is made from the chemical shifts for sodium 1-dodecanesulfonate micelles. The proton chemical shift of ca. 0.5 ppm of M_1 in inner micelle region is much smaller than the chemical shift ca. 1 ppm in aqueous environment and those of outer micellar region. The ratio of the chemical shift of M_5 to that of M_1, 5.0 is

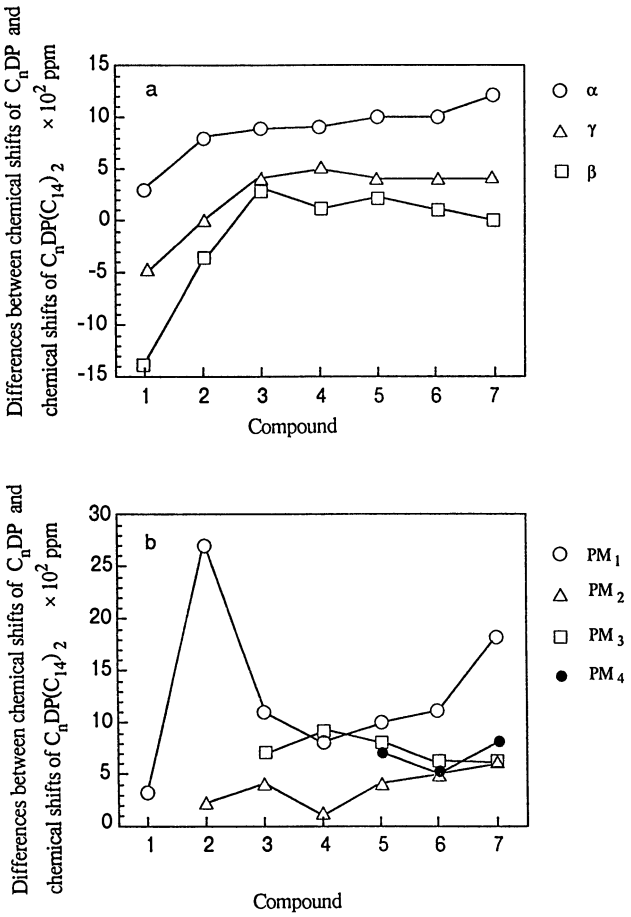

Fig. 2. The difference in the chemical shifts of counterions (a) pyridine protons, (b) polymethylene protons.

larger than that of sodium 1-dodecanesulfonate micelles, 4.0.[27] The higher ratio is due to the effect of the π-electrons of the counterions. These findings indicate the moving about of pyridine rings around the miceller surface region. The chemical shift (δ=0.96—1.08) of methylene groups (PM_3 and PM_4) of the counterions ($n \geqslant 8$) in micellized state are similar to those of methylene groups (M_2 and M_3) of surfactant ion. This suggests that PM_3 and PM_4 methylenes of counterions and M_2 and M_3 methylenes of surfactant ion are located in a similar hydrophobic environment.

The present results by ^{1}H NMR study strongly support the previous result that the polymethylene group with more than eight methylene groups folds and penetrates the hydrophobic micellar interior.

The authors are indebted to Professor Masahiko Suhara of Kanazawa University for his attention to this problem and his kind assistance in the NMR measurements.

Exothermic Reactions in C_2 Hydrocarbon Flames

Seishiro FUKUTANI,* Nílson KUNIOSHI, Keizo SAKAGUCHI, and Hiroshi JINNO†
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida-honmachi, Sakyo-ku, Kyoto 606
†Department of Chemistry, Faculty of Science and Engineering, Sophia University, Kioicho 7-1, Chiyoda-ku, Tokyo 102
(Received June 7, 1991)

Premixed stoichiometric flames of acetylene, ethylene, and ethane with air were investigated using a chemical scheme composed of eighty-two pairs of elementary reactions to illustrate the dependence of the propagation mechanisms of C_2 hydrocarbon flames on the heat release distribution. The general role of heat release distribution through flames was depicted by means of an analytical treatment of the governing equations with the thermal properties of the gases being constant and the temperature profile given by an appropriate function of the position in the flame. It was found that the amount of heat released by chemical reactions at low-temperature regions of a flame is of fundamental importance for its propagation and that the main trigger of exothermic reactions at those zones is hydrogen atoms, which diffuses from the flame front; in the acetylene flame reactions consuming hydrogen atoms at the low-temperature region were found to yield all the heat released at that zone. Heat release distribution extended down to low-temperature regions was found to be able to lead to large burning velocities even though the amount of heat released at each position was small.

Since in the low-temperature region of a premixed flame thermal energy must increase only by the supply from the high-temperature region, the propagation mechanism of a premixed flame can be classified into two types according to the way by which the supply of energy occurs:[1] Thermal propagation and diffusion-controlled propagation. In the latter mode chemical enthalpy is carried by diffusion of active species such as hydrogen atoms and transformed to thermal energy by exothermic reactions occurring in the low-temperature region. Hydrogen–air premixed flames propagate mainly through this mode at least near stoichiometric conditions[2] and methane flames through the former mode.[3]

Acetylene, ethylene, and ethane contain two carbon atoms but different number of hydrogen atoms in their molecules. A hasty consideration may lead to the conclusion that the propagation of ethane flames is governed by the diffusion of hydrogen atoms and that of acetylene by thermal conduction. Experimental measurements of the burning velocity of those three flames,[4] however, have clarified that ethane flames possess burning velocities similar to that of methane, and acetylene flames have velocities which are less than those of hydrogen flames but considerably large among premixed flames. Those facts may warn us not to conclude rashly that the propagation mechanism of a premixed flame is simply deduced on the basis of the chemical composition of the fuel molecule.

The purposes of this paper are to elucidate the following two points by means of computer simulation using a detailed chemical reaction model: (1) What is the decisive factor to determine the propagation mechanism in the three C_2 hydrocarbon premixed flames; and (2) How heat release by chemical reactions controls the burning velocity.

Simulation Model

Some usual assumptions for models of flat flames[2] derive the following governing equations, which were used in the model in this investigation:

$$\frac{\partial \rho}{\partial t}+\frac{\partial}{\partial x}(\rho v)=0, \tag{1}$$

$$\frac{\partial}{\partial t}(c_p\rho T)+\frac{\partial}{\partial x}(c_p\rho T v)=\frac{\partial}{\partial x}\left(\lambda\frac{\partial T}{\partial x}\right)+\sum_i D_i\rho\frac{\partial h_i}{\partial x}\frac{\partial \omega_i}{\partial x}-\sum_i h_i\phi_i, \tag{2}$$

$$\frac{\partial}{\partial t}(\rho\omega_i)+\frac{\partial}{\partial x}(\rho\omega_i v)=\frac{\partial}{\partial x}\left(D_i\rho\frac{\partial \omega_i}{\partial x}\right)+\phi_i, \tag{3}$$

$$p=\rho RT\sum_i\frac{\omega_i}{m_i}, \tag{4}$$

where ρ is the density, v the flow velocity, T the temperature, p the pressure, c_p the specific heat, and λ the thermal conductivity of the gas mixture; ω_i is the mass fraction, ϕ_i the net production rate, h_i the enthalpy, m_i the molar mass and D_i the diffusion coefficient of the i-th species; and R is the gas constant.

The reaction scheme which was proposed in a previous paper[3] comprises eighty-two pairs of elementary reactions among twenty-five chemical species of C_1 and C_2 hydrocarbons and hydrogen–oxygen-containing species. The model gives valid burning velocities for methane flames with a wide range of equivalence ratio.[3]

Table 1. Stoichiometric Hydrocarbon–Air Premixed Flames

Hydrocarbons	C_2H_2	C_2H_4	C_2H_6
Burning velocity/m s^{-1}	1.56	0.76	0.49
Adiabatic flame temperature/K	2550	2380	2260
Experimental burning velocity[4]/m s^{-1}	1.56	0.78	0.48

As for the C_2 flames, however, it gives burning velocities agreed with the experimental values only for the stoichiometric and lean conditions (see Table 1); for rich conditions the calculated burning velocities are larger than the corresponding experimental velocities since the decrease in the burning velocity due to the waste of a small part of the fuel in the soot-forming process is neglected in the reaction scheme. In this work, stoichiometric flames of the C_2 hydrocarbons are, therefore, investigated by using the proposed scheme.

The boundary conditions were given as follows: at the unburned side the temperature is 298 K and the gas mixture contains only the fuel and air, and at the burned side the temperature is raised up to the adiabatic flame temperature, which is obtained by the chemical equilibrium calculation based on the total enthalpy at the unburned side, and the gas has the corresponding equilibrium composition at that temperature. A simulated flame can be kept in the steady state only when the flow velocity just agrees with the burning velocity, and this value was obtained by the trial-and-error method.

Results and Discussion

Structures of the Flames. Figure 1 shows the temperature profiles of the three C_2 hydrocarbon premixed flames. The temperature gradients increase in the order of the increasing burning velocity. In the ethane flame the temperature is elevated gradually at low temperatures just like an exponential function. In the acetylene flame, on the contrary, the temperature gradient increases steeply. The ethylene flame keeps an intermediate temperature gradient between those of the acetylene and ethane flames over the whole region.

Figure 2 shows the exothermic rates of the three flames as functions of temperature. Distinguished differences among those rates are: (1) the rate of the ethane flame is much smaller than that of the acetylene flame; (2) in the acetylene flame heat evolution starts increasing at such a low temperature as 450 K and rises with a large slope particularly at low temperatures, but in the ethane flame it increases from 700 K and keeps almost a constant gradient.

Analytical solution of the thermal energy conservation equation, Eq. 2, neglecting chemical reactions occurring at low temperatures yields the following results: if the thermal properties of the gas mixture can be treated as being constant, (1) the reaction-zone thickness of a premixed flame is inversely proportional to the burning velocity and (2) the burning velocity is proportional to the square root of the averaged reaction rate.[1] Those two predictions seem to be valid in the three C_2 flames as suggested by Figs. 1 and 2. Strictly speaking, however, the simulated burning velocity of the acetylene flame is larger than the value of the analytical prediction. The deviation comes from the indifference to the reaction-rate distribution or, correspondingly, to the exothermic rate distribution in the analytical treatment. The distribution of heat release throughout the flame, particularly at low temperatures, should be considered in order to estimate precisely the burning velocity of a premixed flame.

The inflow of chemical enthalpy into the low-temperature region of a premixed flame is substantially supported by hydrogen atoms diffused from the flame front. The second term in the right-hand side of Eq. 2

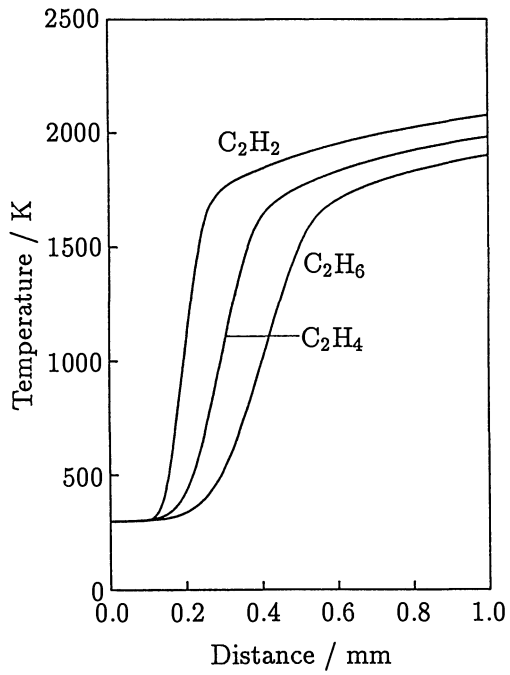

Fig. 1. Profiles of temperature in the stoichiometric C_2 hydrocarbon premixed flames.

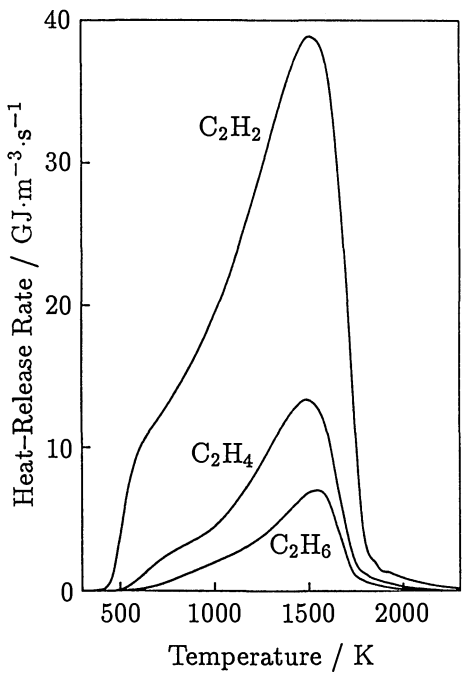

Fig. 2. Distributions of exothermic rates in the stoichiometric C_2 hydrocarbon premixed flames.

is called enthalpy transfer accompanying species diffusion. This popular designation, however, is not correct and that term does not strictly express the rate of enthalpy accumulation by species diffusion. The original enthalpy-conservation equation prescribes the conservation of total enthalpy (thermal enthalpy+chemical enthalpy):

$$\frac{\partial h}{\partial t}+\frac{\partial}{\partial x}(hv)=\frac{\partial}{\partial x}\left(\lambda\frac{\partial T}{\partial x}\right)+\sum_i\frac{\partial}{\partial x}\left(D_i\rho h_i\frac{\partial \omega_i}{\partial x}\right), \quad (5)$$

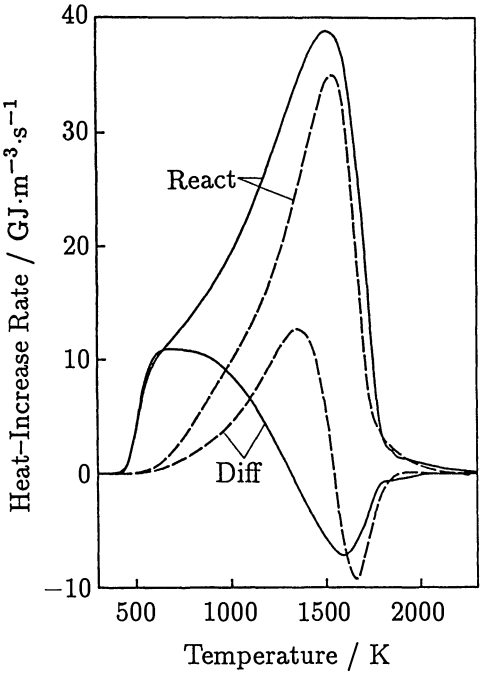

Fig. 3. Rates of the increase in enthalpy accompanying diffusion of hydrogen atoms (Diff) and those of heat release (React) in the acetylene (solid line) and ethane (dashed line) flames; the rates of the ethane flame are multiplied by a factor of 5.

where h is the total enthalpy per unit volume of the gas mixture. The second term in the right-hand side of Eq. 5 does designate the enthalpy carried by diffused species. This equation, however, does not involve explicitly an exothermic term and hence is usually transformed into the conservation equation of thermal enthalpy, Eq. 2. The so-called diffusion term appearing in Eq. 2, moreover, gives only a small contribution to the heat transfer toward low-temperature regions of premixed flames.[2,3]

Figure 3 depicts the rates of the increase in enthalpy due to diffusion of hydrogen atoms calculated according to Eq. 5 and the exothermic rates in the acetylene and ethane flames, as typical examples. In the low-temperature region of the acetylene flame the exothermic rate agrees very well with the enthalpy-increase rate due to diffused hydrogen atoms; it should be noted that the intense heat release observed between 450 K and 600 K is thoroughly ascribable to the exothermic reactions which consume all the diffused hydrogen atoms. In the ethane flame, on the other hand, diffused hydrogen atoms do not work as a direct source of the heat release but work only as a trigger for reactions occurring at low temperatures; the role as a reaction trigger is also essential because combustion reaction cannot be easily initiated in an unburned gas mixture within a short time if they are activated only by rising temperature.

The temperature-increase mode in the low-temperature region of a premixed flame, therefore, does not simply depend on the amount of hydrogen atoms contained in the fuel molecule but on the mechanisms of the reactions occurring in the high- and low-temperature regions.

Reaction Mechanisms of Production and Consumption of Hydrogen Atoms. The mechanisms of combustion reactions in the C_2 hydrocarbon flames have been discussed by many authors based on computer simulation using various reaction schemes.[5–9] Figures 4a and

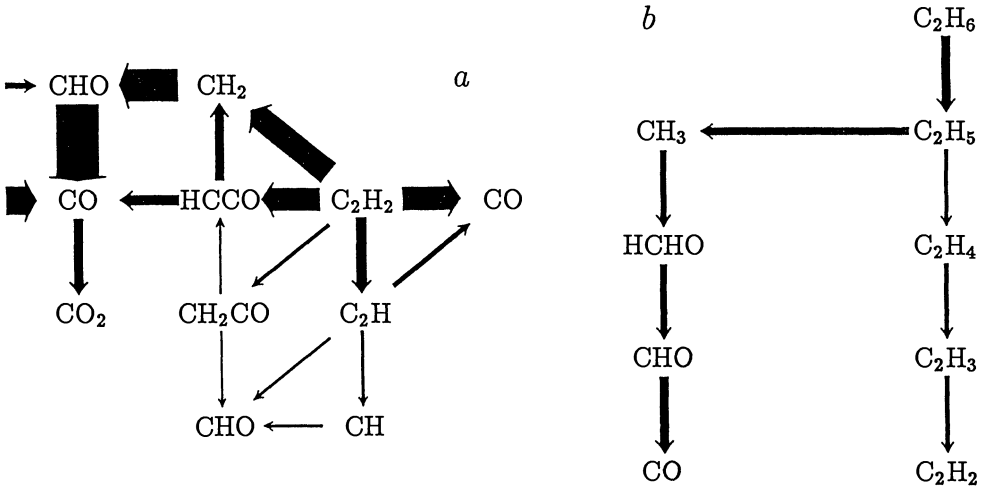

Fig. 4. Reaction pathways in the acetylene flame at 1510 K (a) and in the ethane flame at 1550 K (b). The width of the arrows is proportional to the rate of the corresponding route.

4b show the reaction pathways at the positions of the maximum exothermic rates in the acetylene and ethane flames obtained in this investigation. Carbon monoxide is slowly oxidized even at temperatures higher than 1500 K; only after conversion of all the hydrocarbons to carbon monoxide its oxidation proceeds fast.

A characteristic of the combustion reaction of the acetylene flame is that the reaction pathway from the fuel to carbon monoxide is short. Such a short span in the reaction pathway can lead to easy acceleration of the whole fuel oxidation without congestion of intermediate species. In the ethane flame, on the contrary, the main combustion route proceeds unexpectedly along the so-called C_1 route after the leap from ethyl radicals to methyl radicals through the reaction

$$C_2H_5 + H \rightarrow CH_3 + CH_3 \quad \text{(R10)}$$

at high temperatures. This is a reason why ethane flames have burning velocity similar to that of methane flames. At temperatures lower than 1200 K, however, ethyl radicals are predominantly dehydrogenated to ethylene by the reaction

$$C_2H_5 + O_2 \rightarrow C_2H_4 + HO_2. \quad \text{(R31)}$$

The ethylene flame holds the same mechanism as that of the acetylene flame since the fuel is once dehydrogenated to acetylene and reacts along the same route; the burning velocity settles down at an intermediate value between those of the acetylene and ethane flames.

In order to pursue the production and consumption of hydrogen atoms the rates of the elementary reactions in which hydrogen atoms participate are shown in Figs. 5a and 5b. Differences between the reactions of the acetylene and ethane flames are: (1) the reaction rates in the acetylene flame are much larger, as a whole, than those in the ethane flame; and (2) hydrogen atoms are consumed in a great amount in the low-temperature region of the acetylene flame.

The consumption of hydrogen atoms at low temperatures in the acetylene flame is due to the reactions

$$C_2H_2 + H + M \rightarrow C_2H_3 + M \quad \text{(R42)}$$

and

$$C_2H_3 + H \rightarrow C_2H_2 + H_2. \quad \text{(R40)}$$

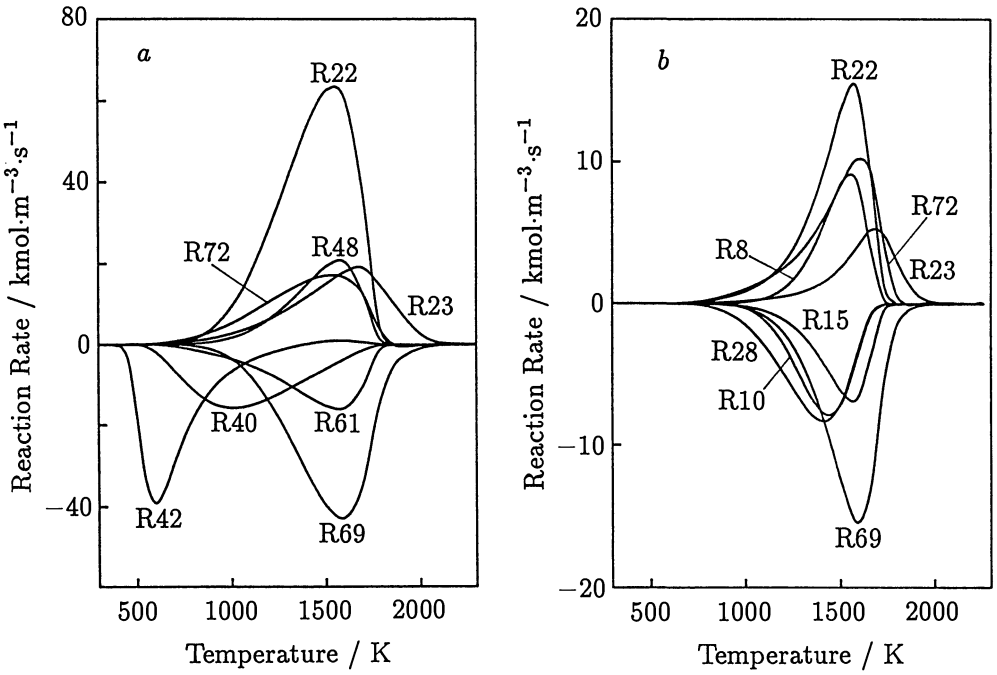

Fig. 5. Rates of the reactions in which hydrogen atoms participate in the acetylene (a) and ethane (b) flames. The negative rates express that the corresponding reactions consume hydrogen atoms.

R8: $CH_3 + O \rightarrow HCHO + H$
R10: $C_2H_5 + H \rightarrow CH_3 + CH_3$
R15: $HCHO + H \rightarrow CHO + H_2$
R22: $CHO + M \rightarrow CO + H + M$
R23: $CO + OH \rightarrow CO_2 + H$
R28: $C_2H_6 + H \rightarrow C_2H_5 + H_2$
R40: $C_2H_3 + H \rightarrow C_2H_2 + H_2$
R42: $C_2H_2 + H + M \rightarrow C_2H_3 + M$
R48: $C_2H_2 + O \rightarrow HCCO + H$
R61: $HCCO + H \rightarrow CH_2 + CO$
R69: $H + O_2 \rightarrow OH + O$
R72: $OH + H_2 \rightarrow H + H_2O$

The rate constant of reaction (R42) changes increasingly with decreasing temperature because of its negative activation energy. Hydrogen atoms diffused from the flame front, therefore, easily react with the fuel at low temperatures releasing a fairly large amount of heat, 193 kJ mol^{-1} at 500 K and 197 kJ mol^{-1} at 1000 K, for example. As temperature rises another possibility for their consumption, that is, reaction (R40) is added to the reaction mechanism. The rate constant of this reaction increases gradually with increasing temperature. This reaction also generates much heat, 249 kJ mol^{-1} at 500 K and 247 kJ mol^{-1} at 1000 K. The steep increase in exothermic rate of the acetylene flame shown in Fig. 2 is ascribed to these two reactions and the shoulder observed around 600 K comes from the intense exothermicity of reaction (R42).

The acetylene flame has thus a very effective source of heat release at low temperatures; the above described pair of reactions convert hydrogen atoms to molecular hydrogen and, at the same time, the fuel to vinyl radicals at the first stage and then the vinyl radicals back to acetylene at the second stage.

The production of hydrogen atoms is predominantly ascribable to the reaction

$$CHO + M \rightarrow CO + H + M \qquad (R22)$$

at the flame fronts of hydrocarbon flames. As described above, the reaction path from the fuel to carbon monoxide is fairly short in the acetylene flame and, therefore, hydrogen atoms are yielded in a great amount at the flame front.

Moreover, the acetylene flame has advantages for fast transport of hydrogen atoms to the low-temperature region because of the thin reaction zone shown in Fig. 1 though this condition is naturally satisfied in a flame having large burning velocity since the reaction-zone thickness is inversely proportional to burning velocity.

Consequently, when the three conditions for supply of a sufficient amount of chemical enthalpy toward the low-temperature region, that is, production of hydrogen atoms at high temperatures, their diffusion toward low-temperature region and their consumption with heat release at low temperatures, are satisfied, the amount of chemical enthalpy easily exceeds that of thermal energy carried by thermal conduction, and therefore the flame is stably maintained according to the so-called diffusion-controlled propagation mechanism.

Role of Heat Release at Low Temperatures on Flame Propagation. As pointed out in the previous subsection the effects of heat release on the burning velocity must be discussed based on the magnitude of its rate and the shape of its distribution as well. The role of the distribution of exothermic rate, particularly at low temperatures, will be investigated here.

The temperature distribution in a flame must satisfy Eq. 2. The second term in the right-hand side of that equation gives the rate of heat transfer related to species diffusion and is negligibly small as described above, and the time-dependent term in the left-hand side equals zero at steady state; therefore Eq. 2 is reduced to an ordinary differential equation

$$\frac{d}{dx}(c_p\rho Tv)=\frac{d}{dx}\left(\lambda\frac{dT}{dx}\right)-\sum_i h_i\phi_i. \qquad (6)$$

In the steady state ρv=const., and c_p and λ can be assumed to be constant in a first-order approximation, and thus Eq. 6 becomes

$$\lambda\frac{d^2T}{dx^2}-c_p\rho v\frac{dT}{dx}-\sum_i h_i\phi_i=0. \qquad (7)$$

In a low-temperature region, Eq. 7 is further simplified by neglect of the exothermic term and gives an analytical solution

$$T=\alpha\exp\left(\frac{c_p\rho v}{\lambda}x\right)+T_u, \qquad (8)$$

where T_u is the temperature of the unburned gas mixture and α is an arbitrary constant fixing the position of the flame along the x-axis. Equation 8 shows that the temperature rises exponentially in the region preceding the exothermic region in a steady premixed flame, and the temperature gradient grows as the burning velocity increases.

On the other hand the temperature of a premixed flame cannot be raised higher than its adiabatic flame temperature. The temperature, therefore, must approach asymptotically the adiabatic flame temperature and have an inflection point in its distribution. The decline of the temperature gradient toward zero should consequently be actualized by the exothermic term, that is, the last term in Eq. 7.

When exothermic reactions start at a high temperature the heat release must reduce the temperature gradient within the small temperature interval remaining before the adiabatic flame temperature; therefore chemical reactions should emit heat with a large rate. On the contrary, when they occur at low temperatures even a small rate of heat release can shift the temperature gradient toward zero. These effects of the heat release are discussed by solving Eq. 7.

Unfortunately Eq. 7 cannot be solved analytically. The subject to elucidate in this subsection is, however, how burning velocity is influenced by heat release at low temperatures. Here, in contrast with the usual method, the temperature distribution in the exothermic region is assumed, at first, as a function of position and substituted into Eq. 7, and then the exothermic term is evaluated for the given temperature distribution.

The temperature distribution is given by using a logistic function:

$$T=\frac{T_0}{1+\beta\exp(-bx)}+T_u, \qquad (9)$$

where T_0, T_u, β and b are four arbitrary constants; such a function asymptotically approaches T_u, the temperature of the unburned gases, at $x=-\infty$, $T_0+T_u\equiv T_{ad}$ at

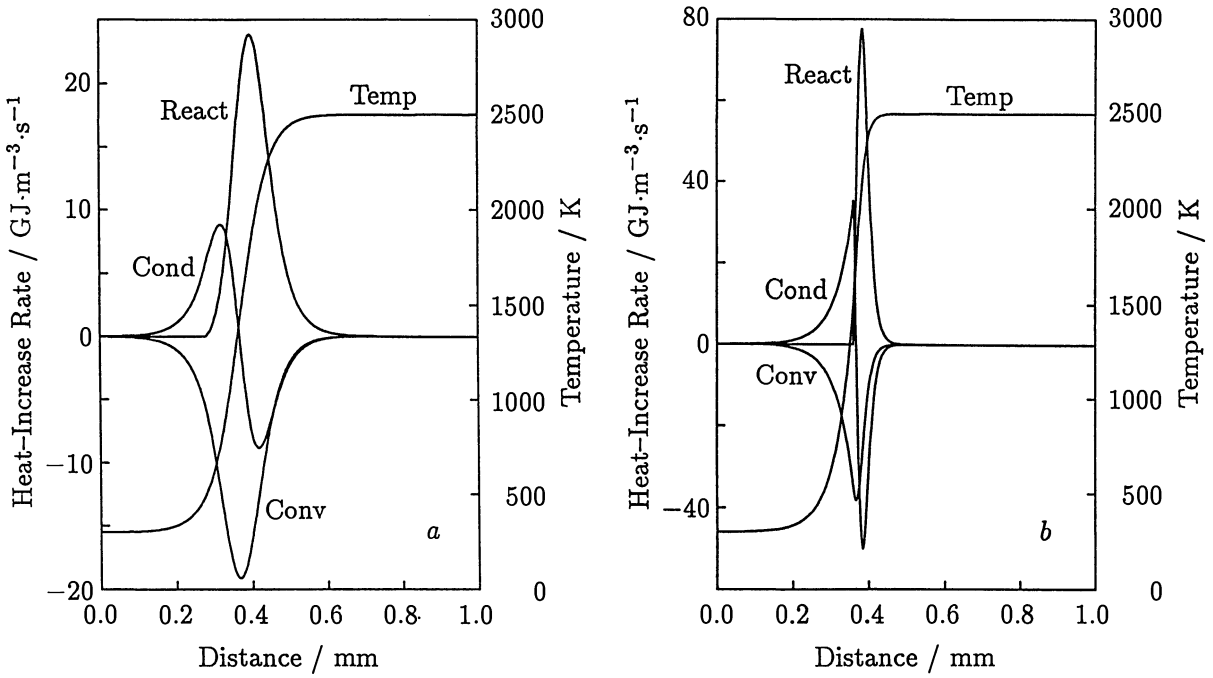

Fig. 6. Profiles of temperature (Temp) and the heat-increase rates due to convection (Conv), conduction (Cond), and the exothermic rate (React) in the flames with T_c=500 K (a) and 1500 K (b).

$x=\infty$, where T_{ad} corresponds to the adiabatic flame temperature, and has an inflection point at $x=\ln \beta/b$. The values of T determined by Eq. 9 are satisfactory for the temperature distributed in a premixed flame. The assumed logistic curve is connected with the exponential curve for the temperature distribution in the nonexothermic region, Eq. 8, in such a way that the temperature itself, and its first and second derivatives have the same values, respectively, at a certain point; the flames are distinguished by the connection temperature, which is designated as T_c. Those three conditions at the connecting point and a given T_{ad} can fix the four constants of the logistic curve.

Figures 6a and 6b show the distributions of the temperature and the heat balance in two flames with the same burning velocity, 1.0 m s^{-1}, and the same adiabatic flame temperature, 2500 K, but different connection temperatures, 500 K and 1500 K. The unburned gases of both flames have constant ρ, c_p, and λ equal to, respectively, 1.3 kg m^{-3}, 1000 J kg^{-1} K^{-1}, and 0.058 W m^{-1} K^{-1}. The two temperature distributions in the nonexothermic regions are expressed, as mentioned above, with the same exponential function of distance, but those in the exothermic regions are clearly different; the reaction zone of the flame with higher T_c is much thinner and its maximum exothermic rate is about four times as large as that of the flame with lower T_c, indicating that the flame front thickness is related to the exothermic-rate distribution.

Figure 7 depicts the exothermic-rate distributions in the various flames with a wide range of T_c. The integration of the exothermic rate of the flames in the range

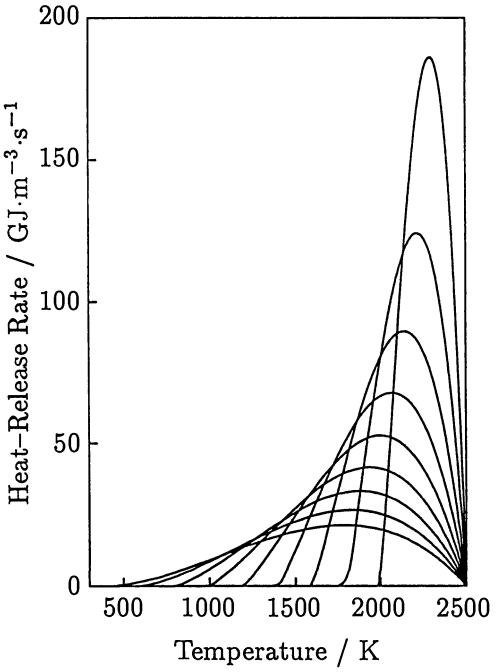

Fig. 7. Distributions of the exothermic rates of the flames having T_c ranging from 400 K to 2000 K with intervals of 200 K.

of x from $-\infty$ to $+\infty$ gives the same value since this value corresponds to the thermal energy necessary for heating the unburned gases from room temperature to the adiabatic flame temperature, 2500 K. The maximum exothermic rate of the flame with the smallest T_c, however, is about 1/9 of that of the flame with the

largest T_c; the temperature range of the exothermic region of the former flame is four times as large as that of the latter flame, and therefore the flame thickness of the former flame is larger. The result that a flame evolving heat at low temperatures can maintain stable flame propagation even if the exothermic rate is small indicates that the flame possibly possesses larger burning velocity when the exothermic rate has almost a similar magnitude.

Conclusions

Simulation of acetylene, ethylene, and ethane premixed flames was performed under the stoichiometric conditions using a detailed reaction scheme, which reproduces the combustion reactions of C_1 and C_2 hydrocarbons, and the following conclusions were obtained:

1. In the acetylene flame, enthalpy is carried into the low-temperature region as the chemical enthalpy of diffused hydrogen atoms, and converted there into thermal enthalpy by a pair of reactions which are substantially reduced to recombination of hydrogen atoms. The unburned gas is heated by those exothermic reactions. The flames where a large amount of hydrogen atoms are produced at high temperatures, diffused to the low-temperature region and consumed there with heat release can propagate according to the diffusion-controlled propagation mechanism. In the ethane flame, on the other hand, combustion reaction proceeds predominantly along the C_1 route and then this flame has the same propagation mechanism as that of a stoichiometric methane flame. In the ethylene flame the fuel is once dehydrogenated to acetylene.

2. When chemical enthalpy is carried by diffused hydrogen atoms and heat is liberated by reactions consuming them at low temperatures, the temperature distribution deviates from an exponential distribution, and the exothermic zone becomes thick. Then even small exothermic rate can maintain stably large burning velocity.

Cationic Self-Diffusion in Ionic Plastic Phases of Thallium Nitrite and Nitrate and in Thallium Thiocyanate

Yoshihiro FURUKAWA,* Hirokazu NAGASE, Ryuichi IKEDA,† and Daiyu NAKAMURA††
Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464-01
(Received June 11, 1991)

Cationic self-diffusion in the ionic plastic phases of $TlNO_2$ and $TlNO_3$ was investigated by measuring temperature dependences of the $^{203,205}Tl$ NMR spin-lattice relaxation time and the electrical conductivity. The NMR results showed that the Tl^+ ions in these phases undergo rapid translational diffusion with the activation energy (E_a) of 48 and 77 kJ mol^{-1} for nitrite and nitrate, respectively. The E_a values agreed well with those obtained from the electrical conductivity, indicating that the cation is the electric carrier. The diffusion constants (D) estimated from the relaxation time and conductivity data were ca. 10^{-12} m^2 s^{-1} at the respective melting point (T_m) of plastic phase. The tendency that D at T_m has the characteristic value given above is recognized for other ionic plastic phases so far reported. The Tl^+ ionic conductivity in TlSCN, which makes no plastic phase, was reported in comparison.

Plastic crystals consist of molecules whose centers of gravity form a regular crystalline lattice, whereas each molecule is in a highly movable state as in liquid. Molecular motions characteristic in the plastic crystals are the isotropic overall rotation and the translational self-diffusion which are attributable to the origin of marked plasticity observed in this phase. Systematic NMR studies on this phase of molecular crystals have revealed that the average time for the self-diffusional jump to the neighboring vacant sites observed at the melting point is independent of molecules as well as temperatures, and becomes almost the same value (ca. 10^{-7} s).[1] Similar results have been obtained in plastic phases of ionic crystals containing methylammonium cations.[2-4]

The highest-temperature solid phases of thallium nitrite and nitrate have been reported to form plastic crystals.[5-8] It has been shown from the TlNMR studies that the Tl^+ ions are diffusing in these phases.[9,10] In the present study, we intend to measure the electrical conductivity of $TlNO_2$ and $TlNO_3$ and the ^{205}Tl NMR spin-lattice relaxation time of $TlNO_3$ to get detailed information on the diffusional motions in the ionic plastic crystals.

Experimental

Commercially available $TlNO_3$ (Nacalai Tesque, GR) and $TlNO_2$ prepared by double decomposition of $Ba(NO_2)_2 \cdot H_2O$ and Tl_2SO_4 are recrystallized from aqueous solution. The ^{205}Tl spin-lattice relaxation time, T_1, was determined by the usual inversion recovery method using a homemade NMR spectrometer.[11] The electrical conductivity, σ, was measured by means of the complex impedance analysis using an Ando Denki AG-4311 LCR meter, which was interfaced to an NEC PC-9801 microcomputer by GP-IB. The impedance was determined over the frequency range between 0.1 and 100 kHz on pelletized samples with the electrodes of colloidal carbon. The sample temperatures were measured by a copper–constantan thermocouple within errors of ±1 K.

Results and Discussion

We have previously reported the temperature dependence of the spin-lattice relaxation times, T_1 and $T_{1\rho}$, in the laboratory and rotating frame, respectively, and the spin–spin relaxation time, T_2, of $^{203,205}Tl$ in $TlNO_2$.[10] These relaxation times were interpreted in terms of the reorientation of the NO_2^- ions in the low-temperature phase obtainable below the phase transitioin temperature (T_c) of 282 K and the translational self-diffusion of the Tl^+ ions in the high-temperature plastic phase above T_c. In the analysis of the relaxation times attributable to the Tl^+ ionic self-diffusion, the usual BPP-type spectral density functions were assumed.[12] A small discrepancy recognized in the motional parameters determined from T_1 and $T_{1\rho}$ analysis may be ascribed to this assumption because it has been expected that the BPP-type spectral density is a rough approximation for diffusing spins.[13]

The temperature dependence of the relaxation times in $TlNO_2$ above 263 K are represented in Fig. 1.[10] The magnetization recovery curve in the T_1 measurements of Tl nuclei usually becomes nonexponential because of the magnetic interactions between two kinds of Tl isotopes, ^{203}Tl and ^{205}Tl, which have only 1% difference in the gyromagnetic ratios.[9,10] From the observed recovery curves, we evaluated the long and short components of T_1 (T_1^l and T_1^s, respectively). The T_1^l values in the high-temperature phase of $TlNO_2$, which are known to be usually determined by lattice vibrations,[10] are ommited in Fig. 1. The T_2 increase observed on heating and the minima in both T_1^s and $T_{1\rho}$ are assignable to the translational self-diffusion of the Tl^+ ions.

The relaxation times of Tl nuclei are mainly governed by scalar (pseudo-exchange) interactions and approximated by[9,10,12]

$$(T_1^s)^{-1} = 2(\langle \delta\omega^2 \rangle_i + \langle \delta\omega^2 \rangle_j)\, j(\omega_{0i} - \omega_{0j}, \tau), \quad (1)$$

$$(T_{1\rho})_i^{-1} = \langle \delta\omega^2 \rangle_i \{ j(\omega_{1i}, \tau) + j(\omega_{0i} - \omega_{0j}, \tau) \}, \quad (2)$$

† Present address: Department of Chemistry, University of Tsukuba, Tsukuba 305.
†† Deceased on 27 February, 1991.

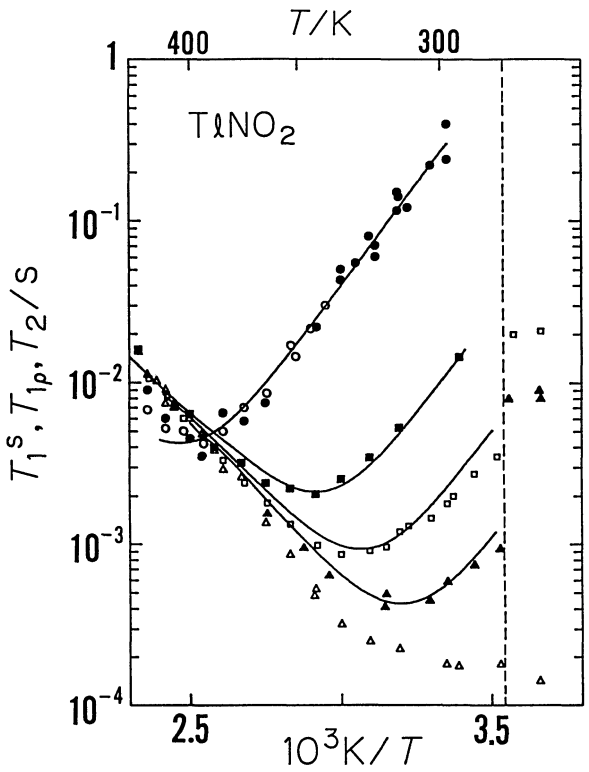

Fig. 1. Temperature dependences of T_1^s (short component), $T_{1\rho}$, and T_2 of ^{203}Tl and ^{205}Tl in $TlNO_2$ observed above 263 K.[10] T_1^s of ^{203}Tl and ^{205}Tl at 34.270 (●) and 34.613 MHz (○), respectively; ^{205}Tl $T_{1\rho}$ at ω_1=157 (■), 68 (□), and 31 krad s^{-1} (▲); ^{205}Tl T_2 (△). ^{203}Tl $T_{1\rho}$ and T_2 were omitted for simplicity. The solid lines were calculated using Eqs. 1 and 2 and the spectral density numerically given for the self-diffusion in the sc lattice.[13] The vertical broken line indicates the phase transition point.

$$(T_2)_i^{-1}=\langle\delta\omega^2\rangle_i\{j(0,\tau)+j(\omega_{0i}-\omega_{0j},\tau)\}. \quad (3)$$

Here, ω_{0i} and ω_{1i} are the Larmor frequencies of thallium-i spins (i=203 or 205) in the laboratory and rotating frame, respectively. $\langle\delta\omega^2\rangle_i$ is the NMR second moment of thallium-i spins determined by the scalar interactions with unlike thallium-j spins. Since the scalar interaction between like spins does not affect the second moment, one can obtain $0.295\langle\delta\omega^2\rangle_{203}=0.705\langle\delta\omega^2\rangle_{205}$ by referring to the natural abundances of ^{203}Tl and ^{205}Tl nuclei. This relation could be confirmed from the ratios of $T_{1\rho}$ or T_2 observed for ^{203}Tl and ^{205}Tl, indicating that the relaxations of the thallium nuclei are dominated by the scalar interactions.[10] τ is the correlation time of the Tl^+ self-diffusioin. $j(\omega,\tau)$ is the spectral density function, and under the assumption that the correlation function is exponential or of the BPP-type, it is expressed as[12]

$$j(\omega,\tau)=\tau/(1+\omega^2\tau^2). \quad (4)$$

Barton and Sholl have reported numerical results of nuclear spin relaxation times due to dipole–dipole interacions between diffusive species in fcc, bcc, and sc lattices.[13] In order to reanalyze the relaxational data given in Fig. 1, we use their numerical values of $g_{poly}(y)$, where $y=\omega\tau/2$, for the sc lattice given in Ref. 13 instead of Eq. 4 by assuming that the spectral density for the scalar interactions is the same shape as that for the dipolar ones; the fitting calculation was carried out using the T_1^s and $T_{1\rho}$ data. The determined diffusional parameters are given in Table 1. These parameters are not significantly different from those given in Ref. 10, but the present analysis can account for the temperature dependence of both T_1^s and $T_{1\rho}$ using the same parameters.

Table 1. Tl^+ Diffusional Parameters Determined from Tl NMR Relaxation Times in the Ionic Plastic Phases of $TlNO_2$ and $TlNO_3$

Compound	$C^{a)}/10^7$ s^{-2}	$\log(\tau_0/\text{s})$	E_a/kJ mol^{-1}
$TlNO_2$	6.6±0.2	−12.3±0.1	48±1
$TlNO_3$	10.2±0.5	−15.6±0.4	77±5

a) $C=(\langle\delta\omega^2\rangle_i+\langle\delta\omega^2\rangle_j)/7.5$, where the factor 7.5 was introduced by comparing the maximum values of $\omega j(\omega,\tau)$ in Eqs. 1 and 2 with that of $y\,g_{poly}(y)$ in Ref. 13.

Villa and Avogadro have studied the temperature dependences of T_1^l, $T_{1\rho}$, and T_2 of Tl nuclei in $TlNO_3$.[9] They, however, reported no T_1^s because, in most cases, it gives the same information as $T_{1\rho}$. Their derivation

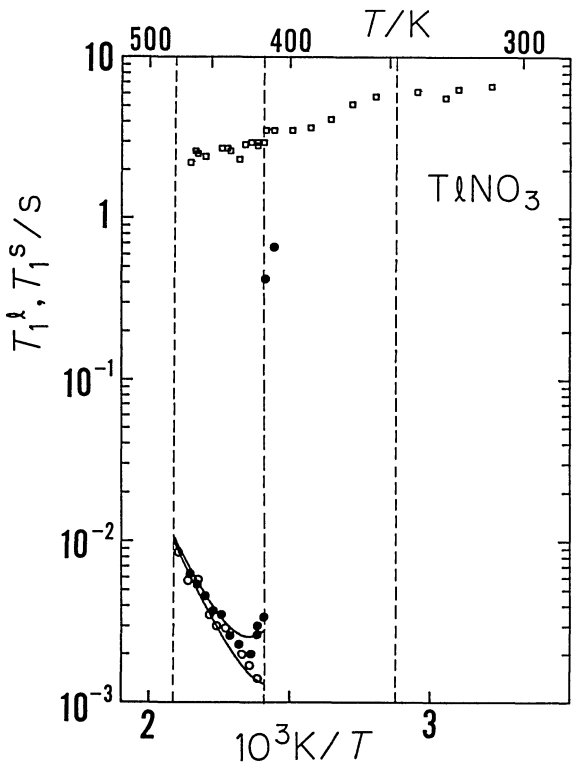

Fig. 2. Temperature dependences of ^{205}Tl T_1^l (□) and T_1^s (●) at 32 MHz, and T_1^s (○) at 16 MHz in $TlNO_3$. The solid lines for T_1^s were calculated in the same procedure as that for $TlNO_2$. Broken lines indicate the melting and two phase-transition points.

of ionic-diffusion correlation time from the $T_{1\rho}$ and T_2 is likely to be less reliable, because no $T_{1\rho}$ minimum was detected. It can be expected from their data that a T_1^s minimum in the highest-temperature phase of $TlNO_3$ will be detected, if one chooses a suitable resonance frequency. This can be derived from the fact that the NMR time scale of T_1^s $\{(\omega_{0i}-\omega_{0j})^{-1}\}$ is just between those of T_1^l (ω_0^{-1}) and $T_{1\rho}$ (ω_1^{-1}). Along this purpose, we measured the temperature dependence of T_1^s at 16 and 32 MHz. A T_1^s minimum could be observed at 32 MHz in the high-temperature plastic phase as shown in Fig. 2. The analytical procedure of the T_1^s is the same as above, and the obtained motional parameters are given in Table 1.

The diffusion constant (D_{NMR}) of the Tl^+ ions is related to the diffusion correlation times by

$$D_{NMR}=\langle l^2\rangle/6\tau, \quad (5)$$

where, $\langle l^2\rangle$ stands for the mean-square jump distance of the ions. When l is assumed to be equal to the lattice parameter of the unit cell, D_{NMR} can be derived, and the values at the melting point (T_m) of $TlNO_2$ and $TlNO_3$ are given in Table 2.

Figure 3 shows the temperature dependence of the electrical conductivity of $TlNO_2$, $TlNO_3$, and TlSCN, where the last compound forms no plastic phase.[14] The diffusion constant (D_σ) of the ions can be related to the electrical conductivity by the Nernst–Einstein equation:

$$D_\sigma=\sigma\, kT/(Ze)^2c. \quad (6)$$

Here, Ze and c are the charge and concentration of the diffusing ions, respectively. Since the Arrhenius relation is assumed for D_σ, the conductivity activation energy (E_σ) can be determined from the slope of the $\log\sigma T$ vs. $1/T$ plot.

$TlNO_2$ gave σ of 2.4×10^{-4} S m^{-1} at 296 K. With increasing temperature, the σT vs. $1/T$ plot of $TlNO_2$ increased exponentially, yielding E_σ of 46.6 kJ mol^{-1}. This is in good agreement with that determined from the relaxation measurements, indicating that the Tl^+ ions are the electric carriers in $TlNO_2$. The σ value of $TlNO_3$ shows a break in the $\log\sigma T$ vs. $1/T$ curve at both phase transition points. The decrease in σ in the intermediate-temperature phase was observed by several authors,[6,9,15] and assigned to some effect of the sample humidity.[6] The highest-temperature plastic phase has E_σ of 79 kJ mol^{-1}, which agrees with 77 kJ mol^{-1} from

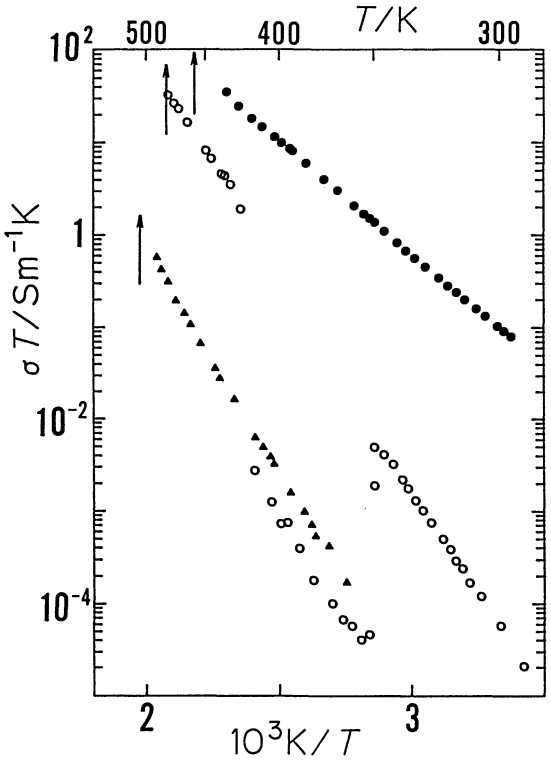

Fig. 3. Temperature dependence of the electrical conductivity (σ) in $TlNO_2$ (●), $TlNO_3$ (○), and TlSCN (▲). The $\log\sigma T$ value is plotted against $1/T$. Arrows indicate the respective melting points. The breaks in the $\log\sigma T$ vs. $1/T$ curve for $TlNO_3$ are due to the phase transitions.

Table 2. Phase Transition Temperature (T_c/K) from the Normal to Plastic Phase, Melting Point (T_m/K), Diffusion Constant ($D_m/10^{-12}$ m^{2}s^{-1}) Extrapolated to Their Melting Points of Several Ionic Plastic Crystals

Compound	$T_c(T_m)$	NMR				Conductivity

a) Asterisks represent the present work. b) Decomposition point. c) Derived from T_2 data. d) TlSCN forms no plastic phase up to T_m.

the T_1^S results. The fact that σ in TlSCN is lower than those of $TlNO_2$ and $TlNO_3$ may imply that TlSCN is not plastic. We have shown that the charge carriers in TlSCN are also the Tl^+ ions.[16] Under the assumtion that c is the total Tl^+ ion concentration, D_σ was estimated to be 2.5×10^{-12}, 1.4×10^{-12}, and 4.8×10^{-14} $m^2 s^{-1}$ at T_m of $TlNO_2$, $TlNO_3$, and TlSCN, respectively.

For many molecular plastic crystals, it has been observed that the diffusion constants at respective T_m are in the range $0.5—2.5\times10^{-13}$ $m^2 s^{-1}$ and the correlation times of the diffusion approach $10^{-7}—10^{-6}$ s.[1]

In order to see whether the diffusion constant in ionic plastic phases approaches a characteristic value at T_m, as in molecular plastic crystals, we collected experimental data on the ionic diffusions studied by electrical conductivities and NMR relaxation times. The collected data of D_{NMR} and D_σ at T_m are summarized in Table 2. Both D values of each compound are in good agreement in spite of the different methods employed to deduce them. With no exception, D_{NMR} as well as D_σ tends to converge into ca. 10^{-12} $m^2 s^{-1}$. This value is thought to be characteristic for ionic plastic phases. It is surprising that these characteristic correlation times are almost the same in both ionic and molecular plastic crystals because the weak van der Walls interaction is the main cohesive force in the molecular crystals whereas the much stronger Coulombic force is opperative in ionic crystals.

Theoretical Study of Phenalenium Systems

Biswanath Ghosh, Debranjan Ghosh, Archana Das Gupta, and Nanda K. Das Gupta*
Department of Chemistry, Visva-Bharati University, Santiniketan, West Bengal 731235, India
(Received July 30, 1990)

Phenalenium systems have been studied using PPP method modified by Dewar et al. Ground state properties and other properties such as $\pi^* \leftarrow \pi$ spectra, ionization potential, electron affinity, half-wave reduction potential, pi-dipole moment have been predicted and correlated with experimental ones where available. Stability and resonance energy have also been discussed.

In recent years the chemistry of nonbenzenoid aromatic hydrocarbons involving the contribution of a dipolar structure in its ground state has created much interest. Azulene and its derivatives constitute the simplest case belonging to this class and they are recognized as a class of condensed and fully conjugated cyclic hydrocarbons exhibiting aromatic character with effective contribution of dipolar structures in the ground state.[1] Phenalenium systems also belong to this class having dipolar structure and they are very much interesting to synthetic organic chemists and theoretical chemists. In this paper we like to report the results of our calculations based on Pariser and Parr[2] and Pople[3] method modified by Dewar et al.[4] on the molecules (**1**—

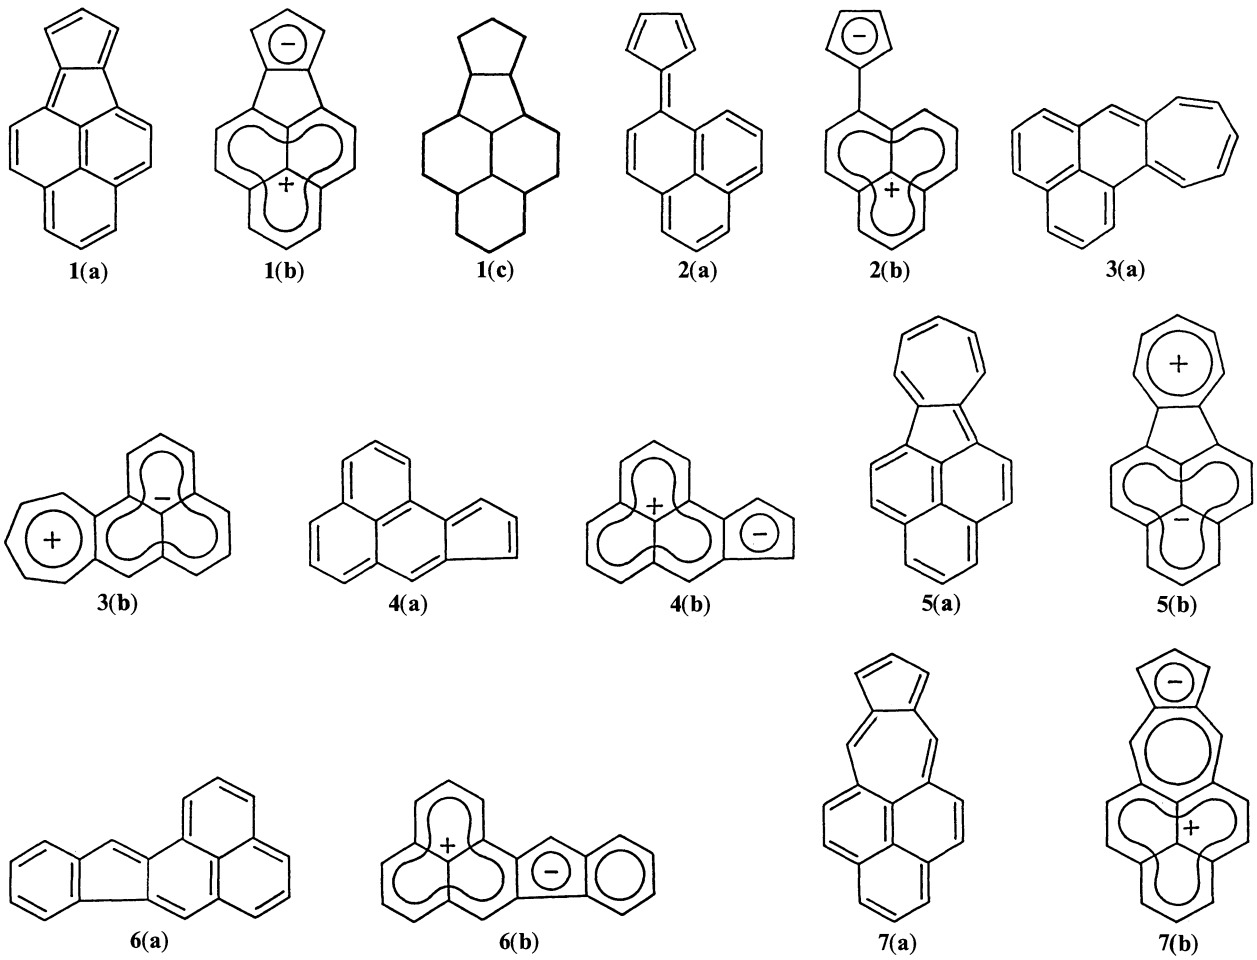

Fig. 1. Molecules studied.

7) in Fig. 1 and predicting the ground state properties and other properties such as $\pi^* \leftarrow \pi$ spectra, ionization potential, electron affinity etc. and compare and correlate them with experimental results where available.

Although the molecule **1** has not yet been synthesized, its derivatives[5] are known. Their properties suggest that molecule **1** might be treated as a novel example of a peripheral 16π-electron model.[5b] Molecule **2**, pentaphenafulvalene is not known but its derivatives have been synthesized by Murata et al.[6] The substantial pi-electron delocalization energy (5.83 β)[7] of phenalenium cation suggests that the molecule pentaphenafulvalene (**2**) would be specially notable for its significant contribution of the resonance form (dipolar structure) and the molecule would have a high value of dipole moment. The molecules **5** and **7** are very much interesting because they contain azulene and phenalene rings and because of their unique electronic structures and their expected carcinogenic activities. The stable crystalline moss green azuleno[5,6,7-*cd*]phenalene (**7**)[8] exhibits considerable carcinogenic activity.[9] The molecule **5** has been synthesized and studied by Murata and co-workers.[10] The molecules **3** and **4** nor their derivatives are known but the molecule **6** has been synthesized and studied by Reid.[11] Some of the molecules have been theoretically studied (**1**,[11] **2**,[6] and **7**[12,13]) with different sets of parameters.

Method and Parameters

The method used here is due to Pariser and Parr[2] and Pople[3] within the zero-differential overlap approximation. The standard notations are used for the necessary parameters.[14] β_{ij} was calculated by the following four methods. SCF(a) due to the method of Lo and Whitehead.[15] SCF(b): given a value of -1.7901 eV suggested by Chung and Dewar[4a] and modified by Birss and Das Gupta.[16] In SCF(a) and (b) β_{ij} was not changed at each iteration. SCF(c): due to Dewar and Harget[4b] and SCF(d): due to Yamaguchi et al.[17] In SCF(c) and (d) β_{ij}, r_{ij}, and γ_{ij} were adjusted at each iteration according to the following relations:

In SCF(c)[4b] the relations used were

$$r_{ij}(\text{Å}) = 1.512 - 0.174\, p_{ij}, \quad (1)$$

$$\beta_{ij} = -6.927\, S_{ij}. \quad (2)$$

In SCF(d)[17] the relations used were

$$r_{ij} = 1.520 - 0.186\, p_{ij}, \quad (3)$$

$$\beta_{ij} = \beta_o \exp[a(r_o - r_{ij})], \quad (4)$$

where β_o is the resonance integral of benzene, $a = -1.7$ Å^{-1} and r_o is the bond length of benzene. The value of β_o decreased as the number of rings[18] increased.

In the SCF(a) and (b) the bond lengths were calculated using the relation of Dewar and Gleicher[19] (Eq. 5)

$$r_{ij}\,(\text{Å}) = 1.503 - 0.166\, p_{ij}, \quad (5)$$

Y_{ii} were calculated using the relation of Pariser.[20]

$$Y_{ii} = I_i - A_i. \quad (6)$$

The values of I and A have been taken from Hinze and Jaffe.[21] The values of Y_{ii} and I for carbon atom are 11.136 and 11.16 eV respectively.

For SCF(d) Y_{ij} were evaluated using the formula of Mataga and Nishimoto[22] and for other methods they were evaluated using the formula of Ohno.[23] In SCF(c) and (d) the values Y_{ij} for non bonded centers, were not varied at each iteration but kept at the values calculated from the initial geometry of the molecules which were assumed to be planar with ideal geometry and bond lengths equal to 1.40 Å.

For the prediction of spectral transitions we have used both SCF and configuration interaction (CI) methods. The final vectors, resonance integrals, and two-center two-electron repulsion integrals obtained at the end of SCF(d) procedure were transferred in the CI method. The value of β_o used in SCF(d) was -2.15 eV.[24] The configuration arising from one-electron excitation was considered. All the occupied and unoccupied orbitals were taken into consideration for the CI method.

Table 1. Correction Terms for IP and EA (in eV)

Method	Correction term for IP	Correction term for EA
SCF(a)	1.29[a]	1.49[b]
SCF(c)	1.88[c]	1.28[b]
SCF(d)	1.06[d]	1.90[d]

Results and Discussion

Molecular Properties Such as Ionization Potential, Electron Affinity, Half-Wave Reduction Potential, and π-Dipole Moment: It has been observed[26] that the values obtained from Koopmans' theorem[25] differ from the experimental values of IP and EA by 1 or 2 eV. Hence a correction term is to be added to the HOMO and LUMO so that we can obtain the correct values of IP and EA respectively. Correction terms are presented in Table 1. The half-wave reduction potential has been evaluated from the relation[27] (Eq. 7) in the context of SCF(c).

$$E_{1/2} = -0.833\, e_j - 3.46, \qquad (7)$$

where e_j is the LUMO. The values of IP, EA, and $E_{1/2}$ have been presented in Table 2. For lack of experimental values we can not compare these results with experimental ones. The values of π-dipole moment have also been included in Table 2 along with experimental values where available.

$\pi^* \leftarrow \pi$ Spectral Transitions: Theoretical spectral transitions along with oscillator strengths, f, have been presented in Table 3 which contains the experimental transitions for the molecules **1**, **2**, **5**, and **7**. Table 4 contains the theoretical transitions and f values of other molecules for which there are no experimental values. The oscillator strengths, f, were obtained from the relation.[31]

$$f = 1.085 \times 10^{-5}\, \bar{\nu}\mu^2 \qquad (8)$$

with $\bar{\nu}$ is the transition energy in cm^{-1}) and μ is the dipole length (in Å) for corresponding transition. Results of SCF(a), (d), and CI are included in the table.

From Table 3 it is clear that the correlation between the theoretical transitions and experimental ones for molecules **1** and **2** is good. However agreement between the theoretical transitions predicted by SCF(d) method is not so good. This is evident from the calculation of standard deviation, σ included in the table. For the calculation of σ, point to point correlation has been taken.

The experimental spectral transitions of molecule **5** have a large number of peak maxima many of which are not clearly resolved. Therefore the best one can do in a comparison of the theoretical and observed transitions is a general correlation over quite wide spectral regions. Table 3 displays this comparison for molecule **5**. The value of σ predicted by the SCF and CI methods suggest that the agreement between the theoretical and experimental transitions is good. Table 3 also displays the experimental transitions for molecule **7** where other theoretical works have also been included along with our work. The molecule is rich in experimental transitions and attempt has been made a point to point correlation. The values predicted by the CI method is very good compared to the values predicted by the SCF methods and other workers.[12,13a]

Stability or Aromaticity: Stability of the molecules has been studied according to the criteria of resonance energy (E_R) and resonance energy per bond (E_R/C–C) or resonance energy per π-electron (RE/PE). The values of E_R of the molecules have been calculated using the methods of Whitehead et al.,[15] Chung and Dewar,[4a] Dewar and de Llano,[32] Dewar and Harget,[4b] and Hess and Schaad.[33] The values of heat of atomization, ΔH_a and π-bond energy, resonance energy, E_R, resonance energy per carbon–carbon bond (E_R/C–C) and resonance energy per π-electron of the molecules have been presented in Table 5. Since the hydrocarbons contain benzene rings fused with five or seven membered rings, they belong to semibenzenoid systems.[34] The criteria for stability or aromaticity of this type of hydrocarbons have been discussed by Das Gupta and Das Gupta[34] and are displayed in Table 6.

The hypothetical molecule **1**, pentaleno[4,5,6-*cd*]-phenalene, can be represented by the dipolar structure. Application of Craig's rule[37] to any one of the Kekule' structure of **1** gives the result $f+g=7$ which predicts the valence-bond ground state to be nontotally symmetric and hence the molecule **1** should be pseudoaromatic. The two non-charge separated resonance forms possess a 16 π-electron moiety peripheral to the central ethylene fragment. If it is considered that the cross links are regarded to contribute only negligible perturbation the present hydrocarbon should be antiaromatic.[38] Low resonance energy and low resonance energy per carbon–carbon bond calculated by all the methods and low resonance energy per π-electron also suggest that the molecule should not be an aromatic one. Moreover, the physical properties of the derivatives of **1**, relatively high chemical shifts of the protons on the phenalene nucleus and small dipole moment [μ=2.31D (D=Debye, 1 Debye=3.3356×10^{-30} C m)][5b] of 5-ethoxy-1,3-di-*t*-butylpentaleno[1,2,3-*cd*]phenalene indicate, however, that the molecule **1** can be best represented by the perturbed [16] annulene **1(c)** rather than the dipolar form **1(b)**.

Although molecule **2** has not been synthesized, its derivatives are known. The derivative 2-ethoxy-9,10,11,12-tetrachloropentaphenafulvalene is a stable one.[6] The resonance energy, E_R/C–C and RE/PE suggest that the molecule would be a stable one in agreement with experiment. The high dipole moment of **2** (6.33 D)[6] together with the relatively low chemical shifts and the identical vicinal coupling constants[39] in its ^{1}H NMR spectrum indicates a significant participation of a dipolar resonance structure in its ground state **2(b)**.

The molecule **3** has not yet been synthesized. Its resonance energy, E_R/C–C and RE/PE which are at the lower side of the range of aromaticity and stability suggest that the molecule might not be an aromatic one.

The molecules **5** and **7** are interesting and may be considered to be composed of azulene and phenalene. Resonance energy, E_R/C–C and RE/PE suggest that they might be a stable aromatic compound. The ease of dehydrogenation during the preparation of **5** is noteworthy suggesting thermodynamic stability[10] of this compound. The diamagnetic susceptibility is 2.7.[10] The above observations furnish convincing evidence for a definite degree of aromaticity of **5**.[10]

HS[b)]	0.03—0.04

a) Dewar–de Llano. b) Hess and Schaad.

Though the molecule **4** has not yet been synthesized, yet its resonance energy, E_R/C–C bond and RE/PE suggest that it might be a stable aromatic compound. It is expected that it might be synthesized in near future.

The molecule **6** has been synthesized and its chemical properties have been studied by Reid.[11)] Its high basicity, the Hammett acidity function H_o for which K' (where K' is the apparent partition coefficient) value which is unity places the molecule **6** alongside the azulenes in order of basicity.[40)] It undergoes electrophilic substitution reaction easily. The dihydroindeno-[2,1-*a*]phenalene undergoes with striking readiness to aromatization reactions.[11)] The above reactions reflect the aromatic character of molecule **6**. This is also predicted from its calculated resonance energy, E_R/C–C and RE/PE.

Conclusion

The methods SCF a, b, and c were parameterized to predict the ground state properties and stability of molecules. SCF(d) method was parameterized to predict the spectral transitions of conjugated systems. It has been observed that the methods SCF a, b, and c are also equally good, if not better than the SCF(d) method, in predicting spectral transitions as seen earlier.

(Received September 3, 1990)

The fixed charge density, the permselectivity, and the transport number in several electrolytic solutions of varying concentration were determined across the pericardial membrane of freshly slaughtered buffalo (*Bof. Bubalis*). The irreversible thermodynamic equations originally meant for understanding the behavior of artificial membranes have been found to be equally applicable to those of the biological membranes.

The behavior of membrane systems has extensively been investigated by studying the transport properties of artificial membranes.[1-12] Some of the recent analytical and electronic techniques have added impetus to such investigations. However, in the cases of biological membranes the experimental difficulties have marred the meaningful electrophysiological studies; such as those of the membrane potential, the transport number, the permselectivity, the effective fixed charge density, the conductance, the capacitance, and the impedance.

The present study has, therefore, been undertaken with a view (i) to ascertaining as to whether or not the principle of passive transport is applicable to biological membranes, and (ii) to characterising their thermodynamic properties. Thus, the duramater, the pericardium, and the peritoneum being easily available intact biological membranes may be chosen for the purpose. Also, the transport number, the permselectivity, and the effective fixed charge density of these biological membranes are almost similar in signifying a common pattern in their behavior. In view of these facts the pericardial membrane has been taken as a test case.

Experimental

The pericardial membrane was taken out immediately after slaughtering the buffalo (*Bof. bubalis*) aged between 18—24 months, and immersed in an ice-cold Ringer solution of pH 7.4±0.2 for the preservation of the membrane tissues. The Ringer solution contained (in g dm^{-3}) NaCl: 9.00, KCl; 0.42, $CaCl_2$: 0.24, glucose: 1.00, and $NaHCO_3$: 0.15. The membrane was then washed three times with the deionized water to remove any traces of Ringer solution, prior to recording the membrane potential. The potential was developed by setting up a concentration cell of the type

S.C.E.|Solution|Membrane|Solution|S.C.E.
C_1 $C_2=10C_1$

in which S.C.E. stands for the saturated calomel electrode employed for measuring the membrane potential. The electrolytes used were the solutions of several concentrations of analytical grade (BDH, India), uni-univalent electrolytes, viz., NaCl, KCl, NH_4Cl, NaF, and KF in deionized water. The same electrolyte with different concentrations was used on both the sides of the pericardial membrane. The dilute side of the solution was taken as negative. Freshly obtained pericardial membranes were used for the potential measurements with each of these electrolytic solutions. The experiments were repeated a number of times with freshly prepared solutions of each of these electrolytes and the maximum potential values thus attained were recorded These measurements were made in a thermostated bath maintained at 25.0±0.1 °C.

Results and Discussion

The values of membrane potential ($\Delta\phi$ or E_m) measured across the pericardial membrane, separating different concentrations of 1 : 1 electrolytes are plotted as a function of $\log(C_1+C_2)/2$, with a fixed ratio of $C_2/C_1=\gamma=10$ (Fig. 1). The membrane potential after an initial increase, has been found to decrease with increase in the value of $\log(C_1+C_2)/2$. Another very important feature observed in the recording of the E_m across the pericardium, provided the concentrated side was hooked up to the positive terminal while the dilute side to that of the negative terminal. Such an observation suggests that the pericardial membrane is positively charged and is anion selective. It may also be noted, however, that for all the electrolytes below 1×10^{-3} M

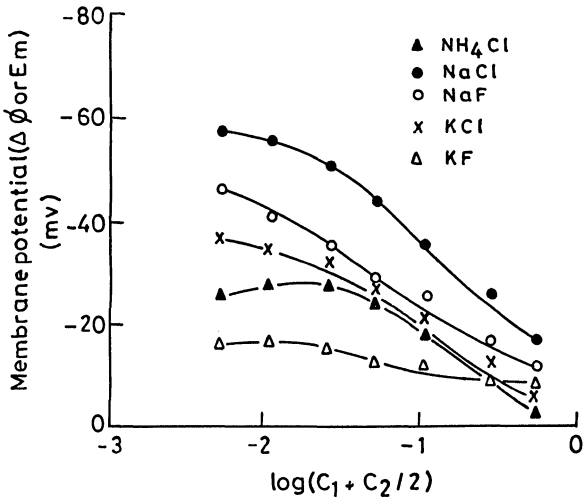

Fig. 1. Plots of observed potentials against log (C_1+C_2)/2 for various electrolytes with pericardium.

concentration (1 M=1 mol dm^{-3}) the number of ions generated matches the number of ions transferred to the other side of the membrane, thereby destroying completely the potential difference generated initially due to slight differences in the concentration of ions. Consequently, no potential differences is observed below the cited dilute concentration.

Starting with the basic flow equations Kobatake et al.[6] obtained the following relations:

$$\Delta\phi=-(RT/F)\left|\frac{1}{\beta}\ln\frac{C_2}{C_1}-\left(1+\frac{1}{\beta}-2\alpha\right)\ln\left(\frac{C_2+\alpha\beta\theta}{C_1+\alpha\beta\theta}\right)\right, \quad (1)$$

where

$$\alpha=\frac{u}{u+v} \quad (1a)$$

and

$$\beta=1+\left(\frac{KF\theta}{u}\right), \quad (1b)$$

for the membrane potential ($\Delta\phi$) which arises between two solutions of 1 : 1 electrolytes of different concentration, C_1 and C_2 ($C_1<C_2$) that are separated by a membrane.

Here, u and v are the mobilities of the positive and the negative ions, respectively, defined in terms of the mass fixed frame of reference, K is a constant, θ is the charge density, and F is the Faraday constant. These parameters are found to be independent of salt concentrations, C_1 and C_2.

For the analysis of the data, Eq. 1 can be used under two sets of conditions, namely, (a) in the dilute range, and (b) in the concentrated range; hence the two limiting forms of the above equation have been obtained as given below: (a) When concentration C_2 becomes sufficiently small, (external dilute range) Eq. 1 can be expanded[6] to given

$$\Delta\phi_r=\frac{1}{\beta}\ln\gamma-\frac{(\gamma-1)}{\alpha\beta\gamma}\left(1+\frac{1}{\beta}-2\alpha\right)\left(\frac{C_2}{\theta}\right)+0\left[\left(\frac{C_2}{\theta}\right)^2\right] \quad (2)$$

where $\Delta\phi_r$ is the absolute value of reduced potential defined by

$$\Delta\phi_r=\frac{F\Delta\phi}{-RT} \quad (3)$$

and

$$\gamma=\frac{C_2}{C_1}.$$

Equation 2, indicates that the value of β; as well as a relation between α and θ can be obtained by evaluating the intercepts and the initial slope of a plot of $\Delta\phi_r$ against C_2. Figure 2 shows a variation of reduced membrane potential, $\Delta\phi_r$ with variation in concentration in the low concentration range of the electrolyte. With an increase in concentration $\Delta\phi_r$ shows an insignificant decrease. The value may be evaluated from the slope, $1/\beta \ln\gamma$ of the above plot listed in Table 1. (b)

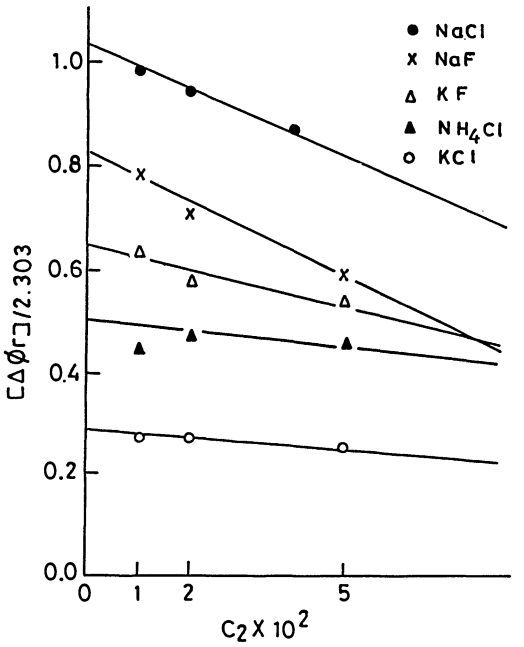

Fig. 2. Plots of $\Delta\phi_r/2.303$ versus $C_2\times10^2$ for various electrolyte with pericardium.

Table 1. Calculated Values of the Parameters α and β for Various Electrolytes at $\gamma=10$

Electrolytes	α	β
NaCl	0.56	0.97
NaF	0.55	1.22
KF	0.49	1.55
NH_4Cl	0.44	2.00
KCl	0.59	3.51

It is found experimentally that at a fixed value of γ, the inverse of an apparent transport number, t_{app}, is proportional to the inverse of concentration, C_2, in higher salt concentration range. Here, t_{app} is defined by the relation,

$$\Delta\phi_r=(1-2\,t_{app})\ln\gamma. \quad (4)$$

The values of the transport number (t_{app}), calculated from the observed membrane potentials using Eq. 4. Figure 3 shows the variation of the inverse of t_{app} of ions with that of the inverse of concentration, C_2. As the inverse of the concentration increases, the inverse of the apparent transference number also increases. This has been observed only in high concentration range. Such an observation, however, has been found to be absent in the dilute concentration range, seemingly due to an inadequate concentration for raising the required polarization.

Kobatake et al.[6] have proposed a simple method using the following approximate equation for the diffusive contribution to the emf of a cell with transport. On substituting Eq. 3 into that of Eq. 4, the following relation between $\Delta\phi$ and t_{app} is obtained:

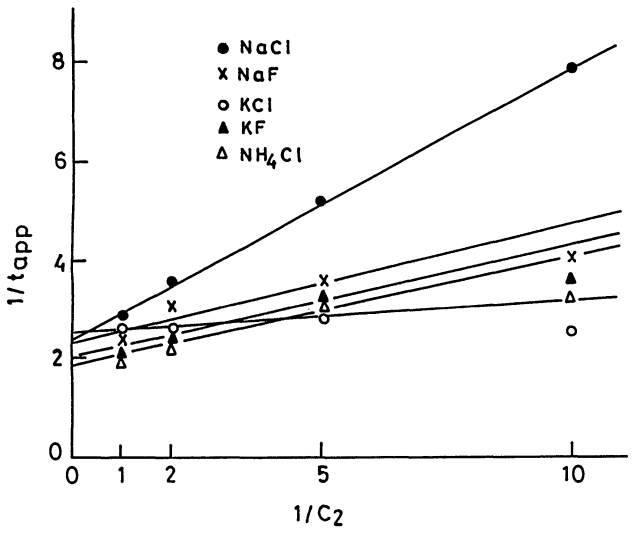

Fig. 3. Plots of $1/t_{app}$ versus $1/C_2$ for various electrolytes with pericardium.

$$\frac{F\Delta\phi}{RT}=(1-2\,t_{app})\ln\gamma, \tag{5}$$

substituting the value of $\Delta\phi$ from Eq. 1 and expanding the resultant for $1/t_{app}$, in powers of $1/C_2$, we get,

$$\frac{1}{t_{app}}=\frac{1}{1-\alpha}+\frac{(1+\beta-2\alpha\beta)(\gamma-1)\alpha}{2(1-\alpha)^2\ln\gamma}\left(\frac{\theta}{C_2}\right)+0\left[\left(\frac{\theta}{C_2}\right)^2\right]. \tag{6}$$

This indicates that the intercept for a plot of $1/t_{app}$ vs. $1/C_2$, at a fixed value of γ allows the value of α to be determined. The value of the intercept is equal to $1/(1-\alpha)$, from which α may be evaluated. Figure 3 illustrates the plots of $1/t_{app}$ vs. $1/C_2$ for various electrolytes.

For the evaluation of charge density, θ, there are two limiting cases. In the dilute range, the value of θ_d was determined by inserting the values of α and β (Table 1) in the relation between α and θ. Once α and β are known in the manner described above, the charge density θ_c (in the concentrated range), is also evaluated from the initial slope of $1/t_{app}$ against $1/C_2$ plot. The present study reveals that the charge density (θ_d) in dilute as well as in concentrated range (θ_c) agree well with each other (Table 2), thereby confirming the applicability of the Kobatake and co-worker's equation to this biological membrane.

Table 2. Charge Density (mol dm^{-3}) of Pericardial Membrane Obtained by Different Methods at γ=10

Theory	Electrolyte				
	NaCl	NaF	KCl	KF	NH_4Cl
$\theta_d\times10^2$ Kobatake's method	20.16	8.84	4.04	13.71	—
$\theta_c\times10^2$ Kobatake's method	10.7	4.93	3.94	6.58	6.71
$\theta_x\times10^2$ Kobatake's Permselectivity method, P_s vs. $\log(C_1+C_2)/2$	15.14	5.01	—	6.07	8.91
$\theta_x\times10^2$ Tasaka's method	4.11	1.29	4.76	1.64	1.90

A general method for the characterization of membranes in terms of permselectivity (P_s), which is applicable to any system, irrespective of ionic species, has been developed by Kamo et al.[9] Kobatake and Kamo[12] derived Eq. 7 for the measurement of permselectivity (P_s) for a positively charged membrane.

$$\frac{1}{(4\,\xi^2+1)^{1/2}}=P_s=\frac{[T_{app}-(1-\alpha)]}{[1-\alpha-(1-2\alpha)T_{app}]}. \tag{7}$$

It may be noted that the P_s value between zero and unity depends on the external salt concentration for the given system of membrane electrolyte pair. Now P_s can be calculated from the data of membrane potential, while the left-hand side of Eq. 7 is a function of the relative concentration $\xi=C/\phi_x$ or $(C_1+C_2)/2\phi_x$. Thus, the value of the right-hand side should be independent of the mobilities of ionic species involved. Equation 7 implies that the plot of P_s vs. $(1+4\,\xi^2)^{-1/2}$ should be a

a) P_s values were obtained using the relation, $P_s=\frac{T_{app}-(1-\alpha)}{1-\alpha-(1-2\alpha)T_{app}}$, $\xi=\frac{c}{\phi_x}$, β' or $n\beta$ values were computed using the relation $P_s=[1/\sqrt{1+4\xi^2}]^{\beta}$.

straight line of unit slope provided the charge density is independent of salt concentration. The various values of permselectivity (Table 3) were calculated by substituting the values of α and t_{app} for pericardium. Another method of determining the charge density, based on permselectivity as developed by Kamo et al.[9] is also used here. The calculated values of P_s of pericardial membrane were plotted against log $(C_1+C_2)/2$. The curves thus obtained with various electrolytes are shown in Fig. 4. When the average concentration, $(C_1+C_2)/2$, becomes equal to the effective fixed charge density ϕ_x, the value of ξ becomes unity, i.e. $C/\phi_x=1$. Substituting this value of $\xi=1$ in $P_s=(1+4\ \xi^2)^{-1/2}$, the value of P_s becomes equal to 0.448. At this particular value (0.448), the corresponding concentration was obtained from the P_s versus log C plot. It is apparent from Fig. 4 that this value of concentration should be equal to a fixed charge density for various electrolytes. The values of charge density obtained with various electrolytes are given in Table 2. Plots of P_s vs. $(1+4\ \xi^2)^{-1/2}$ using different electrolyte is shown in Fig. 5.

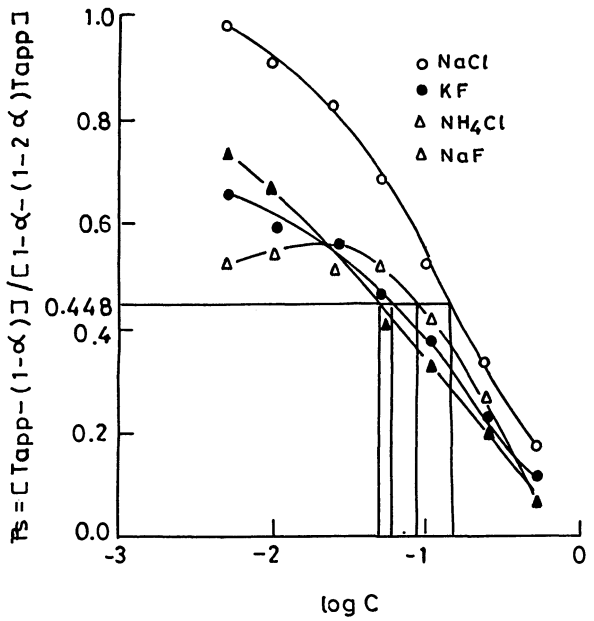

Fig. 4. Plots of P_s versus log $(C_1+C_2)/2$ for various electrolyte with pericardium.

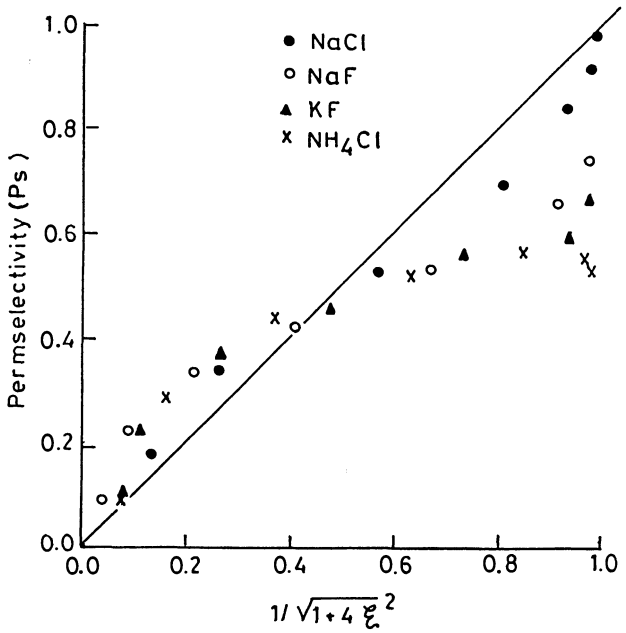

Fig. 5. Plots of P_s versus $1/\sqrt{1+4\ \xi^2}$ for various electrolytes with pericardium.

An apparent straight line of slope close to unity is the theoretical line with the assumption that the values of ϕ_x are independent of salt concentration as seemingly found for the NaCl case unlike those of the other electrolytes for which ϕ_x seems to be a function of salt concentration as apparent from the limiting values of P_s versus $(1+4\ \xi^2)^{-1/2}$ plots. An examination of Table 2 suggests that the extent to which the values of ϕ_x depend on the salt concentration is different in the cases of NaF, NaCl, KF, KCl, and NH_4Cl in which such a dependence is quite marked. Such a behavior may consequently be understood in terms of the nature as well as the concentration of the ionic species present across the pericardial membrane. Consequently, an attempt has been made to express the P_s values in terms of an arbitrary parameter, β', which turns out to be a sort of measure of the extent of deviation from linearity and is equal to $n\beta$ where n is an arbitrary parameter. This has been achieved by accounting for $(1+4\ \xi^2)^{-1/2}$ term contributing to P_s to different extent $(n\beta)$ depending upon the interaction of the solute ions with the solvent. Thus, P_s is expressed as

$$P_s=\left[\frac{1}{(1+4\ \xi^2)^{-1/2}}\right]^{\beta'}=\left[\frac{1}{(1+4\ \xi^2)^{-1/2}}\right]^{n\beta}=\frac{[T_{app}-(1-\alpha)]}{[1-\alpha-(1-2\alpha)\ T_{app}]}. \tag{8}$$

It is worthwhile to note that the proposed Eq. 8 is expected to be applicable to any type of biological membrane irrespective of the extent of deviation shown in the behavior of P_s versus $1/\sqrt{1+4\ \xi^2}$ plots. The β' values for NaCl, NaF, KF, and NH_4Cl solutions were computed (Table 3) using the rearranged form of the above equation, $\beta'=-2\log P_s/\log(1+4\ \xi^2)]$. Finally the plots of P_s against $[1/(1+4\ \xi^2)^{1/2}]^{n\beta}$ (Fig. 6) supports the above equation in which the extent of deviation has already been accounted for in terms of $n\beta$.

Tasaka et al.[13] gave two limiting forms of expressions for the membrane potential, (i) in very low concentrations, it was found that

$$\Delta\phi_r=\ln\gamma, \tag{9}$$

where $\Delta\phi_r$ is the reduced membrane potential, and (ii) at high concentration of electrolyte Eq. 10 was found to be applicable.

$$-\Delta\phi/\frac{\gamma-1}{\gamma}=\frac{RT}{F}(\phi_x/2)\frac{1}{C_1}, \tag{10}$$

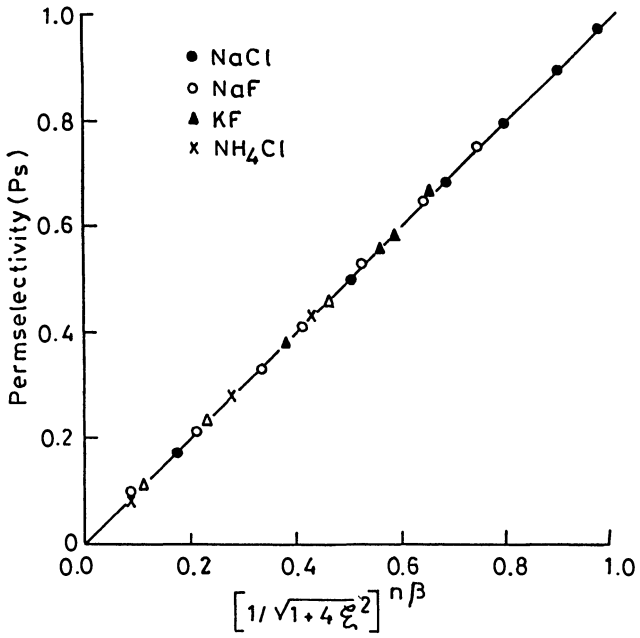

Fig. 6. Plots of P_s versus $[1/\sqrt{1+4\ \xi^2}]^{n\beta}$ for various electrolytes with pericardium.

when $\alpha=0.5$, i.e. in ordinary electrolyte solutions, Eq. 10 leads to

$$\Delta\phi_r=\frac{(2\alpha-1)}{2(1-\alpha)}\ln\gamma+\frac{(\gamma-1)\phi_x}{2(1-\alpha)\,2\gamma\,C_1}, \qquad (11)$$

In extremely high concentrations, Eq. 10 predicts a linear relationship between $\Delta\phi/[(\gamma-1)/\gamma]$ and $1/C_1$ from which the charge density (ϕ_x) can be determined. The different values of ϕ_x, derived from the initial slope of various curves of Fig. 7 are given in Table 2.

The results of these investigations show that the membrane potential can be determined with some reasonable accuracy. Also, when the pericardium separates concentrated solutions, the values of potential generated across the pericardial membrane are negative. This means that the membrane is anion selective and is positively charged. It may be noted that the anion selectivity decreases as the concentration across the membrane is increased. Again it was also observed that the apparant transport number values for the different electrolytes increases by increasing the concentration of the electrolytes across the pericardium. Furthermore, it is noted from Table 2 that the charge density values of the membrane electrolyte system are low.

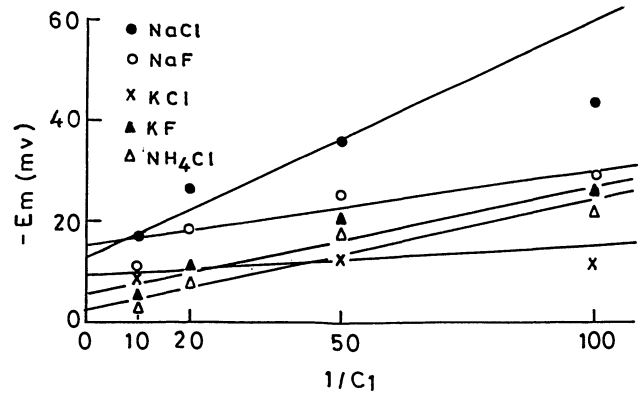

Fig. 7. Plots of E_m versus $1/C_1$ for various electrolytes with pericardium.

One would expect that the thermodynamic properties of biological membranes and those of artificial ones would be very different from each other because of the fact that the biological membranes are hitherto believed to function by active process (Ussing[14–16]), while artificial membranes are governed by the principle of passive transport. However, as stated above the present findings tend to support the contention that the laws of irreversible thermodynamics meant for passive transport are equally good for biomembranes.

The phenomenon of passive transport observed in cases of artificial membranes and that of active transport in those of biological membranes depend essentially on chemical nature of the membrane as well as on the electromotive forces developed across the cell membranes. Such a consideration has led us to examine their applicability to the biological membranes also. Consequently, it was found that the said models originally meant for explaining the behavior of artificial membranes, were equally applicable to biological membrane under investigation. As is well known, the purpose of active transport is to regulate the transfer of ions to suit the requirements of the cell. This cannot be achieved by passive transport. It seems likely that under diseased states, changes in electrolytic concentration, emotional factors etc., active transport may be inhibited and passive transport may become the dominant phenomenon. Such a situation will influence cell nutrition and its longevity because transport of essential materials and prevention of entry of toxic substances into the cell depend on the integrity of membrane function.

Thanks are due to Aligarh Muslim University, Aligarh for providing necessary facilities and to the Indian council of Medical Research, New Delhi for providing financial assistance. The cooperation and support of Professor S. A. A. Zaidi Chairman, Department of Chemistry is appreciated, We are highly indebted to Professor Nural Islam, Professor of Physical Chemistry, A.M.U. Aligarh for the help rendered in revising the manuscript.

(Received November 26, 1990)

In the framework of CNDO (Complete Neglect of Differential Overlap method) VOIP (Valance Orbital Ionization Potential) has been evaluated using the method of Anno and Sakai and for exchange integrals Wolfsberg–Helmholtz approximation has been used. The method has been used for studying the disproportionation of carbon monoxide on titanium and vanadium clusters having two atoms respectively. A large number of theoretical models were designed, based upon various mechanistic possibilities. The bond energies between different atoms have been plotted against the distance, for the purpose of studying the formation and desorption of CO_2. The present studies suggest that the disproportionation of CO on titanium cluster may follow a dissociative path while in case of vanadium cluster this reaction may follow a disproportionation, where disproportionation involves a reaction between a 'bridge site' adsorbed CO molecule with a gas phase CO molecule.

The catalytic properties of transition metal surfaces have motivated much of the surface science research into the chemisorption of atoms and molecules.[1] The interaction of CO with metal surfaces has attracted much attention since it is considered to be a model system for understanding molecular chemisorption. The CO molecule usually bonds vertically to the surface through the carbon atom. However, there are strong-chemisorption (e.g. Nickel) and weak-chemisorption (e.g. Copper) limits, and cases of tilted and lying down molecules are also reported.[2,3] Chemisorption of carbon monoxide with Fe has been studied in detail[4–9] and anomalously low stretching mode in electron energy loss experiment has been observed.

It is thought that molecular specie is a precursor to dissociation and is important in catalytic behavior of iron.[8] Several theoretical models have been suggested to describe the chemisorption of CO.[10–14] Experimental studies based on LEED, UPS, XPS, AES, EELS,[15] and spin polarized photoemission have been reported.[16] Titanium and vanadium are known to be highly reactive transition metals relevant to problems of technological importance such as hydrogen storage[17] and also as active ingredient in some complex catalysts.[18] The adsorption of CO and subsequent build-up of carbon on the catalyst surface is of great importance since these are the key steps in methanation and Fischer–Tropsch synthesis. UPS and AES[19,20] studies have concluded that CO is dissociated on the clean titanium film at room temperature. Lee and coworkers[21] have performed molecular orbital calculation for studying molecular and dissociative chemisorption of CO on several metal surfaces.

The proceeding of a chemical reaction may be described by the splitting and formation of various bonds and therefore the changes in various bond energies may be expected to give useful information on the mechanism of the reaction. In CNDO framework the bond energy is explicitly defined and consequently the method as described here is much simpler than ab-initio method and has already been shown to be quite useful for making comparative studies.[22–24] Here we report our CNDO results on disproportionation of CO on titanium and vanadium clusters.

Method

The CNDO method is widely used and retains the main features of electron repulsion introduced by Pople, Santry, and Segal.[25] In this method the involvement of many parameters makes it less useful for the transition metal system. An effort has been made by Srivastava and Miyazaki[22,23] to reduce the number of parameters in the CNDO technique.

The local core matrix elements U_{ii} have been estimated from the atomic data using the following expression:

$$U_{ii} = -I_p(i) - (N-1)\gamma_{ss} - M\gamma_{sd}.$$

Here $I_p(i)$ is the valence state ionization potential, N denotes the total number of electrons in the valence s and p orbitals and M represents the number of electrons in d-orbital. The I_p's have been calculated by using the method of Anno and Sakai,[26] where valence orbital ionization potential (VOIP) was calculated with the help of a quadratic equation as given below:

$$\mathrm{VOIP} = A_0 + A_1 Z + A_2 Z^2,$$

where Z is the atomic number, A_0 and A_1 were evaluated with the help of the following expressions,

$$A_0 = a_0 + a_1 M + a_2 M^2,$$

$$A_1 = b_0 + b_1 M.$$

Values of a_0, a_1, a_2, b_0, and b_1 have been taken from Ref. 26. The exchange integral H_{ij} has been calculated with the help of Wolfsberg–Helmholtz approximation.[27]

$$H_{ij} = K S_{ij}(H_{ii} + H_{jj})/2.$$

The electronic configuration $3d^m4s^2$ or $3d^m4s4p$ was assumed for the ground state of titanium and vanadium atoms. Thus in the present work only $K(=1.5)$ has been used as an empirical parameter. The bond energy has been evalu-

ated from the following expression.

$$E_{AB}=\sum_{\mu}^{A}\sum_{\nu}^{B}(2P_{\mu\nu}\beta_{\mu\nu}-1/2P_{\mu\nu}{}^{2}\gamma_{AB})$$
$$+(Z_AZ_BR_{AB}{}^{-1}-P_{AA}V_{AB}-P_{BB}V_{BA}+P_{AA}P_{BB}\gamma_{AB}),$$

where all the terms have their usual meaning.

Results and Discussion

Theoretically one can predict the following mechanisms for the disproportionation of CO on the surface of titanium and vanadium.

1. Dissociative Mechanism. It claims that the dissociation of CO is first step with the formation of Ti–C and Ti–O bonds.

$$2Ti+CO\rightarrow Ti\text{-}C+Ti\text{-}O$$

followed by

$$Ti\text{-}O+CO\rightarrow CO_2$$

Similarly for vanadium formation of V–C and V–O bonds is the first step.

2. Disproportionation. It predicts reaction between the CO molecules on the surface

$$(2CO\rightarrow CO_2(g)+C_{ad}),$$

where (g) refers to a gas phase species and (ad) to an adsorbed or surface species.

Here three different possibilities have been considered for this reaction.

(i) Reaction between two adsorbed CO molecules (Model-D)

$$CO_{ad}+CO_{ad}\rightarrow CO_2(g)+C_{ad}.$$

(ii) Dissociation of CO to adsorbed C_{ad} and O_{ad} species follow by a reaction of adsorbed O_{ad} with CO either from the gas phase (Model-B) or in an adsorbed state (Model-A and Model-C)

$$CO\rightarrow C_{ad}+O_{ad},$$
$$O_{ad}+CO(g)\rightarrow CO_2(g),$$
$$O_{ad}+CO_{ad}\rightarrow CO_2(g).$$

(iii) Reaction between adsorbed CO and another CO molecule from the gas phase (Model-E)

$$CO\rightarrow CO_{ad},$$
$$CO_{ad}+CO(g)\rightarrow CO_2+C_{ad}.$$

Based upon the above three theoretically possible mechanisms different models involving Ti_2 and V_2 clusters were designed as shown in Fig. 1. For all these models the energy of interaction E_{int} of a CO molecule to the rest of cluster was calculated by using the following definition:

$$E_{int}=E_t-E_a,$$

where E_t is the total energy of the system containing all the atom as shown in each model and E_a is the total energy of the system which has one molecule of CO less than the original model.

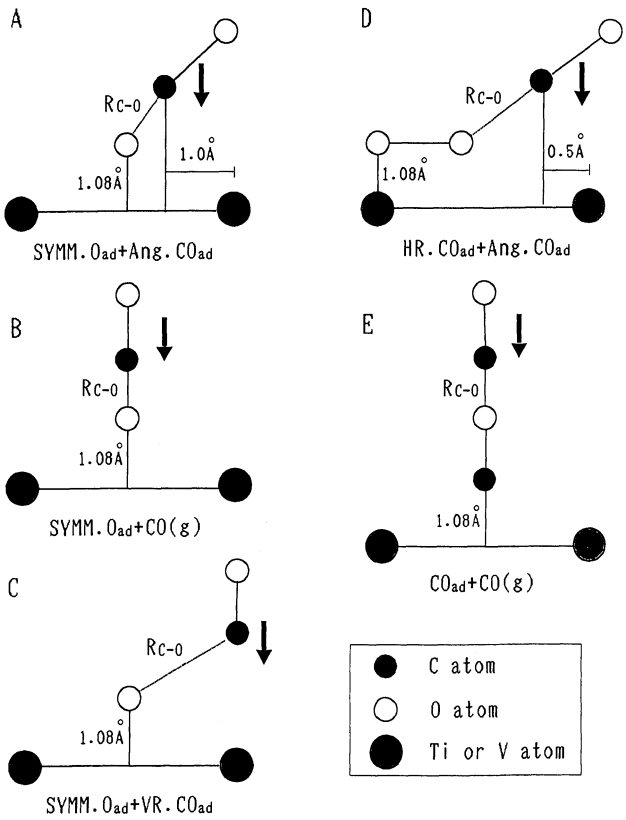

Fig. 1. Disproportionation of CO on Ti_2 or V_2 clusters.

The bond energy of CO bond (the new bond which is being formed and is essential for the formation of CO_2) i.e. E_{C-O} as well as the bond energies of the adsorbed C–O bond and Metal–O bonds were calculated. All these energies have been plotted against R_{C-O} i.e. distance between C and O atoms involved in the new bond formation. The plots of E_{int} and E_{C-O} against R_{C-O} are expected to throw light upon the formation of CO_2 and plot of $E_{metal-O}$ vs. R_{C-O} may give information regarding the desorption of the CO_2 molecules.

(a) Disproportionation of CO on Titanium Cluster (Ti_2). In Fig. 2 the energy of interaction E_{int} of carbon monoxide with rest of the cluster has been plotted against R_{C-O} and it seems that Model-C which represents a dissociative path, may be mechanistically more probable.

Figure 3 contains the plots of E_{C-O} vs. R_{C-O}. A comparative study of various curves shows that Model-C represents a pathway for the reaction which is more favorable for the formation of CO_2.

Figure 4 presents the plot of bond energy E_{Ti-O} against bond distance R_{C-O}. A close study of these curves reveals that as far as the possibility of desorption of CO_2 is concerned Model-C may be comparatively better suited.

Figure 5 presents the plot of $E_{C-O_{ad}}$ i.e. bond between O_{ad} and C against R_{C-O}.

On the basis of the qualitative studies on Ti_2 cluster, it

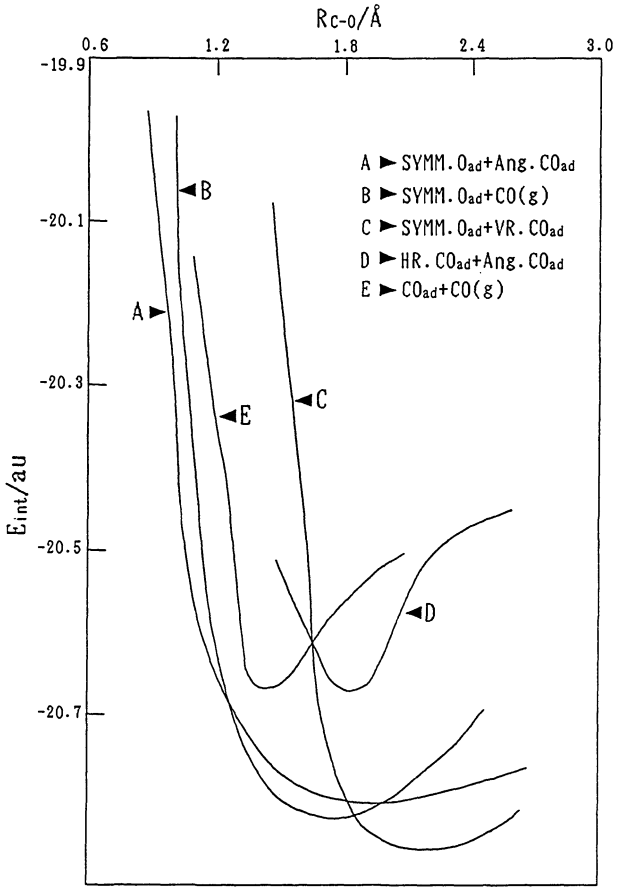

Fig. 2. Interaction energy E_{int} against R_{C-O} involving a Ti_2 cluster.

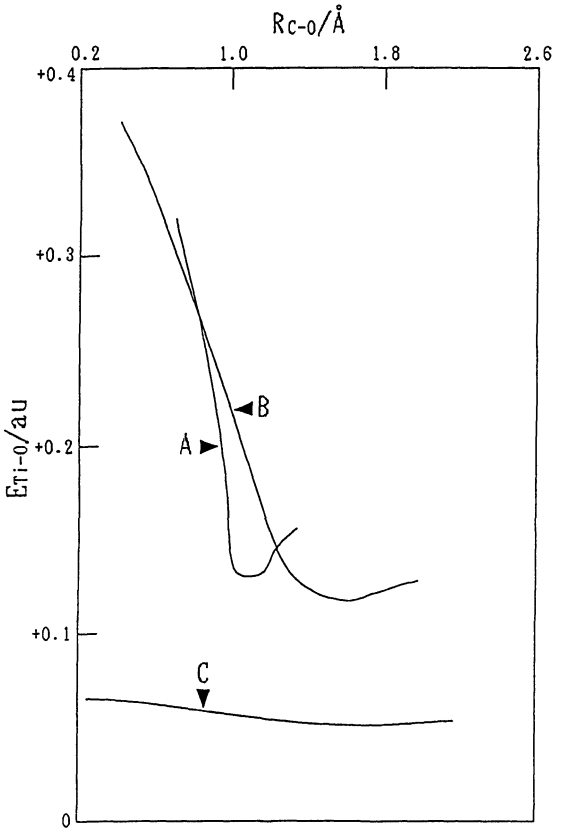

Fig. 4. Bond energy of Ti–O bond i.e. E_{Ti-O} against R_{C-O} involving a Ti_2 cluster.

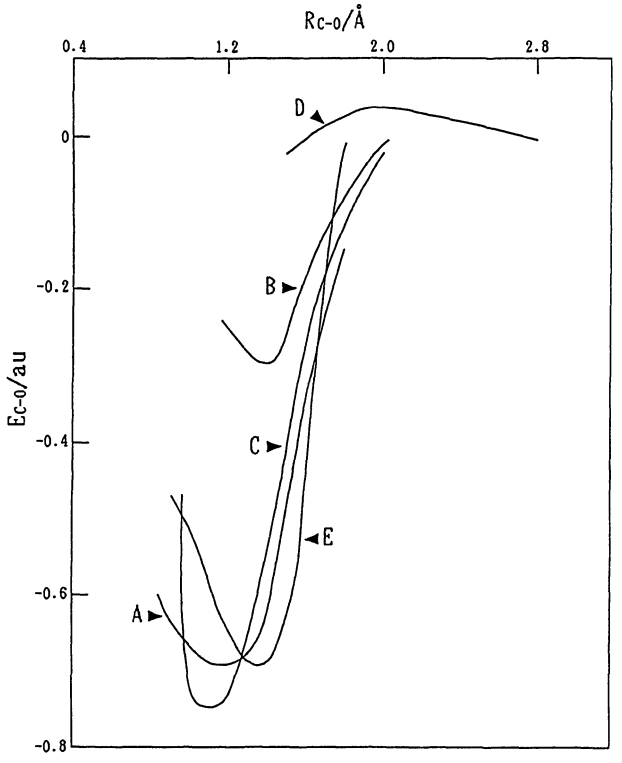

Fig. 3. Energy of C–O bond i.e. E_{C-O} against R_{C-O} involving a Ti_2 cluster.

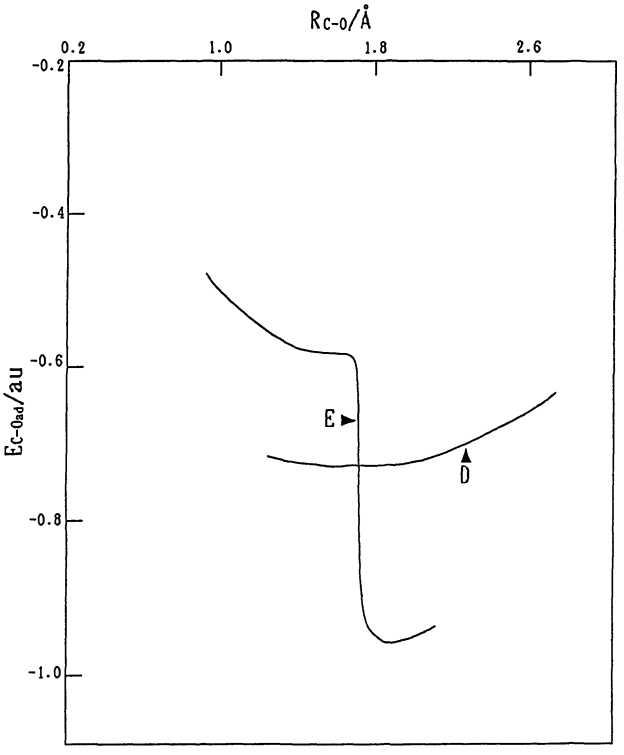

Fig. 5. Energy of $C-O_{ad}$ bond i.e. $E_{C-O_{ad}}$ against R_{C-O} involving a Ti_2 cluster.

seems that Model-C, representing the dissociative path is the only suitable path for the reaction under study. Our findings are in good agreement with the findings of Srivastava et al.[23] The dissociative mechanism for this reaction may be as given below:

$$CO \rightarrow C_{ad} + O_{ad},$$

$$O_{ad} + V : CO_{ad} \rightarrow CO_2.$$

A similar dissociative mechanism has also been proposed by Madden and Ertl,[28] on the basis of their LEED and AES studies.

(b) Disproportionation of CO on Vanadium Cluster (V_2). The energy of interaction E_{int} of carbon monoxide with rest of the cluster has been plotted against R_{C-O} in Fig. 6. From these curves it may be concluded that the Model-E represents a more suitable path for this reaction.

The plots of E_{C-O} against R_{C-O} are given in Fig. 7. A close scrutiny of these curves suggests that Model-E represents a pathway for the reaction which is more favorable for the formation of CO_2.

Plots of E_{V-O} vs. R_{C-O} are given in Fig. 8. It is interesting to note that curves A, B, and C, based upon Models-A, B, and C, respectively, show a strengthening of V–O bond, thus in case of these models there seems to be virtually no possibility of CO_2 desorption after its formation.

From Fig. 9 the weakening of C–O bond is evident in case of Model-E. So it can be concluded that the Model-E may be more favorable for the desorption of

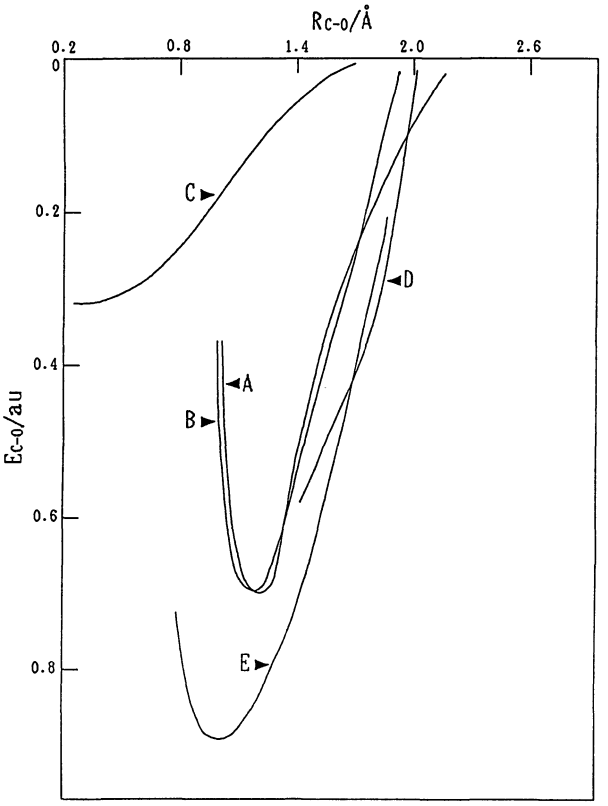

Fig. 7. Energy of C–O bond i.e. E_{C-O} against R_{C-O} involving a V_2 cluster.

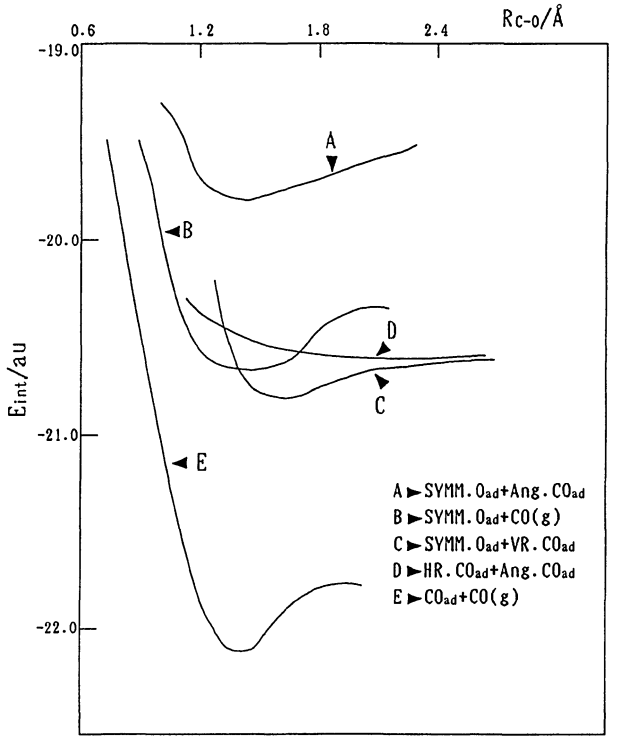

Fig. 6. Interaction energy E_{int} against R_{C-O} involving a V_2 cluster.

