(Received August 1, 1990)

The translational energy distributions of H* (n=3, 4) produced in e-SiH_4 collisions were obtained by measuring the Doppler profiles of the Balmer-α and β lines with a Fabry–Perot interferometer. There are three major components in the translational energy distributions of H* (n=3,4). The first component lies in the 0—3 eV region, the second one peaks at 2—3 eV, and the third one lies at above 4 eV. Thus, dissociation of SiH_4 for the formation of H* (n=3,4) should proceed through three different groups of Rydberg states. The emission cross sections were determined separately for H* (n=3,4) with the translational energy of 0—2, 2—4, 4—6, 6—8, and 8—10 eV, respectively.

The study of electron–silane (SiH_4) interaction has received considerable attention due to its importance to plasma diagnostics in semiconductor technology. The mechanism and cross sections of electron-impact dissociation of SiH_4 are needed for understanding and simulating deposition processes of amorphous silicon films.

High resolution spectroscopy on electron–molecule collision processes is a powerful tool for such studies.[1] The translational energy distribution of fragments,[1,2] the emission cross section of certain fragments produced in a specified dissociation process[1,3] and the symmetry of dissociation processes[1,4] have been obtained with this technique. Reactivity of an excited species may depend on the translational energy it has. Thus, the emission cross section of an excited species should be more useful for a simulation of a plasma, if it is determined separately for species with different translational energies.

Perrin et al.[5–8] investigated the dissociation dynamics of SiH_4 and determined the emission cross section of fragments such as H*, Si*, Si$^+$*, SiH*, and SiH$^+$*. The translational energy distributions of H* (n=4) were obtained with the use of a grating spectrometer and three groups of H* (n=4) were found in the translational energy distribution; their peaks lay at about 0.3 eV, 2.5 eV and a higher energy.[7] The excitation functions of H* (n=3,4) were determined and three major thresholds were found for the formation of H* (n=3,4).[6,9,10] Cooper et al.[11] obtained absolute oscillator strengths for photoabsorption, photoionization, and ionic photofragmentation, and photofragmentation branching ratios of silane, and concluded that the $(3a_1)^{-1}$ state is a many-body state and plays an important role for the formation of H^+.

We have measured high-resolution spectra of the Balmer-α and β lines with a Fabry–Perot interferometer and obtained the translational energy distributions of H* (n=3,4). We have also determined the emission cross sections for the excited hydrogen atom of certain translational energy with an expectation that such values are useful for an understanding and simulation of plasma. To our best knowledge, this is the first attempt to determine the emission cross section separately for species with different translational energies.

Experimental

The experimental apparatus was described in detail in the previous papers.[12,13] In brief, the stainless-steel collision chamber has an electron gun and a gas cell. The sample gas (10.1% SiH_4 in He; obtained from Seitetsu Kagaku) was collided with the electron beam. The typical electron-beam current was 10—100 μA and the typical operating pressure was 1—4×10^{-5} Torr (uncorrected, 1 Torr=133.322 Pa) at the wall of the collision chamber.

The optical radiation was measured perpendicularly with the electron beam with a Spex 1269 monochromator when the broad band spectra were obtained. The Doppler profile of the Balmer lines was measured at 55° (magic angle) with respect to the electron beam with a Mizoziri Fabry–Perot interferometer. The optical resolution was 0.010 nm for the Balmer-α line and 0.007 nm for the Balmer-β line. A DIF-C filter ($\Delta\lambda_{1/2}$=1.0 nm: Vac. Opt. Co. Jpn.) was used for separating the Balmer-α line and another DIF-C filter ($\Delta\lambda_{1/2}$= 1.3 nm) for the Balmer-β line. The photons were counted with a Hamamatsu R585 or R649 photomultiplier.

The relative emission cross sections of the excited hydrogen atom with each translational energy were determined from its translational energy distributions, and the summed totals were normalized to those measured by Sato and Goto[9] in order to make the relative values absolute.

Results and Discussion

Doppler Profiles and Translational Energy Distribution. The silane molecule produces lines of H*, Si*, and Si$^+$*, and bands of SiH* and SiH$^+$*.[5,6,9] We have separated the Balmer lines of H* (n=3,4) and measured their Doppler profiles with the use of a high-resolution Fabry–Perot interferometer, as shown in Fig. 1. The electron energy was 25—100 eV; however, no reliable profile of H* (n=3) was obtained at 25 eV due to poor signal-to-noise ratio. The Doppler profiles are dependent on the electron energy. It

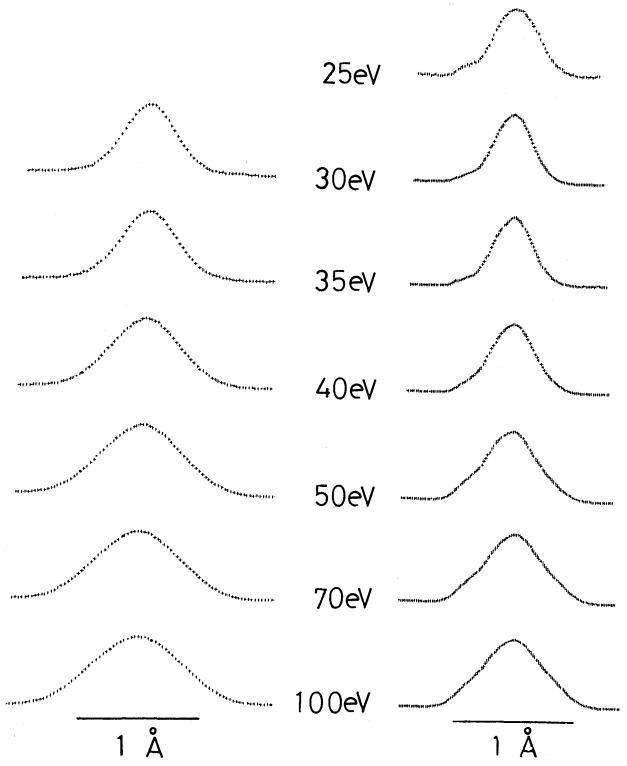

Fig. 1. Doppler profiles of the excited hydrogen atom (n=3, 4) produced in e–SiH_4 collisions. Observation angle: 55° with respect to the electron beam. (left) H*(n=3), (right) H*(n=4).

becomes wider at higher electron energies. There are two helium lines and one unidentified line (probably molecular origin) on the shorter wavelength (left) side of the Balmer-β line; they are clear on the spectrum taken with the Spex monochromator. Thus, the longer wavelength (right) side of the profile was used for the determination of the translational energy distribution of H* (n=4).

The translational enenrgy distribution of an excited species can be obtained by differentiating the Doppler profile obtained at 55° (magic angle),[14] so that any effect due to anisotropy should be negligible. The differentiation was carried out by smoothing the profile curve by a least square procedure using a 5-point cubic convolute.[15] The translational energy distributions of H* (n=3,4) are shown in Figs. 2 and 3. The distribution at 25 eV is noisier due to weak signals.

At incident electron energies of 25 and 30 eV, there is a clear peak in the translational energy distribution at about 0.5 eV, as shown in Figs. 2 and 3. This component is located in the 0—3 eV region and is dominant at electron energies of 25—35 eV. Another component starts to appear on the distribution at an incident energy of 40 eV. This component has a peak at 2—3 eV becomes more intense at higher incident energies. The third one appears on the distribution at

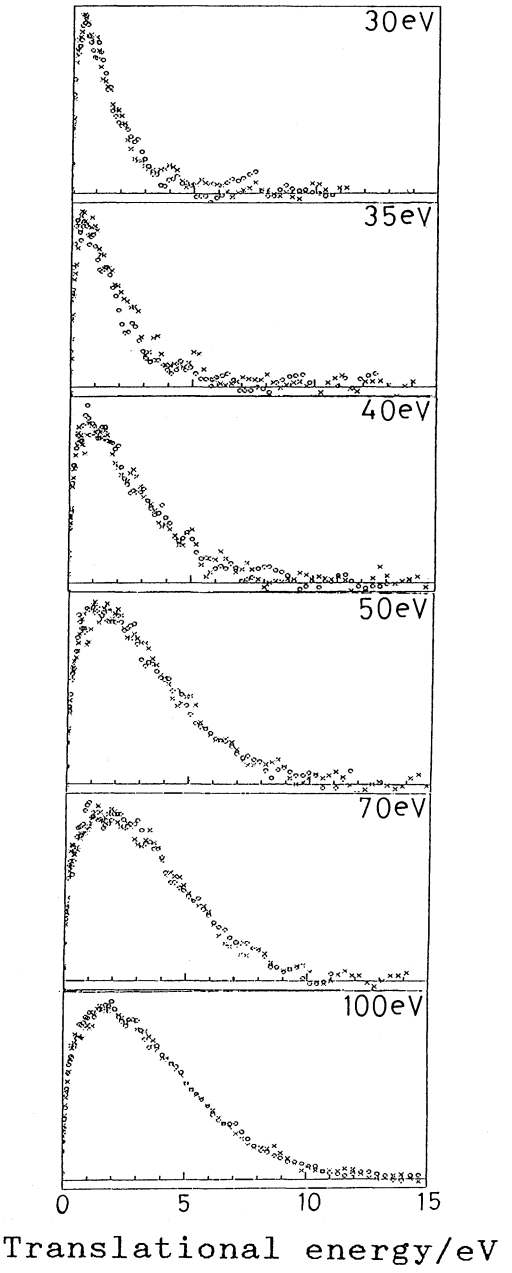

Fig. 2. Translational energy distributions of H*(n=3) produced in e–SiH_4 collisions. The translational energy distribution obtained from the longer wavelength side of the Doppler profile is shown as ○, and that obtained from the shorter wavelength side as ×. The two distributions agree with each other within experimental errors.

above 50 eV; this component lies in the 4—10 eV region of the translational energy. Thus, there are three major components on the translational energy distributions of H* (n=3,4) as Perrin and Schmitt observed.[7] This finding indicates that there should be at least three major dissociation processes for the formation of the excited hydrogen atom from silane.

Both of the translational energy distributions of H*

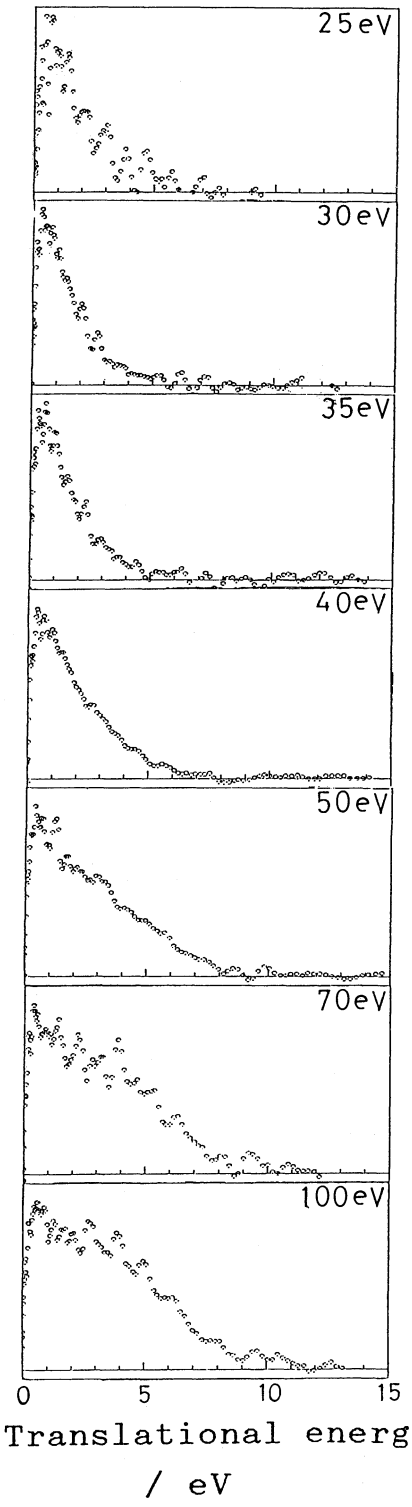

Fig. 3. Translational energy distributions of H*(n=4) produced in e-SiH_4 collisions. The translational energy distribution was obtained from the longer wavelength side of the Doppler profile.

(n=3) and H* (n=4) have three components and they are qualitatively similar. Relative intensity of the three component is, however, different; the second component of H* (n=3) is relatively more intense than that of H* (n=4).

There are three thresholds on the excitation function of H* produced in e-SiH_4 collisions; they lie at about 19 eV, 23 eV, and 35—40 eV.[6,9,10] However, these thresholds and the translational energy distribution do not show one-to-one correspondence. The first and second thresholds can be correlated with the first component of the translational energy distributions. The second component appears at 40 eV and becomes dominant at higher electron energies; the threshold of this component should be slightly below 40 eV. The difference in the relative intensity of the second component of H* (n=3) and H* (n=4) may correspond to the difference of their excitation function; the one for H* (n=3) has a steeper rise at about 40 eV.[9] The threshold of the third component is not clear.

Dissociation Process of Silane. Perrin and Schmitt[7] described that the formation of H* (n=4) proceeds via dissociative superexcited Rydberg states. Importance and contribution of such states were shown on various molecules.[1] The photoelectron spectrum of silane indicated that the $(3a_1)^{-1}$ state lies in the 17—40 eV region.[16] The dipole (e,e) spectrum also indicated that the $(3a_1)^{-1}$ state lies in the 16—40 eV region and that this state consists of the main state (threshold: 18 eV) and a many-body state (threshold: 24 eV); the appearance potential of H^+ was found at 24 eV, and H^+ should be produced through the $(3a_1)^{-1}$ state.[11] The formation of H^+ was correlated specifically with the many-body state of $(3a_1)^{-1}$.[11]

Since there is no onset of H^+ at about 19 eV in the dipole (e,e) spectrum, we can conclude that the threshold of H* (n=3,4) at 19 eV can be correlated with an optically-forbidden minor dissociation process; this process would be a triplet process. The major part of the first component of the translational energy distribution can be correlated with the threshold at 23 eV and the formation of H* (n=3,4) would proceed through Rydberg states converging to the many-body state of the $(3a_1)^{-1}$ state.

The first component has larger translational energy than the second one in the case of methane. The Rydberg state converging to the $(2a_1)^{-1}$ state of methane was correlated with processes leading to the excited hydrogen atom with the translational energy of about 3 eV. While, the second component was slow. The contribution of curve crossing in the excited Rydberg states may be different between methane and silane and such difference can induce the observed difference in the translational energy distributions of H* (n=3,4) produced from the two molecules.

The second component in the translational energy distribution has the threshold at about 35 eV. There may be some doubly-excited Rydberg states such as $(2t_2)^{-2}(nR)^2$ (nR: a Rydberg orbital) in this energy region, which may play important roles for the formation of this component.

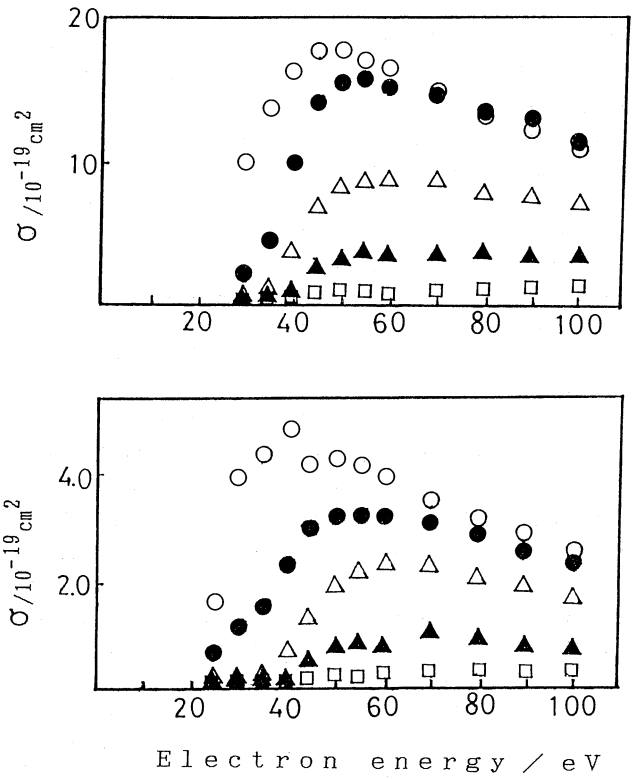

Fig. 4. Emission cross sections of H*(n=3, 4) with certain range of the translational energy distribution. (top) H*(n=3), (bottom) H*(n=4). ○: 0—2 eV, ●: 2—4 eV, △: 4—6 eV, ▲: 6—8 eV, □: 8—10 eV.

Emission Cross Sections. The total emission cross sections of H* (n=3,4) were determined previously.[9] We have determined the emission cross sections of H* (n=3,4) with certain translational energy separately by measuring their relative emission cross sections and by normalizing them to the total. No correction for collection efficiency was carried out, since such correction would be small for the Balmer-α and β lines.[17]

The emission cross sections of H* (n=3,4) of translational energy of 0—2 eV(○), 2—4 eV(●), 4—6 eV(△), 6—8 eV(▲) and 8—10 eV(□) are shown in Fig. 4. The H* (n=3,4) with translational energy above 10 eV is weak and was omitted in this Figure for clarity; its energy dependence is approximately identical with that of 8—10 eV. These results show that the first component is relatively more important for H* (n=4). Whereas the rise of H* (n=3) in the 2—4 eV region is steeper, and this finding indicates that the second component is more important for H* (n=3). The emission cross sections at an electron energy of 100 eV are shown in Table 1.

The chemical reactivity can depend on the translational energy of the species concerned. Such energy dependence is not yet discovered in plasma processing; however the partial emission cross section for each translational energy obtained here may be useful for its simulation.

Table 1. Emission Cross Sections of H* (n=3, 4) Produced in e-SiH_4 Collisions at an Electron Energy of 100 eV

Translational energy/eV	H* (n=3) 10^{-19} cm²	H* (n=4) 10^{-19} cm²
Total[9]	36	7.5
0—2 eV	10.9	2.4
2—4 eV	11.2	2.2
4—6 eV	7.5	1.7
6—8 eV	3.8	0.78
8—10 eV	1.7	0.27
Above 10 eV	1.0	0.15

Temperature Effect on the Adsorption and Micelle Formation of Aqueous Dodecyltrimethylammonium Chloride-Hexane System

Koji ABE,* Ichiro KAJIWARA, Norihiro IKEDA,
Makoto ARATONO, and Kinsi MOTOMURA
Department of Chemistry, Faculty of Science, Kyushu University 33,

(Received August 9, 1990)

The adsorption at water/hexane interface and micelle formation of dodecyltrimethylammonium chloride (DTAC) were studied by measuring its interfacial tension as a function of temperature under atmospheric pressure at various concentrations around the critical micelle concentration (cmc). By applying the thermodynamic equations developed previously, the entropy and energy changes associated with the adsorption from monomeric and micellar states were estimated and compared with those of the DTAC solution-air system. It was found that the entropy and energy of the adsorbed film of DTAC are remarkably depressed by the coexistent hexane phase. This finding explains the positive entropy change associated with the adsorption of DTAC at water/air interface.

The adsorption and micelle formation of surfactants are affected by the oil phase coexisting with its aqueous solution.[1-5] In our series of the thermodynamic studies, we investigated the effect of hexane on the adsorption and micelle formation of dodecylammonium chloride (DAC) and sodium dodecyl sulfate in terms of entropy, volume, and energy.[6,7] Further the pressure dependence of interfacial tension of dodecyltrimethylammonium chloride (DTAC) solution against oil phase was discussed in terms of volume.[8-10] On the other hand, it was found that the entropy change associated with the adsorption of DTAC from the micellar state is positive at water/air interface while that of DAC is negative at both water/air and water/hexane interfaces. It is now required to examine the temperature dependence of the interfacial tension of the DTAC solution-hexane system.

In the present work, the interfacial tension of the aqueous DTAC solution against hexane is measured as a function of temperature at various concentrations around the critical micelle concentration (cmc). By applying the thermodynamics[11] to experimental results, the entropy and energy changes associated with the adsorption and micelle formation are estimated numerically. The thermodynamic quantities obtained of the DTAC solution-hexane system are compared with those of the DTAC solution-air system.[12]

Experimental

Dodecyltrimethylammonium chloride (DTAC) was synthesized and purified by the method described previously.[8] Water was distilled triply from dilute alkaline permanganate solution. Hexane was purified by distillation.

The equilibrium interfacial tension was measured by the pendant drop technique within an experimental error of 0.05 mN m^{-1} under atmospheric pressure.[13] The temperature was kept constant within 0.01 K.

Results and Discussion

The interfacial tension γ of the aqueous DTAC solution against hexane was measured as a function of temperature T at constant molality m_1 of surfactant under atmospheric pressure. Given in Fig. 1a are the γ

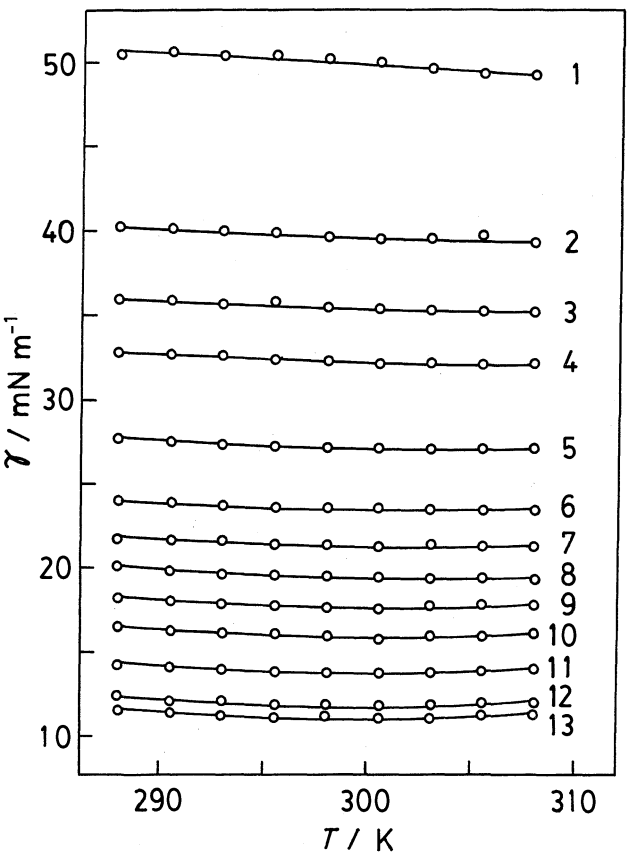

Fig. 1a. Interfacial tension vs. temperature curves at constant molality under atmospheric pressure: (1) m_1=0 mmol kg^{-1}; (2) 1.16; (3) 2.09; (4) 3.02; (5) 5.26; (6) 7.47; (7) 9.08; (8) 10.52; (9) 12.23; (10) 14.10; (11) 16.94; (12) 19.71; (13) 20.62.

vs. T curves at concentrations below the critical micelle concentration (cmc). It is seen that the curve decreases monotonously with increasing temperature at a low concentration while it has the minimum at a higher concentration. In Fig. 1b, a break point is observed on the curve at concentration near the cmc. This finding indicates that micelle formation takes place in the aqueous solution.[11] At a concentration above the cmc, the curve becomes the linear γ vs. T plot with a positive slope.

Picking up the γ values around the cmc at a given temperature from Figs. 1a and 1b, the γ vs. m_1 curves are drawn at constant temperature and illustrated in Fig. 2. It is seen that the curve breaks distinctly at cmc. The values of cmc C are plotted against temperature in Fig. 3; the C vs. T curve shows a shallow minimum and bears a great resemblance in shape to that of the DTAC solution–air (DTAC/A) system.[12] It is noteworthy, however, that the DTAC solution–hexane

(DTAC/H) system has a C value smaller than the DTAC/A system. The similar observation has been reported on the aqueous surfactant solution–oil systems and explained by the solubilization of oil.[1,3-5]

To examine more closely the influence of hexane on interfacial and micellar properties of the aqueous DTAC solution, let us evaluate the interfacial density and the thermodynamic quantities associated with adsorption and micelle formation of surfactant. Assuming the aqueous solution of DTAC to be a dilute ideal solution, the interfacial density Γ_1^H of surfactant is calculated by applying the relation

$$\Gamma_1^H = -(m_1/2RT)(\partial\gamma/\partial m_1)_{T,p} \quad (1)$$

to the γ vs. m_1 curve and is shown as a function of m_1 at constant T in Fig. 4. The interfacial pressure π vs. area per surfactant molecule A curve is useful to consider the state of adsorbed film. Here π and A are defined by

$$\pi = \gamma^0 - \gamma \quad (2)$$

and

$$A = 1/N_A\Gamma_1^H, \quad (3)$$

where γ^0 is the interfacial tension of the DTAC/A and DTAC/H systems without surfactant and N_A is Avogadro's number. The π vs. A curve is depicted at 298.15 K and compared with corresponding curve of the DTAC/A system in Fig. 5. It is obvious that the adsorbed film of the DTAC/H system is more expanded than that of the DTAC/A system.

It has been demonstrated that the thermodynamic treatment of the adsorption of surfactant from its micellar solution is useful.[6-12,14-16] According to the thermodynamics, the entropy change associated with the adsorption of surfactant from its monomeric state, $\Delta s(1)$, and that from its micellar state, $\Delta s(M)$, are evaluated respectively by the equations

$$\Delta s(1) = \Gamma_1^H(s^H/\Gamma_1^H - s_1^W) \quad (4)$$

$$= -(\partial\gamma/\partial T)_{p,m_1}, \quad m_1 < C \quad (5)$$

and

$$\Delta s(M) = \Gamma_1^H(s^H/\Gamma_1^H - s^M/N_1^M) \quad (6)$$

$$= -(\partial\gamma/\partial T)_{p,m_1}, \quad m_1 \geqq C, \quad (7)$$

where s^H, s^M, s_1^W, and N_1^M are the interfacial excess entropy per unit area, the molar entropy of micelle, the

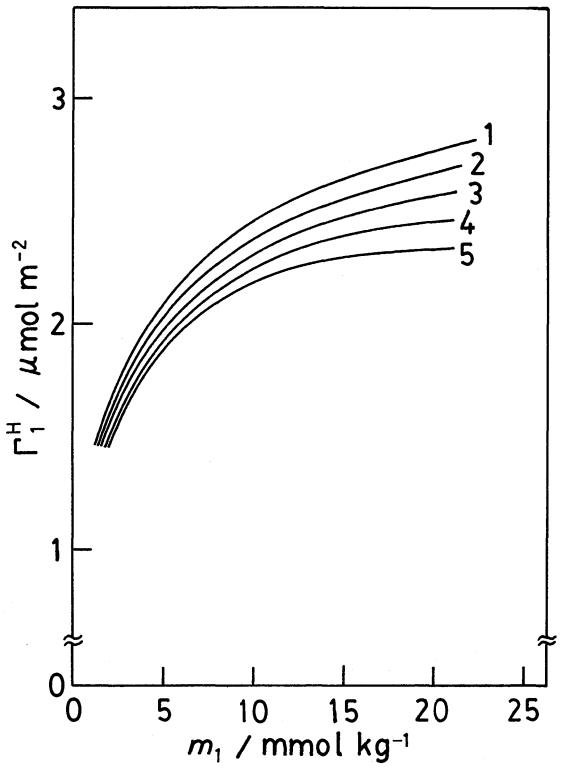

Fig. 4. Interfacial density vs. molality curves at constant temperature under atmospheric pressure: (1) T=288.15 K; (2) 293.15; (3) 298.15; (4) 303.15; (5) 308.15.

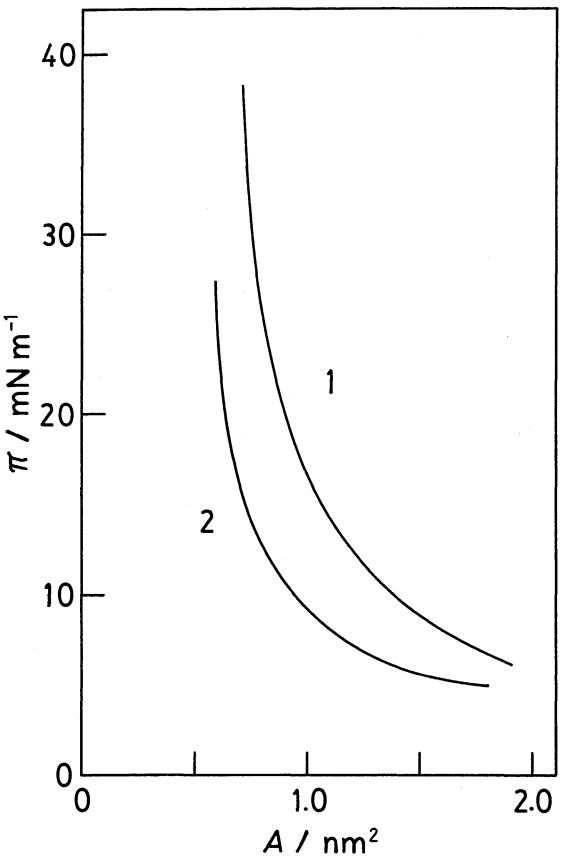

Fig. 5. Interfacial pressure vs. area per molecule curves at 298.15 K under atmospheric pressure: (1) DTAC/H system; (2) DTAC/A system.

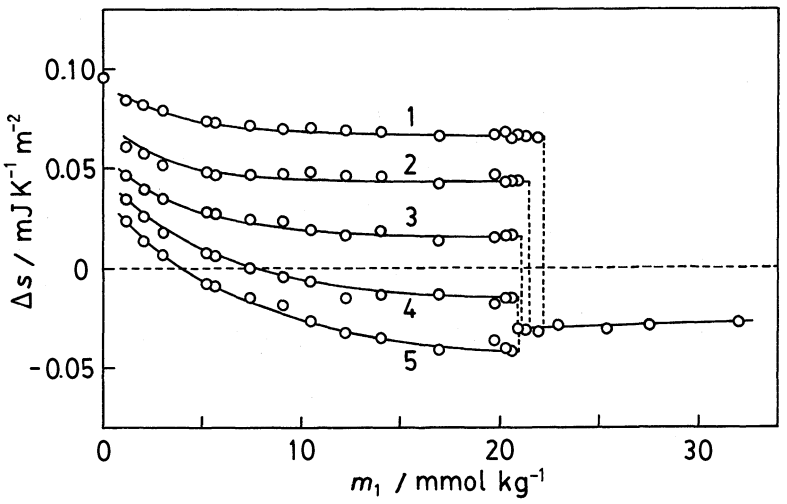

Fig. 6. Entropy change associated with adsorption vs. molality curves at constant temperature under atmospheric pressure: (1) T=288.15 K; (2) 293.15; (3) 298.15; (4) 303.15; (5) 308.15.

partial molar entropy of surfactant in the solution, and the number of surfactant ion in the micelle particle, respectively. Here, Eqs. 6 and 7 were derived on the assumption that the micelle formation can be treated thermodynamically like the appearance of a new macroscopic phase when its thermodynamic quantities are given by the excess thermodynamic quantities similar to those used for the adsorbed film. In Fig. 6, the entropy changes evaluated are plotted against molality at various temperatures. The value of $\Delta s(1)$ is found to decrease with increasing concentration and temperature. On the other hand, the value of $\Delta s(\mathrm{M})$ exhibits little dependence on m_1 and T. These results indicate that the temperature dependence of entropy of the adsorbed film is similar to that of the micelle through markedly different from that of the aqueous solution. Now it is important to note that the $\Delta s(\mathrm{M})$ value of the DTAC/H system is negative while that of the DTAC/A system is positive. In Fig. 7, the $\Delta s/\Gamma_1^{\mathrm{H}}$ vs. m_1 curve is drawn together with that of the DTAC/A system[12] at 298.15 K.

Here, let us consider the difference between the entropies in the solution and micelle at the cmc. The entropy of micelle formation at the cmc is defined by

$$\Delta_{\mathrm{W}}^{\mathrm{M}}s = s^{\mathrm{M}}/N_1^{\mathrm{M}} - s_1^{\mathrm{W}} \tag{8}$$

and evaluated by use of the relation

$$\Delta_{\mathrm{W}}^{\mathrm{M}}s = [\Delta s(1) - \Delta s(\mathrm{M})]/\Gamma_1^{\mathrm{H}}. \tag{9}$$

The $\Delta_{\mathrm{W}}^{\mathrm{M}}s$ value is plotted against T in Fig. 8. It is alternatively evaluated by applying the equation

$$\Delta_{\mathrm{W}}^{\mathrm{M}}s = -(2RT/C)(\partial C/\partial T)_p \tag{10}$$

to the C vs. T curve drawn in Fig. 3. The comparison

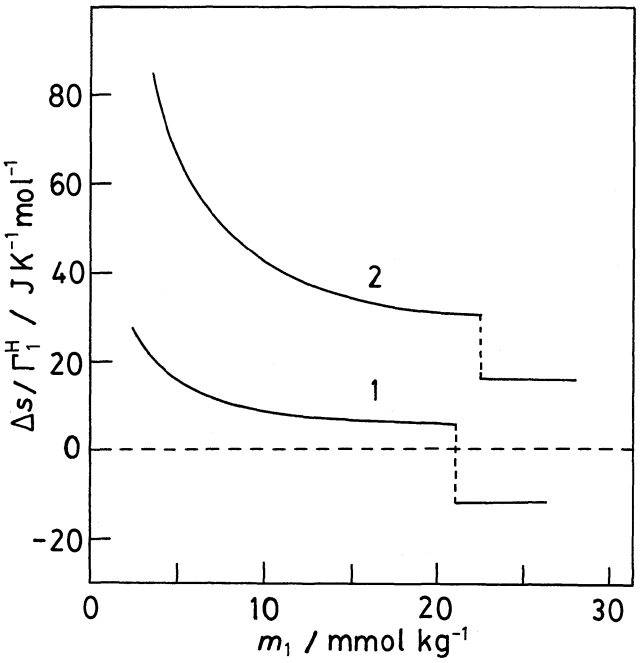

Fig. 7. Entropy change associated with adsorption per mole of surfactant vs. molality curves at 298.15 K under atmospheric pressure: (1) DTAC/H system; (2) DTAC/A system.

between them are also made in Fig. 8; the agreement is satisfactory. This proves that the assumption described above is probable at a concentration near the cmc. Furthermore, the $\Delta_{\mathrm{W}}^{\mathrm{M}}s$ vs. T curve of the DTAC/H system is compared with the curve of the DTAC/A system in Fig. 8. Both the curves seem to be close to each other. Thus, it is found that the micelle formation of DTAC in the DTAC/H system is similar to that in the DTAC/A system. This finding tells us that the difference in $\Delta s(\mathrm{M})$ between the DTAC/H and

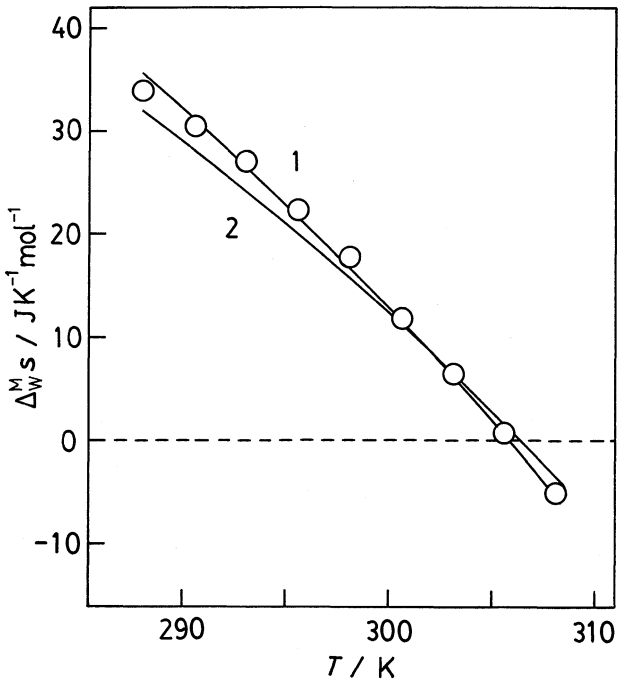

Fig. 8. Entropy of micelle formation vs. temperature curves under atmospheric pressure: (O) Eq. 9; (—) Eq. 10; (1) DTAC/H system; (2) DTAC/A system.

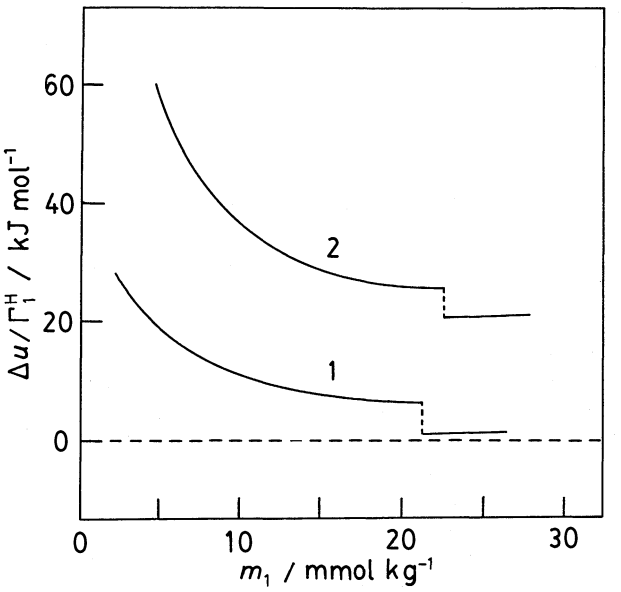

Fig. 9. Energy change associated with adsorption per mole of surfactant vs. molality curves at 298.15 K under atmospheric pressure: (1) DTAC/H system; (2) DTAC/A system.

DTAC/A systems stems from the difference in s^H. Therefore, remembering the results given in Fig. 7, we can conclude that the DTAC molecules adsorbed at water/hexane interface are forced to have a fairly restricted conformation as compared with those at water/air interface. The corresponding results of DAC support this view.[17]

The energy change associated with the adsorption of surfactant from its monomeric state, $\Delta u(1)$, and that from its micellar state, $\Delta u(M)$, are obtained respectively by the equations

$$\Delta u(1) = \gamma + T\Delta s(1) - p\Delta v(1) \quad (11)$$

and

$$\Delta u(M) = \gamma + T\Delta s(M) - p\Delta v(M), \quad (12)$$

where $\Delta v(1)$ and $\Delta v(M)$ are the corresponding volume changes. The Δu value was estimated numerically by making use of γ and Δs values given in Figs. 1 and 6 since the $p\Delta v$ terms are negligibly small compared with other terms under atmospheric pressure.[7-10] The results are shown in the form of $\Delta u/\Gamma_1^H$ vs. m_1 curve at 298.15 K in Fig. 9, where for comparison the curve of the DTAC/A system is also depicted. Further, the plot of the energy of micelle formation $\Delta_W^M u$ defined by a similar equation to Eq. 8 against T are compared between the DTAC/H and DTAC/A systems at the cmc in Fig. 10. Taking into account that the $\Delta_W^M u$ vs. T curves of both systems are quite similar to each other,

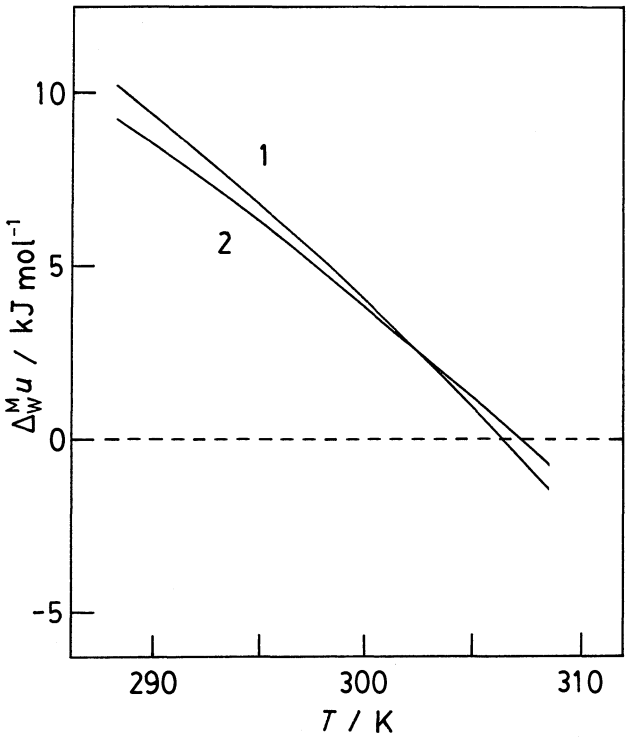

Fig. 10. Energy of micelle formation vs. temperature curves under atmospheric pressure: (1) DTAC/H system; (2) DTAC/A system.

the u^H value of the DTAC/A is said to be significantly larger than that of the DTAC/H system. It is clear that this large u^H value is closely related to the large s^H value cited above. In the case of DAC, an analogous

behavior is obtained. These results indicate that the adsorption of surfactant at the interfaces is remarkably affected by the air phase coexisting with its aqueous solution.

Crystal Structures of Polymorphic $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$

Mamoru SHIMOI,* Asako SATOH, and Hiroshi OGINO*
Department of Chemistry, Faculty of Science, Tohoku University,
Aoba-ku, Sendai 980
(Received June 30, 1990)

$[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$ crystals showed polymorphism depending on the recrystallization conditions. Recrystallization from acetonitrile-H_2O solution gave monoclinic crystals: $C2/c$ with lattice constants a=18.555(2), b=7.650(1), c=17.850(3) Å, β=96.81(2)°, and Z=4. Recrystallization from *N*,*N*-dimethylacetamide-ether solution gave tetragonal crystals: $I\bar{4}$ with lattice constants a=12.917(2), c=7.637(1) Å, and Z=2. Molecular structures of both crystal systems are almost the same as each other, if the structure for the latter was analyzed assuming that enantiomeric cations are disordered.

Cubane type metal clusters $[M_4L_4X_4]$ are known for many kinds of metals, terminal ligands L, and bridging ligands X.[1] Among them $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^{n+}$ as well as $[Fe_4(\eta^5\text{-}C_5H_5)_4Se_4]^{n+}$ have been studied in relation to the structures of clusters and their oxidation states.[1–6] Molecular orbital calculation showed that $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^+$ has a lower symmetry, D_2, than the D_{2d} symmetries of $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]$ and $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^{2+}$ due to a first-order Jahn–Teller effect.[5] In fact, Dahl et al. reported that the Fe_4 core of $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]$ Br has D_2 symmetry.[4]

In the course of our study for isolation of $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^{n+}$ species,[7] we found polymorphism of the hexafluorophosphate of the monocation: monoclinic and tetragonal. As will be shown below, the space group of the tetragonal crystal was determined to be $I\bar{4}$. This space group would impose D_{2d} symmetry on the cation, which contradicts the molecular orbital calculation. To elucidate the origin of this discrepancy, we undertook the X-ray crystal structure analyses for both forms.

Experimental

Materials. $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]$ (PF_6) was prepared as described in a preceding report.[7]

Crystal Structure Determination of Monoclinic $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$. An acetonitrile solution of $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]$ (PF_6) was layered on water in a test tube and allowed to stand for 5 days. The slow diffusion of water into acetonitrile gave black crystals with parallelepiped shape. A crystal with the dimensions 0.1×0.1×0.3 mm was used for the collection of intensity data. The data with $3<2\theta/°<60$ were collected with Mo $K\alpha$ radiation monochromated by graphite, applying ω–2θ scan mode with the use of a Rigaku AFC-6A automated four-circle diffractometer. The unit cell dimensions were determined by the least-squares method with 71 reflection data ($25<2\theta/°<30$). The crystal data are listed in Table 1. The probable space group is either Cc or $C2/c$ according to the systematic absence. The successful

a) $R=\sum\lvert\lvert F_o\rvert-\lvert F_c\rvert\rvert/\sum\lvert F_o\rvert$. b) $R_w=[\sum w(\lvert F_o\rvert-\lvert F_c\rvert)^2/\sum w\lvert F_o\rvert^2]^{1/2}$; $w=[\sigma^2(\lvert F_o\rvert)+aF_o^2]^{-1}$, where a=0.0015 for monoclinic $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$. Unit weighting scheme was applied for tetragonal $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$.

refinement justified the choice of the latter centrosymmetric space group. The conventional heavy atom method was used: A Patterson function gave the positions of two iron atoms, two sulfur atoms, and a phosphorus atom. Other non-hydrogen atoms were located by successive block-diagonal least-squares and Fourier syntheses. Anisotropic temperature factors were applied to non-hydrogen atoms. The hydrogen atoms were located from a difference Fourier synthesis and refined with isotropic temperature factors. Convergence was reached at R=0.053 and R_w=0.067. A final difference Fourier synthesis was virtually featureless.

Crystal Structure Determination of Tetragonal [$Fe_4(\eta^5$-$C_5H_5)_4S_4$] (PF_6). Black columnar tetragonal crystals were obtained by slow diffusion of diethyl ether into a *N,N*-dimethylacetamide solution of [$Fe_4(\eta^5$-$C_5H_5)_4S_4$] (PF_6). A crystal with the dimensions 0.1×0.2×0.3 mm was used for the collection of the intensity data. Crystal data is also included in Table 1. Of the possible space groups, $I4$, $I\bar{4}$, and $I4/m$ according to the systematic absence, $I\bar{4}$ was chosen because a four-fold axis cannot be imposed on the cubane cluster. The structure was solved by the heavy atom method: the positions of each one of the iron and sulfur atoms were obtained from a Patterson function, and the positions of carbon, phosphorus, and fluorine atoms were deduced from successive least-squares and Fourier syntheses. However, unrestricted refinement gave quite large thermal parameters. Therefore the crystal was considered to be disordered. Each atom except for the phosphorus atom on a special position was divided into two halves applying 50% occupancy factors for each atom, for the reason mentioned in the discussion. Anisotropic temperature factors were applied for iron, sulfur, and phosphorus atoms and isotropic ones for carbon and fluorine atoms. The final R value was 0.052.

All the calculations were carried out on an NEC ACOS-2000 computer at the computer center of Tohoku University, using Universal Crystallographic Computation Program System UNICS III.[8] The atomic scattering factors were taken from Ref. 9 for non-hydrogen atoms and from Ref. 10 for hydrogen atoms.

Results and Discussion

Description of the Crystal Structure of Monoclinic [$Fe_4(\eta^5$-$C_5H_5)_4S_4$] (PF_6). The positional and equivalent isotropic temperature factors are listed in Table 2. The bond lengths and angles are listed in Table 3.[11] The structure of the cubane cation is shown in Fig. 1. A crystallographic C_2 axis passes through the centers of the Fe(1)–Fe(1′) and Fe(2)–Fe(2′) bonds. Thus the Fe(1)–Fe(2) bond is equivalent to the Fe(1′)–Fe(2′) bond and the Fe(1)–Fe(2′) bond is equivalent to the Fe(1′)–Fe(2) bond. Furthermore, the interatomic distances of Fe(1)–Fe(1′) and Fe(2)–Fe(2′) are almost the same (3.308 (4) and 3.297 (2) Å). Therefore, the Fe_4 core has approximate D_2 symmetry: opposite bonds of the tetrahedron are equivalent. This feature is compatible with the structure predicted by a molecular orbital calculation.[5] Due to a first-order Jahn–Teller effect, [$Fe_4(\eta^5$-$C_5H_5)_4S_4$]$^+$ should have D_2 symmetry which is lower than the D_{2d} symmetry of [$Fe_4(\eta^5$-$C_5H_5)_4S_4$] and [$Fe_4(\eta^5$-$C_5H_5)_4S_4$]$^{2+}$.[5] Nineteen cluster

a) Average value. b) Ref. 4. c) This work. d) The atomic numbering schemes for the bromide and the tetragonal hexafluorophosphate are made to coincide with monoclinic $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$.

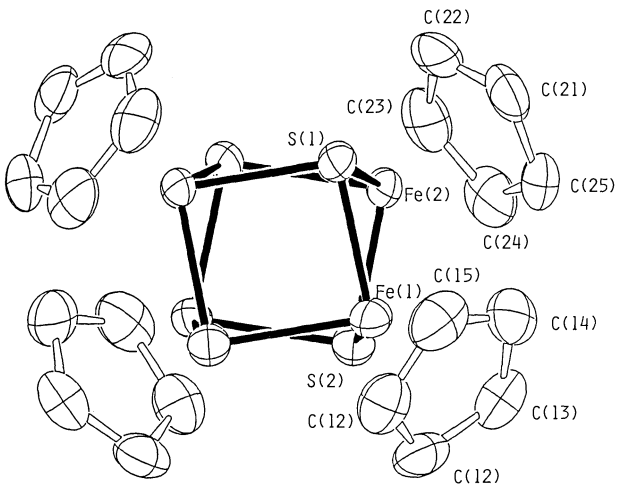

Fig. 1. ORTEP diagram of $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^+$ ion in the monoclinic hexafluorophosphate. Hydrogen atoms are omitted for clarity.

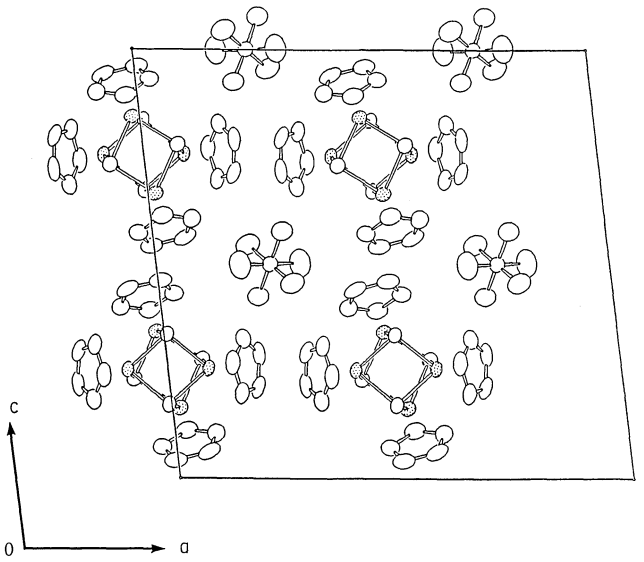

Fig. 2. Packing diagram of monoclinic $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$.

electrons in $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^+$ result in a total Fe–Fe bond order of 2.5 for Fe_4 core. The two shortest Fe–Fe bonds (Fe(1)–Fe(2) and Fe(1′)–Fe(2′) are 2.656 (2) Å) correspond to those with bond order 1; the next shortest Fe–Fe bonds (Fe(1)–Fe(2′) and Fe(1′)–Fe(2) are 3.188 (2) Å) correspond to those with bond order 0.25, and the longest bonds (Fe(1)–Fe(1′) and Fe(2)– Fe(2′)), to those with bond order 0.

The structure is quite similar to that already reported for the monocation complex, $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]Br$.[4] A comparison of the bond lengths and angles including the tetragonal hexafluorophosphate is shown in Table 4. The only difference between the bromide and the monoclinic hexafluorophosphate is that a crystallographic C_2 axis passes through the shortest Fe–Fe bonds for the former, but passes through the longest ones for the latter.

Figure 2 shows the packing diagram of a unit cell. A cation is surrounded by four anions tetrahedrally and four cations form a square surrounding an anion. This packing mode is similar to those for PdO, PtO, and PtS.[12]

Description of Crystal Structure of Tetragonal $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$. Atomic parameters are shown in Table 5. The bond lengths and angles are listed in Table 4.[11] Figure 3 shows the ORTEP diagram of the

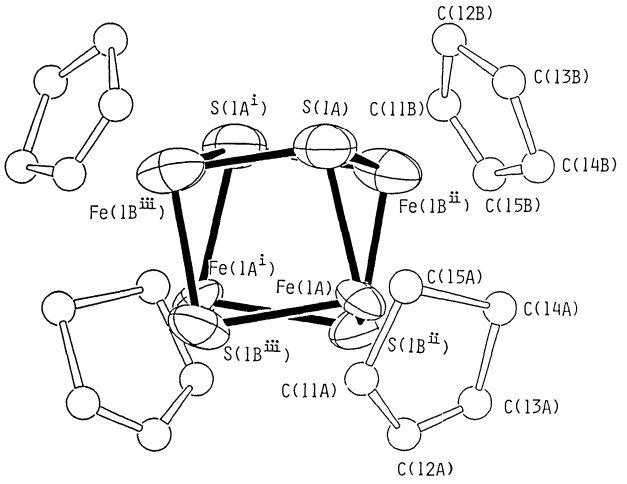

Fig. 3. ORTEP diagram of $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4]^+$ ion in the tetragonal hexafluorophosphate. The atomic numbering scheme corresponds to that in Table 4 as follows: Fe(1A)=Fe(2), Fe(1A^{i})=Fe(1′), Fe(1B^{ii})=Fe(2), Fe(1B^{iii})=Fe(2′), S(1A)=S(1), S(1A^{i})=S(1′), S(1B^{ii})=S(2), S(1B^{iii})=S(2), (Key to the symmetry operation; i, $-x$, $-y$, z; ii, y, $-x$, $-z$; iii, $-y$, x, $-z$).

cation. The conventional analysis applying the space group $I\bar{4}$ gave the cation D_{2d} symmetry which is incompatible with the molecular orbital calculation. Furthermore it gave quite large thermal parameters for the iron, sulfur, and carbon atoms. Therefore we adopted a disordered model by dividing these atoms into two halves, respectively. Thus this model gave a pair of enantiomeric cation structures which has approximate D_2 symmetry, compatible with the molecular orbital calculation. Thermal parameters and reliability factors thus obtained are reasonable. Bond lengths and angles are similar to the monoclinic hexafluorophosphate and the bromide (Table 4). The PF_6 anion showed also a disordered pattern around $\bar{4}$ (S_4) axis.

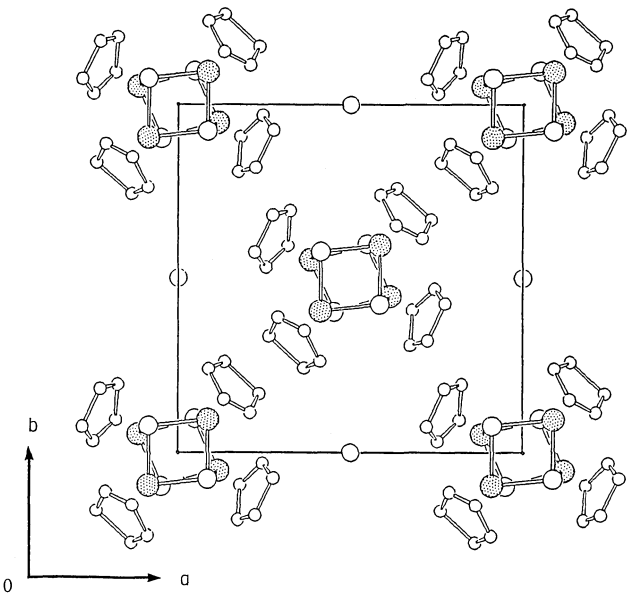

Fig. 4. Packing diagram of tetragonal $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$. Only one orientation of the disordered pairs of cations is depicted and fluorine atoms are omitted for clarity.

Figure 4 shows the packing diagram, only one orientation of disordered molecules being shown for clarity. A cation is surrounded by four anions tetrahedrally and an anion vice versa, in a deformed zinc blende type packing.[12]

The apparent D_{2d} symmetry for tetragonal $[Fe_4(\eta^5\text{-}C_5H_5)_4S_4](PF_6)$ is derived from the disordered packing of enantiomers with D_2 symmetry. The lower density for the tetragonal crystal reflects the disordered packing.

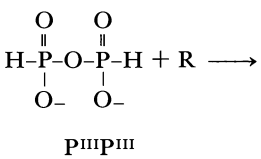
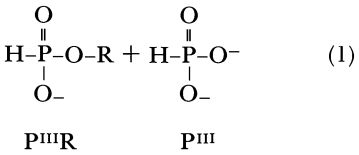
(Received July 5, 1990)

Inorganic diphosphonate with phosphorus of an oxidation number +3 was found to react with orthophosphate (oxidation number +5) at 50 °C to give phosphonylated compounds; dimeric isohypophosphate (oxidation numbers +3 and +5) and a novel trimeric compound (oxidation numbers +3 and +5). Orthophosphate ion is considered to act as a ligand with two or three nucleophilic sites that were phosphonylated stepwise by diphosphonate. Kinetic processes of the nucleophilic reactions were monitored by HPLC and ^{31}P NMR. Two products, the dimer having one P–H bond and the trimer with two P–H bonds, were well-resolved by HPLC and their yields, based on orthophosphate applied, were 85% (dimer) and 3% (trimer) when a mixed solution of 0.5 M diphosphonate and 0.1 M orthophosphate was incubated at 50 °C for 21 h. A complicated ^{31}P NMR spectrum that indicated a large coupling constant(J_{PH}=650 Hz) and grew with incubation time is reasonably assigned to the unsymmetrical isohypophosphate composed of both a phosphate group and a phosphonate group. Apparent formation constants of the dimer and trimer were evaluated.

Inorganic diphosphonate,[1,2] $P^{III}P^{III}$, a dimeric form of phosphonate(phosphite), P^{III}, has been characterized to be very reactive as an acceptor in a nucleophilic substitution reaction in Eq. 1 and its wide applicability in phosphonylating various nucleophilic biomolecules and inorganic phosphorus compounds(R) has been demonstrated.[3–11]



$P^{III}P^{III}$

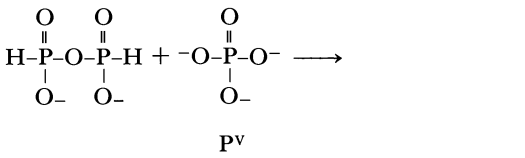


(1)

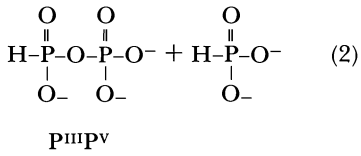
$P^{III}R$ P^{III}

Each phosphorus compound was expressed by an abbreviated nonation based on the arrangement of structural constituents; phosphonyl group with a P–H bond, P(III), and/or phosphoryl group, P(V), and was shown for convenience in a dissociated form.

In the nucleophilic reaction in Eq. 1 one of phosphonyl groups in diphosphonate transfers to R to form a phosphonylated compound, $P^{III}R$, as exemplified by the phosphonylation of ADP which resulted in the formation of an ATP analogue having a terminal phosphonyl group, $P^{III}P^{V}P^{V}A$.[9] If orthophosphate ion, P^{V}, is used as R, isohypophosphate, $P^{III}P^{V}$, is expected to be formed according to Eq. 2 liberating phosphonate.



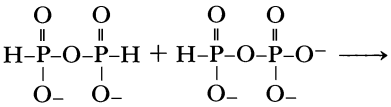
P^{V}

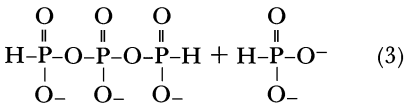


(2)

$P^{III}P^{V}$

Since orthophosphate ion is a ligand with three nucleophilic sites further addition of phosphonyl groups to the $P^{III}P^{V}$ is also expected to produce a trimeric compound in Eq. 3 and, with less probability, a branched compound with three phosphonyl groups, $P^{III}P^{V}(P^{III})P^{III}$.





(3)

$P^{III}P^{V}P^{III}$

Attempts to characterize the substitution reactions in Eqs. 2 and 3 by gel chromatography had been made in our laboratory.[3,4] Analytical methodologies had been proposed capable of resolving and identifying such reaction products that were complex in structure and included unknown species. A preliminary experiment

with HPLC[5] and detailed experiments to give theoretical discussion about kinetics and mechanisms of the substitution reactions[6] have been reported. Baba's works[6] with advanced techniques, HPLC and ^{31}P NMR, presented more improved chromatographic resolution and structural diagnosis of reaction products. The present paper was undertaken to examine the usefulness and reliability of HPLC and ^{31}P NMR in practical synthetic experiments with diphosphonate. In accordance with the earlier observations these techniques were confirmed to be valuable for visualizing the reaction processes in Eqs. 2 and 3.

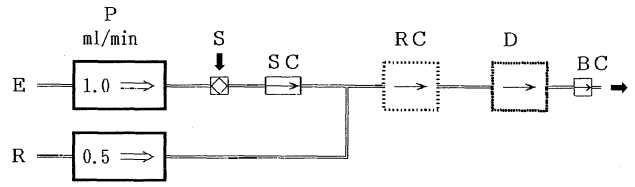


Fig. 1. HPLC system for the selective determination of P(V)-containing compounds. <P> Pump, <S> Sample injector, <SC> Separation column (4 mm I.D.×25 cm, TSK-gel SAX), <RC> Reaction coil (0.5 mm I.D.×20 m, 140 °C), <D> Spectrophotometric detector (820 nm, 650 nm), <BC> Back-pressure coil (0.3 mm I.D.×2 m), <E> Eluent, 0.25 M KCl+0.1% EDTA(4Na), <R> Mo(V)-Mo(VI) reagent.

Experimental

Chemicals. Disodium diphosphonate, $Na_2P_2H_2O_5$, was prepared according to the previous paper.[8] Other chemicals were guaranteed reagents from Wako (Osaka, Japan).

HPLC Measurement. Detailed procedures used for the analysis of phosphorus compounds by employing a high-temperature detection system (Fig. 1) have been shown in the previous papers.[7–11]

NMR Measurement. ^{31}P NMR measurement was made by use of a JEOL JNM-GX-400 (161.8 MHz) spectrometer. Orthophosphoric acid (85%) was used as an external standard.

Results and Discussion

Separation by HPLC. In order to monitor phosphorus compounds in Eqs. 2 and 3 the HPLC system in Fig. 1 was employed. The system consisted of an anion-exchange separation column (TSK-gel SAX) and a post-column detection system using a Mo(V)–Mo(VI) reagent.[7–11] The detection system was able to permit the selective detection of P(V)-units in the presence of P(III)-units. Hence, P^{V} and $P^{III}P^{V}$ in Eq. 2 were detectable, while $P^{III}P^{III}$ and P^{III} did not indicate HPLC peaks.

A mixed solution composed of 0.5 M diphosphonate ($Na_2P_2H_2O_5$, M=mol dm^{-3}) and 0.1 M orthophosphate (Na_2HPO_4) was allowed to stand at 50 °C for 24 h.

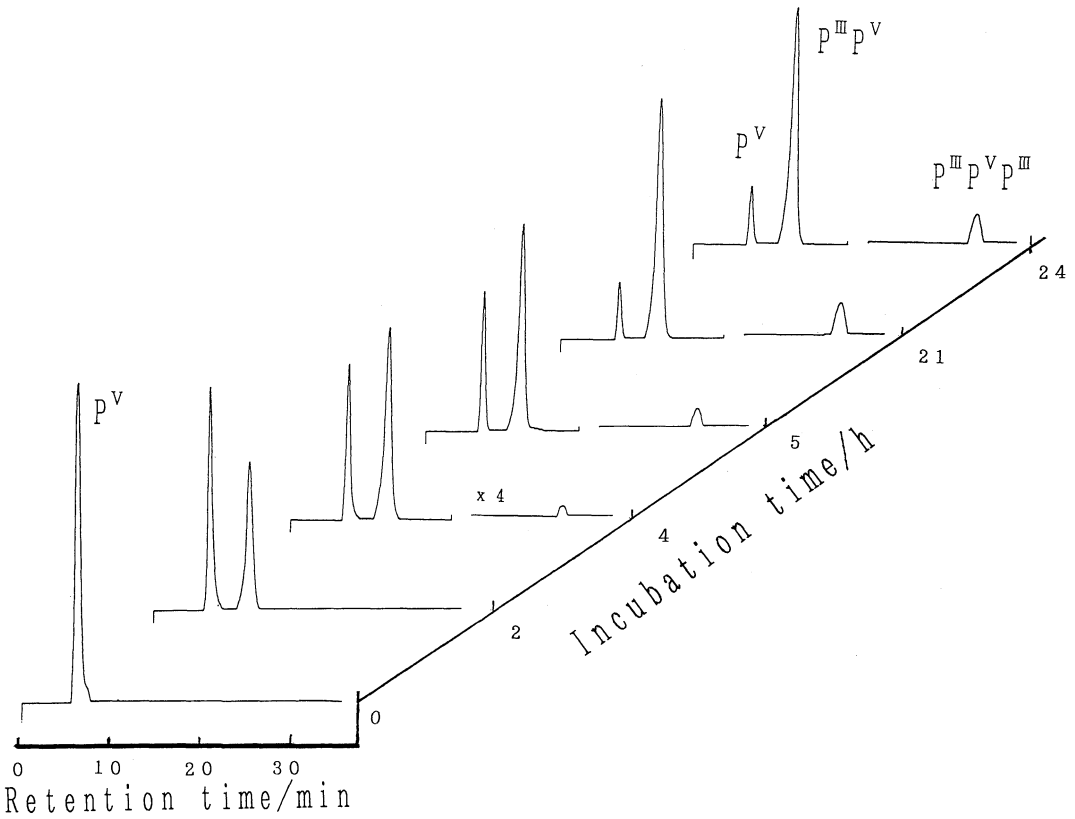

Fig. 2. HPLC profiles indicating progressive phosphonylation of orthophosphate by diphosphonate at 50 °C. <Sample> A mixed solution of 0.1 M P^{V} and 0.5 M $P^{III}P^{III}$.

The pH of the sample solution decreased with the progress of substitution reactions, from initial pH value ca. 7 to final ca. 5.5, because any buffer agents were not used to avoid their side reactions with diphosphonate. Aliquots of the incubated solution were 100-fold diluted and analyzed by HPLC at desired time-intervals to observe the progressive conversion of phosphorus compounds in Eqs. 2 and 3. As shown in Fig. 2 the peak height for $P^{III}P^{V}$ increased with time, in contrast to the decrease of the peak height for the starting material, P^{V}. The peaks for $P^{III}P^{V}P^{III}$ in Eq. 3 were recorded with 4-fold amplification after 4 h incubation. In should be noted that the distributions of P^{III} and $P^{III}P^{III}$ were confirmed by a separate detection method based on the preoxidation of P(III) to P(V) and the chemical compositions of $P^{III}P^{V}$ and $P^{III}P^{V}P^{III}$ were determined by differential analyses of P(III) and P(V) as shown in the previous papers.[3–7]

Since P(III) unit is not to be detected with this spectrophotometric detection method and each species in Fig. 2 includes one detectable P(V) unit per molecule, the relative peak areas of P^{V}, $P^{III}P^{V}$, and $P^{III}P^{V}P^{III}$, calculated by a data processor Shimadzu CR1-B, can be used to represent the relative molar concentrations of the three species. About 50% of the initial P^{V} was phosphonylated at 2 h to form $P^{III}P^{V}$. The relative amounts in molar concentration of P^{V}(12%), $P^{III}P^{V}$(85%), and $P^{III}P^{V}P^{III}$(3%) tended to become unchanged at 21—24 h, suggesting the attainment of equilibrium or steady states[8,9] of the substitution reactions.

The growing rates of the three peaks were dependent on the initial reactant concentrations. With decreased initial sample concentrations, 0.1 M diphosphonate and 0.1 M orthophosphate, the relative amount of $P^{III}P^{V}$ increased more slowly than that in Fig. 2 to attain 42% after 22 h and no peak for $P^{III}P^{V}P^{III}$ was observed. On the other hand, when the initial sample concentrations were increased to 0.25 M orthophosphate and 1.25 M diphosphonate, keeping the same molar ratio of the reactants as in Fig. 2, both peaks of $P^{III}P^{V}$ and $P^{III}P^{V}P^{III}$ appeared as soon as two reactants were mixed. After 3 h the reactions attained to the distribution equilibrium of three species; P^{III}(8%), $P^{III}P^{V}$(78%) and $P^{III}P^{V}P^{III}$(14%).

Characterization by ^{13}P NMR. The NMR spectra to indicate the progress of substitution reactions in Eqs. 2 and 3 are shown in Fig. 3. The sample

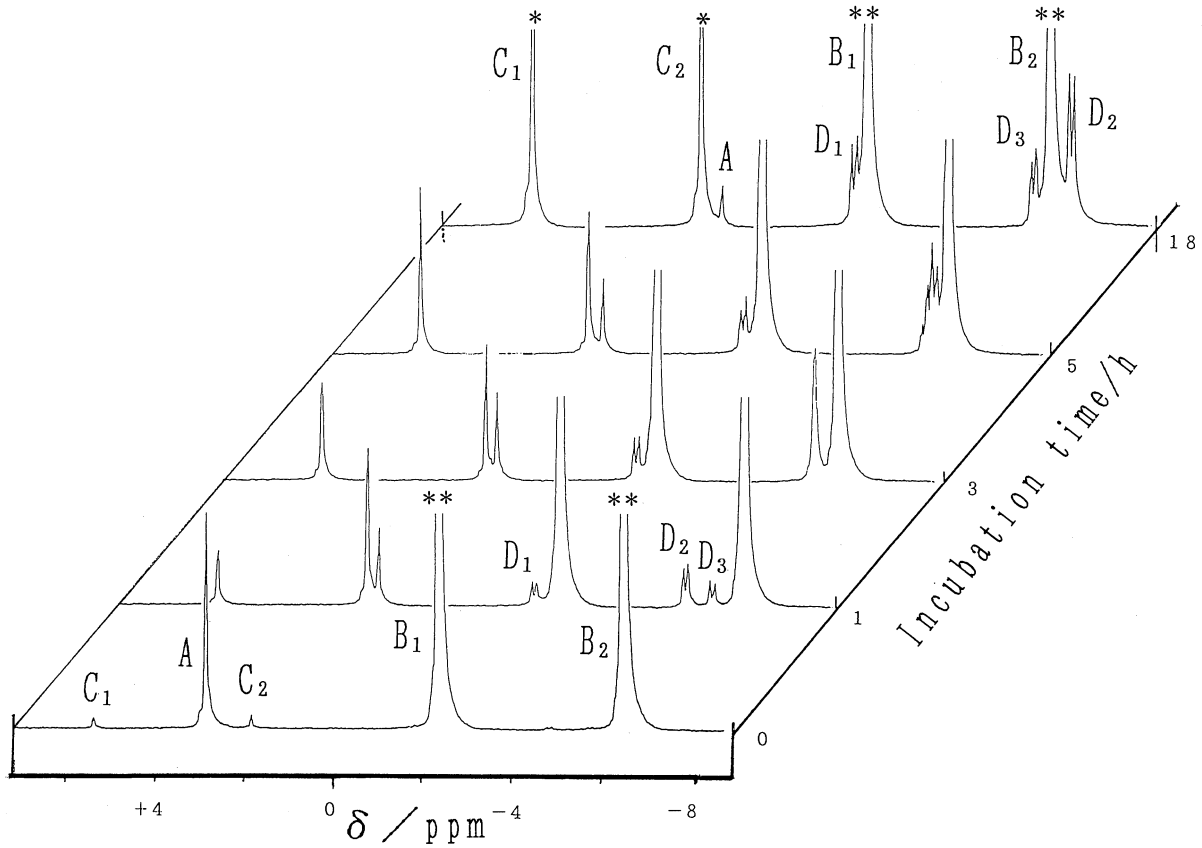

Fig. 3. ^{31}P NMR spectra showing progressive phosphonylation of orthophosphate by diphosphonate at 50 °C. <Sample> A mixed solution of 0.1 M P^{V} and 0.5 M $P^{III}P^{III}$. <Assignment> Signal A for P^{V}; B_1 and B_2 for $P^{III}P^{III}$; C_1 and C_2 for P^{III}; D_1, D_2, and D_3 for $P^{III}P^{V}$. Single asterisk (*) on the cut peaks of P^{III} refers to singlet and double asterisk (**) of $P^{III}P^{III}$ indicates "doublet" that is apparently observed as a doublet, but has been more finely resolved to be a triplet (double triplet for $P^{III}P^{III}$; Refs. 9 and 12).

composition, 0.1 M P^{V} and 0.5 M $P^{III}P^{III}$, was the same as that in Fig. 2. If the reactants and products are composed of P(III) units and/or P(V) units, it is useful in assigning the NMR spectra to keep in mind two general characteristics[2,6-8,11-14] arising from the P–H coupling and the pH dependence of chemical shift: (1) P(V) group gives a singlet signal or a multiplet with small peak splitting, ca. 18 Hz, due to P–P coupling and its chemical shift (δ value) shifts to the high field with decreasing pH, from the initial pH 7 to the final pH 5.5 in Fig. 3 and (2) P(III) group having a P–H bond gives a doublet signal with a coupling constant (J_{PH} value) as large as ca. 600 Hz and its chemical shift is less dependent on pH. Additional small peak splittings due to P–P couplings are also expected to be observed for P(III) groups in polymers.

As shown in Fig. 3 a signal A for P^{V}(δ=2.84 ppm) and a pair of two signals, B_1 and B_2, for $P^{III}P^{III}$ (δ=−4.46 ppm, J_{PH}=670 Hz) were observed as the principal signals when NMR spectra were recorded as soon as P^{V} and $P^{III}P^{III}$ were mixed (ca. pH 7). A pair of small signals C_1 and C_2 are for P^{III}(δ=3.47 ppm, J_{PH}=580 Hz). With increasing incubation time the signal A as well as B_1 and B_2 decreased and the signals C_1 and C_2 increased as could be expected from Eq. 2. Probably due to the decrease in pH to ca. pH 5.5 (final, 18 h), P^{III} indicated small change in δ value (final, 3.2 ppm) and considerable change in J_{PH} value (final, 620 Hz), while both δ value and J_{PH} value for $P^{III}P^{III}$ remained unchanged. The peak A for P^{V} shifted across the signal C_2 to the high field after 3 h and finally appeared at +0.86 ppm.

Three signals, D_1 (doublet: δ=−1.84), D_2 (doublet: δ=−5.25), and D_3 (doublet: δ=−5.85), appeared at 1 h incubation with intensity ratio 1:2:1 (D_1:D_2:D_3), were assigned to $P^{III}P^{V}$. The signal D_2 that shifted remarkably with time, as well as A, to appear finally at the right hand side of B_2 (δ=−6.99) was assigned to the P(V) unit of $P^{III}P^{V}$. The pair of D_1 and D_3 attributable to the P(III) unit of $P^{III}P^{V}$ indicated a large coupling constant (J_{PH}=650 Hz) that was slightly variable with incubation time. The change in δ value from −3.8 ppm to −4.1 ppm (final) was small. The splitting of each D_1, D_2, and D_3, 17.8—18.5 Hz, was ascribed to P–P coupling of unsymmetrical $P^{III}P^{V}$.[2] In addition to the proton-coupled experiments in Fig. 3 proton-decoupled experiments[8,9] were also made. As expected the paired signals of D_1 and D_3 for $P^{III}P^{V}$ in Fig. 3 disappeared to give a signal (doublet) at −3.8 ppm (initial). Similar effects of proton-decoupling were also observed for P^{III} and $P^{III}P^{III}$. Unfortunately, ^{31}P NMR signals for the trimeric $P^{III}P^{V}P^{III}$ could not be recorded, probably due to its low concentration that can be estimated from the chromatographic data in Fig. 2 to be less than 0.003 M.

Equilibrium Constants. In designing synthetic experiments to obtain high yields of products it is convenient to have information about apparent or conditional equilibrium constants of the substitution reactions of interest, even if the constants are based not strictly on thermodynamic consideration. This section deals with the evaluation of such apparent equilibrium constants for Eqs. 2 and 3 on the assumption that no side reactions such as hydrolysis of diphosphonate take place.[6,7]

Equilibrium constants, $K_{III,V}$ and $K_{III,V,III}$, for the formation of $P^{III}P^{V}$ and $P^{III}P^{V}P^{III}$ in Eqs. 2 and 3 are given as follows in terms of molar concentrations of each species at equilibrium conditions.

$$K_{III,V} = \frac{[P^{III}P^{V}][P^{III}]}{[P^{V}][P^{III}P^{III}]}, \quad (4)$$

$$K_{III,V,III} = \frac{[P^{III}P^{V}P^{III}][P^{III}]}{[P^{III}P^{III}][P^{III}P^{V}]}. \quad (5)$$

$[P^{V}]$, $[P^{III}P^{V}]$, and $[P^{III}P^{V}P^{III}]$ can be directly calculated from the relative peak areas in Fig. 2 since the total concentration of three species having P(V) units or the initial concentration of orthophosphate,$[P^{V}]_0$, is known. The initial concentration $[P^{III}P^{III}]_0$ is also known and hence two unknown concentrations are calculated as follows.

$$[P^{III}] = [P^{III}P^{V}] + 2[P^{III}P^{V}P^{III}], \quad (6)$$

$$[P^{III}P^{III}] = [P^{III}P^{III}]_0 - [P^{III}]. \quad (7)$$

The equilibrium constants thus obtained with the sample solution of 0.1 M orthophosphate and 0.5 M diphosphonate in Fig. 2 were; $K_{III,V}$=1.7 and $K_{III,V,III}$=0.008. Higher values, $K_{III,V}$=2.7 and $K_{III,V,III}$=0.05, were obtained for the sample of higher initial concentrations, 0.25 M orthophosphate and 1.25 M diphosphonate, while the sample of lower initial concentrations, 0.1 M orthophosphate and 0.1 M diphosphonate, gave a lower constant, $K_{III,V}$=0.50. The remarkable variation in the equilibrium constant with sample concentrations is not surprising because the experiments were made at high sample concentrations and the variable effects of pH, sodium ion and hydrolysis of diphosphonate[6-10] were not taken into consideration. The equilibrium constants provided by the simple chromatographic procedures are valuable from the practical viewpoint of predicting yields of the reaction products. Extended experiments based on the above prediction are in progress to prepare so much amount of the novel $P^{III}P^{V}P^{III}$ that is enough to do NMR expepriment for its structural characterization.

Preparation and Properties of Heteropoly Molybdovanadate(V) Complexes

Sadayuki HIMENO,* Toshiyuki OSAKAI, and Atsuyoshi SAITO
Department of Chemistry, College of Liberal Arts, Kobe University, Kobe 657
(Received July 30, 1990)

Tetrabutylammonium salts of the mixed heteropoly molybdovanadate(V) anions, $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ (x=1—3) were prepared from a Mo(VI)–V(V)–CH_3CN system at room temperature. These mixed heteropoly anions were distinguished by their voltammetric behavior; the anions with x=1, 2, and 3 were electroreduced by one-, two-, and three-electrons due to the peripheral V atoms at a glassy carbon electrode. The spectroscopic properties were also reported. Their formation conditions were compared with those of 12-molybdovanadate (V), $[VMo_{12}O_{40}]^{3-}$, especially regarding the concentrations of Mo(VI), V(V), acid, and organic solvents, the nature of organic solvents, and the ionic strength of the system. It should be emphasized that the 12-molybdovanadate(V) and mixed molybdovanadate(V) complexes are not formed in the absence of organic solvents.

We have prepared several heteropolymolybdate complexes, which are formed only in the presence of water-miscible organc solvents such as acetonitrile.[1] In the course of the preparative studies from aqueous–organic media, we have recently isolated tetrabutylammonium (n-Bu_4N^+) salts of 12-molybdovanadate(V), which is considered to be a Keggin anion with a central VO_4 tetrahedron, from an acidic Mo(VI)–V(V) solution admixed with acetonitrile.[2] In the present study, the existence of several vanadium-substituted mixed molybdovanadate(V) complexes was ascertained in the solid state and in aqueous–organic solution.

Fortuitously, a mixed-valence reduced crystal of a mixed molybdovanadate(V) complex, $K_6V(V^{IV}V^{V}Mo_{10})O_{40}\cdot 13H_2O$ has been obtained upon slow crystallization of $K_8V_8Mo_4O_{36}\cdot 12H_2O$, and it has been shown by X-ray diffraction analysis that the mixed complex possesses a Keggin-type structure.[3] According to recent ^{51}V NMR studies,[4] heteropoly molybdovanadate(V) complexes are only supposed to be formed in an aqueous Mo(VI)–V(V) system. On the basis of our results, however, it should be stressed that the presence of organic solvents in concentrations greater than 30% (v/v) is essential for the formation of heteropoly molybdovanadate(V) complexes.

The present study was undertaken to characterize the mixed molybdovanadate(V) complexes and to elucidate their formation conditions in relation to those of 12-molybdovanadate(V). This paper also reports voltammetric evidence for the spontaneous conversion of $[VMo_5O_{19}]^{3-}$ into heteropoly molydovanadate(V) anions in acidified aqueous–organic system.

Experimental

UV-visible absorption spectra were recorded on a Hitachi Model 220-A spectrophotometer using a quartz cell with path length of 1.0 cm. Voltammetric measurements were made with a PARC Model 174-A polarographic analyzer equipped with a Yokogawa Model 3023 X-Y recorder. A working electrode was a glassy carbon (Tokai Carbon, GC-30S) with a surface area of 0.071 cm^2. A platinum wire was used as the counter electrode and a saturated calomel electrode (SCE) as the reference. Unless stated otherwise, voltage scan rate was set at 100 mV s^{-1}. UV-visible spectrophotometric and voltammetric measurements were made at 25±0.1 °C. Controlled potential electrolysis was carried out with a Hokuto Denko Model HA-501 potentiostat. TG-DTA was carried out with a Rigaku Denki 8002-SD thermal analyzer. A Hitachi Model 270-30 spectrophotometer was used to record IR spectra using KBr pellets.

Results and Discussion

Preparation of Molybdovanadate(V) Complexes.

(n-Bu_4N)$_3VMo_{12}O_{40}$: This complex was prepared and purified as described.[2]

(n-Bu_4N)$_4V(VMo_{11})O_{40}$: A solution of 1.17 g (10.0 mmol) NH_4VO_3 in 125 ml of 2 M HCl (1 M=1 mol dm^{-3}) was added to a solution of 6.05 g (25.0 mmol) of $Na_2MoO_4\cdot 2H_2O$ in 75 ml of water. Then, 300 ml of acetonitrile was added with stirring to the mixture. This resulted in a rapid color change from pale-yellow due to vanadate(V) to orange-yellow. After the solution was stirred for 1 h at room temperature, 10 g of n-Bu_4NBr was added to precipitate an orange-yellow salt. The salt was isolated by filtration, and washed with water and ethanol (Yield 5.4 g). The salt was purified by recrystallization from 350 ml of acetonitrile.

Anal. Calcd for (n-Bu_4N)$_4V(VMo_{11})O_{40}$: Mo, 38.14; V, 3.68; C, 27.78; H, 5.25; N, 2.02%. Found: Mo, 37.70; V, 3.82; C, 27.71; H, 5.42; N, 2.08%.

(n-Bu_4N)$_4HV(V_2Mo_{10})O_{40}$: This preparation is similar to that of the preceding salt. A solution of 2.05 g (17.5 mmol) of NH_4VO_3 in 100 ml of 2 M HCl was added to a solution of 6.05 g (25.0 mmol) of $Na_2MoO_4\cdot 2H_2O$ in 100 ml of water. After the addition of 300 ml of acetonitrile, the solution was stirred for 1 h at room temperature. The addition of 10 g of n-Bu_4NBr led to immediate precipitation of an orange salt (Yield 6.3 g), which was subsequently recrystallized from 300 ml of acetonitrile.

Anal. Calcd for (n-Bu_4N)$_4HV(V_2Mo_{10})O_{40}$: Mo,

35.25; V, 5.61; C, 28.24; H, 5.37; N, 2.06%. Found: Mo, 34.89; V, 5.63; C, 27.94; H, 5.20; N, 2.06%.

(n-$Bu_4N)_4H_2V(V_3Mo_9)O_{40}$: This compound was prepared with the use of the procedure described for (n-$Bu_4N)_4HV(V_2Mo_{10})O_{40}$ by substituting 2.98 g (25.0 mmol) of NH_4VO_3 for 2.05 g (Yield 6.8 g).

Anal. Calcd for (n-$Bu_4N)_4H_2V(V_3Mo_9)O_{40}$: Mo, 32.23; V, 7.61; C, 28.69; H, 5.49; N, 2.09%. Found: Mo, 32.58; V, 7.57; C, 28.29; H, 5.50; N, 2.13%.

In the TG-DTA, the evolution of water was not observed up to about 260 °C for the mixed heteropoly molybdovanadate(V) complexes.

The mixed molybdovanadate(V) complexes are not distinguished by their IR spectra because they show the strong absorption bands of the same pattern at 946, 880, and 774 cm^{-1}; the 12-molybdovanadate(V) complex gives the corresponding bands at 958, 887, and 776 cm^{-1}.[2] Despite various attempts , complexes with higher vanadium contents were not successfully prepared.

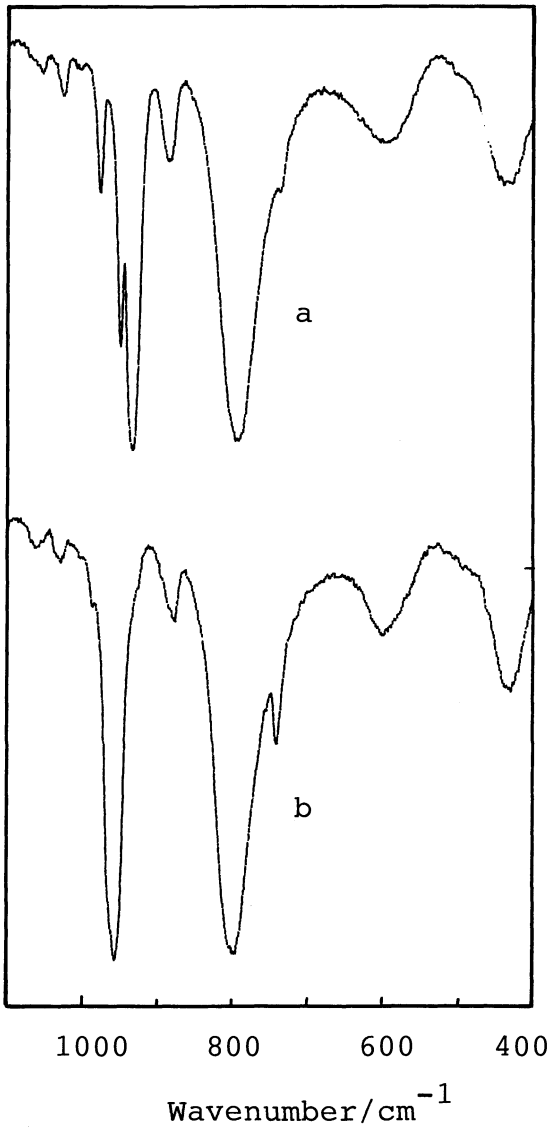

Fig. 1. IR spectra of (a) (n-$Bu_4N)_3VMo_5O_{19}$ and (b) (n-$Bu_4N)_2Mo_6O_{19}$ in the KBr pellets. Numerical data are given in the Text.

In addition, the $[VMo_5O_{19}]^{3-}$ anion was prepared with a view to investigating the possibility of its transformation reaction into hereropoly molybdovanadate(V) anions.[5] According to Flynn, Jr. and Pope,[6] mixed tungstovanadate(V) anions such as $[V(V_2W_{10})O_{40}]^{5-}$ and $[V(V_3W_9)O_{40}]^{6-}$ have been prepared by acidifying the aqueous solution of the mixed Lindqvist anion, $[V_2W_4O_{19}]^{4-}$, although 12-tungstovanadate(V) is still unknown.

(n-$Bu_4N)_3VMo_5O_{19}$: A solution of 0.234 g (2.0 mmol) NH_4VO_3 in 20 ml of 0.15 M NaOH was added to a solution of 2.42 g (10.0 mmol) of $Na_2MoO_4 \cdot 2H_2O$ in 480 ml of water, and the pH of the solution was adjusted to pH 3.2 with HCl.[7] The resulting yellow solution was stirred for 1 h at room temperature. A yellow salt was precipitated by the addition of 5 g of n-Bu_4NBr, being filtered off, washed with water and ethanol, and dried at 40 °C (Yield 2.9 g). The yellow salt was recrystallized from 100 ml of acetonitrile.

Anal. Calcd for (n-$Bu_4N)_3VMo_5O_{19}$; Mo, 30.71; V, 3.26; C, 36.91; H, 6.97; N, 2.69%. Found: Mo, 30.76; V, 3.27; C, 36.76; H, 7.11; N, 2.75%. IR (400—1000 cm^{-1}): 978, 950, 934, 796, 596, 436 cm^{-1} (Fig. 1(a)). For comparison, Fig. 1(b) shows an IR spectrum of (n-$Bu_4N)_2Mo_6O_{19}$ prepared according to the previous procedure.[8] IR (400—1000 cm^{-1}): 956, 798, 598, 436 cm^{-1}.

UV-Visible Spectra. The n-Bu_4N^+ salts of the mixed heteropoly molybdovanadate(V) anions are reasonably soluble in polar aprotic solvents such as

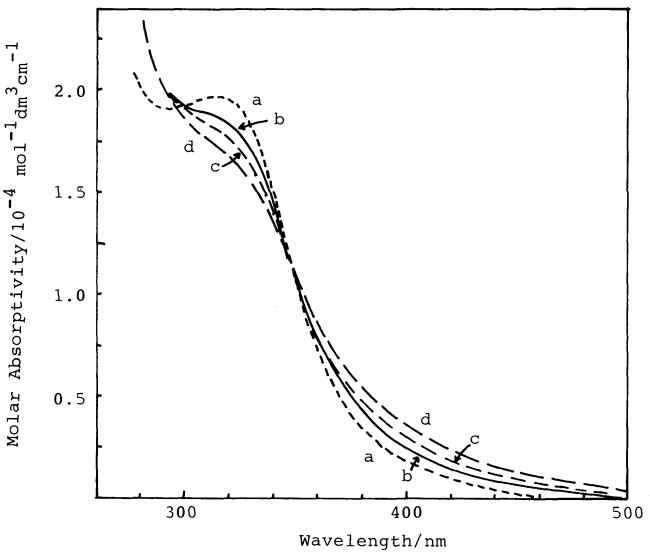

Fig. 2. UV-visible spectra of 0.04 mM $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ in neat acetonitrile. (b), x=1; (c), x=2; (d), x=3. The spectrum of 0.04 mM $[VMo_{12}O_{40}]^{3-}$ is included for comparison (curve (a)).

acetonitrile and acetone, and insoluble in water, ethanol, and 1,4-dioxane. Figure 2 shows UV-visible absorption spectra of 0.04 mM (M=mol dm^{-3}) solutions of the $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ anions in neat acetonitrile. The solutions obeyed Beer's law in the spectral region studied. As the substituted vanadium content increased, the spectrum appeared like a shoulder and there was a decrease in molar absorptivities at 310 nm (1.90×10^4, 1.82×10^4, and 1.75×10^4 mol^{-1} dm^3 cm^{-1} for the $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ anions with x=1, 2, and 3, respectively). These behaviors are similar to those of a series of mixed molybdovanadophosphate(V) complexes with the Keggin-type structure.[9,10]

Voltammetric Characterization of the Heteropoly Molybdovanadate(V) Anions. Figures 3 and 4 show cyclic and normal pulse voltammograms, respectively, of 0.2 mM solutions of the heteropoly molybdovanadate(V) complexes in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$.

The $[VMo_{12}O_{40}]^{3-}$ Anion: Reproducible voltammograms were obtained (curve (a)). As already described,[2] the first reduction wave corresponds to a reversible two-electron transfer. The separation of the cathodic and anodic peaks averages 27—30 mV. The peak-potential (E_p) showed positive shift as the $HClO_4$ concentration was increased in the range of −log

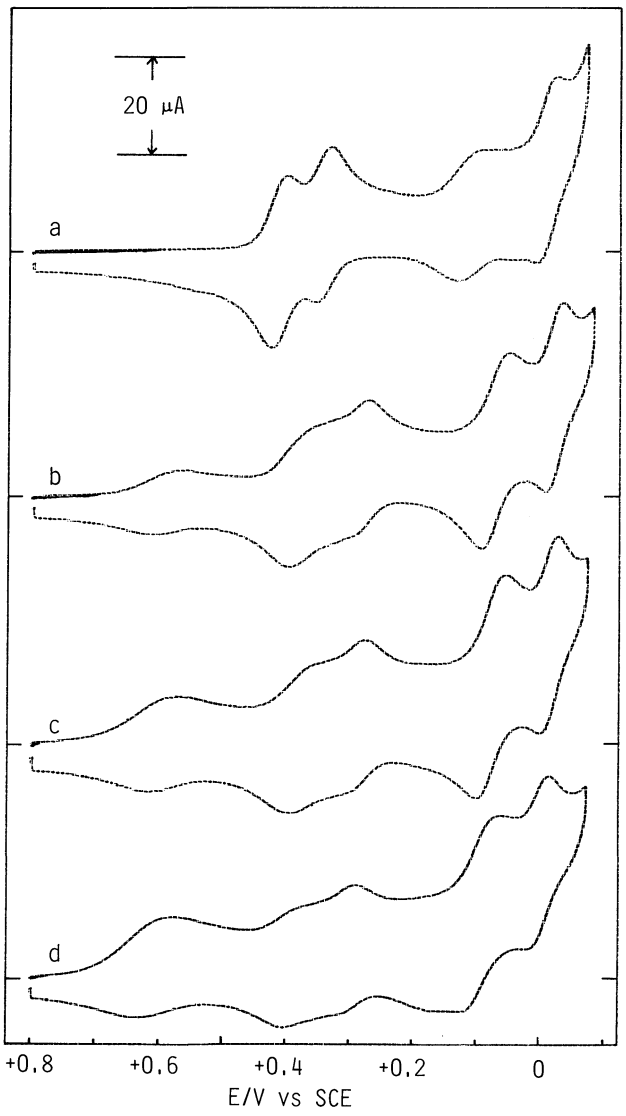

Fig. 3. Cyclic voltammograms of 0.2 mM $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ in 95%(v/v) CH_3CN–water containing 0.1 M $HClO_4$. (b) x=1; (c), x=2; (d), x=3. The voltammogram of 0.2 mM $[VMo_{12}O_{40}]^{3-}$ is included for comparison (curve (a)).

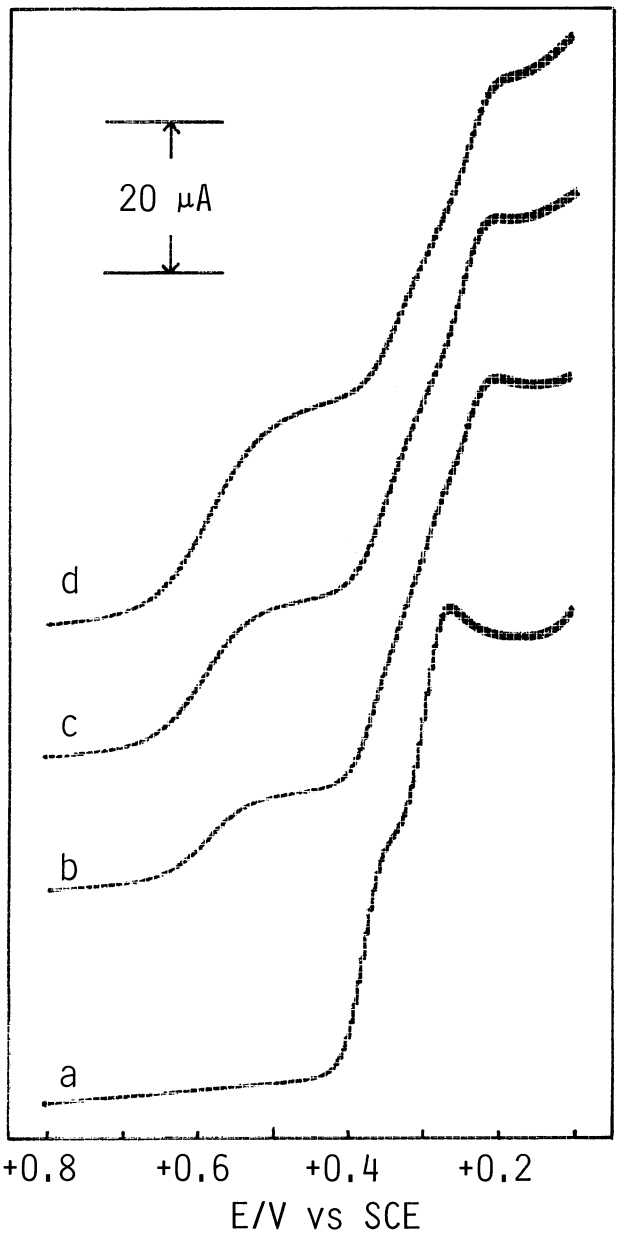

Fig. 4. Normal pulse voltammograms of 0.2 mM $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ in 95%(v/v) CH_3CN–water containing 0.1 M $HClO_4$. (b), x=1; (c), x=2; (d), x=3. The voltammogram of 0.2 mM $[VMo_{12}O_{40}]^{3-}$ is included for comparison (curve (a)).

$[H^+]$=2.6—1.0 (I=0.1 M ($NaClO_4$)), where I=ionic strength. The slope of E_p/−log $[H^+]$ was estimated to be 65 mV, indicating that two protons are consumed in the reduction process:

$$[VMo_{12}O_{40}]^{3-} + 2e + 2H^+ = [H_2V(Mo^V_2Mo_{10})O_{40}]^{3-}$$

The $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{3-}$ Anions: The voltammograms recorded 1 h later remained identical under these conditions; however, the solutions examined after 24 h standing gave decayed or distorted voltammograms, indicating the decomposition of the complexes. Therefore, curves (b)—(d) of Figs. 3 and 4 were recorded for freshly prepared solutions.

The voltammograms for the $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ anions gave additional reduction waves at about 0.2 V more positive than the first reduction wave of $[VMo_{12}O_{40}]^{3-}$. The currents were dependent on the square root of the voltage scan rate (20—200 mV s^{-1}), indicating that the electrode processes are diffusion-controlled. The additional waves can be ascribed to the reduction of the peripheral V atoms, because the reduction currents are dependent on the vanadium content. This is in line with the previous observations that the V atoms in the peripheral structure are more easily reduced than the Mo or W atoms in vanadium-substituted mixed complexes with P as the central heteroatom, i.e., $[P(V_xMo_{12-x})O_{40}]^{(3+x)-}$ and $[P(V_xW_{12-x})O_{40}]^{(3+x)-}$.[11-14]

As long as the $[V(VMo_{11})O_{40}]^{4-}$ anion is concerned, the voltammetric wave corresponds to a reversible one-electron transfer, because the separation of the cathodic and anodic peaks are 60 mV, being independent of the voltage scan rate (20—200 mV s^{-1}) in cyclic voltammetry. The E_p's for the reduction and oxidation waves were shifted to more positive potentials as the $HClO_4$ concentration was increased in the range of −log $[H^+]$=2.6—1.0 (I=0.1 M ($NaClO_4$)), and the slope was estimated to be 65 mV, which indicates that the electrode process corresponds to the reaction:

$$[V(V^VMo_{11})O_{40}]^{4-} + e + H^+ = [HV(V^{IV}Mo_{11})O_{40}]^{4-}$$

Both cyclic and normal pulse voltammetric reduction currents for the $[HV(V_2Mo_{10})O_{40}]^{4-}$ and $[H_2V(V_3Mo_9)O_{40}]^{4-}$ anions were approximately 2 and 3 times that for the one-electron reduction current of the $[V(VMo_{11})O_{40}]^{4-}$ anion. These results indicate that both reduction processes involve a sequence of 2 and 3 one-electron steps with different standard potentials, E^0, rather than single two- and three-electron reductions, respectively:[15-17] In the case of the reduction of the $[HV(V_2Mo_{10})O_{40}]^{4-}$ anion, for example,

$$[HV(V_2^VMo_{10})O_{40}]^{4-} \underset{E_1^0}{\overset{e}{\rightleftarrows}} [HV(V^{IV}V^VMo_{10})O_{40}]^{5-}$$

$$\underset{E_2^0}{\overset{e}{\rightleftarrows}} [HV(V_2^{IV}Mo_{10})O_{40}]^{6-}$$

When $-90\ mV < \Delta E^0 (= E_2^0 - E_1^0) < 0$ mV, the individual waves merge into one broad wave.[17] This is further substantiated by the fact that in cyclic voltammetry, the E_p values for the cathodic and anodic waves were not affected by the voltage scan rate (20—200 mV s^{-1}) (the separation averaged 60—70 mV). These reduction behaviors suggest that the V atoms are not in the adjacent position in the peripheral structure.[15] It has been shown by X-ray crystallographic structural analysis that the Mo and V atoms are randomly distributed in the peripheral structures of $[V(V^{IV}V^V-Mo_{10})O_{40}]^{6-}$ and $[P(V_xMo_{12-x})O_{40}]^{(3+x)-}$ (x=2 and 3).[3,18] It was found that the E_p values shifted to more positive potentials with an increase of the $HClO_4$ concentration. However, quantitative treatment could not be made owing to the complicated electrode processes.

As shown in curves (b)—(d) of Fig. 3, the voltammetric waves due to the reduction of molybdenum appeared at potentials more negative than +0.4 V, being distorted similar to irreversible waves. However, the distorted waves remained unchanged in position on the potential axis as a function of the voltage scan rate (20—200 mV s^{-1}), which indicates the reversible nature of their electrode processes. At present we are unable to account quantitatively for this electrode behavior; however, a possible explanation can be given in terms of the existence of several isomers in oxidized and/or reduced forms with slightly different E^0.[17]

The distorted waves due to the reduction of molybdenum decreased in height with an increase of the vanadium content in the complexes. These results can be accounted for in terms of the decomposition of the vanadium-substituted complexes as a result of the reduction of the peripheral V atoms. This is confirmed by the following observations: For the $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$ anions, the solutions changed from orange to blue by controlled potential electrolysis at a reduction potential of the peripheral V atoms; however, colorless solutions resulted at the end of controlled potential electrolysis because of the decomposition of the blue species.

Formation of the Heteropoly Molybdovanadate(V) Anions. Figure 5 shows cyclic voltammograms of a 10 mM Mo(VI)–0.2 M HCl–50%(v/v) CH_3CN system. In the absence of V(V), as shown in curve (a), no voltammetric waves were obtained until a current rise due to the reduction of $[Mo_6O_{19}]^{2-}$ around +0.1 V.[8,19] On the addition of 0.2 mM V(V), a two-step voltammetric wave with an equal height was obtained (curve (b)). The currents were diffusion-controlled. As shown in curve (a) of Fig. 6, the voltammetric currents attained to a constant value around one min

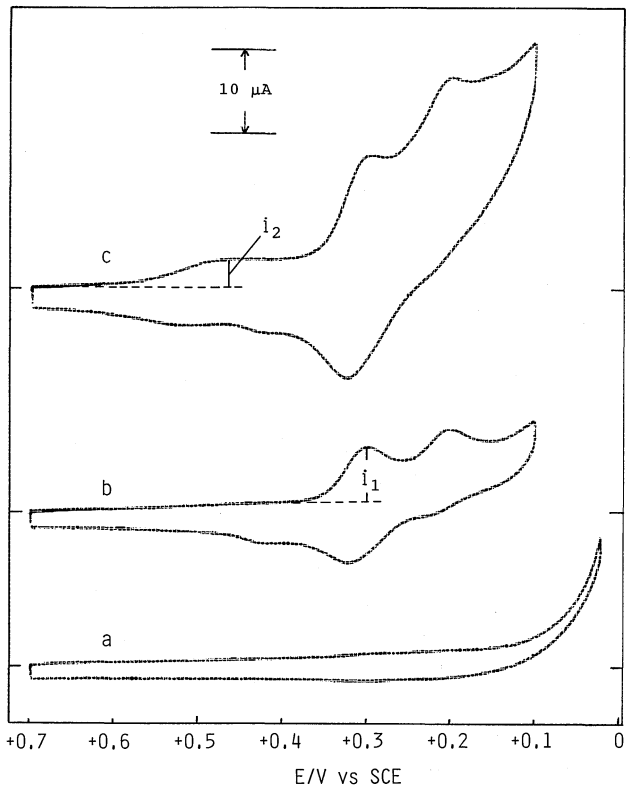

Fig. 5. Cyclic voltammograms of 10 mM Mo(VI)–0.2 M HCl–50%(v/v) CH_3CN systems. [V(V)]/mM, (a) none; (b) 0.2; (c) 1.0.

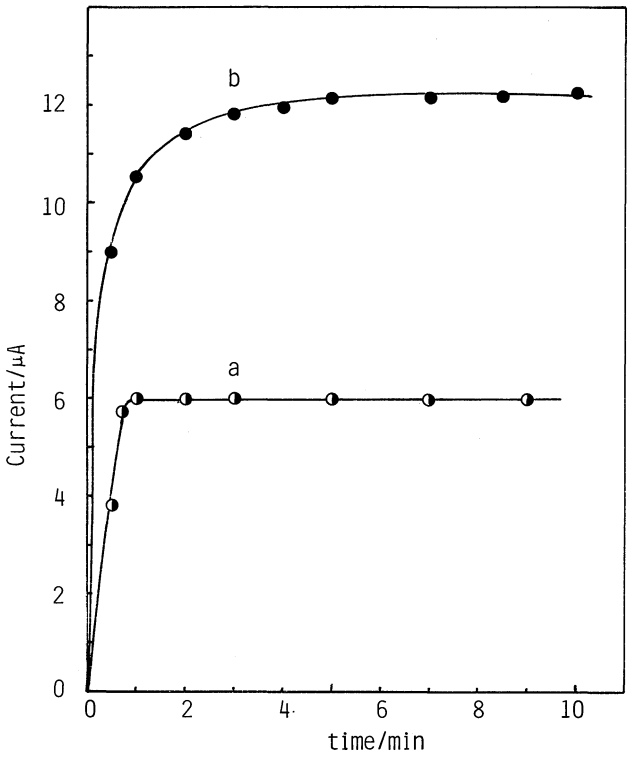

Fig. 6. Current-time profiles for 30 mM Mo(VI)–0.1 M $HClO_4$–50%(v/v) CH_3CN systems. [V(V)]/mM, (a), 0.2 (i_1); (b), 2.0 (i_2).

after the addition of V(V). The $[VMo_{12}O_{40}]^{3-}$ anion is responsible for the voltammetric waves shown in curve (b) of Fig. 5. The first peak current is represented by i_1 in the following.

The increase of the V(V) concentration caused the voltammetric behavior to change significantly. With an increase of the V(V) concentration while other conditions were kept unchanged, the solution turned from yellow to orange. Simultaneously, a new voltammetric wave appeared at more positive potentials than those for the voltammetric wave of $[VMo_{12}O_{40}]^{3-}$ (curve (c) of Fig. 5). The new voltammetric current corresponding to the reduction of the peripheral V atoms attained to a constant value around 5 min after the addition of V(V) as shown in curve (b) of Fig. 6, being denoted as i_2 in the following. This behavior can be ascribed to the formation of vanadium-substituted derivatives of the $[VMo_{12}O_{40}]^{3-}$ anion. After the current-increase periods, both 12-molybdovanadate(V) and vanadium-substituted derivatives are stable under these conditions, as judged by no change of i_1 and i_2.

Figure 7 shows the dependence of i_1 and i_2 on the concentration of V(V) in 10 mM Mo(VI)–0.2 M HCl–50%(v/v) CH_3CN systems. For V(V) concentrations< 0.5 mM, i_2 was hardly detected, which indicates that $[VMo_{12}O_{40}]^{3-}$ is predominant. Both i_1 and i_2 increased as the V(V) concentration was increased from 0.5 to 1 mM. Above 1 mM V(V), i_2 increased further at the expense of i_1.

The formation conditions of 12-molybdovanadate (V) and vanadium-substituted derivatives were inves-

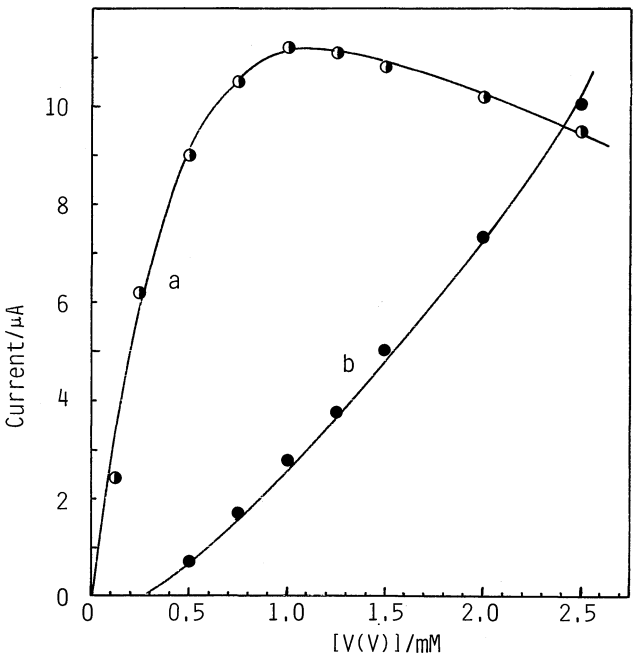

Fig. 7. Dependence of (a) i_1 and (b) i_2 on the concentration of V(V) for 10 mM Mo(VI)–0.2 M HCl–50%(v/v) CH_3CN systems.

tigated by monitoring i_1 and i_2, respectively. Curves (a) and (b) of Fig. 8 show i_1 and i_2 as a function of the $HClO_4$ concentration for 30 mM Mo(VI)–50%(v/v) CH_3CN systems containing 0.1 and 0.5 mM V(V), respectively. The ionic strength was adjusted to be 0.5 M with $NaClO_4$. The 12-molybdovanadate(V) anion is formed in the $HClO_4$ concentration range 0.06—0.6 M while the vanadium-substituted derivative anions are formed in 0.04—0.4 M $HClO_4$. Curve (c) shows absorbance values at 400 nm for 30 mM Mo(VI)–50%(v/v) CH_3CN systems in the absence of V(V) to illustrate the formation conditions of $[Mo_6O_{19}]^{2-}$. The $[VMo_5O_{19}]^{3-}$ ion was not detected in these aqueous–organic solutions; the anion is formed in aqueous solutions of about pH 3,[4,7] or in nonaqueous media.[5]

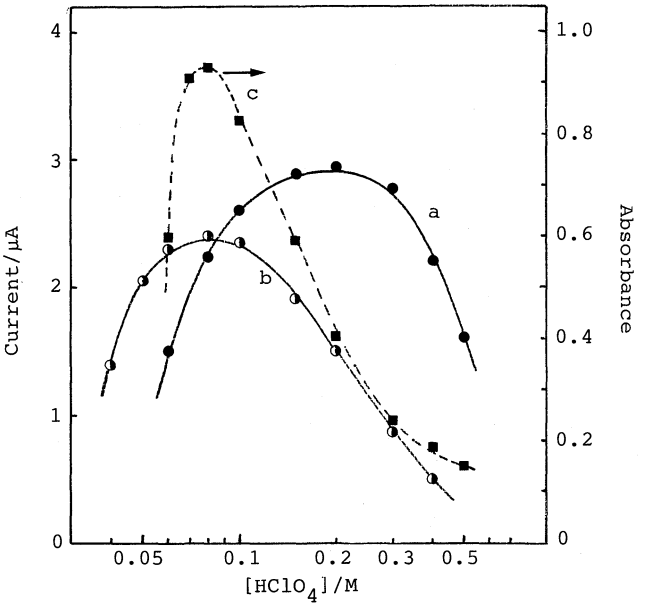

Fig. 8. Formation ranges of (a) $[VMo_{12}O_{40}]^{3-}$, (b), $[H_{x-1}V(V_xMo_{12-x})O_{40}]^{4-}$, and (c) $[Mo_6O_{19}]^{2-}$ for 30 mM Mo(VI)–50%(v/v) CH_3CN systems as a function of the $HClO_4$ concentration (I=0.5 M ($NaClO_4$)). (a), i_1 for [V(V)]=0.1 mM; (b) i_2 for [V(V)]=0.5 mM; (c) absorbances at 400 nm in the absence of V(V).

Figure 9 shows the dependence of i_1 and i_2 on the ionic strength for 30 mM Mo(VI)–0.1 M $HClO_4$–50%-(v/v) CH_3CN systems containing various concentrations of $NaClO_4$ (0—0.4 M). It was found that i_1 decreased while i_2 increased with an increase of the ionic strength from 0.1 to 0.5 M, which means that the increase of the ionic strength of the solution favors the formation of the tetravalent anions rather than the trivalent anion.

The effects of the nature and concentration of organic solvents on the formation of 12-molybdovanadate(V) and vanadium-substituted derivatives were also investigated by measuring i_1 and i_2 in solutions of 30 mM Mo(VI) containing 0.2 and 2.0 mM V(V), respectively. Figures 10 and 11 show the results. It can be concluded that neither of 12-molybdovanadate(V) and vanadium-substituted derivatives is formed in the absence of organic solvents, and the increase of the concentration of organic solvents favors the formation of the heteropoly molybdovanadate(V) complexes.

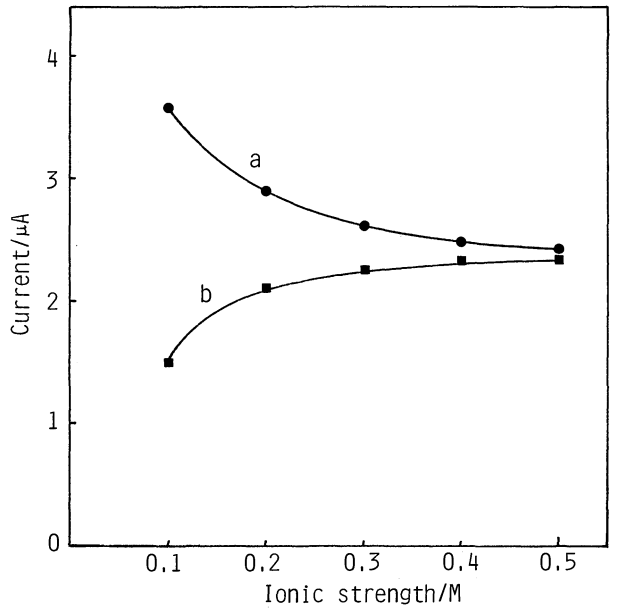

Fig. 9. Effect of ionic strength on (a) i_1 and (b) i_2 for 30 mM Mo(VI)–0.1 M $HClO_4$–50%(v/v) CH_3CN systems containing various concentrations of $NaClO_4$ (0—0.4 M).

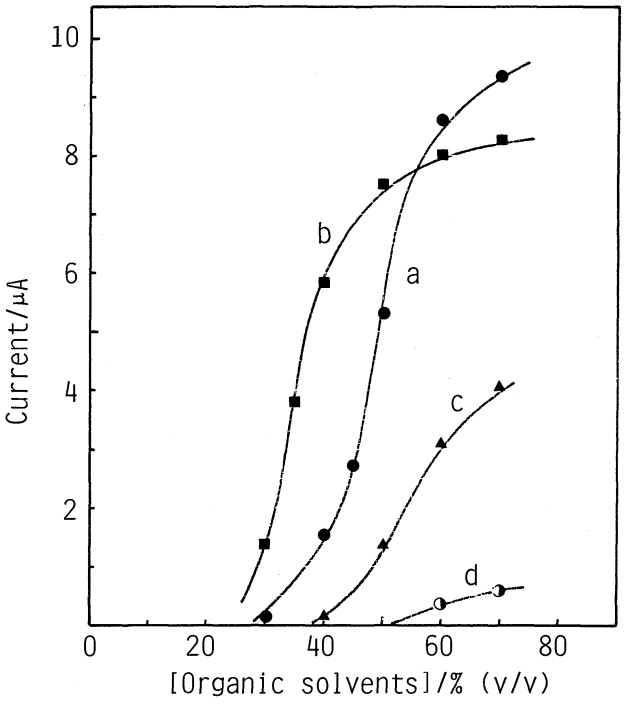

Fig. 10. Effect of concentrations of organic solvents on i_1 for 30 mM Mo(VI)–0.2 mM V(V)–0.3 M $HClO_4$ systems containing (a) acetonitrile; (b), acetone; (c), ethanol; (d), 1,4-dioxane.

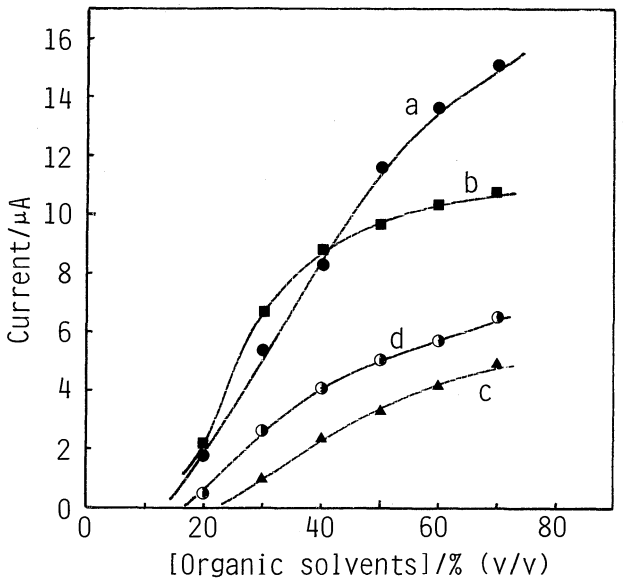

Fig. 11. Effect of concentrations of organic solvents on i_2 for 30 mM Mo(VI)–2.0 mM V(V)–0.05 M $HClO_4$ systems (I=0.1 M ($NaClO_4$)) containing (a), acetonitrile; (b), acetone; (c), ethanol; (d), 1,4-dioxane.

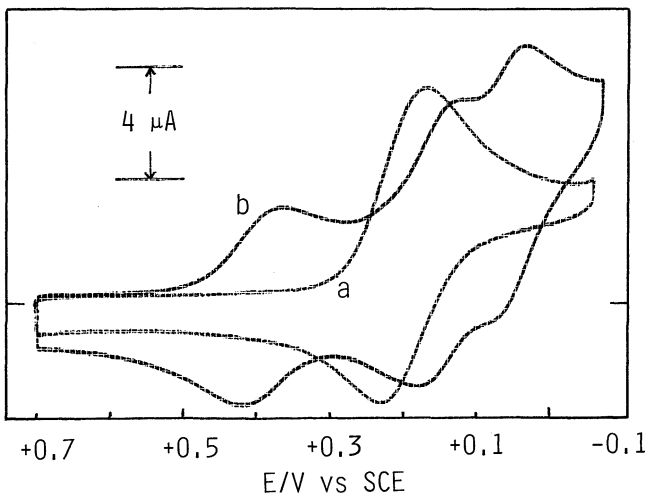

Fig. 12. Cyclic voltammograms of 0.32 mM $[VMo_5O_{19}]^{3-}$ in 90%(v/v) CH_3CN–water containing 0.001 M $HClO_4$ (I=0.1 M ($NaClO_4$)). Recorded (a) immediately after the addition of $[VMo_5O_{19}]^{3-}$; (b) after 60 min.

Conversion of $[VMo_5O_{19}]^{3-}$ into Mixed Heteropoly Molybdovanadate(V) Anions. As shown in curve (a) of Fig. 12, a cyclic voltammogram of 0.32 mM $[VMo_5O_{19}]^{3-}$ showed a couple of reduction and oxidation waves in 90%(v/v) CH_3CN–water containing 0.001 M $HClO_4$ (I=0.1 M ($NaClO_4$)). The waves were diffusion-controlled. The peak-separation for the reduction-oxidation couple was found to be 70 mV, and the E_p values were almost independent of the voltage scan rate (20—100 mV s^{-1}), which indicates that the wave corresponds to the reversible reduction of $[VMo_5O_{19}]^{3-}$ to $[V^{IV}Mo_5O_{19}]^{4-}$. In addition to the reversible wave, an irreversible reduction wave appeared at potentials more negative than −0.1 V. The irreversible wave can be ascribed to the reduction of molybdenum because the four-electron reduction wave of $[Mo_6O_{19}]^{2-}$ appears around the same potentials under these conditions.[19]

As time elapsed, a new reduction wave appeared with an E_p value of +0.37 V; the current increased with time until a constant value was attained in ca. 60 min. The ultimate voltammogram is shown in curve (b). Orange salts were obtained by the addition of tetraethylammonium bromide to the solution, being identified as mixed heteropoly molybdovanadate(V) complexes by the IR spectroscopic measurement. These results clearly show that the $[VMo_5O_{19}]^{3-}$ anion transforms spontaneously into mixed heteropoly molybdovanadate(V) anions under these conditions. Comparison of the reduction currents due to the peripheral V atoms in Fig. 12 with those in Fig. 3 leads to the conclusion that a mixture of $[V(VMo_{11})O_{40}]^{4-}$ and $[HV(V_2Mo_{10})O_{40}]^{4-}$ is formed as a result of the transformation. This conversion reaction was observed for 90%(v/v) CH_3CN–water solutions containing 0.001—0.1 M $HClO_4$ (I=0.1 M); however, it did not occur in the absence of acid. Similar conversion reaction was also observed in acidic solutions containing >60%(v/v) acetone. Flynn, Jr. and Pope have reported similar conversion of $[V_2W_4O_{19}]^{4-}$ into mixed heteropoly tungstovanadate(V) anions in acidified aqueous solutions.[6]

Synthesis and Characterization of Directly Linked Salen-Porphyrin System with Constrained Geometries

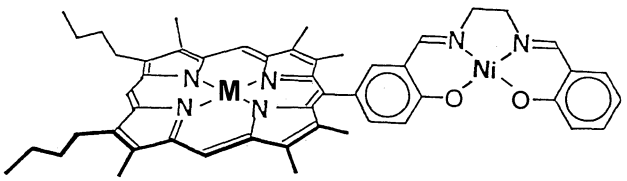
Kazuhiro MARUYAMA,* Fumikazu KOBAYASHI, and Atsuhiro OSUKA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received July 2, 1990)

Novel heterobinucleating porphyrin complexes, in which porphyrin and salen [*N*, *N'*-disalicylideneethylenediamine] subunits were directly linked with restricted geometries, were synthesized. These complexes showed a small change in their UV-vis spectra and oxidation potentials, but the fluorescence of porphyrin was effectively quenched by the linked nickel–salen subunit.

Extensive studies of binuclear metal complexes have been made in recent years as simple chemical models for biological metalloproteins containing bimetallic centers. One of the important aspects for the model complexes is close proximity of two metal centers in a well-defined three dimensional geometry, as such in biological systems.

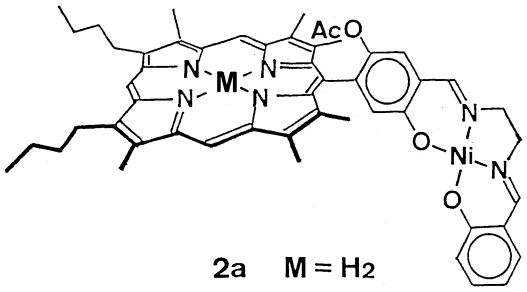
Recently we have reported the synthesis and spectroscopic investigation of salen-capped porphyrins,[1] in which salen subunits were just held over the porphyrin macrocycle. Electronic interactions between these two metal complexes, which were seen in their absorption and fluorescence spectra, and oxidation potentials, were strongly influenced by mutual geometry of the metal complexes.

Now we have synthesized another set of salen-linked porphyrins **1** and **2** as well as salen-bridged dimeric porphyrins **3** and **4**, in which the salen subunit is directly connected to the *meso* position of the porphyrin macrocycle. Since the 5-aryl group was



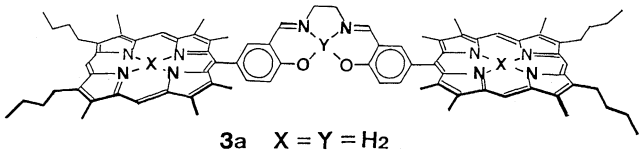
1a M = H_2

1b M = Zn



2a M = H_2

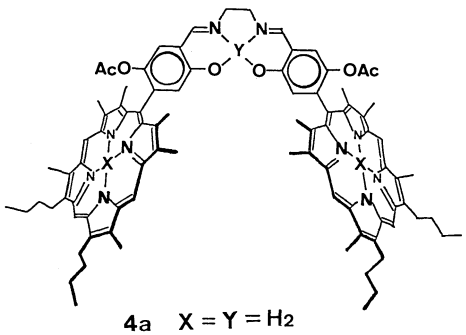
2b M = Zn



3a X = Y = H_2

3b X = H_2, Y = Ni

3c X = Zn, Y = Ni



4a X = Y = H_2

4b X = H_2, Y = Ni

4c X = Zn, Y = Ni

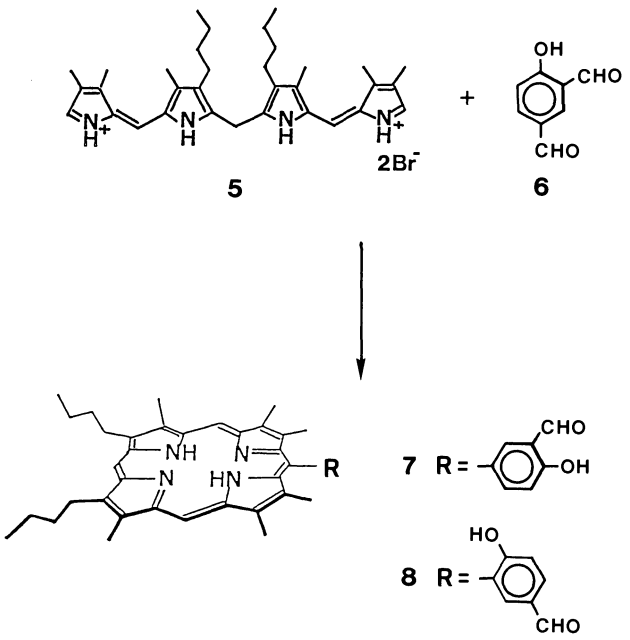
forced to be perpendicular to the porphyrin plane due to the steric hindrance against the β-alkyl groups,[2] the geometry between the porphyrin and the salen complex can be considered to be rigidly fixed. On the basis of Corey–Pauling–Koltun (CPK) models, the metal-to-metal distances of the nickel–salen-linked zinc porphyrins **1b** and **2b** are both estimated to be ca. 10Å. In the case of the salen-bridged dimeric porphyrins **3** and **4**, the salen subunit acts as the bridging group as well as the third metal binding site. In the metal-free salen form, two porphyrins are linked only by flexible ethylene chain, while two porphyrins are expected to adopt a rather fixed geometry upon the nickel complexation at the salen site owing to a preferred planar geometry of the nickel–salen complexes.[3] On the basis of CPK models, the center-to center distances and interplane angles of two porphyrins are estimated to be 20 Å and 180° in **3b—3c**, and 13 Å and 60° in **4b—4c**, respectively.

Results and Discussion

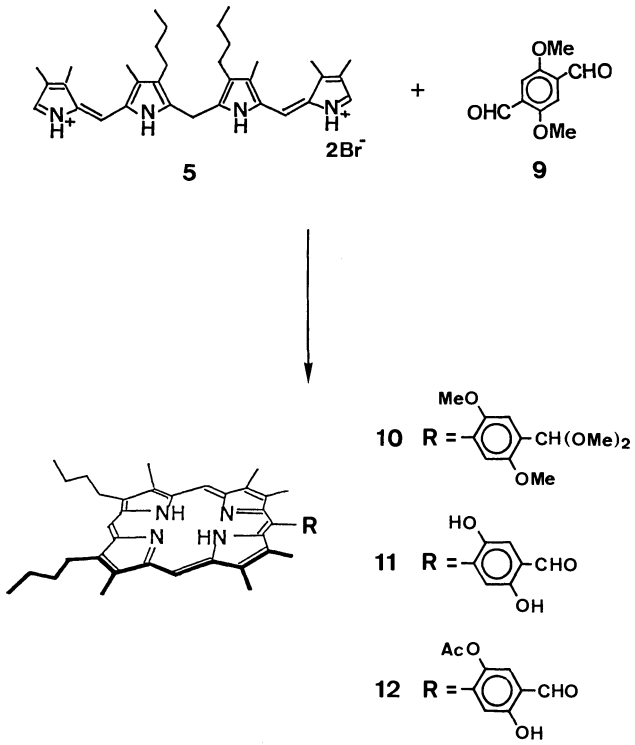
Salen-linked porphyrins **1** and **2** were prepared from

salicylaldehyde-linked porphyrins **7** and **12**, respectively. A key porphyrinic intermediate **7** was prepared by the acid-catalyzed condensation of the biladiene-*ac*-21,24-diium dibromide **5**[4] with 4-hydroxy-1,3-benzenedicarbaldehyde (**6**)[5] (HBr/MeOH, 24 h, reflux), which furnished **7** in 28% yield together with **8** (30%).[6] (Scheme 1) Another salicylaldehyde-linked porphyrinic intermediate **12** was prepared as follows:— Condensation of **5** and 2,5-dimethoxy-1,4-benzenedicarbaldehyde (**9**) afforded an acetal porphyrin **10** in 52% yield, which was treated with BBr_3 in CH_2Cl_2 at low temperature to give a deprotected porphyrin **11** in 95% yield. Selective acetylation of **11** was achieved by the reaction with small excess amounts of acetyl chloride in the presence of pyridine in CH_2Cl_2 (Scheme 2).

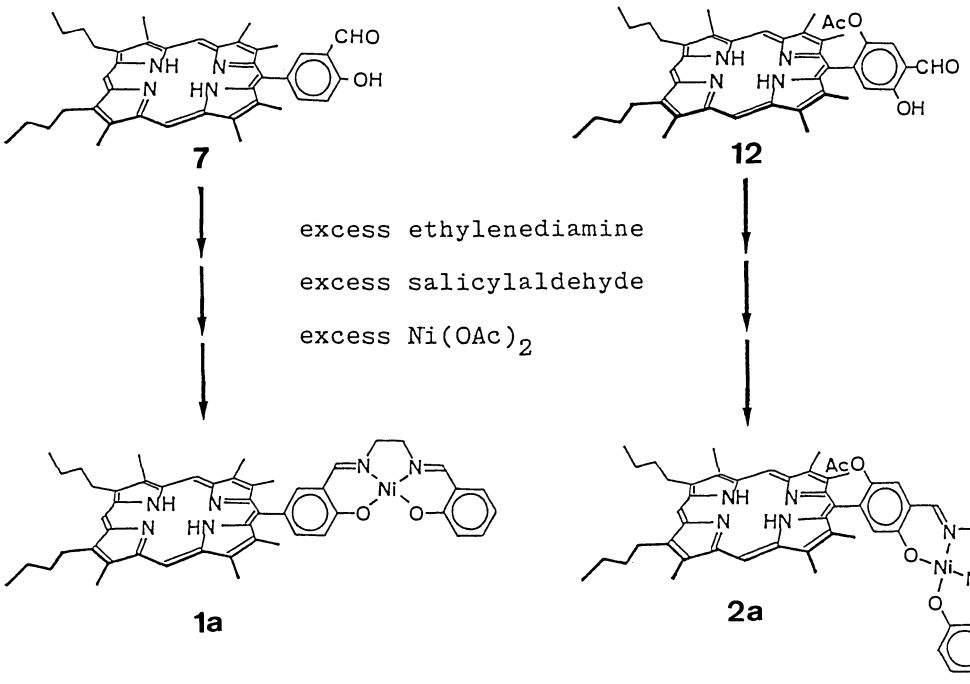
The salicylaldehyde-linked porphyrins **7** thus pre-



Scheme 1.



Scheme 2.



Scheme 3.

pared was dissolved in CH_2Cl_2 and treated with 5 fold excess of ethylenediamine. After 1 h, 7 fold excess of salicylaldehyde was added and the mixture was stirred overnight to yield a crude salen-linked porphyrin. Since a metal free salen moiety was acid-labile, the salen site was converted to the nickel complex by treating with nickel(II) acetate at room temperature. The resulting mixture was separated on silica-gel column eluting with CH_2Cl_2–5% ether (v/v) to yield a nickel–salen-linked porphyrin **1a** in 49% yield. The nickel–salen-linked porphyrin **2a** was prepared in the same manner from the salicylaldehyde-linked porphyrin **12** in 42% yield.

The salen-bridged dimeric porphyrins **3a** and **4a** were prepared by Schiff base condensation of salicylaldehyde-linked porphyrins **7** and **12** with ethylenediamine.[1a] The salicyllaldehyde-linked porphyrins **7** and **12** were treated with 0.5 equimolar amount of ethylenediamine in CH_2Cl_2 at room temperature for 2 weeks to allow a nearly complete transformation into the corresponding salen-bridged dimeric porphyrins **3a** and **4a**, respectively. After recrystallization from CH_2Cl_2–methanol, **3a** and **4a** were obtained in high yields (over 85% yield) in pure form.

In the nickel–salen-linked zinc porphyrin **1b** and **2b**, the absorption of the porphyrin subunit was almost unchanged by covalent linkage with the nickel–salen, but the porphyrin Soret band was slightly broadened and red-shifted (Table 1). The Soret band of dimers were more broadened and red-shifted in **3c** but slightly blue-shifted in **4c**. These additional shifts in the dimers **3c** and **4c** were in agreement with exciton coupling interactions between the two porphyrins in flat and oblique geometries, respectively.[2]

The oxidation potentials of these complexes (**1b**, **2b**, **3c**, and **4c**) were slightly lower than that of the reference zinc porphyrin **13** (Table 2). These results are in contrast to that of the salen-capped porphyrin (**14**) which showed 140 mV lower oxidation potential and red-shifted Soret band.[1b]

Compound	λ_{max}/nm	
	Soret	Q-bands
1b	407 (15)	535 571
2b	407 (15)	535 571
3c	408 (18)	535 571
4c	404 (18)	534 571
13	405 (12)	534 570
14	410 (28)	538 574

a) Measured in CH_2Cl_2 solution. Numbers given in parentheses show full width at half-height of the maximum absorbance of the Soret band (nm).

Table 2. Oxidation Potentials[a]

Compound	$E^{ox}_{1/2}$/mV	
1b	145	380
2b	160	435
3c	140	385
4c	165	420
13	170	415
14	30	460

a) Oxidation potentials (mV vs. ferrocene/ferrocenium, +0.45 V vs. SCE) were measured by cyclic voltammetry at a Pt electrode, in CH_2Cl_2 containing 0.1 M (1 M= 1 mol dm^{-3}) tetrabutylammonium perchlorate at 20 °C; accuracy ±10 mV.

Since it has been well established that porphyrins generally show red-shifted Soret bands and lower oxidation potentials in electron donating solvents or with electron donating axial ligands,[7] these spectral red shift and low oxidation potential of **14** can be ascribed to electron donation from the nickel(II)–salen to the zinc–porphyrin in the ground state, indicating the important role of electron-filled d orbitals (especially

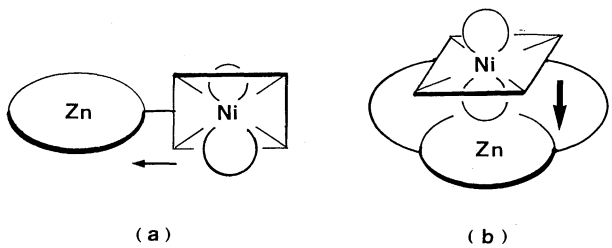

Fig. 1. Schematic representation of molecular geometry and dz^2 orbital of Ni(II) for the salen-linked porphyrin **1b** (a), and the salen-capped porphyrin **14** (b).

dz^2) of nickel(II) to the ground state interactions between zinc porphyrin and nickel-salen moieties (Fig. 1). In contrast, the interactions between the zinc porphyrin and the nickel-salen of **1b**, **2b**, **3c**, and **4c** in their ground states were small. The expected d-orbital interactions shown in Fig. 1b are presumably impossible in the molecules **1b**, **2b**, **3c**, and **4c** (Fig. 1a).

On the other hand, the fluorescence of the zinc porphyrins **1b**, **2b**, **3c**, and **4c** were all strongly quenched by the appended nickel-salen moieties (Table 3). The effective fluorescence quenching and extremely short-lived fluorescence lifetimes of **1b**, **2b**, **3c**, and **4c** suggest the strong interactions between the singlet excited state of the zinc porphyrin and the directly bound nickel-salen. The observed fluorescence lifetimes of **1b**, **2b**, **3c**, and **4c** are much shorter than the salen-capped porphyrins **14**, even though the orbital overlap between the Zn porphyrin π-system and the d-orbitals on Ni(II) seems more favorable in the latter molecule. The fact that a rapid decay of the $S_n \leftarrow S_1$ obsorption observed in the picosecond time-resolved spectra of **14** was followed by no enhancement of the $T_n \leftarrow T_1$ absorption[1b] indicates that the intersystem crossing of the singlet excited state of zinc-porphyrin was not accelerated by the Ni-salen. Although it was difficult to detect clearly the ion pair state presumably due to its rapid charge recombination, the electron transfer mechanism was expected to play a predominant role for the fluorescence quenching in these zinc-porphyrin-nickel-salen linked molecules.

Table 3. Fluorescence Spectral Data[a]

Compd	λ_{em}/nm	Φ_f, rel[b]	τ/ns[c]
1b	577 627	0.01	<0.05
2b	576 626	0.01	0.032 (100%)
3c	574 626	0.04	0.056 (97%)
			1.06 (3%)
4c	576 626	0.03	0.048 (95%)
			1.14 (5%)
13	575 626	1.0	1.5 (100%)
14	569 622	—	0.108 (88%)
			0.710 (12%)

a) Measured in CH_2Cl solution. b) Relative fluorescence intensities of Q(00) bands with respect to **13**; excitation at Soret wavelength. c) Fluorescence lifetime measured by time-correlated single photon counting technique (Ref. 8); excited at 514.5 nm by Ar laser pulse. Numbers in parentheses indicate the normalized pre-exponential factor.

An additional unique character of the salen-bridged dimeric porphyrins **3** and **4** was also observed in their ^{1}H NMR spectra. The changes in the ^{1}H NMR spectra of salen-bridged porphyrin dimers upon complexation of nickel(II) into the salen sites are summarized in Table 4. Nickel(II) complexation can be seen clearly in their up-field shifts of salen protons (CH=N-CH_2). In the metal free salen form, the chemical shifts of the peripheral protons of the porphyrin (*meso*-H, β-CH_3, β-Bu) of **3a** and **4a** were comparable. Upon complexation of nickel(II), these protons were not shifted or slightly downfield shifted in **3b**, but were instead upfield shifted by 0.1 ppm in **4b**, reflecting the ring current effect of the other porphyrin ring in the oblique geometry.

In summary, the directly linked porphyrin-salen system described herein showed only weak interactions in the ground state, while strong interactions were observed in the singlet excited state.

Experimental

The ^{1}H NMR spectra were recorded at 400 MHz on a JEOL JNM-GX-400 spectrometer, with tetramethylsilane or $CHCl_3$ as internal reference. All spectra were measured in $CDCl_3$ solution. Fast atom bombardment mass spectra were recorded on a JEOL JMS-DX-300 (1.5 kV) with *m*-nitrobenzyl alcohol as the matrix. UV-vis spectra were recorded in dichloromethane on a Shimadzu UV-200 and a Shimadzu UV-3000 spectrophotometer. Steady-state fluorescence spectra were recorded by using a Shimadzu RF-502a spectrofluorometer. Fluorescence lifetimes were measured by picosecond time-correlated single photon counting technique.[8] Cyclic Voltammetry was performed with a PAR Model 174.

Flash column chromatography was carried out using Merck Kieselgel 60H Art. 7736.

Unless othewise stated all reactions were performed under an atmosphere of dry nitrogen. All organic extracts were dried over anhydrous sodium sulfate.

5-(3-Formyl-4-hydroxyphenyl)-13,17-dibutyl-2,3,7,8,12,18-hexamethylporphine (7). A suspension of 8,12-dibutyl-2,3,7,13,17,18-hexamethylbiladiene-*ac*-21,24-diium dibromide

a) Chemical shift changes induced by nickel(II) complexation into the salen site. Negative value shows the upfield shift.

(**5**)[4] (230 mg, 0.35 mmol) and 4-hydroxy-1,3-benzenedicarbaldehyde (**6**)[5] (515 mg, 3.4 mmol) in methanol containing acetic acid (four drops) saturated with hydrogen bromide was heated under reflux for 24 h.[6] The mixture was cooled and poured into water, and extracted with $CHCl_3$. The organic layer was washed with aqueous sodium hydrogencarbonate, with water, and then evaporated. The residue was flash chromatographed on silica gel eluted with CH_2Cl_2–5% ether. The first band eluted was the desired porphyrin **7**. Recrystallization from CH_2Cl_2–methanol gave purple microcrystals (61 mg, 0.097 mmol, 28%).

^1H NMR ($CDCl_3$) δ=11.43 (1H, s, OH), 10.16+9.97 (2H+1H, s+s, *meso*-H), 10.07 (1H, s, CHO), 8.22+7.40 (2H+1H, m+d, ArH), 4.04 (4H, t, Bu), 3.63+3.54+2.52 (6H+6H+6H, s+s+s, β-Me), 2.28+1.77+1.13 (4H+4H+6H, m+m+t, Bu), −3.18+−3.30 (1H+1H, br, NH). MS (FAB) *m/z* 627 ($M+H^+$).

5-(2,5-Dimethoxy-4-(dimethoxymethyl)phenyl)-13,17-dibutyl-2,3,7,8,12,18-hexamethylporphine (10). A suspension of the biladiene-*ac*-21,24-diium dibromide (**5**) (206 mg, 0.31 mmol) and 2,5-dihydroxy-1,4-benzenedicarbaldehyde (**9**) (304 mg, 1.57 mmol) in methanol containing acetic acid (four drops) saturated with hydrogen dromide was heated under reflux for 41 h and the product worked up as in the previous experiment. (116 mg, 0.16 mmol, 52%)

^1H NMR ($CDCl_3$) δ=10.13+9.94 (2H+1H, s+s, *meso*-H), 7.54+7.31 (1H+1H, s+s, ArH), 6.05 (1H, s, C<u>H</u>$(OMe)_2$), 4.04 (4H, t, Bu), 3.78+3.71+3.61 (3H+3H+6H, s+s+s, OMe), 3.63+3.54+2.60 (6H+6H+6H, s+s+s, β-Me), 2.29+1.78+1.13 (4H+4H+6H, m+m+t, Bu), −3.14+−3.29 (1H+1H. br, NH). MS(FAB) *m/z* 717 ($M+H^+$).

5-(2,5-Dihydroxy-4-formylphenyl)-13,17-dibutyl-2,3,7,8,12,18-hexamethylporphine (11). The porphyrin **10** (77 mg, 0.11 mmol) was dissolved in dry CH_2Cl_2 (45 ml) and treated with BBr_3 (0.5 ml) at −78 °C. The mixture was stirred overnight and gradually warmed to room temperature, and then poured into water. The product was extracted with CH_2Cl_2 and the extract was washed with aqueous sodium hydrogencarbonate, with water, and then evaporated. Recrystallization from CH_2Cl_2–hexane gave purple microcrystals (68 mg, 0.11 mmol, 99%).

^1H NMR ($CDCl_3$) δ=10.82 (1H, br, OH), 10.21 (1H, s, CHO), 10.19+10.01 (2H+1H, s+s, *meso*-H), 7.53+7.48 (1H+1H, s+s, ArH), 4.04 (4H, t, Bu), 3.64+3.56+2.70 (6H+6H+6H, s+s+s, β-Me), 2.28+1.77+1.13 (4H+4H+6H, m+m+t, Bu). MS (FAB) *m/z* 643 ($M+H^+$).

5-(2-Acetoxy-4-formyl-5-hydroxyphenyl)-13,17-dibutyl-2,3,7,8,12,18-hexamethylporphine (12). The dihydroxy porphyrin **11** (68 mg, 0.11 mmol) was dissolved in dry CH_2Cl_2 (25 ml) containing pyridine (50 µl) and acetyl chloride (50 µl) in CH_2Cl_2 (10 ml) was added. The mixture was stirred for 2 days and then poured into water. The organic layer was washed with water, dried, and evaporated. The residue was purified by flash column chromatography (CH_2Cl_2). The first band eluted was the desired porphyrin **12**. Recrystallization from CH_2Cl_2–methanol gave purple microcrystals (23 mg, 0.033 mmol, 32%).

^1H NMR ($CDCl_3$) δ=11.20 (1H, br, OH), 10.24 (1H, s, CHO), 10.17+9.99 (2H+1H, s+s, *meso*-H), 7.85+7.79 (1H+1H, s+s, ArH), 4.05 (4H, t, Bu), 3.64+3.55+2.69 (6H+6H+6H, s+s+s, β-Me), 2.28+1.77+1.13 (4H+4H+6H, m+m+t, Bu), 1.03 (3H, s, CH_3CO), −3.20 (2H, br, NH). MS (FAB) *m/z* 685 ($M+H^+$).

Salen-Linked Porphyrin 1a. The salicylaldehyde-linked porphyrin **7** (4.7 mg, 0.007 mmol) was dissolved in CH_2Cl_2 (7 ml) and ethylenediamine (0.15 M solution in methanol, 0.2 ml) was added. After the solution was stirred at room temperature for 1 h, salicylaldehyde (0.1 M solution in CH_2Cl_2, 0.65 ml) was added and stirring was continued overnight. To this solution, a saturated methanolic solution of nickel(II) acetate (ca. 1 ml) was added, and the mixture was stirred for 2 h at room temperature. The solvent was removed, and the residue was purified by flash column chromatography (CH_2Cl_2). Recrystallization from CH_2Cl_2–methanol gave purple crystals (3.0 mg, 0.004 mmol, 49%).

1a: ^1H NMR ($CDCl_3$) δ=10.14+9.94 (2H+1H, s+s, *meso*-H), 7.69+7.61 (1H+1H, s+s, CH=N), 7.90+7.68+7.45+7.30+7.17+6.62 (7H, dd+d+d+d+t+t, Ar-H), 4.04 (4H, t, Bu) 3.62+3.53+2.61 (6H+6H+6H, s+s+s, β-Me), 3.49 (4H, s, NCH_2), 2.28+1.77+1.12 (4H+4H+6H, m+m+t, Bu), −3.3 (2H, br, NH). UV-vis (CH_2Cl_2) 407, 504, 537, 572, and 624 nm. MS (FAB) *m/z* 829 ($M+H^+$).

1b: ^1H NMR ($CDCl_3$) δ=10.14+10.05 (2H+1H, s+s, *meso*-H), 7.69+7.64 (1H+1H, s+s, CH=N), 7.91+7.68+7.45+7.3+7.18+6.62 (7H, dd+d+d+d+m+t, Ar-H), 4.06 (4H, t, Bu), 3.63+3.53+2.62 (6H+10H+6H, s+s+s, β-Me and NCH_2), 2.30+1.80+1.15 (4H+4H+6H, m+m+t, Bu). UV-vis (CH_2Cl_2) 407, 535, and 571 nm.

Salen-Linked Porphyrin 2a. From the salicylaldehyde-linked porphyrin **12** (5.0 mg, 0.007 mmol, in CH_2Cl_2 20 ml), the salen-linked porphyrin **2a** was synthesized by the same procedure as described above to give purple crystals (2.7 mg, 0.003 mmol, 42%).

2a: ^1H NMR ($CDCl_3$) δ=10.14+9.95 (2H+1H, s+s, *meso*-H), 7.86+7.58 (1H+1H, s+s, CH=N), 7.73+7.41+7.13+6.95+6.54 (6H, s+s+m+d+t, Ar-H), 4.04 (4H, t, Bu) 3.63+3.53+2.77 (6H+6H+6H, s+s+s, β-Me), 3.6 (4H, m, NCH_2), 2.26+1.75+1.11 (4H+4H+6H, m+m+t, Bu), 0.94 (3H, s, CH_3CO), −3.30 (2H, br, NH). UV-vis (CH_2Cl_2) 405, 503, 537, 572, and 625 nm.

2b: ^1H NMR ($CDCl_3$) δ=10.14+10.05 (2H+1H, s+s, *meso*-H), 7.88+7.62 (1H+1H, s+s, CH=N), 7.78+7.41+7.13+6.95+6.54 (6H, s+s+m+d+t, Ar-H), 4.06 (4H, t, Bu) 3.63+3.53+2.77 (6H+6H+6H, s+s+s, β-Me), 3.58 (4H, m, NCH_2), 2.28+1.78+1.13 (4H+4H+6H, m+m+t, Bu), 0.80 (3H, s, CH_3CO). UV-vis (CH_2Cl_2) 407, 535, and 571 nm.

Salen-Bridged Dimeric Porphyrin 3a. The salicylaldehyde-linked porphyrin **7** (8.9 mg, 0.014 mmol) was dissolved in CH_2Cl_2 (20 ml) and ethylenediamine (0.15 M solution in methanol, 50 µl) was added. The solution was stirred for 2 weeks. Evaporation of the solvent and subsequent recrystallization (CH_2Cl_2–methanol) gave the porphyrin **3a** as purple crystals (8 mg, 0.006 mmol, 88%).

3a: ^1H NMR ($CDCl_3$) δ=10.13+9.96 (4H+2H, s+s, *meso*-H), 8.68 (2H, s, CH=N), 8.01+7.40 (4H+2H, m+d, Ar-H), 4.17 (4H, s, NCH_2), 4.05 (8H, t, Bu), 3.62+3.47+2.56 (12H+12H+12H, s+s+s, β-Me), 2.29+1.78+1.13 (8H+8H+12H, m+m+t, Bu), −3.2 (4H, br, NH). UV-vis (CH_2Cl_2) 405, 503, 536, 570, and 623 nm. MS (FAB) *m/z* 1278 ($M+H^+$).

3b: ^1H NMR ($CDCl_3$) δ=10.17+9.95 (4H+2H, s+s, *meso*-H), 7.77 (2H, s, CH=N), 7.89+7.76+7.57 (2H+2H+2H, dd+d+d, Ar-H), 4.05 (8H, t, Bu), 3.65+3.57+2.69 (12H+12H+12H, s+s+s, β-Me), 3.6 (4H, br, NCH_2), 2.29+1.78+1.14 (8H+8H+12H, m+m+t, Bu), −3.23 (4H, br, NH). UV-vis

(CH_2Cl_2) 406, 503, 536, 571, and 623 nm. MS (FAB) *m/z* 1333—1338 ($M+H^+$).

3c: UV-vis (CH_2Cl_2) 408, 535, and 571 nm. MS (FAB) *m/z* 1457—1464 ($M+H^+$).

Salen-Bridged Dimeric Porphyrin 4a. The salicylaldehyde-linked porphyrin **12** (8.8 mg, 0.013 mmol) was treated with ethylenediamine (0.15 M solution in methanol, 40 μl) by the same procedure as **3a** to give purple crystals (8 mg, 0.006 mmol, 88%).

4a: ^1H NMR ($CDCl_3$) δ=13.46 (2H, br, OH), 10.15+9.98 (4H+2H, s+s, *meso*-H), 8.84 (2H, s, CH=N), 7.79+7.62 (2H+2H, s+s, Ar-H), 4.31 (4H, s, NCH_2), 4.06 (8H, m, Bu), 3.63+3.52+2.75 (12H+12H+12H, s+s+s, β-Me), 2.27+1.76 +1.12 (8H+8H+12H, m+m+m, Bu), 0.95 (6H, s, CH_3CO), −3.18+−3.33 (4H, br, NH). MS (FAB) *m/z* 1392—1398 (M^+).

4b: ^1H NMR ($CDCl_3$) δ=10.04+9.85 (4H+2H, s+s, *meso*-H), 7.95(2H, s, CH=N), 7.64+7.45 (2H+2H, s+s, Ar-H), 3.96 (8H, m, Bu), 3.78(4H, s, NCH_2), 3.54+3.46+2.73 (12H+12H+ 12H, s+s+s, β-Me), 2.18+1.67+1.04 (8H+8H+12H, m+m+ m, Bu), 0.91 (6H, s, CH_3CO), −3.4 (4H, br, NH). UV-vis (CH_2Cl_2) 404, 503, 537, 572, and 624 nm. MS (FAB) *m/z* 1448—1455 (M^+).

4c: ^1H NMR ($CDCl_3$) δ=10.04+9.97 (4H+2H, s+s, *meso*-H), 7.96 (2H, s, CH=N), 7.65+7.45 (2H+2H, s+s, Ar-H), 3.98 (8H, m, Bu), 3.80 (4H, br, NCH_2), 3.55+3.47+2.74 (12H+12H+ 12H, s+s+s, β-Me), 2.20+1.69+1.06 (8H+8H+12H, m+m+ m, Bu), 0.81 (6H, s, CH_3CO). UV-vis (CH_2Cl_2) 404, 534, and 571 nm. MS (FAB) *m/z* 1572—1580 (M^+).

The work was partially supported by the Grant-in-Aid for Scientific Research No. 01649508 from the Ministry of Education, Science and Culture, Nissan Science Foundation, and the Kurata Research Grant. We thank Professor S. Hirayama of Kyoto Institute of Technology for measurement of picosecond fluorescence lifetimes.

(Received August 1, 1990)

The *N*-methylated analogs of gramicidin S, namely [Orn(Me_3^+)$^{2,2'}$]-, [MeOrn$^{2,2'}$, D-MePhe$^{4,4'}$]-, [MeOrn(Me)$^{2,2'}$, D-MePhe$^{4,4'}$]-, and [MeOrn(Me_3^+)$^{2,2'}$, D-MePhe$^{4,4'}$]gramicidin S, were prepared by the use of quaternization reaction of free amino groups with CH_3I–$KHCO_3$ in methanol and/or selective amide-methylation with CH_3I–Ag_2O in DMF. The conformations of these synthetic analogs were shown to be of β-sheet type similar to that of parent gramicidin S by ^1H NMR analysis and CD spectral comparison. The *N*-methyl group-containing analogs exhibited essentially the same antibacterial activity against Gram-positive bacteria as gramicidin S itself.

Gramicidin S (GS) is a cyclic decapeptide with the primary structure cyclo(–Val–Orn–Leu–D-Phe–Pro–)$_2$ showing strong antibacterial activity against Gram-positive bacteria. GS is one of the peptide antibiotics that have been most extensively studied by the synthetic approach.[1] The secondary structure of GS is established as the antiparallel β-sheet conformation having four intramolecular hydrogen bonds between two pairs of Val and Leu residues as shown in Fig. 1. Consequently the twelve nitrogen atoms present in GS are classified into four groups: two free amino groups of Orn side chains, four intramolecularly hydrogen-bonded amide NH's of Val and Leu residues, four solvent-exposed amide NH's of Orn and D-Phe residues, and two secondary amide nitrogens of Pro carrying no hydrogens. This paper deals with preparation of new analogs of GS having methyl groups on different N atoms by the application of two kinds of *N*-methylation reactions to GS or its derivatives. Stereochemistry and antibacterial activity of the *N*-methylated analogs are also described.

Preparation of Analogs

N-Methylation of a free amino group using CH_3I–$KHCO_3$ in methanol to afford a trimethylammonio group was reported by Chen and Benoiton.[2] The quaternization reaction was applied to GS to obtain a new analog of GS.[3] To the solution of GS·2HCl (**1**, 0.1 mmol) in methanol (20 ml) were added CH_3I (32 mmol) and $KHCO_3$ (10 mmol), and the mixture was stirred for 45 h. Workup and purification furnished the desired product [Orn(Me_3^+)$^{2,2'}$]GS·$2I^-$ (**2**),[4] mp 228—231.5 °C, in 75% yield, where Orn(Me_3^+) stands for a side-chain-quaternized Orn residue namely NHCH($CH_2CH_2CH_2N^+Me_3$)CO. The ^1H NMR spectrum of **2** exhibited a singlet peak at δ (DMSO-d_6) 3.11 assignable to the two trimethylammonio groups, and amino acid analysis and elemental analysis were also satisfactory.

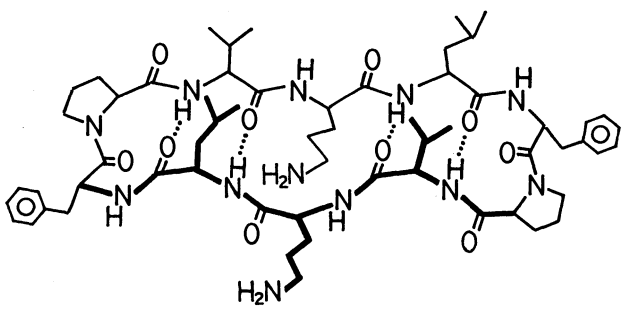

Fig. 1. β-Sheet conformation of GS with four intramolecular hydrogen bonds having C_2-symmetry.

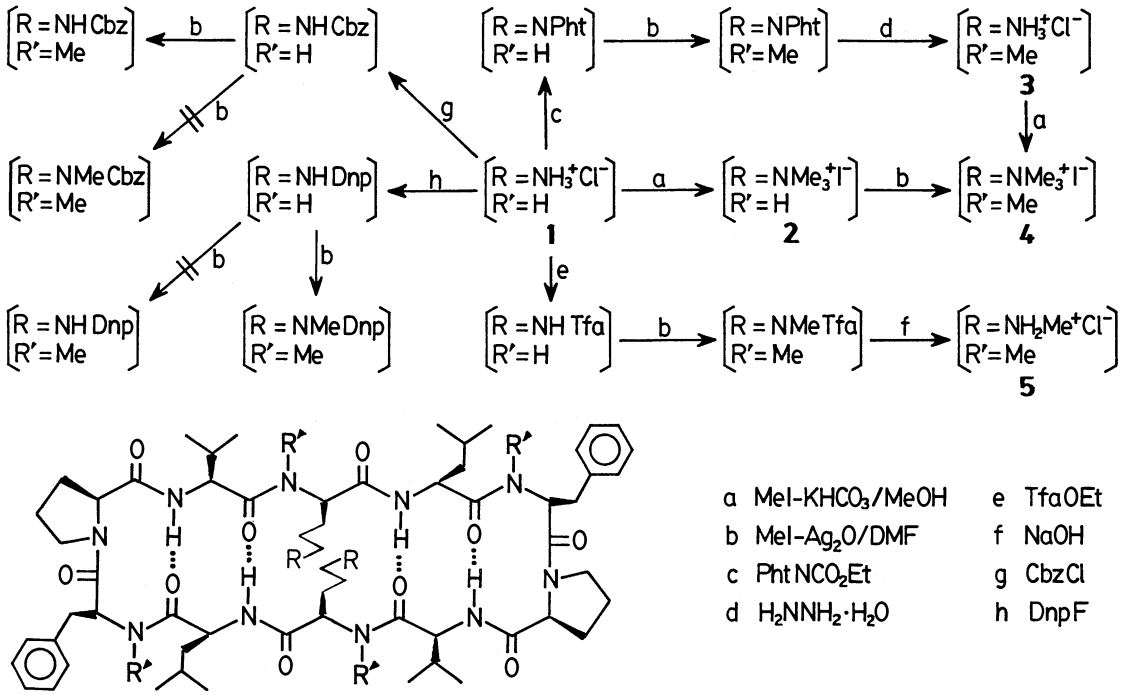
Methylation of amide N atoms of GS was then studied. Kawai and Nagai reported conformational analysis of cyclic peptides in micromolar quantities using selective *N*-methylation with CH_3I and Ag_2O in DMF followed by amino acid analysis of the acid hydrolyzate.[5] In the case of side-chain-protected GS only solvent-exposed amide NH's of Orn and D-Phe residues were methylated while intramolecularly hydrogen-bonded amide NH's of Val and Leu residues being kept intact. The selective methylation of the diphthaloyl derivative, [Orn(Pht)$^{2,2'}$]GS, was carried out in preparative scale to yield a methylated product in 88% yield. Amino acid analysis of the acid hydrolyzate indicated that only the solvent-exposed amide NH's of Orn(Pht) and D-Phe residues had been methylated establishing the structure of the product as the desired tetramethyl derivative, namely [MeOrn-(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS. Removal of the phthaloyl groups with $H_2NNH_2·H_2O$ and column chromatographic purification furnished the tetramethyl analog [MeOrn$^{2,2'}$, D-MePhe$^{4,4'}$]GS·2HCl (**3**),[6] mp 200.5—203 °C, in 58% yield.

The tetramethyl analog **3** was subjected to the quaternization reaction affording a decamethyl analog [MeOrn(Me_3^+)$^{2,2'}$, D-MePhe$^{4,4'}$]GS·$2I^-$ (**4**), mp 226—232.5 °C, in 76% yield. The same compound **4** was also obtained by the application of the selective *N*-



Scheme 1.

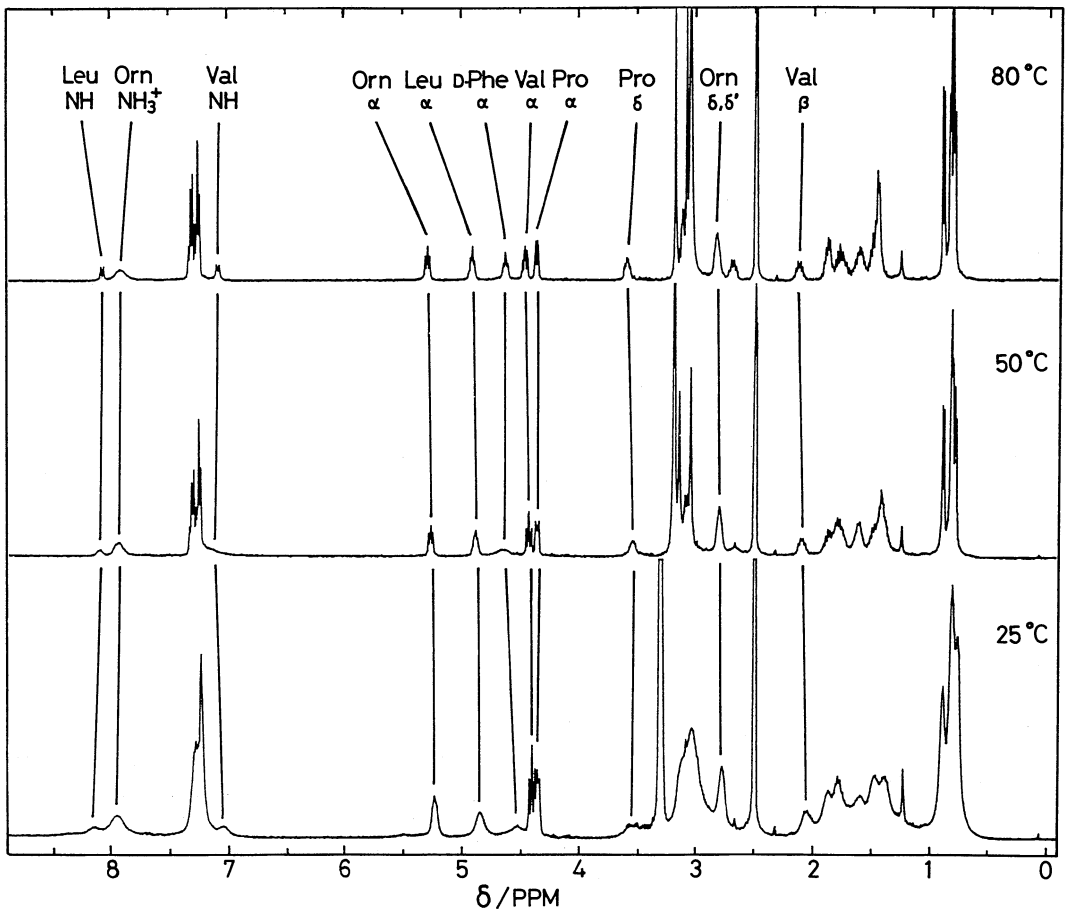


Fig. 2. 400 MHz ^{1}H NMR spectra of [MeOrn$^{2,2'}$,D-MePhe$^{4,4'}$]GS (**3**) measured in DMSO-d_6 at different temperatures.

methylation reaction to the side-chain-quaternized analog **2** in a similar manner to the *N*-methylation of the diphthaloyl derivative.

For the purpose of preparing an analog of GS having monomethylated Orn side chains, namely [MeOrn(Me)$^{2,2'}$, D-MePhe$^{4,4'}$]GS, the selective methylation reaction was applied to the bis(benzyloxycarbonyl) derivative [Orn(Cbz)$^{2,2'}$]GS. Contrary to the expectation no significant methylation at urethane NH of Orn side chain was observed, resulting in the formation of tetramethylated product [MeOrn(Cbz)$^{2,2'}$, D-MePhe$^{4,4'}$]GS. This unexpected resistance to methylation of the protected Orn side chains was noteworthy considering that the bis(2,4-dinitrophenyl) derivative [Orn(Dnp)$^{2,2'}$]GS under the same conditions afforded a hexamethyl derivative [MeOrn(Dnp,Me)$^{2,2'}$, D-MePhe$^{4,4'}$]-GS in good yield in spite of the presence of hydrogen bonding between the NH and *ortho*-NO_2 groups. The bis(trifluoroacetyl) derivative [Orn(Tfa)$^{2,2'}$]GS was found to give a hexamethyl derivative [MeOrn(Me,Tfa)$^{2,2'}$, D-MePhe$^{4,4'}$]GS on selective methylation. Alkaline hydrolysis of the trifluoroacetamido groups furnished the desired hexamethyl analog [MeOrn(Me)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (**5**). Preparation of the methylated analogs **2**—**5** was summarized in Scheme 1.

Conformation of *N*-Methyl Analogs

^{1}H NMR spectral analysis of the synthetic analogs was undertaken to study their stereochemistry. The bis(trimethylammonio) analog **2** exhibited the spectra closely resembling those of GS **1**. The chemical shifts of N$^\alpha$H and coupling constants $J_{N^\alpha H\text{-}C^\alpha H}$ in the ^{1}H NMR spectrum of **2** recorded in DMSO-d_6 at 25 °C (Val δ=ca. 7.2, J=9.5 Hz; Leu δ=8.29, J=9.2 Hz; Orn δ=8.70, J=9.2 Hz; D-Phe δ=9.11, J=4.0 Hz) indicated that **2** adopted a β-sheet conformation with C_2-symmetry closely similar to that of **1**.[7] The ^{1}H NMR spectra of the tetra-*N*-methyl analog **3**, on the other hand, were apparently dissimilar to those of **1** and **2**, showing broad signals indicative of a mixture of slowly interconverting conformers. Varying-temperature study as shown in Fig. 2, however, revealed that **3** also exhibited clearly resolved sharp signals of typical β-sheet conformation at the temperatures higher than 60 °C due to rapid interconvertion of conformers. Thus, it can be assumed that although **3** exists as a comformational mixture at ambient temperature time-averaged conformation of **3** is of β-sheet type with C_2-

symmetry. The analogs **4** and **5** exhibited similar NMR characteristics to **3** showing well-resolved peaks at high temperatures. The ^{1}H NMR spectral data of the analogs **2**—**5** recorded at 80 °C in DMSO-d_6 solutions are summarized in Table 1, which indicates that all these analogs adopt similar conformations to that of parent **1**.

Conformation of the *N*-methyl analogs was also studied by their CD spectra measured in methanol as shown in Fig. 3. The CD spectrum of bis(trimethylammonio)-type analog **2** showing a negative maximum at 206 nm ([θ] −39500) and a shoulder at 215 nm was closely similar to that of **1**,[8] which was also consistent with their conformational similarity established by ^{1}H NMR study. The spectrum of the amide-methylated analog **3**, on the other hand, was of different pattern exhibiting a single negative maximum at the longer wavelength ([θ]$_{221}$ −37500). The difference between the spectra of **1** and **3**, however, did not indicate the conformational dissimilarity but was reasonably assumed to be due to difference of the amide chromophores, -CONH- and -CONMe-. The

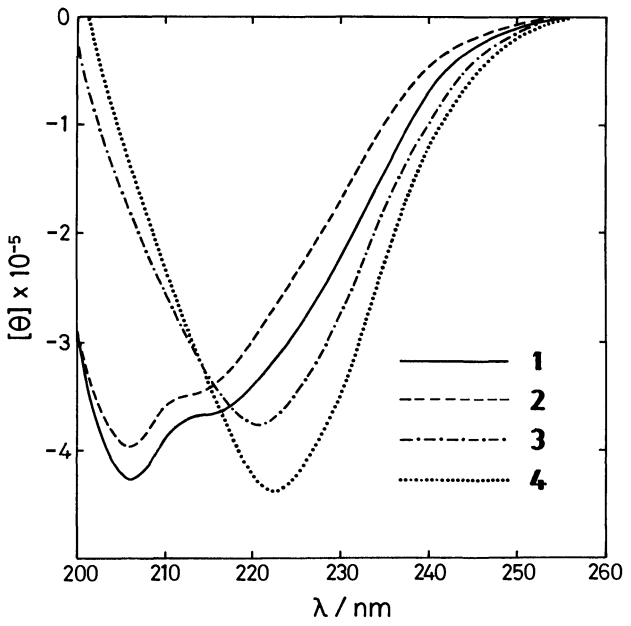

Fig. 3. CD spectra of GS·2HCl (**1**) and the *N*-methyl analogs **2**—**4** measured in MeOH at room temperature.

decamethyl analog **4** possessing also four *N*-methylated amide groups exhibited similar CD spectrum to that of **3** supporting the conformational resemblance of these analogs.

Antibacterial Activities of *N*-Methyl Analogs

Antibacterial activities of the synthetic analogs **2**—**5** were tested against several microorganisms, and minimum inhibitory concentrations of these analogs are summarized in Table 2. As expected from their conformational similarity, the *N*-methylated analogs showed essentially the same antibacterial activity against *Staphylococcus aureus* and *Bacillus subtilis* strains as parent GS **1** itself.

Discussion

Synthesis of analogs containing *N*-methyl group(s) is useful for the study of the structure-activity relationships of biologically active peptides.[9] *N*-Methylamino acid-containing analogs of GS, namely [MeVal^1]GS, [MeVal$^{1,1'}$]GS, [MeLeu^3]GS, and [MeLeu$^{3,3'}$]-GS, were synthesized by Izumiya's group[10] revealing the unexpected antibacterial activities of MeLeu-containing analogs. These analogs were synthesized by the classical methods using protected *N*-methyl-amino acids as building blocks. An alternative way to prepare the *N*-methylated analogs is modification of the parent peptide molecules by the use of selective *N*-methylation reactions. In the present study two kinds of *N*-methylations, quaternization of NH_2 group into NMe_3^+ group and selective methylation of solvent-exposed -CONH- goup into -CONMe- group were employed. Preparation of enkephalin analogs by the application of the *N*-methylation reactions to suitably protected [D-Ala^2, Leu^5]enkephalin derivatives was already reported.[11]

GS derivatives possessing various groups on N^δ atoms of Orn side chains were subjected to amide-methylation and in all cases solvent-exposed N^α atoms of Orn and D-Phe were methylated while Val and Leu residues being kept intact. As an attempt to methylate the N atoms of Val and Leu residues, [Orn(Pht)$^{2,2'}$]GS was subjected to prolonged methylation with larger amount of reagents still resulting in the isolation of only the tetramethyl derivative [MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS. These results indicated that the

Table 2. Antibacterial Activities of GS **1** and Its *N*-Methyl Analogs **2**—**5** (Minimum Inhibitory Concentrations in μg cm^{-3})

Microorganism	1	2	3	4	5
Staphylococcus aureus FDA 209 PJC-1	1.56	1.56	1.56	1.56	1.56
Staphylococcus aureus Terajima	3.1	1.56	3.1	3.1	3.1

intramolecularly hydrogen-bonded β-sheet conformation of GS is very stable regardless of the various modification of Orn side chains and also that the stability of the conformation is maintained during and after the methylation of solvent-exposed amide-N atoms.

It is quite interesting that the side chains of Orn protected with benzyloxycarbonyl groups in GS were intact during the amide-methylation being in contrast to the methylation of [Orn(Tfa)$^{2,2'}$]GS and [Orn(Dnp)$^{2,2'}$]GS, in which N$^{\delta}$ atoms were also methylated in good yield. Model reaction using Ac–Orn(Cbz)–OMe and Ac–Lys(Cbz)–OMe under the same conditions revealed that both urethane NH in the side chain and acetamido groups were methylated without difficulty yielding Ac–MeOrn(Cbz,Me)–OMe and Ac–MeLys(Cbz,Me)–OMe, respectively. The results suggested the presence of some interaction between Orn side chains and the rest of the molecule in [Orn(Cbz)$^{2,2'}$]-GS. Hydrogen bonding of one of the Orn side chains with the CO group of Phe residue was actually observed for GS-urea complex in crystalline state.[12]

NMR and CD spectral studies on conformational characteristics of the synthetic analogs showed the conformational resemblance of the *N*-methyl analogs **2**—**5** and parent GS **1**. ^{1}H NMR spectra of the amide-methylated analogs **3**—**5** measured in DMSO-d_6 solution at 25 °C exhibited broad signals due to slow conformational interconversion. Since sharp signals assignable to β-sheet conformation were observed at higher temperature as a result of rapid interconvertion among conformers, averaged conformation at the low temperature was also considered to resemble the conformation of **1**. In fact ^{1}H NMR spectrum of **3** measured in $CDCl_3$ at 25 °C exhibited well-resolved sharp signals characteristic of GS-type β-sheet conformation. Thus, it can be concluded that all these GS analogs possess essentially the same conformational characteristics as GS and that methyl groups at the solvent-exposed N atoms cause slight decrease in conformational mobility resulting in the slow conformational interchange in strongly solvating DMSO solution. This also suggests that the well-established β-sheet conformation having C_2-symmetry as shown in Fig. 1 of GS and its derivatives can be considered as an averaged structure of the assembly of slightly different conformers in equilibrium.[13]

From the intensive studies on the structure-antibacterial activity relationships of the analogs of GS it is known that both the stable β-sheet conformation of GS and the presence of positively charged side chains are important for the activity. As given in Table 2 the *N*-methylated analogs **2**—**5** showed very similar activity to that of parent **1**, which is consistent with the conformational similarity of all these analogs as described above. As for the Orn side chains the essentially same activity of the trimethylammonio analog **2** as **1** has demonstrared that when these antibiotics bind to bacterial membrane or receptor molecules the function of the charged Orn side chains does not involve interaction through hydrogen bonding but is simply electrostatic in nature. The activity of **3**—**5** has also indicated that the exposed amide NH's of Orn and D-Phe residues do not play any important role in the binding of GS molecules to bacteria and in manifesting the antibactrial activity.

Experimental

GS·2HCl (**1**) was supplied by Nikken Kagaku Ltd. Mp's were determined with a hot-stage apparatus and uncorrected. Silica gel (Merck, #7734) and Sephadex LH-20 were used for column chromatographic separation. Purity of each product was ascertained by TLC, HPLC, and/or ^{1}H NMR spectral analysis. TLC analysis was performed using precoated silica gel plates (Merck, Silica Gel 60 F_{254}) with the solvent systems $CHCl_3$–MeOH, $CHCl_3$–MeOH–AcOH, or 1-butanol–AcOH–H_2O. HPLC was performed using FineSIL 20 (JASCO) with $CHCl_3$–MeOH as eluent or Unisil C18 (Gasukuro Kogyo) with MeOH–$NaClO_4$ aq. ^{1}H NMR spectra were recorded on a JEOL GX-400 or on a Varian XL-200 spectrometer. CD spectra were measured on a JASCO J-40C spectropolarimeter. For amino acid analysis synthetic peptides were hydrolyzed in concd HCl–AcOH (1:1) at 110 °C for 24 h. Proline was taken as an internal standard, and Orn(Me_3^+) and MeOrn were determined by the comparison with the authentic mixture. Antibacterial assay was performed at Research Center, Mitsubishi Kasei Corporation, and elemental analysis was performed at Elemental Analysis Center of Kyoto University.

[Orn(Me_3^+)$^{2,2'}$]GS·2I$^-$ (2). CH_3I (2 cm^3, 32 mmol) and $KHCO_3$ (1.0 g, 10 mmol) were added to the solution of **1** (125 mg, 0.1 mmol) in MeOH (20 cm^3) and the mixture was stirred in the dark for 45 h at room temperature. The solvent was evaporated and the residue was extracted with $CHCl_3$. Sephadex LH-20 column chromatography of the $CHCl_3$ extract using MeOH as eluent and recrystallization from MeOH–H_2O afforded **2** (116 mg, 75%) as colorless needles, mp 228—231.5 °C. Amino acid analysis: Pro (1.00), Val (1.02), Leu (0.97), Phe (1.00), Orn (0.00), Orn (Me_3^+) (1.00).

Found: C, 50.67; H, 7.52; N, 10.89%. Calcd for $C_{66}H_{106}N_{12}O_{10}I_2 \cdot 5H_2O$: C, 50.44; H, 7.44; N, 10.70%.

[MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS. [Orn(Pht)$^{2,2'}$]GS (42 mg, 0.03 mmol), prepared from **1** and *N*-(ethoxycarbonyl)phthalimide,[14] was dissolved in DMF (1 cm^3), and CH_3I (2.5 cm^3, 40 mmol) and Ag_2O (232 mg, 1.0 mmol) were added to the solution. After stirring for 4 h at room temperature MeOH (4 cm^3) was added and the precipitate was filtered off. The solvent was evaporated and the residue was extracted with $CHCl_3$. Silica-gel column chromatography of the $CHCl_3$ extract using $CHCl_3$–MeOH as eluent and crystallization from MeOH–H_2O afforded [MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (38.5 mg, 88%), mp 170.5—173.5 °C. ^{1}H NMR ($CDCl_3$) δ=3.21 (6H, s, N-Me) and 3.52 (6H, s, N-Me). Amino acid analysis: Pro (1.00), Val (1.00), Leu (0.95), Phe (0.00), Orn (0.00), MeOrn (1.05).

Found: C, 64.93; H, 7.09; N, 11.56%. Calcd for $C_{80}H_{104}N_{12}O_{14}I_2 \cdot H_2O$: C, 65.11; H, 7.24; N, 11.39%.

[MeOrn$^{2,2'}$, D-MePhe$^{4,4'}$]GS·2HCl (3). $H_2NNH_2 \cdot H_2O$ (5

cm^3) was added dropwise to the solution of [MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (73 mg, 0.05 mmol) in EtOH (2 cm^3) and the mixture was stirred overnight at room temperature. After the addition of H_2O (10 cm^3) precipitate was collected by filtration and was dissolved in EtOH (5 cm^3), to which 1 M (M=mol dm^{-3}) HCl aq (1 cm^3) was added. The solvent was evaporated and the residue was chromatographed with silica gel ($CHCl_3$–MeOH–AcOH) and then with Sephadex LH-20 (MeOH) affording **3** (37 mg, 58%), mp 200.5—203 °C.

Found: C, 55.97; H, 8.37; N, 11.53%. Calcd for $C_{64}H_{100}N_{12}O_{10}\cdot 2HCl\cdot 3CH_3OH\cdot 4H_2O$: C, 55.94; H, 8.55; N, 11.68%.

[MeOrn(Me$_3^+$)$^{2,2'}$, D-MePhe$^{4,4'}$]GS·2I$^-$ (4) Quaternization of **3** (63 mg 0.05 mmol) was undertaken in a similar manner to the preparation of **2** from **1**. Sephadex LH-20 column chromatography (MeOH) of the product and crystallization from MeOH–Et_2O–hexane gave **2** as colorless needles (57 mg, 76%), mp 226—232.5 °C. Amino acid analysis: Pro (1.00), Val (0.99), Leu (1.06), Phe (0.00), Orn (0.00).

Found: C, 52.13; H, 7.24; N, 10.47%. Calcd for $C_{70}H_{114}N_{12}O_{10}I_2\cdot 4H_2O$: C, 52.23; H, 7.64; N, 10.44%.

N-Methylation of **2** in a similar manner to the preparation of [MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS from [Orn(Pht)$^{2,2'}$]GS afforded the same compound **4** in 32% yield.

[Orn(Tfa)$^{2,2'}$]GS. Ethyl trifluoroacetate (3 cm^3) was added to the solution of **1** (121 mg, 0.1 mmol) and Et_3N (0.03 cm^3, 0.2 mmol) in MeOH (5 cm^3), and the mixture was stirred overnight at room temperature. The solvent was evaporated and the residue was dissolved in $CHCl_3$ and washed with H_2O. Evaporation of $CHCl_3$ and crystallization of the residue from MeOH–H_2O gave [Orn(Tfa)$^{2,2'}$]GS as colorless prisms (112 mg, 83%), mp 273 °C (decomp).

Found: C, 56.49; H, 6.89; N, 12.40%. Calcd for $C_{64}H_{90}N_{12}F_6O_{12}\cdot 1.5H_2O$: C, 56.50; H, 6.89; N, 12.39%.

[MeOrn(Me,Tfa)$^{2,2'}$, D-MePhe$^{4,4'}$]GS. *N*-Methylation of [Orn(Tfa)$^{2,2'}$]GS (45 mg, 0.033 mmol) was carried out in a similar manner to the preparation of [MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS from [Orn(Pht)$^{4,4'}$]GS. Silica-gel column chromatography ($CHCl_3$–MeOH) of the product and crystallization from MeOH–H_2O gave [MeOrn(Me,Tfa)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (39 mg, 83%), mp 125—126.5 °C. ^{1}H NMR ($CDCl_3$) δ=3.14 (6H, s, *N*-Me), 3.25 (6H, s, *N*-Me), and 3.41 (6H, s, *N*-Me). Amino acid analysis: Pro (1.00), Val (0.98), Leu (0.96), Phe (0.00), Orn (0.00).

[MeOrn(Me)$^{2,2'}$, D-MePhe$^{4,4'}$]GS·2HCl (5). To the solution of [MeOrn(Me,Tfa)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (53 mg, 0.043 mmol) in MeOH (3 cm^3) was added 4M NaOH aq (0.7 cm^3) and the mixture was stirred for 2 h at room temperature. The solution was acidified by the addition of 6M HCl aq and was evaporated, and the residue was extracted with $CHCl_3$. Sephadex LH-20 column chromatography (MeOH) of the $CHCl_3$ extract afforded **5** (40 mg, 82%), mp 175—177.5 °C.

Found: C, 56.72; H, 8.21; N, 12.09%. Calcd for $C_{66}H_{104}N_{12}O_{10}\cdot 2HCl\cdot 5.5H_2O$: C, 56.72; H, 8.44; N, 12.03%.

***N*-Methylation of [Orn(Cbz)$^{2,2'}$]GS.** [Orn(Cbz)$^{2,2'}$]GS[15] (127 mg, 0.09 mmol) was subjected to the *N*-methylation reaction in a similar manner to the preparation of [MeOrn(Pht)$^{2,2'}$, D-MePhe$^{4,4'}$]GS from [Orn(Pht)$^{4,4'}$]GS. The crude product showed a prominent single spot on TLC accompanied with some minor spots, and silica-gel column chromatography ($CHCl_3$–MeOH) and crystallization from MeOH–H_2O yielded [MeOrn(Cbz)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (103 mg, 76%), mp 127.5—129.5 °C. Amino acid analysis: Pro (1.00), Val (1.01), Leu (0.93), Phe (0.00), Orn (0.00), MeOrn (1.01).

***N*-Methylation of [Orn(Dnp)$^{2,2'}$]GS.** [Orn(Dnp)$^{2,2'}$]GS[16] (74 mg, 0.05 mmol) was subjected to the *N*-methylation reaction as described above. Silica-gel column chromatography ($CHCl_3$–MeOH) afforded [MeOrn(Me,Dnp)$^{2,2'}$, D-MePhe$^{4,4'}$]GS (73 mg, 95%), mp 135—138 °C. ^{1}H NMR ($CDCl_3$) δ=2.88 (s, 6H, *N*-Me), 3.19 (s, 6H, *N*-Me), and 3.38 (s, 6H, *N*-Me).

Found: C, 58.72; H, 6.85; N, 13.77%. Calcd for $C_{78}H_{108}N_{16}O_{18}\cdot 2H_2O$: C, 58.78; H, 7.08; N, 14.06%.

2,4-Dinitrophenylation of **4** (15 mg, 0.012 mmol) in EtOH (1 cm^3) with DnpF (105 mg, 0.56 mmol) and Et_3N (0.05 cm^3) for 2 h at room temperature also yielded the same compound, mp 135—136 °C, in 87% yield.

The authors are grateful to Mr. Jun'ichi Ohya of Research Center, Mitsubishi Kasei Corporation for the antibacterial assay, to Dr. Showbu Sato of Mitsubishi Kasei Institute of Life Sciences for amino acid analysis, to Dr. Ukon Nagai of the same Institute for helpful discussions, to Professor Tatsuo Miyazawa of The University of Tokyo for ^{1}H NMR analysis, and to Nikken Kagaku Co., Ltd. for the supply of gramicidin S.

Aromatic Nucleophilic Substitution of Halobenzenes with Amines under High Pressure

Toshikazu IBATA,* Yasushi ISOGAMI, and Jiro TOYODA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received August 15, 1990)

The nucleophilic substitution reactions of aromatic halides having electron-attracting groups on ortho or para position with various primary and secondary amines were accelerated by high pressure to give the corresponding *N*-substituted anilines in high yields. The bulkiness of amines affects its reactivity to lower the yields of the products. Although the secondary amines are usually less reactive than primary amines, cyclic secondary amines such as morpholine, piperidine, and pyrrolidine were found very reactive. 1,4-Diazabicyclo[2.2.2]octane and quinuclidine gave *N*-quaternary ammonium halides in high yields in contrast to the low reactivity of acyclic tertiary amines. Dichloro- and trichloro-nitrobenzenes also react with diethylamine, pyrrolidine, and morpholine to give mono-, di-, and trisubstitution products depending upon the amount of amine and the position of nitro group in these chlorides.

Nucleophilic substitutions of aromatic halides with amines are generally difficult to proceed under ordinary pressure,[1] and are limited to some fluorides or chlorides having a strongly electron-attracting group such as nitro group at ortho or para position. These aromatic nucleophilic substitution (S_NAr) reactions are confirmed to proceed through the Meisenheimer type dipolar intermediate.[2] Because bond formation and charge separation are occurring in the transition state of this reaction, the S_NAr reaction is expected to be accelerated under high pressure.[3] However, no S_NAr reaction of aromatic halides with amines had been reported under high pressure from the synthetic point of view,[3] until our preliminary paper was published.[4] Matsumoto and his co-workers reported the high pressure S_NAr reaction of trifluoromethyl-substituted halobenzenes,[5] halogenopyridines,[6] and halogenothiazoles with amines.[7]

Herein, we describe the S_NAr reaction of substituted monohalobenzenes with various primary and secondary amines under high pressure. We also report the reaction of dichloro- and trichloro-nitrobenzenes with secondary amines such as diethylamine, pyrrolidine, and morpholine under high pressure in order to test the applicability of this reaction for the preparation of polyamino-substituted nitrobenzenes.

The high pressure reactions were carried out in a Teflon capsule using a Hikari Kouatsu High Pressure Reaction Apparatus.[8] When *p*-nitrochlorobenzene (**1a**) was treated with five molar equivalents of propylamine in a freshly distilled tetrahydrofuran (THF) solution at 50 °C under 7.2 kbar# for 20 h, *N*-propyl-*p*-nitroaniline (**3a**) was obtained as yellow crystals in 93% yield along with an almost quantitative amount of propylamine hydrochloride. The products were characterized by the spectroscopic measurement. The reaction did not proceed even at 80 °C under ordinary pressure.

3 (1)

In order to ascertain the acceleration effect on the reaction rate, the yields of the reactions of **1a** with propylamine, morpholine, and pyrrolidine were examined under the variation of pressure in the range of 1/1000—10.0 kbar (Table 1). The reactions of **1a** with propylamine and morpholine are dramatically accelerated at the pressure of 6 kbar. However, 6 kbar is not enough for the completion of these reactions. On the other hand, pyrrolidine is more reactive than these amines and the reaction is completed at 6 kbar.

The reactions of *p*-nitrochlorobenzene (**1a**) with other primary amines under the high pressure of 7.2—12.0 kbar also gave the corresponding secondary *p*-nitroanilines as shown in Table 2. The yields of the reactions are affected strongly by the bulkiness of amines. For example, isopropylamine gave *N*-isopropyl-*p*-nitroaniline (**3c**) only in 26% yield under the same reaction conditions with those of propylamine, despite the basicity of these amines is almost same (pK_a; 10.63 and 10.53).[9] Similar results were also observed in the reactions of four butylamines (Table 2, Runs d—i). In these cases the order of the yields of **3** is the same as the order of the bulkiness of the butyl groups. *p*-Nitroiodobenzene (**1b**) is less reactive than **1a** (Table 2, Runs b, e, and i) in accordance with the usual S_NAr reactions of aromatic halides.[10]

Cyclohexylamine gave *N*-cyclohexyl-*p*-nitroaniline (**3k**) in 18% yield similar to the cases of isopropylamine

1 kbar=0.1 GPa

a) All reactions listed were carried out in THF solution at 50 °C using 1.0 mmol of **1** and 5.0 mmol of amines. b) Yields in parentheses refer to reactions under 1 atm at 80 °C, for 50 h. c) H. Suhr, *Ann. Chem.*, **687**, 175 (1965).

(26%) and *s*-butylamine (13%). Aromatic primary amines have lower reactivity than that of the aliphatic amines because of their low basicity. For example, *p*-anisidine gave *p*-nitro-*p'*-methoxydiphenylamine (**3m**) only in 2% yield under the forced reaction conditions (9.0 kbar, 50 h). Aniline and *p*-toluidine gave no substitution product under the same reaction conditions. *p*-Nitrofluorobenzene (**1c**) is more reactive than **1a** and gave substitution products in the reactions with aromatic amines in low yields (Table 2, Runs p—r).

Secondary amines exhibit lower reactivities than the corresponding primary amines as shown in Table 3 (compare Runs c, d, and e in Table 3 with Runs a, c, and d in Table 2, respectively). However, cyclic secondary amines such as morpholine, piperidine, and pyrrolidine indicate extremely higher reactivities (Table 3, Runs h—v) than those of acyclic secondary amines such as diethylamine and diisopropylamine. The difference in reactivities of these high pressure S_NAr reactions seems to be attributed to both basicity and bulkiness of amine.

a) All reactions listed were carried out in THF solution at 50 °C using 1.0 mmol of **4** and 5.0 mmol of amine. b) Yields in parentheses refer to reactions under 1 atm at 80 °C, for 50 h. c) E. Matsumura, Y. Tohda, and M. Ariga, *Bull. Chem. Soc. Jpn.*, **55**, 2174 (1982). d) N. Nagornow, *J. Russ. Phys-Chem. Soc.*, **29**, 699. e) L. Loewe, H. Mieth, and H. Suschitzky, *J. Chem. Soc.*, **1963**, 1666. f) S. F. Beach, J. D. Hepworth, J. Sawyer, G. Hallas, R. Marsden, M. M. Mitchell, D. A. Ibbitson, A. M. Jones, and G. T. Neal, *J. Chem. Soc., Perkin Trans. 2*, **1984**, 217.

This indicates that the nitro group increases the reactivity of chloride only at ortho or para position. However, *m*-nitrofluorobenzene (**4c**) is exceptionally reactive toward pyrrolidine (Run s). *p*-Nitrobromobenzene (**1d**) and *p*-nitroiodobenzene (**1b**) reacted with pyrrolidine to give **6m** in high yields (Runs n and o). *p*-Cyanochlorobenzene (**4e**) and *p*-chloroacetophenone (**4f**) gave the corresponding *N*-arylpyrrolidines in moderate yields (Runs u and v). These results indicate that cyano and acetyl groups are not so good substituent as nitro group to promote the reaction, and that 9.0 kbar is not enough to accelerate the S_NAr reactions of these chlorides.

In contrast to triethylamine, bicyclic tertiary amines such as 1,4-diazabicyclo[2.2.2]octane (DABCO) and quinuclidine react with *p*-nitrohalobenzenes to give the corresponding quaternary ammonium salts **8**[9] in quantitative yields at 6.0 kbar.

The reaction of 2,3-dichloronitrobenzene (**9**) with diethylamine, pyrrolidine, and morpholine gave ortho substitution product **10** in quantitative yield without affording meta substitution product (Table 4). The structure of **10** was determined by the observation that ^1H NMR signal of aromatic proton H_c changes only a little by the reaction of **9**. This substitution pattern is consistent with the observation that *m*-nitrochlorobenzene has very low reactivity as described above.

Similarly, 2,5-dichloronitrobenzene (**11**) and 3,4-dichloronitrobenzene (**13**) react with these amines at ortho or para position to nitro group, respectively, to

a) The reactions were carried out in the following conditions; 6 kbar, 50 °C, 20 h, in THF. b) The values in the parentheses are the chemical shift of starting dichloronitrobenzenes.

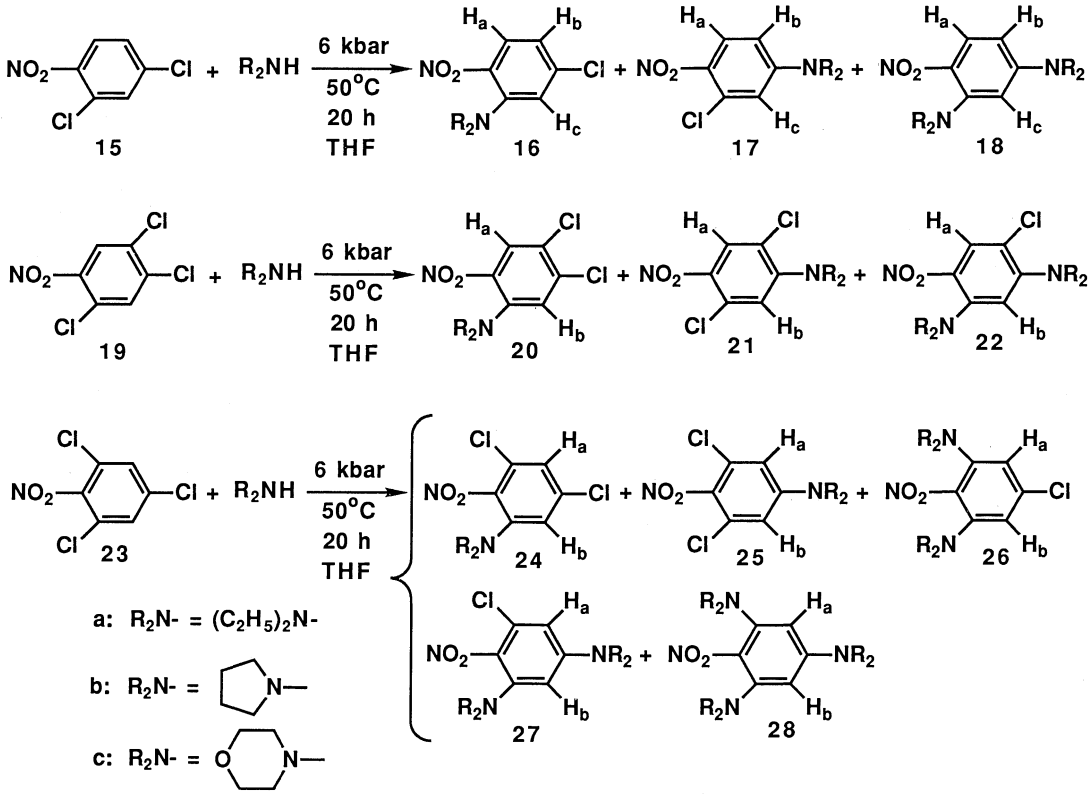

Fig. 2.

give a single product **12** and **14** in quantitative yields (Table 4). The structure of the products was based on the NMR spectra. For example, the fact that only ortho substitution takes place in the reactions of **11**, was concluded by the observation that this reaction caused the largest chemical shift change for H_c in the aromatic protons of **11** (Table 4). These three dichloronitrobezenes were found to be more reactive than monochloronitrobenzenes, and then no difference in the reactivity of amines was observed in these reactions.

2,4-Dichloronitrobenzene (**15**) has ortho and para chlorine atoms which are both reactive. The reactions of **15** gave a mixture of ortho substitution product **16**, para substitution product **17**, and disubstitution product **18**. Yields of these three types of products depend on the reactivity and the amount of the amine used. When five molar equivalents of amine was used, diethylamine gave ortho-mono substitution product in high yield along with a small amount of **18**. On the other hand, pyrrolidine and morpholine gave the disubstitution product **18** as a major product together with a small amount of ortho-mono substitution product **16**. In these cases, isolation of para-mono substitution product was unsuccessful (Table 5). In the case of 1.1 molar equivalent of pyrrolidine or morpholine was used, ortho-mono substitution products became predominant together with a small amount of para-mono and disubstitution products. These results may be explained by the assumption that the para-mono substitution products **17** are more reactive than ortho-mono product **16** in the second substitution. Diethylamine is less reactive than pyrrolidine or morpholine in this second step.

Table 5. Reaction of 2,4-Dichloronitrobenzene (**15**) with Secondary Amines[a]

Amine	Amount of amine[b]	Yield/%		
		16	**17**	**18**
Diethylamine	5.0	90	0	10
Pyrrolidine	5.0	15	0	85
Pyrrolidine	1.1	89	3	2
Morpholine	5.0	36	0	61
Morpholine	1.1	86	2	11

a) The reactions were carried out under the following conditions; 6 kbar, 50 °C, 20 h, in THF. b) Amount of amine was shown in molar equivalent.

In the reactions of 2,4,5-trichloronitrobenzene (**19**), no substitution was observed at meta position and the reaction proceeded in a manner similar to that of 2,4-dichloronitrobenzene (Table 6-1). In these cases, yields of disubstitution products **22** were higher than the case of **15** and even diethylamine gave **22a** as the major product. This means that **19** is more reactive than **15** due to the effect of 5-chlorine atom. When 1.2 molar

equivalent of morpholine was used in the presence of triethylamine to trap hydrogen chloride generated, ortho-mono and disubstitution products were obtained without yielding para-mono product. This is explained by the assumption that the ortho position of para-mono product **21** is more reactive than the para

a) Chemical shifts were shown in δ.

position of **20**, and that **21** produced by the first substitution of **19** was consumed completely in the second substitution.

Product ratio of the reaction of 2,4,6-trichloronitrobenzene (**23**) is affected by the amine used. When five molar equivalents of amine was used, diethylamine gave para-mono substitution product **25a** as a sole product. Pyrrolidine gave trisubstitution product **28b**, and morpholine gave ortho-ortho disubstitution product **26c** as major products (Table 6-2). These results suggest that the order of reactivity of amines in this reaction is as follows; pyrrolidine>morpholine>diethylamine.

The reaction with 1.1 molar equivalent of amine gave mono substitution product as a major product. Pyrrolidine yielded para-mono product **25b** which was confirmed by the singlet signal of aromatic proton observed at 6.66 in its ^{1}H NMR spectrum. On the other hand, morpholine gave ortho-mono product **24c** which has two doublet signals of aromatic protons at 7.06 and 7.18. The difference in the behavior of these two amines may be attributed mainly to the bulkiness of amines.

Experimental

Melting points were measured with a Yanagimoto Melting Point Apparatus and not corrected. IR spectra were recorded on a Perkin-Elmer model 983. ^{1}H NMR spectra were measured on a Varian EM-390 in a $CDCl_3$ solution using TMS as an internal standard.

Materials. All aromatic halides were purified by recrystallization or distillation of commercial compounds just before use. THF and amines were purified by distillation under an atmosphere of nitrogen after appropriate drying procedure.

General Procedure of the S_NAr Reaction of Aromatic Halides with Primary or Secondary Amines under High Pressure. A THF solution (5 cm^3) of aromatic halide (1.0 mmol) and amine (5.0 mmol) was pressurized in Teflon capsule under the cited reaction conditions using Hikari Kouatsu High Pressure Apparatus.[3] After the removal of solvent under reduced pressure the residue was suspended in benzene, and amine hydrohalide was removed by filtration on glass filter and the solid was washed several times with benzene (10 cm^3). The combined benzene solution was separated by medium pressure column chromatography (silica gel, benzene). Products were characterized by IR and ^{1}H NMR spectra. The characteristic ^{1}H NMR data were listed in Tables 4 and 7. In their IR spectra, absorptions of aromatic NO_2 were observed in the regions of 1480—1520 and 1330—1350 cm^{-1}, and the aromatic absorption near 1600 cm^{-1} was very strong. The results of elemental analysis were shown in Table 8. The reactions with 1.1—1.2 molar equivalent of amines were carried out using 1.0 cm^3 (ca. 7.2 mmol) of triethylamine and treated in the same way.

The Reactions of *p*-Nitrohalobenzenes with DABCO or Quinuclidine under High Pressure. The reaction was carried out in the similar manner under the following reaction conditions; 6.0 kbar, 50 °C, 75 h, in THF. After the reaction was over, the yellow crystals that precipitated in the Teflon capsule were collected by filtration and washed with benzene several times, and dried. The melting points of the salts were higher than 300 °C. The elemental analyses of these products did not give correct results for salts **8**[11] because purification of the salts was difficult due to the low solubility in usual organic solvents.

Table 8. Melting Points and Results of Elemental Analysis of the Products[a]

1,3-Diol Fragmentation Using a Reactive Benzylic Hydroxyl Group as a Nucleofuge. Synthesis of a Tobacco Sesquiterpene

Michiharu KATO,* Youichi TOOYAMA, and Akira YOSHIKOSHI
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University,
Katahira 2-1-1, Aoba-ku, Sendai 980
(Received August 23, 1990)

A benzylic hydroxyl group activated by electron-donative aromatic function was found to be a remarkably reactive nucleofuge for 1,3-diol fragmentation. Thus, treatment of α-(2,6-dimethoxy-4-methylphenyl)-2β-hydroxy-2α,5,5,8aβ-tetramethyl-4aα-decahydro-1β-naphthalenemethanol with pyridinium chloride or pyridinium *p*-toluenesulfonate in dichloromethane underwent the 1,3-diol fragmentation smoothly to produce *r*-1-[(*E*)-2-(2,6-dimethoxy-4-methylphenyl)ethenyl]-*t*-2-(3-oxobutyl)-1,3,3-trimethylcyclohexane (**24**) in quantitative yield. Starting from **24**, a tobacco sesquiterpene, 4-(2,2,6-trimethyl-6-vinylcyclohexyl)-2-butanone, was synthesized in racemic form by seven steps.

As one of C–C bond cleavage reactions, fragmentation reaction has been extensively utilized in structural elucidation and synthetic study in the natural product chemistry.[1] On the C(2)–C(3) bond cleavage in 1,3-diol i by fragmentation reaction, a primary hydroxyl group itself is generally less effective as a nucleofuge,[2] as can be judged from the consideration that the more stable a carbonium ion formed is, the easier the 1,3-diol fragmentation reaction occurs. When the diol i is converted to the corresponding benzyl alcohol ii possessing a phenyl group (Ar) substituted by electron-donative groups at ortho and para positions, the benzylic hydroxyl group in ii eliminates easily to give a stable carbonium ion, and therefore, the fragmentation reaction would proceed, to our expectation, providing the desired product iii.

The above conception was founded on the following observation made earlier in the course of our synthetic study on siccanin,[3] an antibiotic mold metabolite. We examined deprotection of the tetrahydropyranyl(THP) ether **1**. Under mild hydrolytic conditions (AcOH–THF–H_2O), well-known for cleavage of THP ethers,[4] not only deprotection of **1** but also concomitant 1,3-diol fragmentation proceeded smoothly to give olefinic ketone **2** in quantitative yield.[5] Surprisingly, treatment of **1** with pyridinium *p*-toluenesulfonate (PPTS) in ethanol also provided **2** in almost quantitative yield.[5] Moreover, oxidation of benzyl alcohol **3** with pyridinium chlorochromate in dichloromethane (CH_2Cl_2) furnished a ring-opened product **4** as one of the products. The olefin **4** could be accounted for by fragmentation, when presuming that a chromate ester group initially formed at the benzylic position of **3** would act as a nucleofuge.[5] These results indicate that generation of a carbonium ion assisted by electron-donative aromatic function causes the remarkably facile 1,3-diol fragmentation of this type. We wish to describe here results of our studies on the 1,3-diol fragmentation using a reactive benzylic hydroxyl group as a nucleofuge, and its application to the synthesis of (±)-4-(2,2,6-trimethyl-6-vinylcyclohexyl)-2-butanone (**5**),[6] a seco-sesquiterpene isolated from sun-cured Greek tobacco, *Nicotiana tabacum* L.[7]

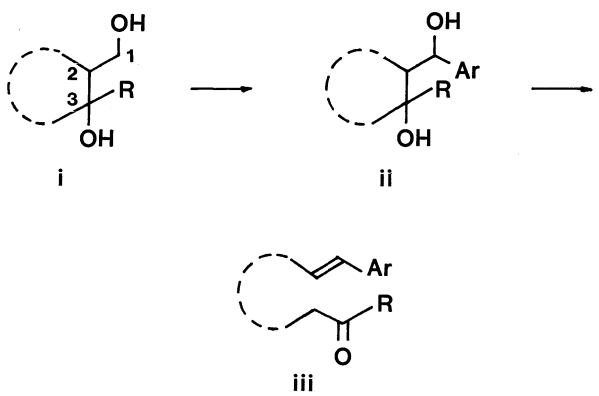

Fig. 1.

Results and Discussion

Our key compound selected for this work was drimane-8β,11-diol (**17**),[8] and its synthesis began with

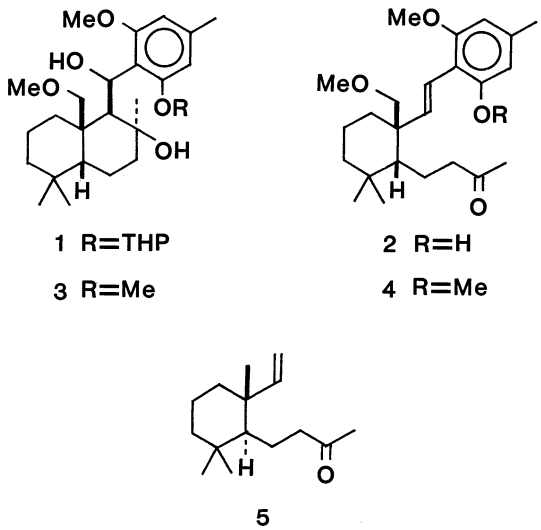

Fig. 2.

protection of the oxo group in the known keto ester **6**[9] (Scheme 1). Acetalization of **6** with ethylene glycol followed by reduction of the resulting ethylenedioxyl ester **7** with lithium aluminium hydride provided crystalline alcohol **8**. Reaction of **8** with PPTS in acetone at 40 °C led to the exclusive formation of hydroxy ketone **9**, whereas treatment of **8** with catalytic *p*-toluenesulfonic acid at room temperature gave a mixture of **9** (45%) and the known enone **18** (32%).[9] Subsequent protection of the hydroxyl group in **9** with 3,4-dihydro-2*H*-pyran gave the THP ether **10** in 73% overall yield from **6**. The compound **10** was also prepared by an alternate route. Hydroxymethylation of the lithium enolate of *trans*-octalone **11**[10] with gaseous formaldehyde under the kinetically controlled conditions occurred stereoselectively from the α-side, affording the α-hydroxymethyl enone **12** in good yield, which was then converted to the corresponding THP ether **13**. Inversion of stereochemistry of the oxygenated side chain in **13** to equatorial configuration was carried out by regioselective deprotonation of **13** with lithium diisopropylamide (LDA) followed by kinetically controlled protonation with 10% citric acid, giving the desired enone **14** and dienone **15** in 45 and 41% yield, respectively. Catalytic hydrogenation of the former **14** afforded **10** in 34% overall yield from **11**. The decalone **10** upon methylation with excess methylmagnesium iodide in ether at −60 °C gave a single alcohol **16**. The stereochemistry of **16** was predicted from the consideration that the Grignard reagent would approach preferentially from the less hindered α face of **10**. This prediction was confirmed as follows. Deprotection of **16** afforded the required diol **17** (mp 133—134 °C) in 86% overall yield from **10**. The physical constants (mp, IR, and ^{1}H NMR) of **17** were identical with those of (±)-drimane-8β,11-diol reported by Pelletier and co-workers.[8]

In order to confirm the consideration mentioned in the beginning, a number of preliminary experiments were undertaken. The diol **17** was treated with pyridinium chloride or PPTS in CH_2Cl_2 at room temperature or under refluxing. However, it was completely recovered unchanged. Hence, **17** was transformed into the tosylate **19**. When **19** was treated with sodium hydride in 1,2-dimethoxyethane (DME) at 60 °C for 15 h, the sole product obtained in 30% yield was the oxetane **20**, and no formation of the fragmentation product, i.e. **5**, was detectable on the careful inspection of the reaction mixture.

At this juncture, we turned our attention to utilization of a reactive benzylic hydroxyl group as a nucleofuge. According to the published procedure,[8] the diol **17** was oxidized by Collins reagent to give the drimanic aldehyde **21** in 47% yield (lit,[8] 42% yield).

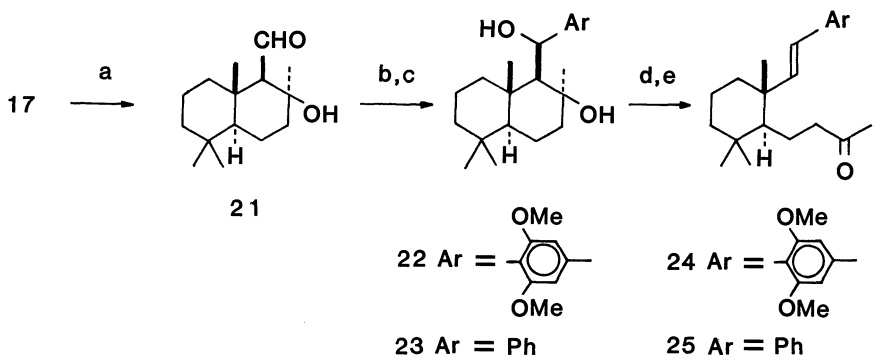
Scheme 1. (a) Ethylene glycol, *p*-TsOH, PhH (99%): (b) $LiAlH_4$, THF (69%): (c) PPTS, acetone (96%): (d) DHP, PPTS (quant): (e) LDA, THF, −78 °C, then CH_2O(g) (78%): (f) LDA, THF, −78 °C, then 10% citric acid (45%): (g) H_2, 10% Pd-C, dioxane (95%): (h) MeMgI, Et_2O, −60 °C (94%): (i) PPTS, MeOH (91%).



Scheme 2. (a) NCS, Me_2S, toluene (63%): (b) 1,3-dimethoxy-5-methylbenzene (**26**), BuLi, DME (92%): (c) PhLi, DME (90%): (d) Py·HCl or PPTS, CH_2Cl_2, rt, a few minutes (quant): (e) *p*-TsCl, Py, 60 °C, 2d (58%).

After a few attempts to improve the yield of **21**, it was found that oxidation by Corey–Kim method[11] employing *N*-chlorosuccinimide (NCS) and dimethyl sulfide was more effective to provide crystalline **21** in 63% yield (Scheme 2). For the purpose of constructing a reactive benzyl alcohol moiety, the use of 1,3-dimethoxy-5-methylbenzene (**26**)[12] was deemed most favorable, because its precursor, 5-methyl-1,3-benzenediol(orcinol) monohydrate, was commercially available and moderate in price, and readily convertible to **26** with dimethyl sulfate.[12] The lithium salt prepared from **26** with butyllithium in DME was submitted to condensation with **21**, providing **22** as an epimeric mixture with a minor quantity of one epimer regarding the newly formed hydroxyl group, from which a major epimer **22**[13] was obtained as crystals in 92% yield. For comparison, benzyl alcohol **23**,[13] a major epimer of stereoisomers, was prepared in high yield by treatment of **21** with phenyllithium followed by recrystallization of products. On exposure to pyridinium chloride in CH_2Cl_2 at room temperature, **22** underwent the 1,3-diol fragmentation within a few minutes to afford olefinic ketone **24**[14] in almost quantitative yield. In similar fashion, almost conversion of **22** into **24** was detected on treatment with PPTS. In contrast to **22**, benzyl alcohol **23** was recovered unchanged under the same reaction conditions described above. On prolonged heating of **23** with *p*-toluenesulfonyl chloride in pyridine at 60 °C, a fragmentation product **25** was obtained in 58% yield. The stereochemistry of the double bond in **25** was assigned to be E on the basis of a coupling constant (J=16.2 Hz) of two olefinic protons in the ^1H NMR spectrum. Obviously unsubstituited phenyl group as an activator was insufficient to cause the fragmentation under the above mild conditions, and difference in reactivity observed in the above two types of reactions is dependent on liability to generate a carbonium ion. After all, it was found that 2,6-dimethyoxy-4-methylphenyl function remarkably assists elimination of the benzylic hydroxyl group in the 1,3-diol fragmentation even under the mild conditions. The reaction conditions used here would be practically useful, especially when the substrate is an acid-labile compound.

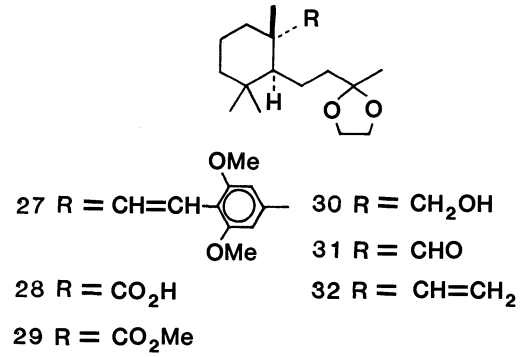


Fig. 4.

As an extension of this study to the natural product synthesis, we envisioned the olefinic ketone **24** to be a resonable intermediate for the synthesis of Tobacco sesquiterpene **5**. Transformation of **24** to **5** was accomplished by a conventional but straightforward sequence of reactions. Acetalization of **24** followed by ozonolysis of the resulting acetal **27** in CH_2Cl_2 directly provided carboxylic acid **28** in 55% overall yield. Esterification of **28** with diazomethane yielded ester **29**. As attempt to reduce the ester **29** with diisobutylaluminium hydride to the corresponding aldehyde **31** failed, **29** was converted to alcohol **30** by lithium aluminium hydride reduction. Collins oxidation of **30** afforded **31** in good yield, and methylenation of the latter with methylenetriphenylphosphorane provided olefin **32**. Finally, deprotection of **32** gave the target molecule (±)-4-(2,2,6-trimethyl-6-vinylcyclohexyl)-2-butanone (**5**), whose physical data (IR and NMR) were identical with those of the natural **5**.[6,15]

Experimental

Melting points are uncorrected. IR spectra were obtained with a JASCO A-3 infrared spectrometer. ^{1}H NMR spectra were recorded on a JEOL FX90Q spectrometer with tetramethylsilane as an internal standard. Dry THF and DME were obtained by distillation over lithium aluminium hydride, and other organic solvents were purified according to the standard procedure. All reactions were carried out under dry N_2 or Ar atmosphere. Extracts obtained on aqueous workup were dried over Na_2SO_4. Column chromatography was performed by using silica gel (Merck, kieselgel 60, 70—230 mesh), and kieselgel GF_{254} was employed for preparative thin-layer chromarography (TLC) as an absorbent. Solvents used for elution are shown in parentheses.

Methyl 2,2-Ethylenedioxy-5,5,8aβ-trimethyl-4aα-decahydro-1β-naphthalenecarboxylate (7). A solution of **6**[9] (1.665 g, 6.61 mmol), ethylene glycol (492 mg, 7.93 mmol), and *p*-toluenesulfonic acid (5 mg) in benzene (70 ml) was refluxed azeotropically for 30 h. After cooling, the mixture was washed successively with aqueous $NaHCO_3$, water, and brine, and dried. Removal of the solvent left a semicrystalline residue, which was filtered through a short silica-gel column with hexane–ether (1:1) to give **7** (1.946 g, 99%) as crystals: Mp 103—104 °C (from hexane–ether); IR (KBr) 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.85 and 0.88 (6H in total, s each $C(CH_3)_2$), 1.22 (3H, s, C–CH_3), 0.9—2.0 (12H, m), 3.63 (3H, s, O–CH_3), 3.7—4.15 (4H, m, $O(CH_2)_2O$).

Found: C, 68.77; H, 9.27%. Calcd for $C_{17}H_{28}O_4$: C, 68.89; H, 9.52%.

2,2-Ethylenedioxy-5,5,8aβ-trimethyl-4aα-decahydro-1β-naphthalenemethanol (8). To a stirred mixture of lithium aluminium hydride (230 mg, 5.97 mmol) in THF (20 ml) wad added a solution of **7** (1.767 g, 5.97 mmol) in THF (2 ml), and the mixture was gently refluxed for 5 h. After cooling, the reaction mixture was quenched by addition of wet ether followed by water, and filtered. The solid was washed with ether, and the combined filtrate and wash were dried. Concentration gave an oil which was chromatographed on silica gel with hexane–ether (1:1) to give **8** (1.103 g, 69%) as crystals: Mp 90—91 °C (from hexane–ether); IR (KBr) 3300 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.81, 0.83, and 0.89 (9H, in total, s each, $C(CH_3)_2$ and C–CH_3), 1.0—2.0 (12H, m), 2.95 (1H, dd, J=7.2 and 3 Hz, OH), 3.5—4.2 (6H, m, CH_2–OH and $O(CH_2)_2O$).

Found: C, 71.44; H, 10.84%. Calcd for $C_{16}H_{28}O_3$: C, 71.60; H, 10.52%.

1β-[(Tetrahydropyranyloxy)methyl]-5,5,8aβ-trimethyl-4aα-octahydro-2(1*H*)-naphthalenone (10). (a) A solution of **8** (890 mg, 3.32 mmol) and PPTS (5 mg) in acetone (15 ml) was warmed with stirring at 40 °C for 15 h. The solvent was mostly taken off under reduced pressure and the residue was dissolved in ether. The ethereal solution was washed with brine and dried. Removal of the solvent left an oil which was filtered through a short silica-gell column with hexane–ether (1:1) to give ketol **9** (714 mg, 96%): IR (film) 3300 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.80, 0.85, and 0.97 (9H in total, s each, $C(CH_3)_2$ and C–CH_3), 1.0—2.6 (13H, m), 3.8—4.1 (2H, m, CH_2–OH). This material was used for the next reaction without further purification. A mixture of **9** (714 mg, 3.18 mmol), 3,4-dihydro-2*H*-pyran (267 mg, 3.18 mmol), PPTS (5 mg), and CH_2Cl_2 (15 ml) was stirred at room temperature for 15 h, and washed with brine, and dried. Evaporation followed by filtration of an oily residue through a short silica-gel column with hexane–ether (3:2) gave **10** (950 mg, 97%): IR (film) 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.75, 0.85, and 0.95 (9H in total, s each, $C(CH_3)_2$ and C–CH_3), 1.1—2.4 (18H, m), 3.3—4.2 (4H, m, CH_2–O–CH–O–CH_2), 4.58 (1H, br s, O–CH–O).

Found: C, 73.90; H, 10.60%. Calcd for $C_{19}H_{32}O_3$: C, 73.98; H, 10.46%.

(b) A mixture of **14** (41 mg, 0.13 mmol), 10% Pd-C (5 mg), and dioxane (1 ml) was stirred at room temperature under H_2 for 20 h, and filtered. Concentration of the filtrate left an oil which was purified by preparative TLC (hexane–ether, 2:1) to give **10** (38 mg, 95%).

1α-Hydroxymethyl-5,5,8aβ-trimethyl-4aα,5,6,7,8,8a-hexahydro-2(1*H*)-naphthalenone (12). To a stirred solution of diisopropylamine (156 mg, 1.10 mmol) in THF (4 ml) was added dropwise at −78 °C a solution of 1.5 M butyllithium in hexane (0.96 ml, 1.43 mmol). The bath was replaced by an ice bath and the mixture was stirred for 30 min, then recooled at −78 °C. A solution of **11**[9] (212 mg, 1.10 mmol) in THF (4 ml) was added dropwise and stirring was continued for an additional 1.5 h. To this solution, Gaseous formaldehyde, generated by heating paraformaldehyde (ca. 3 g) at 160—170 °C, was passed through by means of a stream of dry N_2 for 30 min. The reaction was quenched by addition of aqueous NH_4Cl and the product was extracted with ether. The combined extracts were washed with brine and dried. Evaporation left an oil which was purified by preparative TLC (hexane–ether 1:1) to give **12** (191 mg, 78%) and **11** (15 mg, 7%).

12: a colorless crystals; mp 104—105 °C (from hexane–ether); IR (KBr) 3350 and 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94, 1.04, and 1.08 (9H in total, s each, $C(CH_3)_2$ and C–CH_3), 1.1—1.8 (6H, m), 2.10 (1H, ddd, J=8.2, 4.8, and 1.0 Hz, CH–CH_2O), 2.28 (1H, br t, J=1.7 Hz, CH–C=C), 2.3 (1H, br, OH), 3.65—4.18 (2H, m, CH_2–O), 6.04 (1H, ddd, J=10.4, 3.2, and 1.0 Hz, C=CH–CO), 6.96 (1H, dd, J=10.4 and 1.8 Hz, CH=C–CO). Upon irradiation at 6.04 ppm, the absorptions at 2.10, 2.28, and 6.96 ppm changed a double doublet (J=8.2, 4.8 Hz), a doublet (J=1.8 Hz), and a doublet (J=1.8 Hz), respectively. ^{1}H NMR ($CDCl_3$–D_2O) δ=3.76 (1H, dd, J=10.8, 8.2 Hz, CHH–O), 4.05 (1H, dd, J=10.8, 4.8 Hz, CHH–O).

Found: C, 75.78; H, 9.80%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

1α-[(Tetrahydropyranyloxy)methyl]-5,5,8aβ-trimethyl-4aα,5,6,7,8,8a-hexahydro-2(1*H*)-naphthalenone (13). A mixture of **12** (50 mg, 0.23 mmol), 3,4-dihydro-2*H*-pyran (29 mg, 0.34 mmol), catalytic amount of PPTS, and CH_2Cl_2 (2 ml) was stirred at room temperature for 6 h, and washed with brine. Removal of the solvent left an oil which was purified by preparative TLC (hexane–ether, 3:2) to give **13** (68 mg, quantitative): IR (film) 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.93, 1.02, and 1.07 (9H in total, s each, $C(CH_3)_2$ and C–CH_3), 1.1—1.9 (12H, m), 2.13 (1H, br t, J=5.4 Hz), 2.57 and 2.68 (1H in total, br t, C=C–CH), 3.3—4.2 (4H, m, CH_2–O–CH–O–CH_2), 4.55 (1H, br s, O–CH–O), 6.02 (1H, dd, with fine splittings, J=10.4 and 3.2 Hz, C=CH–CO), 6.90 (1H, dd, J=10.4 and 1.9 Hz, CH=C–CO).

1β-[(Tetrahydropyranyloxy)methyl]-5,5,8aβ-trimethyl-4aα,

5,6,7,8,8a-hexahydro-2(1*H*)-naphthalenone (14) and dienone 15. By the same procedure described in the preceding experiment, LDA solution was prepared from 1.5 M (1 M=1 mol dm^{-3}) butyllithium in hexane (0.52 ml, 0.76 mmol) and diisopropylamine (93 mg, 0.90 mmol) in THF (3 ml). A solution of **13** (120 mg, 0.46 mmol) in THF (2 ml) was added dropwise to the above solution at −78 °C. After stirring for 10 min, 10% citric acid (1 ml) was added and stirring was continued at −78 °C for an additional 30 min. Water was added, and the product was extracted with ether. Evaporation left an oil which was purified by preparative TLC (hexane–ether, 2:1) to give **14** (54 mg, 45%) and **15** (49 mg, 41%).

14: IR (film) 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.84, 0.95, and 1.05 (9H in total, s each, $C(CH_3)_2$ and C–CH_3), 1.0—2.0 (12H, m), 2.2—2.4 (2H, m, C=C–CH and CH–CO), 3.4—4.44 (4H, m, $C\underline{H}_2$–O–CH–O–$C\underline{H}_2$), 4.65 (1H, br s, O–CH–O), 6.08 (1H, dd. J=10.2 and 3.0 Hz, C=CH–CO), 6.92 (1H, dd, J=10.2 and 2.2 Hz, CH=C–CO).

Found: C, 74.57; H, 10.13%. Calcd for $C_{19}H_{30}O_3$: C, 74.47; H, 9.87%.

15: IR (film) 1675 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98, 1.03, and 1.17 (3H, s each, $C(CH_3)_2$ and C–CH_3), 1.1—1.9 (6H, m), 2.22 (1H, br t, C=C–CH), 5.16 and 5.87 (1H s with fine splittings each, $C=CH_2$), 6.20 (1H, dd, J=10.4 and 3.2 Hz, C=CH–CO), 7.01 (1H, dd, J=10.4 and 2.1 Hz, CH=C–CO).

Drimane-8β,11-diol (17). To a stirred solution of **10** (490 mg, 1.59 mmol) in ether (10 ml) was added dropwise at −78 °C a solution of 0.95 M methylmagnesium iodide in ether (7 ml, 4.0 mmol) and stirring was continued for an additional 5 h over a range of −78 to −10 °C. The reaction was quenched by the addition of aqueous NH_4Cl and the product was extracted with ether. Evaporation of the combined extracts gave an oil, which was chromatographed on silica gel with hexane–ether (7:3) to give alcohol **16** (485 mg, 94%): IR (film) 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85 (6H, s, $C(CH_3)_2$), 1.15, 1.22, and 1.30 (6H in total, s each, C–CH_3 and O–C–CH_3), 0.9—2.0 (19H, m), 3.2—4.3 (4H, m, $C\underline{H}_2$O–CH–O–$C\underline{H}_2$), 4.35 (1H, br s, O–CH–O). A mixture of **16** (485 mg, 1.50 mmol), PPTS (5 mg), and methanol (7 ml) was stirred at 60 °C for 15 h. The solvent was removed under reduced pressure to give a semicrystalline residue which was chromatographed on silica gel with hexane–ether (3:7), giving **17** (328 mg, 91%) as crystals: Mp 133—134 °C [lit,[8] 133.8—134.5 °C (from hexane–ether)]; IR (KBr) 3280 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.87 (6H, s, $C(CH_3)_2$), 1.23 (3H, s, C–CH_3), 1.35 (3H, s, O–C–CH_3), 1.0—2.1 (13H, m), 2.94 (1H, br s, OH), 4.06 (2H, d, J=3 Hz, CH_2–O). The physical constants (mp, IR, and ^1H NMR) were identical with those of drimane-8β,11-diol reported by Pelletier.[8]

1β-[(*p*-Tolylsulfonyloxy)methyl]-2α,5,5,8aβ-tetramethyl-4aα-decahydronaphthalen-2β-ol (19). A solution of **17** (60 mg, 0.25 mmol) and *p*-toluenesulfonyl chloride (71 mg, 0.37 mmol) in pyridine (1 ml) was stirred at room temperature for 10 h and diluted with ether. The ethereal solution was washed successively with aqueous copper(II) sulfate, water, and brine, and dried. Evaporation left a solid, which was filtered through a short silica-gel column with hexane–ether (1:1) to give **19** (85 mg, 88%) as crystals: Mp 96—97 °C (from hexane–ether); ^1H NMR ($CDCl_3$) δ=0.80, 0.85, and 0.89 (9H in total, s each, $C(CH_3)_2$ and C–CH_3), 1.12 (3H, s, O–C–CH_3), 0.9—1.8 (13H, m), 2.44 (3H, s, Ar–CH_3), 4.10 (1H, d, J=10.8 and 2.8 Hz, O–C$\underline{H}$H), 4.32 (1H, d, J=10.8 and 3.9 Hz, O–CH$\underline{H}$), 7.32 and 7.78 (1H, dd each, J=8.6 Hz, Ar–H).

Found: C, 66.93; H, 8.79%. Calcd for $C_{22}H_{34}O_4$: C, 66.96; H, 8.63%.

Reaction of 19 with Sodium Hydride. To a stirred mixture of 60% sodium hydride dispersion in mineral oil (6 mg, 0.14 mmol) in DME (1 ml) was added a solution of **19** (50 mg, 0.13 mmol) in DME (1 ml), and the mixture was stirred at 60 °C for 15 h. After cooling, ether was added and the ethereal solution was washed successively with water and brine, and dried. Removal of the solvent left an oil, which was purified by preparative TLC (hexane–ether, 3:1) to give oxetane **20** (10 mg, 30%) and **19** (35 mg, 70%).

20: IR (film) 970 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83, 0.95, and 1.17 (3H, s each, $C(CH_3)_2$ and C–CH_3), 1.98 (3H, s, O–C–CH_3), 1.0—2.0 (11H, m), 2.24 (1H, t, J=6.8 Hz, O–CH_2–C$\underline{H}$), 4.55 (2H, d, J=6.8 Hz, O–$C\underline{H}_2$–CH).

Found: C, 86.39; H, 8.45%. Calcd for $C_{22}H_{26}O$: C, 86.23; H, 8.55%.

2β-Hydroxy-2α,5,5,8aβ-tetramethyl-4aα-decahydro-1β-naphthalenecarbaldehyde (21). To a stirred solution of NCS (400 mg, 3.0 mmol) in toluene (10 ml) was added dropwise at 0 °C a solution of dimethyl sulfide (0.3 ml, 4.1 mmol), and stirring was continued for an additional 30 min. The reaction mixture was cooled at −25 °C, and a solution of **17** (480 mg, 2.0 mmol) in toluene (5 ml) was added. After stirring for 3 h, triethylamine (0.5 ml) was added and the whole was stirred for 30 min, and diluted with ether. The ethereal solution was washed successively with 1% HCl, water and brine, and dried. Removal of the solvent gave an oil, which was chromatographed on silica gel with hexane–ether (4:1) to give **21** (295 mg, 63%) and **17** (50 mg).

21: Crystals; mp 72—73 °C (from hexane–ether); IR (KBr) 3400 and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82 and 0.89 (6H in total, s each, $C(CH_3)_2$), 1.15 and 1.18 (6H in total, s each, C–CH_3 and O–C–CH_3), 1.0—2.8 (11H, m), 2.10 (1H, d, J=3.2 Hz, C$\underline{H}$–CHO), 2.90 (1H, br s, OH), 10.1 (1H, d, J=3.2 Hz, CHO).

Found: C, 75.41; H, 10.86%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

α-(2,6-Dimethyoxy-4-methylphenyl)-(2β-hydroxy-2α,5,5,8aβ-tetramethyl-4aα-decahydro-1β-naphthalenemethanol (22). To a stirred solution of 1,3-dimethoxy-5-methylbenzene[12] (1.272 g, 8.37 mmol) in DME (15 ml) was added dropwise at −60 °C a solution of 1.6 M butyllithium in hexane (5.26 ml, 8.37 mmol). The reaction mixture was stirred at −60 °C for 30 min, and at room temperature for 2 h, and recooled at −60 °C. A solution of **21** (249 mg, 1.05 mmol) in DME (2 ml) was added and the whole was allowed to stir for 2 h over a range of −60 to 0 °C, and then at room temperature for 30 min. After cooling at 0 °C, wet ether followed by water were added, and the product was extracted with ether. The combined extracts were washed with brine and dried. Removal of the solvent left a crystalline residue, whose ^1H NMR spectrum indicated that it is a mixture of stereoisomers with regard to a benzylic hydroxyl group. The residue was chromatographed on silica gel with hexane–ether (1:1) to give **22** (378 mg, 92%) as crystals: Mp 131—133 °C (from hexane–ether); IR (KBr) 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (6H, s, $C(CH_3)_2$), 1.17 (3H, s, C–CH_3), 1.35

(3H, s, O-C-CH_3), 1.0—2.1 (12H, m), 2.32 (3H, s, Ar-CH_3), 3.82 (6H, s, O-CH_3), 4.80 (1H, br s, C-OH), 5.38 (1H, d, J=4.3 Hz, CH-OH), 5.75 (1H, m, CH-OH), 6.35 (2H, s, Ar-H).

Found: C, 73.67; H, 9.85%. Calcd for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81%.

α-Phenyl-2β-hydroxy-2α,5,5,8aβ-tetramethyl-4aα-decahydro-1β-naphthalenemethanol (23). To a stirred solution of **21** (101 mg, 0.42 mmol) in DME (7 ml) was added at −60 °C a solution of 1.8 M phenyllithium in cyclohexane-ether (0.95 ml, 1.69 mmol), and the mixture was stirred for 1 h over a range of −60 to −20 °C, and then at 0 °C for 1 h. The reaction was quenched by addition of aqueous NH_4Cl and the product was extracted with ether. The combined extracts were washed with brine and dried. Evaporation followed by purification of the oily residue by preparative TLC (hexane-ether, 3:1) gave **23** (126 mg, 94%), which crystallized on standing. The ^1H NMR spectrum indicated that it is a mixture of stereoisomers regarding a benzylic hydroxyl group. Recrystallization of the crystals from hexane-ether (5:1) gave analytically pure sample: Mp 155—156 °C; IR (KBr) 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (6H s, $C(CH_3)_2$), 1.01 (3H, s, C-CH_3), 1.35 (3H, s, O-C-CH_3), 1.0—2.0 (11H, m), 2.98 (1H, s, C-OH), 4.23 (1H, d, J=3.6 Hz, CH-OH), 5.35 (1H, br d, J=4 Hz, CH-OH), 7.2—7.58 (5H, Ar-H).

Found: C, 79.82; H, 10.43%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

***r*-1-[(*E*)-2-(2,6-Dimethoxy-4-methylphenyl)ethenyl]-*t*-2-(3-oxobutyl)-1,3,3-trimethylcyclohexane (24).** (a) A solution of **22** (483 mg, 1.24 mmol) and pyridinium chloride (71 mg, 0.62 mmol) in CH_2Cl_2 (10 ml) was stirred at room temperature for 10 min, and washed with brine, and dried. Removal of the solvent gave an oil, which was chromatographed on silica gel with hexane-ether (3:1) to give **24** (459 mg, quantitative) as crystals: Mp 102—103 °C (from hexane-ether); IR (KBr) 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 and 0.95 (6H in total, s each, $C(CH_3)_2$), 1.15 (3H, s, C-CH_3), 1.2—1.7 (7H, m), 1.98 (3H, s, CO-CH_3), 2.33 (3H, s, Ar-CH_3), 2.4—2.6 (2H, m, CH_2-CO), 3.90 (6H, s, O-CH_3), 6.37 (4H, br s, CH=CH and Ar-H).

Found: C, 77.37; H, 9.53%. Calcd for $C_{24}H_{36}O_3$: C, 77.37; H, 9.74%.

(b) A solution of **22** (91 mg, 0.23 mmol) and PPTS (5 mg) in CH_2Cl_2 (2 ml) was stirred at room temperature for 20 min. The solvent was removed and a crystalline residue was purified by preparative TLC (hexane-ether, 1:1) to give **24** (83 mg, 97%).

***t*-2-(3-Oxobutyl)-1,3,3-trimethyl-*r*-1-[(*E*)-styryl]cyclohexane (25).** A solution of **23** (34 mg, 0.11 mmol) and *p*-toluenesulfonyl chloride (31 mg, 0.2 mmol) in pyridine (1 ml) was stirred at 60 °C for 2 d. After cooling, water was added and the product was extracted with ether. The combined extracts were washed successively with aqueous copper(II) sulfate, water, and brine and dried. Evaporation left an oil, which was purified by preparative TLC (hexane-ether, 2:3) to give **25** (18 mg, 58%): IR (film) 1710 and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 and 0.94 (6H in total, s each, $C(CH_3)_2$), 1.14 (3H, s, C-CH_3), 1.95 (3H, s, CO-CH_3), 1.0—2.3 (11H, m), 5.95 and 6.23 (2H in total, d each, J=16.2 Hz, CH=CH), 7.3 (5H, br s, Ar-H).

Found: C, 84.45; H, 10.05%. Calcd for $C_{21}H_{30}O$: C, 84.51; H, 10.13%.

Methyl *t*-2-[3,3-(Ethylenedioxy)butyl]-1,3,3-trimethyl-*r*-1-cyclohexanecarboxylate (29). A mixture of **24** (83 mg, 0.22 mmol), ethylene glycol (28 mg, 0.44 mmol), *p*-toluenesulfonic acid (5 mg) and benzene (10 ml) was refluxed azeotropically for 5 h. After cooling, aqueous $NaHCO_3$ was added and the product was extracted with ether. The combined extracts were washed with brine and dried. The oily residue obtained by evaporation was filtered through a short silica-gel column with hexane-ether (1:1) to give acetal **27** (84 mg, 91%) as crystals: Mp 107—108 °C (from hexane-ether); ^1H NMR ($CDCl_3$) δ=0.94 and 0.97 (6H in total, s each, $C(CH_3)_2$), 1.13 (3H, s, C-CH_3), 1.22 (3H, s, O-CH_3), 1.0—1.8 (11H, m), 2.32 (3H, s, Ar-CH_3), 3.80 (4H, s, O-$(CH_2)_2$-O), 6.38 and 6.40 (4H in total, s each, CH=CH and Ar-H).

To a stirred solution of **27** (143 mg, 0.35 mmol) in CH_2Cl_2 (20 ml) was passed ozone at −78 °C for 20 min. After the excess ozone was removed by bubbling through with N_2, dimethyl sulfide (0.5 ml) was added, and the mixture was stirred at −78 °C for 1 h and at room temperature for 30 min. Evaporation left an oil, which was chromatographed on silica gel with hexane-ether (1:2) to give **28** (46 mg, 52%): IR (film) 3300—2800, 1700, and 1050 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 and 0.92 (6H in total, s each, $C(CH_3)_2$), 1.18 (3H, s, C-CH_3), 2.09 (3H, s, O-C-CH_3), 1.0—1.8 (11H, m), 3.90 (4H, s, O-$(CH_2)_2$-O), 7.7 (1H, br, CO_2H).

To a stirred solution of **28** (40 mg, 0.15 mmol) in ether (5 ml) was added at 0 °C a solution of diazomethane in ether. Evaporation and purification of the oily residue by preparative TLC (hexane-ether, 3:1) gave **29** (41 mg, quntitative): IR (film) 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 and 0.93 (6H in total, s each, $C(CH_3)_2$), 1.18 (3H, s, C-CH_3), 1.28 (3H, s, O-C-CH_3), 1.0—2.0 (11H, m), 3.63 (3H, s, O-CH_3), 3.91 (4H, s, O-$(CH_2)_2$-O).

Found: C, 68.40; H, 10.29%. Calcd for $C_{17}H_{30}O_4$: C, 68.42; H, 10.13%.

4-(2,2,6-Trimethyl-*t*-6-vinylcyclohex-*r*-1-yl)-2-butanone Ethylene Acetal (32). To a stirred mixture of lithium aluminium hydride (14 mg, 0.36 mmol) in THF (4 ml) was added at 0 °C a solution of **29** (54 mg, 0.18 mmol) in THF (1 ml), and the reaction mixture was stirred at room temperature for 7 h, and quenched by addition of wet ether. A solid was filtered and washed with ether. The combined filtrate and wash were dried and evaporated to give an oil. Filtration through a short silica-gel column with hexane-ether (1:1) gave **30** (48 mg, quantitative): IR (film) 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80 and 0.89 (9H in total, s each, $C(CH_3)_2$ and C-CH_3), 1.0—1.9 (12H, m), 1.33 (3H, s, O-C-CH_3), 3.0—3.3 (2H, m, CH_2-OH), 3.96 (4H, s, O-$(CH_2)_2$-O).

Chromium(VI) oxide (118 mg) was added at 0 °C to a stirred solution of pyridine (0.2 ml) in CH_2Cl_2 (4 ml). After stirring for 1 h, Celite 545 (400 mg) followed by a solution of **30** (32 mg, 0.12 mmol) in CH_2Cl_2 (2 ml) was added. After stirring for 10 min, sodium hydrogensulfate monohydrate (400 mg) was added and the whole was stirred for 10 min. Filtration followed by evaporation of the filtrate left an oil, which was purified by preparative TLC (hexane-ether, 3:1) to give **31** (30 mg, quantitative): IR (film) 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 and 0.97 (6H in total, s each, $C(CH_3)_2$), 1.10 (3H, s, C-CH_3), 1.28 (3H, s, O-C-CH_3), 1.0—1.8 (11H, m), 3.90 (4H, s, O-$(CH_2)_2$-O), 9.30 (1H, s, CHO).

To a stirred suspension of 60% sodium hydride dispersion in mineral oil (10 mg, 0.25 mmol) in toluene (0.5 ml) was added a solution of 1-pentanol (23 mg) in toluene (0.5 ml), and the mixture was stirred at 60 °C for 1 h. After cooling, methyltriphenylphosphonium bromide (98 mg, 0.27 mmol) was added, and the resulting mixture was stirred at room temperature for 1 h. To a yellow suspension obtained, a solution of **31** (32 mg, 0.12 mmol) in toluene (0.5 ml) was added, and the whole was allowed to stir for 10 h, and then quenched by addition of wet ether. The ethereal solution was washed successively with water and brine, and dried. Removal of the solvent gave an oil, which was purified by preparative TLC (hexane–ether, 2:1) to give **32** (24 mg, 77%): IR (film) 3060, 1630, and 910 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (6H, s, $C(CH_3)_2$), 1.08 (3H, s, $C-CH_3$), 1.38 (3H, s, $O-C-CH_3$), 1.0—1.8 (11H, m), 3.98 (4H, s, $O-(CH_2)_2-O$), 4.90, 5.02, and 5.77 (3H in total, ABX system, J=18, 9, and 1.8 Hz, $CH=CH_2$).

4-(2,2,6-Trimethyl-*t*-6-vinylcyclohex-*r*-1-yl)-2-butanone (5). A solution of **32** (20 mg, 0.08 mmol) and PPTS (5 mg) in acetone (2 ml) was stirred at 40 °C for 5 h. Removal of the solvent left an oil, whose purification by preparative TLC (hexane–ether, 4:1) gave **5** (18 mg, quantitative). The physical data (IR and ^1H NMR) were identical of those of natural **5** reported by Enzell.[6]

The radical decarboxylation reaction of *N*-alkoxyoxalyloxy-2-thiopyridone which was prepared by the reaction of alcohol, oxalyl chloride, and *N*-hydroxy-2-thiopyridone was studied both in the absence and presence of olefinic compounds. The same reactions with olefinic and acetylenic alcohols gave the corresponding lactone derivatives. On the other hand the unsymmetrical alkyl 2-pyridyl disulfides were obtained by the same reaction with aliphatic thiols.

Recently, free radical reactions have been used in organic synthesis extensively and their high functional abilities have been recognized.[1] In those reactions, Barton's method which is the radical decarboxylation reaction of thiohydroxamic esters (*O*-acyl derivatives of *N*-hydroxy-2-thiopyridone) prepared from carboxylic acid chlorides and *N*-hydroxy-2-thiopyridone, is very attractive because both the reaction procedure and the purification of the reaction products are simple.[2] We studied this reaction for intermolecular carbon–carbon bond formation with olefinic compounds previously.[3] On the other hand a few reports on the same radical decarboxylative reaction with alcohols instead of carboxylic acids have been known.[4] But in those reports, the reactions only with tertiary alcohols were studied and detailed study was not carried out.

As the applications of this decarboxylation reaction to other functional groups instead of carboxylic acids, herein we report the reactions with alcohols, amines, and thiols.

Table 1. Decarboxylative Reaction of Alcohols **1** to Sulfide **4** and S-2-Pyridyl Thiocarbonate **5**[a]

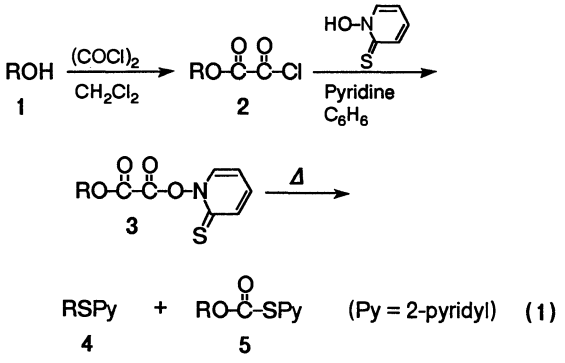
		Dichloromethane[c]	40	0	75

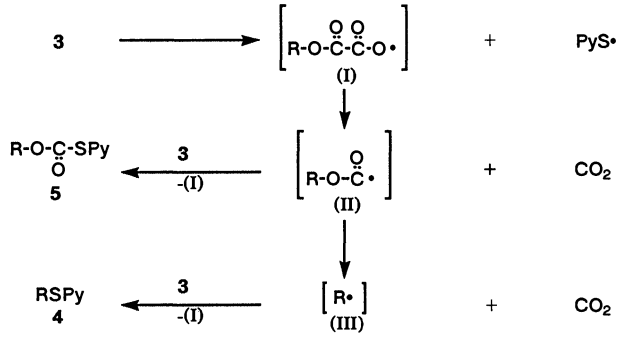
a) The reaction was carried out in refluxing conditions. b) Diethyl oxalate and 2,2′-dipyridyl disulfide were obtained in 26 and 34% yields, respectively. c) The reaction was carried out under irradiation conditions (500 W tungsten lamp) at −16—−18 °C.

Results and Discussion

I). The Reaction with Saturated Alcohols. At first, when the reaction was carried out with 1-octanol we obtained both compounds; **4a** as a minor product and **5a** as a major product. The mixed diester **3**, which is prepared in situ from the corresponding alcohol, oxalyl chloride, and *N*-hydroxy-2-thiopyridone, is so unstable that it is hydrolyzed on silica gel TLC plate easily and completely. But **3** can be observed both by NMR and IR measurements as a crude state. Thus **3k** which was prepared from ethyl chloroglyoxylate with *N*-hydroxy-2-thiopyridone at 0 °C was obtained as a yellow oil, which was unstable on TLC, sunlight, and heat. The compound (**3k**) had two characteristic carbonyl absorptions in its IR spectrum and gave ethyl *S*-2-pyridyl thiocarbonate (**5k**) by heating in benzene. The same reaction was carried out with some primary, secondary, tertiary, and benzylic alcohols as shown in Table 1.



The reaction probably proceeds as follows: Cleavage of N–O bond[2] of ester (**3**) followed by decarboxylation gives alkoxycarbonyl radical (**II**). In the case of primary and secondary alcohols, the dissociation energies of C–O bond are large as compared with those of tertiary and benzylic alcohols.[5] Thus the major product of the former two compounds is a *S*-2-pyridyl thiocarbonate, while that of the latter two compounds is a 2-pyridylthio compound. Especially in both benzylic alcohols and α-hydroxyester, the corresponding 2-pyridylthio compounds **4** were formed dominantly. The result in the reaction with **3j** suggests that the formed benzylic radical does not cyclize to give chroman derivative because of the high stability of benzylic radical.



Scheme 1.

II). Inter- and Intramolecular Carbon–Carbon Bond Formations. Then, we attempted carbon–carbon bond formation starting from alcohol via alkoxycarbonyl radical (**II**) or alkyl radical (**III**) in the presence of phenyl vinyl sulfone. The reaction was carried out by dropping of the prepared chloroglyoxylic ester (**2**) to the mixture of sodium salt of *N*-hydroxy-2-thiopyridone and phenyl vinyl sulfone in refluxing benzene. The results were shown in Table 2.

In the case of cyclohexanol, the major product was **7**, which was formed by the reaction of decarboxylated radical (**II**) with phenyl vinyl sulfone. While the activated alcohol like benzyl alcohol gave **6** as a major product by the reaction of double decarboxylated radical (**III**) with phenyl vinyl sulfone. But, in *p*-nitrobenzyl alcohol (**1h**), *p*-nitrobenzyl 2-pyridyl sulfide was obtained as a sole product. The reason is that the addition reaction of (**IIIh**) onto phenyl vinyl sulfone is reversible as shown in Eq. 3 and its equilibrium declines to left-hand side probably because the high stability of (**IIIh**) as compared with the adduct radical (**IVh**). Next we tried to trap the formed benzyloxycarbonyl radical with 5-*exo* cyclization method starting from **1I**. But the 5-*exo*-trig cyclized lactone derivative (**9I**) was not obtained (Eq. 4). This result suggests that the rate of decarboxylation reaction of (**II**) to (**III**) in benzylic alcohols is perhaps over $>10^5\ s^{-1}$.[6]

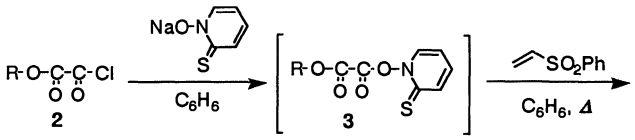
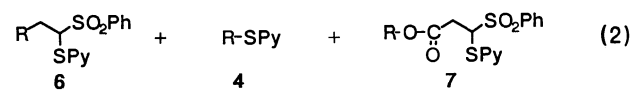
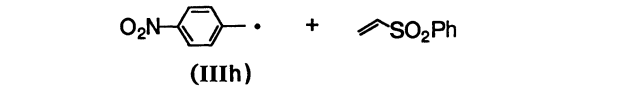
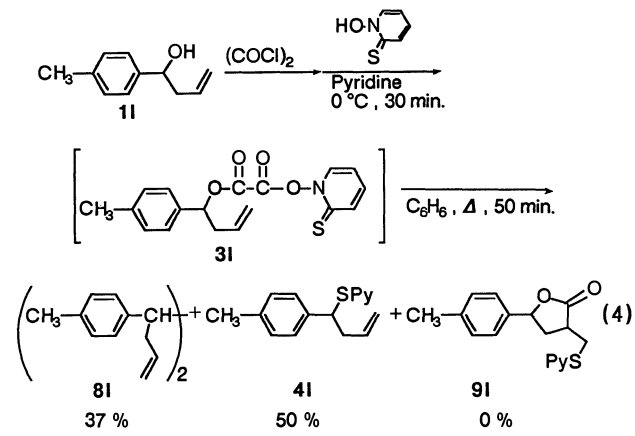
1i		44	12	0

a) The yields were determined by NMR. b) Without H_2NNH_2 treatment.

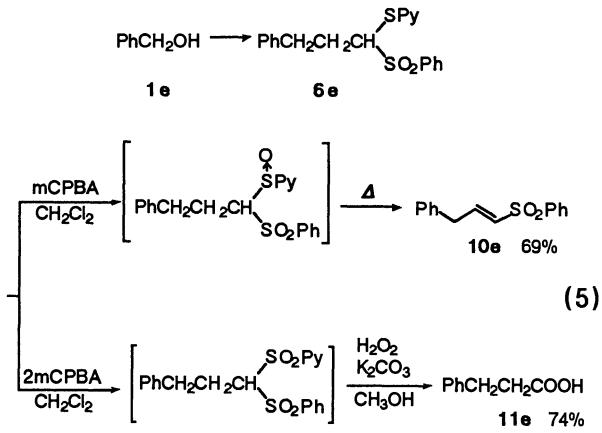








Adduct (**6e**) in Table 2 was converted to the other useful compounds as shown in Eq. 5. Particularly the conversion to carboxylic acid (**11e**) is equivalent to the preparation of C_2-gained carboxylic acid from alcohol.



As mentioned above, the alkoxycarbonyl radical (**II**) formed from non-activated alcohol like primary and secondary alcohols does not decarboxylate to give (**III**). This result suggests that the formed alkoxycarbonyl radical (**II**) can be captured by olefinic groups via intra- and intermolecular carbon-carbon bond formation. Thus, when we carried out this reaction with 3-buten-1-ol (**1m**),[7] the γ-butyrolactone derivative (**12m**), which was a very important component for the synthesis of natural products,[8] was obtained in a moderate yield via intramolecular radical cyclization (5-*exo*-trig) as shown in Table 3 and Scheme 2.

A similar kind of reaction, which was the formation of α-methylene-γ-butyrolactone derivatives by the

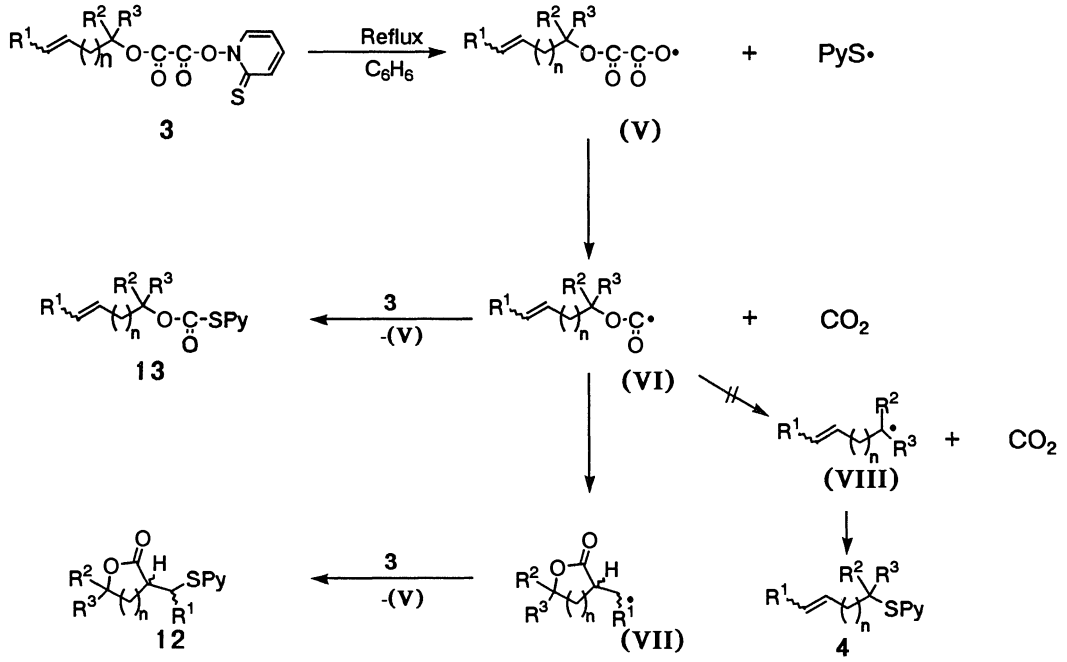
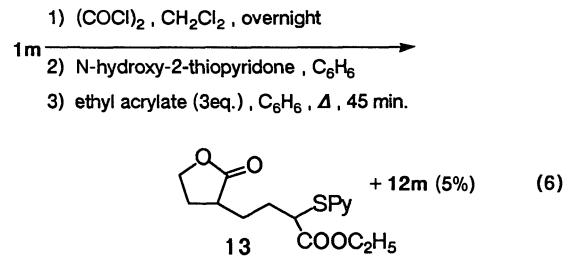


Scheme 2. Reaction Pathway (n=1, 2)

reaction of chloroformates, *Se*-phenyl selenocarbonates, and *S*-methyl dithiocarbonates of homopropargylic alcohol derivatives with Bu_3SnH[9] and Bu_3SnH/Et_3B[10], was reported recently. But in our system, γ-butyrolactone derivatives can be obtained in one pot reaction from olefinic and acetylenic alcohols, and further this reaction does not require the toxic organotin compounds. γ-Butyrolactone derivatives (**12o** and **12p**) could be also obtained in moderate yields from sec- and tert-alcohols (**1o** and **1p**), respectively. Then, the obtained lactone (**12m**) was oxidized with mCPBA (1.1 equiv) and the sulfoxide thus formed was heated at about 100 °C under reduced pressure to give α-methylene-γ-butyrolactone in 49% yield, which was tulipalin A isolated from tulip bulbs.[11] Both *trans* and *cis* isomers of 3-hexen-1-ol (**1n**) gave **12n** in good yields and the ratios of the formed diastereomers of **12n** in both reactions were same. This result suggests that both reactions proceed via the same intermediate (**VIIn**) to give **12n**. While, the use of 4-penten-1-ol (**1q**) yielded *S*-2-pyridyl thiocarbonate (**5q**) as a sole product. This result can be explained by the big difference in the cyclization rates between 3-butenoxycarbonyl radical (**VIm**) and 4-pentenoxycarbonyl radical (**VIq**). Thus, the difference is deduced from the cyclization rates of 5-hexenyl radical (k=2.3×10^5 s^{-1} at 25 °C) and 6-heptenyl radical (k=5.4×10^3 s^{-1} at 25 °C), respectively.[12] However, the formation of δ-valerolactone could be accelerated by adding dropwise a chloroglyoxylic ester (**2q**) (chloroglyoxylic ester of **1q**) to the sodium salt of *N*-hydroxy-2-thiopyridone in benzene. By this procedure, δ-valerolactone was obtained in 18% yield. While 3-propanolide could not be obtained from allyl alcohol.



Further, the present reaction was carried out in the presence of ethyl acrylate to give an ester (**13**) in 40% yield, which was formed via both intra- and intermolecular radical reactions, along with **12m**. Finally α-pyridylthiomethylene-γ-butyrolactone was obtained in 40% yield from 3-butyn-1-ol (**1r**) by this system.

The formations of **12o** and **12p** mean that the formed carbonyl radicals (**VIo**) and (**VIp**) cyclize before the decarboxylation to alkenyl radicals (**VIIIo**) and (**VIIIP**), and therefore the sulfides (**4**) were not formed. While, in these reactions the small amount (≤10%) of dialkenyl oxalates were observed after the reaction. Most of these products were formed by radical coupling reaction[13] of alkenoxycarbonyl radicals (**VI**) because they were not formed during the preparation of **3**. The same reaction was carried out with diethylamine and *N*-(3-butenyl)aniline. In the former reaction, **15**, an *N*-analogue compound of **5**, was obtained in good yield in the presence of triethylamine. While the latter amine gave the cyclized

product (**16**), a γ-lactam derivative, but the yield was low. Even when the dropping procedure of dialkylamidooxalyl chloride to *N*-hydroxy-2-thiopyridone in benzene was employed, the major product was **15**. So, we believe that the cyclization rate of (**IX**) is larger than that of (**X**).

Then we carried out this reaction in the presence of olefinic compound. If the adduct compound (**7**) could be obtained, it would be easily converted to α,β-unsaturated ester (**17**) as shown in Scheme 3. Practically, the alkoxycarbonyl radical (**II**) formed from alcohol (Scheme 1), reacted with some olefinic compounds to give the corresponding adducts (**7**) in good to moderate yields depending upon the olefinic compounds via intermolecular radical addition reaction.

The results in Table 5 suggests that the alkoxycarbonyl radical is nucleophilic. Therefore the yield of addition product with phenyl vinyl sulfone was high, while that with 1-dodecene was lower. These obtained compounds (**7**) were oxidized by mCPBA to give the corresponding sulfoxides which were then heated in benzene to give α,β-unsaturated esters (**17**) in good yields.

III). The Reaction with Thiols. We also studied the radical decarboxylative reaction with thiols. Phenylmethanethiol (**18e**) gave benzyl 2-pyridyl sulfide (**4e**) as a main product like benzyl alcohol. While, cyclohexanethiol (**18b**) and methyl 3-mercaptopropionate (**18t**) gave the corresponding unsymmetrical disulfides (**19b** and **19t**) which disproportionated slowly to two symmetrical disulfides respectively.

This result suggests that the formed alkylthiocarbonyl radical easily decomposes to give alkylthio radical (**XIII**) and carbon monooxide. Even when the reaction was carried out with 3-hexene-1-thiol, the major product was the corresponding unsymmetrical disulfide (**19n**). Therefore, the fragmentation reaction of (**XII**) to (**XIII**) should be extremely fast.

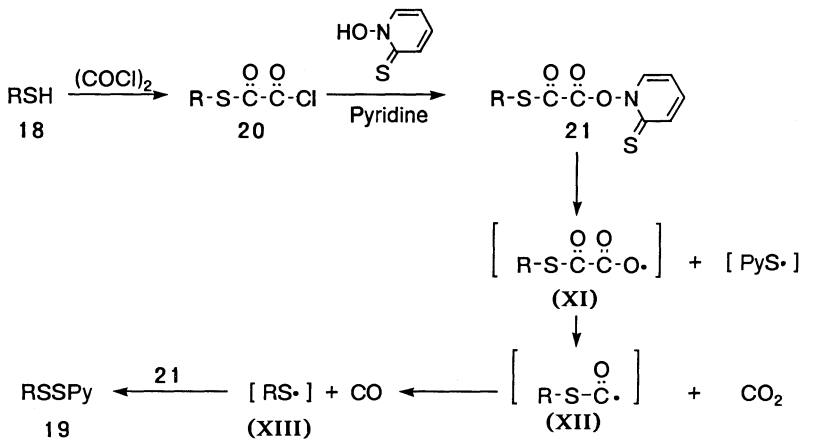
In conclusion, the radical decarboxylative reactions of *N*-alkoxyoxalyloxy-2-thiopyridones which were prepared from activated alcohols, oxalyl chloride, and *N*-hydroxy-2-thiopyridone gave the corresponding sulfides or C–C bonded compounds in the presence of olefinic compounds. On the other hand those reactions with general prim-, sec-, tert-alcohols, and dialkylamines gave the corresponding *S*-2-pyridyl thiocarbonates and thiocarbamates respectively, and the cyclized products, γ-lactones and γ-lactams were obtained starting from 3-olefinic alcohols or amines in one-pot reaction via intramolecular radical cycliza-



Schme 4.

tion. And further the intermolecular radical addition reactions with alcohols onto olefins gave the adducts which were easily converted to the α,β-unsaturated esters. On the other hand, the reactions with thiols gave the unsymmetrical disulfides via alkylthio radical.

Experimental

Microanalyses were performed with a Perkin-Elmer 240 elemental analyser at the Chemical Analysis Center of Chiba University. IR and ^{1}H NMR spectra were measured with Hitachi 215, JEOL-MH-100, JEOL-JNM-FX270, and JEOL-GSX-500 spectrometers, respectively. Wakogel C-200 was used for column chromatography, Kieselgel 60 F_{254} (Merck) was used for TLC, and Wakogel B-5F was used for preparative TLC (pTLC).

N-hydroxy-2-thiopyridone is commercially available as aqueous solution of sodium salt (sodium omadine). This solution (100 ml) was treated with concd HCl at pH 2, and the formed precipitates were separated by filtration and recrystallized from methanol. Sodium salt of *N*-hydroxy-2-thiopyridone was prepared as follows. To the ice-cold solution of *N*-hydroxy-2-thiopyridone (50 mmol) in methanol (100 ml) was added the ice-cold solution of sodium hydroxide (50 mmol) in methanol (100 ml). Then solvent was removed and the residue was washed with benzene and dried with vacuum pump.

1) The Preparation of *N*-Ethoxyoxalyloxy-2-thiopyridone 3k. To ethyl chloroglyoxylate (3.2 mmol) in benzene (7 ml) were added *N*-hydroxy-2-thiopyridone (3 mmol) and pyridine (4 mmol) dissolved in benzene (3 ml) under cooling by ice bath. Then the reaction mixture was stirred at 0 °C for 30 min. During this reaction, the reaction vessel was wrapped with aluminium foil tightly. Then, the reaction mixture was filtered quickly and the filtrate was evaporated to give **3k** as a yellow oil in quantitative yield.

3k: Oil; ^{1}H NMR ($CDCl_3$) δ=1.40 (t, 3H, J=6.7 Hz, $-CH_3$), 4.40 (q, 2H, J=6.7 Hz, $-CH_2-$), 7.00—7.30 (m, 2H, aromatic-4, 5H), 7.72 (dd, 1H, J=7.6, 2.7 Hz, aromatic-3H), 8.10 (dd, 1H, J=6.1, 2.7 Hz, aromatic-6H); IR (NaCl) 1810, 1730—1760 cm^{-1}.

2) General Procedure for the Conversion of Alcohol to 2-Pyridyl Sulfide. A solution of alcohol (2 mmol) in dichloromethane (2 ml) was added to a mixture of oxalyl chloride (1 ml, 11 mmol) and dichloromethane (3 ml). After keeping at room temperature overnight, the excess chloride and solvent were removed by evaporation. Then, the reaction vessel was wrapped with aluminium foil tightly, and benzene (3 ml), *N*-hydroxy-2-thiopyridone (2.1 mmol), and pyridine (3 mmol) in benzene (2 ml) were added successively at 0 °C. After stirring at 0 °C for 30 min, the obtained yellow solution was refluxed for one hour. Then the solvent was removed and the residue was washed with water and purified by pTLC. (eluent; $CHCl_3$). The reaction with thiols was carried out by using the same procedure.

4a: Oil; ^{1}H NMR (CCl_4) δ=0.85 (t, 3H, J=6.1 Hz, $-CH_3$), 1.20—1.80 (m, 12H, $-(CH_2)_2-$), 3.10 (t, 2H, J=7.6 Hz, $-CH_2S$), 6.70—7.40 (m, 3H, Py-3, 4, 5H), 8.30 (d, 1H, J=6.1 Hz, Py-6H); IR (NaCl) 2900, 2840, 1575, 1553 cm^{-1}.

19b: Oil; ^{1}H NMR (CCl_4) δ=1.08—2.12 (m, 10H, $-(CH_2)_5-$), 2.60—2.98 (br, 1H, CH), 6.77—7.02 (m, 1H, Py-5H), 7.30—7.70 (m, 2H, Py-3, 4H), 8.22 (d, 1H, J=4.5 Hz, Py-6H); IR (NaCl) 1570, 1560, 1418, 1122 cm^{-1}.

Found: C, 58.57; H, 6.74; N, 6.20%. Calcd for $C_{11}H_{15}NS_2$: C, 58.62; H, 6.71; N, 6.22%.

19e: Oil; ^{1}H NMR (CCl_4) δ=3.92 (s, 2H, $-CH_2$), 6.72—7.34 (m, 8H, Ph, Py-3, 4, 5H), 8.20 (d, 1H, J=4.5 Hz, Py-6H);

IR (NaCl) 1560, 1392, 1412, 1115 cm^{-1}.

19t: Oil; ^1H NMR (CCl_4) δ=2.55—3.06 (m, 4H, $-CH_2CH_2-$), 3.60 (s, 3H, $-CH_3$), 6.76—6.96 (m, 1H, Py-5H), 7.34—7.60 (m, 2H, Py-3, 4H), 8.26 (d, 1H, J=4.5 Hz, Py-6H); IR (NaCl) 1732, 1570, 1560, 1418, 1360, 1250, 1150, 1120 cm^{-1}.

Found: C, 47.00; H, 4.88; N, 6.04%. Calcd for $C_9H_{11}NO_2S_2$: C, 47.13; H, 4.83; N, 6.11%.

19n: Oil; ^1H NMR ($CDCl_3$) δ=0.95 (t, 3H, J=7.6 Hz, $-CH_3$), 1.80—2.10 (m, 2H, $-CH_2-$), 2.20—2.50 (m, 2H, $-CH_2-$), 2.85 (t, 2H, J=7.6 Hz, $-SCH_2-$), 5.35—5.60 (m, 2H, -CH=CH-), 6.90—7.20 (m, 1H, Py-5H), 7.40—7.80 (m, 2H, Py-3, 4H), 8.50 (d, 1H, J=4.5 Hz, Py-6H); IR (NaCl) 1560, 1442, 1416, 1120 cm^{-1}.

Found: C, 59.24; H, 7.09; N, 5.51%. Calcd for $C_{11}H_{15}NS_2$: C, 58.62; H, 6.71; N, 6.22%.

3) Typical Procedure for the C-C Bond Formation. A solution of a chloroglyoxylic ester (**2**) (2 mmol) prepared as described above in benzene (8 ml) was added dropwise to the refluxing solution of sodium salt of *N*-hydroxyl-2-thiopyridone (2.1 mmol) and phenyl vinyl sulfone (10 mmol) in benzene (4 ml) over one hour. After the addition, refluxing was continued for one hour. Then the solvent was removed and the residue was diluted with THF (16 ml) and hydrazine (1.6 g) was added at 0 °C. After the addition, the ice bath was removed and the solution was stirred at room temperature for 10 min. Then the solvent was removed by evaporation and the residue was chromatographed on silica gel (eluent; CH_2Cl_2:Et_2O=9:1).

6b: Mp 78.2—79.5 °C; ^1H NMR (CCl_4) δ=0.64—2.34 (m, 13H, cyclohexyl), 5.53 (dd, 1H, J=12.0, 3.6 Hz, CH), 6.62—6.91 (m, 3H, aromatic), 7.03—7.34 (m, 5H, aromatic), 7.60—7.84 (m, 2H, aromatic), 8.06 (d, 1H, J=4.5 Hz, Py-6H); IR (Nujol) 1575, 1555, 1420, 1380, 1310, 1300, 1155 cm^{-1}.

6e: Mp 85.0—86.0 °C; ^1H NMR (CCl_4) δ=1.78—3.06 (m, 4H, $-CH_2CH_2-$), 5.50 (dd, 1H, J=10.5, 3.6 Hz, CH), 6.58—7.32 (m, 11H, aromatic), 7.58—7.80 (m, 2H, aromatic), 7.84—8.06 (m, 1H, Py-6H); IR (KBr) 1570, 1415, 1305, 1290, 1145, 1125 cm^{-1}.

Found: C, 64.97; H, 5.20; N, 3.80%. Calcd for $C_{20}H_{19}NO_2S_2$: C, 65.01; H, 5.18; N, 3.79%.

6f: Mp 88.2—89.5 °C; ^1H NMR (CCl_4) δ=2.22 (s, 3H, $-CH_3$), 2.34—3.02 (m, 4H, $-CH_2CH_2-$), 5.50 (dd, 1H, J=10.5, 3.0 Hz, CH), 6.58—7.43 (m, 10H, aromatic), 7.36—7.77 (m, 2H, $PhSO_2$-2, 6H), 7.95 (d, 1H, J=4.5 Hz, Py-6H); IR (KBr) 1570, 1560, 1515, 1415, 1305, 1290, 1150, 1120 cm^{-1}.

Found: C, 65.64; H, 5.51; N, 3.60%. Calcd for $C_{21}H_{21}NO_2S_2$: C, 65.75; H, 5.52; N, 3.65%.

6g: Mp 90.7—91.5 °C; ^1H NMR (CCl_4) δ=1.88—3.08 (m, 4H, $-CH_2CH_2-$), 5.42 (dd, 1H, J=10.5, 3.6 Hz, CH), 6.62—7.38 (m, 11H, aromatic), 7.60—7.82 (m, 2H, $PhSO_2$-2, 6H), 7.96 (d, 1H, J=4.5 Hz, Py-6H); IR (NaCl) 1575, 1560, 1495, 1417, 1310, 1155, 1128 cm^{-1}.

Found: C, 59.39; H, 4.55; N, 3.47%. Calcd for $C_{19}H_{18}NO_2S_2Cl$: C, 59.39; H, 4.63; N, 3.57%.

6i: Oil (diastereomeric mixture); ^1H NMR (CCl_4) δ=1.27 (d, 3H, J=6.0 Hz, CH_3), 1.80—2.20 (m, 1H, CH), 2.36—2.77 (m, 1H, CH), 3.03 (bs, 1H, CH), 5.14 (dd, 1/2H, J=12.0, 3.3 Hz, $CHSO_2$), 6.64 (dd, 1/2H, J=10.5, 3.3 Hz, $CHSO_2$), 6.54—7.40 (m, 11H, aromatic), 7.31—7.84 (m, 2H, $PhSO_2$-2, 6H), 7.97 (d, 1H, J=3.6 Hz, Py-6H); IR (NaCl) 1578, 1560, 1500, 1420, 1320, 1310, 1150, 1122 cm^{-1}.

Found: C, 65.66; H, 5.51; N, 3.59%. Calcd for $C_{21}H_{21}NO_2S_2$: C, 65.76; H, 5.52; N, 3.65%.

4) Conversion of Compound 6e to Vinyl Sulfone 10e. To **6e** (0.28 g, 0.77 mmol) in dichloromethane (8 ml) at 0 °C was added *m*-chloroperbenzoic acid (0.21 g, 1.1equiv). Then, ice bath was removed and the reaction mixture was stirred at room temperature for one hour. The reaction mixture was washed with sat. aq $NaHCO_3$ and water. The organic layer was dried over Na_2SO_4, filtered, and the solvent was removed. 1 M-HCl (10 ml 1 M=1 mol dm^{-3}) was added to the residue and the mixture was heated at 100 °C for 2 h. The organic components were extracted with ethyl acetate, and dried over Na_2SO_4. After the purification by pTLC. (eluent; $CHCl_3$:AcOEt=40:1), 0.14 g of **10e** was obtained (69% yield).

10e: Mp 107—109 °C (Et_2O/hexane); ^1H NMR (CCl_4, $CDCl_3$) δ=7.84—6.82 (m, 11H, aromatic and -CH=), 6.11 (d, 1H, J=13.5 Hz, -CH=), 3.40 (d, 2H, J=6.0 Hz, $-CH_2-$); IR (KBr) 1310, 1150 cm^{-1}.

Found: C, 69.55; H, 5.51%. Calcd for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%.

5) Conversion of 6e to Dihydrocinnamic Acid 11e. To **6e** (0.28 g, 0.76 mmol) in dichloromethane (6 ml) was added mCPBA (0.56 g, 3 equiv) under cooling by ice bath. Then, the reaction mixture was stirred at room temperature for 5 h. The reaction mixture was poured into ether, wased with sat. aq $NaHCO_3$, and dried over Na_2SO_4 to give disulfone as a crude state. The formed disulfone was dissolved in methanol containing K_2CO_3 (8 mmol). Hydrogen peroxide (30%) was added dropwise to the solution under refluxing conditions for 3 h. After the reaction was completed, the solvent was removed and the residue was acidified with concd. HCl and then extracted with ether to give dihydrocinnamic acid in 74% yield which was identified with authentic commercial compound.

6) General Procedure for the Preparation of γ-Lactones 12. Dichloromethane solution containing olefinic alcohol (2 mmol) were added to a stirred oxalyl chloride (0.8—1.5 ml) at room temperature and the mixture was stirred overnight. After the evaporation of solvent and excess oxalyl chloride, *N*-hydroxy-2-thiopyridone (2.1 mmol) and 4 ml of dry benzene solution of pyridine (3 mmol) were added to the mixture and the resulting solution was stirred at 0 °C for 30 min under nitrogen atmosphere. Then the reaction mixture was refluxed for 60 min. After the removal of solvent, compounds (**5** and **12**) were separated by column chromatography on silica gel.

12m: Oil; ^1H NMR ($CDCl_3$, 500 MHz) δ=2.10—2.18 (m, 1H, $-CH_2-$), 2.38—2.45 (m, 1H, $-CH_2-$), 3.05 (dtd, 1H, J=10.5, 8.4, 4.5 Hz, -CHCO-), 3.25 (dd, 1H, J=14.0, 8.4 Hz, $-SCH_2-$), 3.84 (dd, 1H, J=14.0, 4.5 Hz, $-SCH_2-$), 4.16 (td, 1H, J=8.8, 6.6 Hz, $-OCH_2-$), 4.34 (td, 1H, J=8.8, 2.5 Hz, $-OCH_2-$), 6.98 (ddd, 1H, J=7.9, 5.0, 1.0 Hz, Py-5H), 7.17 (dt, 1H, J=7.9, 10 Hz, Py-3H), 7.47 (td, 1H, J=7.9, 2.0 Hz, Py-4H), 8.40 (m, 1H, Py-6H); IR (NaCl) 1765, 1150, 1025 cm^{-1}.

Found: C, 57.22; H, 5.34; N, 6.64%. Calcd for $C_{10}H_{11}NSO_2$: C, 57.39; H, 5.30; N, 6.69%.

5m: Oil; ^1H NMR ($CDCl_3$) δ=2.40 (t, 2H, J=7.6 Hz, $-CH_2-$), 4.23 (t, 2H, J=7.6 Hz, $-OCH_2-$), 4.90—5.20 (m, 2H, $=CH_2$), 5.45—6.00 (m, 1H, =CH-), 7.10—7.20 (m, 1H, Py-5H), 7.55—7.70 (m, 2H, Py-3, 4H), 8.50 (d, 1H, J=6.1 Hz, Py-6H); IR (NaCl) 1720, 1150, 1110 cm^{-1}.

Found: C, 57.72; H, 5.43; N, 6.55%. Calcd for $C_{10}H_{11}NSO_2$:

C, 57.39; H, 5.30; N, 6.69%.

Next, the obtained lactone (**12m**) was oxidized with mCPBA (1.1 equiv) and the sulfoxide thus formed was heated at about 100 °C under reduced pressure to give in 49% yield α-methylene-γ-butyrolactone, which was identified with commercial compound.

13: Oil; ^{1}H NMR ($CDCl_3$, 500 MHz) δ=8.37—8.40 (m, 1H, Py-6H), 7.48—7.51 (m, 1H, Py-3, 4H), 7.19—7.21 (m, 1H, Py-3, 4H), 6.99—7.02 (m, 1H, Py-5H), 4.32—4.38 (m, 1H, $-OCH_2$), 4.14—4.24 (m, 3H, $-OCH_2$), 2.55—2.63 (m, 1H, CHCO), 2.41—2.45 (m, 1H, CHCO), 1.93—2.18 (m, 4H, $-CH_2-$), 1.58—1.69 (m, 2H, $-CH_2-$), 1.22—1.29 (m, 3H, $-CH_3$); IR (NaCl) 1760, 1725, 1245, 1180, 1150, 1025 cm^{-1}.

Found: C, 58.25; H, 6.31; N, 4.26%. Calcd for $C_{15}H_{19}NSO_4$: C, 58.23; H, 6.19; N, 4.53%.

12r: Mp 111—112 °C (AcOEt/Hexane); cis; ^{1}H NMR ($CDCl_3$) δ=2.88 (td, 2H, *J*=7.5, 3.0 Hz, $-CH_2C=$), 4.40 (t, 2H, *J*=7.5 Hz, $-OCH_2-$), 7.00—7.30 (m, 2H, Py), 7.40—7.60 (m, 1H, Py), 8.40—8.55 (m, 2H, Py-6H); IR (NaCl) 1725, 1185 cm^{-1}.

Found: C, 57.98; H, 4.39; N, 6.73%. Calcd for $C_{10}H_9NSO_2$: C, 57.95; H, 4.38; N, 6.76%.

5q: Oil; ^{1}H NMR ($CDCl_3$) δ=1.75 (q, 2H, *J*=6.4 Hz, $-CH_2-$), 2.00—2.25 (m, 2H, $-CH_2-$), 4.20 (t, 2H, *J*=6.8 Hz, $-OCH_2-$), 4.85—5.10 (m, 2H, $CH_2=$), 5.50—6.00 (m, 1H, =CH–), 7.10—7.30 (m, 1H, Py-5H), 7.60—7.70 (m, 2H, Py-3, 4H), 8.50 (d, 1H, *J*=6.1 Hz, Py-6H); IR (NaCl) 1710, 1150, 1110 cm^{-1}.

Found: C, 60.67; H, 6.35; N, 5.87%. Calcd for $C_{11}H_{13}NSO_2$: C, 60.73; H, 6.37; N, 5.90%.

12q: Oil; ^{1}H NMR ($CDCl_3$, 500 MHz) δ=1.64—1.72 (m, 1H, $-CH_2-$), 1.86—1.98 (m, 2H, $-CH_2-$), 2.28—2.35 (m, 1H, $-CH_2-$), 2.91—2.97 (m, 1H, –CH–), 3.33 (dd, 1H, *J*=14.0, 7.40 Hz, $-CH_2-S-$), 3.81 (dd, 1H, *J*=14.0, 5.0 Hz, $-CH_2-S-$), 4.30 (t, 2H, *J*=5.9 Hz, $-OCH_2-$), 6.98 (ddd, 1H, *J*=7.1, 5.0, 1.0 Hz, Py-5H), 7.19 (dt, 1H, *J*=8.3, 1.1 Hz, Py-3H), 7.47 (ddd, 1H, *J*=8.3, 7.1, 1.9 Hz, Py-4H), 8.41 (ddd, 1H, *J*=5.0, 1.9, 1.1 Hz,, Py-6H); IR (NaCl) 1730, 1150, 1130 cm^{-1}.

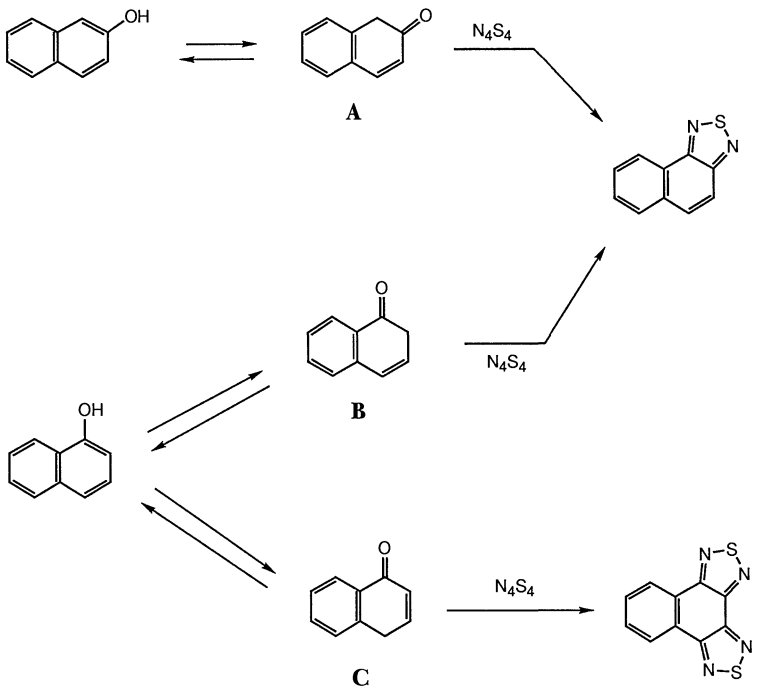
(Received July 21, 1990)

Tetrasulfur tetranitride (N_4S_4) reacted with 2-naphthols to afford naphtho [1,2-*c*][1,2,5] thiadiazoles (**13**) in high yields, while 1-naphthaols gave naphtho[1,2-*c*:3,4-*c'*]bis[1,2,5]thiadiazoles as a major product, together with a small amount of **13**. In the reactions with naphthalenediols such as 1,5-, 2,6-, 2,7-, 1,6-, and 1,7-diol, naphtho[1,2-*c*:5,6-*c'*]- or naphtho[1,2-*c*:7,8-*c'*]bis[1,2,5]thiadiazoles were obtained in varying yields. In some cases, naphtho[1,2-*c*:3,4-*c'*:5,6-*c''*]tris[1,2,5]thiadiazole was formed as a by-product. In reactions with 5-isoquinolinol, 8-quinolinoles, 9*H*-carbazol-2-ol, and dibenzofuran-2-ol, one and/or two 1,2,5-thiadiazole-ring-fused heteroaromatic compounds were obtained.

Recently, it was reported that the reaction of tetrasulfur tetranitride (N_4S_4) (**1**) with phenols and polyhydroxybenzenes afforded benzo-,[2] benzobis-,[1] and benzotris[1,2,5]thiadiazoles.[1] These 1,2,5-thiadiazoles were converted to polyaminobenzenes[1,2] such as benzenediamine, -tetramine, and -hexamine.

It was already reported that the reaction of **1** with benzyl ketone derivatives afforded 4-substituted 3-aryl-1,2,5-thiadiazoles in good yields.[3–5]

As an extention of the above, we investigated the reaction of **1** with naphthalenols from the following viewpoints; in a reaction with 2-naphthol, **1** was expected to attack the benzylic position of tautomer **A**, giving naphtho[1,2-*c*][1,2,5]thiadiazole, while both naphtho[1,2-*c*][1,2,5]thiadiazole and naphtho[1,2-*c*:3,4-*c'*]bis[1,2,5]thiadiazole might be formed in a reaction with 1-naphthol by an attack of **1** on the two tautomers, **B** and **C** (Scheme 1).



Scheme 1.

The present paper describes the reactions of **1** with naphthalenols and some related hydroxy-substituted benzoheterocycles.

Results and Discussion

All reactions of **1** with naphthalenols and hydroxy-substituted benzoheterocycles were carried out in refluxing toluene for 48 h; the results are summarized in Table 1 and Scheme 2.

The reaction of **1** with 1-naphthol (**2a**) afforded naphtho[1,2-*c*][1,2,5]thiadiazole (**13a**) and naphtho-[1,2-*c*:3,4-*c'*]bis[1,2,5]thiadiazole (**14a**) in 9 and 14% yield, respectively. Compound **14a** was obtained from halogenated 1-naphthols, such as 2,4-dichloro-1-naphthol (**2b**) and 2,4-dibromo derivative (**2c**), in better yields than **2a**; the reactions with **2b** and **2c** afforded **14a** in 19 and 27% yield, respectively. In the reaction with **2b**, *N,N'*-thiobis[1,4-naphtoquinone monoimine] (**15**) and 5-chloronaphtho[1,2-*c*][1,2,5]thiadiazole (**13b**) were formed as a side product (3 and 1% yield, respectively).

On the contrary, the reaction with 2-naphthol (**3a**) afforded **13a** as the sole product in fair yield (84%). Similarly, 6-bromo-2-naphthol (**3b**) gave 7-bromo-

Table 1. Reaction of Tetrasulfur Tetranitride (**1**) with Naphthalenols

	Naphthalenols	N_4S_4 (**1**)/substrate[a]	Product/mol %[b]

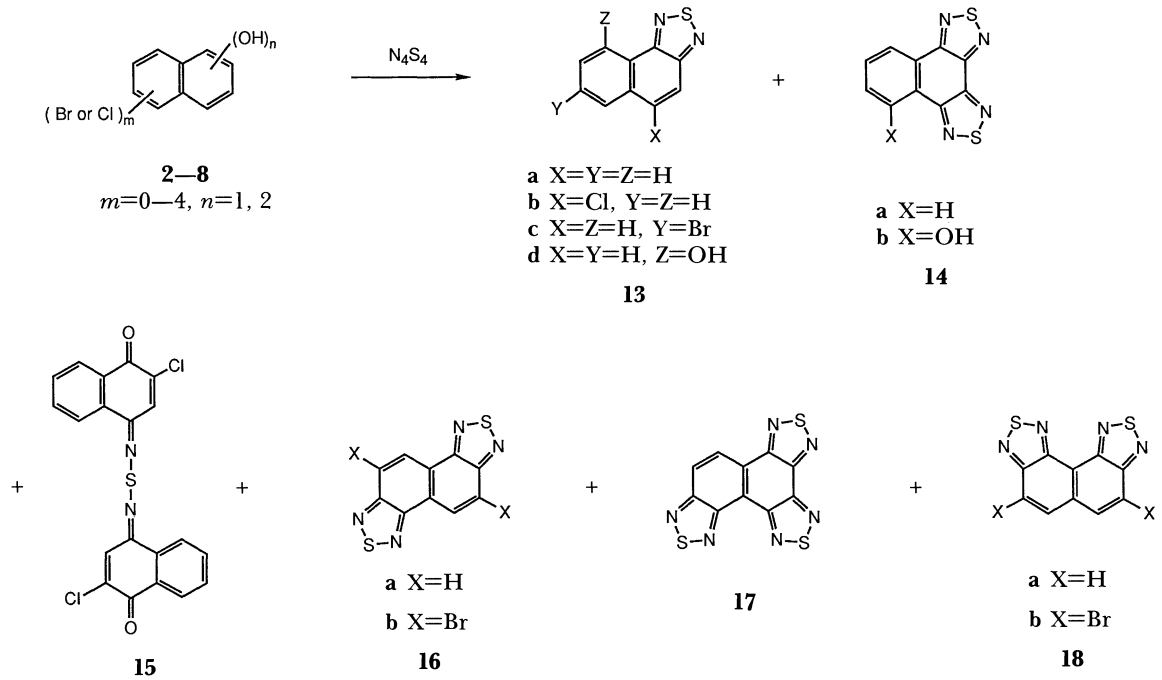
a) Molar ratio. b) Isolated yield; calculated on the basis of the substrate used. c) Plus sign means that the yield is less than 1%.