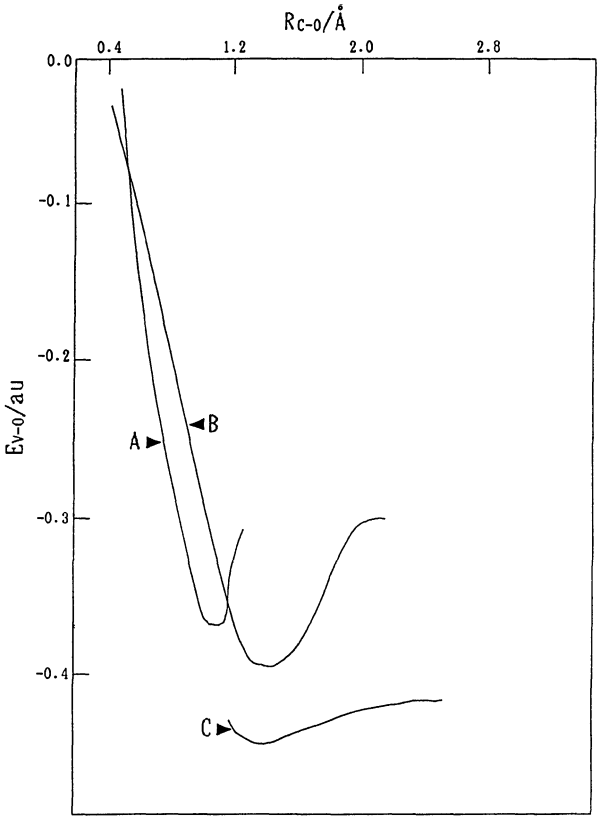

Fig. 8. Bond energy of V–O bond i.e. E_{V-O} against R_{C-O} involving a V_2 cluster.

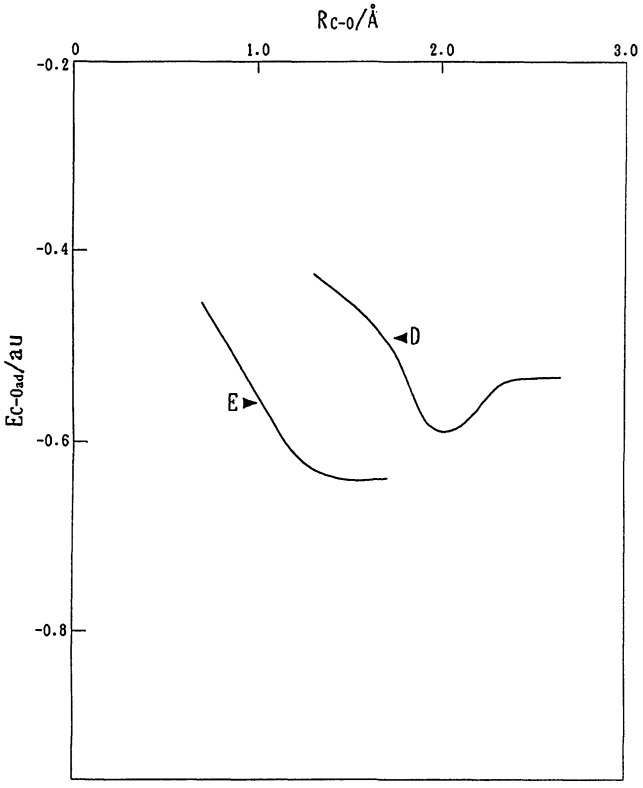

Fig. 9. Energy of C–O_{ad} bond i.e. $E_{C\text{-}O_{ad}}$ against $R_{C\text{-}O}$ involving a V_2 cluster.

CO_2.

Thus on the basis of our qualitative results, it can be suggested that Model-E offers a more suitable course for the reaction under study. The qualitative studies on V_2 cluster have shown that the following mechanism may be suggested for this reaction:

$$CO_{ad} + CO(g) \rightarrow CO_2(g) + C_{ad}.$$

A similar disproportionation mechanism has also been proposed by Keim et al.[29] on the basis of their ellipsometry and AES studies.

One of the authors (K.K.T.) is highly thankful to the CSIR, New Delhi for providing (Senior Research Fellowship) financial assistance. Thanks are also due to Computer Centre, Allahabad University for providing computer facilities in data calculation related to our present work.

(Received January 25, 1991)

Surface-enhanced Raman (SER) spectra have been obtained from *N,N*-dimethylthioacetamide (DMTA) adsorbed on Ag and Cu electrode surfaces. Vibrational analysis of the SER spectra of DMTA is made in comparison to the bulk-phase Raman spectrum of DMTA, and the infrared data on Co, Cu, and Hg complexes of DMTA. It is concluded that the DMTA molecule is bonded through its S atom to Ag and Cu surfaces.

Previously we have studied molecular bondings of several isostructural sulfur compounds containing a thiocarbonyl C=S group, namely, thiourea (TU), thioacetamide (TA), *N,N*-dimethylthioformamide (DMTF), thiosemicarbazide (TSC), and thiocarbohydrazide (TCH) on Ag and Cu electrode surfaces.[1-5] We found that in all cases the adsorbate was bonded via its S atom to Ag and Cu surfaces. The predominantly C=S stretching bands for these molecules were shifted to lower frequencies upon adsorption on metal surfaces with amounts comparable to those observed in their organometallic complexes. We believed that there were considerable electronic interactions between the adsorbates and the substrates such that the C=S bond order was reduced, and perhaps some kind of surface complexes was formed. These surface complexes may be the surface analogs of the organometallic complexes of these molecules. In this work we extend our study to *N,N*-dimethylthioacetamide (DMTA), the second simplest tertiary thioamide. The present work is a part of our continuing effort in the understanding of molecular interactions of adsorbates with metal surfaces.[1-8]

Experimental

N,N-Dimethylthioacetamide was synthesized from *N,N*-dimethyl acetamide (Aldrich) and phosphorus pentasulfide (Aldrich), and repeatedly crystallized from hexane.[9] The experimental procedure for the in situ Raman measurements was similar to that described previously.[2,4]

Results and Discussion

Figure 1 shows the surface-enhanced Raman (SER) spectrum of DMTA adsorbed on an Ag electrode at −0.30 V vs. saturated calomel electrode (SCE), whereas Fig.2 shows the SER spectrum of DMTA adsorbed on a Cu electrode at the same potential. The SER spectra were obtained after the electrodes had undergone an oxidation-reduction cycle.

Except for some minor frequency shifts and relative band intensity differences, the general spectral features for the Ag/DMTA and Cu/DMTA systems are similar to each other. This indicates that DMTA adsorbs in a similar fashion on Ag and Cu surfaces.

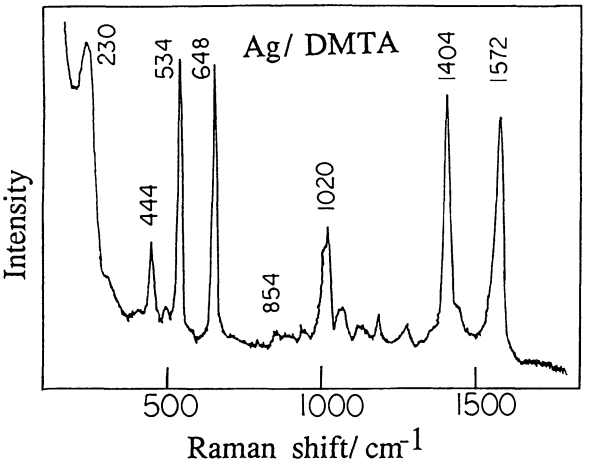

Fig. 1. Surface-enhanced Raman spectrum of DMTA adsorbed on Ag electrode at −0.3 V vs. SCE. The electrolyte was 1.4×10^{-3} M DMTA+0.1 M KCl (acidified with HCl, pH 2.5) (1 M=1 mol dm^{-3}). The electrode was anodized at 0.2 V before the spectrum was taken. The excitation wavelength was Kr^+ 647.1 nm.

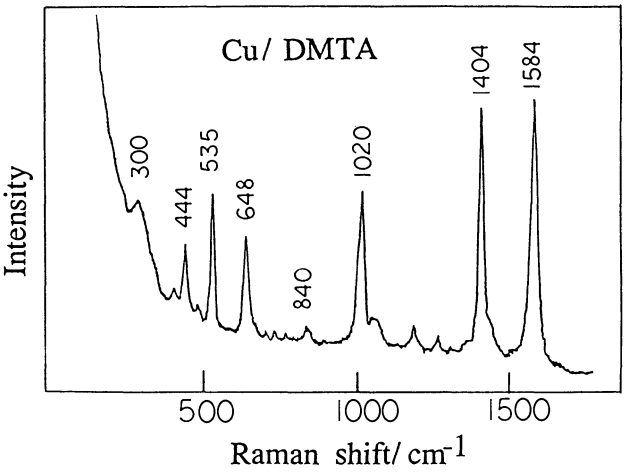

Fig. 2. Surface-enhanced Raman spectrum of DMTA adsorbed on Cu electrode at −0.3 V vs. SCE. The electrolyte was 1×10^{-4} M DMTA +0.1 M KCl (acidified with HCl, pH 2.5). The electrode was anodized at 0.1 V before the spectrum was taken. The excitation wavelength was Kr^+ 647.1 nm.

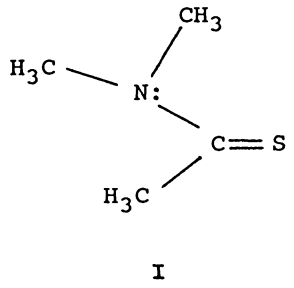
a), b), c) Ref. 10; d) Ref. 10 except *; UBF=Urey-Bradley force; L=DMTA; PED=potential energy distribution; ν=stretch; δ=deformation; r=rock; π=out-of-plane bend; s=symmetric; a=asymmetric; v=very; s=strong; m=medium; w=weak; b=broad; sh=shoulder; C's are used to denote methyl carbons next to the N atom.

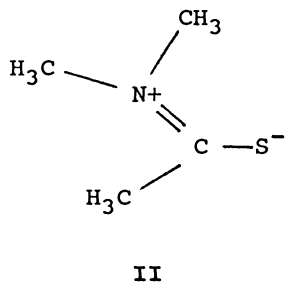
The IR, Raman, and SER frequencies for DMTA, and the vibrational band assignments for DMTA and its Co, Cu, and Hg complexes are given in Table 1. The potential energy distributions (PED's) and the assignments of the bands are also given. The PED calculation was performed by Ray and Sathyanarayana using C_s point group and a Urey-Bradley force field.[10] The present assignments for the SER spectra of the DMTA adsorbed on Ag and Cu surfaces are made by comparing the SER spectra with the solid phase Raman spectrum and with the IR vibrational frequencies of its metallic complexes.[10]

Metal complexes of DMTA were not so well studied when compared to those of TU, TA, DMTF, TSC, and TCH.[11] However, useful information still can be derived from the few complexes of DMTA that had been studied. Madan and Mueller[12] reported the preparation of several Co(II) complexes of DMTA, $Co(DMTA)_2X_2$ [where X=NO_3, Cl, Br or I], and $Co(DMTA)_4$ $(ClO_4)_2$. From the electronic absorption spectra and magnetic measurements of these complexes, they concluded that the DMTA ligand was coordinated to the central Co(II) atom through the S atom. Ray and Sathyanarayana[10] studied the IR spectra of the complexes of DMTA with the chlorides of Co(II), Cu(I), and Hg(II). They found that the C-N stretching frequency occurring at 1540 cm^{-1} in DMTA was increased to 1580—1610 cm^{-1} in the complexes. Additionally, two C=S bands at 870 and 656 cm^{-1} were decreased to 862—845 and 652— 635 cm^{-1}, respectively, in metal complexes. They concluded that the bonding to the metal ions was through the S atom in these complexes. Aarts et al.[13] synthesized DMTA complexes of Au(I), Au(DMTA)X (where X=Cl, Br or I). Again, their IR results indicated that the coordination of DMTA to Au(I) was through the S atom. The ν(CN) frequency of the free molecule at 1535 cm^{-1} was shifted to higher frequencies 1557 to 1572 cm^{-1} whereas the ν(CS) frequency at 657 cm^{-1} was shifted to lower frequencies 650—648 cm^{-1}. The observed metal-sulfur stretching ν(AuS) frequency was at 300 cm^{-1}.

The experimental observations are not difficult to rationalize in view of the fact that the electronic structure of DMTA can be represented by the resonance hybrid structures **I** and **II**, with a greater contribution comes from the polar structure **II**.[14] When the bonding is through the S donor site, the ν(CS) will be shifted to a lower frequency whereas ν(CN) to a higher frequency.



I



II

In the SER spectra of sulfur compounds with a thiocarbonyl group, the C-N and C=S stretching modes were most susceptible to frequency shifts upon adsorption on metal surfaces[1-5] for the same reason we have just mentioned. Thus, the C-N and C=S stretching modes will be monitored for shifts when DMTA is adsorbed on Ag and Cu electrode surfaces. In particu-

Table 2. Metal-Sulfur Vibration of Adsorbate (A) on Ag and Cu Surfaces

A	ν(AgS)/cm^{-1}	ν(CuS)/cm^{-1}
Thiourea	221	287
Thioacetamide	190	280
N,N-Dimethylthioformamide	230	288
Thiosemicarbazide	239	294
Thiocarbohydrazide	221	287
N,N-Dimethylthioacetamide	230	300

lar, the 1540 cm^{-1} Raman band with 46% PED ν(CN) is shifted to 1572 (+32) and 1584 (+44) cm^{-1}, respectively (The values in parentheses refer to the shifts from the corresponding Raman bands for DMTA). There are two bands that have a relative large contribution (about 25% PED) of the C=S stretching, one is at 656 and the other at 864 cm^{-1}. The band at 656 cm^{-1} is shifted to 648 (−8) on both Ag and Cu surfaces, whereas the 864 cm^{-1} band is shifted to 854 (−10) and 840 (−24) cm^{-1} on Ag and Cu surfaces, respectively. From this observation, we can conclude that the DMTA molecule is bonded through its S atom to the Ag and Cu electrode as was observed in previous cases.[1-5]

We assign the low-frequency vibrational modes at 230 cm^{-1} in the Ag/DMTA system and at 300 cm^{-1} in the Cu/DMTA system to the ν(AgS) and ν(CuS) modes, respectively. The intensity of these modes is increased as the applied potential becomes more cathodic, a behavior which is similar to those observed for other systems.[3,4] The frequency values of the metal to sulfur vibrations compare well with the same modes for TU, TA, DMTF, TSC, and TCH on Ag and Cu surfaces (see Table 2).

In conclusion, we have studied the adsorption of DMTA on Ag and Cu electrode surfaces. DMTA, like the other C=S compounds previously studied,[1-5] is also S-bonded to Ag and Cu surfaces.

Adsorption-Induced Unusual Changes in the Electrical Conductivity of Some Ferrocene Derivatives

Ashis BHATTACHARJEE* and Biswanath MALLIK
Department of Spectroscopy, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India
(Received January 28, 1991)

The effects of adsorption of different organic vapors on the electrical conductivity of some ferrocene derivatives have been studied using the sandwich cell technique. A conductivity peak is observed in the plot of measured current versus temperature for a sandwich cell of powdery material with some adsorbed vapors. The dependence of the intensity of the peak and the temperature at which it appears have been studied as a function of grain size of powdery materials, heating rate, amount of adsorbed vapor, and also the nature of the adsorbed vapors. At the vapor-adsorbed state these materials show very high value of activation energy and the pre exponential factor σ_o (in the usual semiconduction equation). Results indicate that the adsorption is a physical adsorption. The usual mechanisms for the adsorption-induced change in conductivity and activation energy are not suitable for explaining the observed results. Adsorption induced reversible structural phase transition seems responsible for the anomalous behavior of the adsorption-induced changes in the electrical properties of these materials. The results obtained with different ferrocene derivatives have been compared with that of ferrocene and possible reason for the adsorption induced phase transition is discussed.

Investigations on the effect of adsorption of vapors on the dark conductivity of organic as well as organometallic solid materials have been stimulated in recent years.[1–5] Adsorption or desorption of vapors changes the dark conductivity of these materials significantly. This effect of adsorption induced changes in dark conductivity can be monitored for the detection of various gases/vapors in the environment using these materials in suitable gas detectors.[1–5] The ultimate aim of such research is to find out suitable new materials that can be utilized as gas detectors for detecting specific gases, which has not yet been possible. The effect of adsorption-induced change in conductivity has shown another application also as the change in conductivity of vitamin A (alcohol and acetate) and some other linear conjugated polyenes could be involved in the primary mechanism of olfactory-transduction process.[6–7] Rosenberg et al.[6] have speculated that a week charge-transfer complex formation between vapor molecules and a semiconductor is responsible for the enhancement of conductivity and the change in activation energy in case of some polyenes. The nature of interaction between vapor or gas molecules and the solid surface is a complicated one and it is not yet clearly understood. Systematic studies are required to understand the nature of such interaction.

Recently, the studies on the effect of adsorption of vapors on ferrocene, the first synthesized organometallic compound has become a subject of great interest to us,[8] following the suggestion[9] that adsorption of minute amounts of moisture on this material may have an important role for the inconsistent results reported in the literature[10,11] regarding the pressure dependence of the electrical conductivity. In our earlier communication[8] we have discussed about the adsorption-induced unusual changes in the electrical conductivity of ferrocene. We have studied the adsorption-induced changes in the electrical conductivity of some ferrocene derivatives for eluciding the effect of substituent groups on the adsorption-induced changes. The results of this investigation are presented in this paper.

Experimental

High-purity microcrystalline ferrocenecarboxylic acid (Fc-COOH), ferrocenecarbaldehyde (Fc-CHO), acetylferrocene (Fc-$COCH_3$) in powdered form were obtained from Aldrich Chem. Co., Inc. (U.S.A.) and then were used after purification by repeated crystallization. Reagent chemicals used in this experiment were of spectrograde (E. Merck) or equivalent quality. The usual sandwich cell technique[7,12,13] with a conducting glass and a stainless steel electrode was used and the cell was placed inside a suitably designed conductivity chamber, made of brass and fashioned with teflon. The experimental arrangement for measurement of semiconduction parameters of these ferrocene derivatives with various adsorbed vapors was the same as described in earlier communications.[12,13] The finely powdered and coarsely powdered materials were used as materials of smaller grain size and larger grain size respectively. The grain size of the powdery materials taken for preparing different sample cells was kept same in each experiment. A d.c. voltage of 27 Volts was applied across the electrodes as a bias potential and a teflon spacer of 2 mil (0.005 cm) thickness was used. The conductivity chamber was first evacuated and then filled with dry nitrogen gas and its flow at a constant rate was maintained throughout the experiment. Repeated heating-cooling cycles were performed for each cell to ensure the absence of any kind of adsorbed vapors or moisture in the material before adsorption studies. For adsorption of vapors on the solid materials, dry nitrogen gas at a constant rate was bubbled through a solvent inside a bubbler kept at a fixed temperature to maintain a constant vapor pressure and then it was passed through the conductivity chamber. The cell temperature was kept at 258 K during adsorption and after obtaining saturation current the cell was further cooled down to about 250 K. Then the cell was heated with a constant heating rate of 0.01 K sec^{-1} (otherwise mentioned in the text) and the values of the dark current were noted with temperature. For current mea-

surement an electrometer (model No. EA815) of Electronic Corporation of India Ltd. was used. The temperature measurements were carried out by a Panel meter (model No. 2301) of HIL, India. It is reported that Fc-$COCH_3$ shows structural phase transition[14] near melting point. Therefore, during heat treatment the maximum temperature of the sample cell was kept much below the melting point for Fc-$COCH_3$. Similarly, in case of Fc-CHO, the maximum temperature of the cell was kept below 317K to avoid the structural phase transitions.[15]

Results and Discussion

The effect of adsorption of different vapors on the electrical conductivity (proportional to current) of the ferrocene derivatives as a function of temperature was studied. Such an effect of adsorption of toluene vapors (30 Torr vapor pressure, 1 Torr=133.322 Pa) on Fc-$COCH_3$ is illustrated in Fig. 1 [curve(1)]. At temperatures near 250 K current observed (not shown) was very low ($<10^{-14}$ A). As the temperature increases initially the current rises slowly and then rapidly; and attains a maximum value of 1.37×10^{-9} A at about 282 K. Then the current starts to decrease sharply with increasing temperature and attains a value almost equal to that of the pure sample near the room temperature. Above room temperature the current rises again with increasing temperature similar to the pure sample in nitrogen atmosphere. Thus a conductivity peak is observed at the adsorbed state by plotting the current values against temperature [curve 1, Fig. 1]. It is interesting to note that the conductivity variation [curve (2), Fig. 1; plotted in a magnified scale] in the same temperature range in pure acetylferrocene in dry nitrogen atmosphere does not show any conductivity peak and the variation is usual one as expected for a pure organic semiconductor. However, the above-mentioned conductivity peaks were also observed with different adsorbed vapors on various ferrocene derivatives.

The effect of adsorption of vapors on the dark conductivity of different ferrocene derivatives were studied under different measurement conditions such as (i) with different grain size of the powdery materials, (ii) change of heating rate, (iii) with different amounts of adsorbed vapors, and (iv) nature of adsorbed vapors. These are described below in detail.

(i) The adsorptive property of a solid surface depends on the grain boundaries of the particles constituting the surface. To investigate such a dependence in case of different polycrystalline ferrocene derivatives, qualitative experiments were performed with two different grain sizes of polycrystalline powders of these materials. The results of such a typical experiment with adsorbed ethanol vapor at 40 Torr vapor pressure on Fc-$COCH_3$ are shown in Fig. 2 for two different grain sizes. The conductivity curve corresponding to bigger grain sizes has shown a higher value of that temperature (T_{max}) at which the conductivity peak appears associated with a slightly lower value of current (I_{max}) corresponding to the conductivity peak compared to that of the smaller grain sizes. The current versus temperature curve corresponding to the former has a larger band width than that of the curve corresponding to the latter one. Dependence of I_{max} and T_{max} on the grain size was observed with other vapors and also with different ferrocene derivatives.

(ii) Similar to ferrocene (Fc-H)[8] in these derivatives also the rate of heating has an influence on the value of I_{max} as well as T_{max}. Figure 3 illustrates two conductivity curves for Fc-$COCH_3$ powders of same grain size on adsorption of ethanol vapor at 40 Torr pressure for

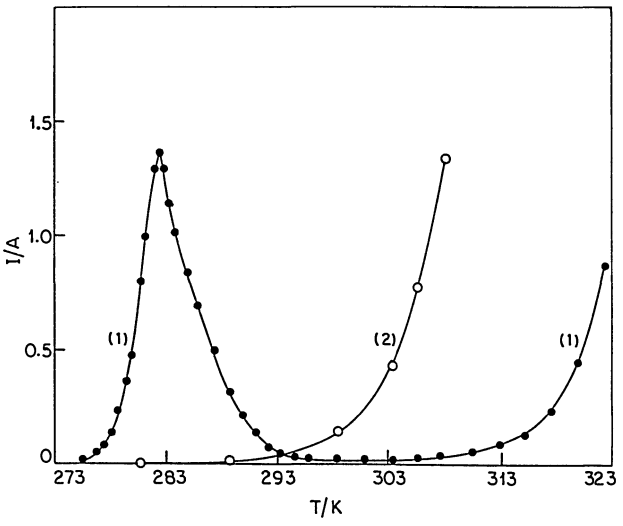

Fig. 1. Variation of dark current (conductivity) as a function of temperature in a powder cell of acetylferrocene:
1) with adsorption of toluene vapor at 30 Torr vapor pressure (left scale$\times10^{-9}$).
2) pure sample in dry nitrogen atmosphere (left scale $\times10^{-11}$).

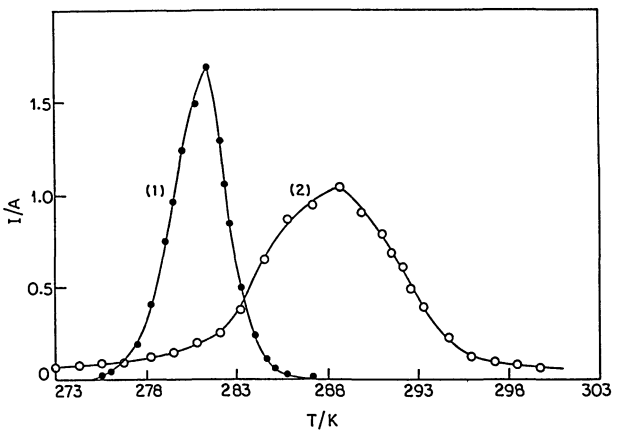

Fig. 2. Variation of dark current as a function of temperature in a powder cell of acetylferrocene with adsorbed ethanol vapor at 40 torr vapor pressure for two different grain sizes: (left scale$\times10^{-9}$)
1) smaller grain size (value of T_{max}=281.3 K),
2) bigger grain size (value of T_{max}=288.6 K).

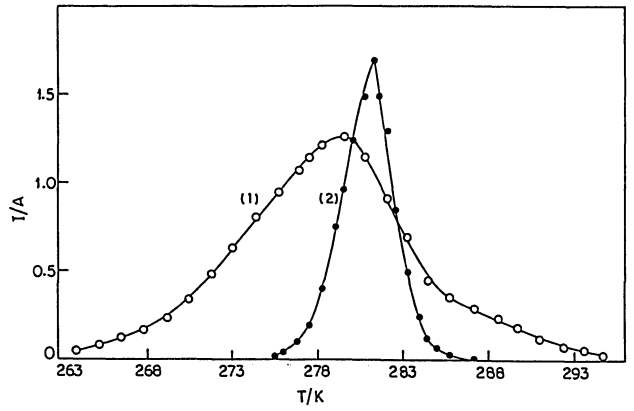

Fig. 3. Variation of dark current as a function of temperature in a powder cell of acetylferrocene with adsorbed ethanol at 40 Torr vapor pressure for two different heating rates: (left scale$\times 10^{-9}$)
1) heating rate: 0.02 K sec^{-1},
2) heating rate: 0.01 K sec^{-1}.

two different heating rates. In case of higher heating rate the conductivity peak appears at lower temperature (i.e., lower value of T_{max}) with a slightly lower value of I_{max}. But the conductivity curve in this case has a higher band width. In poly vinylalcohol, a spontaneous current emission induced by first heating run has been observed.[16] The presence of moisture in the material was thought to be the cause for such a current emission. Though the observed current versus temperature curves in case of poly vinylalcohol were very broad and different in nature from the present case, a shift of T_{max} towards lower temperature with increasing heating rate was also observed in that case as in the present experiment. The location of the conductivity peaks on the temperature scale depends on the heating rate. This is possibly due to the fact that the materials in the adsorbed state change their properties gradually over a certain temperature interval.

(iii) The dependence of I_{max} and T_{max} on the amounts of adsorbed vapors (i.e. on the vapor pressure of the adsorbed vapors) were studied for different ferrocene derivatives under study. Such a dependence is illustrated in Fig. 4 in case of Fc-$COCH_3$, where the values of dark current in a sample cell on adsorption of ethanol vapor at different vapor pressures are plotted as a function of temperature. In general it is observed that the peak value of current (I_{max}) increases with increasing vapor pressure and the temperature (T_{max}) corresponding to this peak value of current shifts a little towards the higher temperature side for larger amount of adsorbed vapors. Similar observations has been reported from the thermal desorption spectroscopic study for oxygen adsorption upon Ge surface.[17]

(iv) To study the effect of different vapors on I_{max} and T_{max} in case of a particular material experiments were performed with various vapors e.g. ethanol, methanol, 2-propanol, benzene, toluene, carbon tetrachloride etc. adsorbed at a fixed vapor pressure. (Benzene vapor solidifies at 278 K. But from the quick response of the current due to adsorption of benzene

*Vapor pressure=30 Torr.

vapor upon the cell at 258 K and the similarity in the nature of the current response due to adsorption of other vapors of much lower freezing temperature it appears that the rate of adsorption is faster than the rate of freezing of benzene vapor). Results of such an experiment is shown in Fig. 5 for Fc-$COCH_3$. With the change of vapor, the change in I_{max} as well as T_{max} is evident from this figure (Fig. 5). In case of toluene vapor though the vapor pressure is less than the others, the current enhancement is comparable to (e.g. ethanol) or even higher than some other vapors (e.g. methanol, benzene). On adsorption of carbon tetrachloride vapor no sharp peak was observed. For the appearance of the conductivity peak, a particular vapor is sensitive (the sensitivity, S, may be defined as the ratio of the value of conductivity corresponding to the abovementioned peak and the value of the conductivity of the pure material without adsorption at the temperature corresponding to the peak) to different ferrocene derivatives to a different extent. This is illustrated in Fig. 6 which shows the variation of dark current with temperature for adsorption of ethanol vapor at 40 Torr vapor pressure on different materials. From this figure the effect of substituent groups on the electrical conductivity is evident. In case of Fc-H adsorbed with ethanol vapor, multiple conductivity peaks have been observed, but no such multiple peaks have been appeared in its derivatives. The effects of adsorption of various vapors on S and T_{max} in case of Fc-H and its different derivatives are summarized in Table 1 (corresponding values for Fc-H is also included for comparison). The following interesting observations may be noted from this table.

(a) For most of the adsorbed vapors the value of T_{max} as well as S in case of Fc-H is higher than the corresponding values for any derivative.

(b) In case of adsorption of different vapors in a particular compound the sequence of vapors for the enhancement of S does not correspond to the same sequence for the increase in T_{max}.

(c) For adsorption of a particular vapor in the different derivatives the increase or decrease in S is accompanied by a simultaneous increase or decrease in T_{max} (except for adsorption of benzene vapor in Fc-CHO).

(d) Either ethanol or 2-propanol shows the maximum value of S in these materials.

(e) In general, methanol shows the minimum value of S for these materials.

The experiments on adsorption of various vapors on various ferrocene derivatives under different measurement conditions indicate that the mechanism behind the appearance of the above mentioned conductivity peaks is expected to have a physical basis.

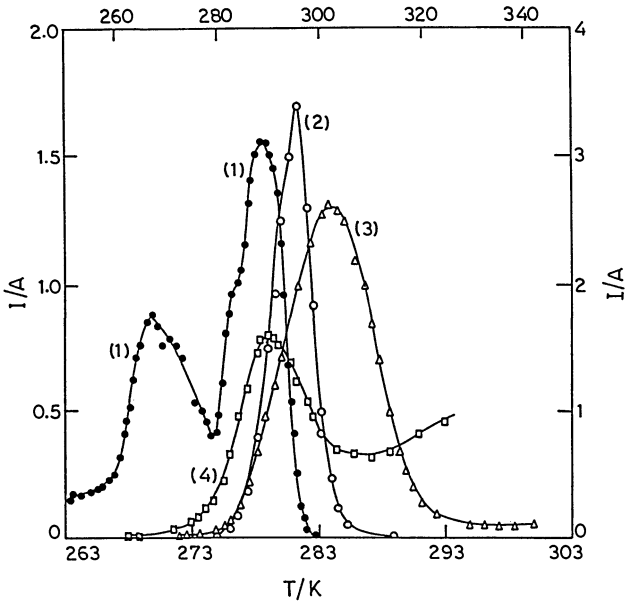

Fig. 6. Variation of dark current as a function of temperature in powder cells of different materials on adsorption of ethanol vapor at 40 Torr vapor pressure:
1) Ferrocene (right scale $\times 10^{-8}$, upper temperature scale),
2) Acetylferrocene (left scale $\times 10^{-9}$),
3) Ferrocenecarbaldehyde (right scale $\times 10^{-9}$),
4) Ferrocenecarboxylic acid (left scale $\times 10^{-11}$).

Table 1. The Values of S and T_{max}(K) for Adsorption of Different Vapors (at 40 Torr Vapor Pressure) on Ferrocene and Some of Its Derivatives at a Cell Temperature of 258 K

a) Vapor pressure in this case is 30 Torr. b) A hump was observed in this case.

The electrical conductivity in organic as well as organometallic materials, charge-transfer complexes, and adsorption induced conductivity is usually expressed[7,13,21] by the Arrhenious relation

$$\sigma(T)=\sigma_0 \exp(-E/2kT), \quad (1)$$

where $\sigma(T)$ is the specific conductivity at any absolute temperature T, σ_0 is the pre exponential factor, E is the activation energy, and k is the Boltzmann constant. Experimentally E is obtained from the slope of the linear plot of $\log\sigma(T)$ or $\log I(T)$ versus $1/T$, where $I(T)$ is the current at the temperature T. As a representative curve the variation of $\log I(T)$ against reciprocal of temperature for a sample cell of Fc-$COCH_3$ with adsorbed toluene vapor is shown in Fig. 7 [curve(1)]. Usually a plot of $\log\sigma(T)$ or $\log I(T)$ versus $1/T$ gives a straight line in the low temperature region,[13,22] which shows the conduction properties of the solid material with adsorbed vapor. The slope of this line gives the activation energy of the material at the adsorbed state and the straight line at higher temperature region gives the activation energy of the pure material in vacuum or nitrogen atmosphere. Similar to the case of Fc-H,[8] in the present case also two different straight lines (AB and BC in curve 1 of Fig. 7) instead of one line have been observed at the adsorbed state and a transition from one line to another is prominent at the point B. The portion of the curve, DE represents the change in current due to desorption of vapors and the portion EF shows the conduction behavior similar to pure material in nitrogen atmosphere. The value of activation energy evaluated from the line EF is 3.7 eV which is equal to the activation energy of pure material in nitrogen atmosphere and these results show that the adsorption is a physical adsorption. The activation energy values evaluated from the portion AB and BC are 5.05 and 9.75 eV respectively. The value of σ_0 for pure Fc-$COCH_3$ is 1.76×10^{17} $\Omega^{-1}\,cm^{-1}$ and for the sample with adsorbed toluene vapor (corresponding to line BC in Fig. 7) at 30 Torr vapor pressure is about 4.48×10^{75} $\Omega^{-1}\,cm^{-1}$. Both the values of activation energy and σ_0 at the adsorbed state are anomalously high. Such an appearance of two straight lines is not a typical property for adsorption of a particular vapor only. For most of the vapors studied similar behavior was observed in each material. Figure 8 shows the appearance of such two straight lines in case of ethanol vapor adsorption on various ferrocene derivatives. The appearance of two straight lines possibly indicates that the adsorption is a two stage process.[24] Out of these two lines, the line at higher temperature (Fig. 8) gives the value of activation energy (E) which is in general much higher than the activation energy of the pure material. In Table 2 we

a) Vapor pressure is 30 Torr in this case. b) In case of ferrocene multiple peaks were observed, so these values could not be evaluated.

show the values of E evaluated from these lines along with some other parameters for adsorption of different vapors on these ferrocene derivatives. This table shows that the value of E and σ_0 are enormously high. These results are certainly unusual.

As the adsorption is a surface phenomenon the observed adsorption-induced change in the electrical conductivity of the solid materials arise mainly due to the change in surface conduction. When adsorption of vapors occurs, an exchange of charges takes place between the adsorbed molecules and the solid materials causing a change in surface electrical conductivity. It needs to be pointed out that depending on the extent of adsorption/absorption of vapors there is a possibility of formation of a solvated surface film (that may form and disappear at different temperatures) producing very high electrical conductivity. The variation of the solvated surface film with changing temperature may be related to the consequent change in conductivity. In fact, in case of the formation of solvated films, usually irreversible change is observed and it is more likely (as we have noticed also) that in a sandwich type of cell configuration due to solvation, the positive and negative electrodes will be short circuited by solvent molecules/dissolved materials. In the present experiment such a situation was carefully avoided by controlling the amount of adsorption (by adjusting the vapor pressure of the adsorbed vapor) and only the reversible adsorption-induced changes were considered. So, the appearance of the observed conductivity peak due to the formation of the solvated surface film can easily be ruled out.

The reason for the change in E in organic/organometallic semiconductors on adsorption of vapors is not yet well understood. The possible mechanism which is quite often considered is the formation of charge-transfer (CT) complexes[6,13] of adsorbed vapor molecules with the solid surface. Rosenberg et al.[23] proposed that such change in E on adsorption is associated with a change in effective dielectric constant of the material at the adsorbed state. We have checked the applicability of these theories and found that these theories are not suitable for the explanation of the change in E as well as conductivity.[8] Again the observed conductivity versus temperature curves look similar to the conventional glow curves (arise due to the thermally stimulated currents or TSC).[24] On adsorption of vapors, trapping states within the band gap of a semiconductor could be populated by charge carriers and consequently on heating TSC may appear due to detrapping of charge carriers.[25,26] But the values of trap depth calculated by the usual theory of TSC[24] are much higher than the activation energy values of the pure materials. So, the theory of TSC can not be considered as the possible mechanism behind the appearance of peak in the observed conductivity versus temperature curve under discussion.

From Eq. 1 it is clear that the increase in σ_0 is responsible for the increase in conductivity and σ_0 contains factors depending on temperature. The pre exponential factor σ_0 of the Eq. 1 can be expressed as[27]

$$\sigma_0 = qN\mu, \tag{2}$$

with

$$N = (N_A \cdot \rho \cdot Z)/M, \tag{3}$$

where q is the charge on the carrier, μ is the mobility, N_A is Avogadro's number, M is the molecular weight of the solid material, ρ is the density, and Z is the number of charge carriers available for excitation per molecule. The mobility of charge carriers for most organic and biological semiconductors usually lies[27] between 10 and 10^{-5} $cm^2\,V^{-1}\,sec^{-1}$. So a large change in σ_0 upon adsorption of vapors can not be considered due to the change in the mobility of these charge carriers in the sample in the adsorbed state. Thus the large value of σ_0 must be associated with a large density of activated charge carriers. In some organic materials an exponential temperature dependence of the charge carrier mobility has been observed.[28] The reported value of the mobility activation energy (E_μ) of a large number of organic materials lies between 0.20 and 0.77 eV.[28] Therefore, even if the exponential temperature depen-

dence of charge carrier mobility is considered, the anomalously large value of E remains unexplained.

It is known that a phase transition occurs in ferrocene under the influence of changes in external parameters like temperature[29] and pressure.[9] The ferrocene derivatives under investigation exhibit[14,15,30,31] various kinds of structural phase transitions associated with intermolecular interactions. From these observations it appears that a structural phase transition in these ferrocene derivatives due to interaction with various vapors in a suitable temperature range is not unlikely. Phase transition in the adsorption process has been reported in the literature.[32,33] It is reported[34] that as result of phase transition, the activation energy of some organic materials increases by a large amount and such phase transition is indicated by a deviation from the linearity of the $\log \sigma(T)$ or $\log I(T)$ versus $1/T$ plots. It is interesting to note that such a deviation from linearity has also been observed in the present case (Figs. 7 and 8). This adds further credence to the idea of adsorption-induced structural phase transition in these ferrocene derivatives. Such phase transitions depend on the nature of adsorbed vapors and these transitions are reversible on desorption of vapors. We have mentioned earlier that a large change in σ_0 (hence in σ) upon adsorption of vapors must be associated with a large density of activated charge carriers. The reason for such a large value of the density of activated charge carriers occuring upon a phase transition can be explained by concept of conformon,[35-37], which is considered as the activated charge carrier plus the accompanying conformational changes (here due to phase transition) carrying energy and entropy. By conformon concept Kemeny and Goklany[36] has suggested that the effective density of states for the activated charge carriers would be greatly increased due to interaction between the activated carriers and the vibrational degrees of the molecules. A change in the electronic state (as involved in transport) gives rise to an activation entropy ΔS because of a change in the vibrational frequency associated with a conformational change and this would contribute to the pre-factor σ_0. Thus, using proper thermodynamic quantities σ_0 can be written as[38]

$$\sigma_0 = A_1 \exp(\Delta S/2k) \cdot \exp(-\Delta H/2kT), \quad (4)$$

where A_1 is a constant, ΔS is known as activation entropy and ΔH is the activation enthalpy. Hence the process of current emission can be represented by the relation

$$\sigma(T) = A \exp(\Delta S/2k) \cdot \exp(-E^*/2kT), \quad (5)$$

where A is another constant and $E^* = (\Delta H + E_\mu + E)$, which accounts for the large value of activation energy in the present case.

The lattice dynamical nature of Fc-$COCH_3$, Fc-COOH, and some other ferrocene derivatives has been investigated[14,30] by some researchers in the solid state (in the tempearature range from 100 K to nearly melting point of these materials) by comparing their Mössbaur spectra with the crystal structure determined by X-ray diffraction spectroscopy. In these ferrocene derivatives the mean square amplitude of lattice vibration (thermal) of iron atoms measured from Mössbaur spectra has been observed[14,30] to be proportional to the absolute temperature nearly upto room temperature (300 K) indicating that the molecules are in harmonic lattice vibration; but a significant deviation has been found near the phase-transition temperature. From X-ray diffraction and Mössbaur spectroscopic studies Daniel et al.[31] have reported that Fc-CHO shows anomalous behavior near phase transition temperature (317 K). These results indicate a substantial modification in the lattice characteristics of the solid due to phase transition. Such phase transition has been thought[14,30,31] to be associated with a cooperative motion of different neighboring molecules. It has been suggested[14] that the orientational motion of Fc-$COCH_3$ may be hindered by interaction with neighboring molecules, for instance the steric hindrance of -$COCH_3$ groups which probably reduces the thermal motion. Two molecules of Fc-COOH have an intermolecular hydrogen bonding[30] between -COOH groups. In Fc-CHO, the -CHO side group is almost coplaner with the ring to which it is attached,[15] thus allowing conjugation of the π-electron system of the $>C=O$ bond and the aromatic cyclopentadienyl ring. As a result of different cooperative interactions, phase transition in different ferrocene derivatives (also in pure ferrocene) occurs at different temperatures. In the temperature range of present experiment the molecules of the pure ferrocene derivatives exhibit harmonic thermal vibration. But possibly due to the presence of adsorbed vapor molecules, the harmonic thermal vibration of the molecules of the ferrocene derivatives is perturbed and due to cooperative interaction such phase transition appears. As mentioned earlier, such adsorption-induced phase transition depends on the nature of the adsorbed vapor and also on the substitution group in a particular ferrocene derivative. In general methanol is less sensitive for the adsorption-induced changes. Though 2-propanol is good sensitive to most of the materials studied (Table 1), it is almost insensitive to Fc-$COCH_3$. Thus, the selectivity in the interaction of vapors with the different derivatives is evident from the observed results. In fact, the cooperative interaction which determines the phase transition is very complicated in nature[31] and it is not possible to correlate the nature of adsorption-induced phase transition with the presence of substituent group in the ferrocene derivatives at the present stage.

Thanks are due to Professor T. N. Misra of this department for his constant encouragement.

Fluorescence Quenching of Few Aromatic Amines by Chlorinated Methanes

Debabrata GOSWAMI, Ranjit S. SARPAL, and Sneh K. DOGRA*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received February 1, 1991)

Fluorescence quenching of few aromatic amines; aniline (AB), 1-naphthylamine (1-AN), 2-naphthylamine (2-AN), 2,3-naphthalenediamine (2,3-DAN), 9-phenanthrenamine (9-AP), 1-pyrenamine (1-APy), 2-chrysenamine (2-AC), 6-chrysenamine (6-AC), and 3-fluoranthenamine (3-AF) by dichloromethane, chloroform, and carbon tetrachloride has been studied in cyclohexane and acetonitrile. The quenching rate constants (k_q) have been determined in both the solvents and these values are nearly independent of the solvent polarity. The values of k_q are nearly equal to diffusion-controlled limits (k_{diff}) for $CHCl_3$ and CCl_4 in both the solvents, whereas for CH_2Cl_2 it is three to four order of magnitude less than k_{diff}. For a given amine, k_q increases with the increase in electron affinity of the quencher, whereas for a given quencher (dichloromethane) k_q increases with the increase in singlet state energy of fluorophore. The results obtained are explained in terms of a quenching mechanism involving an intermediate donor–acceptor (DA)* complex formed between the excited aromatic amine and quencher.

In our recent study, regarding the effect of solvents on the absorption and fluorescence spectra of some aromatic amines,[1] it has been observed that the Stokes shifts [$\bar{\nu}_{abs}(max)-\bar{\nu}_{flu}(max)$], observed in the chlorinated methanes, do not follow the Lippert's equation and in some cases the fluorescence intensity was completely quenched in these solvents, especially the carbon tetrachloride. This indicates that there is some kind of specific interaction between these solvents and the aromatic amines. This kind of behavior has also been observed where the fluorescence of aromatic hydrocarbons,[2–5] ketones,[6,7] and heterocyclic[8,9] molecules has been quenched by halogenated alkanes.

In recent years, the quenching of fluorescence by these systems has been the focus of many investigations, as in the above-mentioned systems, energy transfer from aromatic hydrocarbons to halogenated alkanes are energetically not possible. In the above cases the fluorescence quenching of the fluorophores by the halogenated alkanes is observed without the appearance of any new fluorescence band. Thus in these cases, the formation of a transient excited-state complex as an intermediate in the fluorescene-quenching process is inferred on the basis of more indirect evidence. In any event, it seems clear that in those cases where the quencher possesses no low lying excited singlet state, which can be populated by dipole–dipole resonance transfer of energy from the excited fluorophore, the two molecules must approach one another at least to distances where the mutual interaction of the species is effective i.e. initial step in the fluorescence quenching process will be limited by the diffusion-limited approach of the excited fluorophore and quencher to form an encounter complex. Klein et al.[3] have postulated that halogenated alkanes form contact complexes as an intermediate which lie energetically above the S_1 state of the fluorophores and formation of this exciplex is considered as the rate-determination step in the excitation quenching process. The following equation was derived by Klein et al.[3] to express the quenching rate constant (k_q).

$$k_q \propto \exp[-(I.P.-E.A.-C-P-S_1)/k_bT], \quad (1)$$

where $I.P.$ are S_1 are the ionization potential and singlet state energy of the fluorophore, $E.A.$ is the electron affinity of the quencher, C is the coulomb energy, and P is the polarization energy of the separated charges, k_b is the Boltzman's constant.

The aim of the present study is to test the above model from two points i.e. to correlate (i) $\log k_q$ vs. ($IP-S_1$) for a single quencher and (ii) $\log k_q$ vs. $E.A.$ for a single fluorophore. For this purpose we have chosen nine aromatic amines; aniline (AB), 1-naphthylamine (1-AN), 2-naphthylamine (2-AN), 2,3-naphthalenediamine (2,3-DAN), 1-pyrenamine (1-APy), 9-phenanthrenamine (9-AP), 2-chrysenamine (2-AC), 6-chrysenamine (6-AC), and 3-fluoranthenamine (3-AF), and three different quenchers, dichloromethane, chloroform, and carbon tetrachloride.

Materials and Method

1-AN, 2-AN, 2,3-DAN, 2-AC, 6-AC, 9-AP, 3-AF, and 1-APy were procured from Aldrich Chemical Company. 1-AN, 2-AN, and 2,3-DAN were first crystallized from ethanol and were further purified by vacuum sublimation. 1-APy and 9-AP were purified by repeated crystallization from 50% ethanol (v/v) and ethanol respectively. Aniline (SD Fine Chem.) was purified by distilling under vacuum repeatedly. 2-AC, 6-AC, and 3-AF were purified by repeated crystallization from ethanol. The purity of the compounds was checked by noting the mp and comparing the spectral data with the literature data. Analytical grade cyclohexane (SD Fine Chemicals) and acetonitrile (E. Merck) were further purified according to literature procedures.[10] Spectroscopic grade dichloromethane, chloroform, and carbon tetrachloride (all BDH) were used as such. Chloranil and *p*-benzoquinone were procured from K and K Fine Chemicals. These compounds were further purified by repeated crystallization from acetone.

The absorption spectra were recorded on Shimadzu UV 190, equipped with U-135 chart recorder. Fluorescence measurements were carried out on scanning spectrofluorimeter, details are available elsewhere.[11] The concentration of the fluorophores used was of the order of 0.6—2.5×10^{-5} M (1 M=1

mol dm^{-3}), whereas those of chloroform and carbon tetrachloride varied from 0.001 to 0.7 M, except for 3-AF. Dichloromethane is a very poor quencher and thus very high concentration had to be used to get any meaningful fluorescence quenching.

Fluorescence lifetimes at 300 K were measured with the help of Applied Photophysics limited nanosecond fluorescence spectrofluorimeter (model SP-70/80) using time correlated single photon counting device. The electronic processing equipment was from Ortec. The pulse width of the flash lamp is ca. 4 ns and the convolution method was applied to determine the fluorescence lifetimes less than 10 ns.

Results and Discussion

Absorption Spectra. The absorption spectra of all the aromatic amines in cyclohexane and acetonitrile at various concentrations of chlorinated methanes do not change i.e. the band shape and full band width at half the absorbance remain same. This indicates that no complex formation between the amines and chlorinated quenchers are occuring in the ground state.

Fluorescence Spectra. The fluorescence spectra of all the aromatic amines in cyclohexane and acetonitrile at various concentration of chlorinated methanes were recorded. It has been observed that the fluorescence intensity of the fluorophore decreases with the increase of quencher concentration without the appearance of any other new fluorescence band. The fluorescence band shape and full width at half the maximum intensity did not change. Further, the fluorescence intensity as well as the absorbance of any solution containing highest concentration of quencher did not change when the spectrum was recorded after the experiment was carried out once. This indicates that no detectable photoproduct is formed under our experimental conditions. This could be due to the very small amount of quencher (less than 0.6 M) used and time used to excite the sample is also very small. Dichloromethane was the exception. In this case, the concentration of quencher used was upto 10 M. Even at such a high concentration of dichloromethane, no detectable amount of decomposition of aromatic amines is observed. Further, the Stern-Volmer plot for dichloromethane as a quencher, is linear and thus indicates that no ground state or contact complex between the fluorophore and dichloromethane is formed even at such a high concentration of the quencher.

The Stern-Volmer plot of the fluorescence quenching of 2-AN by CCl_4 is shown in Fig. 1. The plot is linear throughout the concentration of CCl_4 used.

$$\frac{I_o}{I} = 1 + K_{sv}[Q] = 1 + k_q\tau_o[Q] \quad (2)$$

where I and I_o are the fluorescence intensities of the fluorophore with and without the quencher Q, $K_{sv}=k_q\tau_o$ is the Stern-Volmer constant, k_q is the second order fluorescence quenching rate constant and τ_o is the lifetime of the fluorophore in the absence of quencher. Similar plots were observed for other fluorophores using different quenchers. The quenching rate constants k_q for the chlorinated methanes can be easily determined from K_{sv}/τ_o. The values of k_q in cyclohexane and acetonitrile as solvents are compiled in Table 1.

Different values of excitation wavelengths were used

9	3-AF	2.80	8.1	—	0.001	0.046	8.8	—	—	0.147

for 1-AN–$CHCl_3$ system and it was found that the Stern–Volmer plot (thus K_{sv}) did not depend upon the excitation wavelength above 300 nm, (λ_{exc}=300 nm, K_{sv}=20.1 M^{-1}; λ_{exc}=325 nm, K_{sv}=19.6 M^{-1}; λ_{exc}=335 nm, K_{sv}=20.45 M^{-1}). This indicates that no distinct complex formation between $CHCl_3$ and 1-AN in the ground state is observed. Though no similar study has been carried out with other compounds, similarity of the absorption spectra of these compounds with each other does indicate that no ground-state complexes are formed in these systems also. This has also been manifested from the study of absorption characteristics as said earlier. But these results are different from those of anthracene and CCl_4,[2,3] where it has been shown that the photoproducts are formed.

A popular mechanism, generally used to explain the fluorescence quenching has the following reaction scheme:

$$A + h\nu \longrightarrow A^* \tag{2}$$

$$A^* + Q \underset{k_2}{\overset{k_1}{\rightleftarrows}} (AQ)^* \xrightarrow{k_3} A + Q \tag{3}$$

$$(AQ)^* \xrightarrow{k_f} A + h\nu_f, \qquad (AQ)^* \xrightarrow{k_I} A$$

where A, Q and $h\nu$ represent the fluorophore, quencher and the light quantum, A* and (AQ)* are the excited states of the fluorophore and of the encounter complex between A* and Q respectively, k's reaction rate constants, k_f and k_I are the rate constants for radiative and nonradiative decay processes. The apparent quenching rate constant k_q, for the collisional quenching process can be given by

$$K_q = \gamma k_1, \tag{4}$$

where γ is the efficiency of the quenching reaction, which is given by $k_3/(k_2+k_3)$ approaches unity if $k_2 \ll k_3$ (the quenching process is very fast) or it approaches k_3/k_2 when not every encounter between Q and A* results in quenching. Thus the values of $k_q=k_1$ in the former case and k_1k_3/k_2 in the latter case. As said earlier, fluorescence quenching process in the present case requires that the fluorophore and the quencher should approach each other, the maximum value of k_1 can be equal to the diffusion controlled limits. The values of k_1 thus determined, using the modified Debye equation[12] ($8RT/3000\eta$, where η is viscosity of the medium in centipoise, R is a gas constant and T the temperature in Kelvin) are found to be 9.8×10^9 $M^{-1}s^{-1}$ and 1.8×10^{10} $M^{-1}s^{-1}$ in cyclohexane and acetonitrile respectively.

The data of Table 1 clearly indicate that fluorescence quenching rate constants for all the aromatic amines by CCl_4 are nearly equal to the diffusion-controlled rate constant (k_{diff}) whereas the quenching efficiency of CH_2Cl_2 is three to four orders of magnitude less than CCl_4 and that of $CHCl_3$ is between CH_2Cl_2 and CCl_4. The quenching rate constants even in case of CH_2Cl_2 is considerably faster than can be accounted for chemical quenching (for example, the rate constant of alkyl radicals with CCl_4 does not exceed 10^4—10^5 $M^{-1}s^{-1}$, see Ref. 3). The data of Table 1 thus clearly indicate that quenching is believed to proceed via an intermediate donor-acceptor (DA)* complex formed between the excited aromatic amine and quencher and not by classical energy transfer. To test the validity of this model, Eq. 1 can be varified from two angles as mentioned below:

i) Equation 1 reduces to

$$k_q \propto \exp[-(\text{const} - E.A.)/k_bT],$$

i.e.
$$\log k_q = \text{const} + \frac{E.A.}{2.303\,k_bT}, \tag{6}$$

if the fluorophore is kept the same but quencher is varied. Figure 2 depicts the plot of $\log k_q$ vs. $E.A.$ Although the number of quenchers are only three, it is clear from Fig. 2 that plot is a curve for each amine and it levels off to a diffusion controlled rate constant. Though quantitatively we cannot get much information, qualitatively it is clear that k_q increases with increase of $E.A.$ of the quencher. Similar behavior has been observed in case of fluorescence quenching of aromatic molecules by inorganic ions.[14–17]

ii) Equation 1 reduces to Eq. 7 if we choose different fluorophores and one quencher,

$$k_q \propto \exp[-(I.P. - S_1 - \text{const})/k_bT],$$

or
$$\log k_q = \text{const} + \frac{S_1 - I.P.}{2.303\,k_bT}, \tag{7}$$

The singlet state energy of all the aromatic amines were calculated by taking the average of the long wavelength band maximum of absorption spectrum and short wavelength band maximum of fluorescence spectrum in cyclohexane. This is because in this solvent, the interactions between the solvent and the fluorophore is minimum. These values are compiled in Table 1.

The ionization potential data for all the aromatic amines are not available, except for AB, 1-AN, and 2-AN[18] (i.e. 7.7, 7.3, and 7.25 eV respectively). The experiments were carried out to calculate the ionization potentials of aromatic amines by measuring the energy of the charge-transfer band (E_{CT}) of the molecular complexes formed by these amines with different electron acceptor molecules (e.g. chloranil and benzophenone).

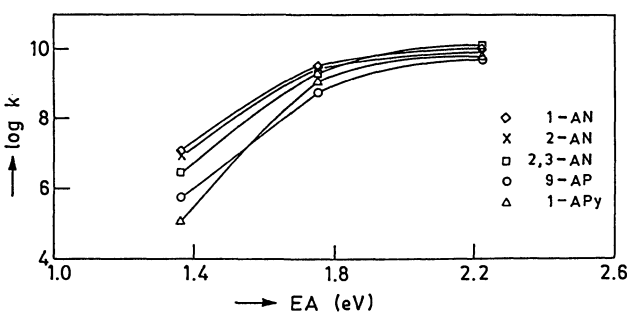

Fig. 2. Plot of $\log k_q$ vs. electron affinity of the quencher, in cyclohexane.

Unfortunately no charge-transfer bands were observed with these acceptor molecules, though simple empirical relations are available to relate the energy of the CT band and *I.P.* of donor molecule. With the limited data available, it is clear that we cannot assume that *I.P.*'s are constant for these amines. However in the absence of *I.P.* values, $\log k_q$ versus singlet state energy of the fluorophores, for CH_2Cl_2, $CHCl_3$, and CCl_4 as quenchers, in cyclohexane and acetonitrile are depicted in Fig. 3. The plots are linear for CH_2Cl_2 and $CHCl_3$ in cyclohexane and acetonitrile, with slopes 3.5 and 2.5 in the former solvent and 2.0 and 1.5 eV^{-1} in the latter solvent, whereas for CCl_4, the plots are horizontal to *x*-axis. The linear correlation suggests that *C* and *P* values are practically constant. The above results further suggest that the *I.P.* of these aromatic amines are proportional to the singlet state energy (i.e. $I.P.-S_1$), thus leading ($S_1-I.P.$) to $(1-a)\ S_1$ where '*a*' is a constant of proportionality. The above results are consistent with the fact that the values of the quenching rate constants are limited by the singlet state energy of the fluorophore so long these are less than k_{diff}. Once the value of k_q is equal to k_{diff}, k_q will be independent of either E_S or *E.A.* The values of slopes obtained in case of CH_2Cl_2 or $CHCl_3$ are much less than the theoretical value [i.e. $1/(2.303\ k_bT)=16.78\ ev^{-1}$].

Thus the above results suggest that fluorescence quenching for these aromatic amines does not occur via charge-transferred state. As said earlier quenching could proceed via an intermediate donor-acceptor (DA)* complex formed between the excited aromatic amine and quencher.

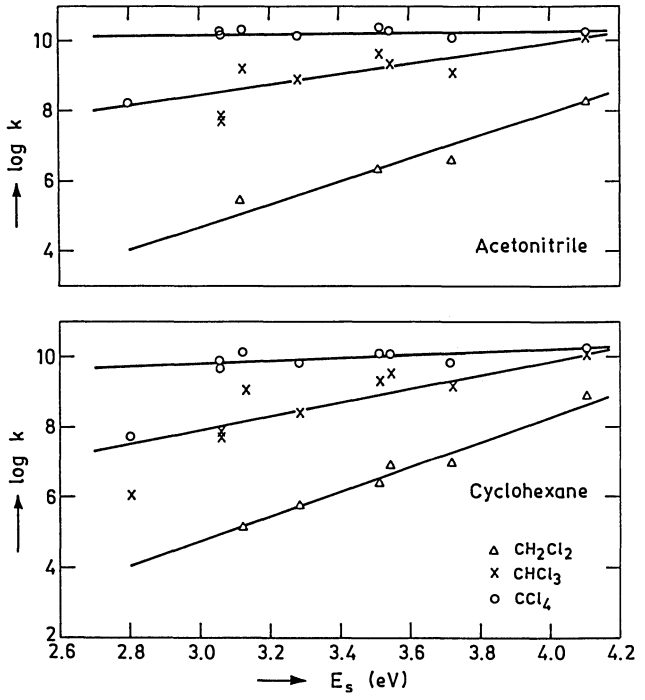

Fig. 3. Plot of log k_q vs. singlet state energy of aromatic amines. (a) Cyclohexane (b) Acetonitrile.

The value of k_q observed for 3-AF is much less than that can be predicted from the $\log k_q$ vs. S_1 plot. Our earlier results[23] have indicated that proton-induced fluorescence quenching of neutral 3-AF is much less than that generally observed in other aromatic amines,[24-28] with few exceptions.[29,30] This indicates that charge transfer character in S_1 state of 3-AF is very less and thus the transfer of charge from 3-AF to chlorinated methanes will not be efficient process.

The results of dichloromethane using as an electron acceptor have indicated that the fluorescence intensity as well as shift in fluorescence band maximum of the donor molecule is observed when the concentration of CH_2Cl_2 is more than 5 M and thus can be explained in term of a change in the rate of unimolecular photoprocesses induced by the change in solvent. At very high concentration of CH_2Cl_2 its effect as a solvent (and the decrease in k_q due to the decrease in the polarity) is more significant than the change in the quencher concentration (i.e. $k_q[Q]$ decreases with increase in [Q]). Similar dependence has also been observed in other systems.[22]

Conclusion. In conclusion, we consider that the dominant quenching pathway involves an intermediate donor-acceptor (DA)* complex formed between the excited aromatic amine and quencher molecules.

The authors are thankful to the Department of Science and Technology, New Delhi for financial support.

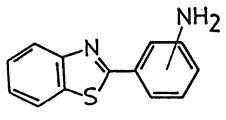
Solvatochromism and Prototropism in 2-(Aminophenyl)benzothiazoles

Joy Krishna Dey and Sneh K. Dogra*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received February 12, 1991)

The absorption and fluorescence spectra of 2-(2-aminophenyl)-, 2-(3-aminophenyl)-, and 2-(4-aminophenyl)benzothiazoles (*o*-APBT, *m*-APBT, and *p*-APBT, respectively) have been studied in different solvents and at various acid/base concentrations. The ultraviolet and fluorescence spectra and the low pK_a value for the monocation–neutral equilibrium have indicated the presence of an intramolecular hydrogen bond (IHB) in *o*-APBT in the S_0 state. Excited state intra-molecular proton transfer (ESIPT) in *o*-APBT, gives rise to a non-fluorescent phototautomer. Large solvatochromic shifts in polar solvents have indicated the increase in the dipolemoment of *m*-APBT in S_1 state. It has been observed that in protic solvents, *m*-APBT forms a complex with solvent molecule in the S_1 state. The equilibrium constants for different prototropic equilibria of the molecules have been determined in both S_0 and S_1 states. The absorption and fluorescence spectra of the prototropic species have been explained and compared with those of 2-phenylbenzothiazole (2-PBT). The monocation (**2**) of *p*-APBT, formed by protonation at the $-NH_2$ group is found to undergo structural reorganization leading to a quinonoid structure (**2'**). The absorption and fluorescence excitation spectra (recorded at 390 nm and 460 nm fluorescence bands) indicate the simultaneous presence of species (**2**) and (**2'**), the former being more favorable in protic and the latter in nonpolar solvents. The molecular orbital calculation (PPP) has been used to calculate the absorption spectra and the charge densities at the basic centers of the neutral molecules.

The study of photophysical properties of heterocyclic organic molecules has achieved considerable importance recently because many of these molecules form an integral part of biologically important compounds and have various uses. Substituted 2-arylbenzothiazoles, although having industrial and commercial uses as fluorescence whitening agents,[1a] photoconducting materials,[1b] and as herbicides in agriculture, have not received much attention. Only 2-(2-hydroxyphenyl)-benzothiazole[2] has been studied extensively and the excited state intramolecular proton transfer (ESIPT) has been well discussed. The present study is centerd on the prototropism and solvatochromism of *o*-APBT, *m*-APBT and *p*-APBT. Since the amino group is strong electron donor in the excited state, the position of the fluorescence spectrum may exhibit a pronounced solvent dependence, but the absorption spectrum is almost insensitive to the nature of the solvent. The importance of this type of molecules (i.e. aromatic amines) in biological studies has led to intensive investigation of the origin of the polar-solvent-induced fluorescence red shift.



$-NH_2$ at 2'-
3'-
4'-

In our recent studies on (aminophenyl)benzimidazoles[3] and (aminophenyl)benzoxazoles,[4] it has been shown that 2-(2-aminophenyl)benzimidazole[3b] (*o*-APBI) exhibits a dual fluorescence in hydrocarbon solvents, whereas, the corresponding benzoxazole derivative[4] (*o*-APBO) gives only a single normal fluorescence band. The dual fluorescence in the former, has been attributed to a phototautomer formed by ESIPT process. The absorption spectra of the monocations of both *p*-APBI and *p*-APBO showed a large red-shifted band along with the blue-shifted band, the origin of which was unknown until the present study. The monocations of *o*-APBO, *m*-APBO, and *p*-APBO were found to undergo biprotonic phototautomerism in the S_1 state.

In order to understand these processes we have undertaken this investigation to include a detailed analysis of the electronic absorption and emission spectra of *o*-APBT, *m*-APBT, and *p*-APBT including 2-PBT and their prototropic species. In addition we have carried out molecular orbital calculation (PPP-SCF-MO-CI) to aid the interpretation of our experimental results.

Experimental

The compounds under study were synthesised by heating *o*-aminothiophenol and corresponding aminobenzoic acid in polyphosphoric acid at 200 °C and purified as described for (aminophenyl)benzoxazole.[5] The purity of the compounds was confirmed by TLC, melting point and excitation spectra recorded in methanol monitoring at different emission wavelengths. Analytical grade cyclohexane (SDS), dioxane (E. Merck), acetonitrile (E. Merck), methanol (BDH), and dichloromethane (E. Merck) were further purified as described elsewhere.[6] Analytical grade ethanediol (SDS) and glycerol (SDS) were used directly. Hexane (SRL), ethyl acetate (SDS), chloroform (SDS), and carbon tetrachloride (SDS) were all spectro grade. KOH, H_2SO_4, and ortho-H_3PO_4 used, were of analytical grade.

Aqueous pH solutions were made by mixing appropriate amounts of dilute (10^{-3} M, M=mol dm^{-3}) KOH and H_3PO_4 solutions. Solutions of pH<3 and pH>12 were made following Hammett's[7a] acidity (H_o) and Yagils[7b] basicity scales (H_-). Because of low aqueous solubility of the compounds, the solutions were prepared in methanol–water mixture containing 0.5% (v/v) methanol and the concentration of the solute was 5×10^{-6} M. Fluorescence quantum yields were calculated

for solutions having absorbance <0.1 at the excitation wavelength, and referred to the quinine sulfate in 0.05 M H_2SO_4 (ϕ_f=0.55).[7c] For fluorimetric titrations the solutions were excited at the isosbestic point.

Absorption spectra were measured in a Shimadzu UV-190U spectrophotometer equipped with a 135U chart recorder. Fluorescence spectra were recorded in a scanning spectrofluorimeter fabricated in our laboratory and the details of which are described elsewhere.[8] The pH measurements have been carried out with a Toshniwal Digital pH meter, model CL 46 fitted with a combined glass electrode (Toshniwal) operating in the range of pH 0 to 12.

Molecular orbital calculations were performed on our Institute's Dec-1090 computer. The program[9] for the calculations was obtained from QCPE, Indiana University, Blumington, USA.

Results and Discussion

1. Effect of Solvent on Absorption and Fluorescence Spectra. In Table 1, the absorption properties of the molecules in several organic solvents are indicated. Apart from the shoulder to the lower energy side of the longest wavelength band (ca. 293 nm), the absorption spectrum of *m*-APBT resembles that of 2-phenylbenzothiazole (PBT).[10] The lowest energy band of *p*-ABPT appears at a wavelength higher than that of *m*-APBT. The absorption spectrum of *o*-APBT is quite different from those of other molecules in the sense that apart from the common band (ca. 290 nm) another large red shifted band appears at 365 nm, which disappeared when the solution was made acidic (pH<3.0). These features are exactly analogous to that of *o*-APBI[3b] and *o*-APBO.[4] The second lowest energy absorption band of *o*-APBT is structured in hydrocarbon solvents and becomes broad in polar protic solvents. With the increase of solvent polarity the absorption maxima of the molecules remain almost unchanged except in *o*-APBT where the longest wavelength band shifts to the blue in protic solvents.

Fluorescence spectral data are collected in Table 2. The fluorescence spectra of *m*-APBT and *o*-APBT are broad and structureless, whereas that of *p*-APBT in hydrocarbon solvents is structured. The fluorescence spectra, unlike absorption spectra in all the cases shift to red as the solvent polarity and proton donor/acceptor capacity increased in going from cyclohexane to water. The order of emission energies, *o*-APBT<*m*-APBT<*p*-

to the resonance interaction of the lone pair of the amino nitrogen atom with the π cloud of the parent hydrocarbon. This interaction increases if an electron withdrawing group is attached at the para position. Thus the nature of electron withdrawing group at the para position decides the percentage charge transfer character in the π→π* transition as well as the value of band maximum. The large red shift observed in the longest wavelength absorption band of *p*-APBT, as compared to that in *m*-APBT, can be attributed to the presence of electron withdrawing group at the para position of aniline and thus leading to the resonance structure **II′** as shown below. This is reflected in the high absorption coefficient (ε_{max}, Table 1) of the lowest energy band, large ϕ_f value (ca. 1.0) and the structured fluorescence band in nonpolar solvents. The presence of structure **II′** can be further established from acid-base behavior of this molecule (see below).

II II′

Scheme 1.

APBT, in cyclohexane changes to the order, *m*-APBT<*o*-APBT<*p*-APBT in polar/protic solvents. The luminescence of *o*-APBT in all the solvents as well as in cyclohexane glass at 77 K exhibits a single fluorescence band at ca. 400 nm.

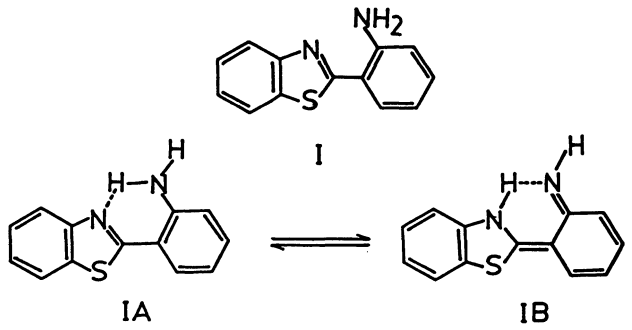
The fluorescence quantum yield (ϕ_f) of *p*-APBT is almost unity in all the solvents, whereas those of *o*-APBT and *m*-APBT are very rlow. *o*-APBT is weakly fluorescent (ϕ_f<0.001) in hydrocarbon solvents and the ϕ_f increases as the solvent polarity is increased. The ϕ_f value decreases for *m*-APBT with the increase of polarity.

Spectral studies of 2-arylbenzoxazoles and corresponding benzothiazoles by Passarini[10] have indicated that the aryl group acts as the main chromophore and its electronic transitions are perturbed by the benzazole moiety. Our experimental studies as well as molecular orbital (MO) calculations (CNDO/s and PPP) on 2-phenylbenzoxazole[11] have confirmed earlier results and have shown that both HOMO and LUMO are localized mostly on the phenyl ring and only partly on the oxazole ring. This means that the longest wavelength transition originates from the phenyl ring. Since benzoxazole and benzothiazole are isoelectronic, their electronic spectra are expected to be similar. Thus, the (aminophenyl)benzothiazoles can be considered as substituted anilines.

The electronic spectra of arylamines have been studied extensively[12–14] and the red shift produced in the absorption spectra of the parent hydrocarbon is due

Even though the amino group in *m*-APBT is nonconjugated with the electron withdrawing benzothiazole group, the fluorescence spectrum, in contrast to absorption spectrum, is large red shifted. This may be due to larger dipole moment of the fluorophore in the S_1 state upon excitation (section 2). The red shift observed in the fluorescence spectrum in protic polar solvents is anomalously large and could be attributed to the formation of 1 : 1 solvent–solute complex in S_1 state. This is based on the fact that (i) the Stokes shift observed in just 0.5% (v/v) methanol–cyclohexane mixture (where the properties of the solution will be close to cyclohexane) is 6210 cm^{-1} as compared to 8500 cm^{-1} in 100% methanol and (ii) full width at half maximum height of fluorescence band in cyclohexane (2959 cm^{-1}) is quite different from that in 0.5% methanol–cyclohexane solution (5640 cm^{-1}). The similar behavior has been observed in 5-aminoindazole[16a] and other aromatic amines.[16,17] This solute–solvent interaction enhances the stability of the singlet and thereby decreasing the S_1–T_1 energy gap, which in turn increases the probability of intersystem crossing.[18] This fact explains the decrease of ϕ_f value in *m*-APBT with the increase of solvent polarity in going from cyclohexane to water.

The geometry of the molecule suggests the formation of an intramolecular hydrogen bond (IHB) between the pyridinic nitrogen atom and one of the amino protons (conformer IA) in *o*-APBT. We feel that the longest wavelength band is due to the hydrogen-bonded structure IA. This is because the presence of IHB in *o*-



Scheme 2.

APBT will force the lone pair of the amino group to be parallel with the π-cloud and thereby increases the resonance character of this group with the benzothiazole moiety. The blue shift observed in protic solvents can be attributed to the partial breaking of the IHB as a result of competition with the intermolecular hydrogen bond formation with the solvent molecules. Similar behavior has also been observed in case of *o*-APBI[3b] and *o*-APBO[4] and can be explained on the same lines.

It is well known that the amino proton becomes strong acid and the tertiary nitrogen atom strong base in S_1 state. Along with the presence of IHB, this will facilitate the proton transfer giving rise to the phototautomer, IB. Since the rate of ESIPT is very high[2] (ca. 10^{12} s^{-1}) and the activation energy is very low (ca. 120 cm^{-1}), an emission band corresponding to the phototautomer can be expected especially in nonpolar solvents. In contrast, only a weak normal Stokes shifted broad band at 400 nm has been observed in hydrocarbon solvents, as in *o*-APBO.[4] But in case of *o*-APBI,[3b] a dual fluorescence was observed in cyclohexane. This indicates that the phototautomer IB is formed but it is nonfluorescent. It is reported[15] that the ESIPT increases the rate of internal conversion 100 times. The very low ϕ_f (<0.001) of normal Stokes shifted fluorescence band in hydrocarbon solvents proves the conversion of IA→IB. Because of the formation of a solvated complex and breaking of IHB (a prime condition for ESIPT) in polar and protic solvents, the rate of ESIPT is reduced. As a result, ϕ_f of *o*-APBT increases as the solvent polarity increases.

2. Correlation of Solvatochromic Shift with the Solvent Polarity. The variation of Stokes shift with the solvent polarity can be represented by the Lippert[19] equation

$$\bar{\nu}_{ss}=\frac{2(\mu_e-\mu_g)^2}{hca^3}f(D,n)+C, \quad (1)$$

where $\bar{\nu}_{ss}$ is the Stokes shift ($\bar{\nu}_{ss}=\bar{\nu}_a-\bar{\nu}_f$, $\bar{\nu}_a$ and $\bar{\nu}_f$ are the absorption and fluorescence maxima, respectively), μ_g and μ_e are respectively the ground and excited state dipole moments of the solute molecule, '*a*' is the "Onsager cavity radius" and $f(D,n)$ is the "Onsager polarity function" defined by the equation

$$f(D,n)=\frac{D-1}{2D+1}-\frac{n^2-1}{2n^2+1}, \quad (2)$$

where D is the static dielectric constant and n is the refractive index of the solvent; C is a constant. The other polarity parameter used is an empirical parameter $E_T(30)$; this is based on the spectral shifts of *N*-phenolbetaine,[20,21] in different solvents of varying polarity and hydrogen bonding.

In this study, the Stokes shifts of the three molecules determined in eleven solvents of varying polarity have been correlated with the $f(D,n)$[22] and $E_T(30)$[23] parameters. Table 3 gives a list of solvents, corresponding polarity parameters and the Stokes shifts. The very good linearity found in the plot of $\bar{\nu}_{ss}$ vs. $f(D,n)$, Fig. 1, in aprotic solvents (except dioxane and chloromethanes) indicates that the unspecific interactions are the key factors in shifting the fluorescence maxima to the red, for these molecules. As evident from the slopes of the plots, these interactions are large in case of *m*-APBT and may be attributed to its increase of dipole moment on excitation. Rigid molecules with limited internal degrees of freedom change the structure of the solvent cage by their dipole moment change in the excited state. This process induces a large Stokes shift in polar solvents. This is true in nonviscous solvents, where the

rate of solvent relaxation (ca. 10^{12} s^{-1}) is faster than the fluorescence rate (10^9—10^{11} s^{-1}). But in a viscous solvent like glycerol (where the relaxation time is of the order ca. 10^{-9} s) or in a polar solvent at 77 K, the solvent relaxation can not occur during the lifetime of the excited state. The fluorescence spectrum of *m*-APBT in glycerol is broad and has the same shape as in nonviscous solvents and no blue shift is observed compared to other solvents at 300 K. This clearly indicates that the solvent relaxation is still faster than the rate of fluorescence. The anomaly in the solvatochromic shift in dioxane and protic solvents may be a result of hydrogen bond formation between the specific sites of the solute and solvent molecules giving rise to 1 : 1 complex as explained earlier.

A good correlation of Stokes shift with the $E_T(30)$ scale (Fig. 2) is indicative of the fact that the dielectric solute–solvent interactions as well as specific solute–solvent interactions, as discussed above, are responsible for the solvatochromic shifts in the molecules. The Stokes shifts observed for these molecules in chloroform and carbon tetrachloride correlate with none of the polarity scales. It is well known that chlorinated methanes quench the fluorescence of fluorophores by forming a CT in the S_1 state,[24] which may be a reason for the deviation complex of the Stokes shift from linearity of solvatochromic plots in Figs. 1 and 2.

Since the position of fluorescence maximum of *m*-APBT has shown much more solvent dependence than the other molecules, we have also investigated the fluorescence properties of this molecule in dioxane–water mixtures. The dioxane–water mixtures provide a wide range of $E_T(30)$ values and allow a convenient solvent system to probe nonspecific effects on fluorescence maximum. The solvent compositions and the corresponding $E_T(30)$ values alongwith the fluorescence maxima are listed in Table 4. A plot of $\bar{\nu}_f$ versus $E_T(30)$ values (Fig. 3) shows very good correlation. This type of effect has been reported earlier and is attributed to the increasing solvation of the solute molecules in its S_1 state by water molecules which impart an enhanced solvent structuring effect.

3. Effect of Hydrogen Ion Concentration. The absorption and fluorescence spectra of all the molecules are studied in various acid-base concentrations in the H_0/pH/H_- range of −10.4 to 16.0 at room temperature (300 K). The spectral properties of their different prototropic species are collected in Tables 1 and 2, and the spectra are shown in Figs. 4 and 5. The behavior of these molecules in the above range of acid-base region is similar, except for *p*-APBT in the pH range of 5 to 1. This will be discussed separately.

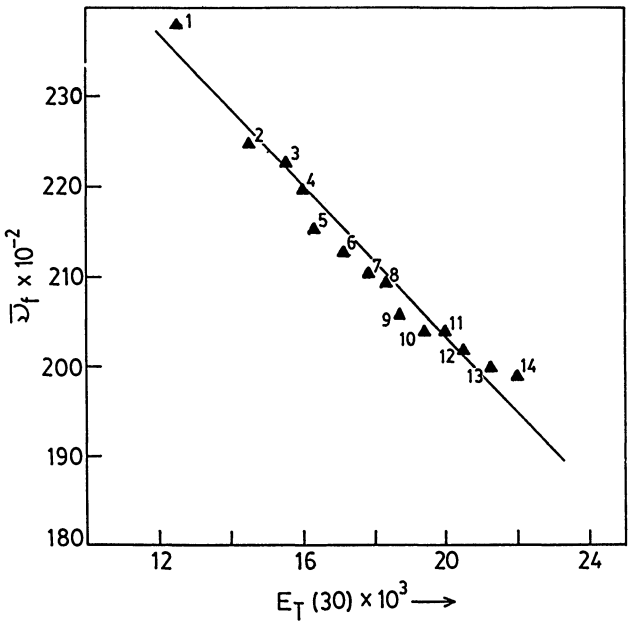

Fig. 3. Plot of $E_T(30)$ parameters versus $\bar{\nu}_f$ in dioxane-water mixtures.

The absorption spectra of *m*-APBT remains unchanged in the pH/H_- range of 5 to 16, but the fluorescence intensity decreases above pH 9. Because of insolubility, neither *o*-APBT nor *p*-APBT could not be studied in the basic media. We attribute the decrease of fluorescence intensity of *m*-APBT with increase of pH to the formation of nonfluorescent monoanion, because the anion formed by the deprotonation of amino group in general is nonfluorescent with few exceptions.[25]

All the molecules are neutral between pH 9 to 5. The blue shift in the absorption and fluorescence spectra and the resemblance of the spectra of these species with those of neutral 2-PBT at pH 4 (λ_a=299 nm, λ_f=380 nm) indicate the formation of monocation as a consequence of the protonation at the amino group. Our theoretical calculations also indicate that the charge density (Table 6) at the amino nitrogen is greater than that at the nitrogen atom of the heterocyclic ring in the S_0 and S_1

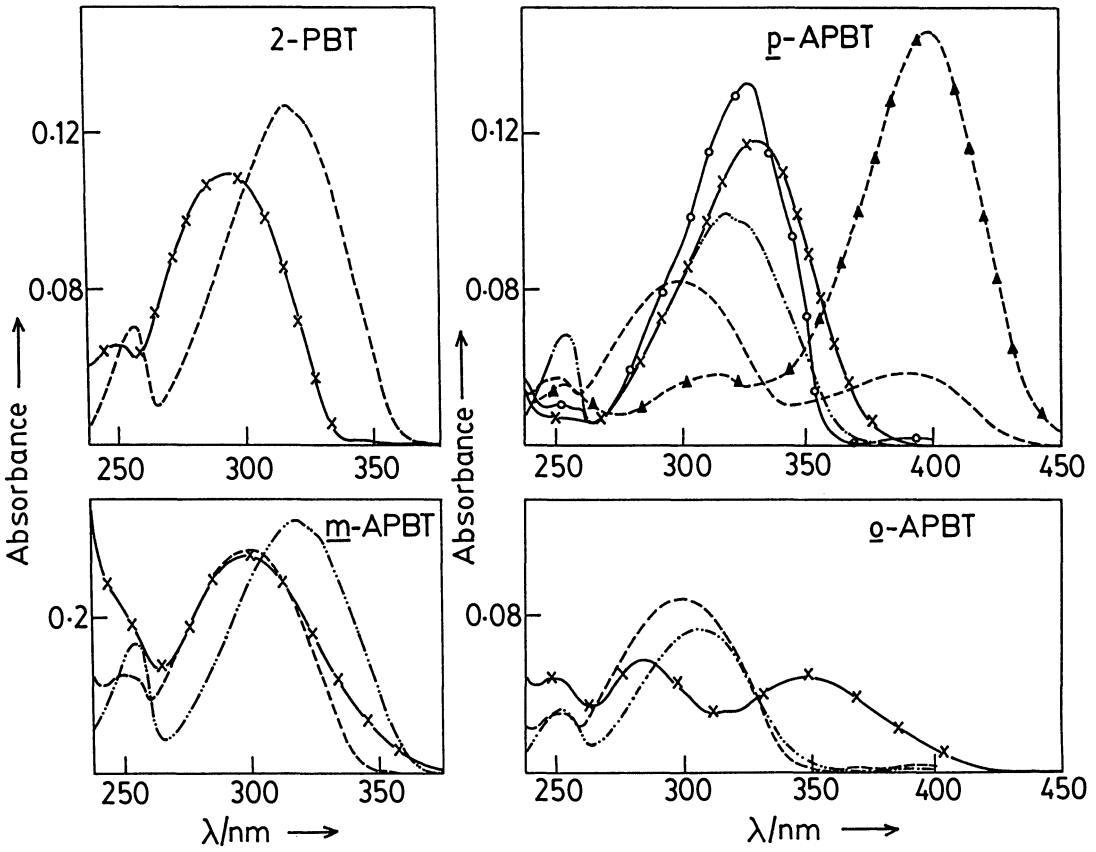

Fig. 4. Absorption spectra of the prototropic species of 2-PBT, *o*-APBT, *m*-APBT, and *p*-APBT; —×— Neutral; —— Monocation; —··— Dication; —▲— Monocation (in cyclohexane); —○— Neutral in cyclohexane.

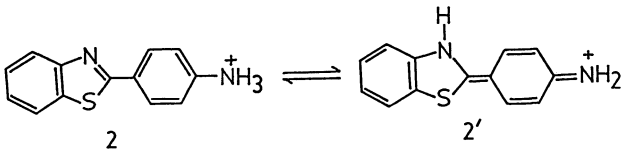
states. The red shift in both the absorption and fluorescence spectra of the monocation below pH 0.5 is due to the dication, formed by the protonation of the pyridinic nitrogen atom and is confirmed by their similarity with the monocation spectra of 2-PBT (λ_a=320 nm, λ_f=400 nm).

The absorption and fluorescence spectral characteristics of *p*-APBT in acidic media are interesting and quite different from those of *o*-APBT and *m*-APBT. With the increase of [H^+] (>10^{-4} M) the intensity of the 333 nm absorption band decreases and at pH 1.5, it is replaced by a large red-shifted band at 392 nm and a blue-shifted band at 300 nm. The intensity of the longest wavelength band is weak compared to the blue-shifted band in aqueous medium. The spectra exhibit two isosbestic points (300 nm and 368 nm). When the titration was carried out in cyclohexane with trifluoroacetic acid, the absorption spectrum of the species (Fig. 4) exhibits the longest wavelength band with much higher intensity compared to the blue shifted band. Further increase of acid concentration shifts the short wavelength band to red side and the lowest energy band is vanished. The absorption spectrum at H_o—4.0 resembles that of the monocation of 2-PBT.

The isosbestic points in the absorption spectra clearly indicate that only two species are involved in the equilibrium. This is also substantiated by the fact that the pK_a values calculated by measuring the intensity change at 390 and 330 nm are exactly same. The pK_a value for this equilibrium (3.0) is not very different from those of *o*-APBT (2.6) and *m*-APBT (3.4). This suggests, and also supported by the charge densities (Table 6) at the basic centers that the species at pH 1.5 is the monocation formed by protonation at the amino group. But, as can be seen from Fig. 4, the monocation spectrum does not resemble the absorption spectrum of 2-PBT. Similar behavior has also been observed in 2-, and 4-aminoquinolines,[26] 4-aminopyridine,[27] and 2-aminobenzimidazole.[28] We feel that the monocation **2** is formed by the same way as discussed in case of *o*-APBT or *m*-APBT and then undergoes a structural reorganization as shown in Scheme 3, leading to the species **2′**. In aqueous medium, the species **2** being highly solvated, this reorganization may be difficult and hence the species **2′** will have less contribution in the ground state. But in cyclohexane, the solvation is less and thus the species **2′** will be more favorable which is exhibited by the higher intensity of the longest wavelength band in



2 2′

Scheme 3.

the monocation spectrum. As the [H^+] is increased, the equilibrium is shifted towards the left and the second protonation occurs at the heterocyclic nitrogen atom giving rise to dication **3**. The resemblance between the absorption spectrum of *p*-APBT at H_o—4.0 and the absorption spectrum of the monocation of 2-PBT supports our explanation.

The fluorescence spectra, recorded for solutions in the pH range (in which the ground state equilibrium exists) by exciting at both the isosbestic points, show a gradual decrease in intensity of the 420 nm band and simultaneous appearance of 390 nm band as shoulder (only noticeable at pH 2.0) with the increase of [H^+] until pH 0.5. The band width at half maximum also increases with increase of acid concentration. When the solutions having pH<3.0 were excited at 400 nm (where the neutral molecule does not absorb) a weak fluorescence band appears at ca. 445 nm, the intensity of which increases with the decrease of pH. The fluorescence excitation spectra at pH 1.5, recorded by monitoring the fluorescence maximum at 390 and 460 nm are different from each other. The former consists of a single band matching with the monocation absorption spectrum of *o*-APBT or *m*-APBT and the latter one consists of two bands at 390 and 340 nm matching with the absorption spectrum of the monocation. The ca. 300 nm absorption band may thus be due to a mixture of species **2** and **2′**. The full width at half maximum observed for the absorption and fluorescence excitation spectra are different form each other and thus supports our conclusion. Analogous to *o*-APBT and *m*-APBT the fluorescence band at 390 nm can be assigned to the fluorescence from monocation **2** having low fluorescence quantum yield. Thus the 445 nm band may be due to the species **2′**. The increase of fluorescence intensity of the 445 nm with further increase of [H^+] can be attributed to the formation of dication **3**. This is because the fluorescence band maxima of the dications of other amines and the monocation of 2-PBT are also nearly at the same wavelength and are formed at the same acid concentration. This suggests that structural reorganization of species **2′** takes place before the dication **3** is formed and thus leading to same emission band maxima. The similar behavior has also been observed in 2-aminobenzimidazole[28] and 2- and 4-aminoquinolines.[26,27]

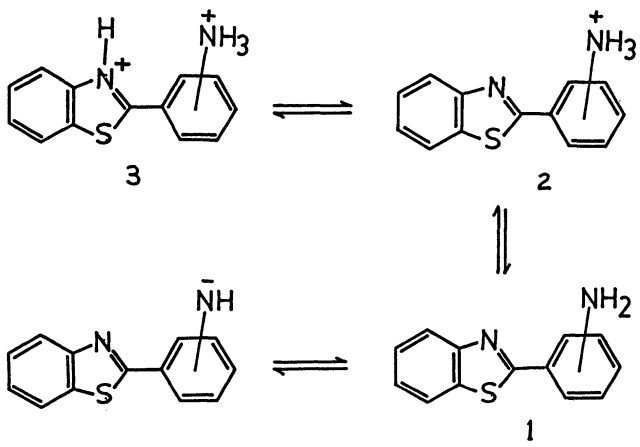
4. Acidity Constants. The pK_a values for different prototropic equilibria (Scheme 4) of the molecules have been determined using absorption data and are collected in Table 5. Since *p*-APBT is resonance stabilized (Scheme 1), the electron density at the amino nitrogen will be low which is reflected by the low pK_a value (3.0) for the monocation–neutral equilibrium compared to that (3.4) of *m*-APBT. The very low pK_a value for the monocation–neutral equilibrium in *o*-APBT than those of other molecules is due to the IHB formation. The pK_a value for the monocation–neutral equilibrium in 2-PBT is greater than the pK_a values for the corresponding dication–monocation equilibria of the amino derivatives. This is due to the presence of the $-\overset{+}{N}H_3$ group in their monocations, which withdraws electron density from the heterocyclic ring. Since, the $-\overset{+}{N}H_3$ group is more closer to the ⩾N atom in *o*-APBT, the decrease of electron density on ⩾N is more compared to other molecules. As a result, the pK_a for the dication-monocation equilibrium is less than that of *m*-APBT which is again lower than that of *p*-APBT.

The pK_a* values for the corresponding equilibria of the molecules including 2-PBT have also been determined by fluorimetric titrations and by Forster cycle calculations, wherever applicable. The results thus obtained are consistent with our conclusions that $-NH_2$ group becomes less basic and pyridinic nitrogen (⩾N) more basic on excitation to the S_1 state. Consequently,



Scheme 4.

a) α° is the angle made by the total transition moment vector with the positive direction of the long axis (directed towards the phenyl ring) of the molecule, measured anti-clockwise.

the pK_a*(1.0) is greater than pK_a(0.7) for 2-PBT. In other molecules fluorimetric titrations have resulted more or less the ground state pK_a values for the monocation–neutral equilibrium. This may be either due to the nonestablishment of the prototropic equilibrium in the S_1 state or no change occurring in pK_a value upon excitation. At present we are unable to specify which one of these mechanisms is playing the role.

The pK_a* values calculated by using the absorption band maxima and fluorescence band maxima are large and differ much from each other. This can be attributed to the difference in solvent relaxation of the conjugate acid-base pair in the S_0 and S_1 states and are consistent with the solvent relaxation data as discussed earlier. The Forster cycle method can not be used for *p*-APBT because of the failure of the assumptions made in the method.

5. Molecular Orbital Calculations. The molecular orbital calculations have been carried out for the three molecules and the hydrogen-bonded conformer of *o*-APBT by using Pariser, Parr, and Popple (PPP) method.[29–31] The parameters used for the calculations are taken from the paper by Dorr et al.[32] Other details of calculations are discussed in our earlier paper.[4]

Table 6 gives a list of values of transition energies (λ_{nm}) and the corresponding oscillator strength (f) and polarizations (α°) alongwith the π-electron densities at various basic centers. The experimental spectral data (Table 1) of *o*-APBT match more closely with those of calculated ones for its hydrogen-bonded conformation (IA). For other molecules also, the agreement between the calculated and the observed values is very good. As it is difficult to find 'f' experimentally, we are unable to compare the same with the calculated values. However, the f values for the corresponding transitions of the molecules are qualitatively consistent with the intensity ($\log\varepsilon$) of the absorption bands. As mentioned earlier, the transition moment corresponding to the longest wavelength band of the molecules is polarized towards the phenyl ring.

The data of Table 6 indicate that the π-electron density on the amino-nitrogen (N_{16}) is greater than that at the nitrogen atom (N_3) of the heterocyclic ring in both the S_0 and S_1 states. Thus, the first protonation should take place at the amino group. In the S_1 state, the electron density on N_{16} has decreased, but on N_3 it has increased, which predicts that the amino group becomes more acidic and the pyridinic nitrogen becomes more basic on excitation and are consistent with the pK_a* values of monocation–neutral and dication–monocation equilibria (Table 5). This change of charge density on the nitrogen atoms of *o*-APBT favors the formation of IHB leading to the structure IA (Scheme 2). Moreover, the calculated electron densities on the amino-nitrogen foretells that the pK_a values for monocation–neutral equilibria of the molecules will be in the order *o*-APBT (IA)<*p*-APBT<*m*-APBT and exactly the same thing can be found from Table 5.

Conclusions

The following conclusions can be made from the above study.

(i) Ultraviolet and fluorescence spectra as well as the

low pK_a value of monocation–neutral equilibrium confirm the presence of intramolecular hydrogen bonding in *o*-APBT in the S_0 and S_1 states.

(ii) Solvatochromic effects confirm that *m*-APBT is more polar in the S_1 state than *o*-APBT and *p*-APBT. Large Stokes shifts observed in protic solvents are due to the solute-solvent complex formation and the charge transfer structure of the S_1 state.

(iii) Molecular orbital calculations (PPP) as well as the pK_a values indicate that the first protonation occurs at the amino group in all the molecules. But in case of *p*-APBT, the structural reorganization of the monocation leads to the quinonoid structure. The similar study carried out in cyclohexane and trifluoroacetic acid indicates that the quinonoid form is more stable in the nonpolar solvents. The absorption, fluorescence, and excitation fluorescence spectra (recorded at 390 and 460 nm) indicate that the species **2** and **2'** are present simultaneous in both S_0 and S_1 states. The dication is formed by protonating amino as well as the tertiary nitrogen atom, having similar structure in each case.

(iv) Although the amino group becomes stronger acid and tertiary nitrogen atom more basic upon excitation, the prototropic equilibria are not established in S_1 state.

(v) Very small fluorescence quantum yield observed for normal Stokes-shifted fluorescence in nonpolar solvents indicates that the phototautomer formed in *o*-APBT is nonfluorescent. The increase of fluorescence quantum yield with hydrogen bonding solvents proves this.

The authors are thankful to the Department of Science and Technology, New Delhi for financial support to the project entitled "Proton transfer reactions in the excited states in micellar media".

Viscometry of Isothermal Urethane Polymerization

John Reji, P. Ravindran, N. R. Neelakantan, and N. Subramanian*
Department of Chemical Engineering, Indian Institute of Technology, Madras 600036, India
(Received September 20, 1990)

The viscosity values of Indian Space Research Organization's (ISRO) hydroxyl terminated polybutadiene (HTPB) at various temperatures, the isothermal viscosity changes during the curing reaction of ISRO-HTPB with dlisocyanatotoluene (TDI) with and without catalyst and with a filler, calcium carbonate have been studied. The effect of temperature on this curing reaction is determined. The viscosity-time profile has shown an anomalous behavior and an explanation is put forward on the basis of polyurethane-HTPB, TDI mixture interaction. The viscosity-time profiles are drawn using normalized coordinates, which is helpful to compare the relative viscosity build up over relative periods.

Urethane polymers have been under active development in industries since inception because of their versatile properties. Urethane elastomers and thermoplastics are two major types of raw materials which are finally fabricated into desired products. Casting is a manufacturing technique for producing the above two classes, from initial liquid reactants to final solid polymer. Before casting, the reactive components have to be precisely metered and mixed. For metering and mixing, from the standpoint of physical handling a precise konwledge of the viscosities of the individual components and also of the mixture, at various conditions of temperature, composition and reaction rate must be known. In addition, rheological considerations are necessary for the design strategies of the mixer type, mixing speed and throughout rate of the mix of the production equipment and for determining mould filling characteristics. There must be a consideration of rheology versus the reaction rate for the length limitation of the hose, which is used for transferring mixed materials from the metering cum mixing machine to the mould for casting.

The purpose of this paper is to characterize the flow behavior of an urethane reacting system involving Indian Space Research Organization's (ISRO) hydroxyl terminated polybutadiene (HTPB) under various conditions.

Experimental

Materials. Uncatalyzed, catalyzed, unfilled and filled Am+Bn liquid urethane reacting systems were used, where Am was hydroxyl terminated polybutadiene (HTPB) developed by the Indian Space Research Organization (a Patented product used for solid rocket propellant binder). Its number average molecular weight ($\bar{M}_n$) was 3000±350 and hydroxyl value was 40. "Bn" was diisocyanatotoluene (TDI) (a mixture of 80:20 2,4 and 2,6 isomers). The catalyst used was tin(II) octanoate. The filler was a fine powder of calcium carbonate with a maximum moisture content of 0.1% and specific surface area of 0.9255 $m^2 ml^{-1}$.

Procedure. HTPB and TDI were mixed according to the stoichiomerty (NCO/OH ratio) equal to one. Three tenth % of the catalyst and 10% of the filler were also added depending on the system selected (unfilled, filled, uncatalyzed and catalyzed). The reactants (also the catalyst and filler wherever necessary) were mixed well at room temperature in a beaker. One ml of the reacting sample was transferred to the plate of the Cone and Plate Brookfield digital viscometer (model DV II) provided with a constant temperature bath and recorder. For the room temperature reaction, the time required for mixing and pouring into the plate were taken into consideration, whereas for the reaction at elevated temperatures this time was neglected. The reactants were allowed to react inside the viscometer. The viscosity was recorded as a function of time at constant shear rates from the initial liquid reactants to the final nearly solid elastomer state.

All the experiments were conducted under isothermal condition using the constant temperature bath. Further because of the small sample size and the longer reaction time, non-isothermal effect due to heat of the reaction could be neglected. To check whether shear thinning was occurring, measurements were periodically made over a range of shear rates, fairly rapidly, so that any viscosity change observed would not be masked by the curing reaction.[1)]

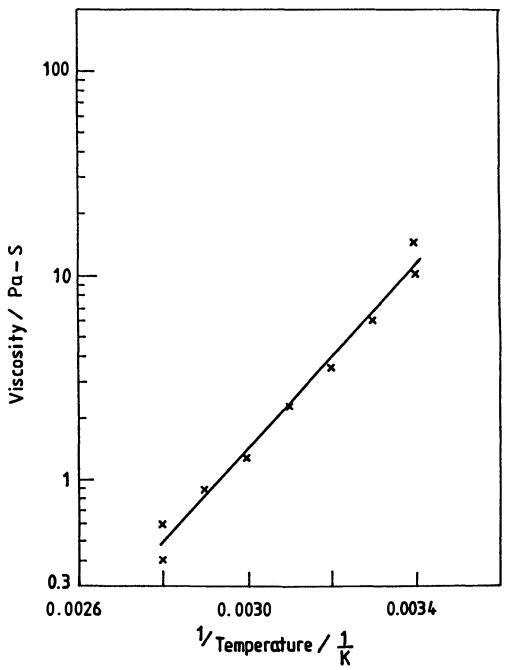

Fig. 1. Effect of temperature on viscosity for HTPB.

Results and Discussion

Figure 1 shows the effect of temperature on the viscosity of HTPB (non reacting and unfilled). The viscosity data indicate that for shear rates in the range of 1 to 40 sec^{-1}, the behavior is newtonian. The effect of temperature has been represented by Arrhenius equation, $\eta = A \exp(E/RT)$, where $A = 2.0488 \times 10^{-7}$ Pa s and $E = 43582$ J kg^{-1} mol^{-1} with η in Pa s and T in Kelvin.

Figure 2 shows the effect of temperature on the viscosity of HTPB and TDI reacting system. At higher temperatures, the initial viscosities of the reacting systems are lower, as expected. At 50 °C, the reaction effect overtakes the temperature effect on viscosity, at 70 min. At 30 and 50 °C, after a gradual increase in viscoity, at a particular time, the viscosity decreases, the decrease continues for some time and then again it increases. At lower temperatures the fall and rise are more. This is believed to be due to the solubility of the solid urethane which is already formed in the reaction medium-in the liquid polyol (HTPB)-TDI reacting system. We have separately tested the solubility of the polyurethane in the HTPB-TDI mixture and we have found that this mixture is a very good solvent for polyurethane especially for the initially formed low molecular weight type. We have separated the gel content (low molecular weight polyurethane that is formed) from sol (unreacted polyol, TDI mixture) by solvent extraction technique, using a separating funnel and benzene as a solvent (initially formed low molecular weight polyurethane is soluble in benzene also, but if we allow the reaction to advance before separation, it is possible to separate a good amount of gel from the sol). We have confirmed the mutual solubility of the gel and sol by putting these together back and seen that this sol is a very good solvent for this gel, whereas there is no dissolution when we put a finally formed polyurethane into the same sol. This shows that the dissolution of urethane in the reaction medium is dependent on its molecular weight. Then it is possible to infer that, as the reaction proceeds the dissolution occurs less readily; but because it is the relatively higher molecular weight polyurethane which dissolves, at this time, the net effect will be a decrease in the viscosity of the system; and it is possible that this effect can overtake the viscosity build up due to reaction, so that the viscosity can come down. This suggests that there may be a critical molecular weight build up above which the dissolution stops suddenly (This can be visualized more readily, if we consider the manner in which molecular weight build up takes place, in step addition polymerization, like urethane formation) and this can cause a sudden increase in viscosity. As this molecular weight build up to a critical molecular weight occurs only at the advanced stage of polymerization, and this is essentially preceded by the predominance of dissolution effect over the reaction effect, there is a fall and sudden rise of the reaction viscosity at the advanced stage of the reaction. Moreover we have seen similar observations in the isothermal viscosity changes of another ISRO-Polyol (castor oil based polyol)-TDI system also.[2] It is also further substantiated from the results of torque rheometry of urethane reacting system[3] where unreacted isocyanate acted as a plasticizer. The dissolution and reaction have two opposing effects on viscosity, the ultimate viscosity depends on which effect is dominating. At a particular point of time the former dominates over the latter, so that viscosity falls down. As time goes on, the left over HTPB-TDI mixture will react to form polyurethane and as the dissolution decreases and stops, the viscosity suddenly rises up to a large value. This is further evident from the variation of the slope after the peak. We have found that this anomalous behavior is temperature dependent. This is because the dissolution and reaction effects are temperature dependent. At higher temperatures there will be more reaction than dissolution so that the decrease in viscosity is less than that at lower temperatures. We can also

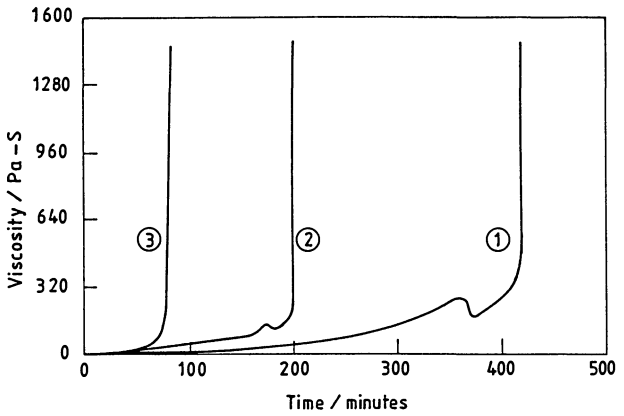

Fig. 2. Viscosity-time profiles for HTPB-TDI reactions at various temperatures; (1) 30 °C, (2) 50 °C, and (3) 70 °C.

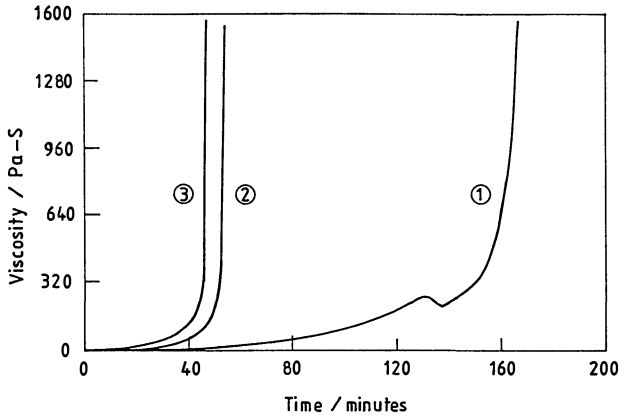

Fig. 3. Viscosity-time profiles for HTPB-TDI reactions in the presence of a catalyst, tin(II) octanoate at various temperatures; (1) 30 °C, (2) 50 °C, and (3) 70 °C.

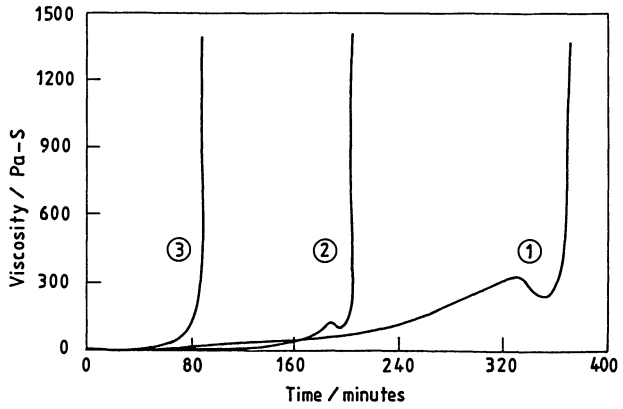

Fig. 4. Viscosity-time profiles for HTPB-TDI reactions in the presence of a catalyst, tin(II) octanoate and a filler, calcium carbonate; at (1) 30 °C, (2) 50 °C, (3) 70 °C.

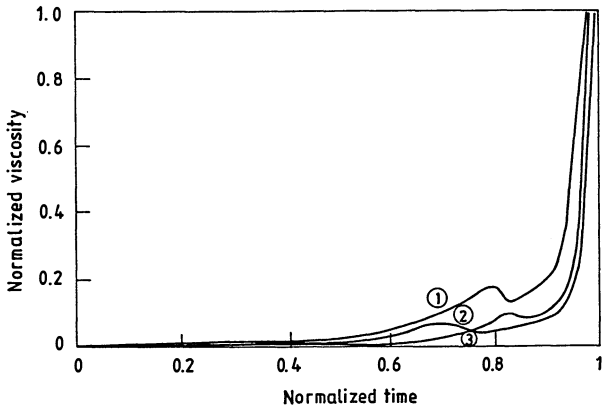

Fig. 5. Normalized viscosity-time profiles for HTPB-TDI reacting systems in the presence of catalyst, tin(II)octanoate; at (1) 30 °C, (2) 50 °C, (3) 70 °C.

obtain a viscosity-time profile where this anomalous behavior is absent, if the reaction rate is always higher than the dissolution effect. That is what happens in the reaction at 70 °C in Fig. 2 and in the reaction with catalyst at 50 °C and 70 °C in Fig. 3 and in chain extended system[4,5] at all temperatures.

Figure 4 shows that the introduction of filler increases the initial viscosity and in this case we have found that $CaCO_3$ is an inert filler, which will not interfere with the polyurethne reaction. So the introduction of a reinforcing type of filler at the reaction stage itself is helpful for better bonding of filler with the urethane matrix, which in turn will increase the mechanical properties of the final urethane polymer formed.

The viscosity data in Fig. 3 are replotted in Fig. 5 using normalized coordinates. The normalized viscosity is defined as $(\eta-\eta_o)/(\eta_{max}-\eta_o)$ where η is the viscosity at any time, t, η_o, is the viscosity at $t=t_o$ and η_{max} is the highest viscosity of this system measured using cone and plate viscometer (it is 1600 Pa s) at $t=t_{max}$, at this condition the material is nearly solid polyurethane. The normalized time is defined as $(t-t_o)/(t_{max}-t_o)$. In these normalized coordinates, the final viscosity is unity. The use of these coordinates helps to compare the relative viscosity build up over relative periods of time. The coordinates are dimensionless. The data for the HTPB-TDI catalyst tin(II) octanoate system in Fig. 5 indicate that at all temperatures the data fall almost on a single curve, till the beginning of the peak, so it is possible to draw a master curve without much deviation from the individual curves in this region and this master curve will be temperature independent.

Conclusion

The viscosity of the isothermal curing reaction of ISRO-HTPB with TDI is found to show an anomalous behavior which is not reported in literature previously. This behavior can be explained qualitatively, in terms of the opposing effects of dissolution and reaction in the system. A calcium carbonate filler does not have much effect on the curing reaction, other than its increase in initial viscosity, so fillers can be incorporated at polymerization stage itself. As the temperature increases the reaction rate can be expected to increase giving rise to an increase in the viscosity of the system; at the same time a temperature increase has a tendency to decrease the viscosity of the system; as these two effects are opposing each other, it would be interesting to follow the kinetics of the polyurethane reaction and relating the conversion to the viscosity of the system.

This work was supported by the Indian Space Research Organizaion.

Interaction of Urea with *p*-Nitrophenol

Prabhat K. Das Gupta, S. P. Moulik, and A. R. Das*,†
Department of Chemistry, Jadavpur University, Calcutta 700032, India
†Polymer Science Unit, Indian Association for the Cultivation of Science, Calcutta 700032, India
(Received December 14, 1990)

Urea(U) can abstract H^+ ion from *p*-nitrophenol (PNP) forming a hydrogen bonded ion pair (proton-transfer complex $PNP^- \cdots H^+U$) of 1:1 stoichiometry with a formation constant 0.42 at 303 K. Infrared spectral measurements of the uronium phenolate and uronium nitrate have supported that the proton transferred from PNP is attached to the oxygen center of the amide. The needle shaped light yellow urea–PNP adduct is fairly stable under ordinary conditions decomposing at 398 K. The standard free energy, enthalpy, and entropy of formation determined from spectrophotometric and calorimetric methods have been found to be 3.62 kJ mol^{-1}, −13.30 kJ mol^{-1}, and −57.5 J mol^{-1} K^{-1}, respectively at 303 K.

Recent studies have indicated that urea can significantly affect the hydrogen ion activity of strong acids in aqueous medium.[1–4] It has been pointed out that the oxygen atom of the amide provides the preferential binding site for the hydrogen ion. Earlier X-ray, IR, and NMR studies have also supported that the binding of urea and strong acids occur at the oxygen rather than the nitrogen center of the amides.[5,6] However, studies on the interaction between urea and weak acids are rare and the nature of the species formed consequent to this is not specifically known. We have observed that urea can affect the dissociation of *p*-nitrophenol, PNP (pK=7.15 at 25 °C) whereas *p*-nitrosalicylic acid, PNSA (pK=10.33 at 25 °C) remains unaffected; a relatively strong base like ethylenediamine can abstract H^+ ion from PNSA yielding a hydrogen-bonded ion pair or proton transfer complex (PTC).[7,8] The formation of PTC is the result of directionally specific interaction and because of much greater charge separation its formation is favored in polar media.[9] The spectrophotometric method is incapable of differentiating between an ion pair and the PTC, therefore, the spectrum of the PTC is the same as that of the ion of the conjugate base of the weak acid.[10] We have assumed that the above arguments are valid in our acid-base system of PNP and urea. Our objective has been to study the interaction between PNP and urea using spectrophotometric, conductometric, and calorimetric methods. It will be seen that the spectral results support PTC formation rather than dissociated ionic species. The energetics of the above interaction has been presented. Besides, the urea–PNP adduct has been prepared and characterized by IR and NMR methods with reference to the nitrate adduct of the amide.

Experimental

Materials. The urea and *p*-nitrophenol used were described earlier.[3,4,8] Nitric acid used was of Anala R grade, E. Merck, Germany. Doubly distilled conductivity water of specific conductance ca. 1.5 μS cm^{-1} was used for the preparation of solution.

Methods. Spectrophotometric measurements were taken in a Carey 17D spectrophotometer in 1 cm cuvettes. Infrared spectra were taken in KBr pellets in a Perkin–Elmer Model 297 Infrared spectrophotometer. About 1.0 mg of the finely ground sample was intimately mixed with approximately 100.0 mg of dried potassium bromide powder in a mortar and pestle. The mixture was then pressed in a special die at 10000 pounds per square inch to yield a transparent disk. The disk was then held in the instrument beam for spectroscopic examination. A JEOL FT NMR FX-100 was used for NMR spectral measurements. Approximately 3.0 mg of the sample dissolved in 0.3 ml of $CDCl_3$ was used for the measurements at 100 MHz with TMS as internal standard. Conductivity measurements of aqueous PNP and PNP–urea solutions were taken with a JENWAY, U.K. conductometer in a cell of cell constant 1.02 in a thermostated bath at 303 K.

Preparation of Adducts: To prepare uronium-nitrophenolate, the amide and the PNP mixed in 1:1 mol ratio was dissolved in a small amount of water and allowed to stand in a beaker at low temperature (283 K) overnight. Fine needle shaped light yellow crystals were found to appear at the bottom. The product was carefully washed with distilled water, dried under vacuum and stored in a desiccator. The elemental analysis has shown the compound to be of 1:1 composition. The compound decomposes at 398 K.

The nitric acid adduct was prepared in the following way. In 1 mol dm^{-3} solution of urea, 1 mol dm^{-3} nitric acid solution was slowly added. Fine crystals of uronium nitrate were formed and settled at the bottom. The crystals were separated, washed with distilled water for a number of times and stored in a desiccator. Elemental analysis confirmed the adduct to be of 1:1 composition. It decomposes at 423 K (lit, value[11] 425 K).

Spectrophotometeric Measurements: Solutions of PNP and urea were prepared in a number of test tubes at constant concentration of the former (10^{-4} mol dm^{-3}) and variable concentrations of the latter from 0.05 to 6.0 mol dm^{-3}. They were placed in a constant temperature thermostated water bath at 303 K for 1 h. The spectra of the solutions were then recorded in the spectrophotometer in the wavelength range 250—450 nm at 303±0.02 K.

Conductance Measurements: The conductances of PNP at concentrations 1,2,4,6,8, and 10 mmol dm^{-3} in water as well as in 8 mol dm^{-3} aqueous urea were measured at 303 K. The conductance of the urea solution was also measured and the value subtracted from each set of the PNP–urea mixtures to compensate for the urea effect on ion transport.[1]

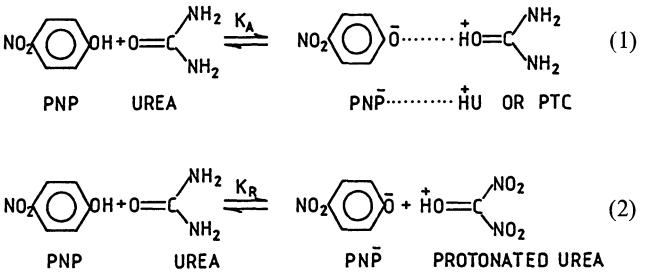
Calorimetric Measurements: The enthalpy of the urea–PNP interaction was determined in a Tronac 458 Isoperibol Calorimeter at 303 K. The calibration of the calorimeter was checked by measuring the heat of neutralisation of HCl with NaOH. In an actual run, urea solution was added into PNP solution keeping the final stoichiometry at least 1 : 100 and the heat liberated was determined at five urea concentrations. The heat of dilution of both the urea solution as well as the PNP solution were also determined and subtracted from the above heat of interaction to calculate the enthalpy following the procedure described elsewhere.[12,13] Since the base was directly added into the aqueous solution of PNP from a syringe in a water bath outside the Dewar flask, the heat of the interaction was calculated from the overall temperature change and the heat capacity determined after the introduction. The reported enthalpy refers to the extrapolated to zero urea concentration. The estimated standard deviation in the enthalpy value was ±0.7 kJ mol^{-1}.

Results and Discussion

The 1 : 1 stoichiometry of the reaction has been supported by the elemental analysis data of the prepared uronium *p*-nitrophenolate. The ^{1}H NMR spectrum of the PNP–urea adduct indicates the presence of the aromatic group as two double doublets centerd at δ=8.12 and 6.98 characteristic of a para substituted phenyl ring. The ^{1}H NMR spectrum of PNP and tetramethylurea[14] showed similar characteristics. In addition, the methyl proton signals appeared at δ=2.84 as a singlet. The signals were in the ratio of 1 : 3 indicating the formation of a 1 : 1 adduct. Analogically we consider that the PNP–urea adduct was also of 1 : 1 mol ratio.

The specific conductance–concentration plot in Fig. 1 suggests specific interaction between PNP and urea. Simple reduction in conductance[15] by the association of the dissociated H^+ ion as evidenced in the cases of HCl and HOAc (acetic acid) is not solely contributing to the ion transport phenomenon. A distinct departure is evidenced at higher PNP concentrations. A specific association of the migrating species PNP^- and UH^+ is anticipated which is regarded as the hydrogen-bonded ion pair.

The interaction between PNP and urea may end up into the following equilibria.



The spectra of the PNP–urea mixtures reveal decrease in the 315 nm band of the parent nondissociated PNP molecule with concomitant increase in the intensity of the 405 nm band of the phenolate anion or the PTC (Fig. 2). The reaction can thus be spectrophotometrically monitored recording the absorbance at 405 nm where PNP does absorb insignificantly. The spectra show a sharp isosbestic point at 345 nm indicating simultaneous existence of two species in equilibrium. The absorbance contributed by the self-dissociation of PNP is minor; it has been subtracted from the absorbance of all the solutions in the presence of urea to eliminate the effect. It has been established earlier[7] that both *p*-nitrosalicylate anion and the hydrogen-bonded ion pair between the said anion and protonated ethylenediamine have the same absorption maxima at 414 nm. The *p*-nitrophenolate anion (PNP^-) and the ion pair between PNP^- and the protonated urea UH^+ are considered also to absorb maximum at the same wavelength,[8] 405 nm. From fundamental considerations and following the line

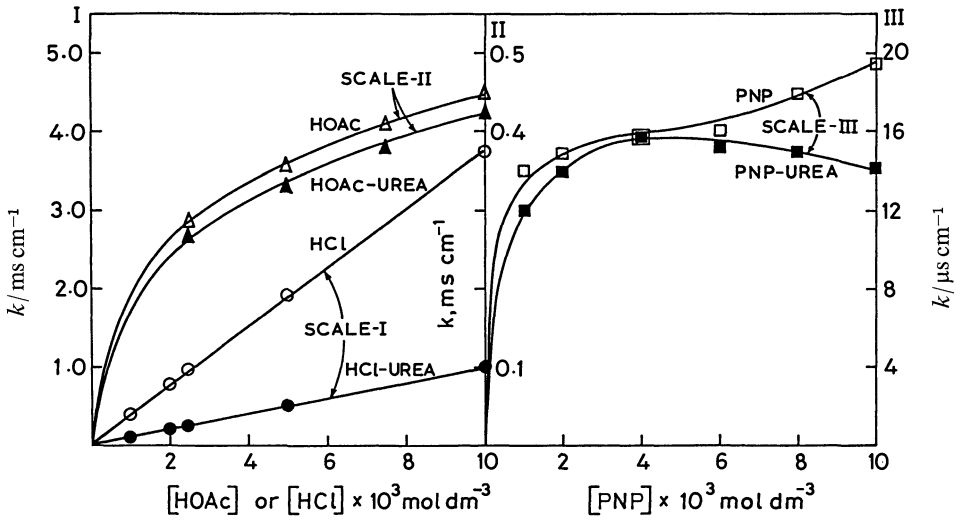


Fig. 1. Specific conductance–concentration profiles for HCl, HOAc, and PNP in aqueous and aquo-urea media at 303 K.

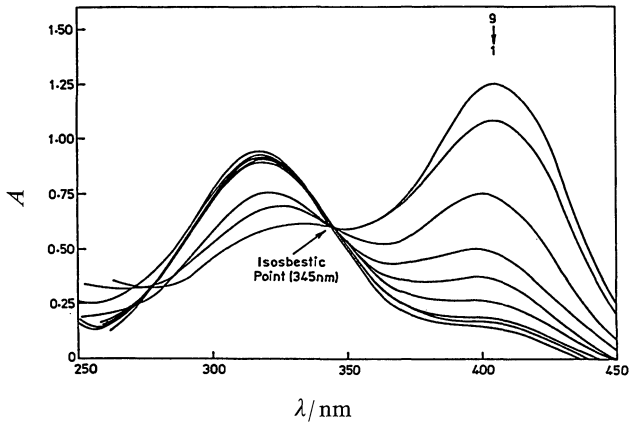

Fig. 2. Spectra of 0.1 mmol dm^{-3} PNP in aqueous urea environment at 303 K. Curves 1 to 9 are at 0, 0.05, 0.1, 0.3, 0.6, 1.0, 2.0, 4.0, and 6.0 mol dm^{-3} urea.

of arguments presented earlier,[7,8] the following Eqs. 3 and 4 can be derived for the above-mentioned Eqs. 1 and 2, respectively,

$$C_{PNP}/A = 1/\varepsilon + (1/K_A\varepsilon^2)\ 1/C_u \quad (3)$$

and

$$C_{PNP}/A = 1/\varepsilon + (1/K_R\varepsilon^2)\ A/C_u \quad (4)$$

where C_{PNP} and C_u are the stoichiometric concentrations of the *p*-nitrophenol and urea respectively, A is the absorbance of the solution at 405 nm, ε is the molar extinction coefficient of the absorbing species and K_R and K_A have significance as defined above. Since dilute solution of PNP has been used and urea is a neutral molecule, the activities of the species arising in solution are considered equal to their concentrations. The validity of Eq. 3 is examplified in Fig. 3, where a nice straight line plot is observed between C_{PNP}/A and C_u^{-1} with a correlation coefficient 0.9996 (curve 1). The ε_A and K_A derived from the slope and the intercept are $(1.78\pm0.08)\times10^4$ dm^3 mol^{-1} cm^{-1} and 0.24 ± 0.01 dm^3 mol^{-1} respectively. The value of ε of the phenolate ion[16] has been reported to be 18330 dm^3 mol^{-1} cm^{-1} at 303 K. It is seen in the figure that the results very

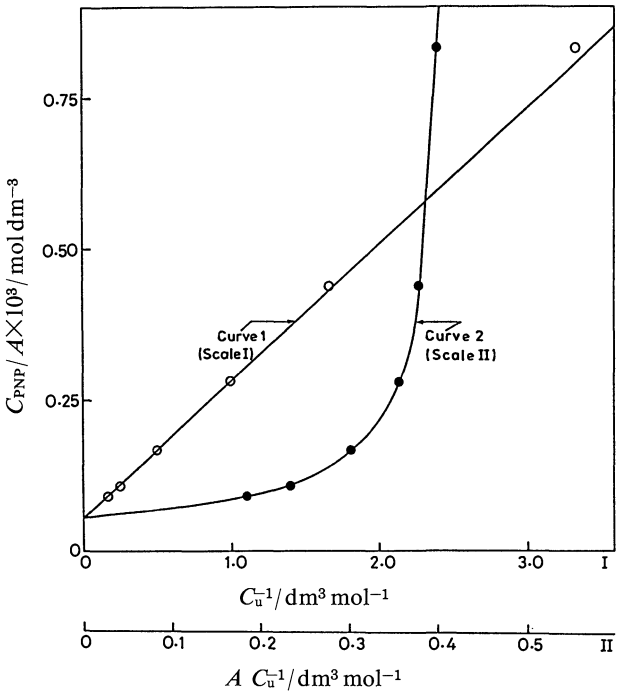

Fig. 3. C_{PNP}/A versus C_u^{-1} and C_{PNP}/A versus A/C_u plots for testing the validity of Eqs. 3 and 4 and the evaluation of the equilibrium constant, K_A and the molar extinction coefficient, ε of the complex at 303 K.

poorly fit Eq. 4. Extrapolation of the curved course (curve 2), however, yields the same intercept as produced by the curve 1, which ought to be so because the values in both the equations refer to the same species. The good correlation of the experimental results with Eq. 3 speaks in favor of the said PTC formation (Eq. 1) rather than replacement reaction (Eq. 2). From pH measurements we have reported the association constants of H^+ ion of HCl with urea to be 1.42—5.38 at 310 K in the urea concentration range of 0.5—6 mol dm^{-3}. The $PNP^- \cdots UH^+$ PTC formation constant is 0.24 dm^3 mol^{-1} at 303 K, the interaction is weaker than H^+ ion binding with the amide.

The reactant concentrations used in the experiments

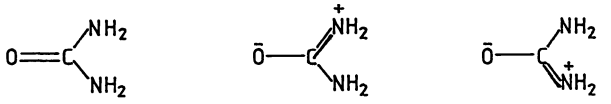
Table 1. Characteristic Infrared Bands of Urea, PNP, Urea–PNP, and Uronium Nitrate

Urea ν/cm^{-1}	PNP ν/cm^{-1}	Urea–PNP[a] ν/cm^{-1}	Uronium nitrate ν/cm^{-1}	Predominant mode
3400		3400	3400	ν_{NH_2} (free)
3500		3500	3500	
	3325			ν_{OH} (H-bonded)
		1690	1700	
1685				$\nu_{C=O}$ stretch
		1650	1670	
1470		1590	1570	ν_{CN} bending
	1590	1590		$\nu_{C=C}$ (skeletal)
	1500	1500	1500	ϕ_{NO_2}
			1380	NO_3^-

a) ν_{CN} for Urea–PNP almost merges with the $\nu_{C=C}$ at 1590 cm^{-1} with a broadening effect.

were low, so the thermodynamic parameters herein reported are standard state values. The calorimetric enthalpy of the interaction (ΔH°) has been found to be -13.8 ± 0.7 kJ mol^{-1}. A value of -57 ± 3 J mol^{-1} K^{-1} has been calculated for the ΔS° from the Gibb's equation using the spectrophotometrically obtained standard free energy change ($\Delta G^\circ=3.60\pm0.01$ kJ mol^{-1}). The interaction has an overall order producing effect. The interacted species are stabilized upon complexation, the environmental solvation also adds to the ordering effect.

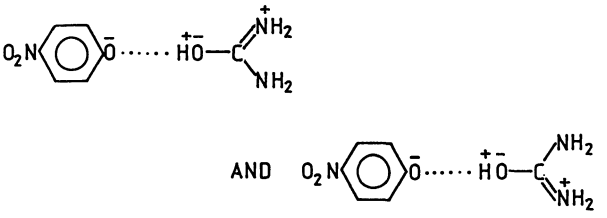
The characteristic IR bands of urea, PNP, urea–PNP, and uronium nitrate are given in Table 1. The amide has the following resonating structures.[17]



I II III

If linkage of hydrogen occurs through nitrogen then contributions of **II** and **III** will decrease and that of **I** will increase. This results in increase of the CO stretching frequency with a decrease in the CN stretching frequency. If, on the other hand, bonding occurs through oxygen then contribution of **I** decreases, the CO stretching frequency may be affected whereas that of the CN stretching should increase, the NH stretching frequency (3400—3500 cm^{-1}) should remain unaffected.

The bands of free NH_2 at 3400 and 3500 cm^{-1} in urea remain unaffected in urea–PHP and uronium nitrate, supporting noninvolvement of the linking between the nitrogen center of urea with the hydrogen of PNP and HNO_3. The stretching frequency of C=O has been little affected in the adduct whereas that of CN has been affected appreciably; in PNP adduct the shifted band of CN has overlapped with C=C skeletal response of PNP in the spectrum which is, therefore, not distinguishable. The appreciable shift in the stretching frequency of CN and nonaffected NH stretching frequency speak in favor of association of PNP and HNO_3 with the oxygen of urea. The intermolecularly bonded OH of pure PNP has shown a band at 3325 cm^{-1}, which is absent in the urea–PNP adduct indicating free OH to link with the C=O of urea. The following are the possible resonating structures of the 1 : 1 PNP adduct of urea.



P.K.D.G. thanks U.G.C., Government of India, for awarding a Teacher Fellowship to carry out this work. We thank M. L. Das and P. K. Jana for the calorimetric and conductance measurements.

Synopsis. The crystal of (BEDT-TTF)$_4$[Ni(CN)$_4$] (BEDT-TTF: bis(ethylenedithio)tetrathiafulvalene) belongs to the triclinic $P\bar{1}$ with the lattice constants of a=10.994(2), b=16.443(2), c=9.703(1) Å, α=97.85(1), β=115.15(1), γ=95.94(1)°. In the crystal, there exists the face to face overlap of the BEDT-TTF molecules along the [201] direction. The intermolecular interaction by the short S···S contact is also observed along the [$\bar{2}$01] direction.

Recently Saito et al. have found the superconductivity of (BEDT-TTF)$_2$[Cu(NCS)$_2$] at an ambient pressure.[1] The charge-transfer complexes between BEDT-TTF and metal complexes have many interesting properties such as the magnetic property in addition to the electrical conductivity, because such metal ion can have the incompletely occupied electron shell. From this point of view, we investigated the magnetic and electronic properties and the crystal structures of several complexes.[2-4] In the present paper, we report the crystal structure of (BEDT-TTF)$_4$[Ni(CN)$_4$].

Experimental

Black hexagonal plate-like crystals (0.25×0.30×0.05 mm) were grown by electrochemical crystallization of BEDT-TTF in 1,1,2-trichloroethane by using K_2[Ni(CN)$_4$] as a supporting electrolyte. D_m (1.80 g dm^{-3}) was measured by flotation and D_c is 1.89 g cm^{-3} for $C_{44}H_{32}N_4S_{32}Ni$. Reflection data# were measured by Rigaku automated four-circle diffractometer AFC-5R. Crystal data: triclinic, space group $P\bar{1}$, a=10.994(2), b=16.443(2), c=9.703(1) Å, α=97.85(1), β=115.15(1), γ=95.94(1)°, and Z=1. 5473 measured reflections, $2\theta_{max}$=126°, $-13\leqslant h\leqslant 13$, $-19\leqslant k\leqslant 19$, $0\leqslant l\leqslant 11$, and R_{int}=0.03. The crystal structure was determined by the Monte-Carlo direct method with the aids of MULTAN78 program system,[5] and refined by the full matrix least squares by using 4268 non-zero unique reflections (Cu $K\alpha$, $|F_o|>3\sigma(F_o)$). Intensities were corrected for the absorption effect by the analytical method, linear absorption coefficient μ=105.45 cm^{-1} and transmission factor in the range 0.043 to 0.59. The final R value was 0.062, S=2.34, $w=1/\sigma^2(F^2)$, $(\Delta/\sigma)_{max}$=0.40 for B_{31} of C(39) atom, and $\Delta\rho_{max}$=0.7 eÅ^{-3}. The atomic parameters were given in Table 1.

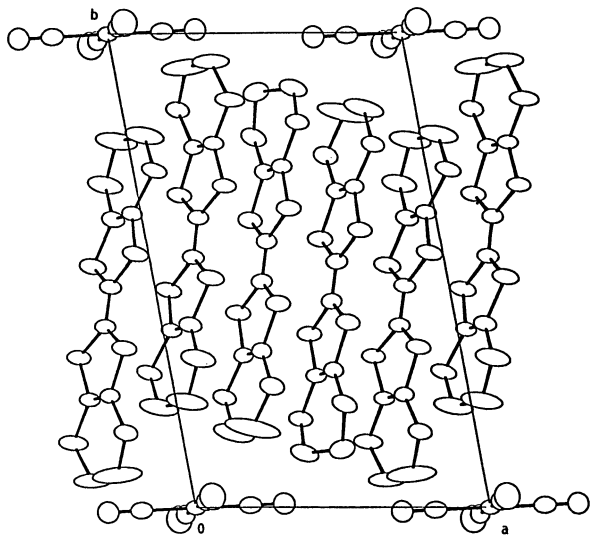

Fig. 1. Crystal structure of (BEDT-TTF)$_4$[Ni(CN)$_4$] projected on the c axis.

The complete F_o-F_c data are deposited as Document No. 8962 at the Office of the Editor of Bull. Chem. Soc. Jpn.

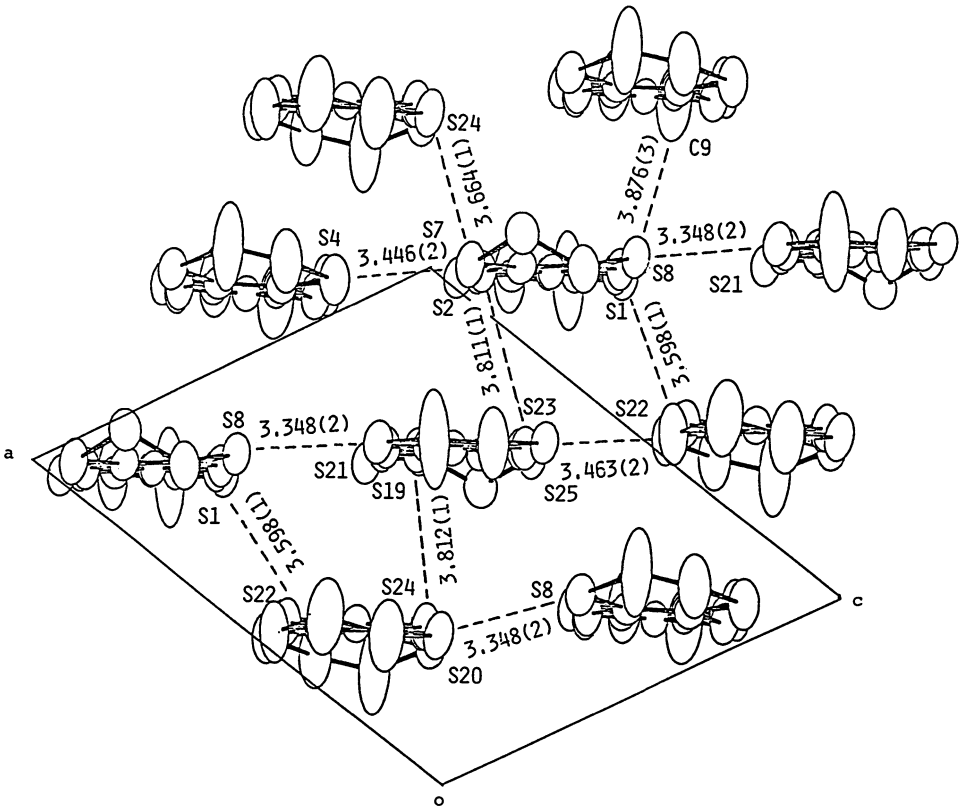

Fig. 2. Intermolecular overlaps in the BEDT-TTF sheet viewed along the molecular long axis.

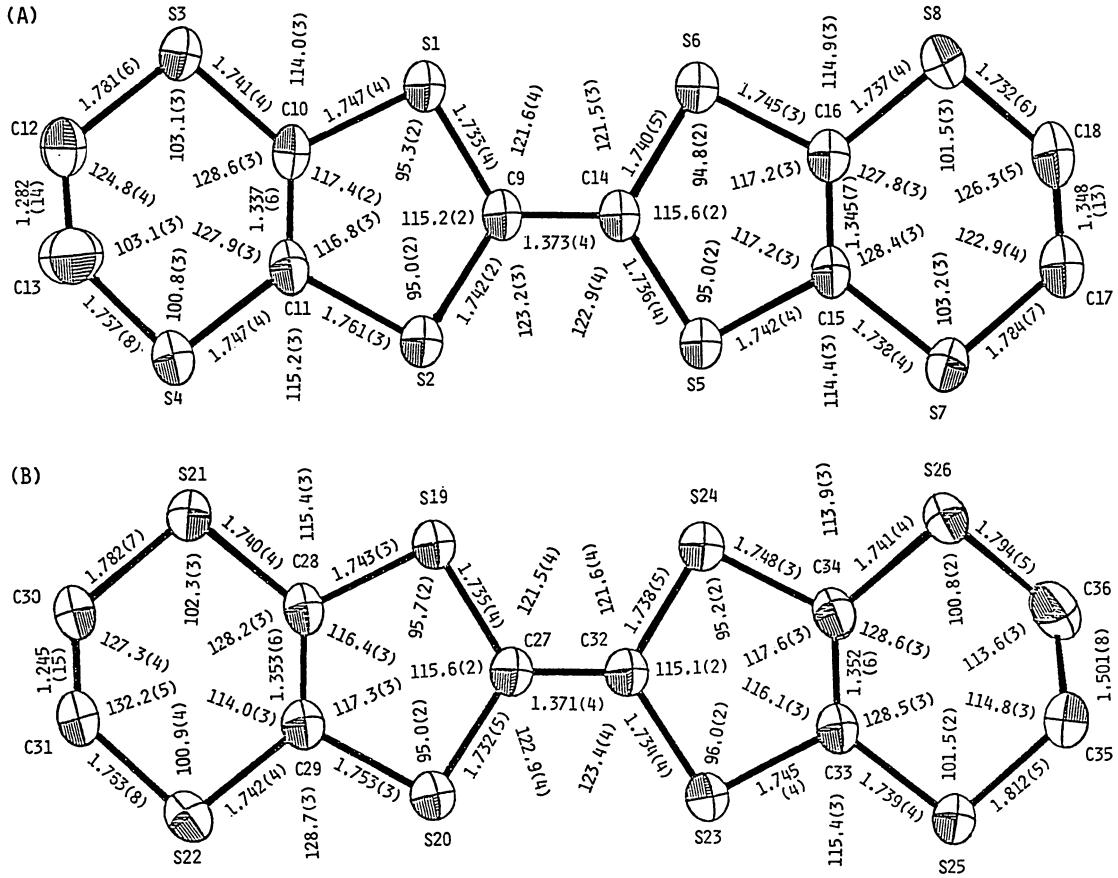

Fig. 3. Molecular dimensions for BEDT-TTF in $(BEDT\text{-}TTF)_4[Ni(CN)_4]$.

Results and Discussion

Figure 1 shows the crystal structure viewed along the *a* axis. There are two independent BEDT-TTF molecules in an asymmetric unit and the Ni atom of $[Ni(CN)_4]^{2-}$ ion is located on the inversion center. The BEDT-TTF molecules are stacked along the [201] direction. This crystal is isostructural to the crystal of $(BEDT\text{-}TTF)_4[Pt(CN)_4]$.[6] Figure 2 shows the arrangement on the (010) plane viewed nearly along the long molecular axis. The interstacking contacts are longer than the sum of the Pauling's van der Waals radii of two sulfur atoms (3.70 Å). Several S–S contacts shorter than 3.70 Å were observed along the [$\bar{2}$01] direction. The $[Ni(CN)_4]^{2-}$ anion has the square planar structure with the average Ni–C and C–N distances of 1.874(5) and 1.146(6) Å and the C–Ni–C angle of 88.3(3)°. The geometries of two crystallographycally independent BEDT-TTF molecules are shown in Fig. 3 and no significant difference could be found between them. One ethylene group of the BEDT-TTF molecule is out of the molecular plane and two carbons in the ethylene plane are located at the opposite side of the molecular plane, while another ethylene groups are in the molecular plane. In Table 2, the bond lengths of the TTF moiety in two BEDT-TTF molecules are compared with those in other BEDT-TTF salts. The average values in $(BEDT\text{-}TTF)_4[Ni(CN)_4]$ are similar to those in half-ionized BEDT-TTF and its charge can be regarded as $\rho=1/2$.

Table 2. Comparison of Averaged Bond Length (Å) of BEDT-TTF ($\rho=0$, 1/2, and 1)[7] (The bond lengths b, c, and d are averaged values)

	Molecule A	Molecule B	$\rho=0$	$\rho=1/2$	$\rho=1$
a	1.373(4)	1.371(4)	1.312(12)	1.365(4)	1.38(3)
b	1.74(1)	1.73(1)	1.757(7)	1.740(2)	1.72(1)
c	1.75(1)	1.75(1)	1.754(8)	1.750(2)	1.73(1)
d	1.34(1)	1.35(1)	1.332(7)	1.345(3)	1.37(2)

Effect of Proteins on the Zeta Potential of Dispersed Vesicular Globules in W/O/W Emulsions

Koichi UEDA and Sachio MATSUMOTO,*,†
Shiga Central Research Laboratories, Noevir Co., Ltd., Okada-cho, Youkaichi, Shiga 527

(Received April 30, 1991)

Synopsis. The zeta potential of dispersed vesicular globules in W/O/W emulsions was found to be reduced systematically at neutral pH by increasing the isoelectric point of proteins immobilized in the inner aqueous phase of the globules. We considered the effect of proteins on the total interactions between vesicular globules.

Dispersed globules of W/O/W emulsions can be characterized by a vesicular structure with an inner aqueous phase separated from an aqueous suspending fluid by a thin layer of the oil-phase components.[1,2] Globules of this type of emulsion also encapsulate a certain amount of water-soluble ingredients including proteins.[3–5] The authors have found that the dispersion state of the globules in W/O/W emulsions is influenced by a kind of proteins immobilized in the inner aqueous phase. Despite the fact that the globules have already been charged negatively in the aqueous phase due to differences in the affinity of the oil and the aqueous phases for ions,[6] the above finding may result from changes in the charged potential of the globules due to the surface activity of proteins, i.e. protein molecules adsorbed tightly onto the inside surface of the oil layer from the inner aqueous phase. It is the purpose of this study to obtain information concerning the correlation between the zeta potential of the vesicular globules and the isoelectric point of proteins immobilized in the globules of W/O/W emulsion systems.

Experimental

The W/O/W emulsions to be tested were divided into liquid-paraffin and olive-oil systems, respectively. The former was stabilized by Span 80 (sorbitan monooleate, produced by ICI America, Inc., U.S.A.) and Tween 80 (poly(oxyethylene) sorbitan monooleate, produced by Difico Laboratories, Inc., U.S.A.), while the latter was prepared by use of TGCR (tetraglyceryl condensed ricinolate) and DGMO (decaglyceryl monooleate). The TGCR and DGMO used were supplied by courtesy of Sakamoto Yakuhin Kogyo, Ltd., Osaka. Each system was also subdivided into four samples according to a kind of proteins immobilized in the inner aqueous phase, i.e. control (without protein), BSA (bovine serum albumin, pI: 4.4—4.9), chymotrypsin (pI: 8.1—8.6), and lysozyme (pI: 10.5—11.0) samples. The liquid paraffin and olive oil were obtained from Wako Pure Chemical Industries, Ltd., Osaka, as reagents of primary standard. BSA and chymotrypsin produced from bovine pancreas were purchased from Sigma Chemical Co., U.S.A., as a grade of biochemical reagents. Purified lysozyme from chicken egg white was provided by Wako Pure Chemical Industries, Ltd., Osaka. These materials were used without further treatment.

All of the W/O/W emulsion samples in a stable form were prepared by a combination[5] of the two separated steps of emulsification[7] and a phase-inversion technique[8,9] in order to immobilize 1 %w/w of each protein in the inner aqueous phase of the samples. According to the results of the preliminary studies, the procedure of emulsification for each sample could be summarized as follows:

(1) A range from 30 to 40 g of the oil phase containing 30 %w/w Span 80 in liquid paraffin or 30 %w/w TGCR in olive oil were placed in a vessel of a pin-mixer (described precisely in Ref. 7).

(2) An aqueous solution of 1 %w/w of each protein was then introduced successively to the oil phase in the vessel, while a stirrer unit of the pin-mixer rotated steadily at 88 rpm at room temperature so as to provide a W/O emulsion. This procedure was carried out over a range from 70 to 80 ml of the amount of the aqueous solution introduced.

(3) A definite amount of the first W/O emulsion, i.e. 90 g for the liquid-paraffin system and 54 g for another, was mixed with 45 ml of an aqueous solution of 1 %w/w Tween 80 in the liquid-paraffin system and with 36 ml of that of 1 %w/w DGMO in the olive-oil system.

(4) The mixture was finally homogenized by means of a mixer at about 5000 rpm of the armature speed for 1 min at room temperature, thus resulting a W/O/W emulsion containing one of the proteins in the inner aqueous phase of the dispersed vesicular globules. Details concerning the mixer used were also described in Ref. 7.

An optical microscopic examination indicated that almost all of the dispersed globules in freshly prepared samples have the vesicular structure with single or multiple compartments of the inner aqueous phase within a range of diameters from 2 to 30 μm.

An assembly with a rectangular cell provided by Mitamura Riken Kogyo, Ltd., Osaka, was employed for evaluating the electrophoretic mobility of the vesicular globules at neutral pH at room temperature. Each W/O/W emulsion was diluted about 100 times by the further addition of an aqueous solution of 1 mmol dm^{-3} KCl immediately before each measurement. The field strengths within a range from 3.3 to 10.0 V cm^{-1} were used to ensure that the electrophoretic mobility is independent of the actual applied voltage. A minimum of 20 readings were taken for each diluted system at any one voltage. The zeta potential (ζ) of the slipping plane of the diffused portion in the electrical double layer on the globules was calculated from the Smoluchowski equation for the electrophoresis of non-conducting spheres,[6] as follows:

$$\mu = \varepsilon_0 D\zeta / \eta, \quad (1)$$

where μ is the electrophoretic mobility, ε_0 is the permittivity of free space, and D and η are the relative permittivity and viscosity of the suspending fluid.

Results and Discussion

The values for the electrophoretic mobility and zeta potential of the vesicular globules in each sample are summarized in Table 1. The effect of proteins on the zeta potential of the globules appears in relation to the different magnitudes for the isoelectric point of the proteins immobilized in the inner aqueous phase, although the values obtained with the liquid-paraffin system are always smaller than those with the olive-oil

Table 1. Micro-Electrophoretic Data of Vesicular Globules in W/O/W Emulsions at Neutral pH at Room Temperature

Inner aqueous phase	Mobility	Zeta potential	Deviation
	$\mu m\ s^{-1}$ per $V\ cm^{-1}$	mV	mV
	Liquid paraffin system		
Without protein	−2.50	−32.1	±0.9
1% BSA	−2.14	−27.4	±0.5
1% Chymotrypsin	−1.67	−21.4	±0.4
1% Lysozyme	−1.06	−13.7	—
	Olive oil system		
Without protein	−5.56	−71.3	2.8[a)]
1% BSA	−4.30	−55.1	3.1[a)]
1% Chymotrypsin	−3.53	−45.3	2.2[a)]
1% Lysozyme	−2.27	−29.0	2.0[a)]

a) Standard deviation.

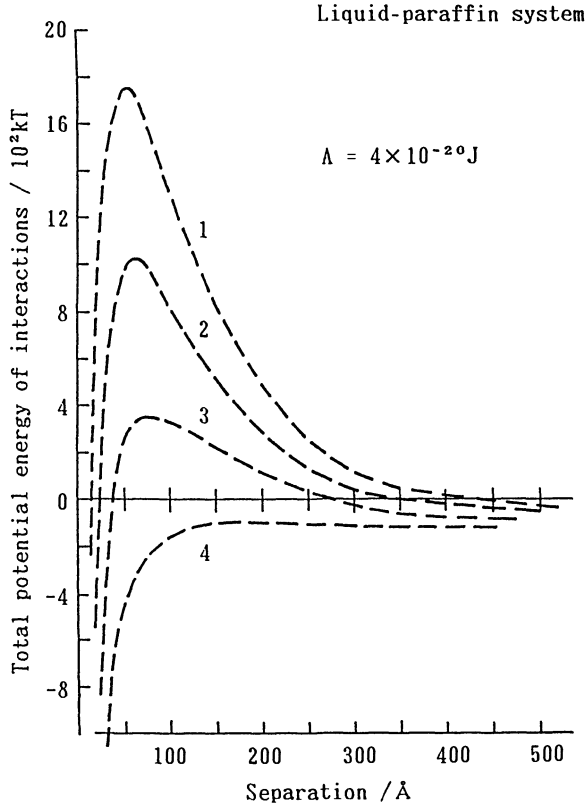

Fig. 1. Effect of proteins immobilized in the inner aqueous phase of a liquid-paraffin system on the total interactions between two vesicular globules at neutral pH at room temperature. Inner aqueous phase: Without protein (1), 1 %w/w BSA (2), 1 %w/w chymotrypsin (3), and 1 %w/w lysozyme (4).

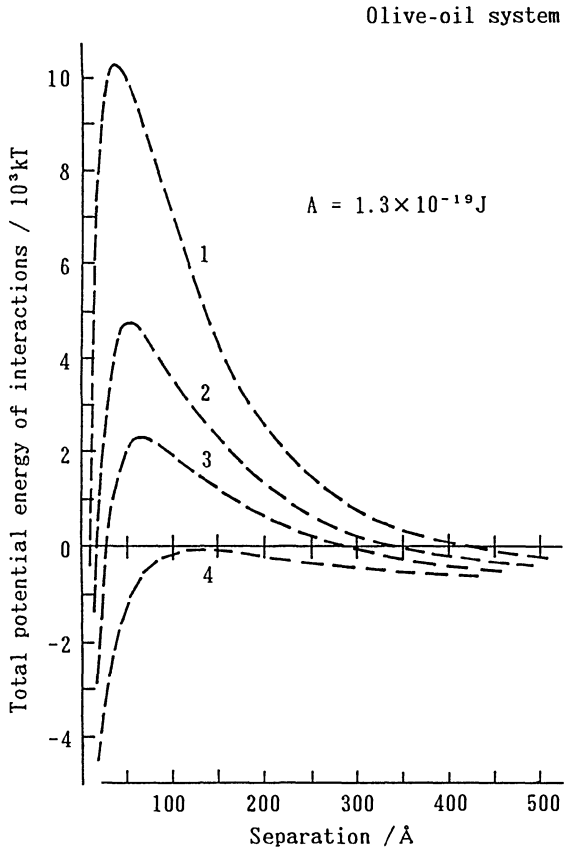

Fig. 2. Effect of proteins immobilized in the inner aqueous phase of an olive-oil system on the total interactions between two vesicular globules at neutral pH at room temperature. Inner aqueous phase: Without protein (1), 1 %w/w BSA (2), 1 %w/w chymotrypsin (3), and 1 %w/w lysozyme (4).

system. Such smaller values of the mobility and zeta potential may be brought about by the relatively longer distance to the slipping plane from the surface of the globules in the liquid-paraffin system, since the globules become to be covered by a deep hydration layer due to the existence of poly(oxyethylene) chains in the adsorbed molecules of Tween 80.[10]

Table 1, however, indicates that the zeta potential of the globules can be ranked with the magnitudes of the isoelectric point of the proteins, irrespective of the kinds of emulsifiers used, while a rapid coagulation occurs irreversively among the vesicular globules in the lysozyme samples showing the lowest zeta potential of the globules in a series of samples to be tested. The surface activity of protein molecules[11] may, more or less, result so as to form an adsorbed layer on the inside surface of the oil layer in the vesicular globules; the adsorbed protein molecules thus seem to play a role in the surface

potential of the vesicular globules according to the value of pH in the two aqueous phases. It is worth noting that the structure of the thin oil layer in a variety of W/O/W emulsions comprises the main lamellar membranes of the hydrophobic emulsifier, according to studies of the water permeation coefficient of the oil layer,[3] although the thickness of such a thin oil layer has not yet been fully investigated.

An attempt was made to estimate the total potential of interactions (V) between the two vesicular globules in each sample as a function of the separation (H) of the slipping planes in light of classical theory,[12] as follows:

$$V = 2\pi\varepsilon_0 D r\zeta^2 \ln[1+\exp(-\kappa H)] - rA/12H, \quad (2)$$

wherer r is the radius of the globules, H the separation, A the Hamaker constant, and κ the Debye-Hückel parameter given by

$$\kappa = (2ne^2z^2/\varepsilon_0 D\, kT)^{1/2}. \quad (3)$$

Here, n, e, and z are the concentration, elementary charge, and valency of counter ions, and kT is the thermal kinetic energy. The authors assumed that there is no energy barrier against the separation between the globules encapsulating lysozyme in each system because of the instability in the dispersion state, as already described. Thus, the value of the Hamaker constant could be estimated as being 4×10^{-20} J for the liquid-paraffin system and 1.3×10^{-19} J for the olive-oil system, respectively. Figures 1 and 2 compare the total potential of interactions against the separation between the two vesicular globules with each sample.

Correlations among One-Bond Deuterium Isotope Shifts in ^{13}C NMR and C-H Stretching Frequencies in IR for Monosubstituted Methane Derivatives

Yasuki NAKASHIMA† and Kensuke TAKAHASHI*
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†Research and Development Department, Menicon Co., Ltd., Biwajima, Nishi-ku, Nagoya 451
(Received May 29, 1991)

Synopsis. The effects of one bond deuterium isotope on ^{13}C NMR chemical shifts ($^1\Delta$) of the title compounds were found to be correlated with the corresponding C-H stretching frequencies(ν_{CH}) in IR spectroscopy, as follows: $^1\Delta$(ppb)= $-8.69\ \nu_{CH}(cm^{-1})+26500$.

The effects of the deuterium isotope on the ^{13}C NMR chemical shifts have been known for a long time. Recently, the true causes for these isotope shifts have been under intensive discussions.[1] However, for polyatomic molecules, there is no suitable model for the isotope shifts, which can be used to interpret all of the observed isotope shifts. We have systematically studied the isotope shifts on ^{13}C NMR.[2,3] As an extension of our studies, we report a correlation between $^1\Delta$ and ν_{CH}. To our knowledge, the NMR isotope shifts are related for the first time to the parameters of IR spectroscopy. Although Forsyth stated that there is no relation between $^1\Delta$ and ν_{CH} (Ref. 1b), we could find a correlation between the two parameters for a series of the title compounds.

Experimental

The isotope shifts were measured for mixtures of deuterated and undeuterated materials within an error of 3 ppb by a Varian XL-200 FT-NMR spectrometer at 50.3 MHz and about 22 °C. The IR spectra were measured for samples in the liquid phase within an error of 4 cm^{-1} using a JASCO FT/IR-8300 spectrometer. The materials were all commercially available.

Results and Discussion

The data concerning $^1\Delta$ and ν_{CH} for thirteen monosubstituted methane derivatives are given in Table 1 and are shown in Fig. 1. As can be seen in, there is a linear correlation between $^1\Delta$ and ν_{CH} with one exception. The largest deviation of CH_3NO_2 (**4**) could not yet be interpreted. The reason for this large deviation, for example, the conjugate effect or the magnetic anisotropy effect of the nitro group, can be considered.

It is well known that the C-H bond lengths can be predicted from the ν_{CH} values with high precision.[4,5] From this knowledge, $^1\Delta$ can be related to the C-H bond lengths of the observed carbons. When a C-H bond in a molecule is shorter than others, the observed ν_{CH} will be larger than that for the latter. Thus, this relation predicts that $^1\Delta$ becomes smaller for a carbon with a shorter C-H bond. This fact strongly supports an isotope shift model proposed by Jameson and Osten.[1c] This model assumes different anharmonic vibrational contributions for the C-H and C-D bonds. Although the energy surfaces for the deuterated and undeuterated materials should exactly coincide, small changes in the bond lengths and bond angles, which

a) $^1\Delta$ were defined as follows: $^1\Delta=\delta_{CH_3}-\delta_{CD_3}$ in ppb. Thus, high field shifts give positive $^1\Delta$. b) Measured in a gas phase (see Ref. 5) in cm^{-1}. c) Estimated values from averaged C-D stretching frequencies which are multiplied by $(13/7)^{1/2}$. See Ref. 13. d) Measured in a liquid phase in cm^{-1}. e) Measured for the d_6 compounds. Then, the contribution through three bonds was assumed to be negligible. f) Averaged for two nonequivalent C-H frequencies. See Ref. 5.

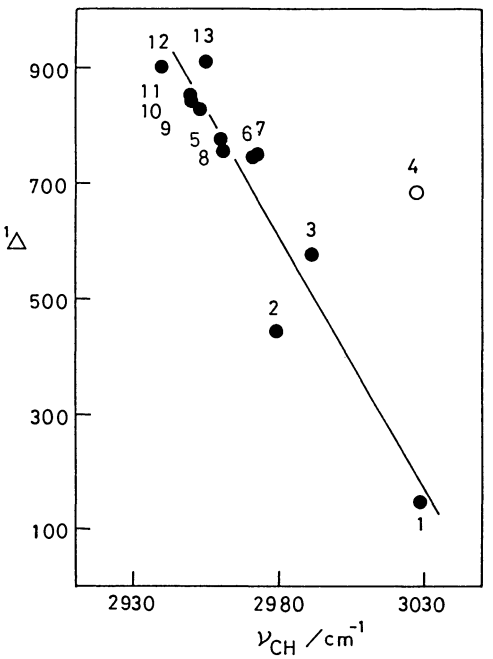

Fig. 1. Correlation of $^1\Delta$ with ν_{CH} of monosubstituted methane derivatives. With an exception of the value for CH_3NO_2, a correlated straight line is expressed as $^1\Delta$ (ppb)=26500−8.69 $\nu_{CH}(cm^{-1})$ with r=0.945 and a standard deviation of 77 ppb.

result from averaging over a vibrational motion in an anharmonic potential well, can be expected to occur.[6] This model assumes that the potential is less anharmonic for shorter, stronger bonds. With shorter bonds, the bond shortenings upon replacement of H by D are smaller, resulting in a smaller $^1\Delta$.

New Crystalline Complexes Composed of a Fatty Acid and Nicotinamide

Shoko YOKOYAMA,* Fumio UEDA,† and Tadao FUJIE
Kyoritsu College of Pharmacy, 1-5-30, Shibakoen, Minato-ku, Tokyo 105
†Research Laboratory, Kawai Seiyaku Co., Ltd., 6-3-5, Nakano, Nakano-ku, Tokyo 164
(Received June 7, 1991)

Synopsis. New crystalline complexes composed of a fatty acid (FA) and nicotinamide (NAA) at a molar ratio of 6:5, $(FA)_6(NAA)_5$, have been isolated. The melting points of $(FA)_6(NAA)_5$ were higher than those of the corresponding equimolar complexes, $(FA)_6(NAA)_6$.

We previously reported[1] that a fatty acid (FA) forms crystalline complexes with nicotinamide (NAA), 3-pyridine carboxamide, at a molar ratio of 1:1. These FA-complexes were obtained only in 1,2-dichloroethane.[1] A fatty acid forms an association complex similar to a reversed micelle in 1,2-dichloroethane.[2] The aggregation number in the association, though not yet determined, appears to be 6.[2] Association of FA molecules in 1,2-dichloroethane may be the first step for the crystalline FA-NAA complex formation. Further, the diameter of the host cavity of $(FA)_6$ is 5.1—6.7 Å if the host structure consists of six molecules of FA.[2] This cavity size is similar to that of α or β-cyclodextrin, though cyclodextrins generally include lipophilic compounds whereas $(FA)_6$ includes water-soluble compounds.

The FA–NAA equimolar complex is suggested to be of a formula $(FA)_6(NAA)_6$, in view of the formation mechanism of FA-complexes in 1,2-dichloroethane, though the actual molecular formula of the complex has not yet been determined. The FA–NAA complex is obtained as a solid, and the complex is decomposed to FA and NAA when dissolved in solvents. The complex is partially dissociated even when it is dissolved in 1,2-dichloroethane: this is because FA forms an association complex similar to a reversed micelle in 1,2-dichloroethane and that FA is in association equilibria, monomer$\rightleftarrows$dimer$\rightleftarrows$trimer$\rightleftarrows$hexamer, in this solvent.[2] Therefore, the molecular weight of the complex cannot be determined by a general method, namely vapor pressure or freezing point depression. Though X-ray crystal structure analysis is currently envisaged, it takes a long time to attain a clear result. In the meantime, we have isolated a new crystalline complex composed of octadecanoic acid (C18) and NAA from a 1,2-dichloroethane solution.[3] The formula of the new complex was $(C18)_6(NAA)_5$, and the C18-NAA equimolar complex is transformed into $(C18)_6(NAA)_5$ at temperatures below 22 °C by releasing 16% ($\fallingdotseq$ 1/6) of NAA, when cooled in acidic aqueous medium at temperature intervals of 5 °C from 37 °C.[3] This verified that the formula of the C18-NAA equimolar complex was $(C18)_6(NAA)_6$. Hereafter we denote the FA-NAA equimolar complex as $(FA)_6(NAA)_6$.

The melting point of $(C18)_6(NAA)_5$ was higher than that of $(C18)_6(NAA)_6$.[3] In view of this, the 6:5 complexes, $(FA)_6(NAA)_5$, with various alkyl chain length were prepared, and their melting points were systematically investigated in this work. The differences in the melting point between $(FA)_6(NAA)_5$ and $(FA)_6(NAA)_6$ will be discussed.

Experimental

Materials. NAA, tetradecanoic acid (C14), pentadecanoic acid (C15), hexadecanoic acid (C16), heptadecanoic acid (C17), and octadecanoic acid (C18) were the same as those used in previous work.[1] 1,2-Dichloroethane, ethanol, and a 0.1 M KOH (M=mol dm^{-3}) ethanol solution were the same as those used previously.[1,3]

Preparation of New Complexes. FA and NAA were dissolved at a molar ratio of about 1.4:1 in warm 1,2-dichloroethane, and the solutions were left standing at 20—25, 15—20, or 5—10 °C. Crystals were then obtained by filtration and dried under reduced pressure at room temperature.

Measurement of Melting Points. Melting points were determined with an apparatus equipped with a microscope (×100).

Quantitative Analysis of FA in the Complexes. Complexes with a unique melting point were chosen for quantitative analysis. Complexes were dissolved in ethanol, and the FA contained in the solution was titrated with a 0.1 M KOH ethanol solution.[1]

Elemental Analysis. Elemental analysis of the complex for C, H, and N was carried out by the thermal conductivity method.

Results

Conditions for Preparing New Complexes. It was difficult to obtain the new crystalline complexes in pure form. Occasionally FA, NAA, or $(FA)_6(NAA)_6$ was coprecipitated by changing the experimental conditions. The preparation conditions when the new complexes were obtained pure are summarized in Table 1, though these conditions are not necessarily the most appropriate ones.

Melting Points of the New Complexes. Since the melting point of $(C18)_6(NAA)_5$ is higher than that of $(C18)_6(NAA)_6$,[3] a compound with a melting point higher than that of $(FA)_6(NAA)_6$ was regarded as a new complex. The melting points of the new complexes are summarized in Table 2.

Table 1. Conditions for $(FA)_6(NAA)_5$ Preparation

Starting material[a]		Solvent	Crystallization[b]
NAA/g	FA/g	1,2-Dichloroethane/ml	temperature/°C
1.0	C18 3.25	200	20—25
1.0	C17 3.10	180	20—25
1.0	C16 3.10	60	15—20
1.0	C15 2.80	80	5—10
1.0	C14 2.55	100	5—10

a) Molar ratios of FA to NAA are approximately 1.4:1.
b) Crystallization time is 7 h in each case.

Table 2. Melting Points of $(FA)_6(NAA)_5$

$(FA)_6(NAA)_5$	Melting point/°C
$(C18)_6(NAA)_5$	87—89
$(C17)_6(NAA)_5$	89—91
$(C16)_6(NAA)_5$	83—85
$(C15)_6(NAA)_5$	85—87
$(C14)_6(NAA)_5$	78—80

Table 3. Quantitative Analysis of FA in the New Complexes

FA	Number of determinations	FA to NAA Molar ratio[a)]
C18	6	1.20±0.00
C17	3	1.20
C16	6	1.19±0.02
C15	3	1.20
C14	6	1.19±0.01

a) Mean±SD.

Quantitative Analysis of FA in the New Complexes. The molar ratio of FA to NAA in the complex was determined by quantitative analysis of FA, and the results are shown in Table 3. As is seen, the molar ratio of FA to NAA is 1.2 : 1 for each case. This is in line with a molecular formula of $(FA)_6(NAA)_5$.

The starting mixing ratio of FA to NAA was 1.4 : 1, while the molar ratio of FA to NAA in the complex was 1.2 : 1. This is because FA exists partly as a monomer, dimer, or trimer in 1,2-dichloroethane.[2)]

Elemental Analysis of the New Complexes. The results of elemental analyses of the new complexes are given in Table 4. The experimental values are well consistent with the theoretical values based on the molecular formula $(FA)_6(NAA)_5$. This further indicates that the new complexes are of the formula $(FA)_6(NAA)_5$.

Discussion

Comparison of $(FA)_6(NAA)_5$ with $(FA)_6(NAA)_6$. The melting points of $(FA)_6(NAA)_5$, $(FA)_6(NAA)_6$, and FA are shown in Fig. 1 against the carbon number (n) of the constituent FA. The melting point of an odd-numbered FA is lower than that of an even-numbered FA with an alkyl chain longer by one carbon atom, and the relationship between the melting point of FA and n takes a zig-zag form. The melting points of $(FA)_6(NAA)_6$ are higher than those of FA, especially with odd-numbered FA, and the melting point of

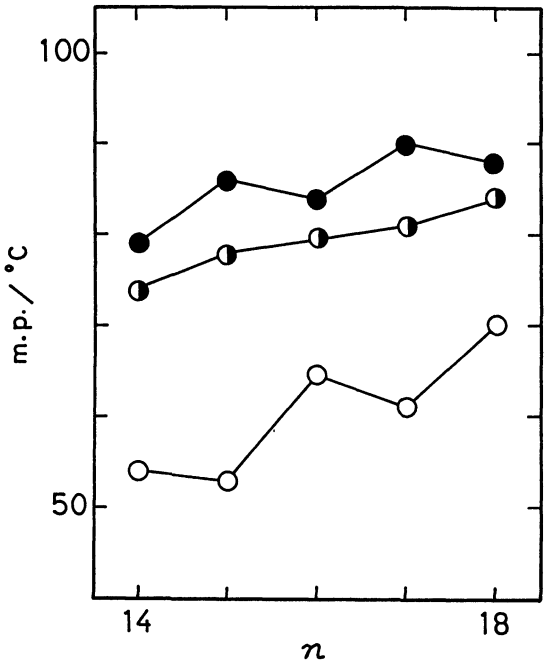

Fig. 1. Relationships between the melting point and n for $(FA)_6(NAA)_5$, $(FA)_6(NAA)_6$, and FA
●, $(FA)_6(NAA)_5$; ◑, $(FA)_6(NAA)_6$; ○, FA.

$(FA)_6(NAA)_6$ changes roughly linearly with n. The melting points of $(FA)_6(NAA)_5$ are higher than those of $(FA)_6(NAA)_6$, and the difference is larger for compounds with odd-numbered FA. The zig-zag form of the melting point curve is neatly reversed between FA and $(FA)_6(NAA)_5$: the difference in melting point between $(FA)_6(NAA)_5$ and $(FA)_6(NAA)_6$ is 4—5 °C for even-numbered FA, and 8—9 °C for odd-numbered FA. This suggests that $(FA)_6(NAA)_5$ with odd-numbered FA is more thermostable than $(FA)_6(NAA)_5$ with even-numbered FA, and is related to an observation that pure $(FA)_6(NAA)_5$ with odd-numbered FA was formed more easily than pure $(FA)_6(NAA)_5$ with even-numbered FA: namely, coprecipitation of $(FA)_6(NAA)_6$ was to a lesser extent for odd-numbered FA.

We now compare $(FA)_6(NAA)_5$ and $(FA)_6(NAA)_6$ for the preparation conditions. In preparing $(FA)_6(NAA)_5$, the mixing ratio of FA to NAA is slightly larger and the temparature for crystallization is lower. The complex formation between a FA and a water-soluble compound in 1,2-dichloroethane presumably begins with the solubilization of the water-soluble compound in the reversed micellar FA hexamer.[2)] The amount of FA hexamer

Table 4. Elemental Analysis of $(FA)_6(NAA)_5$

Formula	Analysis/% Found (Calcd)					
	C		H		N	
$(C_{18}H_{36}O_2)_6(C_6H_6N_2O)_5$	71.63	(71.52)	10.65	(10.70)	6.04	(6.05)
$(C_{17}H_{34}O_2)_6(C_6H_6N_2O)_5$	70.95	(70.99)	10.58	(10.56)	6.28	(6.27)
$(C_{16}H_{32}O_2)_6(C_6H_6N_2O)_5$	70.31	(70.41)	10.33	(10.41)	6.59	(6.52)
$(C_{15}H_{30}O_2)_6(C_6H_6N_2O)_5$	69.80	(69.79)	10.21	(10.25)	6.79	(6.78)
$(C_{14}H_{28}O_2)_6(C_6H_6N_2O)_5$	69.03	(69.12)	10.02	(10.08)	7.12	(7.07)

increases with increasing its concentration. This may have decreased the amount of NAA per FA hexamer $(FA)_6$ and have led to the formation of $(FA)_6(NAA)_5$.

The temperature also plays an important role in the crystallization of the two kinds of complexes. The temperature for crystallization may yield a difference in the tilting angle of FA molecules in the crystal structure of $(FA)_6$ which serves as a host. For example, even-numbered FA occur in three polymorphic modifications, A, B, and C.[4-6] In none of them do the chains rotate: they differ in the angle of the chains with respect to the plane of the carboxyl groups, A=chains vertical; B=chains tilted at 74°40′; C=chains tilted at 59°12′.[4] The latter two can be easily crystallized. Further, the polymorph B is obtained by slow crystallization at room temperature whereas the polymorph C is obtained by rapid crystallization at lower temperatures.[5]

The tilting angle of $(FA)_6$ in the crystal of $(FA)_6(NAA)_5$ may be different from that in $(FA)_6(NAA)_6$, similarly to the difference between the polymorphs B and C. Further, the tilting angle of $(FA)_6$ may depend on the temperature for crystallization. In view of the conditions for preparing $(FA)_6(NAA)_5$ and $(FA)_6(NAA)_6$, $(FA)_6(NAA)_5$ probably corresponds to the polymorph C of FA, while $(FA)_6(NAA)_6$ to the polymorph B. The heat of solution of the polymorph B is larger than that of the polymorph C.[5] The melting point of $(FA)_6(NAA)_5$ is higher than that of $(FA)_6(NAA)_6$, as seen in Fig. 1. These lead us to speculate that five NAA molecules are fit into the more tilted $(FA)_6$ more favorably than six NAA molecules into the less tilted $(FA)_6$, and hence $(FA)_6(NAA)_5$ is stabilized over $(FA)_6(NAA)_6$.

The reason why the thermostable $(FA)_6(NAA)_5$ was not obtained first, is related to the solubility of FA. Especially with C18, the preparing a pure complex is easier at higher temperatures, where coprecipitation of FA is well suppressed, than at lower temperatures, and the higher temperature thus favored the formation of $(FA)_6(NAA)_6$.

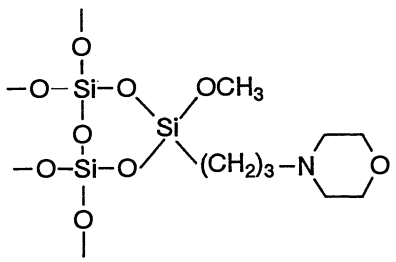
High-Performance Liquid Chromatographic Determination of Components in Eye Lotion Using Methoxy(3-morpholinopropyl)silanediyl Modified Silica Gel Column

Shuzo AKIYAMA,* Kenichiro NAKASHIMA, Kyoko YAMADA, and Nanako SHIRAKAWA
School of Pharmaceutical Sciences, Nagasaki University, 1-14 Bunkyo-machi, Nagasaki 852
(Received April 22, 1991)

Synopsis. A recently developed column packing material, methoxy(3-morpholinopropyl)silanediyl modified silica gel, was successfully applied to the separation and determination of components (pyridoxine, flavin adenine dinucleotide, cyanocobalamin, chlorpheniramine, naphazoline, and neostigmine) in an eye lotion, in a single analysis by a single buffer elution with UV detection.

Quite recently, we reported on the development of new column packing materials for the high-performance liquid chromatographic (HPLC) separation of water-soluble vitamins[1] as well as such substances[2] as inosinic, xanthylic, and guanylic acids related to umami. It was consequently confirmed that methoxy(3-morpholinopropyl)silanediyl modified silica gel (MPS), similar to an ion-exchange resin, is suitable for separating water-soluble compounds. On the other hand, in ophthalmologic or pharmaceutical studies, a simple and rapid determination of components in eye lotions should be useful. Although the determination of a single component, such as boric acid[3] or thimerosal,[4] in an eye lotion by HPLC is known, HPLC-analysis of multicomponents has until now been scarcely reported. In this study, we thus tried to expand on the application of MPS to the separation and determination of components in eye lotions using UV detection.



Formula.

Experimental

Material. MPS was prepared according to a previous report.[1] Pyridoxine (PY) and flavin adenine dinucleotide (FAD) were obtained from Wako Pure Chemicals Co., Ltd. Cyanocobalamin (CC), chlorpheniramine (CP) (as its maleate), naphazoline (NA), and neostigmine (NE) (as its methyl sulfate) were purchased from Sigma Chemical Co. All other reagents used were of analytical grade (Wako).

Apparatus. The chromatograph system comprised a Tosoh CCPD pump with a Rheodyne-type injector (7125) with a 100 μl loop, a Tosoh UV8011 variable-wavelength UV monitor and a Hitachi Model 561 recorder. The eluates were monitored at 270 nm.

HPLC Column and Eluent. The gel (MPS) was packed into a stainless-steel tube (150 mm×6.0 mm I.D.) using a slurry-packing technique [glycerol : methanol, 4 : 6 (v/v)] and applied to the HPLC separation at a flow rate 1.0 ml min^{-1} of 0.1 M (1 M=1 mol dm^{-3}) phosphate buffer (pH 2.3) (column temperature, 30 °C).

Preparation of a Standard Solution of the Components Contained in an Eye Lotion. Six components (PY, FAD, CC, CP, NA, and NE) in a commercially available eye lotion were separately dissolved in the eluent [0.1 M phosphate buffer (pH 2.3)]; the solutions were then arranged to 5×10^{-4} M for PY, CP, and NA, 5×10^{-5} M (CC), and 10^{-3} M (NE).

Determination. Each component was determined by the standard addition method, as follows: To a commercially available eye lotion was added a series of known concentrations of standard solution, and diluted ten times with an eluent. Aliquots (100 μl) were injected onto the HPLC.

Results and Discussion

In the separation of water-soluble components with MPS, a phosphate buffer as an eluent has been studied in detail and found to be useful.[1] We therefore used a phosphate buffer for an eluent. First of all, the effect of the eluent pH was examined in order to separate the six components (PY, FAD, CC, CP, NA, and NE). The use of a 0.1 M phosphate buffer (pH 2.3) gave a relatively good peak separation. Almost no effect was observed after the addition of sodium 1-octanesulfonate. Under the above-mentioned HPLC conditions, it was demonstrated that their water-soluble substances, including maleic acid liberated from CP maleate, can be well separated (except for CP and NA) within 15 min in a single analysis (Fig. 1). The calibra-

Table 2. Analyses of Eye Lotion

Sample	Found (M)[a)] (w/v%)	Indicated (M) (w/v%)
Eye lotion A		
CC	7.5×10^{-5} (0.01)	7.4×10^{-5} (0.01)
CP	2.2×10^{-4} (0.01)	2.6×10^{-4} (0.01)
Eye lotion B		
CP	2.4×10^{-3} (0.09)	5.1×10^{-4} (0.02)
Eye lotion C		
FAD	5.1×10^{-4} (0.04)	4.2×10^{-4} (0.033)
NA	1.8×10^{-4} (0.004)	1.2×10^{-4} (0.003)

a) Mean of duplicate assay.

tion curves for these components obtained by using the corresponding standard solutions were linear in the nmol range of 1.75—14 (PY), 0.98—7.9 (FAD), 0.18—1.4 (CC), 0.88—7 (CP), 3.6—29 (NE), and 6.25—50 (NA). The linear regressions are shown in Table 1 with the correlation coefficients (r). As the application work, three commercially available eye lotions were assayed. Typical chromatograms are shown in Fig. 2. The peaks were confirmed by co-chromatography. Compounds CC, CP, FAD, and NA in commercially available eye lotions (A—C) were determined by the standard addition method (Table 2). Compounds PY and NE could not be determined under the experimental conditions. On the other hand, it was observed that the separation capacity of MPS gradually decreased with increasing the sample loading. This might be caused by the hydrolysis of MPS with a lower pH mobile phase. This point must be improved and is now under study.

In conclusion, MPS could be further applied to the analysis of components in commercially available eye lotions. This method might be useful for pharmaceutical studies on the stability of the components contained in eye lotions.

(Received May 9, 1991)

Synopsis. The title compound has been prepared and used as a new derivatization reagent. The reagent reacts with the carboxylic acids in chloroform in the presence of 1-isopropyl-3-(3-dimethylaminopropyl)carbodiimide to produce the corresponding fluorescent esters, which can be separated on an octadecyl-silica column. Each 5 fmol of hexadecanoic or octadecanoic acids and about 50 fmol of benzoic and *p*-anisic acids (1 μl injection) (S/N=2) were detected.

Recently, we have reported that a thienylpyridine skeleton is a new fluorophore,[2] and that 5-(4-pyridyl)-2-thiophenecarbaldehyde(**1**) is one of the useful derivatization reagents for aliphatic primary amines in HPLC.[1] The present paper deals with the preparation of a new fluorescent compound, 5-(4-pyridyl)-2-thiophenemethanol(**2**), and with its application to the determination of carboxylic acids. The detection limits of most aromatic carboxylic acids were superior to those of all known reagents,[3,4] and those of aliphatic carboxylic acids were also superior to those of known reagents, except for 3-bromomethyl-6,7-dimethoxy-1-methyl-2(1*H*)-quinoxalinone(**3**).[3] The dynamic linear range was over 4 orders of magnitude.

Experimental

Elemental analyses were performed by the Laboratory for Organic Elemental Microanalysis, Faculty of Pharmaceutical Sciences, Kyoto University. Melting points were uncorrected. The ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-GX400 FT spectrometer in $CDCl_3$ using TMS as the internal standard. Mass spectra were recorded on a Hitachi M-80B mass spectrometer.

Liquid chromatography experiments were conducted on a HPLC system consisting of two Tosoh CCPE pumps equipped with an MX-8010 mixer, a Rheodyne Model 7410 fixed loop injector, a Shimadzu Shim-pack CLC-ODS column (15 cm×6 mm i.d.; packed with octadecyl-silica gel), and a Shimadzu RF-535 fluorescence monitor. Chromatograms were recorded with a Shimadzu C-R3A chromatopac or with an EPSON PC-286V computer connected with the chromatopac.

Reagent. All chemicals were of reagent grade and were used as received from commercial sources, except for those noted below. Solvents were distilled and water was purified through a Milli-QII system.

Preparation of 2. Aldehyde **1**[1] (2.0 mmol) and a trace amount of Methyl Orange were dissolved in 40 ml of methanol. Sodium cyanotrihydroborate (2.6 mmol) was added, and concd hydrochloric acid–methanol (1:5) was added dropwise with stirring to maintain the red color. After 5 h, the methanol was evaporated in vacuo. The residue was taken up in 20 ml of 5% sodium hydroxide solution, and extracted with three 20-ml portions of chloroform. The combined extracts were evaporated under reduced pressure and chromatographed on silica gel (eluent, acetone:ethyl acetate=1:1), and recrystallized from chloroform to yield colorless needles **2** in a 60% yield. Mp 139.0—139.5 °C. Found: C, 62.60; H, 4.79; N 7.17%; *m/z*, 191.0404. Calcd for $C_{10}H_9NOS$: C, 62.80; H, 4.74; N, 7.32%; M, 191.0404. ^{1}H NMR (400 MHz, 40 °C) δ=2.5 (1H, br, OH), 4.86 (2H, s, CH_2), 7.01 (1H, d, *J*=3.8 Hz), 7.36 (1H, d, *J*=3.8 Hz), 7.43 (2H, dd, *J*=4.6 and 1.7 Hz, H-3 and H-5 in pyridine ring), and 8.53 (2H, dd, *J*=4.6 and 1.7 Hz, H-2 and H-6 in pyridine ring). ^{13}C NMR (100 MHz) δ=60.12 (s), 119.77 (d, 2C), 125.27 (d), 126.31 (d), 140.85 (s), 141.61 (s), 146.79 (s), and 150.25 (d, 2C). Reagent **2** was stable in the crystalline state for a year or longer in daylight at room temperature.

Derivatization Procedure. One fifth ml of chloroform containing 8.0—1.6×10^5 pmol of carboxylic acids and 0.2 ml of chloroform containing 0.8 μmol of 1-isopropyl-3-(3-dimethylaminopropyl)carbodiimide perchlorate(**4**) were added to 0.2 ml of chloroform containing 0.4 μmol of **2** and 1.6 μmol of 4-dimethylaminopyridine(**5**) in a 20-ml screw-capped reaction vial. The reaction vial was tightly closed, heated at 60 °C for 3 h, and then cooled. Each 1 μl of the solution was subjected to HPLC, and determined by monitoring the fluorescence intensities at 360 nm with excitation of 300 nm.

Results and Discussion

Preparation and Properties of 2. Reagent **2** was prepared in a 60% yield by the reduction of **1** with cyanotrihydroborate ion under the conditions described for the reduction of acetophenone;[5] its structure was proved by its ^{1}H and ^{13}C NMR spectra, MS, and elemental analysis. The alcohol **2** a stable crystalline substance, behaved as a weak base with pK_a 4.64 in 40% aqueous methanol. A nonprotonated form of **2** exhibited more excellent fluorescent properties than a protonated one. Its new carboxylic esters(**6**) also strongly fluorescenced and the pH dependence of the spectra was similar to that of 4-(2-thienyl)pyridine.[6]

Determination of Carboxylic Acids. Figure 1 shows typical chromatograms for the linear saturated fatty acid esters of **2**. The C2—C18 fatty acid esters of **2** were separated on a reversed-phase column (Shim-pack CLC-ODS) with methanol. Methanol gave a complete separation for the C12—C18 long-chain fatty acid esters, though the peaks for the esters of C2—C7 short-chain fatty acids almost overlapped those for the derivatization reagent **2** and/or an adjacent peak. When a gradient elution using 30—0%(v/v) aqueous methanol was applied, however, the esters of short-chain fatty acids were completely separated.

Three condensing reagents, i.e., **4**, dicyclohexylcarbodiimide(**7**), and diethyl phosphorocyanidate(**8**), were examined for the esterification of linear fatty acids with **2** in chloroform, since no esterification occurred in the absence of a condensing reagent; reagents **4** and **7** accelerated the esterification, but reagent **8** did not.[7] Figure 2 shows the effect of the concentration of **4** and **7** on the peak area of the esters of C2—C7 acids. The

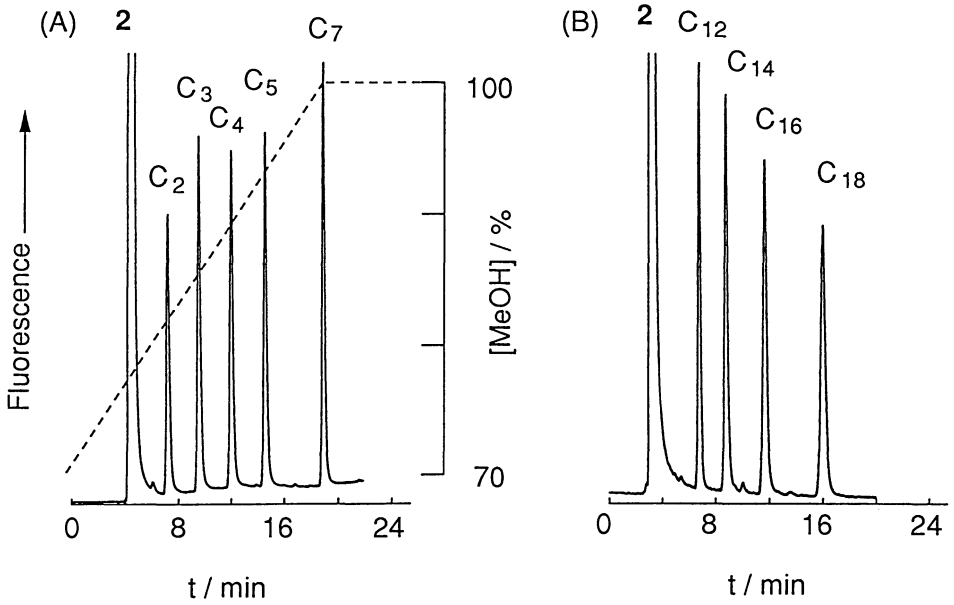

Fig. 1. Chromatograms for the esters of C2—C18 linear saturated fatty acids.
The esters are denoted by the numbers of carbon atoms of fatty acid, C*n*. Column, 150×6 mm i.d. Shim-pack CLC-ODS; eluent, (A) 30—0% (v/v) aqueous methanol and (B) methanol, 1.0 ml min^{-1}; sample size, 1 μl (70 pmol); precolumn reaction, a portion (0.2 ml) of a standard mixture of the acids (each 0.2 mmol dm^{-3}) was derivatized according to the procedure described in the experimental section.

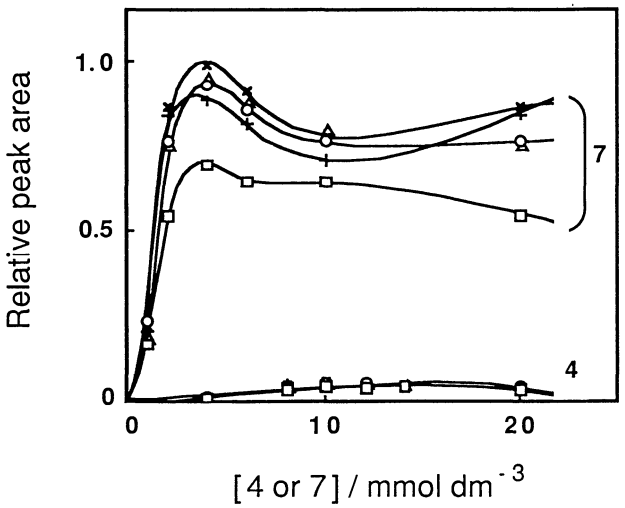

Fig. 2. Effect of the concentration of a condensing reagent, **4** or **7**, on the peak area of the esters of C2—C7 acids: (—□—) C2, (—○—) C3, (—△—) C4, (—×—) C5, and (—+—) C7 acids.
The conditions are as described in Fig. 1, except for a condensing reagent. The values of the vertical axis are represented as the ratio of the peak area of the esters to the maximum area of the C5 acid ester.

largest peaks were obtained at 4 mmol dm^{-3} of the reagent **4** solution for all the acids, where no side reaction occurred, although above this concentration other small peaks were also observed; a 4 mmol dm^{-3} **4** solution was used in subsequent work. The maximum and constant peak area were attained at temperatures higher than 60 °C and heating times longer than 3 h; heating for 3 h at 60 °C was employed in subsequent work.

Table 1. Linear Ranges and Detection Limits of Saturated Fatty Acids[a)]

Saturated fatty acid	Linear range /fmol	Detection limit (S/N=2)/fmol
Acetic acid	5.8×10^3—120×10^3	5800
Propionic acid	170—84×10^3	170
Butyric acid	420—84×10^3	420
Valeric acid	29—58×10^3	15
Heptanoic acid	27—53×10^3	13
Dodecanoic acid	110—110×10^3	110
Tetradecanoic acid	11—110×10^3	11
Hexadecanoic acid	12—120×10^3	5
Octadecanoic acid	12—120×10^3	5

a) Conditions as described in Fig. 1.

The derivatization of C18 acid with **2** went to completion under the present conditions, since both the retention time and the peak area of HPLC for a sample prepared from 2.0×10^{-5} mol dm^{-3} C18 acid solution were consistent with those of a 2.0×10^{-5}mol dm^{-3} 5-(4-pyridyl)-2-thenyl octadecanoate[6)] solution. Table 1 shows the linear ranges and detection limits (S/N=2) obtained from the calibration curves for C2—C18 acids. The linear-correlation coefficients were more than 0.9991 for all the acids within the tabulated ranges of the concentration. These limits were superior to those of the known reagents, except for **3**.[3)] The lower detection limit of C2 acid was higher than that estimated from the IFS value,[6)] because a small peak for a trace amount of the C2 acid ester and a large peak for a large excess of reagent **2** overlapped. The coefficients of

Table 2. Retention Time, Peak Area, and pK_a of Aromatic Carboxylic Acids[a)]

Aromatic carboxylic acid	Retention time/min	Relative peak area[b)]	pK_a	
o-Bromobenzoic acid	6.7	0.10	2.85[c)]	
m-Bromobenzoic acid	10.0	0.19	3.81[c)]	
p-Bromobenzoic acid	9.5	0.28	4.00[c)]	
o-Anisic acid	5.1	0.65	4.09[c)]	
m-Anisic acid	6.7	0.62	4.09[c)]	
p-Anisic acid	7.7	1.43	4.49[c)]	
Benzoic acid	6.9	1.00	4.21[c)]	5.79[d)]
p-Toluic acid	8.9	1.29		6.12[d)]

a) Conditions as stated in Fig. 1, except for the eluent (95% methanol) and concentration of the acid standard solution (each 1.5 mmol dm^{-3}). b) Expressed as a ratio of the peak area of the analyte to that of benzoic acid. c) Ref. 8. d) Ref. 9.

variation for 1.8×10^{-7} mol dm^{-3} C5 and 1.6×10^{-7} mol dm^{-3} C7 acid solutions (n=7) were 2.1 and 1.9%, respectively.

Some aromatic carboxylic acids were made to react with **2** under the derivatization conditions described above in order to produce fluorescent derivatives which could be separated by HPLC. Table 2 shows the retention time and peak area with the pK_a values of the corresponding acids. The samples prepared from 1.5 mmol dm^{-3} acid solutions were analyzed on an ODS column using 85% methanol as the moving phase. The peak area of the esters increased with increasing pK_a: the esterification of aliphatic, benzoic, and *o*-bromobenzoic acids, of which the pK_a values were 4.7—4.9, 4.21, and 2.85,[8)] occurred in 100, 20, and 3% conversions, respectively. The linear ranges for benzoic and *p*-anisic acids were 98 fmol—490 pmol and 110 fmol—550 pmol; the linear-correlation coefficients were 0.9997 and 0.9998, respectively, and the detection limits (S/N=2) were 50 and 40 fmol. The coefficients of variation for 2.5 mmol dm^{-3} benzoic and 2.8 mmol dm^{-3} *p*-anisic acid solutions (n=7) were 2.3 and 2.1%. No description has been found in the literature concerning the limits and ranges for the determination of aromatic carboxylic acids, except that by Lingeman et al.,[4)] who reported that the limit and range for benzoic acid were 100 fmol (S/N=3) and 0.1—1.0 μg (0.8—8.0 nmol), respectively. The present method was therefore superior to that reported by Lingeman et al.

We wish to express our thanks to Mr. Takashi Tamura and Mr. Kei-ichiro Ohnishi for measuring the NMR spectra and MS, respectively. The present work was partially supported by a Science and Engineering Research Grant-in-Aid from The Science and Engineering Research Institute of Doshisha University.

Mechanism of Reaction of *S,S*-Diphenyl-*S*-methoxythiazyne with Thiols

Toshiaki YOSHIMURA,* Eiichi TSUKURIMICHI, Yasuhisa SUGIYAMA, Hiroshi KITA, Choichiro SHIMASAKI, and Kiyoshi HASEGAWA
Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Gofuku, Toyama 930
(Received March 18, 1991)

Synopsis. The reaction of *S, S*-diphenyl-*S*-methoxythiazyne with various thiols gave methyl sulfides. Kinetic investigations support a mechanism involving an initial protonation of the thiazyne nitrogen with thiol followed by a nucleophilic attack of thiolate anion on the methyl group.

Thiazynes[1] are relatively unusual compounds having an SN triple bond, and their chemistry is mostly unexplored.[2] Only a few fluoro derivatives are known.[2,3] Recently we reported the first preparation of *S,S*-diphenyl-*S*-methoxythiazyne (**1**) from the alkaline hydrolysis of *S,S*-diphenyl-N-bromosulfilimine (**2**) in methanol.[4] The structure of the compound **1** was confirmed by the fact that the compound **1** can readily react with benzenethiol to form methyl phenyl sulfide and *S,S*-diphenylsulfoximine (**3**) quantitatively. Therefore, in order to clarify the mechanism of this interesting methylation reaction, kinetic investigation was carried out.

Results and Discussion

The thiazyne **1** was prepared as a mixture with sulfoximine **3** (**1**:**3**=70:30) by the alkaline hydrolysis of *N*-bromosulfilimine **2** since the thiazyne **1** is hard to be separated.[4] The mixture was allowed to react with substituted benzenethiols, α-toluenethiol, and methyl phenyl sulfide at 30 °C in benzene. The products were analyzed by ^{1}H NMR and gas chromatography and the results are summarized in Table 1.

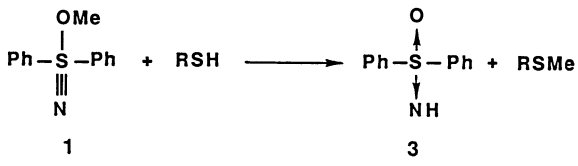
As shown in Table 1, both alkane- and arenethiols gave the corresponding methyl sulfides in high yields but methyl phenyl sulfide showed no reaction. Since the reaction can be readily performed under neutral conditions, this reaction is synthetically useful for methylation of SH groups as is the reaction of diazomethane. Then in order to clarify the mechanism of the reaction, kinetic investigation was carried out in benzene at 20—40 °C using substituted benzenethiols.

The reaction was followed by measuring the increasing GLPC peak of the methyl sulfide formed. The reaction was found to fit the second-order kinetic equation and the results are shown in Table 2.

A small activation energy (29 kJ mol^{-1}) and a large negative activation entropy (−184 JK^{-1} mol^{-1}) were obtained in such nonpolar solvent as benzene suggesting that the reaction involves an ion pair. Contrary to the expectation of negative trend for substituent effect for S_N2 reaction involving a nucleophilic attack of the thiol on the methyl group, a large positive ρ-value (2.63) was obtained from the Hammett plot as shown in Fig. 1.

Since methyl phenyl sulfide does not react with the thiazyne **1**, an active proton is required for this reaction.

Table 1. Reaction of *S,S*-Diphenyl-*S*-methoxythiazyne with Thiols



Thiol	Conditions[a]			RSMe
[RSH]	Time/h	Temp/°C	Solvent	Yield/%[b]

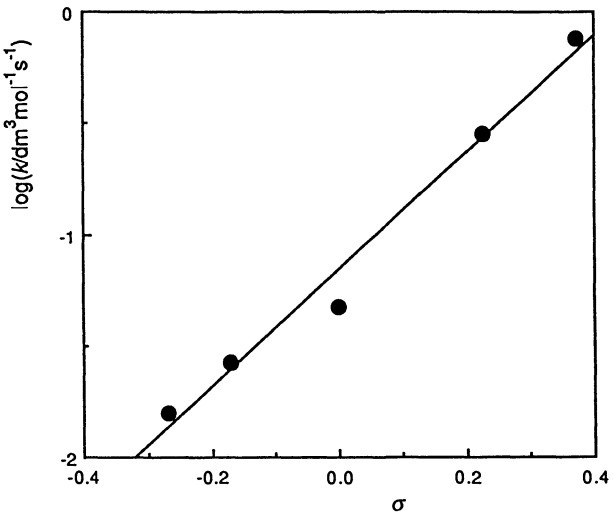

Fig. 1. The Hammett plot for the reaction of *S,S*-diphenyl-*S*-methoxythiazyne (**1**) with substituted benzenethiols.

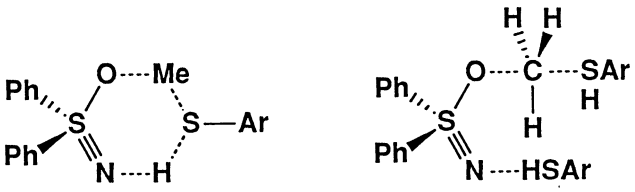

Fig. 2.

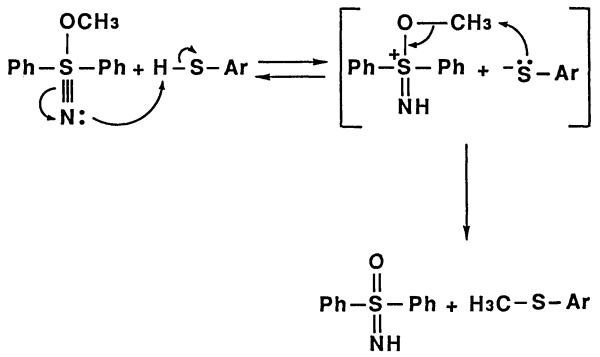
The positive ρ-value suggests that the acidity of thiol is more important than nucleophilicity. There are two possible mechanisms. One is a concerted process involving both proton transfer and nucleophilic attack of thiol sufur to the methyl group. Such a process should involve six-membered transition state or two molecules of thiol as shown in Fig. 2.

However, both mechanisms are unfavorable, because the former involves a nonlinear nucleophilic displacement on the methyl group and the latter is not consistent with present second-order kinetic results. The other one is a two-step mechanism involving an initial protonation of thiol to the nitrogen atom of the thiazyne followed by a nucleophilic attack of thiolate anion to the methyl group as shown in Scheme 1.



Scheme 1.

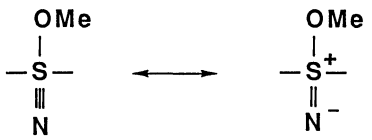


Fig. 3. Resonance structure of methoxythiazyne.

Then in order to examine a possibility of the rate-determining protonation of the nitrogen atom, isotope effect was measured using active proton-deuterated system. The rate constant of the reaction k_D using benzenethiol-*d* was found to be almost the same as k_H (k_H/k_D=1.09). Therefore the rate-determining step cannot be the first protonation step but the second nucleophilic substitution. The lack of appreciable kinetic isotope effect is also inconsistent with the concerted mechanism. The substituent effects for the acidity of benzenethiol are known to be ρ=1.81[5] in 20% EtOH, ρ=2.58[6] in 48% EtOH, and ρ=3.03[7] in 95% EtOH. Namely there is a tendency to increase the ρ-value for acidity in less polar solvent and thus the ρ-value of the predissociation in benzene can be estimated to be more than 3.0. Meanwhile, the substituent effect on benzenethiolate anion for the reaction with benzyl bromide in methanol gives relatively small ρ-values from −0.439 to −1.07 depending on the substituents on benzyl bromide.[8] Although substituent effects depend on substrates and solvents, a smaller negative ρ-value may be expected in the second step nucleophilic substitution reaction. If the substituent effect of the second step is assumed to be small, the observed positive ρ-value can be interpreted as a result of combination of a more positive ρ-value for the first equilibrium protonation step with a negative ρ-value in the second step. From the consideration of this mechanism, it is concluded that the nitrogen atom of the methoxythiazyne is basic to accept the thiol proton and to activate the carbon–oxygen bond to promote the methylation. Therefore the SN triple bond is considered to be polarized as shown in Fig. 3.

Experimental

General. IR spectra were taken on a JEOL-810 spectrometer. GLPC was performed on a Hitachi 163 using a 1-m DEGS column with N_2 gas at 50 ml min^{-1} flow rate. ^{1}H NMR spectra were obtained on a Hitachi R-24B (60MHz) in $CDCl_3$ using TMS as an internal standard.

All reagents were obtained from Wako Pure Chemical Industry Ltd., Tokyo Kasei Co., Ltd. or Aldrich Chemical Co. The reagents and solvents used were further purified by usual methods.

Preparation of *S,S*-Diphenyl-*S*-methoxythiazyne (1).[4] To a stirred solution of *N*-bromosulfilimine[9]**2** (0.4 g, 1.4 mmol) in MeOH (50 ml) was added an aqueous solution of 0.8 M-NaOH (50 ml) (1M=1 mol dm^{-3}). After the solution was warmed at 35 °C for 40 min, it was poured into a cold water, and extracted with $CHCl_3$. The combined extracts were dried over anhydrous Na_2SO_4. The residue obtained by evaporation of the solvent was found to be a mixture of *S,S*-diphenyl-*S*-methoxythiazyne (**1**) (70%) and *S,S*-diphenylsulfoximine (**3**) (30%) from the NMR spectral analysis. ^{1}H NMR and IR spectra were the same as those reported previously.[4]

Reaction of *S,S*-Diphenyl-*S*-methoxythiazyne (1) with Sub-

stituted Benzenethiols. To a solution of the thiazyne **1** in $CDCl_3$ in an NMR tube was added benzenethiol and ^1H NMR was taken immediately. The NMR spectrum showed that the methoxy signal (3.7 ppm) was already disappeared and only one methyl signal was observed at 2.35 ppm which was assigned as that of methyl phenyl sulfide. The solution was analyzed by GLPC to show retention time 52 s consistent with that of the authentic sample. (DEGS, 1 m, column temp 120 °C, injection temp 150 °C, flow rate N_2 50 ml min^{-1})

The reaction of the thiazyne **1** with substituted benzenethiols were carried out in benzene under the conditions shown in Table 1. The product sulfides were all identified by comparing their GLPC retention time with those of the authentic samples and their yields were determined by GLPC calibration curves using naphthalene or methyl phenyl sulfide as an internal standard. The solvent was removed in vacuo and residue was chromatographed on silica gel using chloroform as an eluent to give *S,S*-diphenylsulfoximine (**3**) quantitatively.

Kinetics. A benzene solution of thiazyne **1** (6.0×10^{-3} mol dm^{-3}, 10 ml) and a benzene solution of substituted benzenethiol (1.2×10^{-2} mol dm^{-3}, 10 ml) containing an internal standard (naphthalene 1.2×10^{-2} mol dm^{-3} for PhSH, *p*-$CH_3C_6H_4SH$, and *p*-$CH_3OC_6H_4SH$; methyl phenyl sulfide for *m*- and *p*-ClC_6H_4SH) were immersed in a water bath thermostated at the constant temperature (20—40 °C(±0.1 °C)). After five minutes, two solutions were mixed. At an appropriate time interval, a 0.5 ml portion of the reaction mixture was taken out, added to 1 ml of 1 M-HCl, and shaken to decompose the unreacted thiazyne **1**. The benzene solution was analyzed by GLPC (DEGS, 1 m, column temp 120 °C, injection temp 150 °C). The increasing amount of methyl-substituted phenyl sulfide was followed and the second-order rate constant was calculated by a least squares method using the equation

$$kt = 1n\,((1-fx)/(1-x))/([B]_0-[A]_0)$$

($[A]_0$ is the initial amount of thiazyne **1**, $[B]_0$ is the initial amount of substituted benzenethiol, f is the ratio $[A]_0/[B]_0$, x is the conversion of thiazyne calculated by $(a_t-a_0)/(a_\infty-a_0)$, where a_0 and a_t are the amounts of methyl phenyl sulfide at the initial time and at time t, respectively, and a_∞ is the amount at the infinite time (more than 6 h)).

Isotope Effect. The benzene solution of the thiazyne containing the sulfoximine was shaken with D_2O many times to exchange the NH group to ND and the benzene solution of benzenethiol was also treated similarly with D_2O. The H–D exchange was confirmed by ^1H NMR and IR and the kinetics was carried out similarly.

Preparation of Optically Active Sulfoxides Bearing Heterocycles and Stereoselective Methylation Using Their α-Sulfinyl Carbanions

Takahiro SAGAE, Satoshi OGAWA, and Naomichi FURUKAWA*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received May 16, 1991)

Synopsis. Optically active sulfoxides bearing heterocycles i.e., (1-methyl-2-imidazolyl)methyl and 2-thienylmethyl groups were prepared and their stereoselective methylations were conducted.

Optically active sulfoxides have been widely utilized for asymmetric synthesis,[1] while only a few investigations on the preparation and utilization of optically active heteroaryl sulfoxides have been reported.[2] Recently, we reported the preparation of optically active 2-pyridylmethyl *p*-tolyl sulfoxide (**1**) and highly stereoselective methylation reaction using α-sulfinyl carbanion of **1**.[3] This carbanion also gave highly stereoselective aldol condensation products by treatment with aldehydes.[4] High stereoselectivity of the α-sulfinyl carbanion of **1** observed in the methylation below −70 °C suggests that the structure of carbanion of **1** is highly oriented by chelating Li cation by both the pyridyl nitrogen and the sulfinyl oxygen atoms.[5] This note describes the synthesis of optically active (1-methyl-2-imidazolyl)methyl and 2-thienylmethyl *p*-tolyl sulfoxides (**2** and **3** respectively) together with corresponding racemic sulfoxides and 2-furylmethyl, (1-methyl-2-benzimidazolyl)methyl, and *o*-methoxyphenylmethyl *p*-tolyl sulfoxides (**4**, **5**, and **6** respectively) and a comparison of the stereoselectivity on the methylation reaction of their α-sulfinyl carbanions with iodomethane.

Optically active sulfoxides **2** and **3** were prepared according to the Andersen's procedure[6] as shown in Scheme 1. The reaction of (1-methyl-2-imidazolyl)-

Scheme 1.

methyllithium and *l*-menthyl *p*-toluenesulfinate was carried out in tetrahydrofuran (THF) to give optically active sulfoxide **2** in 41% yield. However, similar treatment of 2-thienylmethyllithium with *l*-menthyl *p*-toluenesulfinate afforded not the desired sulfoxide **3** but 2-[tris(*p*-tolylsulfinyl)methyl]thiophene in quantitative yield and hence the preparation of optically active sulfoxide **3** was performed using the corresponding Grignard reagent generated from 2-(chloromethyl)thiophene. Racemic sulfoxides **2**—**6** were prepared by oxidation of corresponding sulfides with *m*-chloroperbenzoic acid (*m*CPBA) in moderate yields as shown in Scheme 2.

In order to determine the absolute configurations of these sulfoxides **2** and **3**, their CD spectra were taken and compared with those of the sulfoxides (*R*)-(+)-[2-pyridylmethyl *p*-tolyl sulfoxide] (**1**) and (*R*)-(+)-[benzyl *p*-tolyl sulfoxide] (**7**).[7] Mislow has demonstrated that the absolute configurations of optically active compounds having similar structures can be determined by

measurement of their CD spectra and presented the empirical rule that the sulfoxides having positive Cotton curves have *R* configuration and vice versa.[8] The CD spectra are shown in Fig. 1 and the data are summarized in Table 1. The CD spectra of **1**—**3** indicate clearly that all the sulfoxides employed in the present investigation have the same sign of Cotton curves and nearly identical magnitudes of the absorptions $[\theta]_{max}$ even by comparing their spectra with (*R*,*R*)-1-(2-pyridyl)-1-(*p*-tolylsulfinyl)ethane.[3] Therefore, the absolute configurations of sulfoxides **2** and **3** were determined to be *R*.

The methylation reaction was carried out using LDA as a base and then iodomethane in THF as shown in Scheme 3 and Table 2. In the reaction of sulfoxide **2** at −80 °C, *erythro*-1-(1-methyl-2-imidazolyl)]-1-(*p*-tolylsulfinyl)ethane was obtained more preferentially than the *threo* derivative with a ratio of 12.3 : 1. This result reveals that the reaction of the carbanion with iodomethane proceeds via a nearly identical manner with the methylation of sulfoxide **1**, namely via an initial formation of a rigid chelation complex which prevents the approach of iodomethane from its *threo* site as shown in Fig. 2. Interestingly, stereoselectivity for the methylation of the carbanion generated from **2** is rather insensitive to the reaction temperature. This result is markedly contrasted to methylations of other sulfoxides. In the case of sulfoxides **3**—**6** the ratios of isomers were found not to be as high as those obtained from **1** and **2** suggesting that their α-sulfinyl carbanions are unable to form a rigid chelation complexes. These results also support that the chelation of Li cation by the heteroatoms plays an important role in the stereoselectivity. The values of log(*erythro*/*threo*) of the methylation products shown in Table 2 were plotted against the temperatures giving straight lines and the $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ values were calculated by conventional Arrhenius equation; $\Delta\Delta G^{\neq}=\Delta\Delta H^{\neq}-T\Delta\Delta S^{\neq}=-RT \ln[erythro]/[threo]$. The results are summarized in Table 3.

Table 3. Activation Parameter for Methylation of Sulfoxides **2**, **3**, and **4**

Sulfoxide	$\Delta\Delta H^{\neq}$/kJ mol^{-1}	$\Delta\Delta S^{\neq}$/kJ mol^{-1} deg^{-1}
2	1.40	−13.55
3	5.48	16.93
4	6.12	19.62

The results are consistent roughly with our previous result obtained from the methylation reaction of the α-sulfinyl carbanion of **1** with iodomethane. The present results demonstrate that the carbanion generated from sulfoxide **2** is somewhat different from that of other sulfoxides bearing heterocycles. Among these heterocycles, 1-methylimidazolyl group should have highest capability for chelation with Li cation to provide a conformer which is attacked preferentially by iodomethane from the *erythro* site, thus enhancing the *erythro* stereoselectivity of its carbanion. The present investigation demonstrates the synthetic utility of the sulfoxides bearing azaheterocycles.

Experimental

All melting points are uncorrected. IR spectra were recorded on a JASCO A-3 spectrometer. ^{1}H NMR spectra were obtained with a Hitachi R-600 or a Bruker AM-500, or a JEOL EX-270. Preparative liquid chromatography was performed on a Japan Analytical Co., Ltd., LC-09. Elemental analyses were carried out by Chemical Analysis Center at this university. The CD spectra were measured on a JASCO J-600 spectrometer. All reagents were obtained from Wako Pure Chemical Industries Ltd., Tokyo Kasei Co., Ltd., or Aldrich Chemical Co. The solvents were purified by general methods.

Preparation of Optically Active Sulfoxides. (*R*)-(+)-[(1-Methyl-2-imidazolyl)methyl *p*-Tolyl Sulfoxide] (2). To a stirred solution of 1,2-dimethylimidazole (9.6 g, 0.1 mol) in THF (300 mL) at −78 °C was added 1.66 M *n*-BuLi (1 M=1 mol dm^{-3}) in hexane solution (65 mL, 0.11 mol). The mixture was stirred at 0 °C for 30 min and then cooled to −78 °C. The mixture was added dropwise to (*S*)-(−)-*l*-menthyl *p*-toluenesulfinate (29.5 g, 0.1 mol) in THF (300 mL) with stirring at −78 °C for 0.5 h and then −20 °C for 4 h. After hydrolysis and neutralization with aqueous ammonium chloride, the mixture was extracted with chloroform (3×500 mL). The extract was dried over anhydrous magnesium sulfate and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica gel; eluent, ethyl acetate–methanol=10 : 1) to give sulfoxide **2** in 41% yield. Recrystallization from benzene–hexane gave colorless crystals; mp 86—87 °C; ^{1}H NMR ($CDCl_3$) δ=7.36 (d, J=8 Hz, 2H, 2,6-ArH), 7.29 (d, J=8 Hz, 2H, 3,5-ArH), 6.99 (d, J=1 Hz, 1H, 5-ImdH), 6.82 (d, J=1 Hz, 1H, 4-ImdH), 4.26, 4.10 (ABq, J=15 Hz, 2H, CH_2), 3.45 (s, 3H, Imd-CH_3), 2.41 (s, 3H, Ar-CH_3); IR (KBr) 1050 cm^{-1} (SO); $[\alpha]_D$ +177.9° (c=0.5, acetone). Optical purity was estimated ca. 100% by ^{1}H NMR using Eu(tfc)$_3$ as a chiral shift reagent. Found: C, 61.47 H, 6.02; N, 11.92%. Calcd for $C_{12}H_{14}N_2OS$: C, 61.51; H, 6.02; N, 11.96%.

(*R*)-(+)-[2-Thienylmethyl *p*-Tolyl Sulfoxide] (3). This sulfoxide was prepared similarly as sulfoxide **2** using 2-thienylmethylmagnesium chloride. Yield 18%; mp 123—124 °C; ^{1}H NMR ($CDCl_3$) δ=7.33 (d, J=8 Hz, 2H, 2,6-ArH), 7.25 (d, J=8 Hz, 2H, 3,5-ArH), 7.23—7.22 (m, 1H, 5-ThH), 6.94—6.92 (m, 1H, 4-ThH), 6.74 (m, 1H, 3-ThH), 4.24, 4.19 (ABq, J=14 Hz, 2H, CH_2), 2.40 (s, 3H, CH_3); IR (KBr) 1040 cm^{-1} (SO); MS (m/z) 139 (M^+−97); $[\alpha]_D$ +139.7° (c=0.5, chloroform). Found: C, 60.94; H, 5.14%. Calcd for $C_{12}H_{12}OS_2$: C, 60.98; H, 5.12%.

Preparation of Racemic Sulfoxides Bearing Heterocycles. (1-Methyl-2-imidazolyl)methyl *p*-Tolyl Sulfoxide (2). Yield 52%; mp 128—130 °C; ^{1}H NMR ($CDCl_3$) δ=7.36 (d, J=8 Hz, 2H, 2,6-ArH), 7.29 (d, J=8 Hz, 2H, 3,5-ArH), 6.99 (d, J=1 Hz, 1H, 5-ImdH), 6.82 (d, J=1 Hz, 1H, 4-ImdH), 4.26, 4.10 (ABq, J=15 Hz, 2H, CH_2), 3.45 (s, 3H, Imd-CH_3), 2.41 (s, 3H, Ar-CH_3); IR (KBr) 1050 cm^{-1} (SO). Found: C, 61.44; H, 6.03; N, 11.92%. Calcd for $C_{12}H_{14}N_2OS$: C, 61.51; H, 6.02; N, 11.96%.

2-Thienylmethyl *p*-Tolyl Sulfoxide (3). Yield 93%; mp 95—96 °C; ^{1}H NMR ($CDCl_3$) δ=7.33 (d, J=8 Hz, 2H, 2,6-ArH), 7.25 (d, J=8 Hz, 2H, 3,5-ArH), 7.23—7.22 (m, 1H, 5-ThH), 6.94—6.92 (m, 1H, 3-ThH), 6.74 (m, 1H, 4-ThH), 4.24, 4.19 (ABq, J=14 Hz, 2H, CH_2), 2.40 (s, 3H, CH_3); IR (KBr) 1040 cm^{-1} (SO). Found: C, 61.02; H, 5.23%. Calcd for $C_{12}H_{12}OS_2$: C, 60.98; H, 5.12%.

2-Furylmethyl *p*-Tolyl Sulfoxide (4). Yield 74%; colorless liquid; ^{1}H NMR ($CDCl_3$) δ=7.37 (d, J=8 Hz, 2H, 2,6-ArH), 7.33 (m, 1H, 5-FurH), 7.28 (d, J=8 Hz, 2H, 3,5-ArH), 6.31 (m, 1H, 3-FurH), 6.15 (m, 1H, 4-FurH), 4.15, 4.02 (ABq, J=14 Hz, 2H, CH_2), 2.41 (s, 3H, CH_3); IR (neat) 1040 cm^{-1} (SO). Found: C, 65.30; H, 5.52%. Calcd for $C_{12}H_{12}O_2S$: C, 65.43; H, 5.49%.

(1-Methyl-2-benzimidazolyl)methyl *p*-Tolyl Sulfoxide (5). Yield 12%; mp 157—160 °C; ^{1}H NMR ($CDCl_3$) δ=7.72—7.24 (m, 8H, ArH), 4.43, 4.29 (ABq, J=15 Hz, 2H, CH_2), 3.67 (s, 3H, BzImd-CH_3), 2.40 (s, 3H, Ar-CH_3); IR (KBr) 1010 cm^{-1} (SO). Found: C, 67.75; H, 5.51; N, 9.87%. Calcd for $C_{16}H_{16}N_2OS$: C, 67.58; H, 5.67; N, 9.85%.

***o*-Methoxyphenylmethyl *p*-Tolyl Sulfoxide (6).** Yield 90%; colorless liquid; ^{1}H NMR ($CDCl_3$) δ=7.49—6.69 (m, 8H, ArH), 4.18, 4.00 (ABq, J=14 Hz, 2H, CH_2), 3.67 (s, 3H, OCH_3), 2.38 (s, 3H, Ar-CH_3); IR (neat) 1030 cm^{-1} (SO). Found : C, 68.97; H, 6.17%. Calcd for $C_{15}H_{16}O_2S$: C, 69.20; H, 6.19%.

Methylation of Lithiated Sulfoxides 2—6 with Iodomethane. Typical experimental procedure is as follows: Sulfoxide **2** (200 mg, 0.854 mmol) was dissolved into THF (10 mL) under argon atmosphere. The solution was cooled to −80 °C, and solution of LDA (0.928 mmol) in THF (2.7 mL) was added with stirring for 30 min. To this solution was added iodomethane (0.27 mL, 4.34 mmol) and the mixture was stirred for 8 h. The reaction was stopped by adding water (5 mL) and the mixture was warmed to room temperature. After hydrolysis and neutralization with aqueous ammonium chloride, the mixture was extracted with chloroform (3×30 mL) and dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was purified by column chromatography (silica gel; eluent, ethyl acetate) to give 1-(1-methyl-2-imidazolyl)-1-(*p*-tolylsulfinyl)ethane in 87% yield. The products contained in 12.3 : 1 ratio of *erythro* and *threo* isomers. The *erythro* isomer was separated by preparative liquid chromatography. Mp 128—130 °C; ^{1}H NMR ($CDCl_3$) δ=7.28 (s, 4H, ArH), 7.02 (m, 1H, 5-ImdH), 6.92 (m, 1H, 4-ImdH), 4.14 (q, J=7 Hz, 1H, CH), 3.68 (s, 3H, Imd-CH_3), 2.42 (s, 3H, Ar-CH_3), 1.53 (d, J=7 Hz, 3H, CH-CH_3); IR (KBr) 1030 cm^{-1} (SO); MS (m/z) 246 (M^+). Found: C, 62.59 ; H, 6.60; N, 11.29%. Calcd for $C_{13}H_{16}N_2OS$: C, 62.87; H, 6.49; N, 11.28%. The *threo* isomer could not be isolated and was determined the structure by ^{1}H NMR chemical shifts of the mixture. Other sulfoxides were treated similarly and the ratios of isomers were determined by ^{1}H NMR spectra.

This work was supported by a Grant-in-Aid No. 02453018 from the Ministry of Education, Science and Culture.

Simple Preparation of (2,2′-Biphenylylene)phenylphosphine Oxide and Role of Triphenylphosphine Oxide as a Mediator for Formation of Biaryl Derivatives

Satoshi OGAWA, Yoko TAJIRI, and Naomichi FURUKAWA*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received May 16, 1991)

Synopsis. (2,2′-Biphenylylene)phenylphosphine oxide (**3**) was prepared simply by the reaction of triphenylphosphine oxide (**1**) with phenyllithium and subsequently with aqueous hydrogen peroxide in acetic acid. The oxide **3** reacted with lithium diisopropylamide (LDA) and then with several electrophiles to afford regiospecifically ortho-substituted compounds in moderate yields, which were converted to unsymmetrical 2- and 2,3′-substituted 1,1′-biaryls and triphenylphosphine oxide (**1**).

Although numerous phosphines have been utilized in modern organic synthesis, i.e., as starting materials for Wittig reagents[1] and ligands for transition metals,[2] phosphine oxides have been investigated a little and considered as undesired end products for the reactions. The P=O bond energy of triphenylphosphine oxide (**1**) is quite high (130 kcal) and is hardly reduced by simple reducing reagents.[3] This might prevent the utilization of **1** in organic synthesis. Recently, we found that triarylphosphine oxides, diaryl sulfoxides, and diaryl selenoxides underwent facile ligand exchange by the reactions with organolithium reagents.[4] On the other hand, we reported a new ortho-lithiation reaction of diaryl sulfoxides.[5] In the course of studies on the reactions of oxides derived from heteroatom (group 15 or 16 elements)-containing compounds with organolithium or Grignard reagents, we found that the ring closure reaction of triphenylphosphine oxide (**1**) on treatment with phenyllithium took place together with elimination of the oxygen atom to afford (2,2′-biphenylylene)phenylphosphine (**2**) in moderate yield. In this note, we report simple preparation of (2,2′-biphenylylene)phenylphosphine oxide (**3**) and its application for the synthesis of unsymmetrical biaryls. We also emphasize that **1** works as a mediator for the synthesis of biaryls.

When **1** was allowed to react with phenyllithium in refluxing tetrahydrofuran (THF), (2,2′-biphenylylene)-phenylphosphine (**2**) was obtained in 65% yield. Then **2** was treated with aqueous hydrogen peroxide in acetic acid to afford (2,2′-biphenylylene)phenylphosphine oxide (**3**) in 93% yield. In the reaction of **1** with phenyllithium intramolecular carbon-carbon bond formation at the ortho-positions of the two phenyl rings and reduction of phosphine oxide to phosphine took place simultaneously. Although it is hardly to argue the reaction mechanism, the following mechanism involving initial proton abstraction by phenyllithium then the incipient formation of **A** which was also suggested in the reaction of tetraphenylphosphonium salt with organolithium reagents[6] could be the probable process as shown in Scheme 1. Apparently, when one used two equivalents of phenyllithium, **2** was obtained in highest yield, namely, the reactions of **1** with one and two equivalents of phenyllithium gave **2** in 11 and 65% yields respectively. When **3** was treated with LDA and then with electrophiles at −78 °C, lithiation took place regiospecifically at the 3-position in the biphenyl ring to give monosubstituted compounds **4** in moderate yields as shown in Scheme 2 and Table 1. These 3-substituted (2,2′-biphenylylene)phenylphosphine oxides **4** reacted with phenyllithium to give the corresponding substitution products **5** in moderate yields. However, the second electrophile could not be introduced at the 2′-position in the biphenyl ring. These results seem to indicate that in the reactions of lithiated **4** with electrophiles the steric or electronic effect by the one substituent at the 3′-position prevents the approach for the second electrophile at the 2′-position. Although two substituents could not be introduced in one phenyl ring of biphenyl, **5** reacted initially with phenyllithium and subsequently with electrophiles to afford 2,3′-disubstituted 1,1′-biaryls **6** and triphenylphosphine oxide (**1**) in good yields as shown in Scheme 3 and Table 2. The recovered **1** can be used again as a starting material for

the simple reaction system to prepare unsymmetrical biaryls **6** and hence **1** plays a role of a mediator for the system. These procedures can expand the scope for the syntheses of unsymmetrical biaryls.

Experimental

All melting points are uncorrected. IR spectra were recorded on a JASCO FT/IR-5000 spectrometer. NMR spectra were obtained with a Hitachi R-600, a JEOL EX 270, or a Bruker AM-500. Mass spectra were taken with a Hitachi RMU-6MG, a Shimadzu GCMS QP-2000A, or a JEOL JMS-SX 102 mass spectrometer. Elemental analyses were carried out by Chemical Analysis Center at this University. All reagents were obtained from Wako Pure Chemical Industries, Ltd. or Aldrich Chemical Co. The reaction solvents were further purified by general methods.

Synthesis of (2,2′-Biphenylylene)phenylphophine (2). To a stirred solution of **1** (2.8 g, 10.0 mmol) in THF (80 mL) at 0 °C under N_2 atmosphere was added 1.8 M (1 M=1 mol dm^{-3}) phenyllithium (11.2 mL, 20.1 mmol). The mixture was refluxed for 12 h. After hydrolysis, the solvent was removed under reduced pressure. To the residue was added water (100 mL) and the mixture was neutralized with 1 M hydrochloric acid, extracted with dichloromethane (3×100 mL). The extract was dried with anhydrous magnesium sulfate, and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica gel; eluent, hexane–ethyl acetate=4:1) to give phosphine **2** in 65% yield. Recrystallization from ethyl acetate gave colorless crystals; mp 92—93 °C (lit,[7] 93—94 °C); ^{1}H NMR (500 MHz, $CDCl_3$) δ=7.18—7.25 (m, 3H, 3,4,5-PhH), 7.27—7.31 (m, 4H, 5,5′,6,6′-BiphH), 7.43 (t, J=7.8 Hz, 2H, 4,4′-BiphH), 7.66—7.71 (m, 2H, 2,6-PhH), 7.92 (d, J=7.8 Hz, 2H, 3,3′-BiphH); ^{31}P NMR (109 MHz, $CDCl_3$) δ=−11.6; MS m/z 260 (M^+).

Synthesis of (2,2′-Biphenylylene)phenylphosphine Oxide (3). To a stirred solution of **2** (260 mg, 1.0 mmol) in acetic acid (30 mL) was added 30% aqueous hydrogen peroxide (0.0168 mL, 1.47 mmol). The mixture was stirred at room temperature for 3 h, and the solvent was removed under reduced pressure. The residue was dissolved in dichloromethane (40 mL) and washed with saturated aqueous sodium hydrogencarbonate (3×30 mL) and saturated aqueous sodium chloride (2×30 mL). The organic layer was dried with anhydrous magnesium sulfate, and the solvent was evaporated under reduced pressure. The residue was recrystallized with ethyl acetate to give phosphine oxides **3** as colorless crystals in 93% yield. Mp 159—162 °C (lit,[8] 162—164.5 °C); ^{1}H NMR (500 MHz, $CDCl_3$) δ=7.37 (t, J=7.5 Hz, 2H, 4,4′-BiphH), 7.38 (t, J=7.3 Hz, 2H, 3,5-PhH), 7.48 (t, J=7.3 Hz, 1H, 4-PhH), 7.58 (t, J=7.5 Hz, 2H, 5,5′-BiphH), 7.65 (dd, J_{PCCH}=12.8, J=7.3 Hz, 2H, 2,6-PhH), 7.71 (dd, J_{PCCCH}=8.6, J=7.5 Hz, 2H, 6,6′-BiphH), 7.82 (dd, J_{PCCH}=2.9, J=7.5 Hz, 2H, 3,3′-BiphH); ^{31}P NMR (109 MHz, $CDCl_3$) δ=32.2; IR (KBr) 1195 cm^{-1} (PO); MS m/z 276 (M^+).

Reactions of (2,2′-Biphenylylene)phenylphosphine Oxide (3) with LDA and Electrophiles. To a stirred solution of **3** (276 mg, 1.0 mmol) in THF (10 mL) was added 0.17 M LDA (6.0 mL, 1.0 mmol) in THF solution under N_2 atmosphere at −78 °C for 3 h. To the mixture was added trimethylsilyl chloride (0.30 mL, 2.4 mmol) and the mixture was stirred at −78 °C for 3 h. After hydrolysis, the solvent was removed under reduced pressure. To the residue was added water (40 mL) and the mixture was neutralized with 1 M hydrochloric acid, extracted with dichloromethane (3×40 mL). The extract was dried with anhydrous magnesium sulfate, and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica gel; eluent, ethyl acetate) to give **4a** in 52% yield. Recrystallization from hexane–ethyl acetate gave colorless crystals; mp 189—190 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=0.17 (s, 9H, CH_3), 7.29—7.86 (m, 12H, PhH, BiphH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=0.0 (s), 120.8 (d, ^2J=9.8 Hz), 121.5 (d, ^2J=10.0 Hz), 128.6 (d, ^3J=12.3 Hz), 129.1 (d, ^3J=9.6 Hz), 129.3 (d, ^3J=10.8 Hz), 131.0 (d, ^3J=12.3 Hz), 131.4 (d, ^4J=2.6 Hz), 131.8 (d, ^4J=2.7 Hz), 132.6 (d, ^1J=106.7 Hz), 132.9 (s), 133.1 (d, ^1J=106.7 Hz), 135.8 (d, ^3J=14.0 Hz), 137.6 (d, ^1J=108.8 Hz), 140.6 (d, ^2J=21.6 Hz), 142.5 (d, ^2J=24.8 Hz), 145.7 (d, ^2J=16.3 Hz); ^{31}P NMR (109 MHz, $CDCl_3$) δ=32.9; IR (KBr) 1207 cm^{-1} (PO); MS m/z 348 (M^+). Found: C, 72.22; H, 6.06%. Calcd for $C_{21}H_{21}OPSi$: C, 72.38; H, 6.07%. Phosphine oxides **4b** and **4c** were obtained as two diastereomers by the same procedure as **4a**.

4b: One diastereomer; colorless crystals; mp 258—260 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=6.00 (s, 1H, CH), 6.99—7.00 (m, 1H, 2′-ArH), 7.12—7.14 (m, 2H, 3′,5′-ArH), 7.19—7.22 (m, 2H, 4′,6′-ArH), 7.35—7.41 (m, 4H, 4,4′,6,6′-BiphH), 7.48 (t, J=7.4 Hz, 1H, 4-PhH), 7.59—7.65 (m, 2H, 5,5′-BiphH), 7.64 (d, J_{PCCH}=12.9 Hz, 1H, 3′-BiphH), 7.68 (t, J=7.4 Hz, 2H, 3,5-PhH), 7.79 (dd, J_{PCCH}=47.2 Hz, J=7.4 Hz, 2H, 2,6-PhH); ^{31}P NMR (109 MHz, $CDCl_3$) δ=35.8; IR (KBr) 3206 (OH), 1185 cm^{-1} (PO). Found: m/z 382.1136. Calcd for $C_{25}H_{19}O_2P$: M, 382.1123.