Scheme 2.

[1,2-*c*][1,2,5]thiadiazole (**13c**) in an almost quantitative yield. Also, 1-bromo-2-naphthol (**3c**) gave the expected **13a** in modest yield (51%).

The above-mentioned results demonstrated the selective construction of the naphthobis[1,2,5]thiadiazole and naphtho[1,2,5]thiadiazole skeleton by a reaction of **1** with 1-naphthol (**2**) and 2-naphthol (**3**), respectively.

Next, the reaction of **1** with naphthalenediols and their halogenated derivatives, which have one hydroxyl group in each benzene ring, was investigated. Since 1,5-naphthalenediol (**4a**) has two hydroxyl groups at the α-positions in each benzene ring, the formation of naphthotetrakis[1,2,5]thiadiazole was expected. The reaction with **4a** afforded naphtho[1,2-*c*:5,6-*c'*]bis[1,2,5]thiadiazole (**16a**) in only 5% yield, accompanied with a trace amount of naphtho[1,2-*c*:3,4-*c*:5,6-*c''*]tris[1,2,5]thiadiazole (**17**). The yields of **16a** and **17** increased to 35 and 11%, respectively, in the reaction with 2,6-dibromo derivative **4b**. In contrast with this result, the 2,4-dibromo derivative **4c** gave naphtho[1,2-*c*:3,4-*c*]bis[1,2,5]thiadiazol-7-ol (**14b**) (9%) as a main product, accompanied by **17** (4%). Finally, a reaction with the 2,4,6,8-tetrabromo derivative **4d** only gave a complex mixture of unidentified products.

Naphthalenes having two hydroxyl groups on the β-positions gave the expected naphthobis[1,2,5]thiadiazoles in a reaction with **1**, generally in good yield. The reaction with 2,6-naphthalenediol (**5a**) afforded naphtho[1,2-*c*;5,6-*c*]bis[1,2,5]thiadiazole (**16a**) in 43% yield. The yield of **16a** was increased up to 88% in a reaction with the 1,5-dibromo derivative **5b**. As expected, the 1,3,5,7-tetrabromo derivative **5c** gave 4,9-dibromo compound **16b** in 61% yield. On the other hand, another β,β'-dihydroxy type, 2,7-naphthalenediol (**6a**), afforded naphtho[1,2-*c*:7,8-*c'*]bis[1,2,5]thiadiazole (**18a**) in only 5% yield, though the reaction with 1,3,6-tribromo derivative **6b** gave 4,7-dibromo compound **18b** in 61% yield.

Since the unsubstituted compound **18a** was obtained only in poor yield, the hydrodebromination of **18b** was carried out by using $NaBH_4$ in refluxing ethanol, giving **18a** in 58% yield (Scheme 3). Compound **18a** became accessible via **18b** in moderate yield. Compound **16b** was sparingly soluble in any organic solvents and could not be reduced to **16a**.

The reaction of naphthalenediols bearing two hydroxyl groups each on the α and β positions gave poor results: **16a** and **18a** were obtained from **7** and **8** in 5 and 2% yield, respectively. In the reaction with **8**, a trace amount of naphtho[1,2-*c*][1,2,5]thiadiazol-9-ol (**13d**) was formed. The 2,6,8-tribromo derivative (**8b**)

Table 2. Reaction of Tetrasulfur Tetranitride (**1**) with Hydroxy-Substituted Benzoheterocycles

Hydroxy-substituted benzoheterocycle[a]	Products/mole %[b]
9	**19** (18)
10a	**20** (25), **21** (7), **10a** (4)
10b	**21** (27)
11	**22** (26), **23** (6)
12	**24** (97)

a) Molar ratio of N_4S_4 (**1**): substrate=2:1. b) Isolated yield; calculated on the basis of the substrate used.

afforded **17** in 8% yield.

The selective construction of mono- and bis[1,2,5]-thiadiazole-fused skeleton was also observed in the reaction of **1** with hydroxy-substituted benzoheterocycles (Table 2 and Scheme 4), though not so remarkable as in the case of the naphthalenols. The reaction of **1** with 5-isoquinolinol (**9**) afforded only bis[1,2,5]thiadiazolo[3,4-*f*:3′,4′-*h*]isoquinoline (**19**) in 18% yield. Unexpectedly, 8-quinolinol (**10a**) afforded [1,2,5]thiadiazolo[3,4-*h*]quinoline (**20**) in 25% yield and bis[1,2,5]-thiadiazolo[3,4-*f*:3′,4′-*h*]quinoline (**21**) in 7% yield with a 4% yield of recovered **10a**. Only **21** was obtained in 27% yield in a reaction with 5,7-dibromo derivative **10b**. The reaction with 9*H*-carbazol-2-ol (**11**) afforded predominantly [1,2,5]thiadiazolo[3,4-*a*]carbazole (**22**) in 20% yield, with bis[1,2,5]thiadiazolo[3,4-*a*:3′,4′-*c*]carbazole (**23**) as a by-product.

As previously reported,[6] tetra-*t*-butylated dibenzofuran-1-ol reacted with **1**, gave tri-*t*-butylbenzofuro-[3,2-*e*][2,1,3]benzothiadiazole in 61% yield. The reaction with dibenzofuran-2-ol (**12**) afforded benzofurobenzothiadiazole (**24**) in an almost quantitative yield (97%).

The product selectivity observed in the reaction of **1** with **2**—**12** seems to be correlated with the difference in the mode of keto–enol tautomerism of 1-hydroxy derivatives and 2-hydroxy ones, as stated in the introductory part, though the detailed mechanism of the above-mentioned reactions is not known.

Experimental

General. All melting points were determined on a Mitamurariken MELT THERMO and are uncorrected. The IR spectra were measured as KBr pellets on a Nippon-Bunko A-102. The NMR spectra were recorded at 270 MHz with a JEOL GSX-270 using Me_4Si as an internal standard in $CDCl_3$, unless otherwise stated. Mass spectra were obtained on a JEOL JMS-O1SG-2 mass spectrometer at 75 eV using a direct inlet system. UV and VS spectra were measured on a Hitachi 220A spectrophotometer. Column chromatography was carried out on silica gel (Wako gel, C-300).

Materials. Compounds **2c**,[7] **4b**,[8,9] **4c**,[9] **4d**,[8] and **5b**[10] were prepared by the reported methods.

2,4-Dibromo-1-naphthol (2c): Colorless needles (ethanol); mp 98—101 °C (lit,[7] mp 105 °C). Found: C, 40.09; H, 2.11%.

2,6-Dibromo-1,5-naphthalenediol (4b): Gray needles (AcOH); mp >350 °C (it became colored around 200 °C) [lit,[8] mp >300 °C (darkened at 200 °C) and lit,[9] mp 224 °C (decomp)]. Found: C, 37.89; H, 2.02%.

2,4-Dibromo-1,5-naphthalenediol (4c): Colorless needles (hexane); mp 147—149 °C (lit,[9] mp 147.5 °C); ^{1}H NMR δ=6.00 (1H, s, D_2O-exchanged), 7.11 (1H, dd, J=8 and 1 Hz), 7.45 (1H, dd, J=8 and 8 Hz), 7.65 (1H, s), 7.88 (1H, dd, J=8 and 1 Hz), and 7.95 (1H, s, D_2O-exchanged).

2,4,6,8-Tetrabromo-1,5-naphthalenediol (4d): Yellowish white plates (toluene); mp 220—223 °C (lit,[8] mp >300 °C); IR 3460, 3320 cm^{-1}; MS m/z 480 (M^+), 478 (M^+), 476 (M^+), 474 (M^+), and 472 (M^+). Found: C, 25.55; H, 1.11%.

1,5-Dibromo-2,6-naphthalenediol (5b): Colorless prisms (dioxane), mp 209—213 °C (lit,[10] mp >223 °C); ^{1}H NMR (CD_3OD) δ=7.22 (2H, d, J=9 Hz) and 8.00 (2H, d, J=9 Hz). Found: C, 37.98; H, 1.87%.

1,3,5,7-Tetrabromo-2,6-naphthalenediol (5c). A mixture of **5a** (9.1 g, 57 mmol) and bromine (12 ml, 233 mmol) in AcOH (400 ml) was refluxed for 2 h. After it cooled, the mixture was poured into water and the precipitates were filtered, washed well with acetone, and filtered to give **5c** (0.97 g, 4%): Colorless needles; mp 279—282 °C (decomp); IR 3480 and 3350 cm^{-1}; ^{1}H NMR (CD_3OD) δ=8.32 (s); MS m/z 480 (M^+), 478 (M^+), 476 (M^+), 474 (M^+), and 472 (M^+). Found: C, 25.45; H, 0.92%. Calcd for $C_{10}H_4Br_4O_2$:C, 25.25; H, 0.85%.

1,3,6-Tribromo-2,7-naphthalenediol (6b). To a mixture of **6a** (4.0 g, 25 mmol) in AcOH (100 ml), bromine (5.2 ml, 101 mmol) in AcOH (20 ml) was added dropwise. During the addition, the temperature of the mixture was increased to about 40 °C. The mixture was refluxed for 2 h. After it cooled, precipitated **6b** (7.29 g, 74%) was collected by filtration: Colorless powder; mp 183—197 °C; IR 3490 and 3420 cm^{-1}; ^{1}H NMR (CD_3COCD_3) δ=7.57 (1H, s), 8.04 (1H, s), 8.05 (1H, s), 8.69 (1H, s, D_2O-exchanged), 9.57 (1H, s, D_2O-exchanged); MS m/z 400 (M^+), 398 (M^+), 396 (M^+), and 394 (M^+). Found: C, 30.44; H, 1.42%. Calcd for $C_{10}H_5Br_3O_2$:C, 30.26; H, 1.27%.

2,6,8-Tribromo-1,7-naphthalenediol (8b). A mixture of bromine (5 ml, 97 mmol) in AcOH (15 ml) was added dropwise to a mixture of **8a** (5.0 g, 31 mmol) in AcOH (80 ml) at room temperature; the reaction mixture was then stirred for 30 min. The precipitated **8b** (7.56 g, 61%) was collected by filtration and recrystallized from carbon tetrachloride, giving **8b** as grayish blue needles: Mp >300 °C; IR 3500 cm^{-1}; ^{1}H NMR (CD_3COCD_3) δ=7.44 (1H, d, J=9 Hz), 7.81 (1H, s), and 8.09 (1H, d, J=9 Hz); MS m/z 400 (M^+), 398 (M^+), 396 (M^+), and 394 (M^+). Found: C, 30.50; H, 1.69%. Calcd for $C_{10}H_5Br_3O_2$: C, 30.27; H, 1.27%.

5,7-Dibromo-8-quinolinol (10b). A mixture of **10a** (5.0 g, 34 mmol) and bromine (1.8 ml, 35 mmol) in AcOH (120 ml) was stirred at room temperature. Compound **10b** gradually precipitated; after one night it was colllected by filtration (2.02 g, 19%): Yellow needles (AcOH); mp 218—220 °C; IR 3300—2400 cm^{-1}; MS m/z 305 (M^+), 303 (M^+), and 301 (M^+). Found : C, 35.52; H, 2.13; N, 4.52%. Calcd for $C_9H_5Br_2NO$: C, 35.68; H, 1.66; N, 4.62%.

General Procedure for the Reaction of 1 with Naphthalenols (2—8) and Hydroxy-Substituted Benzoheterocycles (9—12). After a mixture of **1** and an appropriate amount of

naphthalenols or hydroxy-substituted benzoheterocycles in toluene (100 ml) was heated under reflux for 48 h, it was cooled to room temperature. An insoluble material containing unidentified inorganic compounds was filtered off and the filtrate was concentrated to 30 ml; the condensate was then chromatographed. Sulfur was first eluted with hexane and unreacted N_4S_4 with a mixture of hexane and benzene. Then, products **10a**, **13a**[11]—**13d**, **14a**—**b**, **16a**, **17**, **18a**—**b**, **19**, **20**, **21**, **22**, and **24** were obtained from the fraction eluted with benzene. Products **15** and **23** were eluted with chloroform.

Compound **16b** was obtained as precipitates during the reaction and washed successively with benzene, chloroform, and then ethanol. An analytical sample of **16b** was obtained by recrystallization from dioxane. The physical properties of the new compounds obtained in this study are shown below.

5-Chloronaphtho[1,2-*c*][1,2,5]thiadiazole (13b): Colorless needles (ethanol); mp 121—123 °C; MS *m/z* 222 (M^+) and 220 (M^+). Found: C, 54.54; H, 2.17; N, 12.49%. Calcd for $C_{10}H_5ClN_2S$: C, 54.43; H, 2.28; N, 12.69%.

7-Bromonaphtho[1,2-*c*][1,2,5]thiadiazole (13c): Colorless plates (ethanol); mp 157—160 °C; ^{1}H NMR δ=7.60—7.85 (3H, m), 7.96 (1H, d, *J*=2 Hz), and 8.51 (1H, d, *J*=8 Hz); ^{13}C NMR δ=121.1, 123.7, 125.6, 127.0, 131.0, 131.1, 131.6, 134.5, 153.7, and 154.3; MS *m/z* 266 (M^+) and 264 (M^+). Found: C, 45.39; H, 1.78; N, 10.73%. Calcd for $C_{10}H_5BrN_2S$: C, 45.30; H, 1.90; N, 10.57%.

Naphtho[1,2-*c*][1,2,5]thiadiazol-9-ol (13d): Pale yellow needles (ethanol); mp 113—116 °C; IR 3300 cm^{-1}; ^{1}H NMR δ=7.32 (1H, d, *J*=8 Hz), 7.44 (1H, d, *J*=7 Hz), 7.65 (1H, dd, *J*=7 and 8 Hz), 7.77 (1H, d, *J*=9 Hz), 7.86 (1H, d, *J*=9 Hz), and 10.26 (1H, s); MS *m/z* 202 (M^+). Found: C, 59.16; H, 2.69; N, 13.63%. Calcd for $C_{10}H_6N_2OS$: C, 59.39; H, 2.99; N, 13.85%.

Naphtho[1,2-*c*:3,4-*c*] bis [1,2,5]thiadiazole (14a): Straw colored needles (ethanol); mp 203—208 °C; UV (MeOH) 331 (ε 17000), 315 (18600), 300 (17400), 263 (16600), and 239 nm (34700); ^{1}H NMR δ=7.78—7.81 (2H, m) and 8.64—8.67 (2H, m); ^{13}C NMR δ=126.4, 127.1, 130.9, 148.2, and 156.4; MS *m/z* 244 (M^+). Found: C, 49.33; H, 1.58; N, 22.53%. Calcd for $C_{10}H_4N_4S_2$: C, 49.17; H, 1.65; N, 22.93%.

Naphtho[1,2-*c*;3,4-*c*]bis[1,2,5]thiadiazol-7-ol (14b): Pale pink needles (ethanol); mp 236—239 °C (it changed to prisms around 175 °C); IR 3255 cm^{-1}; ^{1}H NMR δ=7.37 (1H, dd, *J*=8 and 1 Hz), 7.71 (1H, dd, *J*=8 and 8 Hz), 8.19 (1H, dd, *J*=8 and 1 Hz), and 10.38 (1H, s, D_2O-exchanged); MS *m/z* 260 (M^+). Found: C, 45.64; H, 1.89; N, 21.17%. Calcd for $C_{10}H_4N_4OS_2$: C, 46.14; H, 1.55; N, 21.52%.

***N,N'*-Thiobis[3-chloro-1,4-naphthoquinone 1-imine] (15):** Red needles (ethanol); mp 260—264 °C (decomp); IR 1660 cm^{-1}; ^{1}H NMR δ=7.65—7.69 (2H, m), 7.75—7.78 (2H, m), 7.98 (2H, s), 8.24 (2H, dd, *J*=9 and 1 Hz), and 8.35 (2H, dd, *J*=8 and 2 Hz); MS *m/z* 416 (M^+), 414 (M^+), and 412 (M^+). Found: C, 57.79; H, 2.12; N, 6.86%. Calcd for $C_{20}H_{10}Cl_2N_2O_2S$: C, 58.13; H, 2.44; N, 6.78%.

Naphtho[1,2-*c*:5,6-*c*]bis[1,2,5]thiadiazole (16a): Straw colored needles (ethanol); mp 203—208 °C; UV (MeOH) 331 (ε 16700), 315 (18600), 300 (17400), 263 (16600), and 239 nm (34700); ^{1}H NMR δ=7.78—7.81 (2H, m), 8.64—8.67 (2H, m); ^{13}C NMR δ=126.4, 127.1, 130.9, 148.2, and 156.4; MS *m/z* 244 (M^+). Found: C, 49.33; H, 1.58; N, 22.53%. Calcd for $C_{10}H_4N_4S_2$: C, 49.17; H, 1.65; N, 22.93%.

4,9-Dibromonaphtho[1,2-*c*:5,6-*c'*]bis[1,2,5]thiadiazole (16b): Yellow needles (dioxane); mp >350 °C; MS *m/z* 494 (M^+), 492 (M^+), and 490 (M^+). Found: C, 30.13; H, 0.91; N, 13.75%. Calcd for $C_{10}H_2Br_2N_4S_2$: C, 29.87; H, 0.50; N, 13.93%.

Naphtho[1,2-*c*:3,4-*c'*:5,6-*c''*]tris[1,2,5]thiadiazole (17): Pale yellow needles (ethanol); mp 311—313 °C; ^{1}H NMR δ=8.37 (1H, d, *J*=9 Hz) and 8.97 (1H, d, *J*=9 Hz); MS *m/z* 302 (M^+). Found: C, 39.57; H, 0.53; N, 27.47%. Calcd for $C_{10}H_2N_6S_3$: C, 39.72; H, 0.67; N, 27.79%.

Naphtho[1,2-*c*:7,8-*c'*]bis[1,2,5]thiadiazole (18a): Yellow needles (ethanol); mp 244—248 °C; UV (MeOH) 373 (ε 12300), 356 (14450), 345 (22400), 330 (15850), 255 (46770), and 250 nm (46770); ^{1}H NMR δ=8.14 (2H, *J*=8 Hz), 8.88 (2H, d, *J*=8 Hz); ^{13}C NMR δ=121.6 and 127.5; MS *m/z* 244 (M^+). Hydrolytic Metalloenzyme Models. Micellar Effects on the Activation of the Hydroxyl Groups of *N*-Alkyl-2-(hydroxymethyl)-imidazole Ligands by Cu^{2+} in the Transacylation of *p*-Nitrophenyl Picolinate

Waichiro TAGAKI,* Kenji OGINO, Osamu TANAKA, Koji MACHIYA,

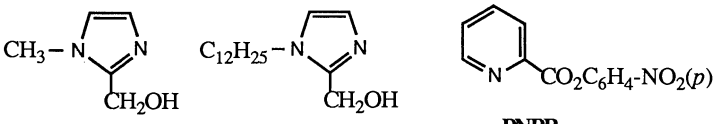
(Received August 24, 1990)

The activation of the hydroxyl groups of two *N*-methyl/dodecyl-2-(hydroxymethyl)imidazole ligands by complexation with Cu^{2+} was investigated kinetically by observing the rates of the release of *p*-nitrophenol in the transacylation of *p*-nitrophenyl picolinate (**PNPP**). The kinetics were carried out in aqueous buffers of pH ranging from 4.5 to 8.0 at 25 °C in the absence of surfactant micelles for a hydrophilic *N*-methyl ligand, and in the presence of micelles for a lipophilic *N*-dodecyl ligand. The kinetic analyses indicated that the 1:1 and 2:1 complexes of the ligand and Cu^{2+} are active nucleophiles with the *N*-methyl and *N*-dodecyl ligand, respectively. The pK_a's of the hydroxyl groups of these complexes were determined to be 7.00 in water and 6.41 in aqueous **CTABr** micelles, respectively, by analyses of the pH-rate profiles. The rate constants, which show the nucleophilic reactivities of ionized hydroxyl anions of complexes toward **PNPP**, were determined to be k_N=1.11×10^4 and 1.25×10^6 mol^{-1} dm^3 s^{-1} with *N*-methyl and *N*-dodecyl ligands, respectively, indicating that the latter micellar complex is 100-times more active than the former non-micellar counterpart.

One of the roles of metal ions in hydrolytic metalloenzymes such as carboxypeptidase A,[1] carbonic anhydrase,[2] or alkaline phosphatase[3] is to activate the substrate as an electrophilic catalysts, stabilizing the negative charges that are formed during the reaction.[4] Another important function of a metal ion is to act as a source of hydroxide ions at neutral pH.[4] It is not uncommon that a metal-bound water molecule ionizes with a pK_a near 7, about 9 units below that of free water, yielding a high fraction of hydroxide ions at neutral pH. Here, a remarkable feature is that such a metal-bound hydroxide ion is a potent nucleophile retaining most of the reactivity of free hydroxide ion.[5,6]

The above-mentioned metal ion functions are quite attractive for designing artificial hydrolytic metalloenzymes. Thus, early in 1972, Sigman and Jorgensen showed that the hydroxyl group of *N*-(2-hydroxyethyl)-ethylenediamine is remarkably activated for the transacylation of *p*-nitrophenyl picolinate (**PNPP**) when complexed with Zn^{2+}.[7] This complex showed the pK_a of the hydroxyl group to be 8.4, much lower than that of the free ligand. More recently, Brown et al. reported that a basic form of the aqua complex of tris(imidazolyl)phosphine and Co^{3+} with pK_a 7.6—7.8 is the active species for the hydrolysis of **PNPP**.[8] Breslow et al. reported that a Zn^{2+} complex of tetraaza-macrocycle is active in the form of hydroxide with a pK_a of 8.7 in the hydrolysis of aryl phosphates.[9] The high reactivities of metal-bound hydroxyl groups with low pK's have also been observed in other recent model studies.[10]

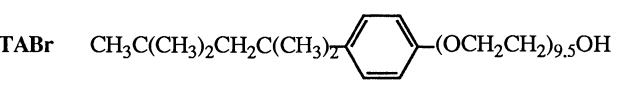
On the other hand, we have been interested in designing micellar models of hydrolytic metalloenzymes.[11] Our search for active ligands has led us to find *N*-alkyl-2-(hydroxymethyl)imidazoles. They were highly active when complexed with bivalent metal ions in the hydrolysis of **PNPP**.[12] Interestingly, the activation was much larger for lipophilic ligands under micellar conditions than for hydrophilic ligands under non-micellar conditions.[13] Recently, there have been an increasing number of studies on the micellar models of hydrolytic metalloenzymes.[13–19] However, most of them were investigated under a particular pH, without dealing with the ionization of a ligand hydroxyl group.



1 **2** **PNPP**

$CH_3(CH_2)_{15}N^+Me_3Br^-$ **CTABr**

$CH_3(CH_2)_{11}OSO_3^-Na^+$ **SDS**



Triton X-100

We wish to report herein the micellar effects on the ionization and reactivity of the hydroxyl group of a Cu^{2+} complex of *N*-dodecyl-2-(hydroxymethyl)imidazole (**2**) ligand, as compared to a non-micellar *N*-methyl counterpart (**1**) in the transacylation of **PNPP**. The surfactants used for micellization were cationic hexadecyltrimethylammonium bromide(**CTABr**), anionic sodium dodecyl sulfate(**SDS**), and non-ionic **Triton X-100**. The ionization of the hydroxyl group of **2** was examined in **CTABr** micelles.

Results

A Survey of Rates at pH 7.03. Ligand **1** was water-soluble, while ligand **2** was hardly soluble in water but, rather, was solubilized by surfactant micelles, so that the kinetics were carried out in plain buffers for the former and in buffered micelles with the latter ligand. The rates of hydrolysis were determined by monitoring the release of *p*-nitrophenol from the substrate **PNPP** spectrophotometrically by using a UV-VIS or a stopped-flow spectrophotometer. In Table 1 are shown the pseudo-first-order rate constants (k_{obsd}) obtained under the conditions of an excess ligand and Cu^{2+} over the substrate at pH 7.03 and 25 °C.

Table 1. Pseudo-First-Order Rate Constants (k_{obsd}) for the Release of *p*-Nitrophenol from **PNPP** at pH 7.03, 25 °C[a)]

Run	System	$k_{obsd}\times10^2/s^{-1}$
1	None	0.00167
2	Cu^{2+}	1.98
3	**1**	0.068
4	**1**+Cu^{2+}	13.8
5	**CTABr**	0.00193
6	**CTABr**+**2**	0.192
7	**CTABr**+Cu^{2+}	3.78
8	**CTABr**+**2**+Cu^{2+}	491

a) In 0.1 mol dm^{-3} 2,6-lutidine–HNO_3 buffer; μ=0.2 (KNO_3), [ligand]=[Cu^{2+}]=1×10^{-4} mol dm^{-3}, [**PNPP**]=5×10^{-5} mol dm^{-3}, [**CTABr**]=1×10^{-2} mol dm^{-3}.

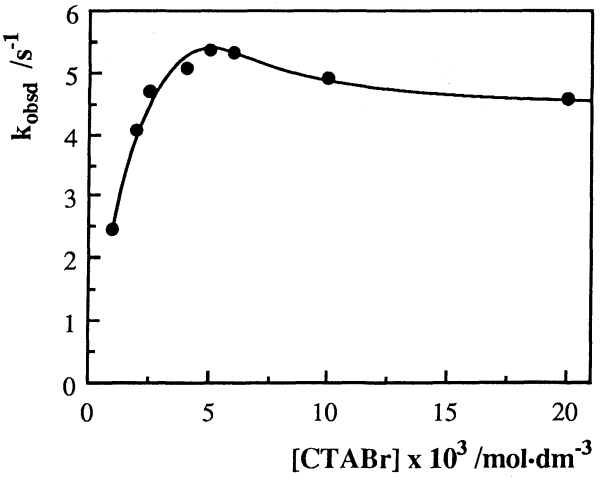


Fig. 1. Effect of **CTABr** concentration on the pseudo-first-order rate constants for the transacylation of **PNPP** at 25 °C, pH 7.03; [**2**]=[Cu^{2+}]=1×10^{-4} mol dm^{-3}, [**PNPP**]=5×10^{-5} mol dm^{-3}.

As indicated, a cationic surfactant **CTABr**, itself, showed almost no rate-enhancing effect (Run 1 vs. 5), although the concentration (1×10^{-2} mol dm^{-3}) used was sufficient to form micelles, i.e larger than the CMC value of about 10^{-3} mol dm^{-3} under the kinetic conditions (see also Fig. 1). The rate enhancement by the ligand alone was also small in each case of **1** under non-micellar (Run 3) and **2** under micellar conditions (Run, 6), as compared to the other cases involving Cu^{2+}. A large rate enhancement of more than 10^3-fold was observed by the addition of 1×10^{-4} mol dm^{-3} of Cu^{2+} (Runs 2 and 7). Even a more remarkable rate acceleration was observed in the coexistence of the ligand and Cu^{2+} (Runs 4 and 8). Thus, a rate enhancement of 4.5×10^5 fold was attained in the presence of 1×10^{-4} mol dm^{-3} each of **2** and Cu^{2+} in **CTABr** micelles (Run 8). As described below, these rate enhancements are dependent on the concentrations of the ligand, Cu^{2+}, and the surfactant, as well as the pH.

Effects of CTABr Concentrations. As shown in Fig. 1, saturation kinetics was observed, i.e. the rates (k_{obsd}) increased with increasing the **CTABr** concentration up to the saturation level. A breaking point in the curve near CMC, usually observed for a micellar reaction,[20,21] could not be detected, simply because of the hardly soluble nature of lipophilic **2** at a low surfactant concentration. The rate saturation of this type can be accounted for as being the saturation of substrate incorporation into the micelles.[20,21] It can be seen that 1×10^{-2} mol dm^{-3} of **CTABr** (Table 1) has sufficient concentration for saturation, and is appropriate as a standard concentration for subsequent experiments.

Reaction Scheme and the Rate Equations. It seems helpful to first explain the reaction schemes and the rate equations used for the analyses of the experimentally observed rates in generalized forms.

As described in the next sections, the rates could be analyzed by assuming a reaction Scheme 1 involving Eqs. 1—3, which is essentially the same as that

$$M + nL \underset{}{\overset{K_M}{\rightleftharpoons}} M\text{-}L_n;\ K_M = [M\text{-}L_n]/[M][L]^n \quad (1)$$

$$S + M\text{-}L_n \xrightarrow{k_N'} P \quad (2)$$

$$S \xrightarrow{k_o'} P \quad (3)$$

Scheme 1.

proposed for the Zn^{2+}-catalyzed reactions.[11-13] The scheme indicates that a metal ion (M) forms a complex (M-L_n) with n ligands (L) with an association constant (K_M) (Eq. 1), and that the complex reacts with the substrate (S) bimolecularly in the rate-limiting step with an apparent second-order rate constant (k_N') to afford the products (P) (Eq. 2). The products are also formed through k_o' process without involving an M-L_n complex (Eq. 3). The scheme leads to rate Eqs. 4-11,

$$k_o' = k_o + k_L[L]_T + k_M[M]_T \quad (4)$$

$$\text{Rate} = k_{obsd}[S] = (k_o' + k_N'[M\text{-}L_n]_T)[S] \quad (5)$$

$$n = 1 \qquad k_{obsd} = k_o' + \frac{k_N'K_M[L]_T[M]_T}{1 + K_M([L]_T + [M]_T)} \quad (6)$$

$$\frac{1}{(k_{obsd} - k_o')} = \frac{1}{k_N'[L]_T} + \frac{1 + K_M[L]_T}{k_N'K_M[L]_T} \cdot \frac{1}{[M]_T} \quad (7)$$

$$n = 2 \qquad k_{obsd} = k_o' + \frac{k_N'K_M[L]_T^2[M]_T}{1 + K_M[L]_T^2 + 4K_M[L]_T[M]_T} \quad (8)$$

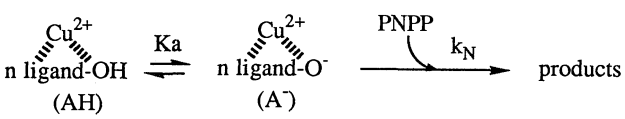
$$\frac{1}{(k_{obsd} - k_o')} = \frac{4}{k_N'[L]_T} + \left(\frac{1}{k_N'} + \frac{1}{k_N'K[L]_T^2}\right) \cdot \frac{1}{[M]_T} \quad (9)$$

$$k_N' = \frac{k_NK_a}{K_a + [H^+]} \quad (10)$$

$$\frac{1}{k_N'} = \frac{1}{k_N} + \frac{1}{k_NK_a} \cdot [H^+] \quad (11)$$

where k_L and k_M are the second-order rate constants due to the ligand and Cu^{2+} alone, and $[L]_T$ and $[M]_T$ are the total concentrations of the ligand and Cu^{2+}, respectively.

An alternative scheme involving a ternary complex, S·M·L_n, may well be considered. The choice of Eq. 2 in Scheme 1 instead of such a ternary complex is simply due to the consideration that the substrate pyridine moiety should be weak as a ligand base in the ground state in aqueous buffers, although it becomes effective upon the formation of an intermediate (see below).



$$[M\text{-}L_n]_T = [AH] + [A^-]$$

Scheme 2.

Eqs. 6 and 8 are approximate equations for 1:1 (n=1) and 2:1 (n=2) complexes of the ligand and metal ion. The validities of these approximations can be confirmed from linear plots of Eqs. 7 and 9. Then, the k_N' and K_M values can be obtained by analyzing the intercepts and slopes. They should be pH-dependent if the active nucleophile is a dissociated complex anion (A^-) as illustrated in Scheme 3. The k_N for the fully dissociated hydroxyl group of the complex and its acid dissociation constants K_a can be obtained based on the relationship between Eqs. 10 and 11.

The Determination of n, k_N, and K_M Values for the Ligands 1 and 2. (a) Job Plots: A convenient method to estimate the above n values is the kinetic version of Job plots,[22] in which the rate constants are plotted as a function of the mole fraction of a ligand or metal ion, keeping their total concentration being constant. The results are shown in Fig. 2. Figure 2 indicates the necessity of the coexistence of the ligand and Cu^{2+} to attain higher rates (k_{obsd}). It also indicates the existence of an optimum γ value to attain a maximum rate. For ligand **1**, the maximum rate is seen at γ=0.5, indicating that the 1:1 complex (n=1) is the active species. For ligand **2**, the rate maxima of three plots are all seen at γ=0.67, indicating that the 2:1 complex (n=2) is the active species in all three kinds of micelles, although the reactivities are variable

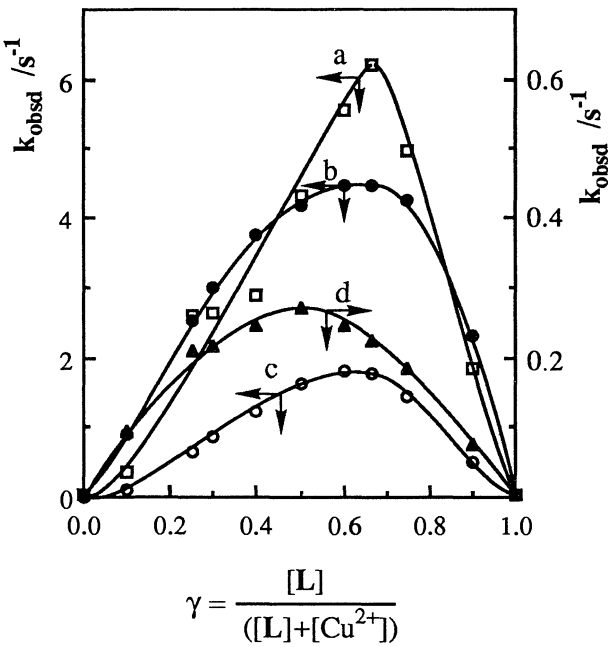


Fig. 2. Job plots for the ligand and Cu^{2+} ion complexation as measured by the rates of transacylation of **PNPP** at 25 °C, pH 7.0: a □, **2**, in [**Triton X-100**]=2×10^{-3} mol dm^{-3}; b ●, **2** in [**CTABr**]=1×10^{-2} mol dm^{-3}; c ○, **2** in [**SDS**]=3×10^{-2} mol dm^{-3}; ([**2**]+[Cu^{2+}])=1×10^{-4} mol dm^{-3}, d ▲, **1** in aqueous buffer, ([**1**]+[Cu^{2+}]=2×10^{-4} mol dm^{-3}, [**PNPP**]=1×10^{-5} mol dm^{-3}.

depending on the micelles.

(b) Saturation Kinetics: As shown in Figs. 3 (**1**) and 4 (**2**), the k_{obsd} values obtained with a constant $[L]_T$ and pH were plotted against Cu^{2+} concentrations ($[M]_T$) to give a saturation curve for each pH. Figures 3 and 4 indicate that the reactivities of **2** under micellar conditions are much higher than those of **1** under non-micellar conditions. Plots of $1/(k_{obsd}-k_o')$ vs. $1/[M]_T$ gave thus straight lines, as shown in Figs. 5 and 6, confirming the relationship between Eqs. 6 and 7 for the ligand **1** (n=1), and Eqs. 8 and 9 for the ligand **2** (n=2). Here, the k_o' values (Eq. 4) were one or two orders smaller than the k_{obsd} values (compare the Runs 2 and 4, or 7 and 8 in Table 1). The intercepts and the slopes of these straight lines allowed us to obtain the k_N' and the K_M values as listed in Tables 2 and 3. The solid lines in Figs. 3 and 4 were calculated by using these k_N' and K_M values and according to Eqs. 6 and 8, again confirming their relationships. The fitting between these calculated solid lines and the experimental k_{obsd} values seems to be satisfactory for most of the pH's

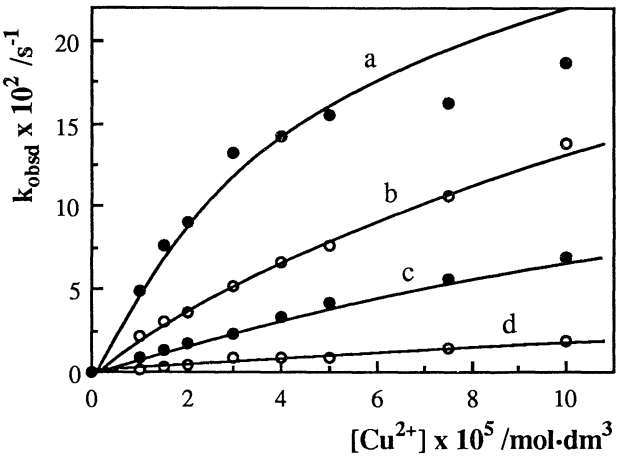

Fig. 3. Pseudo-first-order rate constants for the transacylation of **PNPP** in aqueous buffer at 25 °C as the function of Cu^{2+} concentration: pH's were 7.50(a), 7.00(b), 6.50(c), and 6.00(d); [**1**]=5×10^{-5} mol dm^3, [**PNPP**]=1×10^{-5} mol dm^3.

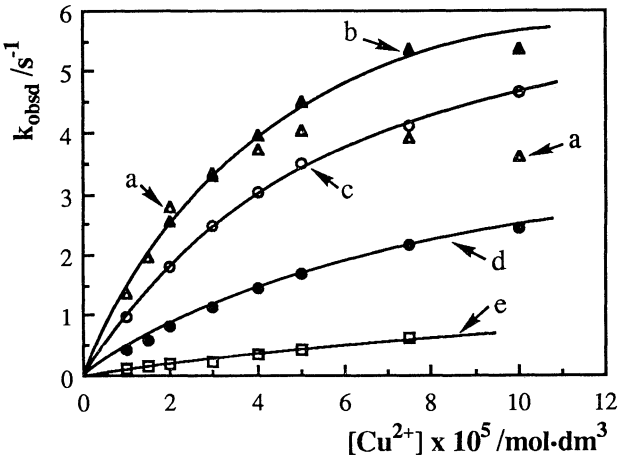

Fig. 4. Pseudo-first-order rate constants for the transacylation of **PNPP** in **CTABr** micelles at 25 °C as the function of Cu^{2+} concentration: pH's were 7.49(a), 7.03(b), 6.50(c), 6.01(d), and 5.51(e); [**2**]= 5×10^{-5} mol dm^3, [**PNPP**]=1×10^{-5} mol dm^3, [**CTABr**]=1×10^{-2} mol dm^3.

Table 2. pH Dependencies of k_N' and K_M of **1**-Cu^{2+} Complex under Non-micellar Conditions, 25 °C

pH	k_N'/mol^{-1} dm^3 s^{-1}	K_M/mol^{-2} dm^3
4.97	1.05×10^2	2.00×10^3
5.50	3.33×10^2	4.34×10^3
6.00	1.00×10^3	2.16×10^3
6.50	3.16×10^3	4.47×10^3
7.00	7.69×10^3	7.03×10^3
7.50	1.00×10^4	2.07×10^4
8.00	8.85×10^3	2.22×10^4

Table 3. pH Dependencies of k_N' and K_M of **2**-Cu^{2+} Complex under Micellar Conditions, of **CTABr**, 25 °C

pH	k_N'/mol^{-1} dm^3 s^{-1}	K_M/mol^{-2} dm^6
4.46	1.36×10^4	6.46×10^6
4.97	4.46×10^4	6.42×10^6
5.51	1.33×10^5	3.61×10^7
6.01	4.00×10^5	5.75×10^7
6.50	7.62×10^5	6.87×10^7
7.03	8.60×10^5	9.29×10^7
7.49	8.70×10^5	9.09×10^7
8.00	4.04×10^5	5.23×10^7

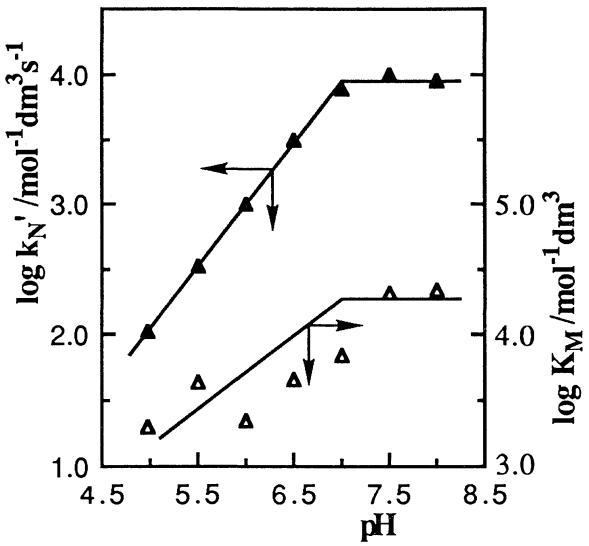

Fig. 7. Plots for log k_N' and log K_M vs. pH for **1**-Cu^{2+} in aqueous buffer.

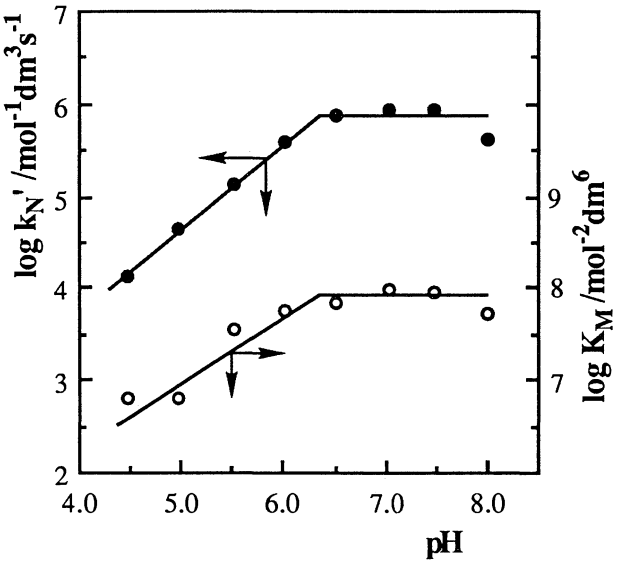

Fig. 8. Plots for log k_N' and log K_M vs. pH for **2**-Cu^{2+} in **CTABr** micelles.

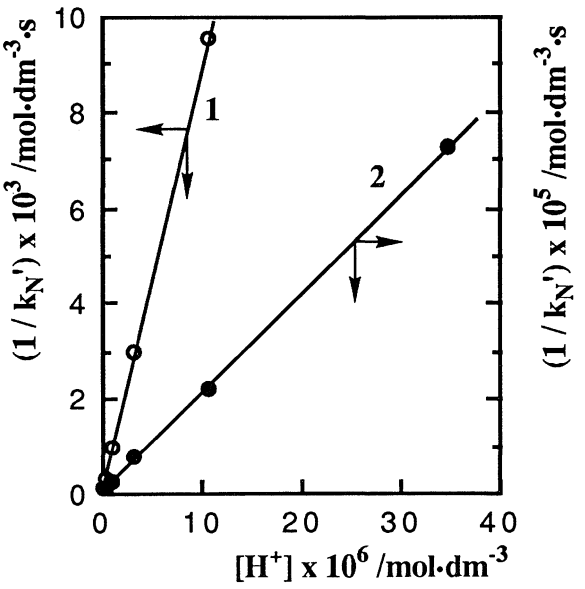

Fig. 9. Plots of $1/k_N'$ vs. $[H^+]$ for the reaction of **PNPP** with Cu^{2+} complexes of **1** and **2**.

examined. However, as can be seen in Figs. 3 and 4, such fitting tends to deviate at higher pH and higher Cu^{2+} concentration, presumably due to the decomposition of active complexes by hydroxide ion as well as the change in the n value.

(c) pH-Rate Profiles: The above k_N' and K_M values were both pH-dependent. As shown in Figs. 7 and 8, the log k_N' values increased linearly with a slope of 1 with increasing pH; they then become pH independent at higher pH. These pH-rate profiles can be accounted for by assuming that the dissociated complex anions (A^- in Scheme 2) are much more active than undissociated complexes (AH). Then, the pK_a's of AH and the k_N values of A^- could be calculated from the plots of $1/k_N'$ vs. $[H^+]$ shown in Fig. 9 (Eq. 11). The results obtained are: $k_N=1.11\times10^4$ mol^{-1} dm^3 s^{-1} and $pK_a=7.00$ for **1**, and 1.25×10^6 mol^{-1} dm^3 s^{-1} and 6.41 for **2**, respectively. The effects of pH on the log K_M values are qualitatively similar to those on the log k_N' values, i.e. the values increase and then level off with increasing pH. It is reasonable that complexation with a metal ion is stronger with dissociated A^- than with undissociated AH.

Discussion

It has already been established that a bivalent metal-ion catalyzed reaction of an *N*-alkyl-2-(hydroxymethyl)-imidazole with **PNPP** occurs through a two-step process involving the acylation of the 2-hydroxymethyl group, followed by deacylation, although the reaction conditions examined were limited in most cases to those at a particular pH near 7.[11-13] Of these two-steps, the above-mentioned kinetics focused on the acylation step (K_a and k_N in Scheme 2), by carrying

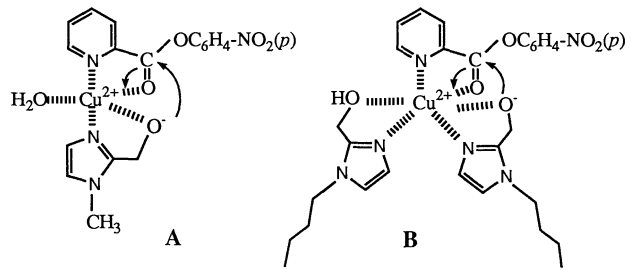

Fig. 10. Proposed structures of ternary complexes of **1** or **2**-Cu^{2+}·**PNPP**.

them out under conditions of excess ligand over the substrate.[23]

These results indicate the following differences between the reactions of non-micellar **1**-Cu^{2+} and micellar **2**-Cu^{2+} complexes: 1) the stoichiometries of complexation, 2) the pK_a's of ligand hydroxyl groups, and 3) the k_N values.

The observed stoichiometry was 1:1 for the former **1**-Cu^{2+}, while 2:1 for the latter **2**-Cu^{2+} complex. Thus, such structures as **A** and **B** are conceivable for the transition states of the two reaction systems, as illustrated in Fig. 10. In both cases, the complexation of **PNPP** with Cu^{2+} involving pyridine nitrogen is presumed to be unimportant at the ground state, but becomes important at the rate-determining step of attacking a ligand-oxido anion nucleophile on the substrate carbonyl carbon to form an addition intermediate.[11,13] The reason for forming a 1:1 complex in a non-micellar system, but a 2:1 complex in a micellar system is not clear. Presumably, the hydration of Cu^{2+} is sufficiently strong to stabilize a 1:1 complex with a hydrophilic ligand in the non-micellar aqueous phase, but not in the micellar phase for a lipophilic ligand; instead, the 2:1 complex becomes more stable. The charge on the micellar surface does not seem to be critical in determining the complex stoichiometry, since the same 2:1 ratio was observed in three different micelles (i.e. anionic, cationic, and non-ionic, Fig. 2).

The pK_a's of the complexes were found to be 7.0 and 6.41 for **1** and **2**, respectively. Thus, for both ligands, a remarkable lowering of pK_a occurred upon complexation with Cu^{2+}, as expected from the previous information.[4] One may notice that the pK_a of **2**-Cu^{2+} is about 0.6 as small as that of **1**-Cu^{2+}. The electron-donating effect as well as the hydrophobic nature to increase pK_a must be larger with the dodecyl than with the methyl group, contrary to observation. However, this reversal of pK_a is not unusual in view of the micellar effect, since it is known that the pK_a of a weak acid, such as phenol, is lowered by 1-2 units when solubilized in cationic micelles, like **CTABr**.[23]

Finally, it is interesting to compare the nucleophilic reactivities of the two systems. At a lower pH, when $[H^+] \gg K_a$, the apparent reactivity is $k_N' = k_N K_a/[H^+]$ (Eq 10). Then, a comparison of the above-mentioned two sets of $k_N K_a$ values indicate that the micellar complex is 428-times more reactive than the non-micellar complex. At a higher pH, when $K_a \gg [H^+]$, k_N' becomes pH independent k_N, that of the dissociated anion (A^-). The ratio of two k_N values indicates that the micellar complex is still 100-times more active than the non-micellar complex. It may be necessary to divide this ratio by a statistical factor of 2 for a fair comparison, since the 2:1 complex has two hydroxyl groups, instead of one in the 1:1 complex. A further correction may be required, since in the micellar reaction the reactants are concentrated in the micellar pseudo-phase so as to enhance the rate of a bimolecular reaction. Bunton et al. proposed a correction factor 0.14 to be multiplied to the experimentally observed second-order rate constant so as to obtain a real micellar rate constant.[20] These two corrections reduce the above 100 to 7. Thus, an apparent large rate enhancement in a micellar system as compared to a non-micellar one seems to be mainly due to a different mode (stoichiometry) of metal ion-ligand complexation as well as to the concentration effect to bring the reactants together in a relatively small volume of a micellar pseudo-phase. However, it should be pointed out that these rate comparisons are still tentative, since the above correction factor (0.14) may not be applied to the present system. The reason is the observation in Fig. 1 that a rate reduction after the maximum is small, as compared to a sharp rate reduction commonly observed for a bimolecular nucleophilic reaction, which requires a correction factor of 0.14 to calculate a real rate constant.

In summary, it has been shown that the Cu^{2+} enhances the apparent reactivity of a coordinated hydroxyl group to a remarkable extent in the neutral pH region by lowering its pK_a. It was further demonstrated that such activation of the hydroxyl group by Cu^{2+} was more pronounced in a micellar system. The obtained information is valuable for any further design of artificial hydrolytic metalloenzymes.

Experimental

Materials. The water used for kinetics was obtained by distilling deionized water twice. Acetonitrile was purified by distillation over P_2O_{10}. Commercially available, 2,6-lutidine, *N*-ethylmorpholine, and acetic acid were purified prior to use by distillation. Commercially available extra-pure $Cu(NO_3)_2 \cdot 6H_2O$ was used without further purification. Other inorganic salts used for buffer preparation were also commercial extra-pure reagents. Hexadecyltrimethylammonium bromide(**CTABr**) and sodium dodecyl sulfate(**SDS**) were recrystallized from acetonitrile before use. Poly(oxyethylene)(9.5) *p*-(1,1,3,3-tetramethylbutyl)phenol (**Triton X-100**, Kishida Chemicals) was used without further purification. The buffers were CH_3COOH–CH_3COONa (pH 4.46—4.97), 2,6-lutidine–HNO_3 (pH 5.50—6.50), and *N*-

ethylmorpholine-HNO_3 (pH 7.03—8.00), and the ionic strength was maintained at 0.2 mol dm^{-3} with NaCl (pH 4.46—4.97) or with KNO_3 (pH 5.50—8.00). *p*-Nitrophenyl picolinate(**PNPP**),[7] *N*-methyl-2-(hydroxymethyl)imidazole,[12b] and *N*-dodecyl-2-(hydroxymethyl)imidazole[13] were prepared and purified according to previous methods. **PNPP** stock solutions for kinetics were prepared in acetonitrile.

Kinetics. Kinetics were carried out according to essentially the same method as reported previously.[11-14] A Hitachi-Horiba pH meter F-8 was used for the pH determination and control. The kinetic runs for slow rates were conducted by using either a Hitachi 220 or 220A spectrophotometer equipped with a thermostated cell compartment. They were initiated by introducing a 10 μl of the **PNPP** stock solution into a 3 ml of a buffer solution containing the desired reagents. Kinetic runs for fast rates were conducted by using an Union Giken RA-401 stopped-flow spectrophotometer equipped with an RA-454 thermobath and an RA-451 computer. The **PNPP** stock solution was diluted by a buffer before use. The reactions were initiated by mixing an equal volume of **PNPP** buffer and the desired reagent solutions. In both slow and fast reactions, the rates were followed by monitoring the release of *p*-nitrophenol at 400 nm (pH 6.5—8.0) or at 320 nm (pH 4.5—6.0). The kinetic runs used for the calculation of rate constants obeyed the pseudo-first-order kinetics for at least 3 half-lives. The absorbance at infinite time (OD_∞) was recorded for each run, and the pseudo-first-order rate constants were obtained by using $k_{obsd}=(2.30/t)\log[(OD_\infty-OD_0)/(OD_\infty-OD_t)]$. The graphical methods for the analyses of these k_{obsd} to obtained k_N', K_M, k_N, and K_a are described in the text (Eqs. 7, 9, and 11).

Four different NAD(P)H analogs have been oxidized by various substituted and unsubstituted 1,4-benzoquinones in the presence or absence of magnesium ion. The stereospecificity of the reaction depends not only on the reactivity of quinone but also on that of the analogs as well as on the presence or absence of magnesium ion. The results are discussed from the viewpoint of reaction mechanism for the transfer of a (net) hydride ion.

The central chirality at the C_4-position in 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-1,2,4-trimethyl-1,4-dihydroquinoline (Me_3MQPH) is converted into the axial chirality with respect to the C_3–$C_{carbonyl}$ bond in 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-1,2,4-trimethylquinolinium ion (Me_3MQP^+) on oxidation.[1] Stereospecificity of the chirality-transformation depends on the reactivity of the oxidizing reagent.[2,3] It is also known that the reverse reaction proceeds with high stereospecificity under appropriate reaction conditions.[4] However, the structure–stereochemistry, or the reactivity–stereochemistry, relationship in the compounds that undergo the chirality-transformation has not yet been studied, because the compound available for the investigation is limited.

Recently, we found that the axial chirality in 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethylpyridinium ion (Me_3PNP^+) in a nonpolar solvent is reasonably stable at room temperature and the stereospecific conversion of the central chirality in 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridine (Me_3PNPH) into the corresponding axial chirality in Me_3PNP^+ can be studied by means of ^1H NMR spectroscopy. 4-Deuteriated Me_3MQPH and Me_3PNPH (Me_3MQPD and Me_3PNPD, respectively) are other substrates to be studied. Having four substrates in hand, we thus studied the stereospecificity associated with the chirality-transformation from the viewpoint of the structure–stereochemistry, or the reactivity–stereochemistry, relationship. The results will be discussed in relation to the mechanism of the (net) hydride transfer.

Results

Absolute Configuration and Alkylation of 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-2,4-dimethylpyridine. In order to study the chirality-transformation, it is neccessary to elucidate the absolute configuration at chiral centers. The absolute configuration with respect to the central chirality in Me_3PNPH has been established by the X-ray analysis on a similar compound, 3-(*N*-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridine (Me_2PNPH).[5,6] The axial chirality in Me_3PNP^+, however, has not been studied yet. Since this onium salt is highly hygroscopic and did not afford a single crystal suitable for the X-ray crystallography, a crystal of 3-(*N*-methyl-*N*-(*R*)-α-methylbenzylcarbamoyl)-2,4-dimethylpyridine ((9*R*)-Me_3PyP) was employed for the structure analysis. Since it can be confirmed that a diastereoisomer which exerts the C_2-methyl signal at a lower field and $N_{carbamoyl}$-methyl signal at a higher field than the corresponding methyl signals from the other diastereoisomer in the ^{1}H NMR spectrum of racemic Me_3PyP corresponds to the diastereoisomer of Me_3PNP^+ which exerts the C_2-methyl signal at a lower field and $N_{carbamoyl}$-methyl signal at a higher field, the absolute configuration of Me_3PNP^+ can be correlated directly to that of Me_3PyP.

The ORTEP drawing for the diastereoisomer which exerts the C_2-methyl signal at a lower field is shown in Fig. 1. Thus, the absolute configuration of this compound is (7*R*,9*R*). The plane of pyridine-ring and that of the carbonyl group in this isomer are set close to perpendicular each other, or the C_2–C_3–C_7–O_{12} dihedral angle is −89.3°. In addition, the atoms O_{12}–C_7–N_8–C_{13} are set in the same plane. That is, it is the $N_{carbamoyl}$-methyl group that produces the axial chiralities in Me_3PyP and its derivatives. Indeed, the axial chiralities in 3-(*N*-(*R*)-α-methylbenzylcarbamoyl)-

2,4-dimethylpyridine (Me_2PyP), the compound which has no methyl group on the carbamoyl-nitrogen, and its derivatives are too unstable to be fixed at room temperature, and their diastereoisomers are unable to be separated each other.

For the transformation of Me_3PyP into Me_3PNP+ by the Menschutkin N-alkylation, it is neccessary, however, to run the reaction at low temperature in order to avoid undesirable racemization. Since the reaction of Me_3PyP with propyl bromide under an atmospheric pressure requires as high temperature as to reflux the solution, the alkylation was carried out at room temperature under a high pressure (10000 kg cm^{-2}) for 25 days, and Me_3PNP+ thus obtained was recrystallized from chloroform. It was found that the propylation of (7*S*,9*R*)-Me_3PyP with propyl bromide yields a racemic mixture of (9*R*)-Me_3PNP+, whereas (7*R*,9*R*)-Me_3PyP affords a 3:1 mixture of (7*R*,9*R*)- and (7*S*,9*R*)-Me_3PNP+. On the other hand, methylation of (7*S*,9*R*)- and (7*R*,9*R*)-Me_3PyP with methyl iodide afforded the corresponding N_{ring}-methylated onium salt with 100% retention of the configuration.

Stereochemistry of the Reaction.[7] Oxidations of Me_3MQPH, Me_3MQPD, Me_3PNPH, and Me_3PNPD with various substituted and unsubstituted 1,4-benzoquinones in the presence or absence of magnesium ion in acetonitrile were run and the R/S ratios with respect to the axial chirality in the corresponding onium salts were measured on ^{1}H NMR spectrometer. The results are summarized in Tables 1 and 2.

Discussion

First of all, it is recognizable that the R/S ratio in Me_3MQP+ obtained from the reactions of Me_3MQPH without magnesium ion is not affected appreciably by the oxidation potentials of the quinones employed. However, in the presence of magnesium ion, the value of log (R/S) changes linearly from negative to positive as the oxidation potential of the quinone becomes larger. On the other hand, the R/S ratio in Me_3PNP+ obtained from the oxidations of Me_3PNPH in the absence of magnesium ion is affected by the oxidation potentials of the quinone, whereas the ratio stays at a constant value of 1/4—1/5 when magnesium ion exists in the reaction mixture.

In a previous paper where we reported the amine-catalyzed stereochemistry, we proposed that earliness and lateness of the transition state in the major process (with the highest activation energy, but not necessarily be the rate-determining step) of the reaction determine the syn/anti configurational preference[8] at the transition state: the early transition state prefers entropically favorable anti-conformation, but the late transition state prefers enthalpically favorable syn-conformation.[9] It was also proposed that the proton-transfer step is involved in the rate-determining step of the reaction of

Me_3MQPH, although the initial electron-transfer step requires larger activation energy than the proton-transfer step in the reaction with non-DDQ quinones.[9]

It is anticipated that the dihydroquinoline ring (a bicyclic system) will resist more strongly than the dihydropyridine ring (a monocyclic system) against the ring-deformation associated with their one-electron oxidation. Therefore, the former may require higher energy for oxidation (with less C_4–H bond deformation) than the latter. In other words, it is reasonable to expect that the transition-state in the stereo-determining step of the reaction with Me_3MQPH comes earlier than that with Me_3PNPH.[10] Since the proton on the C_4-position is not dissociated enough in an early transition state, the reacting quinone has to come close to the substrate.

At the same time, Me_3MQPH is sterically larger than Me_3PNPH. Both electronic and steric effects make the entropically favorable anti-configuration lower in Gibbs energy than enthalpically favored syn-configuration at the transition-state of the reaction with Me_3MQPH as illustrated in Fig. 2.[9]

Magnesium ion is known to interact with both the electron-donor and -acceptor to make the two reacting components in closer approach as an ES-complex in an enzymatic reaction.[11,12] Since the oxidizing and reducing reagents face against each other by sandwiching a magnesium ion between them, steric tightness is less important here than in the reaction without magnesium ion, and the transition state in the reaction with magnesium ion feels no (or little) stress to assume enthalpically favored but entropically disfavored syn-configuration provided the reactivity of the quinone is low enough. The statement is equivalent to say that the presence of magnesium ion retards the abstraction of a proton to set the transition state late, because the coordination of the positively charged magnesium ion makes the radical anion of quinone less reactive toward the proton-abstraction.

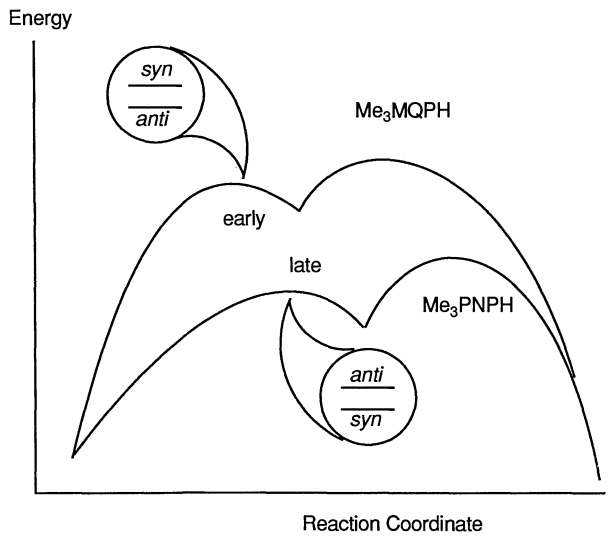

Fig. 2. Energy diagrams for the early and late transition states.

On the other hand, the transition state of the reaction with Me_3PNPH is always later than that with Me_3MQPH (with more C_4–H bond deformation) regardless the reactivity of the quinone,[9] and always passes through the syn-transition state even in the absence of magnesium ion. Of course, the presence of magnesium ion in this reaction shifts the specificity further toward the syn-preferency.

When the C_4-hydrogen in Me_3MQPH is substituted by a deuterium, the energy barrier for the proton-transfer process becomes higher due to kinetic isotope effect, then the *R*/*S* ratio, or the stereospecificity of the reaction, may be the subject of the isotope effect.[13] It is seen in Table 1 that the stereospecificity is reversed by going from Me_3MQPH (anti-preferency) to Me_3MQPD (syn-preferency) in the reactions with the quinones of high reduction potentials such as DDQ, chloranil, and trichloro-1,4-benzoquinone in the presence of magnesium ion. The isotopic difference is not so significant in the absence of magnesium ion.

The results can also be interpreted in terms of tight and loose transition states: in the reaction with Me_3MQPH(D), the proton-migrating step is affected by the isotopic substitution more sensitively than the initial electron-transfer step, and total energy barrier in the reaction of Me_3MQPD becomes higher than that of Me_3MQPH. Thus, the formation of the electron-transfer intermediate is followed by the rate-determining second step in the reaction of the deuteriated compound. Under such a circumstance, the transition state for Me_3MQPD is later and looser than that for Me_3MQPH and the formation of (11*S*,13*R*)-Me_3MQP$^+$ is more preferred by the former than the latter. As the reactivity of the quinone decreases (or in the absence of magnesium ion as well), the energy barrier for the initial electron-transfer process becomes higher, and, consequently, relative importance of the difference in energy barrier for the proton-transfer process becomes less and the isotope effect becomes smaller.

Experimental

Instruments. ^{1}H NMR spectra were recorded at 200 MHz and 400 MHz on a Varian VXR 200 FT-NMR and a JEOL JNM-GX400 FT-NMR spectrometers, respectively. ^{2}H NMR spectra were recorded at 31 MHz on a Varian VXR 200 FT-NMR spectrometer. UV spectra were obtained on a Hitachi U-3210 spectrophotometer with a Hitachi SDR-30 temperature controller. Elemental analyses were performed with a Yanaco MT-3 elemental analyzer.

Materials. Anhydrous solvents were prepared in the following way before the use: benzene, tetrahydrofuran (THF), and ether were distilled over sodium diphenyl ketyl. Acetonitrile was distilled over calcium hydride. Magnesium perchlorate was powdered, dried at 100 °C under reduced

pressure in the presence of diphosphorus pentaoxide, and placed in a sealed tube.

3-(*N*-(*R*)-α-methylbenzylcarbamoyl)-1,2,4-trimethylquinolinium iodide ($Me_2MQP^+I^-$),[14] (4*R*)-3-(*N*-(*R*)-α-methylbenzylcarbamoyl)-1,2,4-trimethyl-1,4-dihydroquinoline (Me_2MQPH)[14], 3-(*N*-(*R*)-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethylpyridinium bromide ($Me_2PNP^+Br^-$),[15] (4*R*)-3-(*N*-(*R*)-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridine (Me_2PNPH),[15] and 3-(*N*-methyl-*N*-(*R*)-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethylpyridinium iodide ($Me_3PNP^+I^-$),[1] were prepared according to the literature procedures. Trichloro-1,4-benzoquinone was prepared according to the literature procedure.[16]

Preparation of (4*R*)-3-(*N*-Methyl-*N*-(*R*)-α-methylbenzylcarbamoyl)-1,2,4-trimethyl-1,4-dihydroquinoline (Me_3-MQPH). In a 20 ml round-bottomed flask equipped with a magnetic stirrer and sealed with a serum cap, 128 mg (0.40 mmol) of Me_2MQPH and 227 mg (2.0 mmol) of potassium *t*-butoxide were placed. Then, the atmosphere inside the flask was replaced with nitrogen and 20 ml of anhydrous THF was injected into it through a syringe. The mixture was stirred for a while. The color turned pale yellow. Therein, 0.125 ml (2.0 mmol) of methyl iodide was injected dropwise with continuous stirring. An exothermic reaction occurred and white precipitates were formed. The mixture was stirred for an hour at room temperature in the dark under an atmosphere of nitrogen. The precipitates were filtered off and the filtrate was concentrated by evaporation of the solvent under reduced pressure. The residue was dissolved into dichloromethane. The solution was washed twice with water, dried over sodium sulfate, passed through a silica pad, and the solvent was evaporated under reduced pressure. Me_3MQPH was obtained in 120 mg (0.35 mmol) as a slightly yellow oil in 87% yield. Spectral data were the same as those reported.[1] The 4-deuteriated compound was prepared similarly.

Preparation of (4*R*)-3-(*N*-Methyl-*N*-(*R*)-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridine (Me_3-PNPH). Me_2PNPH was methylated at the carbamoylnitrogen in 84% yield with the same procedure as described above. The 4-deuteriated compound was prepared similarly. It was recognized that all the six hydrogens in the C_2- and C_4-methyl groups exchanged with deuteriums during the 4-deuteration.

Although Me_3PNPH is reasonably stable in a solution to be reacted with quinones and other oxidizing reagents, it decomposes immediately into unidentified product(s) when the solvent is evaporated completely under reduced pressure at room temperature or below, and elemental analysis of this compound does not give satisfactory results.

^1H NMR ($CDCl_3$): δ^{TMS}=0.89 (t, 3H), 1.11 (m, 3H), 1.53 (br.d, 3H), 1.84 (s, 3H), 2.73 (s, 3H), 2.8—3.3 (m, 3H), 4.45 (br.s, 1H), 6.18 (br.s, 1H), and 7.3—7.4 (m, 5H).

Preparation of 3-(*N*-Methyl-*N*-(*R*)-α-methylbenzylcarbamoyl)-2,4-dimethylpyridine ((9*R*)-Me_3PyP). In a 200 ml three-necked round-bottomed flask equipped with a magnetic stirrer and a reflux condenser protected with a calcium chloride tube, were placed 5 g (27 mmol) of 2,4-dimethylpyridine-3-carboxylic acid hydrochloride[15] and 28 ml (0.38 mol) of thionyl chloride. The solution was refluxed for 40 min. The color of the solution turned red. After excess thionyl chloride was removed by distillation under reduced pressure, the brown residue was obtained. Onto the residue, 13 ml of triethylamine dissolved in 20 ml of dichloromethane was added dropwise with stirring and cooling in an ice-salt bath. A brown solid precipitated. Subsequently, 3.7 g (30 mmol) of *N*-methyl-(*R*)-α-methylbenzylamine dissolved in 20 ml of dichloromethane was added to the solution over an hour with cooling in an ice-salt bath. The reaction mixture was stirred overnight at room temperature. After evaporation of the solvent keeping the temperature below 40 °C under reduced pressure, a brown residue was obtained. To the residue, 25 ml of concd hydrochloric acid and 100 ml of water were added and the solution was treated three times with activated charcoal. Thus obtained yellow solution was neutralized with sodium carbonate to obtain white precipitates. The reaction mixture was extracted with dichloromethane. The combined organic layer was washed with aqueous sodium hydrogencarbonate and two portions of water, and dried over sodium sulfate. Removal of the solvent under reduced pressure gave a white solid, which was washed with ether to give 2.11 g (8.2 mmol) of Me_3PyP in 30.4% yield. This is a mixture of two diastereomers with respect to the carbamoyl rotation.

Each diastereomers were partially separated by silica-gel column chromatography with a 1:1 mixture of acetone and hexane as an eluent. The crystals were recrystallized from a solution of chloroform in a refrigerator to obtain a single crystal of (7*R*,9*R*)-Me_3PyP; mp (uncorrected) 104—105 ° C for the (7*R*,9*R*)-isomer: 80—81 °C for the (7*S*,9*R*)-isomer.

Anal. Calcd for $C_{17}H_{20}N_2O$ (a 3/1 7*R*/7*S* mixture): C, 76.09; H, 7.51; N, 10.44%. Found: C, 75.98; H, 7.58; N, 10.35%.

^1H NMR ($CDCl_3$): (7*R*,9*R*)-Me_3PyP (earlier eluent); δ^{TMS}= 1.64 (d, 3H), 2.31 (s, 3H), 2.44 (s, 3H), 2.47 (s, 3H), 6.32 (q, 1H), 7.02 (d, 1H), 7.30—7.48 (m, 5H), and 8.37 (d, 1H). (7*S*,9*R*)-Me_3PyP (later eluent); δ^{TMS}=1.64 (d, 3H), 2.25 (s, 3H), 2.43 (s, 3H), 2.52 (s, 3H), 6.32 (q, 1H), 6.98 (d, 2H), 7.30—7.48 (m, 5H), and 8.36 (d, 1H).

Preparation of 3-(*N*-Methyl-*N*-(*R*)-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridinium Bromide ($Me_3PNP^+Br^-$). Into a Teflon tube, 106 mg (0.41 mmol) of Me_3PyP and 3.4 g (27 mmol) of propyl bromide in 2 ml of ethanol were placed. The tube was placed in an autoclave under high pressure (10000 kg cm^{-2}) for 25 days at room temperature to undergo the reactions. After the evaporation of the ethanol under reduced pressure, the residue obtained in quantitative yield was washed with ether and subjected to ^1H NMR spectroscopy. The $Me_3PNP^+Br^-$ obtained from (7*R*,9*R*)-Me_3PyP was diastereomerically purer than that obtained from (7*S*,9*R*)-Me_3PyP, which was an equivalent mixture of the two diastereoisomers. This compound is too hygroscopic to obtain satisfactory results from elemental analysis.

^1H NMR ($CDCl_3$): $Me_3PNP^+Br^-$ from (7*R*,9*R*)-Me_3PyP; δ^{TMS}=1.00 (m, 3H), 1.15 (d, 3H), 1.85 (m, 2H), 2.52 (s, 3H), 2.53 (s, 3H), 2.61 (s, 3H), 4.56 (q, 2H), 6.08 (q, 1H), 7.3—7.5 (m, 5H), 7.88 (d, 1H), and 8.98 (d, 1H). $Me_3PNP^+Br^-$ from (7*S*,9*R*)-Me_3PyP; in addition to the signals listed above δ^{TMS}=2.40 (s, 3H), 2.51 (s, 3H), and 2.71 (s, 3H).

X-Ray Analysis. Crystal data of Me_3PyP are as follows: MW=268.36. Orthorhombic. Space group $P2_12_12_1$. a= 14.471(1), b=14.483(2), c=7.387(1) Å. V=1548.2(0.7) Å^3, Z=4 molecules/cell, and D_c=1.156 g cm^{-3}.

A piece of crystal (size 0.4×0.4×0.5 mm^3) was used for the

data collection. Cell dimensions were determined by least squares calculations with 2θ values of 25 reflections measured on a Rigaku AFC-5FOS four-circle diffractometer by using graphite-monochromated Mo-$K\alpha$ radiation (λ= 0.7107 Å). Intensity data of 1537 reflections with $2\theta \leq 55°$ were collected by the use of the θ-2θ mode with a scanning rate of 16° min^{-1} in 2θ. The reflection data were not corrected for absorption.

All of the reflections were used for solution. The structure was solved by means of MULTAN 84.[17] Block-diagonal least squares refinement with anisotropic temperature factors for non-hydrogen atoms converged successfully to R=0.067. Eight hydrogen atoms were included in computation. Calculations were performed on FACOM S3500 superminicomputer in TASMAC, ISIR, Osaka University.

Selected torsional angles are as follows: $\angle C_4$-C_3-C_7-O_{12}= 82.5°, $\angle C_4$-C_3-C_7-N_8=−95.9°, $\angle C_2$-C_3-C_7-O_{12}=−89.3°, $\angle C_2$-C_3-C_7-N_8=92.3°, $\angle C_{11}$-C_4-C_3-C_7=9.0°, $\angle O_{12}$-C_7-N_8-C_9=0.3°, $\angle O_{12}$-C_7-N_8-C_{13}=−177.8°.

The complete F_o−F_c data are deposited as Document No. 9092 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Reaction. In a 50 ml round-bottomed flask equipped with a magnetic stirrer and sealed with a serum cap, 0.03 mmol of a 1,4-benzoquinone derivative was placed. Then, the atmosphere inside the flask was replaced with argon and 28 ml of anhydrous acetonitrile was injected through a syringe. To the solution, 2 ml of acetonitrile solution containing 10 mg (0.03 mmol) of Me_3MQPH (and 6.7 mg (0.03 mmol) of magnesium perchlorate, if necessary) was injected through a syringe. Then, the mixture was stirred for 24 h at room temperature in the dark. After evaporation of the solvent below 40 °C under reduced pressure, the residue was washed twice with ether and the crude Me_3MQP^+ was dissolved in CD_3CN and subjected to ^1H NMR spectroscopy to elucidate the diastereomer ratio and the yield of the product. The ^1H NMR spectrum of Me_3MQP^+ thus obtained was the same as that reported.[1] The R/S ratio was measured by means of the N_{ring}-methyl signals (for Me_3MQP^+) or the C_2- and C_4-methyl signals (For Me_3PNP^+). Therefore, in principle, the ratio in Me_3PNP^+ produced from Me_3PNPD (i.e. $(CD_3)_2MePNP^+$) could not be measured. However, the deuteriums in $(CD_3)_2MePNP^+$ again exchanged with hydrogens during the reaction without magnesium ion, probably due to the presence of trace amount of water in the solvent. Magnesium perchlorate is a well-known drying agent.[18] No doubt that the hydrogen-deuterium exchange does not affect the stereochemistry.[13]

It was confirmed, using 1:1 and 3:1 mixtures of the diastereoisomers, that the conformation of Me_3MQP^+ is sufficiently stable during the reaction, work-up and the spectroscopy.

The stereospecificities in the reactions with other compounds were determined similarly.

We thank financial support for this research by Japanese Ministry of Education, Science and Culture under the Grant-in-Aid Nos. 01470022, 01303007, 02303004, and 02740265.

7) In the present research, the compounds we employed always have the R-configuration at the α-methylbenzyl group on the amide-nitrogen. At the same time, the configuration at the C_4-position in $Me_3MQPH(D)$ or $Me_3PNPH(D)$ is always R. Therefore, we will neglect hereafter, for simplicity of the discussion, the signs to indicate the chirality at these positions in these compounds, unless neccessary. With this understanding, we can only deal with the axial chiralities in Me_3MQP^+ or Me_3PNP^+, which will be indicated by R or S without specifying the position. Stereospecificity of the reaction has been confirmed using other diastereoisomers of Me_3MQPH and Me_3PNPH.[2]

8) The *anti*-transition state is the one in which the C_4–H and C=O bonds in Me_3MQPH or Me_3PNPH point the opposite face of the molecular plane each other, whereas these bonds point the same face in the *syn*-transition state.

Recently, we obtained thermodynamic parameters for the *syn*- and *anti*-transition states to support our proposal on their relative stabilities. The results will be published elsewhere in near future.

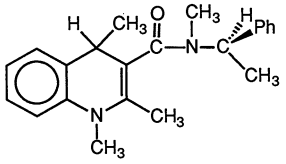
NAD(P)H-NAD(P)+ Models. 74. Entropy-Controlled Kinetics, Stereochemistry, and Tunneling Effect

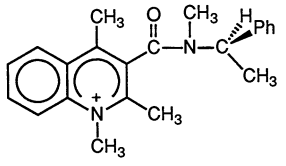
Atsuyoshi OHNO,* Mutsuo GOTO, Yuji MIKATA,
Takeshi KASHIWAGI, and Tetsushi MARUYAMA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received August 31, 1990)

Kinetics have been studied for the reactions of three NAD(P)H analogs and their 4-deuteriated compounds with 2,6-dichloro- and tetrachloro-1,4-benzoquinones. It has been elucidated that the entropy term occupies 50—90% of the Gibbs energy of activation at 298 K. Thus, the reaction is almost entropy-controlled. For certain combinations of the reducing and oxidizing reagents, quantum mechanical tunneling effect plays a large role to determine the reaction rate. The tunneling effect may be another measure of the stereochemistry.

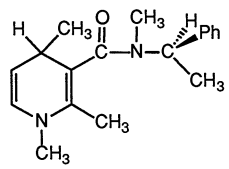
Stereochemistry in the oxidation of 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-1,2,4-trimethyl-1, 4-dihydroquinoline (Me_3MQPH) or 3-(*N*-methyl-*N*-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridine (Me_3PNPH) exert free-energy structure–reactivity–stereochemistry relationship; that is, the stereospecificity associated with the transfer of the central chirality in Me_3MQPH or Me_3PNPH into the axial chirality in their corresponding oxidized forms (Me_3MQP^+ or Me_3PNP^+, respectively) depends on the oxidation and reduction potentials of the reducing and oxidizing reagents.[1,2] The reactive pair prefers the anti-transition state while the less reactive pair prefers the syn-transition state.[3] Based on the stereochemical results, it was concluded that the syn/anti preferency in the transition state stems from the earliness or lateness of the transition state.[1,2]



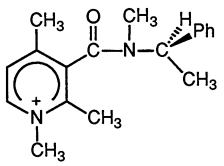
Me_3MQPH



Me_3MQP^+



Me_3PNPH

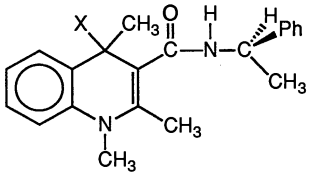


Me_3PNP^+

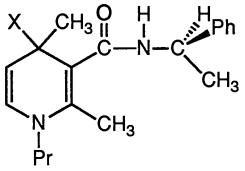
In order to obtain further evidence for the proposed structure of transition state of the reaction, we studied kinetics and elucidated kinetic parameters. Since kinetics become very much complicated in the presence of magnesium ion,[4] the reaction without magnesium ion was studied. 2,6-Dichloro-1,4-benzoquinone (**2Q**) and tetrachloro-1,4-benzoquinone (chloranil, **4Q**) were chosen as the least and most reactive oxidizing reagents, hence, corresponding to the latest and earliest transition states, respectively, under the reaction conditions employed.[5] Although there are many contributions on the kinetics and kinetic isotope effects to discuss on the reaction mechanism of NAD(P)H analogs,[4,6–18] kinetic parameters have scarcely been studied and discussed.[11]

Results

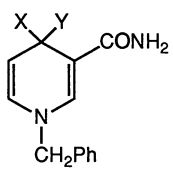
Since the present study does not require to deal with stereochemistry, it is not neccessary to use a compound with a stable axial chirality. Therefore, we employed 3-(*N*-α-methylbenzylcarbamoyl)-1,2,4-trimethyl-1,4-dihydroquinoline (Me_2MQPH) and 3-(*N*-α-methylbenzylcarbamoyl)-1-propyl-2,4-dimethyl-1,4-dihydropyridine (Me_2PNPH) in place of Me_3MQPH and Me_3PNPH.



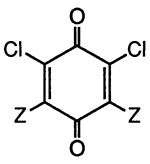
X=H : Me_2MQPH
X=D : Me_2MQPD



X=H : Me_2PNPH
X=D : Me_2PNPD



X=H,Y=H : BNAH
X=H,Y=D : BNAD
X=D,Y=D : $BNAD_2$



Z=H : 2Q
Z=Cl : 4Q

In addition to Me_2MQPH and Me_2PNPH, and their 4-deuteriated derivatives (Me_2MQPD and Me_2PNPD, respectively), *N*-benzyl-1,4-dihydronicotinamide (BNAH) and its 4-deuteriated and 4,4-dideuteriated derivatives (BNAD and $BNAD_2$, respectively) were also studied to convince of the results from the former compounds. BNAH is a compound which has been studied most

extensively.

When an acetonitrile solution of Me_2PNPH was mixed with that of **4Q** under argon atmosphere, a yellow color appeared immediately. This strong absorption band at λ_{max}=449 nm (ε=8,000 M^{-1}) was identified to that of the radical anion from **4Q**.[19] **2Q** behaved similarly (λ_{max}=448 nm). The ESR spectrum of each solution exhibited a signal from the radical anion of the quinone.[19-21] The radical anions thus produced were stable in the presence of excess amount of the quinones, but disappeared gradually at room temperature when the NAD(P)H analog existed in excess amount. The kinetics of the reaction of BNAH with quinones have been studied extensively by Fukuzumi and his co-workers,[11] and we employed the reaction scheme proposed by them.

The observed pseudo-first-order rate constants (with more than 10-fold excess of a reagent), calculated by following the increase in absorbances at the absorption maxima of the corresponding radical anions, are plotted against the concentrations of the analog and of the quinone, respectively, indicating that the reaction is first-order in both the analog and the quinone. Temperatures employed for the measurements ranged from 273 to 323 K with 5 to 15 K intervals. The second-order rate constants, primary and secondary kinetic deuterium isotope effects, and kinetic parameters are summarized in Tables 1 and 2. Primary kinetic deuterium isotope effects in the BNAH systems are in good agreement with those reported.[12]

Discussion

It is apparent that the overall reaction is controlled by the entropy; at 298 K, the entropy term amounts about 10 kcal mol^{-1}, which is about 50—90% of the Gibbs energy of activation. This is a brand-new and important observation because there has ever appeared no discussion on the reaction mechanism of the

a) The values listed in the Table are those at 298 K. Errors in rate constants and kinetic isotope effects are estimated to be ±3 and ±5%, respectively. Those for parameters of activation are less than ±10%. The deuterium content in $BNAD_2$ was 97%, which was corrected to obtain the observed rate constant. b) Calculated from the enthalpy of activation assuming no difference in entropy of activation for protiated and deuteriated compounds. c) Calculated according to the Powell and Bruice's equation; Ref. 28. d) $\delta=X_H-X_D$. e) Ref. 24. f) Ref. 1.

NAD(P)H analog from the viewpoint of entropy.

The entropy of activation changes most evidently on changing Me_2PNPH to Me_2PNPD in the reaction with **2Q**, where the syn-transition state is preferred: That is, the primary kinetic deuterium isotope effect calculated on the basis of enthalpy of activation (7.39) is more than twice as large as that observed (3.03). The result strongly suggests that the quantum mechanical tunneling effect plays a major role in differentiating the reactivities of protiated and deuteriated compounds.[22,23] The importance of the tunneling effect can also be recognized by Kwart's diagnosis.[24] Although a part of Kwart's proposal has been claimed,[25,26] the reaction with a large difference in E_a (ca. 1.5—6 kcal mol^{-1}) and very small A_H/A_D value (<0.6) can safely be attributed to a tunneling transition state. With this criterion, the reaction of Me_2PNPH with **2Q** as well as the reactions of BNAH with both **2Q** and **4Q** is believed to pass through the tunneling transition state.[14–18] This is not true for the reaction with Me_2MQPH which passes through the anti-transition state preferentially.

Namely, although the changes in Gibbs energy of activation at 298 K on deuteriation are the same for the Me_2MQPH and the Me_2PNPH systems in the reaction with **2Q** ($\delta\Delta G^{\neq}=-0.7$ kcal mol^{-1}), the changes in enthalpy and entropy of activation for the Me_2MQPH system ($\delta\Delta H^{\neq}=-0.99$ kcal mol^{-1}; $\delta\Delta S^{\neq}=-0.8$ cal mol^{-1} deg^{-1}) are largely different from those for the Me_2PNPH system ($\delta\Delta H^{\neq}=-1.18$ kcal mol^{-1}; $\delta\Delta S^{\neq}=-1.5$ cal mol^{-1}deg^{-1}) in accord with the proposal of classical transition state for Me_2MQPH and quantum mechanical tunneling effect for Me_2PNPH.

In the reactions with **4Q**, the tunneling effect is smaller (or even negligible) than that in the reaction with **2Q**, which reveals that the proton (or hydrogen atom)-transfer process in a reaction with the former quinone requires larger movement of the nucleus than that in a reaction with the latter quinone. Since the reactivity of **4Q** for the electron-transfer process is much larger than that of **2Q**, the electron-transfer takes place at the early stage of the ring-deformation, or the C_4–H bond in the NADH analog is less elongated, and the C_4-proton (or hydrogen atom) of the NADH analog in the reaction with **4Q** has to migrate longer distance than that in the reaction with **2Q** in the succeding proton (or hydrogen atom)-transfer process.[1)]

The present result again supports the multi-step reaction mechanism for the transfer of a (net) hydride by proving that when the electron-transfer process is associated with a low activation energy and proceeds fast, the succeeding proton (or hydrogen atom)-transfer process becomes slow due to a high activation energy.[7,8)]

The oxidation potentials of Me_2MQPH, Me_2PNPH, and BNAH measured by the scanning rate method[6,13)] are +0.83, +0.62, and +0.59 (lit,[12)] 0.57) V (vs. SCE), respectively, which means that the rate of the initial electron-transfer increases in this order. Taking into consideration the discussion mentioned above for the proton (or hydrogen atom)-transfer process, the energy diagrams along the total reaction coordinate may be those that are represented in Fig. 1.[1)]

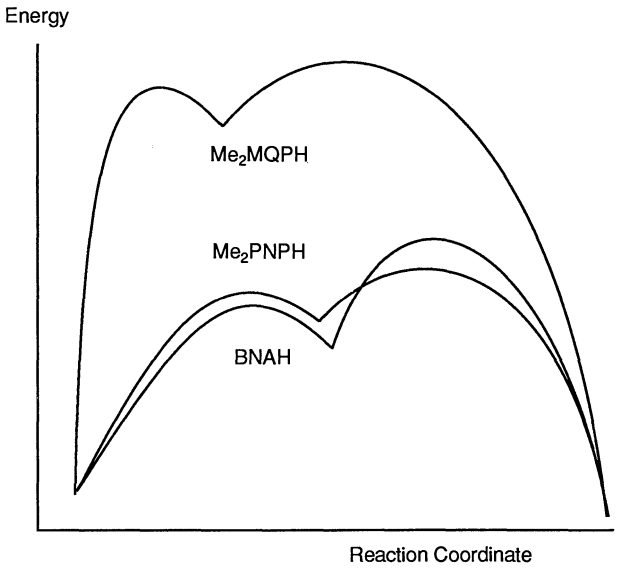

Fig. 1. Energy diagram along the reaction coordinate in the reactions of Me_2MQPH, Me_2PNPH, and BNAH.

The present conclusion is in good agreement with the idea proposed previously that the syn-configuration is favored enthalpically in a late transition state but the anti-configuration is favored entropically in an early transition state.[1,2)] That is, the NAD(P)H analog in a reaction which has to pass through a hindered transition state as a result of strong interaction between two reacting reagents prefers to assume entropically favorable anti-conformation to make the transition state less hindered and entropically favorable, whereas that in another reaction which is accompanied by less small entropy of activation can assume enthalpically favored syn-conformation at the transition state.

It is thus interesting to point out that, although the syn/anti selection is controlled by the electronic effect from the reagent(s), or there holds a linear free-energy reactivity-stereochemistry relationship,[1,2)] the essential of the effect stems from the entropic (or steric) effect instead of the enthalpic effect. That is, the electronic effect controls molecular assembly at the intermediate and/or transition state, and the molecular assembly is the subject of entropy-control, at the same time. Consequently, the electronic effect is related to the entropic effect, then to stereospecificity. In this sense, the electronic effect discussed in this paper is entirely

different from the stereoelectronic effect proposed and developed by Delongchamps and other researchers.[27]

A careful inspection of Tables 1 and 2 suggests that the classical (which corresponds to the early or anti-configurational) or quantum mechanical tunneling (which corresponds to the late or syn-configurational) transition state may be another measure of the stereochemistry of the reaction. We need more data before concluding the stereochemistry–transition-state structure relationship.

Experimental

Instruments. ^{1}H NMR spectra were recorded at 200 and 400 MHz on a Varian VXR 200 FT-NMR and a JEOL JNM-GX400 FT-NMR spectrometers, respectively. ^{2}H NMR spectra were recorded at 31 MHz on a Varian VXR 200 FT-NMR spectrometer. UV spectra were obtained on a Hitachi U-3210 spectrometer with a Hitachi SDR-30 temperature controller. ESR spectra were recorded on a JEOL JES-RE 2XG spectrometer. Kinetic measurements were performed with a Union Giken RA-401 Rapid Reaction Analyzer equipped with a Union Giken K2R temperature controller and a Union Giken System 77 or a NEC PC9801 microcomputer system. Elemental analyses were performed with a Yanako MT-3 elemental analyzer.

Cyclic voltammetry and controlled potential macro-electrolysis were performed with a Hokuto Denko HAB-151 potentiostat/galvanostat. Cyclic voltammograms were recorded on a Riken Denshi F-35 X-Y recorder. A platinum electrode sealed in heat-shrinkable Teflon was employed as the working electrode. A platinum wire and an Ag/AgCl electrodes were used as the counter and reference electrodes, respectively.

Materials. Detailed procedures for the preparation and purification of reagents employed for the present study were described in the previous report.[1]

Kinetics. Kinetics measurements were carried out by using a stopped-flow apparatus from 273 to 323 K with 5 to 15 K intervals under argon atmosphere. Reaction rate was followed by observing the increase in absorbance at the absorption maxima of the anion radical of quinones in acetonitrile under pseudo-first-order conditions by using more than 10-fold excess quinone. Pseudo-first-order rate constants and kinetic parameters were calculated by the least-squares curve-fit, using a personal computer.

Oxidation Potential. The oxidation peak potentials of Me_2MQPH, Me_2PNPH, and BNAH were measured with cyclic voltammetry at 298 K in 10 ml acetonitrile containing 0.1 M (M=mol dm^{-3}) tetraethylammonium perchlorate and 2 mM NADH analog by changing the scan rate in the range 20—2,000 mV/s. The error in observation was estimated to be ±0.005 mV. The detailed procedure has been described in a literacture.[12] The observed potential against Ag/AgCl electrode was corrected for the potential against SCE by subtracting a value of 0.042 V.

We thank financial support for this research by Japanese Ministry of Education, Science and Culture under the Grant-in-Aid Nos. 01470022, 01303007, 02303004, and 02740265. We also wish to thank Professor R. L. Schowen, the University of Kansas, for his valuable advice.

(Received June 22, 1990)

Germacyclopentane, its 1-methyl, and 1,1-dimethyl derivatives together with some germacyclopentenes were prepared and their ^{13}C and ^{73}Ge NMR spectra were determined. Molecular mechanics calculations of germacyclopentanes indicate that the symmetric twist form is the most stable in contrast to cyclopentane where the envelop and twist forms have much the same energy. Though both ^{13}C and ^{73}Ge chemical shifts are less sensitive to the stereochemistry of the methyl group as compared with the corresponding germacyclohexanes, the spectroscopic results can be explained in terms of the structures as depicted by molecular mechanics calculations.

In the previous communications we have reported the preparation and structural study of 1-methyl-[2], 1-phenyl-[3] and 1-*t*-butyl-germacyclohexanes[1] (**GC**) based on ^{13}C and ^{73}Ge chemical shifts, molecular mechanics calculations (MM2) and molecular orbital calculations (MNDO). It was found that the conformational energy of a methyl or a phenyl group bonded to germanium is essentially zero while that of a *t*-butyl group is ca. 1.3 kcal mol^{-1} in a sharp contrast with the case of corresponding cyclohexanes (**C**).

This very small conformational energy is due to the flattening of **GC** ring around germanium atom as well as the extended C–Ge bond length, both of which will reduce the repulsion between the axial substituent on germanium and the C-3, 5 methylene moieties.[2] In this connection it will be interesting to see the structural features of germacyclopentanes (**GP**) which have hitherto never been described.

It is well established that cyclopentane (**1CP**) is a free pseudorotator and the an envelop (hereafter abbreviated as **E**) and a twist-boat (hereafter abbreviated as **T**) form have an identical energy.[4] Alkylcyclopentanes are not any more a free pseudorotator, and in the case of methylcyclopentane (**2CP**) the most stable form is the one with the methyl group at the tip of envelop. The energy difference between **E** and **T** is, however, essentially zero.

This feature of cyclopentanes (**CP**) will make the stereochemical significance of equatorial and axial orientations of the substituent nearly identical. This can most simply be exemplified by the ^{13}C chemical shifts of *trans*-1,3-dimethylcyclohexane and -cyclopentane. In both compounds one of the two methyl groups is necessarily axial (or pseudo-axial), which will be expected to make averaged chemical shifts to highfield than those of corresponding 1,3-*cis* isomers. In the case of dimethylcyclopentanes the chemical shifts difference between *trans*- and *cis*-isomers is only 0.3 ppm (the former is in the higher field)[5] while the similar difference of dimethylcyclohexanes amounts to 2.35 ppm with the *trans*-isomer in the higher field.[6]

Hence three questions have arisen concerning the stereochemistry of **GP**. One is the determination of the most stable structure of germacyclopentane (**1GP**) or **GP** in general. The second one is to determine the extent of difference between (pseudo)equatorial and (pseudo)axial orientations of the methyl group on germanium in **GP**. The second question is interesting in relation to our previous finding that the two conformers (equatorial and axial) of 1-methylgermacyclohexane (**2GC**) have essentially similar MM2 steric energy with a slight preference to the axial isomer (by ca. 0.2 kcal mol^{-1}).[2] The third one is the possibility that a methyl group or any other substituent bonded to the ring carbon might alter the most stable structure from **T** to something else.

With these in mind we prepared **1GP**, 1-methylgermacyclopentane (**2GP**), and 1,1-dimethylgermacyclopentane (**3GP**). We also attempted to prepare 1,1,3-trimethylgermacyclopentane (**4GP**) and 1,1,3,4-tetramethylgermacyclopentane (**5GP**) without success. Instead, 1,1-dimethyl-3,4-epoxygermacyclopentane (**10GP**) and 1,1-dimethylgermacyclopentan-3-ol (**11GP**) were prepared . Compounds **4GP**, **5GP**, **10GP**, and **11GP** were selected because in these compounds the stereochemical environment of two methyl groups bonded to germanium can be different.

Four germacyclopentenes, 1,1-dimethylgermacyclopent-3-ene (**6GP**), 1,1,3-trimethylgermacyclopent-3-ene (**7GP**), 1,1-diethyl-3-methylgermacyclopent-3-ene (**8GP**), and 1,1,3,4-tetramethylgermacyclopent-3-ene (**9GP**) were prepared. Compounds **7GP** and **9GP** were expected to be the precursor for **4GP** and **5GP**, respectively. The compound **8GP** was chosen to assess the effect of an ethyl group bonded to germanium upon chemical shifts.

We deteremined the ^{13}C and ^{73}Ge NMR spectra of the compounds prepared, and carried out molecular mechanics calculations of **1GP—4GP**. For other compounds molecular mechanics calculations were

impossible because of the lack of parameters.

Results and Discussion

Molecular Mechanics Calculations. Molecular mechanics calculations were carried out for germacyclopentanes **1GP—4GP** with the aid of MM2 program[7] to which parameters for germanium as reported by Ouellette[8] were incorporated. The appropriateness of this combination together with the reason why the new germanium parameters reported by Allinger et al.[9] was not employed has already been discussed in our previous paper.[1]

For the input structures for MM2 calculations, **GP** can either be an envelop or a twist and in each structure the germanium atom can have three different positions (a, b, and c for an envelop, and d, e, and f for a twist). In other words, there are six possible input structures for **1GP** (Fig. 1). A similar situation should be involved in the case of **3GP**. In the case of **2GP** the situation is more complicated since for each of the structures a—e, there are two orientations, equatorial (abbreviated as **eq-2GP**) and axial (**ax-2GP**), of the methyl group. For the input structure f, the equatorial and axial structures are degenerated, and hence for **2GP** altogether eleven input structures were considered. For **4GP**, the situation is the same with the case of **2GP**, and eleven input structures were calculated.

The steric energy and its components for each optimized structure are given in Table 1. In MM2 calculations, total steric energies (E_s) are the sum of compression energy (E_c), bending energy (E_b), stretch-bend energy (E_{sb}), torsional energy (E_t) and van der Waals energy which is subdivided into the energy associated with 1,4-interaction ($E_{1,4}$) and that with other interactions (E_{other}). The geometrical parameters for each optimized structures are given in Table 2.

1GP: It is interesting to notice that the input structure **1GP-a** was optimized to an envelop, **E(1GP)**, while the input structure **1GP-b** and **1GP-c** were optimized to a symmetric (in the sence that the germanium nucleus is on the C_2 axis) twist **T(1GP)**. The latter is by ca. 2 kcal mol^{-1} more stable than the former. When the input structure was a twist form, the situation is considerably different, and both **1GP-e** and **1GP-f** were optimized to the same **T**. The input structure **1GP-d** was, however, optimized to a different structure, an unsymmetrical twist **A(1GP)**.

The difference between **T** and **A** is clear when the dihedral angle was compared. In **T** there are two paris of nearly equal dihedral angles while in **A** all five are more or less different. Otherwise, the steric energy of this unsymmetrical species is nearly the same with that of **E(1GP)**.

2GP: The situation is very similar for the case of **1GP**. The most stable structure is again **T(2GP)**, a symmetrical twist. There are two cases (**eq-2GP-a** and **ax-2GP-a**) where the input structures are optimized to **E**. Both envelops have a steric energy about 2 kcal mol^{-1} higher than **T**. The small energy difference between **E** from **eq-2GP-a** and that from **ax-2GP-a** (0.26 kcal mol^{-1}) in favor of the latter is a reminiscence of the situation for equatorial- and axial-1-methylgermacyclohexane (**2GC**).[2]

Two input structures **eq-2GP-c** and **ax-2GP-d** are

optimized to an unsymmetrical twist **A**. These two as well as the optimized structure from an envelop **E(2GP)** have a similar steric energy.

It is interesting to see the conformation of the methyl group bonded to germanium. For optimized **E** structure for **eq-2GP** (which is not the energy minium) the dihedral angles Me–Ge-1–C-2–C-3 (and Me–Ge-1–C-5–C-4) is ca. 155°, which corresponds to 163° for the value of **eq-2CP** (dihedral angle Me–C-1–C-2–C-3). The dihedral angle for optimized *E* structure of **ax-2GP** are 74° while for **ax-2CP** the corresponding values are ca. 82°. Thus, the dihedral angles for **2GP** are generally smaller than those for **2CP**.

The corresponding values for **eq-2GC** (Me–Ge-1–C-2–C-3) and **eq-2C** (Me–C-1–C-2–C-3) are 167° and 180°, respectively, while the corresponding values for **ax-2GC** and **ax-2C** are ca. 69° and 73°, respectively. There is, however, no comparing since both *E* forms of **eq-** and **ax-2GP** are not energy minima. The two dihedral angles for **T** form of **2GP**, 129° and 100°, clearly indicates there is no butane-gauche type interaction between the methyl group and C-3/C-4 methylene moieties in the optimized **T** form.

3GP: An essentially identical situation with the previous case was observed for **3GP**. The most stable structure is a symmetric twist **T(3GP)**. The envelop **E(3GP)**, which is from the input structure **3GP-a**, is 1.8 kcal mol^{-1} higher in energy than **T(3GP)**. An unsymmetrical twist **A(3GP)**, from **3GP-d**, has a similar steric energy with that of **E(3GP)**.

4GP: In order to prove that the most stable structure is in fact **T**, an examination of NMR spectra of such a compound as **4GP** will be helpful. In **T** form the two Ge-1 methyl group remain nearly equivalent regardless of the presence of C-3 methyl group. On the other hand, if **GP** is in **E**, the presence of C-3 methyl will restrain the ring reversal and/or pseudorotation to avoid one of Ge-1 methyl and C-3 methyl will become 1, 3-diaxial. The net effect is that the **GP** ring will remain in **E** in which two Ge-1 methyl groups can be differentiated.

The most stable structure is again **T(4GP)** with an

a) The definition of the structure parameters are as follows: $r_{1,2}$ is the distance between Ge and C-2 in nm, θ_1 is the bond angle C5–Ge–C2 in degrees and $\psi_{1,2}$ is the torsion angle in degrees defined by the C5–Ge–C2–C3. The other parameters are defined analogously.

equatorial methyl at C-3, similar to previous examples. It must be pointed out that **T(4GP)** with an axial C-3 methyl group can be an energy minimum though the steric energy is by more than 1 kcal mol^{-1} larger than the former. The asymmetric twist **A(4GP)** has much higher energy and cannot contribute to the structure.

The values of component energies indicate that the stability of **T** form is to be ascribed to the low E_b term, which is ca. 2.2 kcal mol^{-1} smaller as compared with **E** or **A**. The E_t term of **T** is generally slightly larger than these for **E** and **A**. The E_c and $E_{1,4}$ terms of **T** are slightly but consistently smaller than those for **E** and **A**; the sum is, however, smaller than the gain in E_b.

The difference in steric energy between **E** and **T** may be reflected in the geometrical parameters given in Table 2. Firstly, in the high energy structure (**E** and **A**) of **GP**, the bond angle θ_1 (C5–Ge–C2)(ca. 89°) is always by ca. 4° smaller than that of low energy structures (**T**:93°). This smaller bond angle in **E** and **A** seems to couple with a very small (0.001 nm) but consistent decrease of bond length $r_{1,2}$ and $r_{5,1}$. These two effects associated with germanium in **E** should cause an increase in the E_b term. It must be pointed out such a difference in bond angle also exists for **E** and **T** forms of **CP**.

Another point to be considered is the average flattening. The sum of five dihedral angle is a measure of ring flattening. In **GP** the sum for **E** is less than that for **T** by more than 20° while for **CP** the difference is only ca. 7°. Excessive flattening should increase the steric energy of the system and for this reason the **T** form is the most stable among possible conformers.

Preparation of Germacyclopentanes. The preparation of **1GP—3GP** was carried out in a similar manner that used in the preparation of corresponding germacyclohexanes.[10]

The preparation of **4GP** and **5GP** was attemped, starting from isoprene (2-methyl-1,3-butadiene) and 2,3-dimethyl-1,3-butadiene, respectively, and germanium(II) iodide (GeI_2). 1,1-Diiodo-3-methyl- and 1,1-diiodo-3,4-dimethylgermacyclopent-3-ene initially formed were converted to **7GP** and **9GP**, respectively with the aid of methylmagnesium iodide (MeMgI). **7GP** and **9GP** were hydrogenated with H_2/Ni (50 atm) but the desired **4GP** and **5GP** could not be isolated.

Instead we decided to prepare **10GP** and **11GP** because the possible precursor **6GP** can relatively easily be obtained from butadiene and trichlorogermane ($HGeCl_3$), and a subsequent treatment with MeMgI. **6GP** was treated with *m*-perbenzoic acid to give **10GP** which was treated with lithium aluminum hydride (LAH) to afford **11GP**.

^{73}Ge Chemical Shifts. In Table 3, ^{13}C and ^{73}Ge chemical shifts of germacylopentanes and germacyclopentenes are listed. The values in parentheses are those of the corresponding **GC**.

The chemical shifts of three compounds **1GP—3GP** indicate that the effect of a methyl group is similar in magnitude as that in **GC**. Thus the span is ca. 140 ppm for **GP** and ca. 120 ppm for **GC**. In **GP**, however, the resonances are considerably in lower

Table 3. ^{73}Ge[a] and ^{13}C[b] NMR Chemical Shifts of Germacyclopentanes, Germacyclopentenes, and Germacyclohexanes[c]

Compounds	Ge-1	C-2	C-3	C-4	C-5	Me-1	Me-3
1GP	−101.1 (−130.3)	13.22 (9.32)	29.20 (26.78)	29.20 (26.78)	13.22 (9.32)		
2GP	−27.4 (−65.6)	11.86 (12.61)	28.60 (26.09)	28.60 (26.09)	11.86 (12.61)	−5.20 (−6.55)	
3GP	40.0 (−11.3)	14.45 (15.33)	28.65 (28.65)	28.65 (25.90)	14.45 (15.33)	−2.38 (−3.77)	
6GP	37.0	21.78	134.03	134.03	21.78	0.27	
7GP	44.6	23.88	139.76	125.67	20.41	−2.16	22.63
8GP	70.9	20.77	141.12	127.04	17.30	7.20 (CH_2) 10.19 (Me)	23.67

10GP		16.96	58.01	58.01	16.96	−0.22 −1.89	
11GP		24.22	74.44	36.13	10.89	−1.44 −1.84	

a) In ppm relative to external $GeMe_4$ (δ=0). b) In ppm relative to internal $SiMe_4$ (δ=0). c) Values in pharentheses are corresponding germacyclohexanes. Data taken from Ref. 2.

field. This low field shift is most likely due to the reduced bond angle θ_1. A similar effect was reported for ^{29}Si chemical shifts of 1,1-dimethylsilacyclohexane (−1.0 ppm) and 1,1-dimethylsilacyclopentane (16.8 ppm).[11]

The correlation between ^{73}Ge chemical shifts and those of ^{29}Si was reported as below.[12]

$$\delta(^{73}\text{Ge}) = 3.32\delta(^{29}\text{Si}) + 39.9$$

Thus, the ^{73}Ge shift difference between **3GP** and **3GC** is expected to be about 59 ppm based on the above correlation. The observed difference, 51.3 ppm, is not very far from the prediction, indicating that the correlation is, though empirical, quite general.

^{73}Ge chemical shifts of **GP** (**6GP—9GP**) are puzzling. In view of a very small chemical shift difference between 1,1-dimethylgermacyclohexane (**3GC**; −11.3 ppm) and 1,1,3-trimethylgermacyclohexane (**4GC**; −12.2 ppm), similarly small differences are expected for the chemical shifts of three compounds, **6GP**, **7GP**, and **9GP** since the effect of a pseudo-equatorial methyl group at C-3 should not be large. In fact, the difference between **6GP** and **7GP** is 7.6 ppm, a rather unexpectedly large value. Furthermore, the shift for **9GP** is considerably in high field.

The only possible explanation is the change of most stable structure in **9GP**. According to molecular mechanics calculations, the most stable conformation of cyclopentene is an envelop with nearly planar double bond moiety.[13,14] The *cis*-dimethyl substituents will suffer from a strong repulsion, and the deviation from the planarity will be increased. One of the methyl group will be bent to the direction opposite to the flap while the other to direction of flap. The latter methyl is expected to induce a substantial high field shift induced by the steric interaction with 1,1-dimethyl moiety. Lack of the relevant parameters inhibit us from carrying out molecular mechanics calculations to prove this explanation.

^{73}Ge chemical shift of **8GP** is also puzzling. Since the shift for tetraethylgermane is 17.8 ppm relative to tetramethylgermane (δ=0), a large difference of 26.3 ppm between **7GP** and **8GP** is unexpected. Here the deviation of germanium from tetrahedral structure seem to be involved though more extensive data should be accumulated before a concrete conclusion can be drawn.

^{13}C Chemical Shifts. The assignment of ^{13}C signals is more or less straightforward, based on the comparison with the data for **GC** and on the number of attached proton(s) as indicated by the INEPT experiment.

There is one anomaly in ^{13}C chemical shifts of C-2, 5. In **GC** C-2 exhibits a low field shift as the number of methyl group bonded to germanium increases. This is also the case with methylcyclohexanes.[6] In **GP**, however, the resonance of C-2 of **2GP** is in the highest field among three compounds investigated. We do not have any explanation for this anomaly.

The chemical shift difference between two methyls of **10GP** and **11GP** is informative. In **11GP** the difference is very small even compared with that of 1,1,3-trimethylgermacyclohexane (2.30 ppm).[15] This is consistent with a symmetric twist **T** structure where the effect of pseudo-equatorial substituent to two methyl groups on germanium is very similar. The fact that the epoxide **10GP** shows a larger difference (1.66 ppm) might indicate that in the particular compound the germacyclopentane ring is not **T**. On the other hand, the epoxide ring cannot be coplanar with the ring, to make the stereochemical enviroment of two methyls somewhat different.

In conclusion, it can be assumed that the optimized structure of the germacyclopentane ring is a symmetric twist **T** regardless of the number and orientation of methyl group(s) bonded to germanium. This makes a sharp contrast to the cyclopentane ring, essentially a free rotator, where an envelop and a twist boat has much the same steric energy.

Most of the ^{73}Ge and ^{13}C NMR data are accounted for in terms of the symmetric twist structure of **GP**. How to explain some anomaly remains, however, to be solved in future.

Experimental

Infrared spectra were obtained with a JASCO A102 grating infrared spectrophotometer as a liquid film. The ^{1}H NMR spectra were recorded with a Varian EM-390 spectrometer as $CDCl_3$ solution containing a small amount of tetramethylsilane (TMS) as the internal standard.

The ^{73}Ge NMR spectra were recorded as solutions in $CDCl_3$ (1:1 v/v) on a JEOL FX-90Q spectrometer equipped with an NM-IT 10LF low-frequency insert, operating at 3.10 MHz, in a 10 mm tube at 30 °C. Typical measurement conditions were as follows: pulse width, 150 μs (90°); spectral width, 2000 Hz; number of scans, 5000; pulse delay, 100 ms; data points, 4096. The ^{13}C NMR spectra were determined for the same solutions on the same instrument at 22.50 MHz. Typical measurement conditions were as follows: pulse width, 13 μs (40°); spectral width, 2000 Hz; number of scans, 500; pulse delay, 1 s; data points, 4096. The combined results are given in Table 3.

Molecular Mechanics Calculations. The program used was Allinger's MM2(85).[7] Since in MM2(85) the parameters for germanium are not available, we installed the parameters reported by Ouellette[8] in MM2(85). For the sake of comparison, calculations were also carried out for the corresponding cyclopentanes (**1CP—4CP**) and the results were also included in Tables 1 and 2.

Preparation of Germacyclopentane and Germacyclopentane Derivatives (1GP—11GP). Some of organogermanium compounds are sensitive to air and moisture, and elemental analyses are not necessarily feasible. The purity was in most cases monitored by a combination of gas chromatography, mass and NMR spectra.

Preparation of **1GP—3GP** was carried out, with some modification, according to the literature.[10] Thus, the reaction between the bis-Grignard reagent of 1,4-dibromobutane and tetrachlorogermane afforded 1,1-dichlorogermacyclopentane, which was treated with LAH to give **1GP** and with methylmagnesium iodide (MeMgI) to give **3GP**.

1-Methylgermacyclopentane (2GP): 1,1-Dichlorogermacyclopentane was treated with phenylmagnesium bromide to give 1,1-diphenylgermacyclopentane, which was monobrominated, and treated with methylmagnesium bromide. The resultant 1-methyl-1-phenylgermacyclopentane was successively treated with bromine and LAH to afford the desired **2GP**.

1,1-Dimethylgermacyclopent-3-ene (6GP): An ether solution of trichlorogermane (25.1 g, 0.10 mol) was cooled to −78 °C, to which butadiene (30 ml) was added in one portion. The mixture was stirred for 14 h while the temperature was gradually raised to the room temperature. By usual work-up, 1,1-dichlorogermacyclopent-3-ene (11.6 g, 42%) was obtained, bp 65 °C/15 mmHg (1 mmHg=133.322 Pa). The dichloro compound was treated with MeMgI to afford 1,1-dimethylgermacyclopent-3-ene (**6GP**) (4.87 g, 53%), bp 113 °C/766 mmHg. IR (neat) 1607 (C=C).

1,1,3-Trimethylgermacyclopent-3-ene (7GP): GeI_2 (20.0 g, 61.2 mmol) and isoprene (4.5 g, 66.2 mmol) were placed in a sealed tube, which was heated at 60 °C for 4 h. to give viscous, orange-colored 1, 1-diiodo-3-methylgermacyclopent-3-ene. Since this unsaturated compound was found unstable and hence employed in the next step without isolation nor purification. MeMgI was prepared from MeI (52.1 g; 367 mmol) and Mg (8.92 g, 367 mmol) in diethyl ether (200 ml) under argon. The ether solution of the Grignard reagent was cooled to −45 °C to which the diiodide solution (70 ml) was added and the mixture was gradually brought to room temperature. Under ice-cooling the mixture was treated with HCl (2 mol dm^{-3}), and the organic layer was separated, dried with $CaCl_2$. The ether layer was removed and the residue was distilled under a reduced pressure to give 1,1,3-trimethylgermacyclopent-3-ene (**7GP**) (6.51 g, 62%), bp 70—72 °C/35 mmHg (lit,[16] bp 139 °C/741 mmHg).

Found: C, 49.42; H, 8.09%. Calcd for $C_7H_{14}Ge$; C, 49.23; H, 8.26%.

1,1-Diethyl-3-methylgermacyclopent-3-ene (8GP): GeI_2 (5.88 g, 18 mmol) and isoprene (3.12 g, 46 mmol) were placed in a sealed tube, which was heated at 60 °C for 3 h. to give viscous, orange-colored 1,1-diiodo-3-methylgermacyclopent-3-ene. Ethylmagnesium iodide (150 mmol) was prepared in ether (150 ml) was prepared to which the ether solution (70 ml) of above diiodide was dropwise added at −30 °C, stirred for 2 h and kept at room temperature overnight. Under ice-cooling the mixture was treated with saturated aqueous solution of NH_4Cl, and the organic layer was separated, dried with $CaCl_2$. The ether layer was removed and the residue was distilled under a reduced pressure to give **8GP** (2.42 g, 68%), bp 82 °C/58 mmHg. IR (neat) 1635 (C=C).

1,1,3,4-Tetramethylgermacycloent-3-ene (9GP): GeI_2 (16.6 g, 50.8 mmol) and 2,3-dimethylbutadiene (4.3 g, 52.4 mmol) were mixed and gradually heated under a steam of Ar to 50 °C when the reaction was initiated to give an yellow solution. The mixture was further kept at 110 °C for 2 h to complete the reaction. The crude diiodide was dissolved in ether (100 ml), to which MeMgI (200 mmol) in ether (150 ml) was dropwise added under reflux. Refluxing was further continued for 2 h and hydrolyzed with aqueous saturated NH_4Cl solution under ice cooling. The ether layer was washed with water, dried over $CaCl_2$, and the ether was removed. The residue was distilled in vacuo to afford **9GP** (6.93 g, 74%), bp 88 °C/45 mmHg.

1,1-Dimethyl-3,4-epoxygermacyclopentane (10GP): 6GP (18.9 g, 0.12 mol) was treated with *m*-chloroperbenzoic acid (22.9 g, 0.13 mol) in dichloromethane under ice cooling. Stirring was continued for 2.5 h, and *m*-chlorobenzoic acid was filtered off. The organic layer was successively treated with aqueous sodium hydrogensulfite, sodium carbonate, and ammonium chloride, and dried with magnesium sulfate. By distillation, **10GP** was obtained (13.8 g, 66%), bp 68—70 °C/45 mmHg.

1,1-Dimethylgermacyclopentan-3-ol (11GP): 10GP (118 g, 68 mmol) was dropwise added to LAH (1.3 g, 34 mmol) in diethyl ether (100 ml) in a stream of argon. After refluxed for 3 h, the mixture was decomposed with aqueous HCl (2 mol dm^{-3}) under ice cooling. The organic layer was washed, dried with magnesium sulfate, and distilled to afford **11GP** (9.6 g, 81%), bp 83 °C/15 mmHg. IR (neat) 3330 (O–H).

Attempted Preparation of 1,1,3-Trimethylgermacyclopentane (4GP): 7GP (5.39 g, 31.6 mmol) was dissolved in absolute ethanol (100 ml) to which Raney Ni (W-1) (2.0 g) was added and hydrogenated (110 °C, H_2 pressure 50 kg cm^{-2}) for 5 h. After the completion of reaction, the solvent was removed and the residue was distilled in vacuo, preparative gas chromatography. The NMR spectrum indicated that the sample contains at least three inseparable components.

Thermal Reactions of 6-Methyl-5-[(substituted hydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinediones with Electron-Deficient Olefins and Acetylene[1)]

Michihiko NOGUCHI,* Yasutoshi KIRIKI, Takashi TSURUOKA, Takahiro MIZUI, and Shoji KAJIGAESHI
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received July 20, 1990)

The thermal reactions of some 6-methyl-5-[(substituted hydrazino)methyl]-2,4(1*H*,3*H*)-pyrimidinediones (**1**) were investigated. The 1,5-hydrogen shift in **1** gave 5,6-dihydro-5,6-bis(methylene)-2,4(1*H*,3*H*)-pyrimidinedione intermediates, while the 1,2-hydrogen shift in **1** gave azomethine imine intermediates. These reaction profiles depend on the substituents of hydrazone moieties.

Much attention has been paid for the heterocyclic compounds containing pyrimidine nuclei, since the ring systems are widely found in biologically active compounds.[2)]

Some 5,6-dihydro-5,6-bis(methylene)-2,4(1*H*,3*H*)-pyrimidinediones (**B**) have been reported as being useful intermediates for the synthesis of fused pyrimidine derivatives.[3)] Intermediates **B** could be formed by a 1,5-hydrogen shift of the corresponding precursors **A**. Recently, intermediate **2a** from 1,3,6-trimethyl-5-[(dimethylhydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinedione (**1a**; R^1=R^2=Me) was confirmed by a [4+2]cycloaddition reaction with *N*-methylmaleimide (**3**), giving a pyrrolo[3,4-*g*]quinazoline derivative **4a**.[3d)]

In order to obtain a better understanding of the reaction profiles, the thermal reactions of some 6-methyl-5-[(substituted hydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinediones and their pyrimidine analogs were investigated.

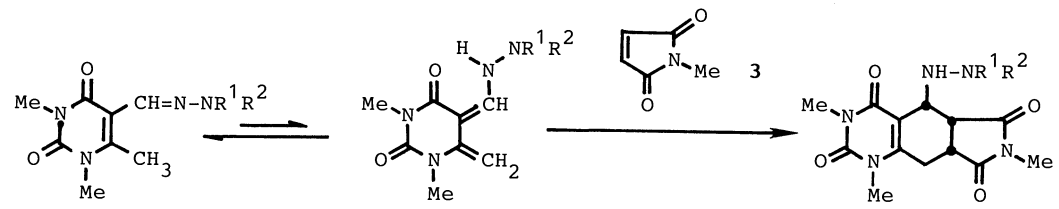
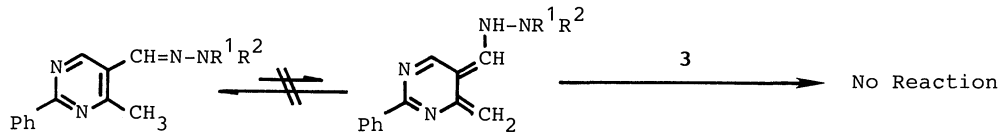
Results and Discussion

Heating of 5-(disubstituted hydrazono)methyl derivatives **1b** (R^1,R^2=$-(CH_2)_5-$) and **1c** (R^1,R^2=$-(CH_2)_2-O-(CH_2)_2-$) and **3** in dioxane under reflux gave the



1a: R^1= R^2= Me
1b: R^1, R^2= $-(CH_2)_5-$
1c: R^1, R^2= $-(CH_2)_2-O-(CH_2)_2-$

2a–c **4a–c**



5a: R^1= R^2= Me
5b: R^1, R^2= $-(CH_2)_5-$
5c: R^1, R^2= $-(CH_2)_2-O-(CH_2)_2-$

6a–c

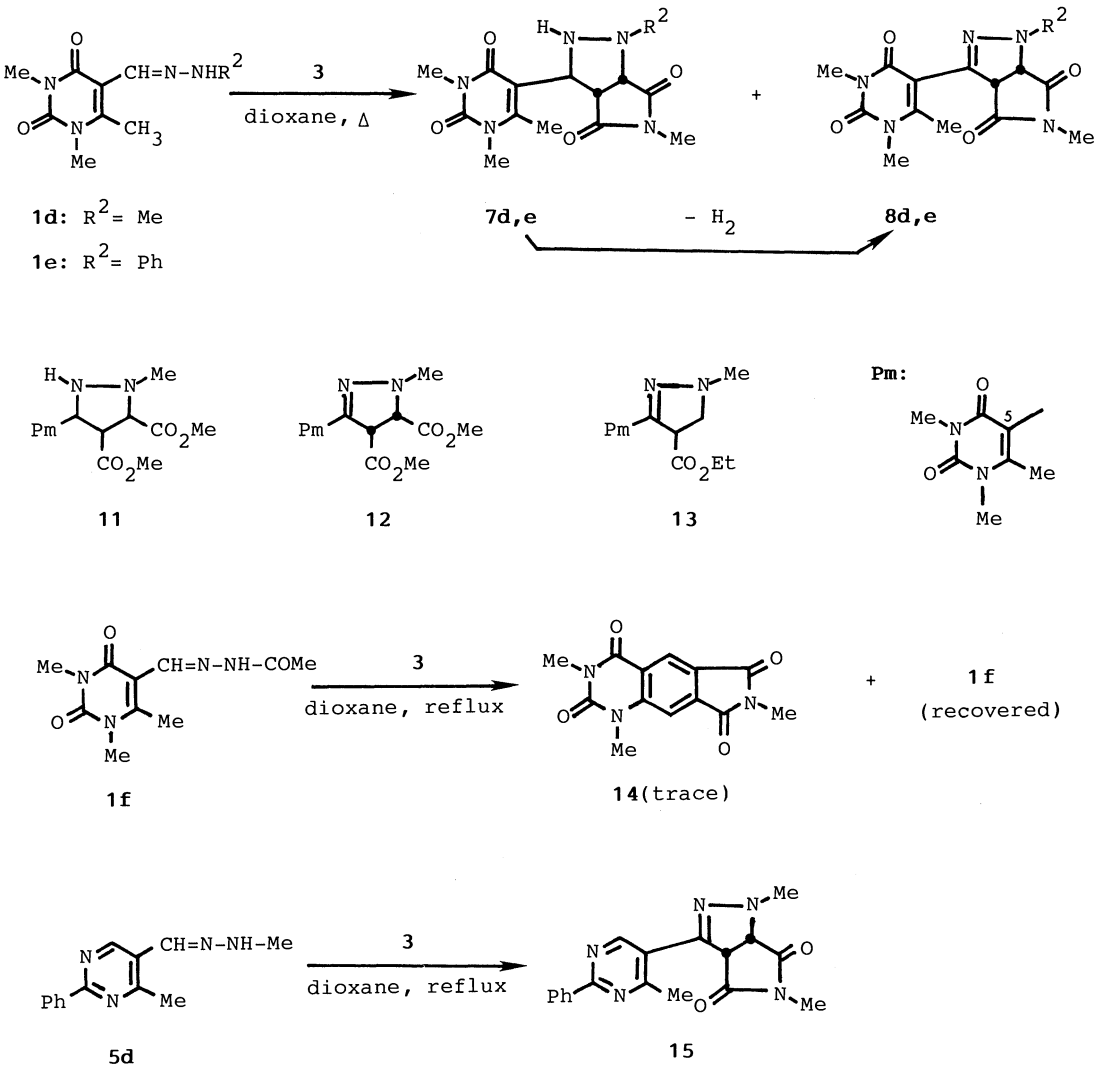
Scheme 1.

expected 5-(2,2-disubstituted hydrazino)pyrrolo[3,4-*g*]-quinazolines **4b**, **c** in good yields (Scheme 1). The synthetic usefulness of the 5,6-dihydro-5,6-bis(methylene)-2,4(1*H*,3*H*)-pyrimidinedione intermediate **2a** leading to quinazoline derivatives was briefly described in a preliminary paper.[3d]

However, a similar reaction of 4-methyl-2-phenyl-5-[(disubstituted hydrazono)methyl]pyrimidines **5a** (R^1=R^2=Me), **5b** (R^1,R^2=$-(CH_2)_5-$), and **5c** (R^1,R^2=$-(CH_2)_2-O-(CH_2)_2-$) with **3** did not give any adducts. This means that a 1,5-hydrogen shift in **5a**—**c** leading to diene-intermediates **6** would be unfavorable because of a loss of the aromaticity of the pyrimidine ring (Scheme 1).

The effect of the N-substituent of the hydrazone moiety on the reaction profiles was also investigated. Heating of 1,3,6-trimethyl-5-[(methylhydrazono)-methyl]-2,4(1*H*,3*H*)-pyrimidinedione (**1d**) and **3** in dioxane under reflux gave two products, **7d** and **8d**, in 86% total yield. Their molecular formula indicate that **7d** is a 1:1 adduct of **1d** and **3**, while **8d** is a dehydrogenated product from **7d**. The pyrrolo[3,4-*c*]-pyrazole structures of **7d** and **8d** were determined by their spectral data; their ^{1}H NMR spectra showed the existence of a 1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl moiety. The five signals in the ^{13}C NMR spectrum of **7d**, δ=51.2(3a-C), 60.7(6a-C), 69.7(3-C), 174.7, 175.6(4- and 6-C), were assignable to carbons of the pyrrolo[3,4-*c*]pyrazole moiety. On the other hand, the ^{13}C NMR spectrum of **8d** showed two sp^3-carbon signals, δ=55.0(3a-C) and 65.0(6a-C), and three sp^2 signals, δ=152.5(3-C), 172.3, 173.4(4- and 6-C), for the pyrrolo[3,4-*c*]pyrazole moiety. The ratio of products **7d** and **8d** depended on both the reaction conditions and the procedures, while the combined yield of **7d** and **8d** was almost constant. The initially formed product **7d** was easily converted to **8d** during the work-up.

In order to elucidate the reaction profiles, **1d** was allowed to react with methyl fumarate (**9**) and ethyl acrylate (**10**). The pyrazolidine **11** and 2-pyrazoline derivatives **12** and **13** were obtained, respectively. The



Scheme 2.

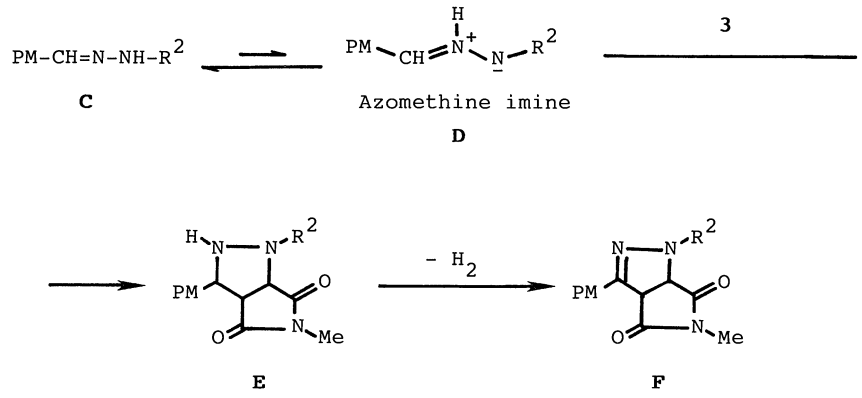
reaction of 5-(phenylhydrazono)methyl derivative **1e** with **3** gave pyrrolopyrazoles **7e** and **8e** in good total yield. On the other hand, the reaction of 5-(acetylhydrazono)methyl derivative **1f** with **3** gave a trace of pyrrolo[3,4-g]quinazoline **14**[3d] (in 3% yield) with a recovery of the starting materials. A similar reaction of 4-methyl-5-[(methylhydrazono)methyl]-2-phenylpyrimidine (**5d**) with **3** in refluxing dioxane gave a pyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione **15** in 75% yield (Scheme 2).

These pyrrolopyrazole preparations are explainable by the intermediacy of azomethine imine 1,3-dipole (**D**), which could be formed via a 1,2-hydrogen shift in hydrazone **C**, as demonstrated by Grigg et al.[4] The 1,3-dipolar cycloaddition of **D** with **3** gave tetrahydropyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione **E**, which was dehydrogenated to 3a,6a-dihydropyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione **F** (Scheme 3).

The differences on the reaction profiles between 5-(monosubstituted hydrazono)methyl derivatives and 5-(disubstituted hydrazono)methyl ones were found in the reaction with dimethyl acetylenedicarboxylate (**16**). Heating of **1a** and **16** in dioxane under reflux gave 5-cyano-1,3,6-trimethyl-2,4(1*H*,3*H*)-pyrimidinedione (**17**) in 58% yield. The same type of product **18** was obtained by the reaction of **5a** with **16**.

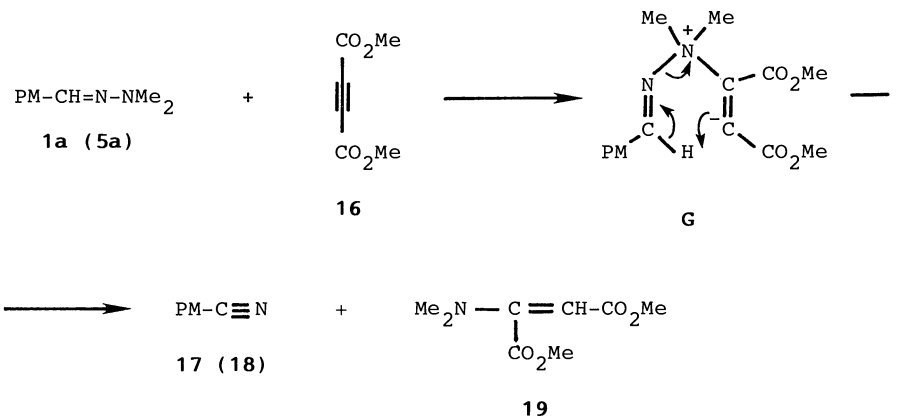
A nucleophilic attack of hydrazone nitrogen to acetylenic carbon would initially take place to give a betaine **G**, which is converted to the cyano compounds, **17** and **18**, with the elimination of 2-(dimethylamino), maleate **19** (Scheme 4). Recently, a similar reaction pathway was proposed for the formation of 2-cyanothiophene by the reaction of 2-[(dimethylhydrazono)methyl]thiophene with **16**.[5]

Heating of **1d** and **16** in dioxane under reflux gave 2-pyrazoline **12**, the same product from the reaction of



PM: 1,2,3,4-Tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl; 4-Methyl-2-phenyl-5-pyrimidinyl

Scheme 3.



PM: 1,2,3,4-Tetrahydro-1,3,6-trimetyl-2,4-dioxo-5-pyrimydinyl; 4-Methyl-2-phenyl-5-pyrimidinyl

1d with dimethyl fumarate (**9**), methyl 2-(1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-acrylate (**20**), and 3,4,5-tris(methoxycarbonyl)-1-methyl-1*H*-pyrazole (**21**). In this reaction a thermal 1,2-hydrogen shift in **1d** gave the 1,3-dipole, which underwent a cycloaddition reaction with **16** to give a 3-pyrazoline derivative **H**. Its isomerization gave 2-pyrazoline derivative **12** with 4,5-cis configuration. A plausible pathway for the formation of **20** and **21** via **H** is demostrated in Scheme 5, which is based on the result of the reaction of benzaldehyde phenylhydrazone with **16**.[6]

In conclusion, the reaction profiles of 6-methyl-5-[(substituted hydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinediones **1** and their pyrimidine analogs **5** depended not only upon the nature of the pyrimidine rings, but also upon the substituents of the hydrazone moieties. The thermal reaction of 6-methyl-5-[(disubstituted hydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinediones **1a—c** gave 5,6-dihydro-5,6-bis(methylene)-2,4(1*H*,3*H*)-pyrimidinedione intermediates (**B**) via the 1,5-hydrogen shift, while that of 6-methyl-5-[(monosubstituted hydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinediones **1d, e** and their pyrimidine analog **5d** gave azomethine imine intermediates (**D**) via the 1,2-hydrogen shift. The cycloaddition reaction using these intermediates, **B** and **D**, gave a useful synthetic tool for the heterocycles containing pyrimidine nuclei.

Experimental

General. All melting points are uncorrected. The IR spectra were measured on a JASCO IR-Report-100 spectrophotometer. The ^1H NMR spectra were obtained on JEOL GSX-400, 270, and/or JMN-MH-100 spectrometers. The chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Splitting patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad signal; and ov, overlapping with each other. The ^{13}C NMR spectra were obtained on a JEOL GSX-400 or 270 spectrometer. The mass spectra were determined with a JEOL JMS-012G-2 or JMS-D spectrometer at an ionization energy of 75 eV. Elemental analyses were performed on a Hitachi 026 CHN analyzer. All nonaqueous reactions were run under a positive pressure of argon. All solvents were dried by standard methods before use. The progress of most reactions was monitored by thin-layer chromatography (Silica Gel 60F-254, Merck). Visualization was made ultraviolet light (254 and 365 nm). Chromatographic purification was performed with Wakogel C-200 (100—200 mesh, Wako Pure Chemical Industries) and/or Silica Gel 60 (230—400 mesh, Merck).

Unknown hydrazones **1b—d,f** and **5a—d** were prepared by usual methods.

1,3,6-Trimethyl-5-[(1-piperidinyl)iminomethyl]-2,4-(1*H*,3*H*)-pyrimidinedione (1b): Colorless prisms (ethanol); mp 138—140 °C. Calcd for $C_{13}H_{20}N_4O_2$: C, 59.07; H, 7.63; N, 21.20%. Found: C, 59.21; H, 7.64; N, 21.35%.

1,3,6-Trimethyl-5-[(morpholinoimino)methyl]-2,4(1*H*,3*H*)-pyrimidinedione (1c): Colorless prisms (ethanol); mp 180—181 °C. Calcd for $C_{12}H_{18}N_4O_3$: C, 54.12; H, 6.81; N, 21.04%. Found: C, 53.93; H, 6.92; N, 21.17%.

1,3,6-Trimethyl-5-[(methylhydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinedione (1d): Colorless prisms (ethanol); mp 108—110 °C. Calcd for $C_9H_{14}N_4O_2$: C, 51.42; H, 6.71; N, 26.65%. Found: C, 51.76; H, 6.80; N, 26.74%.

5-[(Acetylhydrazono)methyl]-1,3,6-trimethyl-2,4(1*H*,3*H*)-pyrimidinedione (1f): Colorless prisms (ethanol); mp 268—271 °C. Calcd for $C_{10}H_{14}N_4O_3$: C, 50.42; H, 5.92; N, 23.52%. Found: C, 50.44; H, 6.00; N, 23.40%.

6-Methyl-5-[(dimethylhydrazono)methyl]-2-phenylpyrimidine (5a): Yellow prisms (hexane); mp 98—99 °C. Calcd

for $C_{14}H_{16}N_4$: C, 69.97; H, 6.71; N, 23.31%. Found: C, 70.02; H, 6.73; N, 23.22%.

6-Methyl-5-[(1-piperidinyl)iminomethyl]-2-phenylpyrimidine (5b): Pale yellow prisms (ethanol); mp 98—100 °C. Calcd for $C_{17}H_{20}N_4$: C, 72.82; H, 7.19; N, 19.99%. Found: C, 72.75; H, 7.38; N, 19.90%.

6-Methyl-5-[(morpholinomethyl)methyl]-2-phenylpyrimidine (5c): Pale yellow plates (ethanol); mp 134—136 °C. Calcd for $C_{16}H_{18}N_4O$: C, 68.06; H, 6.43; N, 19.85%. Found: C, 68.25; H, 6.46; N, 19.80%.

6-Methyl-5-[(methylhydrazono)methyl]-2-phenylpyrimidine (5d): Pale yellow needles (ethanol); mp 108—112 °C. Calcd for $C_{13}H_{14}N_4$: C, 69.00; H, 6.24; N, 24.76%. Found: C, 68.93; H, 6.00; N, 24.45%.

Reaction of 6-Methyl-5-[(disubstituted hydrazono)methyl]-2,4(1*H*,3*H*)-pyrimidinediones with *N*-Methylmaleimide (3). General Procedure: A solution of **1b** (264 mg, 1.0 mmol) and **3** (122 mg, 1.1 mmol) in dioxane (5 ml) was heated under reflux for 2 days. The reaction mixture was evaporated under reduced pressure to give a residue, which was subjected to column chromatography on silica gel to afford **4b** (339 mg, 90%) as an eluate of hexane/ethyl acetate (1/5).

5a,8a-Dihydro-1,3,7-trimethyl-5-[(1-piperidinyl)amino]-1*H*-pyrrolo[3,4-*g*]quinazoline-2,4,6,8(3*H*,5*H*,7*H*,9*H*)-tetrone (4b): Colorless prisms (ethanol); mp 208—209 °C; IR(KBr) 3200 (NH), 1770, 1700, 1650(CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.72 (1H, br s, NH), 1.27, 1.50, 2.08, 2.55—2.75 (total 10H, 4m, piperidinyl methylene), 2.82 (1H, dd, 5a-H, J_{5-5a}=3.9 and J_{5a-8a}=8.8 Hz), 3.05 (3H, s, $-CH_3$), 3.1—3.2 (total 2H, ov, 8a- and 9-H), 3.31(1H, dd, 9-H, J_{8a-9}=5.9 and J_{gem}=15.6 Hz), 3.36, 3.49 (each 3H, 2s, $-CH_3$), 5.02 (1H, d, 5-H, J_{5-5a}=3.9 Hz); ^{13}C NMR ($CDCl_3$) δ=23.0 (9-C), 25.0, 28.4, 31.7 ($-CH_3$), 38.0 (8a-C), 44.8 (5a-C), 48.0 (5-C), 24.0, 25.8, 56.8 (piperidinyl methylene-C), 108.1 (4a-C), 151.6 (9a-C), 151.9 (2-C), 160.8 (4-C), 176.3, 179.2 (6- and 8-C); MS *m/z* 376 (M^+). Calcd for $C_{18}H_{25}N_5O_4$: C, 57.58; H, 6.71; N, 18.66%. Found: C, 57.85; H, 6.69; N, 18.38%.

5a,8a-Dihydro-1,3,7-trimethyl-5-morpholinomethyl-1*H*-pyrrolo[3,4-*g*]quinazoline-2,4,6,8(3*H*,5*H*,7*H*,9*H*)-tetrone (4c): Yield 92%; colorless prisms (hexane–dichloromethane); mp 251—252 °C; IR(KBr) 3200 (NH), 1770, 1700, 1650 (CO) cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.15, 2.35, 2.66 (total 4H, 3m, morpholino methylene), 2.82 (1H, dd, 5a-H, J_{5-5a}=3.9 and J_{5a-8a}=8.3 Hz), 2.96 (3H, s, $-CH_3$), 3.17 (1H, br s, NH), 3.2—3.4 (total 3H, ov, 8a- and 9-H), 3.28, 3.47 (each 3H, 2s, $-CH_3$), 3.6 (4H, m, morpholino methylene), 4.87 (1H, d, 5-H, J_{5-5a}=3.9 Hz); ^{13}C NMR (DMSO-d_6) δ=21.3 (9-C), 23.2, 26.7, 30.0 ($-CH_3$), 30.1 (8a-C), 43.3 (5a-C), 46.1 (5-C), 54.1, 65.0 (morpholino methylene-C), 105.9 (4a-C), 150.2 (9a-C), 150.7 (2-C), 159.2 (4-C), 175.0, 177.8 (6- and 8-C); MS *m/z* 377 (M^+). Calcd for $C_{17}H_{23}N_5O_5$: C, 54.10; H, 6.14; N, 18.56%. Found: C, 54.25; H, 6.11; N, 18.40%.

Reaction of 6-Methyl-5-[(monosubstituted hydrazono)-methyl]-2,4(1*H*,3*H*)-pyrimidinediones with 3. General Procedure: A solution of **1d** (1.0 mmol) and **3** (1.1 mmol) in dioxane (5 ml) was heated under reflux for 20 h. The reaction mixture was evaporated under reduced pressure to give a residue, which was subjected to column chromatography on silica gel to afford **7d** (137 mg, 43%) (hexane/ethyl acetate=1/3) and **8d** (138 mg, 43%) (ethyl acetate). The ratio of **7d** and **8d** varied according to the reaction conditions; prolonged heating (for 36 h) gave **7d** (19%) and **8d** (60%). A treatment of the reaction mixture (under reflux for 20 h) with flash chromatography on silica gel (hexane/ethyl acetate= 1/2—1/4) gave **7d** (55%) and **8d** (29%).

Tetrahydro-3-(1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-1,5-dimethylpyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione (7d): Colorless crystals; mp 110—113 °C; IR(KBr) 3300(NH), 1770, 1710, 1630(CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.40 (3H, s, 6′-CH_3), 2.76, 2.95, 3.22, 3.50 (each 3H, 4s, N-CH_3), 3.4 (1H, ov, 3a-H), 4.10 (1H, dd, 3-H, J_{2-3}=7.7 and J_{3-4a}=9.0 Hz), 4.65 (1H, d, 6a-H, J_{3a-6a}=7.1 Hz), 5.8 (1H, br d, NH, J_{2-3}=7.7 Hz); ^{13}C NMR ($CDCl_3$) δ=16.8 (6′-CH_3), 25.1, 28.0, 32.4, 41.7 (N-CH_3), 51.2 (3a-C), 60.7 (6a-C), 69.7 (3-C), 104.8 (5′-C), 151.0, 153.0 (2′- and 6′-C), 160.8 (4′-C), 172.3, 173.4 (4- and 6-C). Calcd for $C_{14}H_{19}N_5O_4$: C, 52.33; H, 5.96; N, 21.80%. Found: C, 52.70; H, 5.77; N, 22.12%.