The other diastereomer; colorless crystals; mp 240—242.5 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=6.05 (s, 1H, CH), 7.05—7.07 (m, 2H, 2′,6′-ArH), 7.08—7.09 (m, 1H, 4′-ArH), 7.15—7.17 (m, 2H, 3′,5′-ArH), 7.25—7.27 (m, 2H, 4,4′-BiphH), 7.34 (d, J=7.2 Hz, 2H, 6,6′-BiphH), 7.38 (t, J=7.8 Hz, 1H, 4-PhH), 7.44 (d, J=7.2 Hz, 1H, 5-BiphH), 7.46 (d, J=7.2 Hz, 1H, 5′-BiphH), 7.55 (d, J=7.8 Hz, 2H, 3,5-PhH), 7.61 (d, J_{PCCH}=15.0 Hz, 1H, 3′-BiphH), 7.79 (dd, J_{PCCH}=28.2 Hz, J=7.8 Hz, 2H, 2,6-PhH); ^{31}P NMR (109 MHz, $CDCl_3$) δ=35.7; IR (KBr) 3258 (OH), 1180 cm^{-1} (PO). Found: m/z 382.1112. Calcd for $C_{25}H_{19}O_2P$: M, 382.1123.

4c: One diastereomer; colorless crystals; mp 214—215.5 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.36 (d, J=6.5 Hz, 3H, CH_3), 5.10 (q, J=6.5 Hz, 1H, CH), 7.33—7.35 (m, 2H, 4,4′-BiphH), 7.37—7.39 (m, 2H, 6,6′-BiphH), 7.46 (t, J=7.5 Hz, 1H, 4-PhH), 7.54—7.58 (m, 2H, 5,5′-BiphH), 7.62 (d, J_{PCCH}=12.4 Hz, 1H, 3′-BiphH), 7.64 (t, J=7.5 Hz, 2H, 3,5-PhH), 7.78 (dd, J_{PCCH}=33.8, J=7.5 Hz, 2H, 2,6-PhH); ^{31}P NMR (109 MHz, $CDCl_3$) δ=34.4; IR (KBr) 3292 (OH), 1193 cm^{-1} (PO). Found: m/z 320.0928. Calcd for $C_{20}H_{17}O_2P$: M, 320.0966.

The other diastereomer; colorless crystals; mp 222.5—224.5 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.30 (d, J=6.2 Hz, 3H, CH_3), 5.06 (q, J=6.2 Hz, 1H, CH), 7.36—7.39 (m, 4H, 4,4′,6,6′-BiphH), 7.47 (t, J=7.8 Hz, 1H, 4-PhH), 7.55—7.58 (m, 2H, 5,5′-BiphH), 7.61 (d, J_{PCCH}=12.4 Hz, 1H, 3′-BiphH), 7.64 (t, J=7.8 Hz, 2H, 3,5-PhH), 7.78 (dd, J_{PCCH}=45.9, J=7.8 Hz, 2H, 2.6-PhH); ^{31}P NMR (109 MHz, $CDCl_3$) δ=34.9; IR (KBr) 3296 (OH), 1185 cm^{-1} (PO). Found: m/z 320.0937. Calcd for $C_{20}H_{17}O_2P$: M, 320.0966.

Reactions of (2,2′-Biphenylylene)phenylphosphine Oxide (3) and [(3-Trimethylsilyl)-2,2′-biphenylylene]phenylphosphine Oxide (4a) with Phenyllithium. In a typical run, to a stirred solution of **3** (276 mg, 1.0 mmol) in THF (15 mL) at −78 °C under N_2 atmosphere was added 1.8 M phenyllithium (0.8 mL, 1.5 mmol). The mixture was stirred at −78 °C for 30 min. After hydrolysis, the solvent was removed under reduced pressure. To the residue was added water (30 mL) and the mixture was neutralized with 1 M hydrochloric acid, extracted with dichloromethane (3×30 mL). The extract was dried with anhydrous magnesium sulfate, and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica gel; eluent, dichloromethane, ethyl acetate) to give **5a** in 95% yield. Recrystallization from ethyl acetate gave colorless crystals; mp 148.5—150 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=7.01—7.58 (m, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=126.5 (d, ^3J=12.3 Hz), 127.1 (s), 127.2 (s), 128.0 (d, ^3J=12.0 Hz), 130.1 (s), 131.1 (d, ^4J=2.2 Hz), 131.5 (d, ^2J=9.4 Hz), 131.7 (s), 131.7 (d, ^1J=101.1 Hz), 131.9 (d, ^2J=10.1 Hz), 133.1 (d, ^1J=103.6 Hz), 134.0 (d, ^3J=12.1 Hz), 140.3 (d, ^3J=4.4 Hz), 147.7 (d, ^2J=8.9 Hz); ^{31}P NMR (109 MHz, $CDCl_3$) δ=26.3; IR (KBr) 1191 cm^{-1} (PO); MS m/z 354 (M^+). Found: C, 81.15; H, 5.40%. Calcd for $C_{24}H_{19}OP$: C, 81.34; H, 5.40%.

5b: Colorless crystals; mp 137.5—138.5 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=0.14 (s, 9H, CH_3), 7.05—7.57 (m, 18H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=−1.1 (s), 126.6 (d, ^3J=12.3 Hz), 126.7 (s), 128.0 (d, ^3J=11.7 Hz), 130.7 (s), 131.0 (d, ^4J=2.7 Hz), 131.6 (d, ^2J=9.1 Hz), 131.6 (d, ^1J=100.0 Hz), 131.7 (d, ^4J=2.3 Hz), 132.0 (d, ^2J=10.0 Hz), 132.1 (s), 133.0 (d, ^1J=104.0 Hz), 134.2 (d, ^3J=12.0 Hz), 134.7 (s), 139.1 (s), 139.7 (d, ^3J=3.8 Hz), 147.9 (d, ^2J=9.0 Hz); ^{31}P NMR (109 MHz, $CDCl_3$) δ=27.1; MS m/z 426 (M^+). Found: C, 75.97; H, 6.55%. Calcd for $C_{27}H_{27}OPSi$: C, 76.02; H, 6.38%.

Reactions of (2-Biphenylyl)diphenylphosphine Oxide (5a) and [3′-(Trimethylsilyl)-2-biphenylyl]diphenylphosphine Oxide (5b) with Phenyllithium. In a typical run, to a stirred solution of **5a** (200 mg, 0.6 mmol) in THF (10 mL) was added 1.8 M phenyllithium (1.0 mL, 1.8 mmol) in THF solution under N_2 atmosphere at −78 °C for 30 min. To the mixture was added acetaldehyde (0.05 mL, 0.9 mmol) and the mixture was stirred at −20 °C for 3 h. After hydrolysis, the solvent was removed under reduced pressure. To the residue was added water (30 mL) and the mixture was neutralized with 1 M hydrochloric acid, extracted with dichloromethane (3×30 mL). The extract was dried with anhydrous magnesium sulfate, and the solvent was evaporated under reduced pressure. The residue was purified by column chromatography (silica gel; eluent, hexane–ethyl acetate=1 : 2) to give 2-(1-hydroxyethyl)biphenyl (**6d**) and **1** in 55% and 63% yields respectively.

6d: Mp 105—107 °C (lit,[9] 111—112 °C); ^{1}H NMR ($CDCl_3$) δ=1.40 (d, J=6.6 Hz, 3H, CH_3), 4.98 (q, J=6.6 Hz, 1H, CH), 7.21—7.62 (m, 9H, ArH); IR (KBr) 3252 cm^{-1} (OH); MS m/z 198 (M^+). Found: C, 84.66; H, 7.12%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

6b: Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=0.00 (s, 9H, CH_3), 7.15—7.70 (m, 9H, ArH); MS m/z 226 (M^+). Found: C, 79.17; H, 7.96%. Calcd for $C_{15}H_{18}Si$: C, 79.58; H, 8.01%.

6c: Mp 144—145 °C (lit,[10] 146—147 °C); ^{1}H NMR ($CDCl_3$) δ=5.93 (s, 1H, CH), 7.18—7.56 (m, 14H, ArH); IR (KBr) 3358 cm^{-1} (OH); MS m/z 260 (M^+).

6e: Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=0.18 (s, 9H, CH_3), 7.30—8.90 (m, 9H, ArH); MS m/z 266 (M^+). Found: C, 79.71; H, 8.09%. Calcd for $C_{15}H_{18}Si$: C, 79.58; H, 8.01%.

6f: Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=0.29 (s, 9H, CH_3), 0.35 (s, 9H, CH_3), 7.27—7.46 (m, 8H, ArH). Found: m/z 298.1539. Calcd for $C_{18}H_{26}Si_2$: M, 298.1573.

6g: Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=0.28 (s, 9H, CH_3), 1.44 (d, J=6.6 Hz, 3H, CH_3), 4.44 (q, J=6.6 Hz, CH), 7.21—7.62 (m, 8H, ArH); IR (KBr): 3294 cm^{-1} (OH); MS m/z 270 (M^+). Found: C, 75.79; H, 8.38%. Calcd for $C_{17}H_{22}OSi$: C, 75.50; H, 8.20%.

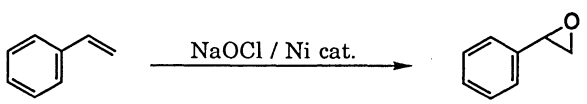
Nickel-Catalyzed Epoxidation of Olefins with NaOCl

Shigekazu YAMAZAKI* and Yasuyuki YAMAZAKI
Toyama Industrial Technology Center, 150 Futagami, Takaoka, Toyama 933
(Received May 18, 1991)

Synopsis. Nickel complexes of bidentate heterocyclic amines such as 2,2′-bipyridine and 1,10-phenanthroline have been found to be active catalysts for the epoxidation of olefins with hypochlorite as terminal oxidant. Nickel complex of 1-methylimidazole which is monodentate ligand also indicated epoxidation ability.

The development of inexpensive systems for the direct epoxidation of olefins is one of the most important theme both industrial and academic field of synthetic chemistry,[1] because epoxides are important intermediates of variety of useful products. And the design of convenient catalytic systems using simple metal complexes with inexpensive oxygen donors such as H_2O_2, *t*-BuOOH and NaOCl as terminal oxidant is current interest.[2] Epoxidation of olefins was extensively investigated in relation to the enzymatic oxygenation for the last decade with metal complex catalysts.[3] In these studies, manganese, iron, and chromium complexes of porphyrins and Schiff bases were chosen as catalysts. Recently, nickel complexes such as Ni(salen)[4] and Ni(cyclam) have been reported to act as catalysts for the epoxidation of olefins with NaOCl[5,6] and PhIO[7,8] as the terminal oxidants.[9] Here we report our results on the epoxidation of olefins catalyzed by nickel complexes of bidentate heterocyclic amine ligands such as 2,2′-bipyridine and 1,10-phenanthroline with NaOCl.



Results and Discussion

The results of the epoxidation of styrene by some nickel complexes of heterocyclic amines with NaOCl were summarized in Table 1. The epoxidation of styrene were performed typically by stirring the mixture of styrene, aqueous solution of nickel catalyst and NaOCl at room temperature. Styrene oxide was mainly obtained, and a considerable amount of benzoic acid was also produced. Among the bidentate ligands examined, 2,2′-bipyridine gave the best result on the selectivity of styrene oxide. $Ni(bpy)Cl_2$ and $Ni(bpy)_2Cl_2$ showed almost the same results (Run 3). Use of organic solvents such as CH_2Cl_2 and benzene in the epoxidation of styrene decreased the selectivity of epoxide (Run 2). Monodentate ligands such as 1-methylimidazole also indicated epoxidation ability but lowered the yield of the epoxide (Run 6).

Unlike the nickel complex catalyzed epoxidation reaction reported so far, the nickel complex described here is used as aqueous solution. Fine black precipitates which act as catalyst were appeared in a few minutes by the addition of NaOCl to the aqueous nickel complex solution. So the quaternary ammonium salts were not effective in this system as the phase-transfer catalysts.[5,6]

Table 2 showed the results of the epoxidation of styrene with various amount of $Ni(bpy)_2Cl_2$ catalyst. The best yield of styrene oxide was obtained when 2 mol% of $Ni(bpy)_2Cl_2$ was used (Run 3). The lower amount of catalyst decreased the selectivity of epoxide (Runs 4—7). On the other hand, the use of higher amount of catalyst did not increase the yield of epoxide (Runs 1, 2), and the conversion of styrene were lowered. When $Ni(bpy)_2Cl_2$ and NaOCl were mixed without styrene, NaOCl decomposed with evolution of gas. These results indicated that considerable amounts of NaOCl decomposed without the oxygen transfer to styrene, when large amount of nickel complex existed.

Epoxidations of other olefins were also investigated, and the results were summarized in Table 3. CH_2Cl_2

Table 1. Nickel Complexes-Catalyzed Epoxidation of Styrene with NaOCl[a]

Run	$Ni(L)_nCl_2$	Conv./%[b]	Yield/% Styrene oxide[b]	Yield/% Benzoic acid[c]

was used as organic solvent in the epoxidation of *trans*-stilbene and norbornene which were solid at room temperature. The epoxidation of olefins were proceeded smoothly under the same reaction conditions with styrene oxide. But the yields of the epoxides were lower than the case of styrene. In the epoxidation of α-methylstyrene, epoxide was mainly obtained in 53% yield with acetophenone and benzoic acid in 12% and 15% yields respectively. The epoxide obtained by the oxidation of *trans*-β-methylstyrene was *trans*-epoxide only. On the other hand, both *trans*- and *cis*-epoxides were obtained in the epoxidation of *cis*-β-methylstyrene in 17% and 8% yields respectively. The epoxide obtained in the epoxidation of *trans*- and *cis*-stilbene were *trans*-stilbene oxide. These results show that this epoxidation is proceeded by radical process. Contrary to the case of styrene, in the epoxidation of cyclohexene and *cis*-stilbene, use of CH_2Cl_2 as organic solvent gave better selectivities of epoxides than the reaction without organic solvent.

Conclusion

The bidentate heterocyclic amines such as 2,2′-bipyridine and 1,10-phenanthroline are good ligands for nickel-catalyzed olefin epoxidation with NaOCl. Bipyridines were more readily available than porphyrin and Schiff base ligands, so the use of catalyst having bipyridine ligand must provide synthetically useful method for the epoxidation of olefins. Since the selectivity of epoxides by the system described above were not satisfactory, we are studying to improve the selectivity of epoxides.

Experimental

cis-β-Methylstyrene was prepared by the hydrogenation of 1-phenylpropyne.[10] Epoxides other than styrene oxide, cyclohexene oxide, and α-methylstyrene oxide used as GC standards were prepared by epoxidation of the corresponding alkenes with *m*-chloroperbenzoic acid under standard conditions.[11] The other olefins, epoxides, and amine ligands were commercially available, and purified by crystallization or distillation before use. NaOCl was obtained as aqueous solution (1.9—1.5 M) and titrated before use (1 M=1 mol dm^{-3}). The NiL_nCl_2 catalysts were prepared by dissolving $NiCl_2 \cdot 6H_2O$ and *n* equivalents of the amine ligand in distilled water as 0.050 M solution. All the catalysts prepared were stand at room temperature for at least 1 day and used as aqueous solution. Analytical TLC and PTLC were performed with Merck $60F_{254}$ and $60PF_{254}$ respectively. Analyses of oxidation products were performed on a Hitachi 163 gas chromatograph attached with Shimadzu CR-5A CHROMATOPAC as integrator. ^1H NMR spectra were recorded at 60 MHz on a JEOL PMX-60Si spectrometer with tetramethylsilane as internal standard.

Styrene Oxidation. In a typical experiment, 1.0 M NaOCl (12.5 mL, 12.5 mmol) was added to the mixture of styrene (0.52 g, 5.0 mmol) and 0.050 M aqueous nickel catalyst (2.0 mL, 0.10 mmol), and the resulted mixture was stirred vigorously at room temperature. A fine black precipitate formed in a few minutes upon addition of NaOCl. After 5 h stirring, the mixture was passed through a short Celite column to remove black precipitate. The filtrate was extracted with CH_2Cl_2 (10 mL×2). The yield of styrene oxide was determined by GC analysis of the CH_2Cl_2 extract. Benzoic acid was isolated from the acidified aqueous layer by CH_2Cl_2 extraction. The oxidations of styrene in Tables 1 and 2 were performed in a same manner with appropriate amount of nickel catalyst.

Oxidations and analyses of *trans*-β-methylstyrene and *cis*-β-methylstyrene were performed in a same manner with styrene oxidation.

Oxidation of α-Methylstyrene. The oxidation was performed in a same manner with styrene oxidation under the conditions described in Table 3. The CH_2Cl_2 extract of the reaction mixture were concentrated, and then distilled by Kugelrohr under reduced pressure (80 °C, 10 mmHg, 1 mmHg=133.322 Pa). The yields of α-methylstyrene oxide and acetophenone were determined by the comparison of the ^1H NMR integration of the distillate with that of dibenzyl ether added as an internal standard. The yields of α-methylstyrene oxide and acetophenone were 53% and 12% respectively. Benzoic acid was isolated from the acidified aqueous layer by CH_2Cl_2 extraction in 15% yield.

Oxidation of *trans*-Stilbene. NaOCl (1.0 M, 20 mL, 20 mmol) was added to the mixture of *trans*-stilbene (0.36 g, 2.0 mmol) in CH_2Cl_2 (10 mL) and aqueous $Ni(bpy)_2Cl_2$ (0.050 M, 0.80 mL, 0.040 mmol). The resulted mixture was stirred vigorously at room temperature. The disappearance of *trans*-stilbene was monitored by TLC. After the complete conversion of *trans*-stilbene, the mixture was passed through a short Celite column and the filtrate was extracted twice with CH_2Cl_2. The CH_2Cl_2 extract was dried over anhydrous Na_2SO_4 and the solvent was removed out by evaporation. The residue obtained was separated on silica-gel PTLC with CH_2Cl_2 : hexane=1 : 1 as eluent. *trans*-Stilbene oxide (R_f=0.6) was obtained in 34% yield. Benzoic acid was isolated by the CH_2Cl_2 extraction of the acidified aqueous layer

in 21% yield. No *cis*-stilbene oxide was detected in the reaction mixture by TLC and ^{1}H NMR.

cis-Stilbene was oxidized and analyzed in a same manner with *trans*-isomer. Cyclohexene and norbornene were oxidized in a same manner with *trans*-stilbene under the conditions described in Table 3, and the yields of epoxides were determined by GC.

Base-Induced Addition-Elimination Reactions of Electron-Deficient Vinylarenes Containing a Carbonyl or Ester Group Utilizing 4-Phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione (PTAD)

Kazuyoshi SEGUCHI* and Satoko TANAKA

(Received March 22, 1991)

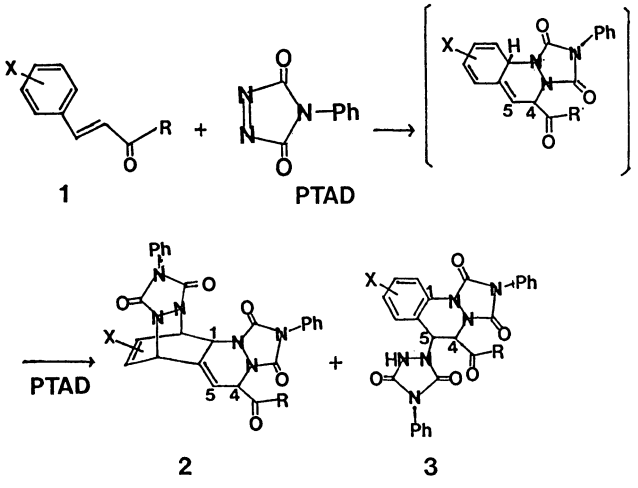
Synopsis. The reaction of electron-deficient vinylarenes such as styrylketones and cinnamate with PTAD afforded double Diels-Alder products and Diels-Alder ene products; the latter underwent novel base-induced elimination of 4-phenyl-1,2,4-triazolidine-3,5-dione via a stable carbanion.

The reactions of 4-phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione (PTAD) have been used extensively in organic syntheses, and a diversity of reactions with alkenes have been documented, such as [4+2],[1] [2+2],[2] ene,[3] and dipolar reactions.[4,5] In particular, the reactions of PTAD with electron-rich vinylarenes exemplified by styrene,[1b] vinylpyridines,[6] and benzylidenebicyclic compounds,[2,5] resulted in 1 : 2 adducts. However, no studies have described that the 3,5-dioxo-4-phenyl-1,2,4-triazolidin-1-yl group (PTAD · H) is a latent leaving group. We have found that PTAD · H served as a good leaving group in the reaction products of PTAD with styrylketones or cinnamate.

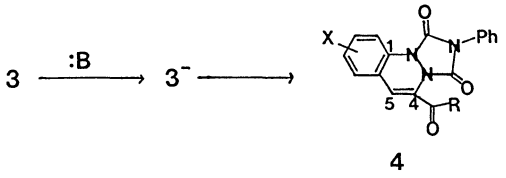
Results and Discussion

The reaction of 1-phenyl-1-penten-3-one **1a** with PTAD in dichloromethane at 25 °C afforded the double Diels-Alder product **2a** and the Diels-Alder ene product **3a** through a 1 : 1 adduct as depicted in Scheme 1 in isolated yields of 27% and 24%, respectively. Pursuit of the reaction by ^{1}H NMR spectroscopy in $CDCl_3$ at appropriate intervals failed to detect the 1 : 1 adduct because of the higher reactivity of the diene. The Diels-Alder ene product decomposed partially during purification procedures (silica-gel chromatography and recrystallization). Careful recrystallization from acetonitrile gave pure **3a** as a white powder. The spectral data and the elemental analyses supported the proposed structure. The ^{1}H NMR showed two doublet signals at δ=5.33 and 6.02 corresponding to 4-H and 5-H, respectively. The ^{13}C NMR also showed two doublet signals at δ=52.7 and 63.9. A molecular ion peak (m/z 510) was observed on the mass spectrum. When a catalytic amount of triethanolamine was added to an acetonitrile solution of **3a** at 25 °C, the solution turned yellow after a few minutes to afford yellow crystals of **4a** in 94% yield after conventional purifications. This structure was again assigned on the basis of spectral and elemental analyses. The ^{1}H NMR showed a singlet proton signal at a lower field (δ=6.21) in addition to an ethyl signal (δ=1.25 and 2.32) and a phenyl signal (δ=7.03—8.35). Compound **4a** resulted from the novel base-induced elimination of 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD · H_2). This elimination reaction could be carried out in situ without isolation of **3a.**

Thus, the in situ reaction was extended to a series of electron-deficient vinylarenes such as styrylketones, cinnamate, and cinnamonitrile.[7] As shown in Table 1, similar successive addition-elimination reactions took place in all cases except for **1h** and **1j**. Concerning **1h**, unidentified products were obtained. **1j** was inert to



Scheme 1.



Scheme 2.

Table 1. Product Yields of **4** by Addition-Elimination Reaction in situ

	Starting compound		Yield (%) of **4**[a]
	X	R	
1a	H	Et	34 (94)
1b	H	Me	27 (90)

1i	*p*-OMe	OEt	27
1j	Cinnamonitrile		0 (78)[b]

a) Yield based on **1**. The values in parentheses show yields based on isolated crude **3**. b) The values in parentheses show recovered yields of starting materials.

PTAD possibly because of the lower electron-density of the diene.

In order to elucidate the elimination mechanism in particular, the deuterium exchange reaction of **3a** was investigated by ^{1}H NMR ($CDCl_3$) spectroscopy in the presence of deuterium oxide and a catalytic amount of sodium carbonate. Addition of sodium carbonate caused the immediate exchange at C-4 more rapidly than the formation of **4a**. Furthermore, the recovered starting material was completely deuterated at C-4. These findings suggest that the elimination reaction may proceed via a carbanion as shown in Scheme 2. Presumably, the electron-withdrawing carbonyl or ester group and amide groups each stabilize the conjugate base of **3**. In summary, the PTAD·H group is a good leaving group in the elimination reaction via a carbanion.

Experimental

Materials and Instruments. Substituted styrylketones, cinnamate, and cinnamonitrile **1a—j** were synthesized according to the reported procedures or obtained from a commercial source. PTAD was freshly prepared by Cookson's method.[8] The ^{1}H NMR and ^{13}C NMR spectra were measured in $CDCl_3$ solution using Me_4Si as an internal standard on a Hitachi R-600 or a JEOL FX-200 spectrometer. The mass spectra were recorded on a JEOL JMS DX-303 spectrometer, operating at an ionizing potential of 70 eV. The IR spectra were taken as KBr disks using a Shimadzu R-460 spectrometer. The elemental analyses were performed using a Yanagimoto Model MT-3 CHN analyzer.

Reaction of 1a with PTAD. PTAD (13.8 mmol) was added portionwise over 2 h in the dark at 25 °C to a solution of **1a** (6.59 mmol) in dichloromethane (10 ml) and the mixture was stirred overnight. The solvent was removed and the residue was flash-chromatographed on silica gel (Wakogel C-200) with dichloromethane as an eluent. **3a** from the first eluate and **2a** from the second eluate were obtained in yields of 24% and 27%, respectively.

General Procedure of in situ Addition-Elimination Reaction. PTAD (13.8 mmol) was added portionwise to the stirred acetonitrile solution (10 ml) of **1** (6.59 mmol) as described above. The mixture was stirred at 25 °C overnight and then a drop of triethanolamine was added to the reaction mixture. The solution turned yellow in a few minutes. After 1 h, conventional purification procedures (concentration by a rotary evaporator, silica-gel column chromatography, and recrystallization) gave yellow crystals.

(Received May 13, 1991)

Synopsis. The hydrogenation of 2-octanone over various types of nickel catalysts was found to be accelerated by the addition of small amounts of carboxylates of alkali metals such as Na, K, and Li.

It is well-documented that the tartaric acid–sodium bromide–modified nickel catalyst (TA–NaBr–MNi) gives high optical yields in the enantioface-differentiating hydrogenation of 2-alkanones,[1] as well as β-keto esters,[2] β-diketones,[3] and β-keto sulfones.[4] Optical yield over this catalyst was controlled by a number of factors. For example, we have reported that the addition of small amounts of sodium ions improved the optical yield of hydrogenation of 2-alkanones over TA–MNi in a reaction media containing both pivalic acid and tetrahydrofuran (THF),[5] whereas the addition of sodium ions resulted in no improvement of the optical yield in THF.[6]

In the course of studies on the enantioface-differentiating hydrogenation of 2-alkanones over TA–MNi, it was found that the addition of a small amount of sodium pivalate to the reaction media resulted in the acceleration of the reaction as well as an increase in the optical yield. As for the acceleration of the hydrogenation over a Raney nickel (RNi) catalyst, addition of strong bases such as sodium hydroxide or potassium hydroxide have been known to be useful.[7] However these strong bases could not be applied to sensitive

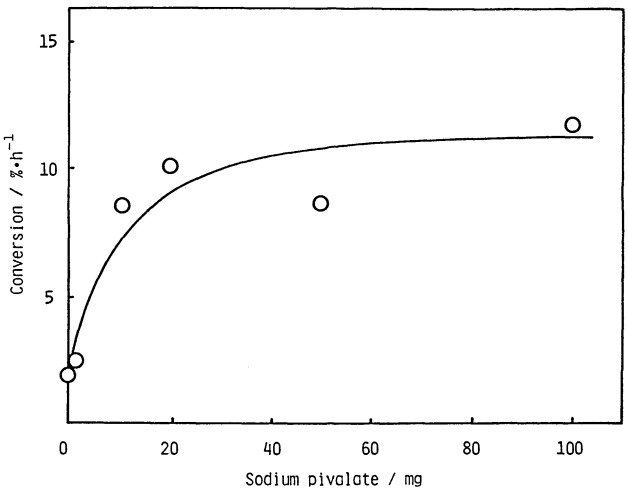

Fig. 1. Relationship between the amount of sodium pivalate in the reaction system and the rate of hydrogenation of 2-octanone.[a)]
Hydrogenation conditions: Catalyst: RNi prepared from 3.8 g of the alloy (Ni/Al=42:58) was modified with 200 ml of an aqueous solution containing TA (2 g) at 100 °C. Reaction media: a mixture of THF (20 ml) and pivalic acid (18 ml). Reaction temperature: 60 °C. Initial hydrogen pressure: 90 kg cm^{-2}.
a) The rate of the hydrogenation is represented by the conversion (%) of 2-octanone in an initial one hour.

Table 1. Effect of the Addition of an Alkali Salt on the Rate of Hydrogenation of 2-Octanone[a)]

No.	Catalyst/g	Reaction temperature/ °C	Alkali salt/mg	Hydrogenation rate[b)]
1	TA-MRNi[c)]	60	—	5
2	TA-MRNi[c)]	60	Na 2-Ethylhexanoate/20	12
3	RNi-A[d)]	60	—	11
4	RNi-A[d)]	60	Na 2-Ethylhexanoate/20	51
5	HNi/4.0[e)]	100	—	13
6	HNi/4.0[e)]	100	Na 2-Ethylhexanoate/20	31
7	Ni-FP/0.8[f)]	60	—	13
8	Ni-FP/0.8[f)]	60	Na 2-Ethylhexanoate/20	42
9	Ni-FP/0.8[f)]	60	Li 2-Ethylhexanoate/20[g)]	28
10	Ni-FP/0.8[f)]	60	K 2-Ethylhexanoate/20	30
11	Ni-FP/0.8[f)]	60	NaCl/20[h)]	17
12	MNi-FP/0.8[i)]	60	—	10

a) Hydrogenation conditions were: Substrate: 2-Octanone (10 ml), Reaction media: THF (20 ml), Initial hydrogen pressure: 90 kg cm^{-2}. b) The rate of the hydrogenation is represented by the conversion (%) of 2-octanone in an initial one hour. c) The catalyst prepared from 3.8 g of the alloy was modified with 200 ml of an aqueous solution containing TA (2 g) at 100 °C. d) The catalyst prepared from 3.8 g of the alloy was treated with 200 ml of a solution containing TA (2 g) and NaBr (12 g), at pH 3.2, 100 °C for 1h. After removal of the solution by decantation, the catalyst was treated with 1 mol dm^{-3} NaOH at 100 °C for 1 h. e) Nickel oxide was reduced at 350 °C for 1 h under a hydrogen stream. f) Nickel fine powder (mean particle size 30 nm) was reduced at 150 °C for 1 h under a hydrogen stream. g) A small amount of lithium 2-ethylhexanoate remained insoluble. h) NaCl was almost insoluble in the reaction mixture. i) Ni-FP was modified at 0 °C with 200 ml of a 0.5% aqueous solution of NaCl.

reactions such as enantioface-differentiating hydrogenation, because a small difference in reaction conditions caused great variations in the optical yield. In this paper, we shall report our findings on the effects of alkali salts on the rate of hydrogenation of 2-octanone.

Figure 1 shows the relationship between the amount of added sodium pivalate and the rate of hydrogenation of 2-octanone over the RNi catalyst modified with tartaric acid. In this experiment, the mixture of pivalic acid and THF, which was the standard reaction media for the enantioface-differentiating hydrogenation, was used as the reaction media. It was shown that the addition of the initial small amount of sodium pivalate to the reaction media resulted in a noticeable increase in the hydrogenation rate. This relationship was similar to that observed between the amount of sodium pivalate and optical yield.[8] Table 1 shows the effects of the addition of alkali ions, when THF was used as the reaction media. Hydrogenation was also accelerated by the addition of alkali ions when the reaction media did not contain pivalic acid. Among the alkali ions examined in this study, sodium ions appeared to accelerate the reaction the most. The reaction rates were enhanced approximately 5-times at maximum by the addition of sodium 2-ethylhexanoate, compared to those rates determined without sodium ions.

Potassium 2-ethylhexanoate and lithium 2-ethylhexanoate were less effective compared to sodium 2-ethylhexanoate. Lithium 2-ethylhexanoate has much less solubility in the reaction mixture than the sodium and potassium salts. When an alkali salt was almost insoluble in the reaction media (NaCl/THF), negligible acceleration effects were observed (Entry 11 in Table 1). Thus the solubility of alkali salts in the reaction mixture appeared to be one of the factors controlling the reaction rate. The cause of the difference between the reaction rate with sodium 2-ethylhexanoate and that with potassium 2-ethylhexanoate is not clear at present. The addition of sodium salts soluble in the reaction media appeared to be the most effective in promoting the reaction according to the present data.

It was found in this study that alkali carboxylates were excellent promoters for enhancing the hydrogenation of ketones over modified or unmodified Nickel catalysts. Although the mechanism of this effect is not certain, the present findings are interesting from a synthetic point of view.

Experimental

The catalysts employed in this study were prepared by the procedures reported previously.[2,8] The hydrogenation of 2-octanone was carried out in a 100-ml autoclave. The conversion (%) of 2-octanone was calculated based on the depression of hydrogen pressure and GLC analysis (5% Tween 80 on Shimalite W, 130 °C).

We thank Professor Yoshiharu Izumi of Osakagakuin University, Professor Akira Tai of Himeji Institute of Technology, and Dr. Hiroshi Ozaki of Osaka University for their many helpful discussions and suggestions in the course of this work.

A Convenient Synthesis of Monofluorobutene Derivatives

Noritada MATSUO* and Andrew S. KENDE†
Sumitomo Chemical Co., Ltd., Takarazuka Research Center, 4-2-1 Takatsukasa, Takarazuka, Hyogo 665
†Department of Chemistry, University of Rochester, Rochester, N. Y., 14627, USA
(Received May 27, 1991)

Synopsis. (*Z*)-1,4-Dibromo-1,1,2-trifluoro-2-butene (**2a**) reacts regioselectively with sodium benzenesulfinate and triethyl phosphite respectively to yield the (*Z*)-isomers of 3,4,4-trifluoro-4-bromo-2-butenyl phenyl sulfone (**3**) and diethyl (*Z*)-4-bromo-3,4,4-trifluoro-2-butenylphosphonate (**6**). These could easily be transformed to a variety of polyfunctional monofluoroalkene derivatives.

The introduction of fluorine into organic molecules often gives rise to enhancement of biological activity. There are various biologically active compounds containing a monofluoroalkene moiety,[1] in spite of the scarcity of simple, general methodology for the stereoselective synthesis of monofluoroalkene compounds.[2]

We have previously reported the versatile transformations of 1,1,2-trifluoro-1,3-butadiene (**1**) to a variety of functionalized monofluoroalkene compounds.[2]

Our continuing interest in monofluoroalkene syntheses from the diene **1** has prompted us to explore the utility of (*Z*)-1,4-dibromo-1,1,2-trifluoro-2-butene (**2a**), easily obtained by bromination of the diene **1**.[3]

In this paper we describe easier formation of C4 monofluoroalkene intermediates.

Bromination of the diene **1** in dichloromethane at −10 °C gave the mixture of (*Z*)-1,4-adduct **2a** and 1,2-adduct **2b** (**2a** : **2b**=2 : 1). The 1,2-adduct **2b** spontaneously rearranged into the (*Z*)-1,4-adduct **2a** at room temperature. The dibromide **2a** was reacted with sodium benzenesulfinate in *N,N*-dimethylformamide to give the sulfone **3** in 60% yield. The sulfone **3** underwent rapid transformation in methanolic potassium carbonate at room temperature to give in high yield the known (*Z*)-orthoester **4**, which we have previously converted[2] to monofluoro-chrysanthemic acid derivative **5**.[4]

On the other hand, the dibromide **2a** reacted with triethyl phosphite to obtain the Horner–Emmons type reagent **6**. This phosphonate was transformed to the known methyl ester **8** via the orthoester **7** by reaction with methanolic potassium carbonate at room temperature, followed by mild hydrolysis in methanol with a catalytic amount of *p*-toluenesulfonic acid.

In addition, the nitrile **9a** and various amide derivatives **9b**, **c**, **d** were easily obtained by reacting with ammonia and corresponding amines in tetrahydrofuran respectively.

The piperidide compound **9d** was transformed to the (2*Z*,4*E*)-2-fluoro analog **10b**[2] of the known insecticide piperine **10a** in high yield by reaction of the phospho-

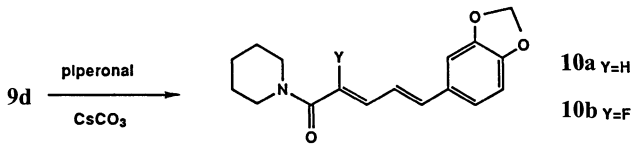

Scheme 3.

nate **9d** with piperonal in 2-propanol in the presence of cesium carbonate. Enhancement of the insecticidal activity was observed by introduction of a fluorine atom at 2 position. The details of the insecticidal activity will soon be published elsewhere.

In conclusion, by use of the 1,4-bromine adduct **2a** of 1,1,2-trifluorobutadiene **1**, important and versatile (*Z*)-monofluorobutene synthons **3** and **6** were readily obtained and these were transformed to various biologically important monofluoroalkene compounds.

Experimental

All the melting points are uncorrected. IR spectra were measured on a Hitachi Model 270-30 spectrometer. ^{1}H and ^{19}F NMR spectra were recorded on a Hitachi R-90 spectrometer in $CDCl_3$ solution, using Me_4Si as an internal standard in ^{1}H NMR and $CFCl_3$ as an external standard in ^{19}F NMR. MS spectra were recorded on a Hitachi DF/GC/MS M-80.

(*Z*)-1,4-Dibromo-1,1,2-trifluoro-2-butene (2a). To a solution of 12.9 g (119 mmol) of 1,1,2-trifluoro-1,3-butadiene in dichloromethane (150 ml) at 0 °C was slowly added 15.5 g of bromine (97 mmol). The resulting mixture was stirred for one hour at 0 °C. The mixture was poured into ice-water, and the liquid was extracted twice with dichloromethane. The organic layers were combined, washed once with brine, and then dried over anhydrous magnesium sulfate. Evaporation of solvent gave a mixture of 1,4-adduct **2a** and 1,2-adduct **2b** as a yellow oil, (**2a**:**2b**=2:1). The 1,2-adduct **2b** rearranged to the 1,4-adduct completely on standing for one day at room temperature. This was purified by distillation to give 21.9 g (84.3%) of (*Z*)-1,4-dibromo-1,1,2-trifluoro-2-butene (**2a**) as a clear oil, bp 65 °C (20 mmHg, 1 mmHg=133.322 Pa); ^{1}H NMR δ=3.96 (dq, 2H), 5.76 (dt, 1H); ^{19}F NMR δ=−57.5 (d, J=18.6), −125.4 (dt, J=28. 9, 18.6). 1,2-adduct **2b**: ^{1}H NMR δ=3.73 (m, 2H), 4.83 (dm, 1H, J=27); ^{19}F NMR δ=−98.0, −115.2, −187.5.

(*Z*)-4-Bromo-3,4,4-trifluoro-2-butenyl Phenyl Sulfone (3). To a solution of 3.1 g (11.6 mmol) of (*Z*)-1,4-dibromo-1,1,2-trifluoro-2-butene **2a** in 20 ml of *N,N*-dimethylformamide was added 2.8 g (14 mmol) of sodium benzenesulfinate. The reaction mixture was stirred for 15 h at room temperature. The contents of the flask were poured into a large excess of ice-water, and the liquid was extracted twice with ethyl acetate. The organic layers were combined, washed once with brine, and then dried over anhydrous magnesium sulfate. Evaporation of solvent gave a yellow liquid which was chromatographed on silica gel (30% ethyl acetate in hexane) to give 2.3 g (60%) of (*Z*)-4-bromo-3,4,4-trifluoro-2-butenyl phenyl sulfone as a yellow oil; ^{1}H NMR δ=3.9 (dq, 2H), 3.6 (dt, 1H), 7.4—8.0 (m, 5H); ^{19}F NMR δ=−122.39 (dt, J=18.6, 31), −57.58 (d, J=18.6).

(*Z*)-3-Fluoro-4,4,4-trimethoxy-2-butenyl Phenyl Sulfone (4). Potassium carbonate (3.8 g, 27.5 mmol) was added to a solution of 2.3 g (7 mmol) of 4-bromo-3,4,4-trifluoro-2-butenyl phenyl sulfone in 20 ml of methanol at room temperature. The resulting mixture was stirred for 12 h at room temperature. The reaction was diluted with 100 ml of diethyl ether. The contents of the flask were filtered and the white solid was washed with excess diethyl ether. The ether solution was evaporated in vacuo to give 1.8 g (85%) of the crude 3-fluoro-4,4,4-trimethoxy-2-butenyl phenyl sulfone as an oil. The physical properties were identical with those we previously reported;[2] ^{1}H NMR δ=3.1 (s, 9H), 4.0 (d, 2H, J=9), 5.5 (dt, 1H, J=9,33), 7.5—7.9 (m, 5H); ^{19}F NMR δ=−120.5 (d, J=31.1). This could be used for the next reaction without further purification.

Diethyl (*Z*)-4-Bromo-3,4,4-trifluoro-2-butenylphosphonate (6). Triethyl phosphite (6.8 g, 41.0 mmol) was added to (*Z*)-1,4-dibromo-1,1,2-trifluoro-2-butene (10.0 g, 37.3 mmol). The mixture was stirred for 10 h at 120 °C over distilling off ethyl bromide formed. The reaction mixture was distilled to obtain 6.9 g (57%) of diethyl (*Z*)-4-bromo-3,4,4-trifluoro-2-butenylphosphonate as a colorless oil; bp 96—98 °C (1 mmHg); IR (neat) 1258, 1024 cm^{-1}; ^{1}H NMR δ=2.67 (ddd, 2H), 4.1 (m, 6H), 5.57 (m, 1H); ^{19}F NMR δ=−126.97 (m), −56.44 (dd, J=20.7, 4.1); MS m/z 324 (M-1), 326 (M+1).

Diethyl (*Z*)-3-Fluoro-3-methoxycarbonyl-2-propenylphosphonate (8). Potassium carbonate (10.2 g, 73.9 mmol) was added to a solution of 6.0 g (18.5 mmol) of diethyl 4-bromo-3,4,4-trifluoro-2-butenylphosphonate in 50 ml of methanol at room temperature. The resulting mixture was stirred for 12 h at room temperature. After removal of solvent in vacuo, the residue was partitioned between 100 ml of diethyl ether and 50 ml of water. The ether layer was washed once with brine. Evaporation of the solvent gave a clear oil. Methanol (20 ml) and *p*-toluenesulfonic acid (50 mg) were added to this oil and the resulting solution was stirred for 0.5 h at room temperature. The reaction mixture was poured into water and the mixture was extracted twice with ethyl acetate. The combined organic layers were washed with brine and dried over anhydrous magnesium sulfate. Evaporation of the solvent in vacuo followed by distillation gave 3.4 g (72%) of diethyl (*Z*)-3-fluoro-3-methoxycarbonyl-2-propenylphosphonate[5] as a colorless oil; bp 125 °C (0.55 mmHg); IR (neat) 1746, 1682, 1256 cm^{-1}; ^{1}H NMR δ=1.30 (t, 6H), 2.73 (ddd, 2H), 3.8 (s, 3H), 4.1 (m, 4H), 6.13 (dq, 1H); ^{19}F NMR δ=−127.8 (dd, J=31, 12.4); MS m/z 254 (M^+).

Diethyl (*Z*)-3-Cyano-3-fluoro-2-propenylphosphonate (9a). Diethyl (*Z*)-4-bromo-3,4,4-trifluoro-2-butenylphosphonate (1.0 g, 3.1 mmol) was stirred with ammonia (15 mmol) in 10 ml of tetrahydrofuran at 0 °C for 1 h and then stirred for 12 h at room temperature. The reaction mixture was poured into ice-cooled 5% aqueous hydrochloric acid and the mixture was extracted three times with ethyl acetate after saturation of the solution with sodium chloride. The combined organic layers were washed successively with 5% sodium hydrogencarbonate solution and brine, and then dried over anhydrous magnesium sulfate. Evaporation of the solvent followed by purification with preparative TLC (hexane–ethyl acetate=1:1) gave 0.54 g (80%) of 3-cyano-3-fluoro-2-propenylphosphonate as a colorless oil: IR (neat) 2240 cm^{-1}; ^{1}H NMR δ=1.3 (t, 6H), 2.76 (ddd, 2H), 4.12 (dq, 4H), 5.81 (m, 1H); ^{19}F NMR δ=−122.34 (dd, J=12.4, 31); MS m/z 221 (M^+).

Diethyl (*Z*)-3-[(1,2-Dimethylpropyl)carbamoyl]-3-fluoro-2-propenylphosphonate (9b). 1,2-Dimethylpropylamine (0.94 g, 10.2 mmol) was added to a solution of 1.0 g (3.1 mmol) of diethyl (*Z*)-4-bromo-3,4,4-trifluoro-2-butenylphosphonate in 10 ml of tetrahydrofuran at 0 °C. The resulting mixture was stirred for 1 h at 0 °C and 12 h at room temperature. The reaction mixture was poured into ice-cooled 5% aqueous hydrochloric acid and the mixture was extracted three times with ethyl acetate after saturation of the solution with sodium chloride. The organic layers were combined, washed successively with 5% sodium hydrogencarbonate solution and brine, and then dried over anhydrous magnesium sulfate. Evaporation of the solvent followed by purification with preparative TLC (hexane–ethyl acetate=1:1) gave 0.71 g (75%) of diethyl

(*Z*)-3-[(1,2-dimethylpropyl)carbamoyl]-3-fluoro-2-propenylphosphonate as a clear oil: IR (neat) 1662 cm^{-1}; ^1H NMR δ=0.90 (d, 6H), 1.12 (d, 3H), 1.31 (t, 6H), 2.72 (ddd, 2H), 4.10 (dq, 4H), 5.7—6.4 (m, 1H); ^{19}F NMR δ=−131.08 (m, 12.4, 33); MS *m/z* 309 (M^+).

Diethyl (*Z*)-3-[(2-Methylpropyl)carbamoyl]-3-fluoro-2-propenylphosphonate (9c). (*Z*)-4-Bromo-3,4,4-trifluoro-2-butenylphosphonate (1.0 g, 3.1 mmol) was allowed to react with 2-methylpropylamine (0.74 g, 10.2 mmol) in tetrahydrofuran according to the same procedure as **9b** to give 0.71 g (78%) of (*Z*)-diethyl 3-*N*-(2-methylpropyl)carbamoyl-3-fluoro-2-propenylphosphonate: IR (neat) 1664 cm^{-1}; ^1H NMR δ=0.92 (d, 6H), 1.30 (t, 3H), 2.72 (ddd, 2H), 3.15 (t, 2H), 4.10 (dq, 4H), 5.7—6.4 (m, 1H); ^{19}F NMR δ=−131.28 (m); MS *m/z* 295 (M^+).

Diethyl (*Z*)-3-Piperidinocarbonyl-3-fluoro-2-propenylphosphonate (9d). Diethyl (*Z*)-4-Bromo-3,4,4-trifluoro-2-butenylphosphonate (1.0 g, 3.1 mmol) was allowed to react with piperidine (1.02 g, 12 mmol) in tetrahydrofuran according to the same procedure as **9b** to give 0.48 g (50%) of diethyl (*Z*)-3-piperidylcarbonyl-3-fluoro-2-propenylphosphonate: IR (neat) 1646 cm^{-1}; ^1H NMR δ=1.26 (t, 3H), 1.6 (bs, 6H), 2.68 (ddd, 2H), 3.45 (bs, 4H), 4.06 (dq, 4H), 5.2—5.9 (m, 1H); ^{19}F NMR δ=−115.3 (dd, *J*=12.4, 35.1); MS *m/z* 307 (M^+).

1-[(2*Z*,4*E*)-2-Fluoro-5-[3,4-(methylenedioxy)phenyl]-2,4-pentadienoyl]piperidine (10b). To a solution of 479 mg (1.56 mmol) of diethyl (*Z*)-3-piperidinocarbonyl-3-fluoro-2-propenylphosphonate and 257 mg (1.72 mmol) of piperonal in 5 ml of 2-propanol at 0 °C was added 1017 mg (3.02 mmol) of cesium carbonate under a nitrogen atmosphere. The reaction mixture was stirred for 3 h at 0 °C and 12 h at 20 °C. The reaction mixture was poured into ice-water and the liquid was extracted with ethyl acetate. The organic layer was washed with brine and dried over anhydrous magnesium sulfate. Evaporation of solvent gave the crude crystalline product (0.5 g). This was purified by recrystallization from hexane and ethyl acetate (3:1) to obtain 359 mg (76%) of 1-[(2*Z*,4*E*)-2-fluoro-5-[3,4-(methylenedioxy)phenyl]-2,4-pentadienoyl]-piperidine as white crystals: Mp 97.5—98.0 °C; ^1H NMR δ=1.62 (m, 6H), 3.53 (m, 4H), 5.95 (s, 2H), 6.39 (dd, 1H, *J*=10, 33), 6.62 (d, 1H, *J*=16), 6.75 (d, 1H, *J*=8), 6.84 (dd, 1H, *J*=10, 16), 6.87 (d, 1H, *J*=8), 6.98 (s, 1H); MS *m/z* 303 (M^+). Found: C, 67.22; H, 6.11; N, 4.66%. Calcd for $C_{17}H_{18}FO_3N$: C, 67.29; H, 5.99; N, 4.62%.

Redox Photochromism of Waterproof Viologen-Matrix Polymer System

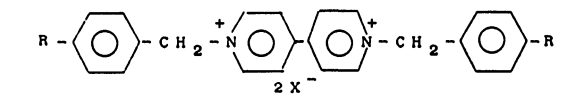
Hiroyoshi KAMOGAWA* and Hiroshi YAMADA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received June 6, 1991)

Synopsis. A waterproof viologen-matrix polymer system exhibiting redox photochromism in thin films was devised using water-insoluble viologens embedded in *N*-vinyl-2-pyrrolidone(VP)–methyl acrylate (MA) copolymers also insoluble in water. Both the photosensitivity and the stability of the colors developed decreased with decrease in the VP-content.

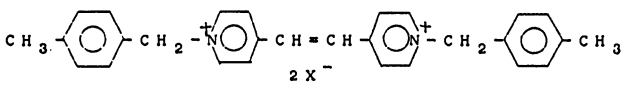
In previous publications,[1–7] it has been reported that bipyridinium salts (viologens) embedded in the poly(1-vinyl-2-pyrrolidone) (PVP) matrix film reversibly develop visible intense colors with radiation of the solar level (redox photochromism).

It is required for some purposes, however, that these photochromic systems are waterproof, since both conventional viologens and PVP are water-soluble. Accordingly, waterproof thin films consisting of the viologen-matrix polymer system have been prepared and their reversible color-developing behaviors induced by near UV-irradiation of the solar level have been investigated.

Water-insoluble viologens employed in the present study were 1,1′-bis(arylmethyl)-4,4′-bipyridinium bis(tetrafluoroborate) and bis(hexafluorophosphate) (**V1**—**V4**) and *trans*-4,4′-vinylenebis[1-(*p*-methylbenzyl)pyridinium] bis(tetrafluoroborate) (**V5**) and bis(hexafluorophosphate) (**V6**).



V1 – V4



V5 – V6

	R	X
V1 :	CH_3	BF_4
V2 :	CH_3	PF_6
V3 :	Cl	BF_4
V4 :	Cl	PF_6
V5 :	–	BF_4
V6 :	–	PF_6

Viologens bearing 4,4′-bipyridinium and *trans*-4,4′-vinylenebispyridinium units were adopted as typical of exhibiting intense visible colors upon near UV irradiation.

Matrix polymers, in which the viologens were to be embedded, were copolymers of 1-vinyl-2-pyrrolidone (VP) with methyl acrylate (MA) in less than 1 : 1 molar ratios, which were insoluble in water.

Experimental

Water-Insoluble Viologens (V1—V6). 1,1′-Bis(*p*-methyl- or *p*-chlorobenzyl)-4,4′-bipyridinium dichloride or *trans*-4,4′-vinylenebis[1-(*p*-methylbenzyl)pyridinium] dichloride (11 mmol) were dissolved in water (200 ml). Aqueous HBF_4 (42 wt%; 4.8 g, 23 mmol) or aqueous HPF_6 (60 wt%; 5.6 g, 23 mmol) was then added to precipitate white to yellowish white crystalline powder (**V1**—**V6**) in more than 90% yield (mp 240, 238, 254, 249 °C for **V1**—**V4**; decomp for **V5**, **V6**). The results of IR (KBr) and elemental analyses were satisfactory.

Matrix VP-MA Copolymers. Prepared in dioxane solutions kept at 80 °C for 72 h with α,α'-azobisisobutyronitrile as initiator, in the conventional manner using glass ampules sealed under N_2. The VP-contents in copolymers were determined by elemental analyses to afford satisfactory agreements with the initial monomer ratios. Values of intrinsic viscosity $[\eta]$ in DMF at 25 °C for the 1 : 5, 1 : 7, and 1 : 10 copolymers, which were insoluble in water, were 0.22, 0.24, and 0.22 dl g^{-1}, respectively.

Films for Irradiation. Films open to air (A) and those tightly sandwiched between two glass plates (B) were prepared in the same manners as in previous studies,[6,7] except that DMF and an elevated temperature (40 °C) were employed

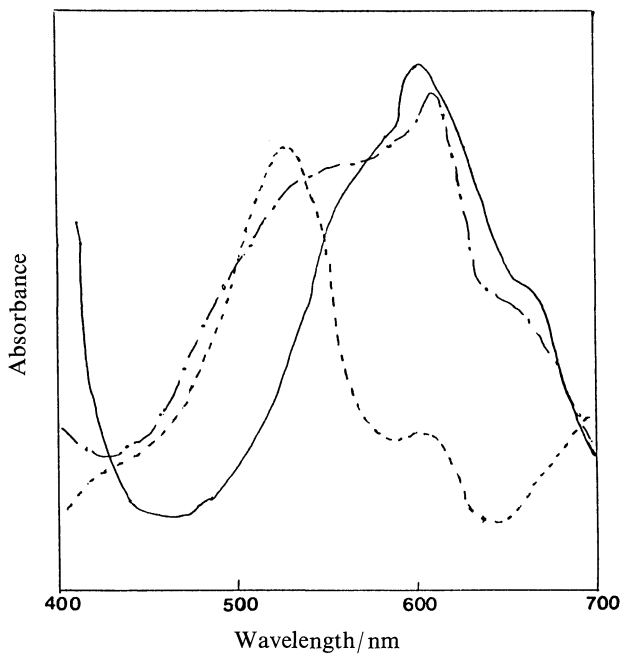


Fig. 1. Typical visible absorption spectra developed for water-insoluble viologens embedded in VP–MA copolymer matrix films with irradiation by near UV light.
—— For **V2** embedded in VP–MA (1 : 5) copolymer; ---- for **V5** in VP–MA (1 : 7) copolymer; —·— for 1, 1′-bis(*p*-methylbenzyl)-4,4′-bipyridinium dichloride in VP homopolymer. Measures of ordinates are arbitrary only to show the shapes of spectra.

instead of water as solvent and evaporation at room temperature, respectively.

Absorption Change. Radiation through a glass plate from a 75 W high pressure Hg lamp (Toshiba SHL-UV100) was applied to either films A or B placed at the distance of 5 cm from the light source, and the resulting visible absorption changes of films were determined by means of a Hitachi 200-10 recording spectrophotometer.

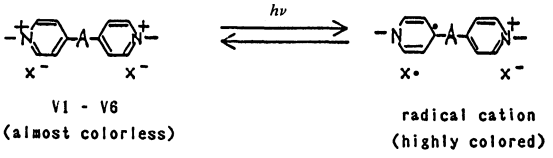
Results and Discussion

Viologens **V1**—**V6** were prepared by the anion exchange reaction of the respective chlorides with excess tetrafluoroboric and hexafluorophosphoric acids without any difficulty.

MA was chosen as the comonomer, since it provides not only water-proofness but also transparency and toughness to copolymer films. Films less than 0.1 mm in thickness were prepared on glass plates by evaporating DMF solutions at 40 °C. In Fig. 1 are given typical absorption spectra developed for the films upon irradiating near UV light of the solar level.

It can be recognized from Fig. 1 that the shapes and absorption maxima (λ_{max}) of the visible absorption spectra developed for the waterproof viologen–VP–MA copolymer system by near UV irradiation are almost identical with those of the radical cations produced in the water-soluble viologen–VP homopolymer one,[1–7] except that, in the latter system, absorptions attributable to associated radical cations[8] are also discernible, e.g. between ca. 500 and 600 nm for 4,4′-bipyridinium. This fact suggests that the species causing these absorption changes were also viologen radical cations generated by the photo-redox reaction, as demonstrated in previous studies.[9,10]

Equation 1 indicates this relationship in the absence



(1)

of air where A is intended to represent none and –CH=CH– for **V1**—**V4** and **V5**, **V6**, respectively.

A remarkable fact in the present case is that almost no

		B	0.370	0.428	16

a) Notations are identical with those in Table 1, unless otherwise noted. b) Values reduced to 0.1 mm thickness at λ_{max} (525 nm).

absorptions attributable to associated radical cations exist especially in the spectra for **V1**—**V4** as exemplified in Fig. 1 (——), presumably suggesting that the species are in thermodynamically less stable states when compared with those generated in VP–homopolymer (— · —). This less stable characteristic is also observed in half-bleaching time ($t_{1/2}$) in Table 1.

Thus, it is known from the values of $t_{1/2}$ that complete bleachings take place even for air-tight films (B), whereas, in the case of VP–homopolymer as matrix, the colors developed by light persist for a long term (life of months to years) under the same film-forming conditions.[7)]

The results in Tables 1 and 2 indicate that the absorbance increase (A_t) at λ_{max} in irradiation time t becomes remarkably smaller with decrease of the VP-content in the copolymers, so that the values of A_t for the 1 : 10 (VP : MA) copolymers open to air (A) amount to less than half (5 min irrad.) and approximately half (30 s irrad.) those for the 1 : 5 copolymers in the cases of **V1**—**V4** and **V5**, **V6**, respectively; $t_{1/2}$ for the tightly glass-sandwiched films (B) appear to show the same tendency.

These facts are considered to demonstrate that the principal mechanism of the photo-reaction in this case is, as shown in Eq. 1, the reductive attack of the X^- highly activated by the VP-portion of the copolymers against the photo-excited viologen dication to produce a highly colored radical cation, which is stabilized in its turn by binding to the VP-portion, by the same reason as for 1-methyl-2-pyrrolidone, a highly efficient polar aprotic solvents.[1)]

Thus, the decrease of the VP-content in polymer may lead to decreases of both reactivity of the counter anion and stability of the radical cation, thereby bringing about decreases of both A_t and $t_{1/2}$.

The photochromic behaviors investigated above were waterproof, as expected, and did not much differ among **V1**—**V4** in Table 1 and between **V5** and **V6** in Table 2 each other, with exception that **V3** and **V4** [1,1′-bis(*p*-chlorobenzyl) derivatives] provided considerably larger values of $t_{1/2}$ than **V1** and **V2** [1,1′-bis(*p*-methylbenzyl) ones] did.

Features of **V5**, **V6** in Table 2, other than providing a λ_{max} at 525 nm (red) instead of 605 nm (blue) for **V1**—**V4**,[1-7)], are high photosensitivities as well as rapid bleachings in dark. The presence of air oxygen (A) also afforded A_t always smaller than the almost absence of air (B) did.

^1H and ^{13}C NMR Relaxation Study of Iron(III) Tetraphenylporphyrin-Imidazole Complexes

Yasuhiko YAMAMOTO,* Norishige NANAI, Riichirô CHÛJÔ, and Yoshio INOUE

Department of Biomolecular Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received June 10, 1991)

Synopsis. ^1H and ^{13}C nuclear relaxation of paramagnetic iron(III) tetraphenylporphyrin–imidazole complexes has been investigated in order to gain insight into the relationship between the paramagnetic relaxation rate and the electron-nucleus distance. The analysis of the nuclear spin–lattice relaxation time (T_1) in terms of the distance indicated that, for the iron porphyrin complexes used, the contribution of the electron–nucleus dipolar coupling no longer contributes significantly to the relaxation process of a proton located at more than 0.75 nm away from the iron. For the complexes studied, the electron spin–lattice relaxation time (T_{1e}) of 6.4 ps was calculated from the T_1 values measured at 26 °C.

Nuclear relaxation has been used to characterize structure and dynamics of molecules. Particularly, in the case of paramagnetic molecules, geometries of complexes in solution, determinations of coordination numbers, and calculations of correlation times have been infered from the investigation of the paramagnetic relaxation.[1–3] Nuclear spin-lattice relaxation time, T_1, in paramagnetic molecules is composed of two terms,

$$T_1^{-1} = T_{1d}^{-1} + T_{1p}^{-1}, \quad (1)$$

where T_{1d} and T_{1p} are the diamagnetic and paramagnetic spin–lattice relaxation times, respectively, and, for the nucleus in the close proximity of the unpaired electron, $T_{1d}^{-1} \ll T_{1p}^{-1}$. T_{1p} is generally expressed in terms of the dipolar and contact interactions between nucleus and unpaired electron as follows,[4–6]

$$T_{1p}^{-1} = (2/15)\gamma_I^2 g^2 \beta^2 S(S+1) r^{-6} [3\tau_c/(1+\omega_I^2\tau_c^2) + 7\tau_e/(1+\omega_S^2\tau_e^2)] + (2/3)S(S+1)(A/\hbar)^2 \tau_e/(1+\omega_S^2\tau_e^2) \quad (2)$$

and

$$\tau_c^{-1} = T_{1e}^{-1} + \tau_r^{-1} + \tau_{ex}^{-1}, \ \tau_e^{-1} = T_{1e}^{-1} + \tau_{ex}^{-1}, \quad (3)$$

where γ_I is the gyromagnetic ratio of the nucleus under consideration and T_{1e}, τ_r, and τ_{ex} are the electron spin–lattice relaxation, the molecular tumbling, and the electron exchange times, respectively. A is the hyperfine coupling constant which is related to the unpaired spin density on the resonating nucleus and the other parameters have been defined previously.[2] The Curie spin relaxation does not contribute significantly to T_{1e} for the present complex.[7–9] In large molecules with highly resolved NMR spectra, $T_{1e} \ll \tau_r$, τ_{ex}, and at high magnetic field, $\omega_I^2 T_{1e}^2 \ll 1$ and $\omega_S^2 T_{1e}^2 > 1$, the nuclear spin–lattice relaxation rate due to the electron-nucleus dipolar coupling is given as,[9,10]

$$T_1^{-1} = (2/5)\gamma_I^2 g^2 \beta^2 S(S+1) r^{-6} T_{1e} \quad (4).$$

Therefore the relaxation rate of a nucleus depends simply on the distance from the unpaired electron and γ_I.

We have measured and analyzed the T_1 values of both ^1H and ^{13}C of iron(III) tetraphenylporphyrin–imidazole complexes (structures in Fig. 1). The T_{1e} value of the complex was determined from the analysis of the observed T_1 values. The relationship between the paramagnetic relaxation rate and the electron–nucleus distance is discussed.

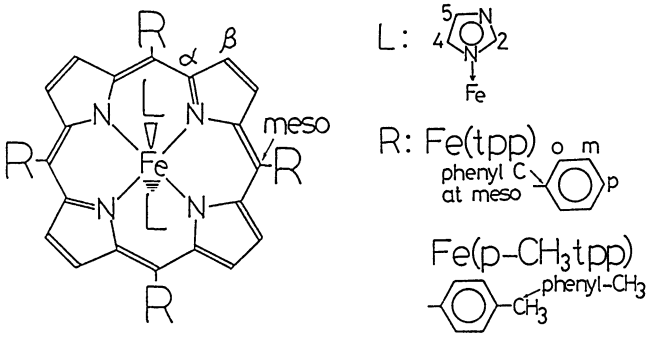

Fig. 1. Structures and numbering system of [Fe(tpp)-(Im)$_2$]Cl and [Fe(p-CH$_3$ tpp)(Im)$_2$]Cl.

Experimental

Iron(III) tetraphenylporphyrin, Fe(tpp), was purchased from Sigma Chemcal Co. and used without further purification. Iron(III) 5, 10, 15, 20-tetrakis (p-tolyl) porphyrin, Fe(p-CH$_3$ tpp), was prepared by the literature method[11] and purified using silica-gel column. Since it has been reported that the NMR spectral features of these porphyrin complexes are essentially independent of concentration (5—50 mM)[12], 10 mM iron(III) porphyrin was prepared in $CDCl_3$ with 0.2 M imidazole (Sigma) for the measurements (1M=1 mol dm^{-3}). ^1H and ^{13}C NMR spectra were recorded using a JEOL GSX-270 FT-NMR spectrometer operating at ^1H and ^{13}C frequencies of 270 and 67.8 MHz, respectively. T_1 was determined by the inversion recovery method[13] and the experimental error is <20%. Chemical shifts are given in parts per million, ppm, downfield from the signal of tetramethylsilane, with the solvent signal as internal reference.

Results and Discussion

NMR Spectra. ^{13}C NMR spectra of 10 mM iron(III) porphyrin derivatives with 0.2 M imidazole in $CDCl_3$ at 26 °C are shown in Fig. 2. The signal assignments were reported previously[12] and have been confirmed by the T_1 measurements and two-dimensional NMR spectroscopies. The resonances for free imidazole are observed at 122 and 136 ppm as indicated by asterisk in the spectra. Relatively small signal intensity for the free imidazole resonances is due to short pulsing interval used for the measurement which selectively enhances the intensity of more rapidly relaxing paramagnetic resonances. Since it has been reported that the equilibrium

constant is of the order of 10^6 M^{-2} for imidazole binding to [Fe(tpp)]Cl in $CHCl_3$ at 25 °C,[14] the iron porphyrin should be almost completely in the bis-ligated form. In addition, the fact that both the free and bound imidazole resonances are separately observed is consistent with its slow exchange rate (ca. 10 s^{-1}).[15] ^1H NMR spectra of the complexes (not shown) were essentially identical to those reported previously.[16,17] The chemical shifts of ^1H and ^{13}C resonances are summarized in Table 1. The comparison of the shift between the two

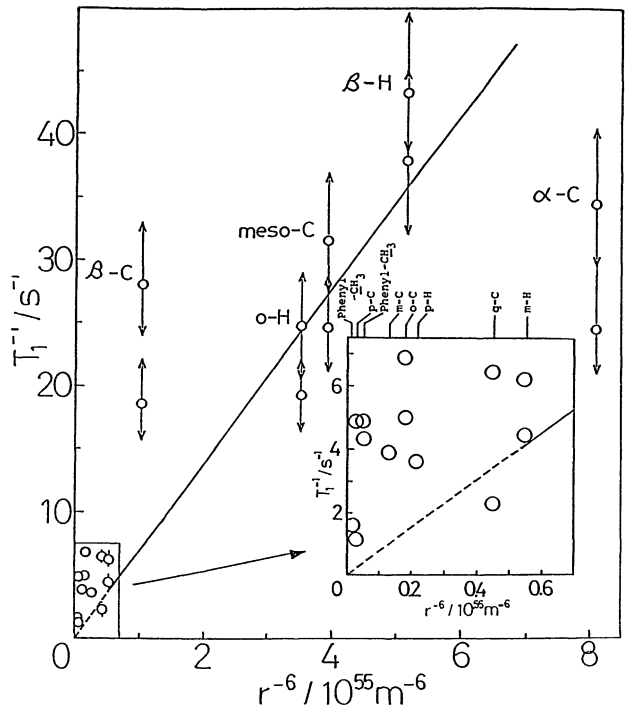

Fig. 3. The plot of T_1^{-1} against r^{-6} for ^1H of the iron porphyrin complexes studied. A straight line passing the origin was drawn with the plots for *o*- and *m*-H. For the ^{13}C data, T_1^{-1} were plotted against $r^{-6}(\gamma_C/\gamma_H)^2$. The plots near the origin was expanded in the inset.

complexes indicates that the influence of the methyl substitution on the resonance frequency is localized at the phenyl resonances.

T_1 Analysis. The observed T_1 values are included in Table 1. The T_1 values of the corresponding nuclei, except the phenyl C at *meso* and the *p*-C, between the two complexes agree within the experimental error of 20%. The difference in the T_1 value of the phenyl C at *meso* between the two complexes may be attributed to the change in the contact contribution, i.e. the second term in Eq. 2, and the presence of the unpaired spin density at this carbon has been suggested earlier.[12] The fact that the T_1 value for the *p*-C in [Fe(tpp)(Im)$_2$]Cl is considerably smaller than that in [Fe(*p*-CH_3 tpp)(Im)$_2$]Cl indicates the significance of the attached ^1H for the relaxation of this carbon. Relatively large difference in the T_1 value of the bound imidazole carbons between the two iron porphyrin complexes may be attributed to the difference in the contact contribution.

The relaxation rates of the iron porphyrin ^1H resonances are plotted against r^{-6} in Fig. 3. The plots for the ^{13}C resonances are also included in the figure in the form of T_1^{-1} vs. $r^{-6}(\gamma_C/\gamma_H)^2$, because Eq. 4 predicts that the ratio of the T_1^{-1} values for the proton and carbon located equidistantly from the metal is $(\gamma_C/\gamma_H)^2$. Since it has been already shown that the unpaired electron density on the *o*-, *m*-, and *p*-C in these complexes is negligible,[12] a straight line passing through the origin was drawn with the plots for the phenyl ^1H resonances. The T_{1e} value can then be calculated from the slope of this line using Eq, 4. The T_{1e} value of 6.4 ps was obtained and is well within the typical value for iron(III) low spin complexes (2—8 ps).[18] The interpretation of the relaxation rates for the porphyrin ring nuclei requires the knowledge about the spin density of the porphyrin skeleton. The plots in Fig. 3 do not converge to the origin as $r^{-6}\rightarrow 0$, but the relaxation rates are larger than those expected from Eq. 4 when $r^{-6}<0.5\times10^{55}m^{-6}$. These results reflect that the paramagnetic dipolar relaxation mechanism is not a predominant relaxation process for a proton located more than 0.75 nm away from the iron in the present complexes and the distance is expected to be reduced with increasing the molecular weight. It has been shown that the interpretation of the nuclear relaxation in paramagnetic hemoproteins, based on Eq. 4, tends to underestimate the iron–nucleus distance and the error becomes larger for nucleus oriented further away from the paramagnetic center.[19]

Synopsis. While the title compounds were oxidized by $NOBF_4$, DDQ only oxidized the cobalt(II) and zinc(II) complexes in dichloromethane. To confirm their chemical oxidation, a cyclic voltammetry was measured.

It is well-known that the electrical conductivity of metallophthalocyanine complexes drastically increases in partial oxidation;[1] the single crystals grown by a slow diffusion of the complexes and oxidants or an electrochemical method exhibit a metallic conductivity, and their detailed properties have been investigated.[2,3] The conductivity also increases in partial reduction of the complexes or their analogues.[4,5] The metallophthalocyanine complexes are partially oxidized by iodine which might have difficulty oxidizing the complexes judging from their redox potentials. That is, the partial oxidation of the complexes is cooperatively promoted by a stacking effect of the oxidized complexes.

The partial oxidation of unsubstituted metallophthalocyanine complexes has been extensively investigated, but few studies have been reported on the oxidation of the complexes with peripherical substituents.[6] This paper describes the oxidation of the soluble metallophthalocyanine complexes peripherically substituted by *t*-butyl groups to investigate the effects of central metal ions and oxidants on the chemical oxidation.

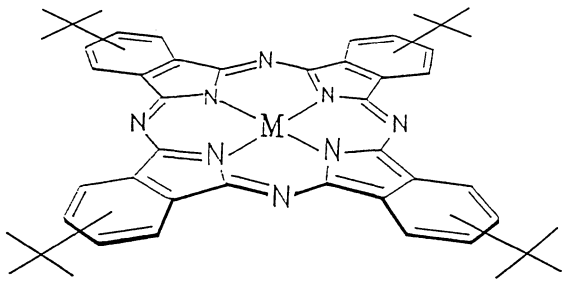

Fig. 1. Schematic representation of the $MPc(t\text{-}Bu)_4$ complex.

Experimental

Materials. Metal-free phthalocyanine and its cobalt(II), nickel(II), copper(II), and zinc(II) complexes were prepared by a method similar to that described in the literature.[6-8] 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) was recrystallized from benzene under an argon atmosphere. Nitrosyl tetrafluoroborate ($NOBF_4$) was used without further purification.

Measurements. The electronic spectra in solution were measured on a Hitachi 200-20 spectrophotometer. The ESR spectra were measured with a JEOL-1X spectrometer. The cyclic voltammetric measurements were performed in a dichloromethane solution containing tetrabutylammonium perchlorate (0.1 mol dm^{-3}) on a Hokuto Denko HA-501 potentiostat with a Hokuto Denko HF-201 function generator. A glassy carbon disk, a platinum coil, and a saturated calomel electrode (SCE) were used as a working electrode, a counter electrode, and a reference electrode, respectively.

Results and Discussion

The metallophthalocyanine complexes are generally insoluble in common organic solvents, but the complexes which are peripherically substituted by *t*-butyl groups readily dissolve in organic solvents such as dichloromethane, chloroform, benzene, and pyridine; e.g., the solubility of $ZnPc(t\text{-}Bu)_4$ in dichloromethane is ca. 2×10^{-2} mol dm^{-3}.

Chemical Oxidation. The blue dichloromethane solution of these compounds turned reddish purple upon the addition of a strong oxidant such as $NOBF_4$. In the case of $ZnPc(t\text{-}Bu)_4$, the Q band (679 nm) extensively decreased in intensity, and new bands appeared at 528 and 721 nm. Similar spectral changes were observed in the addition of $NOBF_4$ to the dichloromethane solution of $H_2Pc(t\text{-}Bu)_4$ and its cobalt(II), nickel(II) or copper(II) complexes. It was reported that oxidation at a central metal ion slightly shifts the Q band, while ring oxidation decreases the intensity of the Q band.[9,10] The intensity of the Q bands of the compounds used in the present study decreased when the compounds were oxidized by $NOBF_4$ in dichloromethane. On the other hand, with an organic oxidant

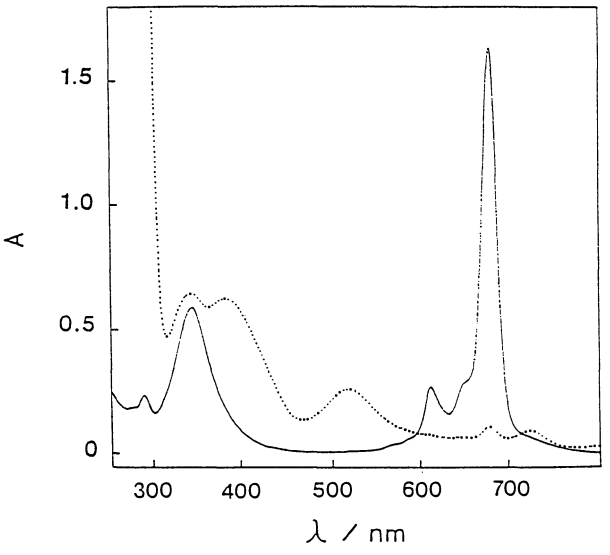

Fig. 2. Electronic spectra of $ZnPc(t\text{-}Bu)_4$ in dichloromethane: (——) [complex]=7.4×10^{-6} mol dm^{-3}; (----) [complex]=7.4×10^{-6} mol dm^{-3}, [DDQ]=1.5×10^{-5} mol dm^{-3}.

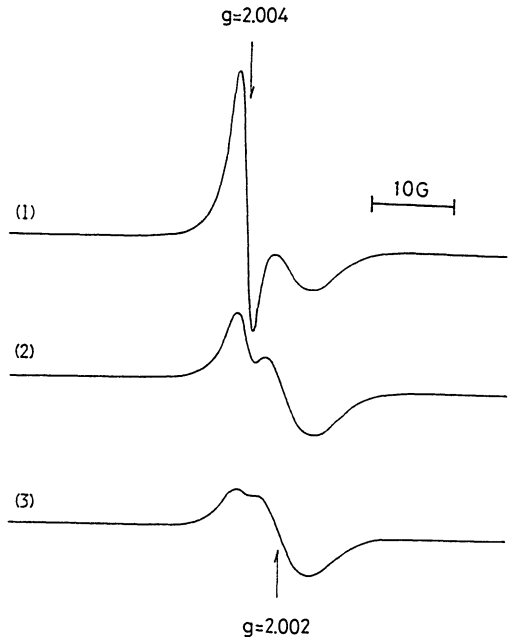

Fig. 3. ESR spectra of $ZnPc(t\text{-}Bu)_4$ oxidized by DDQ in dichloromethane at room temperature: (1) before UV irradiation; (2) irradiated for 2 min; (3) irradiated for 5 min.

such as DDQ, the blue dichloromethane solution of the cobalt(II) or zinc(II) complex turned reddish purple; e. g., the Q band (679 nm) of $ZnPc(t\text{-}Bu)_4$ decreased in intensity, and new bands appeared at 516 and 722 nm (Fig. 2). Within our knowledge, the oxidation of metallophthalocyanine with DDQ only occurs in the case of the polymer complexes of $(SnPcO)_n$ and $(AlPcF)_n$.[11,12] As soluble metallophthalocyanine complexes having simple substituents, these complexes are the first ones which could be oxidized by DDQ.

The dichloromethane solution of $ZnPc(t\text{-}Bu)_4$ oxidized by DDQ showed two ESR signals characteristic of organic radicals (Fig. 3). UV irradiation was employed to clarify the analysis of the signals. The sharp signal (g=2.004) in the lower magnetic field disappeared upon irradiation, and the g value for the signal that remained was estimated to be 2.002. On the other hand, the oxidation of the complex by $NOBF_4$ showed an ESR signal only at g=2.002. That is, the ESR signals at g=2.002 and 2.004 were assigned to those of the cationic phthalocyanine radical and the anionic DDQ radical, respectively. Furthermore, the ESR signal of the anionic DDQ radical (g=2.004) disappeared at liquid nitrogen temperature and recovered its intensity when rising to room temperature. It was reported that the anionic DDQ radicals form a dimer in the solid state, being ESR silent.[13] The concentration of the dimer in the dichloromethane solution might increase at liquid nitrogen temperature, resulting in the disappearance of the ESR signal.

Electrochemistry. The cyclic voltammograms (CV) of these compounds showed four redox couples.[14] Redox steps on the reduction side are reversible, whereas those on the oxidation side are quasi-reversible or irreversible. To confirm the behavior of the chemical oxidation, the half-wave potentials of the first step on the oxidation side are listed in Table 1. The $CoPc(t\text{-}Bu)_4$ and $ZnPc(t\text{-}Bu)_4$ complexes were easily oxidized compared with $H_2Pc(t\text{-}Bu)_4$, $NiPc(t\text{-}Bu)_4$, and $CuPc(t\text{-}Bu)_4$ in dichloromethane. By considering the potential of the first reduction step of DDQ (0.59 V vs. SCE in dichloromethane), it was obvious that only the cobalt(II) and zinc(II) complexes were oxidized by DDQ. The CV data show that the complexes are oxidized in the order of Co(II)>Ni(II) ≈Cu(II)<Zn(II). It was reported that the less the polarizing power (Ze/r) of the ion, the easier it was to oxidize the phthalocyanine ring.[15] As the ionic radii of the metal(II) ions decreased in the order of Co(II)>Ni(II)>Cu(II)<Zn(II), the order of the potentials might be explained by the polarizing power of the central ion.

Table 1. The Half-Weve Potentials of the First Oxidation Steps[a]

Compound	$E_{1/2}$[b]	$E_{1/2}$[c]
$H_2Pc(t\text{-}Bu)_4$	0.95 (irr)	0.66 (irr)
$CoPc(t\text{-}Bu)_4$	0.57 (60)	0.18 (120)
$NiPc(t\text{-}Bu)_4$	0.97 (irr)	0.89 (130)
$CuPc(t\text{-}Bu)_4$	0.82 (90)	0.81 (irr)
$ZnPc(t\text{-}Bu)_4$	0.52 (90)	0.72 (130)

a) $E_{1/2}=(E_{pa}+E_{pc})/2$ (V vs. SCE). b) In dichloromethane. c) In pyridine. Scan rate=100 mV/s^{-1}. The values in parentheses denote ΔE_p (mV). The half-wave potentials were estimated from $E_{pa}/2$ in the case of the irreversible oxidation steps.

The potential of $H_2Pc(t\text{-}Bu)_4$ in pyridine was shifted to the negative side compared with that in dichloromethane (Table 1). It was reported that the acidic protons of the phthalocyanine ring were dissociated in pyridine.[16] Then, the dissociation of the acidic protons resulted in an increase of the electron density on the phthalocyanine ring, leading to the facile oxidation of the ring. The potential of the cobalt complex was also extremely shifted to the negative side in pyridine. With the addition of $NOBF_4$ into the solution, the Q band (660 nm) of the cobalt complex shifted to 679 nm without a decrease in its intensity. That is, the central cobalt(II) ion might have been oxidized to a trivalent state.[14] The low-spin cobalt(III) ion was stabilized by the coordination of pyridine, resulting in the promotion of the oxidation of the cobalt(II) ion. Moreover, it was notable that the zinc(II) complex showed a fairly large positive shift in the potential of pyridine, but the shifts of the nickel(II) and copper(II) complexes were not so remarkable.

Effect of Water Vapor on the Transformation of *cyclo*-Tetraphosphate

Hiroyuki NARIAI,* Itaru MOTOOKA, and Mitsutomo TSUHAKO†
Department of Chemistry, Faculty of General Education, Kobe University, Tsurukabuto, Nada-ku, Kobe 657
†Kobe Women's College of Pharmacy, Kitamachi, Motoyama, Higashinada-ku, Kobe 658
(Received May 29, 1991)

Synopsis. The effect of water vapor on the process of transformation of sodium *cyclo*-tetraphosphate $Na_4P_4O_{12}(P_{4m})$ to sodium *cyclo*-triphosphate $Na_3P_3O_9(P_{3m})$ was investigated by means of DTA-TG, X-ray diffraction analysis, isothermal heating with an electric furnace, and HPLC. The transformation of P_{4m} to P_{3m} proceeded by a radical reaction via different reaction pathways in dry and humid air.

Phosphates hydrolyze or condense on heating to form various kinds of phosphates.[1-11] These reaction processes are affected by many factors including the kind of metal, the ratio of metal to phosphorus, and the duration and rate of heating.

The water vapor pressure is also an important factor in thermal reaction of phosphates. In this study, the effect of water vapor on the thermal transformation of P_{4m} to P_{3m} was investigated.

Experimental

Chemicals. Sodium *cyclo*-tetraphosphate tetrahydrate ($P_{4m}\cdot 4H_2O$) was prepared by the method given in the literature.[1] P_{4m} was prepared by heating of its hydrate at 100 and 150 °C for 2 h and 1 h, respectively. Unless otherwise stated, guaranteed-grade reagents were used without further purification. The analytical procedures and apparatus were essentially the same as those in previous works.[12-15]

Results and Discussion

Thermal Decomposition of P_{4m} Examined by DTA-TG. Figure 1 shows the DTA-TG curves for P_{4m} at atmospheric pressure. Except for a slight decrease by dehydration of adsorbed water, there was no weight loss in the TG curve over the temperature range examined. In the DTA curve, a small exothermic peak at around 500 °C was due to the transformation of P_{4m} to P_{3m} and the endo- and exothermic peaks at about 600 °C due to decomposition of P_{3m}. The influence of water vapor was investigated under the isothermal conditions in a temperature range from 400 to 500 °C.

Isothermal Change. Figure 2 shows the X-ray diffraction patterns of the samples heated for 1 h at several temperatures and humidities. The diffraction lines of P_{4m} remained unchanged at 400 °C. At 420 °C the lines changed partially to those of P_{3m}(I) (JCPDS Card 11-0648) in dry air, while in humid air to P_{3m}(I'), which has a crystal structure different from that of P_{3m}(I).[16,17] The transformation of P_{4m} to P_{3m}(I') has not been reported. At 450 °C P_{4m} changed completely into each type of P_{3m}. Table 1 shows the changes in the amounts of phosphorus compounds in the samples heated at several temperatures. At 420 °C in a dry air atmosphere (r. h.=0%), about 56% of P_{4m} already changed to P_{3m}, while in air of 90% relative humidity at (25 °C), about 21% of P_{4m} changed to P_{3m}. Since the TG curve indicated no weight change, and since no oligophosphates were detected in the 400—500 °C region, it seems

Table 1. Changes in Phosphate Composition (Starting Material: P_{4m})

Temp	Relative humidity	P_{4m}	P_{3m}
°C	%	%	%
400	0	100.0	0
	90	100.0	0
420	0	44.3	55.7
	90	79.3	20.7
450	0	0	100.0
	90	0	100.0

Thermal Decomposition Studies on Amine Complexes of Copper(II) Nitrate in Solid State

Suresh MATHEW, C. G. R. NAIR, and K. N. NINAN*,†
Department of Chemistry, University of Kerala, Trivandrum 695034, India
†Propellant and Special Chemicals Group, Vikram Sarabhai Space Centre, Trivandrum 695022, India
(Received March 9, 1990)

Synopsis. Thermal decomposition of tetraamminecopper(II) nitrate and bis(ethylenediamine)copper(II) nitrate has been studied using TG, DTG, and DTA. The kinetic parameters for the thermal deamination of the former were evaluated. The thermal decomposition of bis(ethylenediamine)copper(II) nitrate involves the concurrent deamination and the oxidation of the liberated amine by the decomposition products of $Cu(NO_3)_2$.

Solid state thermal decomposition of different complexes and salts has been extensively studied employing both isothermal and nonisothermal methods to evaluate the kinetics of their thermal decompositions. Although transition metal amine complexes were known for a long time, investigations on their thermal decomposition behavior have been carried out only recently.[1-4] Thermal studies on the amine complexes containing nitrate anion are relatively few, because of their self oxidative decomposition.

The thermal decomposition studies on tetraamminecopper(II) nitrate and bis(ethylenediamine)copper(II) nitrate in the solid state using TG, DTA, and other accessory techniques are described in this paper. The objectives of this investigation are to explore the kinetic and thermodynamic aspects of the thermal deamination of $[Cu(NH_3)_4](NO_3)_2$ and $[Cu(en)_2](NO_3)_2$.

Experimental

Preparation of Complexes: The preparative methods of $[Cu(NH_3)_4](NO_3)_2$ and $[Cu(en)_2](NO_3)_2$ are given elsewhere.[5] Both complexes were characterized by spectral and chemical methods.

Measurements: The experimental methods and the equipments used to measure TG-DTG, DTA curves, and X-ray powder diffractograms were the same as those described in our earlier work.[3,4] The heating rates employed here are 10, 2, 0.5 °C min^{-1} and sample mass 5±0.3 mg. Area under the DTA curves was evaluated by the sigmoidal curve integration and calibrated using pure indium metal.

Mathematical Treatment of Data: Kinetic parameters were evaluated from the TG and DTA curves using four nonmechanistic methods., viz. Coats-Redfern,[6] MacCallum-Tanner,[7] Horowitz-Metzger,[8] and MKN equations.[9] The iterative determination of the order parameter 'n' is described in our earlier papers.[3,4] The entropy of activation was calculated from the equation.

$$A=[(kT_s/h)\exp(\Delta S^{\neq}/R)]$$

where k=Boltzmann constant, h=Planck's constant, and $\Delta S^{\neq}$=entropy of activation. The heat of reaction ΔH was evaluated from the DTA curve by area integration of the peak.

Results and Discussion

Thermal Decomposition of $[Cu(NH_3)_4](NO_3)_2$: The TG-DTG and DTA curves of tetraamminecopper(II) nitrate are given in Fig. 1. The TG trace revealed a clear cut decomposition state (125—225 °C) but on further heating, the complex gets exploded (ca. 257 °C) at a heating rate of 10 °C min^{-1}. This can be attributed to the presence of the reducing (NH_3) group and the oxidant nitrate group in the same compound. At a lower heating rate of 2 °C min^{-1} neat thermograms could be recorded. The phenomenological data from TG and DTA curves for each stage of decomposition are given in Table 1. From the mass loss data, the two stages of decomposition of tetraamminecopper(II) nitrate can be represented as follows:

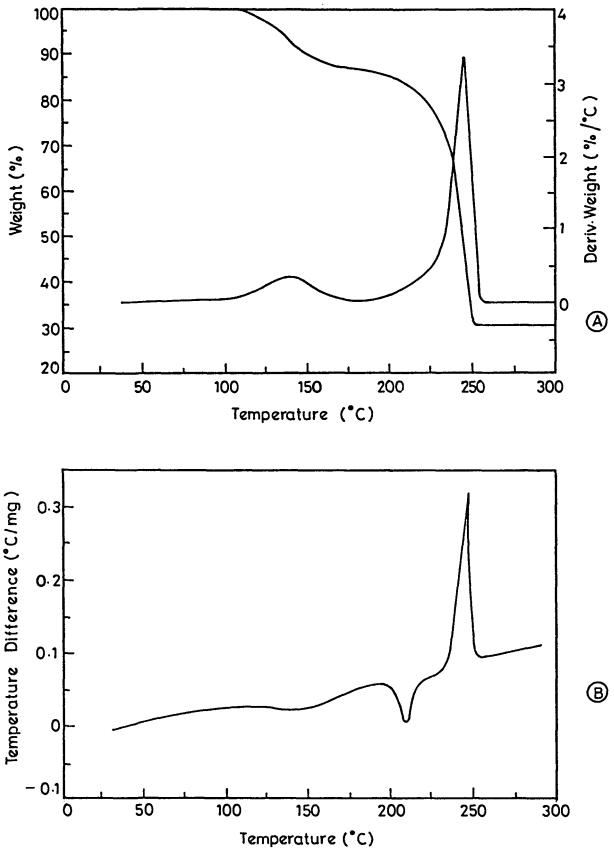

Fig. 1. A: TG and DTG curves of $[Cu(NH_3)_4](NO_3)_2$ at 2 °C min^{-1}. B: DTA curve of $[Cu(NH_3)_4](NO_3)_2$ at 2 °C min^{-1}.

$$[Cu(NH_3)_4](NO_3)_2\,(s) \longrightarrow Cu(NH_3)_2(NO_3)_2\,(s)+2NH_3\,(g)$$
$$Cu(NH_3)_2(NO_3)\,(s) \longrightarrow CuO\,(s)$$

The DTA profile of the complex shows three peaks. The first endothermic peak in the DTA curve at 146 °C is due to the first stage of deamination resulting in the formation of the diammine complex. The second

endothermic peak is immediately followed by a sharp exotherm, contrary to the expected enthalpy changes accompanying the decomposition of a stable complex. The exothermic peak can, however, be explained on the basis of the decomposition of $Cu(NO_3)_2$, overlapping the diammine complex. $Cu(NO_3)_2$ on decomposition gives rise to oxides of nitrogen and oxygen which in turn would oxidize the liberated ammonia. Thus the decomposition of the diammine complex initiates with a small endothermic peak (corresponding to the initial deamination), immediately followed by a sharp exotherm.

The thermal decomposition of tetraamminecopper(II) nitrate is consistent with the crystal structure of the complex.[10] The first deamination stage corresponds to the removal of two molecules of ammonia. From the single crystal study it is revealed that Cu–N bond distance for one pair is 2.03 Å and for the other pair is 2.008 Å. Hence normally the two NH_3 molecules coordinated to the copper at a distance of 2.03 Å can be expected to get liberated first. On subsequent heating, the remaining two NH_3 molecules are lost.

The intermediate diammine complex and the final residue of decomposition were identified by XRD. The final residue is found to be copper(II) oxide. The temperature values agree reasonably with the corresponding values of TG, except that the last two stages of DTA appear as a single stage in TG. However, the DTG peak temperature T_s corresponds to the T_{max} of the third stage in DTA. The ΔH for the first stage of deamination is 297 J gm^{-1} (endo), whereas for the second stage of deamination it is only 180 J gm^{-1} (Table 1). The reduction in enthalpy supports our contention that this stage corresponds only to a partial loss of ammonia. This is followed by the simultaneous loss of the rest of ammonia and the decomposition of $Cu(NO_3)_2$, leading to the exothermic oxidation of the liberated NH_3 by the decomposition products (ΔH=−873 J gm^{-1}).

Thermal Decomposition of $[Cu(en)_2](NO_3)_2$: In order to avoid the explosive decomposition due to the presence of a powerful reductant (en) and the oxidizing nitrate group the TG and DTA curves were recorded at a lower heating rate of 0.5 °C min^{-1} (Fig. 2). The decomposition temperature regime reveals that bis(ethylenediamine) complex is thermally more stable than

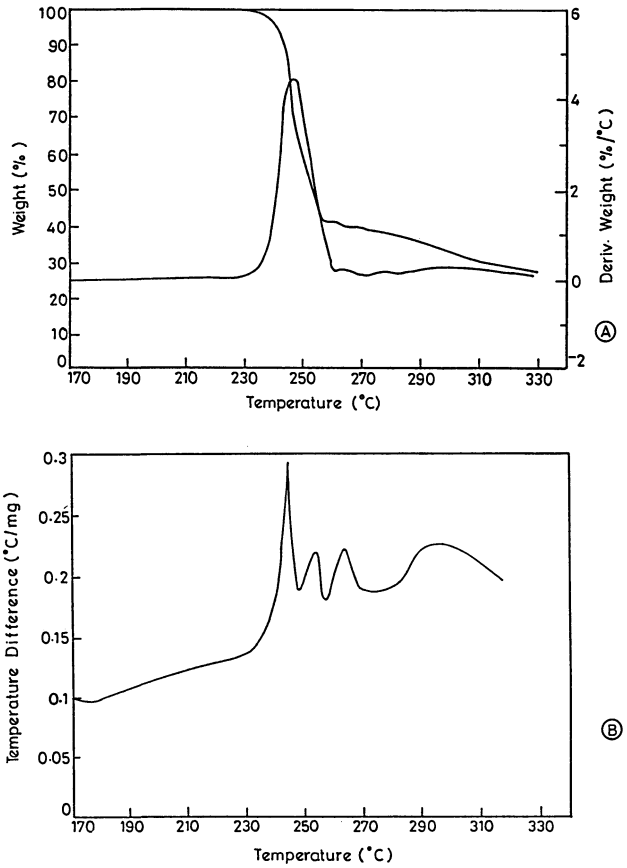

Fig. 2. A: TG and DTG curves of $[Cu(en)_2](NO_3)_2$ at 0.5 °C min^{-1}. B: DTA curve of $[Cu(en)_2](NO_3)_2$ at 0.5 °C min^{-1}.

tetraammine complex, which could be attributed to the bidentate nature of the ligand and hence a stable chelate. The weight loss corresponding to each stage of decomposition is given in Table 1. The powder diffraction pattern of the residue obtained revealed that it is pure copper(II) oxide.

The bis(ethylenediamine) complex starts decomposing at 230 °C. At this temperature, $Cu(NO_3)_2$ also starts to decompose. Due to this overlap, the whole process appears as pseudo exothermic in several steps. It is reasonable to assume that the exothermic peaks in

DTA are due to the simultaneous deamination and the insitu oxidation of the liberated amine. This process takes place in four stages, and all the stages are exothermic. The first sharp exotherm corresponds probably to the loss of one en, overlapping with its partial oxidation by the decomposition products of $Cu(NO_3)_2$.

The value of ΔH computed from the area under the DTA curve along with the T_i, T_f, and T_s values for the four stages of decomposition are given in Table 1. The four exothermic peaks in DTA add upto a heat of reaction $-2313\ J\,gm^{-1}=-711\ kJ\,mol^{-1}$. The heat of combustion of ethylenediamine is $1894\ kJ\,mol^{-1}$ [11] and therefore a complete oxidation of the two moles of en would have given rise to a heat of reaction of $-3787\ kJ\,mol^{-1}$. However the minimum requirement for the complete oxidation of two ethylenediamine molecules is 16 oxygen atoms, whereas only 6 oxygen atoms are available in $Cu(NO_3)_2$. Further, some of the ethylenediamine is likely to escape oxidation in the open system. These result in only partial oxidation of the liberated ethylenediamine. This, coupled with the endothermicities of the deamination process and the decomposition of $Cu(NO_3)_2$ to CuO, leads to an overall heat of reaction much below the heat of combustion of two ethylenediamine molecules.

The kinetic parameters were evaluated for the deamination of tetraamminecopper(II) nitrate to the diammine complex. The data using the four kinetic equations from TG and DTA are tabulated in Table 2. The correlation coefficients indicate nearly perfect fits. This table shows that the order parameter for the deamination process is a fraction, as is possible.[12,13]

Table 2 shows that the kinetic parameters computed with Horowitz-Metzger equation are higher than the values from the other three equations. This is due to the inherent error involved in the approximation method employed in the derivation of the Horowitz-Metzger equation. The deamination reaction of tetraammine complex has a positive value of entropy, indicating a less ordered structure of the activated complex than the reactant and hence the reaction may be described as "faster than normal".[14] The higher values of activation energy from DTA technique may be due to the lag in the measurement of temperature as compared to mass measurement.

The authors are grateful to the authorities of Vikram Sarabhai Space Centre for providing the instrumental facilities. One of the authors (S.M) is grateful to Council of Scientific and Industrial Research, (India) for giving him a Senior Research Fellowship.

Effect of Solvents and Acridine on Dibenzothiophene Hydrodesulfurization

Masatoshi NAGAI
Department of Chemical Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received April 17, 1991)

Synopsis. A selective poisoning pattern was observed for the hydrodesulfurization of dibenzothiophene on the sulfided Mo/Al_2O_3 catalyst in the presence of acridine and the solvents xylene and tetralin, using a microreactor at 270—340 °C and 10.1 MPa total pressure.

The selective poisoning pattern is characteristic of the correlation between hydrogenation and C–S hydrogenolysis during the hydrodesulfurization (HDS) of dibenzothiophene on a sulfided Mo/Al_2O_3 catalyst.[1] When nitrogen and aromatic heterocyclic compounds were added to the feed, the compounds depressed the hydrogenation of dibenzothiophene, but not the C–S hydrogenolysis reactions during the HDS of dibenzothiophene. On the other hand, the addition of sulfur and oxygen compounds depressed the C–S hydrogenolysis of dibenzothiophene to biphenyl and of hexahydrodibenzothiophene to cyclohexylbenzene. This selective poisoning study provided a good perspective for an understanding of the nature of active sites for HDS; hydrogenation and C–S hydrogenolysis occurred on different surface sites of the sulfided molybdenum catalysts.[2]

Although the solvents are used primarily to dissolve a feed such as polynuclear aromatic sulfur compounds, there is little understanding of the effect of solvents on hydrogenation and C–S hydrogenolysis reactions during the HDS reaction. In this study, tetralin and xylene were chosen as the solvents in order to determine which type of site is inhibited by the solvent during the reaction. The present study focused on the selectivity of the sulfided Mo/Al_2O_3 catalyst for the hydrogenation and the C–S hydrogenolysis in the presence of the solvent and a poison compound, acridine, at high hydrogen pressure.

Experimental

The apparatus was a high-pressure system with an 11 mm i.d. microreactor which has been described elsewhere.[3] Hydrogen was dried by passage through a Linde 13X molecular sieve trap prior to use. Dibenzothiophene was synthesized via the same procedure as described in a previous paper.[1] Acridine and all other reagents obtained commercially were used without further purification. The 12.5% MoO_3/Al_2O_3 catalyst (0.84—1.19 mm granules) was packed in the reactor and oxidized for more than 24 h at 450 °C in air. Sulfiding was carried out with a 10% H_2S/H_2 mixture flowing at 30 L h^{-1} at atmospheric pressure and 400 °C for 3 h after reduction of the oxidized catalyst in 10 L h^{-1} hydrogen at 400 °C and 10.1 MPa pressure for 4 h. After sulfiding, the reactor was cooled to 300 °C in the H_2S/H_2 stream, and then a solution containing 5 wt% (3.53 mmol L^{-1}) of dibenzothiophene in xylene (or tetralin) was allowed to flow into the reactor. A typical reaction was carried out at 300 °C and at 28 L h^{-1} hydrogen flow and at 10.1 MPa total pressure. After the reaction had reached a steady state (in about 3 h), acridine was added to the feed at the concentration required to produce 0 to 3.1 kPa. Xylene was barely hydrogenated at 300 °C in the presence of dibenzothiophene or acridine. The liquid product samples were analyzed by FID gas chromatography.

Results and Discussion

The major products were biphenyl and cyclohexylbenzene in the dibenzothiophene HDS: the former product was formed by the direct C–S bond breakage of dibenzothiophene and the latter by the C–S hydrogenolysis of hexahydrodibenzothiophene after successive hydrogenation. The effect of acridine on dibenzothiophene HDS in xylene solvent is shown in Fig. 1. When acridine was added to the xylene solution containing dibenzothiophene, the amount of biphenyl increased in inverse proportion to the amount of cyclohexylbenzene. The addition of 0.1 wt% acridine brought about the maximum amount of 0.42 wt% biphenyl. Acridine was preferentially hydrogenated to perhydroacridine without the direct C–N hydrogenolysis of acridine on a sulfided Mo/Al_2O_3 catalyst at 300 °C, since no hydrocarbon products were observed from the acridine hydrodenitrogenation either in this reaction or in the hydrodenitrogenation of acridine alone.[4] Moreover,

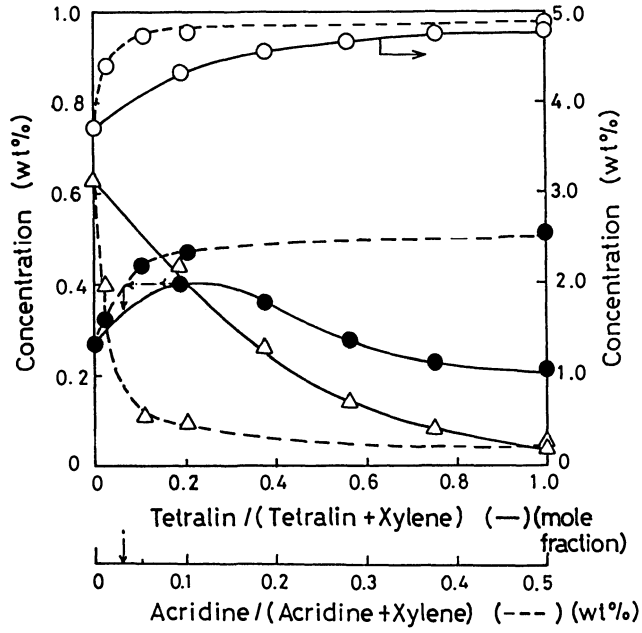

Fig. 1. Effect of xylene/(tetralin+xylene) solvent fraction (——) and of acridine (----)[1] on the major products of the HDS of dibenzothiophene at 300 °C. ○, dibenzothiophene; ●, biphenyl; △, cyclohexylbenzene.

the hydrogenation of biphenyl to cyclohexylbenzene did not occur in the presence of dibenzothiophene even on the sulfided $NiMo/Al_2O_3$ catalyst at 300 °C.[5] Therefore, the preferential hydrogenation of acridine depressed the hydrogenation of dibenzothiophene. Thus, acridine inhibited the hydrogenation sites, but not the C–S hydrogenolysis sites. The addition of acridine to the feed expelled dibenzothiophene from the hydrogenation sites. The dibenzothiophene was in turn adsorbed on the C–S hydrogenolysis sites to be desulfurized to form biphenyl. Therefore, it appeared that the decrease in cyclohexylbenzene resulted in enhanced biphenyl formation in the xylene solvent.

Changes in the ratio of xylene and tetralin in dibenzothiophene HDS are shown in Fig. 1. The amount of biphenyl was increased by increasing the tetralin-fraction and was maximized to 0.405 wt% at a 22% tetralin-fraction and was minimized to 0.2 wt% biphenyl. The amount of cyclohexylbenzene was gradually decreased to 0.035 wt% from 0.63 wt% when the tetralin-fraction was increased to 100% tetralin. The selective poisoning pattern in the presence of less than a 22% tetralin-fraction was observed for the results obtained in the presence of acridine in xylene. This suggested that less than 22% tetralin in xylene did not inhibit the C–S hydrogenolysis sites but did affect the hydrogenation sites at 300 °C. Furthermore, more than 22% tetralin inhibited both the C–S hydrogenolysis and hydrogenation sites.

The amount of a mixture of 78% xylene and 22% tetralin corresponded to the amounts of cyclohexylbenzene and biphenyl in the presence of 0.03 wt% acridine, as shown in Fig. 1. A 22% fraction of tetralin corresponded to 11.9 $mmol\,h^{-1}\,g\text{-}cat^{-1}$ of tetralin which was adsorbed on the hydrogenation sites only. The corresponding amount of acridine was 3.98×10^{-3} $mmol\,h^{-1}\,g\text{-}cat.^{-1}$. This amount was 1/3000 th the value obtained from the mixture of xylene and tetralin. These results showed that acridine was adsorbed on the hydrogenation sites 3000-fold stronger than tetralin. In a previous paper,[1] the poisoning effect of the nitrogen and aromatic compounds on the HDS of dibenzothiophene over the sulfided Mo/Al_2O_3 catalyst was studied. The strength of the adsorption constant of acridine was 67 times as great as that of phenanthrene, although tetralin was not tested in the dibenzothiophene HDS. The result suggested that tetralin was adsorbed on the hydrogenation sites 45 times less than phenanthrene.

The formation of biphenyl and cyclohexylbenzene in the HDS of dibenzothiophene in either xylene or tetralin solvent in the range of 270 to 340 °C is shown in Fig. 2. The concentrations of biphenyl and cyclohexylbenzene in the dibenzothiophene HDS in xylene solvent were 1.2 and 18 times that in tetralin at 300 °C, respectively. Tetralin inhibited both hydrogenation and C–S hydrogenolysis more than did xylene. The apparent activation energies for the formation of biphenyl were 84.9 $kJ\,mol^{-1}$ in tetralin and 76.5 $kJ\,mol^{-1}$ in xylene. The formation of cyclohexylbenzene in tetralin was much less than that in xylene. The apparent activation energies for the formation of cyclohexylbenzene were 186 in tetralin, and 157 (270—300 °C) and 58.9 (300—340 °C) $kJ\,mol^{-1}$ in xylene.[6]

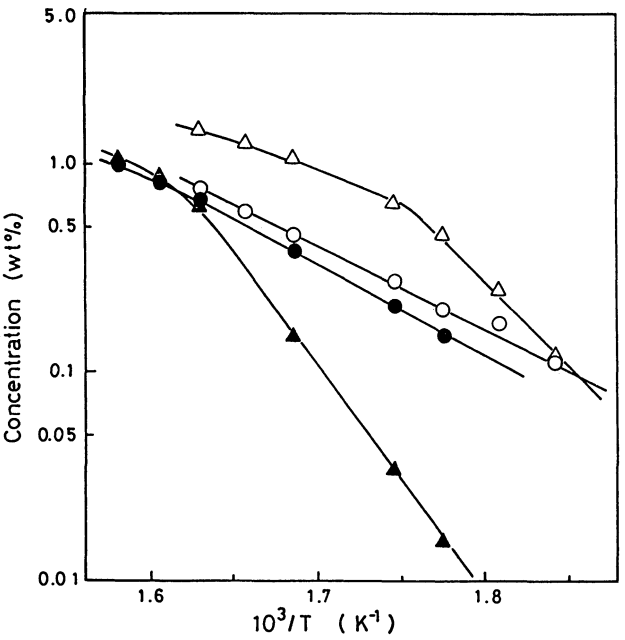

Fig. 2. Arrhenius plots of the formation of biphenyl and cyclohexylbenzene in xylene (open symbol)[6] and tetralin (closed symbol). ○●, biphenyl; △▲, cyclohexylbenzene.

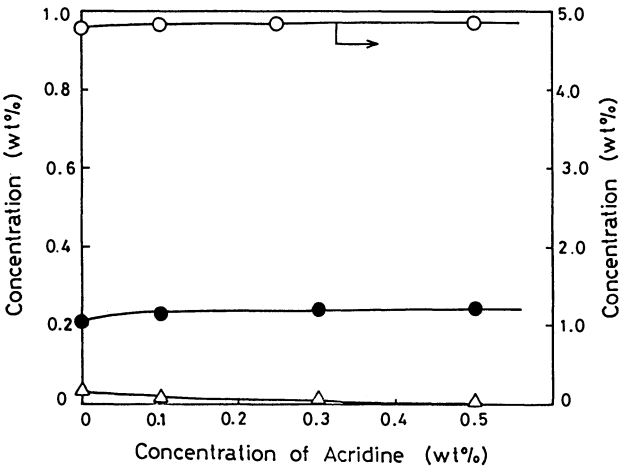

Fig. 3. Effect of acridine on the major products of the HDS of dibenzothiophene in tetralin solvent at 300 °C. The symbols are the same as those in Fig. 1.

The presence of acridine on dibenzothiophene HDS in the tetralin solvent is shown in Fig. 3. The presence of acridine lowered the amount of cyclohexylbenzene, and enhanced the amount of biphenyl, which reached constant values of 0.2% and 0.05%, respectively. The selective pattern was similar to the results of acridine addition in the xylene solvent: The presence of acridine inhibited the hydrogenation sites and resulted in increased biphenyl formation. However, more than 22% tetralin was adsorbed competitively on the active sites for the direct C–S hydrogenolysis of dibenzothiophene to biphenyl, as well as on the active sites for successive hydrogenation of dibenzothiophene. The presence of acridine slightly enhanced biphenyl formation.

In summary, the HDS of dibenzothiophene was catalyzed on two kinds of active sites on the sulfided Mo/Al_2O_3 catalyst: Site I was active for hydrogenation and was very sensitive to poisoning by nitrogen bases, while Site II was active for HDS (C–S hydrogenolysis), and was less susceptible to acridine poisoning. The presence of a small amount of tetralin hindered the hydrogenation of dibenzothiophene, but a large amount of tetralin depressed the C-S hydrogenolysis as well as the hydrogenation reaction.

Several researchers have found it necessary to postulate the existence of two kinds of catalytic sites on molybdenum sulfide catalysts. Massoth and coworkers[7–9] proposed that at least two HDS sites exist, one being poisoned and the other unaffected by pyridine. Hydrogenation was more strongly affected by pyridine than HDS. They suggested that the three reactions (HDS, hydrogenation, and cracking) appeared to take place on different sites.[7] Gates and coworkers[2,10,11] studied the HDS reaction network of dibenzothiophene and found that H_2S depressed hydrogenolysis but left hydrogenation unchanged. They also proposed that there was competitive adsorption of H_2S and the sulfur-containing reactant on one kind of catalytic site and noncompetitive adsorption of hydrogen on another kind of site. Furthermore, Shimada et al.[12] found that two-dimensional polymolybdate structures were favorable for high hydrogenation activity while electronegative molybdenum which induces Brønsted activity was required for high hydrogenolysis activity. They also reported that HDS of dibenzothiophene can be catalyzed on both kinds of active sites.

Addition Effect of NaF on the Deodorant Efficiency of an Iron Phthalocyanine Derivative

Koe ENMANJ,* Itsuo NISHIYAMA, Kenzo TAKAHASHI, and Muneharu SANOH
Materials and Electronic Devices Laboratory, Mitsubishi Electric Corp., Tsukaguchi-Honmachi, Amagasaki 661
(Received May 9, 1991)

Synopsis. A low temperature ESR spectrum shows that Fe(III) of an iron phthalocyanine derivative treated with NaF takes a high spin state. The deodorant efficiency of the derivative treated with NaF is three times higher than that without NaF treatment.

Hydrogen sulfide (H_2S) is one of "the eight bad smells",[1] and many reports have appeared concerning the deodorant method for it.[2] The reaction type deodorant materials containing copper(II) ion as an active substance were investigated for use in air conditioners with cleaner.[3] The lifetime of the copper(II) deodorant materials are not long enough. Biomimetic deodorant materials containing iron phthalocyanine derivatives as an enzyme-like catalyst were then studied in view of their theoretically infinite lifetimes.[4] The efficiency of these deodorant materials is not high enough for air conditioners. We improved the deodorant efficiency of a biomimetic deodorant material for H_2S by adding NaF to an iron phthalocyanine derivative. The relation between the deodorant efficiency and the high spin character of the iron phthalocyanine derivative is discussed.

Experimental

Iron(III)-4,5,4′,5′,4″,5″,4‴,5‴-octacarboxyphthalocyanine (FePc) was synthesized and purified by the method described in the literature.[5] The untreated deodorant material (UTD) was prepared by dipping 10 g of cotton in a 10 mmol dm^{-3} FePc aqueous solution followed by rinsing with 0.1 mol dm^{-3} HCl and drying at 100 °C for 1 h. The NaF-treated deodorant material (FTD) was fabricated by dipping UTD in a 1% NaF aqueous solution and drying at 100 °C for 1 h.

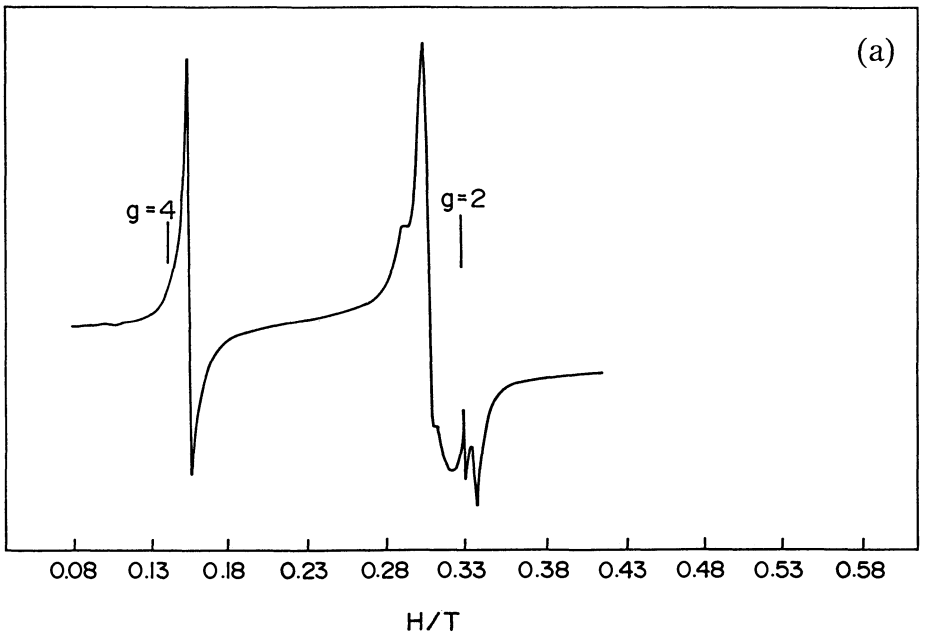
The deodorant efficiency, η (%) for H_2S was evaluated by the formula.[6]

$$\eta = (C_0 - C)/C_0 \times 100 \quad (1)$$

Here C_0 (170 ppb) is the H_2S concentration in the absence of the deodorant material and C the concentration passing through the deodorant material. The flow rate of air was 5 ml min^{-1}. ESR measurements were done with a JEOL JES-FX2XG spectrometer equipped with a temperature controler.

Results and Discussion

Low-temperature ESR spectra of the deodorant materials UTD and FTD are shown in Fig. 1 (a) and (b), respectively. The intensity ratio of the g=4 peak to the g=2 peak was examined. The high-spin signal at g=4 indicates that the axial symmetry of FePC is distorted.[7] Since the g value remained unchanged by addition of NaF, the symmetry arround the Fe(III) ion did not change by coordination of F^- ion to the 5th site of Fe. Because intensity ratio of the g=4 peak to g=2 peak was increased, NaF treatment may increase the ratio of the molecular number of Fe(III) in the high-spin state to that in the low-spin state. Here, g=2 peak is the overlapped signals between high spin state and low spin state.[7] The intensity ratio is 0.96 for UTD and 1.27 for FTD. The superiority of the high-spin state fraction in the FTD sample is due to the addition of F^- to the 5th coordination site of Fe(III). This phenomenon



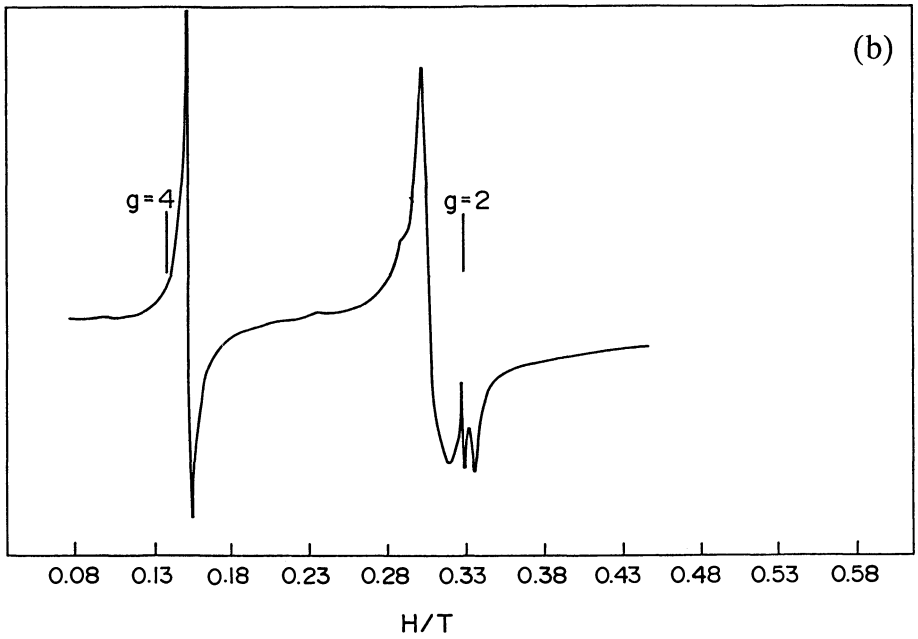


Fig. 1. (a) ESR spectrum of FePc held on cotton. (b) ESR spectrum of FePc treated with NaF and held on cotton. Temp: −143 °C, RF: 1 mW, 9.2 GHz, Field: 0.3287±0.25 T, Mod: 100 kHz, 0.63 mT, Amp: 5×10.

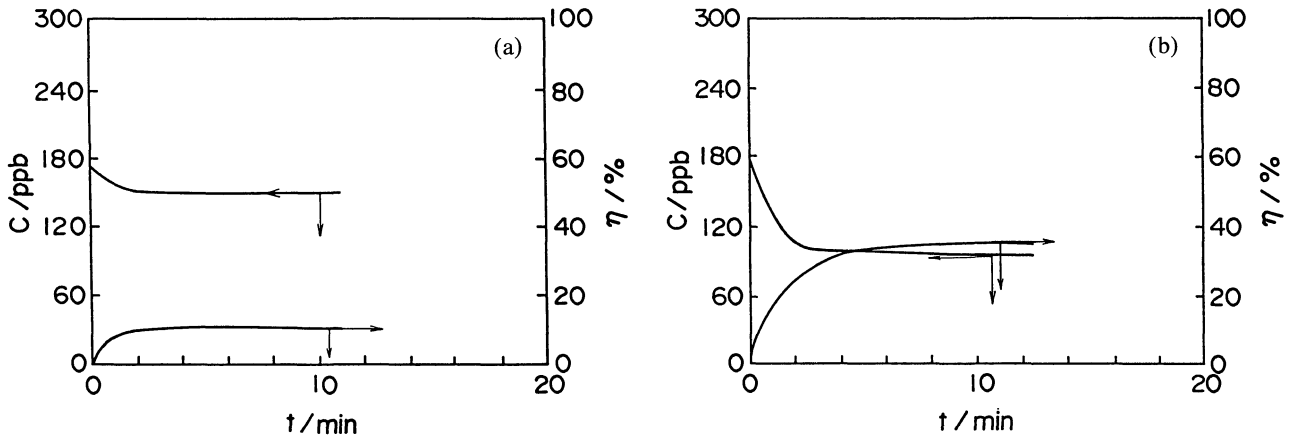

Fig. 2. (a) Time dependent deodorant efficiency of untreated deodorant material. (b) Time dependent deodorant efficiency of NaF treated deodorant material. Initial H_2S concentration, 170 ppb; Flow rate, 5 ml min^{-1}.

is related to the fact that the Bohr magnetic number of methemoglobin, whose 6th coordination site is occupied with F^-, was 5.92.[8]

The small and sharp peak at g=2.0023 originates most probable from the superoxide radical, in view of the generation of superoxide radical in the FePc systems.[4] Comparison of the peak height at g=4.0023 between UTD and FTD shows that the superoxide radical is more abundant in FTD than in UTD.

Fe(III) ion of FePc in the high-spin state has a larger reaction rate of oxidation than that in the low-spin state.[4] The results of deodorant efficiency measurements for UTD and FTD are shown in Fig. 2 (a) and (b), respectively. The efficiency of FTD was three times higher than that of UTD. This could be related to coordination of F^- to the 5th site of Fe in FePc. Details of the reaction mechanism are left for a future study.

Soccerane Derivatives of Given Symmetries

Shinsaku FUJITA
Research Laboratories, Ashigara, Fuji Photo Film Co., Ltd.,
Minami-Ashigara, Kanagawa 250-01
(Received November 26, 1990)

Symmetrical properties of soccerane and its derivatives are discussed in the light of subduction of coset representations (CRs). The 60 vertices of soccerane are equivalent and construct a single orbit governed by the CR, $\mathbf{I}_h(/\mathbf{C}_s)$. This orbit is divided into several orbits in the respective derivative, where the mode of the division is controlled by the subduction. The number of derivatives with a given formula and a given subsymmetry is calculated in terms of unit subduced cycle indices, which are derived from the subduction.

Hydrocarbons of high symmetries and related compounds have attracted continuous attention of organic chemists because of their potential properties.[1] Among them, a fully unsaturated C_{60} compound of $\mathbf{I}_h$ symmetry has once been mentioned by Osawa[2] as a theoretically interesting compound. The corresponding saturated $C_{60}H_{60}$-hydrocarbon (**1**) has been called "footballane" or "soccerane" by Castells and Serratosa.[3] They pointed out: "Since the synthesis of dodecahedrane has been recently accomplished by Paquette and his coworkers at Ohio State University, the synthesis of soccerane appears as the next goal". They later gave this complex hydrocarbon the IUPAC name,[4] i. e., hentriacontacyclo[29.29.0.$0^{2,14}$.$0^{3,29}$.$0^{4,27}$.$0^{5,13}$.$0^{6,25}$.$0^{7,12}$.-$0^{8,23}$.$0^{9,21}$.$0^{10,18}$.$0^{11,16}$.$0^{15,60}$.$0^{17,58}$.$0^{19,56}$.$0^{20,54}$.$0^{22,52}$.$0^{24,50}$.$0^{26,49}$.-$0^{28,47}$.$0^{30,45}$.$0^{32,44}$.$0^{33,59}$.$0^{34,57}$.$0^{35,43}$.$0^{36,55}$.$0^{37,42}$.$0^{38,53}$.$0^{39,51}$.$0^{40,48}$.-$0^{41,46}$]hexacontane.

Recently, a C_{60} peak has been observed in a laser vaporization of graphite by Kroto et al.,[5a] where the peak was assigned to formation of the above $\mathbf{I}_h$ molecule (a C_{60} carbon cluster).[6] This paper has stimulated a large number of theoretical studies on this carbon cluster.[7] Other compounds of $\mathbf{I}_h$ symmetry (Fig. 1) have also attracted theoretical attention of chemists.[8] A brief review has summarized predicted properties of these related compounds.[9] Geometrical properties of soccerane and other $\mathbf{I}_h$-molecules have been discussed.[10] Since soccerane has been so far detected only by physicochemical analysis, total syntheses of such high-symmetry molecules are challenging targets from the viewpoint of synthetic organic chemistry.

Since the $\mathbf{I}_h$ symmetry contains various unusual subsymmetries, derivatization of soccerane ($C_{60}H_{60}$) by substituting an appropriate set of atoms for the same number of hydrogen atoms produces molecules of the subsymmetries, which will be further targets of synthetic organic chemistry. In this connection, the number of derivatives of a given subsymmetry of this series will be of interest to organic chemists. Hosoya[10] has enumerated such soccerane derivatives by using Pólya's theorem.[11] This enumeration is, however, concerned with their molecular formulas and not with their symmetries.

We have reported a systematic enumeration of molecules in terms of unit subduced cycle indices (USCIs).[12,13] This method requires a table of marks (or the inverse) due to Burnside[14] and a table of USCIs introduced by us.[12] We have presented such tables for $\mathbf{C}_2$, $\mathbf{C}_{2v}$, $\mathbf{C}_{3v}$, $\mathbf{D}_2$, $\mathbf{D}_{2d}$, $\mathbf{D}_{2h}$, $\mathbf{D}_3$, $\mathbf{D}_{3h}$, $\mathbf{T}$, and $\mathbf{T}_d$ as well as their applications to various enumerations.[15] We have recently reported construction of such tables for the $\mathbf{I}_h$ group and applications to enumeration of dodecahedrane derivatives.[16] However, the advantage of the USCI approach for enumeration has not been fully investigated, inasmuch as the enumerations have been limited within rather simple molecules. The present paper deals with the enumeration of isomers derived from soccerane in order to exemplify the advantage and generality of the USCI approach.

1. Orbits in $\mathbf{I}_h$ Molecules. Figure 1 collects the soccerane skeleton and the related ones of $\mathbf{I}_h$ symmetry. We first examine the symmetrical properties of the skeletons. Any skeleton has several sets of equivalent positions (vertices, edges or faces). These sets are called *orbits* in accord with the terminology of permutation group. The symmetry properties of each orbit is characterized by the corresponding coset representaion (CR).[17,18] The CR is represented by the symbol $\mathbf{G}(/\mathbf{G}_i)$ that is based on a coset decomposition of $\mathbf{G}$ by $\mathbf{G}_i$, where $\mathbf{G}$ is the point group of the skeleton and $\mathbf{G}_i$ is its subgroup.

Since the $\mathbf{I}_h$ group of order 120 posesses a set of subgroups, SSG=$\{\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_s, \mathbf{C}_i, \mathbf{C}_3, \mathbf{D}_2, \mathbf{C}_{2v}, \mathbf{C}_{2h}, \mathbf{C}_5, \mathbf{D}_3,$

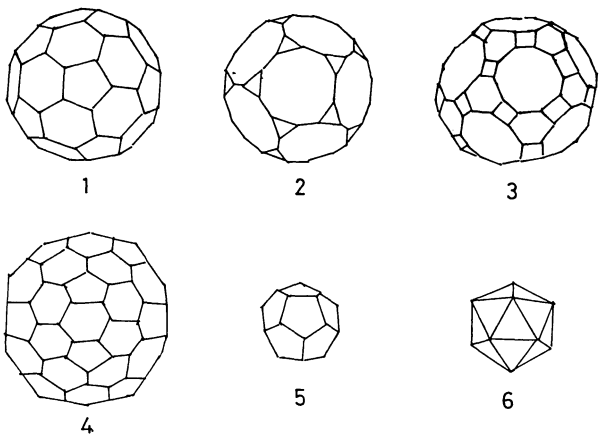

Fig. 1. Skeletons of $\mathbf{I}_h$ symmetry.

Table 1 lists orbits of each skeleton shown in Fig. 1. We have reported a method of assigning a CR to each orbit[17,18] as well as data necessary to this task.[16] For simplicity's sake, we consider the soccerane skeleton to be a truncated icosahedron, which has 60 vertices, 90 edges, and 32 faces. In order to illustrate a procedure of the assignment, we examine the 60 vertices of **1**, which are equivalent and construct a single orbit. We first count fixed points (vertices) for each subgroup during all of the operations contained in the subgroup, affording a fixed-point vector (FPV). We thus obtain an FPV= (60 0 4 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0) for the vertices. This vector is multiplied by the inverse of a mark table for $\mathbf{I}_h$ group (Table 2). The resulting vector (0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0) shows the multiplicities of the subgroups listed in the SSG; in this case, there appears only one $\mathbf{I}_h(/\mathbf{C}_s)$ orbit. If the symbol $\mathbf{P}_{1(\text{vertex})}$ denotes a permutation representation concerning the 60 vertices, we have

$$\mathbf{P}_{1(\text{vertex})} = \mathbf{I}_h(/\mathbf{C}_s). \quad (1)$$

Note that the size of the orbit is equal to $|\mathbf{I}_h|/|\mathbf{C}_s|=120/2=60$. Since a 5-membered ring and two 6-membered rings meet at each vertex, we refer to this vertex as a [5.6.6] vertex. Thereby, we can obtain the SCR notation,[17] $\mathbf{I}_h[/\mathbf{C}_s([5.6.6]_{60})]$ for this skeleton, where the CR and its members are indicated.

There are two kinds of edges in **1**, which construct distinct orbits. With respect to these edges, we have an FPV=(90 2 8 0 0 0 2 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0). This vector is multiplied by the inverse (Table 2), producing a row vector, (0 0 1 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0). This corresponds to the following equation,

$$\mathbf{P}_{1(\text{edge})} = \mathbf{I}_h(/\mathbf{C}_s) + \mathbf{I}_h(/\mathbf{C}_{2v}), \quad (2)$$

in which the symbol $\mathbf{P}_{1(\text{edge})}$ denotes a permutation representation of the 90 edges. Note that the degree of $\mathbf{I}_h(/\mathbf{C}_s)$ is equal to $|\mathbf{I}_h|/|\mathbf{C}_s|=120/2=60$ and that of $\mathbf{I}_h(/\mathbf{C}_{2v})$ is equal to $|\mathbf{I}_h|/|\mathbf{C}_{2v}|=120/4=30$. If the symbol [6:6] denotes an edge at which two 6-membered rings fuse, Eq. 2 concludes that the sixty [6:6]edges in **1** construct an orbit that is subject to $\mathbf{I}_h(/\mathbf{C}_s)$. Similarly,

a) The symbol $\mathbf{G}_i$ is an abbreviation of $\mathbf{I_h}(/\mathbf{G}_i)$, where $\mathbf{G}_1=\mathbf{C}_1$, $\mathbf{G}_2=\mathbf{C}_2$, $\cdots$, $\mathbf{G}_s=\mathbf{I_h}$. For example, we here use $\mathbf{C}_2$ for $\mathbf{I_h}(/\mathbf{C}_2)$. b) $\mathrm{Sum}=\sum_{j=1}^{s}\bar{m}_{ji}$.

thirty [5 : 6]edges are subject to $\mathbf{I_h}(/\mathbf{C_{2v}})$.

The 32 faces of the molecule (**1**) give an FPV= (32 0 8 0 2 0 0 0 2 0 2 0 0 0 2 0 0 0 0 0 0 0). The multiplication of the FPV by the inverse (Table 2) affords a row vector (0 0 0 0 0 0 0 0 0 0 1 0 0 0 1 0 0 0 0 0 0 0), which indicates the appearence of $\mathbf{I_h}(/\mathbf{C_{3v}})$ and $\mathbf{I_h}(/\mathbf{C_{5v}})$. Hence, the 32 faces are characterized by

$$\mathbf{P}_{1(\mathrm{face})} = \mathbf{I_h}(/\mathbf{C_{3v}}) + \mathbf{I_h}(/\mathbf{C_{5v}}). \quad (3)$$

Since $|\mathbf{I_h}|/|\mathbf{C_{3v}}|=120/6=20$ and $|\mathbf{I_h}|/|\mathbf{C_{5v}}|=120/10=12$, Eq. 3 means that 20 hexagonal faces belong to an orbit governed by $\mathbf{I_h}(/\mathbf{C_{3v}})$; and that the remaining 12 pentagonal faces construct an orbit governed by $\mathbf{I_h}(/\mathbf{C_{5v}})$.

In a similar way, the orbits of the other skeletons are assigned to the respective CRs (Table 1). It should be noted that another C_{60} icosahedral skeleton (**2**) has equal numbers of vertices, edges, and faces as compared with **1** and that these are subject to the same CRs. The latter skeleton (**2**) can be differentiated from **1** by the SCR notation, $\mathbf{I_h}[/\mathbf{C_s}([3.10.10]_{60})]$.

2. Subduction of the $\mathbf{I_h}(/\mathbf{C_s})$ Orbit. The replacement of hydrogen atoms of **1** by other atoms produces a derivative of **1** that belongs to a subsymmetry of $\mathbf{I_h}$. Such a desymmetrization process is characterized in terms of subduction of the corresponding CR.[18] For manipulating the soccerane skeleton (**1**), the $\mathbf{I_h}(/\mathbf{C_s})$ CR is subduced into every subgroup. In order to illustrate such a subduction, let us examine $\mathbf{I_h}(/\mathbf{C_s})\downarrow\mathbf{C_{2v}}$, which denotes the subduction of the $\mathbf{I_h}(/\mathbf{C_s})$ representation into the $\mathbf{C_{2v}}$ group. The $\mathbf{I_h}(/\mathbf{C_s})$ row of a mark table is equal to the row vector, FPV=(60 0 4 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0), the elements of which are aligned in the order of the SSG.[19] Since the SSG of the $\mathbf{C_{2v}}$ group is represented by SSG'=$\{\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_s, \mathbf{C}'_s, \mathbf{C_{2v}}\}$, we can obtain a row vector (60 0 4 4 0) by selecting from the FPV the values corresponding to the SSG'. Note that the value 4 for the $\mathbf{C}_s$ subgroup of the $\mathbf{I_h}$ is duplicated to afford the value 4 for the $\mathbf{C}'_s$ of the $\mathbf{C_{2v}}$. This vector for the $\mathbf{C_{2v}}$ group is multiplied by the inverse of a mark table for the $\mathbf{C_{2v}}$ group, i. e.,

$$(60\,0\,4\,4\,0)\begin{pmatrix} 1/4 & 0 & 0 & 0 & 0 \\ -1/4 & 1/2 & 0 & 0 & 0 \\ -1/4 & 0 & 1/2 & 0 & 0 \\ -1/4 & 0 & 0 & 1/2 & 0 \\ 1/2 & -1/2 & -1/2 & -1/2 & 1 \end{pmatrix} = (13\,0\,2\,2\,0), \quad (4)$$

$\mathbf{D_{5d}}$	$2\mathbf{D_{5d}}(/\mathbf{C_1})+2\mathbf{D_{5d}}(/\mathbf{C_s})$	$a_{10}^2c_{20}^2$	$s_{10}^2s_{20}^2$	0
$\mathbf{T_h}$	$2\mathbf{T_h}(/\mathbf{C_1})+\mathbf{T_h}(/\mathbf{C_s})$	$a_{12}c_{24}^2$	$s_{12}s_{24}^2$	0
$\mathbf{I}$	$\mathbf{I}(/\mathbf{C_1})$	b_{60}	s_{60}	0
$\mathbf{I_h}$	$\mathbf{I_h}(/\mathbf{C_s})$	a_{60}	s_{60}	0

a) The sum is obtained by summing up each row of the inverse (Table 2).

where the second 5×5 matrix is the inverse. The resulting vector indicates the multiplicity of each CR. Hence, we have

$$\mathbf{I_h}(/\mathbf{C_s})\downarrow\mathbf{C_{2v}} = 13\mathbf{C_{2v}}(/\mathbf{C_1})+2\mathbf{C_{2v}}(/\mathbf{C_s})+2\mathbf{C_{2v}}(/\mathbf{C_s'}). \quad (5)$$

Other subductions are precalculated in a similar way and collected in the second column of Table 3.

According to the subductions, we obtain unit subduced cycle indices (USCIs)[12] and USCIs with chirality fittingness (USCI-CFs).[20] In the $\mathbf{C_{2v}}$ group, we assign a variable s_4 (or c_4) to $\mathbf{C_{2v}}(/\mathbf{C_1})$, s_2 (or a_2) to $\mathbf{C_{2v}}(/\mathbf{C_s})$, and s_2 (or a_2) to $\mathbf{C_{2v}}(/\mathbf{C_s'})$, where the subscripts come from the equations, $|\mathbf{C_{2v}}|/|\mathbf{C_1}|=4$, $|\mathbf{C_{2v}}|/|\mathbf{C_s}|=2$, and $|\mathbf{C_{2v}}|/|\mathbf{C_s'}|=2$. The variable ($c_4$) is based on the chirality fittingness of the $\mathbf{C_{2v}}(/\mathbf{C_1})$ (enantiospheric);[18] the variable (a_2) stems from that of $\mathbf{C_{2v}}(/\mathbf{C_s})$ or $\mathbf{C_{2v}}(/\mathbf{C_s'})$, which is homospheric. As a result, we have a USCI ($s_2^4s_4^{13}$) and a USCI-CF ($a_2^4c_4^{13}$) in terms of Eq. 5. The other USCIs and USCI-CFs for the $\mathbf{I_h}(/\mathbf{C_s})$ CR listed in Table 3 are obtained in a similar way.

The above procedure of generating subduced representations is purely algebraic; however, the resulting coset representations of each subgroup have geometrical (or chemical) meaning. In order to convert the skeleton to a $\mathbf{C_{2v}}$-molecule, for example, we start from Eq. 5. This equation indicates that there emerge thirteen 4-membered orbits ($\mathbf{C_{2v}}(/\mathbf{C_1})$), two 2-membered orbits ($\mathbf{C_{2v}}(/\mathbf{C_s})$) and two of other 2-membered orbits ($\mathbf{C_{2v}}(/\mathbf{C_s'})$). If these orbits are occupied by different kinds of atoms, we have a $\mathbf{C_{2v}}$ molecule (**7**) with the following packing,

$$\underbrace{X_2Y_2}_{2\text{ kinds}}\quad\underbrace{Z_2W_2}_{2\text{ kinds}}\quad\underbrace{H_4\cdots B_4}_{13\text{ kinds}} \quad (6)$$

The first block of this equation corresponds to the 2-membered orbits of $\mathbf{C_{2v}}(/\mathbf{C_s})$, where ●=X and ○=Y. These vertices are fixed during a reflection concerning the mirror plane that contains ●'s and ○'s. The second block of Eq. 6 is concerned with the 2-membered orbits of $\mathbf{C_{2v}}(/\mathbf{C_s'})$, where △=Z and ▲=W. These vertices are contained in the mirror plane associated with the $\mathbf{C_s'}$ group. The third block of Eq. 6 indicates a mode of packing in the remaining 13 orbits, some of which are, for example, differentiated by distinct marks. Although there exist $\mathbf{C_{2v}}$ molecules (**8**—**10**) having the formula ($C_{60}H_{56}X_2Y_2$), their orbits are also controlled by Eq. 5. In other words, the 56 hydrogen atoms are classified into 15 equivalence classes (orbits).

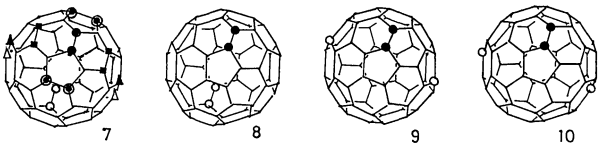

Figure 2 depicts a representative molecule for every subgroup of $\mathbf{I_h}$, where ● and ○ denote X and Y; and

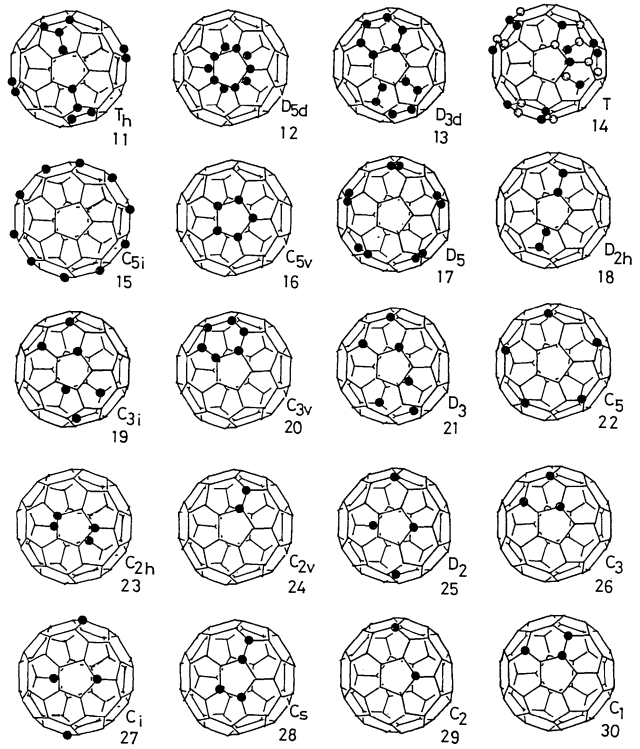

Fig. 2. Molecules derived from the soccerane skeleton (**1**).

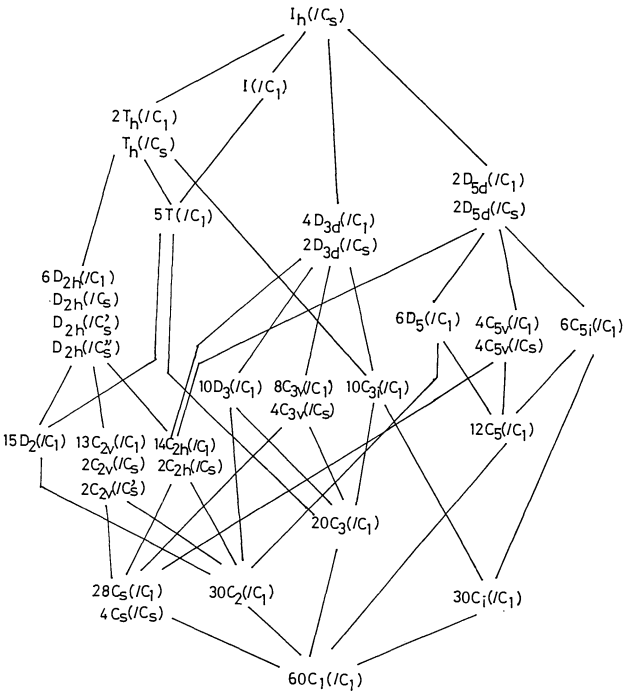

Fig. 3. Desymmetrization lattice for $\mathbf{I}_h(/\mathbf{C}_s)$.

unmarked vertices take hydrogen atoms. The orbits of each of the molecules are subject to the subduction listed in Table 1.

Since any derivation based on the soccerane skeleton (**1**) is regarded as a desymmetrization of the skeleton, the derivation can be determined systematically in terms of a desymmetrization lattice[18] for the $\mathbf{I}_h(/\mathbf{C}_s)$ (Fig. 3). This figure depicts a group-subgroup lattice for the $\mathbf{I}_h$ group which accompanies the results of subduction listed in Table 3.

The absence of a molecule of a subgroup is determined by examining its supergroups: if one of the supergroups has the same USCI as that of the subgroup at issue, the molecule does not exist. This determination can also be accomplished by using the subduction data in Fig. 3. In the present case, the CR $\mathbf{I}(/\mathbf{C}_1)$ corresponds to a 60-membered orbit, whose size is equal to that of an $\mathbf{I}_h(/\mathbf{C}_s)$ orbit. Hence, **I**-molecules are absent; all of the remaining subgroups are possible to exist for the soccerane series. This conclusion can be obtained more conveniently by comparing the corresponding USCIs; the USCI of the $\mathbf{I}(/\mathbf{C}_1)$ orbit is s_{60}, which is equl to that of the $\mathbf{I}_h(/\mathbf{C}_s)$ orbit. On the other hand, the absence of $\mathbf{C}_5$-, $\mathbf{D}_5$-, $\mathbf{C}_{5i}$-, and **I**-molecules has been reported for dodecahedrane derivatives having an $\mathbf{I}_h(/\mathbf{C}_{3v})$ orbit.[16]

3. Soccerane Derivatives with Achiral Substituents. In the preceding section, we have qualitatively examined the desymmetrizations of the soccerane skeleton (**1**) that create derivatives of various subsymmetries. The next issue is to calculate the number of such derivatives. Since the 60 vertices of saccerane (**3**) construct an orbit that is subject to $\mathbf{I}_h(/\mathbf{C}_s)$, we use the USCIs listed in Table 3 as the corresponding subduced cycle indices (SCIs).[12] We consider H and X as substituents. This corresponds to a figure inventory expressed by

$$s_d = 1 + x^d. \tag{7}$$

This was introduced into the SCIs to provide the following generating functions,

$$s_1^{60} = (1 + x)^{60} \text{ for } \mathbf{C}_1, \tag{8}$$

$$s_2^{30} = (1 + x^2)^{30} \text{ for } \mathbf{C}_2, \tag{9}$$

$$s_1^4 s_2^{28} = (1 + x)^4(1 + x^2)^{28} \text{ for } \mathbf{C}_s, \tag{10}$$

$$s_2^{30} = (1 + x^2)^{30} \text{ for } \mathbf{C}_i, \tag{11}$$

$$s_3^{20} = (1 + x^3)^{20} \text{ for } \mathbf{C}_3, \tag{12}$$

$$s_4^{15} = (1 + x^4)^{15} \text{ for } \mathbf{D}_2, \tag{13}$$

$$s_2^4 s_4^{13} = (1 + x^2)^4(1 + x^4)^{13} \text{ for } \mathbf{C}_{2v}, \tag{14}$$

$$s_2^2 s_4^{14} = (1 + x^2)^2(1 + x^4)^{14} \text{ for } \mathbf{C}_{2h}, \tag{15}$$

$$s_5^{12} = (1 + x^5)^{12} \text{ for } \mathbf{C}_5, \tag{16}$$

$$s_6^{10} = (1 + x^6)^{10} \text{ for } \mathbf{D}_3, \tag{17}$$

$$s_3^4 s_6^8 = (1 + x^3)^4(1 + x^6)^8 \text{ for } \mathbf{C}_{3v}, \tag{18}$$

$$s_6^{10} = (1 + x^6)^{10} \text{ for } \mathbf{C}_{3i}, \quad (19)$$

$$s_4^3 s_8^6 = (1 + x^4)^3(1 + x^8)^6 \text{ for } \mathbf{D}_{2h}, \quad (20)$$

$$s_{10}^6 = (1 + x^{10})^6 \text{ for } \mathbf{D}_5, \quad (21)$$

$$s_5^4 s_{10}^4 = (1 + x^5)^4(1 + x^{10})^4 \text{ for } \mathbf{C}_{5v}, \quad (22)$$

$$s_{10}^6 = (1 + x^{10})^6 \text{ for } \mathbf{C}_{5i}, \quad (23)$$

$$s_{12}^5 = (1 + x^{12})^5 \text{ for } \mathbf{T}, \quad (24)$$

$$s_6^2 s_{12}^4 = (1 + x^6)^2(1 + x^{12})^4 \text{ for } \mathbf{D}_{3d}, \quad (25)$$

$$s_{10}^2 s_{20}^2 = (1 + x^{10})^2(1 + x^{20})^2 \text{ for } \mathbf{D}_{5d}, \quad (26)$$

$$s_{12} s_{24}^2 = (1 + x^{12})(1 + x^{24})^2 \text{ for } \mathbf{T}_h, \quad (27)$$

$$s_{60} = 1 + x^{60} \text{ for } \mathbf{I}, \quad (28)$$

and

$$s_{60} = 1 + x^{60} \text{ for } \mathbf{I}_h. \quad (29)$$

After expanding these generating functions, the resulting coefficients are collected to give a matrix, each row of which consists of the coefficients of the term x^m (m=0 to 60). Since the coefficient of the term x^m is equal to that of x^{60-m}, we refer to them as being complementary. In the following discussions, therefore, we take account of the term x^m ($m \leqslant 30$) mainly. The next step is the multiplication of matrix by the inverse of the mark table.[16] For explaining this step, let us examine the term x^{12} only. The corresponding row of the matrix is equal to (1399358844975, 593775, 986895, 593775, 4845, 455, 767, 455, 0, 45, 77, 45, 19, 0, 0, 0, 5, 5, 0, 1, 0, 0). When we multiply this row vector by the inverse (Table 2), we have a row vector (11661121142, 148014, 246200, 9781, 1170, 72, 374, 213, 0, 20, 36, 19, 6, 0, 0, 0, 2, 5, 0, 1, 0, 0), which is listed in the x^{12} (or x^{48}) row of Table 4. These values are aligned in the order of the SSG of the $\mathbf{I}_h$ group. Thus, there emerge 11661121142 $\mathbf{C}_1$-, 148014 $\mathbf{C}_2$-, 246200 $\mathbf{C}_s$-, 9781 $\mathbf{C}_i$-, 1170 $\mathbf{C}_3$-, 72 $\mathbf{D}_2$-, 374 $\mathbf{C}_{2v}$-, 213 $\mathbf{C}_{2h}$-, 20 $\mathbf{D}_3$-, 36 $\mathbf{C}_{3v}$-, 19 $\mathbf{C}_{3i}$-, 6 $\mathbf{D}_{2h}$-, 2 $\mathbf{T}$-, 5 $\mathbf{D}_{3d}$-, and one $\mathbf{T}_h$-isomers, all of which have the molecular formula $C_{60}H_{48}X_{12}$. The other rows of Table 4 are calculated in a similar way. It should be emphasized that these enumerations (Table 4) produce molecules having $\mathbf{C}_5$, $\mathbf{D}_5$, and $\mathbf{C}_{5i}$ symmetries, whereas the dodecahedrane skeleton cannot produce these symmetries.[16] The absence of **I**-derivatives is verified by these enumerations.

Figure 4 depicts **T** molecules, the numbers of which are calculated to be equal to 2 for the term x^{12} and 4 for the term x^{24}. The first two molecules (**31** and **32**) correspond to x^{12}. Note that we depict an arbitrary representative selected from each pair of enantiomers. The alternate labeling in each of the four 6-membered

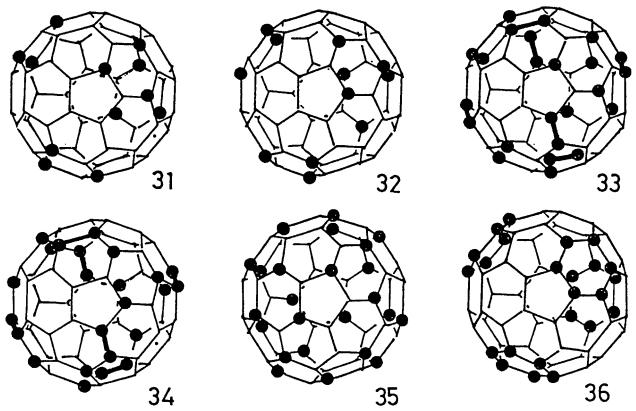

Fig. 4. **T**-Molecules derived from **1** with H and X.

rings of **31** is given just in an inverse fashion as compared with that in the counterpart of **32**. The remaining four (**33**—**36**) have the common molecular formula ($C_{60}H_{36}X_{24}$). The molecule (**33**) can be considered to come from a superposition of **11** and **31**, where heavy lines are tentatively given to show the contribution of **11**. In a similar way, the molecule (**34**) stems from a superposition of **11** and **32**. The molecule (**35**) is created by superposing **31** onto **32** so as to retain the **T**-symmetry. This superposition can be understood by focusing our attention on the eight hexagonal faces. The molecule (**36**) is generated by another mode of superposition of **31** and **32**. In accord with the qualitative discussion in the preceding section, each of these molecules has orbits that are controlled by the subduction listed in Table 3.

Molecules of $\mathbf{T}_h$ symmetry have been scarcely demonstrated by most textbooks of stereochemistry or of chemical group theory. The present enumeration provides us with suitable examples of such $\mathbf{T}_h$ molecules. Thus, there emerge three $\mathbf{T}_h$ molecules (one molecule (**11**) for x^{12} and two for x^{24}). The remaining two are depicted in Fig. 5. Comparisons of **35** (**T**) with **37** ($\mathbf{T}_h$) and with **38** ($\mathbf{T}_h$) afford their interrelation, if we pay attention to the respective eight hexagonal faces.

Figure 6 collects $\mathbf{D}_5$ molecules appearing in this enumeration. Among them, the two molecules (**17** and **39**) correspond to the term x^{10} ($C_{60}H_{50}X_{10}$) or the complementary x^{50} ($C_{60}H_{10}X_{50}$); the six isomers (**40**—**45**) are concerned with the term x^{20} ($C_{60}H_{40}X_{20}$) or the complementary x^{40} ($C_{60}H_{20}X_{40}$); and the 8 isomers (**46**—**53**) agree with the term x^{30} ($C_{60}H_{30}X_{30}$). All these molecules have a five-fold axis perpendicular to the page as well as five two-fold axes all perpendicular to the five-fold axis.

The total number of derivatives with each molecular formula is calculated in the form of a generating function.[21] Here, we give some comments to the previous results. According to Theorem 4 and Lemma 1 in our paper,[12] the number of isomers with W_θ-weight and $\mathbf{G}_i$-symmetry is represented by

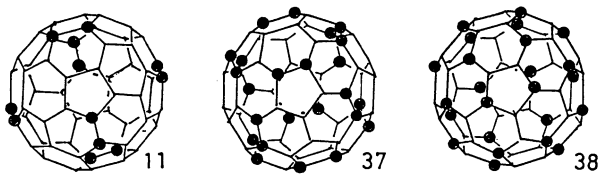

Fig. 5. $\mathbf{T}_h$-Molecules derived from **1** with H and X.

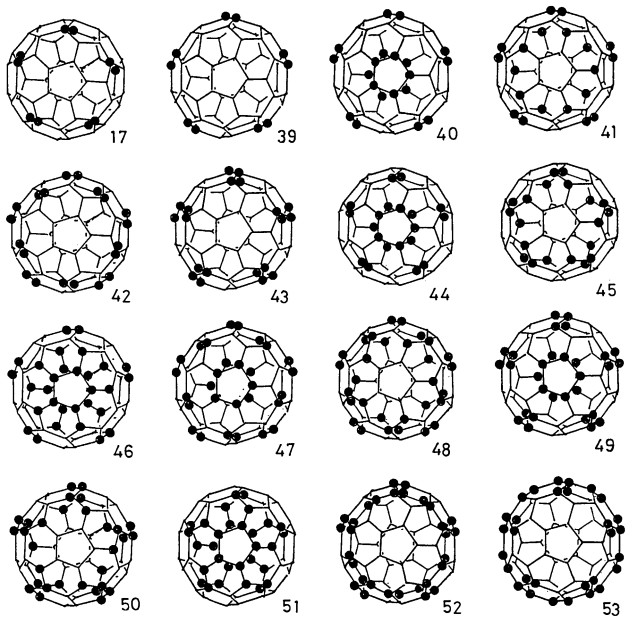

Fig. 6. $\mathbf{D}_5$-Molecules derived from **1** with H and X.

$$A_{\theta i} = \sum_{j=1}^{s} \rho_{\theta j}\overline{m}_{ji} \text{ (for } i=1,2,\cdots, s, j=1,2,\cdots,s) \tag{30}$$

where the symbol $\rho_{\theta j}$ denotes the number of fixed configurations and $\overline{m}_{ji}$ is the jith element of the inverse of the mark table for **G** group. If we tantatively fix $\mathbf{G}_i$-symmetry, then we have

$$\begin{aligned}\sum_{[\theta]} A_{\theta i}W_\theta &= \sum_{[\theta]}\sum_{j=1}^{s} \rho_{\theta j}\overline{m}_{ji}W_\theta \\ &= \sum_{j=1}^{s} \overline{m}_{ji} \sum_{[\theta]} \rho_{\theta j}W_\theta \\ &= \sum_{j=1}^{s} \overline{m}_{ji}\, ZI(\mathbf{G}_j; s_{djk}^{i\alpha}).\end{aligned} \tag{31}$$

The last equation is derived from the fact that the summation ($\sum_{[\theta]}\rho_{\theta j}W_\theta$) is a generating function of $\rho_{\theta i}$. This is in turn given by Lemma 1 of the paper[12] to be

$$\sum_{[\theta]} \rho_{\theta j}W_\theta = ZI(\mathbf{G}_j; s_{djk}^{i\alpha}), \tag{32}$$

where the right-hand side is a subduced cycle index (SCI) and $s_{djk}^{i\alpha}$ is replaced by

$$s_{djk}^{i\alpha} = \sum_{r=1}^{|X|} w_{i\alpha}(X_r)^{djk}. \tag{33}$$

We here introduce a *partial cycle index* by means of the following definition.

Definition 1. A *partial cycle index for* $\mathbf{G}_i$ *group* is defined as

$$\mathrm{PCI}(\mathbf{G}_i; s_{djk}^{i\alpha}) = \sum_{j=1}^{s} \overline{m}_{ji}\, ZI(\mathbf{G}_j; s_{djk}^{i\alpha}) (\text{for } i=1,2,\cdots, s). \tag{34}$$

When we introducte the PCI into Eq. 31, we have the following theorem.

Theorem 1. The number of isomers with W_θ-weight and $\mathbf{G}_i$-symmetry is obtained as a coefficient of the equation,

$$\sum_{[\theta]} A_{\theta i} W_\theta = \mathrm{PCI}(\mathbf{G}_j; s_{djk}^{i\alpha}) (\text{for } i=1,2,\cdots, s), \tag{35}$$

where the right-hand side a partial cycle index (PCI) and $s_{djk}^{i\alpha}$ is replaced by

$$s_{djk}^{i\alpha} = \sum_{r=1}^{|X|} w_{i\alpha}(X_r)^{djk}. \tag{36}$$

In order to count $\mathbf{C}_{2v}$-derivatives of soccerane, we have the following PCI from the data of Tables 2 and 3 by means of Eq. 34.

$$\mathrm{PCI}(\mathbf{C}_{2v}, s_d) = (1/2)s_2^4 s_4^{13} - (1/2)s_4^3 s_8^6. \tag{37}$$

In this equation, we find that the terms corresponding to the $\mathbf{C}_{2v}$- and $\mathbf{D}_{2h}$-rows are effective in the light of the $\mathbf{I}_h(/\mathbf{C}_{2v})$-column of Table 2. Introducing the figure inventory (Eq. 7) in Eq. 37, we obtain the numbers of $\mathbf{C}_{2v}$-derivatives itemized with respect to molecular formulas. They are identical to the values of the $\mathbf{C}_{2v}$ subgroup listed in Table 4. In a similar way, we can obtain a PCI and a generating function of calculating numbers of isomers for every subgroups. Since Theorem 1 is a generating-function version of Theorem 4 of the previous paper,[12] there appear no new matters beyond the previous theorem. A similar generating function has been obtained alternatively by Kerber and Thürlings,[22] though their formulation does not contain the concepts of USCIs, SCI and PCI and take no account of obligatory minimum valency.

By using the PCI, we introduce an alternative definition of a cycle index (CI):

$$\mathrm{CI} = \sum_{j=1}^{s} \mathrm{PCI}(\mathbf{G}_j; s_{djk}^{i\alpha}). \tag{38}$$

This is equivalent to our previous result,[21] i. e.,

$$\mathrm{CI} = \sum_{j=1}^{s} \left(\sum_{i=1}^{s} \overline{m}_{ji}\right) ZI(\mathbf{G}_j; s_{djk}^{i\alpha}). \tag{39}$$

The cycle index (CI) corresponding to the present case is obtained by using the data of Table 3, i. e.,

$$\begin{aligned}\mathrm{CI}(\mathbf{I}_h; s_d) = {} & (1/120)s_1^{60} + (1/8)s_2^{30} + (1/8)s_1^4 s_2^{28} + (1/120)s_2^{30} \\ & + (1/6)s_3^{20} + (1/5)s_5^{12} + (1/6)s_6^{10} + (1/5)s_{10}^6,\end{aligned} \tag{40}$$

where the coefficients of the term in the right-hand side are adopted from the rightmost column of Table 2 or 3. This derivation of the CI is based on such a theorem that is different from Pólya's one. However, these two theorems have been proven to afford the same CI in general.[21] If we introduce the figure inventory (Eq. 7) into the cycle index (Eq. 40), we have the generating function,

$$\begin{aligned}Z(x) = {} & \mathrm{CI}(\mathbf{I}_h; 1 + x^d) \\ = {} & (x^0 + x^{60}) + (x^1 + x^{59}) + 23(x^2 + x^{58}) \\ & + 303(x^3 + x^{57}) + 4190(x^4 + x^{56}) \\ & + 45718(x^5 + x^{55}) + 418470(x^6 + x^{54}) \\ & + 3220218(x^7 + x^{53}) + 21330558(x^8 + x^{52}) \\ & + 123204921(x^9 + x^{51}) + 628330629(x^{10} + x^{50}) \\ & + 2855893755(x^{11} + x^{49}) + 11661527055(x^{12} + x^{48}) \\ & + 43057432740(x^{13} + x^{47}) + 144549869700(x^{14} + x^{46}) \\ & + 443284859624(x^{15} + x^{45}) + 1246738569480(x^{16} + x^{44}) \\ & + 3226849468425(x^{17} + x^{43}) + 7708584971055(x^{18} + x^{42}) \\ & + 17040023323785(x^{19} + x^{41}) + 34932048763560(x^{20} + x^{40}) \\ & + 66537224405790(x^{21} + x^{39}) \\ & + 117952355252550(x^{22} + x^{38}) \\ & + 194877787472550(x^{23} + x^{37}) \\ & + 300436595453640(x^{24} + x^{36}) \\ & + 432628675734195(x^{25} + x^{35}) \\ & + 582384767014701(x^{26} + x^{34}) \\ & + 733373386161407(x^{27} + x^{33}) \\ & + 864332935668892(x^{28} + x^{32}) \\ & + 953746664302456(x^{29} + x^{31}) + 985538239868528x^{30}.\end{aligned} \tag{41}$$

The coefficient of each term is identical with the value that is calculated by the direct summation of the corresponding row of Table 4.

It is worthwhile mentioning the difference between Hosoya's enumeration[10] and the present one (Eq. 41). Since Hosoya has used **I** group for obtaining a CI, both enantiomers of a racemic pair are counted in as two isomers. For example, he has reported that the coefficient of the term x^2 is equal to 37, while our result (Eq. 41) contains $23x^2$. Note that our enumeration uses $\mathbf{I}_h$ group and counts each pair of enantiomers once. Since our enumeration affords such values that are itemized with respect to the terms as well as to the subsymmetries, the Hosoya's value can be calculated in terms of the data listed in Table 4. Thus, the x^2 row of Table 4 affords the expression, $8\times2+6\times2+6+2+1=37$, where the values in the left-hand side are duplicated if they are concerned with chiral subgroups. The value in the right-hand side is equal to the Hosoya's one. Compare this with $8+6+6+2+1=23$ for our result, which no such duplication is taken into account.

4. Conclusion. The 60 vertices of soccerane belong to an $\mathbf{I}_h(/\mathbf{C}_s)$ orbit. Desymmetrization of this orbit by every subgroup ($\mathbf{G}_j$) of $\mathbf{I}_h$ is characterized by the subduced representation $(\mathbf{I}_h(/\mathbf{C}_s)\downarrow\mathbf{G}_j)$. This representation is reduced to the sum of the coset representations of the $\mathbf{G}_j$ group. This subduction affords a unit subduced cycle index (USCI), which is useful for enumeration of

derivatives starting from the soccerane skeleton. The enumeration indicates the versatility of the USCI approach. Although the enumeration is restricted to the soccerane skeleton (the $\mathbf{I}_h(/\mathbf{C}_s)$ orbit), the USCI method can be applied to any other skeletons of the $\mathbf{I}_h$ symmetry (Table 1).

Estimation of Angles between the Ground- and Excited-State Dipole Moments from Solvent Spectral Frequency Shifts

Takehiro ABE
College of General Education, Tohoku University, Kawauchi, Aoba-ku, Sendai 980
(Received April 4, 1991)

A method for estimating the angle between the ground- and excited-state dipole moments is presented on the basis of Abe's improved expressions for the solvent frequency shifts of absorption and fluorescence spectra (*Bull. Chem. Soc. Jpn.*, **54**, 327 (1981); **58**, 3415 (1985); **61**, 3797 (1988)). Applications of the method to *N,N*-dimethylaniline and aniline give angles of 39.5° and 40.0°, respectively; the excited-state dipole moments are both smaller than the corresponding ground-state dipole moments.

On the basis of theories regarding solvent effects on the frequency shifts of absorption and/or fluorescence, the dipole moments and/or polarizabilities have been estimated for the excited states of organic molecules.[1] There have, however, been a few attempts to estimate the angles between the ground- and excited-state dipole moments due to solvent spectral shifts, except for solute molecules in which both the dipole moments are obviously collinear. On the basis of the Onsager model,[15] Suppan[9,16] has presented a method used to obtain the angles between the ground- and excited-state dipole moments due to the solvent shifts of the absorption and fluorescence spectra for such organic molecules as aniline. His method requires data concerning the solvatochromic shifts in two solvents of nearly the same refractive indices. Recently, Ayachit[11] has improved Suppan's method. Upon modifying McRae's expression[17] for solvent absorption-spectral shifts, Prabhumirashi et al.[18,19] attempted to estimate the angles between the ground- and excited-state dipole moments. Later, Ayachit et al.[6] improved the method of Prabhumirashi et al. and obtained several angle values for nitroanilines.

Abe's improved expression[3,20] for the solvent absorption-spectral shift gave excited dipole moments and/or polarizabilities that were comparable to those found by electrooptical measurements.[3] Moreover, on the basis of the same treatment as in the case of the improved expression, an expression for the solvent fluorescence-spectral shift has been presented.[21] In this paper, therefore, an attempt has been made to present a method for estimating the angle between the ground- and excited-state dipole moments by combining the improved expression for the solvent absorption-spectral frequency shifts with that for the solvent fluorescence-spectral shifts.

Theory

The wave numbers of a transition from the ground state to the *i*th-excited state of a neutral solute molecule (A) in vapor and in a solvent (S) are denoted by $\sigma^{\circ}_{0i,a}$ and $\sigma_{0i,a}$ (cm^{-1}), respectively. The wave numbers of the fluorescence frequencies of the solute molecule in the vapor and in the solvent are denoted by $\sigma^{\circ}_{i0,j}$ and $\sigma_{i0,j}$ (cm^{-1}), respectively. The ground and *i*th-excited state dipole moments are denoted by $\boldsymbol{P}_{00}$ and $\boldsymbol{P}_{ii}$, respectively; α_{00} and α_{ii} are the isotropic electric polarizabilities of the ground and *i*th-excited states, respectively. The superscripts/subscripts (A and S) denote the solute and solvent molecules, respectively. Suffix f in $\alpha^{A}_{00,f}$ and $\alpha^{A}_{ii,f}$ indicates that these polarizabilities are not those which correspond ($\alpha^{A}_{00,a}$ and $\alpha^{A}_{ii,a}$ respectively) to absorption, but to fluorescence. Here, the dipole moments of the ground and *i*th-excited states concerning the fluorescence are assumed to be equal to the corresponding dipole moments regarding absorption, as has usually been assumed in all previous theories concerning fluorescence. This assumption is approximately fulfilled if the nuclear equilibrium configuration of the *i*-th excited state does not significantly differ from that of the ground state, as described in a previous paper.[21] The improved expression for $\sigma_{0i,a}$ is given by[3,20]

$$\sigma_{0i,a} = \sigma^{\circ}_{0i,a} + F \times (p^{S}_{00})^2 \times A_a + F \times \alpha^{S}_{00} \times B_a, \tag{1}$$

where

$$F = \frac{\pi}{hc}\left(\frac{4\pi L}{3}\right)^{2/3} \times \frac{(\rho^{S}/M^{S}_{r})^{2/3}}{(r_A + r_S)^4}, \tag{2}$$

$$A_a = \frac{2\{(p^{A}_{00})^2 - \boldsymbol{p}^{A}_{00}\cdot\boldsymbol{p}^{A}_{ii}\}}{3(4\pi\varepsilon_0)^2 kT} + \frac{\alpha^{A}_{00,a} - \alpha^{A}_{ii,a}}{4\pi\varepsilon_0}, \tag{3}$$

and

$$B_a = \frac{1}{4\pi\varepsilon_0} \times \{(p^{A}_{00})^2 - (p^{A}_{ii})^2 + \frac{3}{2} \times \frac{I^{S}_0 \cdot I^{A}_0}{I^{S}_0 + I^{A}_0} \times (\alpha^{A}_{00,a} - \alpha^{A}_{ii,a})\}. \tag{4}$$

Here, c is the speed of light in vacuum, h Planck's constant, L Avogadro's constant, k Boltzmann's constant, T the thermodynamic temperature, ε_0 the permittivity of a vacuum, M_r the relative molecular mass, ρ the

density, r the radius of a spherical molecule, and I_0 the ionization potential of the ground state. On the other hand, the expression for $\sigma_{i0,f}$ is given by[21]

$$\sigma_{i0,f} = \sigma^{\circ}_{i0,f} + F \times (p^{S}_{00})^2 \times A_f + F \times \alpha^{S}_{00} \times B_f, \quad (5)$$

where

$$A_f = \frac{2\{\boldsymbol{p}^{A}_{00}\cdot\boldsymbol{p}^{A}_{00} - (p^{A}_{ii})^2\}}{3(4\pi\varepsilon_0)^2 kT} + \frac{\alpha^{A}_{00,f} - \alpha^{A}_{ii,f}}{4\pi\varepsilon_0}, \quad (6)$$

and

$$B_f = \frac{1}{4\pi\varepsilon_0} \times \{(p^{A}_{00})^2 - (p^{A}_{ii})^2 + \frac{3}{2} \times \frac{I^{S}_0 \cdot I^{A}_0}{I^{S}_0 + I^{A}_0} \times (\alpha^{A}_{00,f} - \alpha^{A}_{ii,f})\}. \quad (7)$$

By combining Eq. 1 and Eq. 5, one can easily obtain the following equations:

$$\sigma_{0i,a} + \sigma_{i0,f} = a + A \times b + B \times d, \quad (8)$$

and

$$\sigma_{0i,a} - \sigma_{i0,f} = a' + C \times b' + B \times d', \quad (9)$$

where

$$A = F \times \left\{\frac{2(p^{S}_{00})^2}{3(4\pi\varepsilon_0)^2 kT} + \frac{2\alpha^{S}_{00}}{(4\pi\varepsilon_0)}\right\}, \quad (10)$$

$$B = F \times \left\{(p^{S}_{00})^2 + \frac{3\alpha^{S}_{00}}{2} \times \frac{I^{S}_0 \cdot I^{A}_0}{I^{S}_0 + I^{A}_0}\right\}, \quad (11)$$

$$C = F \times \frac{2(p^{S}_{00})^2}{3(4\pi\varepsilon_0)^2 kT}, \quad (12)$$

$$a = \sigma^{\circ}_{0i,a} + \sigma^{\circ}_{i0,f}, \quad (13)$$

$$a' = \sigma^{\circ}_{0i,a} - \sigma^{\circ}_{i0,f}, \quad (14)$$

$$b = (p^{A}_{00})^2 - (p^{A}_{ii})^2, \quad (15)$$

$$b' = (p^{A}_{00})^2 - 2(\boldsymbol{P}^{A}_{00}\cdot\boldsymbol{P}^{A}_{ii}) + (p^{A}_{ii})^2, \quad (16)$$

$$d = \frac{1}{4\pi\varepsilon_o} \times \{(\alpha^{A}_{00,a} - \alpha^{A}_{ii,a}) + (\alpha^{A}_{00,f} - \alpha^{A}_{ii,f})\}, \quad (17)$$

and

$$d' = \frac{1}{4\pi\varepsilon_o} \times \{(\alpha^{A}_{00,a} - \alpha^{A}_{ii,a}) - (\alpha^{A}_{00,f} - \alpha^{A}_{ii,f})\}, \quad (18)$$

From Eqs. 13 and 14, one obtains

$$\sigma^{\circ}_{0i,a} = \frac{1}{2} \times (a + a'), \quad (19)$$

and

$$\sigma^{\circ}_{i0,f} = \frac{1}{2} \times (a - a'). \quad (20)$$

From Eqs. 15, one obtains

$$p^{A}_{ii} = \{(p^{A}_{00})^2 - b\}^{1/2}. \quad (21)$$

When one writes $\boldsymbol{p}^{A}_{00}\cdot\boldsymbol{p}^{A}_{ii} = p^{A}_{00} p^{A}_{ii} \cos\theta$, the value of $\cos\theta$ is obtained from Eq. 16 as

$$\cos\theta = \frac{1}{2} \times \left(\frac{p^{A}_{00}}{p^{A}_{ii}} + \frac{p^{A}_{ii}}{p^{A}_{00}} - \frac{b'}{p^{A}_{00} p^{A}_{ii}}\right). \quad (22)$$

The values for F, A, B, and C can be calculated. In calculating these values, the values observed for p_{00} and I_0 in the vapor phase are used, the values for α_{00} are calculated from the sums of the bond refractions and the values for r_{AorS} may be calculated according to $r_{AorS} = (3M_r^{AorS}/4\pi L\rho^{AorS})^{1/3}$, as discussed in a previous paper.[3] Accordingly, the values for a, b, and d and those for a', b', and d' can be obtained by means of a least-squares analysis of data for the solvent absorption- and fluorescence-spectral frequency shifts, according to Eqs. 8 and 9, respectively. One can, therefore, obtain values for $\sigma^{\circ}_{0i,a}$, $\sigma^{\circ}_{i0,f}$, p^{A}_{ii}, and $\cos\theta$ according to Eqs. 19, 20, 21, and 22, respectively. Thus, one can estimate the angle of θ between the ground- and excited-state dipole moments.

Results and Discussion

The present expressions used for the solvent absorption- and fluorescence-spectral frequency shifts have been derived on the assumption that the solvent molecules form no hydrogen bonds or complexes with the solute.[20,21] In applying Eqs. 8 and 9, therefore, data for solvents which are capable of forming hydrogen bonds and complexes with solutes should be excluded. When this restriction is taken into consideration, there is no available data reported for interesting molecules, except for data regarding only *N*,*N*-dimethylaniline. The *N*,*N*-dimethylaniline molecule may be assumed not to be coplanar, since it is well-known that in the similar aniline molecule the plane containing an amino group does not lie in the plane of the benzene ring. Accordingly, the dipole moments of the ground states of *N*,*N*-dimethylaniline and aniline do not lie in the planes of the benzene rings. In view of this point *N*,*N*-dimethylaniline is appropriate for the present purpose.

Therefore, Eqs. 8 and 9 were applied to data reported by Köhler[22] regarding the solvent maximum absorption- and fluorescence-spectral shifts of *N*,*N*-dimethylaniline (22°). The data points for 8 solvents were chosen, out of his reported total of 12 solvents, by excluding protic

solvents. Unfortunately, he did not give all of the numerical values for $\sigma_{0i,a}$ except for three values for hexane, tetrahydrofuran and dioxane.. Therefore, the $\sigma_{0i,a}$ values for the 5 remaining solvents were obtained by using the Stokes shifts ($\sigma_{0i,a}-\sigma_{i0,f}$), from which values could be read off a magnified version of Fig. 1 in Ref. 22. The following values were used for *N*,*N*-dimethylaniline: r_A=0.369 nm, p_{00}^A=1.61 D (gas)[23] (1 D=3.333×10^{-30} C m), α_{00}^A=155.69×10^{-25} cm^3 (see Ref. 3) and I_0^A=7.6 eV[24] (1 eV=1.602×10^{-19} J). For convenience, the temperature was assumed to be 20 °C. Thus, the present analysis by using Eqs. 8 and 9 gives p_{ii}^A=1.02 D, θ=39.5° (cos θ=0.772), $\sigma_{0i,a}^\circ$=34100 cm^{-1} and $\sigma_{i0,f}^\circ$=31820 cm^{-1}. By applying the values of $\sigma_{0i,a}^\circ$=34100 cm^{-1} and cos θ=0.772 to Eq. 1, the same p_{ii}^A value of 1.02 D and the $\alpha_{ii,a}^A$ value of 290.6×10^{-25} cm^3 were estimated by means of Calculation 1 in Ref. 3. A similar calculation, by applying the values of p_{ii}^A=1.02 D and cos θ=0.772 to Eq. 5, gave the same $\sigma_{i0,f}^\circ$ value of 31820 cm^{-1} and $\alpha_{00,f}^A-\alpha_{ii,f}^A$=−435.4×10^{-25} cm^3 by means of a least-squares analysis. According to Eqs. 1 and 5, the values for $\sigma_{0i,a}$ and $\sigma_{i0,f}$, respectively, can be calculated by using the values so estimated for $\sigma_{0i,a}^\circ$, $\sigma_{i0,f}^\circ$, p_{ii}^A, $\alpha_{ii,a}^A$, ($\alpha_{00,f}^A-\alpha_{ii,f}^A$) and cos θ. The values ($\sigma_{0i,calcd}$) so calculated for $\sigma_{0i,a}$ and $\sigma_{i0,f}$ were compared with those ($\sigma_{0i,obsd}$) observed, as shown in Fig. 1. The correlations between the experimental and calculated frequencies are good. The estimated $\sigma_{0i,a}^\circ$ value of 34100 cm^{-1} agrees roughly with the observed value[25] of 34700 cm^{-1}. These facts may support the validity of Eqs. 8 and 9.

The p_{ii}^A value of 1.02 D, estimated in the present work, is smaller than the ground-state dipole moment of 1.61 D by 0.59 D, while the p_{ii}^A values of 3.58 D (θ=66°)[19] and 5.1 D[2] and the ($p_{ii}^A-p_{00}^A$) value of 2.0 D[22] have been estimated from solvent spectral-shift theories. Whether $p_{ii}^A>p_{00}^A$ or $p_{ii}^A<p_{00}^A$ is a serious problem for considering the electronic structure of the excited state of *N*,*N*-dimethylaniline.

In the case of a similar molecule, aniline, Lombardi[26] determined that the magnitude of the dipole moment change is $|p_{ii}^A-p_{00}^A|$=(0.85±0.15) D by a technique involving the optical Stark effect in the gas phase. As mentioned above, aniline is not appropriate for the present purpose, because the amino group of aniline is capable of forming hydrogen bonds with aprotic solvents which are high on the β scale regarding the hydrogen-bond acceptor strength.[27] For example, dioxane (β=0.37), dibutyl ether (β=0.46), diethyl ether (β=0.47), tetrahydrofuran (β=0.55) and acetonitrile (β=0.31) are involved in the solvents used by Köhler.[22] Nevertheless, an attempt has been made to apply Eqs. 8 and 9 to the 8 spectral data points[22] of Köhler for aniline in similar way in order to compare the estimated value of $|p_{ii}^A-p_{00}^A|$ with the reliable one of Lombardi. The values used for aniline are the same as those given in a previous paper:[3] r_A=0.331 nm, p_{00}^A=1.48 D(gas), α_{00}^A=117.3×10^{-25} cm^3, and I_0^A=7.68 eV. According to Eqs. 8 and 9, the results of p_{ii}^A=0.75 D, θ=40.0° (cos θ=0.766), $\sigma_{0i,a}^\circ$=34630 cm^{-1} and $\sigma_{i0,f}^\circ$=31810 cm^{-1} were estimated. By applying the values of $\sigma_{0i,a}^\circ$=34630 cm^{-1} and cos θ=0.766 to Eq. 1, the same p_{ii}^A value of 0.75 D and the $\alpha_{ii,a}^A$ value of 132.0×10^{-25} cm^3 were estimated. A similar calculation, by applying the values of p_{ii}^A=0.75 D and cos θ=0.766 to Eq. 5, gave a $\sigma_{i0,f}^\circ$ value of 34600 cm^{-1} and $\alpha_{00,f}^A-\alpha_{ii,f}^A$=−620.9×10^{-25} cm^3. The correlations between the observed and calculated values for $\sigma_{0i,a}$ and $\sigma_{i0,f}$ are shown in Fig. 2. On the whole, the correlations

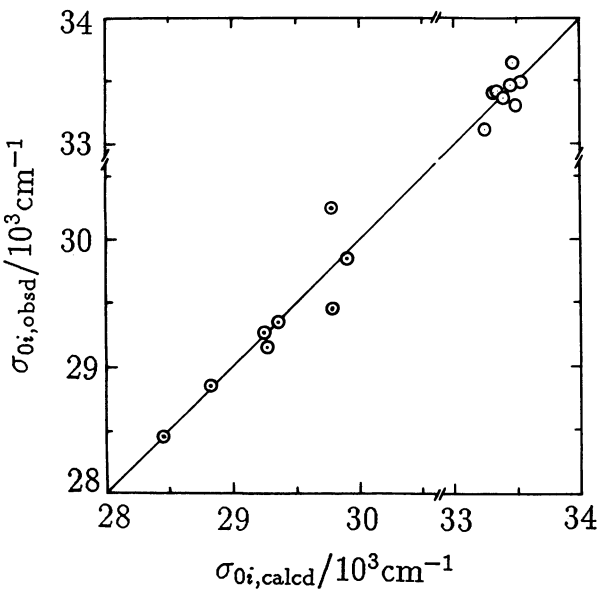

Fig. 1. Plot of the observed frequencies vs. calculated frequencies for *N*,*N*-dimethylaniline. ○, absorption frequencies; ⊙, fluorescence frequencies.

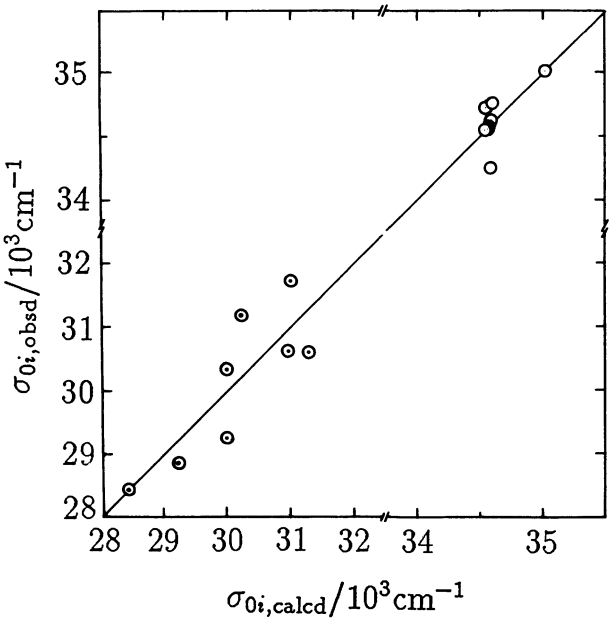

Fig. 2. Plot of the observed frequencies vs. calculated frequencies for aniline. ○, absorption frequencies; ⊙, fluorescence frequencies.

given in Fig. 2 are good, but worse than are those given in Fig. 1. The estimated $\sigma^{\circ}_{0i,a}$ value of 34630 cm^{-1} considerably deviates from the observed values of 35490[28,29] and 35500[25] cm^{-1}. Especially, the $\sigma^{\circ}_{0,f}$ value of 31810 cm^{-1}, estimated according to Eqs. 8 and 9, does not agree with that (34600 cm^{-1}) estimated from Eq. 5, although there is agreement between the corresponding values for *N*,*N*-dimethylaniline, as shown above. These worse results for aniline in comparison with the results for *N*,*N*-dimethylaniline are probably due to the use of data points for the aprotic solvents with which aniline is capable of forming hydrogen bonds. However, the p^{A}_{ii} and θ values estimated by applying Eqs. 8 and 9 for aniline may be roughly correct, since these values are close to the corresponding ones for *N*,*N*-dimethylaniline.

Here, the reliability of the θ value obtained by the present method will be investigated. Baba et al.[30] reported on the solvent effects on the absorption and fluorescence spectra of diazines, although data points for only 3 solvents could be used for the present purpose. Ony data for pyridazine are used, since the solvent spectral shifts of pyrimidine are small and pyrazine has no dipole moments in both the ground and excited states due to molecular symmetry. According to Baba et al.,[30] the cos θ value for pyridazine should be unity, since the directions of p^{A}_{00} and p^{A}_{ii} for the molecule are the same. By using r_A=0.306 nm, p^{A}_{00}=4.221 D,[24] $\alpha^{A}_{00}=91.75\times10^{-25}$ cm^3 and I^{A}_{0}=8.706 eV,[24] Eqs. 8 and 9 were applied to the data for pyridazine in 2,2,4-trimethylpentane, in diethyl ether and in acetonitrile (25 °C). The result that cos θ=1.098 was obtained. This cos θ value is approximately unity, thus leading to the suggestion that the present estimation of θ may be fairly reliable.

The p^{A}_{ii} value (0.75 D) estimated for aniline is smaller than the p^{A}_{00} value (1.48 D), as in the case of *N*,*N*-dimethylaniline. All of the p^{A}_{ii} values which have hitherto been estimated for aniline from the solvent shifts of the absorption and/or fluorescence spectra are larger than p^{A}_{00}: The p^{A}_{ii} value has been estimated by Mataga (2—2.5 D),[31] Murrell (5 D),[32] Iweibo et al. (a value nearly equal to p^{A}_{00}),[33] Suppan (5 D),[2,9,16] and Prabhumirashi et al. (2.13 and 3.30 D, θ=14°).[10,18,19] Recently, Ayachit[11] estimated the values of p^{A}_{ii}=5.3 D and θ=25° for aniline, improving on the method of Suppan.[16] In a previous paper,[3] the p^{A}_{ii} value of 2.33 D was alternatively estimated for aniline by applying Eq. 1 to only three data points for solvents. Even though only three data points are the minimum for applying the expression, it is desirable to use at least several data points. The present estimation of $p^{A}_{00}-p^{A}_{ii}$=0.75 D for aniline agrees well with the reliable value ($|p^{A}_{ii}-p^{A}_{00}|=(0.85\pm0.15)$D) of Lombardi. The discrepancy between the solvatochromic shift measurements and reliable gas phase Stark effect measurements is fundamentally due to insufficient theoretical expressions for the solvatochromic shifts, as pointed out by Lombardi.[34] As mentioned in a previous paper,[3] comparisons between the excited-state dipole moments and/or polarizabilities estimated from the solvent spectral shifts with those determined from the electrooptical measurements are necessary in order to justify the theoretical expressions used for the solvent spectral frequency shifts. Among the many theoretical expressions, those giving excited-state dipole moments and polarizability values that are comparable to those of the electrooptical measurements will survive. As described above, Abe's improved expression (Eq. 1) gave excited-state dipole moments and/or polarizabilities that were comparable to those of electrooptical measurements.[3] The present estimation that $p^{A}_{00}>p^{A}_{ii}$ for aniline can be reasonably accounted for according to MO calculations as follows: All of the MO calculations of Baba,[35] Mataga,[31] and Nagakura et al.[25,36] show a decrease in the π-electron density at the nitrogen atom in the excited state of aniline. As described in a previous paper,[3] this decrease only increases the magnitude of the excited-state dipole moment component parallel to the plane containing both the benzene ring and nitrogen atom in the same direction as that of the corresponding ground-state dipole moment component, the positive and negative terminals of which do not change sign upon excitation. Accordingly, the excited-state dipole moment component should be larger than the corresponding ground-state dipole moment component. The inclination of the calculated ground-state dipole moment (1.44 D) was obtained by Hehre et al.[37] to be 67° to the plane containing the benzene ring by means of ab initio MO theory. The corresponding inclination of p^{A}_{ii} may be smaller than that (67°) of p^{A}_{00} by 40°, since both the p^{A}_{00} and p^{A}_{ii} components parallel to the benzene ring are in the same direction. By using an inclination of 67°, the p^{A}_{00} and p^{A}_{ii} components containing the benzene ring were calculated to be 1.48 D cos 67°=0.58 D and 0.75 D cos (67°−40°)=0.67 D, respectively. These estimations satisfy the result of the above-mentioned MO calculations. Therefore, the result that the excited-state dipole moment (0.75 D) is smaller than the ground-state dipole moment (1.48 D) does not conflict with the result concerning the above-mentioned MO calculations. Accordingly, the p^{A}_{ii} value of 0.75 D estimated for aniline is reasonable.

The MO calculation of Kimura, Tsubomura, and Nagakura[25] for *N*,*N*-dimethylaniline similarly shows a decrease of the π-electron density at the nitrogen atom in the excited state of *N*,*N*-dimethylaniline. Therefore, the circumstances of *N*,*N*-dimethylaniline are the same as those of aniline. Based on the assumption of the same inclination of 67° for *N*,*N*-dimethylaniline as in the case of aniline, the p^{A}_{00} and p^{A}_{ii} components parallel to the plane containing the benzene ring were estimated as 1.61 D cos 67°=0.63 D and 1.02 D cos (67°−39.5°)=0.90 D, respectively. Also, these estimations do not conflict with the MO calculation. Thus, the present estimation of $p^{A}_{00}>p^{A}_{ii}$ for *N*,*N*-dimethylaniline may be reasonable.

As shown above, the θ values have been estimated for

N,N-dimethylaniline and aniline. Prabhumirashi et al.[19] estimated θ values of 66° and 14° for *N,N*-dimethylaniline and aniline, respectively. These θ values seem to differ too greatly. Ayachit[11] estimated a θ value of 25° for aniline. However, his estimation of p_{ii}^{A}=5.3 D is too large in comparison with the magnitude of the dipole moment change of Lombardi.[26] The present estimations using Eqs. 8 and 9 give similar θ values for similar molecules of *N,N*-dimethylaniline and aniline, as does the $|p_{ii}^{A}-p_{00}^{A}|$ value, agreeing with the reliable value of Lombardi for aniline, as described above. In conclusion, the angle between the ground- and excited-state dipole moments may be estimated by applying Eqs. 8 and 9 to data for the solvent absorption- and fluorescence-frequency shifts of a solute molecule.

Femtosecond—Picosecond Laser Photolysis Studies on Reduction Process of Excited Benzophenone with Tertiary Aromatic Amines in Acetonitrile Solution

Hiroshi MIYASAKA*, Kazuhiro MORITA, Kenji KAMADA, Toshihisa NAGATA, Manabu KIRI, and Noboru MATAGA*,†
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received April 30, 1991)

Photoreduction processes of benzophenone (BP)-*N*,*N*-diethylaniline (DEA) system in acetonitrile solution were studied by means of femtosecond—pecosecond laser photolysis and time resolved transient absorption spectroscopy. The reaction processes including the formation of geminate ion pairs (IP) by electron transfer (ET) between BP* and DEA at encounter followed by intra-IP proton transfer giving the ketyl radical (BPH·) were clearly observed in both triplet and singlet excited state, while the IP produced by excitation of the CT complex between BP and amine formed easily in more or less concentrated solutions did not give BPH·. In addition to the detailed investigations on the BP-DEA system, we made comparative studies on BP–tertiary aromatic amine systems including *N*,*N*-diethyl-*p*-toluidine, *N*,*N*-dimethylaniline, and *N*-methyldiphenylamine. We observed clearly the characteristic tendency that the proton transfer rate in the ^{3}IP decreased with decrease of the oxidation potential of the amine. This result was interpreted as due to the increase of the inter-ionic distance in the ^{3}IP with increase of the free energy gap for the charge separation at encounter.

Photoinduced electron transfer (ET) and related phenomena play the most fundamental and important roles in many photophysical and photochemical reactions in condensed phase.[1-4] Hydrogen abstraction of excited benzophenone (BP*) from aliphatic as well as aromatic amines in solution is one of the most important photochemical reactions related to this fundamental process and has been extensively studied for a long time.[5-19] Especially, much attention has been paid to the hydrogen abstraction of triplet benzophenone (^{3}BP*), since the rate of the intersystem crossing from the lowest excited singlet state of BP (^{1}BP*) is very large (ca. 10^{11} s^{-1}). On the basis of the experimental results that the yield of the ketyl radical in the reaction of ^{3}BP* with the amine is usually very high and that the reaction rate is rather close to that of the diffusion-controlled reaction, Cohen et al. proposed the following reaction mechanism for the hydrogen abstraction of ^{3}BP* from amines;[7]

$$^3BP^* + AH \xrightarrow[\text{Electron transfer}]{} {}^3(BP^-\cdots AH^+) \xrightarrow[\text{Proton transfer}]{} (BPH\cdot + A\cdot)$$

where $^3(BP^-\cdots AH^+)$ is the CT complex or ion pair, AH is an amine and BPH· is a ketyl radical.

For the more or less direct elucidation of the reaction mechanism, a number of investigations by using laser photolysis methods have been performed on the reduction processes of ^{3}BP*. In an early research by means of a nanosecond laser photolysis,[8,9] it was suggested that the CT or the ion pair (IP) state prior to the solvation was the species undergoing the proton transfer leading to the BPH· formation, i.e., the proton transfer in the IP state competed with the solvation leading to the ionic dissociation.

The direct measurement on the picosecond dynamics of the excited benzophenone and the amine system was reported by Peters and co-workers.[10-13] On the basis of the observed time-dependent spectral shift of the benzophenone anion radical, they concluded that the structural change of the solvent separated IP formed by the ET between ^{3}BP* and the amine to the contact IP was the key process for the proton transfer to take place. Their conclusion, however, rests upon two postulates: (1) The ET reaction proceeds exclusively between ^{3}BP* and amines (AH) even in such concentrated solutions of the amine as 1—5 M, (2) The time dependent spectral shift of the BP anion band is due to the structural change in the IP of BP^- and AH^+.

These postulates, however, do not seem valid because of the following facts. First, in addition to formation of the IP by the ET between ^{3}BP* and AH, production of the IP by the ET between ^{1}BP* and AH as well as that from the excited state of the CT complex formed between BP and AH in the ground state are inevitable in such concentrated solutions of the amine. The dynamic behaviors of IP's including their ketyl radical formation, ionic dissociation, etc. the reactivity are strongly dependent on their production pathways even if the donor-acceptor pair and the solvent are the same.[20] The different reactivity of the IP depending on the mode of its production must be taken into considerartion for the elucidation of the reaction mechanism and dynamics of the hydrogen abstraction of excited BP from AH in the concentrated solutions of amines. Second, the dynamic behaviors of these various IP's as well as the dissociated free ions produced in longer time regions (a few hundreds of picoseconds—a few nanoseconds after the excitation) in acetonitrile should be included for the interpretation of

† Dedicated to Professor K. Schaffner on the occasion of his 60th birthday.

the spectral shift, because the spectra of dissociated ions and those of IP's, especially the IP formed by CT complex excitation, are different from each other.

Along this line, we have examined the photoreduction process of excited BP by *N,N*-dimethylaniline (DMA) in acetonitrile solution by means of picosecond and femtosecond laser photolysis.[17,18] From these studies it was revealed that the IP produced by the excitation of the ground state CT complex ($^1IP_{com}$), the IP formed by CS at encounter between $^1BP^*$ and DMA ($^1IP_{enc}$), and that produced by CS at encounter between $^3BP^*$ and DMA ($^3IP_{enc}$) exhibit quite different behaviors including the rate constant of the intra-IP proton transfer (PT) and charge recombination deactivation, etc., dependent on the mode of the production. The PT rate constant of $^3IP_{enc}$ was the largest among those of the three kinds of IP's and the production yield of the ketyl radical of $^1IP_{com}$ was practically zero.

We have reported also the results of the picosecond laser photolysis studies on the reaction of the excited benzophenone with diphenylamine (DPA) in several solvents of different polarity.[16] In this case, it was demonstrated that the hydrogen abstraction and CT or IP state formation by ET reaction were competing at encounter between $^3BP^*$ and DPA both in nonpolar and polar solvent, and the CT or IP state relaxed with respect to the donor acceptor configurations and solvation did not contribute to the ketyl radical formation. Such a direct abstraction mechanism was found to be applicable also in the reaction between $^3BP^*$ and DMA in 2-propanol and in isooctane although the consecutive scheme of the ET followed by intra-IP proton transfer was confirmed for the reaction mechanism in acetonitrile.[18]

In addition, proton abstraction of the dissociated free anion of BP from the neutral amine was responsible for the BPH· formation in the photoreaction of BP–1,4-diazabicyclo[2.2.2]octane (DABCO) in acetonitrile solution,[19] where the PT process within the IP state was not observed.

Various experimental results as described above indicate that the reaction mechanism depends on the structure of the amine and the nature of the solvent. Especially, the experimental findings that the reaction mechanism depends on the solvent even if the same amine is used and that the reactivity of the IP between the same donor and acceptor in the same solvent is different depending on the mode of its production indicate that the mutual distance and orientation, including the surrounding solvents, between BP and AH at encounter are of crucial importance for the subsequent reaction processes.

In the present paper, we report the reduction process of BP* with several tertiary amines, such as *N,N*-diethylaniline (DEA), *N,N*-diethyl-*p*-toluidine (*p*-DET), and *N*-methyldiphenylamine (MDPA), in acetonitrile solution. On the basis of the experimental results obtained by picosecond and femtosecond laser photolysis as well as the previous result with DMA, we discuss the reduction process of the excited BP from the viewpoint of the structure of the transient IP which is determined by the mode of its production and by its energy level.

Experimental

A picosecond laser photolysis system with a repetitive mode-locked Nd^{3+}: YAG laser was used for transient absorption spectral measurements in the 10 ps to a few nanosecond region.[21,22] The third harmonic pulse (355 nm) with 22 ps fwhm or Raman scattering light (397 nm) obtained by focusing the 355 nm pulse into cyclohexane liquid was used for exciting the sample solutions. For the measurement of spectra in shorter time region, a femtosecond laser photolysis system was used.[4,23] In this femtosecond photolysis, second harmonics (355 nm) with 500 fs fwhm of pyridine 1 dye laser (710 nm) was used for the excitation.

Benzophenone (Wako, Special Guarantee) was purified by repeated recrystallization from ethanol and sublimation in a vacuum. *N,N*-diethylaniline (DEA) (Wako, Special Guarantee) was refluxed with acetic anhydride, washed with water, dried over potassium hydroxide, distilled under reduced pressure, and stored under vacuum. *N,N*-diethyl-*p*-toluidine (*p*-DET) (Wako, Practical Grade) was also refluxed with acetic anhydride, washed with water, dried over potassium hydroxide, and distilled under reduced pressure three times. *N*-methyldiphenylamine (MDPA) (Tokyo Kasei, Guaranteed Reagent) was distilled under reduced pressure four times. Acetonitrile (Merck Uvasol) was used without further purification for the time resolved transient absorption spectral measurements. All sample solutions were deaerated by repeated freeze-pump-thaw cycles. The BP solution and DEA were deaerated separately and DEA was added to the BP solution by distillation in a vacuum line. All measurements were performed at 22±2 °C.

The extinction coefficients used for the estimation of the reaction yields are as follows; 6500 M^{-1} cm^{-1} at ca. 525 nm for $^3BP^*$, 4600 M^{-1} cm^{-1} at 545 nm for BPH·, and 10000 M^{-1} cm^{-1} for BP^- around 700 nm. The difference of the extinction coefficient of BP^- ($\leqslant$10%) depending on the solvation and on the state such as ion pair and the dissociated free ion was taken into account in the analysis. Detailed discussion on the determination of the extinction coefficient of each species were presented in the previous paper.[16,18]

Results and Discussion

As mentioned in the introductory section and in the previous papers,[17,18] there exist at least three pathways leading to the IP formation in the photoreduction process of BP by AH:

(1) The excitation of the weak CT complex formed in the ground state, $^1IP_{com}$, (2) The ET reaction between the $^1BP^*$ and the amine, $^1IP_{enc}$, and (3) The ET reaction between $^3BP^*$ and the amine, $^3IP_{enc}$. It is of crucial importance to get precise information on the role played by each IP for the elucidation of the reaction mechanisms of the photoreduction process of BP. From such a viewpoint, we proceed to investigate those problems as

follows.

First, we examine the reaction of ^{3}BP* with DEA leading to the ketyl radical formation and make clear the role of $^3IP_{enc}$ in this reaction. Second, we demonstrate the CT complex formation between BP and DEA in the ground state and the dynamic behaviors of this complex in its excited state. Third, we show results obtained by femtosecond laser photolysis, where the ET reaction of ^{1}BP* and DEA is discussed. By summarizing these results and those obtained for the BP-DMA system,[17,18] we discuss the differences among the reactivities of ^{1}BP*, ^{3}BP*, and three kinds of IP's. Finally, we present the experimental results on the reduction process of ^{3}BP* with *p*-DET and that with MDPA. Based on the results of investigation on the ^{3}BP*-tertiary aromatic amine systems in acetonitrile solutions, we discuss the dependence of the reactivity of the $^3IP_{enc}$ on its structure which seems to be related to the energy gap for the ET reaction producing the IP.

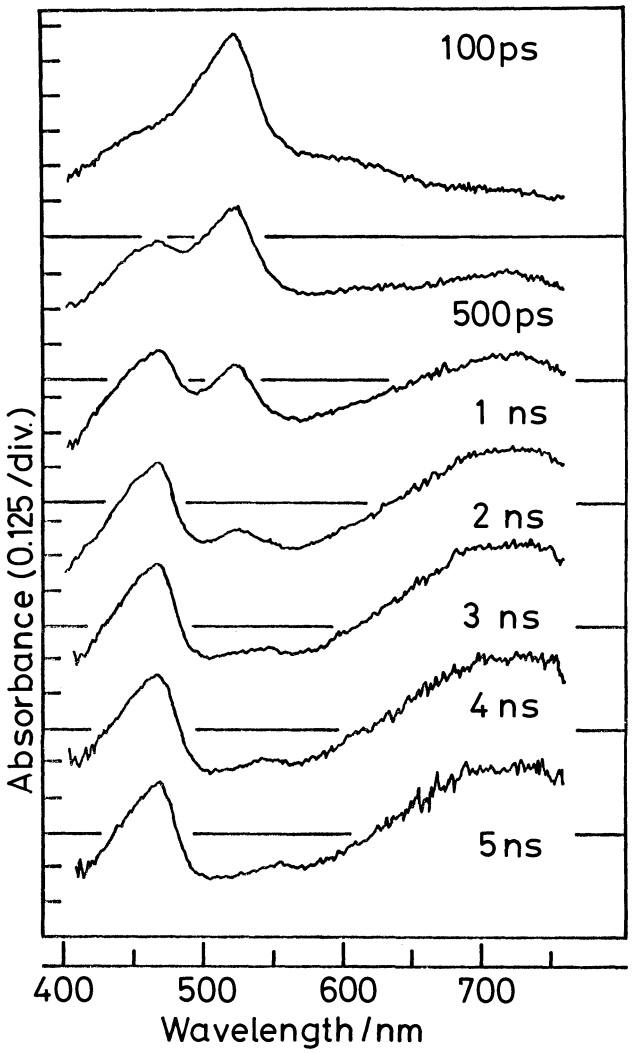

Fig. 1. Time-resolved transient absorption spectra of BP (0.01 M)–DEA (0.05 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse.

1. Reduction processes of ^{3}BP* by DEA in Acetonitrile Solution. Figure 1 shows the time resolved transient absorption spectra of BP (0.01 M)–DEA (0.05 M) (1 M=1 mol dm^{-3}) system in acetonitrile solution excited with a picosecond 355 nm laser pulse. A transient absorption spectrum with an absorption maximum at 525 nm, which is assigned to ^{3}BP*,[16-19,24,25] decreases with increase of the delay time after the excitation and new bands at 470 nm and ca. 700—720 nm appear. The new absorption band at 470 nm is assigned to DEA$^+$, and that at 700—720 nm to BP$^-$,[26] respectively. Although the absorption signal due to the BPH· radical which has an absorption maximum at 545 nm[27] is observed at longer delay times (3—5 ns) after the excitation, its yield is much smaller than those observed in cases where *N*,*N*-dimethylaniline (DMA) and diphenylamine (DPA) were used as hydrogen donors.[16,17,18] The transient absorption spectra in Fig. 1 indicate that ^{3}BP* gradually evolves with increase of the delay time into BPH· formed by the hydrogen abstraction reaction and $^3IP_{enc}$ produced through the ET reaction. No evolution of the transient absorption spectra was observed at longer delay times than 4 ns after the excitation. Taking into consideration the previous result by nanosecond laser photolysis[9] together with the present one, it may be concluded that the ionic species observed at a few nanosecond after the excitation is due to the dissociated free ions.

In order to clarify time profiles of ^{3}BP*, BPH·, and $^3IP_{enc}$, the observed absorption spectrum at each delay time was analyzed into these three species on the basis of each reference spectrum, the result of which is exhibited in Fig. 2. The ordinate represents the concentration of the individual species calculated by using each extinction coefficient given in the Experimental.

Solid lines in Fig. 2(a) represent the calculated time profiles based on the following scheme, where the BPH· and the $^3IP_{enc}$ which is dissociated into free ions at longer delay times are produced in competition with each other at the encounter of ^{3}BP* with DEA.

$$^3BP^* + DEA \longrightarrow {}^3(BP^-\cdots DEA^+)_{enc} \longrightarrow BP^-_s + DEA^+_s$$
$$\searrow\ (BPH\cdots DEA\cdot) \longrightarrow BPH\cdot + DEA\cdot$$

Scheme 1.

where DEA· indicates the neutral radical produced after the abstraction of a hydrogen atom from DEA. As is clear from Fig. 2(a), time profile of the BPH· radical and that of $^3IP_{enc}$ could not be well reproduced by Scheme 1. The deviation of the calculated time profile of the $^3IP_{enc}$ from the experimental one in such a way that the experimental result is always larger than the calculated curve in the course of the formation of the IP indicates some rapid deactivation process of the ionic species competing with the ionic dissociation. Moreover, the

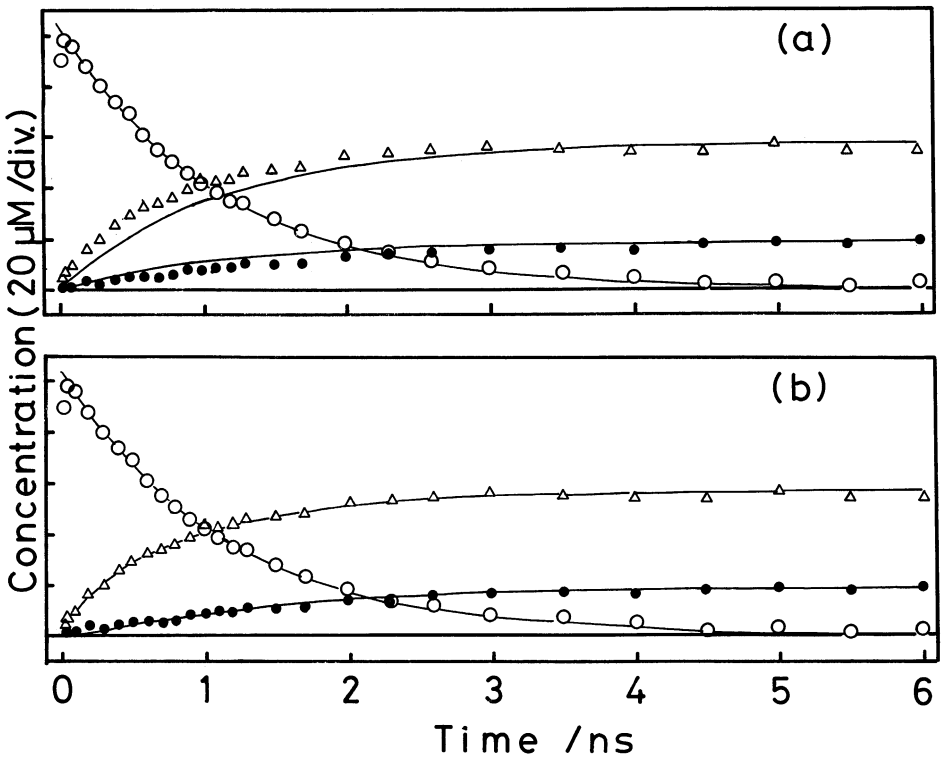

Fig. 2. Time profiles of ^{3}BP* (○), BPH· (●), and BP$^-$ and DEA$^+$ (△) of BP (0.01 M)–DEA (0.05 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse (see text). Solid lines are calculated curves based on Scheme 1(a), and on Scheme 2(b) (see text).

deviation of the time profile of the BPH· in such a way that the experimental result is always smaller than the calculated curve whose rise time is equal to the decay of ^{3}BP* indicates that the production of BPH· is not directly related to the decrease of ^{3}BP* but some intermediate species exists. Accordingly, the mechanism of Scheme 1 is not adequate for the reaction of ^{3}BP* with DEA in acetonitrile solution, although this direct abstraction mechanism competing with $^3IP_{enc}$ formation was suitable for the hydrogen abstraction process of ^{3}BP* from diphehylamine.[16]

On the other hand, the time profiles calculated on the basis of the Scheme 2 are indicated in Fig. 2(b).

$$^3BP^* + DEA \longrightarrow {}^3(BP^{-}\cdots DEA^{+})_{enc} \longrightarrow BP^-_s + DEA^+_s$$
$$\searrow\ (BPH\cdot\cdots DEA\cdot) \longrightarrow BPH\cdot + DEA\cdot$$

Scheme 2.

Scheme 2 represents the successive mechanism for the hydrogen atom transfer; the IP produced by the ET proceeds to the PT reaction competing with the ionic dissociation process. The parameters for the transient species such as the lifetime of the $^3IP_{enc}$ and reaction yields of the proton transfer and the ionic dissociation were determined respectively in such a manner that the time profiles of ^{3}BP*, BPH·, and $^3IP_{enc}$ were consistent with each other. As shown in Fig. 2(b), the time profile of each species is well reproduced by the calculated curve based on the Scheme 2. The lifetime of $^3IP_{enc}$ was 300 ps and the reaction yield of the proton transfer and that of the ionic dissociation were 0.19, and 0.55, respectively.

In order to confirm the validity of the above parameters obtained by the analysis in Fig. 2(b), we have examined several solutions containing different concentration of DEA. Fig. 3 shows time-resolved transient absorption spectra of BP(0.01 M)–DEA (0.3 M) in acetonitrile solution excited with a picosecond 355 nm laser pulse. ^{3}BP* with its absorption maximum at 525 nm decreases and those of the IP at 470 nm and 700—720 nm, and the BPH· radical at 545 nm increases with increase of the delay time after the excitation. These results are rather similar to those in Fig. 1. However, it should be noted here that the transient absorption spectrum at early stage after the excitation shows a rather large amount of the absorption signal due to IP's compared to that observed in the solution containing 0.05 M DEA. This rapid production of IP's is partly due to the formation of $^1IP_{enc}$, by the ET reaction between ^{1}BP* and DEA, and the formation of $^1IP_{com}$ by the excitation of the CT complex formed in the ground state. More details on these species will be described in the later part of the present paper.

Figure 4 shows the time profiles of three kinds of transient species, ^{3}BP*, BPH·, and IP's, of the BP (0.01 M) -DEA (0.3 M) in acetonitrile solution obtained by the same analysis as in Fig. 2. The initial yield of ^{3}BP* and the sum of yields of IP's which were produced via the excitation of the CT complex and the nonstationary quenching of ^{1}BP* by DEA was in the ratio ca. 3 : 1. In other words, almost 25% of the absorbed photon energy was used for the production of the species other than ^{3}BP*. Solid lines in Fig. 4 are calculated curves based on the consecutive reaction scheme as in Fig. 2(b) and parameters were determined in such a manner that time profiles of these three species were consistent with each other. Contributions from singlet IP's including their lifetimes and reaction yields are included in this calculation, details of which will be discussed later in the present paper.

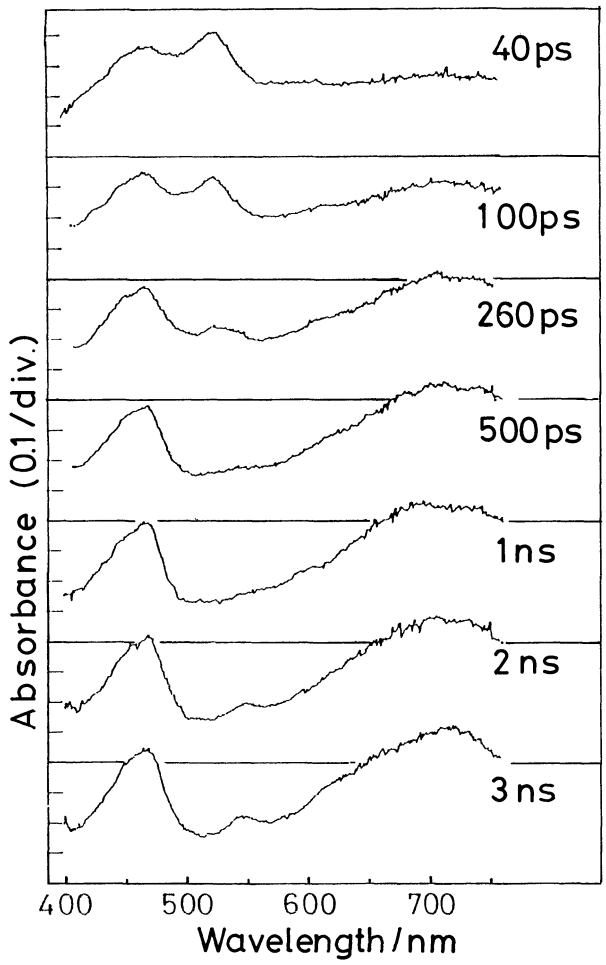

Fig. 3. Time-resolved transient absorption spectra of BP (0.01 M)-DEA (0.3 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse.

As shown in Fig. 4, experimental results are well reproduced by this calculation with following parameters; the lifetime of $^3IP_{enc}$: 290 ps, the yield of BPH·: 0.23 and that for the ionic dissociation: 0.65. The lifetime and reaction yields of $^3IP_{enc}$ agree with those obtained for the solution containing 0.05 M of DEA (Figs. 1 and 2) within the experimental error.

The consecutive reaction mechanism (Scheme 2) was found to reproduce the experimental time profiles over a wide range of DEA concentration (Table 1). Results in Table 1 clearly show that similar values were obtained for the lifetime and the reaction yields of $^3IP_{enc}$ over a wide range of the concentration of DEA by the curve-fitting procedure, indicating clearly that the reaction mechanism of the hydrogen abstraction of ^{3}BP* from DEA in acetonitrile solution can be described by Scheme 2. Moreover, the rate constant for the ionic dissociation, 2.1×10^9 s^{-1}, was similar to those obtained for a number of organic radical ion pairs produced by the electron transfer at encounter collision in acetonitrile solution at room temperature.[20,28] This result also confirms that the values of the lifetime and reaction yields of the $^3IP_{enc}$ obtained by this analysis and the extinction coefficients used here are appropriate.

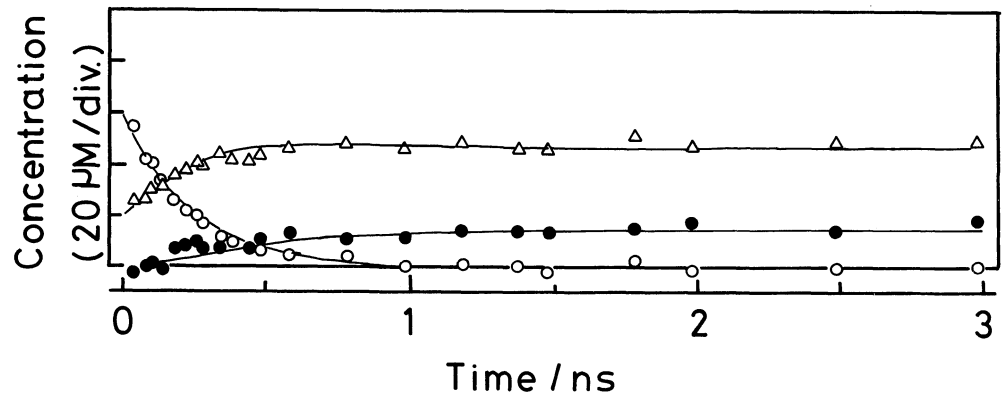

Fig. 4. Time profiles of ^{3}BP* (○), BPH· (●), and BP^- and DEA^+ (△) of BP (0.01 M)-DEA (0.3 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse (see text). Solid lines are calculated curves based on Scheme 2 (see text).

2. Excited State Dynamics of the Weak CT Complex between BP and DEA Formed in the Ground State in Acetonitrile Solution. In Fig. 5, we show the ground state absorption spectra of BP (0.05 M) with added DEA of various concentrations in acetonitrile solution. The increase of the absorbance in the wavelength region longer than 360 nm was observed with increase of the concentration of DEA. This change of the absorption spectrum can be attributed to the formation of weak CT complex between BP and DEA, since the selective excitation of the absorption tail leads to the immediate formation of $^1IP_{com}$ (see Fig. 6). The equilibrium constant of this complex formation, K_g, was estimated to be 0.1—0.5 by Benesi-Hildebrand plot.

Figure 6 shows transient absorption spectra of BP (0.5 M)–DEA (1.0 M) system in acetonitrile solution excited with a picosecond 397 nm laser pulse, at which wavelength the ground state complex is selectively excited as can be seen from Fig. 5. A broad absorption spectrum with an absorption maximum around 740 nm which appears immediately after the excitation can be safely assigned to BP^- in $^1IP_{com}$ on the basis of the absorption maximum and spectral shape.[18,26] The absorption in the wavelength region shorter than 500 nm, which also appears immediately after the excitation, can be ascribed to DEA^+. With increase of the delay time after the excitation, the absorption due to $^1IP_{com}$ decreases and reaches plateau value attributable to the

dissociated free ions. The decay process of the IP was approximately reproduced by the single exponential function and the time constant was obtained to be (93±5) ps. No absorption due to BPH· was detected after the decay of $^1IP_{com}$. Accordingly, it is concluded that the dominant pathway in the decay of $^1IP_{com}$ is the charge recombination (CR) process and ca. 10% of $^1IP_{com}$ dissociates into free ions.

Similar results to those of the present $^1IP_{com}$ were also observed for the excited state dynamics of the weak CT complex between BP and DMA formed in the ground state in acetonitrile solution.[17,18] Namely, short-lived transient IP state, $^1(BP^-\cdots DMA^+)_{com}$, produced by the excitation at the CT absorption band, was deactivated rapidly via the efficient CR process. The lifetime and the yield of the ionic dissociation of $^1(BP^-\cdots DMA^+)_{com}$ were (85±3) ps and <0.04, respectively. In addition, no BPH· formation was observed also in the course of the decay process of $^1(BP^-\cdots DMA^+)_{com}$. Moreover, the peak position of the absorption band due to BP^- in the IP state, $^1(BP^-\cdots DMA^+)_{com}$, was also at 740 nm, while those of $^3IP_{enc}$ and dissociated free BP^- are around 700—720 nm as shown in Fig. 1. In relation to these results, it should be noted here that the peak position of BP^- absorption changes depending on the structure of the IP and the degree of the solvation according to the previous reports.[29,30] The relation between the peak position of the BP^- absorption and the structure of IP including the surrounding solvents will be discussed in detail in the later part of the present paper.

3. Photoreduction Process of $^1BP^*$ by DEA in Acetonitrile Solution. Figure 7 shows the time resolved absorption spectra of BP (0.05 M)–DEA (0.6 M) system in acetonitrile solution excited with a femtosecond 355 nm laser pulse. The spectrum indicated by the dotted line in the first frame is due to the $S_n \leftarrow S_1$ transition of BP measured in the amine free solution.[17,18] In addition to the $S_n \leftarrow S_1$ absorption spectrum, an absorption maximum at 470 nm and broad absorption whose intensity increases toward longer wavelength region than 600 nm are observed at 1 ps after the excitation of the solution containing 0.6 M of DEA. The absorption band at 470 nm and the broad absorption in the region longer than 600 nm are assigned respectively to DEA^+ and BP^- in the IP. This rapid formation of the IP is due to the excitation at the CT band of the complex overlapping the ground state absorption band of free BP, as stated in the previous section. With increase of the delay time after the excitation, the absorption at 575 nm decreases and the absorption due to the IP gradually increases together with the increase of a new band at 525 nm due to $^3BP^*$.

The time profiles of transient absorbance at 575, 660, and 525 nm are exhibited in Fig. 8. The absorbance at 575 nm due to $^1BP^*$ arises with the time resolution of the apparatus, and shows a rapid decay with the time constant of (5.5±0.5) ps followed by a much slower decay process.

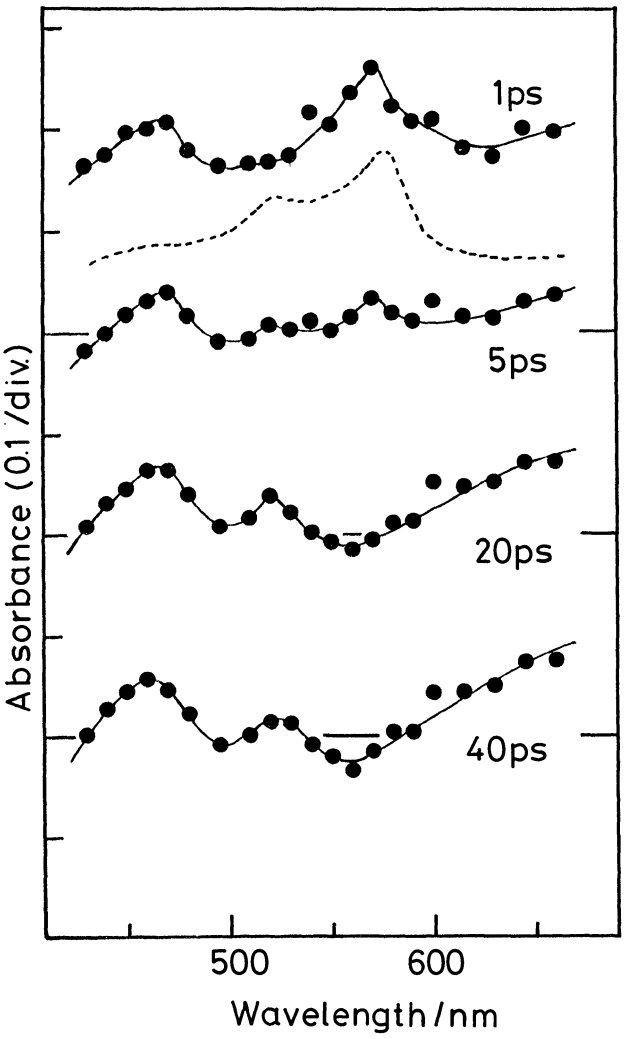

Fig. 7. Time-resolved transient absorption spectra of BP (0.05 M)–DEA (0.6 M) system in acetonitrile, measured by exciting with a 500 fs 355 nm laser pulse.

The rapid decay can be attributed to the quenching process of $^1BP^*$ by DEA on the basis of the time evolution of the spectrum in Figs. 7, 8. Since the lifetime of $^1BP^*$ in amine free solution of acetonitrile was 9.0 ps,[17,18] ca. 30—40% of $^1BP^*$ is quenched by the reaction with the neighboring DEA. On the other hand, the slower decay process with the time constant longer than a few tens of picoseconds may be attributed to the decay of $^3BP^*$ and IP's whose absorptions overlap that of $^1BP^*$ at this wavelength.

The time dependence of the absorbance monitored at 660 nm shows the rapid increase within the response of the apparatus followed by the further increase with the time constant of (5.5±0.3) ps, and then by much slower decay process. The rapid appearance of the IP immediately after the excitation is ascribed to the excitation of the CT complex formed in the ground state. On the other hand, the slower rise with the time constant of (5.5±0.3) ps is due to the IP formation via the ET

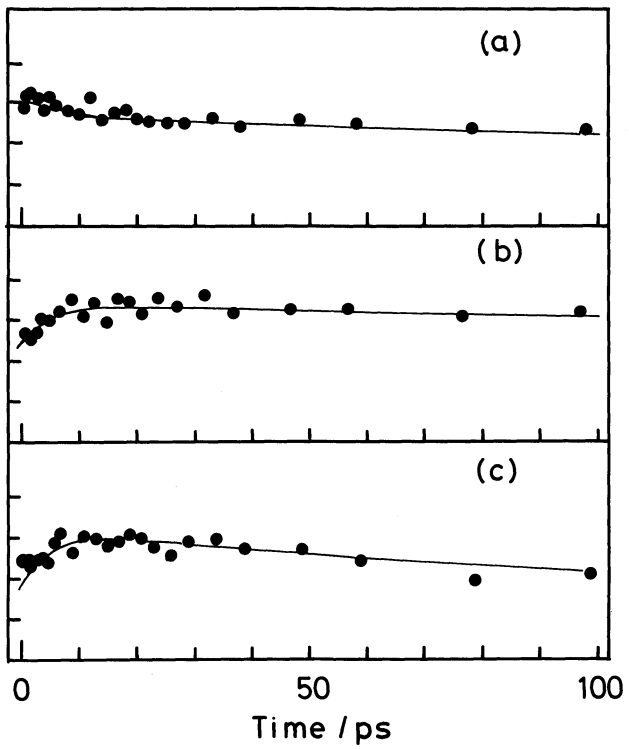

Fig. 8. Time profiles of transient absorbance of BP (0.05 M)–DEA (0.6 M) system in acetonitrile excited with a 500 fs 355 nm laser pulse and observed at 575 nm (a), 670 nm (b), and 525 nm (c).

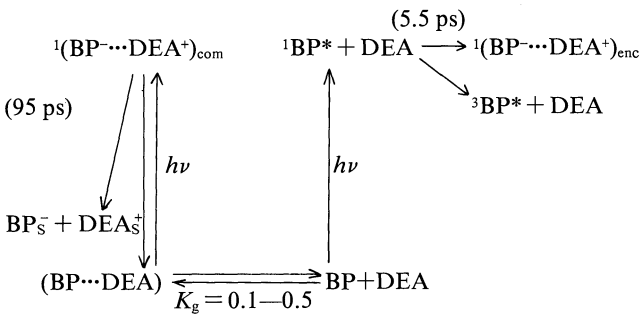
reaction between ^{1}BP* and DEA, since the time constant of the decrease of ^{1}BP* is identical with the rise time of the IP. The quenching rate constant of ^{1}BP* by DEA, 1.6×10^{11} M^{-1} s^{-1}, is about 8—10 times as large as the diffusion controlled rate constant in acetonitrile. This rapid quenching process is probably due to the rapid reaction of ^{1}BP* with the neighboring DEA, the so-called transient effect or non-stationary quenching. Such a large reaction rate constant for the ET process between ^{1}BP* and the amine was also observed in the case of BP–DMA system.[17,18]

Time profile of the absorbance at 525 nm which is an absorption maximum of ^{3}BP* is shown in Fig. 8(c), indicating that the rapid increase of the absorbance immediately after the excitation is followed by the slower rise and much slower decay process. The rapid rise of the absorbance is ascribed to the contribution of ^{1}BP* as can be seen from Fig. 8(a). The slower increase of the absorbance is ascribed to the formation of ^{3}BP* by the intersystem crossing of ^{1}BP* on the basis of the coincidence of the time constant of the rise of ^{3}BP*, (5.4±0.5) ps, with the decay of ^{1}BP* in Fig. 8(a). Much slower decay of the absorbance may be due to the quenching of ^{3}BP* by DEA and the recombination process of IP's. The rapid quenching process of ^{1}BP* by DEA was also observed in acetonitrile solutions containing 1.0 M of DEA and that with 2.0 M of DEA. The lifetime of ^{1}BP* in the solution of [DEA]=1.0 M was 3.7 ps and that for 2.0 M DEA was 2.5 ps, respectively. With increase of [DEA], the increase of the yield of $^1IP_{enc}$ and the decrease of that of ^{3}BP* were observed.

By the analysis of the transient absorption spectrum immediately after the excitation with the femtosecond 355 nm laser pulse into two components, ^{1}BP* and $^1IP_{com}$, and by dividing each spectrum by the extinction coefficient, the fraction of $^1IP_{com}$ and that of ^{1}BP* were obtained to be 0.33 and 0.67, respectively. The fraction of $^1IP_{com}$ increases with increase of [DEA]. The fraction of $^1IP_{com}$ for 1.0 M solution of DEA and that for 2.0 M solution were 0.38 and 0.67, respectively. In addition, the contribution of the rapid quenching process of ^{1}BP* by DEA also increases with increase of [DEA] and, as a consequence, the yield of ^{3}BP* decreases. From the lifetime of ^{1}BP* and spectral evolution, we can evaluate the initial yields of $^1IP_{com}$, $^1IP_{enc}$, and ^{3}BP*, respectively. For example, only 33% of the light energy absorbed in the acetonitrile solution of BP containing 0.6 M of DEA terminated in the production of ^{3}BP*. This value decreases with increase of [DEA]; that for 1.0 M solution was 25% and that for 2.0 M solution was 10%.

From the above results and discussion, we can summarize the ET and related processes in short time regions of the excited benzophenone in the presence of DEA in acetonitrile solution as follows.



Scheme 3.

In this scheme, the $^1IP_{com}$ produced by the excitation of the CT complex formed in the ground state, is discriminated from the $^1IP_{enc}$ produced via the ET reaction between ^{1}BP* and DEA. In the case of the ET reaction in the system of BP and DMA, clear difference in the reaction processes depending on the mode of the production of IP's was observed between these two kinds of IP's.[17,18] The circumstance was similar also in the present case. The detailed discussion on this difference between two kinds of ^{1}IP's will be given in the later part of the present paper.