1,3a-Dihydro-3-(1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-1,5-dimethylpyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione (8d): Colorless prisms (benzene); mp 144—146 °C; IR(KBr) 1780, 1700, 1630(CO)cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.31 (3H, s, 6′-CH_3), 2.99, 3.12, 3.38, 3.47 (each 3H, 4s, N-CH_3), 4.27 (1H, d, 3a-H, J_{3a-6a}=10.7 Hz), 5.16 (1H, d, 6a-H, J_{3a-6a}=10.7 Hz); ^{13}C NMR ($CDCl_3$) δ=17.9 (6′-CH_3), 25.1, 28.3, 32.5, 42.6 (N-CH_3), 55.7 (3a-C), 69.8 (6a-C), 104.2 (5′-C), 140.8 (3-C), 151.5, 152.4 (2′- and 6′-C), 161.4 (4′-C), 173.2, 174.3 (4- and 6-C); MS *m/z* 320 (M^+). Calcd for $C_{14}H_{17}N_5O_4$: C, 52.66; H, 5.37; N, 21.93%. Found: C, 52.90; H, 5.37; N, 22.00%.

A similar reaction of **1e** with **3** gave **7e** and **8e** in a total yield of 98%.

Tetrahydro-3-(1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-5-methyl-1-phenylpyrrolo[3,4-*c*]pyrazole-4,6-(1*H*,5*H*)-dione (7e): Colorless prisms (ethyl acetate); mp 190—193 °C; IR(KBr) 3290 (NH), 1790, 1700, 1630 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.31 (3H, s, 6′-CH_3), 3.00, 3.27, 3.48 (each 3H, 3s, N-CH_3), 3.40(1H, dd, 3a-H, J_{3-3a}=9.0 and J_{3a-6a}=7.7 Hz), 4.30 (1H, dd, 3-H, J_{2-3}=12.3 and J_{3-3a}=9.0 Hz), 4.82 (1H, d, 6a-H, J_{3a-6a}=7.7 Hz), 6.15 (1H, d, NH, J_{2-3}=12.3 Hz), 6.8—7.0, 7.2—7.4 (total 5H, 2m, phenyl); ^{13}C NMR ($CDCl_3$) δ=16.6 (6′-CH_3), 25.2, 28.0, 32.6 (N-CH_3), 51.2 (3a-C), 60.7 (6a-C), 69.7 (3-C), 102.7 (5′-C), 114.4, 120.8, 129.3, 150.4 (phenyl-C), 150.8, 151.4 (2′- and 6′-C), 163.0 (4′-C), 174.7, 175.6 (4- and 6-C); MS *m/z* 383 (M^+). Calcd for $C_{19}H_{21}N_5O_4$: C, 59.52; H, 5.52; N, 18.27%. Found: C, 59.22; H, 5.71; N, 18.62%.

3a,6a-Dihydro-3-(1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-5-methyl-1-phenylpyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione (8e): Colorless prisms (benzene), mp 313—316 °C; IR(KBr) 1790, 1710, 1640(CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.38 (3H, s, 6′-CH_3), 3.02, 3.40, 3.50 (each 3H, 3s, N-CH_3), 5.08 (1H, d, 3a-H, J_{3a-6a}=11.0 Hz), 5.46 (1H, d, 6a-H, J_{3a-6a}=11.0 Hz), 6.9—7.0, 7.2—7.5 (total 5H, 2m, phenyl); ^{13}C NMR ($CDCl_3$) δ=18.0 (6′-CH_3), 25.4, 28.3, 32.6 (N-CH_3), 55.0 (3a-C), 65.0 (6a-C), 103.9 (5′-C), 114.4, 121.6, 129.2, 140.3 (phenyl-C), 144.6 (6′-C), 151.5, 152.5 (3- and 2′-C), 161.3 (4′-C), 172.3, 173.4 (4- and 6-C); MS *m/z* 381 (M^+). Calcd for $C_{19}H_{19}N_5O_4$: C, 59.83; H, 5.02; N, 18.36%. Found: C, 59.98; H, 5.16; N, 18.40%.

1,3,7-Trimethyl-1*H*-pyrrolo[3,4-*g*]quinazoline-2,4,6,8(3*H*,7*H*)-tetrone (14): Yellow prisms (benzene–ethanol); mp 253—238 °C; IR(KBr) 1700, 1650(CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.69 (1H, dd, 9-H, J_{gem}=17.6 and J_{8a-9}=17.1 Hz), 3.10, 3.39, 3.57 (each 3H, 3s, N-CH_3), 3.43 (1H, dd, 9-H, J_{gem}=17.6 and

J_{8a-9}=8.3 Hz), 3.62 (1H, ddd, 8a-H, J_{5-8a}=2.9 and J_{8a-9}=17.1 and 8.3 Hz), 7.56 (1H, d, J_{5-8a}=2.9 Hz); ^{13}C NMR ($CDCl_3$) δ=24.8 (9-C), 25.6, 28.5, 32.3 (N-CH_3), 37.9 (8a-C), 107.6 (4a-C), 120.2, 124.9 (5- and 5a-C), 151.3, 151.5 (2- and 9a-C), 160.0 (4-C), 166.8, 174.1 (6- adn 8-C); MS *m/z* 275 (M^+). Calcd for $C_{13}H_{13}N_3O_4$: C, 56.72; H, 4.76; N, 15.27%. Found: C, 56.85; H, 4.75; N, 15.04%.

The reaction of **1d** with dimethyl fumarate (**9**) gave **11** and **12** in a total yield of 59%. It is too difficult to isolate each other from the mixture as pure forms. The mixture of **11** and **12** in dioxane was heated under reflux in the presence of palladium/charcoal for 5 h to give only product **12**.

3-(1,2,3,4-Tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-4,5-bis(methoxycarbonyl)-1-methylpyrazolidine (11): ^{1}H NMR ($CDCl_3$) δ=2.44 (3H, s, 6′-CH_3), 3.37, 3.53 (each 3H, 2s, N-CH_3), 3.80, 3.91 (each 3H, 2s, O-CH_3), 3.4—3.5, 3.5—3.6 (each 1H, ov, 5- and 6-H).

3-(1,2,3,4-Tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-4,5-bis(methoxycarbonyl)-1-methyl-2-pyrazoline (12): Colorless needles (benzene); mp 124—126 °C; IR(KBr) 1750, 1730, 1700, 1650(CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.36 (3H, s, 6′-CH_3), 3.04, 3.33, 3.47 (each 3H, 3s, N-CH_3), 3.68, 3.82 (each 3H, 2s, O-CH_3), 4.18 (1H, d, 4-H, J_{4-5}=12.5 Hz), 4.57 (1H, d, 5-H, J_{4-5}=12.5 Hz); ^{13}C NMR ($CDCl_3$) δ=17.9 (6′-CH_3), 28.1, 32.5, 42.7 (N-CH_3), 52.7, 52.8 (O-CH_3), 57.7 (4-C), 71.9 (5-C), 104.9 (5′-C), 142.6 (3-C), 151.7, 151.9 (2′- and 6′-C), 161.3 (4′-C), 169.4, 169.8 (COO); MS *m/z* 353 (M^+). Calcd for $C_{15}H_{20}N_4O_6$: C, 51.13; H, 5.72; N, 15.90%. Found: C, 51.14; H, 5.72; N, 15.55%.

The cis configuration between 4- and 5-position of **12** was confirmed by a NOE measurement; the 7.0% enhancement of signal area of 5-H was observed on irradiation at 4-H. Compound **12** was also obtained in the reaction of **1d** and dimethyl acetylenedicarboxylate (**16**). This implies that **12** with the 4,5-cis configuration is more stable than the 4,5-trans isomer. A similar reaction of **1d** with dimethyl maleate gave only an unseparable mixture of products. We therefore proposed the formation of **12** as follows: the 1,3-dipolar cycloaddition of the azomethine imine to fumarate **9** would proceed stereoselectively to give a trans-adduct (*trans*-**11**), as known from many examples.[7] Isomerization to the 4,5-cis configuration should occur during the dehydrogenation process of **11** to **12**, but the mechanism has not been clear.

4-Ethoxycarbonyl-3-(1,2,3,4-tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)-1-methyl-2-pyrazoline (13): Yield 20%; pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, t, -CH_3, J=6.5 Hz), 2.46 (3H, s, 6′-CH_3), 2.90, 3.36, 3.50 (each 3H, 3s, N-CH_3), 3.3—3.5 (1H, ov, 5-H), 3.63 (1H, dd, 5-H, J_{gem}=9.8 and J_{4-5}=5.9 Hz) 4.12 (2H, q, -CH_2-, J=6.5 Hz), 4.57 (1H, dd, 4-H, J_{4-5}=5.9 and J_{4-5}=10.8 Hz); ^{13}C NMR ($CDCl_3$) δ=14.2 (-CH_2-CH_3), 18.0 (6′-CH_3), 28.1, 32.5 (1′- and 3′-CH_3), 43.0 (1-CH_3), 53.2 (4-C), 59.4 (5-C), 61.4 (O-CH_4-), 105.9 (5′-C), 145.4 (3-C), 151.7, 151.9 (2′- and 6′-C), 161.6 (4′-C), 170.8 (COO); MS *m/z* 309 (M^+). This compound could not be isolated as a pure form and did not give satisfactory analytical data.

3a,6a-Dihydro-1,5-dimethyl-3-(4-methyl-2-phenyl-5-pyrimidinyl)pyrrolo[3,4-*c*]pyrazole-4,6(1*H*,5*H*)-dione (15): Colorless prisms (ethanol); mp 199—200 °C; IR(KBr) 1780, 1690(CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.82 (3H, s, 4′-CH_3), 3.02, 3.24 (each 3H, 2s, N-CH_3), 4.33 (1H, d, 3a-H, J_{3a-6a}=10.7 Hz), 4.78 (1H, d, 6a-H, J_{3a-6a}=10.7 Hz), 7.4—7.5, 8.4—8.5 (total 5H, 2m, phenyl), 9.14 (1H, s, 6′-H); ^{13}C NMR ($CDCl_3$) δ=25.4 (4′-CH_3), 26.7, 41.9 (N-CH_3), 54.6 (3a-C), 68.9 (6a-C), 121.5 (5′-C), 128.4, 128.6, 130.8, 137.3 (phenyl-C), 138.8 (3-C), 156.3 (6′-C), 162.1 (4′-C), 165.9 (2′-C), 172.4, 173.2 (4- and 6-C); MS *m/z* 336 (M^+). Calcd for $C_{18}H_{17}N_5O_2$: C, 64.46; H, 5.11; N, 20.89%. Found: C, 64.68; H, 5.10; N, 21.22%.

Reaction of 1a with Dimethyl Acetylenedicarboxylate (16). General Procedure: A solution of **1a** (100 mg, 0.45 mmol) and **16** (71 mg, 0.50 mmol) in dioxane (2 ml) was heated under reflux for 2 d. The reaction mixture was evaporated to dryness, and then subjected to column chromatography on silica gel to give **17** (47 mg, 58%), and dimethyl 2-(dimethylamino)maleate (**19**; 37%) was obtained as eluate of hexane/ethyl acetate (5/1).

5-Cyano-1,3,6-trimethyl-2,4(1*H*,3*H*)-pyrimidinedione (17): Colorless needles (hexane); mp 149—151 °C; IR(KBr) 2220 (CN), 1650(CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.58 (3H, s, 6-CH_3), 3.32, 3.51 (each 3H, 2s, N-CH_3); MS *m/z* 179 (M^+). Calcd for $C_8H_9N_3O_2$: C, 53.62; H, 5.06; N, 23.45%. Found: C, 53.75; H, 4.98; N, 23.59%.

Dimethyl 2-(Dimethylamino)maleate (19): ^{1}H NMR ($CDCl_3$) δ=2.86 (6H, s, N-CH_3), 3.60, 3.90 (each 3H, 2s., O-CH_3), 4.56 (1H, s, -CH_3); MS *m/z* 187 (M^+).

5-Cyano-4-methyl-2-phenylpyrimidine (18): Yield 66%; pale yellow needles (ethanol); mp 171—173 °C; IR(KBr) 2210(CN) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.92 (3H, s, -CH_3), 7.7—7.9, 8.7—8.9 (total 5H, 2m, phenyl), 9.22 (1H, s, 6-H); MS *m/z* 195 (M^+). Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.53%. Found: C, 73.43; H, 4.55; N, 21.20%.

Reaction of 1d with 16. A solution of **1d** (210 mg, 1.0 mmol) and **16** (0.18 ml, 1.4 mmol) in dioxane (5 ml) was heated under reflux for 8 h. The reaction mixture was evaporated to dryness and subjected to column chromatography on silicagel to afford **21** (100 mg, 39%) (hexane/ethyl acetate=3/1), **20** (86 mg, 36%) (2/1), and **12** (79 mg, 23%) (1/1).

Methyl 3-(1,2,3,4-Tetrahydro-1,3,6-trimethyl-2,4-dioxo-5-pyrimidinyl)acrylate (20): This was obtained as *E*/*Z* (= 10/9) mixture.

(*E*)-20: Colorless needles (ethanol); mp 181—183 °C; IR(KBr) 1720, 1700, 1640(CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.48 (3H, s, 6′-CH_3), 3.39, 3.54 (each 3H, 2s, N-CH_3), 3.78 (3H, s, O-CH_3), 7.12 (1H, d, 2-H, J=15.6 Hz), 7.58 (1H, d, 3-H, J=15.6 Hz); ^{13}C NMR ($CDCl_3$) δ=17.0 (6′-CH_3), 28.4, 32.8 (N-CH_3), 51.6 (O-CH_3), 107.1 (5′-C), 120.8 (2-C), 135.7 (2-C), 149.7 (6′-C), 151.8 (4′-C), 161.1 (2′-C), 165.8 (1-C); MS *m/z* 239 (M^+). Calcd for $C_{11}H_{14}N_2O_4$: C, 55.45; H., 5.92; N, 11.76%. Found: C, 55.38; H, 6.03; N, 12.02%.

(*Z*)-20: Colorless plates (ethanol); mp 116—117 °C; IR (KBr) 1720, 1700, 1640(CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.24 (3H, s, 6′-CH_3), 3.36, 3.48 (each 3H, 2s, N-CH_3), 3.69 (3H, s, O-CH_3), 6.15 (1H, d, 2-H, J_{1-2}=11.7 Hz), 6.79 (1H, d, 1-H, J_{1-2}=11.7 Hz); ^{13}C NMR ($CDCl_3$) δ=18.2 (6′-CH_3), 28.3, 32.3 (N-CH_3), 51.5 (O-CH_3), 108.1 (5′-C), 123.5 (2-C), 137.0 (3-C), 149.7 (6′-C), 151.8 (4′-C), 161.1 (2′-C), 165.8 (1-C); MS *m/z* 239 (M^+). Calcd for $C_{11}H_{14}N_2O_4$: C, 55.45; H, 5.92; N, 11.76%. Found: C, 55.38; H, 6.03; N, 12.02%.

3,4,5-Tris(methoxycarbonyl)-1-methyl-1*H*-pyrazole (21): Colorless primsms (ethanol); mp 96—97 °C; IR(KBr) 1740, 1720(CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.00 (total 6H, s, O-CH_3), 4.30 (3H, s, N-CH_3); ^{13}C NMR ($CDCl_3$) δ(off

resonance)=40.7 (q, N-CH_3), 52.5, 52.8, 52.9 (each q, O-CH_3), 121.6 (s, 4-C), 131.6 (s, 5-C), 138.8 (s, 3-C), 158.4, 160.7, 163.6 (each s, COO); MS *m/z* 256(M^+). Calcd for $C_{10}H_{12}N_2O_6$: C, 46.88; H, 4.72; N, 10.93%. Found: C, 46.93; H, 4.72; N, 10.67%.

The authors wish to thank UBE Scientific Analysis Laboratory for the help of the structural analyses using NMR spectrometers at 270 and/or 400 MHz.

Alkane- and arenesulfonyl isocyanates were added to benzocyclopropene across the C–C σ-bond of the three-membered ring, giving 2-sulfonyl-1-isoindolinones. The reaction with *C,N*-diphenylnitrone afforded a similar cyclization product, 3,4-dihydro-3,4-diphenyl-1*H*-2,3-benzoxazine. These reactions are considered to proceed through zwitterionic intermediates formed by the fission of the C–C σ-bond of the three-membered ring by the electrophiles.

Highly strained benzocyclopropene (**1**) has recently attracted much interest of chemists.[2] A fusion of the two rings results in a considerable deformation of the benzene ring and, consequently in a reduction of the aromatic stabilization. Of particular note concerning to the unusual molecular geometry has been a solution to the question of bond fixation[3] and the cleavage mechanism of the three-membered ring in the reaction with electrophiles. Recently, Apeloig and Arad[4] depicted a suggestive FMO picture using a 3-21G method, showing that the HOMO has a higher energy than does the benzene, and is localized at both the fused bond C_1–C_6 and the C_3–C_4 bond.

According to FMO theory, an electrophilic attack should, therefore, occur preferably at the fused bond and more readily than on benzene. Some cycloaddition experiments agree with this argument: **1** reacts smoothly with electron-defficient (hetero)dienes in a concerted [2σs+4πs] fashion to give 1,6-methano[10]-annulenes and the hetero analogues.[5,6] Bond localization was also advocated by its almost quantitative reaction with dihalocarbenes.[7] On the other hand, halogenes, acids, and alcohols with metal ion catalysts provoke the reaction in another way: dissociating the σ-bond of the cyclopropene moiety exclusively to form the benzyl cation intermediates.[8]

The dependence of the different cleavage course on the types of electrophiles prompted us to examine the reactions with electrophilic polar double bonds or charge-separated organic species. To date, there have been only a couple of examples reported in this context; thus with arenecarbonitrile oxides[9] and mesoions,[10] and in both cases, the reaction apparently proceeded in a concerted manner to give the cycloaddition products across the fused bond.[11]

We have examined the reaction with other polar electrophiles to find a contrasting result regarding the yield of [2σ+4π]-type products with some isocyanates and nitrones. These cycloadditions are considered to proceed through an internal coupling of the intermediary zwitterions.

Results

The reaction of benzocyclopropene (**1**) with an equimolar amount of the sulfonyl isocyanate (**2**) was monitored by thin-layer chromatography and NMR spectroscopy. The reactions with methyl and phenyl isocyanates were quite sluggish. The mixture showed practically no change at room temperature over a period of one week.[12] In contrast, the reaction of **1** with *p*-toluenesulfonyl isocyanate (**2d**) proceeded smoothly at 60 °C; the peak at 3.17 ppm of the methylene protons disappeared completely within 40 h. The reaction mixture was subjected to thin-layer chromatography on silica gel to give colorless crystalline 2-*p*-tolylsulfonyl-1-isoindolinone (**3d**) and 1-isoindolinone (**4**) in 39 and 4% yields, respectively. 1-Isoindolinone (**4**) is obviously a secondary product from **3d**, since the isolated **3d** slowly decomposed to **4** in chloroform, and rapidly upon adding a few drops of ammonia water to it.

Similarly, warming a mixture of 1 and benzenesulfonyl isocyanate (**2c**) at 60 °C for 30 h afforded *N*-benzenesulfonyl derivative (**3c**) in 36% yield along with a small quantity of **4**. The cycloadditions with methanesulfonyl isocyanate (**2a**) and 1-butanesulfonyl isocyanate (**2b**) proceeded rather readily even at room temperature, to afford the corresponding 2-alkylsulfonyl-1-isoindolinones (**3a** and **3b**) in more than 20% yields after 3 days.

On the other hand, in reactions with 1,3-dipoles, such as methyl azidoformate and ethyl diazoacetate, we could not detect the corresponding adducts in any case at 60 °C after 4—6 days. In contrast, electrophilic *C,N*-diphenylnitrone (**5**) was sufficiently reactive toward **1** to produce the cycloadduct, 3,4-dihydro-3,4-diphenyl

Fig. 3.

1*H*-2,3-benzoxazine (**6**), in 54% yield.

The structures of **3** were confirmed by IR, ^{1}H NMR, ^{13}C NMR, and mass spectroscopic studies. In ^{1}H NMR spectra the chemical shifts of the methylene protons (around 4.9 ppm) was close to 4.38 ppm of 1-isoindolinone, itself, rather than to 3.50 ppm of the methylene peak of the possible regional isomer, 2-indolinone (**9**). Their ^{13}C NMR spectra indicated carbonyl carbons at between 166 and 167 ppm near to the corresponding value of 158.2 ppm of *N*-methylsaccharin (**10**), composing of the partial structure of $-SO_2NRCO-$.[13] In IR spectra the higher shift of carbonyl absorptions of **3** (around 1720 cm^{-1}) from that of 1-isoindolinone (1680 cm^{-1}) indicated the presence of an electronegative substituent at the nitrogen atom.

In EI mass spectroscopy, the 2-arylsulfonyl-1-isoindolinones (**3c, d**) showed no molecular ion peaks; instead, SO_2-eliminated ions appeared as their parent peaks, which is in contrast with the *N*-alkylsulfonyl derivatives whose parent peaks are 1-oxoisoindolin-2-ylium ion arising from a fragmentation of the alkylsulfonyl radicals. A similar SO_2 extrusion has been observed in *N*-arylsulfonylcarbamates, and the mechanism (not simple cheletropic) has been variously discussed.[14] On the other hand, a milder ionization method (CIMS) using isobutane displayed M$^+$+1 peaks with a distinctively strong intensity.

The structure of the oxazine (**6**) is determined spectroscopically, especially by NMR study. A singlet peak at 5.63 ppm and two doublet peaks at 5.19 and 5.29 ppm with a large geminal coupling constant (J=14 Hz) in ^{1}H NMR as well as the existence of only two aliphatic signals at 67.9 and 70.3 ppm in ^{13}C NMR support the structure (**6**). The formation of a possible regional isomer (**7**) and a norcaradiene derivative (**8**) are excluded.

Discussion

The smooth reaction of **1** with strongly electrophilic sulfonyl isocyanates reflects well the electron-donating nature of **1**. One explanation for the product is that the reaction proceeds in the fashion of an electrophilic aromatic substitution in which an electrophile attacks the HOMO-π-system located at C_1 to form the annelated cyclopropylium ion (**11**). A subsequent ring opening with a relief of strain energy forms a zwitterionic intermediate (**13**), which then recloses to give **3**. However, considering the enormously high strain energy (290 kJ mol^{-1}) of **1**, owing to the fused cyclopropene construction, it is not deniable that at first a σ-bond rupture on the three-membered ring occurs through an intermediate **12**, leading to the zwitterion (**13**). The preferable path between the π-

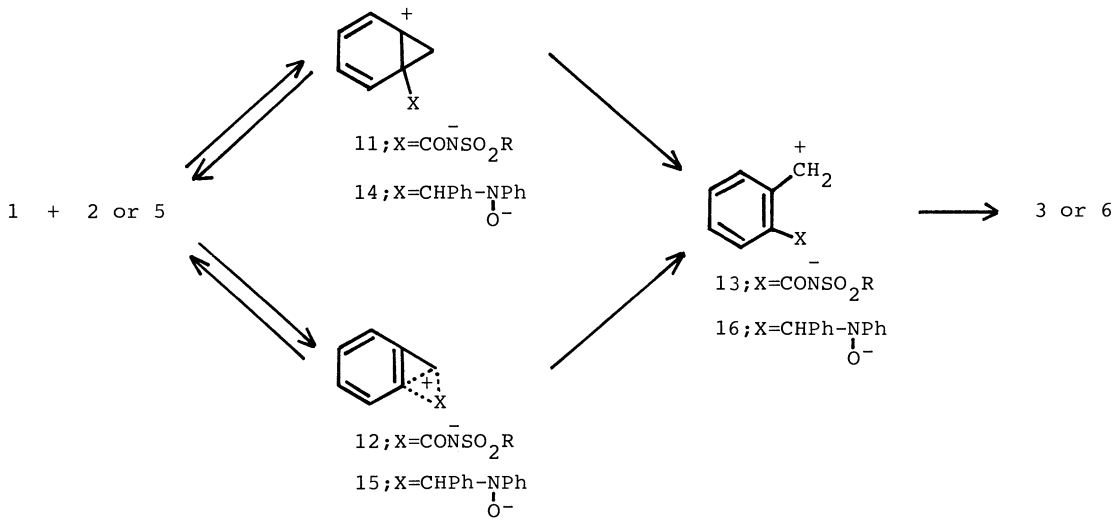

Fig. 4.

and σ-route has not yet been decided at the present stage, due to a lack of information regarding the stability of the intermediates.

Cycloaddition reactions of 1,3-dipoles have been highly studied over the past 20 years by Huisgen and others.[15] Houk et al. have discussed the reactivity and regioselectivity in synchronous dipolar additions in terms of FMO theory.[16] Among various types of 1,3-dipoles, nitrones and nitrile oxides having lower LUMO energies are expected to exert a considerable orbital interaction with the HOMO of **1**, especially when they are perturbated by the phenyl substituent.

The finding by Nitta and his co-workers is in accord with the theoretical prediction; they isolated a bridged norcaradiene, stable up to 120 °C, by a reaction with aromatic nitrile oxides.[9] In our study with diphenyl nitrone (**5**), however, we could not detect the formation of the tricyclic system (**8**); also, the possibility of a [1,3] sigmatropic shift of **8** to **6** is unrealistic under the reaction conditions.

It is most likely that the formation of **6** involved a stepwise process through a zwitterionic intermediate (**16**), which was derived via **14** or **15**. The regioselectivity of the addition is rationally accounted for by a CNDO/2 calculation on **5**, estimating that the LUMO coefficient on the carbon atom is greater than that on the oxygen atoms.[16] Thus, the orbital overlapping between the carbon atom of the nitrone and the π- or σ-bond of the three-membered ring develops as they approach to form the zwitterion (**16**), which leads to the product (**6**) by the resulting internal coupling. However, despite having a close LUMO energy level to that of nitrle oxide, why the nitrone does not add across the fused bond of **1** is still unclear.

As described above regarding the reaction with sulfonyl isocyanates and nitrones, the adjoining σ-bond to the benzene ring of **1** is formally replaced by a new σ-bond supplied from the entering electrophiles. Such an exceptional facile leaving of C–C bond from the aromatic ring is obviously ascribed to a highly strained cyclic system.

Experimental

The melting points were recorded on a Yanagimoto micro melting point apparatus and were uncorreced. The IR spectra were determined on a JASCO A-100 or a JASCO A-102 spectrometers. The NMR spectra were recorded by using a JNM GX-270 or a Varian XL-200 spectrometers in $CDCl_3$ solution with tetramethylsilane as an internal standard. Low- and high-resolution mass spectra were measured using a Shimadzu 9020-DF or a JMX DX-300 spectrometers. The UV spectra were recorded on a Hitachi 210 spectrometer. The solvents used were purified according to the standard procedures.[17] Methyl and phenyl isocyanates and benzene- and *p*-toluenesulfonyl isocyanates were commercially available. Methane- and 1-butanesulfonyl isocyanates were prepared by a method described in the literature.[18] Plates for preparative thin-layer chromatography were prepared with Merck Silica gel PF-254 or Wako gel B5-F.

General Procedure for the Reaction of Sulfonyl Isocyanates with 1. A solution of **1** (1.0 mmol) in chloroform (2.0 ml) was added to an ice-cold solution of sulfonyl isocyanate (**2**) (1.0 mmol) in the same solvent (3.0 ml). The combined solution was gently bubbled with dry nitrogen gas for ten min and allowed to stand at room temperature, or warmed. After the solvent was evaporated, the residual crude reaction mixture was chromatographed on TLC plates using chloroform–ethyl acetate–hexane (2:1:3) as a developing solvent to give crystalline products, which were further purified by recrystallization from 2-propanol. The yields were determined when the sample showed a single spot on TLC and contained practically no contaminates on the NMR spectra. 1-Isoindolinone (**4**) was identified by a comparison of TLC (R_f=0.1) and the melting point of 151—153 °C (Lit,[19] 155—156 °C) with an authentic sample.[19]

2-Methylsulfonyl-1-isoindolinone (3a): Yield: 21%. Colorless needles, mp 162 °C, R_f=0.3. Found: C, 51.17; H, 4.33; N, 6.67; S, 15.32%. Calcd for $C_9H_9NO_3S$: C, 51.17; H, 4.30; N, 6.63; S, 15.18%. EIMS *m/z* (rel intensity) 211 (M^+, 24), 133 (30), 132 (100), 105 (23), 104 (38), 77 (39). CIMS (isobutane) *m/z* (rel intensity) 212 (M^++1, 78), 134 (79), 57 (C_4H_9+1, 100). IR (KBr) 1720, 1340, 1142, 1130, 1092 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.42 (s, 3H), 4.89 (s, 2H), 7.2—7.6 (m, 2H), 7.71 (dd, 1H, *J*=7.3 and 7.3 Hz), 7.92 (d, 1H, *J*=7.7 Hz). ^{13}C NMR ($CDCl_3$) δ=41.1 (q), 49.2 (t), 123.5 (d), 125.2 (d), 129.0 (d), 130.0 (s), 134.2 (d), 141.2 (s), 167.2 (s).

2-Butylsulfonyl-1-isoindolinone (3b): Yield 26%. Calorless needles, mp 102.5 °C, R_f=0.7. Found: C, 56.70; H, 5.93; N, 5.60; S, 12.71%. Calcd for $C_{12}H_{15}NO_3S$: C, 56.89; H, 5.97; N, 5.53; S, 12.66%. EIMS *m/z* (rel intensity) 253 (M^+, 21), 134 (51), 133 (100), 132 (70), 105 (24), 104 (23), 77 (46). CIMS (isobutane) *m/z* (rel intensity) 254 (M^++1, 49), 134 (79), 57 ($C_4H_9^+$, 100). IR (KBr) 1720, 1340, 1320, 1155, 1105 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.94 (t, 3H, *J*=7.3 Hz), 1.48 (m, 2H), 1.83 (m, 2H), 3.61 (t, 2H, *J*=8.1 Hz), 4.88 (s, 2H), 7.5—7.6 (m, 2H), 7.70 (dd, 1H, *J*=6.6 and 6.6 Hz), 7.92 (d, *J*=7.3 Hz). ^{13}C NMR ($CDCl_3$) δ=13.5 (q), 21.4 (t), 24.9 (t), 49.7 (t), 53.2 (t), 123.5 (d), 125.2 (d), 129.0 (d), 130.1 (s), 134.1 (d), 141.3 (s), 167.1 (s).

2-Phenylsulfonyl-1-isoindolinone (3c): The reaction was carried out in benzene. Yield: 36% (1-isoindolinine (**4**) was by-produced in 4% yield). Colorless needles, mp 193.5 °C, R_f=0.5. Found: C, 61.58; H, 3.97; N, 5.08; S, 11.53%. Calcd for $C_{14}H_{11}NO_3S$: C, 61.52; H, 4.06; N, 5.15; S, 11.53%. EIMS *m/z* (rel intensity) 209 (M^+-SO_2, 68), 208 (100), 132 (25), 77 45). CIMS (isobutane) *m/z* (rel intensity) 274 (M^++1, 76), 134 (79), 57 ($C_4H_9^+$, 100). IR (KBr) 1722, 1360, 1182, 1175, 1100 cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.92 (s, 2H), 7.4—7.7 (m, 6H), 7.82 (d, 1H, *J*=8.1 Hz), 8.16 (m, 2H). ^{13}C NMR ($CDCl_3$) δ=49.9 (t), 123.4 (d), 125.1 (d), 128.1 (d), 128.9 (d), 129.1 (d), 130.1 (s), 133.9 (d), 134.1 (d), 138.4 (s), 141.0 (s), 166.1 (s).

2-*p*-Tolylsulfonyl-1-isoindolinone (3d): Yield: 39% (1-isoindolinone (**4**) was by-produced in 4% yield). Colorless needles, mp 218 °C, R_f=0.6. Found: C, 62.63; H, 4.60; N, 4.94; S, 11.15%. Calcd for $C_{15}H_{13}NO_3S$: C, 62.67; H, 4.56; N, 4.88; S, 11.16%. EIMS *m/z* (rel intensity) 223 (M^+-SO_2, 100), 222 (62), 132 (22), 91 (36). CIMS (isobutane) *m/z* (rel intensity) 288 (M^++1, 81), 134 (67), 57 ($C_4H_9^+$, 100). IR (KBr) 1720, 1340, 1142, 1130, 1092 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.41 (s, 3H), 4.91 (s, 2H), 7.33 (d, 2H, *J*=8.4 Hz), 7.4—7.5 (m, 2H), 7.63 (ddd, 1H, *J*=1.1, 7.0, and 9.0 Hz), 7.80 (dd, 1H, *J*=1.1 and 8.1 Hz), 8.03 (d, 2H, *J*=8.4 Hz). ^{13}C NMR ($CDCl_3$) δ=21.7 (q), 49.8 (t), 123.3 (d), 125.0 (d), 128.2 (d), 128.8 (d), 129.8 (d), 130.2 (s), 133.8 (d), 135.5 (s), 141.0 (s), 145.2 (s), 166.1 (s).

Reaction of 1 with 5. A solution of **1** (33 mg, 0.37 mmol) and **5** (145 mg, 0.74 mmol) in deuteriochloroform (0.5 ml) was heated at 60 °C for 70 h. After evaporation of the solvent the resluting mixture was subjected to this-layer chromatography on silica gel using hexane–ethyl acetate (7:3) as a developing solvent to give colorless crystals **6** (57 mg, 54%, R_f=0.74).

6: Mp 104 °C. HRMS *m/z* 287.1309. Calcd for $C_{20}H_{17}NO$ *m/z* 287.1309. EIMS *m/z* (rel intensity) 287 (M^+, 100), 269 (50), 180 (90), 165 (42). IR (KBr) 3050, 3010, 1600, 1500, 760 cm^{-1}. UV (MeOH) 245 nm (log ε, 3.97). ^1H NMR ($CDCl_3$) δ=5.19 (d, 1H, *J*=14.0 Hz), 5.29 (d, 1H, *J*=14.0 Hz), 5.63 (s, 1H), 7.26 (bs, 14H). ^{13}C NMR ($CDCl_3$) δ=67.9, 70.3, 118.3, 122.8, 124.0, 126.6, 127.7, 128.1, 128.4, 129.9, 133.6, 135.9, 139.3, 148.6.

Polypeptide Synthesis Using the *S*-Alkyl Thioester of a Partially Protected Peptide Segment. Synthesis of the DNA-Binding Domain of *c*-Myb Protein (142—193)-NH_2

Hironobu Hojo and Saburo Aimoto*
Institute for Protein Research, Osaka University, 3-2 Yamadaoka, Suita, Osaka 565
(Received August 23, 1990)

A method for polypeptide synthesis using *S*-alkyl thioester of a partially protected peptide segment has been developed. The DNA-binding domain of *c*-Myb protein (142—193) was synthesized by this method to estimate its usefulness. The partially protected peptide segments, Boc-[Lys(Boc)^{143,144,160}]-*c*-Myb protein(142—163)-$SCH_2CH_2CONH_2$ and [Lys(Boc)^{171,182,192}]-*c*-Myb protein(164—193)-NH_2, were highly purified from peptides obtained by a solid-phase method. The thioester in the carboxyl component of the peptide segment was converted to the corresponding *p*-nitrophenyl ester in the presence of silver ions and *p*-nitrophenol and then the two segments were condensed. The coupling reaction proceeded almost completely yielding a highly-purified product after removal of Boc groups.

In our preceding paper,[1] we reported the synthesis of bovine pancreatic trypsin inhibitor (BPTI) consisting of 58 amino acid residues, using partially protected peptide segments prepared from peptides obtained by a solid-phase method. This method was proven to be very effective in reducing the time required for chemical synthesis of polypeptide and to give a highly pure product.

However in this method, it was necessary to protect the side-chain carboxyl groups in peptide segments for selective activation of the terminal carboxyl group. Moreover peptide segments containing side-chain carboxyl groups could be prepared only by the solid-phase method using N^{α}-3-nitro-2-pyridinesulfenyl-amino acids (Npys-amino acids) developed by Matsueda et al.[2]

There arose two problems. The first was that of peptide segment solubility during purification by reversed-phase high-performance liquid chromatography (RPHPLC). Generally, an increase in the number of hydrophobic protecting groups decreases the solubility of a paptide segment in a solvent such as aq acetonitrile. Consequently, the purification of such a peptide by RPHPLC becomes difficult and the recovery yield is usually low. If the number of the protecting groups on a peptide segment can be reduced, the solubility will increase and its purification will be facilitated. The second issue was the complexity of the method for segment preparation. We had to change the procedure for peptide segment preparation depending on the presence or absence of a side-chain carboxyl group. In polypeptide synthesis, it is very important to normalize the procedure for the preparation of a peptide segment.

To overcome these problems, we designed a simpler method based upon our previous protocol and the thiocarboxyl segment strategy, by which Blake et al. achieved perfectly-selective activation of the terminal carboxyl group,[3] and synthesized several proteins.[4,5]

In the new method, the *S*-alkyl thioester of a partially protected peptide segment is used as a building block for polypeptide synthesis. The thioester group should be activated by silver ions. If so, the terminal thioester group will be selectively activated. Furthermore the thioester group does not have such a nucleophilic character as the thiocarboxyl group. Hence, various kinds of protecting groups can be introduced into the side-chain amino groups using a protective reagent such as *N*-(*t*-butoxycarbonyloxy)-succinimide (Boc-ONSu). If an *S*-alkyl thioester of a peptide segment could be synthesized by a solid-phase method with a high yield, a very promising method for polypeptide synthesis would be developed.

To examine the efficiency of this strategy, we attempted to synthesize the DNA-binding domain of *c*-Myb protein consisting of 52 amino acid residues, which is similar in size to BPTI.

In this paper, we describe the preparation of Boc-Gly-SCH_2CH_2CONH-resin, the synthesis of the *S*-alkyl thioester of a partially protected peptide segment, its chemical characteristics and the coupling of the segments and discuss the efficiency of this method.

Results and Discussion

The amino acid sequence of an oncogene product of *c*-Myb protein was deduced from cDNA clones of murine *c-myb* mRNA.[6] This protein binds to DNA at a domain near the N-terminal region.[7] The binding domain was found to have a 3-time tandem repeat of an analogous primary structure.[6] The peptide we synthesized was the third part of the repeat corresponding to the amino acids from 142 to 193. The amino acid sequence is shown in Fig. 1. Two partially protected peptide segments **1** and **2** were prepared and segment coupling of the peptides was carried out at the site indicated by an arrow (Fig. 1) according to the scheme shown in Fig. 2.

Preparation of Boc-Gly-SCH_2CH_2CONH-Resin. Crystalline Boc-Gly-SCH_2CH_2COOH was prepared from Boc-Gly-ONp and $HSCH_2CH_2COOH$. This

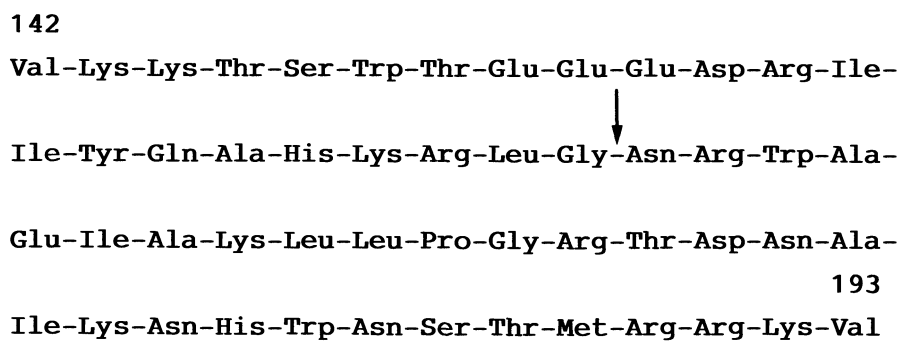

Fig. 1. Primary sequence of *c*-Myb protein(142—193) deduced from cDNA clone of murine *c-myb* mRNA.[6] Arrow indicates the site of segment coupling.

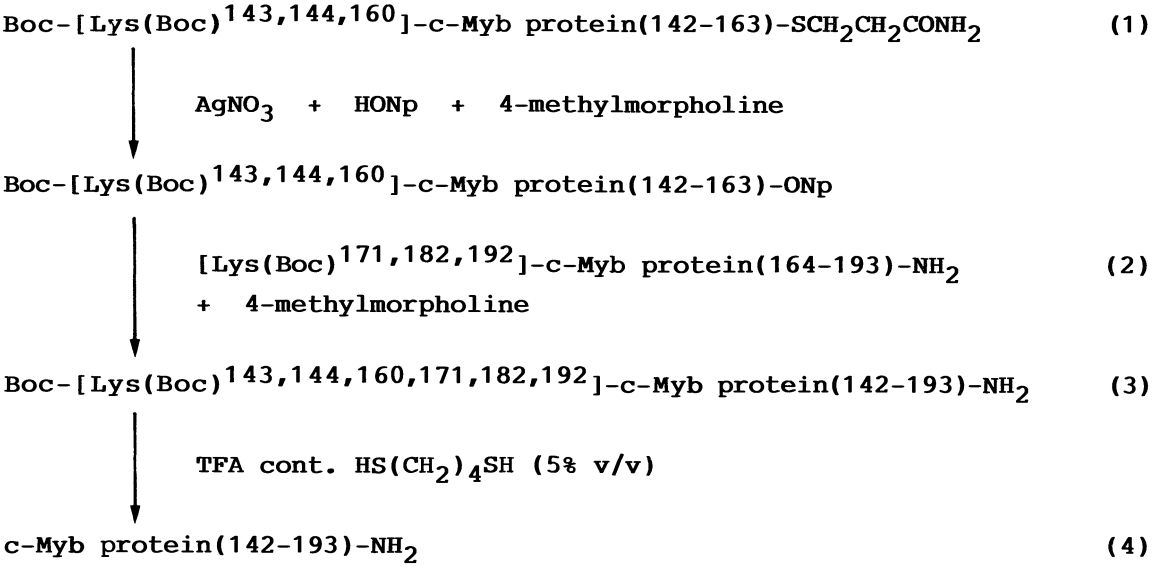

Fig. 2. Synthetic route leading to *c*-Myb protein(142—193)-NH_2 (**4**) by segment coupling.

compound was introduced to a *p*-methylbenzhydrylamine resin (MBHA resin) (NH_2–Resin) by a routine procedure similar to the introduction of Boc–amino acids to an MBHA resin. The resulting thioester resin was stable enough to withstand assemblage of the peptide chain corresponding to *c*-Myb protein(142—163).

Preparation of Boc-[Lys(Boc)^{143,144,160}]-*c*-Myb Protein (142—163)-$SCH_2CH_2CONH_2$ (1). Peptide **1** was prepared according to the route shown in Fig. 3. Starting from Boc–Gly–SCH_2CH_2CONH–resin (Gly 0.33 mmol g^{-1}, 1.5 g), a protected *c*-Myb protein (142—163)–SCH_2CH_2CONH–resin was prepared according to the protocol of the system software version 1.40 NMP/HOBt *t*-Boc without any modifications. End capping by acetic anhydride was carried out after each amino-acid introduction reaction. The resin weight increased by 1.4 g. This resin (500 mg from 2.9 g) was treated by anhydrous HF in the presence of *p*-cresol and 1,4-butanedithiol at 0 °C for 90 min. Judging from the elution profile of the crude product by RPHPLC, the thioester was stable under HF-treatment. The crude peptide was purified by RPHPLC to yield 40 mg (14.4 μmol) of highly pure peptide **5**. The yield was 16.7% based on the glycine in the starting resin. The yield of peptide **5** was about one-half that of peptide amide **6** (29.6%) synthesized on the MBHA resin as described later. This could be mainly due to partial aminolysis or hydrolysis of the thioester bond during the chain elongation reaction. The yield of peptide **5** was acceptable at the present stage, but further investigation of the chemical design as well as the preparation method of the thioester anchoring group is still required to increase the peptide thioester yield. But the thioester in peptide **5** was quite stable during purification on RPHPLC or during prolonged storage at 4 °C. The introduction reaction of Boc groups to peptide **5** proceeded almost quantitatively and did not accompany any side-reaction when

Fig. 3. Synthetic scheme of Boc-[Lys(Boc)^{143,144,160}]-*c*-Myb protein(142—163)-$SCH_2CH_2CONH_2$.

Boc–ONSu was used as the protective reagent. The yield of peptide **1** was practically quantitative.

Preparation of [Lys(Boc)^{171,182,192}]-*c*-Myb Protein(164—193)-NH_2 (2). The preparation of peptide amide **2** was carried out according to the scheme shown in Fig. 4. This procedure functions well in the synthesis of BPTI.[1] A peptide chain of *c*-Myb protein (164—193) was assembled on 0.78 g of MBHA resin (NH_2 0.64 mmol g^{-1}) according to the same protocol described for the synthesis of peptide **1**. After the completion of chain assembly, a 2,2,2-trichloroethoxycarbonyl (Troc) group was introduced to protect the terminal amino group using *N*-(2,2,2-trichloroethoxycarbonyloxy)-succinimide (Troc–ONSu). The final weight of the protected peptide resin was 3.2 g. An aliquot of the resin (0.8 g) was treated with HF in the presence of *p*-cresol and 1,4-butanedithiol at 0 °C for 90 min to yield a crude product (580 mg), which was purified on RPHPLC to give 140 mg of highly purified peptide amide **6**. The yield was 29.6% based on the amino group in the starting MBHA resin. Boc groups were introduced to peptide amide **6** according to the conditions described for the preparation of peptide **1**. The reaction proceeded completely to result in peptide amide **7** at a yield of 82%. The Troc group of peptide amide **7** was removed by zinc dust treatment in 50% aq acetic acid under nitrogen with mild sonication at room temperature for 1 h. Peptide amide **2** was obtained at a yield of 65% without any serious side reactions. But it must be noted that the almost total decomposition of peptide amide **7** was occurred when the peptide solution was sonicated for 4 h under insufficient replacement by nitrogen gas.

Preparation of *c*-Myb Protein(142—193)-NH_2 (4). As shown in Fig. 2 the thioester group in peptide **1** was converted to the corresponding active ester in the presence of *p*-nitrophenol (HONp) and $AgNO_3$ in dimethyl sulfoxide (DMSO). To the DMSO solution, peptide amide **2** and 4-methylmorpholine (NMM) were added and the solution was stirred. The

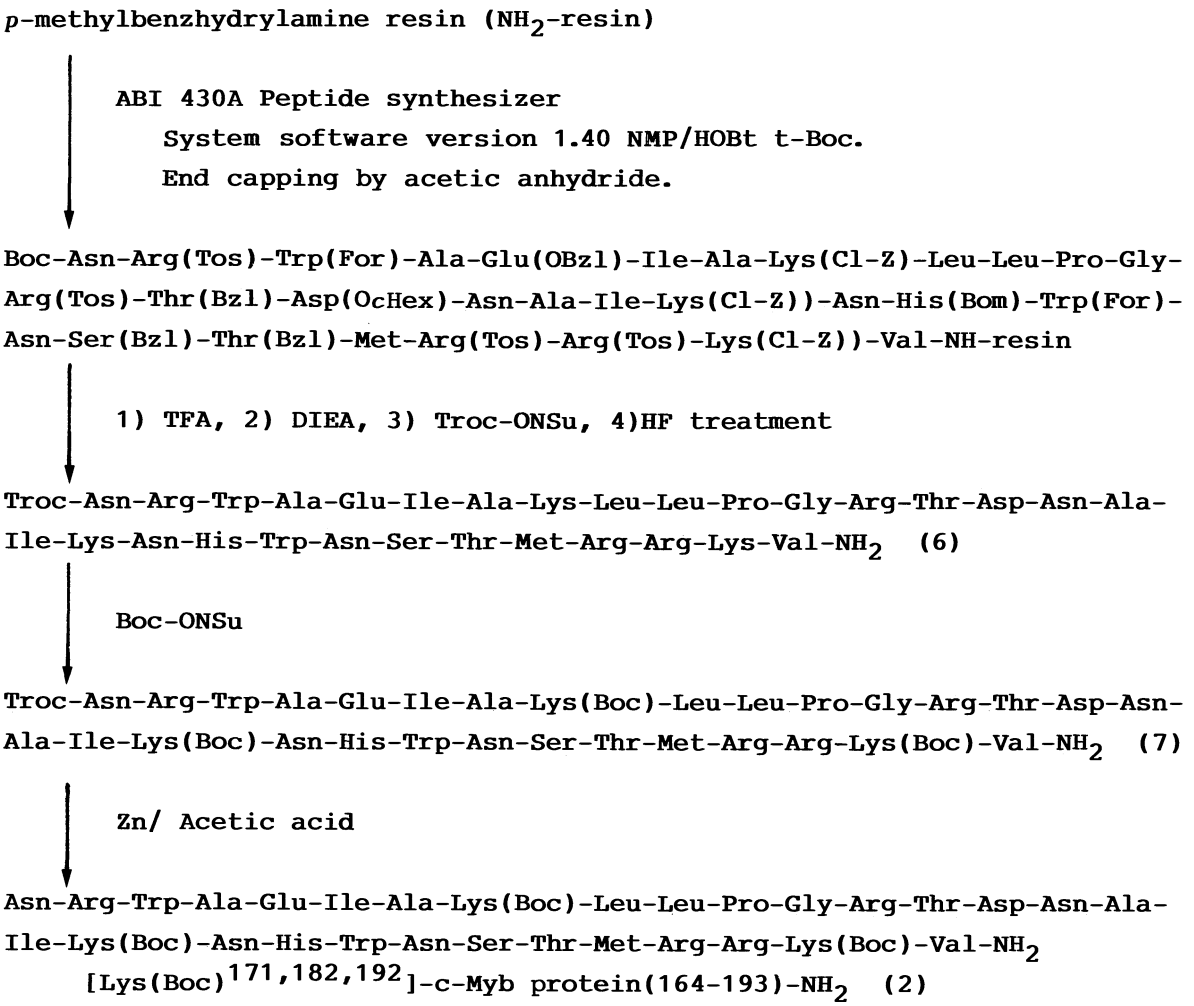

Fig. 4. Synthetic scheme of [Lys(Boc)^{171,182,192}]-*c*-Myb protein(164—193)-NH_2.

concentrations of peptides **1** and **2** were 16 mM# and 10 mM, respectively. The coupling reaction was monitored by RPHPLC. After 3 d, condensation reaction was almost complete (Fig. 5). Silver ions were removed as AgCl. The product was precipitated by adding ethyl acetate, collected by centrifugation, suspended in dioxane and freeze-dried. The powder was treated with TFA containing 1,4-butanedithiol at room temperature for 10 min. After removal of TFA, a product was isolated by RPHPLC (Fig. 6). The yield was 1.1 μmol, 50%. This yield is quite high, if the nonspecific adsorption of peptide amide **4** during the isolation process is taken into account. *N*-Hydroxysuccinimide ester corresponding to peptide **1** gave results as good as those of *p*-nitrophenyl ester with regard to the segment condensation reaction between peptides **1** and **2**. However in this experiment, we employed *p*-nitrophenyl ester, which was mild in reactivity but considerably more stable in the presence of moisture. Methionine was not damaged by silver ions. No serious side reaction was observed during segment coupling under this minimum protection strategy.

Confirmation of Synthetic *c*-Myb Protein(142—193)-NH_2 (4). The amino acid composition of the purified peptide amide **4** obtained from RPHPLC is shown in Table 1. Peptide amide **4** was eluted as a symmetrical peak by ion-exchange chromatography (Fig. 7). These data suggest that highly pure peptide amide **4** was obtained from this synthesis. Two-dimensional NMR spectroscopy of peptide amide **4** also confirmed the purity of this peptide.[8]

Evaluation of the Newly-Developed Method. Partially protected peptide segments **1** and **2** were successfully prepared and all the peptide segments were well characterized by amino acid analysis and fast atom bombardment mass spectrometry. The thioester group of peptide **1** was activated by silver ions and converted to the corresponding active ester. The terminal carbonyl group was selectively activated by a thioester strategy exactly the same as the thiocarboxyl

strategy. As a result, protection of the side-chain carboxyl groups was unnecessary. Only the functional groups that required protection were amino groups in this synthesis. The thioester group did not react with Boc-ONSu though the thiol of the thiocarboxyl group was modified. If a peptide thioester is employed, various kinds of protecting groups may be introduced to the side chain, as well as α-amino groups after purification of a peptide segment on RPHPLC. Protecting groups such as the Boc group enhance the solubility of a partially protected peptide segment in DMSO or *N*,*N*-dimethylformamide (DMF) more than the citraconoyl group. In the thiocarboxyl segment strategy, side-chain amino groups were protected by citraconoyl groups.[4,5]

Only one protecting group existed on peptide **5** or **6** when purified on RPHPLC. Consequently, purification was much simpler compared with BPTI synthesis.[1] Therefore long peptide segments were easily prepared. The yield of segment coupling was also satisfactory.

In conclusion, the partially protected peptide

thioester is a promising building block for polypeptide synthesis.

Materials and Methods

MBHA resin hydrochloride and Boc-amino acid derivatives were purchased from the Peptide Institute Inc. (Minoh, Osaka). Solvents and reagents used for solid-phase peptide synthesis were purchased from Applied Biosystems Japan (Tokyo). Dimethyl sulfoxide used for segment coupling was silylation grade (Pierce, Rockford, IL). Analytical RPHPLC was performed on Cosmosil 5C18 (4.6×250 mm) (Nacalai Tesque, Kyoto) and preparative RPHPLC was on YMC-Gel ODS S-5 AM-type (10×250 mm or 20×250 mm) (YMC, Kyoto). Amino acids were analyzed on an L-8500 amino acid analyzer (Hitachi Ltd., Tokyo) after hydrolysis by 4 M methanesulfonic acid at 110 °C for 24 h in an evacuated sealed tube. Peptide mass number was determined by fast atom bombardment mass spectrometry using a JMS-HX100 (Jeol Ltd., Tokyo) equipped with a JMA-3100 mass data system. Peptide weight was calculated based upon the amino acid analysis data. Ultrasonication was carried out using a Branson Model B-220.

Synthesis

Peptide Chain Elongation on a Solid-Support. Solid-phase synthesis of a peptide segment was carried out on a peptide synthesizer 430A (Applied Biosystems Inc., Foster City, CA.) employing the 0.5 mmol scale standard protocol of the benzotriazole active ester method of the system software version 1.40 NMP/HOBt *t*-Boc. End capping by acetic anhydride was performed after each amino-acid introduction reaction. The side-chain protecting groups of Boc-amino acids used were *o*-chlorobenzyloxycarbonyl (Cl-Z) for the N^{ε} of Lys, *o*-bromobenzyloxycarbonyl (Br-Z) for the phenolic OH of Tyr, benzyl (Bzl) for the alcoholic OH of Thr and Ser, cyclohexyl ester (O*c*Hex) for the β-carboxyl group of Asp, benzyl ester (OBzl) for the γ-carboxyl group of Glu, benzyloxymethyl (Bom) for the N^{π} of imidazole of His, tosyl (Tos) for the N^{g} of Arg and formyl (For) for the N^{i} of Trp.

Preparation of Boc-Gly-SCH_2CH_2COOH. To a solution of Boc-Gly-ONp (1.5 g, 5 mmol) dissolved in DMF (50 ml), 3-mercaptopropionic acid (0.5 g, 5 mmol) and *N,N*-diisopropylethylamine (DIEA) (1.0 g, 7.5 mmol) were added with stirring at room temperature for 15 h. After evaporation of the solvent under reduced pressure, the product was dissolved in ethyl acetate. The ethyl acetate layer was washed with 0.1 M HCl (2×) and water saturated with NaCl (5×) and dried over sodium sulfate. The ethyl acetate solution was concentrated. An oil obtained was dissolved in ether. To the ethereal solution cyclohexylamine (CHA) (450 mg, 4.5 mmol) was added to give crystals, which were recrystallized from hot ethyl acetate: Boc-Gly-$SCH_2CH_2COOH \cdot$CHA; 1.70 g, 94.0%, mp 112.5—123.2 °C. This CHA salt (1.66 g) was suspended in ethyl acetate and CHA was extracted by dilute aq citric acid. The organic layer was washed with water saturated with NaCl (3×) and dried over sodium sulfate. After concentration of the solution, hexane was added to give Boc-Gly-SCH_2CH_2COOH (1.11 g, 91.6%), mp 104—106 °C. Found: H, 6.60; C, 45.49; N, 5.40%. Calcd for $C_{10}H_{17}O_5NS$: H, 6.51; C, 45.61; N, 5.32%.

Preparation of Boc-Gly-SCH_2CH_2CONH-Resin. MBHA resin hydrochloride (NH_2 0.47 mequiv g^{-1}, 3.4 g) was washed with 5% DIEA/dichloromethane (DCM) (2×5 min) and DCM (3×1 min), successively. Boc-Gly-SCH_2CH_2COOH (718 mg, 2.74 mmol) dissolved in 20 ml of DCM and a 0.5 M solution of dicyclohexylcarbodiimide (DCC) in DCM (4 ml) were successively added to the reaction vessel, which was shaken overnight. The resin obtained was treated with 5% acetic anhydride in DCM (2×5 min) and dried after washing the resin with 2-propanol (3×2 min) and DCM (3×1 min) to give 3.77 g of a resin (Gly: 0.33 mmol g^{-1}).

***c*-Myb Protein (142—163)-$SCH_2CH_2CONH_2$ (5).** Starting from Boc-Gly-SCH_2CH_2CONH-resin (1.5 g), peptide chain elongation was carried out by a 430A peptide synthesizer to give 2.9 g of a protected peptide resin. An aliquot of the resin (500 mg) was treated with anhydrous HF (11 ml) containing *p*-cresol (0.5 ml) and 1,4-butanedithiol (1.7 ml) at 0 °C for 90 min. After evaporation of HF, the residual solid was washed with ether (3×). Crude peptide was extracted with 10% aq acetic acid and freeze-dried to give a powder (192 mg). This crude product was purified on RPHPLC to give peptide **5** (40 mg, 14.4 μmol, 16.7%). Found *m/z* 2774.9 $(M+H)^+$. Calcd *m/z* 2774.6 $(M+H)^+$. Amino acid analysis of peptide **5**: $Asp_{1.04}Thr_{1.94}Ser_{0.92}Glu_{4.27}Gly_{1.04}Ala_1Val_{1.02}Ile_{1.23}Leu_{0.97}Tyr_{0.92}His_{1.08}Lys_{2.85}Trp_{0.65}Arg_{1.89}$.

Boc-[Lys(Boc)^{143,144,160}]-*c*-Myb Protein(142—163)-$SCH_2CH_2CONH_2$ (1). Peptide **5** (25 mg, 9.0 μmol) was dissolved in DMSO (0.4 ml) containing triethylamine (TEA) (9.6 μl). Boc-ONSu (15 mg, 72 μ mol) was added to the solution and stirred at room temperature for 2.5 h, after which ethyl acetate and ether were added. The precipitate was washed with ethyl acetate and lyophilized from a dioxane suspension to give peptide **1** (25.8 mg, 90%). Found *m/z* 3174.8 $(M+H)^+$. Calcd *m/z* 3174.8 $(M+H)^+$. Amino acid analysis of peptide **1**: $Asp_{1.00}Thr_{1.98}Ser_{0.90}Glu_{4.39}Gly_{1.07}Ala_1Val_{0.97}Ile_{1.25}Leu_{0.97}Tyr_{0.93}His_{1.08}Lys_{2.82}Trp_{0.63}Arg_{1.84}$.

Troc-*c*-Myb Protein(164—193)-NH_2 (6). Starting from MBHA resin hydrochloride (NH_2 0.64 mequiv g^{-1}, 0.78 g), chain elongation reaction was carried out. After completion of a peptide chain elongation cycle, the peptide resin was treated with 55% trifluoroacetic acid (TFA) in DCM for 5 and then 15 min, followed by neutralization with 5% DIEA in DCM for 5 min twice. Troc-ONSu (440 mg, 1.5 mmol) was allowed to react with the terminal amino group at room temperature for 15 h. The peptide resin thus obtained was 3.2 g. An aliquot of the resin (0.8 g) was treated with anhydrous HF (17.2 ml) containing *p*-cresol (0.8 ml) and 1,4-butanedithiol (2.7 ml) at 0 °C for 90 min. After evaporation of HF, the residual solid was washed with ethyl acetate (3×) and with ether (3×). The peptide amide was extracted with 5% aq acetic acid and lyophilized to give a crude product (580 mg). This peptide was purified on RPHPLC to obtain peptide amide **6** (140 mg, 37 μmol, yield 29.6%). Found *m/z* 3749.3 $(M+H)^+$. Calcd *m/z* 3749.1 $(M+H)^+$. Amino acid analysis of peptide amide **6**: $Asp_{5.10}Thr_{1.93}Ser_{0.79}Glu_{1.29}Pro_{0.75}Gly_{1.12}Ala_3Val_{1.10}Met_{1.01}Ile_{1.94}Leu_{1.94}His_{1.07}Lys_{3.06}Trp_{1.75}Arg_{3.78}$.

Troc-[Lys(Boc)^{171,182,192}]-*c*-Myb Protein(164—193)-NH_2 (7). Peptide amide **6** (24 mg, 6.5 μmol) was dissolved in DMSO (200 μl) containing TEA (7.8 μl) and Boc-ONSu (13 mg, 60 μmol) and stirred for 2.5 h. Peptide amide **7** was obtained according to the procedure of the preparation of peptide **1**: Yield 21 mg, 5.2 μmol, 80%. Found *m/z* 4050.0

$(M+H)^+$. Calcd m/z 4049.3 $(M+H)^+$. Amino acid analysis of peptide amide **7**: $Asp_{5.16}Thr_{1.93}Ser_{0.87}Glu_{1.15}Pro_{0.91}Gly_{1.09}Ala_3Val_{1.03}Met_{1.12}Ile_{2.01}Leu_{1.97}His_{1.07}Lys_{2.85}Trp_{1.30}Arg_{3.81}$.

[Lys(Boc)^{171,182,192}]-*c*-Myb Protein(164—193)-NH_2 (2). Peptide amide **7** (40 mg) was dissolved in a mixture of acetic acid (1 ml) and water (1 ml). Zinc (100 mg) was added under a nitrogen atmosphere and the solution was sonicated for 1 h at room temperature. After centrifugation of the reaction mixture, the supernatant was applied to an ODS column. The isolated product was freeze-dried to give peptide amide **2**: Yield 25 mg, 6.4 μmol, 65%. Found m/z 3875.5 $(M+H)^+$. Calcd m/z 3875.3 $(M+H)^+$. Amino acid analysis of peptide amide **2**: $Asp_{5.23}Thr_{1.95}Ser_{0.90}Glu_{1.37}Pro_{0.78}Gly_{1.25}Ala_3Val_{1.06}Met_{1.15}Ile_{2.05}Leu_{1.99}His_{1.12}Lys_{3.00}Trp_{1.39}Arg_{3.82}$.

***c*-Myb Protein(142—193)-NH_2 (4).** Peptide **1** (11.5 mg, 3.6 μmol) was dissolved in DMSO (220 μl) containing HONp (6.5 mg, 47 μmol) and NMM (0.3 μl, 2.7 μmol). $AgNO_3$ (2.4 mg, 14 μmol) was added and the solution was stirred at room temperature in the dark. After 2 h, peptide amide **2** (8.6 mg, 2.2 μmol) and NMM (0.6 μl, 5.5 μmol) were added. After stirring overnight, NMM (0.3 μl, 2.7 μmol) was added and the solution was stirred for 3 d. To the solution, solid NaCl (1.2 mg) was added. The precipitate formed was removed by centrifugation. Ethyl acetate was added to the supernatant. The precipitate formed was collected by centrifugation and washed with ethyl acetate. The peptide obtained was suspended in dioxane and freeze-dried to give a crude product of peptide amide **3**, which was treated with TFA (200 μl) containing 1,4-butanedithiol (10 μl) at room temperature for 10 min. TFA was removed by N_2 air flush. The residual solid was washed with dry ether (2×) and isolated by RPHPLC to give peptide amide **4** (6.9 mg, 1.1 μmol); yield: 50% based on peptide amide **2** used for coupling reaction. Amino acid analysis of peptide amide **4**: $Asp_{6.08}Thr_{3.93}Ser_{1.78}Glu_{5.13}Pro_{0.93}Gly_{2.15}Ala_4Val_{2.05}Met_{1.09}Ile_{3.19}Leu_{3.03}Tyr_{1.01}His_{2.16}Lys_{6.11}Trp_{2.34}Arg_{6.07}$.

Purity Check by Ion-Exchange Chromatography. Peptide amide **4** purified on RPHPLC was subjected to a TSK gel CM-5PW column (TOSO, Tokyo) (7.5 mm×75 mm) equilibriated with 0.05 M sodium phosphate buffer (pH 8.0) and chromatographed by a linear 0—0.5 M NaCl gradient in buffer over 50 min at a flow rate of 1 ml min^{-1}.

The authors wish to express their thanks to professor Yasutsugu Shimonishi of the Institute for Protein Research, Osaka University for allowing the use of the facilities for mass spectra measurement and professor Yoshifumi Nishimura of Yokohama City University for his valuable comments on *c*-Myb protein. Their thanks also extended to Ms. Shoko Yoshimura for solid-phase synthesis of peptides and Ms. Chieko Maegawa for amino acid analysis. This research was partly supported by grants-in-aid for Scientific Research No. 62540407, No. 01740322, and No. 02263101 from the Ministry of Education, Science and Culture.

Redox Reaction of Aromatic Aldehydes with $Fe_3(CO)_{12}$

(Received August 31, 1990)

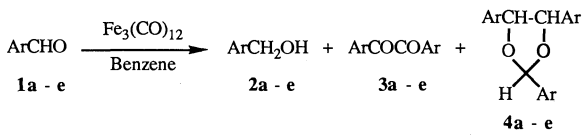
Aromatic aldehydes react with $Fe_3(CO)_{12}$ in refluxing benzene ultimately to give arylmethyl alcohols and 1,2-diaryl-1,2-ethanedione in a 1:1 ratio. In some cases, small amounts of 2,4,5-triaryl-1,3-dioxolanes are formed as minor products. Dinuclear iron complex (1,2-diphenyl-1,2-ethanedioxido)$Fe_2(CO)_7$ has been isolated as an intermediate in the reaction of benzaldehyde with $Fe_3(CO)_{12}$. The mechanism of this redox reaction of aromatic aldehydes are discussed on the basis of the kinetic study of the reaction and also of the reactivity of the isolated dinuclear iron complex.

Iron carbonyl complexes induce a variety of organic transformations.[1] However, no systematic information is yet available, especially about the chemical properties of polynuclear iron complexes. Previously, we reported that a trinuclear iron complex $Fe_3(CO)_{12}$ has a strong reducing ability toward oxygen-containing compounds and induces the reductive deoxygenation of 1,2-oxazines to give pyrroles.[2] We now report the reactivity features of $Fe_3(CO)_{12}$ toward aromatic aldehydes.

Takegami and co-workers have reported that aromatic aldehydes undergo a Tishchenko type reaction to give esters upon treating with $Na_2Fe(CO)_4$.[3] In this reaction, the ferrate complex acts as both of base and hydride-transfer agent. However, neutral iron complexes such as $Fe(CO)_5$ and $Fe_2(CO)_9$ exhibit no or little reactivity toward aromatic aldehydes in less polar solvents under ordinary conditions. We now report that $Fe_3(CO)_{12}$ gives rise to the redox reaction of aromatic aldehydes in benzene to afford arylmethyl alcohols and 1,2-diaryl-1,2-ethanediones as major products. We also discuss the mechanistic features of this reaction on the basis of the reactivity of a dinuclear iron complex isolated from the reaction mixture and also of the kinetic study of the reaction.

Results and Discussion

Reaction of Aromatic Aldehydes with $Fe_3(CO)_{12}$. The reaction of benzaldehyde (**1a**) with one tenth molar equiv of $Fe_3(CO)_{12}$ in refluxing benzene for 20 h, followed by acidification of the reaction mixture with an aqueous HCl, gave benzyl alcohol (**2a**) and 1,2-diphenyl-1,2-ethanedione (**3a**) approximately in a 1:1 ratio, along with a small amount of 2,4,5-triphenyl-1,3-dioxolane (**4a**). These products, except **2a**, were formed only after treating the reaction mixture with an aqueous HCl. Other aromatic aldehydes (**1b—e**) reacted similarly with $Fe_3(CO)_{12}$, giving arylmethyl alcohols (**2b—e**) and 1,2-diaryl-1,2-ethanediones (**3b—e**) as major products. In some cases, 1,3-dioxolanes were obtained as minor products. The results are given in Table 1. For this reaction, $Fe(CO)_5$ was



a: Ar=C_6H_5 **b**: Ar=p-$CH_3C_6H_4$ **c**: Ar=p-$CH_3OC_6H_4$ **d**: Ar=p-ClC_6H_4 **e**: Ar=2-Furyl

Table 1. Reaction of Aromatic Aldehydes with Iron Carbonyls[a]

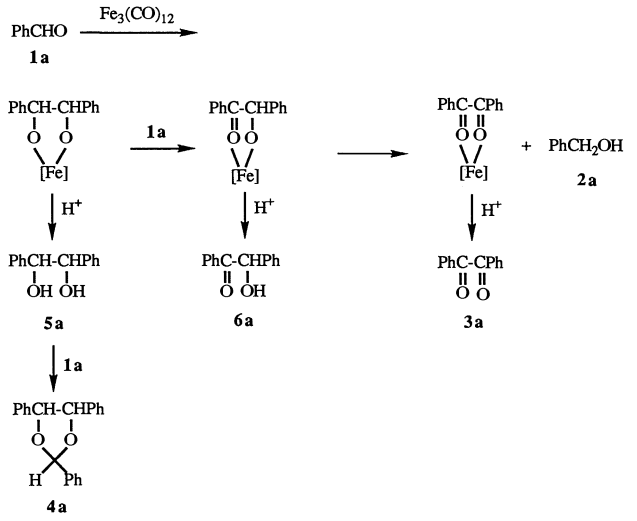
1c: Ar=*p*-$CH_3OC_6H_4$	$Fe_3(CO)_{12}$	**2c** (38)	**3c** (38)	**4c** (Trace)
1d: Ar=*p*-ClC_6H_4	$Fe_3(CO)_{12}$	**2d** (60)	**3d** (64)	**4d** (Trace)
1e: Ar=Furyl	$Fe_3(CO)_{12}$	**2e** (18)	**3e** (18)	—

a) The reaction was carried out in refluxing benzene for 20 h by using an excess aldehyde (20 mmol) and an iron complex ($Fe(CO)_5$: 6.0 mmol, $Fe_2(CO)_9$: 3.0 mmol, $Fe_3(CO)_{12}$: 2.0 mmol). b) The products **3a—e** and **4a—d** were isolated after acidification of the reaction mixtures with an aqueous HCl. c) Isolated yields based on iron carbonyls used.

ineffective, and $Fe_2(CO)_9$ was effective but its efficiency was extremely low as compared with that of $Fe_3(CO)_{12}$.

To elucidate the reaction pathways, kinetic study for the reaction of **1a** with $Fe_3(CO)_{12}$ was carried out under the same conditions as those of the preparative reaction. The reaction was followed by analyzing products produced at appropriate time intervals. The result is shown in Fig. 1. This result suggests that the reaction proceeds via the pathways outlined in Scheme 1. An important feature of this reaction is that **3a**, **5a**, and **6a** exist in the reaction mixture as their iron complexes which can be hydrolyzed with HCl. In the actual reaction, the iron complex of 1,2-diphenyl-1,2-ethanediol (**5a**) is produced at the initial stage. This is converted to final products **2a** and **3a** via the iron complex of 2-hydroxy-1,2-diphenylethanone (**6a**). A separate experiment indicated that in the conversion of the iron complexes of **5a** to **3a**, **1a** acts as a hydrogen acceptor; hence **2a** and **3a** are produced in a 1:1 molar ratio (see later). The acid hydrolysis of the iron complexes gives **3a**, **5a**, and **6a**. Compound **4a** can be formed by the acid-catalyzed condensation of **5a** with **1a**.



Scheme 1.

Isolation Intermediary Iron Complex. Compound **1a** was allowed to react with $Fe_3(CO)_{12}$ in benzene at 80 °C for 30 min. Careful work-up of the reaction mixture gave (1,2-diphenyl-1,2-ethanedioxido)$Fe_2(CO)_7$ (**7**) in a 46% yield. The same iron complex was also obtained by treating **5a** with $Fe_3(CO)_{12}$ in benzene. The structural formula of this complex was assigned from its spectral data and elemental analysis. The elemental analysis was consistent with the assigned structural formula. In the mass spectrum, the parent peak (M^+, m/z 520) was not observed. However, several fragment peaks that support the assigned structural formula were observed. The peaks appeared at m/z 518 (M^+-H_2) and 504 (M^+-16) that are assignable to $[(PhCOCOPh)Fe_2(CO)_7]^+$ and $[(PhCH{=}C(OH)Ph)Fe_2(CO)_7]^+$ or $[(PhCH_2COPh)Fe_2(CO)_7]^+$, re-

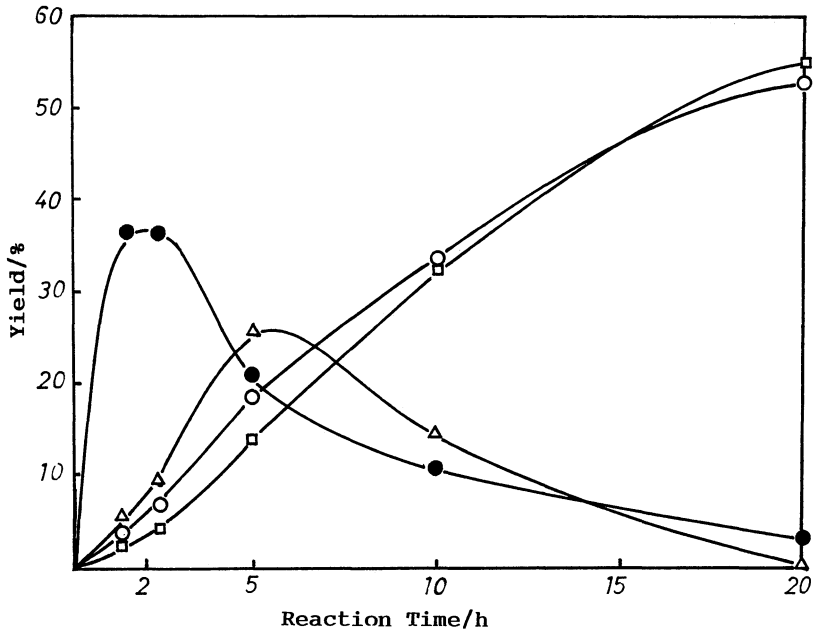


Fig. 1. Kinetic study of the reaction of **1a** with $Fe_3(CO)_{12}$ (**1a**: 20 mmol, $Fe_3(CO)_{12}$: 2.0 mmol, benzene: 15 cm^3. Reaction temperature: 80 °C). ○: Benzyl alcohol (**2a**), □: 1,2-Diphenyl-1,2-ethanedione (**3a**), ●: 1,2-Diphenyl-1,2-ethanediol (**5a**)+2,4,5-triphenyl-1,3-dioxolane (**4a**), △: 2-Hydroxy-1,2-diphenylethanone (**6a**). Compounds **3a**, **4a**, **5a**, and **6a** were isolated after acidification of the reaction mixture with an aqueous HCl.

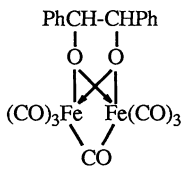
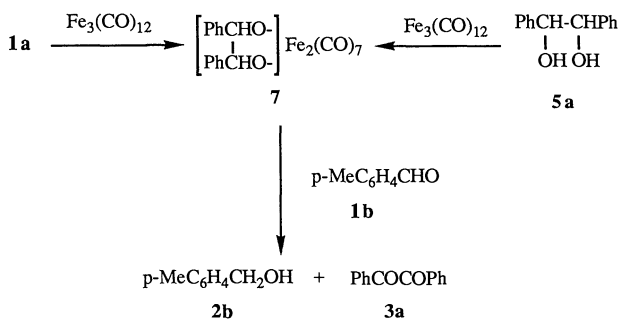
spectively. Organic fragments were also observed at *m/z* 214, 210, 196, and 107 which can be assigned to [PhCH(OH)CH(OH)Ph]$^+$, [PhCOCOPh]$^+$, [$PhCH_2$-COPh]$^+$, and [PhCHOH]$^+$, respectively. Similar fragmentation pattern was observed in the mass spectrometry of **5a** which is the organic ligand of the complex.[4] The IR spectrum in a KBr disk showed complex absorptions due to the CO ligands attached to Fe at 2035, 1990, 1980, 1965, 1950, 1930, and 1815 cm^{-1}. The lowest absorption suggests the existence of one bridging CO ligand. The ^1H NMR spectrum in $CDCl_3$ exhibited two broad signals at δ=4.88 and 7.28 in the relative intensities of 1:5. These signals can apparently be assigned to the methylidyne and phenyl groups, respectively. The ^{13}C NMR spectrum in $CDCl_3$ at room temperature showed only one broad signal for the CO carbon atom at δ=211.9 where is the region of terminal CO ligands in binuclear iron complexes.[5] This implies that all seven CO groups are scrambled rapidly over two Fe atoms on the NMR time scale at room temperature in a $CDCl_3$ solution. This result indicates that the complex is a sort of a fluxional molecule in the sense that bridging and terminal CO groups are interchanging with each other. This kind of fluxionality in CO ligands has been found also in the other binuclear Fe complexes such as (Ph_2PCH_2-PPh_2)$Fe_2(CO)_7$[5] and (1,2-diazine)$Fe_2(CO)_7$.[6] The other feature in the ^{13}C NMR spectrum was that the CH carbon signal in the organic ligand initially appeared at δ=78, but this signal gradually disappeared. This suggests that [PhCH(O)CH(O)Ph]$Fe_2(CO)_7$ is converted to (PhCOCOPh)$Fe_2(CO)_7$ during the NMR measurement. The instability and the limited solubility at lower temperatures of this complex have prevented us from obtaining more detailed information about the structure of the complex. However, from the above results, we propose **8** as a tentative structure of complex **7** by reference to the established structures of dinuclear Fe complexes of the type $XYFe_2(CO)_7$;[5,6] in this structure, the formal 18 electron configuration is attained at each Fe atom.

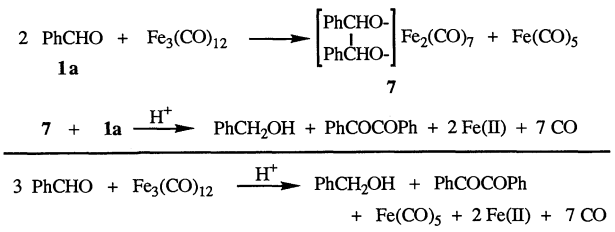


8

Reaction of Intermediary Iron Complex. Treatment of **7** with excess *p*-methylbenzaldeyde (**1b**) in benzene at 80 °C for 15 h afforded *p*-methylbenzyl alcohol (**2b**) and **3a** in a 1:1 molar ratio in good yields. These products were formed after acidification of the reaction mixture with an aqueous HCl. The results are summarized in Scheme 2.



Scheme 2.



Scheme 3.

Stoichiometry. The reaction of **1a** with one tenth molar equiv of $Fe_3(CO)_{12}$ in benzene was carried out in a sealed vessel. This enabled measurement of the volume of a gas evolved during the reaction. The reaction was started by heating the system at 80 °C. The gas evolution started after 3 h, and ceased after 20 h. A comparison of this result with that of Fig. 1 indicates that CO starts to evolve after **1a** is converted to **7**. The GLC analysis of the evolved gas showed that approximately seven molar equiv of CO are evolved from one molar equiv of $Fe_3(CO)_{12}$ at the end of the reacion.

In a separate experiment, a volatile material produced from the reaction of **1a** with $Fe_3(CO)_{12}$ was collected in a cooled vessel. The collected liquid was identified as $Fe(CO)_5$ from its characteristic IR spectrum. Furthermore, the quantitative analysis of this liquid after converting it to Fe(II) ion by oxidizing with nitric acid indicated that one molar equiv of $Fe(CO)_5$ is produced from one molar equiv of $Fe_3(CO)_{12}$. In this reaction, the production of $Fe(CO)_5$ ceased within 1.5 h. This result indicates that $Fe(CO)_5$ is formed only at the initial stage of the reaction. All of the above results can be explained in terms of the stoichiometric equations shown in Scheme 3.

The initial step is the formation of the diiron complex **7** by the reaction of **1a** with $Fe_3(CO)_{12}$, accompanied with elimination of $Fe(CO)_5$. At the second step, the iron complex reacts further with **1a** to give **2a** and the iron complex of **3a** with evolution of CO, probably accompanying production of Fe(II) ion. During this reaction, hydride migration occurs from **7**

to **1a**. This reaction may be assisted by an intramolecular electron transfer from $[Fe_2(CO)_7]$ to the 1,2-diphenyl-1,2-ethanedioxido ligand in **7**.

Experimental

General. ^1H and ^{13}C NMR spectra were recorded on HITACHI R-24B and JEOL FT-270 spectrometers using TMS as an internal standard. The IR, UV, and MS spectra were taken with Shimadzu IR 27G, Hitachi 228, and JEOL JMS-DX300 spectrometers, respectively. GLC analyses were performed on a Shimadzu GC 4CPF chromatograph using a column packed with SE 30 (10%) (3 mm×1 m). Aromatic aldehydes were all commercial products and purified by distillation prior to use. Benzene was purified by a standard procedure and stored under an argon atmosphere. 1,2-Diphenyl-1,2-ethanediol was prepared from 2-hydroxy-1,2-diphenylethanone.[7] Pentacarbonyliron (0) was a commercial product and used without further purification. Nonacarbonyldiiron (0)[8] and dodecacarbonyltriiron (0)[9] were prepared from $Fe(CO)_5$.

General Procedure for the Reaction of Aromatic Aldehydes with Iron Carbonyls. A mixture of benzaldehyde (20 mmol) and $Fe_3(CO)_{12}$ (2.0 mmol) in benzene (15 cm^3) was heated with stirring at 80 °C for 20 h under N_2 atmosphere, and then acidified with 6 M HCl (10 cm^3, 1 M=1 mol dm^{-3}) at room temperature. The mixture was extracted with ether (30 cm^3). The extract was washed with water, dried (Na_2SO_4) and concentrated under reduced pressure. Chromatography of the residue on silica gel successively with benzene, benzene/ether (9/1), and hexane gave 1,2-diphenyl-1,2-ethanedione, benzyl alcohol, and 2,4,5-triphenyl-1,3-dioxolane in 56%, 56%, and 4% yields, respectively. The reactions of other aldehydes with $Fe_3(CO)_{12}$ were carried out in a similar manner. The results are summarized in Table 1. The products were identified by comparison of their IR and NMR spectra with those of authentic specimens. In all cases, when GLC analyses of the reaction mixtures were carried out before acidification with HCl, only benzyl alcohols were detected. Spectral data of the products were as follows.

2a: Bp 205.0—206.0 °C; IR(neat) 3300, 1036, 1022, 736, 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.81 (s, 1H), 4.68 (s, 2H), 7.24 (m, 5H).

2b: Mp 59.5—60.2 °C; IR(neat) 3400, 1035, 812 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.88 (s, 1H), 2.36 (s, 3H), 4.60 (s, 2H), 7.17 (m, 4H).

2c: Mp 23.2—24.0 °C; IR(neat) 3400, 1030, 815 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.93 (s, 1H), 3.80 (s, 3H), 4.55 (s, 2H), 6.83 (d, J=4.12 Hz, 2H), 7.24 (d, J=4.12 Hz, 2H).

2d: Mp 72.4—73.2 °C; IR(neat) 3400, 1030, 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10 (s, 1H), 4.59 (s, 2H), 7.26 (s, 4H).

2e: Bp 168—170 °C; IR(neat) 3380, 1145, 1020, 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.70 (s, 1H), 4.50 (s, 2H), 6.15 (m, 2H), 7.32 (m, 1H).

3a: Mp 94.5—94.9 °C; IR (KBr) 1655, 1592, 1210, 716 cm^{-1}; ^1H NMR δ=7.21—7.65 (m, 6H), 7.67—8.02 (m, 4H).

3b: Mp 104—105 °C; IR(KBr) 3060, 2920, 1665, 1600, 1210, 1165 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.38 (s, 6H), 7.16 (d, J=4.10 Hz, 4H), 7.76 (d, J=4.10 Hz, 4H).

3c: Mp 132—133 °C; IR(KBr) 3030, 1660, 1600, 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.83 (s, 6H), 6.89 (d, J=4.12 Hz, 4H), 7.86 (d, J=4.12 Hz, 4H).

3d: Mp 195—196 °C; IR(KBr) 3030, 1665, 1600, 1165 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.36 (d, J=4.12 Hz, 4H), 7.89 (d, J=4.12 Hz, 4H).

3e: Mp 163—165 °C; IR(KBr) 2835, 1645, 1450, 751 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.59 (dd, J=1.80, 3.53 Hz, 2H), 7.58 (d, J=3.53 Hz, 2H), 7.73 (d, J=1.80 Hz, 2H).

4a: Mp 83—84 °C; IR(KBr) 3030, 2840, 1606, 1100, 1065, 1015, 1000, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.68 (s, 2H), 6.18 (s, 1H), 7.08—7.26 (m, 15H).

4b: Mp 87—89 °C; IR(KBr) 3030, 2920, 1610, 1120, 1080, 1035, 1020, 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.23 (s, 9H), 4.58 (s, 2H), 6.12 (s, 1H), 6.88—7.34 (m, 12H).

4c: Mp 102—103 °C; IR(KBr) 3030, 2930, 1605, 1230, 1080, 1035, 1020, 805 cm^{-1}; ^1H NMR δ=3.73 (s, 9H), 4.67 (s, 2H), 6.18 (s, 1H), 6.55—7.56 (m, 12H).

4d: Mp 97—98 °C; IR(KBr) 3030, 2940, 1610, 1120, 1085, 1035, 835, 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.60 (s, 2H), 6.15 (s, 1H), 7.06—7.70 (m, 12H).

Kinetic Study of Reaction of 1a with $Fe_3(CO)_{12}$. A solution of **1a** (20 mmol) and $Fe_3(CO)_{12}$ (2.0 mmol) in benzene (15 cm^3) was heated under N_2 at 80 °C for a given period of time. The mixture was acidified with aqueous 6M HCl (10 cm^3). The benzene solution was washed with water, dried, and analyzed by GLC using pyrene as an internal standard. The product analyses were performed in a similar manner by changing reaction time. The results are shown in Fig. 1.

5a: Mp 116.2—119.0 °C; IR(KBr) 3630, 3520, 3380, 3060, 2980, 1190, 1038, 770, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.43 (s, 2H), 4.53 (s, 2H), 7.10 (m, 10H).

6a: Mp 132—134 °C; IR(KBr) 3450, 3050, 2980, 1680, 1600, 1283, 1260, 1085, 1068, 978, 680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.50 (br d, 1H), 5.89 (br d, 1H), 7.26—7.40 (m, 8H), 7.73—7.92 (m, 2H).

Isolation of Iron Carbonyl Complex Produced from Reaction of 1a with $Fe_3(CO)_{12}$. A solution of benzaldehyde (20 mmol) and $Fe_3(CO)_{12}$ (2.0 mmol) in benzene (15 cm^3) was heated at 80 °C under N_2 for 30 min. The solvent was evaporated and the residue was washed with ether and then with petroleum ether until excess of benzaldehyde and $Fe_3(CO)_{12}$ were completely removed. The residual solid was dissolved in THF (10 cm^3) and filtered. Concentration of the filtrate gave 480 mg of a dark brown solid. The IR spectral data of the solid were identical in all respects with those of the complex which was prepared from 1,2-diphenyl-1,2-ethanediol (see below).

Preparation of (1,2-Diphenyl-1,2-ethanedioxido)$Fe_2(CO)_7$. All operations were performed under argon. A solution of 1,2-diphenyl-1,2-ethanediol (1.0 mmol) and $Fe_3(CO)_{12}$ (1.0 mmol) in benzene (10 cm^3) was heated at 80 °C for 3 h. The resulting mixture was evaporated to dryness under reduced pressure, and the residue was washed several times with petroleum ether. The residue was taken up in THF (10 cm^3) and filtered. Evaporation of the filtrate gave 260 mg of (1,2-diphenyl-1,2-ethanedioxido)$Fe_2(CO)_7$ as a dark brown solid. IR(KBr) 2035 (s), 1990 (s), 1980 (s), 1965 (sh), 1950 (m), 1930 (sh), 1815 cm^{-1} (m). ^1H NMR ($CDCl_3$) δ=4.88 (br s, 2H), 7.28 (br s, 10H). ^{13}C NMR ($CDCl_3$) δ=78.0, 127.3, 128.2, 128.3, 211.9. Found: C, 48.02; H, 2.56; Fe, 21.50%. Calcd for $C_{21}H_{12}O_9Fe_2$: C, 48.50; H, 2.33; Fe, 21.48%. FD-MS (rel intensity) m/z 518 (0.7), 392 (3), 214 (100), 210 (12), 196 (12),

107 (145) under rapidly increasing emitter current intensities, and *m/z* 504 (2.5), 214 (37), 210 (100), 197 (7), 107 (147 under slowly increasing current intensities.

Reaction of (1,2-Diphenyl-1,2-ethanedioxido)$Fe_2(CO)_7$ with *p*-Methylbenzaldehyde. A solution of benzaldehyde (2 mmol) and $Fe_3(CO)_{12}$ (2.0 mmol) in benzene (15 cm^3) was heated at 80 °C under N_2 for 1.5 h. *p*-Tolualdhyde (**1b**) (15 mmol) was then added to the mixture. The resulting mixture was heated at 80 °C for 15 h, and acidified with 6 M HCl (10 cm^3). The products were isolated as described above. Compounds **3a** and **2b** were obtained in 62% and 58% yields, respectively.

A mixture of 1,2-diphenyl-1,2-ethanediol (1.3 mmol) and $Fe_3(CO)_{12}$ (1.5 mmol) in benzene (10 cm^3) was heated at 80 °C under N_2 for 2 h. Compound **1b** (15 mmol) was added. The resulting mixture was heated at 80 °C for 15 h and acidified with 6 M HCl (10 cm^3). The products were isolated as described above. Compounds **3a** and **2b** were obtained in 56% and 56% yields, respectively.

Quantitative Determination of Evolved CO. A solution of **1a** (10 mmol) and $Fe_3(CO)_{12}$ (1.0 mmol) in benzene (6 cm^3) was placed in a sealed vessel which was connected with a gas burette. The mixture was heated at 80 °C under N_2 atmosphere. At the initial stage, no gas evolution was observed. The gas evolution started after heating for 3 h, but the rate of the gas evolution was moderate. The gas evolution ceased after heating for 20 h. The evolved gas was analyzed by GLC. The analysis showed that the evolved gas contained 6.77 mmol of CO and 0.03 mmol of H_2. The molar ratios of these gases to $Fe_3(CO)_{12}$, which was used initially, were 6.77 for CO and 0.03 for H_2, respectively.

Quantitative Determination of Evolved $Fe(CO)_5$. A solution of **1a** (10 mmol) and $Fe_3(CO)_{12}$ (1.0 mmol) in benzene (5 cm^3) was placed in a flask equipped with a gas trap which was immersed in a Dry Ice-acetone bath. The mixture was heated at 80 °C under N_2 atmosphere for several hours. Benzene and volatile materials were collected in the trapping flask at reduced pressure. The IR spectrum of the trapped material showed that it contained $Fe(CO)_5$. The trapped material was oxidized by adding 4 M HNO_3 (10 cm^3) at room temperature. The resulting aqueous solution was subjected to a Fe(II) ion analysis. The analysis was accomplished by a standard 1,10-phenanthroline method.[10]

Product Selectivity Affected by Cationic Species in Electrochemical Reduction of CO_2 and CO at a Cu Electrode[1)]

Akira MURATA and Yoshio HORI*
Department of Applied Chemistry, Faculty of Engineering,
Chiba University, Yayoi-cho, Chiba 260
(Received May 21, 1990)

Electroreduction of CO_2 and CO was studied with a copper electrode in hydrogencarbonate solutions of various cations. Product selectivity was greatly affected by cationic species as well as HCO_3^- concentration. H_2 evolution prevailed over CO_2 reduction in Li^+ electrolyte, whereas CO_2 reduction was favorable in Na^+, K^+, and Cs^+ solutions. C_2H_4 formation became greater than CH_4 with increase of the cation size, i.e. with sequence of Li^+, Na^+, K^+, Cs^+. The variation of the product selectivity caused by cationic species is rationalized by the difference of outer Helmholtz plane (OHP) potential. The OHP potential will vary with cationic species in accordance with the degree of specific adsorption. The concentration of H^+ at the electrode will depend upon the OHP potential, since H^+ is a charged species. This difference of pH at the electrode will lead to the variation of product selectivity.

Metallic copper is an effective electrocatalyst for reduction of CO and CO_2 to CH_4, C_2H_4, and alcohols as firstly reported by the present authors.[2-5)] Other investigators also confirmed the formation of hydrocarbons and alcohols at Cu electrodes.[6-10)] The electroreduction of CO_2 at Cu proceeds with intermediate formation of CO adsorbed on the electrode as reported in the previous paper.[5,11)] In the course of this study, we found that the product selectivity is significantly affected by cationic species of aqueous electrolyte. The present paper reports the experimental results, discussing the model.

Experimental

A copper electrode (99.999%, 2 cm×2 cm) was electropolished in concentrated phosphoric acid. Aqueous 0.1 M hydrogencarbonate solutions of Li, Na, K, and Cs were employed as the electrolytes, prepared with doubly distilled deionized water. $LiHCO_3$ and $CsHCO_3$ solutions were prepared by dissolving the respective carbonate and saturating with CO_2. The solubility of Li_2CO_3 is 1.31 g in 100 g of saturated solution, or 0.18 M at 20 °C.[12)] The upper limit of concentration of $LiHCO_3$ is thus 0.36 M (1 M=1 mol dm^{-3}). The electrolytes were purified by pre-electrolysis with a Pt black cathode. Coulometric measurements were conducted in a three compartment cell in which two anode compartment faced each side of the cathode. The cathode compartment was separated from two anodes with sheets of cation-exchange membrane. Electrolysis was carried out at 18.5 °C with controlled current densities. The cathode potential was measured with respect to an Ag/AgCl reference electrode, corrected for the IR drop by a potentiostat equipped with a positive feedback electronic circuit. Effluent gas from the cell was analyzed by gas chromatographs. Alcohols and formate ion dissolved in the electrolyte were analyzed by a gas chromatograph and an ion chromatograph after electrolysis. Other experimental details were described elsewhere.[11)]

Results

Some measurements were carried out for 1 h. The concentration of gaseous products remained nearly constant during coulometric measurements. Thus most of the works were conducted for 30 min. Table 1 presents average faradaic efficiencies of products in electroreduction of CO_2 in 0.1 M various hydrogencarbonate solutions with constant current density 5.0 mA cm^{-2}. The sums of the faradaic efficiencies are close to 100%; the tabulated substances will be the major products of this reaction. H_2 evolution is favorable with the sequence of $Li^+ > Na^+ > Cs^+ > K^+$. The faradaic efficiencies of CH_4 and C_2H_4 depend greatly upon cationic species. The highest value of methane formation takes place in Na^+ electrolyte. C_2H_4 formation is the most favorable in Cs^+ electrolyte. CH_4/C_2H_4 faradaic efficiency ratio C_1/C_2 increases in the order of $Cs^+ < K^+ < Na^+ < Li^+$. C_2H_5OH and n-C_3H_7OH are fairly produced in K^+ and Cs^+ electrolytes.

Table 1. Current Efficiencies of the Products in Electrochemical Reduction of CO_2 in 0.1 M Hydrogencarbonate Solutions[a)]

Cation	Potential	Current efficiency/%								C_1/C_2
	V/SHE	CH_4	C_2H_4	CO	EtOH	PrOH	$HCOO^-$	H_2	Total	
Li^+	−1.45	32.2	5.2	Tr	1.6	Tr	4.7	60.5	104.2	6.19
Na^+	−1.45	55.1	12.9	1.0	4.2	0.6	7.0	25.1	105.9	4.27
K^+	−1.39	32.0	30.3	0.5	10.9	1.6	8.3	14.5	98.1	1.06

a) Current density: 5.0 mA cm^{-2}. Temperature: 18.5 °C. pH value at the electrode is estimated to be 9.5 under the experimental conditions (See text).

Table 2. Current Efficiencies of the Products in Electrochemical Reduction of CO in 0.1 M Hydrogencarbonate Solutions[a)]

Cation	Potential	Current efficiency/%						C_1/C_2
	V/SHE	CH_4	C_2H_4	EtOH	PrOH	H_2	Total	
Li^+	−1.40	26.0	13.4	0.4	Tr	61.1	100.9	1.94
Na^+	−1.43	21.6	15.8	1.4	1.1	59.9	99.6	1.37
K^+	−1.37	8.9	25.7	3.1	2.2	54.7	94.6	0.346
Cs^+	−1.31	2.0	15.9	1.7	1.3	76.8	97.7	0.126

a) Current density: 1.5 mA cm^{-2}. Temperature: 18.5 °C. pH value at the electrode is estimated to be 9.1 under the experimental conditions.

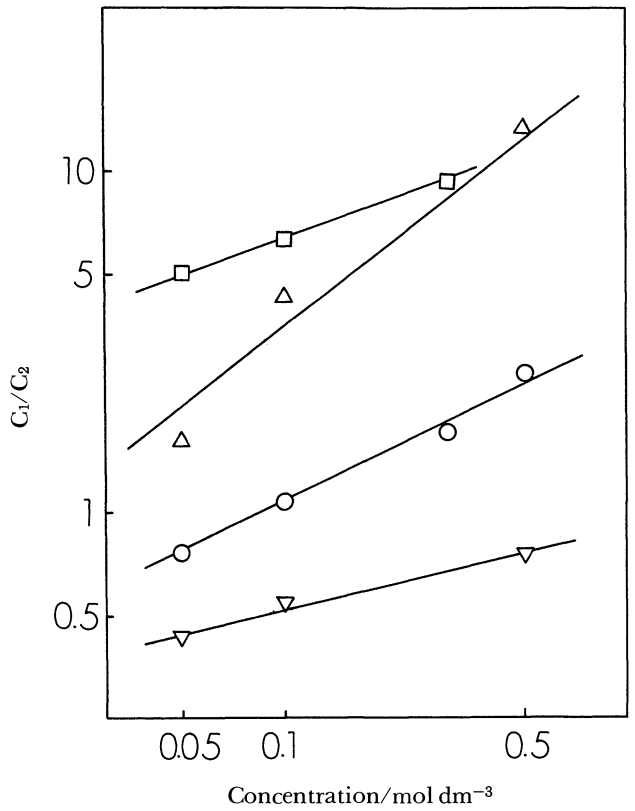

Fig. 1. Variation of the C_1/C_2 in the electroreduction of CO_2 in hydrogencarbonate solutions of various concentration. Current density: 5.0 mA cm^{-2}. Temperature: 18.5 °C. Cationic species; □, Li; △, Na; ○, K; ▽, Cs. Estimated pH values ranged between 8.9 in 0.5 M solution and 10.1 in 0.05 M solution (See text).

CO formation is very low. $HCOO^-$ increases in the order of $Li^+<Na^+<K^+<Cs^+$. C_2H_6 and CH_3OH were not detected at all.

Figure 1 illustrates variation of C_1/C_2 in various electrolytes at the current density 5.0 mA cm^{-2}. C_1/C_2 rises linearly with logarithm of electrolyte concentration, and falls in the order of $Li^+>Na^+>K^+>Cs^+$, identical with the order of cation size. C_2H_4 formation becomes favorable with decrease of HCO_3^- concentration and increase of cation size.

Table 2 presents faradaic efficiencies of products in the electroreduction of CO in 0.1 M hydrogencarbonate solutions at a constant current density 1.5 mA cm^{-2}. The current efficiency of H_2 formation, not much different with one another, is relatively low in Na^+ and K^+ electrolytes, and takes the highest value in Cs^+ electrolyte. These values are higher than those obtained in CO_2 reduction. The solubility of CO is ca. 1/40 that of CO_2.[12] The electrolysis current 1.5 mA cm^{-2} may exceed the limiting current governed by CO diffusion to the electrode, and the H_2 may be evolved more easily. CH_4, C_2H_4, C_2H_5OH, and n-C_3H_7OH are produced in the electroreduction of CO as well. C_1/C_2, ranging to a similar extent with CO_2 reduction, increases with the sequence of $Cs^+<K^+<Na^+<Li^+$.

Discussion

Product Selectivity Affected by Concentration of HCO_3^-. Cathodic reduction of CO_2, CO, and H_2O releases an OH^- per one electron.

$$CO_2 + 6H_2O + 8e^- = CH_4 + 8OH^- \quad (1)$$

$$CO + 5H_2O + 6e^- = CH_4 + 6OH^- \quad (2)$$

$$2H_2O + 2e^- = H_2 + 2OH^- \quad (3)$$

In the case of $HCOO^-$ production, one OH^- is formed per two electrons.

$$CO_2 + H_2O + 2e^- = HCOO^- + OH^- \quad (4)$$

The rate of OH^- formation is thus determined by the current density and the product distribution.

OH^- produced at the electrode will be instantaneously neutralized by HCO_3^- in the diffusion layer.

$$OH^- + HCO_3^- = CO_3^{2-} + H_2O \quad (5)$$

In dilute hydrogencarbonate solutions, the transport of HCO_3^- may be short of neutralization of OH^-; pH value will rise in the neighborhood of the electrode. A simple model may clarify the situation. H_2O is reduced to H_2 at a plane electrode in 0.1 M $KHCO_3$ solution without CO_2. Released OH^- reacts with HCO_3^-, giving CO_3^{2-}. pH value can easily be

Table 3. Current Efficiencies of the Products in Electrochemical Reduction of CO_2 in Various Concentration of KCl Solutions[a)]

Concn	Potential	Current efficiency/%								C_1/C_2

1.0	−1.42	8.7	42.2	15.5	1.8	3.3	9.6	15.8	96.9	0.206

a) Current density: 5.0 mA cm^{-2}. Temperature: 18.5 °C. The values were obtained at 15 min after the start of electrolysis. pH value at the electrode is estimated to be 10.6 under the experimental conditions.

calculated in this case as a simple steady state diffusion problem. With assumption of the diffusion layer thickness 0.0030 cm, pH at the electrode is ca. 9.1 and 9.7 for the current density of 1.5 and 5.0 mA cm^{-2} respectively.[13)] pH at the electrode becomes higher in dilute hydrogencarbonate solution due to low buffer capacity in Eq. 5. The pH values at the electrode during CO reduction will be equal to those calculated in this manner. The details of the procedure were described in the previous paper.[11)]

In CO_2 saturated solution, pH at the electrode may differ from the values obtained by the method described above since OH^- will be partially neutralized by CO_2. However, the rate of neutralization of CO_2 by OH^- is very low as is well-known.[14)] CO_2 will thus be present under non-equilibrium situations at the electrode in spite of high pH value.[11)] We have strictly treated the diffusion problem accompanied with simultaneous neutralization of CO_2 by CO_3^{2-} (or OH^-) and the electroreduction of CO_2 in a mathematical procedure. pH values at the electrode surface have been obtained for hydrogencarbonate solutions saturated with CO_2. The procedure and the results were partially reported[15)] and the details will be published in near future. The pH values at the electrode calculated in this manner ranged between 8.9 in 0.5 M solution and 10.1 in 0.05 M solution as shown in Fig. 1, Tables 1 and 3. However, the calculation was carried out without taking into consideration of the cation effect described below.

CO_2 is reduced to CH_4 and C_2H_4 with CO intermediately produced. In CO electroreduction, C_2H_4 formation relatively increases with pH of the bulk solution.[5,11)] It is thus reasonable that C_1/C_2 tends to smaller value in more dilute hydrogencarbonate solution, in which pH becomes higher at the electrode.

Variation of the Potential at Outer Helmholz Plane with Cationic Species and Its Effects on CO_2 Reduction and Hydrogen Evolution. We previously reported electroreduction of CO_2 to $HCOO^-$ at a Hg pool electrode in various hydrogencarbonate solutions, referring to the effect of cationic species.[16)] The electrode potential at a constant partial current of $HCOO^-$ formation shifts to the positive direction with the sequence of Li^+, Na^+, K^+. We discussed the results in connection with the variation of potential at the outer Helmholz plane (OHP) E_2.

Variation of the product selectivity with cationic species indicated in Tables 1 and 2 can be rationalized in terms of the potential distribution at the electrode surface. If ions are strongly hydrated, they will not be specifically adsorbed on the electrode. The hydration number of Li^+ is the largest, and that of Cs^+ is the smallest among alkali metal ions.[17)] The potential of zero charge (pzc) of Cu is −0.3 to −0.7 V vs. SHE in neutral electrolytes.[18)] The electrode potentials during the electrolysis are far more negative than the pzc, nevertheless there may be some differences with regard to the degree of the cationic adsorptions. The extent of specific adsorption of Li^+ would be the least on the electrode, and that of Cs^+ the greatest. Specific adsorption of cation will shift E_2 to the positive direction. Thus, the value of E_2 would be more positive in the sequence of $Cs^+ > K^+ > Na^+ > Li^+$.

The cation specific adsorption and its effect on H_2 evolution were partly substantiated by Maznichenko et al.[19)] They measured the overvoltages of H^+ reduction at constant current and discussed the relation with E_2. The overvoltages measured in mixtures of HCl and alkali halide aqueous solution are greater in the sequence of $Cs^+ > K^+ > Na^+ > Li^+$.

The effect of E_2 on the rate of an electrode reaction is twofold, according to Frumkin.[20)] First, the concentration of the ions at OHP undergoing an electrode reaction is changed as compared to the bulk concentration in the solution. Second, the effective potential difference which determines the charge transfer current density is $|E-E_2|$, where E is the electrode potential. If E_2 become more positive, E at constant current density will naturally be more positive as well. The situations are depicted in Fig. 2. The potential variations in Tables 1 and 2 confirm the validity of this model.

CO_2 is not electrically charged, and the concentration of CO_2 at OHP will not be changed from that of the bulk of the solution, if we neglect the concentration gradient due to transport process. However, H^+ is positively charged, and the concentration at OHP $[H^+]_s$ will be given as follows.[20)]

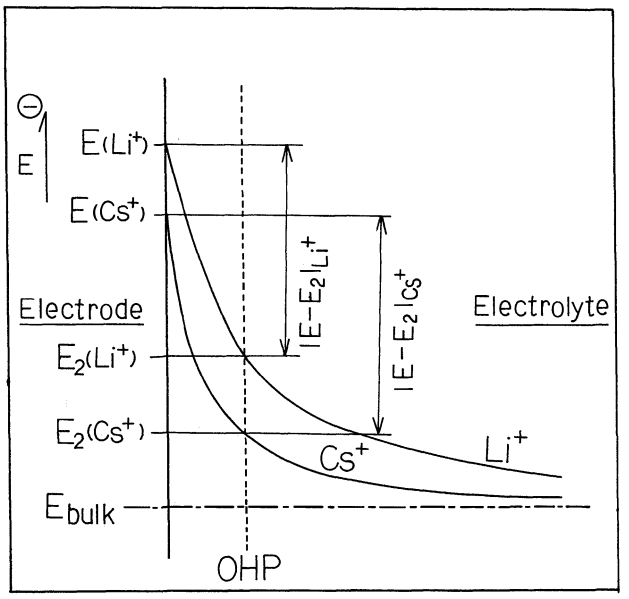

Fig. 2. Potential distribution in the neighborhood of the electrode.

$$[H^+]_s = [H^+] \exp(-FE_2/RT) \quad (6)$$

The more negative E_2 is, the more concentrated H^+ will be. pH at the electrode surface will be lower in the sequence of $Cs^+ > K^+ > Na^+ < Li^+$. During the electrolysis, the rate of OH^- release at the electrode is approximately constant at constant current density. Thus, pH at OHP will be relatively lower in Li^+ solution, and higher in Cs^+ solution. The H_2 evolution will most favorably proceed in Li^+ solution, as is confirmed by Table 1. One would expect that the current efficiency of H_2 would be the least in Cs^+ solution in accordance with the present model. But Cs^+ solution is more advantageous for H_2 evolution than K^+ and Na^+ solutions, especially in the CO electroreduction. The reason is unknown at present.

Ito et al. carried out the electrochemical reduction of CO_2 at an indium electrode in various alkali carbonate solutions.[21] Alkali carbonate solutions must have been converted to hydrogencarbonate ones since the solutions were saturated with CO_2. According to their report, the current efficiency of $HCOO^-$ increases in the sequence of $Rb^+ < K^+ < Na^+ < Li^+$. This result does not agree with ours obtained with a Hg pool electrode.[16] The discrepancy may be caused by the difference of experimental conditions such as the preparation and the treatment of the electrode surface. Additionally, CO_2 reduction is sensitive to contamination of the electrode surface, but Ito et al. did not give any remarks to this point. It is impossible to discuss this problem more extensively.

Product Ratio of CH_4 and C_2H_4. C_1/C_2 significantly decreases with decrease of HCO_3^- concentration (Fig. 1) or increase of pH at the electrode surface; C_2H_4 formation is favorable in high pH conditions. pH at the electrode will be in the order of $Li^+ < Na^+ < K^+ < Cs^+$ as discussed above. Thus C_1/C_2 will decrease in the order of increasing pH at OHP, $Li^+ > Na^+ > K^+ > Cs^+$, as shown in Tables 1, 2 and Fig. 1.

It is remarkable that the variation of cations affects similarly the product distribution of both CO and CO_2 reduction. This fact indicates the validity of the specific adsorption/ OHP potential model. It can also confirm the intermediate formation of CO in the course of CO_2 reduction.

According to Tables 1 and 2, C_1/C_2 takes higher values in CO_2 reduction than CO reduction. pH at the electrode is 9.5 in CO_2 reduction at 5.0 mA cm^{-2}, whereas 9.1 in CO reduction at 1.5 mA cm^{-2}.[22] These facts do not appear compatible with the model described above that high pH value leads to low C_1/C_2. This apparent contradiction may be rationalized as below. The current efficiency of CH_4 exceeds that of C_2H_4 as the electrode potential tends negatively as revealed by the potentiostatic electroreduction of CO_2 in 0.1 M $KHCO_3$ solution.[11] Thus C_1/C_2 is enhanced with increase of negative potential. As shown in Tables 1 and 2, the potential in CO_2 reduction is more negative than in CO reduction, C_1/C_2 becoming higher in CO_2 reduction. We undertook identical experiments under potentiostatic conditions. Potentiostatic electrolysis measurements are accompanied with change of the current density during the measurements probably due to the change of surface condition of the electrode. pH at the electrode will vary if the current is not kept constant in accordance with the model of electrogenerated OH^- mentioned above. However, C_1/C_2 value similarly depended on the cationic species as demonstrated in Tables 1 and 2 obtained in constant current electrolyses.

Table 3 shows the results obtained in CO_2 electroreduction in KCl solutions of various concentrations. C_1/C_2 does not vary to a great extent as those in hydrogencarbonate solutions illustrated in Fig. 1. It is evident that the product distribution does not depend upon concentration of cation and anion which do not neutralize OH^-. The invariant C_1/C_2 values in Table 3 may suggest that the amount of specifically adsorbed cations does not depend upon the concentration; the specific adsorption would be saturated at the electrode in 0.1 M KCl solution. It is also remarkable that C_1/C_2 assumes smaller values since pH at the electrode would be much higher in KCl solutions than in $KHCO_3$ ones.

22) The product distribution of CO_2 reduction may be preferably compared with that of CO reduction at the same current density. However, it is impossible due to the reason below. The CO_2 reduction does not proceed effectively at 1.5 mA cm^{-2} with Li^+ and Cs^+ electrolytes, yielding only H_2 with slight amount of CH_4 and C_2H_4. CO must be adsorbed at the electrode surface for formation of CH_4 and C_2H_4 from CO_2. Under the conditions of 1.5 mA cm^{-2}, H_2 evolution preferentially proceeds, and little CO is formed from CO_2 on the Cu electrode surface.

On the other hand, the solubility of CO in aqueous solution is low, and the current density of 5 mA cm^{-2} will be far beyond the limiting current.

Broadening of the Proton Magnetic Resonance Spectra of Sulfonate Anions by Ion Pairing with Paramagnetic Chromium(III) Complexes

Masayasu IIDA* and Haruhiko YOKOYAMA†
Department of Chemistry, Faculty of Science, Nara Women's University, Kita-uoya-nishi-machi, Nara 630
† Department of Chemistry, Yokohama City University, Seto, Kanazawa-ku, Yokohama 236
(Received May 28, 1990)

The paramagnetic line broadening of both the ^1H spectra of $CH_3SO_3^-$ and $(CH_2SO_3)_2^{2-}$ was observed in aqueous solutions including chromium(III) complexes such as $[Cr(en)_3]^{3+}$ (en=ethylenediamine), $[Cr(phen)_3]^{3+}$ (phen=1,10-phenanthroline), and *lel,lel,lel*-$[Cr(chxn)_3]^{3+}$ (chxn=*trans*-1,2-cyclohexanediamine). The dependence of the line broadening on the concentration of chromium(III) complexes was attributed to contact ion-pair formation. The distances between the Cr atom and the H atoms of the anions in contact ion pairs were derived in order to discuss their configurations. The anions were considered to be in contact with the complex ions through one or two sulfonate groups directed toward the Cr atom in the open space along the C_3-axis of the complex or in hollow regions between the ligands.

The formation of ion pairs between the metal complex cations and the various anions was previously studied using conductivity measurements.[1] The differences between the experimental and theoretical ion-pair formation constants were attributed to the presence of such interactions as the hydrophobic type and hydrogen bonding between the metal complex cations and the anions.

Nuclear magnetic resonance spectroscopy has provided a powerful tool for studying the microdynamic behavior of ions in solution.[2,3] If one of the ions in an ion pair is paramagnetic, the diamagnetic counterions will experience a magnetic field caused by that paramagnetic ion. This paramagnetism on the counterion produces an NMR spectrum that is either a resonance shift, line broadening, or both. From such a spectrum we can obtain configurational information concerning the ion pair.[4] Paramagnetic line-broadening of the diamagnetic ion is related to the dynamic behavior of the ion pair. In the simplest case of isotropic reorientational motion, the dipolar contribution of a paramagnetic ion to the line width, $(\Delta\nu_{1/2})_{IP}$ in Hz, or the transverse relaxation time, T_2, for the proton is expressed as[4,5]

$$\pi(\Delta\nu_{1/2})_{IP} = (T_2^{-1})_{IP} = J\tau_C r_{CrH}^{-6}[7 + 13/(1 + \omega_S^2\tau_C^2)]/15. \quad (1)$$

For the present system, τ_C is the dipolar correlation time, ω_S the electron spin resonance frequency, and r_{CrH} the electron-nuclear distance corresponding to the distance between the chromium(III) atom of the complex and the hydrogen atoms of the anion within the ion pair.

The parameter J is given by

$$J = S(S + 1)\gamma_H^2 g^2\beta^2, \quad (2)$$

where S is the total electron spin of Cr(III), γ_H is the nuclear gyromagnetic ratio of proton, and g and β are the g-factor for the magnetic moment and the Bohr magneton of electron spin in Cr(III), respectively. In the present study, the paramagnetic line-broadening of the hydrogen atoms of $CH_3SO_3^-$ or $(CH_2SO_3)_2^{2-}$ was observed in the presence of chromium(III) complex cations and was analyzed by considering their ion-pair formations. The values of r_{CrH} given in Eq. 1 were estimated through $(\Delta\nu_{1/2})_{IP}$ based on some assumptions; the configurations of the ion pairs are discussed.

Experimental

The ^1H NMR measurements were performed using a JEOL GX-270 Fourier-transform spectrometer operating at 270.0 MHz with 5-mm (diameter) tubes at 27 °C on aqueous solutions of sodium salt of $CH_3SO_3^-$ or $(CH_2SO_3)_2^{2-}$ of 0.0100 mol dm^{-3} in the presence of chlorides of the Cr(III) complexes while changing their concentrations from 0.00600 to 0.0200 mol dm^{-3}. The preparation of the salts used was proviously described.[1]

Results and Discussion

The ^1H NMR spectra of both the $CH_3SO_3^-$ and $(CH_2SO_3)_2^{2-}$ ions were single lines with widths less than 1 Hz; they were assigned to the methyl and the methylene protons, respectively. The observed half widths, $(\nu_{1/2})_{obsd}$, depended on the concentrations of the chromium(III) complexes, while the chemical shifts did not. The concentration dependence of the half width can be attributed to the ion-pair formation of the anions with chromium(III) complexes.[4] In the present study we assumed that a formed ion pair could be classified into a solvent-separated ion pair and a contact type in a similar manner as before.[6] The equilibria for the ion-pair formations are expressed by

$$M+A \rightleftharpoons MA(sep) \rightleftharpoons MA(con), \quad (3)$$

where M is the free complex ion, A the free anion, MA(sep) the solvent-separated ion pair, and MA(con) the contact ion pair. Since the relaxation time for the exchange of anions between free and ion-pairing types

is sufficiently shorter than T_2, the observed half width change, $(\Delta\nu_{1/2})_{obsd}$, can be written as

$$\begin{aligned}(\Delta\nu_{1/2})_{obsd} &= (\nu_{1/2})_{obsd} - (\nu_{1/2})_0 \\ &= [P_A(T_2^{-1})_A + P_{MA(sep)}(T_2^{-1})_{MA(sep)} \\ &\quad + P_{MA(con)}(T_2^{-1})_{MA(con)}]/\pi, \end{aligned} \quad (4)$$

where $(\nu_{1/2})_0$ is the half width in a sodium sulfonate solution having no complex ion and P is the fraction of each species in solution. Since terms including $(T_2^{-1})_A$ and $(T_2^{-1})_{MA(sep)}$ are presumed to be negligible, since the distance between the Cr(III) atom of the complex and the H atoms of the free anions or of the anions in the solvent-separated ion-pair should be considerably larger than that in the contact ion pair ($r_{MA(con)}$), we approximate Eq. 4 as

$$\begin{aligned}(\Delta\nu_{1/2})_{obsd} &= P_{MA(con)}(T_2^{-1})_{MA(con)}/\pi \\ &= P_{MA(con)}(\Delta\nu_{1/2})_{MA(con)} \\ &= (1 - P_A)x_{MA(con)}(\Delta\nu_{1/2})_{MA(con)}, \end{aligned} \quad (5)$$

where the fact that $1-P_A$ is identical to $P_{MA(sep)}+P_{MA(con)}$, and $x_{MA(con)}$ means that the fraction of contact ion pairs out of the total number of ion pairs, which is equivalent to [MA(con)]/{[MA(sep)]+[MA(con)]} or $P_{MA(con)}/(1-P_A)$.

The values of P_A for each solution can be evaluated by using the ion-pair formation constant (K) obtained on the basis of the usual thermodynamic methods. For the present ion-pair systems, the concentration equilibrium constants (K_c),

$$K_c = ([MA(sep)] + [MA(con)])/([M][A]), \quad (6)$$

were determined from conductivity measurements under an ionic strength (I) of 0.01 at 25 °C;[1] the values of K_c are summarized in Table 1. Although the present study was carried out at 27 °C, these K_c values were used without any correction. The P_A values, however, were calculated by correcting K_c for the difference in the ionic strength with the Debye–Hückel equation[1,7] for the activity coefficients of ions and also by considering the effect of ion-pair formation of the complex ion with coexisting chloride ions. The values of P_A, thus obtained, are shown in Table 2, together with those of $(\Delta\nu_{1/2})_{obsd}$.

Using the concentration equilibrium constant for the solvent-separated ion-pair formation,

$$K_{c(sep)} = [MA(sep)]/([M][A]), \quad (7)$$

we can express $x_{MA(con)}$ in Eq. 5 as

$$x_{MA(con)} = 1 - K_{c(sep)}/K_c. \quad (8)$$

The $K_{c(sep)}$ can be estimated by using a theoretical equation for ion association,[1,7,8] since the formation of a solvent-separated ion pair is presumed to be governed by such a simple electrostatic interaction as that explained by theory. The inter-ionic distance for a solvent-separated ion pair, which is included in the theoretical equation, was taken as being the sum of $\sum r_{ef}$ and $2r(H_2O)$, where $2r(H_2O)$ is the diameter of a water molecule and was regarded as being 0.28 nm; $\sum r_{ef}$ is the sum of the effective ionic radii of the cation and the anion, the values of which were regarded as being 0.362 nm for $[Cr(en)_3]^{3+}$, 0.445 nm for *lel*$_3$-$[Cr(chxn)_3]^{3+}$ (*lel*$_3$=*lel,lel,lel*), 0.498 nm for $[Cr(phen)_3]^{3+}$, 0.257 nm for $CH_3SO_3^-$, and 0.315 nm for $(CH_2SO_3)_2^{2-}$.[1] The values of $x_{MA(con)}$, $\sum r_{ef}$, and $K_{c(sep)}$ are summarized in Table 1 and those of $(\Delta\nu_{1/2})_{MA(con)}$ obtained are shown in Table 2.

The theoretical expression for $(\Delta\nu_{1/2})_{MA(con)}$ is given by Eq. 1, where $(\Delta\nu_{1/2})_{IP}$ should be replaced by $(\Delta\nu_{1/2})_{MA(con)}$ and the second term in the brackets can be neglected since $\omega_S^2\tau_C^2 \gg 1$, where ω_S is 1.12×10^{12} s^{-1} and τ_C is larger than 10^{-11} s; the latter condition is demonstrated below. If we assume that the sulfonate anion is tightly bound to the complex ion in the ion pair and that the two ions rotate together, by keeping their configurations we can express the dipolar correlation time (τ_C) by

$$\tau_C^{-1} = \tau_R^{-1} + \tau_{MA(con)}^{-1} + \tau_S^{-1}, \quad (9)$$

where τ_R and $\tau_{MA(con)}$ are the rotational correlation time and the lifetime of the contact ion pair, respectively, and τ_S is the electron spin-lattice relaxation time. In the present systems, the contributions of $\tau_{MA(con)}^{-1}$ and τ_S^{-1} to τ_C^{-1} were neglected, since these are relatively small compared with that of τ_R^{-1}, as described later. A value of 5×10^{-9} s has been reported for $\tau_{MA(con)}$ for the

ion pair $[Co(en)_3]^{3+}SO_4^{2-}$ from an ultrasonic absorption measurement;[9] the value of τ_S for the aqua chromium(III) complex is around 5×10^{-10} s,[10] although those for the chromium(III) complexes used here are not available (we assume that the τ_S values are close to that for the aqua complex). On the other hand, the values of τ_R for the ion pairs of $[Co(en)_3]^{3+}$ with some monovalent and divalent anions are 3.2 to 8.7×10^{-11} s at 33 °C; that for the ion pair of $[Co(phen)_3]^{3+}$ with a sulfate ion is 1.2×10^{-10} s at the same temperature.[2]

The values of τ_R for unpaired $[Co(en)_3]^{3+}$ and $[Co(phen)_3]^{3+}$ are 3.2×10^{-11} and 1.0×10^{-10} s at 33 °C, respectively, and are well represented by assuming nearly sticking hydrodynamic boundary conditions on the Stokes-Einstein-Debye relation:[2]

$$\tau_R = CV_R\eta/kT, \tag{10}$$

where V_R is the volume of rotating molecule, η the viscosity of the solution, and C a dimensionless parameter related to the shape of the rotating molecule and the hydrodynamic boundary condition. We used this equation in order to estimate the possible range of τ_R by assuming a sticking boundary condition with the following two extreme cases: In case 1, the ion pair could be regarded as being a sphere having a volume equal to the sum of the van der Waals' volumes of the cation and the anion; this corresponds to the assumption that $V_R=\sum 4\pi r_{ef}^3/3$ and $C=1$ and gives the smallest τ_R. In case 2, the ion pair could be regarded as being a rotational ellipsoid of prolate shape having major and minor axes lengths of $2a=2\sum r_{ef}$ and $2b=2r_{ef(complex)}$, respectively, and a volume of $V_R=4\pi ab^2/3$. The rotation of the major axis gives the largest τ_R, where C can be calculated as a function of the ratio a/b from the relation $(\xi^*/8)\cdot(a/b)^2$, where ξ^* is a dimensionless friction coefficient defined by Hu and Zwanzig;[11] its values for the sticking boundary condition have been given.[11,12] The values of V_R in both cases and those of C in Case 2 are shown in Table 3.

a) After the viscosity correction. b) See text.

From Eqs. 1, 9, and 10 and the above-mentioned considerations,

$$(\Delta\nu_{1/2})_{MA(con)} = (7J/15\pi)\tau_R/r_{CrH}^6 = (7J\eta/15\pi kT)(CV_R/r_{CrH}^6). \quad (11)$$

Here, J is 9.2×10^{-43} s^{-2} m^6, which was obtained from Eq. 2 by taking $S=3/2$, $\gamma_H=2.675\times10^8$ s^{-1} T^{-1}, $g=2.00$, and $\beta=9.27\times10^{-24}$ JT^{-1}.[5] The viscosities of solutions, η, in Eq. 11 were estimated by using the following approximated expression for the Jones–Dole's equation[13] on a mixed electrolyte solution:

$$\eta = \eta_0(1 + \sum B_i c_i), \quad (12)$$

where η_0 is the viscosity of water at 27 °C (being equal to 8.51×10^{-4} Pa s[14]) c_i is the salt concentration, and B_i is the so-called B coefficient of the salt; the $A\sqrt{c_i}$ term in the Jones–Dole equation was ignored. The following values of B in dm^3 mol^{-1} at 25 °C were used for the present calculations: 0.198 for CH_3SO_3Na,[15] 0.403 for $(CH_2SO_3Na)_2$,[16] 0.53 for $[Cr(en)_3]Cl_3$,[17] and 1.52 for $[Cr(phen)_3]Cl_3$ and *lel*$_3$-$[Cr(chxn)_3]Cl_3$.[18] The difference between η and η_0 were within 3% under the present conditions and led to only small differences within 10 Hz in $(\Delta\nu_{1/2})_{MA(con)}$. The averaged values of $(\Delta\nu_{1/2})_{MA(con)}$ after the viscosity correction were used for the calculation of τ_R/r_{CrH}^6 by the use of Eq. 11.

The values of $(\Delta\nu_{1/2})_{MA(con)}$ and τ_R/r_{CrH}^6 and the resulting ones of r_{CrH} estimated for Case 1 and Case 2 are summarized in Table 3. The differences in r_{CrH} between the two cases were about 0.04—0.05 nm. When r_{CrH} is compared with $\sum r_{ef}$ in Case 1 or Case 2, we can say follows: the differences in r_{CrH} between the contact ion pairs of $CH_3SO_3^-$ and $(CH_2SO_3)_2^{2-}$ for the same complex are very small, in spite of the fact that the anions have a difference of 5.8×10^{-2} nm with $\sum r_{ef}$; the differences in r_{CrH} between different complexes for the same anion are also significantly smaller than those in $\sum r_{ef}$; the absolute values of r_{CrH} are smaller than those of $\sum r_{ef}$. It should be noted that $\sum r_{ef}$ corresponds to a kind of averaged contact distance between the center of the complex ion and that of the anion, since the r_{ef} values of the ions were derived from their van der Waals' volumes by regarding them as spherical.[1] The complex ions, *lel*$_3$-$[Cr(chxn)_3]^{3+}$ and $[Cr(phen)_3]^{3+}$, have open spaces along the C_3-axis and hollows between the ligands, which can receive an anion. When an anion comes into contact with a complex in such a location, their contact distance becomes shorter than $\sum r_{ef}$. However, the distance between the Cr(III) atom of the complex and the H atoms of the anion (r_{CrH}) depends on the stereochemical configuration of the contact ion pair.

The values of r_{CrH} obtained for the ion pairs of $CH_3SO_3^-$ are in a range 0.54 to 0.62 nm (Table 3), in agreement with the configuration of the ion pair that the sulfonate group of the anion is directed toward the Cr(III) atom in the open spaces along the C_3-axis of the complex or in the hollows between the ligands: the Cr–H distances presumed for such configurations from the Stuart-type molecular models are around 0.6 nm for the ion pair of $[Cr(en)_3]^{3+}$ or $[Cr(chxn)_3]^{3+}$ and about 0.6—0.7 nm for that of $[Cr(phen)_3]^{3+}$; if the methyl group of $CH_3SO_3^-$ is directed toward the Cr(III) atom in the same positions around the complex (as stated above), the Cr–H distances are presumed to be around 0.35 nm for an ion pair of $[Cr(en)_3]^{3+}$ or $[Cr(chxn)_3]^{3+}$ and around 0.4 nm for that of $[Cr(phen)_3]^{3+}$. For the last two ion pairs, however, we cannot completely exclude the configuration that the methyl group is directed to the Cr(III) atom across one chxn or phen ligand, since it gives about 0.5—0.7 nm for the Cr(III)–H distance.

The $(CH_2SO_3)_2^{2-}$ ion could stereochemically have two types of conformations (trans and gauche forms) with the two sulfonate groups. The values of r_{CrH} obtained for the ion pairs of $(CH_2SO_3)_2^{2-}$ are in the range 0.55 to 0.63 nm, suggesting the following probable configurations of the contact ion pairs: when the conformation is gauche, one or two sulfonate groups are directed toward the Cr(III) atom in the space along the C_3-axis or in the hollows between the ligands; when the conformation is trans, one sulfonate group is directed toward the Cr(III) atom in the same positions. However, we could not decide which conformation of the $(CH_2SO_3)_2^{2-}$ ion is dominant in the contact ion pairs. The Cr(III)–H distances presumed from the molecular models are as follows: in

the case of the gauche form of the anion, it is about 0.5—0.7 nm for the ion pairs of $[Cr(en)_3]^{3+}$ or $[Cr(chxn)_3]^{3+}$ and about 0.6—0.8 nm for that of $[Cr(phen)_3]^{3+}$; in the case of the trans form, similar distances are estimated for the ion pairs of $CH_3SO_3^-$. The possibility of other configurations is similar, as described for the ion pairs of $CH_3SO_3^-$.

The results obtained for r_{CrH} are consistent with the predictions from the molecular models (as described above). This suggests that the several assumptions made in the present study are reasonable, especially that the lifetimes of detected contact ion pairs having a given configuration are longer than τ_R. Such tight configurations may be maintained by the short-range interactions between the sulfonate group of the anions and the amino groups of $[Cr(en)_3]^{3+}$ or $[Cr(chxn)_3]^{3+}$, and also by a partial separation of anions from the atmosphere of the solvent into the hollows of the complex.

The values of $\log K_c$ or $\log K_{c(con)}$ for ion-pair formation of *lel*$_3$-$[Cr(chxn)_3]^{3+}$ with anions are similar to or slightly larger than those of $[Cr(en)_3]^{3+}$, in spite of the former complex ion having a relatively large ionic size. This may be due to the difference in the hydration of the complex ions and/or to the presence of some specific interactions, such as a hydrophobic type, due to the chxn ligand in the formation of *lel*$_3$-$[Cr(chxn)_3]^{3+}(CH_2SO_3)_2^{2-}$. In either case, not only the positively charged sites, such as the hydrogen atoms of the amino group in the ligand, but also the hollows among the ligands which can receive the anion may contribute to the formation of a contact ion pair. These considerations are supported by the r_{CrH} values obtained in the present study, which give the information concerning the major position of the hydrogen atoms of the anion around the complex ion in the contact ion pair.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 62124039 from the Ministry of Education, Science and Culture. The authors would like to acknowledge Associate Professor Yuichi Masuda of Ochanomizu University for his helpful discussion.

10) The τ_S value is cited from the following book: H. G. Hertz, "Water," ed by F. Franks, Plenum Press (1973), Vol. 3, Chap. 7. If we use this value for $[Cr(phen)_3]^{3+}$ (having the smallest τ_R^{-1} value among the three kinds of the complexes), the τ_S^{-1} value is about 20% of the τ_R^{-1} one as stated in the text. This magnitude results, however, in only 3% contribution to the r_{CrH} value and so the contribution of τ_S^{-1} will be negligible. (Received July 30, 1990)

The acidic property of [Rh(nbd)(dppb)]ClO_4, [Ru(binap)]$(BF_4)_2$, and [Ru(dmso)$_6$]$(ClO_4)_2$ was measured by using the acetalization of cyclohexanone as a test reaction and the temperature-programmed desorption [TPD] of pyridine. The acid strengths were estimated to be $H_0=-2.1$ for [Ru(dmso)$_6$]$(ClO_4)_2$ and $H_0=-2.2$ for [Ru(binap)]$(BF_4)_2$ and [Rh(nbd)(dppb)]ClO_4 by the test reaction method. The TPD method gave consistent results.

Metal complexes are known to be active and highly selective as catalysts for diversified reactions. For the hydroformylation of camphene, rhodium phosphine complexes, such as $RhCl(PPh_3)_3$ and $RhCl(CO)(PPh_3)_2$, have been reported to be active as catalysts,[1,2] the latter being highly selective in the formation of the aldehyde. We recently found that [1,4-bis(diphenylphosphino)butane](η^4-norbornadiene)rhodium perchlorate[3] (abbreviated to [Rh(nbd)(dppb)]ClO_4), [2,2′-bis[bis(4-methylphenyl)phosphino]-1,1′-binaphthyl]-ruthenium bis(tetrafluoroborate)[4] (abbreviated to [Ru(binap)]$(BF_4)_2$), and hexakis(dimethyl sulfoxide)ruthenium diperchlorate[5] (abbreviated to [Ru(dmso)$_6$]$(ClO_4)_2$) showed high catalytic activities for the hydroformylation reaction, the selectivity being different depending on the metal complexes.[6] In order to elucidate the role of the acidic property of the metal complexes regarding catalytic activity and selectivity, the present work was initiated.

Since no study has been made concerning the acidic property of Rh and Ru complexes, a measurement of the acidic property was attempted in the present work. Acidity measurements involving the indicator method, which was applied to uncolored samples;[7] the IR method, which was applied to metal halides by Cook;[8] and the NMR method, which was applied to boron compounds by Pasto and Balasubramaniyan,[9] were found to be unsuccessful in our catalyst system. Therefore, a kinetic method using acetalization of cyclohexanone which is known to be catalyzed by acids and the TPD method were employed in the present research.

Experimental

[Rh(nbd)(dppd)]ClO_4, [Ru(binap)]$(BF_4)_2$, and [Ru(dmso)$_6$]$(ClO_4)_2$ were prepared according to methods described in literature.[3–5] Cyclohexanone and methanol were purified by distillation. Organic acids used as reference catalysts, bases used in the TPD measurement, and indicators used for measuring the acid strength were commercially available and of guaranteed reagent grade. A SiO_2 used as a reference substance in the TPD experiment was Fuji-Davison Type ID.

The acetalization of 37.4 mmol of cyclohexanone in 50 ml of methanol was carried out at 40 °C under a dry nitrogen atmosphere with rapid stirring after 0.01 mmol of the catalyst was added. The products were analyzed by gas chromatography (Shimadzu GC-9A).

The tempeprature-programmed desorption (TPD) experiment was performed as follows. The metal complex catalyst was transferred to an adsorption tube in a dry nitrogen stream and evacuated at room temperature to 1.33×10^{-2} Pa, and then subjected to a TPD run. The TPD background of the sample, itself, was measured at a temperature-increase rate of 5 °C min^{-1}. The relative amounts of desorbed gases were determined as the peak height relative to that of Ar as an internal standard.

The TPD profiles of adsorbed ammonia, pyridine, and triethylamine were obtained by adsorbing ammonia (6.66×10^3 Pa) for 15 min, pyridine (1.33×10^3 Pa) for 10 min, and triethylamine (2.67×10^3 Pa) for 15 min at room temperature on a new sample, respectively, evacuating them at room temperature and desorbing at elevated temperatures at a temperature-increase rate of 5 °C min^{-1}. In the case of an SiO_2 sample evacuated at 600 °C for 2 h, TPD of pyridine was obtained similarly to that mentioned above.

The acid strength of SiO_2 used as a reference substance was estimated by observing the color change of a Hammett indicator adsorbed on the solid sample.[4] The indicators used were *p*-dimethylaminobenzene ($pK_a=+3.3$) and 4-(phenylazo)diphenylamine ($pK_a=+1.5$).

Results and Discussion

Acidic Property by Acetalization. The negative values of the logarithm (pk) of the first-order rate constant (k) with respect to the concentration of cyclohexanone for acetalization of cyclohexanone with methanol were plotted against the pK_a values[10] of various organic acids used as catalysts. As shown in Fig. 1, an almost straight line was obtained between the pk values and the pK_a values. Since the pk values obtained in cases of [Ru(dmso)$_6$]$(ClO_4)_2$, [Ru(binap)]$(BF_4)_2$, and [Rh(nbd)(dppb)]ClO_4 are 4.67, 4.70, and 4.70, respepctively, the acid strengths ($H_0\simeq pK_a$) of the metal complexes are estimated to be −2.1, −2.2, and −2.2 from the straight line.

Acidic Property by TPD. Fig. 2 shows some main peaks of the TPD profile of Rh[(nbd)(dppb)]ClO_4, itself, as background. The fact that the desorption

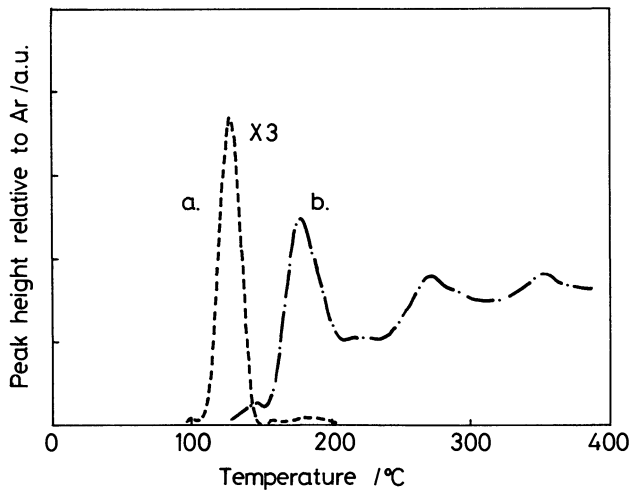

Fig. 2. Temperature programmed decomposition of [Rh(nbd)(dppb)]ClO_4. (a) m/z=42; (b) m/z=78.

peak of m/z=42 appeared at 129 °C is considered to be due to a fragment, cyclopropylium ion, formed by the decomposition of dppb, while the peak of m/z=78 appearing at 189 °C seems to be fragments ($C_6H_6^+$) formd by the decomposition of nbd.

The TPD profile of pyridine adsorbed on Rh[(nbd)-(dppb)]ClO_4 is shown in Fig. 3. A peak of m/z=79 which did not appear in the background profile, attributed to pyridine was observed at 93 °C. When pyridine was adsorbed, the peak at m/z=42 (the fragments of DPPB) shifted to a lower desorption

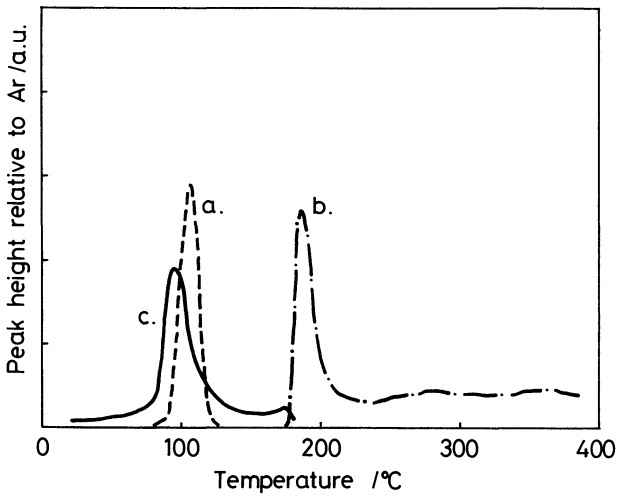

Fig. 3. Temperature programmed desorption of pyridine from [Rh(nbd)(dppb)]ClO_4 and temperature programmed decomposition of [Rh(nbd)(dppb)]ClO_4 after adsorption of pyridine at room temperature. (a) m/z=42; (b) m/z=78; (c) m/z=79.

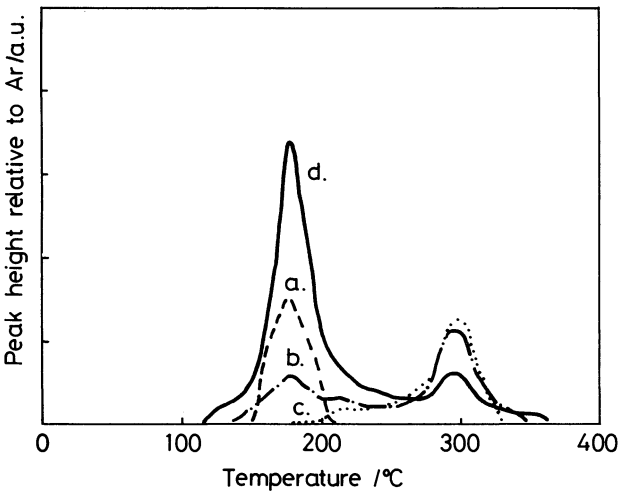

Fig. 4. Temperature programmed decomposition of $[Ru(dmso)_6](ClO_4)_2$. (a) m/z=63; (b) m/z=35; (c) m/z=52; (d) m/z=79.

temperature by 20 °C. This indicates that the bond between dppb and Rh is weakened by pyridine adsorption. In the case of ammonia TOD, no desorption peak was observed as long as the Rh complex did not decompose, probably due to the adsorption of small-size ammonia at strong acid sites where pyridine can not approach. Triethylamine whose acid strength is higher than ammonia did not adsorb on the Rh complex, probably because of its larger steric hindrance.