In order to elucidate dynamic behaviors and reaction pathways of $^1IP_{enc}$ quantitatively, transient absorption spectra of acetonitrile solutions of BP (0.01 M)–DEA (0.6 M) system in picosecond - a few nanosecond region were measured by means of the picosecond 355 nm laser pulse excitation (Fig. 9). A large amount of transient

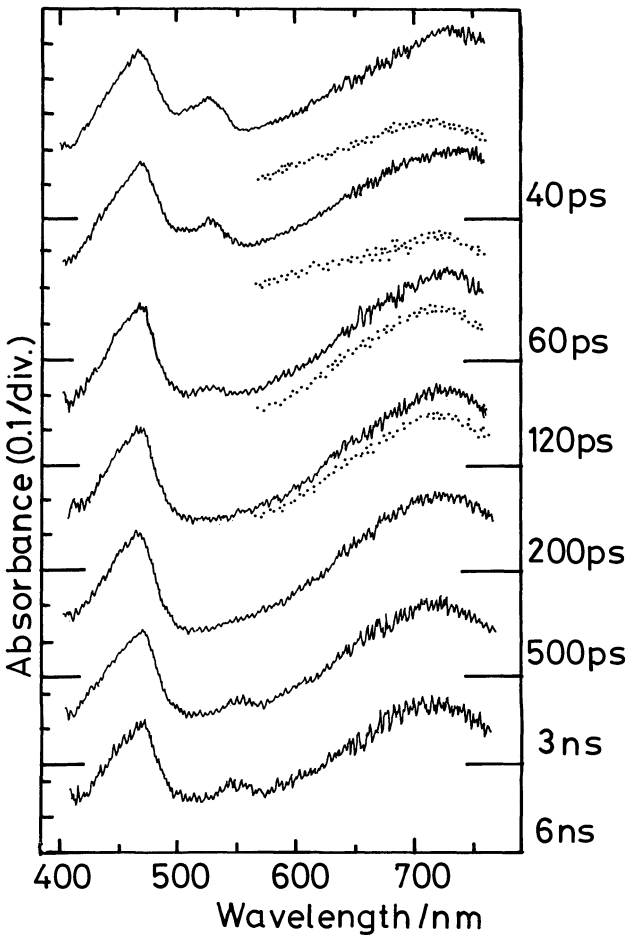


Fig. 9. Time-resolved transient absorption spectra of BP (0.01 M)–DEA (0.6 M) system in acetonitrile solution, excited with a picosecond 355 nm laser pulse. Dotted lines are the absorption spectra obtained by subtracting the contribution of the absorption bands due to $^1(BP^- \cdots DEA^+)_{com}$ from the observed spectra (see text).

absorption due to IP's which involves both $^1IP_{com}$ and $^1IP_{enc}$ was observed immediately after the excitation. In addition to the absorption bands of IP's, clear signal due to the absorption $^3BP^*$ is observed at 525 nm. The initial yield of $^3BP^*$ was 0.33 in this solution containing 0.6 M of DEA as described already in the interpretation of Figs. 7 and 8. With increase of the delay time after the excitation, the absorption of IP's also decreases and reaches a plateau value which is ascribed to the dissociated free ions. Very small absorption signal due to BPH· was observed around 550 nm at longer delay times (3—6 ns).

In Fig. 10, we show the time profiles of $^3BP^*$, BPH·, and IP's, which were obtained by the analysis of the observed spectra in Fig. 9 into these components. The initial yields of $^1IP_{com}$, $^1IP_{enc}$, and $^3BP^*$ were determined by the femtosecond laser photolysis, respectively. In addition, the reaction pathways have been elucidated and their rate constants have been determined respectively for $^3BP^*$, $^3IP_{enc}$, and $^1IP_{com}$. Hence, in principle, informations on the reactions of $^1IP_{enc}$ can be obtained by subtracting from the observed results the contributions from the reaction between $^3BP^*$ and DEA and that of $^1IP_{com}$ on the basis of their initial yields and time dependences. In the actual analysis of the time profiles of $^1IP_{enc}$, we employed the curve-fitting procedure where the lifetime and the reaction yields were varied as parameters. The solid lines in Fig. 10 were calculated curves by assuming that the lifetime, the reaction yield of the proton transfer, and the ionic dissociation yield of $^1IP_{enc}$ were 350 ps, 0.14, and 0.50, respectively. The solid curves for IP's and BPH· in Fig. 10 include the contributions from $^3IP_{enc}$ and $^1IP_{com}$. As shown in Fig. 10, the experimental results are reproduced by the calculated time dependences, and further, parameters for $^1IP_{enc}$ are almost independent of the DEA concentration as shown in Table 2. The averaged lifetime, reaction yields for the proton transfer, ionic dissociation, and charge recombination of $^1IP_{enc}$ were 343 ps, 0.15, 0.48, and 0.37, respectively.

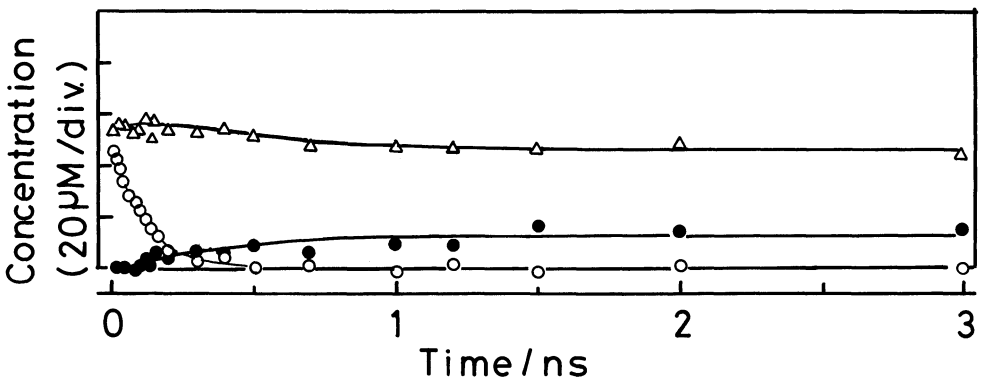

Fig. 10. Time profiles of $^3BP^*$ (○), BPH· (●), and BP^- and DEA^+ (△) of BP (0.01 M)–DEA (0.6 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse.

Table 2. Properties of the Singlet Ion Pair, $^1(BP^-\cdots DEA^+)_{enc}$, in Acetonitrile Solutions with Various Concentrations of DEA. τ: Lifetime, ϕ_{PT} and k_{PT}: Reaction Yield and Rate Constant of the Proton Transfer, ϕ_{ID} and k_{ID}: Reaction Yield and Rate Constant of the Ionic Dissociation, ϕ_{CR} and k_{CR}: Reaction Yield and Rate Constant of the Charge Recombination

1.0	330	0.15	0.50	0.35	4.6×10^8	1.5×10^9	1.1×10^9
Average	(343±9)	0.15±0.005	0.48±0.024	0.37±0.021	$(4.3\pm0.044)\times10^8$	$(1.4\pm0.094)\times10^9$	$(1.1\pm0.04)\times10^9$

4. Absorption Maximum of BP^- and the Structure of IP Including the Surrounding Solvents. Peters et al. reported the time-dependent blue-shift of the absorption spectrum of BP^- in the photoreduction process of excited BP with amines including DEA and they concluded that this shift was due to the structural change of the IP from the solvent-separated IP(SSIP) to the contact IP(CIP) based on the postulate that the ET reaction proceeded exclusively between $^3BP^*$ and amines.[12] As shown in Fig. 9, it was observed also in the present study that the peak position of BP^- absorption band gradually shifted from 730—740 nm to 700—710 nm region with increase of the delay time after the excitation. However, as we have pointed out in the previous sections of this paper and in the previous paper on the reduction of excited BP with DMA,[17,18] the contributions of both $^1IP_{com}$ and $^1IP_{enc}$ to the observed spectra should be taken into account for the elucidation of this spectral shift. The wavelength of the absorption peak of BP^- in $^1IP_{com}$ which decays with the time constant of (93±5) ps, was 740 nm as indicated in Fig. 6, and was different from those of $^3IP_{enc}$ and free BP^-.

In order to clarify whether the spectral shift is the intrinsic one caused by the structural change of IP or the apparent one arising from the disappearance of $^1IP_{com}$, we plotted the spectrum of BP^- obtained by subtracting the contribution of the spectrum due to $^1(BP^-\cdots DEA^+)_{com}$ overlapping those of $^1(BP^-\cdots DEA^+)_{enc}$ and $^3(BP^-\cdots DEA^+)_{enc}$ considering its fraction determined by the analysis of the time profiles of those species and its lifetime (dotted lines in Fig. 9). It is clear that the spectrum from which the contribution of $^1(BP^-\cdots DEA^+)_{com}$ was removed showed an absorption maximum around 700—720 nm although a rather broad spectrum gradually evolved into a sharper one with increase of the delay time after the excitation. From this result, we can conclude that the time dependent spectral shift was caused mainly by the disappearance of the spectrum due to $^1(BP^-\cdots DEA^+)_{com}$. This result is similar to that observed previously in the case on BP–DMA in acetonitrile solution.[17,18]

The fact that the absorption maximum of $^1IP_{com}$ is different from those of $^1IP_{enc}$, $^3IP_{enc}$, and free BP^- in both BP–DMA and BP–DEA systems may be ascribed to the difference of the structure of IP such as the mutual distance and orientation between BP^- and amine cation including the surrounding solvents. The present results clearly indicate that such assignment of the longer wavelength absorption to the SSIP and shorter one to the CIP as made by Peters et al.[12] is erroneous. Since the absorption maximum of the free BP^- was rather close to those of $^1IP_{enc}$ and $^3IP_{enc}$, ca. 700—720 nm, the structure of the solvation surrounding the BP^- in these IP_{enc}'s seems to be rather similar to those of the free BP^-. Hence, it is reasonable to assign the absorption maximum at 740 nm to the compact IP or CIP state of BP^- and amine cation and that at 700—720 nm to a more or less loose IP (LIP) or SSIP and solvated free ion state.

The above assignment is also supported by the recent investigations which demonstrate the large difference in the dynamic behaviors of IP's of various donor acceptor systems depending on the mode of their production.[2,20,28] In these studies, charge recombination (CR) rate of IP produced by the excitation of the CT complex and its dependence on the energy gap between the IP state and the ground state, $-\Delta G^\circ_{ip}$, have been examined in the case of various CT complexes covering a wide range of the energy gap by using femtosecond and picosecond laser photolysis. By these investigations, it has been revealed that the CR rate of IP produced by the CT complex excitation shows an essentially different energy gap dependence from the bell shaped one obtained in the case of IP formed by charge separation at encounter in the fluorescence quenching reaction.[2-4,20,28] Further, the CR rate of IP produced by the CT complex excitation has been confirmed, in general, to be greater than that of IP formed by charge separation at encounter for the same donor (D) and acceptor (A) pair in acetonitrile.[20] From these and related findings, it has been also suggested that the structure of IP's including the surrounding solvent is different from each other; the CIP probably with no intervening solvent molecule between A^- and D^+ would be produced in the case of the excitation of the CT complex, while LIP or SSIP with intervening solvent molecules between A^- and D^+ may be formed in the CS at encounter in the fluorescence quenching reaction. Moreover, from the results of those investigations, it has been concluded that the structures of these IP's could be maintained at least during several hundreds of picoseconds.[2-4,20,28]

Table 3. Dependence of the Reaction Rate Constants of the Ion Pairs upon the Mode of Its Production

	k_{PT}/s^{-1}	k_{ID}/s^{-1}	k_{CR}/s^{-1}
$^3(BP^-\cdots DEA^+)_{enc}$	7.3×10^8	2.1×10^9	
$^1(BP^-\cdots DEA^+)_{enc}$	4.3×10^8	1.4×10^9	1.1×10^9
$^1(BP^-\cdots DEA^+)_{com}$	$\ll10^8$	1.4×10^9	9.3×10^9
$^3(BP^-\cdots DMA^+)_{enc}$	5.4×10^9	1.4×10^9	
$^1(BP^-\cdots DMA^+)_{enc}$	6.6×10^8	9.5×10^8	5.8×10^8
$^1(BP^-\cdots DMA^+)_{com}$	$\ll10^8$	$\leqslant4\times10^8$	1.1×10^{10}

The dependence of the CR rate of IP on its mode of the production as observed in the present study on BP–DEA system as well as BP–DEA system is similar to those observed in the case of the above described various singlet IP's. In addition, we have confirmed that the relation between the CR rate and $-\Delta G^\circ_{ip}$ observed for $^1IP_{com}$ as well as $^1IP_{enc}$ in the BP–DEA and BP–DMA systems is also quantitatively in agreement with that predicted by the experimental results on various singlet IP's covering a wide range of $-\Delta G^\circ_{ip}$.[2-4,20,28] From these results regarding the $-\Delta G^\circ_{ip}$ dependence of the CR rate, the behaviors of the present $^1IP_{com}$ and $^1IP_{enc}$ are considered to be typical of the IP's produced by the excitation of the CT complex and via the ET reaction at encounter collision in the fluorescence state, respectively. By integrating the experimental results on the absorption maxima of the spectrum of BP^- in various kinds of IP's and the energy gap dependence of the CR rate of BP–DEA as well as BP–DMA IP systems, it is reasonable to assign the absorption maximum at 740 nm to the contact or compact IP state of BP^- and amine cation and that at 700—720 nm to LIP or SSIP and solvated free ion state.

5. Difference of the Reactivity between IP's Depending on the Mode of the Production. In Table 3, we list the rate constants of the proton transfer, k_{PT}, the ionic dissociation, k_{ID}, and the the charge recombination, k_{CR}, for the three kinds of IP's, $^1IP_{com}$, $^1IP_{enc}$, and $^3IP_{enc}$. In this table, the results on the IP's of BP–DMA system[17,18] are included also for the purpose of comparison. The CR rate constant of $^3IP_{enc}$ is not listed in this table, since this rate constant is very small, and hence, its quantitative determination was difficult. In both systems, clear difference of each rate constant depending on the mode of the production of the IP was observed. This result indicates that the structure of the IP is different from each other and it is approximately kept during the lifetime of the IP.

Although the rate constant of each process such as the ionic dissociation, the charge recombination, and the proton transfer is different between $(BP^-\cdots DEA^+)$ and $(BP^-\cdots DMA^+)$, the dependence of the rate constant on the mode of the production of the IP is very similar. The k_{PT}, of $^3IP_{enc}$ is the largest among these three kinds of IP's and the yield of BPH· radical of $^1IP_{com}$ was practically zero for both systems. Since the dependence of the rate constant on the production mode of the IP, $(BP^-\cdots DEA^+)$, is very similar to that of $(BP^-\cdots DMA^+)$, the interpretation in the previous paper[17,18] seems applicable also to the present result. In the following, we briefly discuss the difference of the reactivity between different IP's.

5. (a) The Difference of the Reactivity between the Singlet IP's Depending on the Mode of Their Production. In general, the geometric requirement for the proton or the hydrogen atom transfer processes seems to be more severe compared to that for the electron transfer reaction, since the conformational requirement for the latter process is dependent on the electronic molecular orbital spreading over a rather wide region, while the sites for the transfer of proton or hydrogen in the donor and the acceptor are limited within the narrow region. Hence, the difference in the structure of the IP such as the orientation and the distance seems to strongly affect the proton transfer probability.

As we have discussed in the interpretation of the spectral shift of BP^- absorption indicated in Fig. 9, $^1IP_{com}$ between BP and DEA as well as DMA may have quite different structures including the solvation from those of IP_{enc}. As a consequence of this difference in the structure, the reactivity of $^1IP_{enc}$ may be quite different from that of $^1IP_{com}$. At the present stage of the investigation, it is rather difficult to determine the precise structure of the IP composed of two molecules. However, it is strongly suggested that the initial structure of $^1IP_{com}$, especially the orientation of D^+ and A^- in the IP, is quite different from those of IP_{enc}'s. In addition, from the $-\Delta G^\circ_{ip}$ dependence of the CR rate, it is suggested that the $^1IP_{com}$ between BP and DEA or DMA has a rather rigid structure where the ions cannot reorient to take a suitable structure for the proton transfer before the recombination, while $^1IP_{enc}$ produced by the electron transfer between $^1BP^*$ and the amine at encounter has a more or less loose structure and is long-lived to form the suitable geometry for ketyl radical formation.

5. (b) The Difference of the Reactivity between $^3IP_{enc}$ and $^1IP_{enc}$. The reaction mechanism of the ketyl radical formation in the case of BP–DEA and –DMA systems in acetonitrile solutions has been confirmed to be the successive one of the IP formation followed by the proton transfer not only in the case of $^3BP^*$ but also $^1BP^*$. However, reaction rate constants in $^3IP_{enc}$ and $^1IP_{enc}$ are different from each other. The large difference of the charge recombination rate constant, k_{CR}, between two kinds of IP's can be ascribed to the difference of the spin multiplicity of the IP. On the other hand, the rate constant of the proton transfer, k_{PT}, of $^3IP_{enc}$ is larger than that of $^1IP_{enc}$, which cannot be ascribed solely to the difference of the spin multiplicity. This difference of k_{PT} between the two kinds of IP's may be related to the difference in the structure of the IP such as the mutual distance and orientations of ions in the pair including the surrounding solvents. Although it is

rather difficult at the present stage of the investigation to give any definite conclusion on the structures of these IP's, it is plausible that the IP produced by the ET reaction between ^{1}BP* and the amine has a more specific structure since the ET process is mainly due to the very rapid non-stationary reaction between the neighboring pair and, as a consequence, the shorter mutual distance and some specific orientation between the pair may be favorable for the reaction, leading to somewhat different IP structures from those produced via the stationary diffusion process. The difference in the electronic structure of ^{1}BP* from ^{3}BP* may play also some role in determining the mutual configurations favorable for ET between donor and acceptor at the encounter.

Summarizing above results and discussion on the difference of reactivity between ^{1}IP's and that between IP_{enc}'s, it may be concluded that the difference of the reactivity depending on the mode of the production of IP is related mainly to the difference of the mutual orientation of D^+ and A^- in the IP arising from the initial mutual geometry between the BP and amine undergoing the photoinduced CT or ET reaction. The relation between the distance dependence of the ET reaction and that of the intra-IP PT process and its consequence on the final hydrogen abstraction yield will be discussed in the next section.

6. The Difference of the Reactivity of Ion Pairs Depending on the Oxidation Potential of the Amine. In addition to the difference of the reactivity of the IP depending on the mode of the production, a large difference of the reactivity of $^3IP_{enc}$ was also observed between BP–DMA and BP–DEA systems. In order to clarify factors causing this difference, we have investigated photoreduction processes of BP– *N,N*-diethyl-*p*-toluidine (*p*-DET) and BP– *N*-methyldiphenylamine (MDPA) systems. We have selected these tertiary amines on the following reasons. First, the reaction mechanisms for these tertiary amines are all consecutive one of Scheme 2. Second, molecular structures of these tertiary amines are rather close to one another and have different oxidation potentials; MDPA: 0.86 V (vs. S.C.E), DMA: 0.76 V, DEA: 0.72 V, and *p*-DET: 0.69 V.[31] Although the difference of the reactivity depending on the mode of the IP production, i.e. the difference among $^3IP_{enc}$, $^1IP_{enc}$, and $^1IP_{com}$, was observed also in BP–*p*-DET and –MDPA systems[31,32] just as in BP–DEA and BP–DMA systems, we concentrate our discussion on the reduction process of ^{3}BP*.

In Fig. 11, we show transient absorption spectra of BP (0.01 M) –*p*-DET (0.05 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse. The concentration of the amine (0.05 M) was low enough to selectively observe the dynamic behaviors of ^{3}BP*. With increase of the delay time, the transient absorption spectrum due to ^{3}BP* which appeared immediately after excitaion gradually decays together with the increase of

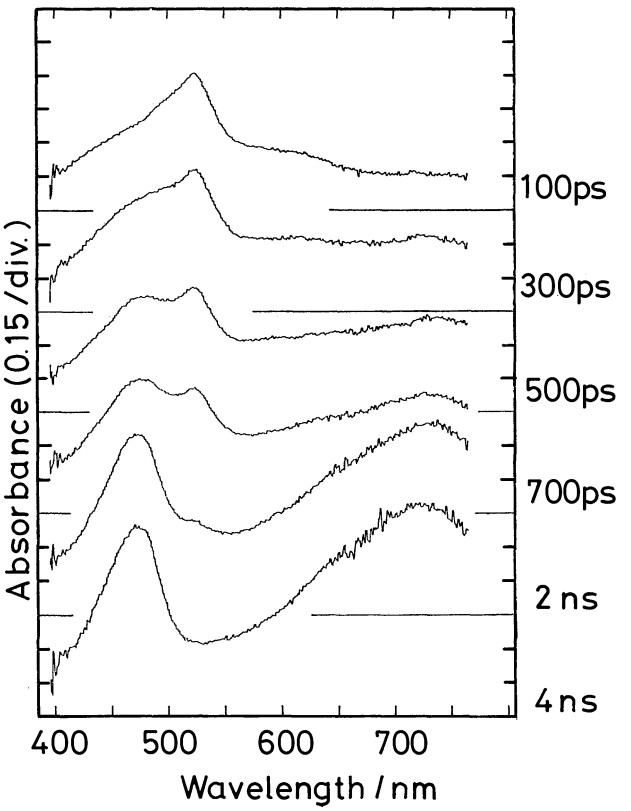

Fig. 11. Time-resolved transient absorption spectra of BP (0.01 M)–*p*-DET (0.05 M) system in acetonitrile solution, excited with a picosecond 355 nm laser pulse.

the absorbance at 700—720 nm (BP^-), and at 480 nm (*p*-DET^+). The absorbance due to BP^- and *p*-DET^+ reaches plateau value at 2—3 ns after the excitation and further evolution of the absorbance was not observed. From this result and those of the previous experiments,[9] the ionic species observed at a few ns after the excitation may be assigned to free ions. The yield of the free ions from ^{3}BP* was obtained to be 0.95±0.05 from the analysis of transient spectra in Fig. 11, where no ketyl radical formation was observed. Since neither decay process of the IP nor the formation of the ketyl radical was observed, it was not possible to determine the lifetime of $^3IP_{enc}$ by the present experiment. Hence, we estimate the lifetime and the reaction rate constants in the following manner. The rate constant for the ionic dissociation process of IP's of various donors and acceptors produced by ET at encounter in acetonitrile at room temperature (ca. 20 °C) has been determined to be $(0.5—2)\times10^9$ s^{-1}.[20,28] As listed in Table 3, k_{ID} for $^3(BP^-\cdots DEA^+)_{enc}$ and that for $^3(BP^-\cdots DMA^+)_{enc}$ were also in this range. Since the yield of the ionic dissociation of the $^3(BP^-\cdots p\text{-}DET^+)_{enc}$ was 0.95±0.05, the lifetime of the IP was estimated to be $\geqslant$500 ps assuming the similar k_{ID} value. Since the ketyl radical formation was not recognized, the rate constant for the proton transfer is estimated to be $\ll 2\times10^8$ s^{-1}. Anyhow, summarizing

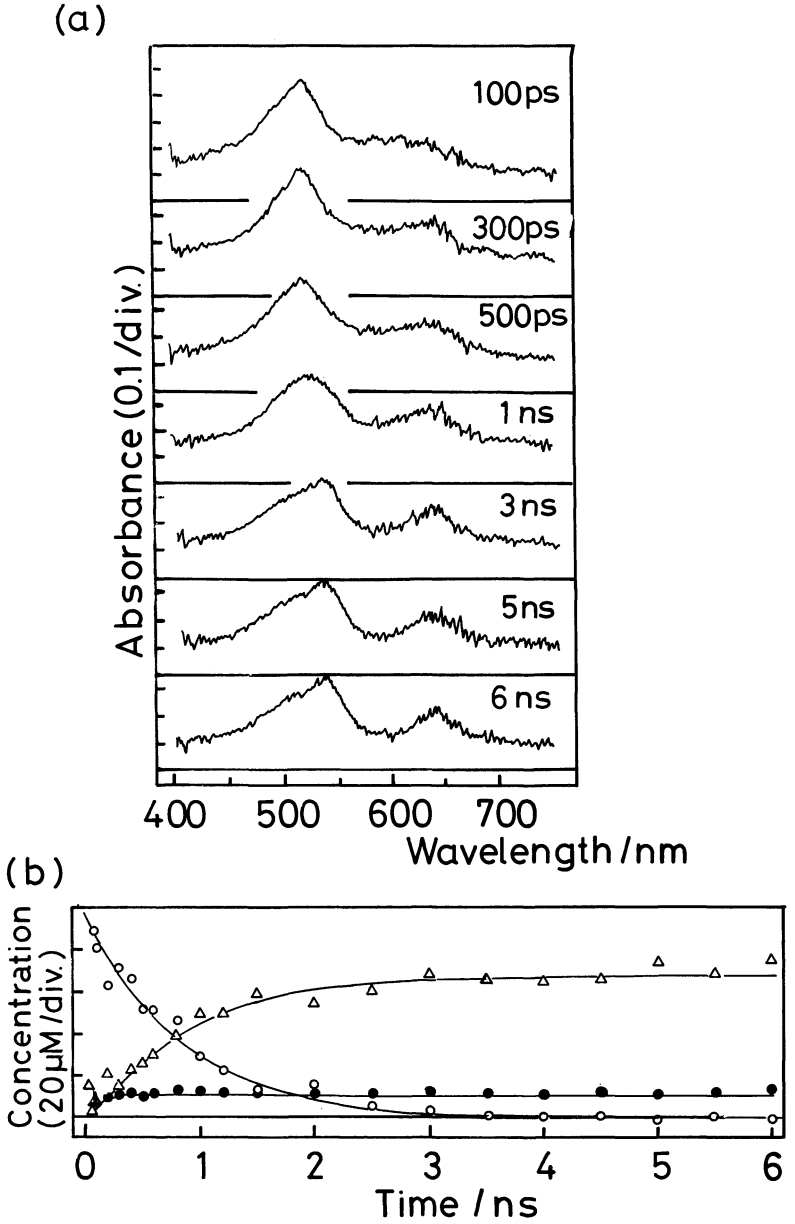

Fig. 12. a) Time-resolved transient absorption spectra of BP (0.01 M)–MDPA (0.07 M) system in acetonitrile solution, excited with a picosecond 355 nm laser pulse. b) Time profiles of ^{3}BP* (○), BPH· (△), and BP^- and $MDPA^+$ (●) of BP (0.01 M)–MDPA (0.07 M) system in acetonitrile solution excited with a picosecond 355 nm laser pulse (see text). Solid lines are calculated curves based on Scheme 2 (see text).

above results on the reduction process of ^{3}BP*-*p*-DET system, it may be concluded that the decrease of the yield of BPH· is attributable to the decrease of k_{PT}. This result indicates that, k_{PT} of $^3IP_{enc}$ between BP and the tertiary aromatic amine decreases with the decrease of the oxidation potential of the amine.

In order to confirm the effect of the oxidation potential of the amine on k_{PT} of $^3IP_{enc}$, the photoreduction process of BP–MDPA system was also investigated. Fig. 12(a) shows transient absorption spectra of BP(0.01 M)–MDPA (0.07 M) in acetonitrile excited with a picosecond 355 nm laser pulse. Although the formation of $^1IP_{com}$ and $^1IP_{enc}$ was found to increase also in this system with increase of [MDPA],[32] contributions from these IP's to the observed spectra of ionic species in Fig. 12(a) is very little. The transient absorption spectra due to ^{3}BP* observed immediately after the excitation gradually evolved in time into those of $MDPA^+$ at 645 nm, BP^- at 700—720 nm and BPH· at 545 nm. In Fig. 12(b), we exhibit the time profiles of ^{3}BP*, BPH·, and the IP.

Table 4. Dependence of the Reaction Rate Constants of the Triplet Ion Pairs upon Their Oxidation Potentials

Amine	MDPA	DMA	DEA	*p*-DET
Oxidation potential/V (vs. S.C.E.)	0.86	0.76	0.72	0.69
Lifetime of $^3IP_{enc}$/ps	90	140	290	(>500)
k_{PT}/s^{-1}	8.0×10^9	5.4×10^9	7.3×10^8	($\ll2\times10^8$)
k_{ID}/s^{-1}	1.1×10^9	1.4×10^9	2.1×10^9	(2×10^9)

Solid lines indicate the calculated curves based on the consecutive mechanisms (Scheme 2), similar to those indicated in Figs. 2 and 4. The lifetime of $^3(BP^{-}\cdots MDPA^{+})_{enc}$ was obtained to be 90 ps and the reaction yields of the proton transfer and the ionic dissociation were obtained to be 0.72 and 0.10, respectively. These values were confirmed to be almost independent of [MDPA].[32]

In Table 4, collected are the obtained values of the lifetime, k_{PT} and k_{ID} of $^3IP_{enc}$ of BP–tertiary aromatic amine systems in acetonitrile. This table shows clear dependence of each rate constant, especially k_{PT}, on the oxidation potential of the amine. This dependence of k_{PT} on the oxidation potential of the aromatic tertiary amine seems to indicate the different structure of the IP depending on the oxidation potential of the amine and seems to be closely related to the problems of the energy gap dependence of the ET reaction. Qualitatively speaking, the rate of the photoinduced ET reaction in polar solutions is regulated by:[33]
(a) Frank–Condon factor for the ET process which is related to the energy gap ($-\Delta G^\circ$) between the initial and final state of ET, (b) the reorganization energy (λ) including the intramolecular vibrational modes and the polarization of the solvent surrounding D and A, (c) the solvent dynamics, and (d) the electronic interaction responsible for ET which depends on mutual distance and orientations between D and A. When the factor (d) is not very strong and is not much different throughout a series of D, A systems, the ET rate may be determined mainly by the factor (a) and (b).

The CR decay rate constant, k_{CR}, of LIP or SSIP formed by CS at encounter in the fluorescence quenching reaction[2,3,28] as well as the phosphorescence quenching reaction[34] has been confirmed to show bell-shaped energy gap dependence. These energy gap dependences are predicted by the usual theories on the ET reaction. On the other hand, the CS rate constant, k_{CS}, at encounter in the luminescence quenching reaction rises steeply around zero energy gap and becomes diffusion-limited at favorable $-\Delta G^\circ$ regions, while no inverted effect has been experimentally confirmed yet. We have evaluated the k_{CS} values in the diffusion-limited $-\Delta G^\circ$ regions by measuring the transient effect in the fluorescence quenching reaction of a series of D, A systems in acetonitrile solutions and have demonstrated that the $-\Delta G^\circ$ dependence of k_{CS} in this top region is rather flat.[35] Such $-\Delta G^\circ$ dependence of k_{CS} in the top region can be interpreted by assuming the change of the ET distance depending on the change of $-\Delta G^\circ$ value.[35,36] That is, for larger $-\Delta G^\circ$ value, CS at a little larger distance is favorable because λ becomes larger at larger D, A distance,[36] which makes the $-\Delta G^\circ$ dependence of k_{CS} broader than that expected from the simple theoretical consideration.[37] We have made quantitative theoretical calculations on this problem, in which we have shown that the observed $-\Delta G^\circ$ dependence of k_{CS} and k_{CR} can be interpreted by assuming D, A distance distributions depending on $-\Delta G^\circ$ values in the CS reaction and also nonlinear polarization of solvent around ions.[36,38]

Along these theoretical treatments, it is expected, for the PT process following the ET reaction, that the PT rate should be drastically slowed down with the increase in the energy gap for the CS reaction in the condition where the orientation of BP^- and AH^+ and the surrounding solvation structure of IP are similar and the $-\Delta G^\circ$ value for the CS reaction is relatively large. In other words, the increase in the inter-ionic distance in the geminate IP with increase of the energy gap for the CS reaction affects the subsequent PT rate to a great extent since the rate for the PT process is much more severely dependent on the mutual distance.

The present result of the dependence of k_{PT} of $^3IP_{enc}$ on the oxidation potential of the amine is in accordance with the above considerations on the mechanism of the energy gap dependence of k_{PT}. The inter-ionic distance in those BP–amine ^3LIP will become longer to a small extent with decrease of the oxidation potential of the amine and it seems to be kept until the proton transfer taking place in competition with the ionic dissociation. The k_{PT} will decrease with decrease of the amine oxidation potential due to the increase of the proton transfer distance.

The effect of the energy gap for the CS reaction on the PT rate which is attributable to the difference in the inter-ionic distance may be expected also in the course of the $^1IP_{enc}$ formation since it is actually observed for $^3IP_{enc}$. However, because the ET between $^1BP^*$ and the amine is restricted rather severely to the pairs in the short range owing to the very short life of $^1BP^*$, such effect of the energy gap in the CS reaction will be small. Actually, k_{PT} in the $^1IP_{enc}$ does not show such energy gap dependence, but rather similar to each other for the series of $^1BP^*$–DEA, –DMA, and –MDPA systems ($k_{PT}=4.3\times10^8\ s^{-1}$, $6.6\times10^8\ s^{-1}$, and $6.0\times10^8\ s^{-1}$, respectively).

7. The Different Reaction Mechanism Depending on the Nature of the Amine. As discussed above, the mechanism of the hydrogen abstraction of ^{3}BP* from tertiary aromatic amines in acetonitrile solution is the successive reaction as given by the Scheme 2, while the hydrogen abstraction process of ^{3}BP* from primary and secondary amines such as aniline, DPA, *N*-methylaniline, and *N*-ethylaniline was the direct abstraction competing with the production of the stable IP which did not undergo the intra-IP proton transfer.[16,31] This difference of the reaction mechanism depending on the structure of the amine might be related to the existence of weak hydrogen bonding interaction between π-electrons on oxygen of the excited BP and the hydrogen directly bonded to the nitrogen of the amine. The CT interaction and this weak hydrogen bonding interaction might to closely connected with each other and facilitate the hydrogen transfer process in the encounter collision.

On the other hand, the mechanism of the hydrogen abstraction of ^{3}BP* from DMA in 2-propanol is not the successive one but can be described by the direct abstraction mechanism. The difference of the mechanism depending on the solvent may be related to the following experimental results on the singlet IP's. Concerning the structure and dynamics of the molecular complex produced by the photoinduced CT or ET reaction, it was reported that the electronic state of the typical singlet exciplex system such as pyrene–DMA was strongly dependent on the nature of the solvent such as the polarity and ability of hydrogen bonding interaction.[39,40] This dependence on the nature of the solvent was not accounted for by assuming the mere stabilization of the single electronic state by the solvation but it is necessary to take into account the change of the electronic and geometrical structures of the complex depending on the nature of the solvent.[39,40] In addition, it was revealed that, in sufficiently polar solvents, the fluorescent exciplex and nonfluorescent solvated IP's were produced competitively, depending upon the solvent polarity, from the non-relaxed CT state immediately after the electron transfer between excited singlet state of pyrene and DMA.[41] Integrating those previous results and the present ones, it is suggested that the mutual geometry such as orientation and distance including the surrounding solvent at the encounter between the reactants strongly affect the subsequent behaviors of the very short-lived transient charge transfer or the IP state.

Summarizing these various mechanisms depending on the structures of the amine, the nature of solvent, and the oxidation potential of the amine as well as the production pathways of IP, it is indicated that the transient charge transfer interaction in a short-lived intermediate formed in the excited benzophenone–amine system is of crucial importance as the factor determining the reaction mechanism.

In relation to this problem, we are now investigating the system where mutual configurations are restricted by connecting BP and amine with the methylene chain, results of which will be published in a forthcoming paper.

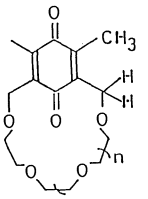
Conformational Change of Benzoquinone Crown Ether Radical Anions Induced by Complexation with Alkali Metal Cation: An ESR Study

Kiichi HASHIMOTO, Hideo TOGO, Kenji MORIHASHI, Yukihiro YOKOYAMA, and Osamu KIKUCHI*
Department of Chemistry, University of Tsukuba, Tsukuba 305
(Received June 5, 1991)

The crowned *p*-benzoquinone anion radicals, **O5**$^-$—**O8**$^-$, were generated either electrochemically or by using a reducing metal, and their ESR spectra were examined in both the absence and presence of the Na^+ or K^+ cation. The hyperfine coupling (hfc) constants of the methylene protons bonded to the quinone ring depend largely on the size of the crown ring; the orientation of the benzoquinone skeleton with respect to the crown ring was analyzed. The metal-free **O5**$^-$ has a fixed conformation in which the benzoquinone ring is nearly perpendicular to the crown ring, while **O8**$^-$ interconverts freely between two equivalent conformations. The critical case is **O6**$^-$; the line-width alternation observed in its ESR spectra was well-analyzed using the two-jump model. Temperature-dependent ESR spectra and MNDO calculations have suggested that **O6**$^-$ undergoes a restricted interconversion between two conformations in which the benzoquinone ring has an orientation similar to that of **O5**$^-$. An activation energy of 10.0 kcal mol^{-1} was determined for this motion. The ESR spectra of the ion-paired **O5**$^-$—**O8**$^-$ anion radicals have suggested that the conformational motion of the anion radicals is fixed by complexation with the Na^+ or K^+ cation. The hfc constants of the methyl protons in the benzoquinone ring increased upon complexation, indirectly confirming the interaction between the carbonyl oxygen of benzoquinone at the crown-ring side and the metal cation.

In the field of host–guest chemistry, studies of molecular switching in macrocyclic polyether systems is of great interest in relation to ion-transport phenomena in biological systems. The crown compounds including redox active functional groups, such as quinone,[1-13] nitrobenzene,[14-17] disulfide,[18] azo moieties,[19] have attracted much attention. Among them, quinone derivatives are especially interesting because they have significant properties due to the ready reversibility of the quinone–semiquinone redox system.

Our previous cyclic voltammetric study has shown that the complexation of crowned quinones, **O5**—**O8**, with alkali metal cations, Li^+, Na^+, or K^+, is enhanced by the reduction of the quinones.[6] Wolf and Cooper showed



O5: $n = 1$
O6: $n = 2$
O7: $n = 3$
O8: $n = 4$

an ESR spectra which confirmed the interaction between **O6**$^-$ and the Na^+ cation.[7] Bock and Herrmann have shown that **O6**$^-$ forms a 1-to-2 complex with two alkali metal cations.[8] Delgado et al. have reported the ESR spectra of anthraquinone podands and anthraquinone crown ether anion radicals and have shown the interaction between these anion radicals and the alkali metal cation.[10-13] However, there have only been few reports[8,20] concerning the electronic structure and conformational change of the crowned anion radicals induced by interactions with alkali metal cations.

In this study, the anion radicals of **O5**—**O8**[6] were generated either electrochemically or using a reducing metal, and their ESR spectra were examined both in the absence and presence of a metal cation. From the determined hfc constants and an MNDO[21] calculation of a model anion radical, the conformational change of anion radicals induced by complexation with metal cations is discussed.

Experimental

Tetrahydrofuran (THF) was distilled from $LiAlH_4$ under an Ar atmosphere and stored over 3 Å molecular sieves. The THF was flask-to-flask distilled in a vacuum line immediately prior to use for reduction with an alkali metal. The acetonitrile (MeCN) used for electrochemical reduction was distilled from CaH_2 under an Ar atmosphere. The MeCN was stored without molecular sieves, since they contain Na^+ cations as a component. Tetrabutylammonium perchlorate (TBAP) was twice recrystallized from EtOAc and dried over vaccum pumping at room temperature for 24 h. Alkali metal perchlorate salts, $NaClO_4$ and $KClO_4$ were recrystallized from deionized water and dried over vaccum pumping at 100 °C for 24 h.

The crowned anion radicals were generated by reduction with Na or K metal in THF, and the ESR spectra of ion-paired anion radicals were recorded. The ESR spectra of "metal-free" anion radicals were obtained by the addition of a large excess amount of cryptand 221 to a sample solution prepared with Na metal. The anion radicals were also generated by electrochemical reduction in MeCN using TBAP as a supporting electrolyte. In order to obtain the ESR spectra of the ion-paired anion radicals, 1.0 or 2.0 equivalent of alkali metal perchlorate was used instead of TBAP.

The ESR spectra were recorded on an X-band JEOL JES-FE-1XG spectrometer. The temperature of the samples was controlled by means of a JEOL ES-DVT 1 variable-temperature unit. The microwave frequency was measured with an Advantest TR5212 Microwave Counter and the magnetic feld strength with an Echo Electronics EFM-2000 NMR Field Meter. Field gradients were corrected by using Fremy's salt as a reference compound.

Results

The well-resolved ESR spectra of the metal-free anion radicals and the anion radicals ion-paired with Na^+ or K^+ were obtained for **O5**—**O8**. The hfc constants were determined by simulation, and are summarized in Tables 1 and 2. In the case of the ion-paired **O5**$^-$ generated by reduction with alkali metal, the spectrum changed rapidly and the hfc constants could not be determined. The ESR spectra have the following common features: (1) each spectrum has splitting due to six methyl protons and the methylene protons attached to the quinone ring; (2) the spectra of the metal-free **O6**$^-$ and **O7**$^-$ exhibit a line-width alternation indicating restricted interconversion between conformers; and (3) the Na splitting is observed for **O5**$^-$—**O8**$^-$, while no K splitting is observed.

Reduced O5. Figure la shows the ESR spectrum of **O5**$^-$ obtained by reduction with Na metal in THF at 25 °C in the presence of cryptand 221. The ESR spectrum comprises seven main lines arising from the six equivalent methyl protons; each of these lines is further split by the methylene protons attached at the quinone ring. The hfc constants are 2.17 G (6H, 1G=10^{-4} T), 0.78 G (2H), and 0.38 G (2H). As was expected, there was no hfc by Na^+ in the presence of the cryptand, and the spectrum of the metal-free **O5**$^-$ was observed. Figure 1b shows the ESR spectra of the metal-free **O5**$^-$ observed by electrochemical reduction. The four methylene protons are equivalent in the MeCN solution. Figure 2 shows the ion-paired **O5**$^-$ observed by electrochemical reduction. The hyperfine coupling of Na was observed, while

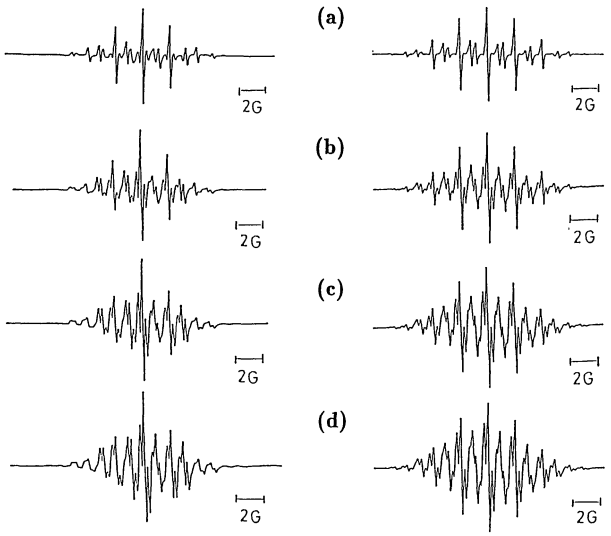

Fig. 3. Temperature-dependent ESR spectra (left) and simulated spectra (right) for metal-free $\mathbf{O6}^-$ in THF at (a) +25 °C, (b) 0 °C, (c) −20 °C, and (d) −40 °C.

that of K was not resolved.

Reduced O6. Figure 3 shows the temperature dependence of the ESR spectra of the metal-free $\mathbf{O6}^-$ obtained by reduction with Na in THF in the presence of cryptand 221. The spectra clearly exhibit an alternating line-width effect at room temperature and below, indicating a conformational interconversion of $\mathbf{O6}^-$. The temperature-dependent spectra were analyzed using a two-jump model between two conformations in which the methylene protons which bonded to the quinone ring were distinguished as being two sets of two equivalent protons. The determined hfc constants are 2.11 G (6H), 0.96 G (2H), and 0.30 G (2H). The rate constant at 25 °C was $k=2.5\times10^6$ s^{-1}. From a plot of log k against $1/T$, an activation energy of 10.0 kcal mol^{-1} was determined for the conformational interconversion.

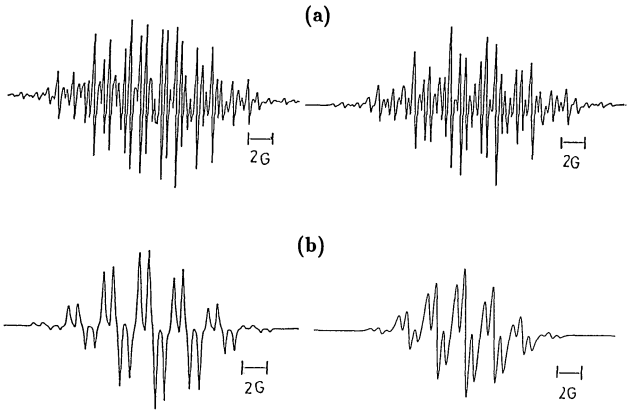

Fig. 4. ESR spectra (left) and simulated spectra (right) for reduced **O6** obtained by reduction with alkali metal (a) in the presence of Na^+ and (b) in the presence of K^+.

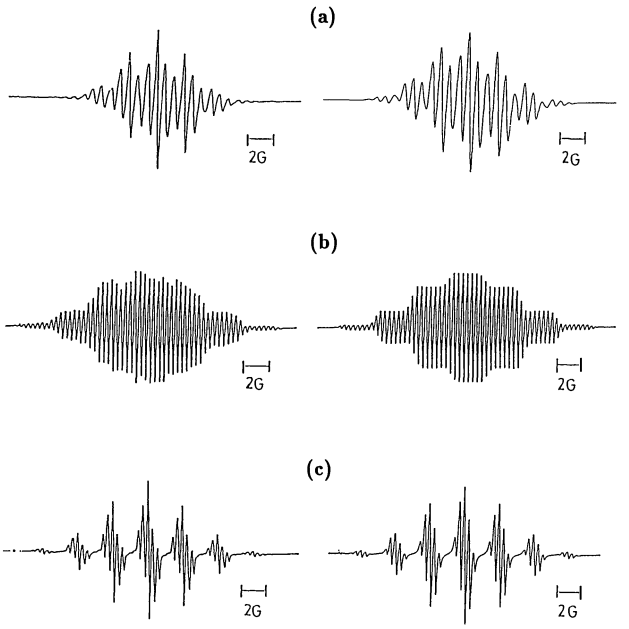

Fig. 5. ESR spectra (left) and simulated spectra (right) for reduced **O7** obtained by reduction with alkali metal (a) in the presence of Na^+ and cryptand 221, (b) in the presence of Na^+ and (c) in the presence of K^+.

Similar hfc constants were obtained for the metal-free $\mathbf{O6}^-$ generated by electrochemical reduction in MeCN.

Figure 4 shows the ESR spectra of the ion-paired $\mathbf{O6}^-$ obtained by reduction with Na or K metal; a splitting of Na was observed. No line-width alternation can be observed in the spectrum, and only one set of methylene protons (2H) has a distinct hfc constant. This characteristic of the ESR spectrum was also observed in the $\mathbf{O6}^-$–Na^+ or $\mathbf{O6}^-$–K^+ system obtained by electrochemical reduction. These results suggest that $\mathbf{O6}^-$ has a conformation in which one of the CH_2 protons lies on the quinone ring plane.

Reduced O7. Figure 5 shows the ESR spectra of $\mathbf{O7}^-$

observed by reduction with alkali metal. The metal-free **O7**$^-$ spectrum observed by reduction with Na metal has hfc constants of $a(2CH_3)$=2.13 G and $a(4H)$=0.64 G. In the metal-free **O7**$^-$ spectrum obtained by electrochemical reduction, a slight line-width alternation effect was observed; the spectrum was well reproduced by the hfc constants of $a(2CH_3)$=2.08 G, $a(2H)$=0.98 G, and $a(2H)$=0.26 G. These hfc constants of methylene protons indicate that the value of 0.64 G for 4H protons of **O7**$^-$ obtained by reduction with alkali metal is due to an average of two different sets of two protons. In the case of ion-paired **O7**$^-$, four methylene protons have the same hfc constants, irrespective of the method of radical generation.

Reduced O8. All ESR spectra of **O8**$^-$ have no line-width alternation effect, and exhibit the hfc of six equivalent methyl protons and four equivalent methylene protons. Although the hyperfine coupling of Na was observed for **O8**$^-$ ion-paired with Na^+ generated by Na metal, no Na splitting was observed when the radical anion was generated by electrochemical reduction (Fig. 6). In the latter case, 2.0 equivalents of Na^+ are present in the solution and two cations bind with **O8**$^-$; this was confirmed by a previous cyclic voltammetric study.[6]

MNDO Calculation. The orientation of the polyether groups relative to the quinone moiety plays an important role in the energy stabilization of **O5**$^-$—**O8**$^-$. Therefore, the MNDO MO calculations were carried out for the anion radical of a simple model compound, **O3**, in order to examine the conformational energy of **O5**$^-$—**O8**$^-$.

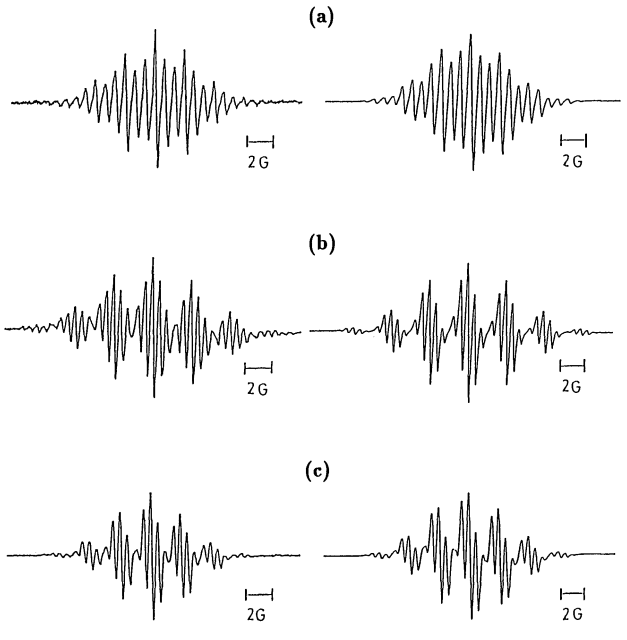

Fig. 6. ESR spectra (left) and simulated spectra (right) for reduced **O8** obtained by electrochemical reduction (a) in the absence of metal cation, (b) in the presence of 2 equivalent of Na^+ and (c) in the presence of 1 equivalent of K^+.

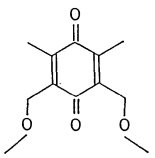

O3

The rotation angle of the CH_2OCH_3 group, ϕ, was measured from the conformation in which the C(methylene)–O(ether) bond lies on the quinone ring plane. Except for the structure of the methyl groups, which was assumed to be tetrahedral with R_{CH}=1.100 Å, all geometrical parameters were optimized under the restriction of Cs symmetry for several ϕ values. The open-shell RHF MNDO method[22] was used. The calculated energy profile is shown in Fig. 7. A similar energy profile was also obtained by a UHF MNDO calculation.

A maximum-energy structure was found at ϕ=0°, where the two C(methylene)–O(ether) bonds are in the quinone ring plane. In such a conformation, the Coulombic repulsion between the ether and carbonyl oxygen atoms becomes maximum. The increase in stabilization in going from ϕ=0° to ϕ=90° is attributed to a decrease in the Coulombic repulsion; a minimum-energy conformation was found near ϕ=90°, where the two C(methylene)–O(ether) bonds are perpendicular to the quinone ring plane. The energy difference between the maximum-energy structure (ϕ=0°) and the minimum-energy one (ϕ=90°) was calculated to be 12.0 kcal mol^{-1}.

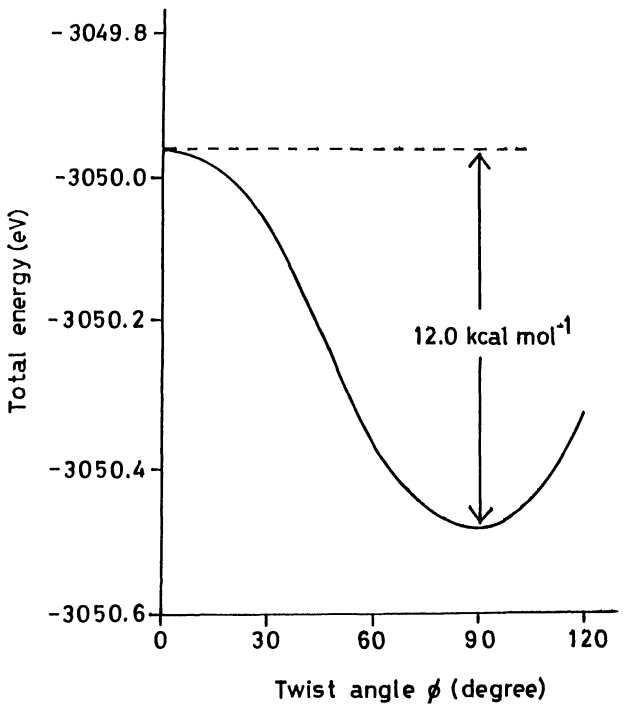

Fig. 7. Energy profile for the rotation of the CH_2OCH_3 groups of the radical anion **O3**$^-$.

Discussion

Metal-Free O6⁻. The present ESR experiment can not determine the conformation of the crown ring skeleton, since the hyperfine coupling due to the methylene protons attached at the quinone ring gives only information concerning the conformational aspects around the C(quinone)–C(methylene) bond. Since the size of the crown ring of **O6⁻** is not large enough to freely undergo a conformational interconversion, the rotation about the C(quinone)–C(methylene) bond is restricted. Because of this steric factor, the four methylene protons attached at the quinone ring are not completely equivalent over the temperature range studied, and the alternating line-width effect was observed.

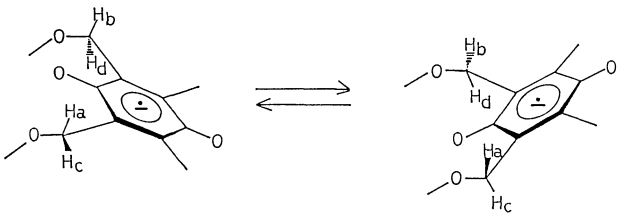
In the two-jump model simulation, four methylene protons attached at the quinone ring were distinguished as being two sets of two equivalent protons: H_a=H_b and H_c=H_d (Scheme 1). We thus assumed an interconversion in which the quinone moiety turns around the C(quinone)–C(methylene) bond. The simulation along this line well reproduced the observed temperature-dependent ESR spectra of the metal-free **O6⁻** (Fig. 3), and the hfc constants listed in Tables 1 and 2 were determined.

The hfc constants of methylene protons depend on the angle, θ, between the C(methylene)–H bond and the $2p_\pi$ orbital of the quinone carbon atom. According to the McConnell–Heller equation,[23]

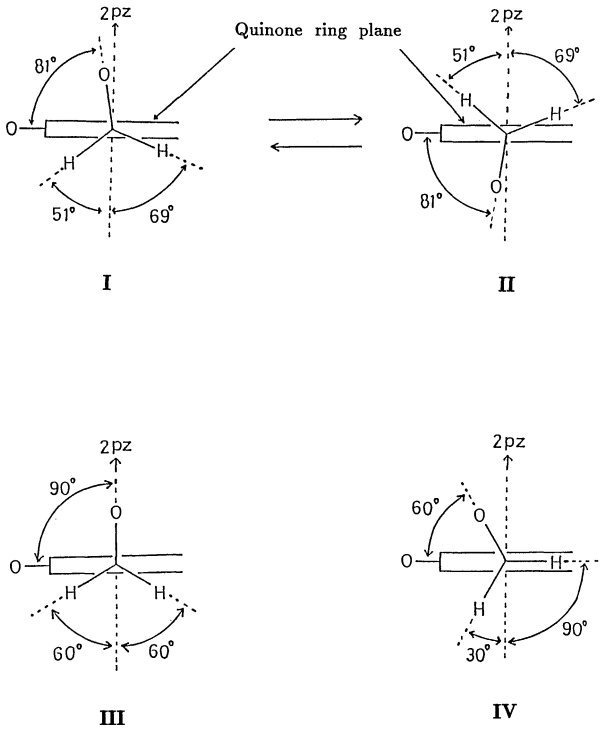
$$a(H_\beta) = B\cos^2\theta,$$

the orientation of the crown ring relative to the quinone moiety can be estimated. From the hfc constant of methyl protons in the duroquinone (2,3,5,6-tetramethyl-*p*-benzoquinone) anion radical, 1.9 G,[24] the empirical parameter, B, was estimated to be ca. 3.8 G for the benzoquinone radical anions. From this B value and the relative magnitude of the methylene hfc constants observed, 0.96 G and 0.30 G, the conformation of the metal-free **O6⁻** was speculated as **I**.

The MNDO calculation of the radical anion of the model compound has shown that the energy-minimum conformation exists near ϕ=90°. It may thus be said that a conformational interconversion occurs between **I** and **II**. The MNDO calculation has shown that the activation energy of this process is 12.0 kcal mol^{-1}; this value agrees well with the experimentally determined activation energy, E_A=10.0 kcal mol^{-1}.



Scheme 1.

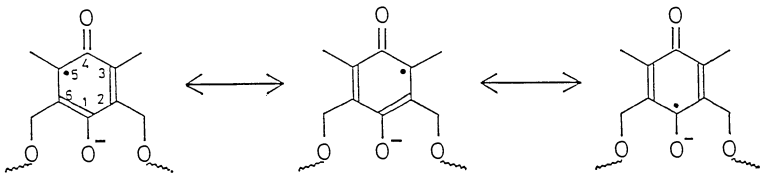


Metal-Free O5⁻. An examination of the CPK model has indicated that the size of the crown ring of the metal-free **O5⁻** is small and that the C(quinone)–C(methylene) bond is hardly allowed to rotate. No alternating line-width effect was observed in the ESR spectrum of the metal-free **O5⁻** and the hfc constants of the methylene protons in THF are similar to those of the metal-free **O6⁻**. These facts suggest that the metal-free **O5⁻** has a fixed conformation which resembles **I** or **II**.

The methylene protons of the metal-free **O5⁻** in MeCN are equivalent. Since the metal-free **O5⁻** has a fixed conformation in THF, it is reasonable to consider that the conformation of the metal-free **O5⁻** is also fixed in MeCN. In this case, the fixed conformer **III** is expected for **O5⁻**.

Metal-Free O7⁻ and O8⁻. The methylene protons of **O7⁻** and **O8⁻** are equivalent in THF. Since metal-free **O6⁻** undergoes a restricted interconversion, the metal-free **O7⁻** and **O8⁻**, which have a larger size crown ring, are expected to undergo interconversion more freely. It is thus natural to consider that the equivalency of methylene protons comes from a rapid exchange between two conformers which resemble **I** and **II**. Actually, the hfc constants of the metal-free **O7⁻** and **O8⁻** are almost the average value of two different hfc constants observed for the metal-free **O6⁻**. In the ESR spectrum of the metal-free **O7⁻** generated by an electrochemical reduction, a line-width alternation was observed; the interconversion is not rapid in this case and the rotation is slightly restricted.

Conformation of Ion-Paired Ligands. For **O5⁻** and **O6⁻** ion-paired with a Na^+ or K^+ cation, only two of four



Scheme 2.

methylene protons exhibit hyperfine coupling. Thus, one of the methylene protons is expected to lie on the quinone ring plane. Therefore, conformation **IV** is suggested for the ion-paired **O5**$^-$ and **O6**$^-$.

In the case of **O7**$^-$ and **O8**$^-$ ion-paired with Na^+ or K^+, four methylene protons were equivalent. As described above, the metal-free **O7**$^-$ shows a restricted conformational interconversion in MeCN. The complexation of **O7**$^-$ with a metal cation is expected to more strongly restrict this interconversion. It is thus reasonable that the equivalency of methylene protons of **O7**$^-$ ion-paired with Na^+ comes from a fixed conformation, like **III**. From the results described above, we believe that all the ligands, **O5**$^-$—**O8**$^-$, have fixed conformations in the presence of alkali metal cations.

hfc Constants of Methyl Protons. As may be seen from Tables 1 and 2, the hfc constant of methyl protons greatly increases (20—30%) when alkali metal cations are present. This may be elucidated on the basis of an interaction between the metal cation and the quinone oxygen atom at the crown ring side. This interaction makes the resonance forms in Scheme 2 more important, and increases the spin densities of the C_1, C_3, and C_5 atoms. This is the reason why the hfc constant of the methyl protons is increased by complexaion with a cation.

It is interesting that the hfc constant of the methyl protons in **O8**$^-$ ion-paired with the Na^+ cation generated by electrochemical reduction is larger than those of other ion pairs. It has been confirmed from a cyclic voltammetric study[6] that **O8**$^-$ forms a 1-to-2 complex with the Na^+ cation. The present large hfc constant suggests that two Na^+ cations are close to the crown ring of **O8**$^-$ and interact with the oxygen atom at the crown ring side, giving a large contribution of the reasonance forms shown in Scheme 2.

Although no K splitting was observed, the hfc constants of the methyl protons increased in the presence of the K^+ cation. This fact suggests that **O5**$^-$—**O8**$^-$ interact with the K^+ cation in the same manner as with the Na^+ cation. It is thus concluded that the semiquinone oxygen atom at the crown ring side interacts with both the Na^+ and K^+ cations and that this interaction influences the spin distribution of the benzosemiquinones anion radicals.

Asymmetric Transformations of Proline and 2-Piperidinecarboxylic Acid via Formation of Salts with Optically Active Tartaric Acid

Tadashi SHIRAIWA,* Kazuyuki SHINJO, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University,
Yamate-cho, Suita, Osaka 564

(Received March 28, 1991)

The rates of racemization of optically active proline [Pro] and 2-piperidinecarboxylic acid [Pia] by using aldehydes as a catalyst tended to increase with a decrease in the acidity of the carboxylic acid used as solvent. Based on these results, the asymmetric transformations of DL-Pro and (*RS*)-Pia were carried out via formation of salts with (2*R*, 3*R*)-tartaric acid to give optically pure L-Pro in over 80% yield and (*R*)-Pia in 70% yield. The asymmetric transformation of L-Pro was more successfully achieved by using (2*S*, 3*S*)-tartaric acid to give optically pure D-Pro in 85% yield based on the starting L-Pro.

L-Proline [abbreviated as L-Pro] as an important amino acid in vivo is a cyclic amino acid with a five-membered ring and is obtained by fermentation or by isolation from protein hydrolysates. D-Pro is difficult to obtain from natural products in large quantities and has been obtained by synthetic transformations from D-glutamic acid.[1] L-Pro, therefore, is inexpensive, whereas D-Pro is significantly costly. Both D- and L-Pro are useful as chiral reagents and catalysts in asymmetric syntheses. (*S*)-2-Piperidinecarboxylic acid [(*S*)-Pia] with a six-membered ring has been synthesized from L-lysine,[2] (*R*)-Pia also from L-lysine by the Walden inversion,[3] and (*RS*)-Pia by reduction of 2-pyridinecarboxylic acid[4,5] and from *N*-benzoyl-1,2,3,6-tetrahydropyridine through cobalt-catalyzed isomerization-carboxylation.[6] (*R*)- and (*S*)-Pia, however, are extremely expensive and only (*RS*)-Pia is readily available. This paper describes easier preparations of optically active Pro and Pia.

An asymmetric transformation has a possibility of converting efficiently a racemate into a desired enantiomer and has been carried out by combination of selective crystallization of a less soluble diastereomeric salt with epimerization of the more soluble one in a solution.[7-10] Although an asymmetric transformation of *N*-butyryl-DL-proline gives L-Pro by combination of preferential crystallization with racemization,[7] such has not been reported for (*RS*)-Pia. Then the asymmetric transformation were attempted without converting Pro and Pia into their derivatives, such as *N*-acyl amino acids. Optically active amino acids are easily racemized by using aldehydes as catalyst in carboxylic acid.[11,12] In addition, optical resolutions of DL-Pro[13] and (*RS*)-Pia[14] by using (2*R*,3*R*)-tartaric acid [(*R*)-TA] as a resolving agent give the salt of L-Pro with (*R*)-TA and that of (*R*)-Pia with (*R*)-TA as a less soluble diastereomeric salt. The asymmetric transformations of DL-Pro and (*RS*)-Pia, therefore, were tried by using butanal and salicylaldehyde as the catalyst via formation of a salt with (*R*)-TA in carboxylic acids. The asymmetric transformation of L-Pro to D-Pro was also examined by using (*S*)-TA.

Experimental

Materials. DL-Pro and (*RS*)-Pia were purchased from Tokyo Kasei Kogyo Co., Ltd., L-Pro from Kokusan Chemical Works Ltd., and (*R*)- and (*S*)-TA from Wako Pure Chemicals Ind. (*R*)-Pia was obtained by asymmetric transformation.

Asymmetric Transformation. Proline: A mixture of 20.0 mmol (2.30 g) of L-Pro, 20.0 mmol (3.00 g) of (*S*)-TA, and 2.00 mmol of butanal in 30 cm^3 of butanoic acid was stirred for 1—6 h at 80 °C and subsequently for 0.5 h in an ice bath. The formed D-Pro·(*S*)-TA salt was collected by filtration, washed thoroughly with diethyl ether, and dried. After adding concentrated aqueous ammonia (0.55 cm^3 g^{-1}) to a solution of the salt in 200 cm^3 of methanol, followed by stirring the mixture for 0.5 h in an ice bath, the precipitated diammonium (2*S*, 3*S*)-tartarate was removed by filtration; the (*S*)-TA used as the resolving agent was recovered in over 90% yield as the diammonium salt; $[\alpha]_D^{20}$ −33—−32° (*c* 1.00, water): lit,[15] of diammonium (2*R*, 3*R*)-tartarate, $[\alpha]_D$ +34.0° (water). Drying of the filtrate gave D-Pro as the residue.

Similarly, the asymmetric transformation of DL-Pro was carried out by using (*R*)-TA and 0.1 mol equivalent of salicylaldehyde and butanal in butanoic acid at 90 °C. The optical purities of the obtained D-Pro·(*S*)-TA and L-Pro·(*R*)-TA salts were estimated on the basis of the specific rotations of the L-Pro·(*R*)-TA salt ($[\alpha]_D^{25}$ −24.2° (*c* 1, water)[13]) and the D-Pro·(*R*)-TA salt ($[\alpha]_D^{25}$ +44.4° (*c* 1, water))[13]) and those of D- and L-Pro from the specific rotation of L-Pro ($[\alpha]_D^{20}$ −86.2° (*c* 1.00, water)).[16]

To a solution of the D-Pro·(*S*)-TA or L-Pro·(*R*)-TA salt with over 90% optical purity in water (1 cm^3 g^{-1}) was added ethanol (20 cm^3 g^{-1}). After stirring the mixture for 1 h in an ice bath, the purified salt was collected by filtration, washed with diethyl ether, and dried. The salt was treated with concentrated aqueous ammonia similarly to the above to obtain optically pure D- and L-Pro.

(*RS*)-2-Piperidinecarboxylic Acid: A mixture of 10.0 mmol (1.29 g) of (*RS*)-Pia, 10.0 mmol (1.50 g) of (*R*)-TA, and 5.00 mmol of salicylaldehyde in 50 cm^3 of butanoic acid, pentanoic acid, or hexanoic acid was stirred for 2—10 h at 110 °C and then for 0.5 h in an ice bath. The formed (*R*)-Pia·

(*R*)-TA salt was treated with concentrated aqueous ammonia to give (*R*)-Pia.

A suspension of the (*R*)-Pia·(*R*)-TA salt with 80% optical purity in methanol (3.3 $cm^3\ g^{-1}$) was stirred for 0.5 h at 50 °C and then for 2 h at 20 °C. The purified (*R*)-Pia·(*R*)-TA salt was collected by filtration, washed with diethyl ether, and dried. Treatment of the salt with concentrated aqueous ammonia gave optically pure (*R*)-Pia; lit,[2] of (*S*)-Pia, $[\alpha]_D^{20}$ −30.6° (*c* 1, water).

Rate Constant of Racemization. After adding 4.00 mmol of butanal or salicylaldehyde to a solution of 40.0 mmol of L-Pro in 100 cm^3 of formic acid, acetic acid, propanoic acid, or butanoic acid at 80 °C, the solution was stirred at 80 °C. Two cubic centimeter portions of the solution were pipetted out at appropriate time intervals, cooled rapidly, and diluted to 10 cm^3 with acetic acid. The optical rotation at 589 nm was measured with a Union Giken PM-101 digital polarimeter equipped with a quartz cell of 5.00 cm path length. The rate constant of racemization (k_R/s^{-1}) was calculated by the least-squares method from the equation

$$\ln \alpha_0/\alpha_t = k_R\, t, \qquad (1)$$

where α_t is the optical rotation at time *t* and α_0 that extrapolated to zero time. The half-conversion period ($t_{1/2}/s$) was calculated by using the k_R value from Eq. 1.

The rate of racemization of (*R*)-Pia was measured at 110 °C for solutions of (*R*)-Pia (20.0 mmol) and butanal or salicylaldehyde (2.00 mmol) in 100 cm^3 of formic acid, acetic acid, and propanoic acid.

Results and Discussion

Racemization of L-Proline and (*R*)-2-Piperidinecarboxylic Acid. One of the major problems in an asymmetric transformation is the rate of epimerization, that is, that of racemization of an optically active substance. The rates of racemization of L-Pro and (*R*)-Pia, therefore, were measured by using butanal or salicylaldehyde in formic acid, acetic acid, propanoic acid, and butanoic acid. The rate of racemization of (*R*)-Pia in butanoic acid and those of L-Pro and (*R*)-Pia in higher carboxylic acids could not be measured because L-Pro and (*R*)-Pia did not completely dissolve in these carboxylic acids even at 110 °C. These racemizations were regarded as a first-order reaction because a linear relationship was found between $\ln \alpha_0/\alpha_t$ and time *t*. The rate constant for racemization (k_R/s^{-1}) and the half-life conversion ($t_{1/2}/s$) are summarized in Table 1.

In these racemizations, the first step is the formation of the Schiff base.[11,12] This dehydration-condensation of a cyclic amino acid with the aldehyde proceeds by protonation from the carboxylic acid used as solvent, and hence the Schiff base formed has a positive charge on the nitrogen atom.[11] The second step is proton abstraction from the α-carbon atom by the resulting carboxylate anion.[11,12]

The rate of racemization of (*R*)-Pia was extremely lower than that of L-Pro, as seen in Table 1. The four carbon and one nitrogen atoms in the five-membered ring on L-Pro lie on the approximately same plane,[17] whereas the six-membered ring on (*R*)-Pia exists in a chair form.[18] Such steric bulkiness of the ring on (*R*)-Pia may hinder the formation of the Schiff base, and hence slow down the rate of racemization compared with the pseudo-planar ring on L-Pro.

As found in racemization by using butanal, the rates of racemization of L-Pro and (*R*)-Pia were dependent on the nature of the carboxylic acid used as solvent, that is, acidity of the carboxylic acid or basicity of its carboxylate anion. The acidity constants (pK_a), estimated from the data at 0—60 °C,[19] at 80 and 110 °C tend to suggest that an order of protonation is formic acid> acetic acid>propanoic acid>butanoic acid and that of proton abstraction is butanoate anion>propanoate anion>acetate anion>formate anion. A relationship between the k_R and pK_a values is shown in Fig. 1.

The k_R value tended to increase with an increase in the pK_a value, as seen in Fig. 1. It has been reported that the rate of racemization of optically active amino acids may be most rapid in acetic acid.[11] The above result,

however, suggests that the rate of racemization of optically active cyclic amino acids, such as L-Pro and (*R*)-Pia, is accelerated with a decrease in acidity of the carboxylic acid used as solvent, and hence its rate-determining step is the α-proton abstraction by the carboxylate anion.

In addition, the racemizations of L-Pro and (*R*)-Pia were more accelerated by using butanal as catalyst than salicylaldehyde.

Asymmetric Transformation of Proline. The asymmetric transformation of DL-Pro was carried out at 90 °C in butanoic acid. The result is summarized in Table 2.

When butanal was used as catalyst, the L-Pro·(*R*)-TA salt with 90% optical purity was obtained in 95% yield by allowing to react for 2 and 3 h. Although the asymmetric transformation by using salicylaldehyde required longer time than that by using butanal, as predicted from the result of racemization, those at 4—6 h gave the L-Pro·(*R*)-TA salt with 88—90% optical purity in 96% yield. These salts were purified to give optically pure L-Pro in over 80% yield based on the starting DL-Pro, as summarized in Table 2.

The asymmetric transformation of L-Pro into D-Pro was more successfully achieved by using butanal as catalyst and (*S*)-TA as the resolving agent, at 80 °C (Table 2). The D-Pro·(*S*)-TA salt with 93—95% optical purity was obtained in 97% yield by a reaction for 3—6 h. The purified salt gave optically pure D-Pro in 85% yield based on the starting L-Pro.

The rate of racemization of an optically active substance is measured under homogeneous conditions, whereas an asymmetric transformation is carried out under heterogeneous ones. Optimum conditions for the asymmetric transformation, therefore, may not always be the same as those for the racemization. However, the asymmetric transformations of DL- and L-Pro gave very good results under the conditions estimated from the result of racemization.

Asymmetric Transformation of (*RS*)-2-Piperidinecarboxylic Acid. The optical resolution of (*RS*)-Pia by using (*R*)-TA gives the (*R*)-Pia·(*R*)-TA salt as a less soluble diastereomeric salt.[14] The result of racemization of (*R*)-Pia suggests that the rate of epimerization of the Pia·(*R*)-TA salt is extremely slower than that of Pro. In addition, the result of racemization of L-Pro allows to predict that the rate of (*R*)-Pia is more rapid in butanoic acid than in acetic acid and propanoic acid. The asymmetric transformation of (*RS*)-Pia, therefore, was tried by consuming 5.00 mmol of the aldehydes per 10.0 mmol of (*RS*)-Pia in butanoic acid at 110 °C. The asymmetric transformation by using butanal, however, could not be carried out because the formed salt became a viscous mass. The asymmetric transformation of (*RS*)-Pia, therefore, was carried out by using salicylaldehyde. The result is summarized in Table 3.

The asymmetric transformation gave the (*R*)-Pia·(*R*)-TA salt with 76—80% optical purity at 3—7 h. Although the purified salt gave optically pure (*R*)-Pia in 61% yield based on the starting (*RS*)-Pia, as summarized in Table 3, the yield was not so high as expected. Such low yield seems to be due to the relatively high solubility of the salt formed in butanoic acid. The formed salt seems to be less soluble in pentanoic acid and hexanoic acid than in butanoic acid. The rates of epimerization in these carboxylic acids are estimated to be approximately equal to that in butanoic acid from the acidity constants of these carboxylic acids at 110 °C.[19,20] The asymmetric transformation was tried by a reaction for 5 h in pentanoic acid and hexanoic acid (Table 3). Comparison of the asymmetric transformations in these carboxylic acids indicated that the yield of the obtained (*R*)-Pia·(*R*)-TA salt tended to rise with an increase in the carbon number of the carboxylic acids, whereas the optical purity to fall.

One more major problem in the asymmetric transformation is the solubility of the diastereomeric salts in the solvent used. The solubility influences not only the yield of the less soluble diastereomeric salt, but its optical purity. If the solubility is too low, the asymmetric transformation in such a solvent may give the salt with low optical purity, and hence require much long time to obtain the salt with high optical purity. The asymmetric transformation in pentanoic acid, however, gave the (*R*)-

Table 3. Asymmetric Transformation of (*RS*)-2-Piperidinecarboxylic Acid[a)]

Carboxylic acid	Reaction time	(*R*)-Pia·(*R*)-TA salt		(*R*)-Pia

	10[g)]	1.99 [71.3]	100	70.2	100
HxA[f)]	5	2.31 [82.8]	52.2	81.9	51.0

a) (*RS*)-2-Piperidinecarboxylic acid [(*RS*)-Pia] 10.0 mmol; (2*R*,3*R*)-tartaric acid [(*R*)-TA] 10.0 mmol; salicylaldehyde 5.00 mmol; carboxylic acid 50 cm^3; temperature 110°C. b) The yield was calculated on the basis of 10.0 mmol (2.79 g) of the salt of (*R*)-Pia with (*R*)-TA. c) The yield was calculated on the basis of 10.0 mmol (1.29 g) of (*R*)-Pia. d) BuA: Butanoic acid. e) PeA: Pentanoic acid. f) HxA: Hexanoic acid. g) The obtained salt was purified by recrystallization.

Pia·(*R*)-TA salt with relatively high optical purity (65%) in higher yield (81%) than that (73%) in butanoic acid. The asymmetric transformation, therefore, was carried out by a reaction for 2—10 h in pentanoic acid (Table 3).

As already mentioned, the asymmetric transformation in butanoic acid gave the salt with 76—80% optical purity at 3—7 h. The yields, however, were less than 75%. The asymmetric transformations at 8 and 10 h in pentanoic acid gave the (*R*)-Pia·(*R*)-TA salt with 80% optical purity in over 80% yield. These salts recrystallized from methanol gave optically pure (*R*)-Pia in 70% yield, based on the starting (*RS*)-Pia, as summarized in Table 3.

Synthetic Application of Benzothiazole Ring System as an On-Off Type of Leaving Group. Synthesis of Ketones and Carboxylic Acid Derivatives from 2-(1-Substituted 1-Hydroxyalkyl)- and 2-(1-Hydroxyalkyl)benzothiazoles

Hidenori CHIKASHITA,* Masayuki ISHIHARA, Katsumi TAKIGAWA, and Kazuyoshi ITOH
Department of Applied Chemistry, Faculty of Engineering, Kansai University,
Suita,Osaka 564
(Received April 30, 1991)

A synthetic and systematic use of benzothiazole ring system as an "on-off" type of leaving group was developed for the preparation of ketones and carboxylic acid derivatives from a variety of 2-(1-substituted 1-hydroxyalkyl)- and 2-(1-hydroxyalkyl)benzothiazoles (off state) via the corresponding benzothiazolium salts (on state) obtained by the quaternization (on switch). A variety of 3-methyl-2-(1-substituted 1-hydroxyalkyl)benzothiazolium iodides (**1**) underwent a carbon–carbon bond cleavage at the 2-position to give the corresponding ketones on the simple treatment with a base under mild reaction conditions. The similar reaction of 3-methyl-2-(1-hydroxyalkyl)benzothiazolium iodides (**2**) to aldehydes proceeded less efficiently. The oxidative reaction of a variety of **2** with base and nonactivated MnO_2 in ethanol afforded the corresponding ethyl esters. This type of oxidative reaction could be also achieved in THF with different nucleophiles such as alcohol, water, thiol, and amine to give the corresponding ester, carboxylic acid, thioester, and amide, respectively.

Thiamine pyrophosphate (TPP) is a coenzyme which participates in a number of important biochemical reactions involving formation and cleavage of carbon–carbon bonds as well as oxidation reactions.[1] The catalytic unit of TPP on these reactions is the thiazolium ring. It is known that various simple thiazolium salts effect TPP type of transformations even in the absence of enzyme,[2] and up to now much interest has been focused on model reaction systems of TPP coenzyme.[3] From the standpoint of synthetic chemistry, these reactions can be regarded to offer a unique example of a heterocyclic molecule acting as an efficient leaving group because the release of the thiazolium salt unit as a thiazolium ylide by carbon–carbon bond fission is a key step and plays an essential role in the model systems. Although reaction intermediates derived from thiazolium salt catalysts have recently been of interest from a synthetic viewpoint,[4] there is little study dealing with synthetic and systematic applications of thiazole ring system by utilizing potential reactivities of the intermediate-like stable compounds themselves such as 2-(1-hydroxyalkyl)thiazolium salts. In our recent studies on benzazole field, we found several functionalities of the benzothiazole ring system available for organic synthesis and reported their applications to the novel synthetic methodologies.[5] In connection with these studies, we now investigated the preparation and reactivities of a variety of 2-(1-substituted 1-hydroxyalkyl)- and 2-(1-hydroxyalkyl)benzothiazolium salts structurally related to the intermediates on the TPP-model reactions and found that ketones and carboxylic acid derivatives were systematically obtained via these salts from the corresponding benzothiazole derivatives, revealing a novel functionality of benzothiazole ring system as an "on-off" type of leaving group. As a different type of systematic use of benzothiazole ring system in organic synthesis, we wish to report here a novel preparation method for ketones and carboxylic acid derivatives based on this concept of leaving group.

Results and Discussion

Preparation and Properties of 3-Methyl-2-(1-substituted 1-Hydroxyalkyl)- and 3-Methyl-2-(1-hydroxyalkyl)benzothiazolium Iodides (1 and 2). Benzothiazolium salts **1** and **2** were prepared as outlined in Scheme 1. The two typical procedures for large scale preparation of **1** and **2** are the following: (i) The reaction of lithiated benzothiazole (2-LiBT) with ketones and aldehydes followed by quaternization of the resulting 2-(1-substituted 1-hydroxyalkyl)- and 2-(1-hydroxyalkyl)benzothiazoles with methyl iodide in DMF; and (ii) the acylation of 2-LiBT with esters and the subsequent alkylation with organometallic reagents or hydride reduction of the resulting 2-acylbenzothiazole **3** under standard conditions, followed by the quaternization with methyl iodide in DMF. As shown in our previous paper,[5f] each step in both methods proceeds in high

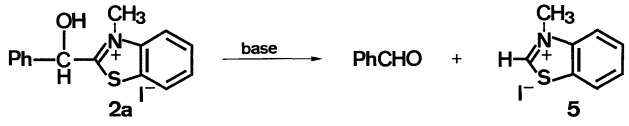

Scheme 3.

yields and benzothiazolium salts **1** and **2** are obtained in good total yields. In addition, benzothiazolium salt **1** could be easily prepared from aldehydes via 2-acylbenzothiazole **3** obtained by the reaction with 2-LiBT followed by pyridinium chlorochromate (PCC) oxidation. Benzothiazolium iodides **1** and **2** are generally obtained as very stable crystalline compounds and can be easily purified by recrystallization from methanol.

Ketone- and Aldehyde-Generating Reactions of 1 and 2. We started our studies by examining the ketone-generating reaction of the salt **1a** under a variety of reaction conditions (Scheme 2). The results are summarized in Table 1. When **1a** was homogeneously treated with 1.5 equiv of 10% aqueous K_2CO_3 in ethanol under refluxing, acetophenone (**4a**) was obtained in excellent yield after a 7-h reaction time (Entry 1). However, heterogeneous reaction by stirring the two-layer mixture consisting of **1a**, hexane, and 1.5 equiv of 10% aqueous K_2CO_3 at lower temperature was found to be more effective and ketone **4a** was obtained in nearly quantitative yield after shortened reaction time (Entry 2). In this reaction, 10% aqueous K_2CO_3 could be replaced by a weaker base such as 10% aqueous AcONa, and excellent yield of ketone **4a** was obtained under similar reaction conditions (Entry 3). On the other hand, we have found that organic bases such as 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) or triethylamine (TEA) were also effective for this type of cleavage reaction. Thus, the treatment of **1a** with 1 equiv of DBU or TEA in ethanol at room temperature afforded ketone **4a** in high yield (Entries 4,6). The use of a catalytic amount of DBU (0.2 equiv) in ethanol at refluxing temperature was also useful for producing ketone **4a** from **1a** in excellent yield (Entry 5). Furthermore, it was discovered that this acetophenone-generating reaction could proceed in the absence of bases by prolonged refluxing in 90% aqueous ethanol giving ketone **4a** in 77% yield together with 3-methylbenzothiazolium iodide (**5**) which was isolated in 83% yield (Entry 7). Although satisfactory results were obtained in all cases examined, the two-layer method using K_2CO_3 in hexane-water is the best reaction in terms of the yield of product and rapidity and cleanliness of the reaction. In fact, almost pure ketone **4a** could be obtained simply by evaporating the organic layer. In contrast to these, the cleavage of benzothiazolium salt **2a** by the methods employed for the cleavage of **1a** or by the heterogeneous reaction with aq NaOH and benzene in the presence of 6-aminohexanoic acid as a trapping agent produced benzaldehyde in generally very low yield (Scheme 3), although the homogeneous reaction in ethanol employing 10% aqueous K_2CO_3 afforded benzaldehyde in 30% isolated yield. In addition, it should be noted that the reactions employing DBU and TEA led to the formation of benzoin derived from 2 equiv of benzaldehyde. The reason for these unsuccessful results will be discussed later.

We next examined a general applicability of the ketone-generating reaction of a variety of 2-(1-substituted 1-hydroxyalkyl)benzothiazolium salts **1b**—**h** with the two-layer method using K_2CO_3 (Scheme 2). The results are summarized in Table 2. Benzothiazolium salts **1b**—**e** were all cleanly cleaved to the corresponding aliphatic and aromatic ketones **4b**—**e** and the reactions were completed within 2 h with nearly quantitative yields of the products (Entries 1—4). Cycloundecyl compound **1f** was similarly reacted to afford cycloundecanone (**4f**) in nearly quantitative yield, hence the reaction of cyclohexyl compound **1g** gave cyclohexanone (**4g**) in modest yield (Entries 5,6). On the other hand, the reaction of the benzothiazolium salt possessing a vinylic substituent, **1h**, under the present conditions did not produce the expected ketone,

Table 2. Preparation of Ketones **4** from a Variety of 2-(1-Substituted 1-Hydroxyalkyl)benzothiazolium Salts **1**[a)]

Entry	Salt **1**	Product **4**	Isolated yield/%
1	**1b**	**4b**	94

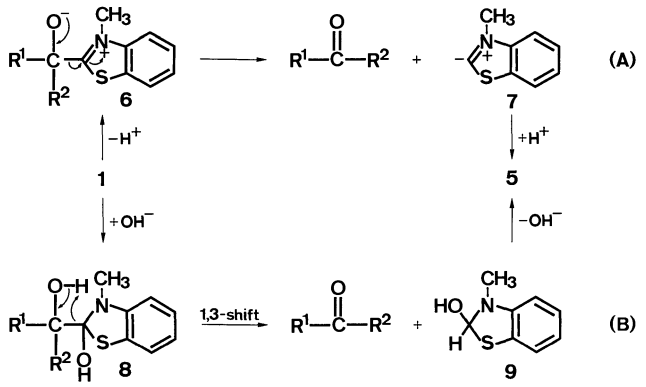
6	**1g**	**4g**	40
7	**1h**	**4h**	0

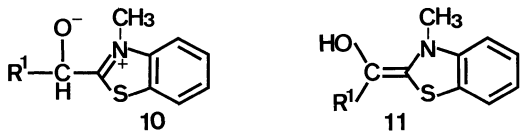
a) All reactions were carried out with the salts **1** (4 mmol) in two-layer mixture of hexane (4 ml) and 10% aqueous K_2CO_3 (8 ml) at 60 °C for 2 h under stirring.

chalcone (**4h**), at all. Thus, the present method was found to be generally applicable to the synthesis of a variety of ketones except for α,β-unsaturated ketones.

Two possible reaction mechanisms for the present cleavage reaction of **1** can be proposed as illustrated in Scheme 4. They involve deprotonation at the HO-site by the base followed by leaving the ylide **7** from the resulting zwitterion intermediate **6** (mechanism A); and hydroxylation at the benzothiazolium ring followed by leaving 2-hydroxy-3-methyl-2,3-dihydrobenzothiazole **9** from the dihydroxy intermediate **8** via 1,3-shift (mechanism B). In the chemistry of thiazolium salt catalyzed reactions, however, the mechanism involving the regeneration of a thiazolium ylide by carbon–carbon bond fission at the 2-position of the thiazolium ring in 2-(1-hydroxyalkyl)thiazolium intermediates has been accepted. In the present case, this type of mechanism is also supported by the fact that the reactions using tertiary amines in a nonaqueous system could proceed in excellent yields. Accordingly, mechanism A via active-aldehyde like intermediate **6** is most likely mechanism for the present ketone-generating reaction and well conforms to the driving force for the formation of the stable benzothiazolium ylide **7**. In addition, this type of mechanism releasing the ylide **7** has been reasonably proposed for the aldehyde formation in the reaction of **2** with organometallic reagents.[5f)] On the other hand, the reaction of **2** in the presence of a base would cause rather

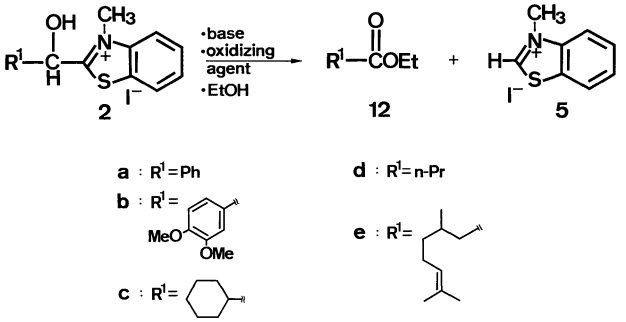


Scheme 4.



complicated equilibriums derived from the reactivity of so called "active-aldehyde" molecules **10** and **11** on the analogy of model reactions of TPP coenzyme.[2-4)] The unsuccessful results in the case of an aldehyde-generating reaction of **2** are well understood based on the formation of these complicated and indiscriminate equilibriums.

Oxidative Ester-Generating Reaction of 2. Treatment of benzothiazolium salt **2** with a base would easily produce the foregoing active-aldehyde molecules **10** and **11** which are intermediates similar to those in TPP-dependent enzymatic pathway and in its catalytic model reactions. It is well known that active-aldehyde molecules in later cases are oxidized in the presence of a variety of oxidizing agents (e.g., flavin or $K_3Fe(CN)_6$) to afford carboxylic acids, esters, or benzoin type of products depending on the reaction conditions.[3,4)] If the intermediate **10** or **11** possessing a variety of substituents can be oxidized controllably in an alcoholic solvent, this would provide a different type of useful application of benzothiazolium unit as a leaving group for the preparation of esters **12** in organic synthesis (Scheme 5). We have first examined this type of oxidative ester-generating reaction of **2a** in ethanol in the presence of a base by employing 10 equiv of nonactivated MnO_2 and $K_3Fe(CN)_6$ as convenient oxidizing agents. As shown in Table 3, all the reactions examined afforded the expected ester, ethyl benzoate (**12a**), even in the absence of a base. Among the series of reactions employing MnO_2 as an oxidizing agent (Entries 1—8), the reaction with 1 equiv of AcONa was found to give the best results affording ester **12a** in 76% isolated yield (Entry 4), while the reaction with relatively strong bases such as K_2CO_3 and Na_2CO_3 or tertiary amines such as DBU and TEA generally gave the product **12a** in modest yield. The result of the reaction in the absence of a base may indicate that compound **2a** itself can be directly oxidized under the present conditions (Entry 8). On the other hand, the reaction employing $K_3Fe(CN)_6$ in the presence of 1 equiv of AcONa proceeded less effectively



Scheme 5.

to give ester **12a** in low yield (Entries 9,10). Thus, this type of oxidative ester synthesis was then applied to several different benzothiazolium salts **2b**—**e** under the optimum conditions, with the results summarized in Table 4. Benzothiazolium salts possessing a 2-(substituted hydroxymethyl) group, **2b**,**c**,**e**, reacted well under the conditions to give the corresponding ethyl esters **12b**,**c**,**e** in good isolated yields (Entries 1,2,4), although the reaction with **2d** exceptionally showed low yield of product **12d** (Entry 3).

Table 3. Conversion of Benzothiazolium Salt **2a** into Ethyl Benzoate (**12a**)[a]

Entry	Oxidizing agent[b]	Base (equiv)	Isolated yield/%
1	MnO_2	K_2CO_3 (1.0)	49
2	MnO_2	K_2CO_3 (3.0)	53
3	MnO_2	Na_2CO_3 (1.0)	41
4	MnO_2	AcONa (1.0)	76
5	MnO_2	AcONa (3.0)	64
6	MnO_2	TEA (1.0)	45
7	MnO_2	DBU (1.0)	56
8	MnO_2	None	45
9	$K_3Fe(CN)_6$[c]	AcONa (1.0)	22
10	$K_3Fe(CN)_6$	AcONa (1.0)	28

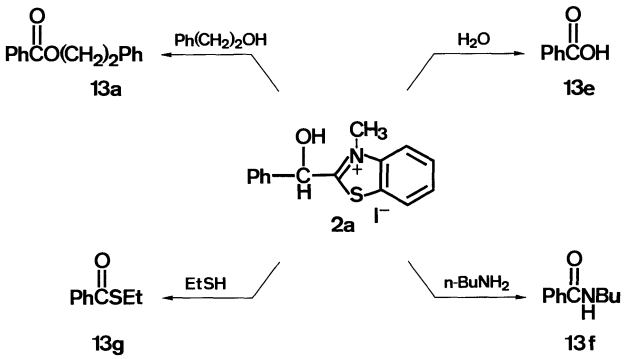
a) All reactions were carried out in ethanol at reflux temperature for 5 h. b) Ten equiv of oxidizing agent was used unless otherwise noted. c) Two equiv of $K_3Fe(CN)_6$ was used.

Table 4. Preparation of Esters **12** from a Variety of 2-(1-Hydroxyalkyl)benzothiazolium Salts **2**[a]

Entry	Salt **2**	Product **12**	Isolated yield/%
1	**2b**	**12b**	78
2	**2c**	**12c**	52
3	**2d**	**12d**	17
4	**2e**	**12e**	70

a) All reactions were carried out with the salts **2** (2 mmol), MnO_2 (10 mmol), and AcONa (2 mmol) in ethanol (30 ml) at reflux temperature for 5 h.

Oxidative Preparation of Carboxylic Acid Derivatives from 2 in Nonnucleophilic Solvent. If it is possible that the active-aldehyde molecule **10** or **11** is also generated and oxidized efficiently in a nonnucleophilic solvent system, the reaction can be carried out in the presence of a variety of nucleophiles. To examine this possibility, we have carried out the reaction of **2** in THF in the presence of AcONa (1 equiv), MnO_2 (10 equiv), and an excess amount of alcohol at refluxing temperature. The results are summarized in Table 5. The reaction of **2a** with a large excess amount of ethanol in THF efficiently proceeded under the conditions to afford ethyl ester **12a** in good yield. Similarly, **2a**,**b**,**d**,**e** reacted with 3 equiv of 2-phenylethanol in THF to give the corresponding phenethyl esters **13a**—**d**. These results clearly show that the formation of active-aldehyde molecule **10** or **11** and its subsequent oxidation by MnO_2 followed by the reaction with an alcohol can proceed in THF as well as in ethanol solvent. We next tried the preparation of the carboxylic acid derivatives by the reaction of **2a** in the presence of several different nucleophiles as a



Scheme 6.

Table 5. Preparation of Esters from a Variety of 2-(1-Hydroxyalkyl)benzothiazolium Salts **2** in THF[a]

Entry	Salt **2**	Nucleophile	Product	Isolated yield/%
1	**2a**	EtOH[b]	**12a**	73
2	**2a**	$Ph(CH_2)_2OH$[c]	$PhCO_2(CH_2)_2Ph$ (**13a**)	54
3	**2b**	$Ph(CH_2)_2OH$	 (**13b**)	35
4	**2d**	$Ph(CH_2)_2OH$	n-$C_5H_{11}CO_2(CH_2)_2Ph$ (**13c**)	21
5	**2e**	$Ph(CH_2)_2OH$	 (**13d**)	52

a) All reactions were carried out with the salts **2** (2 mmol), MnO_2 (10 mmol), and AcONa (2 mmol) in THF (30 ml) at reflux temperature for 5 h. b) Large excess amount of ethanol (10 ml) was used. c) In all cases, 3 equiv of 2-phenylethanol was used.

representative example, as illustrated in Scheme 6. The reaction of **2a** in the presence of an excess amount of water at refluxing temperature gave benzoic acid (**13e**) in 76% isolated yield, while the reaction with 3 equiv of butylamine at 60 °C and the reaction with 3 equiv of ethanethiol at 38 °C also produced the corresponding amide **13f** and thioester **13g** in 42% and 57% isolated yields, respectively. However, it should be noted that the similar reaction employing a secondary amine affording a secondary amide was unsuccessful in contrast to the reaction with a primary amine.

The mechanism of the present oxidative reactions can be explained according to that proposed in a TPP-dependent enzymatic pathway and in its catalytic model reactions (Scheme 7).[3,4] However, so-called "active acyl" molecule such as **14** which is the key species to react with nucleophiles in the mechanism has not been isolated yet. We tried the direct synthesis of the active-acyl compound **15** by the *N*-methylation of 2-benzoylbenzothiazole **3a** (Scheme 8). Although the *N*-methylation of **3a** by the standard method using methyl iodide or dimethyl sulfate was very difficult due to the low nucleophilicity at the nitrogen atom, we have found that the *N*-methylation of **3a** with the powerful methylating reagent, methyl fluorosulfate, in dichloromethane at 100 °C proceeds efficiently to give the salt **15** in excellent isolated yield. The compound **15** is slightly unstable in air but can be stored in vacuo for several days. When compound **15** was treated in ethanol under refluxing, ethyl benzoate (**12a**) could be obtained in 85% isolated yield. Similarly, compound **15** reacted with an excess amount of water and butylamine in THF to give benzoic acid (**13e**) and *N*-butylbenzamide (**13f**) in 63% and 56% isolated yields, respectively. This result directly indicates that the active-acyl intermediate **14** can efficiently react with nucleophiles giving the corresponding carboxylic acid derivatives.

Summary. Synthesis of carbonyl compounds from 2-(1-substituted 1-hydroxyalkyl)- and 2-(1-hydroxyalyl)-benzothiazoles (**16** and **17**) via the corresponding benzothiazolium salts **1** and **2** developed in the present study is summarized as follows. The present study reveals that the benzothiazole ring unit can be used as an "on-off" type of leaving group in the synthesis of ketones and carboxylic acid derivatives under simple operations and mild reaction conditions. That is, benzothiazole unit (off state) was found to be able to act as a leaving group only after conversion (turning on) to benzothiazolium structure (on state) by the treatment with methylating agent (on switch). A simple advantage of this method is that the off-state compounds can be treated under a variety of severe conditions. For example, in the ketone synthesis, **16** (off state) can be regarded as a protected from for ketones because the parent ketones of **16** are regenerated via **1** (on state). In fact, benzothiazoles **16** survived the severe conditions commonly required for removal of other protecting groups.[6] This type of protection requiring an activation step for deprotection is a new method in organic synthesis and is called "locked protection" (i.e., **16** as locked form, MeI as key, **1** as delocked form, and ketones as opened form).[7] Similarly, in the ester synthesis, **17** (off state) can be considered to be a protected form for esters because the parent esters of **3** are regenerated via **2** and **14** (on states). We have already developed the synthetic application of functions of the benzothiazole ring system as a hydride- and enolates-transferring auxiliary, protecting group, and carbonyl equivalent.[5] Thus, the present chemistry of the benzothiazole ring system as an "on-off" type of leaving group should prove a useful addition of function of the system in organic synthesis.

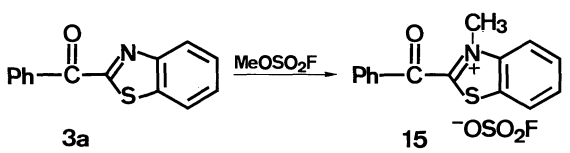

Scheme 8.

Experimental

Melting points were recorded on a Yanagimoto micro melting point apparatus and are uncorrected. ^{1}H NMR spectra were measured on a JEOL JNX PMX-60 spectrometer at 60 MHz with tetramethylsilane as an internal standard. IR spectra were recorded on a JASCO A-202 spectrophotometer. Gas chromatographic analyses were carried out on a Shimadzu Gas chromatograph GC-6AM equipped with a hydrogen flame ionization detector using glass columns (1.5 m) packed with 2% silicone OV-7 on Uniport HP (60—80 mesh). Silica gel (Wakogel C-300) was used for short-column chromatography (SCC).

Materials. 3-Methyl-2-(1-substituted 1-hydroxyalkyl)- and 3-methyl-2-(1-hydroxyalkyl)benzothiazolium iodides (**1** and **2**) and 2-benzoylbenzothiazole (**3a**) were prepared according to the previously reported methods.[5f] Methyl fluorosulfate was prepared by the literature procedure.[8] Solvents were purified according to standard procedures. The other reagents were supplied as high-grade commercial products and used without further purification.

Product Analyses. Identification of ketones and carboxylic acid derivatives obtained in the present reactions was performed by spectroscopic (^{1}H NMR and IR) and GLC methods. These spectral and GLC data were in good agreement with those of the corresponding authentic samples.

General Procedure for the Preparation of Ketone 4 from 3-Methyl-2-(1-substituted 1-Hydroxyalkyl)benzothiazolium Iodide (1). To a two-layer mixture of hexane (4 ml) and 10% aqueous K_2CO_3 (8 ml) was added the benzothiazolium salt **1** (4 mmol) and the mixture was then stirred at 60 °C for 2 h. The aqueous layer was extracted with dichloromethane and the combined organic layer and the extract was dried over $MgSO_4$. Concentration of the solution under reduced pressure afforded almost pure ketone **4**.

Reaction of Benzothiazolium Iodide 1a in Aqueous Ethanol in the Absence of Base. A solution of the benzothiazolium salt **1a** (1.59 g, 4 mmol) in 90% aqueous ethanol (20 ml) was stirred under refluxing for 3 d and then concentrated under reduced pressure. The crystalline residue was triturated with ether, filtered, and washed thoroughly with ether. Recrystallization from methanol–acetone gave pure 3-methylbenzothiazolium iodide (**5**) (0.92 g, 83%): Mp 216—217 °C (decomp) (lit,[5g] 217 °C (decomp)); ^{1}H NMR (DMSO-d_6) δ=4.38 (s, 3H, NCH_3), 7.81 (m, 2H, Arom), 8.40 (m, 2H, Arom), and 10.42 (s, 1H, CH).

The combined filtrate and washings were dried over $MgSO_4$ and concentrated under reduced pressure to give almost pure acetophenone (**4a**) as a pale yellow oil (0.37 g, 77%).

General Procedure for the Oxidative Preparation of Ethyl Ester 12 from 3-Methyl-2-(1-hydroxyalkyl)benzothiazolium Iodide (2) in Ethanol. To a solution of the benzothiazolium salt **2** (2 mmol) in dry ethanol (30 ml), MnO_2 (1.74 g, 20 mmol) and AcONa (0.16 g, 2 mmol) were added with stirring and the suspended mixture was then stirred under refluxing for 5 h. After cooling to room temperature, the insoluble materials were removed by filtration and the filtrate was concentrated under reduced pressure. The residue was diluted with hexane–dichloromethane and filtered through silica-gel pad (Wakogel C-300). Concentration of the filtrate under reduced pressure and SCC purification of the residue gave pure ester **12**.

General Procedure for the Oxidative Preparation of Carboxylic Acid Derivative 13 from 3-Methyl-2-(1-hydroxyalkyl)benzothiazolium Iodide (2) in THF. To a suspension of the benzothiazolium salt **2** (2 mmol) in dry THF (30 ml) was added MnO_2 (1.74 g, 20 mmol), AcONa (0.16 g, 2 mmol), and a nucleophile (6 mmol) and the mixture was stirred under refluxing for 5 h. After cooling to room temperature, the insoluble materials were removed by filtration and the filtrate was concentrated under reduced pressure. The residue was diluted with hexane–dichloromethane and filtered through silica-gel pad (Wakogel C-300). Concentration of the filtrate under reduced pressure and SCC purification of the residue gave pure carboxylic acid derivative **13**.

Preparation of 2-Benzoyl-3-methylbenzothiazolium Fluorosulfate (15). A solution of 2-benzoylbenzothiazole (**3a**) (1.20 g, 5 mmol) in dry dichloromethane (10 ml) was mixed with methyl fluorosulfate (1.71 g, 15 mmol) in a glass tube and the mixture was then degassed several times in vacuo. The tube was sealed in vacuo and kept at 100 °C in an oil bath for 5 h (after about 1 h, yellow needles started to separate). The yellow crystalline product was collected by suction filtration, washed thoroughly with dry dichloromethane and then dried in vacuo to give almost pure salt **15** as yellow needles (1.66 g, 94%): Mp 85—87 °C (decomp). Found: C, 50.27; H, 3.74; N, 3.76%. Calcd for $C_{15}H_{12}NO_4S_2F$: C, 50.98; H, 3.42; N, 3.96%.

The Reaction of Active-Acyl Compound 15 in Ethanol. A mixture of compound **15** (0.71 g, 2 mmol) and dry ethanol (10 ml) was refluxed with stirring for 5 h and then concentrated under reduced pressure. The residue was diluted with hexane–dichloromethane and filtered through silica-gel pad (Wakogel C-300). Concentration of the filtrate under reduced pressure and SCC purification of the residue gave pure ester **12a** in 85% yield.

The Reaction of Active-Acyl Compound 15 with Water and Buthylamine in THF. To a suspension of compound **15** (0.71 g, 2 mmol) in dry THF (30 ml) was added water (1 ml) or butylamine (0.44 g, 6 mmol) and the mixture was then stirred under refluxing for 5 h under a nitrogen atmosphere. After cooling to room temperature, the insoluble materials were removed by filtration and the filtrate was concentrated under reduced pressure. The residue was diluted with hexane–dichloromethane and filtered through silica-gel pad (Wakogel C-300). Concentration of the filtrate under reduced pressure and SCC purification of the residue gave pure carboxylic acid derivative **13e** in 63% yield or **13f** in 56% yield.

Syntheses of Anionic Surfactants Having Two Polyfluoroalkyl Chains and Their Flocculation Ability for Dispersed Magnetite Particles in Water

Norio YOSHINO,* Noboru KOMINE, Jun-ichi SUZUKI, Yuki ARIMA, and Hidefumi HIRAI
Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received July 6, 1991)

Four anionic surfactants having two polyfluoroalkyl chains in a molecule, sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate, $CF_3(CF_2)_7(CH_2)_2OCOCH_2CH(SO_3Na)COO(CH_2)_2(CF_2)_7CF_3$, sodium salt of bis(1*H*,1*H*,9*H*-hexadecafluorononyl) 2-sulfosuccinate, $H(CF_2)_8CH_2OCOCH_2CH(SO_3Na)COOCH_2(CF_2)_8H$, sodium salt of bis(1*H*,1*H*,7*H*-dodecafluoroheptyl) 2-sulfosuccinate, $H(CF_2)_6CH_2OCOCH_2CH(SO_3Na)COOCH_2(CF_2)_6H$ and sodium salt of bis(1*H*,1*H*,5*H*-octafluoropentyl) 2-sulfosuccinate, $H(CF_2)_4CH_2OCOCH_2CH(SO_3Na)COOCH_2(CF_2)_4H$, were prepared from maleic anhydride, the corresponding alcohols having a polyfluoroalkyl chain and sodium hydrogensulfite. The flocculation and redispersion abilities of these surfactants against dispersed magnetite particles in water have been examined in comparison with other four anionic surfactants having a single polyfluoroalkyl chain in a molecule; sodium pentadecafluorooctanoate, $CF_3(CF_2)_6COONa$, sodium 9*H*-hexadecafluorononanoate, $H(CF_2)_8COONa$, sodium 7*H*-dodecafluoroheptanoate, $H(CF_2)_6COONa$, and sodium 5*H*-octafluoropentanoate, $H(CF_2)_4COONa$. These abilities were estimated by measurement of the contact angle against water using pelleted surface-modified magnetite. The abilities of the surfactants having two polyfluoroalkyl chains against flocculation-redispersion were superior to those of the surfactants having one polyfluoroalkyl chain. Especially, sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate was the most effective surface active agent for these abilities.

It is well known that fluorocarbon polymers exhibit the properties of water and oil repellency, high lubricity, thermal and chemical stability, and so on. It is expected that new composite materials with high performance are produced by dispersing some inorganics into these fluorocarbon polymers. To disperse inorganics into organic polymers, the surface of the inorganics should be modified. Normally there are two ways, one is the use of coupling agents[1-6] and the other is the employment of surfactants such as sodium oleate.[7-11]

In this paper, the results of the syntheses and characterizations of anionic surfactants having two polyfluoroalkyl chains in a molecule and their flocculation and redispersion abilities for dispersed magnetite particles in water are reported. These abilities were compared with those of anionic surfactants having one polyfluoroalkyl chain in a molecule.

Experimental

Materials. 1*H*,1*H*,2*H*,2*H*-Heptadecafluoro-1-decanol, $CF_3(CF_2)_7(CH_2)_2OH$ (bp 88—90 °C/500 Pa), 1*H*,1*H*,9*H*-hexadecafluoro-1-nonanol, $H(CF_2)_8CH_2OH$ (bp 63 °C/53 Pa), 1*H*,1*H*,7*H*-dodecafluoro-1-heptanol, $H(CF_2)_6CH_2OH$ (bp 169—170 °C) and 1*H*,1*H*,5*H*-octafluoro-1-pentanol, $H(CF_2)_4CH_2OH$ (bp 139—140 °C), pentadecafluorooctanoic acid, $CF_3(CF_2)_6COOH$ (bp 95 °C/133 Pa), 9*H*-hexadecafluorononanoic acid, $H(CF_2)_8COOH$ (bp 92—93 °C/53 Pa), 7*H*-dodecafluoroheptanoic acid, $H(CF_2)_6COOH$ (bp 69—70 °C/120 Pa) and 5*H*-octafluoropentanoic acid, $H(CF_2)_4COOH$ (bp 40—42 °C/120 Pa) were donated from Daikin Industries, Ltd. or obtained from PCR Inc. and purified by distillation. The purity of these alcohols and carboxylic acids were checked by the use of ^1H NMR, ^{19}F NMR spectra and gas chromatography, and the impurities were not detectable. The reagent grade maleic anhydride (bp 63—65 °C/660 Pa) and solvents (toluene, 1,4-dioxane and tetrahydrofuran(THF)) were commercially obtained and purified by distillation. *p*-Toluenesulfonic acid, sodium hydrogensulfite, sodium carbonate, iron(II) chloride, and iron(III) chloride were used without further purification. Magnetite particles were made by the method of Shimoiizaka et al.[10] and the average particle size was 109 Å (by light scattering).

Measurements and Instruments. FT-IR spectra were measured in a liquid film or by a KBr method with a JEOL JIR-5300 spectrophotometer. Each spectrum was recorded at a resolution of 4 cm^{-1} with the total of 30 scans. Pulsed Fourier Transform 100-MHz ^1H NMR was run in THF-d_8, trifluoroacetic acid, or acetone-d_6 with TMS as an internal standard using a JEOL JNR-PX-100 spectrometer at room temperature. The FT mode 90-MHz ^{19}F NMR was recorded at 27 °C on a JEOL JNM-FX-90Q in THF with fluorobenzene ($\delta=-113.6$[12] from $CFCl_3$ in $CDCl_3$) as an external standard. The assignments of the ^{19}F NMR spectra were referred to in the data book.[12] Gas chromatography was performed with a Hitachi 063 (PEG-6000 supported Chromosorb A NAW 30—60 mesh 5 m packed column, TCD) or Hitachi G-3000 gas chromatograph (OV-1 25 m Fused capillary column, FID) and the intensities were measured with a Hitachi 834 chromato processor or a Hitachi D-2500 chromato integrator. The centrifuge was used with a Hitachi himac CR20B2 (10000 rpm, 10 min at 20 °C). Light scattering measurements were run with Malvern Co. 4700 Submicron Particle Analyzer (Argon Laser, 5 W, 488 nm). Ultrasonic operations were carried out using a Branson Ultrasonics Corporation Model 250 Sonifier Cell Disruptor System (200 W, 20 kHz). Potential difference was measured using Yokogawa Model PH-82 pH meter. The contact angle $\theta(°)$ was measured at 23 °C with an Elma-Kougaku Co. Gonio-type apparatus. ESCA data were taken with a Shimadzu ESCA-750.

Synthesis of Bis(polyfluoroalkyl) Maleate. Synthesis of Bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) Maleate: A mixture of 1*H*,1*H*,2*H*,2*H*-heptadecafluoro-1-decanol 30.12 g (64.9 mmol), maleic anhydride 3.03 g (30.9 mmol) and *p*-toluenesulfonic acid monohydrate 1.18 g (6.2 mmol) as a catalyst in 120 cm^3 toluene was refluxed under stirring at 110 °C for 15 h. During the reaction, the water liberated was removed azeotropically from the reaction system to shift the equilibrium of the esterification reaction. The reaction was finished when 90% or more water being formed, based on the theoretical values. After the reaction, the mixture was cooled at 70 °C and washed sufficiently with 70 °C water to remove *p*-toluenesulfonic acid and excess maleic anhydride. A white solid, bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) maleate, was obtained by fractional distillation (yield 27.1 g, 86.8%): Bp 195—197 °C/400 Pa, mp 62—63 °C; IR 3062, 2980, 2912, 1724, 1641, 1639, 1466, 1464, 1425, 1396, 1375, 1333, 1201, 1146, 1078, 1049, 1016, 1014, 972, 841, 820, 704, 658 cm^{-1}; ^{1}H NMR (in THF-d_8) δ=2.64 (CH_2CF_2, t(t)(triplet(triplet)), J=18.8 (6.7) Hz, 4H), 4.51(OCH_2, t, J=6.7 Hz, 4H), 6.40(CH, s(singlet), 2H).

Syntheses of Bis(1*H*,1*H*,9*H*-hexadecafluorononyl) Maleate, Bis(1*H*,1*H*,7*H*-dodecafluoroheptyl) Maleate, and Bis-(1*H*,1*H*,5*H*-octafluoropentyl) Maleate: The procedure and purification techniques were almost the same as those for the preparation of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) maleate.

Bis(1*H*,1*H*,9*H*-hexadecafluorononyl) maleate was obtained by the reaction of 1*H*,1*H*,9*H*-hexadecafluoro-1-nonanol 39.3 g (90.9 mmol), maleic anhydride 4.30 g (43.9 mmol) and *p*-toluenesulfonic acid monohydrate 1.48 g (7.8 mmol) in 200 cm^3 toluene at 110 °C for 20.5 h. A colorless jelly product 15.9 g (yield 38.4%) was obtained: Bp 129—131 °C/27 Pa; IR 3097, 3076, 3022, 2981, 2960, 1747, 1655, 1454, 1412, 1350, 1288, 1201, 1144, 1088, 1039, 1038, 984, 957, 852, 816, 769, 702, 661, 636, 538 cm^{-1}; ^{1}H NMR (THF-d_8) δ=6.64 (CF_2H, t(t), J=51.0 (5.1) Hz, 2H), 4.83 (OCH_2, t, J=13.6 Hz, 4H), 6.55 (=CH, s, 2H).

Bis(1*H*,1*H*,7*H*-dodecafluoroheptyl) maleate was prepared under the following conditions: 1*H*,1*H*,7*H*-dodecafluoro-1-heptanol 37.6 g (113 mmol), maleic anhydride 5.29 g (53.9 mmol), and *p*-toluenesulfonic acid monohydrate 2.05 g (10.8 mmol) in 210 cm^3 toluene at 110 °C for 14 h. A liquid colorless product 14.8 g (yield 36.9%) was obtained: Bp 126—127 °C/13 Pa; IR 3057, 3010, 2980, 2912, 1757, 1753, 1720, 1707, 1639, 1635, 1587, 1566, 1562, 1550, 1546, 1460, 1410, 1382, 1263, 1196, 1140, 984, 949, 862, 831, 744, 715, 671 cm^{-1}; ^{1}H NMR (THF-d_8) δ=6.11 (CF_2H, t(t), J=50.8(5.0) Hz, 2H), 4.76 (OCH_2, t, J=13.6 Hz, 4H), 6.40 (=CH, s, 2H).