The main peaks of the TPD profile of $[Ru(dmso)_6]$-$(ClO_4)_2$, itself a background, are shown by a, b, c, and d in Fig. 4. The peak of m/z=63 at 177 °C is considered due to the fragment (CH_3SO^+) formed by decomposition

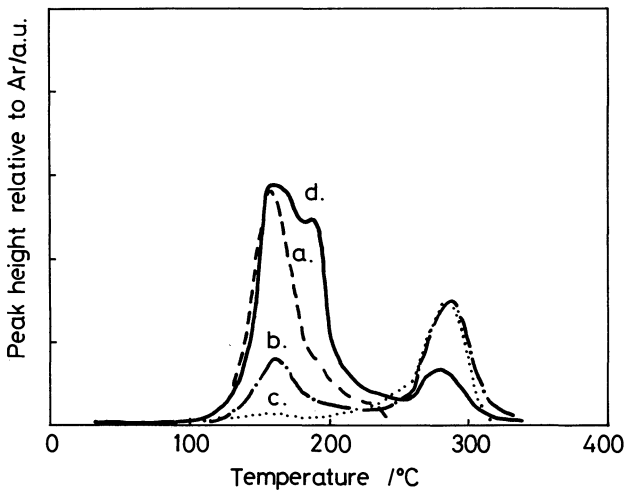

Fig. 5. Temperature programmed desorption of pyridine from $[Ru(dmso)_6](ClO_4)_2$ and temperature programmed decomposition of $[Ru(dmso)_6](ClO_4)_2$ after adsorption of pyridine at room temperature. (a) m/z=63; (b) m/z=35; (c) m/z=52; (d) m/z=79.

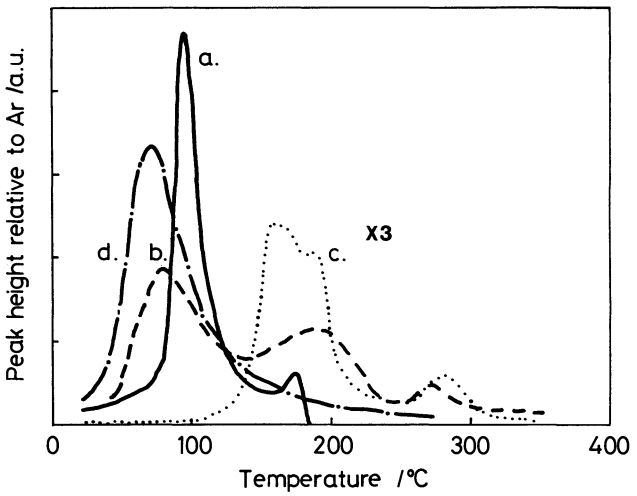

Fig. 6. Temperature programmed desorption of pyridine from (a) $[Rh(nbd)(dppb)]ClO_4$; (b) $[Ru(binap)](BF_4)_2$; (c) $[Ru(dmso)_6](ClO_4)_2$; (d) SiO_2.

of dmso. At 293 °C, the Ru complex is considered to completely decompose, since the peaks of m/z=35 due to the Cl^+ fragment and m/z=52 due to the $HClO^+$ fragment appear. A peak at m/z=79 was also observed in the background. When pyridine was adsorbed on $[Ru(dmso)_6](ClO_4)_2$, a new peak at m/z=79 was observed at 162 °C (Fig. 5); it was assigned to desorbed pyridine by a comparison of Fig. 5 with Fig. 4.

The desorption peak of pyridine (m/z=79) from $[Ru(binap)](BF_4)_2$ appeared at 78, 190, and 268 °C. The decomposition of the complex started at the same temperature, though the TPD profiles are not shown here.

Fig. 6 shows the desorption peaks (a, b, c, and d) of pyridine (m/z=79) adsorbed on $[Rh(nbd)(dppb)]ClO_4$, $[Ru(dmso)_6](ClO_4)_2$, $[Ru(binap)](BF_4)_2$, and SiO_2, respectively. In the temperature range of 70—100 °C, there is no peak of pyridine for $[Ru(dmso)_6](ClO_4)_2$. On the other hand, there is no peak of pyridine for SiO_2 and a relatively small peak was observed for $[Rh(nbd)(dppb)]ClO_4$ in the range of 150—200 °C. In a higher temperature range of 270—300 °C, pyridine desorption peaks were observed only for the Ru complex. Since a material having a higher acid strength shows a higher desorption temperature of pyridine, the order of the acid strength of the metal complexes and SiO_2 is as follows:

$$[Ru(dmso)_6](ClO_4)_2 \simeq [Ru(binap)](BF_4)_2 > [Ru(nbd)(dppb)]ClO_4 \gg SiO_2$$

The highest acid strength of SiO_2 measured by the indicator method was in the range $1.5 < H_0 < 3.3$. Therefore, the fact that the acid strengths of Ru and Rh complexes estimated by TPD method are much stronger than that of SiO_2 is consistent with the result measured by the acetalization method.

The authors thank Dr. H. Kumobayashi for his valuable discussion and Mr. N. Sayo for his preparation of some metal complexes.

Spectroelectrochemistry of New Prussian Blue Films Prepared by a Cast Method

Ru-Jang LIN and Naoki TOSHIMA*
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 31, 1990)

New Prussian Blue (PB) films were prepared by being cast from colloidal PB dispersions in an organic solvent containing cationic surfactants. The electrochromic behaviors of the cast PB films are similar to those of electrodeposited PB films. However, the cyclic voltammetries of both the PB films were quite different from each other. To make the difference clear, scanning electron microscopy (SEM), energy dispersive X-ray analysis (EDX), and X-ray photospectroscopy (XPS) were used in measurements of these films grown on Pt and indium tin oxide electrodes. The EDX results for fresh PB films indicated that cast films contain K^+ ions, suggesting a soluble-form PB, $KFe[Fe(CN)_6]$, while electrodeposited films do not, suggesting an insoluble-form PB, $Fe_4[Fe(CN)_6]_3$. The transient spectral observations indicated the participation of a unique electrochemically active iron(III) site in the reductive cycles of a cast film, although the participation of a plural electrochemically active iron(III) sites was proposed for an electrodeposited film. After a repeated cyclic scan a cast PB film maintained its unique active site, while an electrodeposited film had plural sites comprising both a soluble and an insoluble form of PB.

Prussian Blue (PB, iron(III) hexacyanoferrate(II), Fe(III/II)) is a well-known colorant used extensively in the formulation of paints, lacqures, and painting inks. Recently, Neff devised a chemical method to deposit thin films of this material onto platium and gold electrodes,[1] and were the first to investigate the electrochemistry of these films.[2,3] Neff's preparation method was modified by Itaya et al., who reported on the spectroscopies and electrochemical properties of these films prepared electrochemically on a number of substrates;[4,5] they then applied this knowledge to construct an electrochromic display.[6] For such a device to be practically useful, however, the preparation method must be modified to allow deposits on a large area and to also allow long-term stability. It is not very easy to manufacture a uniform PB film of large area by the above-mentioned methods. Though the casting of PB colloids in a nonaqueous solvent is considered to be effective to overcome this problem, such a cast film has not yet been developed.

We have found that PB colloids can be extracted from an aqueous solution by an organic solvent containing some cationic surfactants.[7,8] A PB composite film was prepared onto a transparent electrode by casting an extracted PB solution. This novel method is unique in that it enables the preparation of uniform PB films of large area. The cast PB film can be electrochemically reduced or oxidized, demonstrating a stable electrochromism, as observed in electrodeposited PB films. In this paper we describe the results of electrochemical, analytical, and spectroelectrochemical studies of a cast PB film and compare them with those of electrodeposited PB film in order to clarify the difference between the two PB films.

Experimental

Materials. Potassium hexacyanoferrate(II), $K_4[Fe(CN)_6]$, and iron(III) chloride, $FeCl_3 \cdot 6H_2O$ were the purest grade commercially available. Cationic surfactants, such as hexadecyltrimethylammonium chloride (HTAC), were purified by the standard procedures.

Preparation of Cast PB Films. The colloidal dispersions of PB were prepared by rapid mixing of aqueous solutions of both $K_4[Fe(CN)_6]$ and $FeCl_3 \cdot 6H_2O$ at an equimolar ratio. The colloidal solution, thus prepared at the concentration of 20 mmol dm^{-3} (or less), was continuously stirred before extraction in order to prevent any aggregation of the colloids; the colloidal PB was then extracted from the solution within 1 d. The extraction was carried out by using a chloroform solution containing two- or three-fold moles of a cationic surfactant.[8] The extracted chloroform solution of PB (hereafter denoted as PB-surfactant) was dried over anhydrous magnesium sulfate. To form a cast PB-surfactant film, the solution of PB-surfactant was cast onto an indium tin oxide electrode (ITO, 1 cm×1 cm, 10 Ω/□) for spectroelectrochemical studies, and onto a Pt electrode for elemental analysis by EDX.

It was found that, in general, a treatment that involved one H_2O-immersing and air-drying of the as-cast film substantially enhanced the adhesion of the cast film on the electrode. To obtain stable voltammograms, all of the cast films were finally immersed in pure H_2O and dried in a desiccator before performing a voltammetric scan.

Preparation of Electrodeposited PB Film. The electrodeposited PB films were prepared by using essentially the same method proposed by Itaya et al.[4,5] The PB was deposited galvanostatically (10 μA cm^{-2}) for 8 min onto the same ITO electrode (1 cm×1 cm, 10Ω/□) from an aqueous solution containing $K_3[Fe(CN)_6]$ (20 mmol dm^{-3}), $FeCl_3 \cdot 6H_2O$ (20 mmol dm^{-3}), KCl (0.01 mol dm^{-3}), and HCl (0.01 mol dm^{-3}).

Voltammetric and Spectroelectrochemical Measurement. Voltammograms were obtained with a Toho Technical Research model PS-2000 potentiostat equipped with a model FG-02 function generator and a model 3320 digital coulometer. A small KCl-saturated Ag–AgCl electrode was used as a reference. The cell used for spectroelectrochemical measurements was almost the same as that designed by Hoang et al.[9] and was purged with pure nitrogen gas. In

order to measure the transient spectral change during the electrochemical process, rapid scanning multichannel photodiode array spectrometers (Otsuka Electronics Co., MCPD-100A and IMUC-7000S) were used with an ITO working electrode. The MCPD coupled with Toho's model FG-02 function generator was triggered and operated by an NEC model 9801-VX personal computer. The transient absorption spectra were recorded at a 12.5 s interval with slow scanning (2 mV s^{-1}) of the ITO potential, and at a 0.08 s interval with stepping of the ITO potential. All potential values cited in this paper refer to Ag/AgCl.

Surface Analyses. A Hitachi S-430 scanning electron microscope (SEM) and a KEVEX-7000 energy-dispersive X-ray analyzer (EDX) were used to examine the alteration in the surface morphology as well as the chemical composition of the films on the surface both before and after immersing into the electrolyte, as well as subsequent voltammetric scanning in an electrolyte of 0.1 mol dm^{-3} $KClO_4$ at pH 4.0.

Results and Discussion

Chemical Composition of the PB in the Extracted Solution and in the Cast Film. We have shown that PB colloids can be extracted by an organic solution containing cationic surfactants.[7,8] The fact that only cationic surfantants can extract the PB colloids from the aqueous solution suggests the formation of composite micelles between the cationic surfactant molecules and negatively charged PB colloids having $Fe^{III}[Fe^{II}(CN)_6]^-$ units.

In general, PBs prepared in various ways can be devided into two formulations (a "soluble" form, $KFe^{III}[Fe^{II}(CN)_6]$, and an "insoluble" form, $Fe^{III}_4[Fe^{II}(CN)_6]_3 \cdot 6H_2O$) depending on the specific preparation conditions.[10] The PB, which was recrystallized[11] or electrodeposited,[4,5] was reported to have the composition of $Fe^{III}_4[Fe^{II}(CN)_6]_3 \cdot 6H_2O$, the "insoluble" form. For PB prepared by mixing $K_4[Fe(CN)_6]$ and $FeCl_3$, Wilde et al. proposed that when an excess of $K_4[Fe(CN)_6]$ to $FeCl_3$ is used a "soluble" PB is formed, while an excess of $FeCl_3$ to $K_4[Fe(CN)_6]$ gives an "insoluble" PB.[12] In fact, the composition of PB as a colloidal form in an aqueous solution was reported by Kaneko et al. as $KFe^{III}[Fe^{II}(CN)_6]$, the "soluble" form.[13]

In order to clarify the relation between the preparation conditions and the extractability by surfactants, an extraction of PB was carried out by an organic solution containing such cationic surfactants as HTAC (hexadecyltrimethylammonium chloride) from various aqueous PB solutions which were prepared by altering the molar ratio between potassium hexacyanoferrate(II) and iron(III) chloride. It was then found that the extraction of PB is effective only when the ratio of $Fe^{II}/(Fe^{II}+Fe^{III})$ is larger than 0.5.[8] This fact strongly suggests that only the "soluble" form PB can be extracted by an organic solution containing cationic surfactants.

The extracted PB solution was cast onto an ITO electrode or a Pt electrode to form a cast PB-surfactant film. Among the cationic surfactants examined, cationic surfactants with a longer alkyl chain than C_{14} were effective to form a stable cast PB film.

The chemical composition of PB in the cast film was measured by energy-dispersive X-ray analysis (EDX), which showed that cast PB film is still composed of the "soluble" form PB.[8] Details are discussed later in the present paper.

Electrochromic Behaviors of the Cast Films. The electrochromic behaviors of the cast PB-surfactant films were investigated by in-situ UV-vis spectroscopy, as mentioned briefly in a preliminary communication.[7] Figure 1(a) shows the absorption spectral changes of the PB-HTAC film measured under voltammetric scanning between −0.3 V and +1.4 V vs. Ag/AgCl with a scan rate of 50 mV s^{-1}. The color changes of the PB-HTAC film are not so large, compared with those of the electrodeposited PB film (Fig. 1(c)), for which the so-called Berlin Brown (BB, Fe(III/III), at +1.4 V vs. Ag/AgCl), and Prussian White (PW, Fe(II/II), at −0.3 V vs. Ag/AgCl) are well-known.[5] This small change in color may be due to the low ionic conductivity of the PB-HTAC film. To improve the conductivity of the PB-HTAC film,

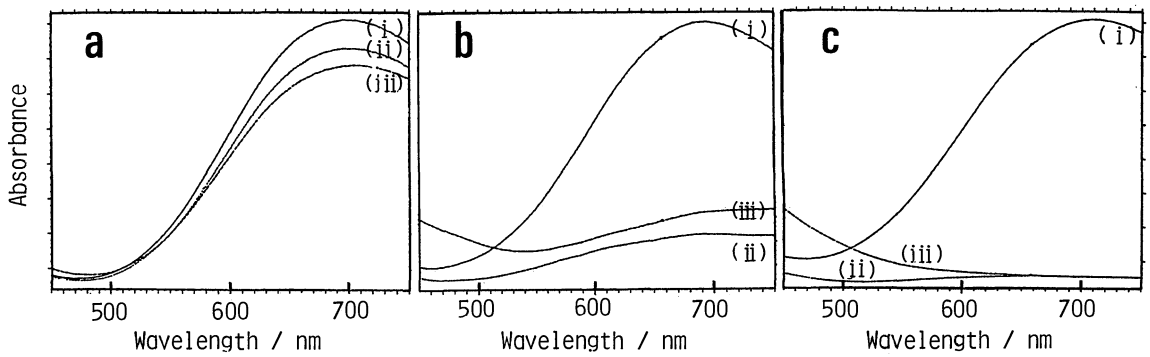

Fig. 1. Absorption spectral changes of the cast PB films, (a) PB-HTAC and (b) PB-HTAC-$LiClO_4$, and (c) the electrodeposited PB film measured under repeated voltammetric scanning. The curves show spectra at (i) +0.5 V, (ii) −0.3 V, and (iii) +1.4 V.

lithium perchlorate $LiClO_4$ in acetone was added to the extracted PB–HTAC solution in chloroform as a promoter for ionic conductivity.[14] The mixed solution was cast to form a PB–HTAC–$LiClO_4$ film. The UV-vis spectra of the PB–HTAC–$LiClO_4$ film at the oxidized and reduced states show a clear and rapid electrochromic behavior, as shown in Fig. 1(b). The oxidized and reduced films are yellow and colorless at +1.4 V and −0.3 V, respectively. The transient spectral changes of the PB–HTAC–$LiClO_4$ film are similar to those of an electrodeposited PB film dipped in an aqueous electrolyte (Fig. 1(c)).

Figure 2 illustrates the change of the absorbance at 700 nm (λ_{max} of PB) in the PB–HTAC, PB–HTAC–$LiClO_4$ and electrodeposited PB films, for which the potential is stepped between +0.5 V and +1.4 V. The electrochromic response of the PB–HTAC–$LiClO_4$ film (b) is remarkably more rapid than that of the PB–HTAC film (a), and close to that of the electrodeposited PB film (c). This would be due to the higher ionic conductivity of the PB–HTAC–$LiClO_4$ film than PB–HTAC. A similar behavior in the electrochromic response of these films was also observed in a reduction by potential stepping between +0.5 and −0.3 V.

The reproducibility of the electrochromic response is one of the most important factors for the practical utilization of the films. The electrodeposited PB film is known to be well reproducible in the reduction and

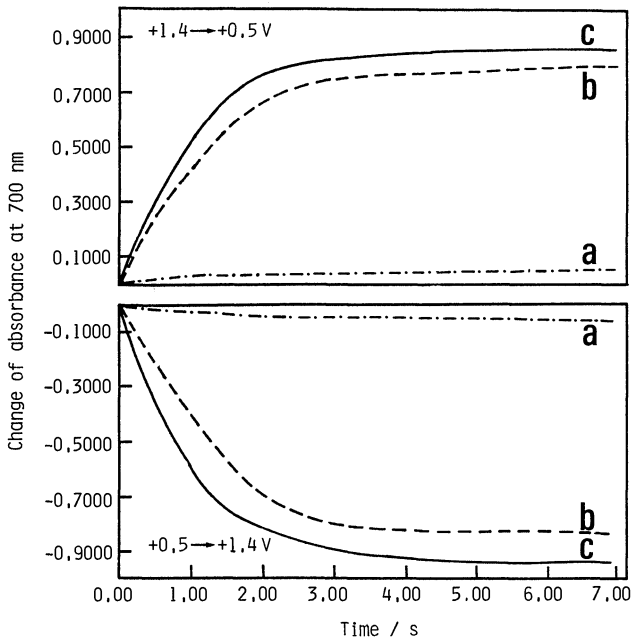

Fig. 2. Absorbance changes at 700 nm with time for (a) PB–HTAC, (b) PB–HTAC–$LiClO_4$, and (c) electrodeposited PB films when the potentials are stepped from +0.5 V to 1.4 V (lower parts) and from +1.4 V to +0.5 V (upper parts) in 0.1 mol dm^{-3} $KClO_4$.

reoxidation of PB. With respect to a cast PB film, on the negative potential step, the electrochromic response of a cast PB–HTAC–$LiClO_4$ film is as stable as that of the electrodeposited PB film during repeated potential steps. On the positive potential step, furthermore, the electrochromic response of the cast PB–HTAC–$LiClO_4$ film is more stable than that of the electrodeposited PB film. This behavior may be due to a higher stability of the oxidized form of PB in a cast film than in an electrodeposited film. More detailed discussions regarding this behavior is given later in terms of a cyclic voltammogram and spectroelectrochemistry.

Voltammetry of PB–HTAC–$LiClO_4$ Films. Cyclic voltammograms (CV) of the cast PB–HTAC–$LiClO_4$ films were taken in a 0.1 mol dm^{-3} $KClO_4$ electrolyte at a scanning rate of 20 mV s^{-1}. An example is shown in Fig. 3(a), as well as the CV of the electrodeposited PB film in Fig. 3(b).

In the region of a negative potential scan (between +0.5 V and −0.3 V), which causes a reduction of PB to PW, the CV curves of both the cast and the electrodeposited PB film are similar to each other regarding fundamental features. However, a precise comparison of both CV curves makes the differences clear. To make the difference more clear, the CVs of both films were measured at a slow scanning rate of 2 mV s^{-1} as well. The results are shown in Figs. 4(a) and (b), which are quite different each other.

The CV curve of the cast film is both sharper and simpler than that of the electrodeposited film, which has a complex curve comprising a sharp peak centered at 0.18 V and broad shoulders at ca. 0.0 V and 0.3 V. In successive scans, the CV peak feature of the cast film remains without any large change, even though the peak current at 0.18 V increases slightly. In contrast, on an electrodeposited film, the broader shoulder observed in the first reductive scan gradually diminishes during repeated scans and becomes sharp; this is rather similar to the simple wave observed for a cast film. This sharp spike was earlier noted by Ellis et al.[2] for a PB-modified gold electrode. Itaya et al.[5] assumed that uncoordinated $[Fe(CN)_6]^{4-/3-}$ and $Fe^{2+/3+}$ ions seem to be reason for the current spike. However, we have found that the sharp spike could not be observed on an electrodeposited PB film voltammetrically scanned in an aqueous KCl solution.[15] On the other hand, such sharp spikes were frequently observed on polymer-modified electrodes,[16,17] for which a structural change was proposed as a possible reason for the spikes, since the structures of polymers are strongly affected by the redox reaction. In the present case, repeated scans caused a structural change of the electrodeposited PB to a new one which has a similar structure to that of cast PB, even though some part of the virgin form of the electrodeposited PB remained. The structural change of the electrodeposited PB is discussed again later on the basis of spectroelectrochemical measure-

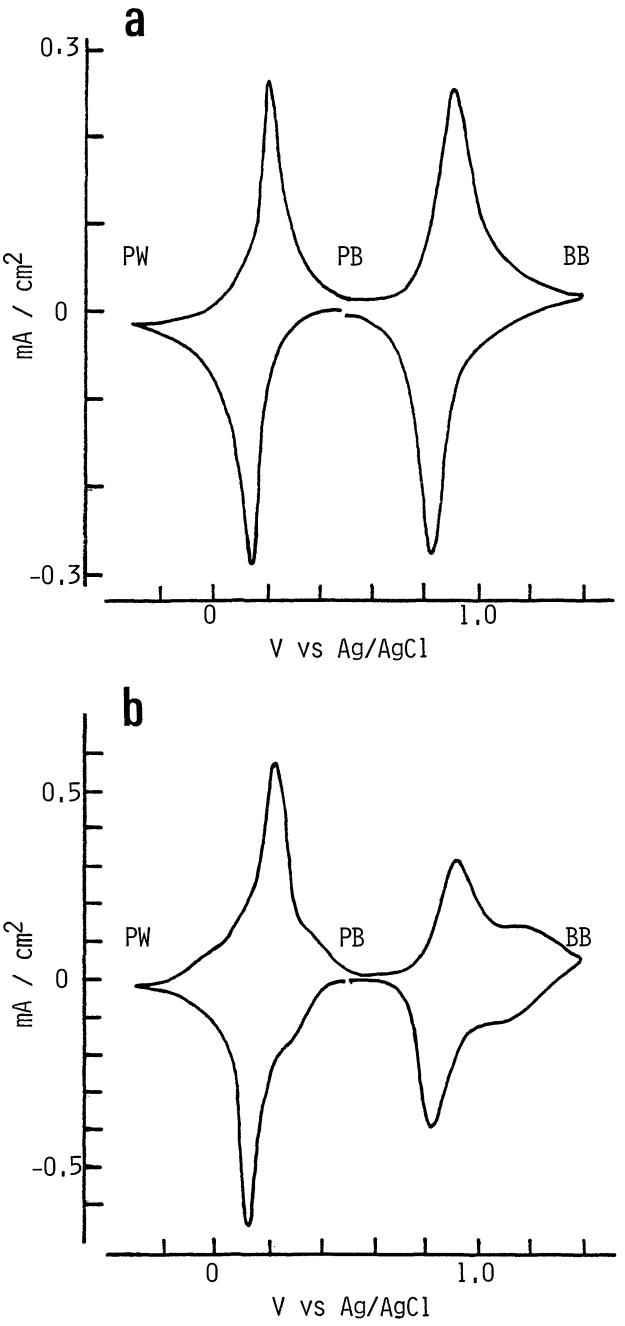

Fig. 3. Cyclic voltammograms of (a) PB–HTAC–$LiClO_4$ and (b) electrodeposited PB films on ITO electrodes in 0.1 mol dm^{-3} $KClO_4$. Scan speed= 20 mV s^{-1}. Only the stable voltammograms are presented.

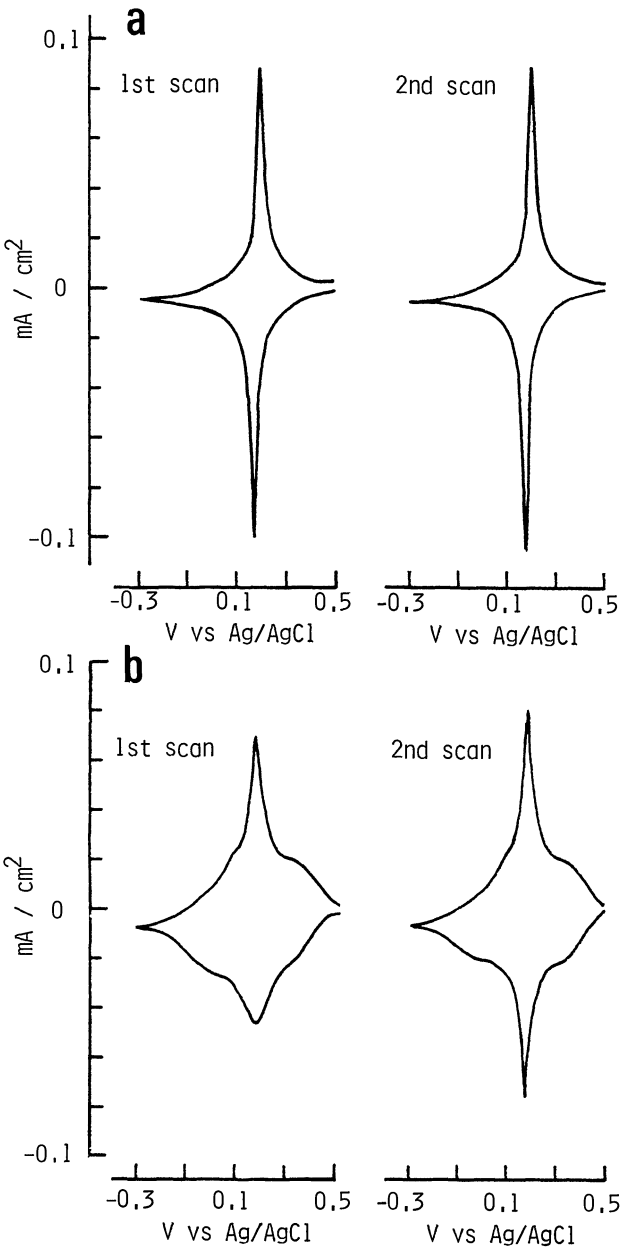

Fig. 4. Cyclic voltammograms of (a) PB–HTAC–$LiClO_4$ and (b) electrodeposited PB films on ITO electrodes in 0.1 mol dm^{-3} $KClO_4$. Scan speed= 2 mV s^{-1}. The first and second reductions are presented, respectively.

ments.

On the other hand, the oxidation of PB in a positive potential scan has been reported to correspond to a partial of full oxidation of the hexacyanoferrate(II) sites to Berlin Green (BG) or Berlin Brown, depending on the positive extent of the potential scan.[4,5] A positive potential scan (between +0.5 V and +1.4 V) causes an oxidation of PB to BB. If the voltammetric scanning started directly from Fe(III/II) to Fe(III/III) for a cyclic electrochemical oxidation of PB, a small loss of the peak current occurred for the cast film in successive scans, while a considerable decay of the peak current was observed for the electrodeposited PB film. It is possible that a cast film can be oxidized to a fully oxidized form with considerable stability, as proposed above. However, a cast film is highly stable if it is pretreated by a reductive cycle from Fe(III/II) to Fe(II/II) before the oxidative scan, as was reported for electrodeposited films.[5]

In an oxidative scan of a pretreated PB film, the CV

curve of a cast PB film is much sharper and simpler than that of an electrodeposited film, as well as in the reductive curve. A symmetrical single redox peak was observed for a cast film in a positive potential scan, while two separate waves were observed for an electrodeposited PB film at electrode potentials higher than +1.0 V in addition to the main redox peak at +0.92 V, as previously reported.[4,5] This indicates that the oxidation of a cast film is also much simpler than that of an electrodeposited film.

These voltammetric differences suggest that electrochromism occur under different reactions in both cast and electrodeposited films. The electric charge used for the oxidation wave is about 70% of that for the reduction wave in an electrodeposited PB film. The ratio was reported to give fairly accurate proof for the formula of the electrodeposited PB, proposing the redox reactions according to the Eqs. 1 and 2:[4,5]

$$Fe^{III}_4[Fe^{II}(CN)_6]_3 + 4K^+ + 4e^- = K_4Fe^{II}_4[Fe^{II}(CN)_6]_3 \quad (1)$$

and

$$Fe^{III}_4[Fe^{II}(CN)_6]_3 + 3X^- - 3e^- = Fe^{III}_4[Fe^{III}(CN)_6]X_3. \quad (2)$$

On the basis of the above considerations, the ratio of the charges for the cast film was measured. The ratio shown in Fig. 3(a) is about 1.05, rather than 0.7 for an electrodeposited film. This result gives the first fairly consistent proof that the formula of cast PB is the "soluble" form, $KFe[Fe(CN)_6]$, which had been proposed due to the result of extractability, as mentioned above. On the basis of the results of coulometry and the EDX (vide infra), the possible electrochemical reactions of the "soluble" PB in the cast film can be proposed as follows:

$$KFe[Fe(CN)_6] + K^+ + e^- = K_2Fe[Fe(CN)_6] \quad (3)$$

and

$$KFe[Fe(CN)_6] - K^+ - e^- = Fe[Fe(CN)_6]. \quad (4)$$

SEM and Analytical Studies. SEM photographs of cast PB–HTAC–$LiClO_4$ films and electrodeposited PB films are shown in Figs. 5 and 6, respectively. Included in these Figures for a comparison are SEM photographs of the electrodes (a) before and (b) after treatment by immersing or voltammetric scanning in aqueous $KClO_4$. No morphological change was observed for the electrodeposited PB film after immersing or voltammetric scanning. On the contrary, the integrity of the cast PB–HTAC–$LiClO_4$ film, which has been kept after immersing in pure H_2O, became breached in places after immersing in aqueous $KClO_4$, and the porous substructure became visible. The typical rough, porous surface was retained and no decomposition of the film was observed during repeated voltammetric scanning. A similar morphological change was also observed for cast PB–HTAC films during the same treatments. These results suggest that though a morphological change is rarely brought

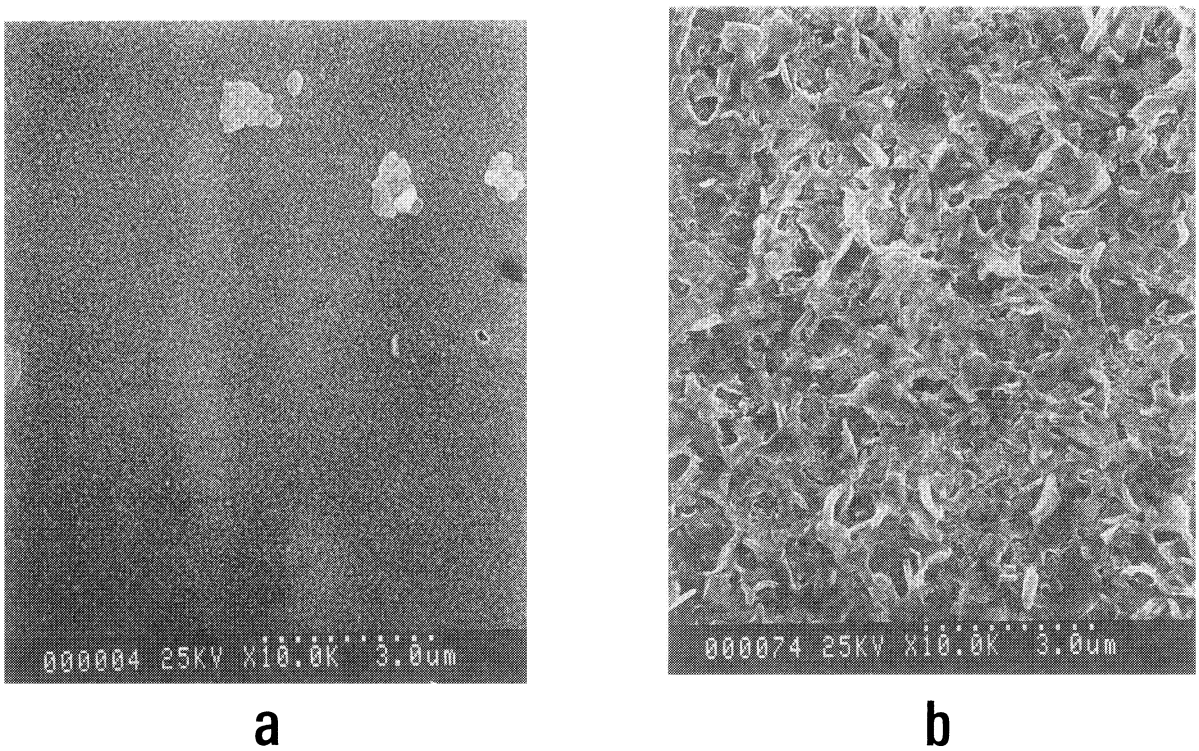

Fig. 5. Scanning electron micrographs of the cast PB–HTAC–$LiClO_4$ film (a) before and (b) after the treatment of immersing or voltammetric scanning in 0.1 mol dm^{-3} $KClO_4$. Mag.$\times 10^4$.

about by an electrochemical reaction, it is probably due to a rearrangement of the surface structures of a film composed of PB and surfactants. In other words an "improvement" of the conductivity of the cast film by the addition of $LiClO_4$ is a probable reason for accelerating the electrochromic and voltammetric response, as mentioned above.

Since the uncertainty in composition of PB has hampered any interpretation of electrochemical studies concerning PB films, studies on the chemical composition are considered to give key knowledge on such films. In particular, the K^+ content of the films should reflect which form (soluble or insoluble) of mixed-valence complex is present. A series of the cast PB–HTAC–$LiClO_4$ films were analyzed by EDX and XPS in order to explore this problem; the EDX results were compared with those of electroposited PB films, as shown in Figs. 7 and 8.

The EDX (and some XPS) measurements reveal the presence of the K^+ ions on the cast PB–HTAC–$LiClO_4$ films, although K^+ is absent on the electrodeposited PB film in the as-deposited state, as previously reported.[18] The EDX data support the idea that a cast PB film comprises the "soluble" form, $KFe[(CN)_6]$, as proposed above.

The changes in the chemical composition of these films with a subsequent treatment were traced by EDX measurements. The K^+ ions appear in the electrodeposited PB film (Fig. 8(b)) as a result of simply immersing an as-deposited film in 0.1 mol dm^{-3} $KClO_4$ (at open circuit), while the K^+ content of the cast PB–HTAC–$LiClO_4$ film (Fig. 7(b)) is kept constant after immersion. On the contrary, the Cl^- content of a cast PB–HTAC–$LiClO_4$ film (Fig. 7(b)) increases in quantity, while the Cl^- peak of an electrodeposited PB film (Fig. 8(b)) scarcely changes after immersion. Since the chlorine atoms in different species can be distinguished by the peak position in XPS, i.e., chlorine atoms in a HTAC surfactant, PB and perchlorate appear at 198, 199, and 208 eV, respectively, the XPS measurements of the cast film clearly indicated the origin of the chlorine atoms. Based on the results of XPS measurements, the incease in the Cl^- content of the cast film by simple immersion in $KClO_4$ can be accounted for by the incorporation of ClO_4^- into the cast film by an exchange with Cl^- in the reverse micelles.

When the iron(III) states are reduced at −0.3 V in a 0.1 mol dm^{-3} $KClO_4$ solution at pH 4.0, the K^+ peak of the cast PB–HTAC–$LiClO_4$ films in the EDX spectra increases, as shown in Fig. 7(c), indicating the incorporation of a large quantity of K^+ ions into the cast films. As for the oxidation of the hexacyanoferrate(II) states of the cast films in which the iron(III) states have been reductively cycled in advance, the oxidation of the hexacyanoferrate(II) sites at +1.0 V in $KClO_4$ drives all of the K^+ ions from the cast film, as shown in Fig. 7(d). This oxidation reaction can be

Fig. 7. Accelerating voltage=10 kV.

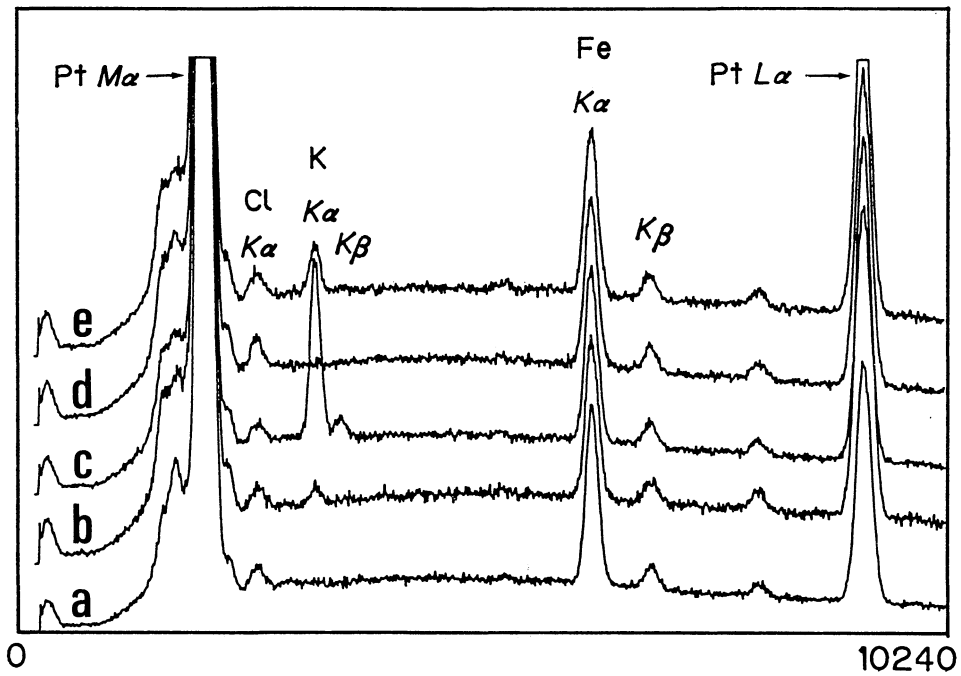

Fig. 8. EDX spectra of the electrodeposited PB films on Pt electrodes: (a) as-grown, (b) immersed in 0.1 mol dm^{-3} $KClO_4$, (c) reduced in 0.1 mol dm^{-3} $KClO_4$ three times, (d) oxidized at 1.0 V in 0.1 mol dm^{-3} $KClO_4$, and (e) oxidized at +1.0 V and then re-reduced to Fe(III/II) in 0.1 mol dm^{-3} $KClO_4$. Accelerating voltage=10 kV.

represented by Eq. 4. Re-reduction back to the Fe (III/II) state reproduces the original K^+ content, as shown in Fig. 7(e). However, the Cl^- content of the cast film is little changed by cyclic electrochemical redox between the Fe(II/II) and Fe(III/III) states.

In a similar investigation concerning an electrodeposited film (Fig. 8(c)—(e)) the contents of both K^+ and Cl^- ions change during the redox cycle in the same manner as for a cast film, as previously reported for 0.5 mol dm^{-3} KCl.[18]

These results have clarified several points concerning the change in the chemical composition of a cast PB–HTAC–$LiClO_4$ film as well as an electrodeposited PB film during the electrochemical reaction: (a) The K^+ content of the as-cast state of a cast PB film is consistent with the "soluble" form of PB, while an electrodeposited PB film does not contain K^+, suggesting an "insoluble" form of PB. (b) The ion exchange between ClO_4^- of the supporting electrolyte and Cl^- of the surfactant probably leads to the micelle swelling and morphological change observed in the SEM micrograph. (c) The fact that ClO_4^- enters into a

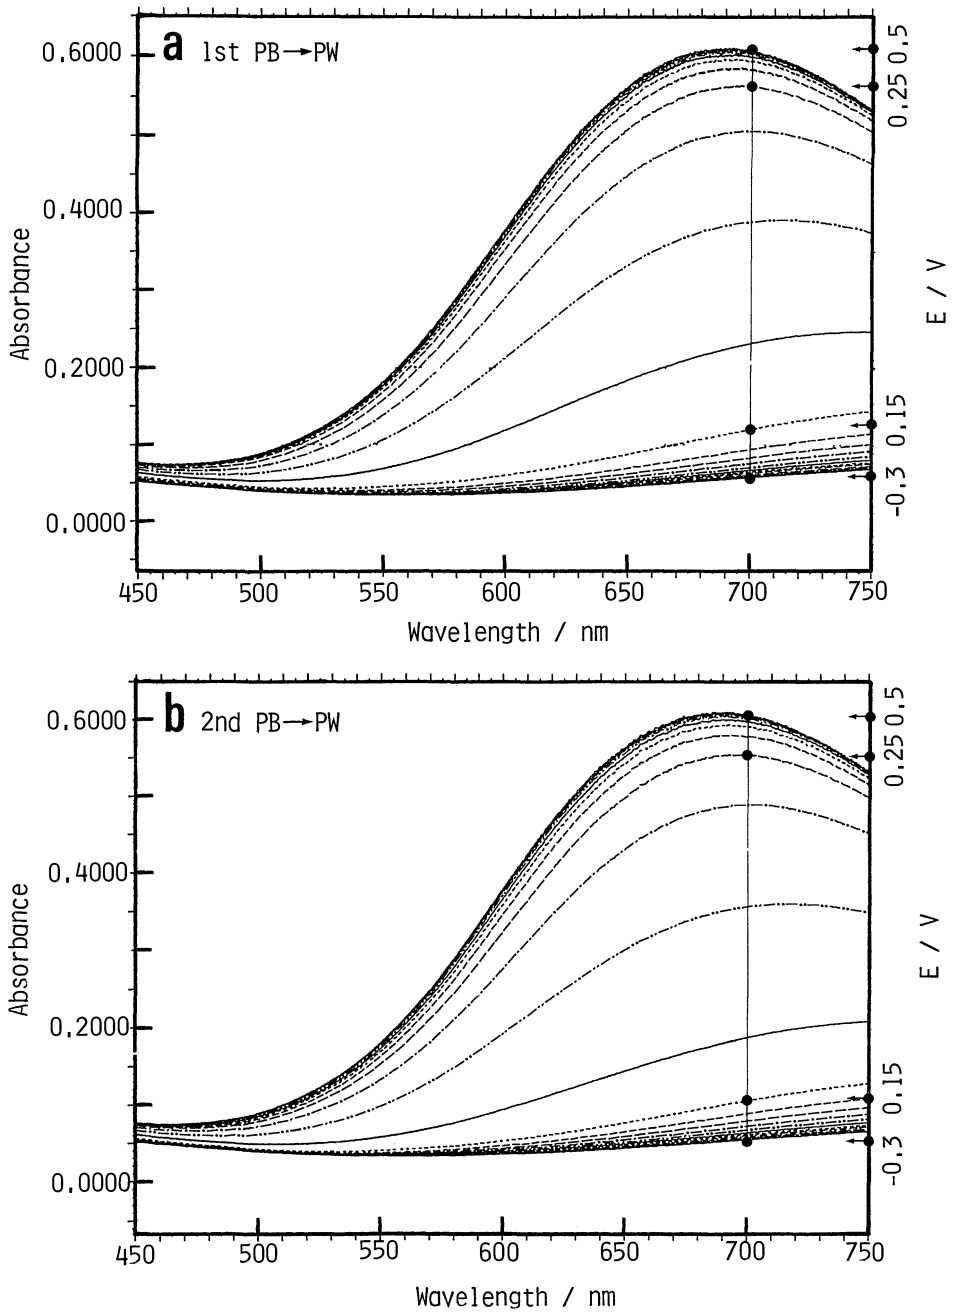

Fig. 9. Visible absorption spectra of the PB–HTAC–$LiClO_4$ film cast on an ITO electrode during the reduction in 0.1 mol dm^{-3} $KClO_4$; (a) the first and (b) the second reduction of PB to PW. Scan speed=2 mV s^{-1}. Spectra were recorded in 25-mV intervals.

reversed micelle upon immersion in a 0.1 mol dm^{-3} $KClO_4$ solution may be accounted for both in terms of a delocalization of the electric charge of ClO_4^-, based on the large molecular size and (probably more importantly) the hydrophobic affinity of the ClO_4^- to the reversed micelle. (d) The absence of a K^+ exchange, observed for a cast PB–HTAC–$LiClO_4$ film during immersion in 0.1 mol dm^{-3} $KClO_4$, may be accounted for by a repulsive force between the strong ionic property of small K^+ ions and a reversed micelle having a hydrophobic environment.

Spectroelectrochemistry. The transient visible spectra of a cast PB–HTAC–$LiClO_4$ film and an electrodeposited PB film on ITO electrodes were taken at closely spaced potential intervals during a negative potential scan from +0.5 to −0.3 V in 0.1 mol dm^{-3} $KClO_4$. The spectra of the cast and electrodeposited films are shown in Figs. 9 and 10, respentively.

Both spectra of the as-cast PB–HTAC–$LiClO_4$ film and the as-deposited PB film are similar to each other, but differ regarding some points. The major difference is in the wavelengths of the maximum absorbance

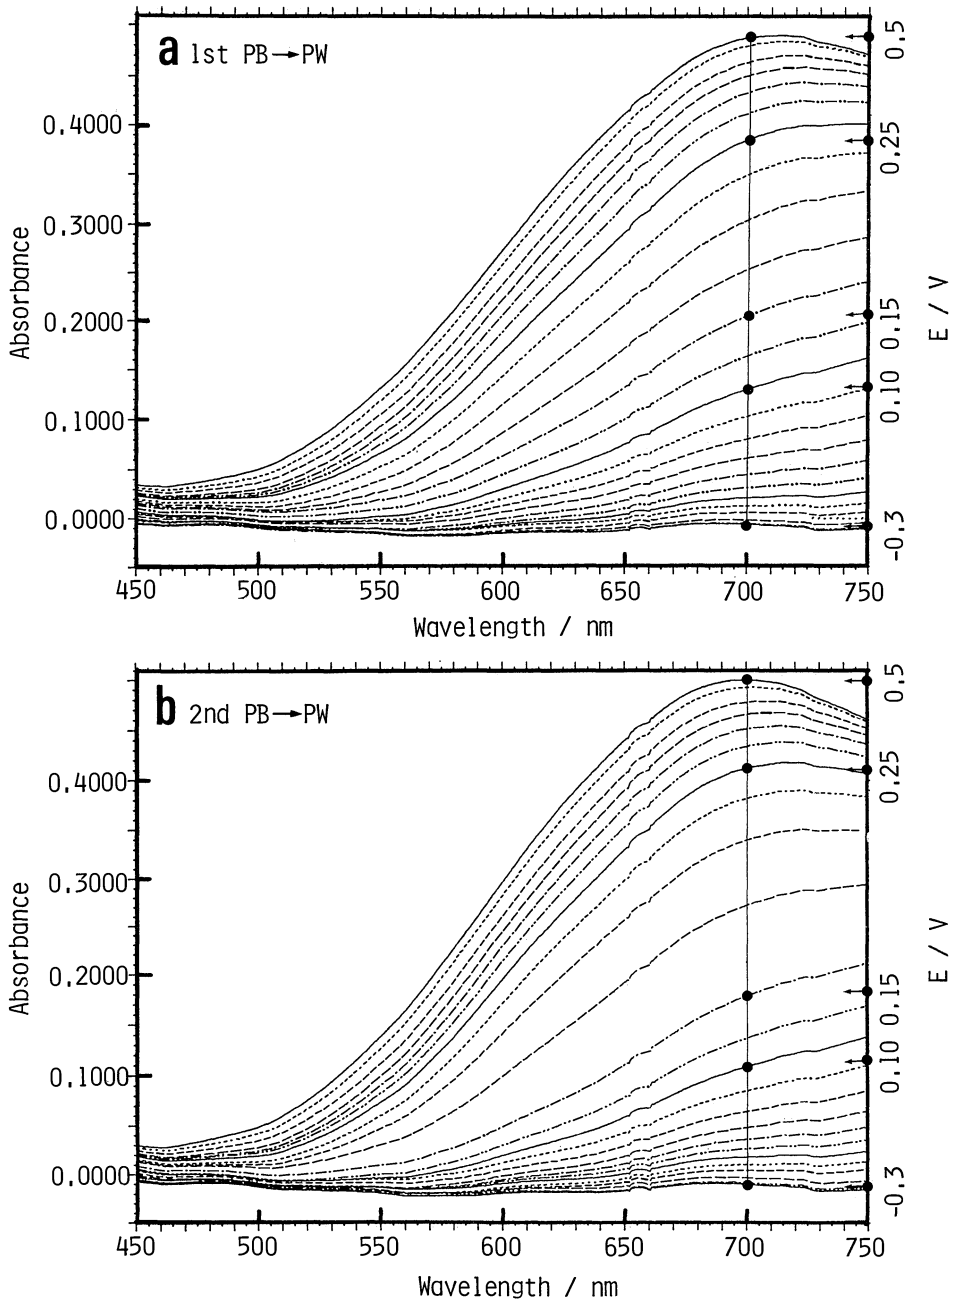

Fig. 10. Visible absorption spectra of the electrodeposited PB film on an ITO electrode during the reduction in 0.1 mol dm^{-3} $KClO_4$; (a) the first and (b) the second reduction of PB to PW. Scan speed= 2 mV s^{-1}. Spectra were recorded in 25-mV intervals.

(λ_{max}), which are in the 690 and 715 nm regions for the cast and electrodeposited films, respectively. The λ_{max} of the cast PB–HTAC–$LiClO_4$ film remained unchanged after voltammetric scanning (compare the first (a) and second (b) scans in Fig. 9). On the contrary, the λ_{max} of the electrodeposited film shifts from about 715 nm to a lower wavelength of about 695 nm after initial reduction cycle (compare (a) and (b) in Fig. 10). This is consistent with the spectroelectrochemical data of Mortimer and Rosseinsky[19] who showed a shift in the spectra of an electrodeposited PB film after the first reduction cycle. The spectral shift was proposed to be due to a partial conversion of an "insoluble" PB into a "soluble" PB. The absence of a λ_{max} shift for the cast PB film directly supports the idea that cast films comprise only "soluble" PB, as mentioned above.

Figures 11 and 12 show how the 600, 645, 701, and 745 nm absorbances change with a reductive applied potential in a $KClO_4$ electrolyte for a cast PB–HTAC–$LiClO_4$ film and an electrodeposited PB film, respectively. The absorbances are normalized to the highest initial value for ease of comparison. In the case of a cast film, the absorbance–potential response (Fig. 11) is the same at each wavelength and remains unchanged during subsequent scans in a $KClO_4$ electrolyte (compare (a) and (b) in Fig. 11). Each absorbance change is very sharp and centered at +0.18 V, agreeing with the sharp central peak in the voltammogram in a $KClO_4$ electrolyte (Fig. 4a). In the case of an electrodeposited film, the initial absorbance–potential response (Fig. 12a) is different at each wavelength centered at between +0.4 and −0.1 V, agreeing with the broad peak in the initial voltammogram shown in Fig. 4b. Upon a subsequent scan (Fig. 12b), the absorbance change at each wavelength was slightly sharper than the first scan and centered at +0.17 V, but still tailed between +0.1 V and −0.1 V. This feature is clearly associated with the +0.17 V sharp central peak and the 0.0 V shoulder in the voltammetry in $KClO_4$ shown in Fig. 4b, the 2nd scan.

The results of Figs. 11 and 12 are consistent with the voltammetric and compositional results mentioned above, i.e., cast films maintain a soluble form structure, even after a reduction cycle. On the contrary, in electrodeposited films, some parts of the PBs in the insoluble form probably change to a soluble form structure after the reduction cycle; other parts, however, retain their insoluble form. The consistency of the absorbance–potential response with the voltammetric result suggests that a cast PB–HTAC–$LiClO_4$ film contains single species in which a unique electrochemical iron(III) site participates in the cyclic electrochemical reduction. In contrast, plural species are suggested in an electrodeposited PB film as a

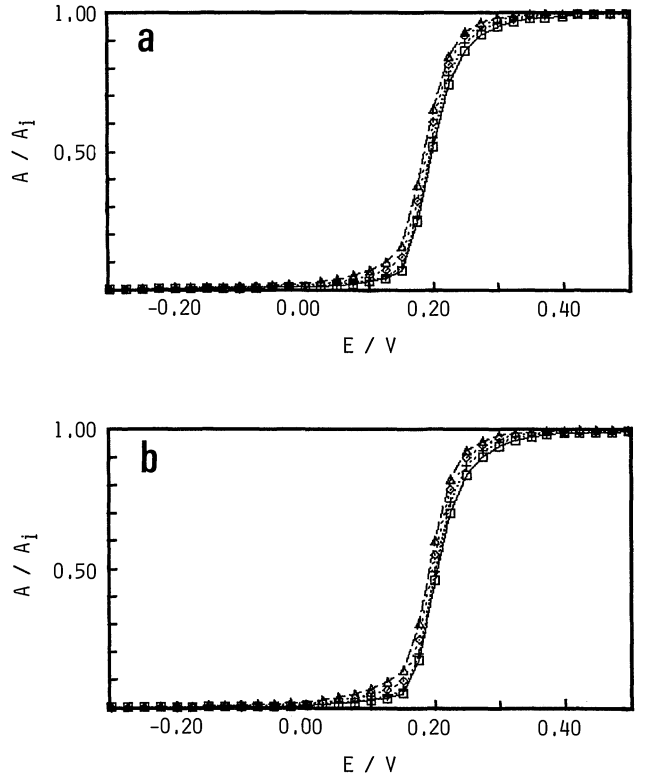

Fig. 11. Normalized absorption vs. potential curves of the cast PB–HTAC–$LiClO_4$ film in 0.1 mol dm^{-3} $KClO_4$ at (□) 600, (+) 645, (◇) 701, and (△) 745 nm: (a) The first and (b) the second reduction.

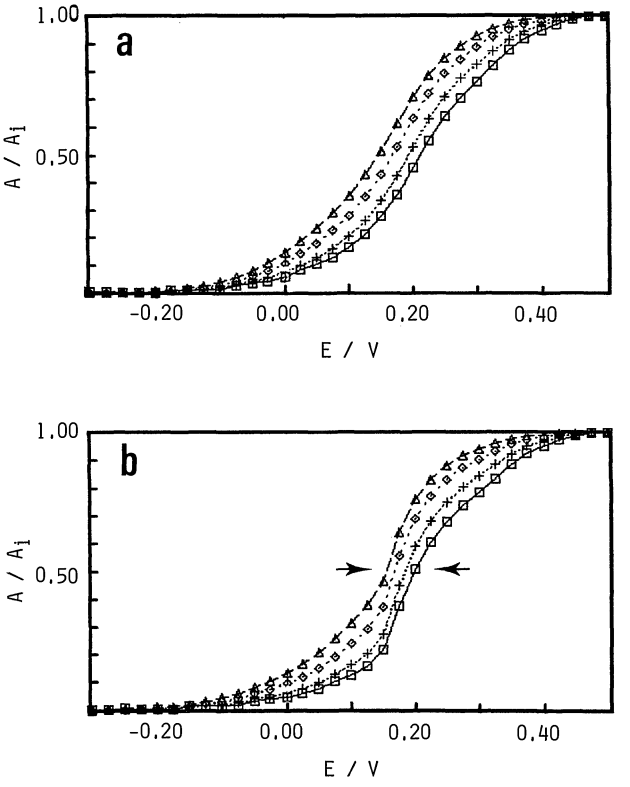

Fig. 12. Normalized absorption vs. potential curves of the electrodeposited PB film in 0.1 mol dm^{-3} $KClO_4$ at (□) 600, (+) 645, (◇) 701, and (△) 745 nm: (a) The first and (b) the second reduction.

mixture of nonequivalent electrochemical iron(III) sites. This somewhat complicated behavior appears to be attractive, but difficult to explain.

The spectral changes for the oxidation of cast PB–HTAC–$LiClO_4$ and the electrodeposited PB films in $KClO_4$ are illustrated in Figs. 13 and 14, respectively. The absorbance–potential response for the oxidation are plotted at 600, 645, 701, and 745 nm in Figs. 15 and 16 in a similar way to that in Figs. 11 and 12 for the reduction. The difference in patterns between Figs. 15 and 16 for the oxidation is less distinct than that between Figs. 11 and 12 for the reduction. Nevertheless, the absorbance response of the cast PB–HTAC–$LiClO_4$ film in Fig. 15 is quick and singly centered at about

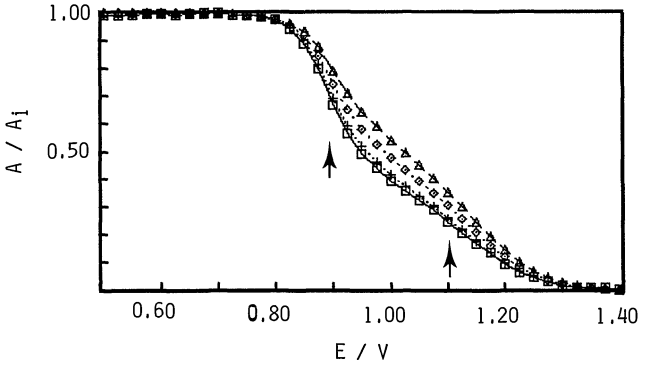

Fig. 16. Normalized absorption vs. potential curves of the electrodeposited PB film in 0.1 mol dm^{-3} $KClO_4$ at (□) 600, (+) 645, (◇) 701, and (△) 745 nm for oxidation.

+0.89 V, while the electrodeposited PB film in Fig. 16 shows an additional change centered at about +1.1 V in addition to the main change at about +0.89 V.

On the other hand, the spectrum of the fully oxidized form of the cast film at +1.4 V was different from that of the electrodeposited film. The spectral change with the application of a potential in the cast film (Fig. 13) is also faster than in the electrodeposited film (Fig. 14). The extent of the oxidation between +0.5 and +1.0 V is about 80% of the full oxidation for the cast film, while the electrodeposited film is oxidized by about 50%. Although a reasonable explanation for the oxidation has not been yet offered, the inset of Fig. 13, as well as the inset of Fig. 14, indicates that spectral changes with the application of the oxidative potential give two isosbestic points, as previously reported,[18,20] and that the transition from one isosbestic point to the other occurs at +0.89 V of the applied potential. The spectral changes giving the two isosbestic points are common to both the cast (Fig. 13) and electrodeposited (Fig. 14) films, and the applied potential giving the two isosbestic points (+0.89 V) is consistent with the main oxidation peaks from PB to BB in the cyclic voltammograms (Fig. 3) of both the cast and electrodeposited films. Although the reason for two isosbestic points is not clear yet, the common spectral change suggests that the change arises from the oxidation of a soluble form of PB both in the cast and the electrodeposited films. The oxidation shoulder wave of the electrodeposited film at +1.1 V observed in Fig. 3b may be attributed to the peculiar oxidation of the insoluble form of PB in the electrodeposited film. Though this specific change in oxidative voltammetry can not be readily resolved, some unknown species (nonequivalent complicated iron sites) probably exist only in the electrodeposited PB film. It is so hard for the species to be oxidized that the potential required for full oxidation is more positive than that for the simple species in the cast PB-HTAC-$LiClO_4$ film.

Conclusion

For the practical usage of the PB films, a simplified method of preparing a uniform film with large area and long-term stability is required. The casting of a colloidal PB dispersion in an organic solution provides an effective answer to this request.

According to the present experiments concerning the extraction of colloid PB dispersion, only cationic surfactants can extract PB colloids from an aqueous solution. PB composite films can be prepared onto ITO and Pt electrodes with a novel, simplified casting method by using an extracted PB solution. Particularly, when the ratio of $Fe^{II}/(Fe^{II}+Fe^{III})$ is larger than 0.5, the extraction of PB is considerably effective. This extraction result suggests that only the "soluble" form of PB can be extracted by an organic solution containing cationic surfactants.

The electrochemical behavior of cast films was compared with those of electrodeposited films. Some new facts found in the present investigation are listed:

1) The electrochromism of a cast film was observed to be similar to that of an electrodeposited PB film in a $KClO_4$ solution. The electrochromic response was improved by the addition of $LiClO_4$ to the cast film.

2) Cyclic voltammograms of a cast PB-HTAC-$LiClO_4$ film measured in a $KClO_4$ solution was simpler and more symmetrical than that of an electrodeposited PB film.

3) EDX (and some XPS) measurements show that as-cast films contain K^+ ions, which suggests a "soluble" form of PB, while electrodeposited films do not contain K^+ ions, which suggests an "insoluble" form of PB.

4) The λ_{max} of a cast film remains unchanged, even after successive scans, while that of an electrodeposited film shifts to lower wavelength after the first reduction cycle.

Although some points are not readily resolved in oxidative voltammetry, the present method provides a promising prospect for preparing a simple, stable, and

useful PB cast film.

The authors wish to express their sincere thanks to Dr. Masao Kaneko in Riken for his helpful discussion, as well as Dr. Masanori Owari at Institute of Industrial Science, The University of Tokyo (EDX) and Dr. Mitsuhiro Adachi at Engineering Research Institute, The University of Tokyo (SEM) for their technical assistance. This work was supported by the Grant-in Aid for Scientific Research on Priority Area of "Macromolecular Complexes" Nos. 62612002, 63612003, and 01612002 from the Ministry of Education, Science and Culture.

(Received May 31, 1990)

The crystal and the molecular structures of the title complex were determined by means of the single-crystal X-ray diffraction method. The crystal of $PtC_{28}H_{23}O_5N_2Cl_4$, F. W. 804.40, (black-violet in color) is monoclinic, with the space group of $P2_1/a$, a=18.293(4), b=9.682(2), c=15.797(3) Å, β=96.55(2)°, U=2779.6(9) Å^3, Z=4, D_m=1.90, D_x=1.92 g cm^{-3}, and μ (Mo $K\alpha$)=57.37 cm^{-1}. The platinum atom is in a hexa-coordinated octahedral geometry, where one 2-(2-benzoxazolyl)phenolate (bxp^-) ion is chelated with its N and phenolato O atoms. The bxp^- ligand as well as the free Hbxp molecule are both approximately planar, and their planes are approximately in parallel: They are arranged alternately and are laid roughly along the a-axis. Although the overlappling areas of the neighboring rings are only 23 and 13% respectively of the whole ring area, the interplane distances are 3.42 and 3.49 Å.

The 2-(2-benzoxazolyl)phenol (Hbxp) is known to make chelates with many kinds of metal ions, where the ligand acts as the uninegative ion, bxp^-. Among these, the structures of its copper(II),[1] cadmium(II),[1] and iron(III),[2] chelates have already been elucidated. In these complexes, the benzoxazolyl (bxz) and the phenolate (pho) rings of the chelating ligand are approximately on the same plane. In the iron(III) complex, the bxp^- rings of the neighboring complexes are approximately in parallel and they are partly overlapped with each other, so some π–π interaction between them is expected.[2] On the other hand, the platinum(II) cmplex, $[PtCl_2(Hbxp)_2]\cdot C_2H_5OH$ (**2**), on which the present authors recently reported, has unidentate non-charged Hbxp ligands, and the bxz and Hpho planes of each ligand are not in parallel.[3,4] During the process of synthesizing this platinum(II) complex, it was found unexpectedly that the title complex crystals, black-violet in color, were deposited together with the yellow platinum(II) crystals from the mother liquor, and in some cases they also precipitated from the filtrate of the main product. Although efforts to synthesize this complex separately have not yet been successful, its crystals have a characteristic color and shape different from the yellow platinum(II) complex **2**, so they can easily be separated by hand. Its crystal and molecular structures have been determined by the single crystal X-ray diffraction method.

Experimental

Growth of the Crystals of the Title Complex. The mother liquor used to obtain the title complex, [2-(2-benzoxazolyl)phenolatotetrachloroplatinum]·[2-(2-benzoxazolyl)phenol]·ethanol (**1**), has the same composition as that used to synthesize the Pt(II) complex **2**:[3,4] A solution of platinum(IV) chloride pentahydrate (1 g, 2 mmol in 15 cm^3 of ethanol) was mixed with a solution of Hbxp (1.5 g, 7 mmol in 300 cm^3 of ethanol), and the mixture was stirred, and left standing at room temperature for one month or longer. By this procedure, the yellow platinum(II) complex **2** crystals[3,4] can be reliably obtained, but the black-violet crystals of the title complex have appeared only in a few cases, always coprecipitated as a minor component with **2**. All attempts to precipitate only the black-violet crystals including addtion of some oxydizing agents, or changing the composition of the mother liquor, have ended in failure so far. In the best results to date, the amount of the obtained title complex, which appeared as the minor component of the bivalent complex, is approximately 0.02 g (1.1%) from the starting materials of the above mentioned quantities. Found: C, 40.87; H, 2.76; N, 3.39%. Calcd for $PtC_{28}H_{23}O_5N_2Cl_4$: C, 41.79; H, 2.88; N, 3.48 %.

X-Ray Crystal Structure Analysis. The black-violet crystal used for the structure determination was shaped into a sphere (ϕ=0.31 mm). The intensities of the range of $3<2\theta<55°$ (2θ) were collected on a Rigaku AFC-6A automated four-circle X-ray differactiometer using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å), by means of ω–2θ scan technique (scan speed, 4° min^{-1} (ω), scan width, 1.14+0.35 tan θ (ω/°)). The intensities were corrected for Lorentz and polarization factors, as well as for absorption. Of 6817 indenpendent intensities collected, 4217 with $|F_o|>3\sigma(|F_o|)$ were used for the structure calculation.

All the calculations were carried out on a HITAC M-682H computer at the Computer Centre of the University of Tokyo using a local version of UNICS program.[5] The scattering factors were taken from Ref. 6.

The structure was solved by the heavy-atom method. The positional and thermal parameters were refined by a block-diagonal least-squares method. At the final stage, all the non-hydrogen atoms were found and were refined anisotropically. All the hydrogen atoms were excluded from the

structure calculations. The final R and R_w values obtained were reduced to 0.057 and 0.064, respectively.[7]

The proton nmr spectra were recorded using JEOL JNM-GX270 FT NMR Spectrometer.

Results and Discussion

The selected bond lengths and bond angles are tabulated in Table 1, the perspective view of the complex together with the numbering scheme of the atoms is shown in Fig. 1, the projection of the unit cell along b-axis in Fig. 2, and the projection of the atoms of the bxp$^-$ ring on both sides to a mean square plane of one Hbxp ring in Fig. 3.[8]

As shown in Fig. 1, the central platinum atom is in a 4Cl, N, O-hexa-coordinated octahedral geometry, where the bxp$^-$ ligand acts as a bidentate ligand forming a

I II

Fig. 1. Perspective drawing of the complex with the numbering scheme of the atoms.

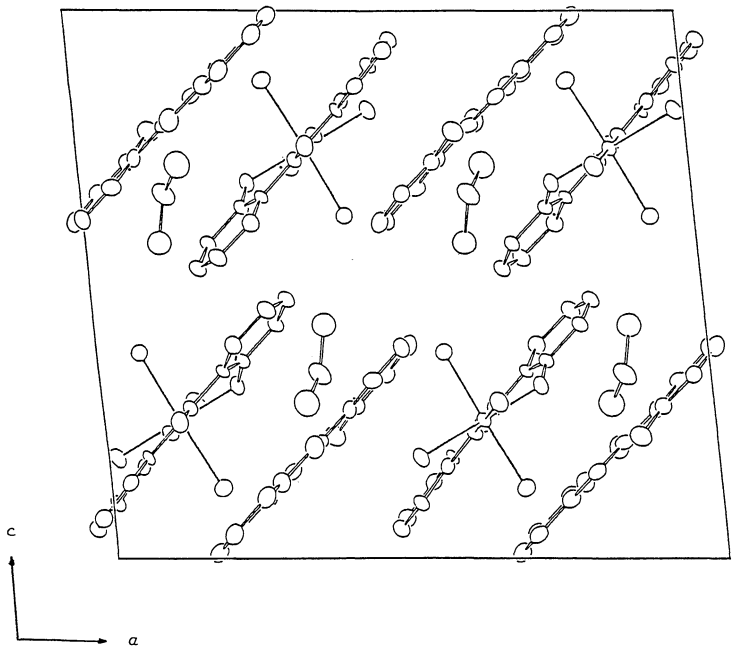

Fig. 2. A projection of the unit cell along c-axis. (i, 0.5+x, 1.5−y, z).

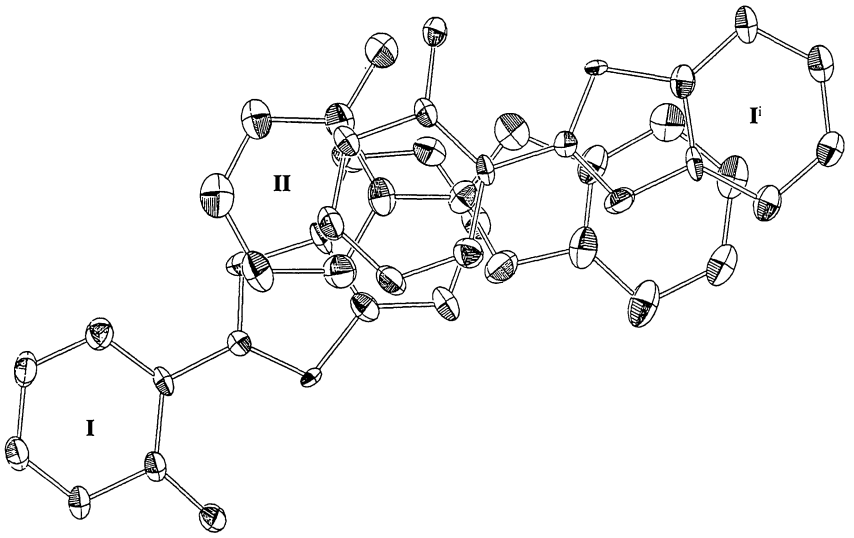

Fig. 3. A projection of the chelated ligand rings on the mean square plane of the non-coordinated Hbxp ring. (i, 0.5+x, 1.5−y, z).

five-membered ring chelate. The coordination geometry is not much deformed from the typical octahedron. As shown in Table 1, the average Pt–Cl, and Pt–N(1), and Pt–O(2) bond lengths are, 2.311 on the average (2.301(3)—2.331(6)), 2.008(7), and 2.005(9) Å, respectively.

The oxidation state of the central platinum seems to be somewhat peculiar, because the 2-(2-benzoxazolyl)-phenol ligand acts as a uninegative bxp$^-$ ion in these complexes. Considering the stoichiometry as well as the characteristically intense color of the crystals, the oxidation number of the central platinum can be expected to be +5. As the bond lengths are usually affected by the valence and coordination number of the bonding atoms, the bond lengths around the platinum atom were compared with the sum of the Shannon's ionic radii.[9] In the hexa-coordinated octahedral complexes, Pt–Cl, Pt–N, and Pt–O bond lengths estimated from the Shannon's ionic radii show clearly different values for Pt(V) and Pt(IV). For Pt(V) complexes, Pt–Cl, Pt–N, and Pt–O bond lengths are: 2.435, 2.085, and 1.975 Å, and for Pt(IV) complexes,

2.38, 2.03, and 1.92 Å respectively. However, the observed bond lengths of Pt–Cl and Pt–N for our complex **1** were much shorter than those of these Pt(V) and Pt(IV) complexes, and Pt–O bond length was a little longer than the Shannon's values. Therefore, it cannot be decided whether the valence of the platinum ion in **1** is +5 or +4 from X-ray analysis. The relatively large covalent character of the Pt–Cl bond of **1** may decrease the bond length, and the steric effect of the large bxp$^-$ ligand may also affect the bond lengths of Pt–N and Pt–O.

Although there is a possibility that the chelating ligand is a non-changed Hbxp and that the central metal platinum ion has the oxidation number of +4, such type chelate ring of the bxp ligand has not yet been found in any metal complexes.

The benzoxazolyl (bxz) ring and the phenol (Hpho) or phenolato (pho) ring of a bxp$^-$ as well as of Hbxp in **1** are approximately planar: The average of the deviation of all the atomic positions from their respective ring planes (mean square planes of the bxz or the pho ring atoms) is only 0.016 Å (0.0018—0.0503 Å). The dihedral angles between the mean square planes of the whole ring atoms and the respective mean square planes of the bxz and pho or Hpho ring atoms are bxp$^-$=12.3°, and Hbxp=3.2°. This is much different from what was found in **2**, where the Hbxp act as unidentate ligands where the dihedral angle between the two ring planes in each ligand is much larger.[3,4] The dihedral angle between the mean square plane of the Hbxp(II) ring atoms and the bxp$^-$ ring atoms neighboring on both sides of the former plane (I, and I^i; i, 0.5+x, 1.5−y, z) are 3.7° and 4.5° respectively. As a result, in the crystal of **1**, bxp$^-$ and Hbxp rings are arranged approximately in parallel and are laid alternately along a-axis. The interplanar distances between the neighboring bxp$^-$

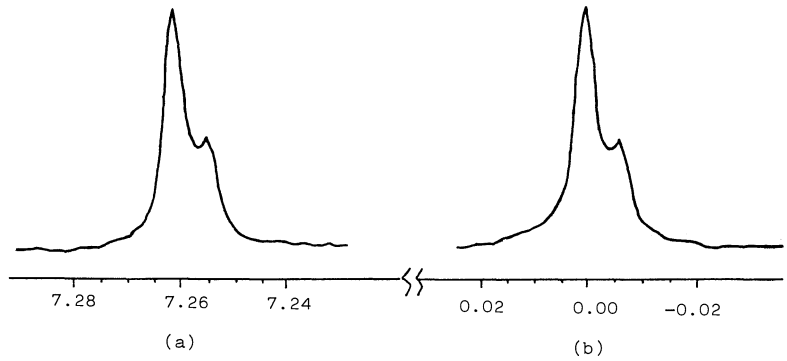

Fig. 4. 270 MHz proton NMR spectra of TMS-containing deuteriochloroform with centrally placed black-violet platinum complex (2.0 mg inserted in coaxially placed capillary of 1.0 mm outer diameter) in the ordinary 5 mm sample tube. (a) $CHCl_3$ (impurity in $CDCl_3$) (b) TMS. Paramagnetically shifted signals are clearly shown in both species.

(I) plane and a Hbxp (II) plane (calculated by the average distance between the bxp^- ring atom positions and the mean square plane of the Hbxp) is 3.42 Å, while that of the Hbxp (II) and the other neighboring bxp^- (I^i) ring is 3.49 Å. The overlapping of the rings II and I or I^i are calculated from the overlapping areas between the rings of II and the projection of the ring I or I^i on it as show in Fig. 3: They were 23% (I–II) and 13% (II–I^i) respectively. Consequently, the π-electron clouds of the neighboring bxp^- and Hbxp rings are thought to be interacting by overlapping each other.

If the platinum ion has an oxidation number of +5, it must have unpaired electrons and should show clear paramagnetism due to these unpaired electrons.[10] Unfortunately the small quantity of the obtained sample prevented us from measuring the magnetic susceptibility by ordinary methods such as Gouy balances. Moreover, this complex is not readily soluble in appropriate solvents, or decomposes gradually by the reaction with solvents.

An attempt to detect paramagnetism with the highly sensitive customary NMR technique,[11–13] was carried out with slight modification.[14] A capillary containing about 2 mg of the sample was coaxially placed in an NMR tube filled with deuterio-chloroform with TMS as a standard of chemical shift. The two proton signals due to $CHCl_3$ (impurity in $CDCl_3$) and TMS were recorded by the usual procedure. The two chemical shift values of the main peak (bulk liquid) remained unchanged, and the smaller components of both signals showed a clear upfield shift (Fig. 4) which showed that the closely neighboring nuclei surrounding the capillary tube are affected by the paramagnetism.

As this signal splitting was observed only when the sample in the capillary is paramagnetic,[14] it may be safely concluded that the present complex is paramagnetic.

These rather queer characteristics of complex **1** suggest that there is some possibility of the existence of apparently pentavalent platinum in this complex.

Although more detailed studies would be needed to elucidate this peculiar oxidation state, it seems quite interesting to compare our complex with the other already-known Pt(V) complexes. Some Pt(V) complexes, mainly its fluoro complexes, have been already reported: For example, $XePt(V)F_6$,[15] and $(O_2)Pt(V)F_6$.[16] However, these compounds are not stable and are easily reduced. On the other hand, the obtained complex is stable in open air.

Probably the electrons of the complex are diffused, not only in the ligated bxp^- ligand, but also all throughout the lined up complexes and Hbxp molecules via overlapping π-electron clouds. This delocalization of the electrons may be the cause of the extraordinary apparent valence of the metal ion in this complex.

Local Structure, T_g, and IR Transparency of Potassium Titanate Glasses and the Local Structure of Calcium Titanate Ceramics

Tetsuaki NISHIDA,* Yasuharu YAMAGUCHI, Miho YAMADA, and Yoshimasa TAKASHIMA
Department of Chemistry, Faculty of Science, Kyushu University,
Hakozaki, Higashiku, Fukuoka 812
(Received June 16, 1990)

The Mössbauer spectrum of xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses (x=35—60), consisting of a paramagnetic doublet peak due to tetrahedral Fe^{3+}, suggests that the Fe^{3+} is substituted for the tetrahedral Ti^{4+}. The isomer shift (δ=0.20—0.23 mm s^{-1}) and the quadrupole splitting (Δ=0.72—0.81 mm s^{-1}) decrease linearly with the increasing K$_2$O content. The glass transition temperature (T_g) decreases similarly as the Δ does, supporting the "T_g–Δ rule" discovered by Nishida et al., i.e., the T_g of oxide glasses is expressed by $T_g=a\Delta+b$. (The slope "a" is 680 °C mm^{-1} s.) The IR absorption spectra show two peaks at 880 and 640 cm^{-1} corresponding to the Ti(Fe)O$_4$ and TiO$_6$ units, respectively. The relative absorption intensity of the Ti(Fe)O$_4$ units becomes higher when the K$_2$O content increases. The potassium titanate glasses (plate) show IR transparency, having the transmission edge of 5.4 μm. The Mössbauer spectrum of xCaO·(95−x)TiO$_2$·5Fe$_2$O$_3$ ceramics (x=5—50) consists of two doublet peaks due to Fe^{3+} and Fe^{2+}. Both the δ and Δ of the Fe^{3+} are constant irrespective of the CaO content, whereas the fraction (relative absorption area) of the Fe^{3+} decreases linearly from 94 to 75% when the CaO content is increased from 5 to 50 mol%.

It is known that TiO$_2$-based (titanate) crystals such as BaTiO$_3$ and CaTiO$_3$ are excellent dielectric compounds. Titanate glasses are also known to have high dielectric constants and low thermal expansion coefficients. Structural study of the titanate glasses carried out by some groups revealed that Ti^{4+} ions are four- and six-fold coordinated with oxygen atoms.[1–3] In the IR and PAS (photoacoustic spectroscopy) study, Yoshimaru et al.[1] elucidated that the coordination number of Ti^{4+} depends on the basicity of the glass. Greegor et al.[4] reported that the coordination number of Ti^{4+} was four in the TiO$_2$–SiO$_2$ glass system, in which the TiO$_2$ content was several mol%.

The Mössbauer spectroscopy is useful for the structural study of oxide glasses, because the Mössbauer ions (e. g. Fe^{3+}) are easily substituted for the network forming ions (NWF) such as Al^{3+}, Ga^{3+}, Te^{4+}, and V^{5+}.[5–12] The present Mössbauer study was carried out in order to elucidate the coordination number of Fe^{3+} and Ti^{4+} in the K$_2$O–TiO$_2$ glasses and that in the CaO–TiO$_2$ ceramics. Five mol% of Fe$_2$O$_3$ is incorporated in these samples for the Mössbauer measurement. IR absorption measurement was carried out in order to elucidate the coordination number of Ti^{4+} and Fe^{3+} and also to confirm whether the Fe^{3+} is substituted for the Ti^{4+}, as was done for the Al^{3+} in the study of calcium aluminate glass.[6] The IR transparency of the K$_2$O–Ti(Fe)O$_2$ glasses was found by measuring the IR spectrum of a piece of block (plate) sample. The other aim of this study is to confirm whether the "T_g–Δ rule", discovered by Nishida et al.[5] for several oxide glasses, holds for the titanate glasses.

Experimental

Potassium titanate glasses denoted by xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ were prepared by melting individual mixtures (1 g) of commercially available K$_2$CO$_3$, TiO$_2$, and Fe$_2$O$_3$ of guaranteed reagent grade. Each mixture in a platinum crucible was melted at 1400 °C for 2 h by use of an electric muffle furnace. After the fusion in air, each melt was quenched by quickly immersing the bottom of the platinum crucible into ice-cold water. As the result, brown glass samples could be obtained when the x was 35—60. Calcium titanate ceramics denoted by xCaO·(95−x)TiO$_2$·5Fe$_2$O$_3$ were prepared by fusing individual mixtures (1 g) composed of CaCO$_3$, TiO$_2$, and Fe$_2$O$_3$ at 1400 °C for 30 min. After the fusion, the melt was gradually cooled down to 150 °C. As the result, ceramic samples of reddish brown to gray color were obtained, depending on the CaO content. In the xCaO·(95−x)TiO$_2$·5Fe$_2$O$_3$ system, no glass sample was prepared by the quenching procedure described above.

Mössbauer measurement was made on pulverized samples at room temperature by a constant acceleration method. Ten mCi (3.7×10^8 Bq) of cobalt-57 diffused into a palladium foil was used as the Mössbauer source. As the reference of the isomer shift (δ), a piece of metallic iron foil was used. The iron was also used for calibrating the velocity scale of the spectrometer. Each Mössbauer spectrum of the xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses was analyzed into a doublet peak having an equal linewidth by a least-squares method. In the case of xCaO·(95−x)TiO$_2$·5Fe$_2$O$_3$ ceramic system, the Mössbauer spectrum was analyzed into two doublet peaks. DTA was conducted at the heating rate of 5 °C min^{-1}, ranging from room temperature to 900 °C. Alpha-Al$_2$O$_3$ powder was used as the standard in the DTA measurements. IR absorption measurement was performed by the conventional KBr disk method, whereas the IR transmission measurement was made on the untreated xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses by use of a small block (plate) sample.

Results and Discussion

Potassium Titanate Glasses. The Mössbauer spectrum of potassium titanate glasses consists of a paramagnetic quadrupole doublet, as is illustrated in Fig. 1a. The quadrupole doublet indicates the presence of paramagnetic Fe^{3+} ions homogeneously

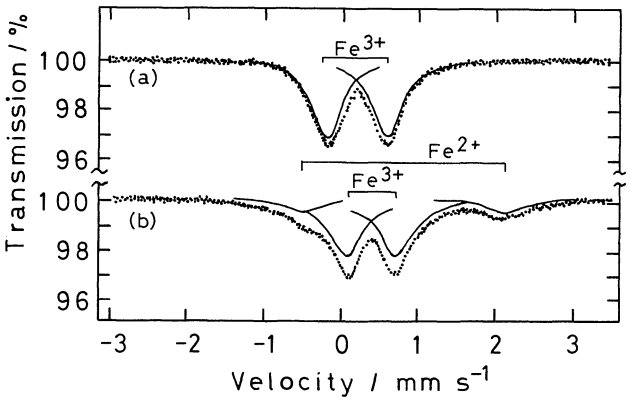

Fig. 1. The Mössbauer spectra of (a) $45K_2O \cdot 50TiO_2 \cdot 5Fe_2O_3$ glass and (b) $45CaO \cdot 50TiO_2 \cdot 5Fe_2O_3$ ceramic, measured at room temperature.

distributed in the glass matrix; no magnetic species due to iron or iron oxide is observed. The isomer shift (δ), ranging from 0.20 to 0.23 mm s^{-1}, indicates the presence of tetrahedrally coordinated Fe^{3+} ions with oxygen atoms, as was observed for several oxide glasses.[5-10] The experimental error of the δ is estimated to be ± 0.01 mm s^{-1}. The relatively small δ values reflect that the Fe^{3+}–O bond is fairly covalent. The compositional dependence of the δ is illustrated in Fig. 2, which shows a slight decrease when the K_2O content is increased from 35 to 60 mol%. A similar phenomenon has recently been observed in the Mössbauer studies of aluminate,[5] gallate,[5,7] and vanadate[8-10] glasses; the formation of nonbridging oxygen (NBO) causes the decrease of δ, corresponding to the increase of 4s-electron density at the nuclear site of iron, because the bond length of the Fe^{3+}–NBO bond is smaller than that of the Fe^{3+}–BO (bridging oxygen) bond. The coordination number of network former (NWF), i.e. Ti^{4+} in this study, can easily be known from the IR spectra.[13] Tarte reported that tetrahedrally and octahedrally coordinated Ti^{4+} have the IR absorption bands at 690—800 cm^{-1} and 500—650 cm^{-1}, respectively. The IR absorption spectra of the $xK_2O \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ glasses studied in this paper are shown in Fig. 3, together with the IR spectrum of α-Fe_2O_3 (Fig. 3g) used for the sample preparation. According to Tarte,[13] the absorption peaks observed at 880 and 640 cm^{-1} in Figs. 3a—f are ascribed to the tetrahedral and octahedral Ti^{4+}, respectively. Figures 3a—f shows a systematic change, i.e., the relative absorption intensity A_{tet}/A_{oct} increases with the increasing K_2O content. (The subscript "tet" and "oct" refer to the tetrahedral and octahedral Ti^{4+}, respectively.) Figure 3 indicates that the $xK_2O \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ glasses are composed of only the TiO_4 tetrahedra and the TiO_6 octahedra, and that no absorption peak due to Fe–O bond is observed. It is seen from Fig. 3 that the fraction of TiO_4 tetrahedra is increased at the expense of TiO_6 octahedra when the K_2O content is increased, as was observed in the case of iron-free titanate glasses.[1] These results suggest that the structural change occurring at the Fe^{3+} site is essentially the same as that occurring at the tetrahedral Ti^{4+} site, and that small amount (5 mol%) of Fe_2O_3 itself brings about no specific structural change in the

K_2O–TiO_2 glasses. (We can obtain the structural information on the tetrahedral Ti^{4+} from the Mössbauer measurements.)

It is the characteristic feature of Figs. 3a—f that the Fe–O stretching vibration is not observed, whereas it was originally observed at 542 cm^{-1} in the IR spectrum of α-Fe_2O_3 (Fig. 3g). The absence of the Fe–O vibration suggests that no aggregate or precipitate of iron (Fe^{3+}) oxide is present in the $xK_2O\cdot(95-x)TiO_2\cdot 5Fe_2O_3$ glasses, and that the Fe^{3+} is vibrating at the substitutional site of the Ti^{4+}. In other words, the Fe^{3+} in the potassium titanate glasses seems to behave as if it were Ti^{4+} from the lattice vibrational point of view. It is noted that the Ti^{4+}/Fe^{3+} ratio is large, being in the range of 7—12 when the K_2O content is 35—60 mol%. The atomic substitution of Fe^{3+} for the NWF has also been confirmed in the case of Al^{3+}, which constitutes the network structure of calcium aluminate glass,[6] i.e., only the stretching vibration due to the Al^{3+}–O bond was observed in the original aluminate glass having 5 mol% of Fe_2O_3. No characteristic vibration due to the Fe^{3+}–O bond was observed in the aluminate glass,[6] whereas the corresponding vibration appeared as the crystallization (precipitation of $12CaO\cdot 7Al_2O_3$ phase) proceeded. In the present study, it is concluded that the Fe^{3+} ions are forming FeO_4 tetrahedra at the substitutional site of the TiO_4 tetrahedra, and therefore it is considered that the bond length of the Fe^{3+}–O bond is essentially the same as that of the Ti^{4+}–O bond. (The ionic radius of the Fe^{3+} (0.64 Å) is reported to be almost identical with that of the Ti^{4+} (0.68 Å).[14])

The quadrupole splitting (Δ), corresponding to the difference in the energy level of nucleus (I=3/2) at the excited state, is expressed by

$$\Delta = (e^2qQ/2)\times(1+\eta^2/3)^{1/2}, \quad (1)$$

where eq and Q are the electric field gradient tensor (=V_{zz}) along the z-axis and the nuclear quadrupole moment, respectively.[15] The η is an asymmetry parameter of the electric field gradient tensor, i.e., $(V_{xx}-V_{yy})/V_{zz}$.[15] We can obtain useful information on the local distortion in the glasses, i.e., a deviation from the cubic symmetry of the NWF-oxygen polyhedra, since the Mössbauer ions (Fe^{3+} in this paper) are substituted for the NWF. Figure 4 demonstrates the compositional dependence of the Δ for Fe^{3+} in the $xK_2O\cdot(95-x)TiO_2\cdot 5Fe_2O_3$ glasses. The experimental error is estimated to be ± 0.02 mm s^{-1}. The Δ shows a linear decrease with the increasing K_2O content, suggesting that the symmetry of FeO_4 tetrahedra becomes higher. This is also the case for the TiO_4 tetrahedra, because the FeO_4 tetrahedra are substituted for the TiO_4 tetrahedra, as described above. The decrease of the Δ (i.e. an increase of the symmetry) is ascribed to the formation of NBO in the $Ti(Fe)O_4$ tetrahedra, as was observed for the $V(Fe)O_4$ tetrahedra

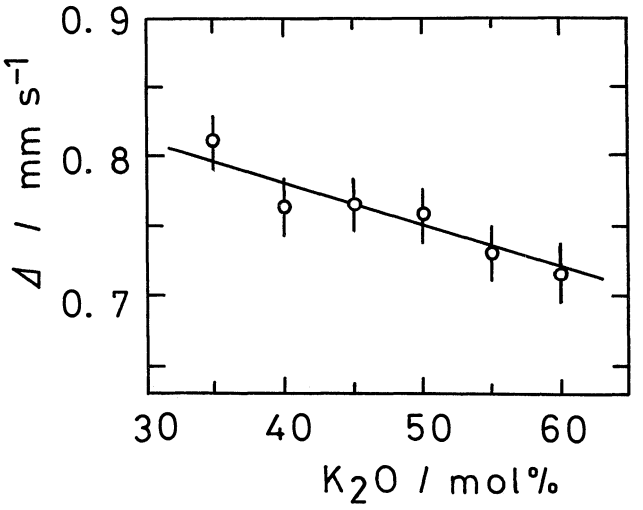

Fig. 4. The quadrupole splitting (Δ) for the $xK_2O\cdot(95-x)TiO_2\cdot 5Fe_2O_3$ glasses plotted against the K_2O content.

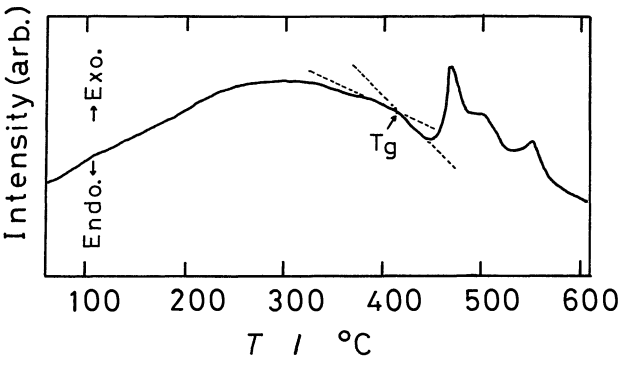

Fig. 5. A DTA curve of the $45K_2O\cdot 50TiO_2\cdot 5Fe_2O_3$ glass.

in the vanadate glasses.[8–10] The formation of NBO in the present titanate glasses indicates the destruction of three-dimensional network structure composed of TiO_4 and TiO_6 octahedra.

One of the DTA curve is shown in Fig. 5, in which the T_g is observed at about 415 °C. The compositional change of the T_g is illustrated in Fig. 6. The experimental error for the T_g is estimated to be ± 1 °C. A linear decrease of the T_g from 436 to 398 °C, observed when the K_2O content is increased from 35 to 60 mol%, is consistent with the decrease of δ (Fig. 2) and that of Δ (Fig. 4), from which the formation of NBO was deduced. The decrease of the T_g ascribed to the formation of NBO suggests that the rotation of oxygen atoms becomes frequently at lower temperatures. The less complicated structure of the titanate glasses will be directly concerned with the lowering of the T_g.

The T_g obtained for the $xK_2O\cdot(95-x)TiO_2\cdot 5Fe_2O_3$ glasses is plotted against the Δ of Fe^{3+} (Fig. 7). It is seen from Fig. 7 that a linear relationship exists. The linear relationship ("T_g–Δ rule") has recently been discovered by Nishida et al.[5] for several oxide glasses,

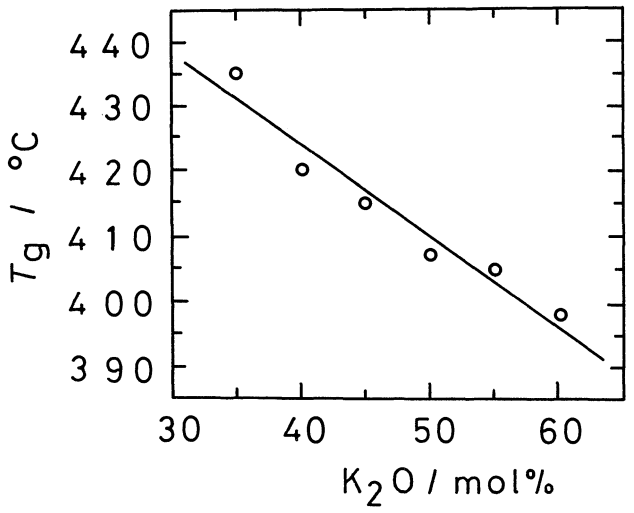

Fig. 6. The glass transition temperature (T_g) of xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses plotted against the K$_2$O content.

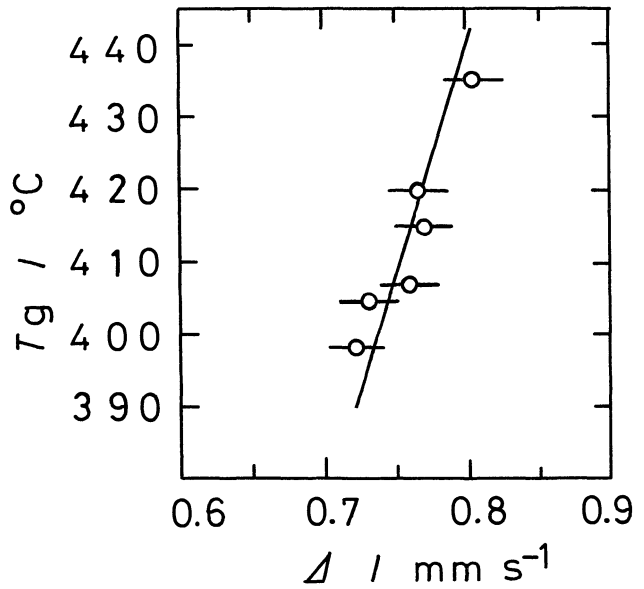

Fig. 7. The T_g-Δ plot for the xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses.

i.e., the T_g (°C) and the Δ (mm s^{-1}) can be expressed by the following equation,

$$T_g = a\Delta + b, \quad (2)$$

where "a" is 680 °C mm^{-1} s and "b" is −180 °C (±100 °C) when the Fe^{3+} is present at the substitutional site of the NWF. The slope "a" of the straight line shown in Fig. 7 is estimated to be 680 °C mm^{-1} s and the intercept "b" is −100 °C, which is identical to that obtained for several oxide glasses, i.e. −180 °C,[5] if we take account of the experimental error of ±100 °C. The "T_g-Δ rule" indicates that the T_g is closely concerned with the Δ, being proportional to the asymmetry of NWF (Ti^{4+} in this study)-oxygen polyhedra, i.e., to the local distortion of the network structure. It should be noted that the T_g is little related to the binding energy of the NWF–oxygen bond, as was discussed in Ref. 5.

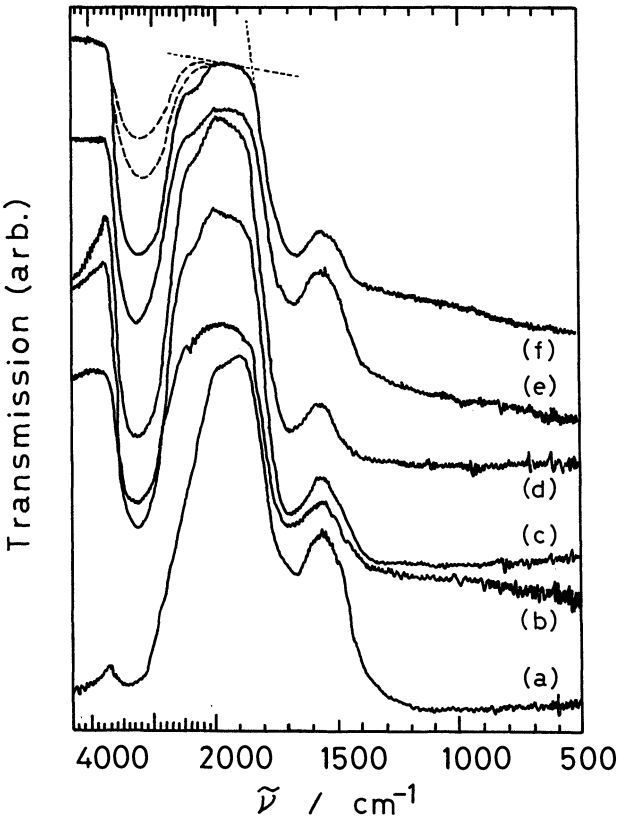

Fig. 8. The IR transmission spectra of the xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses; (a): x=35, (b): x=40, (c): x=45, (d): x=50, (e): x=55, (f): x=60. The transmission edge is indicated by the intersection point of two straight lines (dotted line).

A small block (plate) of the xK$_2$O·(95−x)TiO$_2$·5Fe$_2$O$_3$ glasses shows IR transparency, as is illustrated in Fig. 8. All the titanate glasses have the identical transmission edge of 5.4 μm (1850 cm^{-1}). The absorption edge is estimated to be about 7 μm (1400 cm^{-1}). The IR transparency, having the similar transmission edge as the present titanate glasses, is reported in the case of aluminate glasses with[16] and without[17] TiO$_2$ as well as gallate and tellurite glasses.[5] It seems that the highly optical transparency of the titanate glasses in the IR region is closely concerned with the noticeable local distortion and the large number of NBO atoms, similarly to the case of aluminate, gallate, and tellurite glasses.[5] The optical transparency in the IR region indicates that the titanate glasses can be a good candidate for the "optical memory" in the field of optoelectronics, in analogy with the aluminate, gallate, and tellurite glasses. We can utilize a change (usually a decrease) of the IR transmittance caused by the crystallization of the IR-transmitting glasses.

Figure 8 demonstrates an intense absorption due to the OH group around the wave number of 3 μm (3300 cm^{-1}). The absorption intensity due to the OH group is little changed by the heat treatment at 110 °C for 2 h, whereas it is reduced to ca. 63 and 45% by the treatment at 200 °C for 2 and 17 h, respectively. This is shown with broken lines in Fig. 8. These experimental results suggest that the OH group is not physically adsorbed on the surface of the glass sample, but is chemically bonded to the Ti^{4+} or Fe^{3+} constituting the network structure.

Calcium Titanate Ceramics. The Mössbauer spectrum of $45CaO \cdot 50TiO_2 \cdot 5Fe_2O_3$ ceramic is shown in Fig. 1b, which consists of a quadrupole doublet due to Fe^{3+} and a weak doublet due to Fe^{2+}. (Mössbauer measurements were performed in the velocity range of ±5.0 mm s^{-1}, and no magnetic species was observed.) All the Mössbauer spectra of $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramics consist of the two kinds of doublet peaks. The linewidth (Γ) of the doublet peaks is in the range of 0.36—0.60 mm s^{-1}, being almost comparable to that of several oxide glasses such as aluminate,[5,6] gallate,[5,7] vanadate,[8–10] and tellurite[11,12] glasses. It is seen from Fig. 1a and 1b that the Γ of $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramics is comparable to that of $xK_2O \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ glasses. This means that both the Fe^{3+} and Fe^{2+} are present in the glassy phase of the $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramics. They should be called glass-ceramics rather than ceramics. The formation of crystalline phase in the glass-ceramics was confirmed from the X-ray diffraction measurements. Figure 9 indicates the presence of TiO_2 phase precipitated in all the $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramic samples. Each diffraction peak corresponding to the TiO_2 phase is marked with an open circle in Fig. 9a.

The isomer shift (δ) of the Fe^{3+} falls in the range of 0.37—0.40 mm s^{-1}, irrespective of the CaO content, and the average is 0.38 mm s^{-1} (Fig. 10a). The δ indicates the tetrahedral Fe^{3+}–O bond in the glassy phase of the $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ glass-ceramics, since the δ of tetrahedral Fe^{3+} is reported to be equal to or less than 0.4 mm s^{-1}.[5–10] Almost identical δ values have been obtained in the case of $V(Fe)O_4$ tetrahedra constituting several vanadate glasses.[8–10] The δ of the octahedral Fe^{3+} is reported to be more than 0.42 mm s^{-1}, as was observed in the case of phosphate glasses.[18] Recently, Menil reported that the δ of tetrahedral Fe^{3+} is less than 0.30 mm s^{-1} (with respect to metallic iron (α-Fe)) in the case of several crystalline compounds, and that the δ of octahedral Fe^{3+} is more than 0.30 mm s^{-1}.[19] It is noted that the δ (0.30 mm s^{-1}), criterion between the octahedral and tetrahedral Fe^{3+} in crystals, is smaller than the corresponding δ (0.40 mm s^{-1}) reported for glasses.[5–10,18] The difference of the δ (0.40—0.30=0.10 mm s^{-1}) is ascribed to the difference of the mean Fe^{3+}–O bond

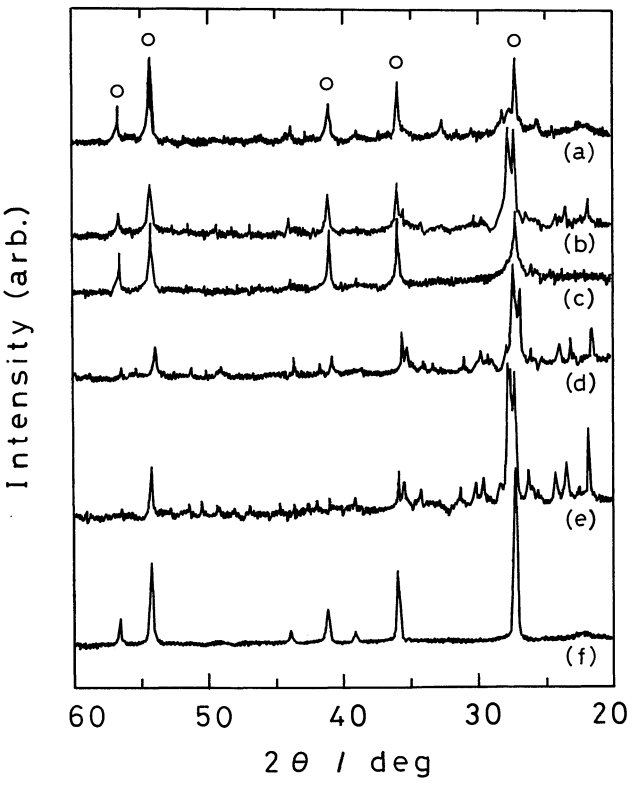

Fig. 9. The X-ray diffraction patterns of $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramics; (a): x=10, (b): x=20, (c): x=30, (d): x=40, (e): x=50. (f): The X-ray diffraction pattern due to TiO_2.

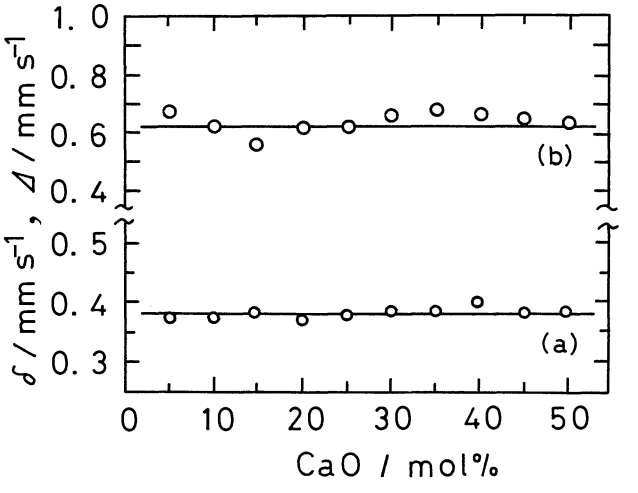

Fig. 10. The compositional dependence of (a): the isomer shift (δ) of the Fe^{3+} and (b): the quadrupole splitting (Δ) of the Fe^{3+} for the $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramics.

length; the longer Fe^{3+}–O bond length will cause the larger δ values for the glasses. (It is well known that the molar volume of "glass" is larger than that of "crystal." This is also the case for each the bond length.) The δ of Fe^{3+} obtained for the $xCaO \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ ceramics (Fig. 10a) is much larger than that of the $xK_2O \cdot (95-x)TiO_2 \cdot 5Fe_2O_3$ glasses

(δ=0.20—0.23 mm s^{-1}) illustrated in Fig. 2, indicating the highly ionic character of the Fe^{3+}–O bond. The constant δ (Fig. 10a) suggests that a change of the CaO content results in little structural change in the $Ti(Fe)O_4$ tetrahedra. This is consistent with the compositional dependence of the Δ of Fe^{3+} obtained for the xCaO·(95−x)TiO_2·5Fe_2O_3 ceramics (Fig. 10b); the Δ is almost constant irrespective of the CaO content, having an average value of 0.63 mm s^{-1}. This means that the symmetry of TiO_4 and FeO_4 tetrahedra is little changed when the chemical composition is changed. The DTA curve of the xCaO·(95−x)TiO_2·5Fe_2O_3 ceramics comprises a broad exothermic curve, of which maximum is observed at the identical temperature of 384±1 °C. No endothermic peak corresponding to the T_g is observed in the DTA curve. The experimental results shown in Fig. 10 are quite different from those obtained for the $x$$K_2O$·(95−$x$)$TiO_2$·5$Fe_2O_3$ glasses (Figs. 2 and 4), in which the increase of K_2O content resulted in the decrease both of the δ and Δ owing to the formation of NBO in the $Ti(Fe)O_4$ tetrahedra.

The distinct change brought about in the xCaO·(95−x)TiO_2·5Fe_2O_3 ceramics is reflected in the relative absorption area of Fe^{3+} and Fe^{2+}, as is shown in Fig. 11. The relative absorption area (A) of the Fe^{3+} (fraction of the Fe^{3+}) decreases linearly from 94 to 75%, while that of the Fe^{2+} increases from 6 to 25% when the CaO content is stepwise increased from 5 to 50 mol%. A similar phenomenon was observed in the case of potassium phosphate glasses,[18] in which the electron transfer from the neighboring oxygen atom to the Fe^{3+} was speculated on the basis of the ESR measurements of the PO_4^{2-} radicals produced by the γ-ray irradiation. Figures 10 and 11 suggest that the introduction of CaO into the TiO_2 matrix results in the reduction of Fe^{3+} into Fe^{2+}, without changing the δ and Δ of the Fe^{3+}.

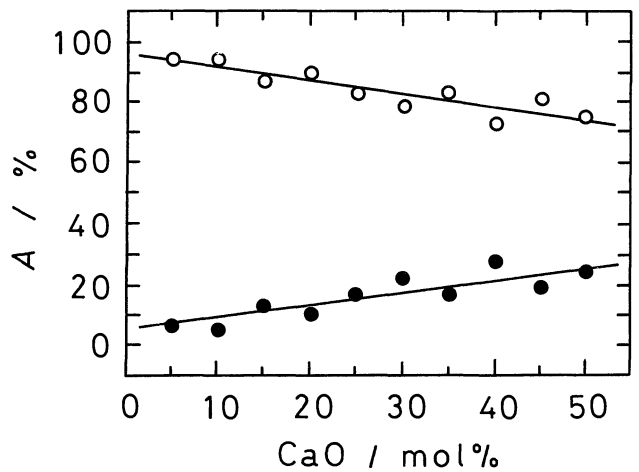

Fig. 11. Relative absorption area (fraction) of the Fe^{3+} (○) and that of the Fe^{2+} (●) obtained from the Mössbauer spectra of the xCaO·(95−x)TiO_2·5Fe_2O_3 ceramics.

The δ of Fe^{2+} falls in the range of 0.70—0.83 mm s^{-1}, having the average of 0.76 mm s^{-1}. These δ values indicate the presence of four-fold coordinated Fe^{2+} species.[15,19] (It is known that the δ of octahedral Fe^{2+} species is larger than 1.0 mm s^{-1}).[15,19] The δ values are almost constant irrespective of the CaO content, similarly to the case of the δ obtained for Fe^{3+} (Fig. 10a). The small δ for the Fe^{2+} (ca. 0.76 mm s^{-1}) indicates a strong covalency, reflecting a much shorter Fe^{2+}–O bond length. (It is considered that the short bond length was favorable for the electron transfer from oxygen to Fe^{3+}.) The Δ of Fe^{2+} falls in the range of 2.13—2.60 mm s^{-1}, being increased with an increasing CaO content. It is considered that the mixed valence state of Fe^{2+} and Fe^{3+} causes the decrease of the symmetry of Fe^{2+} O_4 tetrahedra.

Conclusion

1) In the K_2O–TiO_2–Fe_2O_3 glasses, the Fe^{3+} is substituted for the tetrahedral Ti^{4+}. This is confirmed from the Mössbauer and IR measurements. The Fe^{3+} plays a role of NWF.

2) The TiO_4 tetrahedra/TiO_6 octahedra ratio becomes higher in the K_2O–TiO_2 glasses when the K_2O content is increased.

3) The fraction of NBO in the TiO_4 tetrahedra also increases when the K_2O content is increased.

4) The K_2O–TiO_2–Fe_2O_3 glasses have the IR transparency. The transmission edge and the absorption edge are 5.4 and 7 μm, respectively.

5) A TiO_2 phase is precipitated in the matrix of the CaO–TiO_2–Fe_2O_3 ceramics.

6) Reduction of the Fe^{3+} into Fe^{2+} is observed in the CaO–TiO_2–Fe_2O_3 ceramics. This becomes noticeable with the increasing CaO content.

The authors are grateful to Prof. Yasukuni Matsumoto (Kinki University in Kyushu) for the help in the X-ray diffraction measurements. On of the authors, Tetsuaki Nishida, is indebted to the Japan Securities Scholarship Foundation for the financial support.

The transformations of hydrated sodium molybdenum bronze, $Na_{0.23}(H_2O)_{0.78}MoO_3$, with heat treatments in a nitrogen atmosphere are as follows: $Na_{0.23}(H_2O)_{0.78}MoO_3$ (AD) $\xrightarrow{\text{at 330 K}}$ $Na_{0.23}(H_2O)_{0.5}MoO_3$ (VD) $\xrightarrow{\text{at 457 K}}$ $Na_{0.23}MoO_3$ (with VD structure) $\xrightarrow{\text{at 583 K}}$ $Na_{0.9}Mo_6O_{17}$ + a small amount of other materials $\xrightarrow{\text{at 800 and 900 K}}$ melt. This indicates a new and variable formation process of alkali metal molybdenum bronzes. In this process, $Na_{0.9}Mo_6O_{17}$ was formed in the solid phase without the formation of any intermediate products. Its formation temperature was about 600 K, which was less than those of the usual preparation methods by about 200 K.

It is well-known that alkali metal molybdenum bronzes exhibit low-dimensional electronic properties.[1-3] They are semiconductors and most of them show a semiconductor-metal transition.[4-7] In particular, $Li_{0.9}Mo_6O_{17}$ is known to exhibit superconductivity.[8] They have been extensively studied because of interest in these properties.[1-11] On the other hand, hydrated alkali molybdenum bronzes, $A_x(H_2O)_yMoO_3$, have been synthesized by Schöllhorn et al.[12] These bronzes are apparently different regarding their Mo–O frameworks from the metal bronzes; i.e., hydrated bronzes possess a Mo–O framework based on the MoO_3 structure, while the metal bronzes possess different Mo–O frameworks.[13] However, their compositions are similar to each other, excluding the hydration water. We have thus been interested in the structural changes of hydrated molybdenum bronzes after removing the hydration water. We therefore investigated the structural changes of a hydrated sodium molybdenum bronze with heat treatments in a nitrogen atmosphere and found that $Na_{0.9}Mo_6O_{17}$ is formed from the hydrated bronze. Alkali metal molybdenum bronzes have usually been synthesized by an electrolytic reduction of A_2MoO_4–MoO_3 melts and by heating stoichiometric mixtures of A_2MoO_4, MoO_3, and MoO_2 in a vacuum.[1-11] In these syntheses, the formations of the bronzes proceed in a liquid phase above 800 K. The formation of $Na_{0.9}Mo_6O_{17}$ from a hydrated bronze proceeds at about 600 K in the solid phase without the formation of any intermediate products. This fact not only suggests that the formation proceeds by way of a new mechanism, but also provides a new and variable synthesis method of alkali metal molybdenum bronzes. This paper describes them in full detail.

Experimental Procedure and Results

Preparation. Hydrated sodium molybdenum bronze was prepared by Thomas and McCarron, III's method.[13] The composition of the hydrated bronze was $Na_{0.23}(H_2O)_{0.78}MoO_3$.

Differential Thermal Analysis. TG-DTA was carried out in a nitrogen atmosphere on a MAC SCIENCE TG-DTA 2000. A TG-DTA heating curve was obtained at a heating rate of 10 K min^{-1}, while a cooling curve was gotten by cooling naturally.

The TG-DTA curve of hydrated sodium molybdenum bronze is shown in Fig. 1. Four endothermic (at 330, 457, 800, and 927 K) and two exothermic peaks (at 583 and 633 K) can be seen. The endothermic peaks at 330 and 457 K are

Table 1. The Results of Analysis

Treatment condition	H_2O wt%[a]	Mo wt%	Na wt%	Mo^{5+}/total Mo
As-prepared	8.7	59.4 (65.1)	3.3 (3.6)	0.23
420 K	5.7	62.1 (65.9)	3.5 (3.7)	0.21
520 K	4.3[b]	62.2 (65.0)	3.5 (3.7)	0.21
600 K	0	65.8 (65.8)	3.5 (3.5)	0.22
650 K	0	64.8 (64.8)	3.6 (3.6)	0.23
840 K	0	64.8 (64.8)	3.6 (3.6)	0.22

a) This value is given by TG analysis. b) This value means the re-hydration water on cooling. Values in parentheses are calculated by excluding water contents.

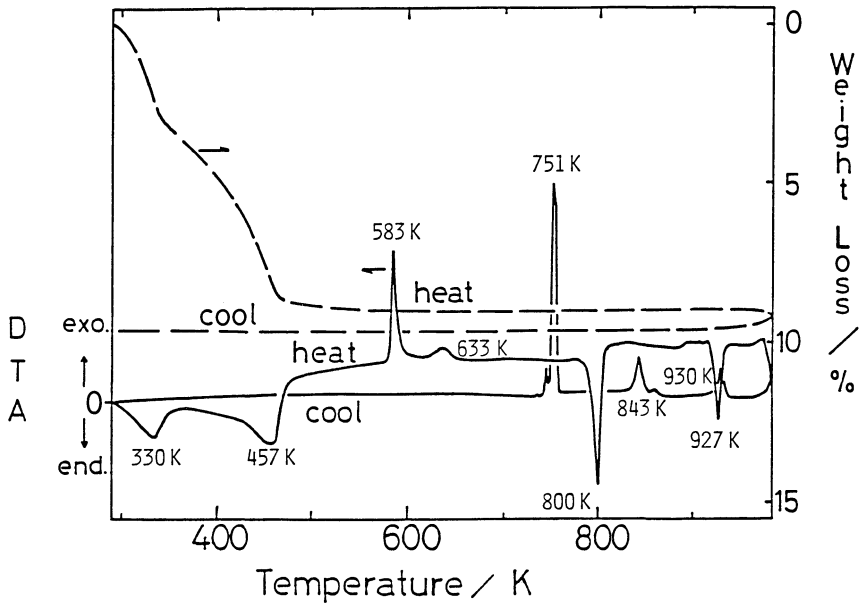

Fig. 1. TG–DTA curve of the hydrated sodium molybdenum bronze in a nitrogen atmosphere on heating and on cooling.

accompanied by a large weight loss, while the other peaks are not. The peaks at 330, 457, 583, and 633 K disappear upon cooling, and arise from irreversible phase transformations, while the peaks at 800 and 927 K are reversible transformations. The peaks at 330 and 457 K are attributed to the release of hydration water, due to the large weight losses.

Investigation of Phase Transformations. The samples heated both before and after each DTA peak temperature were investigated in detail using chemical analysis and an X-ray diffraction (XRD) method. Samples heated below 520 K were dark blue in color and those heated above 600 K were dark red. Sintering of the sample occurred above 800 K. The Na and Mo contents in the samples were measured by using a HITACHI 180-80 atomic absorption spectrophotometer with the 3302.3 Å line of Na and the 3132.6 Å line of Mo. The Mo^{5+} contents of the samples were determined chemically by Choain and Marion's method.[14] XRD patterns were obtained by using a RIGAKUDENKI GEIGER D-1 FLEX diffractometer with Cu $K\alpha$ radiation. Samples for the measurements were mixed with an internal standard (ca. 5 wt% Si).

The analytical results are summarized in Table 1. The quantity of Mo^{5+} remains constant. Upon heat treatments, as increase in the heating temperature, the H_2O content of the sample decreases. Samples heated below 520 K contain H_2O and those heated above 600 K do not. According to a differential thermal analysis, a sample after an endotherm at 457 K should contain no hydration water. Nevertheless, a sample heated at 520 K contains 4.3 wt% of water. When the sample was cooled to room temperature, the weight gain was observed by TG measurements. Therefore, the water in the sample is re-hydration water. The composition of a sample heated above 600 K is $Na_{0.23}MoO_3$, while that of a sample heated at 420 K is $Na_{0.23}(H_2O)_{0.5}MoO_3$. The real composition of a sample at 520 K is $Na_{0.23}MoO_3$. The XRD patterns of the

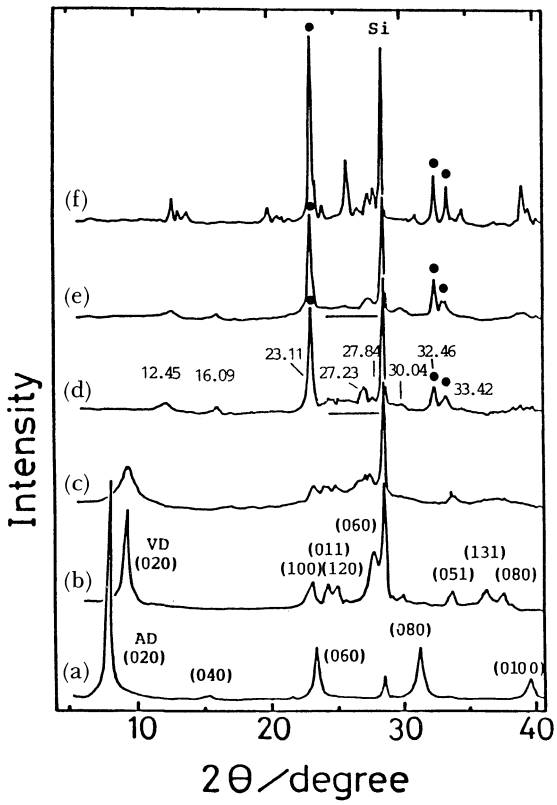

Fig. 2. Changes in X-ray diffraction patterns of the hydrated sodium molybdenum bronze by heat treatments in a nitrogen atmosphere. (a) as-prepared, and heated (b) at 420 K, (c) at 520 K, (d) at 600 K, (e) at 650 K, and (f) at 840 K.

samples are shown in Fig. 2. An as-prepared sample and a sample heated at 420 K are identical with an air-dried

hydrated sodium molybdenum bronze (denoted as AD), $[Na(H_2O)_x]_{0.25}MoO_3$ ($2<x\leqslant 6$), and an vacuum-dried hydrated sodium molybdenum bronze (denoted as VD), $[Na(H_2O)_2]_{0.25}MoO_3$, of Thomas and McCarron, III, respectively.[13] A sample heated at 520 K still maintains its VD structure, although the diffraction peaks become rather broad. By heating at 600 K, the diffraction peaks of VD disappear and new peaks appear at 12.45, 16.09, 23.11, 27.23, 27.84, 30.04, 32.46, and 33.42°. The peaks marked by the symbol ● are attributed to $Na_{0.9}Mo_6O_{17}$.[10] Others show the formation of a small amount of MoO_3 and $Na_2Mo_2O_7$. A sample heated at 650 K gives nearly the same diffraction pattern as that at 600 K, except for minor differences in the range 24—28°. For a sample heated at 840 K, the diffraction peaks of $Na_{0.9}Mo_6O_{17}$ remain, though many other peaks also appear. These peaks are attributed to MoO_3 and a solid solution of $Na_2Mo_4O_{13}$+ MoO_3.[15]

Discussion

Transformations in a Nitrogen Atmosphere. The first release of hydration water gives rise to a transformation from AD to VD. After the second release of hydration water, i.e., the complete removal of the hydration water, the sample still retains the VD structure up to 583 K. This sample can incorporate water molecules from the atmosphere. The broadening in the XRD pattern of this sample (Fig. 2(c)) may be due to inadequate hydration.[16] The main product of a sample heated at 600 K was $Na_{0.9}Mo_6O_{17}$. The DTA peak at 583 K is, therefore, attributed to a transformation from VD to $Na_{0.9}Mo_6O_{17}$. According to the X-ray results, though the sample before and after the DTA peak at 633 K give no characteristic change, a minor difference appears in the range 24—28°. A differential thermal analysis of the hydrated bronze with lower Na content[17] revealed that the peak at 633 K is also correlated to the formation of $Na_{0.9}Mo_6O_{17}$. The DTA endothermic peaks at 800 and 927 K are reversible. Appreciable sintering of the sample took place above 800 K, as mentioned above. Thus, these peaks are due to melting of the sample. Compared with the phase diagram of Na_2MoO_4 and MoO_3,[15] we presume that the peaks at 800 and 927 K arise from transformations to an equilibrium mixture of the solid and solution and to solution, respectively. According to chemical analyses, the compositions of the samples heated above 583 K are $Na_{0.23}MoO_3$. On the other hand, the composition of the dominant product is $Na_{0.9}Mo_6O_{17}$. The appearance of a few materials other than $Na_{0.9}Mo_6O_{17}$ in samples heated above 600 K may result from a deviation of the compositions of the samples from $Na_{0.9}Mo_6O_{17}$. Transformations of the hydrated bronze with heat treatments in a nitrogen atmosphere are formulated as follows:

$$\underset{(Na_{0.23}(H_2O)_{0.78}MoO_3)}{\overset{\text{AD}}{}} \xrightarrow[\text{end. peak at 330 K}]{\uparrow H_2O}$$

$$\underset{(Na_{0.23}(H_2O)_{0.50}MoO_3)}{\overset{\text{VD}}{}} \xrightarrow[\text{end. peak at 457 K}]{\uparrow H_2O}$$

$$\underset{(Na_{0.23}MoO_3^{\#})}{\overset{\text{VD structure}}{}} \xrightarrow[\text{exo. peak at 583 K}]{} Na_{0.9}Mo_6O_{17} + \text{other} \xrightarrow[\text{exo. peak at 633 K}]{}$$

$$Na_{0.9}Mo_6O_{17} + \text{other}^{\dagger} \xrightarrow[\text{end. peaks at 800 K and 927 K}]{} \text{melt}$$

#When cooled in the presence of water vapor, this sample with a VD structure can easily contain re-hydration water. †Other materials, which are identical with MoO_3 and $Na_2Mo_2O_7$, are contained in small amounts.

Formation Mechanism of $Na_{0.9}Mo_6O_{17}$. $Na_{0.9}Mo_6O_{17}$ was formed at 583 K from a hydrated sodium molybdenum bronze. The sample has a VD structure just before the formation of $Na_{0.9}Mo_6O_{17}$. The formation temperature is lower than the melting points of the sample by at least 200 K. These facts indicate that the formation proceeds directly from VD in the solid-phase process. This formation mechanism is different from those by usual methods. By the usual methods, the formation proceeds in the liquid phase and via intermediate products with similar structures.[7,10] The formation of $Na_{0.9}Mo_6O_{17}$ from VD is a structural phase transition. Formation at a lower temperature (based on the phase transition) may arise from the fact that the hydrated bronze possesses Na atoms already inserted in the Mo–O framework. The structures of $Na_{0.9}Mo_6O_{17}$ and VD have already been reported,[11,13] as shown in Fig. 3. These structures can be described as being slabs connected by Na atoms. The slab of $Na_{0.9}Mo_6O_{17}$ is build up of 4 layers of Mo octahedra and 2 layers of tetrahedra sharing corners, while that of VD contains 2 layers of Mo octahedra sharing edges. An inspection of these two structures suggests that the direct formation of $Na_{0.9}Mo_6O_{17}$ from VD is possible through the following steps, as shown in Fig. 3(b): (i) passing of Na atoms through the slabs, (ii) linkage of each two slabs, and (iii) reformation of the Mo–O framework. The radius of a sphere which can pass through an open space in the slabs of VD may be smaller than 0.3 Å. This value is obtained from well established atomic positions of $D_{0.36}MoO_3$,[18] of which the Mo–O framework is comparable to that of VD. (An ion radius of O atom, 1.4 Å, was used.[19]) The ion radius of Na atoms is 1.12 Å[20] and is too large to pass through the open space. However, the chemical bonds in the bronze are expected to be rather loose at 600 K, which corresponds to a few hundred degree below its melting point. The loose bonds may permit Na atoms to pass through the slabs.

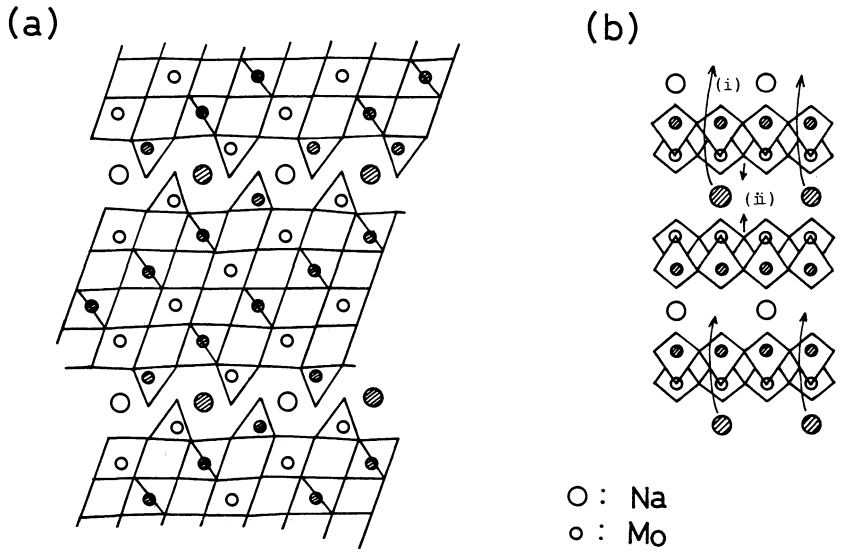

Fig. 3. Crystal structures of (a) $Na_{0.9}Mo_6O_{17}$ and (b) VD. Open and hatched circles indicate atomic positions at $Z=0$ and $1/2$, respectively.

The formation of $Na_{0.9}Mo_6O_{17}$ from VD is a new formation process, which stimulates not only great interest in the physical phenomenon, but also merits for applications. The preparation of alkali metal molybdenum bronzes from hydrated alkali molybdenum bronzes can be performed at a lower temperature than by the usual fused methods. The preparation of bronzes in a thin film or a complex form is also possible, since the formation of bronzes proceeds in a solid-phase process without any formation of melts. In this work, the formation of $Na_{0.9}Mo_6O_{17}$ was accompanied by the coexistence of a small amount of other materials. This prevents a realization of the above applications. To prepare bronzes without such a coexistence, the composition of the hydrated sodium molybdenum bronze must be controlled. Methods to control the composition are now being studied. Moreover, an investigation regarding other hydrated alkali molybdenum bronzes is also in progress.

16) Sodium atoms in original VD are octahedrally coordinated by two oxygen atoms of hydration water molecules and four terminal oxygen atoms of MoO_3.[13] However, some of sodium atoms in this sample are not octahedrally coordinated, because of the lack of hydration water. This generates distortions of the lattice and gives rises to the broadening.
17) Thermal differential analysis was carried out for the hydrated sodium bronze of which Na content was reduced by a treatment with an acidic solution, i.e., Na^+–H^+ ion-exchange. As Na content decreased, the exothermic peak at 583 K shifted to a higher temperature side and finally overlapped with the peak at 633 K. For the bronze with Na/Mo=0.16, which showed only one exothermic peak at 633 K, $Na_{0.9}Mo_6O_{17}$ was formed at the peak temperature.

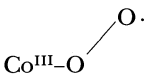
Physical and Chemical Properties of Mononuclear Cobalt Dioxygen Complexes with Tetraimidazolyl-Substituted Pyridine Chelates

Seizo TAMAGAKI, Yutaka KANAMARU, Masanori UENO, and Waichiro TAGAKI*
Department of Bioapplied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3, Sumiyoshi-ku, Osaka 558
(Received May 7, 1990)

A new calss of mononuclear superoxocobalt complexs containing four equal imidazolyl-donors and one pyridyl-donor per cobalt(II) ion was prepared and their chemical and physical properties were compared with those of cobalt(II) Schiff-base type dioxygen complexes.

Since the first recoginition of oxygen fixation by the Co^{II} complex of a synthetic chelate, *N,N'*-disalicylideneethylenediamine (salen),[1] reversible oxygenations with mononuclear peroxo complexes of low valent transition metals such as Ir^{I}, Rh^{I}, Co^{I}, and Ni^{0} have been reported, in which the two oxygen atoms are equidistant from the metal.[2,3] Meanwhile, a wide variety of binuclear μ-peroxo complexes have been synthesized[2,4] and it has been found that in the presence of pyridine and imidazole reversible dioxygenation is possible with analogs of Co^{II} (salen) complexes such as Co^{II} (3-methoxysalen)[5,6] and Co^{II} (acacen), [*N,N'*-ethylenebis(4-imino-2-pentanonato)]-cobalt(II)),[7] forming the corresponding dioxygen complexes, whose structures were characterized as paramagnetic mononuclear superoxocobalt(III) complexes being in equilibrium with the corresponding μ-peroxo complexes;



Metal dioxygen complexes are important for (1) a better understanding of the role of hemoglobin and myoglobin in biological systems;[8] (2) development of efficient catalysts for oxygenation of organic substrates;[9] (3) use in separating dioxygen from air or removing traces of dioxygen from inert gases.[10] In this work we have synthesized a new class of imidazolylmethyl-substituted pyridine chelates (hereinafter this will be referred to as tip) and have studied the physical and chemical properties of their cobalt dioxygen complexes as well as their utility for oxygenations of phenols to fully characterize them.

CH_3CH_2 (tip(e))

Experimental

Materials. Solvents used in this study were purified via standard procedures by distillation, and only the central fraction was used. Special grade cobalt nitrate and perchlorate as the hydrates were purchased from Kishida Chemical Co. and used without further purification. Tetraimidazolylmethyl-substituted pyridine ligands, tip (tip-(a)—tip(d)), were prepared by the procedure previously described with minor modifications:[11] A 500 mL flask was flame-dried. After cooling it with a stream of nitrogen, 200 mL of freshly distilled, dry THF containing 0.1 mol of *N*-alkylimidazole was added with cooling to Dry Ice/acetone temperature (−78 °C) under nitrogen. Sixty-three mL of a 1.6 M solution of butyllithium in hexane (M=mol dm^{-3}) was injected dropwise to that solution using a glass syringe. To assure the completion of the reaction, the reaction temperature was maintained at the same temperature for additional one hour. To the solution diethyl 2,6-pyridinedicarboxylate (5.6 g, 0.024 mol) in 50 mL of THF was added dropwise. The reaction temperature was then allowed to rise to room temperatue. After the mixture was stirred for 4 h, water was added and the organic solvent was stripped off. Continuous extraction of the water layer with ethyl acetate gave a white crystalline solid, tip(a), which was recrystallized from $CHCl_3$–hexane.

Tip(a): Yield 54.3%; mp 181—184 °C; NMR ($CDCl_3$) δ=3.09 (16H, s, CH_3), 6.10 (2H, s, OH), 6.68 (4H, s, Im-2H), 6.89 (4H, s, Im-3H), 7.13 (1H, m, py-4H), 7.52 (2H, m, py-3,5H).

Tip(b) was purified by recrystallization from benzene–hexane after evaporation of the THF, extraction with $CHCl_3$ and evaporation of the $CHCl_3$.

Tip(b): Yield 48.7%; mp 164—166 °C; NMR ($CDCl_3$) δ=0.7—1.6 (28H, m, $(CH_2)_2CH_3$), 3.58 (8H, t, N-CH_2), 6.04 (2H, s, OH), 6.79 (8H, s, Im-CH=CH), 7.23—7.70 (3H, m, py-3,4,5H).

With tip(c) and tip(d), the $CHCl_3$ extracts were subjected to preparative TLC and the solids obtained were recrystallized from hexane (yield 34.7% mp 107—108 °C) and from benzene–hexane (yield 45.1%; mp 178—179 °C), respectively.

Tip(d): 2.92 (12H, s, OCH_3), 6.60 (2H, s, OH), 6.78, 6.91 (8H, d, CH=CH), 7.1—7.8 (3H, m, py-3,4,5H).

Isolation of [Co(tip) $(O_2)]^{2+}$ and Its Reaction Product. Tip(a) (0.1 mmol) was mixed at −30 °C with an equimolar amount of $Co(NO_3)_2 \cdot 6H_2O$ in 25 mL of nitromethane, and tip(b) or tip(c) in 25 mL of CH_2Cl_2, and bubbling of oxygen gave immediately dark-red solutions of $[Co(tip)(O_2)]^{2+}$ complexes, which were entirely stable to a further reaction at such a low temperature in solution. Evaporation of the solvent below −30 °C under a reduced pressure of 1 mmHg (1 mmHg=133.322 Pa) afforded dark-red colored solids. [Co(tip(a)) $(O_2)]^{2+}$ salt: yield 98%. Meanwhile, when tip(a) (0.1 mmol) was added with stirring to $Co(NO_3)_2 \cdot 6H_2O$ (0.1 mmol) in 10 mL of acetone at room temperature under oxygen, dark-red solids began to precipitate. (The $[Co(tip)]^{2+}$ complex itself did not precipitate out under nitrogen.) After 1 h, the precipitates were filtered, washed with acetone, and dried under vacuum, affording an analytical sample.

$[Co(tip(a))(O_2)](NO_3)_2(H_2O)_2$: Yield 91%; decomp 140—143 °C.

Anal. Calcd for $C_{23}H_{29}N_{11}O_{12}Co$: C, 38.88; H, 4.11; N, 21.69%. Found: C, 39.11; H, 4.43; N, 21.27%.

When tip(a) (0.2 mmol) was mixed with $Co(NO_3)_2 \cdot 6H_2O$ (0.2 mmol) in 25 mL of acetonitrile under oxygen at room temperature, complete bleaching of the solution was effected in 2 days. The solution was then evaporated to dryness and the residue was washed thoroughly with acetonitrile. Yield 90% in weight; decomp. 187—190 °C. Because of its tendency to decompose when subjection to recrystallization or precipitation, it is not possible to obtain the product in the pure form. The elemental analysis of this product gave no constant value within analytical accuracy with samples taken from different runs, but most likely agrees with a dimeric complex $[Co_2(tip(a))_2(O_2)](NO_3)_4$.

Isolation of [Co(tip(a))(base)]$^{2+}$ Complexes. To stoichiometric amounts of tip(a) and $Co(NO_3)_2 \cdot 6H_2O$ (0.3 mmol each) was added a large excess of a desired base, for example, *N*-methylimidazole (Meim) under nitrogen in 25 mL of nitromethane. Rotary evaporation of the solvent provided slightly pink powders in 96% yield, which were precipitated from nitromethane/CH_2Cl_2/benzene in the presence of excess 1-methylimidazole.

[Co(tip(a)) (Meim)] $(NO_3)_2(H_2O)_2$: decomp. 245—250 °C. Anal. Calcd for $C_{27}H_{35}N_{13}O_{10}Co$: C, 42.65; H, 4.61; N, 23.95%. Found: C, 42.33; H, 4.8; N, 24.45%.

Oxygen Uptake Experiment. The amount of oxygen absorbed by $[Co((tip(a))]^{2+}$ was determined at 20 °C according to the Warburg's manometry.[12] K_{O_2} is the equilibrium constant defined according to the equation below:

$$LCo^{2+} + O_2 \rightleftharpoons LCoO_2^{2+} \qquad K_{O_2} = \frac{[LCoO_2^{2+}]}{[LCo^{2+}] \times P_{O_2}}$$

where P_{O_2} is the oxygen pressure in mmHg. The full equilibriation was presumed to be quickly attained.

Kinetic Procedure for Disappearance of the Superoxocobalt Complexes. All experiments have been done at 25 °C under 1 atm oxygen pressure. The progress of disappearance of a cobalt oxygen complex was followed by monitoring the disappearance of absorption at 505 nm. As the superoxo complex is formed in relatively fast equiliblium, its disappearance reaction was monitored soon after injecting a needed volume of acetonitrile solution of $Co(NO_3)_2$ into 3 mL of a tip acetonitrile (0.5 mM each) in a 1 cm UV-cell capped with a rubber septum.

Electrochemistry. Cyclic voltammetric measurements were performed under nitrogen using a NP-IR 1000 potentiostat/galvanostat. Special grade acetonitrile was distilled from P_4O_{10}. Tetrabutylammonium perchlorate was used as the supporting electrolyte. To 20 mL of an acetonitrile solution containing 3 mM tip(b) and 0.1M Bu_4NClO_4 was added 100 μL of 0.6 M $Co(ClO_4)_2$ under nitrogen. The measurements utilized a platina wire working electrode, a platina wire auxiliary electrode, and an Ag/AgCl reference electrode in a one-compartment cell. The cyclic voltammograph of $[Co(tip(b))]^{2+}$ thus obtained is given in Fig. 1a. Figure 1b shows a cyclic voltammograph in the presence of 5-fold excess of pyridine. The $E_{1/2}$ values were estimated from cyclic voltammograms using the expression $E_{1/2}=(E_P+E_{p/2})/2$ where E_p is the peak potential and $E_{p/2}$ is the half peak potential.

ESR Spectrum. The solid cobalt–oxygen complex was placed in an ESR tube, after which the tube was degassed. The ESR signals were recorded at −196 °C on a JES-ME-3X spectrometer with an X-band microwave unit and 100 KHz field modulation.

Oxygenation of 2,4-Di-*t*-butylphenol. To a red solution of an equimolar mixture of $Co(ClO_4)_2 \cdot 6H_2O$ (9.15 mg, 0.025 mmol, 0.5 M) and tip(b) (15.68 mg) in 50 ml of various solvents was added 1.0 mmol (206 mg) of 2,4-di-*t*-butylphenol. The reaction was allowed to proceed under oxygen at room temperature for 44 h. For determination of product yields, the solvent was rotary evaporated at room temperature, and then the residue was subjected to thin-layer chromatography with Kiesel gel G/$CHCl_3$, affording 3,5-di-*t*-butyl-*o*-benzoquinone and 3,3′,5,5′-tetra-*t*-butyl-1,1′-biphenyl-2,2′-diol (hereafter designated as biphenyl-2,2′-diol): Mp 193—195 °C; NMR ($CDCl_3$) δ=1.3 (36H, d, *t*-butyl), 5.08 (2H, s, Ar-O<u>H</u>), 6.94—7.21 (4H, m, Ar-<u>H</u>); MS (70 eV) *m/z* (rel intensity) 410 (M^+; 100), 395(52), 339(20), 283(15), and 190(48). Determination of the quinone yield was made spectrophotometrically at 400 nm (δ=1704) in MeCN within experimental error of ±3%.[13] The yields in various solvents are collected in Table 2.

Oxygenation of 2,6-Di-*t*-butylphenol. To a solution of 0.05 mmol each of tip(b) and $Co(NO_3)_2 \cdot 6H_2O$ in 25 ml solvents was added 2,6-*t*-butylphenol (103 mg, 0.5 mmol). The reaction was continued with gentle stirring at room temperature under oxygen. After 24 h, the solvent was stripped off under reduced pressure at room temperature and the residue was subjected to preparative thin-layer chromatography using benzene–hexane (1:1) as eluant giving two products. The yields were determined spectrophotometrically. 2,6-Di-*t*-butyl-*p*-benzoquinone (*p*-BQ): 450 nm (ε=39)[14] and a diphenoquinone (DPQ): 260 nm (ε=4056).[15]

Kinetic Method for Oxygenation. Reactions were performed under the conditions specified in Fig. 8. Unless otherwise noted, the concentration of 3,5-di-*t*-butylphenol was in 10-fold excess over the catalyst. In a typical experiment, a septum-capped flask containing pure O_2-saturated acetone solution of $Co(NO_3)_2$ and tip(b) was maintained at 25 °C. Reactions were initiated by injecting the phenol dissolved in acetone. A 75 μL aliquot of the reaction mixture was then transferred by a microsyringe into a UV cell containing 3 mL of acetonitrile. The increasing absorbance at 400 nm characteristic of the product quinone

was monitored every 30 minutes.

Instrumentals. NMR, IR, and UV spectra were obtained on a Hitachi R-24B, a Nihon Bunko A-202 infrared spectrometer, and a Hitachi 220 spectrophotometer, respectively.

Results and Discussion

Physical Properties of $[Co(tips)]^{2+}$ and Their Oxygen Complexes. In cyclic voltammograms of oxygen-free $[Co(tip(b))]^{2+}$ and $[Co(tip(b))(base)]^{2+}$ complexes a single quasi-reversible redox wave associated with cobalt(II/III) couples appears at negative potentials. (Fig. 1a and 1b). The redox-potentials are summarized in Table 1. There is no distinct correlation between

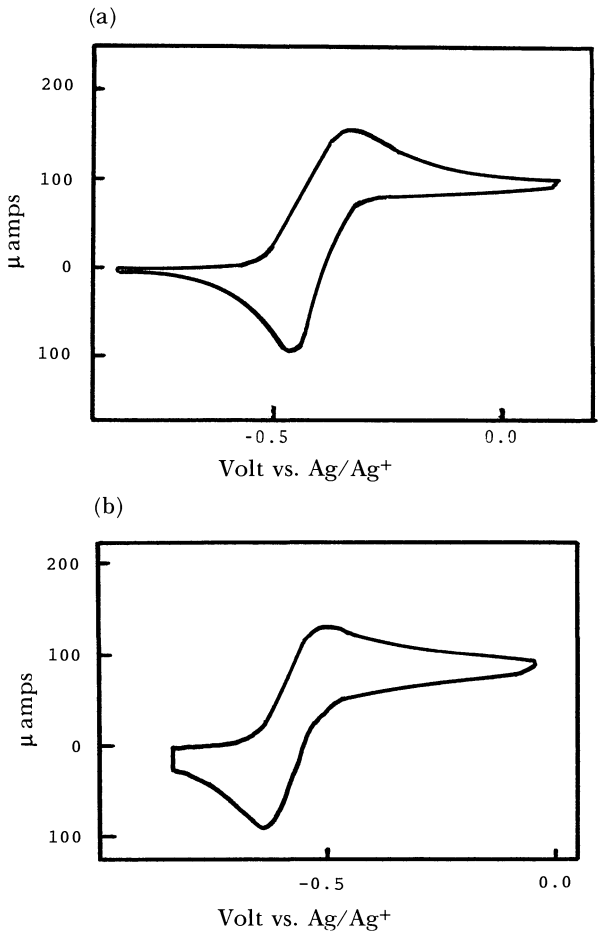

Fig. 1. Cyclic voltammograph of a) $[Co(tip(b))]^{2+}$ and b) $[Co(tip(b)(py)]^{2+}$. Scan rate 50 mV^{-1}. E versus Ag/Ag^+. Counter anion: ClO_4^- in MeCN.

Table 1. Redox Potentials of $[Co(tip(b))(base)]^{2+}$ Complexes[a)]

Base	pK_a	$E_{1/2}$/V vs. Ag/AgCl
Pyridine	5.27	−0.51
Piperidine	11.3	−0.54
1-Methylimidazole	7.25	−0.65
Butylamine	10.61	−0.66

a) Conditions: $[tip(b)]=[Co(ClO_4)_2]=3$ mM; [Base]= 15 mM; $[Bu_4NClO_4]=0.1$ M in MeCN at 27 °C.

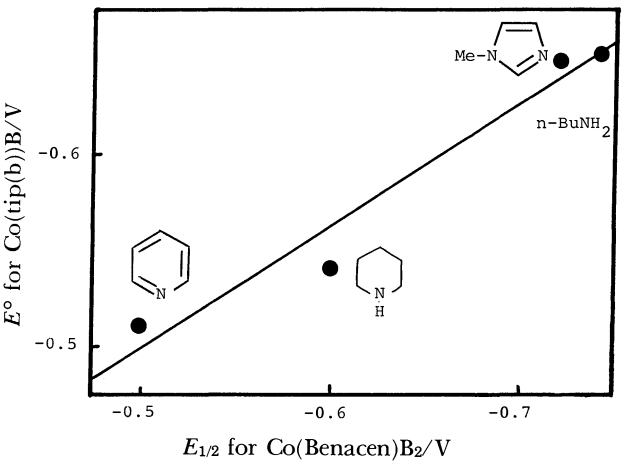

Fig. 2. Correlation of $E_{1/2}$ for $[Co(tip(b))(B)]^{2+}$ with that for $Co(benacen)B_2$. $[Co(tip(b))^{2+}]=3$ mM; [B]= 15 mM; $[Bu_4NClO]_4=0.1$ M in MeCN at 27 °C.

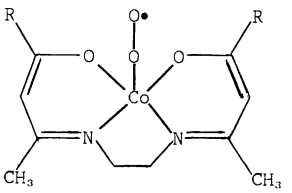
$E_{1/2}$ values and pK_a values of bases, probably because piperidine, a secondary cyclic amine, is sterically hindered and N-methylimidazole is a good π-electron donating base. In Fig. 2 is shown a plot of the redox potentials of $[Co(tip(b))]^{2+}$ vs. those of Co(benacen) complex, [N,N'-ethylenebis(3-imino-1-phenyl-1-butanonato)]cobalt(II), in the presence of various bases.[16] The $E_{1/2}$ values of $[Co(tip(b))(B)]^{2+}$ (B=base) are linearly related to those of $Co(benacen)(B)_2$ with a



R = Ph: $Co(benacen)(O_2)$

R = Me: $Co(acacen)(O_2)$

slope of 0.66. The slope close to 0.5 is simply interpreted by considering that the latter has one more additional base than the former. Figure 3 shows a plot of the absorbance against cobalt nitrate concentrations under an atmosphere of dioxygen gas in acetonitrile, keeping the concentration of tip(b) fixed. A nearly linear correlation up to a 1:1 molar ratio of cobalt nitrate to the chelate demonstrates that the chelate and cobalt ion form a 1:1 complex.

In our preliminary report, it was established that addition of dioxygen to $[Co(tip(a))]^{2+}$ in acetonitrile is apparently reversible since a stream of nitrogen bubbling into the solution at ambident temperature resulted in the disappearance of its original red color characteristic of the $[Co(tip(O_2)]^{2+}$ complex.[11] Subsequent bubbling of oxygen through the solution restored the red color and, hence, the complex was formulated as a mononuclear superoxocobalt(III) complex. The elemantal analysis for $[Co(tip(a)(O_2)]^{2+}\cdot 2NO_3^-$ supports the validity of the proposed

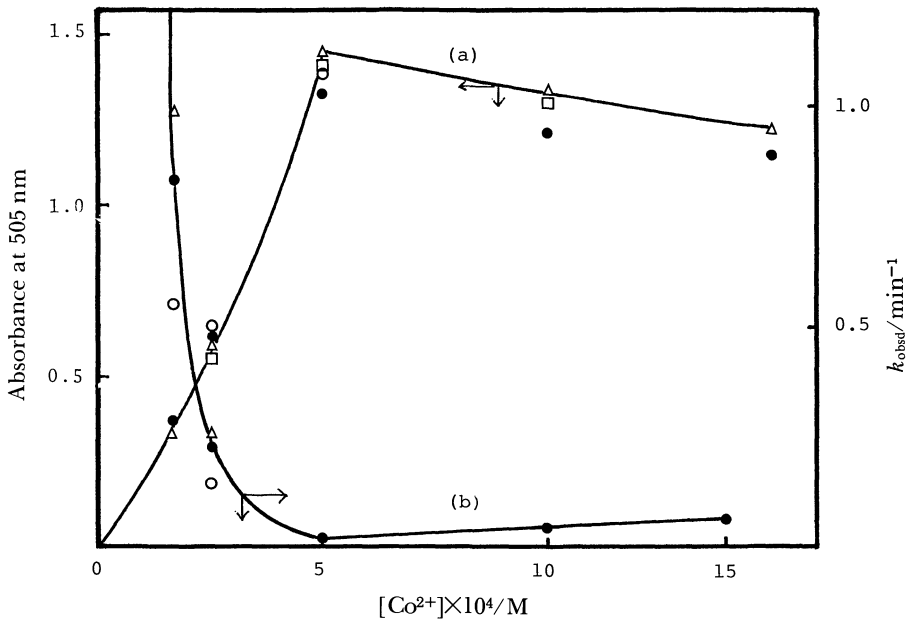


Fig. 3. Effects of altering concentrations of $Co(NO_3)_2$ on the formation (a) and disappearance (b) of $[Co(tip)(O_2)]^{2+}$ complexes under oxygen in $MeNO_2$ at 25 °C, the tip concentration being fixed constant at 0.5 mM. ○: tip(a); △: tip(b); □: tip(c); ●: tip(e).

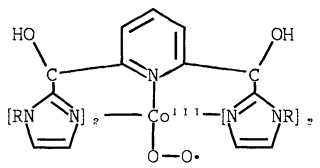

$[Co(tip)(O_2)]^{2+}$

structure.

The apparent extinction coefficient at 505 nm of the superoxocobalt complex thus formed is ε=1.4×10^3 and 1.9×10^3 M^{-1} cm^{-1} in acetonitrile and water, respectively, but the observed small reversible oxygen binding constant (log K_{O_2} mm^{-1}=−4.1, −4.0, and −3.9 in water, acetonitrile, and nitromethane, respectively, at 20 °C) indicates that only a portion of $[Co(tip(b))]^{2+}$ is oxygenated in solution; hence, the real extinction coefficient is ε=2.5×10^4 in water. The K_{O_2} value is roughly the same in magnitude as that of Co(benacen) (py) in toluene (log K_{O_2}=−1.36 mm^{-1} at −31 °C; −4.4 at 20 °C (extrapolated))[16] and nearly 3-order of magnitude smaller than that of Co(salen) (py) (log K_{O_2}=−1.05, 20 °C).[17] The comparable oxygen-binding stabilities for $[Co(tip)]^{2+}$ and Co(benacen) (py) reflect a similarity in their reducing ability; $E_{1/2}$=−0.51 V for $[Co(tip)(py)]^{2+}$ and −0.50 V (vs. SCE) for Co(benacen) $(py)_2$.[18]

The immediate formation of the superoxocobalt complex was observed as soon as $Co(NO_3)_2$ was added to an oxygen-saturated solution of a tip ligand, then followed by its slow disappearance. In Fig. 3 a plot of rate constants for the disappearance of absorbance at 505 nm in nitromethane is also displayed, showing that the rate is significantly dependent on changing

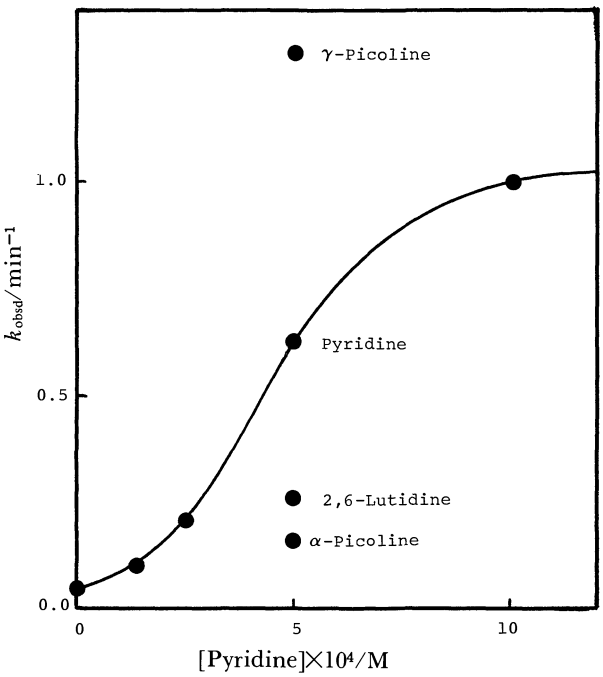

Fig. 4. Effect of changing concentrations of pyridine bases on the rate of disappearance of $[Co(tip(c))(O_2)]^{2+}$ under oxygen in $MeNO_2$ at 25 °C. [tip(c)]=[$Co(NO_3)_2$]= 0.5 mM.

concentrations of the metal ion. In particular, the use of a large excess of the chelate vs. metal ion causes rapid loss of the superoxocobalt complex. This is interpreted as due to interception of $[Co(tip(b))]^{2+}$ by free imidazolyl chelate (tip(b)) to make a new stable

$[Co(tip(b))]^{2+}$–tip(b) adduct. In fact, as one can see in Fig. 4, a simple base, pyridine or *N*-methylimidazole (Meim), was also found to bring about facile disappearance of the superoxo complex to form the $[Co(tip)]^{2+}$–base complex. In order to confirm this interpretation, we performed product analysis using tip(a) as the ligand under two extreme conditions; without added pyridine (or 1-methylimidazole) the reaction produced a slightly pink-colored solid, which evolved gas when heated to >150 °C (140 °C) in a capilary tube, while, addition of a large excess of pyridine (Meim) afforded a white solid which melted out at 258—265 °C (235—240 °C) without gas evolution and, when dissolved in solvents, exhibited at 505 nm an absorption band characteristic of the superoxo complex. These observations strongly support that the former is the dimer $[Co_2(tip(a))_2(O)_2]^{4+}$ and the latter is the adduct [Co(tip(a)) (B)]$^{2+}$. When the former was reacted with excess pyridine or when the latter was dissolved in nitromethane under oxygen, the $[Co(tip)]^{2+}$ was present as a mixture of $[Co_2(tip)_2(O_2)]^{4+}$ and [Co(tip) (B)]$^{2+}$ in either case. Thus, they are interconvertible with each other. However, the equilibrium below lies so far to the left.

$$[Co_2(tip)_2(O_2)]^{4+} + 2B \rightleftharpoons 2[Co(tip)(B)]^{2+} + O_2$$

The rate of disappearance of the superoxocobalt complex itself is strongly solvent-dependent, and the kinetic orders with regard to the complex concentrations are changing from zero-order in THF to first-order in acetone, dichloromethane, nitromethane, and *t*-butyl alcohol (the rate increases along this solvent series), and to second-order in ethyl acetate, chlorobenzene, benzene, *o*-tolunitrile, nitrobenzene, benzonitrile, acetonitrile, and 1,2-dimethoxyethane (the rate increases in this order) (Fig. 5). As can be seen in, for example, Fig. 6, we could find no simple relationship between initial rates and any solvent properties like dielectric constant, steric bulkiness, polarity, donor number, and degree of oxygen saturation etc., which we could not determine. The irregularlity might be due to involvement of several comparable equilibria, which contribute to the overall rate in a complicated way. However, in contrast to the suggestion by Martell and co-wokers that Co(benacen) and Co(porphyrin) superoxo complexes are more favored in nonpolar solvents such as toluene, the $[Co(tip)]^{2+}$ and O_2 1:1 complex is destabilized either in low or highly polar solvents. Furthermore, this $[Co(tip)]^{2+}$–O_2 system is very interesting, since it can exist even in an aqueous solvent; to date, no superoxocobalt(III) complexes in aqueous solution at room temperature have been reported in the literature.[2,19]

In the meantime, the superoxo complex [(Co(tip(a)) $(O_2)]^{2+}$ in the solid state was dark-red and so stable toward deoxygenation at room temperature even

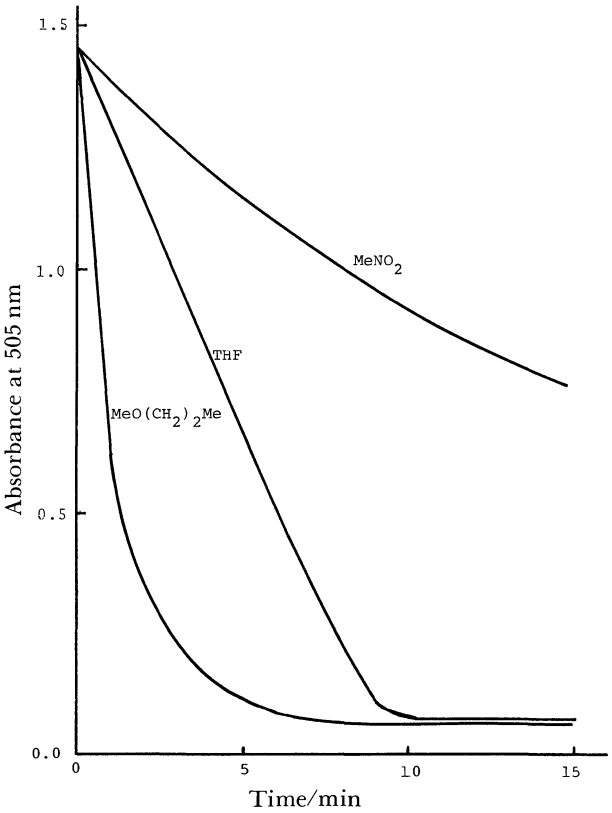

Fig. 5. Time courses of disappearance of absorption due to $[Co(tip(c))(O_2)]^{2+}$ in various solvents. [tip(c)]= $[Co(NO_3)_2]$=0.5 mM.

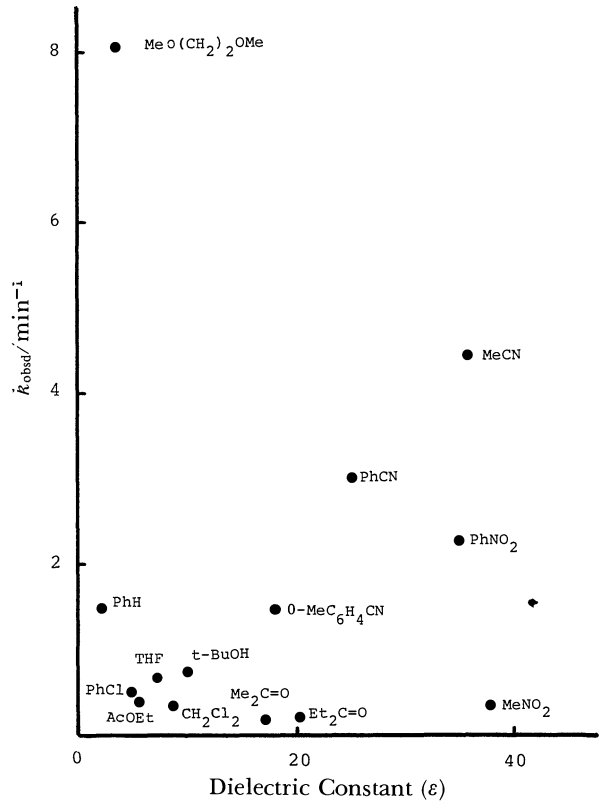

Fig. 6. Influence of solvent change on rate of disappearance of $[Co(tip(c))(O_2)]^{2+}$. Counter anion: NO_3^-.

under a reduced pressure (1 mmHg). However, heating it for one hour at 140 °C in vacuo results in loss of the color. Upon its exposure to air at room temperature for one day the decolorized complex takes up dioxygen and the original red color is restored. Thus, addition of oxygen to the cobalt-tip(a) complex is apparently reversible. In the reported case of brown-colored oxygenated Co(salen),[20] heating it at 100 °C forms red solids. As is revealed by Table 2, the shorter the ligand alkyl-chain length, the higher is the decolorization temperature and the melting point of the superoxo complex. This follows the same order as the melting points of the ligands themselves. The extent of recovery of $[Co(tip(a))(O_2)]^{2+}$ complex was measured at 505 nm to be 54% on each deoxygenation–oxygenation cycle. This recovery extent is almost the same both in the solid and liquid states.

Figure 7 displays the ESR spectrum of $[Co(tip(a))(O_2)](NO_3)_2$ in the solid state at liquid nitrogen temperature, where eight equivalent hyperfine-splitting signals with low intensity due to ^{59}Co (I=7/2) can be observed. Just analogous spectral patterns were reported for Co(acacen) (py) (O_2)[21] in a toluene matrix at −58 °C and $[Co(CN)_5(O_2)]^{3-}$.[22] $Co(NO_3)_2$ and $[Co(tip(a))(py)]NO_3)_2$ exhibited no ESR signals owing probably to their electron configurations of high spin states.

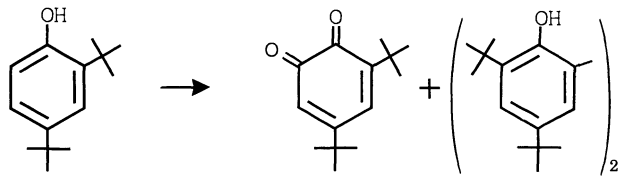
Conditions: 2,4-di-t-butylphenol 1 mmol; solvent 50mL; under O_2 at room temperature. a) tip(b) 0.025 mmol; $Co(ClO_4)_2$ 0.025 mmol. b) tip(b) 0.1 mmol; $Co(ClO_4)_2$ 0.1 mmol. c) $Co(NO_3)_2$ was used. d) A blank denotes that a yield was not determined. e) tip(b) 0.2 mmol; $Co(NO_3)_2$ 0.2 mmol; the phenol 1 mmol under N_2.

phenols; for instance, 2,4-di-*t*-butylphenol was selectively oxidized with Co(salen) catalyst to the corresponding quinone in DMF and to 3,3′,5,5′-tetra-*t*-butyl-1,1′-biphenyl-2,2′-diol (biphenyl-2,2′-diol) in dichloromethane or methanol.[23,24] In the present study the $[Co(tip(b))]^{2+}$ complex was tested as catalyst for oxygenations of two typical phenols.

The reaction of 2,4-di-*t*-butylphenol catalytically gave rise to 3,5-di-*t*-butyl-*o*-benzoquinone (*o*-BQ) together with biphenyl-2,2′-diol, irrespective of the nature of used solvents (Table 3), without accompanying oxidative cleavage of the aromatic ring as with $MnCl_2$.[25] However, the yield was largely dependent on the solvent employed; generally, nonpolar solvents



are least effective. Highly polar solvents such as methanol or *N*,*N*-dimethylformamide led to poorer yields than moderately polar solvents such as nitromethane, acetone, or acetonitrile This seems to reflect an absolutely low concentration of the reaction-triggering superoxocobalt complexes in those solvents, probably because a $[Co(tip(b))]^{2+}$–solvent adduct rather than the superoxo complex predominantly exists, such as was observed when basic pyridines were added. As a result, a poorer yield of the *o*-BQ was obtained.

$$[Co(tip(b))(O_2)]^{2+} \underset{+B}{\overset{+O_2}{\rightleftharpoons}} [Co(tip(b))B]^{2+}$$

B: base

As is demonstrated in the same table or Fig. 8, the dimeric μ-peroxo complex retains considerable activity under the identical conditions although it is less effective than the in situ generated oxygen complex. This is because, even if the μ-peroxo species itself is inactive, the active superoxo species is produced from it according to the back-reaction of the equilibrium below.

$$[Co(tip(b))(O_2)]^{2+} + [Co(tip(b))(S)]^{2+} \rightleftharpoons [Co_2(tip(b))_2(O_2)]^{4+} + S$$

S: solvent

The following tentative mechanism, being consistent with the above observations and reported literature results, completes the sequence of events, where LCo denotes chelated cobalts, H-PH a di-*t*-butylphenol, and PH· and PH^- a phenoxyl radical and phenolate ion, respectively.

$$LCo^{II} + O_2 \rightleftharpoons \underset{[I]}{LCo^{III}O_2^-} \rightleftharpoons LCo^{III}\text{-}OO\text{-}Co^{III}L \quad (1)$$

III $\xrightarrow{\text{slow}}$  $+ LCo^{III}OH^-$ (7)

$2\cdot PH \longrightarrow$  (8)

At first, the reaction sequence appears to be triggered by abstraction of the hydrogen atom of the phenol by the superoxocobalt complex yielding the hydrogenperoxocobalt complex (Eq. 2), which decomposes to yield a hydroxocobalt complex and oxygen (Eq. 3). Then, the hydroxo complex abstracts the proton from the phenol to form the phenolato LCo^{III} complex (II) with resonance forms II_r and II_i (Eqs. 4 and 5); the ionic form (II_i) would be favored in polar solvents such as acetonitrile and acetone to eventually produce *o*-BQ by reacting with molecular oxygen in its ortho-position (Eq. 6 followed by Eq. 7), while the radicalish form (II_r), which is expected to be favored in nonpolar solvents, is thought to be in equilibrium with the phenoxyl free radical (Eq. 5). The increasing stability of the phenolato complex in a polar solvent, accordingly, resulted in a higher proportion of the quinone vs. the radical coupling product, biphenyl-2,2′-diol, and vice versa in nonpolar solvents, as was observed. A similar metal–phenolate interaction has been proposed by Nishinaga[26] and Que[27] for an explanation of quinone formations.

Nishinaga et al. have kinetically studied the closely related oxidation in detail using 4-substituted 2,6-di-*t*-butylphenol and Co(salpr) and have proposed a similar mechanism which involves a fast superoxo complex formation followed by the rate-determining phenolic hydrogen atom abstraction (Eqs. 1 and 2).[23] A comparison of kinetic curves (a) and (b) in Fig. 8 shows, however, that the conversion of 2,4-di-*t*-butylphenol to *o*-BQ continued to increase linearly with time up to 80% completion, while the superoxo-

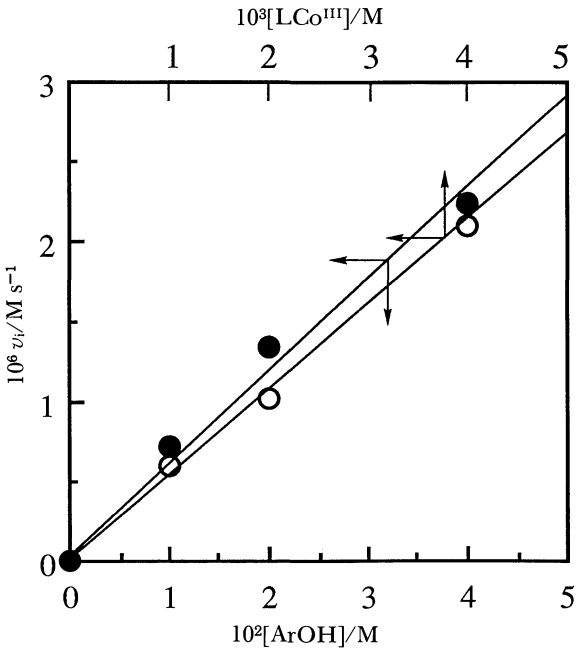

Fig. 9. Plots of initial rates (v_i) vs. initial concentrations of $[Co(tip(b))]^{2+}$ and 2,4-di-*t*-butylphenol (ArOH) concentrations with constant concentrations of the phenol (2.0×10^{-2} M) and $[Co(tip(b))]^{2+}$ (2.0×10^{-3} M) in Me_2CO under oxygen.

cobalt had completely disappeared early in the course of the reaction. It is evident that the present reaction does not involve hydrogen atom abstraction by the superoxide as rate-determining. Meanwhile, as Fig. 9 shows, the initial rates, which were calculated from a slope at time zero in an absorbance–time profile, were proportional to the added catalyst and phenol concentrations and dependent on the exerted oxygen pressure over the solution. Because of the complexity of the present system, no quantitative description of the concentration-dependency of the rate is attempted. In order to explain these results only qualitatively, therefore, we presents two assumptions that (1) the decomposition of III to *o*-BQ is virtually rate-determining and (2) the hydroxocobalt complex ($LCoOH^-$) plays an important role as a limiting intermediate species in a catalytic cycle (Eqs. 4, 5, 6, and 7); the aforementioned finding that the amount of produced *o*-BQ increased linearly with reaction time evidences that the steady state is reached and thus the steady-state concentrations of the hydroxo complex and III must be kept constant during the course of the reaction. Since catalytic levels of III as well as the hydroxo complex or its precursor would rise with the increasing concentrations of the phenol, metal catalyst, and dissolved oxygen, the overall rate would increase accordingly, as was observed.

Meanwhile, product analysis for the catalytic oxygenation of 2,6-di-*t*-butylphenol,[28] yielding 2,6-di-*t*-butyl-*p*-benzoquinone (*p*-BQ) and a diphenoquinone

Table 4. Oxygenation of 2,6-Di-*t*-butylphenol (±2% error in yield)[a)]

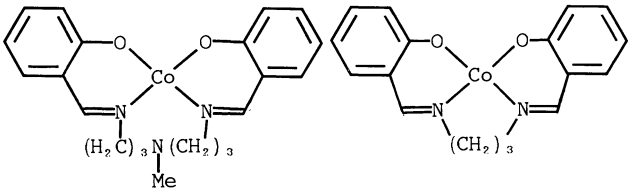
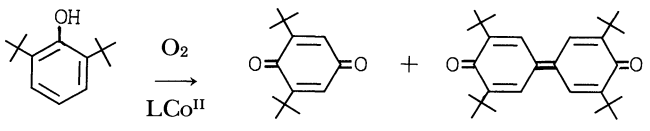
a) Conditions: substrate 0.5 mmol; catalyst 0.05 mmol in 25 ml solvent under an oxygen atmosphere at room temperature. NMesalpr: *N*,*N*′-disalicylidene-4-methyl-4-azaheptane-1,7-diamine; Salpn: *N*,*N*′-disalicylidene-1,3-propanediamine.



(DPQ),[29)] is somewhat instructive to implicate the reaction mechanism. The results obtained in this work are compared with reported literature data, which are also included in Table 4. Complete interpretation for these results is still rather difficult owing to a lack of available data. However, the mechanism analogous to that for 2,4-di-*t*-butylphenol seems most plausible; the reaction proceeds either via a radical pathway including a phenoxyl radical or via an ionic pathway involving the phenolato LCo^{III} complex.[30)] Several points about Table 4 are noteworthy; as with the case of 2,4-di-*t*-butylphenol, generally, use of polar solvents such as nitromethane and acetonitrile gave rise to better total yields and



(*p*-BQ) (DPQ)

preferred formation of *p*-BQ over DPQ, since polar solvents would enhance the production of the metal-complexed phenolate [II_i] and hence would increase the contribution of the ionic process. Replacement of the alkyl group in the imidazolyl ligand with an electron-withdrawing methoxymethyl group diminishes the reducing ability of the central Co^{II} toward a phenoxyl radical, resulting in a higher yield of DPQ vs. *p*-BQ.[31)]

In conclusion, the pyridyl ligand symmetrically substituted with four imidazolyl groups stoichiometrically binds Co^{2+} ion at a 1:1 ratio to form $[Co(tip)]^{2+}$, which then immediately takes up molecular oxygen to form the cobalt-dioxygen complex entirely stable in the solid state and enough stable below −30 °C in solution. As is visualized by the CPK space filling molecular model, $[Co(tip)]^{2+}$ adopts a loose square-pyramidal geometry; ineffective interaction between the four equivalent imidazolyl nitrogen lone-pairs and the central metal cation causes elongation of the Co–N(py) bond to reduce the fifth coordination of the pyridyl nitrogen to the metal ion, which coordination appears to be a necessary prerequisite of oxygen fixation. In accord with this inference, the catalytic behavior of $[Co(tip)]^{2+}$ differs greatly from those of tetra-coordinated Co(salen) in non-coordinating solvents and penta-coordinate Co(salpr), which selectively afford biphenyl-2,2′-diol and the *o*-quinone, respectively (Table 3). Thus, the catalytic behavior of $[Co(tip)]^{2+}$ becomes intermediate between them. The present cobalt oxygen complex is unique in structure among oxygen complexes because it possesses four equal imidazolyl groups as peripheral ligands. However, it should be born in mind that our structural assignment is based on an only limited data. The O–O streching frequencies of cobalt oxygen adduct has been the focus of recent studies since it is a measure of electron donating ability of the chelate. Therefore, resonance Raman or IR studies are under investigation for a detailed characterization of the Co–O and O–O bonding. The results will be published in the near future.

(Received June 21, 1990)

A simple and practical synthetic route has been developed for the synthesis of a chiral α-(aminooxy) ester (*S*)-**16**, which is a synthetic intermediate for a potent antipseudomonal cephalosporin antibiotic M-14659. In this synthetic route, the key intermediate is α-hydroxy acid (*R*)-**7** (100%ee), which is prepared by an asymmetric reduction of α-keto ester with $NaBH_4$-(*R*,*R*)-tartaric acid followed by a hydrolysis and an optical resolution using L-Leu-$NHNH_2$. (*S*)-**16** is obtained stereoselectively through 3 steps from (*R*)-**7**. HPLC analyses and NMR studies have proved that the (*S*)-**16** thus prepared is completely optically pure.

Although α-(aminooxy) acid derivatives **1** are regarded as analogues of α-amino acids, there have been very few studies concerning the synthesis of optically active **1**[2]. α-(Aminooxy) esters of structure **2** were required as synthetic intermediates for M-14659 (**3**),[3] which is a potent antipseudomonal cephalosporin antibiotic. In the preceding report[1] we have shown that optically active α-(aminooxy) ester (*S*)-**4** can be prepared from α-(phthalimidooxy) acid (*S*)-**5** which is obtained by optical resolution.

In search for a simpler and more practical synthetic route to α-(aminooxy) esters of structure **2**, we turned our attention to the following facts found in the course of investigations previously reported:[1] (1) α-hydroxy acid (*R*)-**7** in nearly 100%ee is obtainable by an optical resolution using L-Leu-$NHNH_2$ (Eq. 1), and accordingly, we can use (*R*)-**7** as a chiral starting material; (2) although, as previously described, attempts to obtain optically active 2-halo derivatives (*R*)-**6** were unsuccessful due to the presence of an electron-donating group at the para position, an S_N2 reaction itself at the benzylic position proceeds with virtually complete inversion of configuration (Eq. 2).

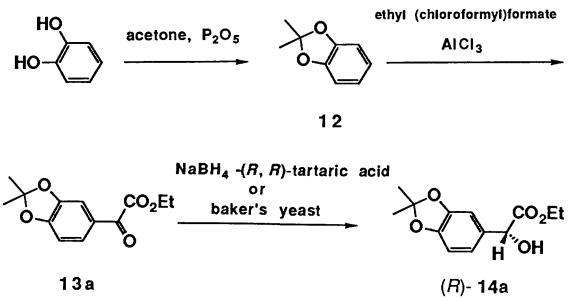
R: a protecting group

Namely, it appeared to us that α-(phthalimidooxy) ester (*S*)-**11** could be prepared from α-hydroxy acid (*R*)-**10** with a steric inversion under appropriate conditions (Eq. 3). In addition, tedious operations involved in the recovery of the undesired enantiomer and its racemization might be omitted in this approach. In this paper, we report some details of this synthetic strategy.

Results and Discussion

We have already shown two synthetic sequences to racemic **7** starting from catechol[1] and, as described above, (*R*)-**7** is obtainable by optical resolution of racemic **7**.[1] On the other hand, however, one of the most convenient methods for the preparation of optically active α-hydroxy esters is asymmetric reduction of their corresponding α-keto esters. Consequently, an asymmetric reduction of α-keto ester **13a** was first explored in order to obtain ethyl (*R*)-2-(3,4-isopropylidenedioxyphenyl)-2-hydroxyacetate [(*R*)-**14a**] (Scheme 1). Starting material **13a** was prepared by the method shown in Scheme 1.



Scheme 1.

An isopropylidenation of catechol in toluene by using acetone in the presence of phosphorus pentaoxide gave 1,2-isopropylidenedioxybenzene (**12**) in 70% yield. α-Keto ester **13a** was prepared by the Friedel–Crafts acylation[4] of **12** with ethyl (chloroformyl)formate in 86% yield without cleavage of isopropylidene protection.[5]

Asymmetric reduction of α-keto esters has been widely studied. One of them utilizes chiral reducing agents[6] and another is a catalytic hydrogenation in the presence of chiral ligands.[7] Although high optical purities are obtained in these cases, neither the chiral reducing agents nor hydrogenation catalysts are necessarily easily accessible. Also, diastereoselective reductions of chiral α-keto amides or α-keto esters with metal hydrides have been well documented.[8] However, because these methods are of multi-step process, they do not fill our requirements for the practical preparation of (*R*)-**14a**. On the other hand, asymmetric reductions of prochiral ketones and cyclic imines with chiral $NaBH_4$ derived systems which are prepared by a reaction of $NaBH_4$ with a monosaccharide[9] or with an α-amino acid derivative (especially L-Pro derivative),[10] have been investigated actively. Although these methods result in moderate optical purities, their simple systems seem applicable to our needs which aim at a more efficient and economical synthetic method for (*R*)-**14a**. Accordingly, we focused

Table 1. Asymmetric Reduction of **13a** with Modified Reagents Prepared from $NaBH_4$ and Various Chiral Compounds[a]

10	(*R*,*R*)-Diethyl tartarate	c)	0

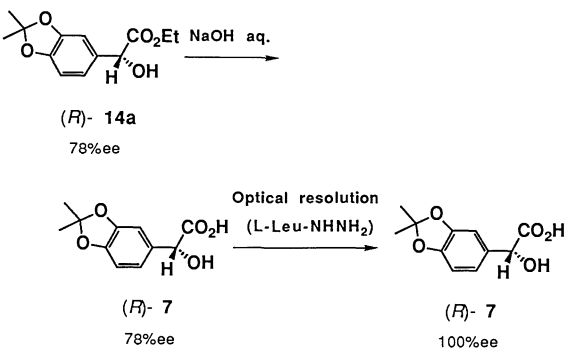
a) Reaction conditions: A solution of **13a** (1.0 mmol) in THF (5 ml) was added at 0 °C to a stirred suspension of chiral reducing agent prepared from $NaBH_4$ (1.0 mmol) and a chiral compound (1.0 mmol) in THF (5 ml) at room temperature for 3 h; the whole was then stirred at 0 °C for 1 d. b) See Ref. 10(e). c) Not estimated. d) Assayed by HPLC analysis using a chiral column. See Experimental Section.

on the asymmetric reduction of **13a** by using chiral $NaBH_4$ derived systems prepared in situ. Reductions of **13a** with reagents prepared in situ from $NaBH_4$ (1.0 equiv) and various chiral compounds (1.0 equiv) were carried out in THF at 0 °C (Table 1).

As can be seen in Table 1, the system derived from $NaBH_4$ and (*R*,*R*)-tartaric acid provided (*R*)-**14a** with an enantiomeric excess as high as 70% (Run 2, Table 1). The optical purity in this system was enhanced to 78%ee by using 1.5 equiv of (*R*,*R*)-tartaric acid and lowering the reaction temperature to −20 °C.[11] The chiral reducing agents derived from L-Pro (Run 1, Table 1) and its derivatives (Runs 3 and 4, Table 1) were found to be less effective. The asymmetric reduction of propiophenone with the reagent prepared from $NaBH_4$ and (*S*,*S*)-tartaric acid has already been reported, which, however, gives (*S*)-1-phenyl-1-propanol in only 10% optical yield.[12] Interestingly, the systems using other chiral α-hydroxy acids were found to be much less effective (Runs 6, 7, and 8, Table 1). Also, in the case where either a hydroxyl group or a carboxyl group of (*R*,*R*)-tartaric acid was protected, the stereoselectivities were completely out of operation (Runs 9 and 10, Table 1). Presumably, the steric configuration in the chelation between $NaBH_4$ and bidentate (*R*,*R*)-tartaric acid exerts and effect on the course of the hydride-transfer step in the transition state.

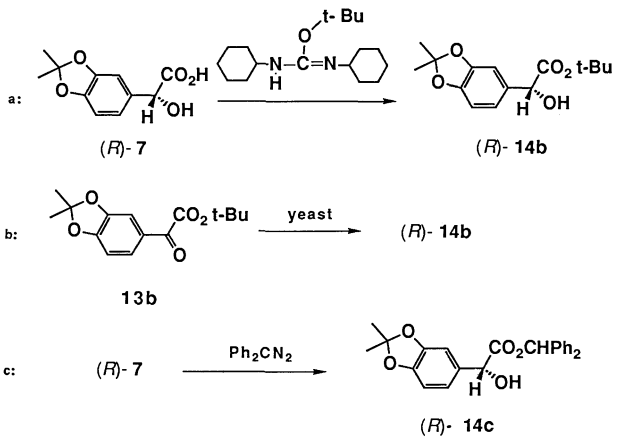
Asymmetric reductions of keto esters to hydroxy esters by microbial transformation have also been widely studied.[13] Consequently, we undertook a study aiming at an asymmetric reduction of **13a** by using a yeast. A reduction of **13a** with baker's yeast in water containing sucrose gave (*R*)-**14a** in 94%ee optical yield (65% chemical yield). The absolute configuration of the product obtained by reduction of a carbonyl group containing a large group and a small group to an alcohol is known to be determined by application of Prelog's rule.[14] Because 3,4-isopropylidenedioxyphenyl group is larger than ethoxycarbonyl group in bulkiness, the absolute configuration of **14a** obtained by yeast reduction is expected to be an (*R*)-configuration. Furthermore, **14a** obtained by yeast reduction showed a Cotton effect $[\theta]_{241}=-14900$ ($c=2.64\times10^{-4}$ M, 17 °C) (1 M=1 mol dm^{-3}). It has been reported that the sign of Cotton effect in the low-wavelength region is negative for the aromatic chromophere of (*R*)-mandelic acid esters.[15] Therefore, it is concluded that **14a** obtained by yeast reduction has an (*R*)-configuration. The absolute configuration of the products in Table 1 was determined by a comparison with (*R*)-**14a** obtained by yeast reduction in HPLC analysis using a chiral column.

A treatment of (*R*)-**14a** (78%ee) with NaOH in aq MeOH gave (*R*)-**7** quantitatively (Scheme 2). The optical purity of the obtained (*R*)-**7** proved that none of (*R*)-**7** racemized in the course of the alkaline hydrolysis. The obtained (*R*)-**7** was treated with L-Leu–$NHNH_2$ in aq MeOH and subjected to a pH adjustment with H_2SO_4 aq to give a diastereomer salt, which was recrystallized by pH adjustment to afford a purified diastereomer salt [100%ee as (*R*)-**7**]. Subsequently acidification of the diastereomer salt followed by crystallization gave (*R*)-**7** (100%ee) in 75% chemical yield from (*R*)-**14a** (Scheme 2).[16] The optical purity of (*R*)-**7** was confirmed by HPLC analysis of a diastereomer prepared from (*R*)-**7** and L-Leu-OMe. Thus, (*R*)-**7** was coupled with L-Leu-OMe by using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (WSC·HCl) and 1-hydroxybenzotriazole (HOBt) to give *N*-[2-(3,4-isopropylidenedioxyphenyl)-2-hydroxyacetyl]-L-Leu-OMe. The optical purity determined by the diastereomer was in accord with that determined by the assay of the enantiomer.



Scheme 2.

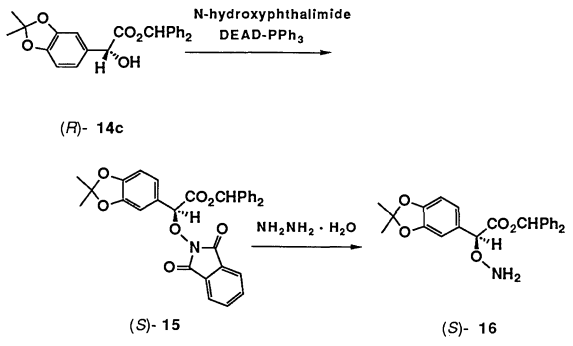
As previously described, the protective group R_3 in a compound of structure **2** should be removable under conditions in which β-lactam ring is stable. Although *t*-butyl group seemed to be suitable for R_3, attempts to obtain α-hydroxy *t*-butyl ester (*R*)-**14b** in both chemically and optically high yield were unsuccessful. Namely, an initial attempt to treat (*R*)-**7** with *O*-*t*-butyl-*N*,*N*′-dicyclohexylisourea[17] gave (*R*)-**14b** in 72% yield even in using 5.0 equiv of the alkylating agent (Scheme 3a). Also, an asymmetric reduction of *t*-butyl



Scheme 3.

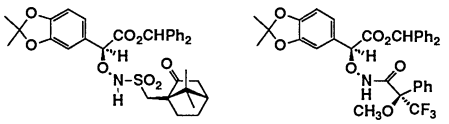
ester of α-keto acid **13b** by using baker's yeast gave (*R*)-**14b** in 87%ee (Scheme 3b).[18] Consequently, we chose a diphenylmethyl group as the protective group R_3. A treatment of (*R*)-**7** with Ph_2CN_2 in AcOEt gave diphenylmethyl ester of α-hydroxy acid (*R*)-**14c** quantitatively (Scheme 3c). No decrease in optical purity was observed in this esterification.

The Mitsunobu reaction has proven to be a useful and practical method for conversion of alcohols to various derivatives.[19] Especially it is known that the reaction proceeds with virtually complete inversion of configuration.[20] Accordingly, we made a study on an application of the Mitsunobu reaction to the conversion of (*R*)-**14c** into α-(phthalimidooxy) ester (*S*)-**15**. The reaction of alcohols with *N*-hydroxyphthalimide under the Mitsunobu conditions has been known.[21] An initial attempt to obtain (*S*)-**15** from (*R*)-**14c** (100%ee) by the treatment with *N*-hydroxyphthalimide in the presence of triphenylphosphine and diethyl azodicarboxylate in AcOEt at room temperature, gave (*S*)-**15** in only 30%ee optical purity and in 46% chemical yield. However, both the optical purity and chemical yield were enhanced to 99.4%ee and 95%, respectively, by carrying out the reaction at −20 °C and by minimizing the H_2O content in the reaction solution (Scheme 4). Because the pK_a value of *N*-hydroxyphthalimide is 6.91 in aqueous medium,[22] the rate-determining step of the whole Mitsunobu process may be the S_N2 step rather than the alcohol activation step.[20d] Actually the reaction followed the S_N2 kinetics, being first order in each of (*R*)-**14c** and *N*-hydroxyphthalimide. Attempts to detect phosphorus-containing intermediates, phosphoranes[23] or alkoxyphosphonium salts,[20d,24] by using HPLC analyses or ^{31}P NMR studies were unsuccessful.[25] A recrystallization of (*S*)-**15** (99.4%ee) from MeOH gave (*S*)-**15** (100%ee) as white crystals (isolated yield 86% from (*R*)-**14c**). It is important to run the Mitsunobu reaction under controlled conditions in order to obtain (*S*)-**15** (100%ee).



Scheme 4.

Finally, the removal of the phthalimido group by using hydrazine hydrate in CH_2Cl_2 gave (*S*)-**16** (100%ee) in 97% chemical yield (Scheme 4). Furthermore, it was confirmed by an HPLC analysis of the diastereomer prepared from (*S*)-**16** and (+)-10-camphorsulfonyl chloride. Thus, the obtained (*S*)-**16** was treated with (+)-10-camphorsulfonyl chloride in CH_3CN containing NEt_3 to give sulfoneamide (*S*)-**17**. The optical purity of the diastereomer was in accord with the enantiomer. It was also reconfirmed by ^1H NMR spectra of (*S*)-**17** and (+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionamide[26] ((*S*)-**18**) that the obtained (*S*)-**16** was completely free from (*R*)-enantiomer. The signals of the methylene proton at position 10 in (*S*)-**17** and the methyl proton of methoxyl group in (*S*)-**18** were usable to detect the (*R*)-enantiomer.



(*S*)-17 (*S*)-18

In conclusion, a simpler and more practical synthetic route for the chiral α-(aminooxy) ester (*S*)-**16** (100%ee) has been established. In this synthetic route, (*S*)-**16** was prepared through 3 steps from α-hydroxy acid (*R*)-**7** (100%ee), which was obtained by the asymmetric reduction of α-keto ester **13a** with $NaBH_4$-(*R*,*R*)-tartaric acid followed by a hydrolysis and an optical resolution using L-Leu-$NHNH_2$. The procedures described here have been used to prepare multikilogram batches of (*S*)-**16**, which is in turn converted to M-14659, a potent antipseudomonal cephalosporin antibiotic.

Experimental

General. All reactions except optical resolution were carried out under nitrogen atmosphere. Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. Melting points were determined using a Büchi 510 apparatus and are uncorrected. ^1H NMR spectra were obtained on a Varian VXR-300 (300 MHz) spectrometer with tetramethylsilane as the internal standard. IR spectra were obtained on a JASCO IR-800

or a Perkin–Elmer 1640 spectrometer in the indicated phase. Mass spectra were measured on a JEOL DX-300 mass spectrometer. Optical rotations were recorded on a JEOL DIP-140 polarimeter. Analytical thin-layer chromatography (TLC) was performed on Merck silica gel 60 F_{254} glass-backed plates. Column chromatography was done using Merck silica gel 60 (70—230 mesh). Chemical purities of the synthetic intermediates (accordingly, yields in each step) were determined by HPLC analysis. All compounds were assayed under the same conditions. The HPLC conditions and the retention times of all intermediates were tabulated in Table 2. Optical purities of enantiomeric intermediates were also determined by HPLC analysis using a chiral column. Some of optically active intermediates were converted to diastereomers whose optical purities were determined. The conditions were summarized in Table 3.

1,2-Isopropylidenedioxybenzene (12). A mixture of catechol (110 g, 1.0 mol) and P_2O_5 (28.4 g, 0.20 mol) in toluene (500 ml) was heated at 75 °C. To the suspension was added dropwise acetone (147 ml, 2.0 mol) over 3 h. After the addition had been started, four portions of P_2O_5 (28.4 g, 0.20 mol) were added to the reaction mixture every 30 min. Totally 142 g of P_2O_5 was used. After the addition of acetone, the mixture was stirred at 75 °C for further 1 h. After removing the oily compound (the lower layer), 150 ml of 25% NaOH was added. The organic layer was separated, washed with H_2O and concentrated in vacuo to give an oil, from which **12** was obtained by distillation as a colorless liquid: Yield 105 g (70%); bp 75—78 °C/23.5 mmHg (1 mmHg=133.322 Pa); ^{1}H NMR ($CDCl_3$) δ=1.65 (s, 6H) and 6.7—6.8 (m, 4H).

Ethyl 2-(3,4-Isopropylidenedioxyphenyl)-2-oxoacetate (13a). To a suspension of $AlCl_3$ (5.0 g, 37.5 mmol) in CH_2Cl_2 (30 ml) cooled to 5 °C was added slowly ethyl (chloroformyl)formate (3.41 g, 25.0 mmol) and the resulting solution was stirred for 15 min at 5 °C. To the solution was added **12** (3.75 g, 25.0 mmol) over 5 min. After the addition the mixture was stirred at room temperature for 1 h. The reaction mixture cooled to 5 °C was poured slowly into 25 ml of H_2O cooled to 5 °C. The organic layer was separated, washed (satd. $NaHCO_3$ and then H_2O), dried ($MgSO_4$), filtered and concentrated in vacuo to give a wine-red liquid, from which **13a** was obtained by distillation as a yellowish liquid: Yield 5.38 g (86%); bp 129—131 °C/0.65 mmHg; ^{1}H NMR ($CDCl_3$) δ=1.40 (t, 3H), 1.68 (s, 6H), 4.42 (q, 2H), 6.69 (d, 1H, *J*=11), 7.38 (d, 1H, *J*=2.5), and 7.55 (dd, 1H, *J*=11, 2.5); MS (FD) *m/z* 250 (M^+).

Ethyl (*R*)-2-(3,4-Isopropylidenedioxyphenyl)-2-hydroxyacetate [(*R*)-14a]. Reduction by $NaBH_4$-(*R*, *R*)-Tartaric Acid. $NaBH_4$ (1.26 g, purity 90%, 30.0 mmol) and (*R*,*R*)-tartaric acid (4.50 g, 30.0 mmol) were suspended in THF (100 ml) and the resulting suspension was heated at 70 °C for 4 h. The suspension cooled to −20 °C was added dropwise **13a** (5.0 g, 20.0 mmol) in 10 ml of THF over 5 min. After the addition, the reaction mixture was stirred at −20 °C for 15 h. To the mixture were added 50 ml of AcOEt and 25 ml of 1M (1 M=1 mol dm^{-3}) HCl at −20 °C. The organic layer was separated, washed (satd. $NaHCO_3$), dried ($MgSO_4$), filtered and concentrated in vacuo to give a pale yellow oil. Chromatographic separation on silica gel (30 g, hexane–AcOEt, 6:1 v/v) gave **14a** as an oil: Yield 4.74 g (94%, optical purity 78%ee); ^{1}H NMR ($CDCl_3$) δ=1.25 (t, 3H), 1.65 (s, 6H), 3.25 (b, 1H), 4.22 (m, 2H), 5.03 (s, 1H), 6.68 (d, 1H, *J*=10), 6.79 (d, 1H, *J*=2.5), and 6.82 (dd, 1H, *J*=10, 2.5); MS (FD) *m/z* 252 (M^+).

Reduction by $NaBH_4$-L-Pro. $NaBH_4$ (5.04 g, 90% purity, 120 mmol) and L-Pro (13.8 g, 120 mmol) were suspended in 240 ml of THF and the resulting suspension was stirred at room temperature for 3.5 h. To the resulting clear solution cooled to 0 °C was added **13a** (30.0 g, 120 mmol) in 30 ml of THF over 10 min and the mixture was stirred at 0 °C for 17.5 h. The solvent of the reaction mixture was removed in vacuo. The obtained oil was dissolved in toluene (120 ml) and H_2O (120 ml). The organic layer was separated, washed (H_2O), dried ($MgSO_4$), filtered and concentrated in vacuo to give **14a** as an oil: Yield 29.5 g (86% chemical purity, 84% yield, 52%ee). The NMR spectra were identical with those of **14a** prepared above.

Reduction by Yeast. A mixture of sucrose (15 g) and baker's yeast[27] (14 g) in 100 ml of distilled water was stirred

at 30 °C for 1 h. To the mixture was added **13a** (7.84 g, 31.4 mmol) and the fermenting suspension was stirred at 30 °C for another 22 h. The mixture was worked up by adding 3 g of Celite and filtering. The Celite was washed with 50 ml of AcOEt and then with 50 ml of H_2O. The washings were combined with the filtrate. The organic layer was separated and the aquesous layer was washed with AcOEt (30 ml×3). The combined AcOEt extracts were washed (brine), dried ($MgSO_4$), filtered and concentrated in vacuo to give an oil. Chlomatographic separation on silica gel (30 g, hexane–AcOEt, 6:1 v/v) gave **14a** as a pale yellow oil: Yield 5.14 g (65%, 94%ee). The NMR spectra were identical with those of **14a** prepared above.

(*R*)-2-(3,4-Isopropylidenedioxyphenyl)-2-hydroxyacetic Acid [(*R*)-7]. α-Hydroxy ester **14a** [56.3 g, chemical purity 88%, optical purity 76%ee, 173 mmol as (*R*)-**14a**] was dissolved in a mixture of MeOH (150 ml) and 48% NaOH (17 ml). The mixture was stirred at 30 °C for 1.5 h. To the mixture was added L-Leu-$NHNH_2$ (28.6 g, 197 mmol) in 150 ml of MeOH. An adjustment of pH to 6.8 with 95% H_2SO_4 followed by a crystallization with stirring at 28 °C for 2 h gave white crystals, which were recrystallized by a pH adjustment to give a diastereomer salt [58.7 g, 100%ee, 92% from (*R*)-**14a**]. The obtained salt was suspended in 300 ml of H_2O and the pH of the mixture was adjusted to 2.0 with 95% H_2SO_4. A crystallization with stirring at 33 °C for 3.5 h gave (*R*)-**7** as a white powder: Yield 30.7 g [optical purity 100%ee, 79% from (*R*)-**14a**]; mp 132—133 °C; $[\alpha]_D^{24}$ −88.7° (*c*=1.36, MeOH); ^1H NMR (Me_2SO-d_6) δ=1.61 (s, 6H), 3.3 (b, 1H), 4.85 (s, 1H), and 6.73—6.88 (m, 3H); IR(KBr) 1702 cm^{-1} (C=O). Found: C, 58.80; H, 5.63%. Calcd for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40%.

Optical Purity Determination of (*R*)-7 by HPLC Analysis of a Diastereomer Prepared from (*R*)-7 and L-Leu-OMe. A sample of (*R*)-**7** (0.224 g, 1.0 mmol) and L-Leu-OMe·HCl (0.272 g, 1.50 mmol) were suspended in 7 ml of CH_3CN containing NEt_3 (0.21 ml, 1.50 mmol). To the obtained clear solution cooled to 0 °C were added 1-hydroxybenzotriazole (0.177 g, 1.0 mmol) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (0.211 g, 1.10 mmol) and the reaction mixture was stirred at room temperature for another 2 h. Et_2O (15 ml) was added to the reaction mixture. The organic layer was separated and washed with 1 M HCl and then with saturated $NaHCO_3$. After dilution with an eluent, the organic layer was analyzed by HPLC under the conditions which are shown in Table 3.

Diphenylmethyl (*R*)-2-(3,4-Isopropylidenedioxyphenyl)-2-hydroxyacetate [(*R*)-14c]. α-Hydroxy acid (*R*)-**7** (22.4 g, 100 mmol, 100%ee) was suspended in 120 ml of AcOEt and to the suspension was added dropwise Ph_2CN_2 (20.4 g, 105 mmol) in 15 ml of CH_2Cl_2 over 1 h. During the addition the inner temperature was kept below 35 °C. After the addition, the reaction was stirred for another 1 h. After quenching the excess Ph_2CN_2 with AcOH, the reaction mixture was washed with saturated $NaHCO_3$. The organic layer was separated and concentrated in vacuo to give a white powder, which was recrystallized from EtOH to give (*R*)-**14c** as a white powder: Yield 35.9 g (92%, 100%ee); mp 136—136.5 °C; $[\alpha]_D^{22}$ −34.7° (*c*=0.944, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.65 (s, 6H), 5.15 (s, 1H), 6.84 (d, 1H, *J*=10), 6.88 (d, 1H, *J*=2.4), 6.92 (dd, 1H, *J*=10, 2.4), 6.94 (s, 1H), 6.99 (m, 2H), and 7.15—7.4 (m, 8H); IR(KBr) 1731 cm^{-1} (C=O); MS (FD) *m/z* 390 (M^+). Found: C, 73.79; H, 5.74%. Calcd for $C_{24}H_{22}O_5$: C, 73.83; H, 5.68%.

Diphenylmethyl (*S*)-2-(3,4-Isopropylidenedioxyphenyl)-2-(phthalimidooxy)acetate [(*S*)-15]. To a solution of (*R*)-**14c** (19.5 g, 50.0 mmol, 100%ee) in 200 ml of AcOEt were added triphenylphosphine (17.6 g, 67.0 mmol) and *N*-hydroxyphthalimide (9.79 g, 60.0 mmol). To the obtained suspension cooled to −20 °C was added diethyl azodicarboxylate (11.7 g, 67.0 mmol) in one mass. The reaction mixture was stirred at −20 °C for 1 h. The solvent was removed in vacuo. A recrystallization from 160 ml of MeOH at 5 °C gave (*S*)-**15a** as white crystals: Yield 23.0 g (86%, 100%ee); mp 117.5—118 °C; $[\alpha]_D^{22}$ +116.7° (*c*=1.30, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.65 (s, 6H), 5.29 (s, 1H), 6.66 (d, 1H, *J*=10), 6.92 (d, 1H, *J*=2.4), 6.97 (dd, 1H, *J*=10, 2.4), 6.99 (s, 1H), 7.1—7.35 (m, 10H), and 7.65—7.8 (m, 4H); IR(KBr) 1793, 1752, and 1734 cm^{-1} (C=O). Found: C, 71.49; H, 4.94; N, 2.51%. Calcd for $C_{32}H_{25}NO_7$: C, 71.76; H, 4.71; N, 2.62%.

Diphenylmethyl (*S*)-2-(3,4-Isopropylidenedioxyphenyl)-2-(aminooxy)acetate [(*S*)-16]. To a solution of (*S*)-**15** (16.1 g, 30.0 mmol, 100%ee) in 60 ml of CH_2Cl_2 was added NH_2NH_2·H_2O (3.60 g, 72.0 mmol). The mixture was stirred at room temperature for 1 h. H_2O (150 ml) was added to the reaction mixture and the resulting precipitates were removed by filtration. The organic layer of the filtrate was separated, washed (H_2O), dried ($MgSO_4$), filtered and concentrated in vacuo to give a white solid. A recrystallization from MeOH gave (*S*)-**16** as a white powder: Yield 11.8 g (97%, 100%ee); mp 96—97 °C; $[\alpha]_D^{24}$ +24.5° (*c*=0.669, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.66 (s, 6H), 5.22 (s, 1H), 6.66 (d, 1H, *J*=10), 6.75 (d, 1H, *J*=2.4), 6.81 (dd, 1H, *J*=10, 2.4), 6.92 (s, 1H), 7.07—7.11 (m, 2H), and 7.20—7.32 (m, 10H); IR(KBr) 1730 cm^{-1} (C=O); Found: C, 70.89; H, 5.60; N, 3.40%. Calcd for $C_{24}H_{23}NO_5$: C, 71.10; H, 5.72; N, 3.45%.

Diphenylmethyl (*S*)-2-(3,4-Isopropylidenedioxyphenyl)-2-[[(+)-10-camphorsulfonyl]aminooxy]acetate [(*S*)-17]. To a solution of (*S*)-**16** (81 mg, 0.20 mmol, 92.0%ee by HPLC analysis using a chiral column) in 2 ml of CH_3CN were added NEt_3 (0.056 ml, 0.40 mmol) and (+)-10-camphorsulfonyl chloride (100 mg, 0.40 mmol). The reaction mixture was stirred at room temperature for 1 h. The solvent was removed in vacuo to give an oil, which was dissolved in 20 ml of AcOEt. After washed with 1 M HCl aq, saturated $NaHCO_3$ and brine in this order, the organic layer was assayed by HPLC under the conditions which are shown in Table 3 to result in 92.3%ee. Racemic **16** was converted to racemic **17** by the method shown above. Each of (*S*)-**17** and (*R*)-**17** was isolated by preparative HPLC under the conditions shown in Table 3. (*S*)-**17**: ^1H NMR ($CDCl_3$) δ=0.94 (s, 3H), 1.00 (s, 3H), 1.67 (s, 3H), 1.68 (s, 3H), 1.87—2.14 (m, 6H), 2.41 (m, 1H), 2.89, 2.94, 3.81, and 3.86 (ABq, 2H, methylene proton at position 10), 5.58 (s, 1H), 6.68 (d, 1H, *J*=10), 6.77 (d, 1H, *J*=2.4), 6.84 (dd, 1H, *J*=10, 2.4), 6.88 (s, 1H), 7.07—7.11 (m, 2H), 7.18—7.30 (m, 8H), and 8.43 (s, 1H). (*R*)-**17**: ^1H NMR ($CDCl_3$) δ=0.90 (s, 3H), 0.95 (s, 3H), 1.665 (s, 3H), 1.662 (s, 3H), 1.90—2.20 (m, 6H), 2.41 (m, 1H), 2.79, 2.84, 3.70, and 3.75 (ABq, 2H, methylene proton at position 10), 5.61 (s, 1H), 6.63 (d, 1H, *J*=10), 6.76(d, 1H, *J*=2.4), 6.80 (dd, 1H, *J*=10, 2.4), 6.95 (s, 1H), 7.13—7.33 (m, 10H), and 9.12 (s, 1H).

Diphenylmethyl (*S*)-2-(3,4-Isopropylidenedioxyphenyl)-2-[[(2*R*)-3,3,3-trifluoro-2-methoxy-2-phenylpropionyl]aminooxy]acetate [(*S*)-18]. To a solution of (*S*)-**16** (203 mg, 0.50 mmol, 100%ee) in 5 ml of CH_3CN containing NEt_3 (0.075 ml, 0.60 mmol) was added (*R*)-(+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionyl chloride[29] (0.150 mg, 0.60 mmol). The reaction mixture was stirred at room temperature for 1 h. The solvent was removed in vacuo and the obtained oil was dissolved in 20 ml of Et_2O. The Et_2O solution was washed with 1 M HCl, saturated $NaHCO_3$ and brine in this order and then concentrated in vacuo to give an oil, which was analyzed by NMR: ^1H NMR ($CDCl_3$) δ=1.66 (s, 6H), 3.25 (s, 3H, methyl proton in methoxyl group), 5.53 (s, 1H), 6.68 (d, 1H, J=10), 6.79 (s, 1H, J=2.4), 6.82 (dd, 1H, J=10, 2.4), 6.88 (s, 1H), 7.03—7.48 (m, 15H), and 9.52 (s, 1H). On the other hand, racemic **18** showed two peaks at δ=3.25 and 3.18 corresponding to methyl proton in methoxyl group.

The anthors wish to thank Drs. Kazuo Kato and Kimihiro Murakami, Fuji Central Research Laboratory, Mochida Pharmaceutical Co., Ltd for their helpful discussions.

25) In the absence of *N*-hydroxyphthalimide, there were three major peaks, one at +30.8 ppm (positive chemical shifts are in ppm downfield of PPh_3 as an internal standard) corresponding to $Ph_3P=O$, another at +50.5 ppm corresponding to the betaine prepared from DEAD and triphenylphosphine, and the other at −43.7 ppm consistent with the pentavalent phosphorane, in the ^{31}P NMR spectra of the reaction mixture. The addition of *N*-hydroxyphthalimide to the above reaction mixture resulted in the complete disappearance of the peak at −43.7 ppm. However, in the presence of *N*-hydroxyphthalimide, the observed peaks in ^{31}P NMR spectra of the reaction mixture were only those corresponding to $Ph_3P=O$ and the remaining Ph_3P.

Palladium-Catalyzed Vinylation of Haloazulenes and Halotropolones with Olefins. Utility of the Heck Reaction in the Conjugated Carbon Chain Preparation[1,2]

Hiroshi Horino,* Toyonobu Asao, and Naoto Inoue
Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Aoba-ku, Sendai 980
(Received July 18, 1990)

The reactions of 3-iodotropolone with styrenes (styrene, *p*-methoxystyrene, and 2-vinylpyridine), methyl acrylate, and allylic compounds (methyl 3-butenoate, 3-butenenitrile, 1-allyl-3,4-dimethoxybenzene, and 1-allyl-3,4-methylenedioxybenzene) were carried out, according to the modified Heck's procedure, to give 3-styryl-, 3-(2-carboxyvinyl)-, and 3-(3-substituted 1-propenyl)tropolones, respectively. Similarly, 4-bromo- or 5-bromotropolone was made to react with these olefins to yield 4-styryltropolone or the corresponding 5-(2-substituted vinyl)- and 5-(3-substituted 1-propenyl)tropolones. Substitution of 2-chlorotropone by styrenes produced 2-styryltropones. Extension of the vinylation to 2-amino-6-bromoazulenes, ethyl 3-bromo-1-azulenecarboxylate, and diethyl 2-chloro-1,3-azulenedicarboxylate resulted in a similar substitution.

Many investigations have been undertaken on the chemical and spectroscopic properties of the conjugated or cross-conjugated compounds including azulenes and tropolones. For example, the absorption spectra of azulenes are known to be strongly influenced by the degree of conjugation of the carbon chain substituents as well as their positions.[3d] Such a study needs the synthetic methods for elongation or introduction of a conjugated carbon chain to these compounds. Although many efforts have been devoted, the hitherto-known methods making a carbon–carbon double bond on azulene nuclei or tropolone rings are limited.[3] However, the recent development of the carbon–carbon coupling reactions by transition metal complexes is providing us short-step syntheses of new nonbenzenoid aromatic compounds by coupling the common azulenes or tropolones with easily accessible reagents. Since we reported the palladium-catalyzed vinylation of halotropolones and halotropones about a decade ago,[4] the palladium-catalyzed cross-coupling reactions such as carbonylative coupling[5] as well as alkenyl, alkyl, and aryl coupling with organostannanes,[6] aryl coupling with organoboranes,[7] and aryl coupling with organozinc compounds[8] have been published successively. Nickel-assisted coupling of halotropones or haloazulene to synthesize bitropones and bitropolones[9a,c] or biazulene[9b] has also reported. The benzidine-type rearrangement of 2-(2-arylhydrazino)tropones to 2-amino-5-(4-aminoaryl)tropones,[10] and the base-catalyzed[11] or homolytic rearrangement[12] of 2-benzyloxytropones to 3-arylmethyltropolones have recently been reported as another category of carbon–carbon bond formation. Extension of the metal-assisted or catalyzed coupling reactions to the azulene chemistry is still unsatisfactory except for the copper-promoted coupling of haloazulenes and acetylene moieties.[13] Application of the Heck's vinylation to halotropolones and haloazulenes aiming to conjugated carbon substituents seems promising, because the halogen atoms of easily available halotropolones or haloazulenes are replaced regioselectively by the vinyl groups of commercially available olefins to give a variety of substituted vinyl compounds in one step under mild conditions. In this paper, we describe the details of the vinylic substitution of halotropolones with various olefins catalyzed by palladium complexes and its extension to haloazulenes.

Results and Discussion

The reactions of 3-iodotropolone **1a** with styrene, *p*-methoxystyrene, 2-vinylpyridine, and methyl acrylate were carried out in sealed tubes by heating the THF solutions of the mixtures in the presence of triethylamine and tetrakis(triphenylphosphine)palladium, $Pd(PPh_3)_4$. The change of the reaction products to their sodium salts to remove the catalyst and excess base, and the subsequent acidification gave 3-styryl- **2a**, 3-[2-(*p*-methoxyphenyl)vinyl]- **2b**, 3-[2-(2-pyridyl)-vinyl]tropolone **2c**, and 3-(2-carboxylvinyl)tropolone **2d**, respectively, in moderate yields. Methyl 3-butenoate and other allylic compounds were made to react similarly to produce the corresponding 3-(3-substituted 1-propenyl)tropolones **2e—2h**, as listed in Table 1. The allylic products **2e—2f** having electron-withdrawing groups were the mixtures of allylic double bond isomers from their NMR spectra. An allylic isomerization appears to have produced the thermodynamically stable products during the vinylation as described by Heck[14] or during the treatment of the products with alkaline solutions. An extension of the reaction to 4-bromotropolone **1b** afforded 4-styryltropolone **2i** in the same procedure. All of the olefins used in the reaction of **1a** could be applied to the reaction with 5-bromotropolone **1c**, which produced 5-(2-substituted vinyl)tropolones **2j—2m** and 5-(3-substituted 1-propenyl)tropolones **2n—2o** in good yields. Nozoe et al. proposed and partially succeeded in the synthetic pathway directed toward colchicine, a tricyclic alkaloid including tropolone ring, which consisted of intra-

molecular cyclization of 4-(3-arylpropyl)tropolone derivatives.[15] Then, 3-substituted tropolones **2g** and **2h** and 5-substituted products **2n** and **2o** are regarded as the model compounds approaching to the synthetic precursor for colchicine.

Although aryl iodides are usually more reactive than the corresponding aryl bromides,[14] the yields of **2a**—**2h** from 3-iodotropolone **1a** are lower than those of **2j**—**2o** from 5-bromotropolone **1c**. Surprisingly, the reaction of 5-iodotropolone **1d** with styrene or *p*-methoxystyrene gave mainly unexpected bitropolone **3**, accompanied by a small amount of **2j** as shown in

a) Carried out by heating the mixture of halotropolone (2 mmol), olefin (6 mmol), triethylamine (0.7 cm^3), and $Pd(PPh_3)_4$ (0.1 mmol) in THF (10 cm^3) at 100—110 °C for 18—20 h. b) Isolated yields based on halotropolones and 2-chlorotropone. c) A 1:1 mixture of allylic double bond isomers. d) A mixture of 3-(3-cyano-1-propenyl)- and 3-(3-cyano-2-propenyl)tropolones by a ratio of 1:2. e) $Pd_2(dba)_3 \cdot CHCl_3$ (0.1 mmol) was used as the catalyst. f) The mixture of $Pd_2(dba)_3 \cdot CHCl_3$ (0.1 mmol) and PPh_3 (0.4 mmol) as the catalyst. g) The mixture of $Pd_2Cl_4(PPh_3)_2$[18] (0.1 mmol) and PPh_3 (0.4 mmol) was used as the catalyst. h) The mixture of $Pd(OAc)_2$ (0.1 mmol) and PPh_3 (0.4 mmol) was used as the catalyst. i) Purified yield through picrate formation.

Entries 20 and 21. The structure of **3** was determined by the comparison with the authentic sample, which was previously synthesized by the nickel-catalyzed homocoupling of 5-bromo-2-diethylaminotropone and the following hydrolysis.[9c] The dimerization of organic iodides is known to occur when the unreactive olefins such as trisubstituted compounds are used.[14] Therefore, it is remarkable that **1d** dimerizes in preference to vinylic substitution with the reactive styrene. The reactivity of halogen at the 3-position of the tropolone ring may be retarded sterically by the neighboring carbonyl or hydroxyl group, which prevents from the homocoupling of **1a**. The steric effect by the neighboring group was also examined by the reaction of 5-bromo-4-phenyltropolone **4** with styrene and methyl acrylate. The yields of the reaction products **5a** and **5b** (Entries 22 and 23) were considerably lower than those of **2j** and **2m** (Entries 10 and 17), in accordance with the reported results for sterically hindered halides.[14]

The reaction of 5-chlorotropolone **1e** with styrene did not occur even in a more prolonged reaction period (40 h). The difference in the reactivity of the halogen can be utilized for selective vinylation at a desired halogen position of polyhalotropolones. Divinylation of 3,7-dibromo-5-chlorotropolone **6** was carried out by the reaction with styrene to produce 5-chloro-3,7-distyryltropolone **7**. Such a selective dialkenylation at the iodinated carbons of polyhaloarenes in preference to the brominated carbons had reported recently.[16] It is noteworthy that 2-chlorotropone **8** reacted with styrenes to give 2-styryltropones **9a—9c**, though the yields were relatively low, probably by the steric factor found in the behavior of **1a**.

When both of the cis- and trans-isomers are produced in the vinylation products, the thermodynamically stable olefin is known to be favored.[14] The coupling constants of the vinylic protons (about 16 Hz) in the NMR spectra illustrate that most vinylated products are trans-isomers. However, some unresolved signals of aromatic and vinylic protons have been observed by superposition upon each other,

Scheme 2.

and a further investigation should be done before determining which product is cis- or trans-isomer. Some kinds of palladium complexes are effective for the vinylation of **1c** with styrene (Entries 11 to 14). Tris(dibenzylideneacetone)dipalladium(0), $Pd_2(dba)_3\cdot CHCl_3$[17] was used as the reaction catalyst. Addition of triphenylphosphine to the system somewhat improved the yield, so that phosphine complexes appear to be favorable for the vinylic substitution. Divalent palladium complex $Pd_2Cl_4(PPh_3)_2$[18] as well as $Pd(OAc)_2$ can be used as the catalyst without interference of the tropolone moiety for chelation.

The vinylic substitution with olefins was then extended to azulene derivatives, using easily available 1-, 2-, and 6-haloazulenes[3d] as the starting materials. These results are listed in Table 2. Diethyl 2-amino-6-bromo-1,3-azulenedicarboxylate **10a** was made to react with styrene, 2-vinylpyridine, and methyl acrylate in a similar way to the vinylation of halotropolones to afford the corresponding 6-styryl- **11a**, 6-[2-(2-pyridyl)-vinyl]- **11b**, and 6-[2-(methoxycarbonyl)vinyl]azulene **11c** in fairly good yields. Similarly, 2-acetamido-6-bromoazulene **10b** gave 2-acetamido-6-styrylazulene **11d**. The bromine atom at the 1-position of **12** was easily replaced by the vinyl groups of styrene and methyl acrylate to give the corresponding vinylated azulenes **13a** and **13b**. It is remarkable that diethyl 2-chloro-1,3-azulenedicarboxylate **14a** reacted with all kinds of used olefins at the sterically crowded 2-position, and the corresponding 2-substituted azulenes **15a—15c** were obtained in moderate yields. Activation

Table 2. Vinylic Substitution of Haloazulenes (**10**, **12**, and **14**)[a]

Entry	Haloazulene	Olefin	Product	Yield (%)[b]

8	**14a**	2-Vinylpyridine	**15b**	(52)
9	**14a**	Methyl acrylate	**15c**	(57)
10	**14b**	Styrene	**15d**	(30)

a) The reactions were carried out in the same manner as in Table 1. b) Isolated yields based on haloazulenes after purification by column chromatography.

of the chlorine atom at the 2-position may be attributed to the electron-withdrawing character of the neighboring ethoxycarbonyl groups. A similar phenomenon was reported in the reaction of **14a** with copper(I) phenylacetylide.[13] As for the synthesis of unsubstituted azulenes except for the unsaturated carbon chain in question, the reaction of 2-iodoazulene **14b** with styrene was carried out to give 2-styrylazulene **15d**, which had previously been synthesized by partial hydrogenation of the corresponding ethynyl compound[13] or by condensation of 2-methylazulene with benzaldehyde.[19] The results mentioned above show that the vinylation reaction catalyzed by palladium complexes can be effectively applied to most of azulenes, tropolones, and related compounds, and that the reaction will be a handy tool for preparing a conjugated carbon chain at the desired halogen position on the nonbenzenoid aromatic compounds.

Experimental

Melting points were obtained by a Yanaco Micro-melting point apparatus and are uncorrected. The IR spectra were recorded on a Hitachi 215 using KBr disk. Most of the ^{1}H NMR spectra were measured on a Hitachi R-22 spectrometer (90 MHz) using TMS as the internal standard, and some spectra were obtained by a Hitachi 90H FT-NMR spectrometer (90 MHz). The UV-visible spectra were recorded on a Hitachi 340 spectrophotometer. Elemental analyses were performed by the Instrumental Analysis Center for Chemistry, Faculty of Science, Tohoku University. Solvents used for the reactions were distilled over sodium, and stored under an inert atmosphere. Chromatography was done on a 300 mesh silica gel (Wako C-300). Palladium complexes, $Pd(PPh_3)_4$,[20] and $Pd_2(dba)_3 \cdot CHCl_3$ (dba=dibenzylideneacetone),[17] were prepared according to the literatures. The following haloazulenes and halotropolones were also prepared according to the literatures: 3-iodotropolones **1a**,[21] 4-bromotropolone **1b**,[22] 5-bromo- **1c**,[23] 5-chloro- **1e**,[23] and 5-iodotropolone **1d**,[23] 2-chlorotropone **8**,[24] diethyl 2-amino-6-bromo-1,3-azulenedicarboxylate **9a**,[25] 2-acetamido-6-bromoazulene **9b**,[26] ethyl 3-bromo-1-azulenecarboxylate **12**,[27] diethyl 2-chloro-1,3-azulenedicarboxylate **14a**,[25] and 2-iodoazulene **14b**.[25]

As the typical procedures, the reactions of **1a**, **1d**, **8**, and **10a** with styrene are given as follows.

3-Styryltropolone 2a: The ampoule (60 cm^3) was purged with nitrogen, and **1a** (545 mg, 2 mmol) and $Pd(PPh_3)_4$ (120 mg, 0.1 mmol) were placed successively. The mixture was dissolved in deaerated THF (10 cm^3), and styrene (0.7 cm^3, 6.1 mmol) and triethylamine (0.7 cm^3) were added as rapidly as possible. The ampoule was sealed, and heated in an oil bath at 100—110 °C for 20 h. The reaction mixture was transferred into a flask equipped with a rotatory evaporator, and concentrated under reduced pressure. The residue was dissolved in benzene (30 cm^3), and extracted with 5% NaOH solution (50 cm^3×3). Acidification of the solution with 6 M HCl (M=mol dm^{-3}) gave a white turbid solution, which was then extracted with ethyl acetate. After the solution was dried (Na_2SO_4) and concentrated under reduced pressure, the yellow oil (298 mg) obtained was chromatographed on silica gel (9.0 g) using benzene as an eluent, to give yellow crystals of **2a** (173 mg, 39%), mp 58—62 °C. Recrystallization from ethanol raised the melting point of **2a** up to 73—75 °C. (lit,[28] mp 111.5—112.5 °C; Discrepancy between the melting points of **2a** and the authentic sample is unexplainable yet, but the following spectra of **2a** are consistent with the strucure of 3-styryltropolone). IR (KBr) 3160 (OH), 1650, 1550 (CO, C=C), 685 (Ph) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.95—7.65 (10H, m), 7.83 (1H, d, J=6 Hz). Found: C, 80.23; H, 5.63%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%.

3-[2-(*p*-Methoxyphenyl)vinyl]tropolone 2b: Mp 134—136 °C (benzene); IR (KBr) 3170 (OH), 1605, 1580 (C=C, CO), 1250 (C–O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.78 (3H, s), 6.82 (1H, d, J=12 Hz), 7.29 (2H, d, J=11 Hz), 7.32 (2H, d, J=12 Hz), 6.90—7.65 (8H, m), 7.77 (1H, d, J=10 Hz). (EtOH); IR (KBr) 3240, (OH), 1620, 1590, 1555 (C=C, CO, C=N) cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.95—7.80 (10H, m), 8.59 (1H, d, J=7 Hz). Found: C, 74.46; H, 4.85; N, 6.13%. Calcd for $C_{14}H_{11}O_2N$: C, 74.65; H, 4.92; N, 6.22%.

5-(2-Carboxyvinyl)tropolone 2m: Mp 238—239 °C (decomp) (EtOH) [lit,[29] mp 239 °C (decomp)]; IR (KBr) 3200—2500, 1700 (carboxyl), 1615, 1565 (CO, C=C) cm^{-1}; ^1H NMR (DMSO-d_6) δ=6.42 (1H, d, J=16 Hz), 7.12 (2H, d, J=11 Hz), 7.50 (2H, d, J=16 Hz), 7.70 (2H, d, J=11 Hz).

5-[3-(3,4-Dimethoxyphenyl)-1-propenyl]tropolone 2n: Mp 140.5—142 °C (EtOH); IR (KBr) 3200 (OH), 1610, 1550 (C=C, C=O), 1270, 1215, 1140 (C-O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.50 (2H, d, J=7 Hz), 3.88 (6H, s), 6.32 (1H, m), 6.75—6.95 (3H, m), 7.30 (5H, s), 7.32 (1H, s). Found: C, 72.21; H, 6.17%. Calcd for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

5-[3-(3,4-Methylenedioxyphenyl)-1-propenyl]tropolone 2o: Mp 123—124 °C (EtOH); IR (KBr) 3230 (OH), 1620, 1550 (C=C, CO), 1260, 1210 (C-O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.52 (2H, d, J=7 Hz), 5.92 (2H, s), 6.32 (1H, m), 6.78 (3H, m), 7.30 (4H, s), 7.96 (1H, s). Found: C, 72.38; H, 5.03%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

Formation of 5,5′-Bitropolone 3: A mixture of **1d** (545 mg, 2.0 mmol), styrene (0.6 cm^3), $Pd(PPh_3)_4$ (120 mg, 0.1 mmol), triethylamine (0.8 cm^3) in THF (10 cm^3) was heated at 115—120 °C for 21 h, and the resulting mixture was treated similarly. Acidification of the alkaline solution with 6 M HCl yielded brownish yellow precipitates, which were collected by filtration, and washed with ethyl acetate (50 cm^3) to give 106 mg (0.44 mmol, 44%) of **3**; mp 255 °C (decomp), which was identical with the authentic sample[9c] by the comparison of their IR spectra [lit,[9c] 260 °C (decomp)]; IR (KBr) 3460 (OH), 1620, 1552 (C=C, CO) cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.52 (4H, d, J=12 Hz), 7.84 (4H, d, J=12 Hz). The filtrate was extracted with ethyl acetate, which was combined with the solvent used for washing the precipitates, and dried over Na_2SO_4. Concentrating the solution followed by extracting the residue with ethanol gave 38 mg (0.17 mmol, 8.5%) of **2j**.

5-Bromo-4-phenyltropolone 4: To a solution of 5-amino-4-phenyltropolone[32] (1.28 g, 6.0 mmol) in dioxane (10 cm^3) and water (6 cm^3), concd H_2SO_4 (1.0 cm^3) and then a solution of sodium nitrite (0.50 g, 7.2 mmol) in water (2 cm^3) were added at 0—5 °C in 15 min. After the successive addition of copper(I) bromide (2.20 g, 15.3 mmol) and 48% HBr (8 cm^3) during 15 min, the solution was stirred for 1 h, until the temperature reached to room temperature. Then the solution was heated at 60 °C for 10 min, and poured into water (60 cm^3). The produced precipitates (1.60 g) were dissolved in dichloromethane (100 cm^3), and treated with a flow of hydrogen sulfide. After evaporating the solvent, crystallization from ethanol gave yellow crystals of **3** (1.25 g, 75%). Mp 188—189 °C ($CHCl_3$–EtOH); IR (KBr) 3230 (OH), 1600, 1550 (C=C, C=O) 700 (Ph) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.07 (1H, d, J=12 Hz), 7.21 (1H, s), 7.22—7.43 (5H, m), 7.80 (1H, d, J=12 Hz). Found: C, 56.58; H, 3.45%. Calcd for $C_{13}H_9O_2Br$: C, 56.34; H, 3.27%.

4-Phenyl-5-styryltropolone 5a: Mp 95—96 °C (EtOH); IR (KBr) 3200 (OH), 1600, 1530 (C=C, C=O), 700 (Ph) cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.86 (1H, d, J=11 Hz), 7.0—7.7 (13H, m), 7.88 (1H, d, J=11 Hz). Found: C, 79.00; H, 5.13%. Calcd for $C_{21}H_{16}O_2$: C, 79.02; H, 5.00%.

5-(2-Carboxyvinyl)-4-phenyltropolone 5b: Mp 242—243 °C (THF); IR (KBr) 3150 (OH), 3050—2550 (carboxyl), 1590, 1560 (C=C, C=O), 695 (Ph) cm^{-1}; ^1H NMR (THF-d_8) δ=6.25 (1H, d, J=16 Hz), 7.10—7.45 (7H, m), 7.20 (1H, d, J=16 Hz), 7.85 (1H, d, J=11 Hz). Found: C, 71.18; H, 4.68%. Calcd for $C_{16}H_{12}O_4$: C, 71.68; H, 4.51%.

5-Chloro-3,7-distyryltropolone 7: Mp 185 °C ($CHCl_3$–EtOH); IR (KBr) 3050 (OH), 1625, 1550 (C=C, C=O), 690 (Ph) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.15—7.20 (1H, t, J=5 Hz), 7.20—7.40 (7H, m), 7.45—7.60 (6H, m), 7.70—7.90 (3H, m). Found: C, 76.28; H, 4.87%. Calcd for $C_{23}H_{17}O_2Cl$: C, 76.55; H, 4.75%.

2-Styryltropone 9a: A mixture of **8** (280 mg, 2.0 mmol), styrene (310 mg, 3.0 mmol), and triethylamine (0.4 cm^3) in THF (15 cm^3) was heated at 120 °C for 18 h in the presence of $Pd(PPh_3)_4$ (120 mg, 0.1 mmol) in a sealed tube. After filtration of palladium that had been deposited during the reaction, the filtrate was concentrated, and the residue was chromatographed on silica gel (10 g) using benzene–ethyl acetate (1 : 0—1 : 1). Evaporation of the benzene–ethyl acetate (10 : 1) eluent gave yellow crystals of **9a** (102 mg, 49.0%), which were recrystallized from carbon tetrachloride: Mp 91—92 °C (CCl_4) (lit,[33] mp 94—95 °C); IR (KBr) 1620, 1565 (C=C, C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.85—7.10 (4H, m), 7.20—7.65 (8H, m).

2-[2-(*p*-Methoxyphenyl)vinyl]tropone 9b: Mp 93—95 °C (benzene) (lit,[33] mp 98 °C); IR (neat) 1625, 1580 (C=C, C=O) cm^{-1}. (Found: C, 79.57; H, 5.94%).

2-[2-(2-Pyridyl)vinyl]tropone 9c: Mp 90—91.5 °C (benzene–cyclohexane); picrate, mp 202—204 °C (decomp); IR (KBr) 1625, 1570 (C=C, CO, C=N), 770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.75—7.10 (4H, m), 7.30—7.70 (6H, m). Found: C, 80.27; H, 5.22; N, 6.62%. Calcd for $C_{14}H_{11}ON$: C, 80.36; H, 5.30; N, 6.69%.

Diethyl 2-Amino-6-styryl-1,3-azulenedicarboxylate 11a: A THF solution (10 cm^3) of **10a** (735 mg, 2 mmol), $Pd(PPh_3)_4$ (120 mg, 0.1 mmol), styrene (1.2 cm^3, 10.5 mmol), and triethylamine (1.5 cm^3) was sealed in an ampoule (60 cm^3). After heating in an oil bath at 110—120 °C for 18 h, the mixture was concentrated under reduced pressure, and then the residue was chromatographed on silica gel (10 g). Elution with a mixture of benzene and ethyl acetate (1 : 1) gave reddish-orange crystals of **11a** (551 mg, 70%). Mp 148—149 °C (EtOH) (lit,[34] mp 147.5—148 °C); IR (KBr) 3450, 3350 (NH_2), 1680 (ester), 990 (Ph) cm^{-1}. (Found: C, 74.32; H, 5.92; N, 3.54%).

Diethyl 2-Amino-6-[2-(2-pyridyl)vinyl]-1,3-azulenedicarboxylate 11b: Mp 146—148 °C (benzene); IR (KBr) 3480, 3340 (NH_2), 1680 (ester) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.47 (6H, t, J=7 Hz), 4.46 (4H, q, J=7 Hz), 7.04—7.35 (4H, m), 7.55—7.82 (5H, m), 8.54 (1H, d, J=5 Hz), 8.98 (2H, d, J=11 Hz); UV (MeOH) 250 (log ε 4.53), 349 (4.75), 454 nm (4.49). Found: C, 71.04; H, 5.38; N, 6.92%. Calcd for $C_{23}H_{22}O_4N_2$: C, 70.75; H, 5.18; N, 7.18%.

Diethyl 2-Amino-6-[2-(methoxycarbonyl)vinyl]-1,3-azulenedicarboxylate 11c: Mp 197—198 °C (THF); IR (KBr) 3490, 3350 (NH_2), 1705, 1685, 1650 (ester) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50 (6H, t, J=7 Hz), 3.80 (3H, s), 4.46 (4H, q, J=7 Hz), 6.47 (1H, d, J=16 Hz), 7.50—7.90 (5H, m), 9.01 (2H, d, J=11 Hz); UV (EtOH) 248 (log ε 4.29), 340 (4.61), 447 nm (4.19). Found: C, 64.66; H, 5.74; N, 3.71%. Calcd for $C_{20}H_{21}O_6N$: C, 64.68; H, 5.70; N, 3.77%.

2-Acetamido-6-styrylazulene 11d: Mp 257 °C (THF); IR (KBr) 3290 (NH), 1600, 1595, 1570, 1530 (amide) cm^{-1};

^{1}H NMR (DMSO-d_6) δ=3.10 (3H, s), 7.10—7.70 (11H, m), 8.35 (2H, d, J=16 Hz), 11.50 (1H, s); UV (MeOH) 224 (log ε 4.50), 313 (4.70), 325 (4.70), 411 (4.58), 432 (4.59), 559 nm (2.72). Found: C, 78.14; H, 6.00; N, 4.45%. Calcd for $C_{20}H_{17}ON \cdot H_2O$: C, 78.66; H, 6.27; N, 4.59%.

Ethyl 3-Styryl-1-azulenecarboxylate 13a: Mp 80—82 °C (EtOH); IR (KBr) 1690 (ester), 1215—1205 (C-O), 690 (Ph) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.49 (3H, t, J=7 Hz), 4.47 (2H, q, J=7 Hz), 7.10—7.70 (10H, m), 8.54 (1H, d, J=9 Hz), 8.67 (1H, s), 9.48 (1H, d, J=9 Hz); UV (MeOH) 237 (log ε 4.22), 277 (4.28), 316 (4.60), 395 (4.44), 409 (3.94), 597 nm (2.70). Found: C, 83.52; H, 6.02%. Calcd for $C_{21}H_{18}O_2$: C, 83.42; H, 6.00%.

Ethyl 3-[2-(Methoxycarbonyl)vinyl]-1-azulenecarboxylate 13b: Mp 114—115.5 °C (benzene); IR (KBr) 1690, 1620 (ester), 1220, 1160 (C-O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.45 (3H, t, J=7 Hz), 3.80 (3H, s), 4.45 (2H, q, J=7 Hz), 6.45 (1H, d, J=16 Hz), 7.40—7.85 (3H, m), 8.20 (1H, d, J=16 Hz), 8.85—8.70 (2H, m), 9.58 (1H, d, J=11 Hz); UV (MeOH) 247 (log ε 4.37), 306 (4.65), 346 (sh, 4.31), 387 (4.19), 551 nm (2.95). Found: C, 71.59; H, 5.63%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

Diethyl 2-Styryl-1,3-azulenedicarboxylate 15a: Mp 79—81 °C (EtOH); IR (KBr) 1670 (ester), 1200, 1170 (C-O), 990 (Ph) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.23 (6H, t, J=7 Hz), 4.44 (2H, q, J=7 Hz), 6.82 (1H, d, J=16 Hz), 7.22—7.80 (10H, m), 8.04 (1H, d, J=16 Hz); UV (MeOH) 230 (log ε 4.24), 292 (4.34), 335 (4.48), 397 (3.89), 527 nm (2.54).

Diethyl 2-[2-(2-Pyridyl)vinyl]-1,3-azulenedicarboxylate 15b: Mp 95—97.5 °C (EtOH); IR (KBr) 1670 (ester), 1200, 1175 (C-O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.37 (6H, t, J=7 Hz), 4.47 (4H, q, J=7 Hz), 6.92 (1H, d, J=17 Hz), 7.05—7.85 (7H, m), 8.48 (1H, d, J=17 Hz), 9.35 (2H, d, J=12 Hz); UV (MeOH) 230 (log ε 4.33), 330 (4.67), 392 (sh, 4.00), 530 nm (3.19). Found: C, 73.83; H, 5.71; N, 3.62%. Calcd for $C_{23}H_{21}O_4N$: C, 73.58; H, 5.64; N, 3.73%.

Diethyl 2-[2-(Methoxycarbonyl)vinyl]-1,3-azulenedicarboxylate 15c: Mp 93—94 °C; IR (KBr) 1720, 1685 (ester), 1190, 1180 (C-O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.88 (6H, t, J=7 Hz), 3.80 (3H, s), 4.40 (4H, q, J=7 Hz), 6.06 (1H, d, J=18 Hz), 7.68 (2H, d, J=11 Hz), 7.79 (1H, t, J=11 Hz), 8.47 (1H, d, J=18 Hz), 9.40 (2H, d, J=11 Hz); UV (MeOH) 236 (log ε 4.34), 306 (4.72), 355 (3.91), 529 nm (2.78). Found: C, 67.18; H, 5.77%. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%.

2-Styrylazulene 15d: Mp 207—208 °C (benzene) (lit,[19] mp 207—208 °C). The IR spectrum of **15d** was identical with the authentic sample.[19]

The authors wish to express their thanks to Emeritus Professor Tetsuo Nozoe of Tohoku University and Professor Takashi Toda of Utsunomiya University for their encouragement throughout this work. We are grateful to Professor Masafumi Yasunami and Dr. Tadayoshi Morita of Tohoku University for a gift of some halotropolones, and for a kind guidance of preparing 3-iodotropolone and some azulene derivatives. We also wish to thank Professor Masaji Oda of Osaka University for the comparison of the IR spectra of 5,5′-bitropolone. The present work was partially supported by Grant-in-Aid for Scientific Reserach No. 57540270 from the Ministry of Education, Science and Culture.

Asymmetric Transformation of (*RS*)-2-Phenylglycine via Formation of Salt with (1*S*)-10-Camphorsulfonic Acid

Tadashi SHIRAIWA,* Shinji SAKATA, Keiko FUJISHIMA, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received July 20, 1990)

An asymmetric transformation of (*RS*)-2-phenylglycine [(*RS*)-Phg] was carried out via formation of a salt with (1*S*)-10-camphorsulfonic acid [(*S*)-CS] in acetic acid, propanoic acid, or butanoic acid by heating at 100 °C without using any catalysts such as aldehydes. The rate of epimerization of a more soluble salt of (*S*)-Phg with (*S*)-CS was estimated to be lowest in acetic acid and highest in butanoic acid. The asymmetric transformation in propanoic acid, however, was achieved successfully to give the salt of (*R*)-Phg with (*S*)-CS with 100% optical purity in 82% yield. Optically pure (*R*)-Phg was obtained from the salt in 80% yield based on the (*RS*)-Phg used as the starting material.

(*R*)-2-Phenylglycine [abbreviated as (*R*)-Phg] as a useful material for ampicillin has been obtained from synthetic (*RS*)-Phg by optical resolution[1–6] because (*R*)-Phg is not found in natural amino acids. (*S*)-Phg, however, is also given by optical resolution but is not of value as a material for ampicillin. Asymmetric transformation is carried out by combination of selective crystallization of a less soluble diastereomeric salt with epimerization of a more soluble salt, and has a possibility of converting a racemate solely into a desirable enantiomer. (1*S*)-10-Camphorsulfonic acid [(*S*)-CS] is a good resolving agent for the optical resolution of (*RS*)-Phg because (*S*)-CS is easily available and forms a salt with (*R*)-Phg as a less soluble diastereomeric salt without coverting (*RS*)-Phg into any derivatives such as ester. The asymmetric transformation of (*RS*)-Phg has been attempted via formation of the salt with (*S*)-CS in acetic acid in the presence of salicylaldehyde as a catalyst for epimerization.[7] Since the presence of aldehyde, such as salicylaldehyde, in the reaction system raises the solubility of the less soluble salt, the yield of the salt of (*R*)-Phg with (*S*)-CS [(*R*)·(S) salt] seems not to be so high.[7]

Optically active (*R*)- and (*S*)-Phg were apt to racemize on heating in carboxylic acid. We, therefore, tried asymmetric transformations of (*RS*)-Phg by heating in acetic acid, propanoic acid, or butanoic acid without using any catalyst, such as aldehyde, to establish a more efficient method for obtaining (*R*)-Phg. In addition, rates of racemization of (*R*)-Phg and (*R*)-2-(4-hydroxyphenyl)glycine [(*R*)-Hpg] were examined in these carboxylic acids to estimate the rate of epimerization of the more soluble salt of (*S*)-Phg with (*S*)-CS [(*S*)·(S) salt].

Experimental

Materials. (*RS*)- and (*R*)-Phg, (*R*)-Hpg, and (*RS*)- and (*S*)-CS were purchased from Wako Pure Chemicals Ind.

Asymmetric Transformation. A mixture of 20.0 mmol (3.02 g) of (*RS*)-Phg and 18.0 (4.18 g), 19.0 (4.41 g), or 20.0 (4.64 g) mmol of (*S*)-CS in 10 cm^3 of acetic acid, propanoic acid, or butanoic acid was stirred for 1—10 h at 100 °C. After further adding 1.00 mmol (0.232 g) and 2.00 mmol (0.464 g) of (*S*)-CS to the mixture at 60 °C in the reaction consuming 19.0 and 18.0 mmol of (*S*)-CS, respectively, the mixture was stirred for 5 min at 60 °C and successively for 20 min in an ice bath. The formed (*R*)·(*S*) salt was filtered off, washed with diethyl ether, and dried. The optical purity of the obtained salt was determined on the basis of the specific rotations of the salts of Phg with (*S*)-CS: (*R*)·(S) salt, $[\alpha]_D^{25}$ −49.7° (*c* 2, 1 mol dm^{-3} HCl);[7] the salt of (*RS*)-Phg with (*S*)-CS, $[\alpha]_D^{25}$ +13.6° (*c* 2, 1 mol dm^{-3} HCl).[7] The degrees of crystallization of the (*R*)·(*S*) and (*S*)·(*S*) salts ($DC_{(R)}$ and $DC_{(S)}$/%) were calculated by

$$DC_{(S)}/\% = (1/2)[\text{Yield}/\% \times (100 - \text{Optical purity}/\%)]/100, \quad (1)$$

$$DC_{(R)}/\% = [\text{Yield}/\% \times \text{Optical purity}/\%] + DC_{(S)}/\%. \quad (2)$$

The obtained salt was dissolved in methanol (10 cm^3 g^{-1}) at room temperature. After adding an equivalent of triethylamine to the solution, the mixture was stirred for 0.5 h in an ice bath. The precipitated (*R*)-Phg was filtered off, washed with methanol, and dried. The optical purity of the obtained (*R*)-Phg was determined on the basis of the specific rotation ($[\alpha]_D^{20}$ −157.8° (dil HCl))[8] of authentic (*R*)-Phg.

Rate Constant for Racemization. (*R*)-Phg (0.151 g, 1.00 mmol) or (*R*)-Hpg (0.167 g, 1.00 mmol) and (*RS*)-CS (0.220 g, 0.950 mmol or 0.232 g, 1.00 mmol) were immediately dissolved in 30 cm^3 of acetic acid, propanoic acid, or butanoic acid or in a mixture of 30 cm^3 of the carboxylic acid and 3 cm^3 of water at 100 °C, respectively. Portions of the solution were pipetted out at appropriate time intervals and the optical rotation was measured. The rate constant (k_R/s^{-1}) for racemization was calculated by the least-squares method from

$$\ln \alpha_0/\alpha_t = k_R \cdot t, \quad (3)$$

where α_t is the optical rotation at time t and α_0 that extrapolated to zero time. The half-life period ($t_{1/2}$/s) was calculated on the basis of the obtained k_R value.

Measurement. Optical and specific rotations at 589 nm were measured with a Union Giken PM-101 digital

polarimeter equipped with a quartz cell of 0.100 or 0.500 dm path length.

A mixture of (*RS*)-Phg (20.0 mmol) and (*RS*)-CS (20.0 mmol) in 20 cm^3 of acetic acid, propanoic acid, or butanoic acid was stirred for 2 h at 100 °C and successively for 5 h at 10 °C. The formed salt of (*RS*)-Phg with (*RS*)-CS [(*RS*)·(*RS*) salt] was rapidly filtered off, washed with diethyl ether, and thoroughly dried. The solubilities of the (*RS*)·(*RS*) salt in acetic acid, propanoic acid, or butanoic acid at 10 °C were estimated on the basis of the weight of the (*RS*)·(*RS*) salt and those of the (*RS*)-Phg and (*RS*)-CS used as the starting materials.

Results and Discussion

Racemization of (*R*)-2-Phenylglycine and (*R*)-2-(4-Hydroxyphenyl)glycine. One of the major problems in asymmetric transformation is the rate of epimerization of a more soluble diastereomeric salt, that is, the racemization of optically active substances. (*R*)-Phg was racemized by heating in carboxylic acid; for example, (*R*)-Phg (20.0 mmol) was stirred for 3 h at 100 °C in 10 cm^3 of acetic acid and successively for 20 min in an ice bath to give approximately racemic Phg ($[\alpha]_D^{20}$ −3.6° (*c* 1.00, 1 mol dm^{-3} HCl)) in 97.7% (2.95 g) yield. The rates of racemization of (*R*)-Phg and (*R*)-Hpg, therefore, were measured in acetic acid, propanoic acid, or butanoic acid in the presence of (*RS*)-CS at 100 °C, as described in the experimental section. The rates of (*R*)-Hpg in propanoic acid or butanoic acid were measured in mixtures of 30 cm^3 of the carboxylic acid and 3 cm^3 of water because (*R*)-Hpg did not dissolve completely in these carboxylic acids. Since the racemization of (*R*)-Phg and (*R*)-Hpg in the carboxylic acids is an acid-catalyzed reaction, the rates depend upon the concentration of (*R*)-Phg or (*R*)-Hpg and the carboxylic acid. The racemization, however, could be regarded as a pseudo first-order reaction because the carboxylic acids existed in large excess in the reaction system and linear relationships were found between $\ln \alpha_0/\alpha_t$ and time *t*. The rate constant of racemization (k_R/s^{-1}) and the half-life period ($t_{1/2}/s$) are listed in Table 1.

The racemization involves protonation of the carbonyl oxygen atom in the carboxyl group, followed by the loss of α-hydrogen atom by formation of the enol; these steps are reversible.[9] (*RS*)-CS acts as an extremely stronger proton donor for the amino groups in (*R*)-Phg and (*R*)-Hpg than the carboxylic acids. The presence of the positively charged nitrogen atom resulting from such a protonation hinders the second protonation of the carbonyl oxygen atom.[9] The rate of racemization in the presence of free (*R*)-Phg or (*R*)-Hpg, therefore, is more speeded up than in the presence of equimolar amounts of (*R*)-Phg or (*R*)-Hpg and (*RS*)-CS. The ammonium ion in (*R*)-Hpg is estimated to be more stable by the presence of the hydroxyl group on the aromatic ring than in (*R*)-Phg. The rate of racemization of (*R*)-Hpg, therefore, is slower than that of (*R*)-Phg.

Since the rate-determining step is the formation of

a) Conditions: (*R*)-2-phenylglycine [(*R*)-Phg] 1.00 mmol; (*R*)-2-(4-hydroxyphenyl)glycine [(*R*)-Hpg] 1.00 mmol; carboxylic acid 30 cm^3; temperature 100 °C. b) AcA=acetic acid; PrA=propanoic acid; BuA=butanoic acid. c) (*RS*)-CS: (1*RS*,4*SR*)-10-Camphorsulfonic acid. d) k_R: Rate constant for racemization. e) $t_{1/2}$: Half-life period.

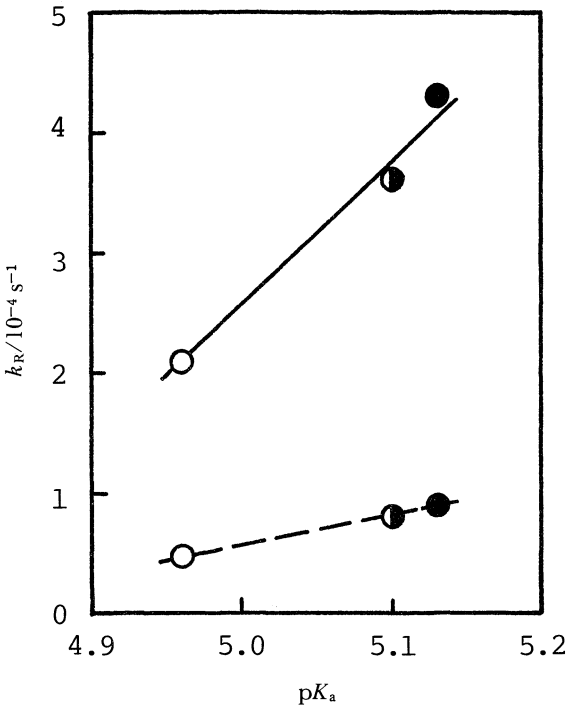

Fig. 1. Rate constant for racemization in carboxylic acids. pK_a: The value at 100 °C was estimated from data 0—60 °C. —: (*R*)-2-Phenylglycine (1.00 mmol). ---: (*R*)-2-(4-Hydroxyphenyl)glycine (1.00 mmol). (1*RS*,4*SR*)-10-Camphorsulfonic acid: 0.95 mmol. Temperature: 100 °C. Solvent: Mixture of 30 cm^3 of carboxylic acid and 3 cm^3 of water. k_R: Rate constant for racemization. Carboxylic acid: ○ Acetic acid; ◑ propanoic acid; ● butanoic acid.

the enol by abstract of the α-hydrogen atom by the carboxylate anion, the rates of racemization of (*R*)-Phg and (*R*)-Hpg seem to be dependent of the basicity of the carboxylate anions, that is, the acidity of the carboxylic acids employed as the solvent. The acidity constants at 100 °C of the carboxylic acids were estimated from data at 0—60 °C;[10] the pK_a values of acetic acid, propanoic acid, and butanoic acid were calculated to be 4.96, 5.10, and 5.13,[10] respectively. The relationship between the k_R and pK_a values is shown in Fig. 1.

The k_R value increased with increase in the pK_a value; k_R values obtained under other conditions, in Table 1, had a tendency to change similar to that shown in Fig. 1. The acidity constant suggests that the order of proton abstraction at 100 °C should be butanoate anion>propanoate anion>acetate anion, and hence the racemization of (*R*)-Phg and (*R*)-Hpg are speeded up in this order. The epimerization of the more soluble (*S*)·(*S*) salt, therefore, is estimated to be most rapid in butanoic acid and to be slowest in acetic acid.

Asymmetric Transformation of (*RS*)-2-Phenylglycine. Influence of Reaction Amount of (1*S*)-10-Camphorsulfonic Acid: The preceding result suggests that

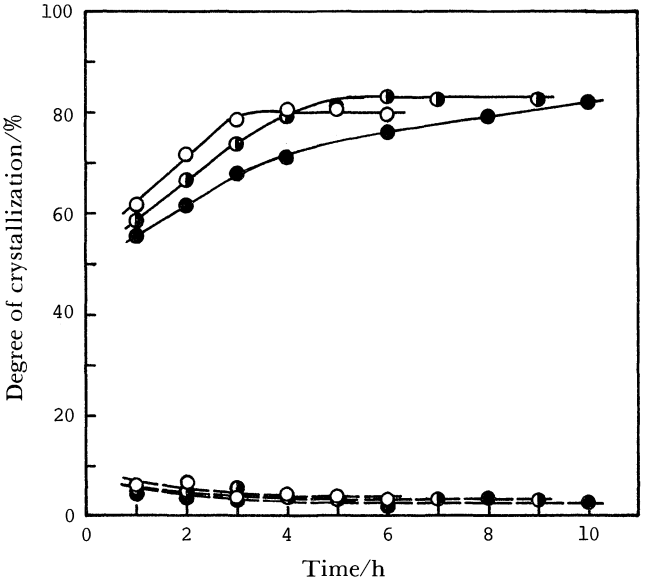

Fig. 2. Influence of amount of (1*S*)-10-camphorsulfonic acid on asymmetric transformation. (*RS*)-2-Phenylglycine [(*RS*)-Phg]: 20.0 mmol. (1*S*)-10-Camphorsulfonic acid [(*S*)-CS]: ○ 18.0 mmol; ◑ 19.0 mmol; ● 20.0 mmol. Solvent: 10 cm^3 of butanoic acid. Temperature: 100 °C. —: Salt of (*R*)-Phg with (*S*)-CS. ---: Salt of (*S*)-Phg with (*S*)-CS.

the rate of epimerization of the more soluble (*S*)·(*S*) salt is most rapid in butanoic acid and is increased in the presence of free (*RS*)-Phg. The asymmetric transformation of (*RS*)-Phg was tried in butanoic acid by consuming 20.0 mmol of (*RS*)-Phg and 18.0, 19.0, or 20.0 mmol of (*S*)-CS. The relationship between the degree of crystallization of the (*R*)·(*S*) and (*S*)·(*S*) salts and reaction time is shown in Fig. 2. Although the asymmetric transformation of (*RS*)-Hpg was attempted similarly to that of (*RS*)-Phg, the formed salt could not be obtained because the salt was strongly hygroscopic.

As shown in Fig. 2, after a rapid crystallization of the (*R*)·(*S*) salt in a short time period, the degree of crystallization of the (*R*)·(*S*) salt reached a maximal value and subsequently became constant in spite of elapse of time; when 20.0 mmol of (*S*)-CS was consumed, the degree of crystallization seemed to increase gradually even at 10 h. The epimerization of the (*S*)·(*S*) salt seems to be most rapid when 18.0 mmol of (*S*)-CS was consumed, as shown in Fig. 2. This result agreed with the estimate from the racemization of (*R*)-Phg. The asymmetric transformation consuming 18.0 mmol of (*S*)-CS, however, requires the addition of 2.00 mmol of (*S*)-CS after reaction at 100 °C and the formed salt should be the salt of (*RS*)-Phg with (*S*)-CS. The optical purity of the obtained (*R*)·(*S*) salt, therefore, was lower than those obtained by consuming 19.0 and 20.0 mmol of (*S*)-CS. Although the asymmetric transformation consuming 20.0 mmol of (*S*)-CS may give the (*R*)·(*S*) salt

with higher optical purity in higher yield, acquisition of such (*R*)·(*S*) salt requires extremely long time. The asymmetric transformation consuming 19.0 mmol of (*S*)-CS gave the (*R*)·(*S*) salt with 92% optical purity in 86% yield after reaction for 6 h. These results suggest that the favorable amount of (*S*)-CS is 19.0 mmol for 20.0 mmol of (*RS*)-Phg.

Influence of Carboxylic Acid Used as Solvent: The asymmetric transformation was carried out by reacting 20.0 mmol of (*RS*)-Phg and 19.0 mmol of (*S*)-CS at 100 °C in acetic acid, propanoic acid, or butanoic acid. These results are listed in Table 2 and shown in Fig. 3.

The solubilities of the salt of (*RS*)-Phg with (*RS*)-CS [(*RS*)·(*RS*) salt] at 10 °C in acetic acid, propanoic acid, and butanoic acid were 6.97, 4.19, and 2.61 g/(100 cm^3 of carboxylic acid), respectively; the (*RS*)·(*RS*) salt is estimated to consist of equimolar amounts of the (*R*)·(*S*) salt and its enantiomer. The order of solubilities of the (*R*)·(*S*) and (*S*)·(*S*) salts are estimated to be equal to that of the (*RS*)·(*RS*) salt. The asymmetric transformation in propanoic acid and butanoic acid gave the (*R*)·(*S*) salt with over 90% optical purity in over 80% yield by reaction for 5—9 h. Although the (*R*)·(*S*) salt obtained by a reaction for 1—5 h in acetic acid had 92—95% optical purity, the yield was low (55—60%) because the (*R*)·(*S*) and (*S*)·(*S*) salts are more soluble in acetic acid than in propanoic acid or butanoic acid. In addition, the epimerization of the (*S*)·(*S*) salt in acetic acid seems to be extremely slower than those in propanoic acid or

a) Conditions: (*RS*)-2-Phenylglycine [(*RS*)-Phg] 20.0 mmol; (1*S*)-10-(camphorsulfonic acid [(*S*)-CS] 19.0 mmol; carboxylic acid 10 cm^3; temperature 100 °C. b) AcA=Acetic acid; PrA=propanoic acid; BuA=butanoic acid. c) (*R*)·(*S*) Salt: Salt of (*R*)-Phg with (*S*)-CS. d) The yield was calculated on the basis of 20.0 mmol (7.67 g) of the (*R*)·(*S*) salt. The yield was calculated on the basis of 20.0 mmol (3.02 g) of (*R*)-Phg.

butanoic acid, as shown in Fig. 3, and is estimated from the racemization of (*R*)-Phg. Acetic acid, therefore, is not favorable as the solvent for the asymmetric transformation of (*RS*)-Phg.

The epimerization of the (*S*)·(*S*) salt in butanoic acid seems to be a little faster than in propanoic acid. Although the asymmetric transformation in butanoic acid gave the (*R*)·(*S*) salt with 92% optical purity in over 86% yield, recrystallization of the salt from water lowers the yield extremely.[7]

The (*R*)·(*S*) salt with 100% optical purity was obtained in 82% yield by the asymmetric transformation in propanoic acid. Isolation of (*R*)-Phg from the optically pure salt was carried out almost quantitatively by treatment of the methanol solution of the salt with triethylamine to obtain optically pure (*R*)-Phg in 80% yield based on the (*RS*)-Phg used as the starting material.

The above results show that the asymmetric transformation of (*RS*)-Phg is possible by heating in the carboxylic acids without using any catalysts such as aldehydes and gives optically pure (*R*)-Phg efficiently.

Aryliminodimagnesium Reagents. XIX.[1] Effects of Miscellaneous Metal Halides on Oxidative Self-Coupling of the Reagent, and on Its Condensation with Nitrobenzene. A New Preparative Route to *o,o'*-Dihydroxyazobenzene

Masao Ōkubo* and Haruko Shiku
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received August 1, 1990)

Fourteen metal halides (MX_n) were each added to the solutions of aryliminodimagnesium (*p*-$RC_6H_4N(MgBr)_2$, IDMg) in tetrahydrofuran, and the effect of MX_n on relative yields of products was examined in the following three IDMg reactions: (A) oxidative coupling leading to symmetrical azobenzene, (B) condensation with nitrobenzene, and (C) condensation with *o*-hydroxy-substituted (*o*-HO) nitrobenzene. Reaction A was promoted by addition of $CuCl_2$, and the yield of azoxybenzenes in reaction B was improved by addition of $NiCl_2$ or $CdCl_2$. Reaction C was similarly modified by addition of $CdCl_2$ so as to improve the yield of *o*-HO-azoxybenzenes. Their acetyl derivatives underwent a facile photoinduced migration of azoxy oxygen and were successively hydrolyzed to afford bidentate chelating agents, *o,o'*-$(HO)_2$-azobenzenes.

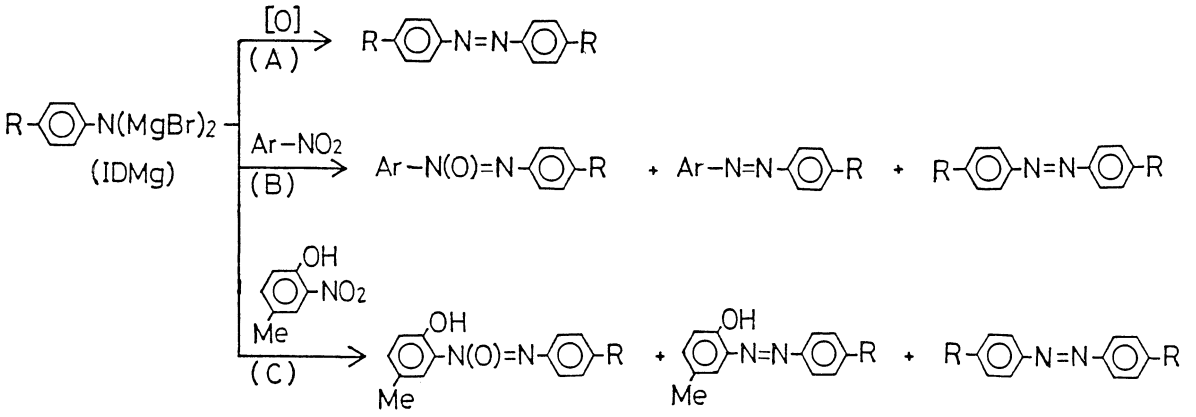
Modification of the reaction mode and reactivity of Grignard reagents by addition of miscellaneous metal halides was studied early by Kharasch[2] and later by Kochi[3] and their co-workers. The studies have contributed to the development of the vast and fascinating field of organometallic chemistry.

The nitrogenating ability of N–Mg reagent, aryliminodimagnesium ($RC_6H_4N(MgBr)_2$, IDMg) derived from anilines, via condensation with aromatic carbonyl and nitro compounds has been established.[4] The utility of the IDMg procedure is thus desired to be developed, and the effect of addition of each of fourteen metal halides on typical IDMg reactions was examined. The reactions selected are oxidative coupling to give symmetrical (*sym*-) azobenzenes[5] and condensation with nitrobenzenes to give unsymmetrical (*unsym*-) azoxy- and azobenzenes[4b,c] (Scheme 1: A and B). Reaction A was sufficiently promoted solely by $CuCl_2$ of the metal halides examined, whereas reaction B was modified by $NiCl_2$ or $CdCl_2$ to improve the yield of *unsym*-azoxybenzenes. The latter result was applied to condensation with *o*-hydroxy-substituted (*o*-HO) nitrobenzene (reaction C),[6a] and the obtained *o*-HO-azoxybenzene in improved yield was converted into a bidentate chelating agent, *o,o'*-$(HO)_2$-azobenzene. The results will be summarized and reported in this paper.

Results and Discussion

The metal halides examined are listed below according to their atomic numbers given in brackets: $TiCl_3$[22], $CrCl_3$[24], $MnCl_2$[25], $FeCl_3$[26], $CoCl_2$[27], $NiCl_2$[28], Cu(I)Cl[29], Cu(II)X_2[29], (X=Cl, Br), $ZrCl_4$[40], $MoCl_5$[42], AgCl[47], $CdCl_2$[48], Sn(II)Cl_2[50], Sn(IV)Cl_4[50], $HgCl_2$[80], and $BiCl_3$[83].

Relative yields of products will be discussed in terms of reported governing factors. The principal factor of reactions of IDMg and ArMgBr is the relative efficiency of single electron transfer (SET) regardless of the normal condensation and addition modes; the combination of electron-donating and -accepting abilities (EDA and EAA) was evaluated by the difference (ΔE) between oxidation and reduction potentials of reactants.[7] Owing to the weaker EDA of



Scheme 1.

IDMg than that of ArMgBr,[6] a second factor originating from aggregation of IDMg molecules was disclosed.[6]

(A) Effect of Added $CuCl_2$ on Oxidative Coupling of IDMg. Concerning the formation of *sym*-azobenzenes from anilines, air oxidation in the presence of Cu(I)Cl and pyridine[9] and oxidative coupling of IDMg[5] by use of I_2, $C_6H_5IO_2$, and OsO_4 in tetrahydrofuran (THF) were reported. The use of Cu(II)Cl_2 for reaction A leads to higher yield than that in a previous study,[5] and is available for *sym*-azobenzene preparation. The coupling took place only by use of CuX_2 (X=Cl, Br) or $FeCl_3$, the latter giving poor yield. The use of $CuBr_2$ led to lower conversion probably due to its larger redox potential than that of $CuCl_2$.

Figure 1a illustrates the effect of substituents (R) of IDMg on its conversion by use of two molar equivalents of $CuCl_2$ under fixed conditions: R=*p*-Me and H are more favorable than R=*p*-MeO and *p*-Cl, whereas R=*o*-Me and *o*-MeO give poor yields due to steric hindrance. Figure 1b illustrating effects of reaction conditions shows that *p*-Me reagent is sufficiently converted by use of $CuCl_2$ in two molar equivalents. The maximum yield, 75%, however, was not further improved by adding $CuCl_2$ at −20 or 0 °C. Neither addition at lower temperatures (−40 and −78 °C) nor use of greater amounts of $CuCl_2$ was effective. Mechanistic reasons why the retained 25% is not overcome and the *p*-MeO and *p*-Cl groups are less favorable, remain to be examined.

(B) Moderating Effect of $NiCl_2$ and $CdCl_2$ on the Condensation with Nitrobenzene. The condensation

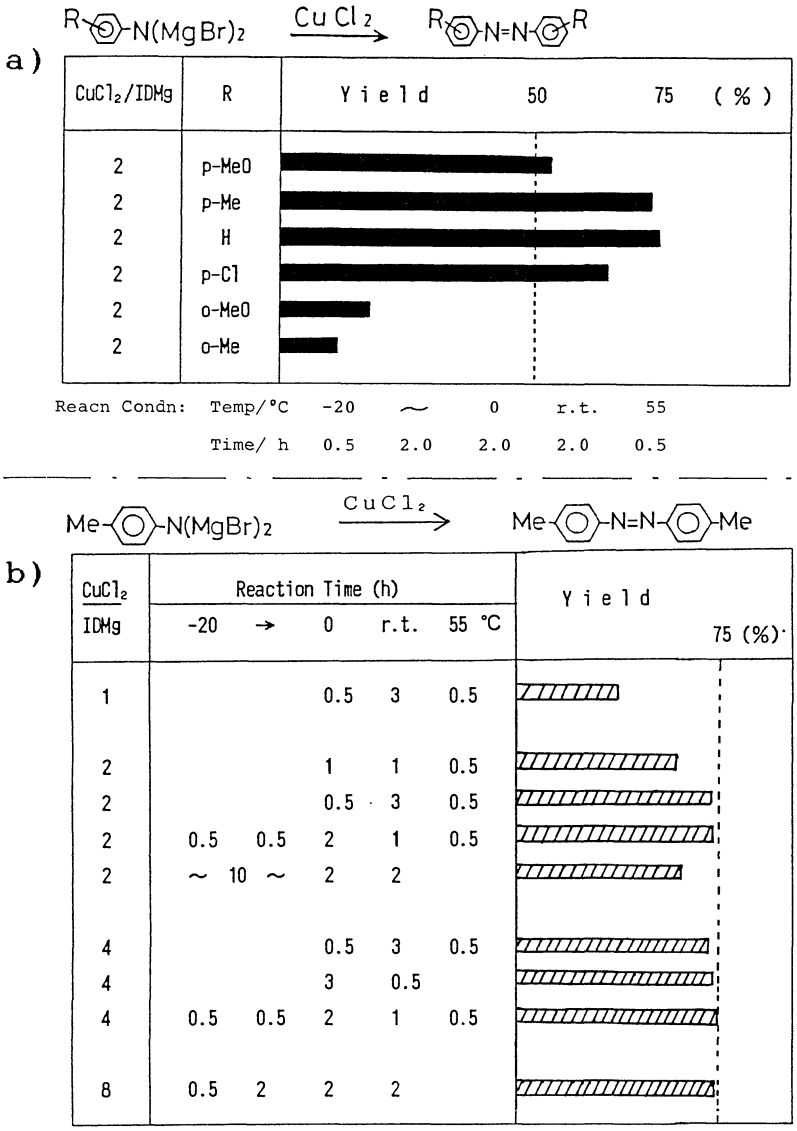


Fig. 1. Effect of $CuCl_2$ addition on the oxidative coupling of IDMg reagents (reaction A). a): Substituent effect on the yield of azobenzene under fixed conditions of reaction. b): Effect of reaction conditions on the oxidative coupling of *p*-MeC_6H_4-IDMg.

with nitrobenzene (Scheme 1B) is composed of two normal successive processes, I (condesation) and II (deoxygenation), both being favored by aggregation of IDMg.[6a,b] Of reactions of IDMg, reaction B is most important not only because this provides a new method for independent preparation of ONN and NNO isomers of *unsym*-azoxybenzenes by exchange of substituents of the nitro- and aminobenzenes[4c] but also because this and the Grignard addition to Ar_2CO are "SET-controlled" reactions having comparable ΔE values.[7] Thus, preparation of azoxybenzene (**1**) from combination of R=MeO and Ar=*p*-ClC_6H_4 (Scheme 2) encounters difficulties under ordinary conditions: High SET efficiency (small ΔE) is responsible not only for rapid I and II but also for oxidative and reductive couplings of IDMg and $ArNO_2$, respectively, to give **2**,

a) Yields obtained at the ratio [IDMg]:[$ArNO_2$]:[MX_n]=4:1:4 unless otherwise noted. b) Yield of **2** in cludes that of **6** (see text). c) [IDMg]:[$ArNO_2$]:[MX_n]=4:1:1. d) [IDMg]:[$ArNO_2$]:[MX_n]=4:1:0.5.

3, and **4**. The dimeric abnormal products, **3** and **4**, are formed via SET taking place from aggregated IDMg due to "pre-interaction[7b] between reactants having small ΔE." With use of this combination, "moderating effect" caused by $NiCl_2$ or $CdCl_2$ to improve the yield of **1** was disclosed.

By comparison with the yields of **1**—**5** without use of MX_n (Table 1), characteristic variation in the yields caused by an equimolar amount of MX_n was surveyed, and manners of variation were classified into three types **a**—**c**. Type **a**: no recovery and improved combined yield of **1** plus **2** with two exceptional cases; **b**: no recovery and poor overall yield; **c**: appreciable recovery and fairly good overall yields.

In type **a**, i.e., improved efficiency of the reaction indicated by no recovery, effects of MX_n on the relative yields of **1** and **2** are classified into four kinds: (i) Improved effciency of I at the expense of **4** by addition of Ni, Ag, Cd, or Sn(IV) chloride; (ii) improved efficiency of II by addition of $CrCl_3$; (iii) the combined yield of **1** and **2** is not improved due to reductive coupling to give **4** by addition of Mn(II) or Cu(I) chloride; (iv) the highest yield of azo products, including **2** and an *o*-anilino-substituted one **6**, indicating a very rapid SET,[10] by addition of $ZrCl_4$.

According to the EDA-EAA concept, type **b**, poor efficiency of I and II and no recovery, implies that $ArNO_2$ is decomposed via a much accelerated SET. Type **c**, depression of the reaction itself indicated by recovery of $ArNO_2$, implies that the SET is retarded. The peculiar effect caused by $MoCl_5$ is noted; only **3** was formed due to oxidative coupling of IDMg in the presence of $ArNO_2$ but not formed in the absence.

Even from the preliminary results obtained under unoptimized conditions, the effect of MX_n on IDMg reactions is distinct from that on Grignard reactions. Whereas Grignard reagent is oxidatively coupled by Co(II) and Ag(I) salts,[2b,3b] IDMg is unaffected (see Reaction A). The formation of mild C–Cd reagent by addition of Cd(II) salt to Grignard solution[11] seems different from a "catalytic" effect suggested from the comparable yields obtained by use of $NiCl_2$ and $CdCl_2$ in 1/1 and 1/4 or 1/8 molar amounts (see Table 1); no evidence for N–Cd bond formation is obtained.

The effect of $NiCl_2$ and $CdCl_2$, i.e., improved yield of **1** at the expense of **4** (Table 1), is noted. The EDA-EAA concept claims that[7,8] this originates from moderate SET, modified EDA being suggested. Moreover, a modified state of IDMg aggregation[6] is also suggested from the almost completely reduced yield of **4** contrary to the difficultly reduced yield of **3**. The modifications must arise from interaction of IDMg with d-orbitals of metal ions, remaining to be studied in detail. Nevertheless, the "catalytic moderating effect" is applied to preparation of *unsym-o*-HO-azoxybenzenes described below.

(C)-Synthetic Use of $CdCl_2$: Preparation of *o*-HO-Azoxybenzene and Conversion into *o,o'*-$(HO)_2$-Azobenzene. *sym-o,o'*-$(HO)_2$-Azobenzenes, utilizable as chelating agents, have so far been prepared by coupling of appropriate aryldiazonium salt by use of hydroxylamine–$CuSO_4$.[12] *unsym-p'*-Methyl- and *p'*-octyl-*o*-HO-azobenzenes, also utilized for selective solvent extraction of Ag(I) and Cu(II) ions,[13] are prepared by coupling of the cooresponding arenediazonium salt with phenols. An alternative prepara-

Fig. 2. Effect of addition of $NiCl_2$ and $CdCl_2$ on the condensation of *p*-octyl-C_6H_4–IDMg with 2-HO-5-Me-nitrobenzene (reaction C).

tion of *unsym-o*-HO-azo compounds by use of IDMg (Scheme 1C) was reported,[6a] and modified by addition of $CdCl_2$ to provide a synthetic route to *unsym-o,o'*-$(HO)_2$-azo compounds.

Reaction C using 2-HO-5-Me-nitrobenzene and 4.0 or 8.0 molar equivalents of *p*-octyl-C_6H_4-IDMg was carried out in the absence and presence of $NiCl_2$ or $CdCl_2$. Figure 2 illustrates the effect of reaction conditions on the yields of *o*-HO-azoxybenzene (**7**), *o*-HO-azobenzene (**8**), *sym*-azobenzene (**9**), and the amount of recovery. In accord with previous results obtained by use of *p*-Me-C_6H_4-IDMg,[6a] the use of four molar equivalents of *p*-octyl-C_6H_4-IDMg (both in the absence and in the presence of $NiCl_2$) led to a combined yield of **7** plus **8** lower than 50%, i.e., insufficient efficiency of condensation. Though the combined yield was improved so as to exceed 70% by the use of eight molar equivalents of IDMg, the yield of **7** was still lower than 45% in the absence of $NiCl_2$ or $CdCl_2$.[6a] However, in the presence of the latter, the yield of **7** was improved to more than 60%.

Direct photoconversion of the *o*-HO-azoxy compound **7** (R=Me) into *o,o'*-$(HO)_2$-azo product by Wallach-type azoxy-ortho migration of oxygen[14] is quite sluggish due to intramolecular hydrogen bonding, and instead, deoxygenation predominates after a longer time of irradiation (see Table 2). However, evoking the behavior of some *o*-MeO- and *o*-halo-azoxybenzenes,[14] the *o*-acetyl-azoxy compound derived from **7** was easily photoconverted into *o*-acetyl-*o'*-HO-azo product, which was successively hydrolyzed to give the desired *o,o'*-$(HO)_2$-azo compound (Scheme 3). The *p'*-octyl derivative of **7** (R=octyl) behaves similarly.

For the use of bidentate *o,o'*-$(HO)_2$-azobenzenes for solvent extraction, the facile and complete recovery of *p'*-octyl derivative from the binary solvent system due to reduced solubility in water is of greater advantage than for *p'*-methyl derivative.

Experimental

Materials and Procedures. Guaranteed grade anhydrous metal halides were commercially available and used without further purification. The IDMg reagents were prepared on a 6—8 mmol scale in 50 ml THF by treatment of the corresponding anilines with two molar equivalents of EtMgBr.[4b,8] For reaction A, a calculated amount of $CuCl_2$ was added to the IDMg solution in THF at −20 or 0 °C, and the mixture was stirred under the time and temperature conditions indicated in Figs. 1a and 1b. The mixture was quenched with aqueous ammonium chloride, and the azobenzene was chromatographically separated on silica gel (Wako Gel FC-40).

For reaction B (see Scheme 2), a calculated amount of MX_n was added at 0 °C to the THF solution of IDMg with subsequent addition of the nitrobenzene. The resulting mixture was stirred at room temperature for 3 h and at 55 °C for 0.5 h. Product mixtures were similarly separated. The yields of products **1—6** are given in Table 1. Reaction C was similarly carried out, and molar ratios of reagent versus substrate, reaction temperatures and times, and yields of products **7—9** are shown in Fig. 2. The distinctive behavior of *o*-HO- and o-acetoxy-azoxy compounds under photo-irradiation using the given concentration in ethanol[14] (see Scheme 3) is shown by the product yields given in Table 2.

All the products are known, and the structures were determined by ^1H NMR spectra: The signals appearing at δ=8.1—8.3 and δ=7.7—7.9 were assigned to the ortho protons of azoxy and azo products, respectively.[4c] The

Thermally Irreversible Photochromic Systems. Photoreaction of Diarylethene Derivatives with Imidazo[1,2-*a*]pyridine Rings

Yasuhide NAKAYAMA, Koichiro HAYASHI, and Masahiro IRIE*,†

(Received September 13, 1990)

A non-symmetrical diarylethene with imidazo[1,2-*a*]pyridine ring on one end and thiophene ring on the other end, 1,2-dicyano-1-(2-methylimidazo[1,2-*a*]pyridin-3-yl)-2-(2,4,5-trimetyl-3-thienyl)ethene **2Z** underwent a hexatriene-cyclohexadiene type reversible ring-closure reaction by photoirradiation, while an only *Z*–*E* isomerization was observed for a symmetrical diarylenthene with two imidazo[1,2-*a*]pyridine rings, 1,2-dicyano-1,2-bis(2-methylimidazo[1,2-*a*]pyridin-3-yl)ethene **1Z**. The ring-closure reaction was not discerned. The photogenerated closed-ring form **2C** had the absorption band at 535 nm, which is 23 nm longer wavelengths than that of the corresponding dithienylethene, and kept the absorption intensity constant for more than 24 h at 80 °C. The quantum yield close to unity was observed for the photochemical ring-opening reaction of **2C** with 546 nm light.

Recently, a new type of thermally stable photochromic systems, diarylethene derivatives with heterocyclic rings, has been developed, such as 1,2-dicyano-1,2-bis(2,4,5-trimethyl-3-thienyl)ethene and 2,3-bis-(2,4,5-trimethyl-3-thienyl)maleic anhydride.[1] The compounds have no thermochromic property even at 300 °C and the closed-ring forms are stable for more than 3 months at 80 °C.[2,3] In addition, no appreciable fatigue was observed for the diarylethenes with benzothiophene rings even after 8×10^3 ring closure/opening cycles.[2]

Although these compounds have promising properties for optical data storage media,[4–6] they still lack several indispensable conditions, such as diode laser sensitivity and non-destructive read out capability. The absorption edges of the closed-ring forms are less than 700 nm. Replacement of the thiophene rings with indole ones, which have high electron-donating ability, shifted the absorption maximum of the closed-ring form as much as 60 nm, and the absorption edge of the acid anhydride derivative reached 800 nm.[7] Although the compound has the sensitivity at the diode laser wavelength ($780<\lambda<830$ nm), the conversion of the open-ring to the closed-ring form in the photostationary state under irradiation with 474 nm light is less than a few percent, and the thermal stability of the closed-ring form is insufficient.

In the present study, we synthesized a symmetrical diarylethene derivative with two imidazo[1,2-*a*]pyridine rings, which have higher electron-donating ability than indole ring, and a non-symmetrical one with imidazo[1,2-*a*]pyridine ring on one end and thiophene ring on the other end in attempting to shift the absorption bands to longer wavelengths.

Results and Discussion

A Symmetrical Diarylethene Derivative with Two Imidazo[1,2-*a*]pyridine Rings. A diarylethene derivative with two imidazo[1,2-*a*]pyridine rings was prepared by a self-coupling reaction[1] of two 3-(cyanomethyl)-2-methylimidazo[1,2-*a*]pyridine. The mixture of *Z* and *E* forms was dissolved in benzene and exposed to 490 nm light to convert the *E* form to the *Z* form. The *Z* form was separated from the mixture of *Z* and *E* forms by HPLC and purified by crystallization from a hexane–ether mixture.

The *Z* form, **1Z**, was irradiated in benzene (6.8×10^{-5} mol dm^{-3}) in the presence of air with 475 nm light, and the reaction was followed by absorption and HPLC measurements (silica-gel column, 1:1 chloroform–acetone). Figure 1 shows the spectra of **1Z** before and after photoirradiation with 475 nm light in the

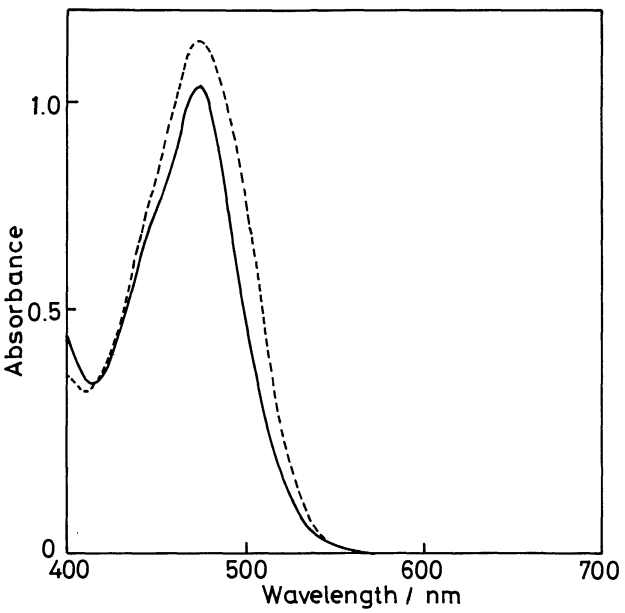

Fig. 1. Absorption spectra of **1Z** (6.8×10^{-5} mol dm^{-3}) (—) before photoirradiation and (---) in the photostationary state under irradiation with 475 nm light.

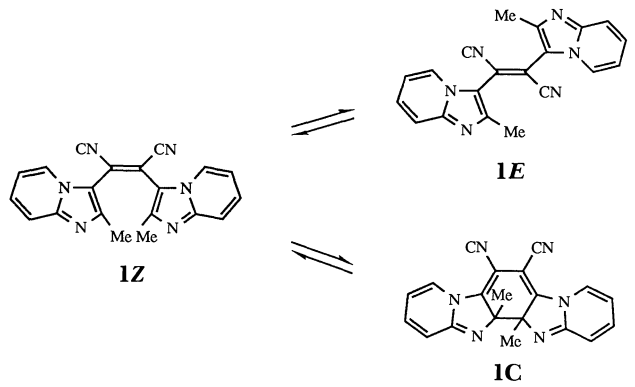
dilute benzene solution. The absorption maximum of **1Z** was observed at 475 nm and the molar absorption coefficient was 15,000 $dm^3\,mol^{-1}\,cm^{-1}$. The absorption maximum shifts to a longer wavelength as much as 40 nm in comparison with *Z* form of 1,2-dicyano-1,2-bis(1,2-dimethyl-3-indolyl)ethene.[7] Upon irradiation with 475 nm light, the intensity of the absorption in 420—550 nm region increases. Any new absorption was not observed at longer wavelengths. It was inferred from the NMR measurement that the absorption intensity change is due to the *Z*–*E* isomerization from **1Z** to **1E** (see below). Under the photostationary state, the *Z* to *E* ratio was estimated by HPLC to be **1E**/**1Z**=33/67. A ring-closure reaction was not discerned even after prolonged irradiation with lights of 420—550 nm wavelengths.



Scheme 1.

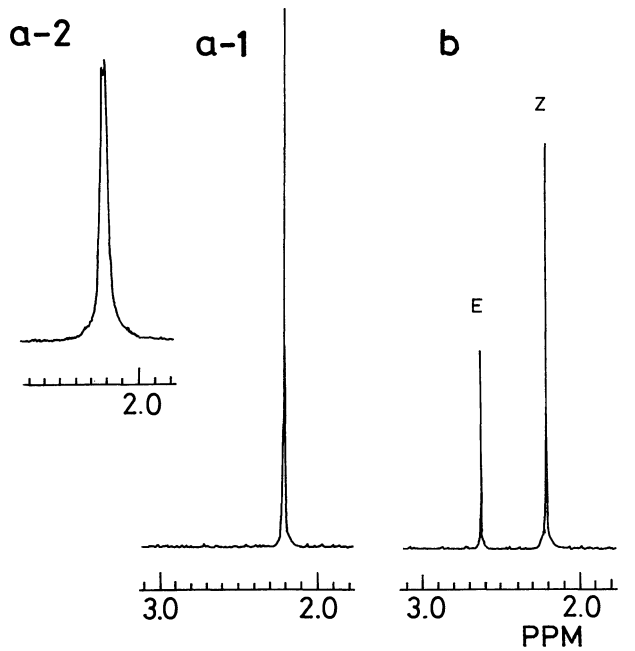


Fig. 2. ^1H NMR spectra (270-MHz) of **1E** in $CDCl_3$: (a-1) before irradiation at room temperature; (a-2) at −25 °C; (b) after irradiation with 475 nm light.

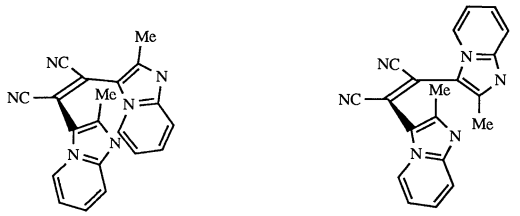
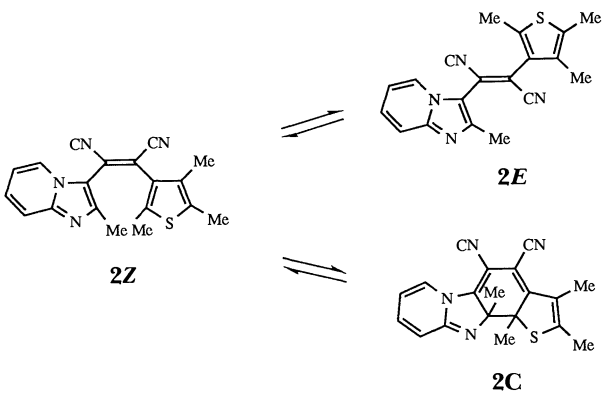
Figure 2 a-1 and b show the 270-MHz ^1H NMR spectra of methyl protons of **1Z** in $CDCl_3$ before and after photoirradiation with 475 nm light in benzene solution, respectively. Figure 2 a-2 shows the signals of methyl protons of **1Z** in $CDCl_3$ at −25 °C. At this temperature, the sharp singlet splits into two peaks at 2.19 and 2.21 ppm. The two methyl protons indicate the existence of two atropisomers in the compound **1Z**. A similar line-shape change was reported for dibenzothiophene derivatives.[8] One conformer has two imidazo[1,2-*a*]pyridine rings in mirror symmetry (in parallel orientation) and the other C_2 symmetry (in anti-parallel orientation).

After photoirradiation a new signal appeared at 2.63 ppm (Fig. 2). The absence of other signals except the one line indicates that the signal is ascribable to the *E* form and the ring-closure reaction is negligible. The assignment was further confirmed by the ^{13}C NMR measurement. Any signal ascribable to sp^3 carbons was not discerned after photoirradiation.

A Non-symmetrical Diarylethene Derivative with Imidazo[1,2-*a*]pyridine and Thiophene Rings. A diarylethene derivative with imidazo[1,2-*a*]pyridine ring on one end and thiophene ring on the other end was prepared by a cross-coupling reaction[2] of 3-(cyanomethyl)-2-methylimidazo[1,2-*a*]pyridine[9] and 4-(cyanomethyl)-2,3,5-trimethylthiophene.[1] The mixture of *E* and *Z* forms was dissolved in benzene and exposed to the light longer than 450 nm. The



Scheme 2.



Scheme 3.

irradiation is expected to convert the *E* form to the *Z* form. The *Z* form was separated by HPLC and purified by crystallization from a hexane–ether mixture.