Bis(1*H*,1*H*,5*H*-octafluoropentyl) maleate: 1*H*,1*H*,5*H*-octafluoro-1-pentanol 37.7 g (162 mmol), maleic anhydride 7.27 g (74.1 mmol) and *p*-toluenesulfonic acid monohydrate 2.83 g (14.9 mmol) in 300 cm^3 toluene at 110 °C for 21 h. A liquid colorless product 15.4 g (yield 38.2%) was obtained: Bp 109—110 °C/40 Pa; IR 3070, 3012, 2980, 1755, 1701, 1684, 1653, 1646, 1645, 1558, 1538, 1522, 1506, 1456, 1409, 1383, 1288, 1172, 1132, 1085, 1043, 980, 904, 808, 754, 711, 605, 546, 437, 418, 415, 407, 401 cm^{-1}; ^{1}H NMR (THF-d_8) δ=6.13 (CF_2H, t(t), J=51.4 (5.4) Hz, 2H), 4.74 (OCH_2, t, J=14.0 Hz, 4H), 6.41 (=CH, s, 2H).

Synthesis of Surfactant Having Two Polyfluoroalkyl Chains. Synthesis of Sodium Salt of Bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-Sulfosuccinate: Sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate was prepared as follows. To a stirred clear solution of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) maleate 5.00 g (5.0 mmol) in 85 cm^3 1,4-dioxane, aqueous sodium hydrogensulfite (11.9 g (7.0 mmol) of sodium hydrogensulfite in 35 cm^3 water) was added at 50 °C. The mixture was refluxed under stirring until many foams began to appear for about 10—15 h from the start of reaction. Then the reaction temperature was held at 98 °C for about 30—40 h. The white solid product precipitated was separated from the reaction mixture through a sintered glass disk, washed with 50 cm^3 hot (50 °C) 1,4-dioxane on the disk to remove the unreacted bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) maleate. The product was dispersed ultrasonically in 50 cm^3 water. This colloidal dispersion was separated by centrifugation and the upper aqueous layer was decanted off to remove the excess sodium hydrogensulfite. The purification by the water washing/centrifugation was repeated three times or more. The products free from sodium hydrogensulfite were washed with 100 cm^3 THF on a sintered glass disk to remove water. A white powder, sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate, was obtained after vacuum drying (yield 4.74 g, 86.0%): IR 1736, 1726, 1600, 1461, 1369, 1333, 1201, 1147, 1120, 1049, 1012, 870, 836, 739, 702, 656 cm^{-1}; ^{1}H NMR (CF_3COOH) δ=2.51 (a and f, t(m(multiplet)), J=17.7 Hz, 4H), 3.36 (c, broad, 2H), 4.50 (b, d, and e, m, 5H) for $C_8F_{17}CH_2^aCH_2^bOCOCH_2^cCH^d(SO_3Na)COOCH_2^eCH_2^fC_8F_{17}$.

Syntheses of Sodium Salt of Bis(1*H*,1*H*,9*H*-hexadecafluorononyl) 2-Sulfosuccinate, Sodium Salt of Bis(1*H*,1*H*,7*H*-dodecafluoroheptyl) 2-Sulfosuccinate, and Sodium Salt of Bis-(1*H*,1*H*,5*H*-octafluoropentyl) 2-Sulfosuccinate: The synthetic method and purification techniques were almost the same as those for the preparation of sodium salt of bis-(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate.

Sodium salt of bis(1*H*,1*H*,9*H*-hexadecafluorononyl) 2-sulfosuccinate was obtained by the reaction of bis(1*H*,1*H*,9*H*-hexadecafluorononyl) maleate 17.8 g (18.9 mmol) in 100 cm^3 1,4-dioxane with aqueous sodium hydrogensulfite (2.54 g (24.4 mmol) in 50 cm^3 water) at 98 °C for 50 h. A white powder 9.54 g (yield 48.3%) was obtained: IR 2983, 2937, 1759, 1730, 1400, 1396, 1351, 1277, 1242, 1201, 1146, 1080, 941, 874, 808, 706, 688, 654 cm^{-1}; ^{1}H NMR (CF_3COOH) δ=3.15 (c, broad, 2H), 3.8—4.9 (b, d, and e, broad, 5H), 5.50 (a and f, t(m), J=51.4 Hz, 2H) for $H^a(CF_2)_8CH_2^bOCOCH_2^cCH^d(SO_3Na)$-$COOCH_2^e(CF_2)_8H^f$.

Sodium salf of bis(1*H*,1*H*,7*H*-dodecafluoroheptyl) 2-sulfosuccinate was prepared by the reaction of bis(1*H*,1*H*,7*H*-dodecafluoroheptyl) maleate 6.63 g (8.9 mmol) in 50 cm^3 1,4-dioxane with aqueous sodium hydrogensulfite (0.93 g (8.96 mmol)/25 cm^3 water) at 98 °C for 50 h. A white powder 4.29 g (yield 56.1%) was obtained: IR 2983, 2939, 1761, 1733, 1441, 1396, 1354, 1350, 1315, 1242, 1194, 1140, 1078, 1014, 972, 928, 862, 829, 798, 739, 735, 687, 665, 655 cm^{-1}; ^{1}H NMR (CD_3COCD_3) δ=3.28 (c, d, J=6.8 Hz, 2H), 4.22 (d, t, J=6.8 Hz, 1H), 4.66 (b, t, J=14.4 Hz, 2H), 4.77 (e, t, J=14.4 Hz, 2H), 6.57 (a and f, t(t), J=51.3 (5.7) Hz, 2H) for $H^a(CF_2)_6CH_2^b$-$OCOCH_2^cCH^d(SO_3Na)COOCH_2^e(CF_2)_6H^f$.

Sodium salt of bis(1*H*,1*H*,5*H*-octafluoropentyl) 2-sulfosuccinate 5.39 g (87.9%) was synthesized as a white powder from the reaction of 1,4-dioxane solution of bis(1*H*,1*H*,5*H*-octafluoropentyl) maleate (5.15 g (9.46 mmol) in 50 cm^3 1,4-dioxane) with aqueous sodium hydrogensulfite (1.08 g

(10.4 mmol)/25 cm^3 water) at 98 °C for 50 h: IR 2985, 2939, 1763, 1741, 1483, 1441, 1433, 1405, 1354, 1315, 1263, 1240, 1165, 1132, 1049, 968, 903, 806, 758, 707, 675, 655 cm^{-1}; ^1H NMR (CD_3COCD_3) δ=3.30 (c, d, J=6.8 Hz, 2H), 4.53 (d, t, J=6.8 Hz, 1H), 4.80(b and e, t, J=14.4 Hz, 4H), 7.72(a and f, t(t), J=51.3 (5.7) Hz, 2H) for $H^a(CF_2)_4CH_2^bOCOCH_2^cCH^d(SO_3Na)COOCH_2^e(CF_2)_4H^f$.

Synthesis of Surfactant Having One Polyfluoroalkyl Chain. Syntheses of Sodium Pentadecafluorooctanoate, $C_7F_{15}COONa$, Sodium 9*H*-Hexadecafluorononanoate, $H(CF_2)_8COONa$, Sodium 7*H*-Dodecafluoroheptanoate, $H(CF_2)_6COONa$, and Sodium 5*H*-Octafluoropentanoate, $H(CF_2)_4COONa$: These surfactants were prepared from the corresponding carboxylic acids with an excess of sodium carbonate in purified THF. After the reaction at 66 °C for 10 h, the excess sodium carbonate was removed by filtration. White powdery surfactants were obtained after vaccum drying. In each case, the yield of the surfactants was higher than 95%. The purity of these surfactants was confirmed on the basis of ^1H NMR (measured in THF-d_8) and IR spectra, and the impurities were not detectable.

Sodium pentadecafluorooctanoate: IR 1695, 1425, 1365, 1325, 1234, 1205, 1147, 1105, 1020, 987, 891, 823, 777, 739, 737, 735, 671, 665, 640, 561, 530 cm^{-1}; ^1H NMR no proton.

Sodium 9*H*-hexadecafluorononanoate: IR 2933, 1697, 1659, 1425, 1342, 1288, 1196, 1151, 1083, 982, 864, 823, 771, 735, 733, 667, 650, 586, 559, 536, 507 cm^{-1}; ^1H NMR δ=6.47 (HCF_2, t(t), 50.0 (5.3) Hz), no -COOH proton.

Sodium 7*H*-dodecafluoroheptanoate: IR 2927, 2912, 2872, 1697, 1421, 1327, 1259, 1184, 1138, 1135, 1082, 945, 823, 822, 819, 769, 719, 669 cm^{-1}; ^1H NMR δ=6.22 (HCF_2, t(t), 51.0 (5.4) Hz), no -COOH proton.

Sodium 5*H*-octafluoropentanoate: IR 2919, 2862, 1696, 1428, 1403, 1303, 1240, 1172, 1126, 1082, 1050, 921, 896, 834, 819, 726, 649 cm^{-1}; ^1H NMR δ=6.58 (HCF_2, t(t), 51.7 (6.1) Hz), no -COOH proton.

Stability of Dispersed Magnetite in Water: Magnetite powder 1.00 g was put into 50 cm^3 water, and the mixture was dispersed ultrasonically for 15 min. It was confirmed that the dispersion was not sedimented and that the colloidal precipitate did not appear for 3 days or more.

Measurement of Flocculation Ability: The adsorption of the surfactants was achieved by ultrasonic irradiation (200 W, 20 kHz, 15 min) to magnetite particles (0.100 g) in 40 cm^3 aqueous solution of the surfactants at various concentrations. The ultrasonic irradiation was utilized to progress an adsorption reaction and to prevent aggregation of magnetite particles. The flocculation and redispersion abilities of the surfactants against magnetite particles were observed after leaving them standing for 24 h at room temperature.

Measurement of Contact Angles of Water on Surface-Modified Magnetite: The surface wettabilities of the modified magnetite were evaluated by the contact angle θ(°) against water on the pelleted magnetite. The pellets to measure the contact angle were prepared as follows. Pressed cellulose disks were preliminary made by pressing 40 mg cellulose powder in a die for IR pellets at 200 kg cm^{-2} for 10 min; 0.15 g of surface-modified magnetite was then placed on it. The surface-flattened pellets of magnetite were obtained by pressing again at 200 kg cm^{-2} for 15 min in the die. The contact angles were measured using 1.0×10^{-6} dm^3 of water drops. The contact angles were evaluated by extrapolating to time zero from a plot of the advancing contact angle θ(°) vs. time.[13]

Amount of Adsorbed Surfactant: The amounts of adsorbed surfactant on the surface-modified magnetite just after the beginning of flocculation and just before the beginning of redispersion were quantitated from the measurement of the potential difference of the upper clear solution, using the calibration curve obtained with an aqueous surfactant solution at various concentrations.

ESCA Measurement: The samples for ESCA measurement were obtained from the middle point of the flocculation range; the sample treated with sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate was obtained from the ratio of [Surfactant/Magnetite]=0.07 (see Fig. 1) and another one treated with sodium pentadecafluorooctanoate was prepared from that of 0.90. These samples were washed sufficiently with water, dried in a reduced pressure and powdered with an agate mortar.

Results and Discussion

The yields of several sodium salt of bis(polyfluoroalkyl) 2-sulfosuccinate derivatives were not very high. This is probably because water-soluble surfactants, although the solubility was considerably low, had to be washed with water to remove the unreacted sodium hydrogensulfite.

The surfactants are known to change the surface properties of many substances by adsorption. We examined the surface modification ability of the surfactants having polyfluoroalkyl chain(s) by use of magnetite particles. Figure 1 shows the regions of flocculation and redispersion of magnetite particles obtained by adding the solution of the eight different surfactants at various initial concentrations. In a range of a lower surfactant concentration, the magnetite particles were flocculated with an increase in the surfactant concentration. On the contrary, the flocculated magnetite particles were dispersed again as the surfactant concentration was further increased. The region of flocculation-redispersion depended on the surfactant used. The relationship between the flocculation and the redispersion of magnetite particles is schematically illustrated in Fig. 2. The surface of magnetite particles in water is positively charged, then the surface adsorbs surfactants at a moiety of negatively charged ion ($-SO_3^-$ or $-COO^-$).[14] In a lower concentration range of surfactant, the magnetite particles adsorb the surfactants in a monolayer and the particles are surrounded by the surfactants orientating the polyfluoroalkyl chains outside. Thus, the modified magnetite particles are flocculated in water, since the surface of the modified particles have a hydrophobic property. The flocculating magnetite particles were, however, dispersed again when the surfactant concentration increased further. This means that the magnetite particles modified with a surfactant in a monolayer are surrounded by the second surfactants to make a bilayer by an interaction of polyfluoroalkyl chains, in which the second surfactants are orientated

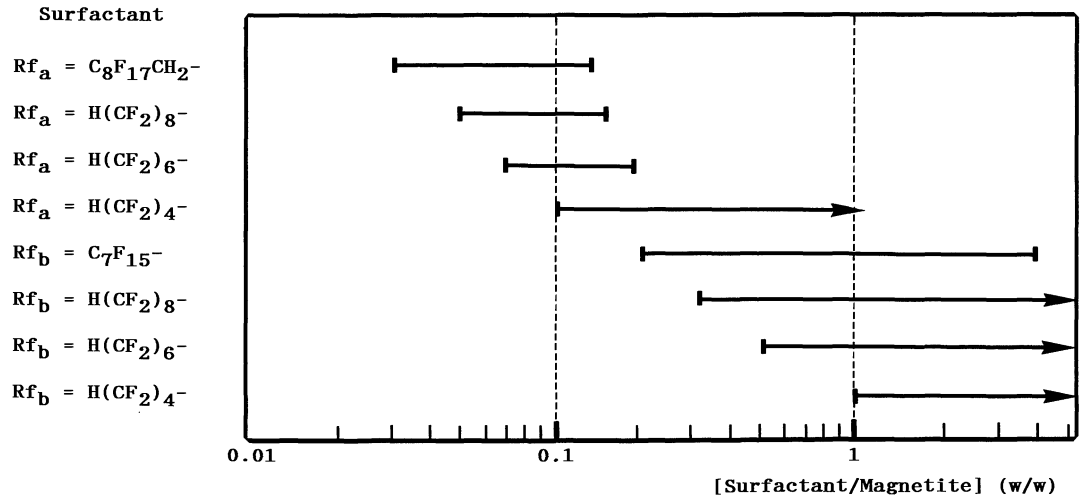

Fig. 1. Comparison of flocculation and redispersion abilities of the surfactants having polyfluoroalkyl chain(s) using magnetite particles. Rf_a and Rf_b groups are for $Rf_aCH_2OCOCH_2CH(SO_3Na)COOCH_2Rf_a$ and Rf_bCOONa, respectively.

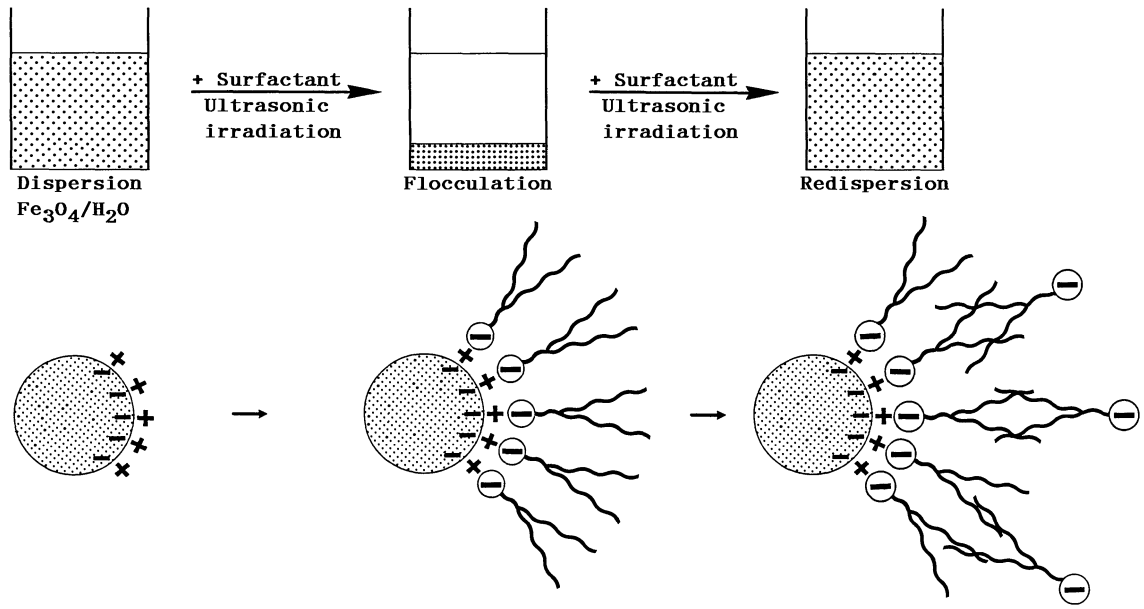

Fig. 2. Schematic illustration for flocculation and redispersion of magnetite particles.

outside at the ion moiety. From the relationship between flocculation and redispersion shown in Fig. 1, it is concluded that the ability of surfactants having two polyfluoroalkyl chains against flocculation-redispersion is superior to that of the surfactants having one polyfluoroalkyl chain. Especially, the surfactants having those two polyfluoroalkyl chains which include a trifluoromethyl group at the end of the chains were the most effective. Some of the beginning points of redispersion were incomplete to measure (drawn by the arrows in Fig. 1), because of the low solubility of these surfactants.

The results of the measurement of the contact angle against water on the modified magnetite, whose samples were obtained from the middle point in each flocculation range and pelleted, are listed in Table 1. Since the untreated magnetite pellet absorbed water drops too rapidly to determine the contact angle, the contact angle was described 0°. The values of the contact angle indicate that the surfactants having a trifluoromethyl group at the end of the chain(s) have higher hydrophobicity than the others. In the case of the surfactants having hydrogen at the end of the chain(s), the value increases with an increase in the chain length. However, these values are independent of the flocculation ability, because the amount of surfactant

Table 1. Contact Angles of Water on the Surface-Modified Magnetite Treated with the Surfactants Having Polyfluoroalkyl Chain(s)

Surfactant[a)]	Contact angle θ(°) of water
Untreated	0
$Rf_a=CF_3(CF_2)_7CH_2-$	125
$Rf_a=H(CF_2)_8-$	106
$Rf_a=H(CF_2)_6-$	80
$Rf_a=H(CF_2)_4-$	65
$Rf_b=CF_3(CF_2)_6-$	119
$Rf_b=H(CF_2)_8-$	95
$Rf_b=H(CF_2)_6-$	71
$Rf_b=H(CF_2)_4-$	64

a) $Rf_aCH_2OCOCH_2CH(SO_3Na)COOCH_2Rf_a$, Rf_bCOONa.

Table 2. Amount of Adsorbed Surfactant

Surfactant	Amount of adsorbed surfactant (mg/g magnetite)
$CF_3(CF_2)_7(CH_2)_2OCOCH_2-CH(SO_3Na)COO(CH_2)_2(CF_2)_7CF_3$	
After flocculation	29.5
Before redispersion	109
$CF_3(CF_2)_6COONa$	
After flocculation	176
Before redispersion	440

adsorbed on the magnetite surface in the middle point of the flocculation range should be different from one another.

Some of the results of the amount of adsorbed surfactant on the magnetite surface are listed in Table 2. In the case of sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate, only 29.5 mg of surfactant were needed to flocculate 1 g of magnetite particles, and 109 mg for redispersion. On the other hand, in the case of sodium pentadecafluorooctanoate, much more surfactant was required for the flocculation (176 mg) and redispersion (440 mg). These observations also suggest that the ability of the surfactants having two polyfluoroalkyl chains for the flocculation and redispersion against the magnetite particles in water is superior to that of the surfactants having one polyfluoroalkyl chain in a molecule.

The two surface-modified magnetite samples for the ESCA measurements were obtained from the middle point of the flocculation range given in Fig. 1 ($Rf_a=C_8F_{17}CH_2-$ and $Rf_b=C_7F_{15}-$). It was found that the atomic ratio of Fe : F in the vicinity of the surface modified with sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate was 1 : 7.53, and the ratio 1 : 4.86 was obtained from the surface treated with sodium pentadecafluorooctanoate. From these values, it was calculated that the molar ratio of Fe_3O_4: surfactant was 1 : 0.66 and 1 : 0.85, respectively. Although the initial surfactant concentration ratio (molar ratio) used to make these two samples was [sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate] : [sodium pentadecafluorooctanoate]=1 : 33, the molar ratio obtained from these two samples was [adsorbed sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate] : [adsorbed sodium pentadecafluorooctanoate]=0.66 : 0.85. These data also suggest that the surfactant having two polyfluoroalkyl chains has a relatively high adsorption ability; in these cases, the adsorption ability ratio is [sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate] : [sodium pentadecafluorooctanoate]=(0.66/1) : (0.85/33)=1 : 0.04.

In conclusion, the abilities of the anionic surfactants having two polyfluoroalkyl chains for the flocculation and the redispersion against magnetite particles in water were superior to those of the surfactants having one polyfluoroalkyl chain in a molecule. Especially sodium salt of bis(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) 2-sulfosuccinate possessing a CF_3- group at the end of the polyfluoroalkyl chains, was the most effective surface active agent for these abilities.

The authors are grateful to Dr. Masahiko Abe of the Science University of Tokyo for the light scattering measurements. We also thank Messrs. Yukihide Shiraishi, Shin-ichi Tominaga, Tadashi Hakomori, and Munetoshi Morita for their assistance in carrying out part of the present experiments.

The present work was partially supported by a Grant-in-Aid of Scientific Research No. 62550618 from the Ministry of Education, Science and Culture, to which the authors are also grateful.

(Received June 24, 1991)

Allyl glycosides (ketosides) of pyranosidic 3-deoxy-D-*manno*-2-octulosonic acid (Kdo), phosphorylated at either positions 4 or 5 were synthesized with the aim to study the biological properties of phosphorylated Kdo. The α- and β-allyl glycosides prepared from a pyranosidic fluoride of diisopropylidene Kdo were protected at the 7- and 8-positions, and then *O*-phosphorylated at the 4- or 5-position by the phosphoramidite procedure. Separation of the positional isomers followed by deprotection afforded four compounds in pure states.

3-Deoxy-D-*manno*-2-octulosonic acid (Kdo) is a common and obligatory constituent of lipopolysaccharides (LPS) of Gram-negative bacteria.[1] It is structurally important as it forms the link between the polysaccharide region and the lipid A component of LPS.[2] Thus, Kdo is located at the reducing terminal of the polysaccharide region and α-ketosidically bound to lipid A.[3] Kdo is also of biological importance, since it modulates the endotoxic activity of lipid A[1,4] and, further, since it appears to be essential in the biosynthesis of LPS, and, thus, for the viability of Gram-negative bacteria.[5-7]

The intracatenarian Kdo-residue is, depending on the bacterial source, substituted by glycosyl or phosphoryl groups.[1,2,7] Kdo phosphate has been found in the LPS of *Bordetella pertussis*,[8] *Vibrio cholerae*,[9] *Bacteroides gingivalis*,[10] *Haemophilus influenzae*,[11] and *Vibrio parahaemolyticus*.[12] In the latter case, Kdo-4-phosphate was found to be present, whereas in the other LPS, Kdo 4-phosphate and/or Kdo 5-phosphate was identified.

As part of our synthetic work related to the elucidation of the biological significance of Kdo residues in LPS[13,14] we report here on the synthesis of α- and β-allyl glycoside (ketoside) of Kdo 4- and 5-phosphates.[15] In analogy to other Kdo derivatives these compounds are regarded as targets for serological studies aiming at the characterization of the immunoreactivity of the Kdo-containing inner core region of LPS.[16,17] The allyl groups were introduced to serve as a link for the preparation of Kdo phosphate containing antigens, i.e. the conjugation with proteins or the copolymerization with acrylamide.[17]

Results and Discussion

In the present study, the α-fluoride of diisopropylidene Kdo **4**, prepared from the Kdo ammonium salt, was employed for the formation of allyl glycosides of Kdo. The same fluoride **4** had been prepared from D-mannose in our previous work and shown to be an efficient pyranosidic glycosyl donor of Kdo.[18] In that work, it was also demonstrated that the fluoride **4** gives a mixture of α- and β-glycosides of Kdo on Lewis acid-catalyzed glycosidation when a lower alcohol is employed as the glycosyl acceptor.[18] Thus, the formation of both α- and β-allyl glycosides of Kdo could be expected in one reaction with the fluoride **4**.

The methyl ester of Kdo, obtained from the ammonium salt, was converted to the 4,5 : 7,8-di-*O*-isopropylidene 2-acetate (**5**) of the pyranose form. Reaction of **5** with hydrogen fluoride in pyridine gave the α-fluoride (**4**) which was identical with the specimen obtained in our previous work.[18] The glycosidation

† Present address: Peptide Institute, Protein Research Foundation, 4-1-2, Ina, Minoh, Osaka 562

reaction with the fluoride using dry allyl alcohol was carried out in the presence of boron trifluoride etherate and *N*,*N*-diisopropylethylamine in dichloromethane.[19] The anomeric mixture of the allyl glycosides obtained was separated by column chromatography on silica gel to give the α-allyl glycoside **6a** (58%) and the β-anomer **6b** (24%). The former was accompanied with a small amount (2.7%) of the glycal **7** which could not be separated at this stage: the ratio of **6a** to **7** was determined spectrometrically by ^{1}H NMR.

The glycosidic configuration of these allyl glycosides was determined by examination of the differences in the chemical shift values of H_{3a} and H_{3e} in ^{1}H NMR spectra.[18,20] The large $\Delta_{3e\text{-}3a}$ value of 0.91 for **6a** assures its α-anomeric configuration, since the values are around the range of 0.6—1.19 for the various known α-anomers of 4,5 : 7,8-di-*O*-isopropylidene derivatives of Kdo. In the case of the other anomer **6b**, the corresponding $\Delta_{3e\text{-}3a}$ value was 0.24 which was close to the range of 0.26—0.28 so far observed for β-anomers.

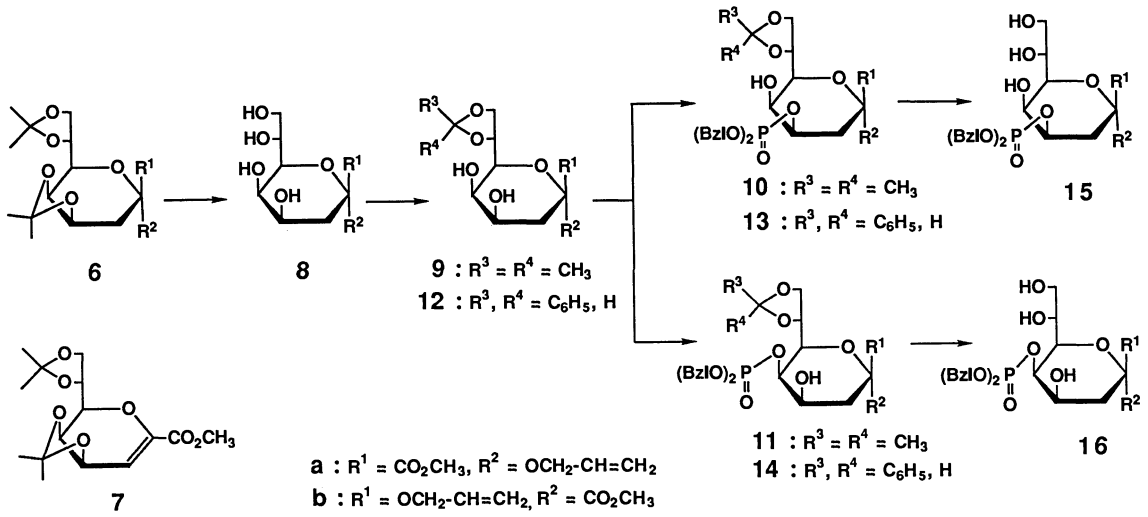
Introduction of the phosphate moiety was first examined at the 4- or 5-position of the α-allyl glycoside. Thus, both isopropylidene groups of **6a** were once removed to give the free α-allyl glycoside methyl ester **8a**, whose 7- and 8-hydroxyl groups were again protected by selective monoisopropylidenation. When **8a** was treated with 2-methoxypropene in the presence of (+)-camphor-10-sulfonic acid (CSA) at −35 °C, TLC analysis indicated that a smooth reaction had occurred to give a monoisopropylidene derivative as the main product. This compound was assumed to be the desired 7,8-*O*-isopropylidene **9a** as judged from the result of our previous work.[14] However, the yield of purified **9a** was poor largely due to the low recovery after silica-gel column chromatography. Therefore, the crude monoisopropylidene derivative was used for the subsequent phosphorylation reaction, without any chromatographic purification.

Subsequently, the nonselective monophosphorylation of the vicinal diol function of the crude **9a** obtained above was attempted expecting that separation of the products will give both of the required 4- and 5-phosphates (**10a** and **11a**). In order to avoid the formation of a 4,5-cyclic phosphate, the phosphoramidite procedure was applied to this monophosphorylation.[21] Phosphitylation of the crude monoisopropylidene derivative **9a** with dibenzyl diisopropylphosphoramidite[22-24] and 1*H*-tetrazole at −30 °C in a mixture of dichloromethane and acetonitrile. The latter solvent was used to improve the solubility of 1*H*-tetrazole. Direct oxidation with *m*-chloroperbenzoic acid (mCPBA), without isolation of the *O*-bis(benzyloxy)phosphino derivatives, afforded a mixture of two products. Their structures were unequivocally determined as 4- and 5-phosphate of Kdo after separation by careful examination of their ^{1}H NMR spectra, where each proton signal was clearly assigned by analysis of the H–H COSY spectra. The product whose H-4 signal appeared at lower field with splitting due to the coupling with phosphorus,[25] was assigned to the 4-*O*-[bis(benzyloxy)phosphinoyl] derivative **10a**. Similarly, based on comparison of chemical shift values and H–P coupling, the other compound was the 5-*O*-[bis(benzyloxy)phosphinoyl] derivative **11a**. Both position isomers were, thus, obtained. However, their total yield was only 21% after the two-step conversion from **8a**, owing mainly to the competitive formation of the corresponding 4,5-bisphosphate and to the insufficient stability of the protecting isopropylidene group.

In order to improve the yield of the phosphorylated products, the use of a benzylidene group was next examined for the protection of the 7- and 8-hydroxyl groups. Treatment of **8a** with α,α-dimethoxytoluene and CSA at room temperature resulted in a diastereomeric mixture of the 7,8-*O*-benzylidene derivative **12a** which gave a single spot on TLC but which showed two signals (total 1H), both attributed to the benzylidene CH in its ^{1}H NMR spectrum. Reaction of this benzylidene derivative **12a** with the dibenzyl phosphoramidite and 1*H*-tetrazole was carried out as described above. The progress of the reaction was monitored by TLC and the amidite reagent was added to complete the conversion. Subsequent oxidation with mCPBA gave a mixture of products which gave two spots on silica gel TLC (R_f 0.77 and 0.54; chloroform–acetone, 9 : 1). After their separation by silica-gel column chromatography, ^{1}H NMR analysis revealed that the faster moving compound was yet a mixture composed of 5-phosphate **14a** and a diastereomer of 4-phosphate **13a**. The slower-moving compound was the other diastereomer of the 4-phosphate.

For preparative purposes, the benzylidene group of the phosphorylation product was removed with trifluoroacetic acid (TFA), prior to the separation. The debenzylidenated product was subjected to preparative HPLC on a reversed phase column to give the dibenzyl esters of 4- and 5-phosphates (**15a** and **16a**) which were identical with the products obtained by TFA treatment of the isopropylidene derivatives **10a** and **11a**, respectively. The yield was much improved by the latter route via the 7,8-*O*-benzylidene derivatives.

Cleavage of the benzyl esters of the phosphate moiety was effected quite smoothly with trimethylsilyl (TMS) bromide in dichloromethane at room temperature.[26] The hydrogenolytic removal of the benzyl group had to be avoided here because the allyl group was to be retained. The final alkaline hydrolysis of the methyl ester, and purification by HPLC on an anion-exchange resin, afforded the deprotected α-allyl glycoside 4- and 5-phosphate (**2a** and **3a**) as their ammonium salt. The purity and the structure of each product were confirmed by ^{1}H NMR and high-resolution negative FAB-mass spectra. Additional evidence excluding the possibility of mutual contamination of 4- and 5-phosphate, which may have resulted from the phosphate migration or



insufficient separation, was also obtained by analytical ion-pair HPLC on a reversed phase column.

The β-allyl glycoside of the Kdo methyl ester **6b** was also converted to the corresponding 4- and 5-phosphate (**2b** and **3b**) in the same way via 7,8-*O*-benzylidene derivative (**12b**).

Cleavage of the benzyl esters of the 5-phosphate **16b** proceeded satisfactorily with TMS bromide followed by sodium hydroxide to give the 5-phosphate of the β-allyl glycoside **3b**. In contrast, cleavage of the benzyl esters of the corresponding 4-phosphate **15b** with TMS bromide gave a mixture of more polar compounds, which lacked the glycosidic allyl group as judged from the positive reaction on TLC with the 2,3,5-triphenyl-2*H*-tetrazolium chloride reagent for reducing sugars.[27] In the NMR spectrum of **15b**, the signals of H-7 and H-8 appeared as rather broad peaks, most likely indicating the presence of hydrogen bonds between the bis(benzyloxy)phosphinoyl group and the two hydroxyl groups at 7- and 8-positions. Such hydrogen bonding is sterically not possible if the pyranoside ring of **15b** exists in a normal $^5C_2$ conformation, where the C7–C8 side chain and the bis(benzyloxy)phosphinoyl group are in a 1,3-diequatorial relation to each other. The ring of **15b** was therefore assumed to be distorted from the chair to $^{0,4}B$ or similar conformation, in which the benzylated phosphate moiety comes also very close to the glycosidic position. We thus anticipated that the glycosidic allyl group was cleaved by direct intramolecular attack of the acidic 4-*O*-phosphono group after the removal of the benzyl esters with TMS bromide.[28] In order to avoid such possible assistance of the free hydroxyl groups to the undesirable conformational change, the hydroxyl groups were acetylated prior to the reaction with TMS bromide. In fact, the reaction of the resultant peracetate with TMS bromide gave a single product, which, on alkaline hydrolysis, gave the desired 4-phosphate **2b** with the intact β-allyl group. The structures and the purities of both 4- and 5-phosphates of the β-allyl glycoside (**2b** and **3b**) were also confirmed in the same way as their α-anomers.

The synthetic phosphates of pyranosidic Kdo with α- and β-linked allyl groups are now being subjected to serological and other biological studies. In addition, the present work has also provided a synthetic procedure applicable to the future chemical synthesis of LPS which contains phosphorylated Kdo(s) in its inner core region.

Experimental

^{1}H NMR spectra were measured on a Varian XL-100-15 spectrometer (100 MHz) or a JEOL JNM-GSX 270, 400, or 500 spectrometer for $CDCl_3$ solutions unless otherwise noted. The chemical shifts are given in δ values either from TMS as the internal standard in $CDCl_3$ solutions or from sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the external standard in D_2O solutions. High-resolution negative FAB-mass spectra were recorded on a JEOL SX-102 mass spectrometer with glycerol as the matrix, where cluster peaks of glycerol served as standards for calculation. Optical rotations were measured with a Perkin–Elmer 241 polarimeter. High-performance liquid chromatography (HPLC) was carried out with a Shimadzu LC-6A liquid chromatography apparatus with a column specified: The peaks were detected by the absorbance at 220 nm. Analytical ion-pair HPLC was carried out on a Cosmosil 5C18 column (4×250 mm) with a solvent system composed of 0.05 M (1M=1 mol dm^{-3}) *n*-Bu_4NHSO_4 and 0.05 M $(NH_4)_2SO_4$ in 3% CH_3CN at a flow rate of 1.0 ml min^{-1}. Peaks were detected at 210 nm. Kieselgel 60 (E. Merck), 0.040—0.063 mm, was used for silica-gel column chromatography at medium pressure (2—4 kg cm^{-2}). Organic solutions were dried over $MgSO_4$ and evaporated in vacuo.

Methyl 2-*O*-Acetyl-3-deoxy-4,5 : 7,8-di-*O*-isopropylidene-α-D-*manno*-2-octulosonate (5). Kdo ammonium salt (4.00 g, 15.7 mmol) was dissolved in water (15 ml) and passed through a column of Amberlite IRCG-120 (H^+ form, 40×150 mm). The column was eluted with water, and the acidic eluate was combined and lyophilized. A solution of the lyophilizate in MeOH (150 ml) was treated with an ethereal solution of CH_2N_2. The residue obtained by evaporation of the solvent was suspended in dry acetone (300 ml). After the addition of *p*-

toluenesulfonic acid monohydrate (600 mg, 3.15 mmol), the mixture was stirred at room temperature for 13 h and then neutralized by addition of Na_2CO_3 (677 mg, 6.30 mmol). The insoluble materials were filtered off, the filtrate evaporated, and the residue was dissolved in dry CH_2Cl_2 (80 ml). To the solution cooled in an ice bath were added pyridine (9.8 ml, 125 mmol), acetic anhydride (5.9 ml, 63 mmol), and 4-dimethylaminopyridine (766 mg, 6.27 mmol). The mixture was stirred at room temperature for 1 h, diluted with AcOEt (1.2 l) and worked up as usual. The crude product was subjected to column chromatography on silica gel (180 g; $CHCl_3$–acetone, 50 : 1) to give syrup; yield 4.30 g (73%). $[\alpha]_D^{18}$ +74.2° (*c* 1.12, $CHCl_3$). ^1H NMR (100 MHz) δ=4.70—3.90 (5H, m, H-4, 5, 7, 8, 8′), 3.78 (3H, s, OCH_3), 3.60 (1H, dd, *J*=8 and 2 Hz, H-6), 2.72 (1H, dd, *J*=16 and 3 Hz, H-3_{eq}), 2.10 (3H, s, $COCH_3$), 2.08 (1H, dd, *J*=16 and 3 Hz, H-3_{ax}), 1.46, 1.41. 1.39, 1.32 (each 3H, s, isopropylidene CH_3). Found: C, 54.51; H, 7.05%. Calcd for $C_{17}H_{26}O_9$: C, 54.54; H, 700%.

Methyl (3-Deoxy-4,5 : 7,8-di-*O*-isopropylidene-α-D-*manno*-2-octulopyranosyl fluorid)onate (4). To a solution of **5** (390 mg, 1.04 mmol) in pyridine (0.65 ml) cooled to −70 °C was added 70% HF–pyridine (3.0 ml) and CH_2Cl_2 (1.2 ml). The mixture was stirred at −20 °C for 10 min and at 0 °C for 10 min, and then diluted with AcOEt (70 ml). The solution was washed successively with aq solutions of 10% KF (3 times), saturated NaCl, saturated $NaHCO_3$, and NaCl and then dried. The residue obtained after evaporation of the solvent was purified by silica-gel column chromatography (10 g; $CHCl_3$–acetone, 20 : 1); yield 231 mg (66%). Mp 121—122 °C. The product was identified with the compound obtained previously.[18] $[\alpha]_D^{18}$ +11.9° (*c* 1.06, $CHCl_3$). ^1H NMR (270 MHz) δ=4.57 (1H, m, H-4), 4.43—4.35 (2H, m, H-5, 7), 4.15 (1H, dd, *J*=8.9, 5.9 Hz, H-8), 4.08 (1H, dd, *J*=8.9, 4.0 Hz, H-8′), 3.81 (3H, s, OCH_3), 3.67 (1H, ddd, *J*=8.5, 2.2, 2.2 Hz, H-6), 3.06 (1H, ddd, *J*=15.6, 3.7, $J_{3e,F}$=3.7 Hz, H-3_{eq}), 1.98 (1H, ddd, *J*=15.6, 2.8, $J_{3a,F}$=18.4 Hz, H-3_{ax}), 1.44, 1.39, 1.38, 1.33 (each 3H, s, isopropylidene CH_3). Found: C, 53.91; H, 6.96%. Calcd for $C_{15}H_{23}O_7F$: C, 53.89; H, 6.93%.

Methyl (Allyl 3-Deoxy-4,5 : 7,8-di-*O*-isopropylidene-α-D-*manno*-2-octulopyranosid)onate (6a) and Methyl (Allyl 3-Deoxy-4,5 : 7,8-di-*O*-isopropylidene-β-D-*manno*-2-octulopyranosid)onate (6b). To an ice-cooled solution of **4** (1.85 g, 5.53 mmol) in dry CH_2Cl_2 (40 ml) were successively added allyl alcohol (489 μl, 7.19 mmol), *N*,*N*-diisopropylethylamine (963 μl, 5.53 mmol) and BF_3 etherate (1.43 ml, 11.6 mmol) under N_2. The solution was stirred for 5 min at 0 °C, then cooled to −70 °C and *N*,*N*-diisopropylethylamine (1.5 ml, 8.6 mmol) was added.[29] The mixture was diluted with CH_2Cl_2 (200 ml), washed with saturated aq NaCl solution, and dried. Separation by silica-gel column chromatography (160 g; $CHCl_3$–acetone, 70 : 1) gave **6a** and **6b** as colorless syrup.

6a, yield 1.20 g (58%). This fraction was contaminated with small amount of **7** (**6a** : **7**=20 : 1 as judged from ^1H NMR data). $[\alpha]_D^{18}$ +36.5° (*c* 1.03, $CHCl_3$). ^1H NMR (500 MHz) δ=5.86 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.26 and 5.16 (each 1H, m, $-OCH_2-CH=C\underline{H_2}$), 4.52 (1H, ddd, *J*=7.4, 4.0, 3.0 Hz, H-4), 4.39 (1H, ddd, *J*=7.9, 6.4, 4.6 Hz, H-7), 4.29 (1H, dd, *J*=7.4, 1.8 Hz, H-5), 4.16 (1H, dd, *J*=8.7, 6.4 Hz, H-8), 4.15 (1H, m, $-OC\underline{H_2}-CH=CH_2$), 3.99 (1H, dd, *J*=8.7, 4.6 Hz, H-8′), 3.82 (1H, m, $-OC\underline{H_2}-CH=CH_2$), 3.76 (3H, s, OCH_3), 3.60 (1H, dd, *J*=7.9, 1.8 Hz, H-6), 2.82 (1H, dd, *J*=15.5, 4.0 Hz, H-3_{eq}), 1.91 (1H, dd, *J*=15.5, 3.0 Hz, H-3_{ax}), 1.43, 1.41, 1.38, 1.32 (each 3H, s, isopropylidene CH_3).

6b, yield 490 mg (24%). $[\alpha]_D^{18}$ +4.0° (*c*, 1.01, $CHCl_3$). ^1H NMR (400 MHz) δ=5.89 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.25 and 5.12 (each 1H, m, $-OCH_2-CH=C\underline{H_2}$), 4.50 (1H, ddd, *J*=7.5, 4.2, 4.2 Hz, H-4), 4.32 (1H, ddd, *J*=8.2, 6.2, 4.2 Hz, H-7), 4.29 (1H, dd, *J*=7.5, 2.0 Hz, H-5), 4.25 (1H, dd, *J*=8.7, 4.2 Hz, H-8), 4.22 (1H, m, $-OC\underline{H_2}-CH=CH_2$), 4.12 (1H, dd, *J*=8.7, 6.2 Hz, H-8′), 3.96 (1H, m, $-OC\underline{H_2}-CH=CH_2$), 3.77 (3H, s, OCH_3), 3.51 (1H, dd, *J*=8.2, 2.0 Hz, H-6), 2.29 (1H, dd, *J*=15.4, 4.2 Hz, H-3_{eq}), 2.05 (1H, dd, *J*=15.4, 4.2 Hz, H-3_{ax}), 1.50, 1.42, 1.38, 1.36 (each 3H, s, isopropylidene CH_3). Found: C, 57.94; H, 7.60%. Calcd for $C_{18}H_{28}O_8$: C, 58.05; H, 7.58%.

Methyl (Allyl 3-Deoxy-7,8-*O*-isopropylidene-α-D-*manno*-2-octulopyranosid)onate (9a). Trifluoroacetic acid (TFA) (6 ml) containing 5% of water was added to an ice-cooled solution of **6a** (680 mg, 1.83 mmol) in CH_2Cl_2 (70 ml), and the mixture stirred at the same temperature for 1 h. Evaporation under reduced pressure after addition of toluene was repeated three times followed by lyophilization from dioxane gave methyl (allyl 3-deoxy-α-D-*manno*-2-octulopyranosid)onate (**8a**) as resinous solid (yield 530 mg, 99%).

To a solution of **8a** (295 mg, 1.01 mmol) in dry acetone (40 ml) cooled to −35 °C were added 2-methoxypropene (193 μl, 2.02 mmol) and (+)-camphor-10-sulfonic acid (CSA) (23 mg, 0.10 mmol). The mixture was stirred at that temperature for 5 min, neutralized by addition of aq $NaHCO_3$ solution, and filtered. The filtrate was diluted with $CHCl_3$ (300 ml), worked up as usual, and evaporated to give colorless syrup; yield 286 mg (85%). This compound was used without purification for the subsequent reaction. ^1H NMR (270 MHz) δ=5.89 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.28 and 5.18 (each 1H, m, $-OCH_2-CH=C\underline{H_2}$), 4.40 (1H, ddd, *J*=7.9, 6.2, 4.9 Hz, H-7), 4.17 (1H, dd, *J*=8.7, 6.2 Hz, H-8), 4.13 (1H, m, H-4), 4.10—3.80 (4H, m, H-5, 8′, and $-OC\underline{H_2}-CH=CH_2$), 3.78 (3H, s, OCH_3), 3.57 (1H, dd, *J*=7.9, 1.2 Hz, H-6), 2.19 (1H, ddd, *J*=12.9, 5.2, 0.7 Hz, H-3_{eq}), 1.91 (1H, dd, *J*=12.9, 11.4 Hz, H-3_{ax}), 1.41 and 1.37 (each 3H, s, isopropylidene CH_3).

Methyl [Allyl 4-*O*-[Bis(benzyloxy)phosphinoyl]-3-deoxy-7,8-*O*-isopropylidene-α-D-*manno*-2-octulopyranosid]onate (10a) and Methyl [Allyl 5-*O*-[Bis(benzyloxy)phosphinoyl]-3-deoxy-7,8-*O*-isopropylidene-α-D-*manno*-2-octulopyranosid]-onate (11a). A mixture of **9a** (62 mg, 0.19 mmol) and 1*H*-tetrazole (30 mg, 0.43 mmol) in dry CH_2Cl_2 (9 ml) and dry CH_3CN (0.9 ml) was cooled to −35 °C under Ar atmosphere. A solution of dibenzyl diisopropylphosphoramidite[22] (128 mg, 0.372 mmol) in dry CH_2Cl_2 (500 μl) was added to the mixture, and the whole mixture was stirred at −30 °C for 2 h. Stirring was further continued at −30 °C for 5 min after addition of a solution of mCPBA (96 mg, 0.56 mmol) in CH_2Cl_2 (2 ml). Then the mixture was diluted with CH_2Cl_2 (60 ml), washed with 10% aq $NaHSO_3$ solution, and worked up as usual. The product was subjected to separation by preparative HPLC under the following conditions and lyophilized: Cosmosil 5C18 (8×250 mm), 60—80% CH_3CN (linear gradient, 1% min^{-1}), 3 ml min^{-1}.

10a, yield 14 mg (13% from **8a**) as colorless solid. Retention time in HPLC, 9.9 min. $[\alpha]_D^{26}$ +47.1° (*c* 1.00, $CHCl_3$). ^1H NMR (270 MHz) δ=7.4—7.25 (10H, aromatic), 5.85 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.27 (1H, m, $-OCH_2-CH=C\underline{H_2}$), 5.21—5.01 (5H, m, $-OC\underline{H_2}-CH=CH_2$, benzyl CH_2), 4.87 (1H, broad m, H-4), 4.34 (1H, ddd, *J*=8.7, 6.2, 4.5 Hz, H-7), 4.08 (1H, dd, *J*=8.7, 6.2 Hz, H-8), 3.96—3.89 (4H, m, H-5, 8′, $-OC\underline{H_2}-$

CH=CH$_2$), 3.75 (3H, s, OCH$_3$), 3.55 (1H, dd, J=8.7, 1.7, 0.5 Hz, H-6), 2.32 (1H, ddd, J=12.4, 4.2, 0.5 Hz, H-3$_{eq}$), 2.03 (1H, dd, J=12.1, 12.4 Hz, H-3$_{ax}$), 1.38 and 1.24 (each 3H, s, isopropylidene CH$_3$). Found: C, 58.05; H, 6.43%. Calcd for $C_{29}H_{37}O_{11}P\cdot 0.4H_2O$: C, 58.07; H, 6.35%.

11a, yield 10 mg (9% from **8a**) as colorless solid. Retention time in HPLC, 11.2 min. $[\alpha]_D^{26}$ +21.0° (c 1.00, CHCl$_3$). ^{1}H NMR (270 MHz) δ=7.35 (10H, aromatic), 5.87 (1H, m, -OCH$_2$-CH=CH$_2$), 5.28 and 5.18 (each, 1H, m, -OCH$_2$-CH=CH$_2$), 5.15—5.05 (4H, benzyl CH$_2$), 4.81 (1H, m, H-5), 4.27 (1H, ddd, J=8.4, 6.2, 4.4 Hz, H-7), 4.20 (1H, ddd, J=12.1, 4.9, 2.5 Hz, H-4), 4.11 (1H, dd, J=8.6, 6.2 Hz, H-8), 3.97—3.93 (3H, m, H-8′, -OCH$_2$-CH=CH$_2$), 3.77 (3H, s, OCH$_3$), 3.60 (1H, ddd, J=8.4, 3.7, 0.9 Hz, H-6), 2.24 (1H, ddd, J=13.0, 4.9, 0.7 Hz, H-3$_{eq}$), 1.87 (1H, dd, J=13.0, 12.1 Hz, H-3$_{ax}$), 1.36 and 1.23 (each 3H, s, isopropylidene CH$_3$). Found: C, 58.21; H, 6.62%. Calcd for $C_{29}H_{37}O_{11}P\cdot 0.4H_2O$: C, 58.07; H, 6.35%.

Methyl (Allyl 7,8-*O*-Benzylidene-3-deoxy-α-D-*manno*-2-octulopyranosid)onate (12a). To a solution of **8a** (50 mg, 0.17 mmol) in dry THF (1 ml) were added α,α-dimethoxytoluene (50 μl, 0.33 mmol) and CSA (5.5 mg, 24 μmol). The mixture was stirred at room temperature for 2 h and neutralized with aq NaHCO$_3$. After usual work up, the product was purified by silica-gel column chromatography (10 g; CHCl$_3$–acetone, 10 : 1) to give colorless solid; yield 37 mg (56%). $[\alpha]_D^{18}$ +58.8° (c, 1.02, CHCl$_3$). ^{1}H NMR (270 MHz) δ=7.9—7.35 (5H, aromatic), 5.93 and 5.82 (total 1H, s, benzylidene CH), 5.88 (1H, m, -OCH$_2$-CH=CH$_2$), 5.34—5.14 (2H, m, -OCH$_2$-CH=CH$_2$), 4.70—3.80 (7H, m, H-4, 5, 7, 8, 8′, -OCH$_2$-CH=CH$_2$), 3.78 (3H, s, OCH$_3$), 3.7—3.6 (1H, m, H-6), 2.30—2.15 (1H, m, H-3$_{eq}$), 1.94—1.84 (1H, m, H-3$_{ax}$). Found: C, 59.96; H, 6.27%. Calcd for $C_{19}H_{24}O_8$: 59.99; H, 6.36%.

Methyl [Allyl 4-*O*-[Bis(benzyloxy)phosphinoyl]-3-deoxy-α-D-*manno*-2-octulopyranosid]onate (15a) and Methyl [Allyl 5-*O*-[Bis(benzyloxy)phosphinoyl]-3-deoxy-α-D-*manno*-2-octulopyranosid]onate (16a). A suspension of **12a** (58 mg, 0.15 mmol) and 1*H*-tetrazole (21 mg, 0.31 mmol) in dry CH$_2$Cl$_2$ (2 ml) and dry CH$_3$CN (0.2 ml) was cooled to −35 °C under Ar atmosphere. To this cooled mixture was added a solution of dibenzyl diisopropylphosphoramidite (80 mg, 0.23 mmol) in dry CH$_2$Cl$_2$ (270 μl) with stirring. After 2 h, a solution of the amidite (40 mg, 0.12 mmol) was added and stirring was further continued for 1 h. After addition of mCPBA (61 mg, 0.35 mmol), the mixture was stirred for 5 min and then worked up as described above for the preparation of **10a** and **11a**. Column chromatography on silica gel (4 g; CHCl$_3$–acetone, 12 : 1) gave a mixture of **13a** and **14a** as solid, which was dissolved in CH$_2$Cl$_2$ (3 ml) and treated with TFA (150 μl) containing 5% of water under ice-cooling for 30 min. The mixture was worked up as described above and the products were separated by HPLC: Cosmosil 5C18 (16.7×250 mm), 40—50% CH$_3$CN (linear gradient, 1% min^{-1}), 8.0 ml min^{-1}.

15a: Resinous solid; yield 32 mg (38%). Retention time in HPLC under above conditions, 13.8 min. $[\alpha]_D^{20}$ +58.2° (c 1.00, CHCl$_3$). ^{1}H NMR (270 MHz) δ=7.35 (10H, aromatic), 5.85 (1H, m, -OCH$_2$-CH=CH$_2$), 5.25 and 5.16 (each 1H, m, -OCH$_2$-CH=CH$_2$), 5.10—4.98 (4H, benzyl CH$_2$), 4.70 (1H, broad m, H-4), 4.14 (1H, m, H-5), 4.02 (1H, m, H-7), 3.96 and 3.91 (each 1H, m, -OCH$_2$-CH=CH$_2$), 3.81 (1H, m, H-8), 3.75 (3H, s, OCH$_3$), 3.75 (1H, m, H-8′), 3.62 (1H, dd, J=7.2, 1.0 Hz, H-6), 2.25—2.05 (2H, m, H-3$_{ax\ and\ eq}$). Found: C, 55.79; H, 6.16%. Calcd for $C_{26}H_{33}O_{11}P\cdot 0.4H_2O$: C, 55.79; H, 6.09%.

16a: Resinous solid; yield 17 mg (20%). Retention time in HPLC, 15.8 min. $[\alpha]_D^{20}$ +59.6° (c 1.10, CHCl$_3$). ^{1}H NMR (400 MHz) δ=7.27 (10H, aromatic), 5.79 (1H, m, -OCH$_2$-CH=CH$_2$), 5.20 and 5.08 (each 1H, m, -OCH$_2$-CH=CH$_2$), 5.05—4.95 (4H, benzyl CH$_2$), 4.74 (1H, dd, J=2.4 Hz, $J_{H,P}$=9.4 Hz, H-5), 4.13 (1H, m, J=12.4, 4.6, 2.4, 2.4 Hz, H-4), 3.94 and 3.82 (each 1H, m, -OCH$_2$-CH=CH$_2$), 3.82—3.75 (2H, m, H-7, 8), 3.70 (3H, s, OCH$_3$), 3.67—3.62 (2H, m, H-6, 8′) 2.15 (1H, dd, J=12.4, 4.6 Hz, H-3$_{eq}$), 1.75 (1H, dd, J=12.4, 12.4 Hz, H-3$_{ax}$). Found: C, 55.99; H, 6.22%. Calcd for $C_{26}H_{33}O_{11}P\cdot 0.3H_2O$: C, 55.97; H, 6.07%.

Allyl 3-Deoxy-4-*O*-phosphono-α-D-*manno*-2-octulopyranosidonic Acid Diammonium Salt (2a). Compound **15a** (30 mg, 54 μmol) was dissolved in dry CH$_2$Cl$_2$ (2 ml) and treated with TMS bromide (43 μl, 0.33 mmol) at room temperature for 10 min. After evaporation of the mixture, the residue was lyophilized from dioxane and suspended in water (1.5 ml). The mixture was stirred with 1 M NaOH (216 μl, 216 μmol) at room temperature for 35 min and then neutralized with acetic acid, and lyophilized. The crude product was purified by HPLC: TSK-GEL DEAE-5PW (21.5×150 mm), 0.2 M ammonium formate, 7.5 ml min^{-1}. The peak with retention time of 8.4 min was collected and lyophilized to give a resinous solid; yield 19 mg (91%). Retention time in the ion-pair HPLC, 7.3 min. $[\alpha]_D^{15}$ +57.7° (c 1.00, H$_2$O). ^{1}H NMR (400 MHz, D$_2$O) δ=5.95 (1H, m, -OCH$_2$-CH=CH$_2$), 5.34 and 5.21 (each 1H, m, -OCH$_2$-CH=CH$_2$), 4.50 (1H, broad m, H-4), 4.18 (1H, broad, s, H-5), 3.97—3.90 (3H, m, H-7, 8, -OCH$_2$-CH=CH$_2$), 3.82 (1H, m, -OCH$_2$-CH=CH$_2$), 3.65—3.60 (2H, m, H-6, 8′), 2.16 (1H, dd, J=12.7, 4.4 Hz, H-3$_{eq}$), 1.92 (1H, dd, J=12.7, 12.7 Hz, H-3$_{ax}$). High resolution FAB-MS (negative). Found: m/z 357.0592. Calcd for $C_{11}H_{18}O_{11}P$: M−H, 357.0587.

Allyl 3-Deoxy-5-*O*-phosphono-α-D-*manno*-2-octulopyranosidonic Acid Diammonium Salt (3a). Compound **16a** (32 mg, 58 μmol) was treated successively with TMS bromide (48 μl, 0.35 mmol) and 1 M NaOH (174 μl, 174 μmol) as described above for **2a**. The crude product was purified by HPLC with the same column and solvent that used for **2a**: The peak with retention time of 9.6 min with a flow rate of 8.0 ml min^{-1} was collected and lyophilized to give resinous solid: Yield 18 mg (80%). Retention time in the ion-pair HPLC, 16.6 min. $[\alpha]_D^{15}$ +52.5° (c 1.00, H$_2$O). ^{1}H NMR (400 MHz, D$_2$O) δ=5.95 (1H, m, -OCH$_2$-CH=CH$_2$), 5.32 and 5.21 (each 1H, m, -OCH$_2$-CH=CH$_2$), 4.49 (1H, dd, J=2.6 Hz, $J_{H,P}$=9.2 Hz, H-5), 4.14 (1H, ddd, J=12.5, 4.8, 2.6 Hz, H-4), 3.96—3.92 (2H, m, H-7, 8), 3.90 and 3.82 (each 1H, m, -OCH$_2$-CH=CH$_2$), 3.63 (1H, dd, J=12.1, 7.1 Hz, H-8′), 3.59 (1H, d, J=8.2 Hz, H-6), 2.05 (1H, dd, J=12.5, 4.8 Hz, H-3$_{eq}$), 1.86 (1H, dd, J=12.5, 12.5 Hz, H-3$_{ax}$). High resolution FAB-MS (negative). Found: m/z 357.0552. Calcd for $C_{11}H_{18}O_{11}P$: M−H, 357.0587. Found: C, 29.31; H, 6.79; N, 6.19%. Calcd for $C_{11}H_{25}O_{11}PN_2\cdot 3H_2O$; C, 29.60; H, 7.00; N, 6.28%.

Methyl (Allyl 7,8-*O*-Benzylidene-3-deoxy-β-D-*manno*-2-octulopyranosid)onate (12b). An ice-cooled solution of **6b** (470 mg, 1.26 mmol) in CH$_2$Cl$_2$ (40 ml) was treated with 95% TFA (170 μl) and worked up as described above for the preparation of **8a** to yield **8b** (yield 366 mg, 99%) as resinous solid.

Compound **12b** was prepared from **8b** (144 mg, 0.49 mmol) with action of α,α-dimethoxytoluene (98 μl, 0.65 mmol) and CSA (8.5 mg, 37 μmol) under the same conditions described

above for **12a**. The product was purified by silica-gel column chromatography (20 g; $CHCl_3$–acetone, 10 : 1) to give colorless solid; yield 120 mg (64%). $[\alpha]_D^{20}$ +51.7° (*c* 1.00, $CHCl_3$). ^1H NMR (270 MHz) δ=7.47—7.36 (5H, aromatic), 5.90 and 5.81 (total 1H, s, benzylidene CH), 5.87 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.25 and 5.15 (each 1H, m, $-OCH_2-CH=C\underline{H}_2$), 4.56—3.66 (10H, m, H-4, 5, 7, 8, 8′, OCH_3, $-OC\underline{H}_2-CH=CH_2$), 3.59 (1H, dd, *J*=8.5, 1.2 Hz, H-6), 2.48 (1H, m, H-3_{eq}), 1.96 (1H, m, H-3_{ax}). Found: C, 59.94; H, 6.34%. Calcd for $C_{19}H_{24}O_8$: C, 59.99; H, 6.36%.

Methyl [Allyl 4-*O*-[Bis(benzyloxy)phosphinoyl]-3-deoxy-β-D-*manno*-2-octulopyranosid]onate (15b) and Methyl [Allyl 5-*O*-[Bis(benzyloxy)phosphinoyl]-3-deoxy-β-D-*manno*-2-octulopyranosid]onate (16b). To a cooled suspension of **12b** (142 mg, 0.37 mmol) and 1*H*-tetrazole (65 mg, 0.93 mmol) in dry CH_2Cl_2 (6 ml) and dry CH_3CN (0.6 ml) were added two portions of a solution of dibenzyl diisopropylphosphoramidite (194 mg, 0.56 mmol, and 38 mg, 0.11 mmol) in dry CH_2Cl_2 under the same conditions as described for the synthesis of **15a** and **16a**. Then mCPBA (122 mg, 0.71 mmol) was added to the mixture, and the mixture worked up as described above. Column chromatography on silica gel (7 g; $CHCl_3$–acetone, 12 : 1) gave a mixture of **13b** and **14b** as syrup, which was dissolved in CH_2Cl_2 and treated with aq TFA. The products were separated by HPLC: Cosmosil 5C18 (16.7×250 mm), 55—70% CH_3CN (linear gradient, 1% min^{-1}), 8.0 ml min^{-1}.

15b: Resinous solid; yield 55 mg (27%). Retention time in HPLC under above conditions, 9.7 min. $[\alpha]_D^{18}$ +41.7° (*c* 1.06, $CHCl_3$). ^1H NMR (400 MHz) δ=7.30—7.24 (10H, aromatic), 5.75 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.15 and 5.06 (each 1H, m, $-OCH_2-CH=C\underline{H}_2$), 5.05—4.90 (4H, benzyl CH_2), 4.21 (1H, broad m, H-4), 4.15 (1H, m, $-OC\underline{H}_2-CH=CH_2$), 4.10 (1H, broad s, H-5), 3.92 (1H, broad m, H-7), 3.88—3.78 (2H, H-8, $-OC\underline{H}_2-CH=CH_2$), 3.72 (1H, m, H-8′), 3.66 (3H, s, OCH_3), 3.31 (1H, d, *J*=8.4 Hz, H-6), 2.41 (1H, dd, *J*=12.5, 4.8 Hz, H-3_{eq}), 2.17 (1H, dd, *J*=12.5, 12.5 Hz, H-3_{ax}). Found: C, 56.11; H, 6.03%. Calcd for $C_{26}H_{33}O_{11}P$: C, 56.52; H, 6.02%.

16b: Resinous solid; yield 68 mg (33%). Retention time in HPLC, 15.8 min. $[\alpha]_D^{18}$ +40.5° (*c* 1.10, $CHCl_3$). ^1H NMR (400 MHz) δ=7.30—7.25 (10H, aromatic), 5.78 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.18 and 5.09 (each 1H, m, $-OCH_2-CH=C\underline{H}_2$), 5.05—4.95 (4H, benzyl CH_2), 4.66 (1H, dd, *J*=2.3 Hz, J_{HP}=8.7 Hz, H-5), 4.15 and 3.85 (each 1H, m, $-OC\underline{H}_2-CH=CH_2$), 3.75—3.72 (2H, m, H-8,8′), 3.71 (3H, s, OCH_3), 3.74—3.62 (2H, m, H-4,7), 3.53 (1H, dd, *J*=9.0, 0.9 Hz, H-6), 2.43 (1H, dd, *J*=12.7, 4.7 Hz, H-3_{eq}), 1.85 (1H, dd, *J*=12.7, 12.7 Hz, H-3_{ax}). Found: C, 56.25; H, 6.20%. Calcd for $C_{26}H_{33}O_{11}P$: C, 56.52; H, 6.02%.

Allyl 3-Deoxy-5-*O*-phosphono-α-D-*manno*-2-octulopyranosidonic Acid Diammonium Salt (3b). Compound **16b** (49 mg, 89 μmol) was treated with TMS bromide (70 μl, 0.53 mmol) and 1 M NaOH, and the crude product was purified by HPLC with the same column and solvent that used for **2a**: The peak with retention time of 10.8 min at an elution rate of 8.0 ml min^{-1} was collected and lyophilized to give resinous solid; yield 25 mg (71%). Retention time in ion-pair HPLC, 13.4 min. $[\alpha]_D^5$ +26.0° (*c* 1.00, H_2O). ^1H NMR (400 MHz, D_2O) δ=5.91 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.30 and 5.20 (each 1H, m, $-OCH_2-CH=C\underline{H}_2$), 4.41 (1H, broad d, $J_{H,P}$=8.3 Hz, H-5), 4.19 and 3.94 (each 1H, m, $-OC\underline{H}_2-CH=CH_2$), 3.92 (1H, m, H-7), 3.83—3.80 (2H, m, H-8,8′), 3.77 (1H, m, H-4), 3.75 (1H, d, *J*=9.2 Hz, H-6), 2.40 (1H, dd, *J*=12.1, 4.4 Hz, H-3_{eq}), 1.87 (1H, dd, *J*=12.4, 12.1 Hz, H-3_{ax}). High resolution FAB-MS (negative). Found: *m/z* 337.0595. Calcd for $C_{11}H_{18}O_{11}P$: M−H, 357.0587.

Allyl 3-Deoxy-4-*O*-phosphono-β-D-*manno*-2-octulopyranosidonic Acid Diammonium Salt (2b). To a solution of **15b** (45 mg, 81 mmol) in dry CH_2Cl_2 (1.0 ml) were added pyridine (51 μl, 0.65 mmol), acetic anhydride (31 μl, 0.33 mmol), and 4-dimethylaminopyridine (4.0 mg, 33 μmol). The mixture was stirred at room temperature for 1 h and worked up as usual. The acetylated product (54 mg) was dissolved in dry CH_2Cl_2 and treated with TMS bromide (42 μl, 0.32 mmol) and worked up as described above. The crude product (40 mg) was dissolved in MeOH (2 ml) without purification. To this solution was added 1 M NaOH (400 μl) under ice-cooling, and the mixture was stirred at room temperature for 1 h.

The crude product was purified by HPLC under the same conditions (elution rate, 7.0 ml min^{-1}) as described for **2a**. The peak with retention time of 7.9 min was collected and lyophilized to give a resinous solid; yield 25 mg (79%). Retention time in ion pair HPLC, 7.0 min. $[\alpha]_D^5$ +52.5° (*c* 1.00, H_2O). ^1H NMR (400 MHz, D_2O) δ=5.91 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 5.30 and 5.19 (each, 1H, m, $-OCH_2-CH=C\underline{H}_2$), 4.19 (1H, m, $-OC\underline{H}_2-CH=CH_2$), 4.10 (1H, broad s, H-5), 4.06 (1H, broad m, H-4), 3.95 (1H, m, $-OC\underline{H}_2-CH-CH_2$), 3.91 (1H, ddd, *J*=8.8, 4.4, 1.7 Hz, H-7), 3.87 (1H, dd, *J*=12.1, 4.4 Hz, H-8), 3.73 (1H, dd, *J*=12.1, 1.7 Hz, H-8′), 3.63 (1H, d, *J*=8.8 Hz, H-6), 2.50 (1H, dd, *J*=12.3, 4.6 Hz, H-3_{eq}), 1.88 (1H, dd, *J*=12.3, 12.3 Hz, H-3_{ax}). High resolution FAB-MS (negative). Found: *m/z* 357.0601. Calcd for $C_{11}H_{18}O_{11}P$: M−H, 357.0587.

The authors acknowledge the partial financial support to this work by Yamada Science Foundation and Grant-in-Aid for Scientific Research on Priority Areas Nos. 01607002 and 02250107 from the Ministry of Education, Science, and Culture. Thanks are also due to Dr. B. Ekström, Astra, Sweden, for the generous gift of Kdo ammonium salt used in this work, and to Mr. H. Adachi, Osaka University, for the skillful measurement of high resolution FAB-mass spectra.

19) H. Kunz and W. Sager, *Helv. Chim. Acta*, **68**, 283 (1985).

20) 4,5;7,8-Di-*O*-isopropylidene derivatives of Kdo occupy the $B_{3,6}$ boat conformation, where the empirical rule described in the text is valid concerning $\Delta_{3eq\text{-}3ax}$ values (see Ref. 18). In case of Kdo derivatives which lack the 4,5-*O*-isopropylidene group and are thus expected to occupy the normal $^5C_2$ chair conformation, β-anomers have larger Δ-values than the corresponding α-anomers as described by Unger: F. M. Unger, *Adv. Carbohydr. Chem. Biochem.*, **38**, 323 (1981). This rule for chair-form Kdo applies also to the anomeric pairs of **2**, **3**, **9**, and **16**, respectively, the present assignment of the anomeric configurations being again assured. However, this rule was exceptionally not valid for one anomeric pair, i.e., **10a** and **10b** ($\Delta_{3eq\text{-}3ax}$: **10a**, 0.29; **10b**, 0.27). Presumably, this discrepancy is due to conformational change caused by the presence of the dibenzyl phosphate and the isopropylidene groups.

21) A cyclic phosphate is readily formed under base-catalyzed attack of a neighboring hydroxyl group with concomitant elimination of one of the alkoxy components of a phosphotriester; for example, see note 10) of Ref. 14.

22) Dibenzyl diisopropylphosphoramidite was prepared via (diisopropylamino)dichlorophosphine: Cf. E. Ülmann and J. Engels, *Tetrahedron Lett.*, **27**, 1023 (1986). In brief, benzyl alcohol (505 µl, 2.90 mmol) was added to a stirred solution of (diisopropylamino)dichlorophosphine (294 mg, 1.45 mmol) and *N*,*N*-diisopropylethylamine (300 µl, 2.90 mmol) in freshly distilled THF (4 ml) at 0 °C. The mixture was stirred at room temperature for 1.5 h, filtered, and the filtrate evaporated in vacuo to give a colorless syrup (499 mg), which gave one dominant spot on silica-gel TLC ($CHCl_3$–acetone 5 : 1, R_f 0.90) and very weak several other spots. The syrup was used without further purification.

23) W. Bannwarth and A. Truzeciak, *Helv. Chim. Acta*, **70**, 175 (1987).

24) K. L. Yu and B. Fraser-Reid, *Tetrahedron Lett.*, **29**, 979 (1988).

25) In the ^1H NMR spectra of many phosphorylated compounds prepared in this study, the protons on the carbon atoms bearing the phosphorylated hydroxyl groups appeared as broad signals with fine splitting but distinct $^3J_{H,P}$ values were not always obtained.

26) P. M. Chouinard and P. A. Bartlett, *J. Org. Chem.*, **51**, 75 (1986).

27) H. Metz, *Naturwissenschaften*, **48**, 567 (1961).

28) This explanation is based on the assumption that the boat-like conformation favorable for the hydrogen bonding was retained even after cleavage of the benzyl esters. However, we can not exclude the possibility that the allyl group was lost during the reaction with TMS bromide under not yet understood participation of the phosphate moiety.

29) Addition of *N*,*N*-diisopropylethylamine at higher temperature resulted in considerable cleavage of the isopropylidene groups.

Asymmetric Dipolar Cycloaddition of Nitrile Oxides to the α,β-Unsaturated Esters Bearing an Imidazolidine Chiral Controller at the β-Position

(Received June 26, 1991)

Some α,β-unsaturated esters bearing an imidazolidine chiral controller at the β-position were employed in the asymmetric cycloaddition to nitrile oxides. Regio- and diastereoselectivities were both poor when the chiral controller was a perhydropyrrolo[1,2-*c*]imidazol-3-yl auxiliary, while the reaction of the esters bearing a C_2-symmetric imidazolidine chiral controller was exclusively regioselective or diastereoselective depending upon the nature of *N*-substituent. The transition state was briefly discussed.

Nitrile oxide is one of the 1,3-dipoles with high synthetic potential[1] because 1) their ready cycloadditions with a wide variety of dipolarophiles (electron-deficient, eletron-rich, and nonactivated types) produce 2-isoxazolines or isoxazoles bearing various functional groups, 2) these cycloadditions take place in excellent yields in a highly stereospecific and often regioselective manner, 3) the 2-isoxazolines and isoxazoles can be converted to a variety of synthetically useful functional building blocks such as β-hydroxy ketones, β-amino alcohols, α,β-unsaturated ketones, and so on.

This is why the researches directing to the development of asymmetric versions of nitrile oxide cycloaddition are now enthusiastically under way. Since there are so far few reported examples for the catalyzed nitrile oxide cycloaddition, the diastereoselective reaction by the use of chiral dipolarophiles is the only effective way to establish the asymmetric reaction. The acrylates and crotonates derived from readily available simple chiral alcohols have shown low diastereoselectivities in the cycloaddition with nitrile oxides.[2] Several recent reports presented the highly diastereoselective asymmetric cycloaddition of nitrile oxides employing the Oppolzer's sultam[3] or the chiral auxiliary derived from the Kemp's triacid.[4] However, the auxiliary-controlled asymmetric cycloaddition of nitrile oxides is still of current interest.

We have recently developed the highly diastereoselective asymmetric cycloaddition of azomethine ylide with the α,β-unsaturated esters bearing a 2-imidazolidinyl or 2-oxazolidinyl chiral controller at the β-position.[5] In the present paper, these chiral α,β-unsaturated esters were successfully applied to the asymmetric cycloaddition of nitrile oxides.

Results and Discussion

Diastereoselectivity and Regioselectivity. Reaction of benzonitrile oxide (**1**) with the α,β-unsaturated ester **3**[5a,b] bearing the (3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl chiral controller at the β-position, in tetrahydrofuran (THF) at room temperature, produced a mixture of two regioisomeric cycloadducts **A** and **A'**, where **1** had been generated from benzohydroximoyl chloride and triethylamine (Scheme 1). The cycloadduct mixture **A** and **A'** was converted into the acetal mixture **4** and **4'** by treatment with refluxing methanol in the presence of concentrated sulfuric acid because separation of **A** and **A'** from each other or from the dimer of **1** through column chromatography was unsuccessful. The resulting acetals **4** (38%) and **4'** (14%) were separated from each other by column chromatography on silica gel (Table 1).

The relative stereochemistry and regiochemistry of **4** and **4'** were unambiguously determined by ^{1}H NMR analysis. The observed small coupling constants for J_{4-5} (4.4 Hz for both **4** and **4'**) indicated the trans relationship of H-4 and H-5. Based on the chemical shifts as well as the coupling patterns of H-4 and H-5, their regiochemistry was confirmed (the 4-ester **4**: δ=4.43

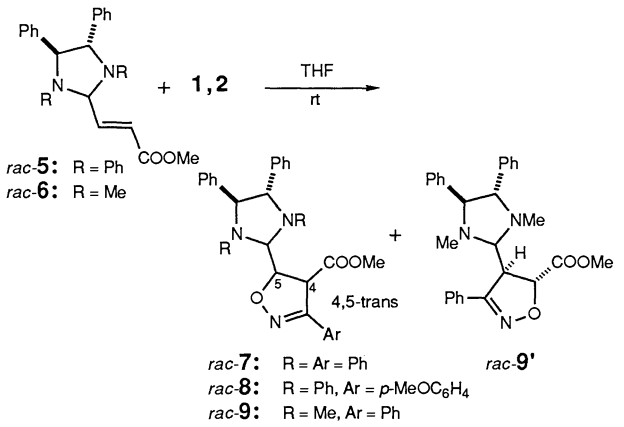
a) All reactions were performed in THF at room temperature. Nitrile oxides **1**, **2** were generated from the corresponding hydroximoyl chlorides and triethylamine. b) Isolated yield. c) Determined by ^{1}H NMR spectrum. d) Determined by HPLC (column: Chiral pack OD). e) Recovered **5**: 39%.



Scheme 2.

(d, H-4) and 5.01 (dd, H-5); the 5-ester **4′**: 4.29 (dd, H-4) and 5.32 (d, H-5)).

The major product **4** showed a positive optical rotation ($[\alpha]_D^{24}$=+65.9° (*c* 0.73, $CHCl_3$)) and its enantiomeric excess was determined to be 40% ee by the analysis on a high performance liquid chromatography (HPLC) using a chiral column (Daicel, Chiral pack OD). The absolute configuration of the major enantiomer of **4** was assigned to be 4*S*,5*S* by comparison of the optical rotation with that of the authentic derivative as discussed below. The minor product **4′** was found to be optically pure on the basis of the chiral HPLC analysis, whose optical rotation was recorded as $[\alpha]_D^{22}$=+133.5° (*c* 0.37, $CHCl_3$).

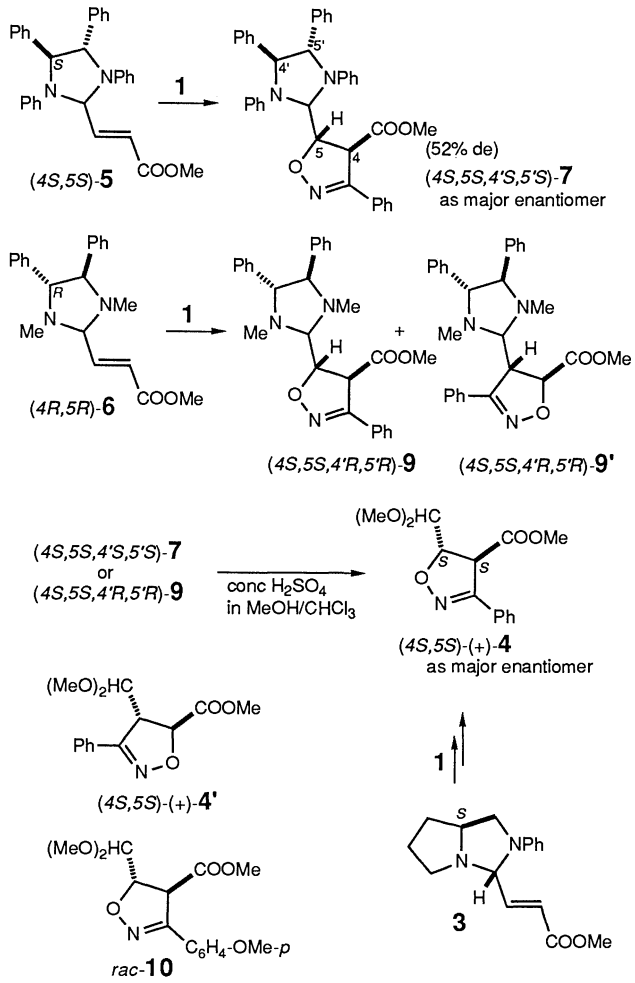
The α,β-unsaturated ester *rac*-**5**[5c)] bearing the 1,3,4,5-tetraphenyl-2-imidazolidinyl chiral controller at the β-position, hereafter referred to as the *N*-phenyl-substituted ester, was applied to the cycloaddition with nitrile oxide **1** at room temperature (Scheme 2). This reaction proceeded in an absolutely regioselective manner to produce a mixture of two diastereomeric 2-isoxazoline-4-carboxylates *rac*-**7** in 52% yield as the sole regioisomer (Table 1, Entry 2). This exclusively high regioselectivity was surprising because the nitrile oxide cycloaddition with α,β-unsaturated ester bearing a β-alkyl substituent is usually very poor in regioselectivity.[1a)] It is found that steric factor may be responsible for this exclusive selectivity, as mentioned later in the discussion of transition state. The diastereoselectivity of the reaction forming *rac*-**7** was only 74:26 (by ^{1}H NMR).

Since the starting α,β-unsaturated ester *rac*-**5** was partly recovered (39% yield) in the above reaction using 2-equivalents of **1**, a large excess amount of nitrile oxide **1** (8 equivalents) was used and *rac*-**7** was obtained in 71% yield (ds 76:24). A similar result was obtained in the reaction of *rac*-**5** with *p*-methoxybenzonitrile oxide **2** (Entry 4).

The reaction of **1** with the α,β-unsaturated ester *rac*-**6**[5c)] bearing the 1,3-dimethyl-4,5-diphenyl-2-imidazolidinyl chiral controller at the β-position, hereafter referred to as the *N*-methyl-substituted ester, made a striking contrast against the aforementioned reaction using the *N*-phenyl-substituted ester *rac*-**5**. Although both yield and regioselectivity were poor (the 2-isoxazoline-4-carboxylate isomer *rac*-**9**: 29%; the 2-isoxazoline-5-carboxylate one *rac*-**9′**: 10%), these regioisomers *rac*-**9** and *rac*-**9′**, separated from each other through silica-gel column chromatography, were found to be both absolutely pure diastereomers (Scheme 2 and Table 1, Entry 5).

Assignment of Absolute Configurations. The 76:24 diastereomeric mixture of **7** obtained from **1** and the optically pure (4*S*,5*S*)-(−)-**5** was treated with methanol in chloroform together with concentrated sulfuric acid to give **4** (a 75:25 mixture of enantiomers by chiral HPLC, $[\alpha]_D^{24}$=+82.8° (*c* 0.61, $CHCl_3$)) in quantitative yield (Scheme 3). The major enantiomer of so obtained 2-isoxazoline-4-carboxylate **4** was found to be identical with the major enantiomer derived from the cycloadduct **A** (Scheme 1). As a result, the same diastereotopic faces of the α,β-unsaturated ester moiety of **3** and (4*S*,5*S*)-(−)-**5** were preferred by nitrile oxide **1**.

On the other hand, the cycloadducts (+)-**9** and (+)-**9′**, obtained as the sole diastereomers from **1** and the optically pure (4*R*,5*R*)-(+)-**6**, were similarly transformed to (+)-**4** and (+)-**4′** in 73% and 96% yields, respectively.



Scheme 3.

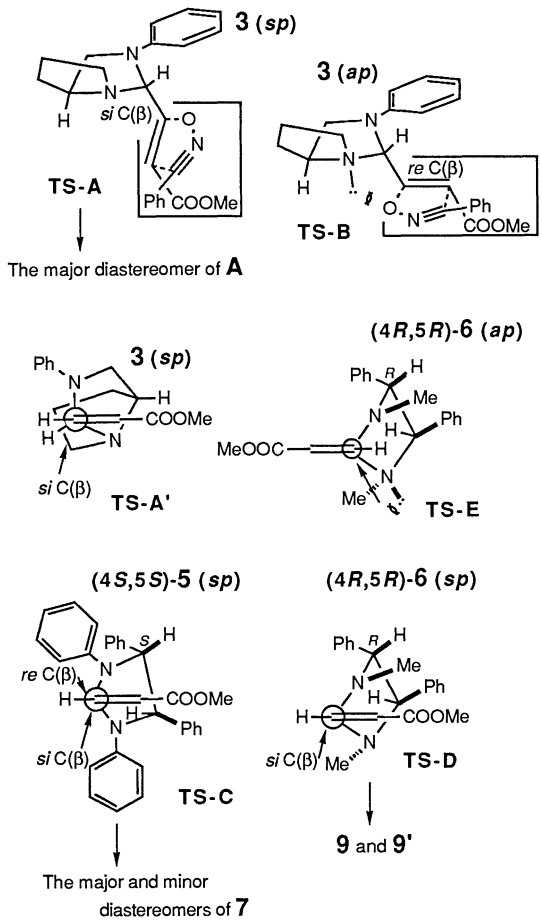


Fig. 1. Transition states for the cycloaddition of nitrile oxide **1** to **3**, **5**, or **6**.

The absolute configurations of the 2-isoxazoline-4-carboxylate skeleton of cycloadducts **A**, **7**, and **9** derived from the optically pure α,β-unsaturated esters **3**, (4*S*,5*S*)-(−)-**5**, and (4*R*,5*R*)-(+)-**6** were definitely assigned on the basis of the X-ray crystallography of *rac*-**9** and the optical rotations of 2-isoxazoline-4-carboxylates **4** derived from them. Thus, the 2-isoxazoline-4-carboxylate regioisomer *rac*-**9** derived from *rac*-**6** was assigned to be 4*RS*,5*RS*,4'*RS*,5'*SR* relative stereochemistry by X-ray crystallography. Accordingly, the 2-isoxazoline-4-carboxylate (+)-**4**, derived from *N*-methyl-substituted ester (4*R*,5*R*)-(+)-**6** via the optically pure (+)-**9**, was determined to be the 4*S*,5*S* enantiomer; the 2-isoxazoline-4-carboxylate (+)-**4**, produced as the major diastereomer from *N*-phenyl-substituted ester (4*S*,5*S*)-(−)-**5** via **7**, has the 4*S*,5*S* configuration.

Transition State. It is now clear, in the cycloaddition of nitrile oxide **1** with the α,β-unsaturated esters **5** and **6** bearing a C_2-symmetric 2-imidazolidinyl chiral controller, that the different diastereotopic faces were predominantly selected between *N*-phenyl-substituted ester **5** and *N*-methyl-substituted one **6**. The degree of diastereoselectivity also depended upon the nature of *N*-substituents of the chiral controller.

The result that the *si* C(β)-face attack of **1** to the α,β-unsaturated ester moiety of **3** was the major reaction path is explained as follows. Although the *re* C(β)-face of the thermodynamically more stable antiperiplanar conformer **3** (*ap*) is sterically open to the attack by **1**, the electrostatic repulsion working between the negative oxygen atom of **1** and the unshared electron pair at the bridgehead nitrogen of **3** would disfavor this approach (**TS-B**, Fig. 1). Accordingly, the *si* C(β)-face attack to the thermodynamically less stable synperiplanar conformer of **3** became the major approach (**TS-A**). Since the terminal oxygen atom of **1** is not so bulky, the occurrence of competitive attack of the *re* C(β)-face of **3** (*sp*) reducing the diastereoselectivity is not surprising. The partial contribution of the *re* C(β)-face attack in **TS-B** would be also a reason for the poor diastereoselectivity.

Another explanation is possible by application of the Kozikowski's "antiperiplanar effect" rule[6] or the Houk's "inside alkoxy effect" rule.[7] Three substituents are attaching to C-3 of the imidazolidine ring of **3**, a phenyl-substituted nitrogen, a bridgehead nitrogen, and a

hydrogen. The anilino type nitrogen is the bulkiest so that it occupies anti position according to the Houk's rule. The second bulky bridgehead nitrogen is inside and the smallest hydrogen is outside positions (**TS-A'**). Therefore, the nitrile oxide cycloaddition has occurred more favorably at the *si* C(β)-face.

Absolute configurations of the regioisomeric 2-isoxazoline-5-carboxylate cycloadduct **A'** and (+)-**9'** could not be assigned on the basis of spectral data and chemical conversion. In the transition state producing the cycloadduct **A'** nitrile oxide **1** has to access to the α,β-unsaturated ester moiety of **3** with the bulky phenyl substituent directing toward the bulky chiral auxiliary. As a result the only possible attack of **1** may have been at the *si* C(β)-face of **3** (*sp*) conformer, the 2-isoxazoline-5-carboxylate ring of (+)-**4'** derived from the minor regioisomers **A'** and (+)-**9'** being tentatively assigned to be 4*S*,5*S* enantiomer.

As previously reported,[5c] the perhydroimidazole ring of the *N*-phenyl-substituted ester **5** is almost flat in solution and both phenyl planes lie in the same plane as the imidazolidine ring. Since these *N*-phenyl substituents become serious steric obstacles to the approach of **1** in the transition state through which the corresponding 2-isoxazoline-5-carboxylate regioisomer is produced, the reaction of **1** with **5** produced 2-isoxazoline-4-carboxylate **7** as the exclusively regioselective cycloadduct. In **TS-C**, where two identical nitrogen substituents are located at C-2 of the imidazolidine ring of (4*S*,5*S*)-**5**, the *si* C(β)-face attack by **1** seems to be a little more favored than the *re* C(β)-face attack. The 76:24 ratio of observed diastereoselectivity is reasonable.

On the other hand, the *re* C(β)-face attack of **1** to the synperiplanar conformer of *N*-methyl-substituted ester (4*R*,5*R*)-**6** (*sp*) was totally inhibited by the top-lying *N*-methyl substituent so that the *si* C(β)-face attacks of **1** leading to (4*S*,5*S*,4'*R*,5'*R*)-**9** and (4*S*,5*S*,4'*R*,5'*R*)-**9'** became the only observed reaction (**TS-D**). Participation of the thermodynamically more stable antiperiplanar conformer **6** (*ap*) was again disfavored because of the aforementioned electrostatic repulsion (**TS-E**).

Experimental

General. Melting points were recorded on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with JASCO IRA-1 and A-702 spectrometers. ^{1}H and ^{13}C NMR spectra were recorded with Hitachi R-40 (^{1}H NMR: 90 MHz) and GSX-270 (270 MHz for ^{1}H NMR and 67.94 MHz for ^{13}C NMR) instruments. Chemical shifts are reported in parts per million downfield (δ) from internal tetramethylsilane. Mass spectra and high resolution mass spectra (HRMS) were recorded with a JEOL-01SG-2 spectrometer operating at an ionization energy of 70 eV. Elemental analyses were performed with a Hitachi 026 CHN analyzer. Optical rotations were recorded with a Horiba SEPA-200 polarimeter. The X-ray diffraction data were collected with graphite-monochromatized Mo $K\alpha$ radiation (λ=0.71069). Structure analyses were performed with a TEXSAN system.[8] The structure was solved by the MITHRIL[9] direct method and defined by full-matrix least squares. For preparative column chromatography, Wakogel C-200, Wako C-300, and Merck Silica gel 60 were employed. Flash chromatography was performed with an Eyera EF-10 apparatus on a 20×180 mm column packed with 0.04—0.063 mm silica gel 60.

Reaction of 1 with 3 Followed by Acetal Exchange Leading to 4 and 4'. To a solution of Et_3N (0.101 g, 1 mmol) in dry THF (4 ml) were added benzohydroximoyl chloride (0.156 g, 1 mmol) and **3** (0.136 g, 0.5 mmol) in that order. The mixture was stirred for 24 h, poured into saturated aqueous NaCl (100 ml), and extracted with Et_2O (30 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.26 g) was dissolved in MeOH (10 ml) containing concentrated H_2SO_4 (1 ml). The mixture was refluxed for 24 h, neutralized with saturated aqueous $NaHCO_3$ and extracted with CH_2Cl_2 (30 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue was chromatographed (silica gel) with hexane–EtOAc (4:1 v/v) to give **4** (0.054 g, 38%) and **4'** (0.019 g, 14%). The major product **4** was found to be a 70:30 mixture of 4*S*,5*S* and 4*R*,5*R* enantiomers (HPLC, Daicel, Chiral pack OD, hexane–isopropyl alcohol (9:1 v/v) as an eluent, $[\alpha]_D^{24}$=+65.9° (*c* 0.73, $CHCl_3$)).

Methyl *trans*-5-Dimethoxymethyl-3-phenyl-2-isoxazoline-4-carboxylate (4): Colorless liquid; IR (neat) 2935, 1736, 1432, 1336, 1260, 1192, 1124, 1064, 892, and 756 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.47, 3.49 (each 3H, each s, 2×OMe), 3.70 (3H, s, COOMe), 4.43 (1H, d, $J_{4\text{-}5}$=4.4 Hz, H-4), 4.58 (1H, d, $J_{CH\text{-}5}$=5.5 Hz, 5-CH), 5.01 (1H, dd, $J_{5\text{-}4}$=5.5 and $J_{5\text{-}CH}$=4.4 Hz, H-5), 7.39—7.43, and 7.69—7.76 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=53.00 (C-4), 54.18, 55.55, 56.54 (2×OMe and COOMe), 85.38 (C-5), 103.65 (5-CH), 127.09, 128.25, 128.74, 130.33 (each Ph), 154.38 (C-3), and 169.76 (COOMe); MS *m*/*z* (rel intensity, %) 279 (M^+, 2), 76 (3), 75 (base peak). HRMS Found: *m*/*z* 279.1103. Calcd for $C_{14}H_{17}NO_5$: M, 279.1107.

Methyl *trans*-4-Dimethoxymethyl-3-phenyl-2-isoxazoline-5-carboxylate (4'): Colorless liquid; IR (neat) 3919, 1728, 1427, 1332, 1192, 1108, 1060, 880, 756, and 684 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.32, 3.37 (each 3H, each s, 2×OMe), 3.80 (3H, s, COOMe), 4.29 (1H, t, $J_{4\text{-}5}$=$J_{4\text{-}CH}$=4.4 Hz, H-4), 4.55 (1H, d, $J_{CH\text{-}4}$=4.4 Hz, 4-CH), 5.32 (1H, d, $J_{5\text{-}4}$=4.4 Hz, H-5), and 7.40–7.75 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=52.89 (C-4), 55.62, 55.75, 55.98 (2×OMe, COOMe), 79.75 (C-5), 102.95 (4-CH), 127.44, 128.36, 128.75, 130.36 (each Ph), 156.14 (C-3), and 170.87 (COOMe); MS *m*/*z* (rel intensity, %) 279 (M^+, 6), 160 (4), 76 (3), and 75 (base peak). Found: C, 60.36; H, 6.08; N, 5.11%. Calcd for $C_{14}H_{17}NO_5$: C, 60.19; H, 6.14; N, 5.02%.

Reaction of 1 with *rac*-5 Leading to *rac*-7. Triethylamine (0.14 ml, 1 mmol) was added dropwise to a solution of benzohydroximoyl chloride (0.156 g, 1 mmol) in THF (8 ml) under nitrogen at room temperature. After 5 min, the solution of *rac*-**5** (0.458 g, 1 mmol) in THF (2 ml) was added. The mixture was stirred at room temperature for 16 h, poured into saturated aqueous NH_4Cl, and then extracted with Et_2O (20 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.367 g) was chromatographed (silica gel) with hexane–EtOAc (3:1 v/v) to give *rac*-**7** (0.15 g, 52%) and *rac*-**5** (0.09 g, 39%). Compound *rac*-**7** was found to be a 74:26 mixture of (4*RS*,5*RS*,4'*RS*,5'*RS*)-**7** and

(4*RS*,5*RS*,4′*SR*,5′*SR*)-**7** (by ^{1}H NMR).

From a similar reaction of **1** with optically pure (4*S*,5*S*)-**5**, a 76:24 diastereomeric mixture of (4*S*,5*S*,4′*S*,5′*S*)-**7** and (4*R*,5*R*,4′*S*,5′*S*)-**7** was obtained (by ^{1}H NMR).

Methyl *trans*-3-Phenyl-5-(*trans*-1,3,4,5-tetraphenylperhydro-2-imidazolyl)-2-isoxazoline-4-carboxylate (*rac*-**7**, a 74:26 mixture of two diastereomers): Colorless prisms (MeOH); mp 97—101 °C; IR(KBr) 3000, 1732, 1589, 1491, 1252, 984, 872, 744, and 684 cm^{-1}; ^{1}H NMR ($CDCl_3$) (4*RS*,5*RS*,4′*RS*,5′*RS*)-**7**: δ=3.63 (3H, s, COOMe), 4.67 (2H, d, J_{4-5}=$J_{4'-5'}$=8.1 Hz, H-4 and H-4′), 5.06 (1H, d, $J_{5'-4'}$=8.1 Hz, H-5′), 5.52 (1H, dd, J_{5-4}=8.1 and $J_{5-2'}$=3.3 Hz, H-5), 6.16 (1H, d, $J_{2'-5}$=3.3Hz, H-2′), 6.63—7.55 (25H, m, 5×Ph); (4*RS*,5*RS*,4′*SR*,5′*SR*)-**7**: δ=3.53 (3H, s, COOMe), 4.73 (1H, d, $J_{4'-5'}$=8.1 Hz, H-4′), 4.84 (1H, d, J_{4-5}=6.2 Hz, H-4), 5.02 (1H, d, $J_{5'-4'}$=8.1 Hz, H-5′), 5.54 (1H, dd, J_{5-4}=6.2 and $J_{5-2'}$=2.7 Hz, H-5), and 6.14 (1H, d, $J_{2'-5}$=2.7 Hz, H-2′). Other signals are overlapping with those of (4*RS*,5*RS*,4′*SR*,5′*SR*)-**7**. ^{13}C NMR ($CDCl_3$) (4*RS*,5*RS*,4′*RS*,5′*RS*)-**7**: δ=52.97 (C-4), 55.71 (COOMe), 70.58 (C-5), 75.10, 80.92 (C-4′ and C-5′), 87.47 (C-2′), 114.90, 119.41, 120.27, 120.85, 126.48, 126.68, 126.85, 127.02, 127.66, 127.75, 127.86, 128.55, 128.88, 129.25, 130.15, 138.74, 139.88, 143.13, 147.89 (each Ph), 154.53 (C-3), and 169.70 (COOMe); (4*RS*,5*RS*,4′*SR*,5′*SR*)-**7**: δ=52.83 (C-4), 69.64 (C-5), 74.44, 80.92 (C-4′ and C-5′), 88.02 (C-2′), 114.77, 119.26, 120.54, 120.74, 130.19, 138.51, 139.43, 142.59, 147.48 (each Ph), 154.28 (C-3), and 169.34 (COOMe). Other signals are overlapping with those of (4*RS*,5*RS*,4′*SR*,5′*SR*)-**7**. MS (20 eV) *m*/*z* (rel intensity, %) 548 (M^+—MeO, 0.2), 377 (4), 376 (30), 375 (base peak), 279 (2), 220 (1), 195 (1), 194 (2), 180 (4), and 103 (1). Found: C, 78.59; H, 5.86; N, 7.10%. Calcd for $C_{38}H_{33}N_3O_3$: C, 78.73; H, 5.74; N, 7.25%.

Reaction of 2 with *rac*-5 Leading to *rac*-8. Triethylamine (0.14 ml, 1 mmol) was added dropwise to a solution of *p*-methoxybenzohydroximoyl chloride (0.186 g, 1 mmol) in THF (4 ml) under nitrogen at 0 °C. After 5 min, the solution of *rac*-**5** (0.23 g, 0.5 mmol) in THF (2 ml) was added. The mixture was stirred at room temperature for 24 h, poured into saturated aqueous NH_4Cl, and then extracted with Et_2O (20 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.396 g) was chromatographed (silica gel) with hexane–EtOAc (10:1 v/v) to give *rac*-**8** (0.194 g, 64%). Compound *rac*-**8** was assigned, by analogy with **7**, to be a 70:30 mixture of (4*RS*,5*RS*,4′*RS*,5′*RS*)-**8** and (4*RS*,5*RS*,4′*SR*,5′*SR*)-**8** (by ^{1}H NMR).

Methyl *trans*-3-(*p*-Methoxyphenyl)-5-(*trans*-1,3,4,5-tetraphenylperhydro-2-imidazolyl)-2-isoxazoline-4-carboxylate (*rac*-**8**, a 70:30 mixture of two diastereomers): Colorless prisms (MeOH); mp 92—94 °C; IR (KBr) 2850, 1700, 1568, 1476, 1232, 875, 820, 732, and 680 cm^{-1}, ^{1}H NMR ($CDCl_3$) major diastereomer: δ=3.61 (3H, s, COOMe), 3.76 (3H, s, OMe), 4.63 (2H, d, $J_{4'-5'}$=7.7 Hz, H-4′), 4.66 (1H, d, J_{4-5}=8.4 Hz, H-4), 5.06 (1H, d, $J_{5'-4'}$=7.7 Hz, H-5′), 5.49 (1H, dd, J_{5-4}=8.4 and $J_{5-2'}$=2.7 Hz, H-5), 6.15 (1H, d, $J_{2'-5}$=2.7 Hz, H-2′), and 6.66—7.50 (24H, m, Ar); minor diastereomer: δ=3.51 (3H, s, COOMe), 3.77 (3H, s, OMe), 4.73 (1H, d, $J_{4'-5'}$=7.7 Hz, H-4′), 4.82 (1H, d, J_{4-5}=5.9 Hz, H-4), and 5.01 (1H, d, $J_{5'-4'}$=7.7 Hz, H-5′). Other signals are overlapping with those of the major diastereomer. ^{13}C NMR ($CDCl_3$) major diastereomer: δ=52.94 (C-4), 55.26, 55.97 (OMe and COOMe), 70.54 (C-5), 75.09 and 79.93 (C-4′ and C-5′), 87.20 (C-2′), 113.99, 114.87, 120.31, 120.74, 120.85, 126.71, 127.64, 127.74, 127.89, 128.43, 128.57, 128.74, 128.87, 129.08, 129.23, 138.77, 139.92, 143.19, 147.91 (each Ar), 154.06 (C-3), 161.06 (Ar), and 169.83 (COOMe); minor diastereomer: δ=52.80 (C-4), 69.62 (C-5), 74.44 and 80.95 (C-4′ and C-5′), 87.72 (C-2′), 113.93, 114.76, 119.32, 138.54, 139.48, 142.63, and 147.54 (each Ar), 153.80 (C-3), 161.12 (Ar), and 169.47 (COOMe). Other signals are overlapping with those of the major diastereomer. MS (20 eV) *m*/*z* (rel intensity, %) 607 (M^+—2, 0.2), 376 (32), 375 (base peak), 233 (10), 196 (13), and 180 (25). Found: C, 76.69; H, 5.95; N, 6.76%. Calcd for $C_{39}H_{35}N_3O_4$: C, 76.82; H, 5.79; N, 6.89%.

Reaction of 1 with *rac*-6 Leading to *rac*-9 and *rac*-9′. Triethylamine (0.35 ml, 2.5 mmol) was added dropwise to a solution of benzohydroximoyl chloride (0.389 g, 2.5 mmol) in THF (8 ml) under nitrogen at room temperature. After 5 min, the solution of *rac*-**6** (0.168 g, 0.5 mmol) in THF (2 ml) was added. The mixture was stirred at room temperature for 23 h, poured into saturated aqueous NH_4Cl, and then extracted with Et_2O (20 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.455 g) was chromatographed (silica gel) with hexane–EtOAc (20:1 v/v) to give *rac*-**9** (0.066 g, 29%) and *rac*-**9′** (0.023 g, 10%).

From a similar reaction of **1** with optically pure (4*R*,5*R*)-**6**, (4*S*,5*S*,4′*R*,5′*R*)-**9** and (4*S*,5*S*,4′*R*,5′*R*)-**9′** were obtained. Optical rotations of these (4*S*,5*S*,4′*R*,5′*R*)-**9** and (4*S*,5*S*,4′*R*,5′*R*)-**9′** were recorded as $[\alpha]_D^{22}$=+59.8 ° (*c* 2.22, $CHCl_3$) and $[\alpha]_D^{23}$=+104.9 ° (*c* 0.67, $CHCl_3$), respectively.

Methyl *trans*-5-(*trans*-1,3-Dimethyl-4,5-diphenylperhydro-2-imidazolyl)-3-phenyl-2-isoxazoline-4-carboxylate (*rac*-**9**): Colorless prisms (MeOH); mp 139—139.5 °C; IR (KBr) 2729, 1656, 1416, 1228, 1112, 952, 880, and 736 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.30, 2.50 (each 3H, each s, 2×NMe), 3.64 (1H, d, $J_{4'-5'}$=8.1 Hz, H-4′), 3.74 (3H, s, COOMe), 3.80 (1H, d, $J_{5'-4'}$=8.1 Hz, H-5′), 4.25 (1H, d, $J_{2'-5}$=4.4 Hz, H-2′), 4.94 (1H, d, $J_{4-5'}$=6.2 Hz, H-4), 5.35 (1H, dd, J_{5-4}=6.2 and $J_{5-2'}$=4.4 Hz, H-5), 6.95—7.31, 7.42—7.47, and 7.80—7.84 (each 10H, 3H, and 2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=33.61, 42.14 (2×NMe), 52.89 (C-4), 55.35 (COOMe), 75.25, 78.54 (C-4′ and C-5′), 84.13 (C-2′), 87.76 (C-5), 126.98, 127.30, 127.84, 128.03, 128.32, 128.45, 128.69, 128.81, 130.28, 138.38, 139.48 (each Ph), 154.55 (C-3), and 170.45 (COOMe); MS (20 eV) *m*/*z* (rel intensity, %) 424 (M^+—MeO, 0.4), 253 (2), 252 (20), 251 (base peak), 180 (2), and 103 (2). Found: C, 74.16; H, 6.44; N, 9.24%. Calcd for $C_{28}H_{29}N_3O_3$: C, 73.82; H, 6.42; N, 9.22%.

Methyl *trans*-4-(*trans*-1,3-Dimethyl-4,5-diphenylperhydro-2-imidazolyl)-3-phenyl-2-isoxazoline-5-carboxylate (*rac*-9′): Colorless liquid; IR (neat) 3700, 2800, 2340, 1720, 1445, 1200, 1020, 875, 760, and 670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.18, 2.37 (each 3H, each s, 2×NMe), 3.63 (1H, d, $J_{4'-5'}$=8.1 Hz, H-4′), 3.82 (3H, s, COOMe), 3.95 (1H, d, $J_{5'-4'}$=8.1 Hz, H-5′), 4.46 (1H, d, $J_{5'-4'}$=1.5 Hz, H-2′), 4.56 (1H, dd, J_{4-5}=4.0 and $J_{4-2'}$=1.5 Hz, H-4), 5.73 (1H, d, J_{5-4}=4.0 Hz, H-5), 7.10—7.32, 7.43—7.49, and 7.77—7.82 (each, 10H, 3H, and 2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=33.55, 40.17 (2×NMe), 52.73 (C-4), 55.84 (COOMe), 75.20, 78.28 (C-4′ and C-5′), 80.67 (C-2′), 82.32 (C-5), 127.15, 127.35, 127.45, 127.84, 128.35, 128.51, 129.08, 130.42, 139.26, 139.32 (each Ph), 157.23 (C-3), and 171.57 (COOMe); Found: C, 73.98; H, 6.39; N, 9.20%. Calcd for $C_{28}H_{29}N_3O_3$: C, 73.82; H, 6.42; N, 9.22%.

X-Ray Structure Analysis of *rac*-9. A single crystal grown from MeOH had space group $P2_1/n$, a=9.13 (5), b=28.39 (1), and c=10.08 (1) Å, β=107.9 (2) °, V=2488 (1) Å^3, Z=4. The

final R factor was 0.051 for 1421 observed reflections.[10]

Removal of the Chiral Auxiliary from 7, 9, and 9′ Leading to 4 and 4′. A) **From 7:** Concentrated H_2SO_4 (0.5 ml) was added to a solution of (4*S*,5*S*,4′*S*,5′*S*)-**7** (a 76:24 diastereomeric mixture, 0.048 g, 0.083 mmol) in MeOH (3 ml) and $CHCl_3$ (2 ml). After heating under reflux for 20 h, the mixture was neutralized with saturated aqueous $NaHCO_3$, and extracted with CH_2Cl_2 (20 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.041 g) was chromatographed (silica gel) with hexane–EtOAc (3:1 v/v) to give a mixture of (4*S*,5*S*)-(+)-**4** and (4*R*,5*R*)-(−)-**4** (0.023 g, 100%, a 75:25 mixture of enantiomers by HPLC using Daicel, Chiral pack OD). $[\alpha]_D^{23}=+82.8°$ (*c* 0.61, $CHCl_3$).

B) **From 9:** Concentrated H_2SO_4 (0.5 ml) was added to a solution of (4*S*,5*S*,4′*R*,5′*R*)-**9** (0.089 g, 0.195 mmol) in MeOH (5 ml) and $CHCl_3$ (3 ml). After heating under reflux for 19 h, the mixture was neutralized with saturated aqueous $NaHCO_3$ and extracted with Et_2O (40 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.094 g) was chromatographed (silica gel) with hexane–EtOAc (3:1 v/v) to give (4*S*,5*S*)-(+)-**4** (0.04 g, 73%, a single enantiomer by HPLC using Daicel, Chiral pack OD, $[\alpha]_D^{22}=+166.8°$ (*c* 1.90, $CHCl_3$).

C) **From 9′**: Concentrated H_2SO_4 (0.5 ml) was added to a solution of (4*S*,5*S*,4′*R*,5′*R*)-**9′** (0.091 g, 0.2 mmol) in MeOH (5 ml) and $CHCl_3$ (3 ml). After heating under reflux for 10 h, the mixture was neutralized with saturated aqueous $NaHCO_3$ and extracted with Et_2O (30 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.093 g) was chromatographed (silica gel) with hexane–EtOAc (5:1 v/v) to give (4*S*,5*S*)-(+)-**4′** (0.054 g, 96%, a single enantiomer by HPLC using Daicel, Chiral pack OD). $[\alpha]_D^{22}=+133.5°$ (*c* 0.37, $CHCl_3$).

Conversion of *rac*-8 to *rac*-10. Concentrated H_2SO_4 (0.2 ml) was added to a solution of *rac*-**8** (0.051 g, 0.084 mmol) in MeOH (3 ml) and $CHCl_3$ (2 ml). After heating under reflux for 4 h, the mixture was neutralized with saturated aqueous $NaHCO_3$, and extracted with Et_2O (40 ml×2). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.056 g) was chromatographed (silica gel) with hexane–EtOAc (3:1 v/v) to give *rac*-**10** (0.016 g, 64%). From the subsequent fractions *rac*-**8** (0.018 g, 35%) and *dl*-1,2-dianilino-1,2-diphenylethane (0.02 g, 65%) were obtained.

Methyl *trans*-5-Dimethoxymethyl-3-(*p*-methoxyphenyl)-2-isoxazoline-4-carboxylate (*rac*-**10**): Colorless needles (MeOH); mp 97.5—98 °C; ^{1}H NMR ($CDCl_3$) δ=3.46, 3.49 (each 3H, each s, 2×OMe), 3.71 (3H, s, COOMe), 3.83 (3H, s, *p*-OMe), 4.41 (1H, d, $J_{CH\text{-}5}$=4.8 Hz, 5-CH), 4.54 (1H, d, $J_{4\text{-}5}$= 5.1 Hz, H-4), 4.98 (1H, dd, $J_{5\text{-}4}$=5.1 and $J_{5\text{-}CH}$=4.8 Hz, H-5), 6.81, and 7.68 (each 2H, each d, Ar); ^{13}C NMR ($CDCl_3$) δ=52.99 (4-C), 54.47, 55.35, 55.53, 56.46 (2×OMe, *p*-OMe, and COOMe), 85.08 (C-5), 103.67 (5-CH), 114.16, 120.69, 128.68, 153.90 (each Ar), 161.23 (C-3), and 169.86 (COOMe); MS *m*/*z* (rel intensity, %) 309 (M^+, 8) and 75 (base peak). Found: C, 58.50; H, 6.29; N, 4.54%. Calcd for $C_{15}H_{19}NO_6$: C, 58.25; H, 6.19; N, 4.53%.

Silicon Effects. III. Rates and Products for Solvolysis of α-(Pentamethyldisilanyl)benzyl Halides and 1,1,2,2-Tetramethyl-1,2-disilaindan-3-yl Chloride. Structure and Stability of α-(Pentamethyldisilanyl)benzyl Cation in Solution[1,2]

Nobujiro SHIMIZU,* Chieko KINOSHITA, Erika OSAJIMA, Fumie HAYAKAWA, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812
(Received July 3, 1991)

Detailed kinetic and product studies have been made on solvolysis of α-(pentamethyldisilanyl)benzyl halides (**1a-X**; X=Cl and Br) and 1,1,2,2-tetramethyl-1,2-disilaindan-3-yl chloride (**2-Cl**) in various solvents. The solvolysis of **1a-X** at 25 °C is characterized by (1) a complete 1,2-$SiMe_3$ rearrangement in the products, (2) m (sensitivity to the solvent ionizing power Y_x) values of 0.98 (X=Cl) and 0.91 (X=Br) for the solvolyses in aq acetone, (3) α-deuterium isotope effects of 1.167 and 1.163 for **1a-Cl** in 97% aq 2,2,2-trifluoroethanol (TFE) and 40% aq ethanol respectively, and (4) substituent effect expressed by a Yukawa-Tsuno LArSR equation: $\log k/k^H=-3.71$ ($\sigma^\circ+1.16\Delta\bar{\sigma}_R^+$) for the solvolysis of **1a-Cl** and the p-Me, m-Me, p-Cl, and m-Cl derivatives in 40% aq ethanol. These findings are consistent with k_c mechanism. The relative rates for **1a-Br**, α-(trimethylsilyl)benzyl bromide, and α-(*t*-butyldimethylsilyl)benzyl bromide are $1.07\times10^5:0.54:1.0$ in 97% aq TFE at 25 °C indicating solvolytic generation of α-(pentamethyldisilanyl)benzyl cation to be ca. 7 kcal mol^{-1} energetically more favorable than that of the corresponding α-(trialkylsilyl)benzyl cations. In contrast, **2-Cl** solvolyzes 0.209 times less rapidly than does 2,2-dimethyl-2-silaindan-1-yl chloride in 97% aq TFE indicating that a β-Si–Si σ bond orthogonal to the leaving group does not enhance the rate of ionization at all.

Silicon–silicon single bonds possess unusual low ionization potentials[3] and are capable of interacting with π-systems intermolecularly as well as intramolecularly.[4-6]

The Si–Si bonds are expected to interact strongly with neighboring electron-deficient centers. Eaborn and coworkers[7] have shown that p-disilanyl groups [$(Me_3Si)_nSiMe_{3-n}$] exert small and additive rate-acceleration effects in the protodestannylation of aryltrimethyltins indicative of inductive and hyperconjugative electron release from the Si–Si bonds. Kumada and coworkers[8] have reported several cationoid reactions of (halomethyl)disilanes undergoing a 1,2-silyl rearrangement from the silicon to the carbenium carbon suggestive of neighboring group participation of the Si–Si σ bond in ionization of the adjacent carbon–halogen bonds. However, neither precise mechanism for the solvolysis of the (halomethyl)disilanes nor structures of carbocations bearing α-disilanyl groups have been elucidated.

The α and β-silicon effects on stability of carbocations have received considerable mechanistic[9-11] and theoretical interests[12,13] in recent years. Previously,[1,14] we estimated the α- and β-silicon effects in the benzylic k_c solvolysis and it is of interest to compare the β-silicon effects in two benzylic cation systems, $PhHC^+$–Si–$SiMe_3$ and $PhHC^+$–C–$SiMe_3$. In order to estimate the β-silicon effect in the former system, we selected the solvolysis of α-(pentamethyldisilanyl)benzyl halides (**1a-X**; X=Br and Cl) and compared their solvolysis rates with those for structurally related α-(trialkylsilyl)benzyl halides.[14] In this paper we describe detailed kinetic and product studies on the solvolysis of **1a-X** and its cyclic analogue, 1,1,2,2-tetramethyl-1,2-disilaindan-3-yl chloride (**2-Cl**), in which the Si–Si bond is orthogonal to the leaving group, and discuss mechanistic implications on the β-silicon effects of the disilanyl groups.