The *Z* form, **2Z**, was irradiated in benzene (1.25×10^{-4} mol dm^{-3}) in the presence of air with 450 nm light, and the reaction was followed by absorption and HPLC measurement (silica-gel column, chloroform). Figure 3 shows the spectra of **2Z** before and after photoirradiation with 450 nm light. Irradiation of the yellow benzene solution with 450 nm light led to the formation of a red solution, in which a visible absorption was observed at 535 nm and a shoulder at 580 nm. The visible absorption was ascribed to the closed-ring form, **2C**, from the NMR measurement (see below).

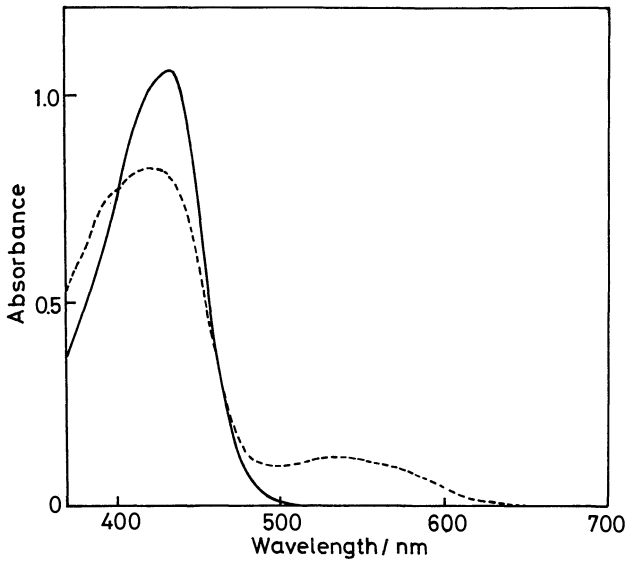


Fig. 3. Absorption spectra of **2*E*** (1.25×10^{-4} mol dm^{-3}) (—) before photoirradiation and (---) in the photostationary state under irradiation with 450 nm light.

The replacement of one of imidazo[1,2-*a*]pyridine rings with a thiophene ring enables the diarylethene to undergo the ring-closure reaction. The absorption maximum wavelength is 23 nm longer than that of the dithienylethene derivative.[1] The conversion from **2Z** to **2C** in the photostationary state under irradiation with 450 nm light was estimated to be 30% by HPLC analysis.

The irradiation was also accompanied with a *Z–E* isomerization from **2Z** to **2*E***. In the photostationary state, the contents of each isomer were estimated by HPLC as **2Z** (40%), **2C** (30%), and **2*E*** (30%). The yield of the closed-ring form depended on the irradiation wavelength. When the solution was irradiated with 425 nm light, the conversion was decreased to less than 15%.

The ^{1}H NMR spectra (360-MHz) of **2Z** in C_6D_6 before photoirradiation and after irradiation with 450 nm light are shown in Fig. 4 a and b. Before photoirradiation, 4 lines were observed at 1.41, 1.50, 1.62, and 1.96 ppm, which are assigned to the **2Z** form.

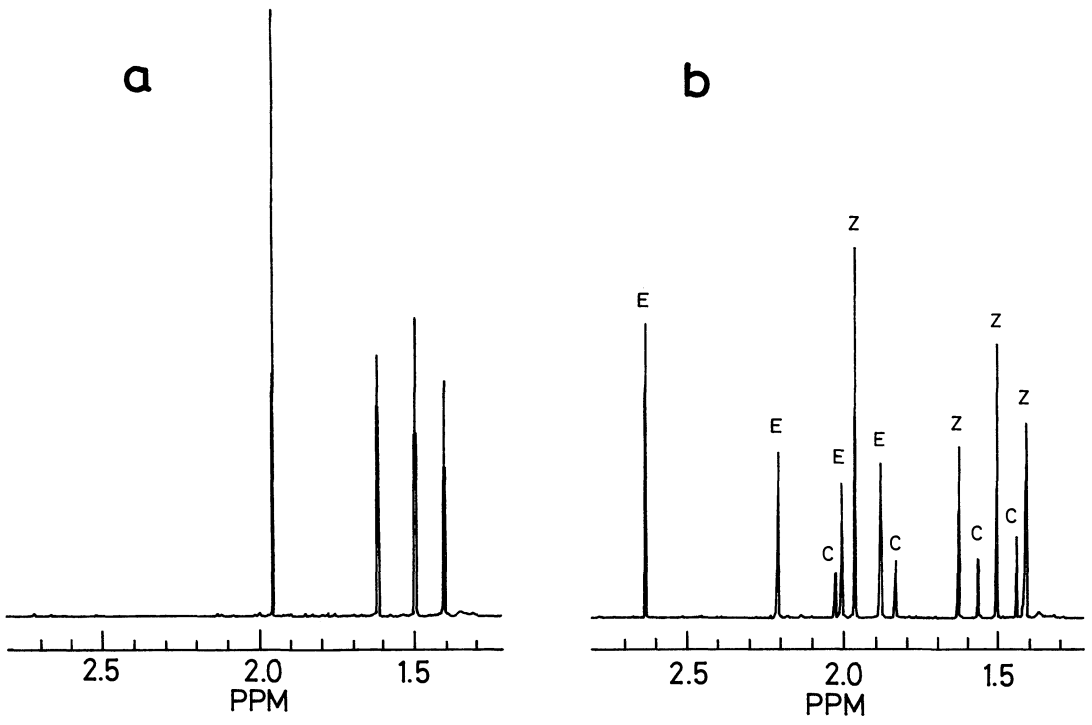

Fig. 4. ^{1}H NMR spectra (360-MHz) of **2Z** in C_6D_6: (a) before irradiation (b) after irradiation with 450 nm light.

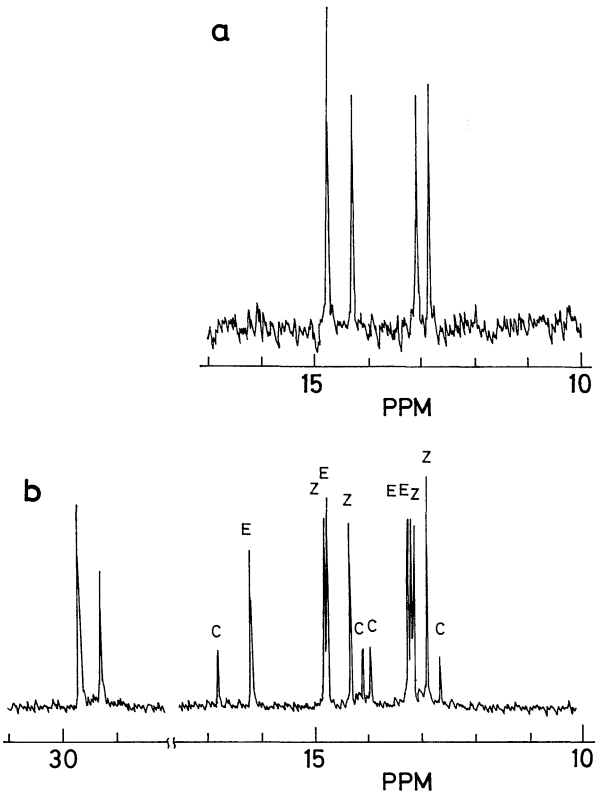

Fig. 5. ^{13}C NMR spectra (68-MHz) of **2Z** in $CDCl_3$: (a) before irradiation (b) after irradiation with 450 nm light.

Upon irradiation with 450 nm light, new 8 lines appeared at 1.43, 1.56, 1.83, 1.87, 2.00, 2.02, 2.20, and 2.62 ppm along with a decrease of the intensity of the 4 lines. The eight lines observed after photoirradiation indicate the co-existence of three isomers, **2Z**, **2C**, and **2*E***. The assignments are shown in the figure.

Figure 5 a and b show the 68-MHz ^{13}C NMR spectra of methyl carbon of **2** in $CDCl_3$ before photoirradiation and after irradiation with 450 nm light, respectively. Before photoirradiation, 4 lines were observed at 12.86, 13.09, 14.32, and 14.77 ppm, which are due to **2Z** form. Upon irradiation, new 8 lines appeared at 12.57, 13.12, 13.19, 13.92, 14.11, 14.74, 16.17, and 17.01. These 8 lines may be classified into two groups (13.12, 13.19, 14.74, and 16.17 ppm) and (12.57, 13.92, 14.11, and 17.01 ppm). The former is assigned to the *E* form, **2*E***, and the latter to the closed-ring form, **2C**. The other two lines at 29.29 and 29.69 ppm observed after photoirradiation indicate the existence of sp^3 carbon after photoirradiation. This result confirms that closed-ring form, **2C**, was formed by photoirradiation.

The photogenerated closed-ring form, **2C** was thermally stable. Any changes of the absorption intensity at 535 nm was not observed even at 80 °C. The absorption intensity remained constant for more than 24 h, at 80 °C.

Table 1. Quantum Yields for Ring-Closure and Ring-Opening Reactions in Benzene Solution

Reaction	Excitation wavelength / nm	Quantum yield
2Z→**2C**	405	0.06
2C→**2Z**	546	1.00

Quantum yields for the cyclization and the ring-opening reactions of **2** were determined in benzene solution in the presence of air at 25 °C. Table 1 summarized the results. The cyclization quantum yield of the imidazo[1,2-*a*]pyridine-thiophene derivative **2Z** at 405 nm was 0.06, which is similar value observed for 1,2-dicyano-1,2-bis(1,2-dimethyl-3-indolyl)-ethene[7] and 2,3-bis(2,4,5-trimethyl-3-thienyl)maleic anhydride.[1] The quantum yield of the ring-opening reaction at 546 nm was obtained to be close to unity. The value is 8 times larger than that observed for dithienylethene derivative.[1] The large value is possibly due to the steric strain of the closed-ring form, especially the strain of the imidazo[1,2-*a*]pyridine ring.[7,8]

Summary

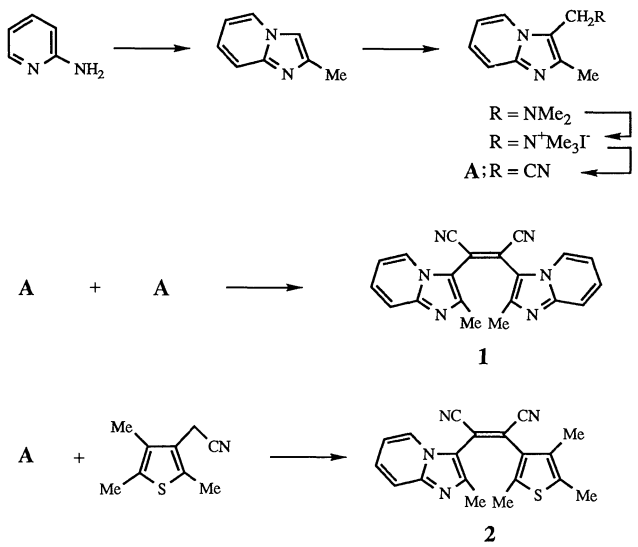
Diarylethene derivatives with imidazo[1,2-*a*]pyridine rings were synthesized. The symmetric diarylethene derivative with two imidazo[1,2-*a*]pyridine rings underwent only the *Z*–*E* photoisomerization. The ring-closure reaction was not observed. On the other hand, the non-symmetrical diarylethene derivative with imidazo[1,2-*a*]pyridine ring on one end and thiophene ring on the other end underwent both the *Z*–*E* isomerization and the ring-closure reaction. The absorption maximum showed a bathochromic shift as much as 23 nm in comparison with that of dithienylethene derivative. A quantum yield close to unity was observed for the ring-opening reaction of **2C**.

Experimental

General Method. IR spectra were measured with a Perkin Elmer Model 1618 spectrophotometer using KBr disks. ^1H NMR spectra (360 MHz) were recorded with a Bruker WN-360 spectrometer. Samples were measured in C_6D_6 or $CDCl_3$ using the tetramethylsilane (0 ppm) as an internal standard. ^{13}C NMR spectra (68 MHz) were recorded on JOEL JNM-GSX-270 spectrometer using $CDCl_3$ as the solvent with tetramethylsilane as an internal standard. Mass spectra and elemental analyses were performed in the Material Analysis Center of Osaka University. Melting points were determined by using a Gallenkamp melting point apparatus (MP-41). HPLC analysis was carried out on a JASCO 800 system. Stainless-steel columns (length, 250 mm; i.d., 4.6 mm, for analytical purposes, length, 250 mm; i.d., 10.0 mm, for preparative purposes) were slurry packed using silica gel (Fine SIL-5). Absorption spectra were measured with a Shimadzu MPS-200 instrument.

Photoirradiation was carried out with a EWIG XC-500 Xenon lamp. The wavelength of light was selected by passing the light through a monochrometer (Jobin Yvon H10-UV). Quantum yields were determined by measuring the rate of isomerization in the initial stage of the reaction at low concentration (absorbance at the irradiation wavelength <0.2) and the light intensity was measured with a photometer (International Light IL1700).

Materials. 1,2-Dicyano-1,2-bis(2-methylimidazo[1,2-*a*]-pyridin-3-yl)ethene and 1,2-dicyano-1-(2-methylimidazo[1,2-*a*]pyridin-3-yl)-2-(2,4,5-trimethyl-3-thienyl)ethene were synthesized as follows.



2-Methylimidazo[1,2-*a*]pyridine.[9] A mixture of 11.3 g (0.12 mol) of 2-aminopyridine and 11.1 g (0.12 mol) of chloroacetone in 120 mL of ethanol was heated under reflux for 20 h. The ethanol was removed by evaporation, and the residual material was dissolved in 100 mL of water. The aqueous solution was extracted with dichloromethane (4×20 mL). The dichloromethane extracts were washed with water (20 mL). The aqueous solutions were combined, and adjusted to pH 11.5—12 by the addition of 50% sodium hydroxide (ca. 12 mL). The basic aqueous solution was extracted with dichloromethane (3×20 mL). The dichloromethane extracts were combined and washed with water (20 mL). The aqueous solution was cooled with ice and was adjusted to pH 7 by the addition of 6 M hydrochloric acid (ca. 20 mL, M=mol dm^{-3}). After the solution was allowed to stand overnight, the solid that precipitated was isolated by filtration, washed with water and dried. Recrystallization from dichloromethane–methanol gave 5.6 g (0.042 mol) (35%) of 2-methylimidazo[1,2-*a*]pyridine. bp 120 °C/0.35 mmHg (1 mmHg=133.322 Pa). ^{1}H NMR ($CDCl_3$), δ=2.45 (s, 3H), 7.00 (dt, J=1.1 and 6.8 Hz, 1H), 7.09 (ddd, J=1.4, 6.8, and 9.4 Hz, 1H), 7.32 (s, 1H), 7.49 (d, J=9.4 Hz, 1H), 8.01 (dt, J=6.5 and 1.1 Hz, 1H).

3-[(Dimethylamino)methyl]-2-methylimidazo[1,2-*a*]pyridine.[9] A mixture of 5.6 g (0.042 mol) of 2-methylimidazo-[1,2-*a*]pyridine, 4.45 g (0.055 mol) of dimethylamine hydrochloride and 1.64 g (0.055 mol) of paraformaldehyde in 40 mL of methanol was heated under reflux for 1.5 h with stirring. Thereafter, the mixture was evaporated. Upon cooling to ambient temperature, the reaction mixture was acidified by the addition of concentrated hydrochloric acid (ca. 4 mL) and stirred for 18 h. The solid was isolated by filtration and washed with methanol and finally ether. After drying the solid was dissolved in 52 mL of hot water. The aqueous solution was adjusted to pH 11—12 by adding 50% sodium hydroxide. The mixture was cooled to 0 °C and extracted with dichloromethane (3×20 mL). The extracts were combined and washed with aqueous NaCl solution (20 mL). The dichloromethane was removed under reduced pressure to give an oil 3-[(dimethylamino)methyl]-2-methylimidazo[1,2-*a*]pyridine 7.9 g (0.042 mol) (100%). This material was used without further purification. ^{1}H NMR ($CDCl_3$), δ=2.22 (s, 6H), 2.44 (s, 3H), 3.65 (s, 2H), 6.75 (td, J=7.0 and 1.1 Hz, 1H), 7.13 (ddd, J=1.1, 6.8, and 9.0 Hz, 1H), 7.49 (d, J=9.0 Hz, 1H), 8.17 (d, J=7.2 Hz, 1H).

2-Methyl-3-[(trimethylammonio)methyl]imidazo[1,2-*a*]pyridine Iodide.[9] 3-[(Dimethylamino)methyl]-2-methylimidazo-[1,2-*a*]pyridine 7.9 g (0.042 mol) was dissolved in 58 mL of ethanol. To the ethanol solution at 0 °C was added dropwise with stirring 6.6 g (0.047 mol) of methyl iodide. The reaction mixture was stirred at ambient temperature overnight. The solid that formed was isolated by filtration and washed with ethanol (10 mL) and finally ether (35 mL). After drying, 14.0 g (0.042 mol) (100%) of 2-methyl-3-[(trimethylammonio)methyl]imidazo[1,2-*a*]pyridine iodide was obtained.

3-(Cyanomethyl)-2-methylimidazo[1,2-*a*]pyridine.[9] A mixture of 14.0 g (0.042 mol) of 2-methyl-3-[(trimethylammonio)-methyl]imidazo[1,2-*a*]pyridine iodide and 2.16 g (0.044 mol) of sodium cyanide in 120 mL of *N*,*N*-dimethylformamide was heated on a steam bath for 1 h with stirring. The mixture was poured into ice/water (360 mL) and stirred for 1 h. The solid was isolated by filtration, washed with water, and dried. Recrystallization from acetonitrile gave 2.4 g (0.014 mol) (33%) of 3-(cyanomethyl)-2-methylimidazo[1,2-*a*]pyridine. IR(KBr) 2246 cm^{-1}; MS (EI) *m*/*z* (rel intensity), 171 (M^+, 100), 156 (M^+—Me, 29), 145 (M^+—CN, 37); ^{1}H NMR ($CDCl_3$), δ=2.47 (s, 3H), 3.98 (s, 2H), 6.91 (t, J=6.8 Hz, 1H), 7.24 (t, J=7.9 Hz, 1H), 7.57 (d, J=9.0 Hz, 1H), 7.94 (d, J=6.8 Hz, 1H); mp 157—9 °C; Found: C, 70.31; H, 5.23; N, 24.46%. Calcd for $C_{10}H_9N_3$: C, 70.16; H, 5.30; N, 24.54%.

1,2-Dicyano-1,2-bis(2-methylimidazo[1,2-*a*]pyridin-3-yl)-ethene 1*Z*. This was prepared by a self-coupling reaction of 3-(cyanomethyl)-2-methylimidazo[1,2-*a*]pyridines by the method of Irie et al.[1] To 1.1 mL of 50% NaOH aqueous solution containing tetrabutylammonium bromide (0.07 g, 0.2 mmol) was added over a period 0.5 h a mixture of 3-(cyanomethyl)-2-methylimidazo[1,2-*a*]pyridine (462 mg, 2.7 mmol) and carbon tetrachloride (0.79 mL, 8 mmol), benzene 0.79 mL and acetone 1.0 mL at 40 °C. The solution was stirred for 3 h at 45 °C. Then the reaction mixture was poured into water. The aqueous solution was extracted with $CHCl_3$ and the organic phase was dried over $MgSO_4$. After the solvent was removed, the mixture of *Z* and *E* form was obtained in 79% yield by column chromatography on silica gel. The mixture of *Z* and *E* forms was dissolved in benzene and then exposed to 490 nm light. The *Z* form was separated from the solution by HPLC and then purified by recrystallization from a hexane–ether mixture. Mp 250—2 °C; IR(KBr) 2211 cm^{-1}; ^{1}H NMR[10] ($CDCl_3$), δ=2.21 (s, 6H), 6.75

(td, J=6.8 and 1.3 Hz, 2H), 7.27 (ddd, J=1.4, 6.5, and 8.3 Hz, 2H), 7.53 (d, J=9.7 Hz, 2H), 7.54 (d, J=6.8 Hz, 2H); ^{1}H NMR (C_6D_6), δ=2.02 (s, 6H), 5.77 (td, J=6.8 and 1.4 Hz, 2H), 6.31 (ddd, J=8.6, 7.2, and 1.4 Hz, 2H), 6.71 (d, J=6.8 Hz, 2H), 7.07 (d, J=8.6 Hz, 2H); MS (EI) m/z (rel intensity) 338 (M^+, 100) 323 (M^+−Me, 8); Found: C, 70.93; H, 3.98; N, 24.83%. Calcd for $C_{20}H_{14}N_6$: C, 70.99; H, 4.17; N, 24.84%.

1,2-Dicyano-1-(2-methylimidazo[1,2-*a*]pyridin-3-yl)-2-(2,3,5-trimethyl-3-thienyl)ethene 2*Z*.[2] This was prepared by a cross-coupling reaction of 3-(cyanomethyl)-2-methylimidazo-[1,2-*a*]pyridine and 4-(cyanomethyl)-2,3,5-trimethylthiophene[1] and isolated in 18% yield, mp>300 °C; IR(KBr) 2215 cm^{-1}; ^{1}H NMR[11] ($CDCl_3$), δ=1.79 (s, 6H), 2.00 (s, 6H), 2.12 (s, 6H), 2.18 (s, 6H), 6.88 (td, J=6.8 and 1.4 Hz, 2H), 7.39 (ddd, J=1.4, 6.8, and 9.0 Hz, 2H), 7.58 (d, J=8.6 Hz, 2H), 7.87 (td, J=6.8 and 1.1 Hz, 2H); ^{1}H NMR (C_6D_6) δ=1.41 (s, 6H), 1.50 (s, 6H), 1.62 (s, 6H), 1.96 (s, 6H), 6.05 (td, J=6.8 and 1.1 Hz, 2H), 6.49 (ddd, J=7.6, 6.8, and 1.1 Hz, 2H), 7.22 (d, J=7.6 Hz, 2H), 7.33 (d, J=6.8 Hz, 2H); ^{13}C NMR ($CDCl_3$), δ=12.86, 13.09, 14.32, 14.77, 113.00, 113.75, 114.383, 114.529, 116.01, 117.38, 119.59, 124.08, 127.15, 128.85, 130.26, 132.55, 137.69, 146.88, 147.95; MS (EI) m/z (rel intensity), 332 (M^+, 100), 317 (M^+−Me, 63); Found: C, 68.58; H, 4.96; N, 16.71%. Calcd for $C_{19}H_{16}N_4S_1$: C, 68.65; H, 4.85; N, 16.85%.

We thank Mr. Masato Sekiguchi (Osaka Univ.) for his helps in NMR measurements.

(Received September 25, 1990)

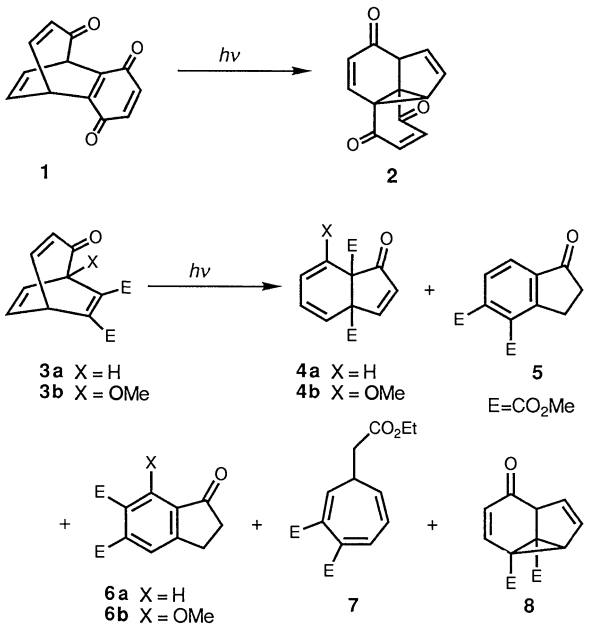
The direct irradiation of dimethyl 2-oxohomobarrelene-6,7-dicarboxylates in chloroform gave indanone derivatives. A benzophenone-sensitized reaction gave a new tricyclic compound, dimethyl 5-oxotricyclo-[4.3.0.0^{2,9}]nona-3,7-diene-1,2-dicarboxylate, the formation of which was quenched by isoprene.

Bicyclo[3.2.2]nona-3,6,8-trien-2-ones (homobarrelenones) are interesting molecules with regard to the photochemical reactivity, since they have a transannular conjugated tri-π-methane chromophore, in which one of the double bonds is conjugated with a carbonyl group. The photochemical reactivity of these transannularly delocalized π-systems has attracted much attention and, indeed, the photochemical reactions for parent homobarrelenone[2] and benzo and dibenzo derivatives[3,4] as well as 2-methylenehomobarrelenes[5] have already been investigated. However, the reactions of the homobarrelenones with substituents were limited, since their preparation was somewhat difficult.

We recently developed a new synthetic method for producing homobarrelenones, the Diels–Alder cycloaddition of tropones to dimethyl 7-oxabicyclo[2.2.1]hepta-2,5-diene-2,3-dicarboxylate and subsequent fragmentation.[6] Furthermore, we could synthesize quinone-fused homobarrelenones, e.g., tricyclo[6.3.2.0^{2,7}]trideca-2(7),4,10,12-tetraene-3,6,9-trione (**1**) via a high-pressure Diels–Alder reaction of tropone with *p*-benzoquinone followed by dehydrogenation. We have verified that **1**, upon UV-irradiation, exclusively gave tetracyclo-[6.5.0.0^{1,9}.0^{5,9}]trideca-2,6,11-triene-4,10,13-trione (**2**).[7] This photochemical reaction of **1** has been shown to be different with regard to the product distribution to that of the parent homobarrelenone. It is therefore worth investigating other homobarrelenone derivatives having different chromophores. Herein, we describe the photorearrangement of dimethyl 2-oxohomobarrelene-6,7-dicarboxylate (**3**) with some mechanistic aspects.

When dimethyl 2-oxohomobarrelene-6,7-dicarboxylate (**3a**)[8] was irradiated in chloroform by means of a 100-W high-pressure mercury lamp, four products (**4a**, **5**, **6a**, **7**) were obtained in 24, 2.3, 16, and 3.8% yields, respectively. The major product, **4a**, was identified as dimethyl 7-oxobicyclo[4.3.0]nona-2,4,8-triene-1,6-dicarboxylate by an ^{1}H NMR spectral comparison with an authentic sample, which has already been isolated from the thermal reaction of **3a**.[8] While the minor product, **5**, could not be separated completely from **3a**, its ^{1}H NMR spectrum was identical with that of authentic dimethyl 1-oxoindan-4,5-dicarboxylate.[8] The structure of **6a** was determined to be isomeric dimethyl 1-oxoindan-5,6-dicarboxylate, since aromatic proton signals appeared separately at δ=7.74 and 8.19 as singlets. Compound **7** had an ethoxycarbonyl group instead of the ketonic carbonyl group in the ^{13}C NMR spectrum, and its UV spectrum indicated a cycloheptatriene derivative. Since the signals for four olefinic protons and six olefinic carbons were recognized, **7** was deduced to be ethyl 3,4-bis(methoxycarbonyl)-2,4,6-cycloheptatrienylacetate. Evidently, **7** was formed via a ketene intermediate.

The irradiation of **3a** in chloroform in the presence of benzophenone afforded five products, four of which were the same as those characterized by direct irradiation. The structure of a new tricyclic compound (**8**) was determined as depicted on the basis of ^{1}H and ^{13}C NMR spectral analyses; the NMR spectral data for a common unsaturated ring moiety of **8** and **2**[7] were almost superimposable on each other.



Scheme 1.

On the other hand, dimethyl 1-methoxy-2-oxohomobarrelene-6,7-dicarboxylate (**3b**) was irradiated under similar conditions; two products (**4b** and **6b**) were obtained in 41 and 42.4% yields, respectively.

The structure of **4b** was elucidated to be dimethyl 5-methoxy-7-oxobicyclo[4.3.0]nona-2,4,8-triene-1,6-dicarboxylate according to the NMR spectral similarity with **4a**. **6b** was identified to be dimethyl 7-methoxy-1-oxoindan-5,6-dicarboxylate, since no NOE was observed between the aromatic proton signal and the methoxyl signal. The irradiation of **3b** in the presence of benzophenone resulted in the formation of the same products (**4b** and **6b**) as those produced by direct irradiation.

When the benzophenone-sensitized photoreaction of **3a** was monitored by the ^{1}H NMR spectra, as shown in Fig. 1, the consumption of **3a** was accelerated and the ratios of **3a**/**4a** increased.

In parallel, a quenching effect of the photoreaction of **3a** was analyzed by using isoprene. As shown in Table 1, compound **8** was undetectable and the product distribution was similar to that produced by direct irradiation. These results clearly show that **8** was formed via the triplet excited state and that the other products (indanones and **7**) were formed via singlet excited state, as illustrated in Scheme 2. The pathway to **8** can be explained in terms of di-π-methane rearrangements[2] of the diradical, **A**, which must be more stable than the alternative diradical, **B**, since both radical moieties of **A** were stabilized by the adjacent carbonyl groups.

Ketene intermediates, **C** and **D**, as has already been proposed regarding indanone formation in the thermal reaction of **3a**,[8,9] would be involved in photorear-

Table 1. Product Distributions of Photoreactions of **3a**

Solvent (Additive)	Yield/% 4a	5	6a	7	8	Recovered 3a
Chloroform	24	2.3	16	3.8	0	21
Chloroform (Benzophenone)	16	4.3	7.5	2.4	13	10
Chloroform (Isoprene)	28	1.9	13	3.7	0	24

rangements of **3**. The [3,5] shifts of bond a in **C** and bond b in **D** give **4** and **6**, respectively. Two paths, [3,5] shift of bond b in **C** and [1,3] shift of bond a in **D**, were equally possible to give **5** and were undistinguishable. In **3b**, the methoxyl group at C-1 assisted the [3,5] shifts of bond a in **C** and bond b in **D** to give **4b** and **6b**. The selective bridging between the enone part and the ethene part with substituents in the thermal reaction of **3** could be explained by a molecular orbital consideration.[9] However, according to the present photoreaction of **3**, both ketene intermediates were equally reactive and no selectivity of the bridging was observed.

In conclusion, the present study confirmed that the photoreaction of homobarrelenones having electron-withdrawing substituents, **3**, was different from the other electron-withdrawing homobarrelenone, **1**. Though the photoisomerization of **1** exclusively gave **2**, **3** afforded various products. The different product distributions between these two fundamental derivatives may be attributable to a difference in the primary excitation part; **3** absorbs light at the α,β-unsaturated keto group, while **1** does so at the ene-dione chromophore.

Experimental

Elemental analyses were performed by Miss S. Hirashima and Miss T. Mizoguchi of the Institute of Advanced Material Study, Kyushu University. The NMR spectra were measured by means of a JEOL FX 100 Model and JEOL GSX 270 H Model spectrometer in a $CDCl_3$ solution (unless otherwise specified); The chemical shifts are expressed in units of δ. The mass spectra were measured with a JEOL O1SG-2 spectrometer. The IR spectra were taken as KBr disks or as a liquid film inserted between NaCl plates using a JASCO IR-A 102 spectrometer. The UV spectra were measured by using a Hitachi U-3200 spectrophotometer.

Irradiation of 3a. a) A $CHCl_3$ solution (3 cm^3) of **3a** (101 mg) in a Pyrex vessel was irradiated by means of a 100-W high-pressure mercury lamp for 5 h. The solvent was removed and the mixture was purified by silica-gel column chromatography and HPLC to give 18.8 mg (24%) of **4a**, 1.8 mg (2.3%) of **5**, 12.5 mg (16%) of **6a**, and 3.4 mg (3.8%) of **7** together with 21.6 mg (21%) of recovered **3a**.

4: Colorless crystals, mp 78.5—79.0 °C (lit,[8] mp 79.5—80.5 °C); ^1H NMR δ=3.70 (3H, s), 3.71 (3H, s), 5.65 (1H, dt, J=9.2, 1.1 Hz), 6.02 (1H, ddd, J=9.2, 5.5, 1.1 Hz), 6.09 (1H, ddd, J=9.5, 5.5, 1.1 Hz), 6.18 (1H, dt, J=9.5, 1.1 Hz), 6.55 (1H, d, J=5.8 Hz), and 7.95 (1H, d, J=5.8 Hz).

5: Not isolated as a pure form (lit,[8] mp 114—115 °C); ^1H NMR δ=2.7—2.8 (2H, m), 3.2 (2H, m), 3.94 (3H, s), 3.97 (3H, s), 7.86 (1H, d, J=7.7 Hz), and 7.89 (1H, d, J=7.7 Hz).

6a: Colorless crystals, mp 59—60 °C; ^1H NMR δ=2.7—2.8 (2H, m), 3.2 (2H, m), 3.93 (3H, s), 3.95 (3H, s), 7.74 (1H, s), and 8.19 (1H, s); ^{13}C NMR δ=26.0, 36.5, 52.6, 53.0, 125.1, 127.0, 129.9, 130.3, 138.5, 157.9, 166.5, 168.1, and 205.1; IR(KBr) 2956, 1741, 1714, 1618, 1274, 1201, and 1074 cm^{-1}; MS m/z (%) 248 (M^+, 26), 217 (100), and 189 (8).

Found: m/z 248.0684 (M^+). Calcd for $C_{13}H_{12}O_5$: 248.0684 (M).

7: A pale yellow oil; ^1H NMR δ=1.27 (3H, t, J=7.0 Hz), 2.3—2.4 (1H, m), 2.78 (2H, dd, J=7.0, 1.1 Hz), 3.72 (3H, s), 3.80 (3H, s), 4.20 (2H, q, J=7.0 Hz), 5.67 (1H, dd, J=9.8, 5.1 Hz), 6.31 (1H, d, J=6.6 Hz), 6.31 (1H, ddd, J=9.8, 6.6, 1.5 Hz), and 7.69 (1H, dd, J=5.9, 1.1 Hz); ^{13}C NMR δ=14.2, 35.4, 37.0, 52.3 (2C), 60.8, 125.8, 128.0, 132.5, 133.7, 136.6, 138.0, 166.8, 167.4, and 171.3; IR (oil) 2984, 2952, 1729, 1260, 1208, and 742 cm^{-1}; UV (MeOH) 220 nm (ε: 12800 sh) and 270 (4900); MS m/z (%) 294 (M^+, 8), 262 (100), 248 (18), and 189 (39).

Found: m/z 294.1101 (M^+). Calcd for $C_{15}H_{18}O_6$:1 294.1102 (M).

b) A $CHCl_3$ solution (3 cm^3) of **3a** (97.5 mg) and benzophenone (72.8 mg) was irradiated as mentioned above for 5 h to give 14.2 mg (16%) of **4a**, 3.8 mg (4.3%) of **5**, 6.6 mg (7.5%) of **6a**, 2.5 mg (2.4%) of **7**, and 11.5 mg (13%) of **8** together with 9.9 mg (10%) of recovered **3a**.

8: A colorless oil; ^1H NMR δ=3.71 (3H, s), 3.81 (3H, s), 3.9 (1H, m), 3.98 (1H, d, J=2.2 Hz), 5.73 (1H, dd, J=5.5, 2.2 Hz), 5.92 (1H, ddd, J=5.5, 2.2, 1.1 Hz), 6.22 (1H, dd, J=10.3, 0.7 Hz), and 6.69 (1H, d, J=10.3 Hz); ^{13}C NMR δ=39.5, 51.5, 52.7, 53.2, 55.1, 59.4, 129.7, 130.1, 134.7, 137.6, 168.4, 168.9, and 195.8; IR(oil) 3454, 2956, 1732, 1695 and 1268 cm^{-1}; UV (MeOH) 214 nm (ε: 9100), 251 (4100), 303 (1500 sh), and 336 (1100 sh); MS m/z (%) 248 (M^+, 46), 220 (38), 216 (100), and 188 (34).

Found; m/z 248.0685 (M^+). Calcd for $C_{13}H_{12}O_5$: 248.0684 (M).

c) A $CHCl_3$ solution (3 cm^3) of **3a** (102 mg) was irradiated as mentioned above for 5 h in the presence of isoprene (47.8 mg) to give 22.1 mg (28%) of **4a**, 1.5 mg (1.9%) of **5**, 10.2 mg (13%) of **6a**, and 3.4 mg (3.7%) of **7** together with 24.3 mg (24%) of **3a**.

d) A $CHCl_3$ solution (3 cm^3) of **3a** (134.5 mg) and benzophenone (100 mg) was irradiated by means of 400 W high-pressure lamp for 5 h to give 14.7 mg (11%) of **4a**, 3.3 mg (2%) of **6a**, 40.5 mg (22%) of **7**, and 14 mg (10%) of **8**.

Irradiation of 3b. a) A $CHCl_3$ solution (2 cm^3) of **3b** (50 mg) was irradiated for 5 h under similar conditions. The solvent was removed and the mixture was purified by a silica-gel column chromatography and HPLC to give 20.5 mg (41%) of **4b** and 21.2 mg (42.4%) of **6b**.

4b: Colorless needles, mp 128—130 °C; ^1H NMR δ=3.69 (6H, s), 3.70 (3H, s), 5.27 (1H, d, J=6.6 Hz), 5.53 (1H, J=9.5 Hz), 6.12 (1H, dd, J=9.5, 6.6 Hz), 6.58 (1H, d, J=5.9 Hz), and 7.47 (1H, J=5.9 Hz); ^{13}C NMR δ=52.9, 53.2, 56.1, 62.8, 94.1, 115.4, 123.0, 123.3, 133.9, 151.8, 159.3, 167.8, 170.7, and 197.8; IR(KBr) 1746, 1732, 1592, 1436, 1263, 1231, 1189, and 1049 cm^{-1}; UV (MeOH) 211 nm (ε: 13380) and 282 (4770); MS m/z (%) 278 (M^+, 38), 219 (100), 191 (66), 175 (67), 160 (25), and 132 (28).

Found: m/z 278.0789. Calcd for $C_{14}H_{14}O_6$: 278.0789 (M).

6b: Colorless needles, mp 148—149 °C; ^1H NMR δ=2.76 (2H, m), 3.17 (2H, m), 3.92 (3H, s), 3.95 (3H, s), 4.03 (3H, s), and 7.80 (1H, s); ^{13}C NMR δ=25.8, 37.1, 52.8, 53.0, 63.5, 123.0, 129.0, 131.7, 134.2, 155.4, 158.0, 165.1, 167.0, and 202.8; IR(KBr) 1743, 1711, 1453, 1302, 1272, 1231, 1194, 1150, and 1078 cm^{-1}; UV (MeOH) 206 nm (ε: 24360), 258 (12200), and 316 (2730); MS m/z (%) 278 (M^+, 54), 247 (100), 233 (54), and 160 (68).

Found: C, 60.40; H, 5.41%. Calcd for $C_{14}H_{14}O_6$: C, 60.46; H, 5.04%.

b) A $CHCl_3$ solution (2 cm^3) of **3b** (150 mg) and

benzophenone (100 mg) was irradiated for 3 h. A similar work-up gave 51.5 mg (34.3%) of **4b** and 50.3 mg (33.5%) of **6b**.

Kinetics. A $CDCl_3$ solution (0.6 cm^3) of **3a** (72.6 mg) and a $CDCl_3$ solution (0.6 cm^3) of **3a** (73.7 mg) and benzophenone (51.2 mg) were irradiated using a "Merry-Go-Round" apparatus. The reaction was monitored by means of the ^1H NMR spectra. The results are summarized in Fig. 1.

The authors wish to express their thanks to Dr. Tadao Uyehara of Tohoku University for providing the spectral data of **4a** and **5**.

(Received June 19, 1990)

The crystal structure of $(DMET)_2BF_4$: 5,6-dihydro-2-(4,5-dimethyl-1,3-diselenol-2-ylidene)dithiolo[4,5-*b*][1,4]dithiinium tetrafluoroborate (2:1), $(C_{10}H_{10}S_4Se_2)_2BF_4$, is determined. Crystal data: M_r=919.49, triclinic, $P\bar{1}$, a=7.032(2), b=7.812(3), c=27.502(11) Å, α=90.87(2), β=90.28(2), γ=106.22(2)°, V=1450.5(15) Å^3, Z=2, D_x=2.11 Mg m^{-3}, λ(Mo $K\alpha$)=0.71068 Å, μ=5.60 mm^{-1}, $F(000)$=890, T=297 K, R=0.077 for 4600 reflections. Two crystallographically independent DMET molecules separately form columns along nearly perpendicular directions, and ordered BF_4 anions are located between the DMET columns.

In recent years, radical salts of DMET, which is a hybrid donor between TMTSF and BEDT-TTF, with some monovalent anions have been studied.[1–5] In the course of the study, seven superconductors have been discovered. The DMET salts, in addition to superconductivity, exhibit a variety of electronic properties; metal, semiconductor, and spin density wave (SDW) transition.[3,5] The DMET salts were classified into five Groups on the basis of temperature dependence of conductivity and the shape of counter anions. The salts of Group 2, which is with tetrahedral anions, show metallic behavior at room temperature under the normal pressure. A metal-insulator transition occurs at low temperature.

Besides these attractive electronic properties, crystal structures of DMET salts are interesting from the point of view of the asymmetry of donor molecule. The crystal structure has been determined for PF_6,[6] ReO_4,[7] $Au(CN)_2$,[8] AuI_2,[9] $AuBr_2$,[10] $AuCl_2$,[11] IBr_2,[12] and I_3[13] salts. In these salts, except for the $AuBr_2$ salt of Group 5, DMET molecules are stacked with an alternate molecular orientation and form one-dimensional columns. Within the columns some short intermolecular contacts exist and some salts additionally have intermolecular contacts between the columns. These intra- and intercolumnar contacts highten the dimensionality of the salt.

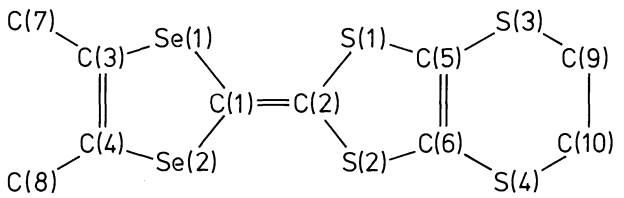
The title compound show the room temperature conductivity of about 130 S cm^{-1}.[6] On cooling, the metallic character continues down to about 40 K, where the temperature dependence of the conductivity changes to that of insulator. These behaviors are characteristic to the salts of Group 2.[1] The EPR study revealed that an SDW transition occurred at 20 K. Although the transition temperature is a little lower than the temperature of the conductivity maximum, the metal-insulator transition is probably due to the formation of SDW.

† Present address: Tokyo Research Center, TOSOH Corp., Hayakawa, Ayase, Kanagawa 252.

The shape of $(DMET)_2BF_4$ crystals is not needle-like as seen in other DMET salts, but rhombus-like. It is suggested that $(DMET)_2BF_4$ has two-dimensionality. This conjecture was supported by the fact that the anisotropy of steady[14] and optical[15] conductivity of $(DMET)_2BF_4$ crystal was about 1 to 4, and was confirmed through the crystal structure determination reported preliminarily.[4] In this paper, the molecular structure and crystal structure of $(DMET)_2BF_4$ are reported in detail.

Experimental

Crystals of $(DMET)_2BF_4$ were prepared by electrochemical oxidation of DMET in 1,1,2-trichloroethane solution in the presence of $(n\text{-}Bu_4N)\cdot BF_4$ at a constant current (1 μA). D_m was not determined. The crystal used for the data collection was black and rhombus-like: 0.35×0.25×0.13 mm^3. The data collection was performed with the Rigaku AFC-M automated four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71068 Å). Unit-cell dimensions were determined from 38 selected reflections ($16°<2\theta<28°$). The intensity data were collected using the ω-scan technique ($2\theta<30°$) and the ω–2θ scan technique ($2\theta>30°$) with a scan rate 3.75° min^{-1} ($\Delta\omega=1.55°+0.50°\cdot\tan\theta$) in ω to $(\sin\theta)/\lambda$= 0.65 Å^{-1} ($0\leq h\leq 8$, $-9\leq k\leq 9$, $-35\leq l\leq 35$). Two standard reflections (measured at an interval of 100 reflections) showed small (<0.6%) random variations. The data were corrected for absorption effect using a Gaussian integration procedure; T_{min}=0.26, T_{max}=0.50. 6516 independent reflections were collected and 4600 reflections ($|F_o|>3\sigma(|F_o|)$) were used in the structure refinement. Intensity statistics indicated space group $P\bar{1}$ rather than $P1$ and this choice was later confirmed by the successful structure solution and least-squares refinement. The Se and S atoms were located by the Patterson method and the structure was solved by successive Fourier synthesis and refined by the block-diagonal least-squares method. The atomic and anomalous scattering factors were taken from International Tables for X-ray Crystallography.[16] All computations were carried out using UNICS III program.[17] No hydrogen atoms were located. $\sum w\cdot(|F_o|-|F_c|)^2$ was minimized, where $w=\sigma^{-2}(|F_o|)$, with σ ($|F_o|$) based on counting statistics. The maximum value of Δ/σ was 0.01 for B_{23} of C(8A) in the final least-squares cycle.



It resulted in the agreement factors R=0.077, wR=0.047 and S=8.32. No correction was made for the secondary extinction. A difference synthesis based on the structure factors derived from the final parameter values showed some peaks of density (−1.4 to 1.3 $e \cdot Å^{-3}$). The temperature factor of the ethylene group in one DMET molecule was anomalously large. Although a difference synthesis using all parameters showed no significant peak around the C(10A) atom, the difference synthesis using the final parameters except those for C(10A) showed double peaks (3.7 and 2.0 $e \cdot Å^{-3}$). The parameters reported for the C(10A) atom are, therefore, averaged ones in some way. ORTEP II[18] was used to produce crystal structure illustrations.

Results and Discussion

The final positional and thermal parameters are tabulated in Table 1.[19] The bond lengths and angles are given in Tables 2 and 3, respectively. The geometry of the DMET molecule A, which consists in the column along the a axis, is in reasonable agreement with those observed in other DMET salts[7-9,11,12] except ethylenedithio moiety (-S-CH_2-CH_2-S-). The apparent bond length of C(9A)-C(10A), given in the table, is shorter than those in other salts (ca. 1.51 Å) owing to the positional disorder of C(10A).

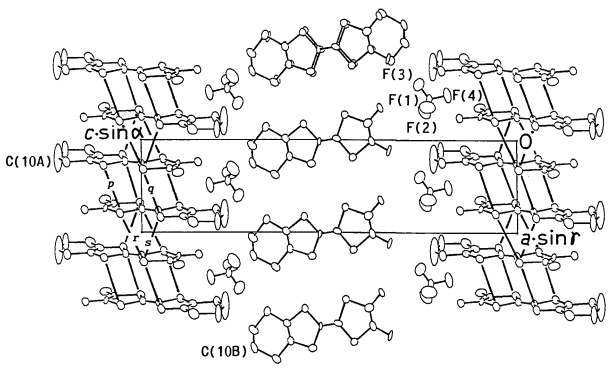

Fig. 1. Crystal structure of $(DMET)_2BF_4$ viewed along the b axis. Thermal ellipsoids indicate the region of 50% probability. Thin solid lines show the shorter intermolecular contacts than the sum of van der Waals radii. Their distances; p=3.771(3) Å, q=3.735(3) Å, r=3.939(2) Å and s=3.803(3) Å.

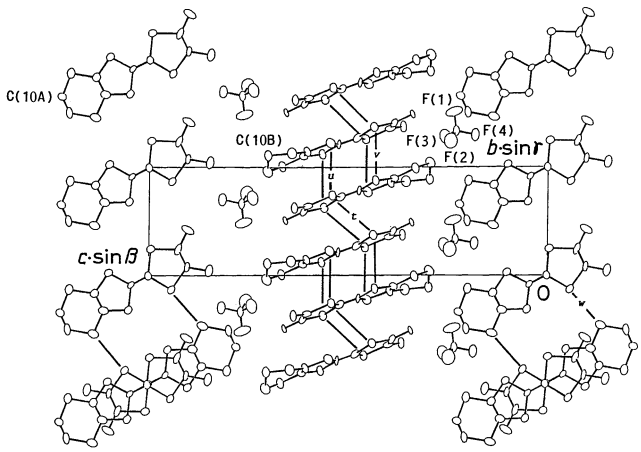

Fig. 2. Crystal structure of $(DMET)_2BF_4$ viewed along the a axis. Thermal ellipsoids indicate the region of 50% probability. Thin solid lines show the shorter intermolecular contacts than the sum of van der Waals radii. Their distances; t=3.924(2) Å, u=3.825(4) Å, v=3.837(4) Å and w=3.618(4) Å.

The DMET molecule A is almost planar except for the "averaged" C(10A) atom. The other atoms are within about 0.07 Å from the molecular plane determined by the Se(1A), Se(2A), S(1A), S(2A), C(1A), and C(2A) atoms.

The geometry of the molecule B, which consists in the column along the b axis, is slightly different from those observed in other salts. In the molecule B the bond length of C(1B)–C(2B) is longer and that of C(5B)–C(6B) is shorter than the corresponding lengths in other DMET salts. The molecule B is almost planar except for the C(10B) atom. It is about 0.8 Å apart from the molecular plane determined as molecule A; the other atoms are within about 0.2 Å from the plane. Such magnitude of the deviation from the planality has been reported for other DMET salts.

As seen in Fig. 1, there exist two types of DMET columns along the a and the b axes. A similar structure was reported for $(DIMET)_2ClO_4$;[20] DIMET ($C_{10}H_{10}S_6$) is a 2-(4,5-dimethyl-1,3-dithiol-2-yliden) analog of DMET. In both types of columns A and B, DMET molecules stack with an alternate orientation related by an inversion center. The BF_4 anion is located in between two types of columns (a crystallographic general point), and no orientational disorder is detected.

In the column A, the molecular plane determined with two Se, two inner S and two central C atoms is almost normal to the a axis (87.4°). The angle between the normal to the plane and the stacking axis (2.6°) is very small as compared with those in other $(DMET)_2X$ (typically ca. 20°).[7–9,11,12] Although two interplanar distances are almost equal (3.51 and 3.52 Å) to each other, two intermolecular contact patterns between the neighboring molecules in the columns are different.

One type of overlap has four Se–S contacts (refered as *p* and *q* in the Figure) shorter than the sum of the van der Waals radii, the other has two Se–Se (*r*) and two Se–S (*s*) ones. It is noted that the ethylenedithio moiety is not responsible for shorter contacts. There also exist short intermolecular contacts between the adjacent two columns A as seen in Fig. 2, where the interatomic (two Se–S) contacts (*w*) indicated are shorter than the sum of the van der Waals radii. These contacts lie between the molecules related by an inversion. The pattern of the intermolecular contacts within and between columns A has not been seen in other DMET salts and is different from that of the column B of this salt. This stacking mode, however, resemble that of TMTSF salts.[21]

In the column B, the normal to the molecular plane is tilted by 23.7° from the *b* axis. The DMET molecules are stacked with an alternate molecular orientation related by an inversion center as in the column A. Two interplanar distances are not equal (3.56 and 3.59 Å) to each other. One type of overlap has four shorter Se–S contacts (*u* and *v*), and the other has two shorter Se–Se contacts (*t*) and four slightly longer Se–S ones. This stacking mode has widely been observed in other DMET salts.[6–13] As shown in Fig. 1, there is no short intermolecular contact between the columns B. It is noted that the ethylenedithio moiety is not responsible for shorter contacts in both types of overlap of DMET molecules within the columns A and B.

Between the column A and the column B there is no short intermolecular contact. The BF_4 anions exist between the columns A and B, and are ordered. They are surrounded by four DMET molecules, and each BF_4 anion contacts with four methyl groups and two ethylene groups.

The little dimerization of DMET molecules within the one-dimensional columns seems responsible for metallic behavior at room temperature under the normal pressure. The same conjecture will apply to $(DMET)_2BF_4$. Comparing the structure of the column with those in other DMET salts, the structure of the column B resembles those of $(DMET)_2[Au(CN)_2]$[8] and $(DMET)_2[AuCl_2]$.[11] Interatomic distances of $(DMET)_2BF_4$ within the column are, however, slightly longer than those of the $Au(CN)_2$ and the $AuCl_2$ salts. Accordingly, the interaction within the column is weak in the BF_4 salt. The lower conductivity at room temperature than $Au(CN)_2$ and $AuCl_2$ salts is probably due to these differences in the interatomic distances and interaction.

Although ReO_4 is the same in shape, i.e., tetrahedral, the crystal structure of $(DMET)_2[ReO_4]$ is very different from that of $(DMET)_2BF_4$ probably because of the larger anion size.[7] In this respect, crystal structures of other tetrahedral anions are interesting, and the result will be published shortly.[12,22]

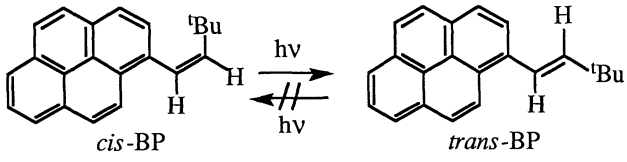
Behavior of the Excited Cis Singlet State of a One-Way Isomerizing Olefin. Further Insight into Potential Energy Surfaces of 1-(3,3-Dimethyl-1-butenyl)pyrene

Hiroaki Okamoto, Tatsuo Arai,* Hirochika Sakuragi, Katsumi Tokumaru,* and Yuji Kawanishi†
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
† Research Institute for Polymers and Textiles, Tsukuba, Ibaraki 305
(Received July 20, 1990)

The decay processes of the excited singlet state and potential energy surfaces of 1-(3,3-dimethyl-1-butenyl)pyrene (BP) were investigated. A long-lived fluorescence from the cis isomer and involvement of a quantum chain process for one-way isomerization suggest that the isomerization on direct excitation proceeds in the triplet manifold after intersystem crossing at the cis conformation.

On direct excitation, olefins can undergo photoisomerization in the singlet manifold, triplet manifold, or both depending on the properties of substituents on the ethylenic carbons. In the case of stilbene, cis-trans two-way isomerization occurs mutually between the both isomers in the singlet manifold.[1] However, 2-anthrylethylenes undergo cis-to-trans one-way isomerization in the triplet manifold even on direct irradiation; the initially produced singlet excited state does not undergo isomerization at all, but undergoes efficiently intersystem crossing to the triplet state.[2-4]

We reported previously that 1-(3,3-dimethyl-1-butenyl)-pyrene (BP) undergoes cis-to-trans one-way isomerization on triplet sensitization.[5] In this paper we elucidate the mechanism of its photoisomerization on direct irradiation, which is now revealed to proceed in the triplet state after intersystem crossing of the singlet excited state. In addition, on the basis of fluorescence studies and differential scanning calorimetry we propose the potential energy surfaces of the ground and excited singlet states of BP.



Experimental

Materials. Preparation of *cis*- and *trans*-1-(3,3-dimethyl-1-butenyl)pyrene (BP)[5] and purification of benzil and solvent benzene were done as described previously.[3]

Fluorescence Studies. Fluorescence spectra were measured on a Hitachi F-4000 spectrofluorimeter, and fluorecsence lifetimes were determined using a single photon counting apparatus, Horiba NAES-1100.

Steady Irradiations. Photostationary state isomer ratios and isomerization quantum yields were measured by irradiating degassed benzene solutions of BP with 366-nm light from a 400-W high-pressure mercury lamp through a band pass filter (Corning 7-60, 0-52). The isomer ratio was determined by HPLC (Waters 600 Multisolvent Delivery System) equipped with an LC spectrophotometer (Waters 490 Programmable Multiwavelength Detector) using 1,3-bis(bromomethyl)benzene as an internal standard. Light intensity was determined by potassium tris(oxalato)ferrate(III) actinometry.

Laser Flash Photolyses. Laser flash photolyses were performed with 308-nm (XeCl, 10-ns fwhm) and 435-nm laser pulses (Stilbene 3, 10-ns fwhm) from an excimer laser (Lambda Physik EMG-101) and an excimer laser-pumped dye laser (Lambda Physik FL-3002), respectively, and with a pulsed xenon arc (Wacom KXL-151, 150 W) as a monitoring light source. The detailed laser photolysis set-up was described previously.[3,5] Sample solutions containing BP (1.2×10^{-4} M, M=mol dm^{-3}) were deaerated by three freeze-pump-thaw cycles or by bubbling with argon for 30 min.

Differential Scanning Calorimetry. Energy difference between the ground-state trans (^{0}t) and cis isomer (^{0}c) was obtained by using differential scanning calorimetry (DSC). A Seiko Electric DSC-200/SSC5000 was used at the laboratory of Research Institute for Polymers and Textiles after calibration.[6] Approximately 2 mg of samples were scanned at 2—7.5 °C min^{-1}.

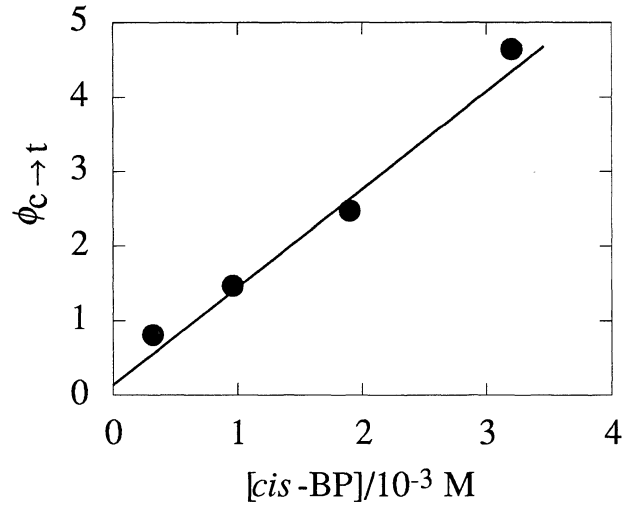


Fig. 1. Plot of quantum yields for cis→trans isomerization of BP ($\phi_{c\rightarrow t}$) in benzene as a function of *cis*-BP concentration on direct irradiation.

Results

Photostationary State Isomer Ratios and Isomerization Quantum Yields. Direct irradiation of BP ($0.16-1.6\times10^{-3}$ M) with 366-nm light in degassed benzene resulted in 100% of the trans isomer on starting from either cis or trans isomer as observed on triplet sensitized irradiation.[3] The quantum yield for cis→trans isomerization ($\phi_{c\to t}$) increased almost linearly with increasing cis isomer concentration ($0.32-3.2\times10^{-3}$ M), attaining 4.6 at the highest *cis*-BP concentration employed (Fig. 1).

Fluorescence Studies. A freshly prepared sample of *cis*-BP in benzene gave a fluorescence (Fig. 2a) different from that of *trans*-BP (Fig. 2b) at room temperature, while the spectrum was changed gradually to that of *trans*-BP at every scanning (Fig. 3). This is attributed to the photoexcitation of the trans isomer accumulated by photoisomerization of the cis isomer under excitation beam in the spectrometer during the measurement. At 77 K, each isomer showed a fluorescence spectrum (Figs. 2c and 2d) slightly more sharp than that observed at room temperature, without spectral change during the measurement.

The singlet excitation energies were estimated from the 0–0 band of the fluorescence spectrum (378 and 392 nm) to be 76 and 73 kcal mol^{-1} (1 cal=4.184 J) for *cis*- and *trans*-BP, respectively (Fig. 2). The quantum yields (ϕ_f) of fluorescence emission of *trans*- and *cis*-BP (3×10^{-6} M) were determined in benzene as 0.64 and 0.43, respectively, by using pyrene (ϕ_f=0.58)[7] and phenanthrene (ϕ_f=0.11)[7] as standards.

The fluorescence lifetime of *trans*-BP was measured in benzene at room temperature as 65 ns by single photon counting (SPC) technique. It is clear that the excited singlet state of *cis*-BP has a sufficient lifetime to emit its own fluorescence; however, its gradual isomerization to the trans isomer at room temperature during SPC measurements prevented to determine its lifetime directly.

The fluorescence spectra of *cis*- and *trans*-BP were efficiently quenched by oxygen without changing the spectral profile. The Stern–Volmer constants, $K_{SV}=k_q\tau_s$, for fluorescence quenching with oxygen were determined as 1760 and 1170 M^{-1} for *trans*- and *cis*-BP, respectively. By use of the lifetime of singlet excited *trans*-BP (τ_s=65 ns) the quenching rate constant for *trans*-BP was determined as $k_q=2.7\times10^{10}$ M^{-1} s^{-1}. If

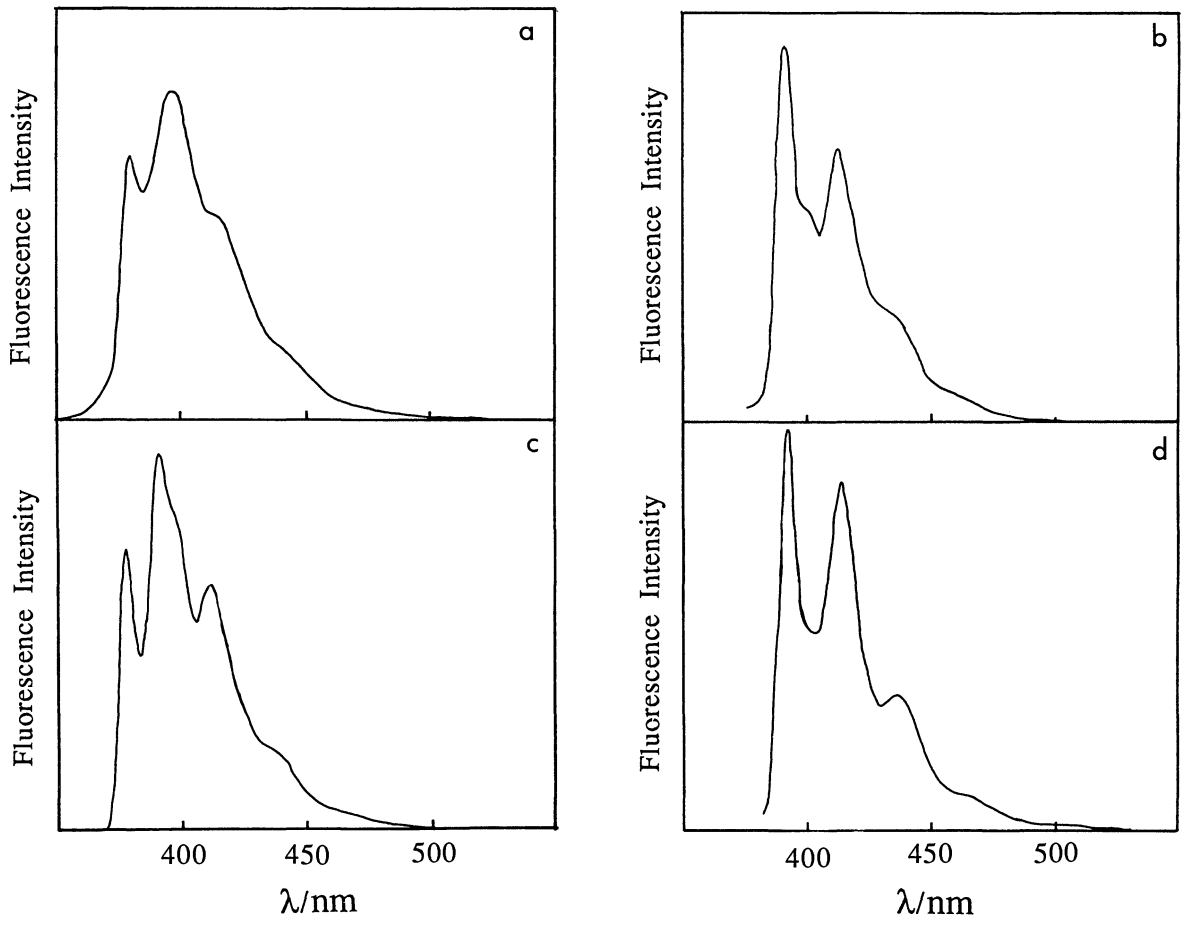

Fig. 2. Fluorescence spectra of *cis*- (a) and *trans*-BP (b) in benzene at room temperature and of *cis*- (c) and *trans*-BP (d) in EPA at 77 K.

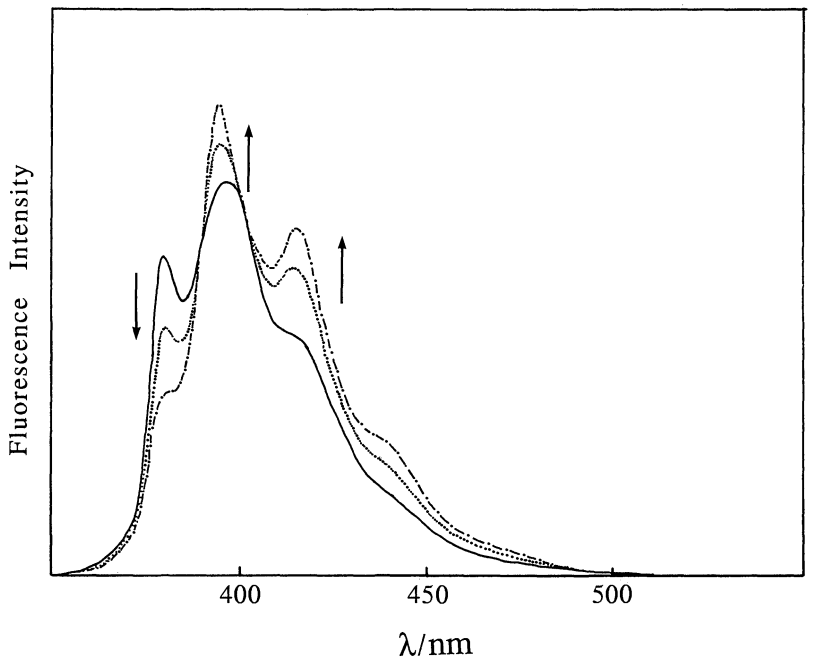

Fig. 3. Fluorescence spectrum change of *cis*-BP in benzene at room temperature.

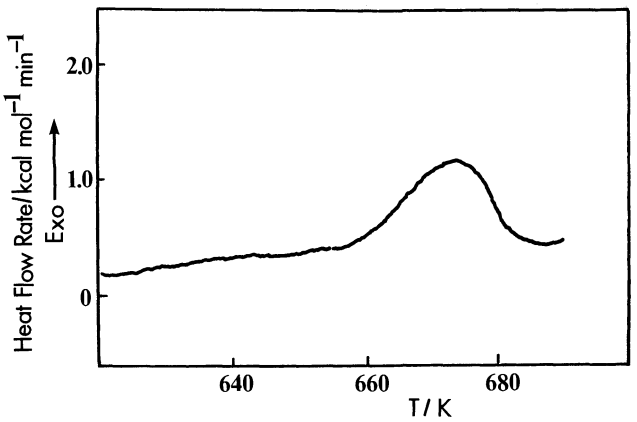

Fig. 4. DSC thermogram obtained for *cis*-BP at a rising rate of temperature of 2.5 °C min^{-1}.

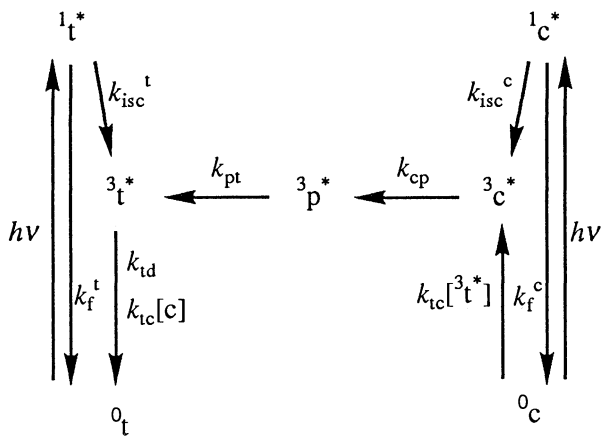
singlet excited *cis*-BP is assumed to be quenched by oxygen with the same rate constant as *trans*-BP, its lifetime is estimated as 43 ns.

Quantum Yields for Intersystem Crossing. Solutions of anthracene and *cis*-BP optically matched at 308 nm (in the absence of benzil) or at 435 nm (in the presence of benzil as a sensitizer) were irradiated with 308-nm or 435-nm laser pulses and the initial T-T absorption intensities (ΔOD_0) were estimated by extrapolating the decay curve to time zero. These ΔOD_0 values combined with the quantum yield for intersystem crossing of anthracene, ϕ_{isc}(An) (=0.75[7]), give ϕ_{isc}(*cis*-BP) of 0.21. This value is almost identical to that of *trans*-BP (0.23).[5]

Energy Difference between Ground-State Cis (^{0}c) and Trans (^{0}t) Isomers. Energy difference between *cis*-BP (^{0}c) and *trans*-BP (^{0}t) in the ground state was obtained from the DSC thermogram (Fig. 4) as 4.9±0.3 kcal mol^{-1} at different rising rates of temperature (2—7.5 °C min^{-1}).

Discussion

Isomerization Mechanism on Direct Excitation. Stilbene isomerizes in a two-way mode in the excited singlet state as well as in the triplet state through a decay at the perpendicular conformation, resulting in a photostationary state mixture of a finite isomer ratio, $([t]/[c])_s$.[1] In contrast to stilbene, BP undergoes cis-to-trans one-way isomerization with a quantum chain process not only on triplet sensitization but on direct excitation, as evidenced by the photostationary state isomer ratios and isomerization quantum yields. For the one-way isomerization of BP observed on direct irradiation, the following mechanisms can be considered: i) an adiabatic cis-to-trans conversion in the singlet manifold involving a quantum chain process, ii) an isomerization through a decay from the perpendicular conformation on a stilbene-like excited singlet energy surface, and iii) an isomerization on the triplet energy surface after intersystem crossing at the cis conformation. The isomerization mechanism similar to that proposed for the stilbene singlet (mechanism ii) is ruled out since the decay at the perpendicular conformation to the ground state should afford a finite photostationary state isomer



Scheme 1.

ratio instead of 100/0 and also cannot account for the chain process.

cis-BP and *trans*-BP exhibit the fluorescence spectra different from each other. Both spectra were efficiently quenched by oxygen, while the spectral profile of each isomer was essentially unchanged under oxygenated atmosphere. If an adiabatic cis-to-trans conversion in the singlet manifold efficiently took place, the fluorescence spectrum observed for *cis*-BP might consist of those emitted by the cis singlets and the resulting trans singlets, and under oxygenated atmosphere that of *cis*-BP might be more sustained compared to *trans*-BP fluorescence. However, the above results indicate that the *cis*-BP excited singlet is not converted to the *trans*-BP excited singlet, but emits fluorescence or intersystem crosses to the cis triplet. These facts indicate that the *cis*-BP excited singlet is located at an energy minimum, and exclude the possibility of the first mechanism.

Therefore, it is reasonable to propose that the isomerization of *cis*-BP on direct excitation proceeds in the triplet manifold after intersystem crossing of the cis singlet state as depicted in Scheme 1, where k's are the rate constants for the corresponding processes. According to Scheme 1, the quantum yield under direct irradiation is expressed by the following equation, Eq 1,[5,8] where ϕ_{isc}, k_{tc}, and τ_T denote the quantum yield for intersystem crossing of the cis singlet, the rate constant for energy transfer from the resulting trans triplet to the cis isomer, a key step for the quantum chain process, and the lifetime of the trans triplet state, respectively.

$$\phi_{c\to t}=\phi_{isc}(1+k_{tc}\tau_T[cis\text{-BP}]). \quad (1)$$

The linear dependence of $\phi_{c\to t}$ on [*cis*-BP] in Fig. 1 affords $\phi_{isc}=0.27$ and $\phi_{isc}k_{tc}\tau_T=1.3\times10^3\ M^{-1}$ as the intercept and the slope, respectively. Use of the values reported previously,[5] $\tau_T=1/k_{td}=54\ \mu s$ and $k_{tc}=1.2\times10^8\ M^{-1}\ s^{-1}$, gives $\phi_{isc}=0.25$. The value for ϕ_{isc} is in good agreement with the aforementioned value obtained by laser photolysis (0.21). This result strongly supports that the isomerization takes place at the triplet surface and eliminates a possibility of participation of the singlet state to the isomerization.

The following consideration also supports the mechanism iii. In Fig. 1 the ratio of slope/intercept ($1.3\times10^3\ M^{-1}/0.27=5\times10^3\ M^{-1}$) corresponds to the quenching constant ($k_q\tau$) of the excited state responsible for the quantum chain process. In the singlet state this magnitude of quenching constant could be achieved only when the quenching rate constant is larger than the diffusion-controlled value, because the singlet lifetime of *trans*-BP is 65 ns; thus, k_q should be $7.7\times10^{10}\ M^{-1}\ s^{-1}$. However, energy transfer from $^1t^*$ to *cis*-BP, if it occurs, should take place as an endothermic process with a rate constant much lower than the diffusion controlled, since the singlet excitation energy of *cis*-BP is 3 kcal mol^{-1} higher than that of *trans*-BP. This is contrasted with a reasonable value for k_{tc} in the triplet state.

Potential Energy Surfaces of BP. The energy difference (ΔH) between ^0c and ^0t was obtained as 4.9 kcal mol^{-1} from DSC experiments. This value is very similar to the most reliable value for stilbene (4.6 kcal mol^{-1}).[9] Thus, the energy differences between ^0c and ^0t for diarylethylenes and arylalkylethylenes seem to be similar (ca. 5 kcal mol^{-1}) as we usually assume.

As mentioned above, the cis and trans conformations of the excited singlet state are located at the energy minima with the excitation energies of 76 and 73 kcal mol^{-1}, respectively. The aforementioned failure of isomerization in the excited singlet state indicates the presence of a considerably high energy barrier which prevents the isomerization of $^1c^*$ on the singlet excited energy surface at room temperature. A rough estimation of the cis-to-trans conversion rate (k_{isom}) might be less than 1/100 of the total decay rate ($1/\tau_s=1.5\times10^7\ s^{-1}$). This corresponds to an activation energy higher than at least ca. 7 kcal mol^{-1}, when a range of 10^{11}—$10^{12}\ s^{-1}$ is assumed as the frequency factor, A, in Eq 2.

$$k_{isom}=A\exp(-E_a/RT). \quad (2)$$

Taking into account the energy barrier for twisting, the top of the energy surface of the singlet excited state must be located at the energy of 88 kcal mol^{-1} higher than ground-state *trans*-BP. There is still no evidence clarifying whether the energy barrier exists at the perpendicular conformation ($^1p^*$) or between $^1c^*$ (or $^1t^*$) and $^1p^*$. However, it is likely that the latter is the case because the energy of $^1p^*$ is usually assumed to be less than 80 kcal mol^{-1} over ^0t.[1]

Previously, we proposed the energy surface of the triplet state of BP undergoing cis-to-trans one-way isomerization by way of an adiabatic process; the

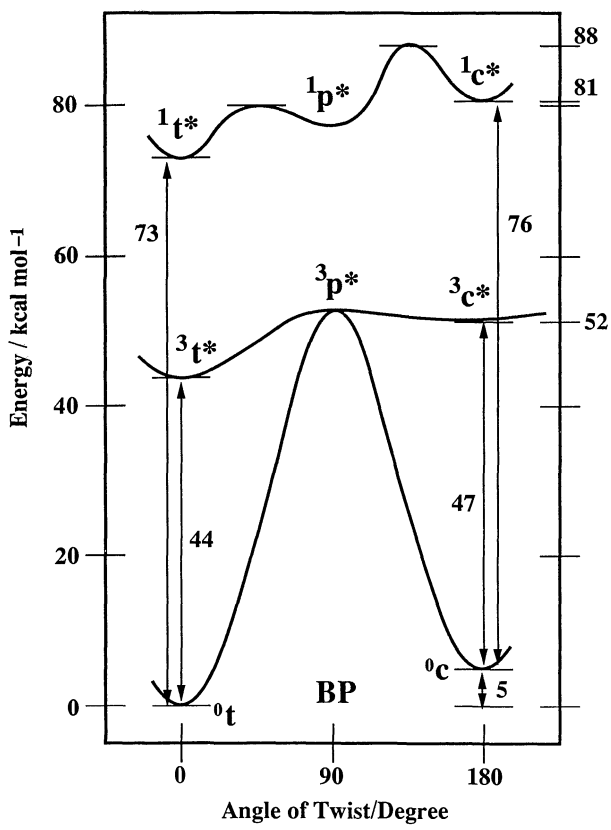


Fig. 5. Potential energy surfaces of cis-trans isomerization of BP.

initially resulting $^3c^*$ is converted to $^3t^*$, which either undergoes unimolecular deactivation to trans or transfers energy to cis to give trans and to regenerate $^3c^*$.

The present experimental results provide us sound basis to depict the potential energy surfaces of BP as shown in Fig. 5.

The spin-lattice relaxation times of ^1H and ^{17}O nuclei of hydrated H_2O molecules in alkali metal bromide (LiBr, NaBr, KBr, and CsBr) dilute aqueous solutions in the concentration range from 0.2 to 1.0 mol kg^{-1} at 25 °C were measured by NMR spectroscopy. The reorientational correlation times for the intramolecular ^1H–^1H (τ_{HH}^{+}) and ^1H–^{17}O (τ_{OH}^{+}) axes, as well as the perpendicular axis (^{17}O nuclei, $\tau_{\perp O}^{+}$) to the molecular plane of a hydrated H_2O molecule were determied. The two reorientational correlation times (τ_{HH}^{+} and τ_{OH}^{+}) of pure H_2O and hydrated H_2O molecules in Li^+, Na^+, K^+, and Cs^+ ions were equal, respectively. Comparing previous data for hydrated D_2O molecules with that calculated by using correction values (r_{HH}, r_{OH}, and quadrupolar constant) for H_2O molecules, the ratios of $\tau_D^{+}(D_2O)/\tau_{OH}^{+}(H_2O)$ and $\tau_{\perp O}^{+}(D_2O)/\tau_{\perp O}^{+}(H_2O)$ were found to be of the same order as $\eta(D_2O)/\eta(H_2O)$, except for the $\tau_{\perp O}^{+}(D_2O)/\tau_{\perp O}^{+}(H_2O)$ value for the Li^+ ion.

To comprehend the complete picture regarding the dynamic properties of ionic hydration in water it is necessary to consider both macro- and microdynamic approaches. Regarding aqueous solutions, studies have accumulated many precise limiting values at infinite dilution regarding both the thermodynamic and transport properties.[1] On the other hand, our understanding concerning electrolyte solutions and the microdynamic properties of hydrated H_2O molecules of ions in water studied by NMR spectroscopy is very poor due to a lack of fundamental research concerning the concentration dependence, except for studies of Hertz et al.[2–5] and Leyte et al.[6–10] They have provided limiting values of the reorientational relaxation rates of hydrated water molecules of ions at infinite dilution by using a polynominal expression of the relaxation rates as a function of high concentrations, including both ion–ion and ion–water interactions.

Presently, the NMR technique that was developed is preferable for studying the reorientational motion of hydrated water molecules at lower concentrations, due to the ion–water interaction, to any other available experimental techniques. A study of the spin–lattice relaxation rates (R_1) of the ^1H, ^2D, and ^{17}O nuclei of water molecules in electrolyte solutions provides information about the reorientational motion of water molecules. The ^2D and ^{17}O relaxations are determined intramolecularly by quadrupole interactions, due to a rotational motion for the reorientation of the ^2D and ^{17}O electric field gradient tensor. The proton R_1 however, is governed by both intra and intermolecular ^1H–^1H dipolar interactions due to the reorientational and translational motions. The intra and intermolecular contributions to proton R_1 can be divided and determined from each theoretical expression by applying the extreme narrowing limit as well as measurements of the self-diffusion coefficient of water molecules by the spin–echo method;[2] it is also possible to study the ^1H relaxation in ^{17}O enriched water.[6]

From a previous study concerning the concentration dependence on the nuclear relaxation rates of the ^2D and ^{17}O nuclei of hydrated D_2O molecules of ions in dilute electrolyte solutions,[11] we found the both rates can be represented by linear functions against the concentrations of electrolyte solutions. The relationship between R_1 and the salt concentration is important for determining the limiting value, exclusively, due to the ion–water interaction on the base of the two-state model, i.e., hydrated water molecules and water molecules having a bulk water structure. By analysing these results, the reorientational motion along the O–D axis of the D_2O molecule was found to be 10% faster than those perpendicular to the D_2O molecular plane for the structure-making ions of Li^+ and Na^+ ions; for the structure-breaking ions of K^+ and Cs^+ ions, the tendency was inversed. This significant anisotropy regarding the reorientational motion of hydrated D_2O molecules in salt solutions comes from a local dynamic structure induced by a difference in the intermolecular interactions among ions, hydrated water molecules, and water molecules having a bulk water structure.

The local dynamic structure of hydrated water molecules in the vicinity of ions is strongly controlled by the solvent viscosity, which can be changed by various factors: i.e., temperature, pressure, solvent, and isotope effects. Though the isotope effect is a unique factor among them, no systematic study has been carried out by the NMR method. The dielectric properties of H_2O and D_2O are almost identical as most the other macroscopic properties.[12] The largest difference in the properties of pure water is its viscosity, which is 23% higher in D_2O than in H_2O at

25 °C.[13] Such differences as the thermodynamic properties of liquid H_2O and D_2O are consistent due to the O–D···O hydrogen bond being somewhat stronger than the O–H···O hydrogen bond. Therefore, in addition to the earlier study concerning the D_2O molecule,[11] NMR studies of the reorientational motion of H_2O molecules in dilute alkali metal bromide (LiBr, NaBr, KBr, CsBr) solutions have usefully helped to reach definite conclusions about both the hydration and anisotropy of the reorientational motion of hydrated water molecules of alkali metal ions in an H_2O system.

Experimental

Samples. Alkali metal bromide (LiBr, NaBr, KBr, CsBr) salts from Nakarai Tesque. Inc (extra-pure grade) were recrystallized from either water or ethanol. Deionized water was destilled with the addition of a small amount potassium permanganate. Sample preparation before an NMR measurement was reported previously.[11]

NMR Measurement. The ^1H relaxation times were measured on a JEOL GX-270 pulsed spectrometer operating at 270.0 MHz. Samples were kept in 4 mm diameter glass tubes and then inserted in 5 mm diameter glass tubes containing neat D_2O. The spin–lattice relaxation times (T_1) were measured by inversion-recovery methods, using a pulse sequence of 180°—t—90° pulses; The T_1 values were determined for each sample at 16 different time intervals (t), and the pulse delay time (PD) was more than $10T_1$. The frequency was 700 Hz for the ^1H nucleus. The free indicational decay of the ^1H nucleus was accumulated 4 times for all concentrations. Measurements of the ^{17}O nucleus relaxation times were carried out under the same condition which were reported previously.[11] The temperature was controlled to 25±0.1 °C by means of gas-thermostating.

Results and Discussion

Concentration Dependence of R_1 of H_2O Molecules in Aqueous Bromide Solutions. The relation between the spin–lattice relaxation rates ($R_1=1/T_1$) of the ^1H and ^{17}O nuclei of H_2O molecules and their concentrations in bromide solutions at 25 °C is shown in Figs. 1 and 2 and Table 1 along with data concerning the ^1H nucleus at 1 mol kg^{-1}, studied by Endom et al.[2] Our relaxation rates for the ^1H nucleus at 1 mol kg^{-1} agree with those of Endom et al.[2] within the experimental error. The ratios (R_1/R_1^0) vary linearly with increasing concentration up to 1.0 mol kg^{-1}. The R_1/R_1^0 (R_1^0 for pure H_2O) values are expressed as a linear function of the concentration, up to 1.0 mol kg^{-1}. Their values of ^1H and ^{17}O nuclei at a certain concentration are in the order LiBr>NaBr>KBr>CsBr. The structure-making salts of Li and Na increase the R_1/R_1^0 values of ^1H and ^{17}O of H_2O. On the other hand, the structure-breaking salts of K and Cs decrease the R_1/R_1^0 value of H_2O.

For ^1H and ^{17}O nuclei the concentration dependence of R_1 is given by linear equations at a concentration below 1.0 mol kg^{-1}, as follows:

$$R_1 = (1 + Bm)R_1^0, \quad (1)$$

where R_1 and R_1^0 are the spin–lattice relaxation rates at an electrolyte concentration of m and for pure H_2O, respectively. The B_H, $B_{^{17}O}$, and B_H–$B_{^{17}O}$ values are shown in Table 2 along with those of the D_2O system. From these results, the structure-making effect of Li and Na salts and the structure-breaking effect of K and Cs salts predominantly affect the B coefficient of the ^1H nucleus, rather than those of the ^{17}O nucleus of the

hydrated H_2O molecules of ions. There are no differences between the effect of the structure-breaking salts of K and Cs on the B coefficients of the both nuclei in H_2O and D_2O systems. However, the effect of the structure-making salts of Li and Na on the B coefficients of the ^1H nucleus in H_2O is enhanced more than those of the ^2D nucleus in D_2O; its effect on the B coefficient of the ^{17}O nucleus is vice versa to that in H_2O and D_2O systems. The correlation factors of the B coefficients between the NMR and viscosity of solutions are ca. 1.0 for B_H and ca. 0.4 for $B_{^{17}O}$.

Reorientational Motion of Hydrated H_2O Molecules. A linear relation between the relaxation rates and the salt concentration shown in Figs. 1 and 2 has been established in dilute salt solutions below 1.0 mol kg^{-1}. We can therefore consider that the ion–ion interaction is eliminated in this system and that each observed relaxation can be expressed as a weighted sum of the limiting relaxation rates in infinite dilution on the

base of two state model, as follows:

$$(R_1)_X = (1 - x^+ - x^-)(R_1)_X^0 + x^+(R_1)_X^+ + x^-(R_1)_X^- \quad (2)$$

and

$$(R_1)_X/(R_1)_X^0 = 1 + x^+\{(R_1)_X^+/(R_1)_X^0 - 1\} + x^-\{(R_1)_X^-/(R_1)_X^0 - 1\}, \quad (3)$$

where $(R_1)_X^0$, $(R_1)_X^+$, $(R_1)_X^-$, x^+, and x^- are the spin-lattice relaxation rates of pure water, cation and anion hydrated water, and the mole fraction of the cation and anion, respectively. The subscript X can be ^{17}O, HH, or OH when the relaxation path is, respectively, ^{17}O quadrupolar, an intramolecular ^1H–^1H dipolar interaction, or an intramolecular ^1H–^{17}O dipolar interaction.

By defining a coordination number, $n^\pm$, the mole fraction $x^\pm$ can be expressed in terms of the molarlity m of the solution,

$$x^\pm = n^\pm \times m/55.5. \quad (4)$$

The observed proton, R_1, in H_2O molecules is given by intra and intermolecular ^1H–^1H interactions, as follows:

$$(R_1)_H = (R_1)_{HH}^{intra} + (R_1)_{HH}^{inter}. \quad (5)$$

As compared to $(R_1)_H$=0.281 s^{-1} at 25 °C, Hertz[13] obtained the $(R_1)_{HH}^{inter}$=0.106 s^{-1} using experimental data of the self-diffusion coefficients of water as well as the theoretical jumping model of translational motion. If we arbitrarily take this value, $(R_1)_{HH}^{intra}$ contributes 62% of $(R_1)_H$. Later, Lankhorst et al.[6] measured the ^1H relaxation rates in ^{17}O-enriched water as a function of the ^{17}O mole fraction, $\chi(^{17}O)$. In view of the observed lineality, they obtained

$$(R_1)_H = (R_1)_{HH} + \chi(^{17}O)R_{OH}. \quad (6)$$

Of course, the R_{OH} value is the sum of the intra- and intermolecular ^1H–^{17}O dipolar interactions. For various salt solutions and pure water, they observed that the average ratios, $(R_1)_H/(R_1)_{HH}$ and $(R_1)_H/(R_1)_{OH}$ (^{17}O is a natural abundance), for various salts are 1.00±0.02 and 1.03±0.10, respectively.[9,10] The intramolecular contribution to $(R_1)_{HH}$ is 57%, and the intermolecular contribution to $(R_1)_{OH}$ is 2%.[9,10] The ^{17}O nucleus relaxes intramolecularly by quadrupole interactions, and the observed relaxation rates are directly correlated to the intramolecular term. Assuming that $R_1^+(K^+)=R_1^-(Cl^-)$ is satisfied for a KCl solution, in the case of an equal splitting of the B-coefficient into an ionic component[11,14] in Eq. 3, the $(R_1)_{HH}^{+,intra}$ $(R_1)_{OH}^{+,intra}$, $(R_1)_{^{17}O}^{\pm}$ values for various cations are determined from the both relations of the 57% intramolecular contribution to $(R_1)_{HH}$ and the 2% intermolecular contribution to $(R_1)_{OH}$. Table 3 shows the calculated R_1^+ values of ^1H and ^{17}O nuclei, and the $(R_1)_{HH}^{+,intra}$ and $(R_1)_{OH}^{+,intra}$ relaxation rates of intramolecular ^1H–^1H and ^1H–^{17}O dipolar interactions of hydrated H_2O molecules of the alkali metal ions. It was concluded that the intramoleculer contribution of ca. 62% to $(R_1)_{HH}^{+,intra}$ determined by Hertz et al.[15,16] is considerably overestimated.[10] Comparing the relaxation rates of the intramolecular ^1H–^1H dipolar interaction, the intramolecular ^1H–^{17}O dipolar interaction, and the ^{17}O quadrupolar interaction of hydrated H_2O molecules with those of pure H_2O molecules, the ^1H nucleus relative relaxation rate ($(R_1)_{HH}^{+,intra}/(R_1)_{HH}^{0,intra}$= $(R_1)_{OH}^{+,intra}/(R_1)_{OH}^{0,intra}$=$(R_1)_H^+/(R_1)_H^0$) are almost of the same order as the ^{17}O nucleus relative relaxation rates ($(R_1)_{^{17}O}^+/(R_1)_{^{17}O}^0$) for the structure-breaking ions of K^+ and Cs^+ ions. On the other hand, the structure-making effect of Li^+ and K^+ ions on the ^1H nucleus relaxation rates are larger than those of the ^{17}O nucleus.

Under extra narrowing conditions the intramolecular term of the spin-lattice relaxation rate, $(R_1)_X^{\pm,intra}$, of hydrated water molecules is the product of an interaction constant, $C_X^\pm$, and a reorientational correlation time, $\tau_X^\pm$:

$$(R_1)_X^{\pm,intra} = C_X^\pm \times \tau_X^\pm. \quad (7)$$

The intramolecular ^1H–^1H dipolar interaction is given by

$$(R_1)_{HH}^{\pm,intra} = \frac{3\gamma_H^4\hbar^2}{2r_{HH}^6}\tau_{HH}^\pm, \quad (8)$$

where γ_H is the proton gyromagnetic ratio, $\hbar$ Planck's constant divided by 2π, r_{HH} the intraproton distance of the water molecule, and $\tau^{\pm}_{HH}$ the reorientational correlation time for the intramolecular ^1H–^1H axis.

The intramolecular contribution of the ^1H–^{17}O dipolar interaction is given by

$$(R_1)^{\pm,\mathrm{intra}}_{OH} = \frac{35}{3}\frac{\gamma_H^2\gamma_{^{17}O}^2\hbar^2}{r_{OH}^6}\tau^{\pm}_{OH}, \quad (9)$$

where $\gamma_{^{17}O}$ is the oxygen gyromagnetic ratio, r_{OH} the interdistance between the oxygen and the proton of the water molecule, and $\tau^{\pm}_{OH}$ the reorientational correlation time for the intramolecular ^1H–^{17}O axis. The ^{17}O (I=5/2) relaxation is determined intramolecularly by quadrupolar interactions; the rate is give by

$$(R_1)_{^{17}O} = \frac{3}{135}\left(\frac{e^2qQ}{\hbar}\right)^2\left(1+\frac{\eta^2}{3}\right)\tau_{^{17}O}, \quad (10)$$

where e^2q is the electric field gradient at the nucleus, Q the electric quadrupole moment of the nucleus, η the asymmetry parameter, and $\tau_{^{17}O}$ the correlation time for the reorientational of the oxygen electric field gradient tensor (perpendicular axis to the H_2O molecular plane). From Eqs. 3 and 10, the following relation is derived:

$$\frac{(R_1)_{^{17}O}}{(R_1)^0_{^{17}O}} = 1 + \left\{x^+\left(k^+\frac{\tau^+_{^{17}O}}{\tau^0_{^{17}O}} - 1\right) + x^-\left(k^-\frac{\tau^-_{^{17}O}}{\tau^0_{^{17}O}} - 1\right)\right\} \quad (11)$$

and

$$k^{\pm} = \{(e^2qQ/\hbar)^{\pm}/(e^2qQ/\hbar)^0\}^2, \quad (12)$$

where $\tau^0_{^{17}O}$, $\tau^+_{^{17}O}$, and $\tau^-_{^{17}O}$, are the correlation times of pure H_2O and H_2O in the hydration sphere of a cation and an anion, respectively. Here, k=1 is for the case when the e^2qQ of hydrated water molecules in cations equals that of pure water molecules; and k=0.82 is the correction value reported by van der Maarel et al.,[9] i.e., the e^2qQ value is about 10% smaller than that of pure water molecules. Table 4 shows the three reorientational correlation times of pure and hydrated H_2O molecules for alkali metal ions calculated by two assumptions at 25 °C. One is that the three parameters (r_{HH}, r_{OH}, and k) of hydratd water molecules equal that of pure H_2O molecules; the other equals the correction values reported by van der Maarel et al.[9] From those results, it is clarified that the reorientational correlation time (τ^+_{HH}=τ^+_{OH}) for two parallel axes to the H_2O molecular plane is the same values for each cation within the experimental error. Therefore, the reorientational motion of these two axes is isotropic.

Table 5 shows the anisotropy ($\tau^+_{HH}/\tau^+_{^{17}O}$ or $\tau^+_{OH}/\tau^+_{^{17}O}$) and the solvent isotope effects for the reorientational motion of hydrated H_2O molecules for alkali metal ions in a dilute aqueous solution. The τ^+_{OH} and τ^+_D values are the reorientational correlation times for the intramolecular ^1H–^{17}O axis and O–D axis, respectively. Consequently, these two reorientational correlation times give information concerning the reorientational motion of the similar axis (^1H–^{17}O axis and O–D axis). The reorientational motion of a hydrated H_2O molecule in alkali metal bromide solutions is anisotropic, similar to the tendency of a hydrated D_2O molecule. That is, for a hydrated H_2O molecule of positive hydration of Li^+ and Na^+ ions, the reorientational motion of the perpendicular axis to the H_2O molecular plane ($\tau^+_{^{17}O}$) is faster than the reorientational

Table 4. Reorientational Correlation Times of a Hydrated H_2O Molecule and Pure Water at 25 °C[a]

a) The values of left sides are calculated by using the parameters (r_{HH}=0.1549 nm, r_{OH}=0.098 nm, and k=1.00) of pure water molecule. The values of right sides are calculated by using the parameters (r_{HH}=0.1566 nm, r_{OH}=0.099 nm, and k=0.82). The $\tau^+_D/\tau^+_{^{17}O}$ and $\tau^+_{^{17}O}(D_2O)/\tau^+_{^{17}O}(H_2O)$ values are the same for each k. b) D_2O data are from Ref. 11.

motion of the intramolecular ^1H–^1H and ^1H–^{17}O axes. The reorientational anisotropies for the negative hydration of K^+ and Cs^+ ions are vice versa. The reorientational anisotropy of a H_2O molecule around the positive hydration ions, especially for the Li^+ ion, is larger than that of a D_2O molecule, in spite of the anisotropy of H_2O molecules around the negative hydration ions is almost the same order of a D_2O molecule.

As shown the last column in Table 5, we can observe the large solvent isotope effect on the reorientational anisotropy of a water molecule in the Li^+ hydration sphere. The reasons may be explained by comparing the solvent isotope effect on the reorientational correlation times within the hydration sphere with the effect on the correlation times in water molecules having a bulk water structure. Our results for the ^2D and ^{17}O isotope effects on the reorientational correlation times of a pure water molecule ($\tau_D^+(D_2O)/\tau_{OH}^+(H_2O)=1.23$ and $\tau_{^{17}O}^+(D_2O)/\tau_{^{17}O}^+(H_2O)=1.27$) are in good agreement with the ^2D isotope effect on the reorientational correlation time obtained by Lankhorst et al. ($\tau(D_2O)/\tau(H_2O)=1.28$)[6] and some related dynamical properties, such as the self-diffusion ($(D(H_2O)/D(D_2O)=1.23$)[17] and viscosity ($\eta(D_2O)/\eta(H_2O)=1.23$).[13] The solvent isotope effects on the reorientational correlation times in negative hydration water molecules (calculated assuming pure water parameters (r_{HH}, r_{OH}, and e^2qQ)), are almost of the same order as that of the isotope effects on the reorientational correlation times in pure water molecules. The solvent isotope effects on the reorientational correlation time of ^1H and ^{17}O nuclei in the positive hydration water of Li^+ ion are remarkable compared with those of a hydration water molecule in the nagetive hydration sphere of another cation and a pure water molecule in water. This isotope effect on the reorientational correlation time of the intermolecular ^1H–^{17}O and ^1H–^1H dipolar interactions is smaller than that of a pure water molecule, and the effect of the ^{17}O nucleus of the hydration water molecule of the Li^+ ion is larger. On the other hand, the solvent isotope effect on the reorientational correlation time of the negative and positive hydration water molecule calculated by using the correction values are of the same order in pure water, except for that of ^{17}O nucleus. The solvent isotope effect on the ^{17}O nucleus of the hydrated water molecule of the Li^+ ion is enhanced to be 1.45. It is natural that the ^1H–^1H, ^1H–^{17}O distance, and the quadrupole coupling constant of water molecules in the hydration sphere change with respect to pure water.[9] Therefore, the solvent isotope effect by using the correction values may give a true value; thus, the ^{17}O nuclei of the hydrated water molecule of the Li^+ ion only shows a different large solvent isotope effect against that of a pure water molecule. The hydrated water molecule of the Li^+ cation is orientated with their oxygen atom pointing towards the ion, and the Li^+ ion has the largest surface charge density among the univalent cations. Consequently, H_2O molecules around the Li^+ ion are strongly hydrated, so that the largest solvent isotope effect is observed on the ^{17}O nucleus of a hydrated water molecule of the Li^+ ion.

Pillared Tetrasilicic Mica Catalysts Having Fixed Interlayer Ca Ions. Comparison with Other Clays

Hiroaki SAKURAI,† Kazuo URABE,* and Yusuke IZUMI*
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received July 30, 1990)

Three kinds of Ca^{2+}-modified pillared clays (TSM, taeniolite, and montmorillonite) were prepared from Ca^{2+}-exchanged clays. The cumene cracking activity over the TSM-based catalyst was greatly dependent on the calcination temperature before pillaring, and gave a maximum at 300—400 °C. In contrast, no appreciable increase in the activity with the calcination temperature before pillaring was observed in montmorillonite- and taeniolite-based catalysts. The amount of residual Ca in the modified pillared TSM was increased with a rise in the calcination temperature before pillaring, whereas the amount of Al incorporated through pillaring was decreased, showing the progress of Ca^{2+} fixation during the stage of thermal treatment of Ca^{2+}-exchanged unpillared TSM. Thus, the cracking activity was greatly enhanced by the fixation of Ca^{2+}. The cracking activity, however, dropped due to a pretreatment above 400 °C, since the Al-pillars which prop silicate layers are reduced while causing a decline in the surface area of the resulting pillared TSM; also, the strong acid sites were decreased due to excessive packing of Ca^{2+} fixed over the surface of silicate layers. In the cases of montmorillonite and taeniolite, the remaining amounts of Ca and Al were almost constant, irrespective of the calcination temperature before pillaring. This indicates that Ca^{2+} fixation does not occur in these clays.

Since pillared clay as a heat-stable porous material was synthesized by Brindley and Sempels in 1977,[1] clay minerals have attracted attention as potential catalytic materials, since pillared clays have both acidity and a molecular sieve ability. Pillared clay can be regarded as being an intercalated compound comprising a host silicate and guest oxide pillars. An aluminum hydroxy cluster cation, $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$, with a diameter of ca. 9 Å is most widely employed as a precursor of a pillar. To intercalate such a large cation between layers, the host clay, which has a free-swelling property in an aqueous medium, must be employed. Besides smectite clays (such as montmorillonite, hectorite, and saponite), the sodium form of fluor-tetrasilicic mica (TSM) fulfills the above-mentioned requisites; the clay is also swellable and cation exchangeable, and can form a porous pillared variant. Though the resulted pillared TSM (PTSM) had few acidic sites and was unattractive as an acidic catalyst, the acidity of the PTSM can be greatly enhanced by the fixation of interlayer cations onto the silicate layer of pillared TSM.[2] The fixation mode was classified into five types according to the valence and size of the cation to be fixed.[3] In these studies, TSM was employed as a host layer silicate. Since cation fixation into or onto a layered structure is due to an electrostatic force between dehydrated positive cations and negatively charged silicate layers, the ease of fixation might be affected not only by the nature of the cation, but also by the structure of the silicate layer.

The migration of small cations (such as Li^+, Al^{3+}, and Mg^{2+}) into a layer structure is known as the Hofmann–Klemen effect,[4–6] and occurs only in dioctahedral and octahedrally substituted clay minerals.[7] This principle, therefore, has been applied to the diagnostic method for montmorillonite.[7,8] It was found that the TSM layer with octahedral vacancies also gave rise to this type of migration-fixation.[3] The fixation of monovalent and fairly large cations (such as K^+ and Cs^+) has also been investigated in detail, and some factors that contribute to this type of fixation have already been reviewed in connection with both the interlayer cations and the silicate layer.[9,10]

On the other hand, the detailed controlling factors concerning the silicate layer are not yet known regarding the fixation of polyvalent and large cations. Only a few examples of La^{3+} and Ca^{2+} fixation by montmorillonite can be found in the literature.[11–13] No notable improving effect on the catalytic activity of pillared clay by the fixation of these cations has been ascertained in the case of clays other than TSM.

In this study, a similar modification of pillared clay was applied to other two clays, montmorillonite and taeniolite. Although the highest catalytic activity was exhibited by La^{3+}–PTSM among various cation modified catalysts, Ca^{2+} was employed here as a modifier, because Ca^{2+} is less susceptible to hydrolysis than is La^{3+}; a more quantitative discussion may be possible concerning fixation. Three kinds of pillared clays (Ca^{2+}–PTSM, Ca^{2+}–PM, and Ca^{2+}–PT) were compared with respect to their cracking activity. The residual cations (Ca^{2+}, Na^+) and the incorporated Al as a pillar component were determined. We also discuss here the relationship between cation-fixation and the change in the catalytic activity. Moreover, the distribution of Ca on the silicate surface was calculated based on a random distribution modes as a function of the amount of fixed Ca and is discussed in connection with the catalytic activity.

† Present address: Government Industrial Research Institute of Osaka, Midorigaoka 1, Ikeda 563.

Experimental

Material Clay. Both the sodium form of fluor-tetrasilicic mica and the lithium form of taeniolite were supplied from Topy Ind. These samples were refined by means of a conventional sedimentation technique, and a <5 μm fraction was collected. The refined TSM contained only small amounts of impurities, such as α-cristobalite. Reportedly, the composition of TSM by chemical analysis is[14,15] $Na_{1.00}(Mg_{2.63})^{oct}(Si_{3.94}Al_{0.05}Mg_{0.01})^{tet}O_{10.19}F_{1.81}$.

Refined natural montmorillonite (Kunipia F) with high purity was supplied by Kunimine Ind., and used without further purification. The chemical formula of this montmorillonite is[15] $(K_{0.01}Na_{0.43}Mg_{0.01})(Al_{1.57}Fe^{3+}_{0.08}Fe^{2+}_{0.02}Mg_{0.34})^{oct}(Si_{3.88}Al_{0.12})^{tet}O_{10}(OH)_2$.

These clays were Ca^{2+}-exchanged by the use of either aqueous calcium nitrate or calcium chloride. In the case of TSM and taeniolite, an in situ cation exchange was performed during the sedimentation stage; that is, aqueous calcium chloride was added to an aqueous dispersion of clay containing a <5 μm fraction of TSM or taeniolite particles. Ca^{2+}-exchanged clays were washed repeatedly with deionized water until salt free; they were then dried at 60°C.

Catalyst Preparation. Ca^{2+}-modified pillared clays (Ca^{2+}-PTSM, TSM; Ca^{2+}-PM, montmorillonite; Ca^{2+}-PT, taeniolite) were prepared according to a previously reported method.[2] The preparative procedure is as follows. Ca^{2+}-exchanged clays (Ca^{2+}-TSM, Ca^{2+}-M, and Ca^{2+}-T) were first calcined at 60—700°C for 3 h (procedure of calc. 1). The calcined clays were dispersed in a mixed solution of acetone and water; an aluminum cluster cation solution (OH/Al=2.0)[2] was then added as a pillaring agent and stirred for 12 h. After air-drying at 60°C, the clay samples were finally calcined at 300°C for 3 h. The second calcination operation is referred to as calc. 2.

Reaction Procedure and Analysis. Cumene cracking was carried out using a conventional continuous-flow system under atmospheric pressure. All of the liquid products were collected in an ice trap and were analyzed by GLC using Bentone 34 and DNP column (4 m).

Characterization. X-Ray diffraction (XRD) analysis was carried out employing oriented clay films formed on glass slides.

The nitrogen adsorption over the catalyst was measured at 78 K after evacuation at 300°C for 1 h; its surface area was calculated by either BET or Langmuir equation according to the type of adsorption isotherm. The pore-size distribution was computed from the isotherm according to the Cranston-Inkley method.[16]

The solid acidity of various catalysts was examined by the temperature-programmed desorption (TPD) of the adsorbed ammonia. The experimental conditions have already been described in a previous paper.[3]

The IR spectra of adsorbed pyridine were recorded on a JASCO IR-810 spectrophotometer according to a method described in a previous paper.[2]

Quantitative measurements of Ca, Al, and Na were carried out by use of an X-ray fluorescence spectrometer, VF-310 (Shimadzu Co., Ltd.). The clay sample (0.3 g) was fused with $Li_2B_4O_7$ (5.0 g) at 1100°C, cooled in air, and a glass bead sample was obtained for the measurement.

Results and Discussion

Catalytic Activity Change. Figure 1 and Table 1 show the cumene cracking activity as a function of the calc. 1 temperature over a Ca^{2+}-modified pillared TSM catalyst (Ca^{2+}-PTSM). When the catalyst was dried at 60°C as calc. 1, the cumene conversion (0.21%) was almost the same as that of nonmodified PTSM (0.18%). Beyond 200°C, the activity drastically increased with a rise in temperature, and reached a maximum at 300—400°C; it then decreased monotonously. The maximum conversion was 4.2%, which was about half the conversion on La^{3+}-PTSM (max. 7.6% at 300°C).[2] While La^{3+}-PTSM became almost inactive at 500°C (0.1% conversion) due to an interlayer collapse, Ca^{2+}-PTSM maintained a >1.5% conversion, even at 700°C.

In the case of the other two clays Ca^{2+}-PM, montmorillonite; Ca^{2+}-PT, taeniolite), both catalysts dried at 60°C already had a >10% conversion (Table 1). The conversion of Ca^{2+}-PM (13.3%) was about the

Table 1. Cumene Cracking Activity of Ca^{2+}-Modified Pillared Clays[a]

Calc. 1 Temp	Conversion over each catalyst/%		
°C	Ca^{2+}-PTSM	Ca^{2+}-PM	Ca^{2+}-PT
60	0.21	13.3	11.9
200	0.30	—	—
300	4.2	15.4	9.4
400	4.2	—	—
500	2.3	—	—
600	2.0	—	—
700	1.5	—	—

a) Reaction temp 300°C, W/F=33 g-cat. h mol^{-1} (W= weight of catalyst, F=feed rate of reactant), flow rate of N_2 carrier gas 600 ml h^{-1}, averaged initial activity for 1 h after feeding of reactant.

same level as that of nonmodified conventional pillared montmorillonite (PM; 14.3% conversion). No outstanding increase in the activity with a rise in the calc. 1 temperature until 300°C was found in these clays, which was the most significant difference from the case of TSM.

The Amount of Ca Fixed in Pillared Clay. Figure 2 shows the residual amounts of Ca in Ca^{2+}–PTSM, Ca^{2+}–PM, and Ca^{2+}–PT after calc. 2 at 300°C. The amount of Ca is expressed for convenience as the mole ratio of Ca to Si when taking 4.00 for Si, because TSM ideally has a half unit cell formula, $Na^{+}(Mg_{5/2})^{oct.}(Si_4)^{tet.}O_{10}F_2$.

The Ca^{2+}-exchanged TSM before pillaring (Ca^{2+}–TSM) had a Ca amount of 1.03 (left side of Fig. 2), which corresponded to about twice the amount (0.50) calculated from the theoretical CEC (Cation Exchange Capacity) of TSM. Though the reason for this discrepancy is not clear, it is possibly due to an unavoidable hydrolysis of Ca^{2+} to form $Ca(OH)_2$. Reportedly, in cation-exchange process on H^{+}-montmorillonite with Cu^{2+}, Zn^{2+},[17] and La^{3+},[18] montmorillonite can retain these polyvalent cations beyond the CEC under a certain condition (pH, concentration, and the kind of coexisting anions), which is considered to be due to hydroxide precipitation.[17,18] Ca^{2+}-exchanged taeniolite (Ca^{2+}–T) also had excess Ca (0.80), as shown in Fig. 2. Under the present experimental conditions, however, Ca^{2+}-montmorillonite (Ca^{2+}–M) had a nearly equivalent amount (0.20) to the theoretical value (0.23) corresponding to the CEC which was calculated from the chemical formula shown above. Thus, the extensive hydrolysis of Ca^{2+} appears to be related to the layer charge of the clay.

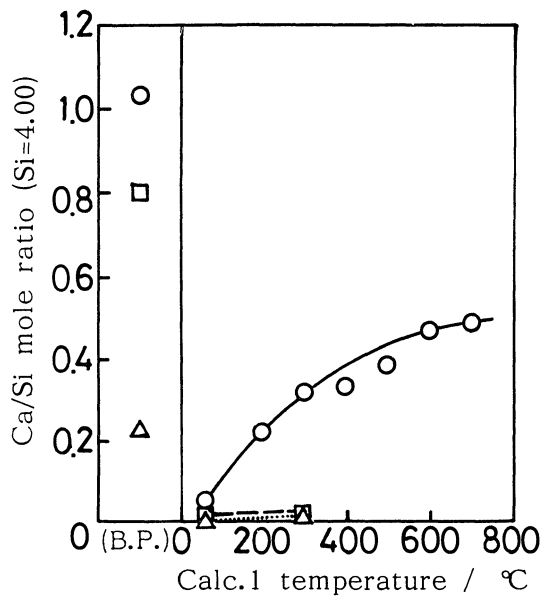

Fig. 2. Effect of the temperature of calc. 1 on the residual amount of Ca in Ca^{2+}-modified pillared clays. (○) TSM, (△) montmorillonite, (□) taeniolite. (B.P.) Ca^{2+}-exchanged clay before pillaring.

When calc. 1 was carried out at 60°C, most parts of both the exchangeable Ca^{2+} and the above-mentioned excess of Ca incorporated in these clays were released after pillaring manipulation, being replaced by aluminum hydroxy cluster cations. Fortunately, under such circumstances, thermally fixed Ca is clearly quantitatively distinguishable from other types of Ca at higher temperatures of calc. 1. Indeed, the residual amount of Ca in Ca^{2+}–PTSM progressively increased with increasing calc. 1 temperature and reached 0.48 at 700°C, coming near to a critical amount (0.50) limited by the CEC. This result is direct evidence of thermally induced Ca^{2+} fixation by the TSM layers. On the contrary, the residual Ca^{2+} did not increase at 300°C at all in montmorillonite and taeniolite, suggesting that fixation did not occur in these clays. The fixation phenomenon well accounts for the change in catalytic activity shown in Fig. 1; that is, the activity of TSM is greatly enhanced with the progress of fixation, though no noticeable changes in the activity (see Table 1) are found in montmorillonite and taeniolite because of the absence of fixation.

The Ca^{2+} fixation by bentonite or montmorillonite, which brings about a reduction of CEC by a heat treatment, was reported by Hofmann and Endell[12] and Kondo.[13] Nevertheless, the fixation of Ca^{2+} by montmorillonite was not observed in the present study. The CEC of clay minerals is usually measured by the use of an aqueous salt solution under neutral conditions,[19] while in this study, the heated Ca^{2+}-montmorillonite was dispersed in a mixed solvent of acetone and water and then Ca^{2+} ions were subjected to exchange with an aqueous solution of aluminum hydroxy cluster cations (pH=4.0). The use of acetone and an acidic cation-exchange condition is possibly related to the difficulty of Ca^{2+} fixation onto the layer surface of montmorillonite. The large dipole moment of the acetone molecule facilitates the solvation of interlayer cations of charge-reduced montmorillonite.[20]

The most important question is what factor influence the ease of Ca^{2+} fixation in the three different clays. For an explanation, some of the known factors[9,10] controlling K^{+} fixation in soils and clay minerals are applicable, since both K^{+} and Ca^{2+} fix onto a silicate-layer surface, partly lodging in the hexagonal holes in a similar way.[3] These factors involve a layer charge as well as a substitution of F for OH in the octahedral sheet.[10] TSM has a much larger layer charge than dose montmorillonite, and can hold any fixed cations firmly. When a clay has an OH at the bottom of a hexagonal hole, the K^{+} ion receives an electrostatic repulsion force from the protonic part of the OH group. The substitution of F for OH removes this repulsion effect and facillitates the fixation of K^{+}.[10] Therefore, the F substitution in TSM must further facilitate the fixation of Ca^{2+} in addition

to the effect of a large layer charge. However, these factors cannot account for the difference between TSM and taeniolite. The octahedral vacancies which exist in TSM must play an important role. In the case of K^+ fixation, it is also known that dioctahedral minerals hold K^+ ions more tightly than do trioctahedral minerals.[9] The Ca^{2+} fixation observed in TSM thus suggests the dioctahedral-like character of TSM.

The Amount of Al Incorporated by Pillaring. Figure 3 shows the amount of Al in the three catalysts after calc. 2. These clays had different amounts of Al before pillaring. The amounts of Al in TSM (0.05) and montmorillonite (1.61) determined by the present study agreed very well with the reported values[14,15] shown in the experimental section.

After pillaring, each clay increased in Al amount by intercalation of aluminum hydroxy cluster cations. When the calc. 1 procedure was performed at 60°C, the amount that increased from the value before pillaring corresponded to the amount of Al incorporated by pillaring in the absence of Ca^{2+} fixation. These amounts of Al in TSM (1.06) and taeniolite (0.95) were greater than that of montmorillonite (0.79), reflecting a difference in the layer charge of native calys. The average positive charge per Al atom incorporated (Q_{Al}) was calculated using the following equation for both montmorillonite and TSM:

$$Q_{Al} = (Q_{layer} - M_{Na} - 2M_{Ca})/M_{Al},$$

where Q_{layer} denotes the layer charge of montmorillonite (0.46) or TSM (1.00) after Ref. 15; M_{Na} and M_{Ca} are the amounts of Na and Ca, respectively, remaining after pillaring, and M_{Al} is the amount of incorporated Al. The calculated values of Q_{Al} for TSM (0.56) and montmorillonite (0.57) were not only in fair agreement with a reported value on montmorillonite (0.56),[21] but were also very close to the Al charge (0.54) calculated from the formula of aluminum hydroxy cluster cation, $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$. This indicates that a direct exchange of Al_{13} cations occurred in these two clays.

The amount of incorporated Al monotonously decreased with increasing calc. 1 temperature in TSM. The decline curve was just upside-down to the rising curve of the Ca^{2+} amount in Fig. 2, suggesting that the layer charge reduction caused by Ca^{2+} fixation led to the decrease in the uptake of Al_{13} polycations. In contrast, no decrease in the Al amount was observed in montmorillonite and taeniolite, which is in harmony with the result that these clays do not fix Ca^{2+} ions.

Residual Amount of Na. The residual amount of Na in Ca^{2+}–PTSM is also plotted in Fig. 4 as a function of the calc. 1 temperature.

Ca^{2+}-exchanged TSM before pillaring had a considerable amount of residual Na (0.41; not shown in Fig. 4). Goto et al. reported that the cation exchange ratio of Na^+–TSM by divalent cations (Ca^{2+}, Mg^{2+}, and Ba^{2+}) was ca. 75%.[14] Ohtsuka et al. also described that 60—80% of Na^+ in TSM could be exchanged by Ni^{2+},[22] Co^{2+},[23] or Fe^{2+}.[24] Moreover, Kitajima et al. stated that 50—65% of the Li^+ ions in Li^+-taeniolite was exchangeable by monovalent cations and 70—85% by divalent cations.[25] The low exchange ratio in these expandable micas must be related to their high layer charges, since Na-type fluor-hectorite with a low layer

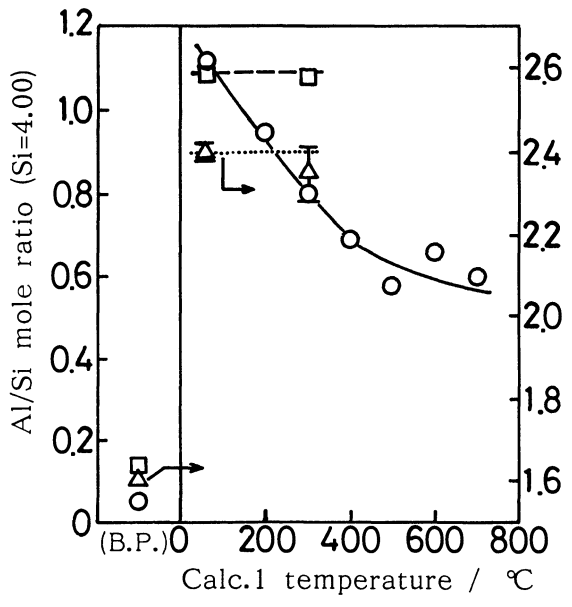

Fig. 3. Effect of the temperature of calc. 1 on the amount of Al in Ca^{2+}-modified pillared clays. (○) TSM, (△) montmorillonite, (□) taeniolite. (B.P.) Ca^{2+}-exchanged clay before pillaring.

Table 2. Basal Spacing of Each Catalyst

Calc. 1 temp	Basal spacing d_{001}/Å				
	Ca^{2+}-PTSM			Ca^{2+}-PM	Ca^{2+}-PT
	After calc. 1	After pillaring	After calc. 2	After calc. 2	After calc. 2
60	15.4	17.5	17.7	17.8	17.0
200	15.2	17.7	17.8	—	—
300	12.5	17.5	17.8	17.8	17.0
400	12.5	17.7	17.8	—	—
500	12.4/9.6	17.3	17.8	—	—
600	12.5/9.7	17.3	18.4	—	—
700	12.4	17.8	18.4	—	—

charge (1/3 per half unit cell) can exchange cations in a higher ratio than does taeniolite (90—95% of Na^+ are exchangeable by monovalent cations and 95—98% by divalent cations).[25]

The residual Na was decreased from 0.41 ro 0.29 due to a subsequent cation exchange with Al hydroxy cluster cations in a pillaring procedure when calc. 1 was performed at 60°C. Quite different from the case of Ca, the Na amount was further decreased with a rise in temperature at calc. 1. This implies that a thermally induced fixation of Na never occurs, supporting the classification of the fixation mode already discussed in a preceding paper.[3]

Change in Basal Spacing and Surface Area. Table 2 shows the change in the basal spacing with the temperature in the calc. 1 procedure. Ca^{2+}-exchanged TSM after calc. 1 at 60 or 200°C had a double-layer hydrated form (d_{001}=15.2—15.4 Å). The spacing decreased to 12.5 Å at 300—400°C, where the clay is a single-layer hydrated form. In addition to the appearance of an anhydrous phase at 500—600°C (d_{001}=9.6—9.7 Å), Ca^{2+}-TSM still maintained the single-layer hydrated form, even above 500°C. This feature was very different from that of La^{3+}-TSM, since only an anhydrous form was observed at 400°C or above in La^{3+}-TSM. An expansion of the basal spacing to 17—18 Å by pillaring was observed throughout the temperature range 60—700°C; this spacing was maintained after calc. 2 at 300°C. The Ca^{2+}-PTSM, thereby, showed a >1.5% cumene cracking conversion, even when the temperature of calc. 1 exceeded 500°C, whereas La^{3+}-PTSM was almost inactive in toluene alkylation due to a collapsed basal spacing (d=9.7 Å) when treated at 500°C in calc. 1. This structural difference beween Ca^{2+}-PTSM and La^{3+}-PTSM is possibly ascribed to a difference in the charge of the modification cations. The higher charge of La^{3+} can neutralize the negative charge of TSM layers more effectively than Ca^{2+}, as revealed from the ^{29}Si-MASNMR data.[3] The highly charge-reduced La^{3+} exchanged TSM (above 500°C of calc. 1 temperature) is too much decreased in swellability to uptake Al polycations between layers in a pillaring manipulation.[2]

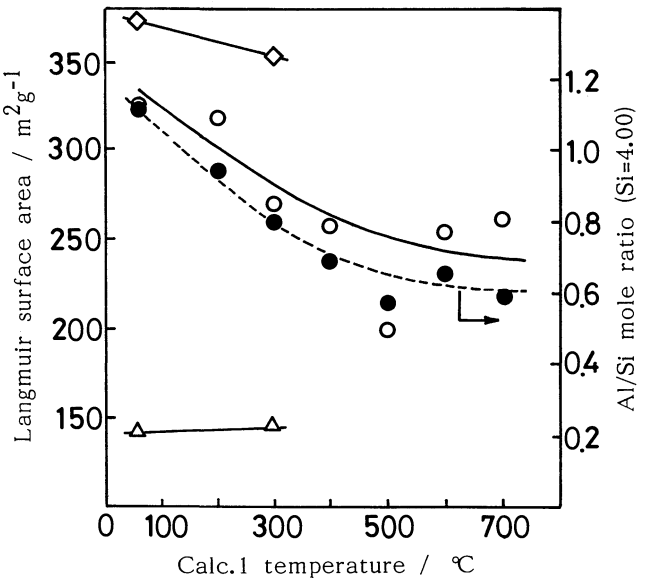

Fig. 5. Effect of the temperature of calc. 1 on the surface area of catalysts. (○) TSM, (◇) montmorillonite, (△) taeniolite. (●) The amount of Al in Ca^{2+}-PTSM.

Table 3. Surface Area of Ca^{2+}-PTSM

		Calc. 1 at 60°C	Calc. 1 at 300°C
Surface area[a] / $m^2 g^{-1}$	S_{all}	324	270
	S_{ext}	37.0	41.8
	S_{int}	287	228

a) S_{all}: Total Langmuir surface area, S_{ext}: external surface area, S_{int}: internal surface area.

The formation of a pillared structure with a basal spacing of 17—18 Å was also confirmed both in Ca^{2+}-PM and in Ca^{2+}-PT. No difference in the basal spacing was found when each of them was subjected to a thermal treatment in calc. 1 at temperature of 60 and 300°C.

Figure 5 shows the change in the surface area. Ca^{2+}-PTSM diminished its surface area with a rise in the calc. 1 temperature. The decreasing curve was similar to that of the change (Fig. 3) in the amount of

Al remaining in the catalyst. On the basis of a pore-size distribution analysis, the surface areas belonging to both the internal micropore (S_{int}) and the exteranl mesopore (S_{ext}) were calculated (Table 3). S_{int} is a measure of the micropores formed between silicate layers by pillaring.[26] When S_{int} and S_{ext} are compared after thermal treatments at between 60 and 300°C, it is noticed that the reduction of the total surface area (S_{all}) is ascribed to a decrease in the internal micropore surface area (S_{int}). The reduction in the surface area is, thus, based on a reduction in the amount of the Al-pillar, which prop silicate layers according to the progress of Ca^{2+} fixation.

In Ca^{2+}-PT, however, the surface area did not decrease. Though the surface area decreased by 20 $m^2 g^{-1}$ between 60 and 300°C in Ca^{2+}-PM, the decreasing ratio (5%) was much smaller than that of Ca^{2+}-PTSM (17%). From these data it is concluded that the structural change is little in catalyst systems where cation fixation does not occur.

Change in Acidic Property. Figure 6 shows the IR spectra of the pyridine adsorbed on Ca^{2+}-PTSM treated at 300°C on the calc. 1 procedure, which exhibited the highest conversion (4.2%) in cumene cracking. The features of the spectra were similar to that of La^{3+}-PTSM, as a whole. This similarity is reasonable, since both cations (Ca^{2+} and La^{3+}) belong to the same group according to the classification given in the preceding paper.[3] After pyridine adsorption at 150°C, followed by evacuation, both a strong band at 1450 and a weaker band at 1490 cm^{-1} were observed, indicating the Lewis acidic nature of the catalyst. The 1450 cm^{-1} band remained constant, even after successive evacuation at 450°C. When water adsorbed on this catalyst 200°C followed by evacuation, the 1550 cm^{-1} band appeared silightly and the genesis of Brønsted acidity was suggested. It is well-known that cumene cracking is catalyzed by Brønsted acidity.[27] The active sites of Ca^{2+}-PTSM must be situated close to fixed Ca, and they must exist as the Brønsted acid sites formed by the reaction of residual water and Ca^{2+}, as already reported.[2]

The above-mentioned Ca^{2+}-PTSM (calc. 1 temp 300°C), most active for cumene cracking, had an acid amount of 222 μmol g^{-1}, which was estimated from the amount of desorbed ammonia in the TPD spectra shown in Fig. 7. The acid amount slightly increased at 400°C, and then decreased above this temperature. The change in the acid amount exhibited a good

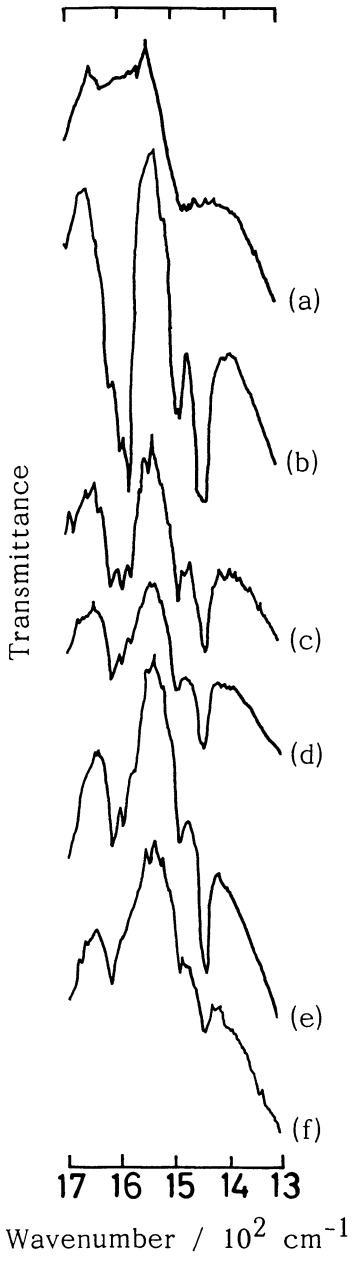

Fig. 6. IR spectra of pyridine adsorbed on Ca^{2+}-PTSM (both calc. 1 and calc. 2 at 300°C). (a) Back ground spectra, (b) after pyridine adsorption followed by evacuation at 150°C, (c—e) followed by successive evacuation at 250°C (c), 350°C (d) and at 450°C (e), (f) followed by water vapor adsorption and evacuation at 200°C.

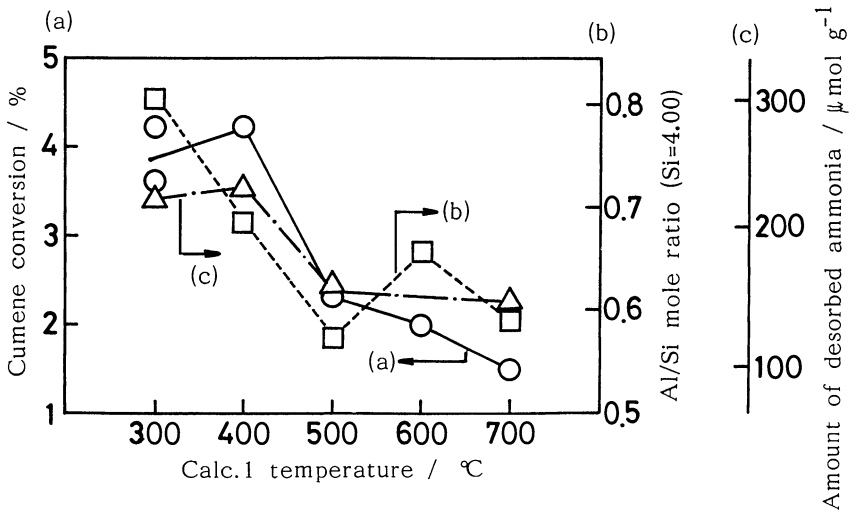

Fig. 8. Cumene cracking activity of Ca^{2+}–PTSM (a), the amount of Al (b), and the amount of desorbed ammonia in TPD (c) as a function of calc. 1 temperature.

correlation with the change in the cracking activity (Fig. 8). A similar relationship between cumene cracking activity, or the measure of Brønsted acidity, and the acid amount estimated from TPD has been ascertained for various-cation fixed pillared TSM catalysts.[3)]

The acid amount further correlated with the residual amount of Al at 400°C or above, which may be associated with the fact that the precursor of pillar (Al hydroxy cluster cation) functions as a proton source, since it releases protons upon calcination. The released protons migrate onto the silicate layers and can form acidic sites near the Ca-fixed sites.

In connection with the acid strength, a decrease in the number of strong acidic sites was observed with an increase in the calc. 1 temperature, which is indicated in Fig. 8 by the gradual decrease in the amount of ammonia desorbed between 400 and 650°C.

Distribution of Fixed Ca Ion on the Surface of Silicate Layer. Figure 9 depicts the basal oxygen plane of the silicate layer of TSM. The open circles represnt the center of hexagonal holes, or the possible sites of fixed Ca ions. When one of these sites is analyzed, it can be seen that there are six nearest-neighbor sites around it. When a fixed Ca is surrounded by several nearest-neighbor Ca ions (k in number), the Ca is called a "type nk calcium." Thus, seven types of Ca (n0, n1, .., n6) are distinguishable. The proportion of each type, which depends on the total occupancy of hexagonal holes by Ca, can be calculated based on the two following assumptions.

1. Fixed Ca ions are distributed in a completely random fashion.

2. The fixed ions are divided into halves on both surfaces of silicate layers when Al-pillars are inserted between them.

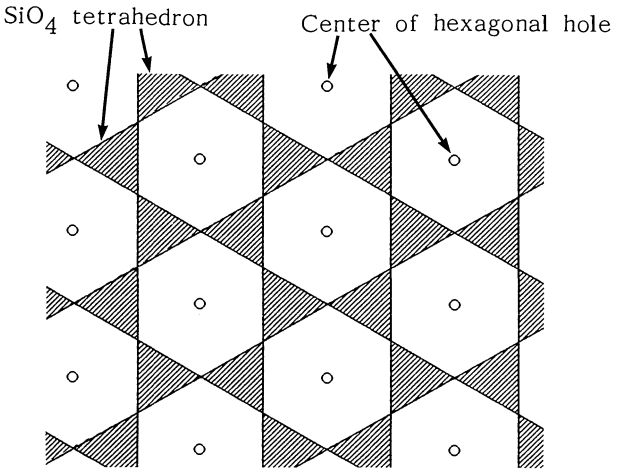

Fig. 9. Basal oxygen plane of layer silicate.

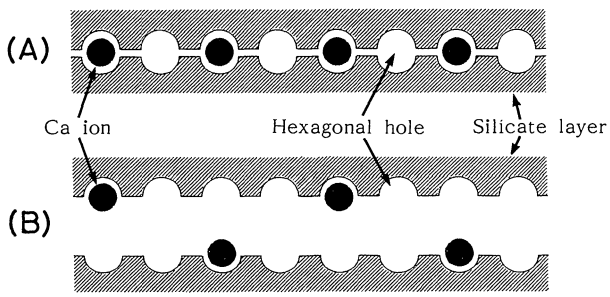

Fig. 10. Schematic diagram of Ca distribution on layer surface. (A) Before pillaring (Ca exchange rate of 100%). (B) After pillaring.

The first assumption is reasonable from the result of ^{29}Si-MASNMR, since the Q^3(0Al) signal in Ca^{2+}–TSM is markedly broadened upon heating, and such broadening is reasonably understood by Ca fixation in

a random fashion.[3] Fig. 10 illustrates the situation regarding the second assumption. At a maximum cation-exchange ratio of 100%, the exchanged Ca^{2+} ions should occupy half the hexagonal holes of TSM, which has a layers charge of 1.00 per Si_4O_{10} unit. Since these Ca ions are divided into halves after pillaring, the occupancy of hexagonal holes by Ca becomes 25% if all of the Ca ions are fixed and remain on the silicate surface.

The distributions were then calculated according to the following binominal equations, which are similar to the equation employed for the calculation of the siting of Si and Al atoms in the faujasite-type zeolite lattice:[28]

$$F_{nk} = \frac{6!}{k!(6-k)!} x^k(1-x)^{6-k}$$

and

$$N_{nk} = \frac{6!}{k!(6-k)!} x^{k+1}(1-x)^{6-k}.$$

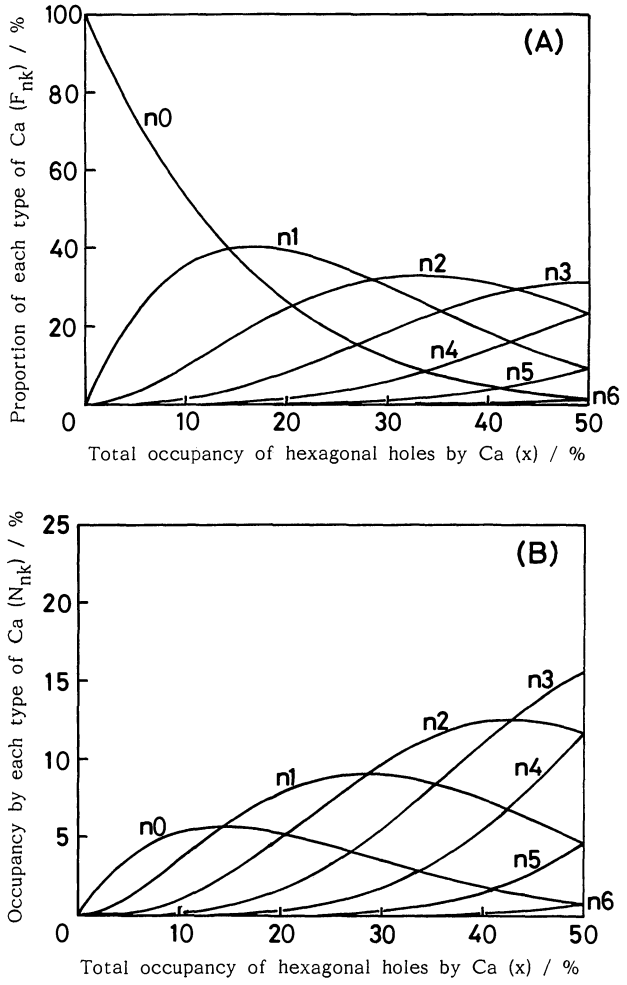

Fig. 11. Distribution of types of Ca atoms in Ca^{2+}–PTSM. (A) Proportion of each type of Ca. (B) Occupancy of hexagonal holes by each type of Ca.

Here, x is the occupancy of hexagonal holes by all types of Ca, F_{nk} the proportion of each type of Ca (type nk, k=0..6), and N_{nk} the occupancy of hexagonal holes by each types of Ca. The result of computing is shown in Figs. 11 (A) and (B). These curves of the Ca distribution are similar to that of Al in the framework of faujasite-type zeolites.[29–31] Since in zeolites two Al ions can not occupy adjacent tetrahedral sites (Loewenstein's rule), the next nearest-neighbor sites are considered for the calculations. Since zeolite acidity arises from an isomorphous substitution of Al for Si, the distribution state of Al sensitively influences the catalytic activity. Only isolated Al, which has no next nearest-neighbor Al, generates strong acidity.[32] The catalyst which has such sites in maximum number shows the highest activity in reactions which require strong acidity, such as cracking.[32,33]

In the case of the Ca^{2+}–PTSM catalysts, the acid strength must depend entirely on the distribution of the fixed Ca. Because neither silicate layers, themselves, nor pillars have acidic sites, the acidic sites are formed on silicate layers by Ca fixation. The obtained Ca distribution on a TSM layer, then, is discussed in connection with the cracking activity. When Ca^{2+}–PTSM is most active for cumene cracking, or when the catalyst is treated at 300—400°C on calc. 1 procedure (Fig. 1), the fixed amount of Ca is 0.31—0.33 per Si=4 (Fig. 2). This amount corresponds to a total occupancy of 16% under the above-mentioned second assumption. Fig. 11 indicates that the isolated Ca (type n0) is predominant until this Ca content. Moreover, the number of type n0 calcium becomes maximum near this total occupancy (according to the above equation, N_{n0} gives a maximum value at x=0.143), showing good agreement with the maximum catalytic activity. This agreement strongly supports the fixation model in the present study: that the Ca cations fix onto the silicate-layers while lodging in the hexagonal holes and taking charge of the genesis of acidic sites.

Concluding Remarks

When the same procedure for the preparation of Ca^{2+}-modified pillared clays were applied to three different clays (TSM, montmorillonite, and taeniolite), only Ca^{2+}–PTSM showed a notable acidity enhancement by Ca^{2+} fixation. Ca^{2+} was not fixed by the other two clays under the same preparation conditions. The ease of Ca fixation onto the TSM layer must come from the structural characteristics of TSM: a high layer charge and the existence of an octahedral vacancy. The dependence of the catalytic activity of Ca^{2+}–PTSM on the calcination temperature before pillaring was successfully interpreted in terms of the random distribution model for Ca^{2+} fixed on the surface of the TSM layer.

We thank the Iwatani Memorial Foundation for financial support of this work, JGC Co., Ltd. for permitting us to use the X-ray fluorescence spectrometer, Mr. Kenichiro Sugimori (Chemical Div., Topy Ind.) for supplying the synthetic TSM and taeniolite samples, and Prof. Kunio Kitajima (Dept. Chemistry and Material Engineering, Shinshu Univ.) for his helpful discussions.

Effect of ZnO Addition on Cobalt-Alumina Interaction Species

Yasuaki Okamoto,* Toshinori Adachi, Akinori Maezawa,† and Toshinobu Imanaka
Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received August 10, 1990)

The effect of ZnO addition on cobalt–alumina interaction modes was studied using TPR and XPS. It was found that the addition of 2 wt% ZnO markedly affects the distribution of the cobalt species in CoO/Al_2O_3 (5 wt% CoO): cobalt–alumina surface interaction species are removed and migration of cobalt into an alumina subsurface phase is promoted by ZnO. A formation of Co–Zn–O mixed oxide is proposed for $ZnO–CoO/Al_2O_3$ at high ZnO content. The dispersion and distribution of ZnO on Al_2O_3 are also strongly modified by the presence of cobalt.

In connection with $CoO–MoO_3/Al_2O_3$ hydrodesulfurization (HDS) catalyst systems, CoO/Al_2O_3 catalysts have been extensively studied using various physicochemical techniques.[1–12] It has been shown that several $CoO–Al_2O_3$ interaction species are formed on CoO/Al_2O_3 catalysts and that the interaction mode depends on the CoO content and calcination temperature. At usual calcination temperatures (670—870 K), (sub)surface cobalt species in tetrahedral configurations (aluminate like species) are selectively formed at an initial dose of cobalt.[2,4,6–9] Formation of surface cobalt species in octahedral symmetries are also proposed on the basis of XPS and ISS studies coupled with H_2-reduction.[8] A crystalline Co_3O_4 phase appears above about 2 wt% CoO and increases precipitously in the amount with a further increase of cobalt content.[2,6,8,10] With CoO/Al_2O_3 systems calcined at various temperatures, a detailed characterization of cobalt species was conducted by Arnoldy and Moulijn[11,12] using temperature-programmed reduction (TPR) techniques. The formations of surface Co^{3+} and Co^{2+} species, $Co^{3+}–Al^{3+}$ mixed oxide, and subsurface Co^{2+} are proposed in addition to Co_3O_4 and aluminate-like species.

The cobalt–alumina interaction modes are expected to be strongly modified by adding metal oxide which interacts with Al_2O_3, such as ZnO. The additive effects on the cobalt–alumina interactions are, accordingly, considered to provide more detailed information of the interaction species. Furthermore, doping of a small amount of a second promoter, such as ZnO, NiO, or MgO, is often claimed to improve the HDS activity and stability of $CoO–MoO_3/Al_2O_3$ catalysts.[13] However, only a few fundamental investigations have been made to reveal the additive effect on cobalt–alumina interaction modes and the beneficial effects of the second promoter.[14–20]

It has been demonstrated in our previous study[21] using XPS that molybdenum oxide–alumina interaction modes are not appreciably affected on the addition of ZnO. This may suggest that ZnO alters the cobalt oxide–alumina or cobalt oxide–molybdenum oxide interaction modes. With $ZnO–CoO/Al_2O_3$ at varying CoO contents and 1 wt% Zn, Chin and Hercules[15] have actually shown by XPS and ISS that the presence of ZnO enhances the formation of cobalt "surface spinel" at $\leqslant$8 wt% Co, while at higher Co loadings the addition of 1% Zn drastically increases the dispersion of cobalt oxide. No further detailed information on $ZnO–CoO/Al_2O_3$ systems has been reported. A more detailed study on $ZnO–CoO/Al_2O_3$ might provide information about the role of the second promoter in $CoO–MoO_3/Al_2O_3$ catalysts as well as cobalt–alumina interaction modes.

In the present study, the effect of ZnO addition was investigated on the cobalt–alumina interaction modes in CoO/Al_2O_3 using TPR and XPS. It was found that the addition of a small amount of ZnO remarkably altered the distribution of cobalt–alumina interaction species.

Experimental

Supported cobalt catalysts were prepared by impregnating γ-Al_2O_3 with an aqueous solution of cobalt salt. γ-Al_2O_3 (pore volume: 0.66 $cm^3\,g^{-1}$, 163 $m^2\,g^{-1}$) was supplied by the Catalysis Society of Japan as a reference catalyst (JRC-ALO-4).[22] The amount of the aqueous solution of cobalt nitrate was adjusted to be 1.3 cm^3 per g-Al_2O_3 to prepare CoO/Al_2O_3 containing 5 wt% CoO. The supported amount of CoO is represented with respect to the support. After the catalyst precursor was dried at 383 K for 16 h, it was calcined at 673, 823, or 1073 K for 5 h in air by using an electric furnace. $ZnO–CoO/Al_2O_3$ samples containing 5 wt% CoO and varying amounts of ZnO were prepared by simultaneous impregnation of appropriate amounts of cobalt and zinc nitrates.