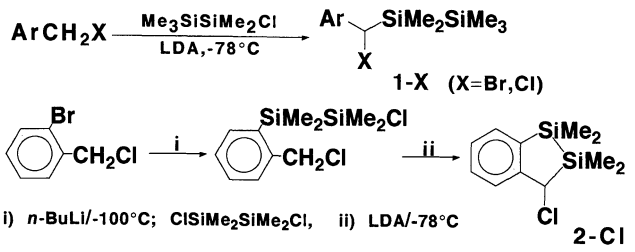
Results

Synthesis. The bromide **1a-Br** was prepared by treatment of benzyl bromide with LDA at −78 °C in the presence of chloropentamethyldisilane.[14] The chloride **1a-Cl** and the p-Me, m-Me, p-Cl, and m-Cl derivatives (**1b-Cl-1e-Cl**) were prepared in a similar procedure. The cyclic chloride, **2-Cl**, was synthesized from *o*-bromobenzyl chloride via *o*-lithiation, a coupling reaction with 1,2-dichlorotetramethyldisilane, and ring closure of the resulting *o*-(2-chlorotetramethyldisilanyl)benzyl chloride by use of LDA, as shown in Scheme 1. 2,2-Dimethyl-2-silaindan-1-yl chloride (**3-Cl**), a reference standard for **2-Cl**, was prepared by chlorination of 2,2-dimethyl-2-silaindan with sulfuryl chloride.

Kinetic Studies. The rates of solvolysis of the halides



Scheme 1.

1-X, **2-Cl**, and **3-Cl** were determined UV spectrometrically in various solvents including 80/20 to 30/70 (v/v) ethanol–water (E series), 80/20 to 30/70 (v/v) acetone–water (A series), and 97/3 (w/w) to 40/60 (v/v) 2,2,2-trifluoroethanol (TFE)–water (T series) binary solvent mixtures by measuring either decrease in the reactant or increase in acid formed as its acridinium salt by using $(0.1—1.0)\times10^{-4}$ M (M= mol dm^{-3}) solutions in the presence or absence of 2—3 equiv acridine.[14] The rates were reproducible within ±3% in the both measurements and the first-order rate constants determined at 25.0±0.05 °C for **1a-Br**, **1a-Cl**, **2-Cl**, and **3-Cl** were given in Tables 1 and 2. Table 1 includes rate data for 1-phenylethyl bromide (**4-Br**) for comparison.

The solvolysis of **2-Cl** in 97% aq TFE (97T) in the presence of 2 equiv acridine also followed excellent first-order kinetics (correlation coefficient R=0.99998). Unexpectedly, however, the solvolyses in aq ethanol and aq acetone did not follow the first-order kinetics probably due to occurrence of a side reaction (vide infra) and we could not measure the rates in these solvents.

Table 3 compares the solvolysis rates of **1a-Br** in 97T and 30% aq acetone (30A) with those of its β-alkyl reference standards, α-(*t*-butyldimethylsilyl)benzyl and α-(trimethylsilyl)benzyl bromides[14] (**5-Br** and **6-Br** respectively), and the rate of solvolysis of **2-Cl** in 97T with

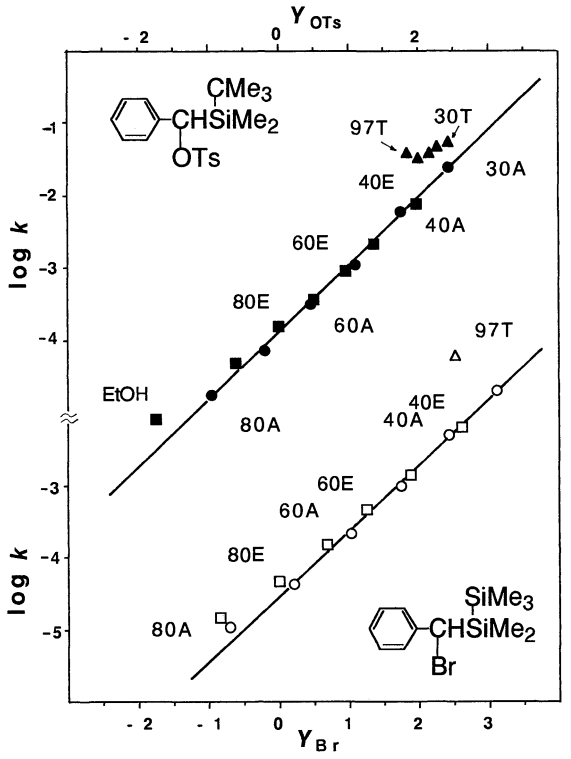

Fig. 1. Plot of log k vs. Y_{Br} for **1a-Br** (open marks) and log k vs. Y_{OTs} for **5-OTs** (closed marks) for aq acetone (circles), aq ethanol (squares), and aq TFE (triangles).

that of its standard compound **3-Cl**. Rate data[1] for 1-phenylethyl trifluoroacetate (**4-OTFA**), 1-phenyl-2-(trimethylsilyl)ethyl trifluoroacetate (**7-OTFA**), and 3,3-dimethyl-1-phenylbutyl trifluoroacetate (**8-OTFA**) were also included in Table 3 for comparison.

Figure 1 represents dependence of the solvolysis rates (log k) of **1a-Br** on solvent ionizing power Y_{Br}.[15] A separate mY plot for α-(*t*-butyldimethylsilyl)benzyl *p*-toluenesulfonate (**5-OTs**) against Y_{OTs}[16] is included for comparison. A plot of log k for **1a-Cl** vs. Y_{Cl}[15] exhibited a very similar mY plot pattern to that for **1a-Br** for the A, E, and T solvent series. Table 4 compares m values for the five different substrates, **1a-Cl**, **1a-Br**, **3-Cl**, **4-Br**, and **5-OTs**, determined from the linear correlation observed in acetone–water binary solvent mixtures.

Table 5 shows α-deuterium kinetic isotope effects (α-KIE) for the solvolysis of **1a-Cl** in 40% aq ethanol (40E) and in 97T at 25 °C.

Table 6 shows the solvolysis rates for **1a-Cl**—**1e-Cl** measured in 40E at 25 °C. The substituent effect was linearly expressed by the Yukawa-Tsuno LArSR equation (Eq. 1)[17] with an r value of 1.16 and a ρ value of −3.71 (n=5, R=0.998, SD=0.066).

$$\log k/k^{H} = \rho(\sigma^{\circ} + r\Delta\bar{\sigma}_{R}^{+}) \quad (1)$$

Table 7 shows salt effects on the solvolysis of **1a-Cl** in 40E. Neither common ion rate depression nor special salt effect was significant, indicative of unimportance of return processes. Activation parameters for the solvolyses of **1a-Br** and **1a-Cl** are given in Table 8.

Product Studies. Reductive dehalogenation of **1a-Br** and **2-Cl** with $LiAlH_4$ cleanly gave the corresponding reduction products, benzylpentamethyldisilane (**1a-H**) and 2,2-dimethyl-2-silaindan (**2-H**), suggestive of structural conservation in S_N2-type reactions. In contrast, a solvolytic reaction of **1a-Br** with ethanol in the presence or absence of a buffer base quantitatively gave a 1,2-$SiMe_3$ rearranged compound, an ethoxysilane **9a-OEt** (Scheme 2). We could not detect the formation of a structure-retained product **1a-OEt**. Similarly, buffered

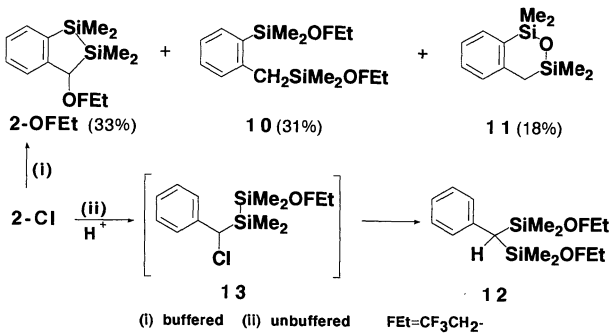


Scheme 3.

solvolyses in TFE and in 50% aq acetone respectively gave rearranged compounds, a (2,2,2-trifluoroethoxy)silane **9a-OFEt** (FEt=CH_2CF_3) and a silanol **9a-OH**, as a single product in each case. The same was true for the chlorides **1a-Cl** and **1b-Cl**. The 1,2-$SiMe_3$ migration must be directly associated with the ionization of the C–X bond of the halides **1-X**. The 1,2-silyl rearrangement has already been observed in several cationoid reactions of (halomethyl)disilanes.[8] A related 1,2-alkyl shift from the α-silicon to a carbenium carbon has also been reported by Apeloig and Stanger in the solvolysis of 2-trimethylsilyl-2-adamantyl *p*-nitrobenzoate.[18]

The solvolysis of **1b-Cl** in TFE in the presence of 1 M sodium cyanotrihydroborate gave a mixture of two rearranged products, **9b-OFEt** and a silane **9b-H**, in a ratio of 95:5, while the solvolysis in ethanol in the presence of 1 M sodium cyanotrihydroborate afforded a mixture of **9b-OEt** and a reduction product **1b-H** in the ratio 98:2. Apparently, an S_N2 reduction by the hydroborate can compete with the S_N1 solvolysis in ethanol of low ionizing power, but not in a strong ionizing solvent, TFE (Y_{OTs}=−1.75 and 1.80 for ethanol and TFE respectively). On the other hand, the hydroborate can attack a solvolysis intermediate in competition with solvent in a weakly nucleophilic solvent TFE but not in a strongly nucleophilic solvent ethanol (N_{OTs}=−3.0 and 0.0 for TFE and ethanol respectively[16]).

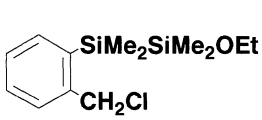
The halides **1-X** underwent the skeletal rearrangement thermally as well; for example, **1a-Cl** quantitatively gave a chorosilane **9a-Cl** on heating at 150 °C. We also examined a silver(I)-assisted reaction of **1a-Br**; it reacted instantaneously with silver perchlorate in THF at −78 °C and gave **9a-OEt** when ethanol was added to the mixture. Since **1a-Br** did not react with ethanol at this temperature, a precursory species must be a silyl perchlorate **9a-OClO$_3$**.

The cyclic halide **3-Cl** solvolyzed in aq acetone cleanly to give an expected alcohol **3-OH**, as does the bromide **3-Br**.[14] On the other hand, solvolytic reactions of **2-Cl** were complicated. A buffered reaction of **2-Cl** with TFE gave two solvolysis products, a structure-retained ether **2-OFEt** (33%) and an open compound **10** (31%), together with a cyclic disiloxane **11** (18%) which was presumably formed from **10** during isolation processes (Scheme 3). The result is consistent with the observed good first-order kinetics for the buffered solvolysis in 97T.

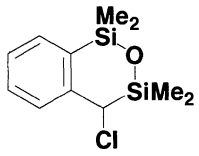
On the other hand, an unbuffered reaction with TFE led to the formation of a completely different compound, α,α-bis[dimethyl(2,2,2-trifluoroethoxy)silyl]toluene **12**. Initial protodesilylation of **2-Cl** accounts for this; as soon as hydrogen chloride is liberated on solvolysis, it must catalyze a ring opening of **2-Cl** to an α-(disilanyl)benzyl chloride **13** which would give **12** upon solvolysis (Scheme 3).

Furthermore, a buffered reaction of **2-Cl** with ethanol at 25 °C did not give solvolysis products; instead, *o*-(2-ethoxytetramethyldisilanyl)benzyl chloride **14** was ob-

tained as the major product. Although precise mechanism for the formation of **14** is not clear at present, **2-Cl** appears to undergo solvolysis only in strongly ionizing but weakly nucleophilic media like TFE; a strongly nucleophilic solvent like ethanol prefers attack on the α-silicon rather than it promotes ionization of the C–Cl bond. Oxidation of the Si–Si bond in **2-Cl** occurred predominantly at higher temperatures. For example, an attempted solvolysis in 70% aq acetone at 70 °C led to the formation of a cyclic disiloxane **15** as the major product. Compound **2-Cl** was rapidly oxidized to **15** when heated in carbon tetrachloride in the air.



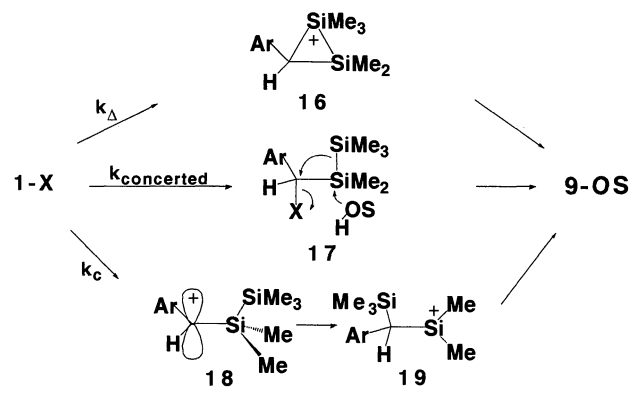
14



15

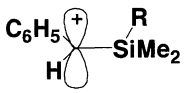
Discussion

Mechanism. Two observations characterizing the solvolysis of **1a-X** are a marked rate acceleration of $(0.34—1.1)\times10^5$ by the α-$SiMe_2SiMe_3$ group relative to the structurally related $SiMe_2(t\text{-Bu})$ group (Table 3) and the clean formation of the rearranged product via a 1,2-$SiMe_3$ shift. The accelerated rate coupled with the skeletal rearrangement is a general feature suggestive of neighboring group participation[19] and hence a σ-participation mechanism (k_Δ) via a bridged siliconium ion intermediate **16** is seemingly operative. However, these findings can also be accounted for by two other mechanisms. They are a concerted pathway[8] involving simultaneous solvent attack on the α-silicon, migration of an $SiMe_3$ group from the silicon to the benzylic carbon, and cleavage of the C–X bond as illustrated by the structure **17** and a simple ionization mechanism (k_c) via rate-determining formation of an open α-(pentamethyldisilanyl)benzyl cation **18** which rapidly decays to the rearranged product most likely via a silylenium ion **19** (Scheme 4).

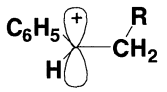


Scheme 4.

On the precise mechanism the following findings are instructive. First, the halides **1a-X** exhibit high sensitivities to the solvent ionizing power for their solvolyses in acetone–water binary solvent mixtures (Table 4), i.e., m=0.91 and 0.98 for the bromide and chloride respectively, supporting an unassisted ionization. Noteworthy is a striking resemblane in the mY plot for **1a-Br** to that for the solvolysis of the structurally related α-trialkylsilyl compound **5-OTs** (Fig. 1) indicative of a close similarity in the mechanism between the two solvolysis reactions. We have proposed the k_c mechanism for the solvolysis of **5-OTs** via a benzylic cation **20**.[14] Thus, the solvent effect is obviously more in accord with the k_c mechanism via **18** than the k_Δ and concerted mechanisms. Aq ethanol of low water content (80E and 90E) deviates upward from the aq acetone correlation line; however, this is not a result of nucleophilic solvent assistance because such interaction should lead to significant downward deviations for T solvents which are much less nucleophilic than aq acetone against the observation. The upward deviation for 97T by about one log k unit is striking but this is not associated with the 1,2-$SiMe_3$ rearrangement either because a similar large deviation of 97T is also observed for **5-OTs** which does not undergo a skeletal rearrangement. The diverging mY plot instead of a single linear correlation for A, E, and T solvent series does not mean a mechanistic shift from the k_c solvolysis but probably arises from the different responses to the ionizing power between the present benzylic derivatives and the standard adamantyl compounds.[14]



20; R=*t*-Bu



21; R=$SiMe_3$
22; R=*t*-Bu

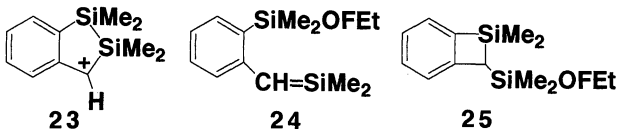
Second, the α-KIEs (k_H/k_D) of 1.16—1.17 (Table 5) for the solvolysis of the chloride **1a-Cl** are comparable with those (1.15—1.16) for the related 1-arylethyl chlorides which undergo S_N1 solvolysis.[20] The result suggests that **1a-Cl** solvolyzes via a transition state structurally close to the cation **18**.

Thirdly, the LArSR analysis reveals that the transition state of the solvolysis of **1-Cl** requires a rather high resonance demand $r>1$ (Table 6). This is obviously incompatible with the k_Δ and concerted mechanisms and is most reasonably accommodated with the k_c mechanism. Noteworthy is a marked reduction in ρ value (−3.7) as compared to typical values around −5.5 for the S_N1 solvolysis of structurally related α-alkylbenzyl compounds.[21,22] This is undoubtedly associated with low ionization potentials of the Si–Si σ bonds.[3] The positive charge on the benzylic carbon must be significantly delocalized to the Si–Si bond mainly through hyperconjugation.[23]

Thus, the combined results lead us to conclude the k_c mechanism for the solvolysis of α-(pentamethyldisilanyl-)benzyl halides. It is worth stating that 1-phenyl-2-(trimethylsilyl)ethyl trifluoroacetate **7-OTFA** has been shown to solvolyze also by the k_c mechanism via an open benzylic cation **21**.[1] The k_c solvolysis for these benzylic systems is in agreement with recent experimental[10] and theoretical[12] results that an open bisected structure of 2-silylalkyl cations is more stable than a bridged form except for the primary cation where a bridged form is slightly more favorable than an open structure.

The absence of the common ion rate depression and special salt effect (Table 7) indicates unimportance of return processes. This is in agreement with the clean formation of the rearranged products suggestive of a rapid decay of the cation **18** to the products via a 1,2-$SiMe_3$ shift. It is of interest whether the silylenium ion **19** is really involved in the product-forming step. We have no compelling evidence for the formation of **19** but the rearrangement of **18** to **19** appears energetically favorable.[24,25]

Previously,[14] we showed the S_N1 solvolysis of 2,2-dimethyl-2-silaindan-1-yl bromide (**3-Br**). The same mechanism would probably be operative in the solvolysis of the chloride **3-Cl**. The *m* value of 0.98 (Table 4) strongly supports this. Judging from a structural similarity, we can assume the k_c solvolysis of the related chloride **2-Cl** in 97T. The formation of **2-OFEt** and **10** is compatible with intervention of 1,1,2,2-tetramethyl-1,2-disilaindan-3-yl cation **23**; the cation gives either **2-OFEt** directly or **10** after cleavage of the Si–Si bond presumably via a silene **24** or a silacyclobutene **25**.



23 24 25

β-Silicon Effect. The $SiMe_2SiMe_3$ group exerts α- and β-silicon effects on the stability of the adjacent carbocations. The β-silicon effect can be estimated by comparing the rates of the α-(pentamethyldisilanyl)benzyl and the structurally related α-(trialkylsilyl)benzyl compounds. Although the rates of solvolysis of α-alkylbenzyl compounds are subjected to the steric effect of the α-alkyl group,[26] we have shown that there is little difference in the steric effect between the two α-trialkylsilyl groups, $SiMe_3$ and $SiMe_2$(*t*-Bu), in the benzylic k_c solvolysis.[14] This suggests that the steric effect of the α-$SiMe_2SiMe_3$ group is practically the same as that of $SiMe_2$(*t*-Bu) or $SiMe_3$. Thus, the k(**1a-Br**)/k(**5-Br**) rate ratios of (0.34—1.1)×10^5 (Table 3) provide a reasonable estimate for the β-silicon effect of the pentamethydisilanyl group indicating the solvolytic generation of **18** to be 6.2—6.8 kcal mol^{-1} (1 kcal= 4.18 kJ) energetically more favorable than that of **20**. A similar β-silicon effect has also been observed in the related k_c solvolysis of α-alkylbenzyl derivatives (Table 3); **7-OTFA** solvolyzes 2.99×10^5 times more rapidly than **8-OTFA** suggesting the formation of the cation **21** to be 7.5 kcal mol^{-1} more favorable than that of the corresponding β-alkyl cation **22**.[1]

It is worth stating that despite the huge β-silicon effect of the $SiMe_2SiMe_3$ group relative to $SiMe_2$(*t*-Bu), the overall effect is comparable to that of methyl (Table 1). This arises from the fact that an α-silyl group exerts a marked deactivating effect in the benzylic solvolysis. For example, **6-Br** solvolyzes (1.6—3.3)×10^4 times less rapidly than **4-Br** due to the electronic and steric effects of the trimethylsilyl group relative to methyl.[14]

Noteworthy is the fact that **2-Cl** solvolyzes slightly less rapidly than **3-Cl** (Table 3). This means that the Si–Si bond orthogonal to the leaving group does not enhance the ionization of the adjacent C–Cl bond at all. The result not only shows a striking conformational dependence of the β-silicon effect but also indicates unimportance of the inductive electron release from the β-silicon. The observed small inverse rate ratio, k(**2-Cl**)/k(**3-Cl**)=0.209, can be attributed to differences in the electronic effects and/or the steric effects between the silyl group and the alkyl group at the ortho position (*A*-value, σ_I, and σ_R° are ca. 2.5, −0.10, and 0.12 for $SiMe_3$ and 1.70, −0.01, and −0.16 for CH_3.[27,28]).

The β-silicon effect depends on the electronic demands of the carbenium carbon of the parent cation.[10,12] For example, a theoretical study indicates that the stabilization energy of a cation $R^1R^2C^+$–CH_2R^3 afforded by replacement of R^3 from hydrogen to SiH_3 increases from 15.9 kcal mol^{-1} for *t*-butyl cation (R^1=R^2=Me) to 22.1 kcal mol^{-1} for 1-methylethyl cation (R^1=Me, R^2=H) which is 18 kcal mol^{-1} less stable than *t*-butyl cation.[12] Therefore, in order to compare the β-silicon effect in the two benzylic cation systems, $PhHC^+$–$SiMe_2$–R and $PhHC^+$–CH_2–R (R=$SiMe_3$ and *t*-Bu), we must consider the stabilities of the parent cations (R=*t*-Bu) in the two systems, i.e., **20** and **22**. We can assume **22** to be 3—4 kcal mol^{-1} more stable than **20** in view of the fact that the solvolytic generation of 2,2-dimethyl-1-indanyl cation is 3—4 kcal mol^{-1} more favorable than that of 2,2-dimethyl-2-silaindan-1-yl cation.[14] Consequently, a more pronounced β-silicon effect than the observed value of 7.5 kcal mol^{-1} is expected in the $PhHC^+$–CH_2R system if **22** exhibits the same electronic demand as that of **20**; a value of more than 8.5 kcal mol^{-1} can be evaluated if we simply assume that the difference in stability between *t*-butyl cation and 1-methylethyl cation by 18 kcal mol^{-1} causes a change in the β-silicon effect by about 6 kcal mol^{-1}. Thus, it is concluded that the hyperconjugative interaction of the Si–Si bonds with the empty 2p orbital of the benzylic cation is 1—2 kcal mol^{-1} less effective than that of the corresponding C–Si bonds in agreement with the earlier suggestion that π–σ(Si–Si) conjugation is weaker than π–σ(C–Si) conjugation.[23,29]

Finally, we must point out that a direct comparison of the solvolysis rates of the two α-disilanyl compounds, **1a-Cl** and **2-Cl**, may lead to an erroneous conclusion; a k(**1a-Cl**)/k(**2-Cl**) rate ratio of 20 would suggest a very small rate enhancement by the Si–Si bond through hyperconjugation contrary to the rate enhancement of 10^5 mentioned earlier. This is obviously not justified. Since there is a marked intrinsic difference in reactivity between 1-indanyl ring system and the corresponding open benzylic system,[14,30] the k(**1a-Cl**)/k(**2-Cl**) rate ratio itself tells us nothing about the effect of the Si–Si bonds. It should be noted that a cyclic bromide **3-Br** is 7.1×10^3 times as reactive as an open compound **6-Br**.[14] If we take this rate factor as an effect of the indanyl ring system, we can estimate the rate (k_{calcd}) of solvolysis of **2-Cl** from 7.1×10^3 times k(**1a-Cl**), i.e., $k_{calcd}=56$ s^{-1} in 97T; however, **2-Cl** in fact solvolyzes with a rate constant of $k_{obsd}=3.86\times10^{-4}$ s^{-1} which is 1.5×10^5 times smaller than the expected one. The actual low reactivity of **2-Cl** undoubtedly arises from the orthogonal alignment of the Si–Si bond to the empty p-orbital of the carbenium carbon incapable of hyperconjugation. Thus, the k_{calcd}/k_{obsd} rate ratio of ca. 10^5 corresponds to a rate enhancement by the Si–Si bond mainly through hyperconjugation in the open system in good agreement with the earlier discussion.

Experimental

IR spectra were recorded on a Hitachi R-215 spectrophotometer. NMR spectra were recorded on a Hitachi R-20B spectrometer in carbon tetrachloride. Mass spectra were recorded on a Hitachi M-60 mass spectrometer. Kinetic measurements were performed with a Hitachi 220A spectrophotometer equipped with a programmed data printer. GLC analysis was performed with a Hitachi 163 gas chromatograph by using glass columns (6 mm×1.5 and 2.0 m) packed with 10% Silicone DC 550 on Chamelite CS (Column A) and 25% Apiezon grease L on Chromosorb W (Column B).

Materials. α-(Pentamethyldisilanyl)benzyl Bromide (**1a-Br**), α-(pentamethyldisilanyl)benzyl chloride (**1a-Cl**), its *p*-Me, *m*-Me, *p*-Cl, and *m*-Cl derivatives (**1b-Cl**—**1e-Cl**), and α-deuterio-α-(pentamethyldisilanyl)benzyl chloride (**1a-Cl**-d_1) were prepared by in situ coupling reaction of the corresponding benzyl halides with chloropentamethyldisilane in the presence of LDA. The following procedure for preparation of **1a-Br** is representative.

Into a stirred solution of LDA prepared from butyllithium (20 cm³, 1.7 M in hexane) and diisopropylamine (3.5 g) in THF (25 cm³) was added dropwise a solution of chloropentamethyldisilane (5.1 g) in THF (5 cm³) at −78 °C and subsequently a solution of benzyl bromide (5.2 g) in THF (5 cm³) over a period of 15 min at −78 °C. The resulting mixture was stirred overnight at that temperature. Pentane (75 cm³) was added, the mixture poured into water, and separated. Water layer was extracted with pentane (50 cm³). A combined organic layer was washed with 10% sulfuric acid, aq $NaHCO_3$, aq NaCl, and dried ($MgSO_4$). Solvent was removed on a rotary evaporator and the residual oil was distilled to give 5.32 g (58%) of **1a-Br** as a colorless oil, bp 98—99 °C (1 Torr; 1 Torr= 133.3 Pa): IR 1600, 1245, 835, 800, 695 cm^{-1}; ^{1}H NMR δ=0.0 (9H, s), 0.13 (3H, s), 0.19 (3H, s), 4.32 (1H, s), 7.20 (5H, almost s). Found: C, 48.01; H, 6.96%. Calcd for $C_{12}H_{21}BrSi_2$: C, 47.83; H, 7.02%.

1a-Cl: Bp 94—95 °C (3 Torr); IR 1595, 1245, 1065, 1025, 830, 800 cm^{-1}; UV (95% EtOH) λ_{max} (log ε) 207 (4.16), 229 (4.01); ^{1}H NMR δ=0.02 (9H, s), 0.07 (3H, s), 0.13 (3H, s), 4.38 (1H, s), 7.19 (5H, almost s). Found: C, 55.90; H, 8.17%. Calcd for $C_{12}H_{21}ClSi_2$: C, 56.10; H, 8.24%.

1a-Cl-d_1: Bp 87—88 °C (1 Torr); IR 1245, 950, 830, 795 cm^{-1}; ^{1}H NMR δ=0.02 (9H, s), 0.07 (3H, s), 0.13 (3H, s), 7.19 (5H, almost s). Found: C, 55.88; H, 8.28%. Calcd for $C_{12}H_{20}DClSi_2$: C, 55.88; H, 8.22%. ^{1}H NMR analysis indicated isotopic purity of more than 99%.

1b-Cl: Bp 106—107 °C (1 Torr); IR 1245, 1105, 830, 795 cm^{-1}; ^{1}H NMR δ=0.02 (9H, s), 0.06 (3H, s), 0.11 (3H, s), 4.33 (1H, s), 7.03 (4H, almost s). Found: C, 57.43; H, 8.42%. Calcd for $C_{13}H_{23}ClSi_2$: C, 57.63; H, 8.56%.

1c-Cl: Bp 107—108 °C (1 Torr); IR 1245, 1120, 865, 830, 800 cm^{-1}; ^{1}H NMR δ=0.02 (9H, s), 0.07 (3H, s), 0.11 (3H, s), 2.31 (3H, s), 4.33 (1H, s), 6.8—7.2 (4H, m). Found: C, 57.41; H, 8.43%. Calcd for $C_{13}H_{23}ClSi_2$: C, 57.63; H, 8.56%.

1d-Cl: Bp 92—93 °C (0.5 Torr); IR 1245, 1120, 1090, 1010, 830, 790 cm^{-1}; ^{1}H NMR δ=0.05 (12H, s), 0.11 (3H, s), 4.35 (1H, s), 7.18 (4H, A_2B_2, J=9.0 Hz). Found: C, 49.19; H, 6.86%. Calcd for $C_{12}H_{20}Cl_2Si_2$: C, 49.47; H, 6.92%.

1e-Cl: Bp 105—106 °C (1 Torr); IR 1245, 1110, 1090, 1075, 880, 830, 800 cm^{-1}; ^{1}H NMR δ=0.05 (9H, s), 0.08 (3H, s), 0.13 (3H, s), 4.34 (1H, s), 7.14 (4H, m). Found: C, 49.27; H, 6.92%. Calcd for $C_{12}H_{20}Cl_2Si_2$: C, 49.47; H, 6.92%.

1,1,2,2-Tetramethyl-1,2-disilaindan-3-yl Chloride (2-Cl): Into a solution of *o*-bromobenzyl chloride (7.65 g, 37.2 mmol) in a mixture of THF (130 cm³) and hexane (40 cm³) was added butyllithium (25 cm³, 1.6 M in hexane) at temperature around −100 °C and the mixture was stirred for 10 min at −100 °C under argon. A solution of 1,2-dichlorotetramethyldisilane (7.0 g) in THF (15 cm³) was added at such a rate as to maintain the temperature of the solution below −90 °C. The bath was removed and the mixture was allowed to warm to room temperature. Solvent was removed by distillation under reduced pressure. Dry pentane (150 cm³) was added to the residue and decanted. Pentane was removed on a rotary evaporator and the residue was distilled to give 7.02 g (68%) of *o*-(2-chlorotetramethyldisilanyl)benzyl chloride: Bp 124—125 °C (2.5 Torr); ^{1}H NMR δ=0.45 (6H, s), 0.56 (6H, s), 4.57 (2H, s), 7.18—7.56 (4H, m). Into a solution of LDA (23 mmol) in THF (20 cm³) was added a solution of this compound in THF (5 cm³) at −78 °C and the mixture was stirred for 2 h at −78 °C. Usual workup gave 2.90 g (57%) of **2-Cl** as a colorless oil: Bp 80—80.5 °C (0.5 Torr); IR 1585, 1250, 1130, 995, 860, 830, 735 m^{-1}; UV(CH_3CN) λ_{max} (log ε) 208 (4.22), 220 (shoulder, 3.92), 265 (shoulder, 2.85) 280 nm (2.55); ^{1}H NMR δ=0.20 (3H, s), 0.31 (3H, s), 0.35 (3H, s), 0.41 (3H, s), 4.46 (1H, s), 7.08—7.65 (4H, m). Found: C, 54.80; H, 7.12%. Calcd for $C_{11}H_{17}ClSi_2$: C, 54.86; H, 7.12%.

2,2-Dimethyl-2-silaindan-1-yl Chloride (3-Cl): A solution of 2,2-dimethyl-2-silaindan (3.24 g, 20 mmol),[14] sulfuryl chloride (1.35 g), and benzoyl peroxide (24 mg) in carbon tetrachloride (5 cm³) was heated under reflux for 30 min. Usual workup gave 1.2 g of **3-Cl:** Bp 86—87 °C (4 Torr); IR 1600, 1255, 1130, 1115, 850, 830, 820 cm^{-1}; UV (CH_3CN) λ_{max} (log ε) 203 (4.39), 225 (3.76), 2.77 nm (2.92); ^{1}H NMR δ=0.22

(3H, s), 0.40 (3H, s), 1.94 (1H, d, J=17.4 Hz), 2.22 (1H, d, J=17.4 Hz), 4.30 (1H, s), 6.95—7.56 (4H, m). Found: C; 60.95; H, 6.61%. Calcd for $C_{10}H_{16}ClSi$: C, 61.05; H, 6.66%.

Kinetics. Purification of solvents and kinetic procedure for rate measurements have been described elsewhere.[14] All the solvolysis reactions were followed UV spectrometrically by measuring either decrease in a reactant [243 nm for **1a-Br** and **1a-Cl** to **1e-Cl**, 245 nm for **2-Cl**, and 240 nm for **3-Cl**] or increase in a produced acid at 402.5 nm as its acridinium salt. The solvolyses followed excellent first-order kinetics over 3 to 4 half-lives (correlation coefficient R>0.9999).

Product Studies. Solvolysis of 1-X: Solvolytic reactions of **1a-Br**, **1a-Cl**, and **1b-Cl** in TFE, ethanol, and aq acetone were carried out by using 0.01—0.1 M solutions containing equimolar amounts of 2,6-dimethylpyridine at 25 °C and higher temperatures in some cases. In all cases, a single product was formed almost quantitatively and the following products were characterized.

2-Ethoxy-2,4-dimethyl-3-phenyl-2,4-disilapentane (9a-OEt): IR 1250, 1200, 1105, 1080, 1030, 940, 905, 840, 780 cm^{-1}; ^{1}H NMR δ=0.02 (12H, s), 0.06 (3H, s), 1.15 (3H, t, J=7.2 Hz), 1.52 (1H, s), 3.61 (2H, q, J=7.2 Hz), 6.6—7.3 (5H, m). Found: C, 62.80; H, 9.71%. Calcd for $C_{14}H_{26}OSi_2$: C, 63.09; H, 9.83.

2,4-Dimethyl-3-phenyl-2,4-disilapentan-2-ol (9a-OH): IR 3400, 1600, 1250, 1200, 1030, 845 cm^{-1}; ^{1}H NMR δ=0.03 (12H, s), 0.12 (3H, s), 1.35 (1H, s, disappeared on addition of D_2O), 1.51 (1H, s), 6.8—7.3 (5H, m); MS m/z 238 (M^+, 10), 223 (23), 148 (60), 147 (100), 73 (30). Found: C, 60.17; H, 9.31%. Calcd for $C_{12}H_{22}OSi_2$: C, 60.45; H, 9.30%.

2,4-Dimethyl-3-phenyl-2-(2,2,2-trifluoroethoxy)-2,4-disilapentane (9a-OFEt): IR 1600, 1300, 1285, 1255, 1160, 1030, 960, 850, 695 cm^{-1}; ^{1}H NMR δ=0.02 (9H, s), 0.09 (3H, s), 0.14 (3H, s), 1.55 (1H, s), 3.80 (2H, q, J=8.6 Hz), 6.7—7.2 (5H, m). Pure sample was obtained by GLC. Found: C, 52.80; H, 7.44%. Calcd for $C_{14}H_{23}F_3OSi_2$: C, 52.47; H, 7.23%.

2,4-Dimethyl-3-(4-methylphenyl)-2,4-disilapentan-2-ol (9b-OH): IR 3390, 1600, 1245, 1215, 1195, 1030, 850, 770 cm^{-1}; ^{1}H NMR δ=0.02 (9H, s), 0.04 (3H, s), 0.10 (3H, s), 1.47 (1H, s), 1.78 (1H, disappeared on addition of D_2O), 2.26 (3H, s), 6.88 (4H, AA′BB′, J=9.0 Hz).

2-Ethoxy-2,4-dimethyl-3-(4-methylphenyl)-2,4-disilapentane (9b-OEt): IR 1605, 1250, 1080, 1030, 945, 860, 835, 780 cm^{-1}; ^{1}H NMR δ=0.0 (12H, s), 0.03 (3H, s), 1.14 (3H, t, J=7.0 Hz), 1.44 (1H, s), 2.25 (3H, s), 3.59 (2H, q, J=7.0 Hz), 6.83 (4H, AA′BB′, J=9.0 Hz). Found: C, 71.10; H, 11.01%. Calcd for $C_{15}H_{28}OSi_2$: C, 71.37; H, 11.18%.

3-(4-Methylphenyl)-2-(2,2,2-trifluoroethoxy)-2,4,4-trimethyl-2,4-disilapentane (9b-OFEt): ^{1}H NMR δ=0.0 (9H, s), 0.07 (3H, s), 0.13 (3H, s), 1.62 (1H, s), 2.25 (3H, s), 3.81 (2H, q, J=9.0 Hz), 6.68 (4H, A_2B_2).

Solvolysis of 2-Cl: Compound **2-Cl** (399 mg) was dissolved in TFE (15 cm^3) containing acetone (1.0 cm^3) and 2,6-dimethylpyridine (182 mg) and the solution was allowed to stand for 3 d at 25 °C. A crude oil (464 mg) obtained after usual workup was shown to be a mixture of four compounds in the ratio 20:38:36:4 by GLC [Column A, 180 °C; retention time (t_R):4.0, 6.4, 13.2, and 18.4 min, respectively]. The first three components were isolated by GLC and were respectively assinged to 1,1,3,3-tetramethyl-1,3-disilaisochroman (**11**), 1,1,2,2-tetramethyl-3-(2,2,2-trifluoroethoxy)-1,2-disilaindan (**2-OFEt**), and α,o-bis[dimethyl(2,2,2-trifluoroethoxy)silyl]toluene (**10**) from the following spectral data.

2-OFEt: IR 1590, 1300, 1280, 1250, 1160, 1115, 965, 830, 670 cm^{-1}; ^{1}H NMR δ=0.04 (3H, s), 0.31 (3H, s), 0.35 (6H, s), 3.61 (2H, q, J=8.9 Hz), 4.31 (1H, s), 6.91—7.77 (4H, m). Found: C, 51.02; H, 6.30%. Calcd for $C_{13}H_{19}F_3OSi_2$: C, 51.29; H, 6.29%.

10: IR 1590, 1305, 1290, 1260, 1170, 965, 850, 840 cm^{-1}; ^{1}H NMR δ=0.14 (6H, s), 0.44 (6H, s), 2.42 (2H, s), 3.74 (2H, q, J=8.4 Hz), 3.88 (2H, q, J=8.4 Hz), 6.90—7.53 (4H, m). Found: C, 44.69; H, 5.69%. Calcd for $C_{15}H_{22}F_6O_2Si_2$: C, 44.54; H, 5.48%.

11: ^{1}H NMR δ=0.09 (6H, s), 0.31 (6H, s), 2.08 (2H, s), 6.9—7.4 (4H, m). Found: C, 59.38; H, 8.15%. Calcd for $C_{11}H_{18}OSi_2$: C, 59.41; H, 8.16%.

A solution of **2-Cl** (50 mg) in TFE (5 cm^3) was allowed to stand for 3 d at 25 °C. A crude oil (55 mg) obtained after usual workup was shown to be a mixture of 2,4-dimethyl-2,4-bis(2,2,2-trifluoroethoxy)-3-phenyl-2,4-disilapentane (**12**) and other two unidentified compounds in the GLC area ratio of 8:1:1.

12: ^{1}H NMR δ=0.13 (6H, s), 0.17 (6H, s), 1.73 (1H, s), 3.82 (4H, q, J=8.4 Hz), 6.82—7.32 (5H, m). Found: C, 45.01; H, 5.78%. Calcd for $C_{15}H_{22}F_6O_2Si_2$: C, 44.54; H, 5.48%.

The chloride **2-Cl** (420 mg) was heated in ethanol (25 cm^3) in the presence of triethylamine (185 mg) at 60 °C for 3 d. A crude oil obtained after usual workup was subjected to bulb-to-bulb distillation (130 °C, 3 Torr) to give 406 mg (81%) of 1-ethoxy-2-[o-(chloromethyl)phenyl]-1,1,2,2-tetramethyldisilane (**14**): IR 1250, 1105, 1075, 945, 830, 790, 765, 735 cm^{-1}; ^{1}H NMR δ=0.18 (6H, s), 0.44 (6H, s), 1.10 (3H, t, J=7.2 Hz), 3.54 (2H, q, J=7.2 Hz), 4.63 (1H, s), 7.04—7.56 (4H, m). Found: C, 54.72; H, 8.15%. Calcd for $C_{13}H_{23}ClOSi_2$: C, 54.42; H, 8.08%.

The chloride **2-Cl** (60 mg) was heated in 70% aq acetone (25 cm^3) at 70 °C for 4 d. A crude oil obtained after workup was subjected to chromatography over silica gel eluting with benzene to give 26 mg (40%) of 4-chloro-1,1,3,3-tetramethyl-1,3-disilaisochroman (**15**): Mp 77—78 °C; IR 1595, 1255, 1330, 1075, 990, 880, 855, 825, 790, 740 cm^{-1}; ^{1}H NMR δ=0.12 (3H, s), 0.33 (3H, s), 0.40 (3H, s), 4.18 (1H, s), 7.08—7.50 (4H, m). Found: C, 51.44; H, 6.61%. Calcd for $C_{11}H_{17}ClOSi_2$: C, 51.44; H, 6.67%.

Reactions of 1a-Br, 1b-Cl, and 2-Cl with $LiAlH_4$: A reaction of **1a-Br** (1.10 g) with $LiAlH_4$ (0.3 g) in THF (25 cm^3) (room temperature, 1 h) gave 672 mg (82%) of benzylpentamethyldisilane (**1a-H**): Bp 125—126 °C (22 Torr); IR 1600, 1250, 835, 805, 785, 695 cm^{-1}; ^{1}H NMR δ=0.0 (15H, almost s), 2.11 (2H, s), 6.75—7.30 (5H, s). Found: C, 64.77; H, 9.91%. Calcd for $C_{12}H_{22}Si_2$: C, 64.80; H, 9.97%. A reaction of **1b-Cl** with $LiAlH_4$ in THF cleanly gave **1b-H**: ^{1}H NMR δ=0.0 (15H, s), 2.06 (2H, s), 2.27 (3H, s), 6.67—7.14 (4H, m). Found: C, 65.80; H, 10.03%. Calcd for $C_{13}H_{24}Si$: C, 66.02; H, 10.23%.

A reaction of **2-Cl** (471 mg) with $LiAlH_4$ (100 mg) in THF (5 cm^3) gave 1,1,2,2-tetramethyl-1,2-disilaindan (**2-H**)[6] (353 mg, 87%).

Oxidation of 2-Cl: A solution of **2-Cl** (150 mg) in carbon tetrachloride (20 cm^3) was heated at 70 °C for 2 h, while a slow stream of oxygen being bubbled into the solution. Solvent was removed and the residue was recrystallized from pentane to give 123 mg (83%) of **15**.

Thermolysis of 1-Cl: **1a-Cl** was heated to 150 °C for 1 h in a glass ampoule. ^{1}H NMR analysis indicated clean formation of 1-chloro-2,4-dimethyl-3-phenyl-2,4-disilapentane (**9a-Cl**):

IR 1250, 1200, 1030, 840, 800, 700 cm^{-1}; ^1H NMR δ=0.07 (9H, s), 0.35 (6H, s), 1.73 (1H, s), 6.86—7.24 (5H, m). Similarly, **1e-Cl** cleanly gave **9e-Cl** on heating to 150 °C: IR 1250, 1190, 1030, 860, 830, 800, 780 cm^{-1}; ^1H NMR δ=0.06 (9H, s), 0.34 (6H, s), 1.67 (1H, s), 2.27 (3H, s), 6.72—7.05 (4H, m). Reduction of **9b-Cl** with $LiAlH_4$ in ether gave the corresponding hydrosilane **9b-H:** IR 2110, 1250, 1030, 890, 850, 830 cm^{-1}; ^1H NMR δ=0.04 (3H, s, J=3.6 Hz), 0.0 (9H, s), 0.05 (3H, d, J=3.6 Hz), 1.39 (1H, d, J=3.6 Hz), 2.23 (3H, s), 3.87—4.23 (1H, m), 6.61—7.04 (4H, m). Found: C, 65.55; H, 10.17%. Calcd for $C_{12}H_{24}Si_2$: C, 66.02; H, 10.23%.

(Received April 24, 1991)

Potassium 2-indolizinethiolates, generated in situ from the treatment of dialkyl 2-[(2-ethoxycarbonylethyl)thio]indolizine-1,3-dicarboxylates with potassium *t*-butoxide in *N*,*N*-dimethylformamide, reacted smoothly with various isothiocyanates and isocyanates with the elimination of alkoxide ions to give new heterocyclic compounds, alkyl 4(3*H*)-oxo-2-thioxo- and 2,4(3*H*)-dioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine-10-carboxylates, in moderate to good yields. The structures of these 1,3-thiazino[6,5-*b*]indolizine derivatives were determined mainly by elemental analyses and spectral inspections, and the structural assignment was finally confirmed by the single crystal X-ray analyses of two compounds.

Recently, we reported the simple and convenient syntheses of various indolizine derivatives possessing an active methylene group at the 2-position and electron-withdrawing groups at the 1- and 3-positions and their smooth intramolecular cyclizations to the corresponding thieno[3,2-*a*]- and thieno[2,3-*b*]indolizine derivatives in the presence of a base.[2] In particular, potassium 2-indolizinethiolate derivatives[2c] generated in situ by the treatment of the corresponding 2-[(2-ethoxycarbonylethyl)thio]- or 2-[(2-cyanoethyl)thio]indolizines with potassium *t*-butoxide were key intermediates for the syntheses of these polyfunctionalized indolizines and thiophene-fused indolizines, and their very high reactivities toward various alkylating agents were shown.[2d] The ready availability, high nucleophilicity, and wide structural versatility of these potassium 2-indolizinethiolate derivatives promped us to investigate further their reactivity toward some heterocumulenes which are well known as reactive electrophilic species.[3] In this paper, we wish to report the reactions of 2-indolizinethiolate derivatives with some isothiocyanates and isocyanates, affording new heterocycles, 2-thioxo-2*H*-1,3-thiazino[6,5-*b*]indolizin-4(3*H*)-one and 2*H*-1,3-thiazino[6,5-*b*]indolizine-2,4(3*H*)-dione derivatives.

Results and Discussion

Reactions of Potassium 2-Indolizinethiolates with Isothiocyanates and Isocyanates. The treatment of dialkyl 2-[(2-ethoxycarbonylethyl)thio]indolizine-1,3-dicarboxylates (**1a**—**e**)[2c] with potassium *t*-butoxide in *N*,*N*-dimethylformamide (DMF) at 60—70 °C, the removal of the ethyl acrylate generated, and the addition of methyl isothiocyanate (**3a**) to the resulting potassium 2-indolizinethiolate derivatives (**2a**—**e**) afforded ethyl or *t*-butyl 3-methyl-4(3*H*)-oxo-2-thioxo-2*H*-1,3-thiazino-[6,5-*b*]indolizine-10-carboxylates (**4a**—**e**) in 41—97% yields. Similar reactions of indolizine derivatives **1a**—**d** with ethyl isothiocyanate (**3b**), phenyl isothiocyanate (**3c**), and allyl isothiocyanate (**3d**) gave the corresponding 4(3*H*)-oxo-2-thioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine derivatives **4f**—**q** in moderate to good yields. The reactions of **2a**—**e** with ethyl isocyanate (**3e**), and propyl isocyanate (**3f**) also provided the expected products, alkyl 3-ethyl- or 3-propyl-2,4(3*H*)-dioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine-10-carboxylates **4r**—**v**, **x**—**a′**, except compound **4w**. Interestingly, no product such as 4(3*H*)-oxo-2-thioxo- or 2,4(3*H*)-dioxo-2*H*-1,3-thiazino[5,6-*a*]indolizine **5** was formed even in the reactions of heterocumulenes **3a**—**f** with dialkyl 6,8-dimethylindolizine-1,3-dicarboxylates (**1d**, **e**), in which the reactivity of the 1-alkoxycarbonyl group is fairly enhanced owing to the steric hindrance of the 8-methyl group at the peri-position (Scheme 1).[2b,d] On the other hand, the reactions of indolizines **1f**, **g** having a cyano or an acetyl group at the 1- or 3-position with reagents **3a**—**f** did not afford any products such as **7** and **8** under the reaction conditions employed here, and only the deprotected 2-indolizinethiols **6a**, **b** were obtained in 64 and 71% yields, respectively. The reactions of 2-indolizinethiols **6a**, **b**, obtained in this reaction, with **3a**—**f** were also unsuccessful. (Scheme 2)

Furthermore, any condensation products were not given in the reactions of **1a**, **b** with phenylketene and dichloroketene generated in situ by the addition of phenylacetyl chloride or dichloroacetyl chloride to the reaction mixtures.

The structural assignments for the products **4a**—**v**,**x**—**a′** were accomplised mainly by their elemental and spectral analyses and mechanistic considerations. For example, their elemental analyses coincided well with the compositions for our proposed structures and their IR spectra (see Table 5) distinctly showed the carbonyl absorption bands due to an aromatic ester and an amide group in the ranges of 1659—1721 and 1637—1664 cm^{-1}, respectively. The ^1H NMR spectra (Table 1) of **4a**—**v**, **x**—**a′** showed the presence of an alkyl, allyl, or phenyl group derived from isothiocyanates **3a**—**d** or isocyanates **3e**, **f** employed here, and the absence of an ethoxyl group of two ester alkoxyl groups which were present at the 1-

a) The coupling constants were as follows: $J_{6,7}=J_{7,8}=7.0$, $J_{8,9}=9.0$, $J_{6,8}=2.0$, and $J_{Et}=7.0$ Hz. b) Overlapped with the phenyl proton signals.

and 3-positions in starting indolizines **1a**—**e**. However, these considerations for products **4a**—**d**, **f**—**u**,**x**—**z**, except **4e**, **v**, **a′** which bear a *t*-butoxycarbonyl group, were not only true for the structures of the 1,3-thiazino[6,5-*b*]indolizines but also for an alternative structure, 1,3-thiazino[5,6-*a*]indolizine **5**. Finally, the structures of compounds **4a**—**d**, **f**—**u**, **x**—**z** were determined by analogy with the high reactivity of the 3-alkoxycarbonyl group superior to the 1-alkoxycarbonyl group[2d)] and confirmed by the X-ray analyses of compounds **4i**, **u** (see below).

Crystallography of 1,3-Thiazino[6,5-*b*]indolizines (4i,u).

a) $B_{eq}=\frac{8\pi^2}{3}\sum_{i=1}^{3}\sum_{j=1}^{3}U_{ij}a_i^*a_j^*\boldsymbol{a}_i\cdot\boldsymbol{a}_j$.

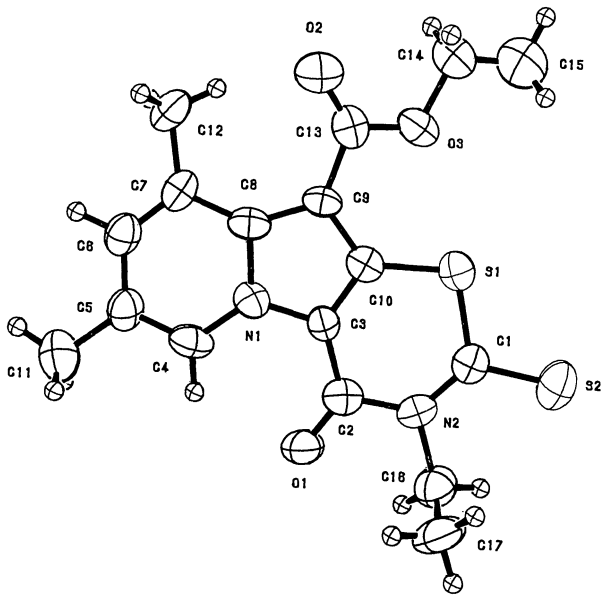

Fig. 1. ORTEP drawing of 4(3*H*)-oxo-2-thioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine derivative **4i** showing the atom labeling scheme and 50% probability thermal ellipsoids.

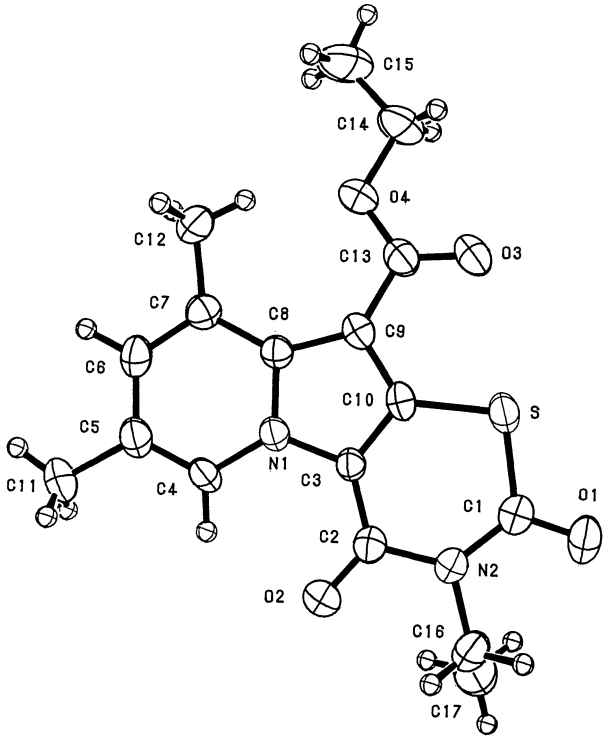

Fig. 2. ORTEP drawing of 2,4(3*H*)-dioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine derivative **4u** showing the atom labeling scheme and 50% probability thermal ellipsoids.

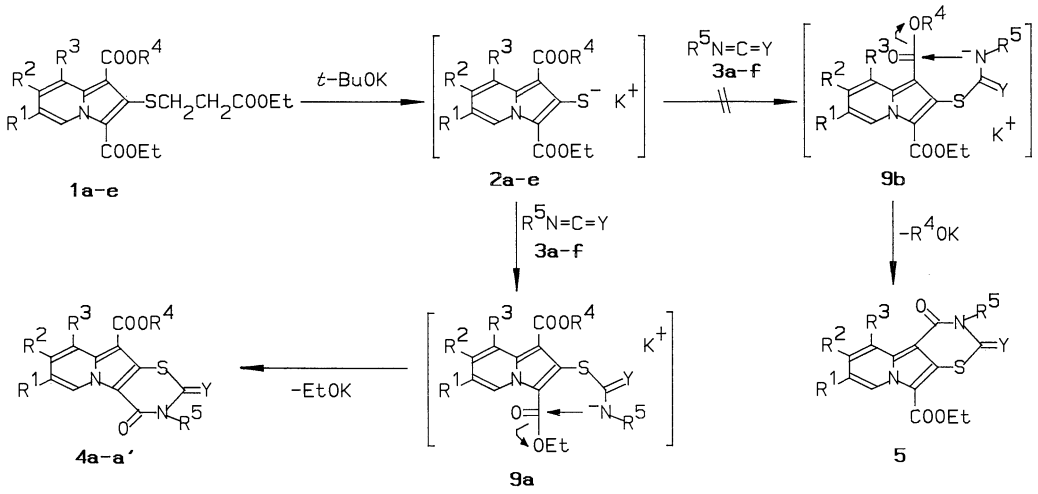
oxo-2-thioxo- (**4i**) and ethyl 3-ethyl-7,9-dimethyl-2,4-(3*H*)-dioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine-10-carboxylate (**4u**) were grown from their ethanolic solutions, respectively. A yellow monoclinic crystal for **4i** and a white triclinic crystal for **4u** were used for structure determinations. Crystal data and details of structure analyses are shown in Tables 2—4.[4] The ORTEP drawings[5] of compounds **4i**, **u** are shown in Figs. 1 and 2, respectively. Interestingly, the only difference between the structures of **4i**, **u** was observed in the conformations of their 10-ethoxycarbonyl groups, but the reason for their different packings in the crystal lattices is still unclear.

Reaction Mechanisms. These reactions were considered to proceed via the nucleophilic attack of 2-indolizinethiolate derivatives **2a**—**e** on the central carbon of heterocumulenes **3a**—**f** followed by the intramolecular nucleophilic reaction of the resulting intermediate, such as **9a**, with the elimination of an ethoxide ion. (See Scheme 3) As has been described in the transformations of 8-unsubstituted diethyl 2-(substituted methylthio)indolizine-1,3-dicarboxylates to 3-hydroxythieno[2,3-*b*]indolizines, the exclusive formation of 1,3-thiazino[6,5-*b*]indolizine derivatives **4a**—**c**, **f**—**h**, **j**—**l**,**n**—**p**, **r**—**t**, **x**, **y** from the reactions of 8-unsubstituted 2-indolizinethiolates **2a**—**c** with heterocumulenes **3a**—**f** was easily supported owing to the higher reactivity of the 3-alkoxycarbonyl group over the 1-alkoxycarbonyl group.[2b,d] However, the unavailability of 1,3-thiazino[5,6-*a*]indolizine derivatives, such as **5**, in the reactions of 6,8-dimethyl-2-indolizinethiolates **2d**, **e**, whose 1-alkoxycarbonyl group is activated by the steric hindrance of the 8-methyl group at the peri position, with **3a**—**f** was mysterious. The examination of the molecule of **5** using Dreiding models clearly showed the presence of severe repulsive interaction between the 4-oxo oxygen and the 8-methyl group. In order to avoid an unfavorable interaction like this, the exclusive intramolecular nucleophilic attack of the nitrogen anion to the carbonyl carbon of the 3-position could have occurred. On the other hand, the reason why some reactions of **2** with ketenes were unsuccessful is still unclear, but it may have been attributable in part to the bulkiness of these ketenes against the approach to the thiolate anion **2**.

In conclusion, the reactions of potassium 2-indolizinethiolate derivatives **2a**—**e** with some heterocumulenes **3a**—**f** was found to be a useful method for the preparation of new condensed indolizine derivatives.

Experimental

Melting points were measured with a Yanagimoto micromelting point apparatus and were not corrected. The microanalyses were carried out on a Perkin-Elmer 240 elemental analyzer. The ^{1}H NMR spectra were determined with a Varian EM360A spectrometer in deuteriochloroform with tetramethylsilane as an internal standard and the chemical



Scheme 3.

shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 infrared spectrophotometer.

Reaction of Indolizines with Isothiocyanates and Isocyanates in the Presence of Base. General Method. A solution of a dialkyl 2-[(2-ethoxycarbonylethyl)thio]indolizine-1,3-dicarboxylate (**1**, 1 mmol) in 2 ml of DMF was treated with potassium *t*-butoxide (0.168 g, 1.5 mmol) at 60—70 °C in a water bath for 1 h, and ethyl acrylate generated in this reaction was removed completely by a rotatory evaporator under reduced pressure. An isothiocyanate or isocyanate (**3**, 1.2 mmol) was added to the mixture and the resulting solution was allowed to react at 60—70 °C for an additional 2 h. The reaction mixture was acidified with diluted hydrochloric acid and water was then added to bring the total volume to 30 ml. The precipitates were colleted by filtration. The precipitates were then dissolved in 30 ml of chloroform and water was removed from the solution by filtration through phase-separating filter paper. The filtrate was concentrated under reduced pressure and the residue was separated by column chromatography on activated alumina using chloroform as an

a) Compounds **4a**—**q** were obtained as pale yellow needles and **4r**—**v**, **x**—**a′** as colorless needles.
b) Satisfactory analytical data (within 0.3% for C, H, and N) were obtained for all compounds.

eluent. Evaporation of the chloroform and recrystallization of the crude products from ethanol afforded the corresponding ethyl or *t*-butyl 4(3*H*)-oxo-2-thioxo- (**4a**—**q**) and 2,4(3*H*)-dioxo-2*H*-1,3-thiazino[6,5-*b*]indolizine-10-carboxylates (**4r**—**v**, **x**—**a'**). These results and some spectral data are summarized in Tables 1 and 5.

On the other hand, similar treatment of ethyl 3-acetyl-2-[(2-ethoxycarbonylethyl)thio]indolizine-1-carboxylate **1f** and ethyl 1-cyano-2-[(2-ethoxycarbonylethyl)thio]indolizine-3-carboxylate **1g** with methyl isothiocyanate **3a** gave only the corresponding 2-thiol derivatives, ethyl 3-acetyl-2-mercaptoindolizine-1-carboxylate (**6a**, mp 114—116 °C, 64% yield) and ethyl 1-cyano-2-mercaptoindolizine-3-carboxylate (**6b**, mp 130—131 °C, 71% yield), and did not afford any condensation products. Compounds **6a**, **b** were completely in accord with authentic samples in all respects.[2c] The 2-indolizinethiols **6a**, **b** did not react with reagents **3a**—**f** even under heating conditions.

The reactions of indolizines **1a**, **b** with ketene precursors such as phenylacetyl chloride and dichloroacetyl chloride under the alkaline conditions employed here were also unsuccessful.

The reactions of 2-[mercapto(methylthio)methylene]-2(3*H*)-indolizinones with alkyl isothiocyanates in the presence of potassium *t*-butoxide in *N*,*N*-dimethylformamide afforded new heterocycles, 3-alkyl-2*H*-1,3-oxazino-[6,5-*b*]indolizine-2,4(3*H*)-dithione derivatives, in moderate yields. On the other hand, their reactions with phenyl isothiocyanate did not afford the corresponding 2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithiones, although the reaction of 2-[mercapto(methylthio)methylene]-1-methyl-2(3*H*)-indolizinone with phenyl isothiocyanate gave 10-methyl-3-phenyl-2-phenylimino-2,3-dihydro-4*H*-1,3-oxazino[6,5-*b*]indolizine-4-thione in a very low yield (10%). The structures of these 2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithiones and the 2-phenylimino analogue were determined by inspections of their physical and spectral data and by a single crystal X-ray analysis of one of these compounds.

In previous work, we have documented that 3-(mercaptomethylene)-2(3*H*)-indolizinones reacted with some (acyl- or cyano-substituted)methyl halides in the presence of a base to give the corresponding new heterocycles, 8,8a-dihydro[1,4]thiazino[3,4,5-*cd*]indolizin-4(1*H*)-ones, which were formed via the smooth intramolelcular Michael addition of the resulting *S*-alkylated products.[2] The high nucleophilicity of the mercapto group in these molecules[2,3] and our recent success in the preparation of 2*H*-1,3-thiazino[6,5-*b*]indolizine derivatives from potassium 2-indolizinethiolates[1] prompted us to examine the reactions between these molecules and electron-poor heterocumulenes such as isocyanate and isothiocyanate. In contrast with the smooth *S*-alkylations of 3-(mercaptomethylene)-2(3*H*)-indolizinones, their reactions with alkyl or aryl isocyanates and isothiocyanates did not proceed under ordinary reaction conditions. They reacted only with isothiocyanates under more forceful conditions in the presence of a strong base, but the products were not the initially expected 5*H*-[1,3,5]thiadiazepino[6,5,4-*cd*]indolizine derivatives. In this paper we wish to report the first synthesis of 2*H*-1,3-oxazino[6,5-*b*]indolizine derivatives by the reactions of 3-[mercapto-(methylthio)methylene]-2(3*H*)-indolizinones with some isothiocyanates in the presence of a strong base.

Results and Discussion

Reactions of 3-[Mercapto(methylthio)methylene]-2(3*H*)-indolizinones with Some Isothiocyanates. Since the high reactivity of the mercapto group of 3-(mercaptomethylene)-2(3*H*)-indolizinone derivatives toward various alkylating agents in the presence of a base was clearly shown,[2,3] their reactions with unsaturated electrophiles such as isocyanates and isothiocyanates were initially expected to form the corresponding 5*H*-[1,3,5]thiadiazepino[6,5,4-*cd*]indolizine derivatives such as **4** (see Scheme 1) via the electrophilic attack of the reagent on the sulfur atom followed by the Michael addition of the resulting aminide ion to the 5-position on the indolizine ring. Hence, the reactions of 3-[mercapto(methylthio)methylene]-2(3*H*)-indolizinones (**1a**—**e**), readily available from the alkaline treatment of 2-(substutited methyl)pyridinium bromides, carbon disulfide, and dimethyl sulfate,[3] with some isocyanates and isothiocyanates were examined carefully under various reaction conditions, and we found that, although their reactions with isocyanates did not provide any significant products, those with isothiocyanates afforded significant amounts of products when a strong base, potassium *t*-butoxide, was present. The structures of the products, however, were different from the expected ones (**4**) (See below). When a mixture of 2(3*H*)-indolizinone **1a**—**e**, methyl isothiocyanate (**2a**), and potassium *t*-butoxide was allowed to react in DMF at 70—80 °C for 20 min, the title compounds, 3-methyl-2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithiones **3a**—**e**, were obtained in 10—77% yields as orange crystals. Similar reactions of **1a**—**e** with ethyl isothiocyanate (**2b**), allyl isothiocyanate (**2c**), propyl isothiocyanate (**2d**), and butyl isothiocyanate (**2e**) in the presence of potassium *t*-butoxide gave the corresponding crystalline products **3f**—**j**, **l**—**s** except **3k**, in moderate yields. These results are shown in Scheme 1. On the other hand, the reaction of 2(3*H*)-indolizinone **1b** with phenyl isothiocyanate (**2f**) in the presence of potassium *t*-butoxide at 70—80 °C for 2 h provided an alternative product, 10-methyl-3-phenyl-2-phenylimino-2,3-dihydro-4*H*-1,3-oxazino[6,5-*b*]indolizine-4-thione **5a**, in a low yield (10%). The reactions of **1a**, **c**—**e** with the same reagent **2f** did not give any products. Furthermore, the type of product such as **5f**—**h** could not be obtained by the reactions of 2*H*-1,3-

Scheme 2.

oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithione (**3b**, **g**,**p**) with **2f**. (Scheme 2)

As described above, the structures of compounds **3a**—**s** were first considered to be 5*H*-[1,3,5]thiadiazepino-[6,5,4-*cd*]indolizin-5-one derivatives such as **4**, but their ^{1}H NMR (see Table 1) and mass spectra and elemental analyses clearly excluded this structure. For example, the ^{1}H NMR spectrum of compound **3a** showed only the signals due to the aromatic indolizine ring protons (δ=10.64 (1H, br d, J=7.0 Hz, 6-H), 7.2—7.7 (2H, m, 8-H and 9-H), 7.00 (1H, m, 7-H), and 6.25 (1H, s, 10-H)) and the *N*-methyl protons (δ=4.23 (3H, s)); any other signals attributable to the methylthio group were not present. The ^{1}H NMR spectra of the products **3a**—**j**, **l**—**s** were very similar to each other, and the mass spectra of **3a**,**b**,**d** and elemental analyses of **3a**—**j**, **l**—**s** were also in good accord with the proposed structures.

Furthermore, the X-ray analysis of a single crystal of 3,10-dimethyl-2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithione (**3b**) was performed and its structure was confirmed. The single crystal of this molecule **3b** was grown from an ethanolic solution. An orange monoclinic crystal for **3b** was used. Crystal data and details of the structure analysis are shown in Tables 2 and 3.[4] The ORTEP[5] drawing is shown in Fig. 1.

On the other hand, the structure of product **5b** was determined by elemental analysis and by spectral comparison with those of the 2*H*-1,3-oxazino[6,5-*b*]-

Table 1. ^{1}H NMR Spectral Data of 2*H*-1,3-Oxazino[6,5-*b*]indolizines

a) The coupling constants were as follows: $J_{6,7}=J_{7,8}=7.0$, $J_{8,9}=9.0$, $J_{6,8}=2.0$, and $J_{Et}=7.0$ Hz. b) Overlapped with the phenyl proton signals.

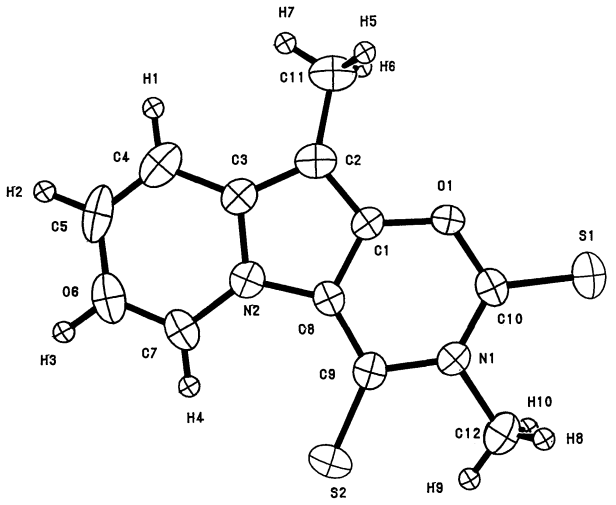

Fig. 1. ORTEP drawing of 3,10-dimethyl-2*H*-oxazino[6,5-*b*]indolizin-2,4(3*H*)-dithione (**3b**) showing the atom labeling scheme and 50% probability thermal ellipsoids.

indolizine-2,4(3*H*)-dithiones **3**. The mass spectrum (M^+ 383) and the elemental analysis of **5b** showed that the molecular formula was $C_{23}H_{17}N_3OS$ which corresponded to the subtraction of one mole of carbon disulfied from the 1:2 adduct between indolizinone **1b** and phenyl isothiocyanate (**2f**). The structural formula presumed from these findings and the mechanistic considerations was either 10-methyl-3-phenyl-2-phenylimino-2,3-dihydro-4*H*-1,3-oxazino[6,5-*b*]indolizine-4-thione **5b** or an alternative 4-phenylimino derivative **6**. The largely deshielded chemical shift (δ=10.57) attributable to the 6-H proton in **5b** was very similar to those (δ=10.53—10.78) of **3a—j**, **l—s**, indicating the similarity of the magnetic circumstances between them. Furthermore, the interpretation of the fragmentations in the mass spectra of **5b** and **3a,b,d** confirmed the structure of **5b**: The mass spectrum of **5b** exhibited *m/z* 383 (21%, M^+), 248 (13%, M^+—PhN=C=S), 189 (100%, M^+—PhN=C=NPh), 161 (3%, M^+—222), 105 (13%, M^+—278), and 78 (4%,

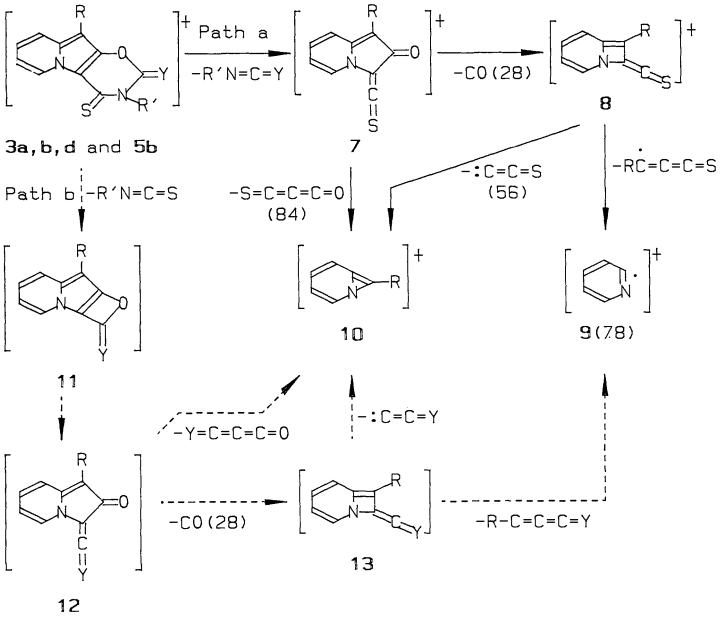
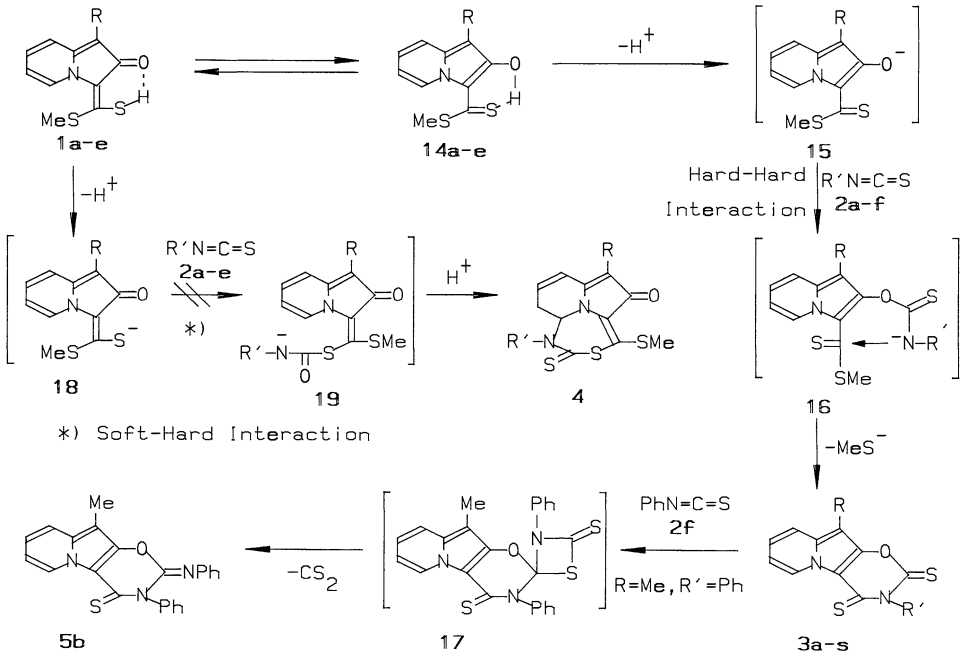


Scheme 3.

M$^+$−305), and those of **3a**,**b**,**d** showed definite peaks due to the corresponding M$^+$, (M$^+$−MeN=C=S), (M$^+$−101), (M$^+$−157), and 78 ions, respectively. The possible fragmentation patterns of the molecules **3a**,**b**,**d**, and **5b** are illustrated in Scheme 3. Although respective ions can be generally derived from both Path a (solid line) and Path b (dashed line), Path a is energetically more favorable than Path b because the fissions of any bonds



Scheme 4.

connected with the aromatic indolizine ring are not involved in this route.[6] The predominance of the *m/z* 189 ion (M^+—PhN=C=NPh) over the *m/z* 248 ion (M^+—PhN=C=S) strongly supported that this product was **5b** but not **6**.

Reaction Mechanisms. The formation of the 3-alkyl-2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithiones (**3a—j, l—s**) were explained by the initial abstraction of the active hydrogen in 3-[mercapto(methylthio)-methylene]-2(3*H*)-indolizinones **1a—e** or their 2-hydroxy tautomers **14a—e** with potassium *t*-butoxide, the electrophilic addition of isothiocyanate **2** to the resulting 2-indolizineolate ions **15**, and by the intramolecular nucleophilic attack of the aminide ion **16** to the thiocarbonyl carbon at the 3-position followed by the elimination of a methylthio anion. This mechanism is very similar to those proposed for the syntheses of 2*H*-1,3-benzoxazine-2-thiones[7] and 2*H*-1,3-thiazino[6,5-*b*]indolizin-2-thiones.[1] The reason why the initially expected product **4** could not be formed by the reaction between the alternative thiolate ion **18** and isothiocyanate **2** may be explained by considering the unfavorable interaction between this anion **18** and reagents **2** based on a HSAB principle.[8] On the other hand, 2-phenylimino derivative **5b** must be formed via the [2+2] cycloaddition of phenyl isothiocyanate (**2f**) to 10-methyl-3-phenyl-2*H*-[1,3]oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithione once formed followed by the cycloreversion of the 2*H*-1,3-thiazetidine-2-thione ring in the resulting **17** with the elimination of carbon disulfide. However, the reason why other compounds **5a**, **c—h** could not be obtained by similar reactions of **1a**, **c—e** and **3b,g,p** with **2f** is still unclear. These mechanism are summarized in Scheme 4.

Experimental

Melting points were measured with a Yanagimoto micromelting point apparatus and were not corrected. The microanalyses were carried out on a Perkin-Elmer 2400 elemental analyzer. The ^{1}H NMR spectra were determined with a Varian EM360A spectrometer in deuteriochloroform with tetramethylsilane as an internal standard and the chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 infrared spectrophotometer.

Preparations of 3-[Mercapto(methylthio)methylene]-2(3*H*)-indolizinones. The preparation of 3-[mercapto(methylthio)-methylene]-1-phenyl-2(3*H*)-indolizinone **1d**, mp 121—122 °C (Lit,[3] mp 121—122 °C), was carried out according to our previous procedure, and those of **1a—c, e** by modified procedures: **General Method.** An ethanolic solution (100 ml) of 2-methyl-, 2-ethyl-, 2-propyl-, or 2-(*p*-chlorobenzyl)pyridinium bromide (10 mmol) was treated with ethanolic sodium ethoxide at room temperature for 15—20 min. Carbon disulfide (12 mmol) and then dimethyl sulfate (11 mmol) were added to the mixture and the resulting solution was stirred for an additional 20 min. The reaction mixture was poured into 300 ml of water and was extracted with two portions of chloroform (300 ml). The chloroform layer was dried over sodium sulfate, filtered, and concentrated under reduced pressure. The residue was chromatographed on a column of alumina using chloroform as an eluent to give the crude 2(3*H*)-indolizinone, which was recrystalized from ethanol (**1a,c**) or chloroform (**1b,e**).

Some data for new compounds are as follows: **1a**, 19% yield, orange needles, mp 128—131 °C, ν (KBr) 2570 (SH) and 1570 (CO) cm^{-1}, Anal. ($C_{10}H_9NOS_2$) C,H,N.

a) All compounds were obtained as orange needles. b) Satisfactory analytical data (within 0.3% for C, H, and N) were obtained for all compounds.

1b, 65% yield, orange needles, mp 134—135 °C, ν (KBr) 2580 (SH) and 1588 (CO) cm^{-1}, Anal. ($C_{11}H_{11}NOS_2$) C,H,N.

1c, 30% yield, orange needles, mp 78—80 °C, ν (KBr) 2580 (SH) and 1585 (CO) cm^{-1}, Anal. ($C_{12}H_{13}NOS_2$) C,H,N.

1e, 71% yield, orange needles, mp 153—154 °C, ν (KBr) 2520 (SH) and 1585 (CO) cm^{-1}, Anal. ($C_{16}H_{12}ClNOS_2$) C,H,N.

Reactions of 2(3*H*)-Indolizinones with Alkyl Isothiocyanates. General Method. A DMF solution (1 ml) of 3-[mercapto(methylthio)methylene]-2(3*H*)-indolizinone (**1**, 1 mmol) and isothiocyanate (**2**, 2 mmol) was treated with potassium *t*-butoxide (2 mmol) at 70—80 °C for 20 min. The reaction mixture was neutralized with diluted hydrochloric acid and then extracted with chloroform (20 ml). Water was removed from the chloroform solution by passage through phase-separating filter paper and the filtrate was concentrated under reduced pressure. The residue was separated by column chromatography on alumina using chloroform as an eluent. The chloroform solution was concentrated under reduced pressure and the recrystallization of the crude products from ethanol gave the corresponding 2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4-dithione derivatives **3a**—**s** as orange needles. The results and some physical and spectral data of **3a**—**s** are listed in Tables 1 and 4.

The prolonged reactions (1—4 h) of indolizinones **1** and isothiocyanates **2** gave diminished yields of the products **3**.

Reaction of 1-Methyl-2(3*H*)-indolizinone 1b with Phenyl Isothiocyanate (2f). A DMF solution (1 ml) of **1b** (1 mmol) and **2f** (2 mmol) was heated at 70—80 °C for 2 h in the presence of potassium *t*-butoxide (2 mmol). The usual work-up of the resulting mixture gave 10-methyl-3-phenyl-2-phenylimino-2,3-dihydro-4*H*-1,3-oxazino[6,5-*b*]indolizine-4-thione (**5b**), 10% yield, orange needles, mp 266—268 °C, ν (KBr) 1675 (C=N) cm^{-1}, Anal. ($C_{23}H_{17}N_3OS$) C,H,N (See Table 1 for its ^1H NMR spectrum)

On the other hand, the reactions of indolizinones **1a**,**c**—**e** and 2*H*-1,3-oxazino[6,5-*b*]indolizine-2,4(3*H*)-dithiones **3b**,**g**,**p** with phenyl isothiocyanate (**2f**) did not afford any significant products under various reaction conditions.

(Received May 14, 1991)

The electrocatalytic hydrogenation of the title compound was examined over Raney Ni, Raney Co, Pt-carbon and Pd-carbon as hydrogen-active powder electrodes. A high conversion of ketone to alcohol was observed on the Raney catalysts when the pK_a values of the proton sources employed were around 5. The metal-on-carbon catalysts showed a relatively low conversion of ketone regardless of the proton sources. The stereochemistry of the reaction was examined.

Since Raney Ni has been known as a useful hydrogenation catalyst, its electronic properties have also allowed its use as cathodic material.[1,2] Osa et al.[3] pointed out that hydrogenation with catalytically-active powder electrodes of group VIII transition metal had several intrinsic advantage over direct, uncatalyzed electroreductions. This reaction involved the chemisorption of atomic hydrogen from the solvent on the electrodes in the first step (Fig. 1a). The potential of this step was usually much less positive than that required to reduce a functional group via an EC mechanism (Fig. 1b). Also, the electrochemical catalysis produced hydrogen in situ and avoided the need to introduce hydrogen from an external source. The reaction could be controlled by changing the electric potential and the current. In other words, the electrocatalytic hydro-

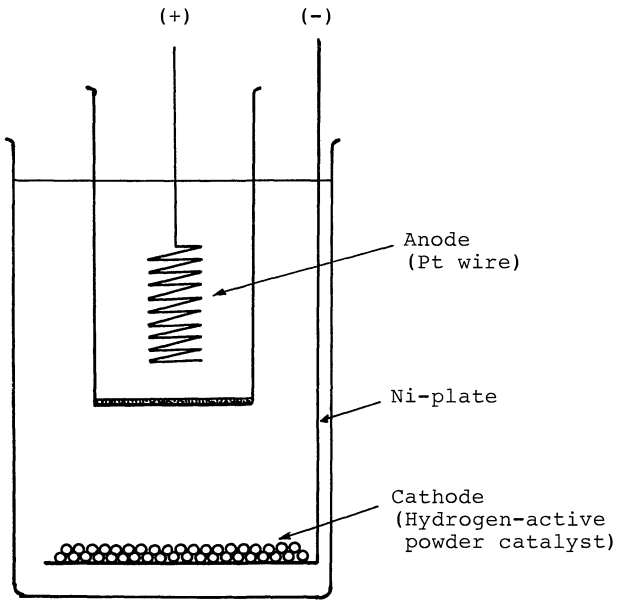

Fig. 2. Electrolysis cell.

genation on hydrogen-active powder electrodes is situated in boundaries between uncatalyzed electroreduction via an EC mechanism and ordinary catalytic hydrogenation. A number of mechanistic studies over group VIII transition metal catalysts are also found in the literature.[4)]

To the best of our knowledge, there has been no study on the stereoselective hydrogenation with active powder electrodes. 4-*t*-Butylcyclohexanone (**1**) was selected as the substrate and the stereochemistry of hydrogenation with an electrocatalytic electrode which consisted of Raney Ni, Raney Co, Pt-carbon or Pd-carbon was examined. The hydrogen adsorbed on the Raney catalyst surface was removed by treating with pentene. The electrolysis was carried out in a divided cell with the catalyst cathode and a Pt wire or graphite rod anode (Fig. 2). Table 1 tabulates the results of the electrocatalytic hydrogenation with various types of proton sources after the passage of 5×96500 C mol^{-1} of electrical charge.

Table 2. Effect of the Amount of the Catalyst on the Electrocatalytic Hydrogenation of 4-*t*-Butylcyclohexanone

Catalyst	Weight g	Yield %	Isomer ratio (cis%)
Raney Ni	1.0	68	72
	1.5	73	74
	2.0	78	70
Pt-carbon	0.02	15	19
	0.04	24	24
	0.06	23	22

The conversion of **1** to 4-*t*-butylcyclohexanol over Raney catalysts depended on the pK_a values of the proton sources. The highest conversion was 78% in a proton source with a pK_a value at around 5 under the reaction conditions employed. Decreasing or increasing the pK_a values of the proton sources reduced the conversion. The conversion was only 5% and 20%, respectively, over the Raney Ni catalyst, when chloroacetic acid and phenol were used as a proton source. When metal-on-carbon catalysts were used, the conversion of ketone to alcohol was relatively low, but no appreciable change in the conversion was observed depending on the pK_a values of the proton sources. Increasing the amount of catalyst resulted in an increase in the conversion (Table 2). In the absence of a metal catalyst, the cathodic reduction with pivalic acid as a proton source proceeded very slowly. The conversion was only 4% and the amount of *cis* alcohol was 44%.

In the ordinary catalytic hydrogenation in which sufficient hydrogen is supplied, 77 and 69% *cis* alcohol was obtained over the Raney Ni and Co catalysts, respectively, while 80% and 85% *trans* alcohol was obtained over the Pt-carbon and Pd-carbon catalysts (Table 3). In the electrocatalytic hydrogenation, the *cis*

Table 3. Comparison of the Isomeric Product Ratio between Ordinary Catalytic and Electrocatalytic Hydrogenation of 4-*t*-Butylcyclohexanone

Catalyst	Product ratio (cis%)		
	Catalytic	Electrocatalytic proton source	
		$(CH_3)_2CHCOOH$	$(CH_3)_3COH$
Raney Ni	77	72	35
Raney Co	69	69	37
Pt-carbon	20	19	22
Pd-carbon	15	26	16

alcohol was predominantly obtained at a high conversion rate over Raney catalysts (similar to ordinary catalytic hydrogenation), but the *trans* alcohol became predominant at a low conversion rate (Table 1). On the other hand, the *trans* alcohol was predominantly obtained (similar to the case of ordinary catalytic hydrogenation), and the isomeric product distribution was independent of the pK_a values of the proton sources when the carbon-supported catalysts were employed. Cathodic reduction without the electrocatalyst gave more of the *trans* alcohol than the *cis*.

The stereochemistry of the ordinary catalytic hydrogenation was interpreted in terms of the Horiuti–Polanyi mechanism which is one of the most satisfactory theories.[5] The change in the product-controlling step, depending on the catalysts, coincides with a change in the ratio of the products. The Horiuti–Polanyi formulation of the mechanism of hydrogenation of unsaturated bonds may be represented by four elementary reactions; dissociation of hydrogen, adsorption of the substrate on the catalyst, first hydrogen transfer to the adsorbed species and second hydrogen transfer to the half-hydrogenated intermediate. The proportion of the stereoisomeric products will depend upon which of the elementary reactions is a product-controlling step, because the geometry and/or composition of the several possible transition states differ from one another. When the product-controlling step is the adsorption of the substrate on the catalyst or the first hydrogen transfer from the catalyst to the adsorbed species, the stereochemistry of the reaction is controlled by the interaction between the substrate and the catalyst. On the other hand, when the product-controlling step is the second hydrogen transfer from the catalyst to the half-hydrogenated species, the stereochemistry of hydrogenation is controlled by the relative stabilities of the two epimeric half-hydrogenated species.

When the pK_a value of the proton source employed in a system was more than 5, the conversion of ketone to alcohol decreased over the Raney catalyst. Since the electron transfer to protons on the cathode is more difficult in a proton source with a higher pK_a value, an insufficient supply of active hydrogen results in a decrease in the amount of hydrogen available on the catalyst surface. This permits equilibration between the *cis* and the *trans* half-hydrogenated intermediates, thus resulting in a decrease of *cis* stereoselectivity of the reaction and the *trans* alcohol becomes predominant.

When the pK_a value of the proton source was less than 5, the conversion of ketone was also small the *trans* alcohol was preferably obtained over a Raney catalyst. The surface of the Raney catalyst is damaged in acidic conditions so that metal ions are gradually eluted from the surface and the catalyst surface poisoned by those ions. This results in a low conversion and the predominant formation of the *trans* alcohol. The optimum pK_a value of the electrocatalytic hydrogenation over a Raney catalyst is around 5. On the other hand, no poisoning under acidic conditions was observed over the metal carbon catalysts and the conversion and the isomer ratio were relatively constant under all reaction conditions employed here.

The effect of current density on the conversion of ketone to alcohol and the stereochemistry was also examined (Table 4). A change in current density had no appreciable effect on the conversion and the isomeric product distribution in the hydrogenation over Raney Ni catalyst when isobutyric acid was used as the proton source. On the other hand, the conversion was improved at a lower current density when *t*-butyl alcohol was used as the proton source. In the hydrogenation over Pt-carbon, a decrease in the current density increased the conversion of ketone to alcohol. These results indicated that a part of the produced active hydrogen by electrochemical reductrion was not used in hydrogenation but was lost as molecular hydrogen to the

Table 4. Effect of the Current Density on the Electrocatalytic Hydrogenation of 4-*t*-Butylcyclohexanone

Catalyst	Proton source	Current density	Yield	Isomer ratio

outside of the system at a relatively high current density, while the generation of active hydrogen is moderate and is efficiently used for the hydrogenation at a low current density.

When a graphite electrode was used as the anode, no appreciable change in the results of hydrogenation was observed (Table 5).

Experimental

Electrocatalytic Hydrogenation. Metal-on-carbon catalysts were commercially available. Raney catalysts which were prepared from metal-alloy were treated with pentene to remove the hydrogen adsorbed on the catalyst surface. The electrochemical cell was a conventional divided cell with a metal catalyst cathode and a platinum coil (surface area 7.48 cm^2) or graphite rod (surface area 9.86 cm^2) anode. For making contact with the metal catalyst powder, a nickel plate electrode (surface area 12.56 cm^2) was first placed on the bottom of the flask on which a known amount of metal catalyst powder was then stacked in the presence of an electrolyte solution. The electrolyte solution consisted of 50 cm^3 of a 10% tetrahydrofuran:H_2O (9:1 volume ratio) solution containing 163 mmol of $NaClO_4$, 3.1 mmol of 4-*t*-butylcyclohexanone (**1**), and 25.0 mmol of a proton source. The electrolysis was carried out at room temperature. After the passage of 5×96500 C mol^{-1} of electrical charge, the catholyte was filtered off from the catalyst and extracted three times with ether, washed with saturated NaCl solution and analyzed by gas chromatography.

Gas Chromatographic Analysis. Analyses were performed with a Simadzu GC-8A with a glass capillary column CPB20 (0.2 mm×25 m) at 120 °C. The products were compared with the authentic sample which was prepared by the LAH reduction of **1**.

Neighboring Effect of a Carbonyl Group in Base-Induced Wittig-Type Rearrangements of Poly(4-nitrobenzyloxy)tropones to Bis- and Mono(α-hydroxy-4-nitrobenzyl)tropones

Bing Zhu YIN,† Akira MORI, and Hitoshi TAKESHITA*
Institute of Advanced Material Study, 86, Kyushu University,
Kasuga-koen, Kasuga, Fukuoka 816
(Received May 24, 1991)

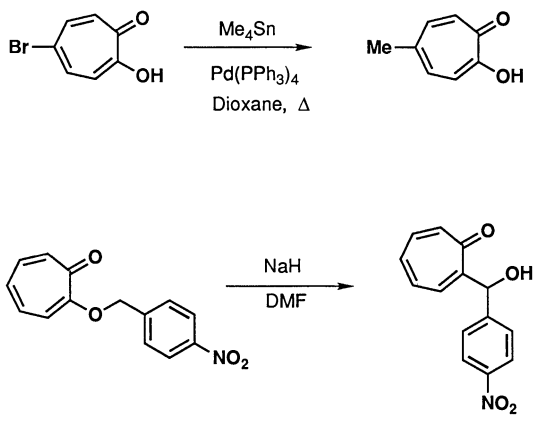
The base-catalyzed rearrangement of bis- and tris(4-nitrobenzyloxy)tropones gave (α-hydroxy-4-nitrobenzyl)tropones through a Wittig-type mechanism. Only the 4-nitrobenzyloxy group adjacent to the carbonyl group migrated. The carbonyl group played a role in facilitating the rearrangement by chelation with the sodium on the adjacent carbanion.

To overcome severe restrictions in introducing carbon substituents into the tropone ring,[1,2] several new approaches were recently elaborated: e.g., Banwell reported efficient palladium-mediated *ipso*-substitution processes of bromotropolones with various aryl-, alkenyl-, and alkyltrimethylstannanes.[3]

Recently, we exploited a new carbon–carbon bond formation in troponoids by means of base-catalyzed rearrangements of 2-(4-cyano-, 2-nitro-, and 4-nitrobenzyloxy)tropones and 2-(2-oxo-2-phenylethoxy)tropone to 2-[α-hydroxy-(4-cyano-, 2-nitro-, and 4-nitrobenzyl)]tropones and 2-(1-hydroxy-2-oxo-2-phenylethyl)tropone, respectively, via a Wittig-type mechanism.[4] This constituted a new regio-controlled introduction of carbon substituents into a tropone ring. In this paper, we describe an extention of this base-induced rearrangement to poly(benzyloxy)tropones to prepare poly(α-hydroxy-4-nitrobenzyl)tropones, in which only the benzyloxy group adjacent to the carbonyl group rearranged.

Results and Discussion

5-Hydroxytropolone dipotassium salt (**1**) and 4-nitrobenzyl bromide (**2**) in a hexamethylphosphoric triamide (HMPA) solution gave only a single product, 2,5-bis(4-nitrobenzyloxy)tropone (**3**). However, 3-hydroxytropolone dipotassium salt (**4**) and **2** gave three products (**5**—**7**); products **5** and **6** were identified to be 2,7-bis(4-nitrobenzyloxy)- and 2,3-bis(4-nitrobenzyloxy)tropones, respectively, from the NMR spectral data and **7** was identified as monobenzylated 3-(4-nitrobenzyloxy)tropolone. Along with these, an air-oxidized by-product **8**, which was no longer a troponoid derivative, was obtained. Its ^{1}H and ^{13}C NMR spectral data indicated it was bis(4-nitrobenzyl) (*Z*,*Z*)-2,4-hexadienedioate.



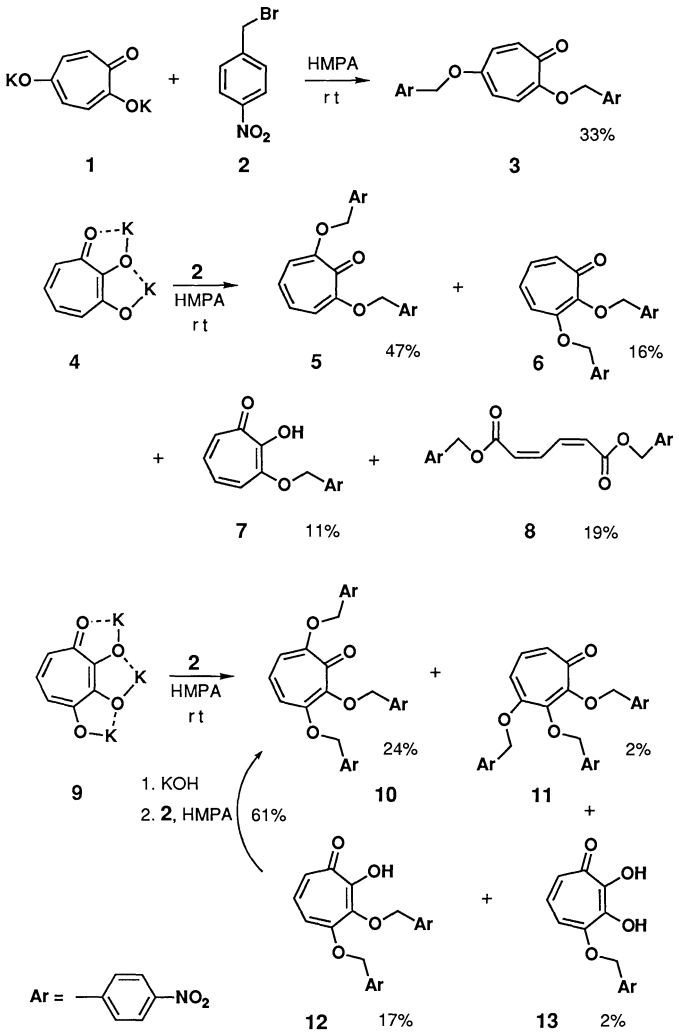
Scheme 1.

The reaction of 3,4-dihydroxytropolone tripotassium salt (**9**) with **2** gave four products (**10**—**13**): Two of them (**10** and **11**) were tris(4-nitrobenzyloxy)tropones; **10** had two singlets at a lower field (δ=5.37 and 5.40) than the other singlet at δ=5.12, whereas **11** had two singlets at a higher field (δ=5.09 and 5.16) than the other singlet at δ=5.29. Assuming that the chemical shift of benzylic methylene protons adjacent to the carbonyl group was lower, **10** was a 2,3,7-isomer, and **11** was a 2,3,4-isomer. With a similar series, chemical shifts of the methylene protons of **12** at δ=5.17 and 5.39 showed **12** to be 3,4-bis(4-nitrobenzyloxy)tropolone. The remaining isomer, **13**, was 3-hydroxy-4-(4-nitrobenzyloxy)tropolone.

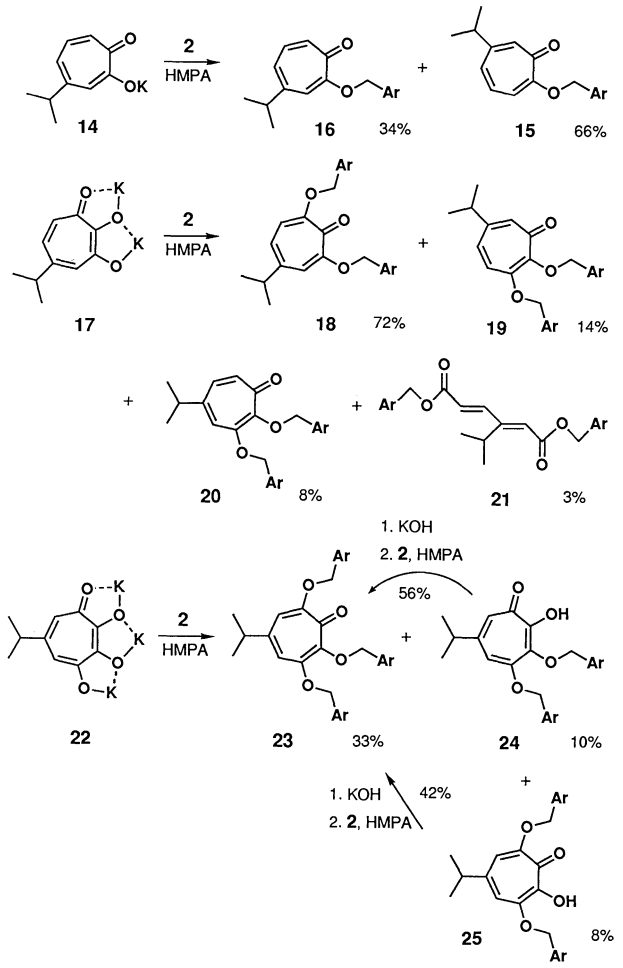
When 4-isopropyltropolone potassium salt (**14**) was allowed to react with **2**, two isomeric condensates, **15** and **16**, were isolated in 66 and 34% yields, respectively. The ^{1}H NMR spectrum of **15** showed a doublet signal at δ=6.67 (*J*=9.5 Hz), which was ascribable to the proton adjacent to the benzyloxy group. The magnitude of this vicinal coupling constant indicated that the two carbons bearing these protons had a single bond character. Therefore, **15** was 6-isopropyl-2-(4-nitrobenzyloxy)tropone and **16** was a 4-isopropyl-2-(4-nitrobenzyloxy) derivative.

From 3-hydroxy-5-isopropyltropolone dipotassium salt (**17**),[5] four products (**18**—**21**) were isolated in 72, 14, 8, and 3% yields, respectively. Three of them (**18**—**20**) were isomeric bis(4-nitrobenzyloxy)tropones. The coupling constant between H-5 and H-6 (*J*=10.2 Hz) of the main product **18** showed it to be 4-isopropyl-2,7-bis(4-nitrobenzyloxy)tropone. The structures of **19** and **20**

† On leave from Yanbian University, Yanji, Jilin, People's Republic of China.



Scheme 2.



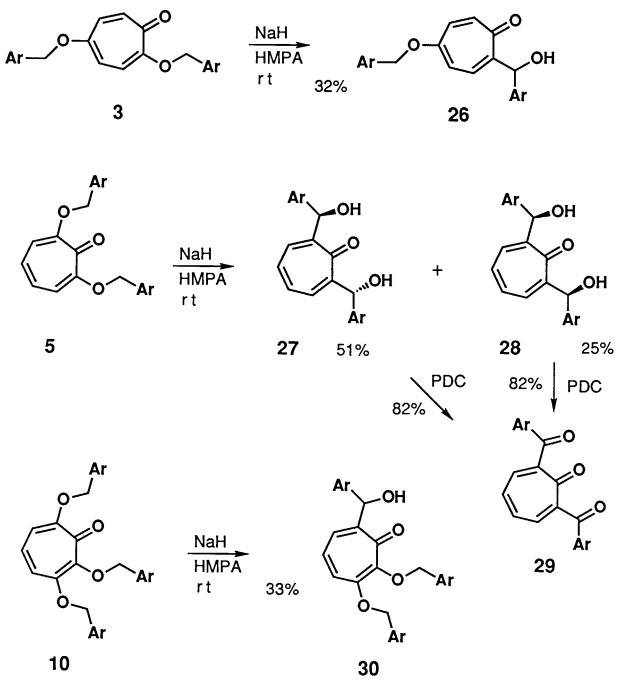
Scheme 3.

were deduced from the chemical shifts of seven-membered ring protons; **20** had a lower doublet at δ=7.21 (J=12.5 Hz) than that of **19** at δ=6.97 (J=12.0 Hz). Therefore, **19** was 6-isopropyl-2,3-bis(4-nitrobenzyloxy)-tropone and **20** was 5-isopropyl-2,3-bis(4-nitrobenzyl-oxy)tropone. The remaining **21** was an air-oxidized bis(4-nitrobenzyl) (*E*,*E*)-3-isopropyl-2,4-hexadiene-dioate.

The reaction of 3,4-dihydroxy-6-isopropyltropolone tripotassium salt (**22**) gave three products (**23**—**25**); two minor products **24** and **25** were bis(benzyloxy) derivatives and the latter was deduced to be 5-isopropyl-2,7-bis(4-nitrobenzyloxy)tropolone, whose NMR spectrum revealed an element of symmetry. Since the main product, **23**, was obtained by further reaction of **25**, it was 5-isopropyl-2,3,7-tri(4-nitrobenzyloxy)tropone. The remaining **24** is, therefore, assigned as 6-isopropyl-3,4-bis(4-nitrobenzyloxy)tropolone.

Base-Induced Rearrangements of Benzyloxytropones. When an HMPA solution of **3** was stirred in the presence of sodium hydride (NaH) at room temperature for 1 h, a single product, **26**, was obtained in 32% yield together with recovered **3** in 13% yield. The ^{1}H NMR spectrum of **26** in dimethyl-d_6 sulfoxide (DMSO-d_6) showed a singlet signal of two protons at δ=5.31 and a pair of doublet signals (J=4.4 Hz) at δ=5.92 and 6.23. One of the 4-nitrobenzyloxy groups migrated. The proton signals of the seven-membered ring of **3** appeared at δ=7.06 (d, J=11.0 Hz, H-2), which was assigned to H-2, and 6.63 (dd, J=11.0, 3.0 Hz, H-3) and those of **26** at δ=7.74 (d, J=10.3 Hz, H-2) and 6.81 (dd, J=10.3, 3.0 Hz, H-3). Therefore, **26** was 2-(α-hydroxy-4-nitrobenzyl)-5-(4-nitrobenzyloxy)tropone. Thus, the 4-nitrobenzyl group adjacent to the carbonyl group migrated exclusively.

On the other hand, a similar treatment of **5** afforded two products, **27** and **28**, in 51 and 25% yields, respectively. Pyridinium dichromate (PDC) oxidation of both **27** and **28** gave 2,7-bis(4-nitrobenzoyl)tropone (**29**). Therefore, **27** and **28** were stereoisomers. The stereochemistry of **27** and **28** was determined by liquid chromatography with a chiral stationary phase. Since the chromatogram of **27** was further separated into two peaks, **27** was a *dl*-mixture (R_f=12.2 and 16 min). On



Scheme 4.

the other hand, a meso isomer, **28**, remained as a single peak (R_f=13.3 min).

The base-induced reaction of **10** gave a single product, **30**. Its ^{1}H NMR spectrum in deuteriochloroform ($CDCl_3$) revealed two singlet signals due to benzylic methylene protons at δ=5.15 and 5.25 and a singlet single at δ=6.00, a benzylic methine proton. Therefore, two benzyloxy groups were intact. The low-field-shifted H-4 (7.47 from 7.22) and H-6 (7.56 from 7.06) of **30** indicated that the benzyloxy group at C-7 migrated.

Interestingly, the ^{1}H NMR spectrum of **30** in DMSO-d_6 showed a singlet signal of benzylic methylene protons at δ=5.37 and two pairs of AB quartets at δ=5.04 and 5.13 (J=12.8 Hz) and 6.10 and 6.34 (J=4.4 Hz). In $CDCl_3$, however, it showed three singlets at δ=5.15 (2H), 5.25 (2H), and 6.00 (1H). The latter of the AB quartets in DMSO-d_6 was assigned to be a benzylic methine proton signal and a hydroxyl proton signal. The appearance of the spin-coupling in DMSO-d_6 showed the formation of an intermolecular hydrogen bond involving the hydroxyl proton. On the other hand, the former of the quartets was assigned to be benzylic methylene protons; two benzylic protons are magnetically nonequivalent. The free rotation of the benzyloxy group at C-2 was hindered by the chelation between both carbonyl and hydroxyl groups and DMSO-d_6 as shown in **A** of Fig. 1.

Similarly, base-induced reactions of **15** and **16** gave the corresponding products **31** and **32**. From **18**, a diastereoisomeric mixture of **33** and **34** was obtained in 36 and 22% yields as observed with **5**. However, their chromatographic analyses with a chiral stationary phase

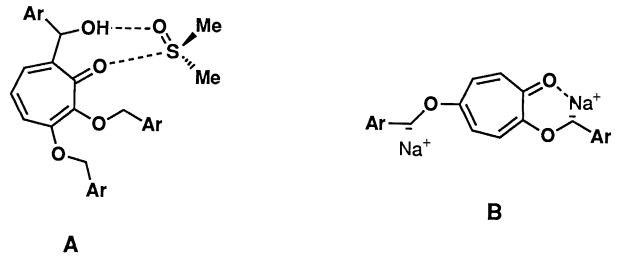


Fig. 1.

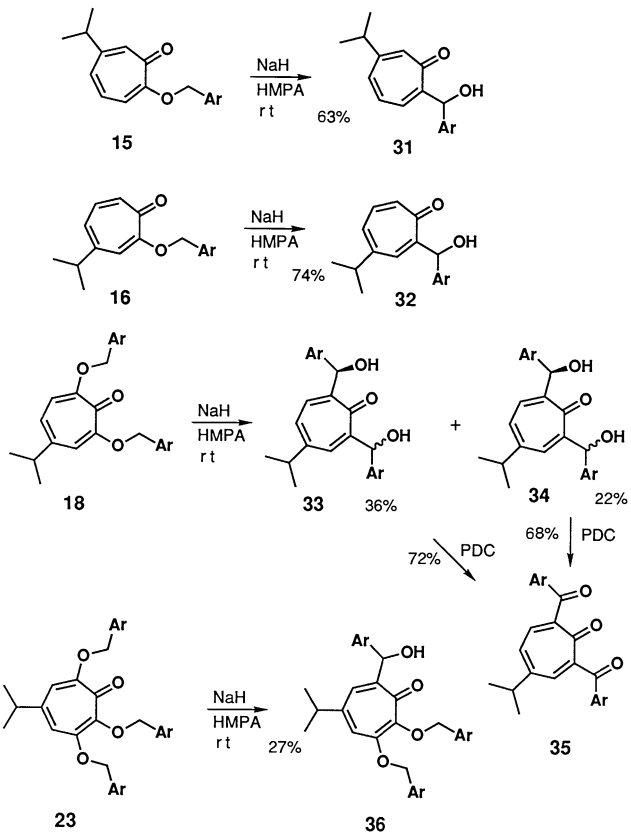

Scheme 5.

were unsuccessful. Oxidations of **33** and **34** gave the same **35**.

Finally, the reaction of **23** gave a single product, 5-isopropyl-7-(α-hydroxy-4-nitrobenzyl)-2,3-bis(4-nitrobenzyloxy)tropone (**36**).

A base-induced rearrangement of **3** gave only **26**. In 2,7-bis(4-nitrobenzyloxy)tropones, **5** and **18**, both benzyl groups migrated. Thus, the 4-nitrobenzyloxy group adjacent to the carbonyl group migrated exclusively. In tris(4-nitrobenzyloxy)tropones, **10** and **23**, only a 4-nitrobenzyloxy group at C-7 migrated. The inner benzyl group at C-2 was inactive due to the inhibition of an attack by NaH on methylene protons.

In conclusion, a Wittig-type rearrangement occurred exclusively at the benzyl group adjacent to the carbonyl

group. The carbonyl group acted as an acceptor of the sodium cation to form an active naked carbanion at the neighboring position as shown in **B** of Fig. 1. Thus, the base-catalyzed rearrangement occurred at the *ipso*-position of bis- and tris(4-nitrobenzyloxy)tropones to give (α-hydroxy-4-nitrobenzyl)tropones. This method is currently being applied to prepare a 2,7-bis(functionalized)tropone derivative, which is a versatile starting material of functioned materials such as crown ethers with a tropone skeleton.

Experimental

Elemental analyses were performed by Mrs. M. Miyazawa of this Institute, Kyushu University. Melting points were measured with a Yanagimoto micro mp apparatus and were not corrected. NMR spectra were measured by JEOL FX 100 and GSX 270H spectrometers in $CDCl_3$, unless otherwise specified, and the chemical shifts were expressed in δ units. IR spectra were taken as KBr disks for crystalline compounds or as liquid films inserted between NaCl plates for oily materials using a JASCO IR-A 102 spectrometer. UV spectra were measured by the use of Hitachi U-3200 and U-3410 spectrophotometers. Mass spectra were measured with a JEOL 01SG-2 spectrometer. The stationary phase for the column chromatography was Wakogel C-300 and the elution solvents were mixtures of hexane–ethyl acetate. HPLC was performed on a Chiralcel OJ column (Daicel Chemical Industries) by using a Waters M-45 pump and an S-301A UV detector (Soma Science) at 254 nm and by eluting with hexane–ethanol (1:2) with a flow rate of 3.5 $cm^3\ min^{-1}$.

General Procedure of Condensation Reactions of Potassium Tropolonates (1, 4, 9, 14, 17, and 22) with 2. An EtOH solution (4 cm^3) of a tropolone derivative (1 mmol) and ca. two molar equivalents of KOH was stirred at room temperature for 1 h under a nitrogen atmosphere. After removing the solvent under reduced pressure, the residue was exhaustively dried under reduced pressure to give the potassium salt. An HMPA solution (6 cm^3) of the potassium salt and **2** (577 mg) was stirred at room temperature for 2 h. The mixture was diluted with water, acidified with 5% aqueous HCl solution (pH=4), and extracted with AcOEt. The organic layer was washed with water, dried with $MgSO_4$, and removed under reduced pressure. The residue was recrystallized and/or chromatographed on a silica-gel column (AcOEt–hexane=2:1 or $CHCl_3$) to give the product.

Theoretical Foundation of Prochirality. Chirogenic Sites in an Enantiospheric Orbit

(Received November 19, 1990)

Prochirality is one of the inherent properties of an enantiospheric orbit that is designated by a coset representation $\mathbf{G}(/\mathbf{G}_i)$. Desymmetrization of the $\mathbf{G}(/\mathbf{G}_i)$ orbit is discussed to present a new concept "**H**-chirogenic site". The chirogenic site in the $\mathbf{G}(/\mathbf{G}_i)$ orbit is capable of producing a chiral **H**-molecule under the influence of an appropriate chiral reagent. The condition for the existence of such a chirogenic site is discussed. A convenient method using a desymmetrization lattice is presented for determining chirogenic sites.

The concept of "prochirality" has been proposed by Hanson for specifying the steric course of asymmetric syntheses.[1,2] From the beginning, his definition has been polysemous; and its successor, the IUPAC rule, has afforded two distinct definitions of prochirality (rules E-4.12(a) and (b)).[3] Thus, the intrinsic meaning of the prochirality term ("pro"=before) has thus been changed to connote cases in which chiral compounds are converted into other chiral compounds (IUPAC rule E-4.12(b)). Prelog and Helmchen[4] have used the term "stereogenic" in order to get rid of confusion provided by the prochirality. Although they have carefully avoided the use of the term "prochirality", the essence of their proposal concerning prochirality is to differentiate between reflection-variant and -invariant stereogenic units. Seebach and Prelog[5] have proposed a method of specifying asymmetric syntheses. Hanson's definition and Prelog's proposal are implicity based upon permutation-group theory and play down point-group theory, though the latter is essential to discuss stereochemistry. Moreover, the prochirality has been restricted to molecular systems in which two ligands or faces are differentiated to create a chiral compound.

Mislow and Siegel[6] have discussed the prochirality concept. Their comment can be summarized as follows: Hanson's definition refers to (pro)stereogenicity rather than to prochirality. They have also proposed (pro)^p-chirality, which has been modified by Halevi.[7]

We have presented a new definition of prochirality, which is based on the concept of *chirality fittingness* derived by integrating the permutation- and point-group theories.[8] This definition affords a general approach that treats two or more ligands successfully. The renewed prochirality is one of the symmetrical properties inherent in an enantiospheric orbit. We have summarized our results in the form of a theorem.

Theorem 1.[8] *An enantiospheric orbit is capable of separating into two hemispheric orbits of the same length under a chiral environment, whether the change is reversible or irreversible.*

Then, we have defined a *prochiral* molecule as the one that has at least one enantiospheric orbit. In previous papers,[8,9] we have given a proof of this theorem in a rather intuitive fashion. We have also developed another concept *subduction of coset representations (CRs).*[10] Combining this concept with the chirality fittingness, we have clarified the prochirality to some extent. However, the previous discussion[8] are rather qualitative. In order to understand the renewed prochirality concept comprehensively, a stricter and more detailed discussion is desirable. In a continuation of the work, the present paper deals with discussions on desymmetrization of enantiospheric orbits, where more detailed results are available for formulating prochirality. In addition, the related new concept "chirogenic" is proposed.