In TPR studies, the cobalt catalyst (0.2 g) was reduced in a 5% H_2/Ar stream (72 cm^3 STP min^{-1}), which was purified by passing through a deoxygenation catalyst layer, followed by a zeolite trap cooled at a methanol–Dry Ice temperature. After evacuation at 623 K for 1 h, the reduction temperature was raised from 300 to ca. 920 K at an uniform heating rate (β) of 2.5 K min^{-1}. The H_2 concentration in the effluent gas was analyzed by a TCD cell at 303 K after removing water vapor by a cold trap at a methanol–Dry Ice temperature.

† Present address; Shizuoka University, Shirokita, Hamamatsu 432.

The XPS measurements were made on a Hitachi 507 photoelectron spectrometer using Al $K\alpha_{1,2}$ radiation (1486.6 eV). The anode was operated at 9 kV and 50 mA. Assuming linear backgrounds, XPS intensity ratios were obtained by using the planimetered peak areas of the Co 2p, Al 2p, Zn 2p, and Zn($L_3M_{4,5}M_{4,5}$) levels. Binding energies were referenced to the Al 2p level (74.3 eV) of the support, which had been separately determined by using the C 1s band at 285.0 eV due to adventitious carbon.

Results

The TPR profiles for $ZnO-CoO/Al_2O_3$ are shown in Fig. 1 as a function of ZnO content and calcination temperature (673 and 823 K). The profiles for CoO/Al_2O_3 consisted of several distinctly different reduction peaks as reported by Arnoldy and Moulijn.[11] The cobalt species are characterized by the reduction temperatures of 503—553 K (Co-I), 633—643 K (Co-IIA), 693 K (Co-IIB), 753—773 K (Co-III), and 853—873 K (Co-IV) in the present study. The reduction temperatures depended on the calcination temperature and loading level of CoO. Since the rate of temperature increase, flow rate of H_2/Ar, and H_2-concentration are different, the reduction temperatures in Fig. 1 cannot be directly compared with the values reported by Arnoldy and Moulijn.[11] The present

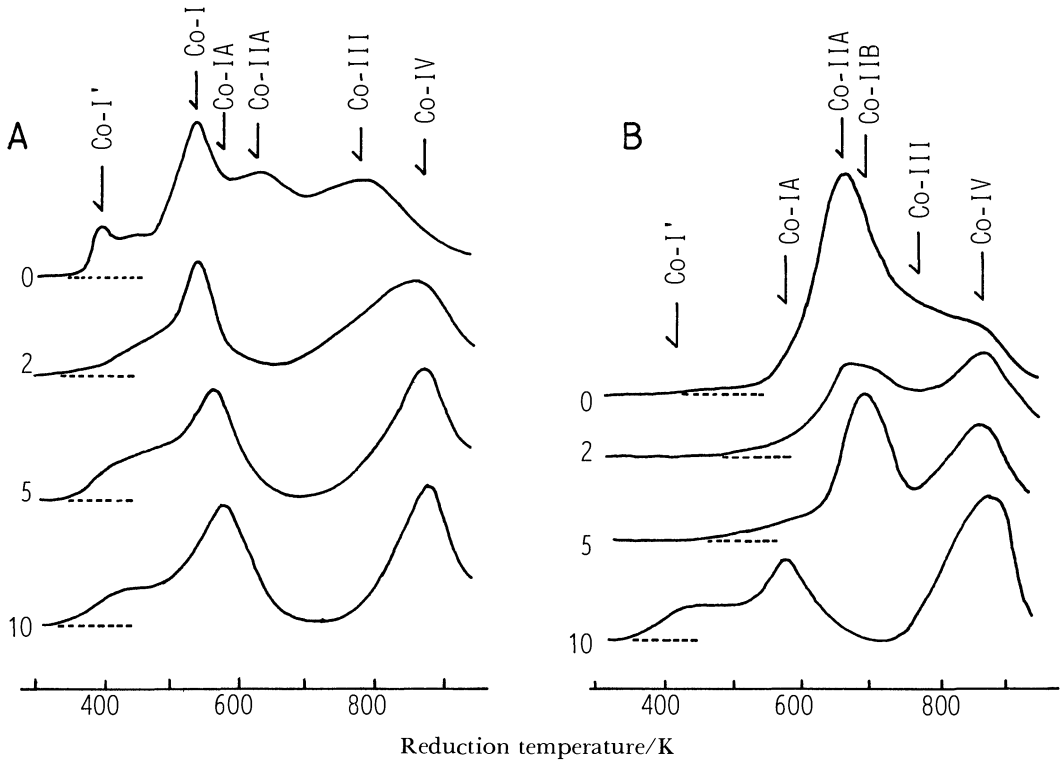

Fig. 1. TPR profiles of $ZnO-CoO/Al_2O_3$ (CoO; 5 wt%) as a function of ZnO content and calcination temperature. (A): calcined at 673 K and (B): 823 K. Numbers in the figure denote ZnO content (wt%). Dotted lines show backgrounds after vertical replacements. β=2.5 K min^{-1}.

Table 1. TPR Results on CoO/Al_2O_3

Cobalt species	Reduction temperature/K		Assignments[a]
	Moulijn et al.[a]	This work[b]	
Co-I'	—	400—450	Amorphous Co-oxide[c]
Co-I	600	503—553	Crystalline Co_3O_4
Co-IA	—	580	Co-Zn-O[b]
Co-IIA	750	633—643	Surface Co^{3+}
Co-IIB	750	693	Co^{3+}-Al^{3+}-oxide
Co-III	900	753—773	Surface Co^{2+}
Co-IV	1130—1240	853—873	(Sub)surface Co^{2+}
Co-V[d]	1150—1230	>920	$Co_xAl_{(8/3-2x/3)}O_4$ $CoAl_2O_4$

a) Refs. 11 and 12, β=10 K min^{-1}. b) β=2.5 K min^{-1}, this work. c) Ref. 26. d) Co-IVC and IVD in Refs. 11 and 12.

reduction temperatures of cobalt species are compared in Table 1 with those in Ref. 11. A good parallel correlation in Table 1 indicates that the cobalt species detected here correspond well to those observed by Arnoldy and Moulijn.[11] The reduction peaks are denoted as in Table 1 according to Arnoldy et at.[11,12] in the order of the reduction temperature. Co-IVC and Co-IVD observed at 1150—1230 K by Arnoldy and Moulijn[11] are supposed to be detected at >920 K in the present study. Hydrogen consumptions at >920 K in the TPR profiles in Fig. 1 indicate the presence of these reduction peaks (denoted Co-V here). In addition to Co-I—V peaks, Co-I′ appeared at 400—450 K in the present study.

The TPR profile of Co_3O_4 consisted of a slightly asymmetric single peak. The reduction temperature depended on the particle size of Co_3O_4 and the samples with the particle diameter of 50 and 1200 nm (SEM observations) showed the TPR peaks at 570 and 590 K, respectively.

The addition of ZnO into CoO/Al_2O_3 was found to strongly affect the TPR profiles. As shown in Fig. 1, the addition of 2 wt% ZnO into 5 wt% CoO/Al_2O_3 catalyst (673 K) removed almost completely Co-IIA and most of Co-III. Further additions of ZnO completely eliminated Co-III. Although the TPR intensity of Co-I was not signicantly altered by the addition of 5 and 10 wt% ZnO, the reduction temperature of Co-I (538 K) increased by 20 K at 5 wt% ZnO and additionally augmented by 20 K, reaching 580 K at 10 wt% ZnO. Co-I species could not be found at such a high temperature of 580 K for supported CoO systems, for instance, CoO/Al_2O_3 and CoO/SiO_2 containing up to 20 wt% CoO. No appreciable change in the crystallite size of Co_3O_4 was observed by means of XRD on the addition of ZnO. Accordingly, the reduction peak at 580 K is concluded to be ascribed to a new cobalt phase and denoted Co-IA here.

With $ZnO–CoO/Al_2O_3$ calcined at 823 K, the intensities of Co-IIA and III were significantly decreased by the addition of 2 wt% ZnO as observed with the sample calcined at 673 K. The presence of Co-IIB became clearly observable by the elimination of Co-IIA. Co-IIB remaind intact on the addition of 5 wt% ZnO. On the other hand, the addition of 10 wt% ZnO removed Co-IIB and brought about the formations of Co-IA and I′. The intensity of Co-IV increased at 2 wt% ZnO but was not strongly affected by a further addition of ZnO, irrespective of the calcination temperature. As for ZnO/Al_2O_3 systems (below 10 wt% ZnO), no reduction peaks were observed below 900 K under the present TPR conditions.

The intensity of TPR profile was found to depend on the ZnO content. The total TPR areas between room temperature and 920 K are shown in Fig. 2 as a function of ZnO content. It was found that the addition of ZnO also strongly affected the TPR

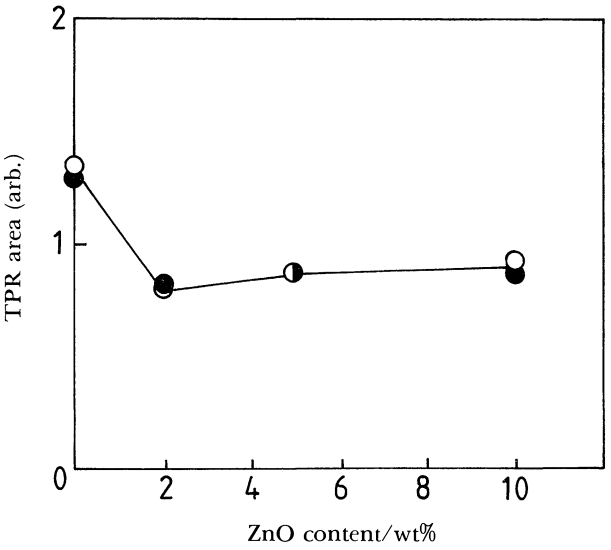

Fig. 2. Variations of the TPR area intensity with ZnO content (wt%) for $ZnO–CoO/Al_2O_3$ catalysts (5 wt% CoO) calcined at 673 K (○) and at 823 K (●).

intensity of CoO/Al_2O_3 (5 wt% CoO). The TPR areas decreased by 40% at 2 wt% ZnO and were almost invariant on a further addition of ZnO at the calcination temperatures of 673 and 823 K. On the basis of the XPS study of CoO/Al_2O_3 (8 wt% Co) calcined at 673 K, Chin and Hercules[15] have reported that the fraction of cobalt which is H_2-reducible at 623 K decreases from 20 to 15% (by 25% decrease) on the addition of 1% Zn. The TPR results in Fig. 2 are in line with their XPS observations.

XPS characterization of the $ZnO–CoO/Al_2O_3$ systems was carried out as a function of ZnO loading. The BE values of Co $2p_{3/2}$ band for 5 wt% CoO/Al_2O_3 calcined at 673 and 823 K were 780.3 and 781.2 eV, respectively. They are in between those for $CoAl_2O_4$ (781.3—782.2 eV)[4,6–8] and Co_3O_4 (779.6—779.8 eV).[6,7] When CoO/Al_2O_3 was calcined at 1073 K, the BE of Co $2p_{3/2}$ band (781.5 eV) was very close to that of $CoAl_2O_4$. The Co $2p_{3/2}$ BE was not influenced by the addition of ZnO within experimental accuracy (±0.2 eV). The BE of Zn 2p level and the kinetic energy (KE) of Zn($L_3M_{4,5}M_{4,5}$) Auger band were independent of ZnO and CoO contents and calcination temperature and were 1021.8 and 987.5 eV, respectively. These BE and KE values for Zn indicate that Zn^{2+} cations are in an aluminate-like phase.[21,23]

The Co 2p/Al 2p or Zn 2p/Al 2p XPS intensity ratio depends on both dispersion and surface concentration of Co or Zn. A higher XPS intensity ratio is expected for higher dispersion and/or higher surface concentration of Co or Zn.[24] The effect of ZnO addition on the Co 2p/Al 2p ratio for CoO/Al_2O_3 is shown in Fig. 3 as a function of ZnO content. When $ZnO–CoO/Al_2O_3$ was calcined at 673 or 823 K, no appreciable change in

the Co 2p/Al 2p ratio was detected, except for the 2 wt% ZnO sample calcined at 673 K, while the ratio for $ZnO-CoO/Al_2O_3$ calcined at 1073 K decreased gradually with increasing ZnO content. A small decrease in the Co 2p/Al 2p ratio for 2 wt% CoO/Al_2O_3 calcined at 673 K is consistent with the observations by Chin and Hercules.[15]

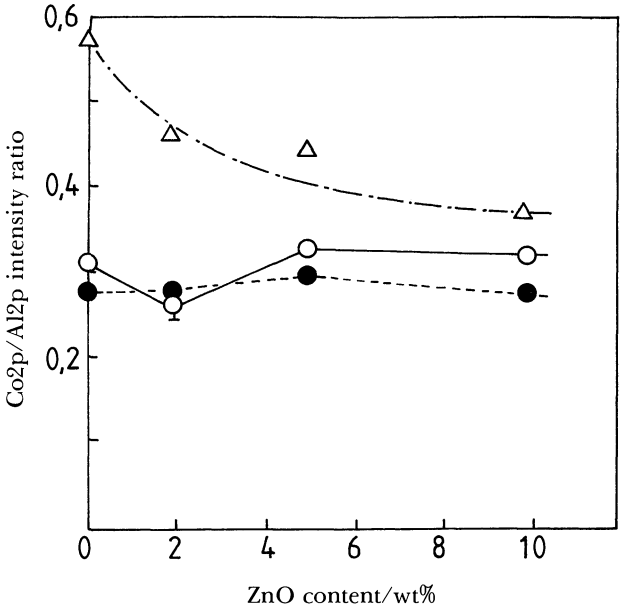

Fig. 3. Dependencies of the Co 2p/Al 2p XPS intensity ratio on ZnO content (wt%) for $ZnO-CoO/Al_2O_3$ (CoO; 5 wt%) calcined at 673 K (○), 823 K (●), and 1073 K (△).

Figure 4 depicts the Zn 2p/Al 2p (A) and Zn(LMM)/Zn 2p (B) intensity ratios to estimate the dispersion and depth profile of Zn^{2+} cations in $ZnO-CoO/Al_2O_3$ samples containing 5 wt% CoO. According to Penn,[25] the escape depths of the photo- and Auger-electrons are estimated to be 0.8 and 1.5 nm, respectively. The Zn-Auger/Zn 2p ratio for pure ZnO was 1.2 for the present spectrometer.[21]

The Zn 2p/Al 2p ratio for $ZnO-CoO/Al_2O_3$ decreased with increasing calcination temperature, whereas the Zn Auger/Zn 2p ratio increased. These behaviors are analogous to those for ZnO/Al_2O_3 samples[21] as presented in Fig. 4. However, it was found that when $ZnO-CoO/Al_2O_3$ is calcined at 673 or 823 K the coimpregnation of CoO significantly decreases the Zn 2p/Al 2p intensity ratios compared to those for ZnO/Al_2O_3, whereas the presence of CoO increases the Zn(LMM)/Zn 2p ratio. Both ratios for the samples calcined at 1073 K were not affected by the presence of CoO (5 wt%).

Discussion

The TPR and XPS studies of $ZnO-CoO/Al_2O_3$ catalysts with varying ZnO contents were carried out to reveal the effect of ZnO addition on the cobalt-alumina interaction species. In the present study, it has been definitely demonstrated for the first time that the addition of a small amount of ZnO greatly affects the cobalt-alumina interaction modes and the distribution of cobalt species.

In the TPR experiments, it is assumed that the respective reduction peaks correspond to distinct

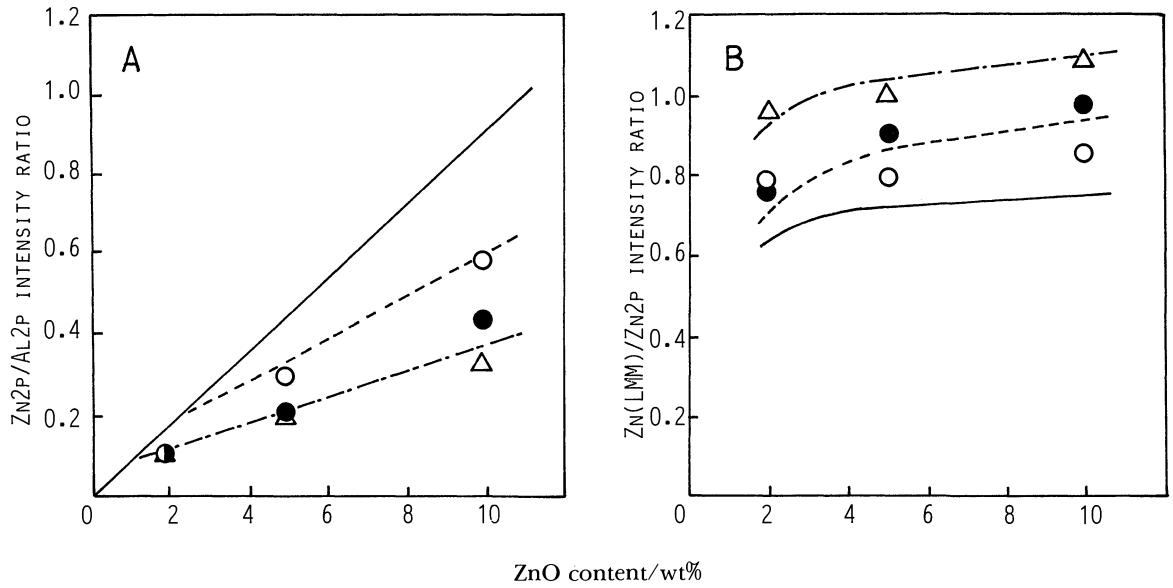

Fig. 4. Zn 2p/Al 2p XPS intensity ratio (A) and Zn(LMM)/Al 2p intensity ratio (B) vs. ZnO content (wt%) for $ZnO-CoO/Al_2O_3$ (CoO; 5 wt%). ○: calcined at 673 K, ●: 823 K, and △: 1073 K. Solid line: ZnO/Al_2O_3 calcined at 673 K, dotted line: 823 K, and dashed line: 1073 K.[21]

cobalt species in different oxidation states and/or different chemical environments, since the reduction of Co_3O_4 showed only a relatively narrow peak with slight shoulder and since the peak separations among Co-I—IV seem to be too large to assign them to successive reduction processes of cobalt, e.g. Co^{3+} to Co^{2+} and Co^{2+} to Co metal. The TPR peaks for CoO/Al_2O_3 have been assigned by Moulijn et al.[11,12] as summarized in Table 1 on the basis of XRD and the amount of H_2-consumption. A combined TPR and XPS study[26] on CoO/Al_2O_3 with varying CoO loadings essentially support their assignments in Table 1.

It is demonstrated from the TPR spectra in Fig. 1 that dramatic alterations in cobalt–alumina interaction modes in CoO/Al_2O_3 are brought about by the addition of ZnO. The addition of 2 wt% ZnO effectively eliminates surface cobalt–alumina interaction species (Co-IIA and III) and enhances a formation of (sub)surface spinel species, while the amount of bulk Co_3O_4 phase is not affected in the presence of ZnO. On the base of XPS and ISS studies on ZnO–CoO/Al_2O_3, Chin and Hercules[15] suggested that the formation of cobalt "surface spinel" is enhanced by the addition of 1 or 2% Zn at $\leqslant$8 wt% Co. The TPR results in Figs. 1 and 2 definitely support their conclusions and provide more convincing and detailed information on the effect of ZnO on $CoO–Al_2O_3$ interaction modes.

The changes in cobalt species on the addition of ZnO are considered to result from competitive occupations of limited numbers of surface and bulk sites of Al_2O_3 by Co^{2+}, Co^{3+}, Al^{3+}, and Zn^{2+} cations. The structure of γ-Al_2O_3 is described as a defect spinel[27] and these cations occupy octahedral and/or tetrahedral sites of Al_2O_3 on solid state reactions during calcination.[1,2,28–30] Before discussing the cobalt species in ZnO–CoO/Al_2O_3, it is considered first how the distribution and dispersion of Zn^{2+} cations in ZnO/Al_2O_3 are affected by the cobalt addition.

The escape depth of the Zn(LMM) Auger band is higher than that of the Zn 2p band. Since the Zn(LMM)/Zn 2p ratios for ZnO/Al_2O_3 (673 K) are significantly lower than that of pure ZnO, in which zinc is expected to be homogeneously distributed in depth, it is concluded that Zn^{2+} cations are segregated in the surface layer of ZnO/Al_2O_3 at 673 K.[21] The intensity ratio of Zn(LMM)/Zn 2p can be expressed as follows for Al_2O_3 with a zinc–aluminate surface layer of thickness, d.

$$[\mathrm{Zn(LMM)/Zn\ 2p}] = [\mathrm{Zn(LMM)/Zn\ 2p}]_0 \times [1 - \exp(-d/\lambda_{\mathrm{Zn(LMM)}})]/[1 - \exp(-d/\lambda_{\mathrm{Zn\,2p}})] \quad (1)$$

where $[\mathrm{Zn(LMM)/Zn\ 2p}]_0$ indicates the intensity ratio for an infinitely thick, homogeneous Zn-layer and is observed to be 1.2 for ZnO.[21] $\lambda_{\mathrm{Zn(LMM)}}$ and $\lambda_{\mathrm{Zn\,2p}}$ denote the escape depths of the Zn(LMM) Auger- and Zn 2p photo-electrons and are 1.5 and 0.8 nm, respectively. The intensity ratios are calculated to be 0.68, 0.82, 0.96, and 1.13 from Eq. 1 for Zn-containing layers of thickness of 0.2 (monolayer), 1, 2, and 4 nm, respectively. A comparison with the results in Fig. 4-B implies that Zn^{2+} cations preferentially occupy surface sites forming a monolayer in ZnO/Al_2O_3 calcinated at 673 K and containing less than about 6 wt% ZnO.

The increase in the Zn(LMM)/Zn 2p ratio with increasing calcination temperature indicates the diffusion of Zn^{2+} cations into the Al_2O_3 bulk (1—2 nm at 823 K and 2—5 nm at 1073 K). The increase in the thickness of Zn layer is obviously observed as ZnO content increases. These findings are a consequence of enhanced diffusivity of Zn^{2+} cations at a higher temperature and limited surface sites for Zn^{2+} cations. These behaviors of Zn^{2+} cations in ZnO/Al_2O_3 were qualitatively confirmed by Ar^+ sputtering techniques.[21]

With the ZnO–CoO/Al_2O_3 systems calcined at 673 and 823 K, the Zn(LMM)/Zn 2p intensity ratios increased on the addition of CoO, indicating that the cobalt addition enhances the diffusion of Zn^{2+} cations into the Al_2O_3 bulk phase. This is also supported by the decrease in the Zn 2p/Al 2p XPS intensity ratios on the addition of CoO. On the other hand, it should be noted that the Zn(LMM)/Zn 2p ratios for ZnO–CoO/Al_2O_3 are still far below the ratio for pure ZnO and, in consequence, that a considerable proportion of Zn^{2+} cations occupies surface sites in ZnO–CoO/Al_2O_3 calcined at 673 or 823 K. A significant depletion of Zn^{2+} at surface would lead to the ratio Zn(LMM)/Zn 2p$>$1.2, which is contrary to the experimental observations.

The differences in the site preference between Zn^{2+}, Co^{2+}, Co^{3+}, and Al^{3+} cations are considered to determine the site distributions of cations in the ZnO–CoO/Al_2O_3 systems. Surface Zn^{2+} cations are expected to occupy tetrahedral sites of Al_2O_3 because of low stability in octahedral sites (octahedral preference energy: +7.6 kcal mol^{-1}) as compared to Al^{3+} (−10.6 kcal mol^{-1}).[31] This was confirmed by the BE of Zn 2p band and KE of Zn(LMM) level for ZnO/Al_2O_3 and ZnO–CoO/Al_2O_3. Divalent cobalt cations are also anticipated to be present mainly in tetrahedral sites (95% in $CoAl_2O_4$ spinel structure) (+3 kcal mol^{-1}). On the other hand, it is suggested by Arnoldy and Moulijn[11] using a ligand field theory that Co^{3+} shows a tendency to occupy octahedral sites in an Al_2O_3 lattice. The order of tetrahedral site preference in spinel structures is, accordingly, estimated to be $Zn^{2+}>Co^{2+}>Al^{3+}>Co^{3+}$.

As aforementioned, the Zn^{2+} cations in ZnO–CoO/Al_2O_3 occupy preferentially surface tetrahedral sites of Al_2O_3 at a low ZnO content. This eventually results in an occupation of octahedral sites with Al^{3+} cations as in $ZnAl_2O_4$. It is deduced that the preferential incor-

poration of Zn^{2+} cations in surface tetrahedral sites significantly retards formations of both surface Co^{2+} (Co-IIA) and Co^{3+} (Co-III) species in octahedral and tetrahedral sites, respectively, in conformity with the TPR profiles in Fig. 1. The cobalt cations expelled from the surface sites are expected to be incorporated into tetrahedral sites in an Al_2O_3 lattice as long as these sites are available because of higher thermodynamic stability of cobalt aluminate formation. The enhanced diffusions of Zn^{2+} and Co^{2+} cations into subsurface layer of Al_2O_3 result from competitive occupations of surface and bulk sites.

The ratio of bulk oxide (Co-I and IIB) and (sub)-surface cobalt species may depend on the calcination temperature and ZnO content, but actually it was almost invariant at 673 and 823 K (Fig. 2). The bulk oxide species are conjectured to be produced via oxidation of Co^{2+} to Co^{3+} during calcination.[26] The proportion of Co^{3+} depends strongly on the starting salt but weakly on the calcination temperature ($\leqslant$823 K) and ZnO content. This is because the calcination temperature of 673 or 823 K is too low for the cations to attain equilibrium distributions in an Al_2O_3 lattice (Tammann temperature: ca. 1140 K) as suggested by Burggraf et al.[9] On the contrary, diffusions of Co^{2+} and Zn^{2+} are significantly enhanced at 1073 K because of competitive site occupation and elevated calcination temperature which facilitates bulk diffusion to attain equilibrium distribution.

The formation of Co-IA was observed at high ZnO content. It is proposed that the high reduction temperature of Co-IA as compared to that of Co_3O_4 is attributed to the dissolution of Zn^{2+} into Co_3O_4 phase. The Zn^{2+} cations are expected to occupy tetrahedral sites in Co_3O_4 as in $ZnCo_2O_4$ (normal spinel structure).[30] The amount of Co-IA is very close to Co_3O_4 (Co-I) at 673 K, indicating no formation of Co_3O_4 is promoted by the addition of ZnO at this temperature. On the other hand, when 10 wt% $ZnO–CoO/Al_2O_3$ was calcined at 823 K, Co-IA was produced in spite of the absence of precursor Co_3O_4 (Fig. 1-B). This finding is interpreted in terms of an extensive occupation of tetrahedral sites of an Al_2O_3 lattice with Zn^{2+} cations due to an enhanced diffusivity at 823 K and a large number of Zn^{2+} cations doped.

Mixed oxide formation between dispersed Co_3O_4 particles and the support constituent increases the reduction temperature of cobalt as a consequence of enhanced polarization of Co–O bondings.[11] The incorporation of Al^{3+} into octahedral interstices of Co_3O_4 (Co-IIB) significantly increase the reduction temperature (ca. 150 K) of Co_3O_4. Formation of $Si^{4+}{}_{x/2}Co^{2+}{}_{1-x}Co^{3+}{}_2O_4$ with spinel structure is proposed for CoO/SiO_2 and the reduction temperature increases by 55 K compared with Co_3O_4.[32] The effect of cation incorporation is in the order $Al^{3+} \gg Si^{4+} > Zn^{2+}$ as might be expected, taking into account a cation charge and a low concentration of Si^{4+} in the lattice.

Analogously to the enhanced bulk diffusion of Zn^{2+} in the presence of Co^{2+}, the diffusion of Co^{2+} cations into the bulk phase is promoted by a simultaneous impregnation of ZnO as evidenced by a considerable decrease in the TPR area in Fig. 2. This is partly substantiated by the decrease in the Co 2p/Al 2p XPS intensity ratio at 2 wt% ZnO in Fig. 3 for $ZnO–CoO/Al_2O_3$ (673 K) in line with the observations by Chin and Hercules.[15] With $ZnO–CoO/Al_2O_3$ at high ZnO or calcined at 823 K, however, the Co 2p/Al 2p XPS intensity ratios are not appreciably affected by the addition of ZnO in spite of the bulk diffusion of cobalt species. This may be interpreted in terms of compensating effects on the XPS intensity ratio, that is, diffusion of the surface cobalt species into a bulk phase deeper than the sampling depth of XPS (2—3 nm) and the increase in cobalt dispersion due to the reactions with Al_2O_3 (formations of Co-IV and V at the expense of Co-IIB).

In summary, it was found that the addition of 2 wt% ZnO markedly affected the cobalt–alumina interaction modes. The distribution of the cobalt species in CoO/Al_2O_3 was greatly altered: cobalt–alumina surface interaction species were removed and migration of cobalt into alumina subsurface phase was promoted by ZnO. A formation of Co–Zn–O mixed oxide is proposed for $ZnO–CoO/Al_2O_3$ at high ZnO contents (5—10 wt%).

We gratefully acknowledge Messrs. K. Inamura and T. Takyu in Central Research Laboratory, Idemitsu Kosan Co., Ltd. for helpful discussions and the TPR (TPRS-200) and SEM measurements of Co_3O_4 and CoO/Al_2O_3.

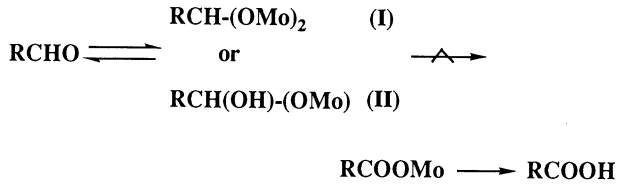
(Received September 6, 1990)

The reaction scheme for the methacrylaldehyde oxidation over heteropoly compounds proposed previously (M. Misono et al., Proc. 7th Intl. Congr. Catal., 1980) was confirmed by ^{18}O tracer experiments using the Pulse-MS method (combination of pulse reactor/mass spectrometer). The occurrence of direct and rapid oxygen exchange between methacrylaldehyde and the polyanion of $M_xH_{3-x}PMo_{12}O_{40}$ (M=Na, Cs, x=0—3.15) was verified under the reaction conditions. The results also suggested that this reaction is catalyzed by Brønsted acid sites of the catalysts via such intermediates as (**I**) and/or (**II**) in scheme 1. It was shown that the methacrylaldehyde oxidation is a surface-tyepe reaction and the catalytic activity is controlled by the oxidizing ability of the catalyst surface.

The selective oxidation of methacrylaldehyde to methacrylic acid has recently been industrialized by utilizing 12-molybdovanadophosphates,[1] although improvements in the selectivity and durability are still desirable. As for the reaction mechanism, we previously proposed the following scheme.[2]



Scheme 1.

We also showed that the oxygen atoms of the polyanion and/or water are directly incorporated into the products in accordance with the scheme, and that the oxygen in the feed gas reoxidizes the reduced polyanion (i.e., a redox mechanism). In this mechanism, such intermediates as (**I**) and (**II**), having C–O–Mo bonds, are assumed to exist. Isopoly compounds having partial structures similar to (**I**) and (**II**) have been synthesized,[3] and it was suggested that they are the intermediates in the oxidation of aldehydes.[3,4] If (**I**) and (**II**) are indeed the intermediates and the first step of Scheme 1 is rapid, direct exchange of oxygen must proceed rapidly between 12-molybdophosphoric acid and aldehyde. We actually found rapid oxygen isotopic exchange among aldehyde, water, and the catalyst in the case of acrylaldehyde oxidation over 12-molybdophosphoric acid.[2] However, in that case it was not clear whether the exchange proceeds directly between the catalyst and aldehyde, or via oxygen exchange with water.

A direct exchange would be good evidence for the existence of (**I**) or (**II**). In view of this, we investigated in the present work the oxygen exchange between methacrylaldehyde and 12-molybdophosphates. The factors controlling each step of Scheme 1 have also been examined. If the second step is rate-limiting, the oxidizing ability of catalysts should control the overall rate. Further, attempts were made to clarify whether the methacrylaldehyde oxidation belongs to a bulk (**II**)-type or surface-type reaction.[5,6]

Experimental

Catalysts and Reagents. 12-Molybdophosphoric acid ($H_3PMo_{12}O_{40}\cdot 27.4H_2O$, abbreviated as PMo_{12}) was commercially obtained. The Na and Cs salts ($M_xH_{3-x}PMo_{12}O_{40}$, M=Na, Cs, x=0—3.15) were prepared with Na_2CO_3 and Cs_2CO_3 by a method described previously.[6] The surface areas of catalysts were measured by the BET method based on N_2 adsorption after the same pretreatments as those for the reactions.

Methacrylaldehyde (MAL) from Aldrich Chem. Co., Inc. was distilled and stored at ca. 253 K. No impurity was detected in it by gas chromatography. Pyridine (Py) was used after removing water as impurity with Molecular Sieve 3A. $H_2{}^{18}O$ (^{18}O content; 98—99%, Japan Radioisotope Association) was used for the ^{18}O exchange reaction.

Reactions. ^{18}O exchange reactions were carried out at 473 K with a pulse reactor directly connected to a mass spectrometer (NEVA NAG 531) (Pulse-MS method, Figure 1). The path from the injection port at the top of the reactor up to the inlet of mass spectrometer, was heated at 423 K to suppress isotopic contamination by oxygen exchange with water adsorbed on the wall. The influence of the adsorbed water was minimized by pretreating the system properly as detailed in Results and Discussion. The ^{18}O content in each reactant was measured with the mass spectrometer directly connected to the outlet of the reactor. The weight of catalysts used was 100 mg. After exposing the catalysts to a He stream (30 $cm^3\ min^{-1}$) at 473 K for 1.5 h, water, MAL, or Py was injected at the top of the reactor at 473 K. No

methacrylic acid formation took place when MAL was injected at the outlet of the reactor.

The oxidation of MAL was carried out with a conventional flow reactor as described previously.[2] The conditions were as follows; temperature, 573 K; weight of catalyst, 0.5 g; flow rate, 32.5 $cm^3\ min^{-1}$; MAL, 2%; O_2, 12%; N_2, balance.

Results and Discussion

Direct Oxygen Isotopic Exchange between MAL and PMo_{12}. Table 1 summarizes the results of the ^{18}O exchange reaction among PMo_{12}, MAL, and water. Different run numbers denote separate experiments carried out with fresh catalysts. PMo_{12} and M_xPMo_{12}, to which 3 μl of $H_2{}^{18}O$ was injected 10—14 times, are denoted as ^{18}O-PMo_{12} and ^{18}O-M_xPMo_{12}, respectively. After $H_2{}^{18}O$ was injected 10—14 times, the ^{18}O content in water at the outlet of the reactor reached a constant value in a range of 90—100%. The amount of ^{18}O incorporated into the catalyst corresponded to approximately three quarters the amount of oxide ions in the whole polyanions. Therefore, the whole bulk was nearly equilibrated with $H_2{}^{18}O$; the ^{18}O content in the polyanions not only on the surface but also in the large portion of the bulk is close to 90—100%. The oxygen isotopic exchange between the polyanion and water has already been reported.[7,8]

The agreements of the ^{18}O contents in water and MAL between Runs No. 1 and 2 and among Runs No. 3—5 in Table 1 ensure a high reproducibility of the experiments. In Runs No. 2′ and 5′, the reactants were injected at the outlet of the reactor. The results were also highly reproducible. These experiments were carried out to estimate the oxygen exchange between the reactants injected and water adsorbed on the wall from the outlet of the reactor to the detector of the mass spectrometer. The ^{18}O contents in MAL in Runs No. 2′ and 5′ were less than 1%. The low ^{18}O content in MAL ($\leqslant$1%) indicates that the oxygen exchange of MAL proceeded to a small extent in the absence of the catalysts. Oxygen exchange between water and the wall proceeded to some extent.

The occurrence of direct isotopic exchange between MAL and PMo_{12} can be concluded from the results of Runs No. 1, 2, and 2′, as follows. The ^{18}O content in MAL (40—44%) was greater than that in water (35—37%) in Runs No. 1 and 2, which were carried out after the system was equilibrated with $H_2{}^{18}O$. This difference is meaningful, because the isotopic exchange with water adsorbed on the wall was much slower for MAL than for water (No. 2′). Hence ^{18}O was incorporated into MAL not only from water but also directly from PMo_{12}, because the ^{18}O content in MAL will never exceed that in water if a direct exchange is absent.

The following explanation based on Fig. 2, which illustrates the results of Runs No. 1, 2 (top), and 3—5 (bottom), would make clearer the occurrence of direct oxygen exchange between MAL and PMo_{12}. The ^{18}O content in MAL at the outlet in Runs No. 3—5 (23—

Table 1. Oxygen Isotopic Exchange among Methacrylaldehyde, Water, and $H_3PMo_{12}O_{40}$ at 473 K (Pulse-MS Method)

Run	Catalyst	Reactants injected	^{18}O content in water	^{18}O content in MAL
			%	
1	^{18}O-PMo_{12}[a]	$H_2{}^{16}O$(0.5)+MAL(3)[b]	37	44
2	^{18}O-PMo_{12}[a]	$H_2{}^{16}O$(0.5)+MAL(3)[b]	35	40
2′[c]	^{18}O-PMo_{12}[a]	$H_2{}^{16}O$(0.5)+MAL(3)[b]	8	<1
3	PMo_{12}	$H_2{}^{18}O$(3)+MAL(3)	34	26
4	PMo_{12}	$H_2{}^{18}O$(3)+MAL(3)	32	23

7	Py-^{18}O-PMo_{12}[a]	$H_2{}^{18}O$(3)+MAL(3)[b]	75	17
8	Py-^{18}O-PMo_{12}[a]	Py(2)+$H_2{}^{18}O$(3)+MAL(3)	79	3

a) Oxide ions of polyanion were fully exchanged (equilibrated) with ^{18}O of water prior to pulse. b) The value in parenthesis is the amount (μl) of reactant injected. c) Reactants were injected at the outlet of reactor.

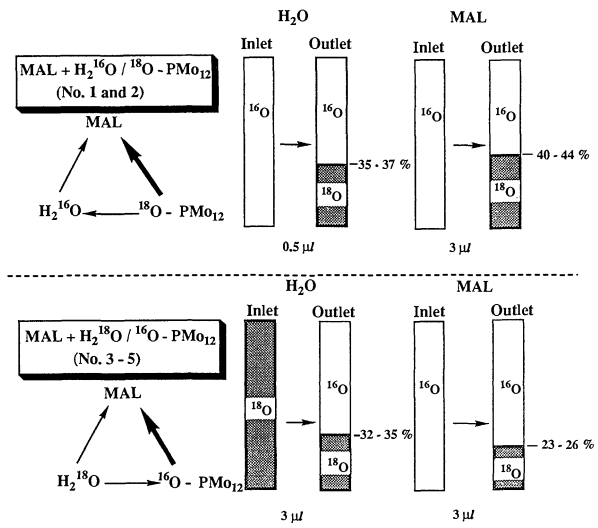

Fig. 2. Explanation of the presence of the direct ^{18}O exchange between methacrylaldehyde and $H_3PMo_{12}O_{40}$. Arrows indicate the flow of ^{18}O. Solid; indirect path, bold; direct path.

26%) was lower than those for Runs No. 1 and 2 (40, 44%), although the ^{18}O content in water which was in contact with MAL during the passage of the pulse through the catalyst bed was much greater for Runs No. 3—5 (100% at the inlet to ca. 35% at the outlet, bottom in Fig. 2) than for Runs No. 1 and 2 (0 to ca. 35%, top in Fig. 2). If the oxygen of MAL was exchanged with that of PMo_{12} only via water (absence of the direct path, bold arrows in Fig. 2), the ^{18}O content in MAL should be higher for Runs No. 3—5 than that for Runs No. 1 and 2. However, the experimental observations were definitely opposite. In addition, this would favor a conclusion that the amount of water injected in Runs No. 3—5 was larger than that in Runs No. 1 and 2. Therefore, these findings evidence the occurrence of "direct" oxygen exchange between MAL and the polyanion of PMo_{12}.

The occurrence of direct oxygen exchange demonstrates the formation of such intermediates as (**I**) and (**II**), which possess direct bonds between PMo_{12} and MAL (i.e., C–O–Mo bond), and supports the mechanism of Scheme 1.

Roles of Water Vapor and Acidity in Isotopic Exchange. The quantity of MAL pulsed in the present study was 3 μl (36 μmol). This corresponds to ca. three times and 2%, respectively, of those of surface and bulk oxide ions of PMo_{12} (12 μmol surface oxide ions and 1.7 mmol bulk oxide ions for 0.1 g of PMo_{12} ($3.8\ m^2\ g^{-1}$)). If the oxygen exchange between MAL (^{16}O) and ^{18}O–PMo_{12} proceeds only on the surface of PMo_{12}, the ^{18}O content in MAL at the isotopic equilibrium would never exceed 25%. Therefore, the ^{18}O content greater than 25% in the presence of $H_2{}^{16}O$ (in Runs No. 1 and 2) demonstrates that the oxide ion of the polyanion in the catalyst bulk was transferred to MAL. The acceleration of the ^{18}O incorporation into MAL by water (^{16}O) (No. 1 and 2) may be due to the promotion of oxide ion diffusion from the bulk in the form of water molecules or hydroxide ions, as was suggested previously.[2,5,6]

On the other hand, when MAL (^{16}O, 3 μl) was injected without water onto ^{18}O–M_xPMo_{12}, the ^{18}O content in MAL at the outlet was only 8—10%. Therefore, the exchange of oxygen between MAL and PMo_{12} in the absence of water probably proceeds on the surface alone. This is consistent with a view that aldehyde oxidation is a surface-type reaction.

The results from Runs No. 6—8 show the effects of Py poisoning on the oxygen isotopic exchange. ^{18}O–PMo_{12}, to which 2 μl of Py was injected 7 times, is denoted as Py–^{18}O–PMo_{12}. The amount of Py absorbed corresponded to 2.7 molecules·anion^{-1}. The extent of ^{18}O exchange of MAL decreased from 70% (No. 6) to 17% (No. 7) when Py was pre-absorbed. Further, the ^{18}O content in MAL dramatically decreased to 3% when Py was co-pulsed with MAL over Py–^{18}O–PMo_{12} (No. 8). The inhibition of ^{18}O exchange by Py suggests that the oxygen exchange between MAL and the polyanion directly (first step in Scheme 1) and/or indirectly via water is catalyzed by Brønsted acid sites as was previously suggested.[2] This is probably not due to a decrease in the absorptivity of water or MAL by the salt formation of PMo_{12} with Py.

The following observations are also in line with a view that the first step in Scheme 1 is catalyzed by a Brønsted acid. When MAL was injected to ^{18}O–M_x-PMo_{12} at the inlet of the reactor, the ^{18}O content in MAL divided by the surface area of catalyst decreased with x as seen in Fig. 3. Since the amount of water

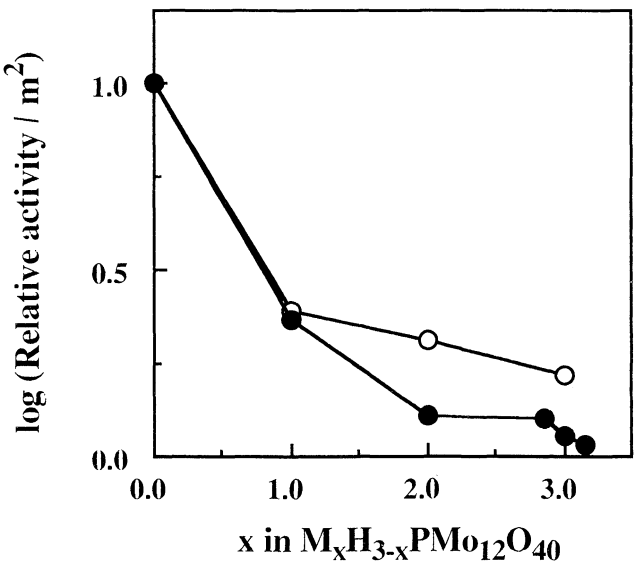

Fig. 3. Effect of alkali content on the ^{18}O exchange between methacrylaldehyde and $M_xH_{3-x}PMo_{12}O_{40}$. ●: $Cs_xH_{3-x}PMo_{12}O_{40}$. ○: $Na_xH_{3-x}PMo_{12}O_{40}$. The activity of $H_3PMo_{12}O_{40}$ was taken as unity.

evolved was only 0.04—0.05 μl, the ^{18}O exchange between water evolved and MAL could be ignored in this case and the ^{18}O content in MAL may be considered as a measure of the catalytic activity for direct oxygen exchange between MAL and the polyanion. A similar dependence of the amount of Brønsted acid sites on the Na or Cs content was observed.[3]

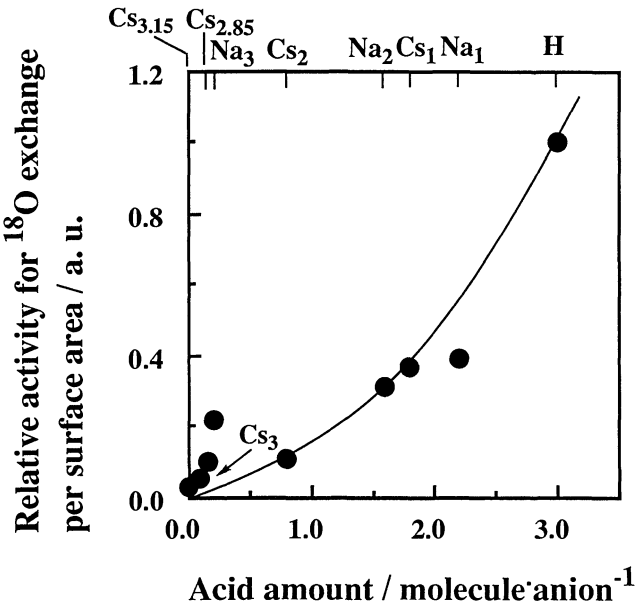

Fig. 4. Dependency of the catalytic activity for the ^{18}O exchange on the amount of Brønsted acid measured by the amount of pyridine absorbed or adsorbed. H and M_x denote $H_3PMo_{12}O_{40}$ and $M_xH_{3-x}PMo_{12}O_{40}$, respectively. The relative activity for the ^{18}O exchange per surface area of $H_3PMo_{12}O_{40}$ was taken as unity.

Figure 4 shows the correlation between the amount of Brønsted acid sites of 12-molybdophosphates measured by Py uptake (taken from Ref. 9) and their relative activity for oxygen exchange between MAL and the polyanion. The relative activity increased with an increase in the amount of Brønsted acid sites. This result would indicate that direct oxygen exchange between MAL and the polyanion, namely the first step in scheme 1 is catalyzed by a Brønsted acid.

Type of Catalysis and Factors Controlling the Rate. We previously reported that there are two different groups of reactions as classified by the dependency of the rate of non-catalytic reduction of 12-molybdophosphates on the specific surface area.[6,9] One is the oxidative dehydrogenation reaction, for which the rate per unit weight of catalyst does not depend on the specific surface area. H_2, isobutyric acid, and cyclohexene are typical reactants. In this case, rapid migration of protons and electrons leads to reduction of the whole solid.

The other is the oxygen-addition reaction, for which the rate is proportional to the surface area, presumably because the redox carrier is oxide ion with slow diffusion.

We also reported that the catalyst oxidizing ability as assayed with CO (a surface-type reductant) represents the oxidizing ability of catalyst surface, and is correlated with such surface-type catalysis as oxidations of acetaldehyde and CO.[5,6] Here, we will extend this

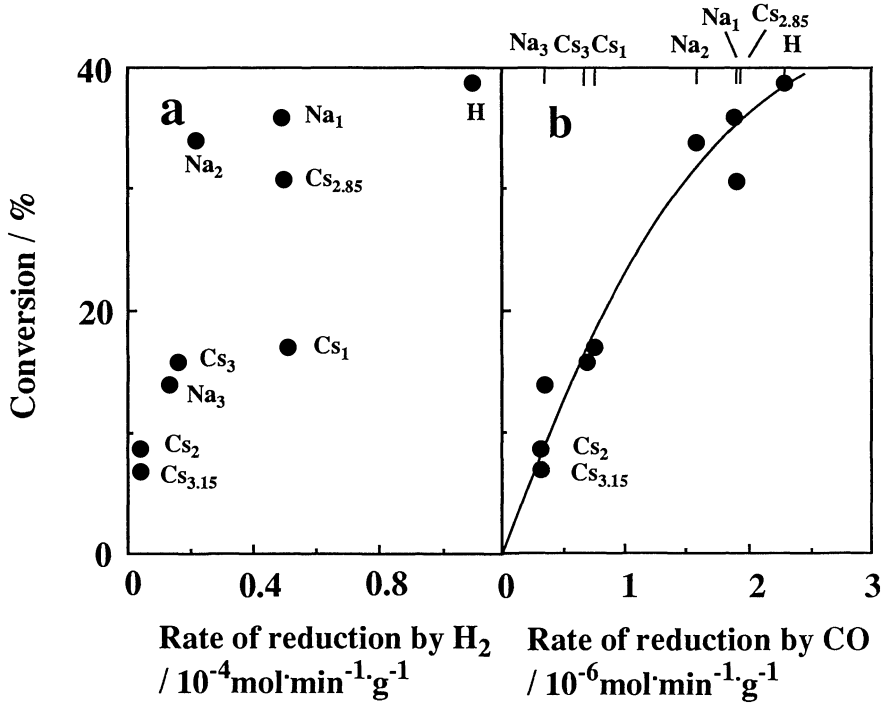

Fig. 5. Correlations between the conversion of methacrylaldehyde and the rate of reduction of catalyst by H_2 (a) or CO (b).

classification to the catalytic oxidation of MAL.

The main products of the oxidation of MAL over M_xPMo_{12} were methacrylic acid, acetic acid, CO, and CO_2. Since they all are oxygenated products, the reaction would belong to the surface-type.[5,10] The selectivities to methacrylic acid, acetic acid, and CO_x ($CO+CO_2$) are slightly different among the M_xPMo_{12} catalysts.

Figure 5 shows a correlation between the % conversion of MAL and the rates of non-catalytic reduction of catalysts by H_2 or CO. In Fig. 5, the results of oxidation reactions in the absence of water vapor are displayed, because the presence of water would make a surface-type reaction behave like a bulk-type reaction.[5] A good correlation exists between the catalytic activity (conversion of MAL) and the rate of catalyst reduction by CO (Fig. 5b), while the correlation is poor between the catalytic activity and the rate of catalyst reduction by H_2 (Fig. 5a).

These results are very similar to those observed for other surface-type reactions such as the oxidation of acetaldehyde and CO.[5,6] The good correlation noted in Fig. 5b not only confirms that the oxidation of MAL (in the absence of water vapor) is a surface-type reaction, but also indicates that the catalytic activity is controlled by the oxidizing ability of catalysts. The formation of methacrylate by oxidative dehydrogenation in scheme 1 is most probably the rate-determining step.

This study has been supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan.

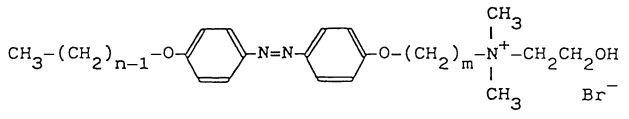
Molecular and Crystal Structure of Azobenzene-Containing Amphiphile, $C_6AzoC_{10}N^+Br^-$

Guiqing Xu, Kenji Okuyama,* and Masatsugu Shimomura
Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received May 1, 1990)

A totally synthetic azobenzene-containing amphiphile $C_{32}H_{52}N_3O_3Br$ ($C_6AzoC_{10}N^+Br^-$) was crystallized from its solution in trichloromethane and ethanol. The crystal is triclinic with space group $P\bar{1}$; Z=2; a=24.317(5), b=8.632(1), and c=8.043(2) Å; and α=91.41(2), β=80.62(2), and γ=99.01(1)°. The structure was solved by the direct method and refined by the full-matrix least-squares method: R=0.038 for 4305 observed reflections ($2\theta<120°$, Cu $K\alpha$, λ=1.5418 Å). Two molecules in a unit cell are related by a center of symmetry and pack tail-to-tail in a bilayer structure. The plane of the azobenzene chromophore is almost perpendicular to the layer surface and is overlapped with that of the azobenzene chromophore along its long axis with a separation of 3.55 Å. Different from other homologous compounds, this molecule bends almost 90° at the neck of the hydrophilic head group.

Totally synthetic azobenzene-containing amphiphiles with a single alkyl chain, $C_nAzoC_mN^+Br^-$, show several types of azobenzene chromophore aggregation states, depending on the number of carbon atoms in the tail part (n) and the spacer part (m).[1] The J-like aggregation between adjacent chromophores was found in single crystals, casted films, and aqueous dispersions of $C_nAzoC_5N^+Br^-$ (n=6, 8, 10, and 12). Their detailed crystal structures were determined by X-ray single crystal structure analyses and bore out the J-like aggregation of azobenzene chromophores at an atomic level.[2-4] Compared with $C_nAzoC_5N^+Br^-$, the title amphiphile, $C_6AzoC_{10}N^+Br^-$, shows several different properties, such as thermal properties, spectroscopic properties, and shapes of single crystals.



Scheme 1.

In this paper, we discuss the detailed molecular and crystal structure of this compound for understanding the relationship between its structure and physical properties.

Experimental and Structure Determination

4-(Hexyloxy)-4′-[ω-(dimethylethanolammonio)-decyloxy]-azobenzenebromide (abbreviated as $C_6AzoC_{10}N^+Br^-$) (30 mg) was dissolved in a solution (3 ml) of trichloromethane and ethanol (trichloromethane/ethanol=1/5 by volume). Yellow, plate-like crystals with dimensions of 0.5×0.2×0.1 mm³ were obtained by keeping the solution at room temperature for about a week. The density was measured by the flotation method in a solution of hexane and tetrachloromethane.

Lattice parameters and diffraction intensities were

measured on a Rigaku four circle diffractometer (RASA-5RII) with graphite monochromatized Cu $K\alpha$ radiation (λ=1.5418 Å). The lattice parameters were refined by the least-squares fit using 21 reflections ($40.0° \leqslant 2\theta \leqslant 60.0°$). By using the ω–2θ scan mode with a scan rate of 6° min^{-1}, intensities of 4725 reflections were measured up to 120° in 2θ. The scan width was $\Delta\omega=(1.3+0.14\tan\theta)°$. Three reflections monitored every 100 reflections showed no significant intensity deterioration. Corrections were made for the Lorentz and polarization factors, but not for absorption effect. A total of 4305 reflections with $|F_o|>3\sigma(F)$ was used for the calculation.

The structure was solved by the direct method using the program SAPI-85.[5] All the non-hydrogen atoms were found on the E-map. After several cycles of full-matrix least-squares refinements, positions of hydrogen atoms were obtained from the D-Fourier map. The final refinement with the anisotropic parameters for all non-hydrogen atoms and isotropic ones for 49 hydrogen atoms gave finally R=0.038 and R_W=0.037. The quantity minimized in the refinement was $\sum w(|F_o|-|F_c|)^2$ with $w=1/[\sigma^2(F_o)+(0.005\times F_o)^2]$. The final atomic parameters for non-hydrogen atoms are

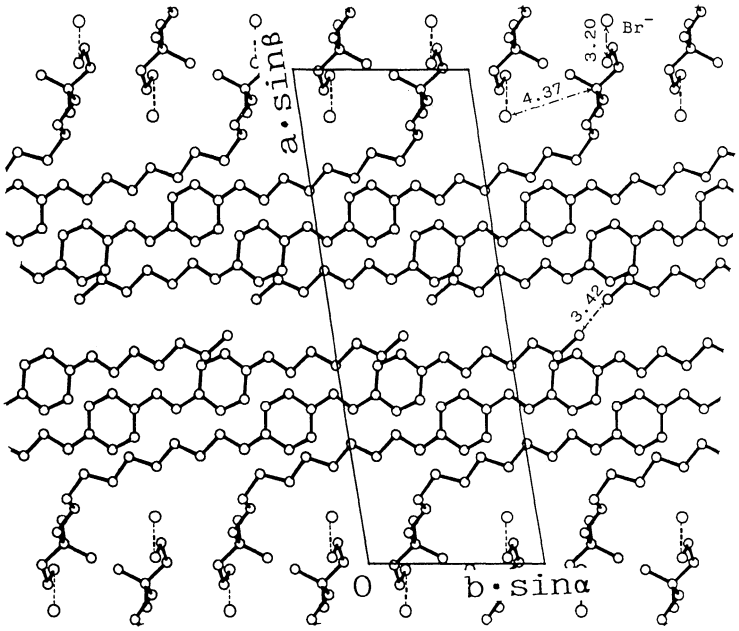

Fig. 2. Packing of $C_6AzoC_{10}N^+Br^-$ projected along the c axis. Hydrogen bonds between bromide anions and hydroxyl groups are indicated by broken lines. Some short interatomic distances (l/Å) are shown (ORTEP[11]).

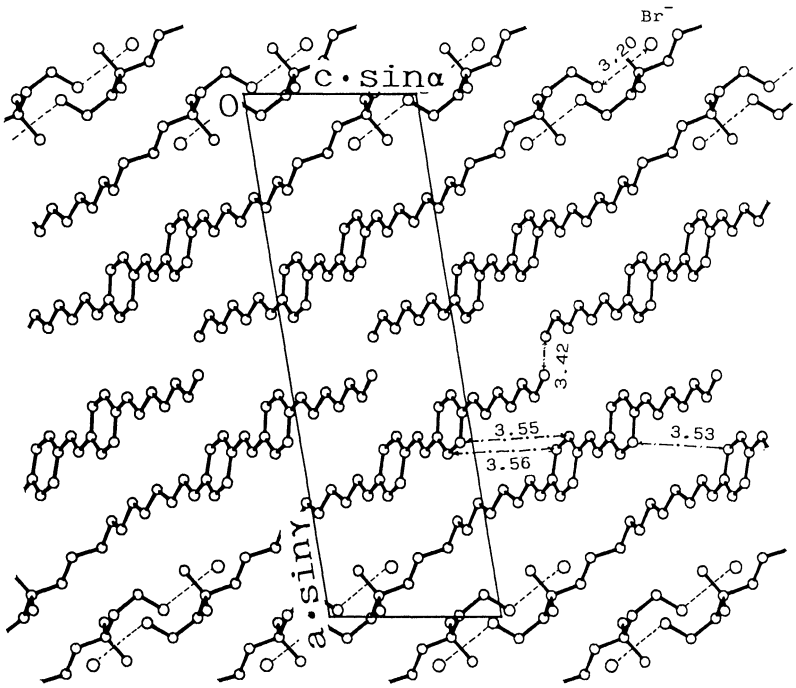

Fig. 3. Packing of $C_6AzoC_{10}N^+Br^-$ projected along the b axis (ORTEP[11]).

given in Table 1.[6]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[7] All calculations have been performed on an A-70 minicomputer with the aid of the CRYSTAN program in RASA5R-II system (Rigaku Denki).

Results and Discussion

Molecular Structure of $C_6AzoC_{10}N^+Br^-$. The molecular structure and the atom numbering scheme are given in Fig. 1. Bond distances and angles are shown in Table 2. The average C–C bond distance and C–C–C bond angle in the alkyl spacer and tail parts are 1.520(5) Å and 112.4(3)°, respectively. They are in good agreement with values previously found in other amphiphilic compounds with long hydrocarbon chains.[2–4,8,9]

The main difference in molecular conformation between $C_nAzoC_5N^+Br^-$ and $C_6AzoC_{10}N^+Br^-$ is the dihedral angle of C(6)–C(7)–C(8)–C(9). That is, in the former it is *trans*, while in the latter it is *gauche*, which makes the section (70 Å^2=bc sin α) of the hydrophilic part larger than that of $C_nAzoC_5N^+Br^-$ by about 20 Å^2.

Crystal Structure of $C_6AzoC_{10}N^+Br^-$. The packing arrangement viewd along the c- and b-axis are shown in Figs. 2 and 3, respectively. The crystal structure can be considered as an alternation of the hydrophobic and hydrophilic layers stacked along the a axis. In the hydrophobic layer, two molecules are related by the inversion symmetry in the tail-to-tail fashion with the shortest distance of 3.42(1) Å. The alkyl chains and azobenzene moieties are stabilized by the van der Waals interaction. In the hydrophilic layer, the bromide anion is linked to the hydroxyl group of the adjacent molecule by a hydrogen bond with a distance of 3.200(2) Å. Through the hydrogen bonds between the bromide anions and hydroxyl groups, the hydrophilic head groups of amphiphiles are interdigitate mutually in adjacent bilayers. In addition to the electrostatic interaction between the cationic ammonium nitrogens and bromide anions, this interdigitated orientation stabilizes the crystal.

In the case of $C_nAzoC_5N^+Br^-$ crystals, the ammonium cations and bromide anions have almost the same values of x fractional coordinates,[2–4] so they make the common plane parallel to the layer surface. In this crystal, however, the ammonium cation is separated from the bromide anion about 1.34 Å along the a-direction (Table 1).

The azobenzene chromophores in the $C_6AzoC_{10}N^+Br^-$ crystal show an absorption maximum (λ_{max}) at 365 nm. On the other hand, those in the typical J-aggregates, $C_nAzoC_5N^+Br^-$, show λ_{max} at 375 nm.[10] The difference in λ_{max} must be due to the difference of the chromophore orientations in the crystals. In the case of $C_6AzoC_{10}N^+Br^-$, the adjacent azobenzenes are overlapped with each other along their long axes with a separation of about 3.55 Å. On the other hand, in the case of $C_nAzoC_5N^+Br^-$, the adjacent azobenzenes are overlapped in a similar way, but the overlapped region is small and the interplanar spacing is large (about 3.62 Å).

† Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received June 2, 1990)

Mixed Ni(II) chelates with *N,N,N′,N″,N″*-pentamethyldiethylenetriamine (pmdt) and a β-diketonate (dike) such as acetylacetonate(acac), dipivaloylmethanate(dipm), pivaloyltrifluoroacetonate(pfac), trifluoroacetylacetonate(tfac) or hexafluoroacetylacetonate(hfac) were prepared, and their structure and properites were studied. X-Ray crystal analysis confirmed that [Ni(acac)(pmdt)]ClO_4 is a distorted square pyramidal complex, and the solid reflection spectra of the remaining chelates indicated that most of them are also essentially square pyramidal. This structure is retained in a nonpolar solvent like 1,2-dichloroethane, but in strong donor solvents like DMSO or DMF it is converted into a 6-coordinated structure, [Ni(dike)(pmdt)(Solvent)]$^+$, containing a solvent molecule. The formation of this species is favored by increasing donor number(DN) of the solvent, and in the following order of dike:dipm<acac≪tfac, pfac≪hfac, which is almost opposite to the order of their pK_a values.

In the foregoing papers of this series[2–4)], it was reported that the 4-coordinate Ni(II) chelates with *N,N,N′,N′*-tetramethylethylenediamine(tmen; $Me_2N(CH_2)_2NMe_2$) and a β-diketonate (dike), [Ni(dike)(tmen)]X (X=ClO_4^- or BPh_4^-) are soluble in various organic solvents, and are strongly solvatochromic, changing from red(square planar form) in 1,2-dichloroethane(DCE) to green (octahedral disolvated form) in dimethyl sulfoxide(DMSO) or *N,N*-dimethylformamide(DMF). The equilibrium between these two forms depends upon the donor properties of the solvent:

$$[Ni(acac)(tmen)]^+ + 2Solvent \rightleftharpoons [Ni(acac)(tmen)(Solvent)_2]^+$$

4-coordinate(red) 6-coordinate(green)

It shifts extremely to the left hand side in a weak donor solvent like DCE, and vice versa in a strong donor solvent like DMSO.

In order to compare with them, we have now prepared the corresponding mixed Ni(II) chelates with *N,N,N′,N″,N″*-pentamethyldiethylenetriamine(pmdt; $Me_2N(CH_2)_2NMe(CH_2)_2NMe_2$) and a dike, and studied their structure and solvatochromic changes. Pmdt is a bulky tridentate ligand which, like tmen, cannot form bis-type chelates with the metal ions of the first transition series, and has a marked tendency of forming 5-coordinate complex species with them. After the pioneering work of Ciampolini and Speroni,[5)] a large amount of works has been published on its complexes (cf., e.g., the series of Hendrickson et al.[6)] on its characteristic dimeric complexes with Cu(II)). As to its Ni(II) complexes, the species such as [NiX_2(pmdt)],[5)] [NiX(NH_3)(pmdt)]X·nH_2O(X$^-$=Cl^-, Br^- or I^-),[7)] and [Ni(NH_3)$_2$(pmdt)](ClO_4)$_2$[7)] have been studied; all of them are typically 5-coordinate, evidently owning to the bulkiness of pmdt which hinders the coordination of the 6th ligand.

As can be expected, most of the newly obtained mixed chelate were also found to be 5-coordinate, and they show a new kind of solvatochromism which will be discussed in this paper.

Experimental

Materials. The ligands used are pmdt, acetylacetone(Hacac), dipivaloylmethane(Hdipm), pivaloyltrifluoroacetone(Hpfac), trifluoroacetylacetone(Htfac) and hexafluoroacetylacetone(Hhfac). These and other reagents used are of the best commercial grade, and were used without further purification. Solvents used for spectral measurements are "Spectro-grade"; if necessary, they were purified by distillation.

Syntheses of the Chelates, [Ni(dike)(pmdt)]ClO_4. 10 mmol of Ni(ClO_4)$_2$·6H_2O were dissolved in 30 ml of methanol (MeOH), and 10 mmol of pmdt were added to it with stirring. Then a solution containing a diketone (Hdike) and KOH (10 mmol each) in 30 ml of MeOH was added to the mixture with heating and stirring. The resultant solution was filtered, and let stand for a few days. Crude green crystals which precipitated were recrystallized from DCE.

The analytical data, colors, and magnetic moments of the obtained chelates are shown in Table 1. The pfac and hfac chelates were found to be monohydrates; TG-DTA data show that they lose their water at about 70 °C in static air.

Measurements of Electronic Spectra. Electronic spectra of solutions were obtained with a Hitachi 340 recording spectrophotometer using 10 mm quartz cells at room temperature (ca. 20 °C). The electronic spectral data ($\tilde{\nu}_{max}$ and ε_{max}) in various organic solvents are deposited as Document No. 9099 (Table A) at the Office of the Editor of Bull. Chem. Soc. Jpn. Powder reflection spectra were recorded with the same instrument equipped with an

a) Calculated values are in parentheses. b) See text. c) Measured with dehydrated chelates. d) The reason for this smaller value is an open question.

integrating sphere, using $BaSO_4$ as the reference. The determination of the equilibrium constants(K) of the equilibrium(1) (see text) was made with a JASCO Ubest-30 spectrophotometer. A series of DCE solutions containing 10 mM (M=mol·dm^{-3}) of the 5-coordinate species and various amounts (between 0.2 M and 1.5 M) of DMSO was prepared with each chelate, and their spectra between 500 and 850 nm were measured at 25±0.5 °C, using the DCE solution (10 mM) of the same chelate with no DMSO as the reference. The values of K were then calculated from the obtained absorbances by means of the Benesi-Hildebrand plots.[8]

Other Physical Measurements. Infrared spectra (400—5000 cm^{-1}) were measured in Nujol mulls with a JASCO IR-A3 Grating Spectrophotometer. Magnetic susceptibility measurements were performed with a Shimadzu Torsion Magnetometer MB-100 at room temperature. Thermogravimetry-differential thermal analysis (TG-DTA) measurements were performed with a Differential Thermal Analyser TGD-3000M (Shinku-Riko) under static air with the heating rate of 3 °C min^{-1} or 1 °C min^{-1}.

Crystal Structure Analysis of [Ni(acac)(pmdt)]ClO_4. Green plate crystals were grown from a DCE solution. Crystals of approximate dimensions 0.3×0.3×0.4 mm^3 were used. The unit cell dimensions and space group were determined from oscillation and Weissenberg photographs. Accurate cell parameters were determined by a least-squares fit for 18 reflections within the range $18°<2\theta<28°$ measured on a Rigaku AFC-4 diffractometer with Mo $K\alpha$ radiation (λ= 0.71069 Å) monochromated by graphite.

Crystal Data: Mr=430.57, $NiC_{14}ClH_{30}N_3O_6$, monoclinic, $P2_1$, a=8.8285(8), b=13.467(1), c=8.590(1) Å, β=92.25(2), V=1020.5(2) Å^3, Z=2, d=1.401 g cm^{-3}, μ=10.49 cm^{-1}, $F(000)$= 456.

Reflection data were collected on a 2θ-ω scan mode, up to 2θ=55° with scan widths of $\Delta\omega=(1.0+0.35\tan\theta)$. Backgrounds were counted for 5 s at both ends of scan. Three standard reflections were recorded after every 50 reflections. This crystal was slowly decomposed probably due to deliquescence, of which intensity data decreased by 10%. The data were corrected using standard reflections. A total of 2447 reflections were collected at the rate of 8° (2θ) min^{-1}, of which 2203 were treated as significant ($|F_o|>3\sigma(|F_o|)$). The structure was solved by the direct method by using the program MALTAN78[9] and was refined by full matrix least-squares with SHELX76.[10] The quantity minimized was $\sum\omega(|F_o|-|F_c|)^2$, where $\omega=(\sigma(F_o)^2+0.004|F_o|^2)^{-1}$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[11] All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms found in the difference Fourier maps and derived geometrically were refined isotropically. Max. Δ/ρ and max. $\Delta\rho$ in the final difference map were 0.30 and 0.55 e Å^{-3} (within 1 Å from Nickel). Final R (and R_w) was 0.053 (0.059). The final coordinates of non-hydrogen atoms are given in Table 2. Computations were carried out on IBM 4381-R24 computer at the Computer Center of Ochanomizu University. The tables for the anisotropic temperature factors for non-hydrogen atoms (Table B), the F_o—F_c list (Table C), the atomic parameters for the H atoms (Table D) and remaining bond distances and angles (Table E) are deposited as Document No. 9099 at the Office of the Editor of Bull.

Chem. Soc. Jpn.

Results and Discussion

Structure of Crystalline Chelates. As can be seen from Table 1, we obtained five new chelates of two types, one formulated as $[Ni(dike)(pmdt)]ClO_4$ and the other as $[Ni(dike)(pmdt)(H_2O)]ClO_4$. They are all green high-spin d^8 chelates, with magnetic moments corresponding to two unpaired electrons.

The structure of $[Ni(acac)(pmdt)]ClO_4$ with the atomic numbering is presented in Fig. 1, and its selected bond lengths and angles are shown in Table 3. The atoms in the first coordination sphere form a distorted square pyramid, a typical 5-coordinate structure; the three N atoms of pmdt (N1, N2, N3) and one O atom of acac (O1) form a distorted square around Ni(II), which is capped by another O of acac (O2). The four atoms forming the distorted square are not exactly coplanar; two (N1, N3) are below and two (N2, O1) are above, each ca. 0.1 Å away from the mean plane. The central Ni(II), on the other hand, lies at 0.31 Å above it. It is also noted that an O(O6) of ClO_4^- is located at the opposite side of the cap, seemingly occupying the 6th coordination site. But the Ni-O6 distance is so long (4.33 Å) that no significant bonding is expected along it. The bond lengths between the nickel(II) ion and five donor atoms are nearly the same as those reported for another distorted square pyramidal nickel(II) complex $[Ni\{5\text{-Cl-SALen-N}(C_2H_5)_2\}_2]$,[12] and

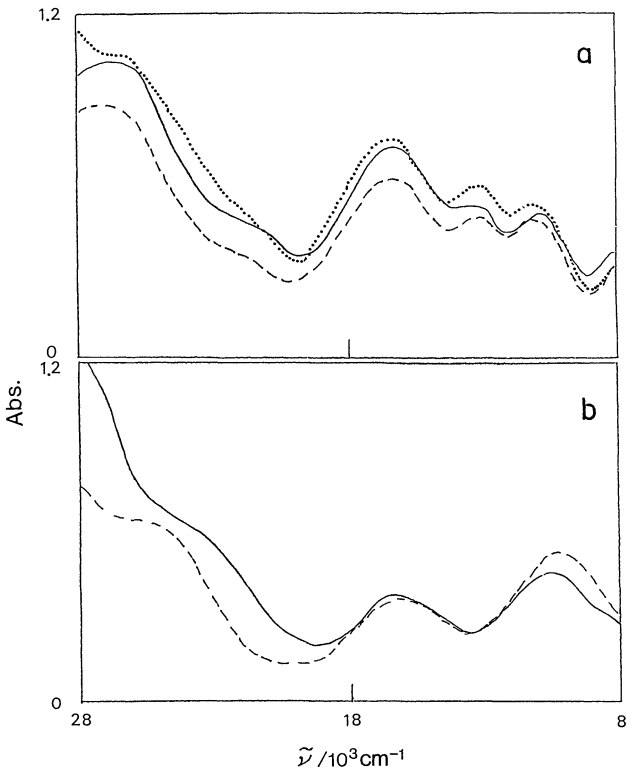

Fig. 2. Powder reflection spectra of the new 5-coordinate chelates [Ni(dike)(pmdt)]ClO_4 (a) and 6-coordinate hydrates [Ni(dike)(pmdt)(H_2O)]ClO_4 (b). The dike's in (a) are dipm (—), acac (----), and tfac (·····); those in (b) are hfac (—) and pfac (----).

for the related octahedral Ni(II) complexes.[13]

The solid reflection spectra of the dipm, acac, and tfac chelates are now very similar (cf. Fig. 2a), showing 4 bands at ca. 11×10^3 cm^{-1}, 13×10^3 cm^{-1}, 16×10^3 cm^{-1} and 27×10^3 cm^{-1}. This fact indicates that all these chelates are stereochemically similar, i.e., are 5-coordinated square pyramidal chelates; in fact the positions of these bands are not very different from those of the square pyramidal Ni(II) chelate mentioned above, the spectrum of which was explained with a crystal field model.[12,14] Although the angular overlap model shows that such a Ni(II) complex should be unstable in comparison with the 6-coordinate octahedral one,[15] the obtained complexes are apparently very stable, probably owing to the steric hindrance of the bulky groups on pmdt.

On the other hand, the hydrated pfac and hfac chelates show spectra of a different type, with only two bands at ca. 10×10^3 cm^{-1} and 16×10^3 cm^{-1}, which is characteristic to Ni(II) chelates of 6-coordinate structure (Fig. 2b). This indicates that these chelates should be formulated as [Ni(dike)(pmdt)(H_2O)]ClO_4 with an H_2O molecule at the 6th coordination site. When the hydrated pfac chelate is heated at 60 °C in vacuum, a remarkable spectral change takes place, until the spectrum becomes quite similar to those in Fig. 2a. The ν_{OH} band in its IR spectrum is lost at the same time. These changes show that the chelate become 5-coordinated by dehydration.

The reflection and IR spectra of the hydrated hfac chelate, however, were found to change only little by such a treatment, although TG-DTA data show that it is dehydrated nearly as easily as the hydrated pfac chelate. Here it seems that the dehydrated chelate absorbs atmospheric water so readily, that most of it reverts to the hydrated state in the course of spectral measurements. Thus the spectrum of the dehydrated hfac chelate in solid state has not yet been obtained.

Solvatochromism in Organic Solvents. When these chelates are dissolved in DCE, they form green solutions. The spectra of the solutions of the acac, dipm, tfac chelates show strong bands at ca. 16×10^3 cm^{-1} and 26×10^3 cm^{-1}, and weaker bands (or shoulders) at ca. 11×10^3 cm^{-1} and 13×10^3 cm^{-1}. The spectra thus resemble those of their solids (in the case of the pfac chelate, that of the dehydrated one), indicating that the 5-coordinate structure in the solid state is retained in DCE solution.

In the case of the dipm and acac chelates, similar spectra are observed also in a number of other solvents, i.e., nitromethane(NM), methanol(MeOH), ethanol(EtOH), acetone, and acetonitrile(MeCN). However, the solutions in DMF and DMSO show different spectra with two peaks at ca. 9×10^3 cm^{-1} and 16×10^3 cm^{-1}, which are similar to the solid spectra of hydrated chelates of pfac and hfac. This spectral change indicates that, in these solvents of very high DN (Gutmann's donor number),[16] a solvent molecule combines with the 5-coordinated chelate, and converts it into a 6-coordinate species, [Ni(dike)(pmdt)(Solvent)]$^+$.

A closer look at these spectral data, some of which are shown in Figs. 3a—3c, reveals further that, in the case of the acac chelate, the ε values of the two strong bands of the 5-coordinated species gradually decrease in the order of

$$DCE>NM>Acetone>EtOH>MeOH$$

with the increase of the DN of the solvent, indicating that the equilibrium

$$[Ni(dike)(pmdt)]^+ + Solvent \rightleftharpoons [Ni(dike)(pmdt)(Solvent)]^+ \quad (1)$$

established in these solutions is shifted to the right hand side with the increase of solvent DN. In the case of the dipm chelate, on the other hand, the ε values in these solvents are mostly not very different from each other, showing that the 5-coordinated species predominates in them. (A notable exception from these general tendencies is the case of MeCN; while its DN lies between those of NM and acetone, the ε values of the bands of the 5-coordinate species in it are lower than

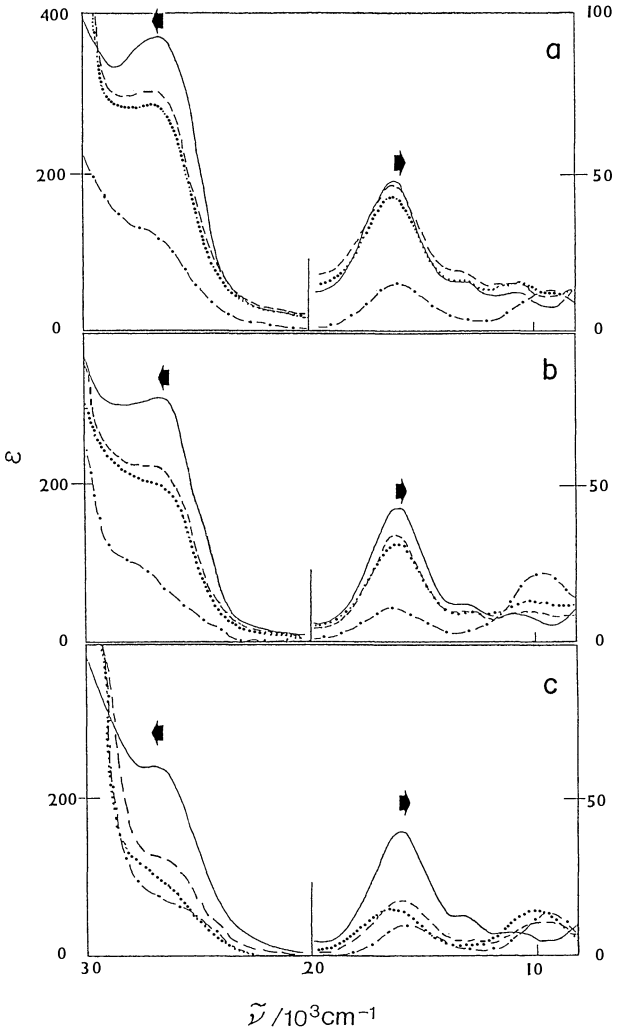

Fig. 3. Electronic spectra of [Ni(dipm)(pmdt)]ClO_4 (a), [Ni(acac)(pmdt)]ClO_4 (b), and [Ni(tfac)(pmdt)]-ClO_4 (c) in DCE (—), MeOH (----), MeCN (·····), and DMSO (-·-·-). Concn: ca. 1.0×10^{-3} M (M= mol dm^{-3}).

those in methanol, suggesting that the rod-like (and π-electron rich) molecule of MeCN can get into the sterically hindered 6th coordination site of Ni(II) more easily than alcohols and acetone, as was observed also in other cases[17]).

In the case of the tfac chelate, the ε values of the bands of the 5-coordinate species in acetone (e.g., 31 at 16.13×10^3 cm^{-1}) are notably lower than those in DCE(40) and NM(37), and the spectra in alcohols and MeCN are nearly those of the 6-coordinate species. Similar trends are observed also with the pfac chelate; here the coordinated H_2O molecule in the solid hydrate readily dissociates from Ni in an organic solvent, so that the spectra of the hydrated and dehydrated chelates in it are nearly the same. In the case of the hydrated hfac chelate, the spectra show that the 6-coordinate species exist predominantly in all solvents, even in DCE; comparison of their $\tilde{\nu}_{max}$ values

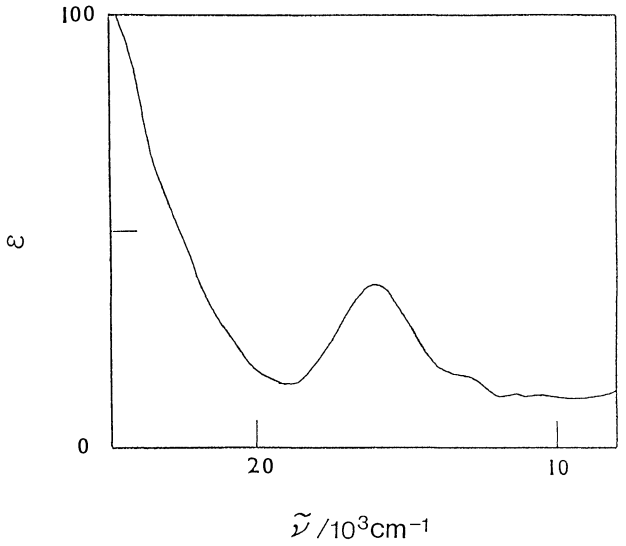

Fig. 4. Electronic spectrum of a DCE solution containing [Ni(hfac)(pmdt)]ClO_4 (see text). Concn: ca. 1.0×10^{-3} M.

(e.g., 10.4 and 16.1 in DCE, 9.8 and 16.0 in Me_2CO and 9.4 and 15.7 in DMSO, in 10^3 cm^{-1}) with those of the solid (10.5 and 16.3) shows that the 6th ligand is water in solvents of low DN, but it is substituted by a solvent molecule in more polar solvents.

Comparison of all these spectra thus leads to the conclusion that the equilibrium (1) is shifted to the right hand side with the increase of solvent DN (except MeCN; see above), and in the following order of the dike ligands:

$$\text{dipm} < \text{acac} \ll \text{tfac},\ \text{pfac} \ll \text{hfac} \qquad (2)$$

That is to say, the hfac chelate tends to be 6-coordinate in all solvents, combining with water when the coordination ability of the solvent is too low. The tfac and pfac chelates are 5-coordinate in DCE, but are converted to the 6-coordinate species even in solvents of relatively low DN. On the other hand, the dipm chelate is 5-coordinate (or mainly so) in most solvents tried, and gets 6-coordinate only in solvents of very high DN, and the acac chelate comes between these extremes.

A quantitative support to this view was obtained by the determination of K of the equilibrium(1) for each chelate, using DMSO as the coordinating solvent and studying the equilibrium in DCE. In the case of the hfac chelate, special care was taken to remove water from the system; using freshly dehydrated materials, a DCE solution which shows a typical spectrum of a 5-coordinate species (i.e., which contains the 5-coordinate chelate $[Ni(hfac)(pmdt)]^+$; cf. Fig. 4) was obtained and used for study. The obtained K values (Table 1) increase in the order of (2), or with the decrease of the pK_a of the dike ligand (cf. Fig. 5);[18–20] since the latter values can be taken as the measures of the ligand field strengths of the dike ligands, these

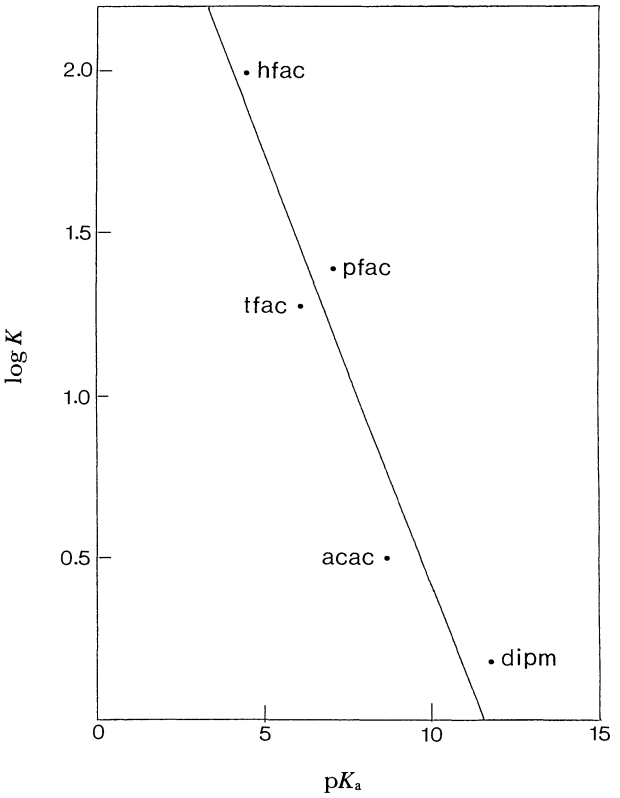

Fig. 5. Relation between pK_a of dike[19,20] and $\log K$ for the formation of [Ni(dike)(pmdt)(DMSO)]ClO_4 in DCE.

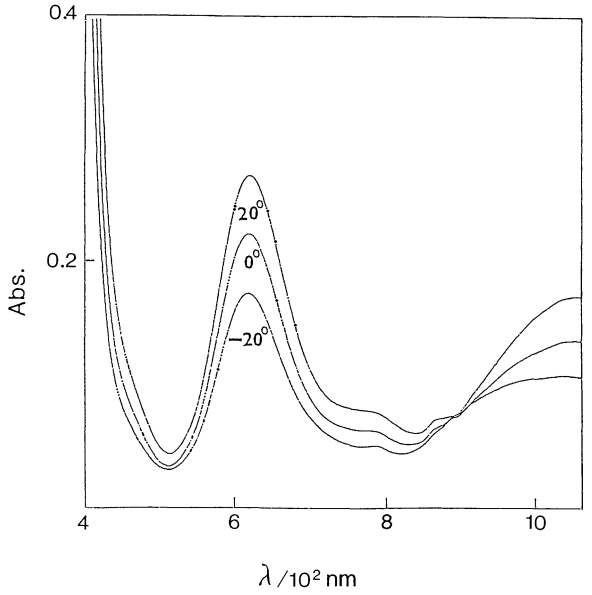

Fig. 6. Temperature dependence of the spectrum of [Ni(acac)(pmdt)]ClO_4 in a DCE–DMSO solution. Concn of the chelate: 9.88×10^{-3} M; concn of DMSO: 2.26×10^{-1} M.

results lead to the reasonable conclusion that the tendency of a $[Ni(dike)(pmdt)]^+$ type chelate to combine with solvent (i.e., its Lewis acidity) increases with the decrease of the ligand field strength (i.e., Lewis basicity) of dike.

It was also found that the DCE solutions of the dipm, acac, tfac, and pfac chelates containing DMSO are thermochromic; the data of the acac chelate are in Fig. 6. The band at 16×10^3 cm^{-1} becomes stronger and that at 10×10^3 cm^{-1} weaker, with the rise of temperature, forming an isosbestic point, and showing that the equilibrium(1) is shifted to the left hand side by heating. Similar but smaller spectral changes were also obtained with the dipm, tfac, and pfac chelates; in these cases, the equilibrium (1) is shifted more strongly to the left (dipm) or right (tfac, pfac) hand side than acac, so that the systems seem to be more insensitive to the temperature change.

We are grateful to Ms. Yuko Kojima (Ochanomizu Univ.) and Ms. Akiko Sekine (Tokyo Institute of Technology) for their technical assistance in the crystal structure analysis. This work was partially supported by a Grant-in-Aid for Scientific Research No. 02453038 from the Ministry of Education, Science and Culture.

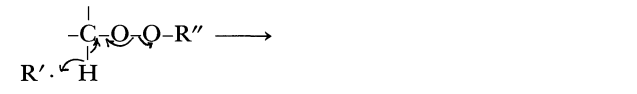
Substituent Effects in the Decomposition of *t*-Alkyl *t*-Butyl Peroxides

Kazuo MATSUYAMA* and Yoshiki HIGUCHI
Chemicals & Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd.,
Taketoyo-cho, Chita-gun, Aichi 470-23
(Received August 2, 1990)

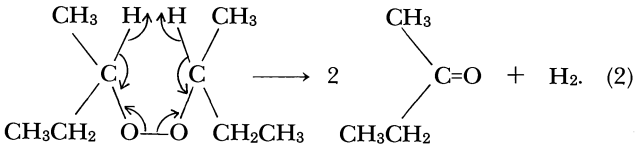
The decomposition rates and products of various *t*-alkyl *t*-butyl peroxides were examined in cumene at several temperatures. The decomposition of these peroxides took place homolytically, depending on the structure of the *t*-alkoxyl moieties ($RC(CH_3)_2$–O), and was retarded in the order: $R=(CH_3)_3CCH_2>(CH_3)_2CH>CH_3CH_2CH_2>PhCH_2>CH_3CH_2>ClCH_2>CH_3$. The rate constants for the electron-donating alkyl substitutents at 150 °C are correlated very well to a Taft equation ($\log k_d=-10.93\,\Sigma\sigma^*-6.61$ (correlation coefficient of 0.9501)), which is fairly different from the equation $\log k_d=-0.131\,\Sigma\sigma^*-3.422$ for electorn-withdrawing polar substituents. From this correlation and a product analysis, the nature of the polar character at the transition state of the decomposition is discussed.

Dialkyl peroxides have received considerable attention as clean sources of alkoxyl radicals and important intermediates in the oxidation or combustion of hydrocarbons. So far, many studies concerning the decomposition of dialkyl peroxides have been carried out.[1] The decomposition of di-*t*-butyl peroxide, which is probably one of the best-studied reaction in chemical kinetics, is accompanied by a slight radical-induced decomposition in most cases. However, the substituent effect correlation on the decomposition of dialkyl peroxides has not yet been made sufficiently clear, though it is believed that the decomposition rates are accelerated by electron-donating alkyl substituents.

Richardson et al. found a linear free-energy correlation concerning the decomposition of di-*t*-alkyl peroxides (*t*-alkyl denotes 1,1-dimethylalkyl through this paper) having electron-withdrawing polar substituents, where there was a very small change in the rates (ca. 1.5 times with 1.0 σ^* unit variation of the substituents studied).[2] On the other hand, the substituent effect correlation regarding the decomposition of dialkyl peroxides having electron-donating alkyl substituents was unsuccessful, because they contained primary and secondary dialkyl peroxides. Probably, the decomposition rates of bis(primary and secondary alkyl) peroxides were somewhat enhanced by an induced decomposition (Eq. 1) and a concerted decomposition (Eq. 2):[1b]

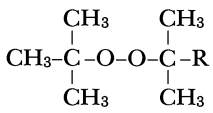


$$R'H + \rangle C{=}O + \cdot OR'' \qquad (1)$$



(2)

Di-*t*-alkyl peroxides, having a smaller possibility for induced decomposition, are most suitable for studying the substituent effect on O–O bond homolysis. In this work we studied the decomposition rates and products in the homolytic decomposition of *t*-alkyl *t*-butyl peroxides (**1**) in cumene in order to clearify the substituent effect. Cumene is a good solvent for investigating the homolytic reaction due to the formation of simple decomposition products:



(**1**$_a$; R=CH_3, **1**$_b$; R=CH_3CH_2, **1**$_c$; R=$CH_3CH_2CH_2$, **1**$_d$; R=$(CH_3)_3CCH_2$, **1**$_e$; R=$(CH_3)_2CH$, **1**$_f$; R=$PhCH_2$, **1**$_g$; R=$ClCH_2$)

Results

The di-*t*-alkyl peroxides **1** were prepared mainly by the reaction of *t*-butyl hydroperoxide with the corresponding alcohols or olefins in the presence of sulfuric acid. The rates and products for the decomposition of **1** in cumene were determined with gas–liquid chromatography (GC) using alkanes as internal standards. Good first-order rate constants were obtained over 10—80% conversion in all cases. Decomposition rates and products data are given in Tables 1 and 2, respectively, together with calculated activation parameters. The rate constants had no appreciable change for a 10-fold increase in the concentration, thus seeming rule out any induced decomposition.

An isokinetic relationship was obtained for the decomposition of **1** in cumene (Fig. 1). Here, the steric interaction in the ground state was not important, since the values of the activation entropy decreased with those of the activation enthalpy.

Table 1 also includes a sum of the substituent constant for each peroxide. Where substituent constants were not reported, they were calculated by

the known method.[2] With the exception of $\mathbf{1}_f$ and $\mathbf{1}_g$, the data in Table 1 satisfy the Taft equation as follows:

$$\log k_d = \rho^*\Sigma\sigma^* + c \quad (3)$$

Here, k_d is the rate constant for the decomposition of **1**, $\Sigma\sigma^*$ is the sum of the substituent constants by Taft, ρ^* is a reaction constant and c is an intercept, respectively. The calculated ρ^* values are shown in Table 3, together with the intercepts and correlation coefficients.

The yields of acetone and alcohols formed from **1**, and 2,3-dimethyl-2, 3-diphenylbutane (**2**) from cumene are given in Table 2, respectively. The alcohols corresponding to the *t*-alkoxyl moieties were not detected for $\mathbf{1}_e$ and $\mathbf{1}_f$. The yields of **2** were over ca. 90 %, with the exception of $\mathbf{1}_f$. The decomposition of $\mathbf{1}_f$ gave, in addition to **2** (53%), 2-methyl-2-propanol (73%), acetone (111%), toluene (45%), 1,2-diphenylethane (5%), and 1,2-diphenyl-2-methylpropane (23%). The products from the benzyl segment of $\mathbf{1}_f$ were detected in 78% yield. All of these products were formed by radical reactions. These facts suggest that **1** decomposes homolytically to follow a radical reaction outside of the solvent cage. The yield of the β-scission product, acetone from the *t*-butoxyl moiety for each peroxide of $\mathbf{1}_b$—$\mathbf{1}_f$, is equal to half that for $\mathbf{1}_a$. The acetone is obtained indpendently from the *t*-alkoxyl ($RC(CH_3)_2$-O) and *t*-butoxyl ($C(CH_3)_3$-O) moieties in each peroxide, respectively. Accordingly, the yield of the acetone from a *t*-alkoxyl moiety can be estimated by subtracting 0.39/2 (cf. $\mathbf{1}_a$) from the total acetone obtained by the decomposition of each peroxide. The ratio of the yield of the acetone against that of the corresponding alcohol formed from the *t*-alkoxyl moiety is shown in Table 2.[2]

Discussion

The effects of electron-withdrawing polar substituents on the decomposition were reported to be small. For example, Richardson et al. found the following Taft equation:

$$\log k_d = -0.131\Sigma\sigma^* - 3.422 \quad (4)$$

This equation is for the decomposition of the di-*t*-alkyl peroxides with polar substituents in chlorobenzene at 150 °C.[2] Similarly, kinetic data regarding the decomposition of bis(trifluoromethyl) peroxide in the gas phase were within the experiment error of those measured for $\mathbf{1}_a$, and the expected inductive effect of the electronegatively substituted fluorine atoms ($\Sigma\sigma^* > +2.65$) was not found.[3]

However, the electron-donating alkyl substituents considerably accelerated the decomposition of **1** in this work. Table 4 shows the relative rates (k_d/k_{d0}) of **1** against $\mathbf{1}_a$ at 150 °C, together with the data of Richardson et al. A plot of $\log(k_d/k_{d0})$ vs. $\Sigma\sigma^*$ consists of two straight lines intersecting each other at the point of $\mathbf{1}_a$ (Fig. 2). One is for the electron-donating alkyl substituents with a large slop of $\rho^* = -10.99$; the other is for the electron-withdrawing polar substituents with a small slope of $\rho^* = -0.131$. The considerable rate acceleration by the electron-donating alkyl substituents suggests that the polar character of an activation complex seems to stabilize the transition state much more. Huyser and Van Scoy investigated the effects of solvents on the unimolecular decomposition of $\mathbf{1}_a$, and indicated the dipolar character in the C–O bond of the *t*-butoxyl moiety at the transition state.[4] Similarly, the polar character of the *t*-alkoxyl moiety at the transition state was pointed out in the decomposition of *t*-alkyl 2,2-dimethylperoxypropionates,[5] which showed a similar substituent effect as that of **1**, though not sufficiently correlated with $\Sigma\sigma^*$ (correlation coefficient of 0.3890 in Table 4).

The O–O bond may be polarized when stretched at the transition state of the decomposition. That is to say, the activation complexes of **3** and **4** are stabilized by the electron-donating alkyl and electron-with-

drawing polar substituents, respectively. The substituent effects of **3** and **4** are expepcted to be $\rho^*<0$ and $\rho^*>0$, respectively, but the absolute value of ρ^* in the former seems to be much larger than that in the later, by considering the difficulty that the *t*-butoxyl group is hardly able to stabilize the positive charge in **4**. On the other hand, the substituent effect in the ground state is expected to be $\rho^*<0$ on account of the stabilization by electron-withdrawing polar substituent.[2,6] Consequently, the experimental results in Fig. 2 can be understood in terms of the fact that

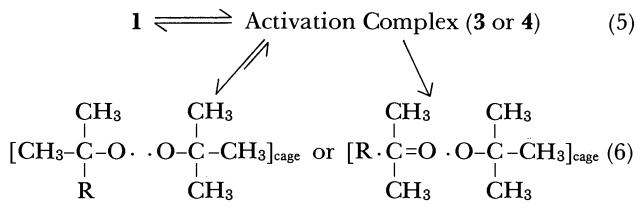
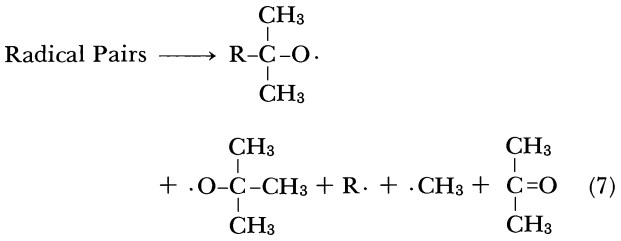
negatively large ρ^* value is due to an overlap of the substituent effects at the transition and ground states in the same direction, and that the negatively small ρ^* value is a compensation of those in the opposite direction.

The substituent effect on β-scission products from the *t*-alkoxyl moiety in the decomposition of **1** is shown in Table 5 as the relative rates of **1** against $\mathbf{1_b}$ on the formation ratios of acetone against the corresponding alcohols and compared with those of *t*-alkyl 2,2-dimethylperoxypropinates[5] and *t*-alkyl hypochlorites.[7] The β-scission from **1** in this work was a non-chain decomposition, and reactions between radical pairs within a solvent cage were very few, as shown by high yields of **2**. The relative rate of **1** against $\mathbf{1_b}$ on acetone formation decreased in the following order: $R=(CH_3)_2CH\approx PhCH_2\gg CH_3CH_2>CH_3CH_2CH_2>ClCH_2\approx CH_3$. These results seem to approximately correspond to those of the peroxy esters, through the both are a little different because acetone formation in the later was suppressed by disproportionation between the *t*-butyl and the *t*-alkoxyl radicals within a solvent cage. The difference from the hypochlorites (particularly, R=$PhCH_2$ and $(CH_3)_3CCH_2$) suggests that the acetone from **1** may be formed by β-scission within a solvent cage or directly from the activation complex at the transition state.

Based on these facts, it is speculated that the C_α–C_β bond neighbouring the peroxyl oxygen atom in the di-*t*-alkyl peroxides may be slightly stretched, together with the homolytic scission of the O–O bond at the transition state.[8] Consequently, the decomposition of **1** proceeds mainly as follows:

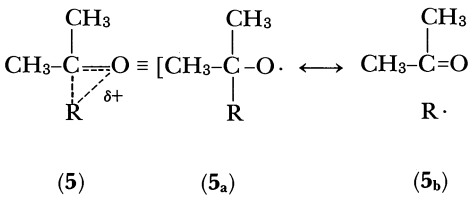


(Radical Pairs)



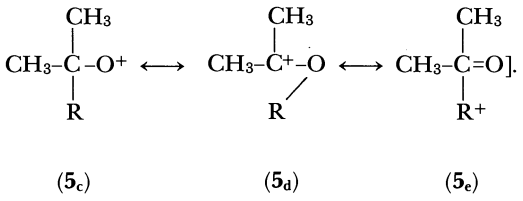
The β-scission of *t*-alkoxyl radicals out of a solvent cage competes with hydrogen abstraction from cumene. The various radicals produced in these ways easily abstract the hydrogen of cumene to form the 1-methyl-1-phenylethyl radical which couples mainly with each other to give **2**.

A positively charged partner, **5**, of the activation complex, **3**, may be written as a resonance hybrid of the following limiting formulas:



(**5**) (**5**$_a$) (**5**$_b$)

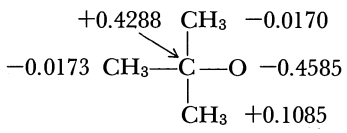
and



(**5**$_c$) (**5**$_d$) (**5**$_e$)

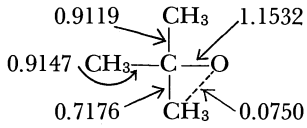
It can well explain the substituent effects on the decomposition rates and products of **1**. These structures are supported by data regarding the *t*-butoxyl radical optimalized energetically by the MINDO/3-RHF method using the MOPAC program to give both atomic charges and bond orders as follows:

Atomic charge:



and

Bond order:



The deviation from the Taft equation and the formation of an additional β-scission product for $\mathbf{1_f}$ may be understood in terms of stabilization by a resonance effect of the $PhCH_2$ radical ($\mathbf{5_b}$).

Experimental

IR, NMR and UV spectra were recorded on JASCO A-3, JEOL JNM-MH-100 and Shimadzu UV-200S spectrometers, respectively. GC-MS spectra were recorded on a JEOL JMS-D 300 mass spectrometer. GC analysis was carried out using Shimadzu GC-2D gas chromatography with columns: SE-30 (5%) and PEG-20M (25%) on Shimalite W (QW-DMCS). A LC analysis was carried out using a JASCO TRIROTAR-V with a column: JASCO Finepak SIL C_{18} and an eluent ($MeOH:H_2O=9:1$). A TLC analysis was carried out using columns with a Merck Kieselgel 60 F_{254} and a Kieselgel 60. The products were purified by flash chromatography on a Merck Kieselgel (40 and 60). The purities of the dialkyl peroxides were determined by GC.

Materials. *t*-Butyl, 1,1-dimethylbutyl, and 1,1,3,3-tetramethylbutyl hydroperoxides were the products of Nippon Oil & Fats Co., Ltd. 2-Methyl-2-butanol, 2-methyl-1-pentene, 2-methyl-2-pentanol, 2-methyl-1-phenyl-2-propanol, and 2-methyl-2-propanol were the products of Wako Pure Chemical Ind., Co. Cumene was stirred for several hours with concentrated sulfuric acid, washed with 10% NaOH aqueous solution and distilled H_2O, dried with drying agents and distilled through a 24-in Vigreaux column.

Preparation of Di-*t*-Alkyl Peroxides. Di-*t*-butyl peroxide ($\mathbf{1_a}$) was purified to 99.2% by distillation (62—63 °C/58 mmHg, 1 mmHg=133.322 Pa) of a commercial product of Nippon Oil & Fats Co., Ltd.

***t*-Butyl *t*-Pentyl Peroxide ($\mathbf{1_b}$).** To an aquous solution of 80% H_2SO_4 (59.0 g, 0.48 mol) there was added dropwise 2-methyl-2-butanol (35.5 g, 0.40 mol) below 10 °C. Then, the solution was kept at 0 °C for 15 min, added dropwise for 5 min by 70% *t*-butyl hydroperoxide (53.0 g, 0.41 mol), and stirred for 2 h at 20 °C to complete the reaction. The oil layer was separated from the reaction mixture, washed with 10% NaOH and H_2O, dried with anhydrous $MgSO_4$ and distilled at reduced pressure (62—63 °C/58 mmHg) to give $\mathbf{1_b}$ of 53.7 g (purity 95.5%, yield 80.0%). IR ν_{O-O} 880 cm^{-1}; ^1H NMR δ=0.99 [3H, t, $-CH_2CH_3$], 1.44 [6H, s, $-OO-C(CH_3)_2-CH_2-$], 1.21 [9H, s, $-OO-C(CH_3)_2$], and 1.53 [2H, q, $-CH_2-CH_3$]; MS (m/z) 160 [M^+].

***t*-Butyl 1,1-Dimethylbutyl Peroxide ($\mathbf{1_c}$).** To an aquous solution of 65% H_2SO_4 (90.6 g, 0.60 mol) there was added dropwise 2-methyl-1-penten (42.1 g, 0.50 mol) below 10 °C. Then, the solution was kept for 10 min at 0 °C, added dropwise for 5 min by 70% *t*-butyl hydroperoxide (64.4 g, 0.50 mol), and stirred for 2 hr at 20 °C to complete the reaction. The oil layer was separated from the reaction mixture, washed with 10% NaOH and H_2O, dried with anhydrous $MgSO_4$ and distilled at reduced pressure (75—76 °C/57 mmHg) to give $\mathbf{1_c}$ of 69.5 g (purity 96.9%, yield 77.3%). IR ν_{O-O} 880 cm^{-1}; ^1H NMR δ=0.98 [3H, t, $-CH_2-CH_3$], 1.16 [6H, s, $-OO-C(CH_3)_2-CH_2-$], 1.20 [9H, m, $-OO-C(CH_3)_3$], and 1.3—1.5 [4H, m, $-(CH_2)_2-CH_3$]; MS(m/z) 174 [M^+].

***t*-Butyl 1,1,3,3-Tetramethylbutyl Peroxide ($\mathbf{1_d}$).** To an aqueous solution of 80% H_2SO_4 (14.8 g, 0.12 mol) there was added dropwise 2-methyl-2-propanol (22.2 g, 0.30 mol) below 10 °C. Then, the solution was kept at 0 °C for 20 min, added dropwise for 10 min by 1,1,3,3-tetramethylbutyl hydroperoxide (15.0 g, 0.10 mol), stirred for 2 h at 25 °C to complete the reaction. The oil layer was separated from the reaction mixture, added with hexane and H_2O, washed with 10% NaOH and H_2O, dried with anhydrous $MgSO_4$, and distilled at reduced pressure (57—58 °C/6 mmHg) to give $\mathbf{1_d}$ of 17.8 g (purity 95.7%, yield 60.5%). IR ν_{O-O} 880 cm^{-1}; ^1H NMR δ=1.02 [9H, s, $-CH_2-C(CH_3)_3$], 1.22 [6H, s, $-OO-C(CH_3)_3$], 1.28 [6H, s, $-OO-C(CH_3)_2-CH_2-$] and 1.54 [2H, s, $-CH_2-$]; MS (m/z) 202 [M^+].

***t*-Butyl 1,1,2-Trimethylpropyl Peroxide ($\mathbf{1_e}$).** To an aqueous solution of 80% H_2SO_4 (33.7 g, 0.275 mol) there was added dropwise 2,3-dimethyl-2-butanol (25.5 g, 0.25 mol) below 10 °C. Then, the solution was kept at 0 °C for 10 min, added dropwise for 15 min by 70% *t*-butyl hydroperoxide (36.3 g, 0.25 mol), and stirred for 2 h at 20 °C to complete the reaction. The oil layer was separated from the reaction mixture, washed with 10% NaOH and H_2O, dried with anhydrous $MgSO_4$ and distilled at reduced pressure (73—75 °C/47 mmHg) to give $\mathbf{1_e}$ of 10.6 g (purity 95.6%, yield 23.2%). IR ν_{O-O} 865 cm^{-1}; ^1H NMR δ=0.89 ppm [6H, d, $-CH(CH_3)_3$], 1.12 [6H, s, $-OO-C(CH_3)_2-$], 1.21 [9H, s, $-OO-C(CH_3)_3$], and 1.91 [1H, m, $-CH(CH_3)_2$]; MS (m/z) 174 [M^+].

***t*-Butyl 1,1-Dimethyl-2-phenylethyl Peroxide ($\mathbf{1_f}$).** To an aqueous solution of 80% H_2SO_4 (4.54 g, 37 mmol) there was added dropwise 2-methyl-2-propanol (7.41 g, 100 mmol) below 10 °C. Then, the solution was kept at 0 °C for 20 min, added dropwise for 5 min by a solution of diethyl ether (3 cm^3) and 1,1-dimethyl-2-phenylethyl hydroperoxide (4.73 g, 28.5 mmol) which was prepared by reaction of the corresponding alcohol with 50% H_2O_2 in the presence of 72% H_2SO_4 at 40 °C in THF,[5] and stirred for 2 h at 20 °C to complete the reaction. The oil layer was separated from the reaction mixture, washed with 10% NaOH and H_2O, and dried with anhydrous $MgSO_4$. The crude product (5.2 g) after evaporation of solvent was purified by flash chromatography to give $\mathbf{1_f}$ of 3.68 g (purity 99.5%, yield 57.8%). IR ν_{O-O} 880 cm^{-1}; ^1H NMR δ=1.15 [6H, s, $-C(CH_3)_2-CH_2-$], 1.22 [9H, s, $-OO-C(CH_3)_3$], 1.28 [6H, s, $-CH_2-Ph$] and 1.54 [2H, s, $-Ph$]; MS (m/z) 222 [M^+].

***t*-Butyl 2-Chloro-1,1-dimethylethyl Peroxide ($\mathbf{1_g}$)** was prepared by the method of Richardson et al.[2] and purified to

95.2% by distillation (54—55 °C/20 mmHg) of the crude reaction product.

Kinetic Procedure. A dilute solution of dialkyl peroxide in cumene was placed in sealed tubes (content of 7.5 cm^3) under vacuum and heated in a constant-temperature bath (±0.2 °C). The remaining amount of dialkyl peroxide was determined by GC with a column of SE-30 (5%) using unternal standards. The reaction was followed up to 70—80% decomposition and exhibited first-order kinetics.

Decomposition Products. Di-*t*-alkyl peroxide at the concentration of 0.05 mol dm^{-3} in cumene was decomposed completely at 130 °C and the solution was analyzed by GC using internal standards. The yields of acetone and 2-methyl-2-propanol were determined with columns of PEG-20M (25%), and the others, SE-30 (5%).

Effect of Oxidants on the Oxidative Coupling of Methane over a Lead Oxide Catalyst

Kenji ASAMI,† Tsutomu SHIKADA,†† and Kaoru FUJIMOTO*
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo 113
(Received July 3, 1990)

Oxidative coupling of methane was studied over a PbO/MgO catalyst using a variety of oxidants such as N_2O, NO, CO_2, and SO_2. While N_2O showed both high activity and selectivity for the title reaction, NO produced CO_2, exclusively. The coupling reaction was assumed to proceed via the redox cycle of Pb and PbO on each oxidant mentioned above. Carbon dioxide produced small amounts of C_2 hydrocarbons and CO, while SO_2, was inactive for the reaction. Oxygen, N_2O, CO_2 could oxidize the Pb/MgO which had been formed by the reaction of PbO/MgO with methane at 1023 K. Thus-prepared PbO/MgO produced C_2 hydrocarbons from methane. Even NO, which gave no C_2 hydrocarbons in the CH_4–NO cofeed reaction, converted the Pb/MgO to PbO/MgO and the PbO/MgO gave C_2 hydrocarbons exclusively upon reacting with CH_4. NO seems to oxidize the methyl radical, which is an intermediate of the coupling reaction to CO_2. The ineffectiveness of SO_2 as an oxidant was attributed to the formation of PbS, which is inactive in the methane activation.

Since the pioneering work by Keller and Bashin,[1] a great number of catalysts have been found to be effective for the title reaction. The reaction systems reported so far are classified into 4 groups:

(A) Metal oxides, which exhibit abilities to change the oxidation state easily under reaction conditions, such as PbO,[2,3] MnO,[5] Bi_2O_3,[6] NiO,[7] and Tl_2O_3.[8]

(B) Alkaline earth metal oxides, such as MgO and CaO, which are undoped[9,10] or doped with Li^+,[11–14] Na^+,[15] K^+,[16] alkaline earth metal halide[17,18] or rare earth oxides.[19]

(C) Rare earth oxides, which are undoped[20] or doped with alkali metal compounds.[21]

(D) Noncatalyzed gas-phase reaction.[22,23]

Active oxygen species for the catalysts which belong to group (A) have been claimed to be bulk oxygen in metal oxides,[7,24] while the surface oxide ion or adsorbed oxygen has been proposed for the catalysts of group (B) and group (C).[12,25,26]

Oxidants other than O_2, such as N_2O or CO_2, have been applied to the methane coupling reaction. Ito et al. compared the reactivity of dinitrogen monoxide to methane with O_2 over a lithium promoted magnesium oxide catalyst and concluded that dinitrogen monoxide is not a preferable oxidant.[12] Otsuka et al. studied the effect of N_2O oxidation over a series of rare earth oxides and confirmed that N_2O gave a lower conversion of methane but a higher selectivity for C_2 hydrocarbons than O_2.[27] Meng et al. examined methane activation by N_2O over lead oxide catalysts supported on γ-Al_2O_3 and NaY zeolite to find that C_2 hydrocarbons were formed with a selectivity of 40%.[28] Hutching et al. found that on a Li/MgO catalyst N_2O promoted CH_4 coupling but NO inhibited the reaction while giving CO_2, exclusively and claimed the presence of two oxidizing species on the catalyst.[29] We have reported that in the noncatalyzed gas-phase system N_2O gave a higher selectivity than O_2 for the formation of C_2 hydrocarbons from CH_4, whereas NO was inactive for the reaction.[22] We also reported that methane reacted with CO_2 to form C_2 hydrocarbons and CO over a PbO/MgO catalyst.[30] Aika and Nishiyama also reported a promotional effect of added CO_2 on the CH_4–O_2 cofeed reaction over PbO/MgO.[31]

In this study the effects of a series of oxidants such as O_2, N_2O, NO, SO_2 and CO_2 were examined systematically over a PbO/MgO catalyst in order to clarify how each oxidant activates methane and the active oxygen species for the coupling reaction.

Experimental

The catalyst used was 20 wt%-PbO/MgO, prepared by impregnating commercially available magnesium with lead(2) nitrate from aqueous solution and then calcining it at 800 °C.[10] Methane oxidation reactions were conducted with a fixed-bed flow-type reaction apparatus under atmospheric pressure; the catalyst charge was 1 g. The reactor was a quartz tube with an inner diameter of 10 mm, in which another quqartz tube (6 mm o. d.) was inserted as a thermocouple holder. Methane conversions were performed according to the following two procedures: One was a CH_4–oxidant cofeed reaction and another was a periodic oxidation–reduction reaction. The reaction conditions of the cofeed reaction were 650—800 °C, W/F=1 g h mol^{-1}, $P(CH_4)$=14 kPa, P(oxidant)=1—4 kPa, and helium balance. In the case of CO_2, the composition of the reactant was CH_4: CO_2=1:1 and W/F was 5 g h mol^{-1}.

A periodic reaction was conducted along the following flow module: Air oxidation⟶N_2 purge(5 min)⟶CH_4 reaction(20 min) N_2 purge(20 min)⟶Oxidation(10 min). The cycle of the CH_4 reaction and oxidation was repeated at least 2 times. The procedure of the periodic reaction has

been described elsewhere.[24] However, the first activation of the catalyst was performed by oxygen (air); then the second and the third activations were performed by each oxidant. All of the reactions and products were analyzed by gas chromatography. The separation columns used were Porapak R for dinitrogen monoxide and sulfur dioxide and MS-13 X for nitrogen monoxide, respectively. The analysis methods for other reactants and produucts have been described elsewhere.[24] A Toshiba-Beckmann 951 NO/NO_x meter was also used for the analysis of nitrogen monoxide. X-Ray diffraction (XRD) measurements of the catalysts were recorded with a Rigaku Denki Ru-200 diffractometer with Ni-filtered Cu-K radiation.

Results and Discussion

Thermodynamic Consideration. The free-energy changes of ethane formation from methane with these oxidants are shown in Table 1. From a thermodynamic perspective, oxygen and nitrogen oxides are favorable oxidants for a coupling reaction ($G°_f<0$), whereas sulfur dioxide and carbon dioxide are unfavorable ($G°_f>0$). However, the equilibrium conversion of methane by CO_2 oxidation is about 10% under the conditions of 750 °C, $CH_4/CO_2=1$, and normal pressure.

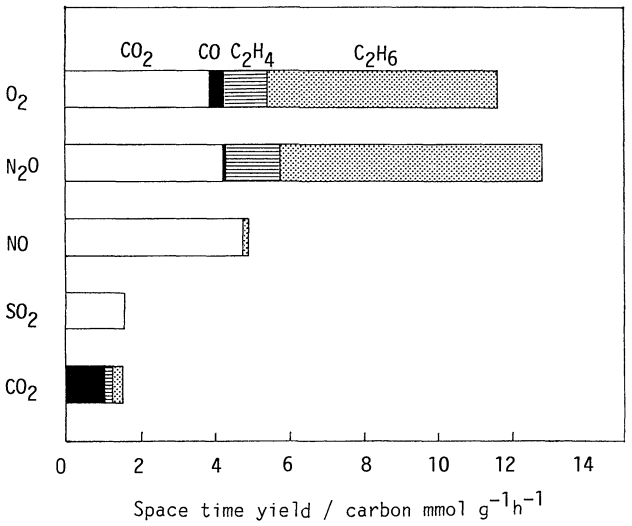

Fig. 1. Effect of oxidant on oxidative coupling of methane. Cat.; 20 wt%-PbO/MgO, 750 °C, W/F= 1.0 g h mol^{-1}, $P(CH_4)$=14 kPa, P(oxidant)=1.6 kPa (for O_2, N_2O, NO, SO_2), W/F=5.0 g h mol^{-1}, $P(CH_4)$= 5 kPa, $P(CO_2)$=5 kPa, (for CO_2).

CH_4-Oxidant Cofeed Reaction. In Fig. 1 are shown the space-time yields (STY) of the reaction products obtained by various cofeed reactions at 750 °C over a 20 wt%-PbO/MgO catalyst. The partial pressure of dinitrogen monoxide and nitrogen monoxide in the feed gas was set to be about twice that of oxygen in order to adjust the CH_4–O stoichiometry. In the case of the CH_4–CO_2 reaction, $P(CO_2)$ and the modified residence time (W/F) were 50 kPa and 5 g h mol^{-1}, respepctively, because of the low reaction rate.

(a) N_2O. Dinitrogen monoxide gave a similar STY of CH_4 oxidation (12.8 mmol $g^{-1}h^{-1}$) to that obtained by O_2 (11.6 mmol g^{-1} h^{-1}), the values of which correspond to CH_4 conversions of 8.5 and 8.1%, respepctively (Fig. 1). The product distribution was also similar to that of the CH_4–O_2 reaction, except for the lack of CO. The temperature dependence of the reaction using N_2O revealed that a higher temperature is favored for making C_2 hydrocarbons (Fig. 2), which is also similar to the case of O_2 oxidation.[10] We have reported that N_2O is effective to make C_2 hydrocarbons in a noncatalyzed system[22] while giving a higher selectivity (88%). However, the production rate was lower by about two orders of magnitude than that in the

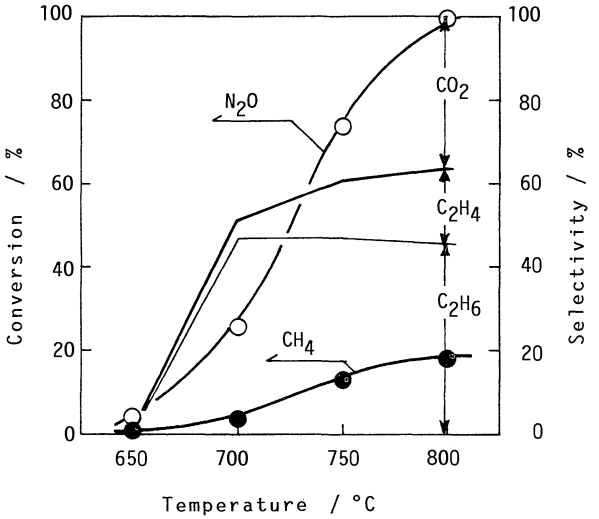

Fig. 2. Effect of temperature on the oxidative coupling of methane with N_2O as oxidant. Cat.; 20 wt%-PbO/MgO, 1.0 g h mol^{-1}, CH_4: N_2O: He= 10:4:86.

Table 1. Changes in Gibbs Free Energy in Oxidative Coupling of Methane with Various Oxidants

Reaction		$\Delta G_f°$/kcal mol^{-1}		
		700 °C	750 °C	800 °C
$2CH_4+1/2O_2 \rightarrow C_2H_6+H_2O$	(1)	−28.9	−28.1	−27.3
$2CH_4+N_2O \rightarrow C_2H_6+H_2O+N_2$	(2)	−66.2	−66.5	−66.7
$2CH_4+1/2NO \rightarrow C_2H_6+H_2O+1/2N_2$	(3)	−47.7	−46.8	−45.9
$2CH_4+1/2SO_2 \rightarrow C_2H_6+H_2O+S$	(4)	7.2	7.9	8.7
$2CH_4+1/3SO_2 \rightarrow C_2H_6+2/3H_2O+1/3H_2S$	(5)	6.2	6.6	7.0
$2CH_4+CO_2 \rightarrow C_2H_6+H_2O+CO$	(6)	17.8	17.4	16.9

present case, indicating that the reaction in the present system proceeds mainly on the catalyst surface.

The oxidative coupling of CH_4 over PbO/MgO has been clarified to be consist of a redox cycle between Pb and PbO; that is, a methane conversion into C_2 hydrocarbons by PbO (Eq. 7) and a reoxidation of metallic Pb with dioxygen (Eq. 8):

$$2\,CH_4 + PbO \longrightarrow C_2H_6 + H_2O + Pb, \quad (7)$$

and

$$Pb + 1/2O_2 \longrightarrow PbO. \quad (8)$$

The Gibbs free energy changes for the oxidation of Pb by N_2O oxidants shows as listed in Table 2 that the N_2O reaction with PbO (Eq. 9) is also thermodynamically favorable, as well as O_2. Therefore, the mechanism for the formation of C_2 hydrocarbons by N_2O is believed to be the same as that by O_2; namely, the reaction of CH_4 with PbO (Eq. 7) and the reoxidation reaction of reduced lead by N_2O (Eq. 9). We have confirmed that N_2O was completely decomposed to N_2 and O_2 on the PbO/MgO catalyst at 750 °C. Therefore, it is not clear whether N_2O reacts directly with Pb or after being converted to O_2.

(b) NO. Although a methane oxidation with NO is thermodynamically favorable (Table 1), the yield of C_2 hydrocarbons in the CH_4–NO reaction was much lower than those in the O_2–or N_2O– oxidation on the PbO/MgO catalyst, as indicated in Fig. 1. As shown in Table 3, CO_2 was formed exclusively (selectivity; >97%) under all reaction conditions. However, NO exhibited a strong oxidative ability of Pb; the oxidized Pb by NO gave C_2 hydrocarbons as well as N_2O or O_2 (Table 4). Therefore, the extremely low selectivity of C_2 hydrocarbons in a cofeed reaction might be interpreted in terms of the two possible reasons given below.

[1] surface oxygen species derived from NO is active only for a complete oxidation of methane. The species would be an adsorbed one on PbO ($PbO\text{–}O_x$), since such a species derived from O_2 is considered to be active regarding the formation of carbon oxides.[24]

[2] NO inhibits a coupling reaction; thus molecular NO attacks the methyl radical, which is formed by the reaction of CH_4 with PbO, in the gas phase to form CH_3NO. It is then finally decomposed to CO_2. It is well-known that nitrogen monoxide is a radical inhibitor.[32] The fact that NO oxidized Pb to PbO and PbO oxidized CH_4 to C_2H_6 by periodic oxidation (Table 4 and Fig. 4) suggests that concept [2] is more plausible.

(c) SO_2. When sulfur dioxide was used as an oxidant, CO_2 was produced exclusively, as shown in Fig. 1. Though other by-products (not shown) were carbonyl sulfide and elemental sulfur, neither hydrogen sulfide nor methane thiol was formed. Further consideration is presented later.

(d) CO_2. It is noticeable that the oxidative coupling of methane proceeded to some extent by utilizing CO_2 as an oxidant (Fig. 1). The product distribution is explained by assuming the following reaction stoichiometry (Eq. 14—16):

$$CO_2 \longrightarrow CO + (O), \quad (14)$$

$$2\,CH_4 + (O) \longrightarrow C_2H_6 + H_2O, \quad (15)$$

Table 2. Changes in Gibbs Free Energy in Oxidation of Lead with Various Oxidants

Reaction		$\Delta G_f°$/kcal mol^{-1} 700 °C	750 °C	800 °C

and

$$2\,CH_4 + 2\,(O) \longrightarrow C_2H_4 + 2H_2O. \quad (16)$$

Carbon dioxide is dissociated to carbon monoxide and a reactive surface oxygen species (O) (Eq. 14), which may react with methane to form ethane (Eq. 15) and ethylene (Eq. 16). In fact, CO_2 oxidized Pb to PbO and PbO oxidized CH_4 to C_2H_6 (Table 4 and Fig. 5). However, the amount of CO formed was larger than the amount calculated from reactions (14)—(16). Thus, reaction (17) should be accounted for. Reactions (14) and (17) are converted to the reaction stoichiometry shown in Eq. 18, which means that one fourth of the CO was formed from CH_4.

$$CH_4 + 3\,(O) \longrightarrow CO + 2\,H_2O \quad (17)$$

$$C^*H_4 + 3\,CO_2 \longrightarrow C^*O + 3\,CO + 2\,H_2O \quad (18)$$

The product distribution is shown as Fig. 1. Even at 800 °C the selectivity of C_2 hydrocarbons was not high. Thus low selectivity might be attributed to the formation of surface $MgCO_3$, which is not a favorable

support material. This subject will be discussed later.

Periodic Oxidation-Reduction Reaction. In the case of the CH_4–oxidant cofeed reaction, O_2 and N_2O exhibited excellent performance in the formation of C_2 hydrocarbons, similar to that of O_2, whereas other oxidants (NO, SO_2, and CO_2) did not produce the desired products selectively (as described above). However, a periodic oxidation–reduction reaction gave different results, as shown in Figs. 3 to 6. Also, the lead species identified after each reaction are shown in Table 4.

(a) N_2O, NO, and CO_2. Dinitrogen monoxide gave a similar result to that of the cofeed reaction containing O_2. Also, the periodic reaction gave C_2H_6 selectively over a catalyst which was oxidized by N_2O as demonstrated in Fig. 3. These facts correspond to that regarding O_2, which suggests that the oxidation state of lead oxidized by N_2O is similar to that oxidized by O_2 (Table 2).

Although little C_2 hydrocarbons were formed in a cofeed reaction containing NO (Fig. 1), they were formed with high selectivity in the CH_4–NO periodic reaction (Fig. 4). It was also clarified that NO has an ability to oxidize metallic Pb to PbO, and PbO gave C_2

hydrocarbons upon a reaction with CH_4, as demonstrated in Table 4. This means that although the redox cycle is possible in the CH_4–NO cofeed reaction system, NO inhibits the coupling reaction, probably because it reacts with the methyl radical to form CO_2. C_2 hydrocarbons were formed selectively at a comparable rate in a periodic CH_4–CO_2 operation (Fig. 5), while the rate of C_2 formation in a cofeed reaction was much lower than that in the O_2-containing cofeed reaction (Fig. 1). However, the amount of C_2 hydrocarbons formed in the second treatment was slightly smaller and the amount of CO formed was slightly larger than that obtained in the first treatment. This observation might be attributed to the formation of a surface carbonate species of carrier material of the catalyst (MgO) which is unfavorable for the coupling reaction.[24]

(b) SO_2. When sulfur dioxide was used as an oxidant, a small amount of C_2 hydrocarbons was formed in the periodic reaction (Fig. 6), although no C_2 hydrocarbons were formed at all in the cofeed reaction. The low CH_4 selectivity even in a periodic reaction, should be attribuuted to the formation of PbS according to Eqs. 11 and 13 during a reaction with SO_2 (Table 4), since PbS is never reduced by a reaction with CH_4. It is thus concluded that the redox cycle expressed as reactions (7) and (11) is inhibited by the formation of PbS.

Conclusion

Methane activation with a MgO-supported PbO catalyst was studied by using a variety of oxidants such as O_2, N_2O, NO, SO_2, and CO_2 resulting in the following conclusion:

1) In a CH_4–oxidant cofeed reaction, N_2O exhibited excellent activity and selectivity for the formation of C_2 hydrocarbons as well as O_2, whereas NO and CO_2 gave only small amounts of the desired product and SO_2 made no C_2 hydrocarbons.

2) Not only O_2 and N_2O, but also NO and CO_2, showed high selectivity for the formation of C_2 hydrocarbons in a periodic oxidation–reduction operation. This was because of the formation of PbO, which gave C_2 hydrocarbons upon a reaction with CH_4, with the reaction of a reduced catalyst and these oxidants as well as O_2 and N_2O. However, NO or CO_2 seems to have some inhibiting effect on the coupling reaction.

3) When SO_2 was used as an oxidant for methane conversion, lead sulfide was formed, which impeded the coupling reaction in either the cofeed reaction or the periodic reaction.

We thank Professor H. Tominaga for his discussion.

Characteristics of Suspended Ru/Carbon Catalyst for 2-Propanol Dehydrogenation Applicable to Chemical Heat Pump

Masaru YAMASHITA,* Tokiji KAWAMURA, Minoru SUZUKI, and Yasukazu SAITO
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113
(Received July 19, 1990)

Liquid-phase dehydrogenation of $(CH_3)_2CHOH$, $(CH_3)_2CHOD$ and $(CH_3)_2CDOH$ was performed at 82.4 °C with high activity and selectivity under refluxing conditions by heating the suspended solution at 100 °C with a carbon-supported ruthenium catalyst. Since the mixture of $(CH_3)_2CHOH$ and $(CD_3)_2CO$(10 vol%) gave 2-propan-1,1,1,3,3,3-d_6-ol at a rate 7.15-times higher than that of hydrogen evolution, hydrogen transfer from 2-propanol to acetone ought to proceed simultaneously with dehydrogenation. Relatively small kinetic isotope effects of 1.69 and 1.57, obtained from $(CH_3)_2CHOD$ and $(CH_3)_2CDOH$, respectively, on the Ru/carbon catalyst for dehydrogenation, suggests that the slowest step is not a splitting of the methine C–H bond but, rather, the formation of molecular hydrogen from surface hydrogen species. Further improvements regarding easy desorption of both acetone and hydrogen are necessary for the catalyst most suitable for 2-propanol dehydrogenation in a chemical heat pump system.

The utilization of solar and geothermal heat as well as waste heat in factories has recently attracted considerable attention. Chemical heat pumps are important from this viewpoint.[1] Aiming at large temperature rises, high thermal efficiencies and the functions of energy storage and transport, a new chemical heat pump system has been proposed in which an endothermic reaction at low temperature was coupled with its exothermic reverse reaction at high temperature.[2,3] Among the three processes shown in Eqs. 1—3, 2-propanol dehydrogenation in the liquid phase is the most difficult, but essential, reaction, since the endothermic reaction at low temperature converts thermal energy of low quality into chemical energy.

$$(CH_3)_2CHOH(l) \longrightarrow (CH_3)_2CO(g) + H_2(g), \quad (1)$$

$$(CH_3)_2CO(g) + H_2(g) \longrightarrow (CH_3)_2CHOH(g), \quad (2)$$

$$(CH_3)_2CHOH(g) \longrightarrow (CH_3)_2CHOH(l). \quad (3)$$

In spite of the thermodynamic disadvantage, the liquid-phase dehydrogenation of 2-propanol takes place catalytically under boiling conditions, where the product hydrogen is expelled from the reaction medium immediately. On the other hand, acetone hydrogenation is favorable below 202 °C at atmospheric pressure,[4] which is much higher than the boiling temperature of the 2-propanol/acetone mixed solution(82.4—56.3 °C). The role of a coolant at ambient temperature is also to be noted, because the separation of 2-propanol from the gaseous mixture makes it possible to raise the temperature from 80 °C to 200 °C in one effort.

As for the present chemical heat pump system, the development of excellent catalysts is indispensable for both gaseous hydrogenation of acetone and 2-propanol dehydrogenation in the liquid phase.

Hydrogenation of geseous acetone was widely investigated using various metal catalysts,[5] whereas Raney nickel,[6] nickel boride,[7] and fine-particle nickel,[8,9] prepared by a gas-evaporation technique,[10] were both active and selective for 2-propanol dehydrogenation. Homogeneous catalysts comprising rhodium,[11] ruthenium,[12] and iridium complexes[13] were useful for this reaction as well.

High thermal efficiency in the present heat pump system is attainable with high endothermic reaction rates in low temperature regions. A ruthenium catalyst supported on carbon (abbreviated hereafter as Ru/carbon) was recently found to be superior for 2-propanol dehydrogenation in a well-dispersed state.[14]

In the present paper, an elucidation of the characteristics has been attempted for a suspended Ru/carbon catalyst with deuterium-substituted 2-propanol and acetone for the purpose of designing the most suitable catalyst for a chemical heat pump system.

Experimental

Dehydrogenation of unlabled 2-propanol(hereinafter described as propanol-d_0) and its deuterio-isomers, i.e., $(CH_3)_2CHOD$ and $(CH_3)_2CDOH$ (Division of Merck, Frost, Inc.), as well as $(CH_3)_2CHOH$ including 10 vol% $(CH_3)_2CO$ or $(CD_3)_2CO$ were performed under boiling and refluxing conditions at atmospheric pressure. An appropriate amount (200 mg) of a Ru(5 wt%)/carbon powder catalyst (supplied by N. E. Chemcat Co.) and 5 ml of reactant 2-propanol were placed at room temperature in a Schlenk flask(20 ml), through which nitrogen was passed in order to remove both water and oxygen in sufficient amounts.

After the Ru/carbon catalyst was dispersed ultrasonically (Kaijyo Denki Co., Sona 50a) in 2-propanol, the suspension was agitated vigorously by a magnetic stirrer (500 rpm) and heated with an oil bath kept at 100 °C. The product gas was collected in a gas burette (250 ml) through a refluxing condenser cooled to 20 °C.

A gas-chromatographic analysis for gaseous and liquid-phase products was performed with active carbon and PEG

20M columns, respectively. The deuterium distribution in product dihydrogen was determined every fifteen or thirty minutes using a quadrupole-type mass spectrometer(NEC Anelva Co., AQA 360), whereas the ^2H NMR spectra of the solution were taken after appropriate reaction periods in order analyze how the substituted deuterium atoms were transferred among the liquid-phase components using an FT-NMR spectrometer(JEOL Co, GX-400).

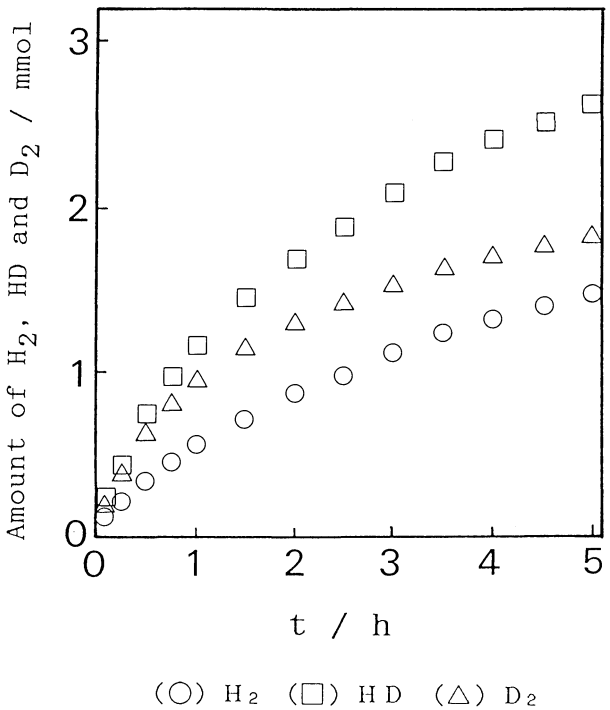

Fig. 1. Accumulation of H_2, HD, and D_2 evolved at 82.4°C from $(CH_3)_2CHOD$ under refluxing conditions (heat at 100°C) with Ru(5 wt%)/carbon catalyst.

Results

Dehydrogenation of 2-Propanol-*d*. The Ru/carbon catalyst suspended in $(CH_3)_2CHOD$ under boiling and refluxing conditions gave acetone and gaseous hydrogen as a mixture of H_2, HD, and D_2:

$$(CH_3)_2CHOD(l) \longrightarrow (CH_3)_2CO(l) + H_2, HD, D_2. \quad (4)$$

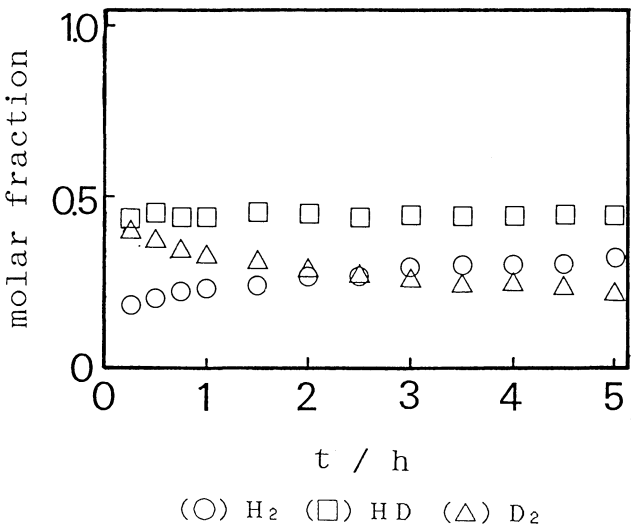

Fig. 2. Deuterium distribution among gaseous hydrogen at the time of evolution from $(CH_3)_2CHOD$ at 82.4°C under refluxing conditions (heat at 100°C) with Ru(5 wt%)/carbon catalyst.

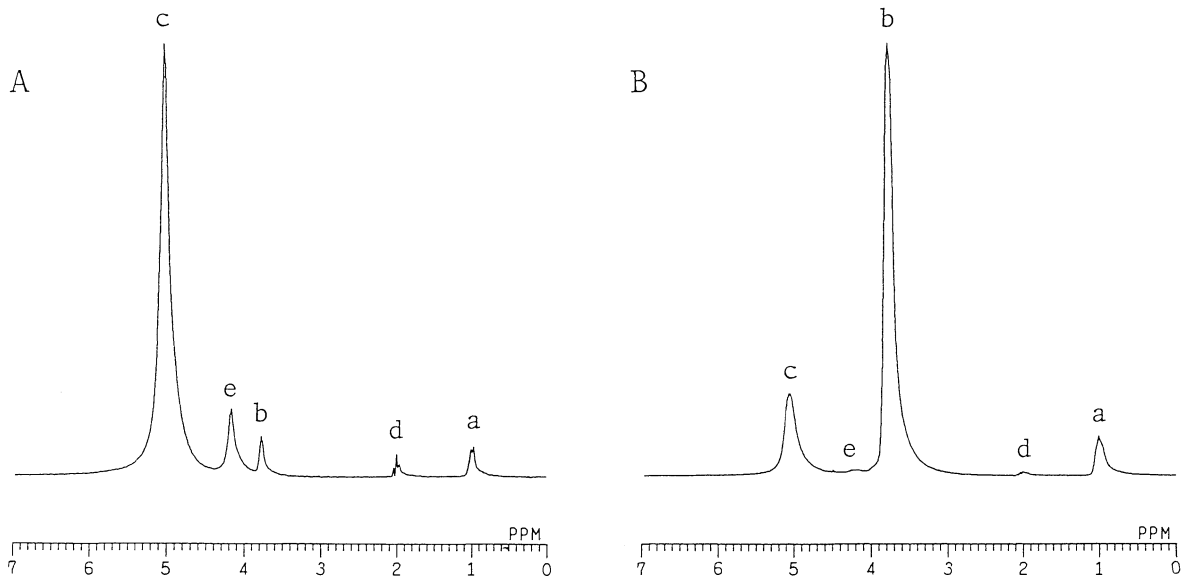

Fig. 3. ^2H NMR spectra of $(CH_3)_2CHOD$ (A) and $(CH_3)_2CDOH$ (B) solutions after 5-h reaction at 82.4°C under refluxing conditions (heat at 100°C) with Ru(5 wt%)/carbon catalyst. Peaks identified as 2-propanol methyl (a), methine (b) and hydroxyl (c) groups, acetone (d), and water (e).

A kinetic isotope effect of 1.69 was obtained from the initial dehydrogenation rates of $(CH_3)_2CHOH$ and $(CH_3)_2CHOD$. The amounts of H_2, HD, and D_2 produced from $(CH_3)_2CHOD$ are shown in Fig. 1 as a function of time.

The H/D ratio of gaseous hydrogen was smaller than unity (0.65) during the initial stage (15 min). The constitution of evolving hydrogen, however, changed with time, as represented in the variation of H_2, HD, and D_2 (Fig. 2). After 5 h from the start of the reaction, the H/D ratio of hydrogen newly-evolved increased to 1.22 at a conversion of 8.5%.

The deuterium distribution among the liquid-phase components after the 5-h reaction can be seen in the ^2H NMR spectrum (Fig. 3A). A part of the hydrogen atoms in the methine and methyl groups of $(CH_3)_2$-CHOD, as well as in the methyl group of $(CH_3)_2CO$, was exchanged with the deuterium supplied from the OD group of the reactant. In addition, a new peak due to HDO appeared, since water exuded from the carbon support was contaminated with deuterium.

The total amount of deuterium remaining in the solution was 58.27 mg-atom, as calculated from the $(CH_3)_2CHOD$ charged (64.51 mmol) and gaseous deuterium evolved (6.24 mg-atom). The deuterium distribution among the liquid-phase components is summarized in Table 1.

Dehydrogenation of 2-Propan-2-*d*-ol. The dehydrogenation products of $(CH_3)_2CDOH$ were acetone and the mixture of H_2, HD, and D_2:

$$(CH_3)_2CDOH(l) \longrightarrow (CH_3)_2CO(l) + H_2, HD, D_2. \quad (5)$$

The amounts of H_2, HD, and D_2 produced from $(CH_3)_2CDOH$ are shown in Fig. 4 as a function of time. Figure 5 depicts the variation in the molar fractions of H_2, HD, and D_2 produced at the reaction time concerned. As for $(CH_3)_2CDOH$, the H/D ratio of newly-evolved hydrogen changed from 1.7 to 6.9 during a 5-h reaction. In contrast to slight deuterium transfer to the methyl groups of 2-propanol and acetone, an H–D exchange at the hydroxyl group

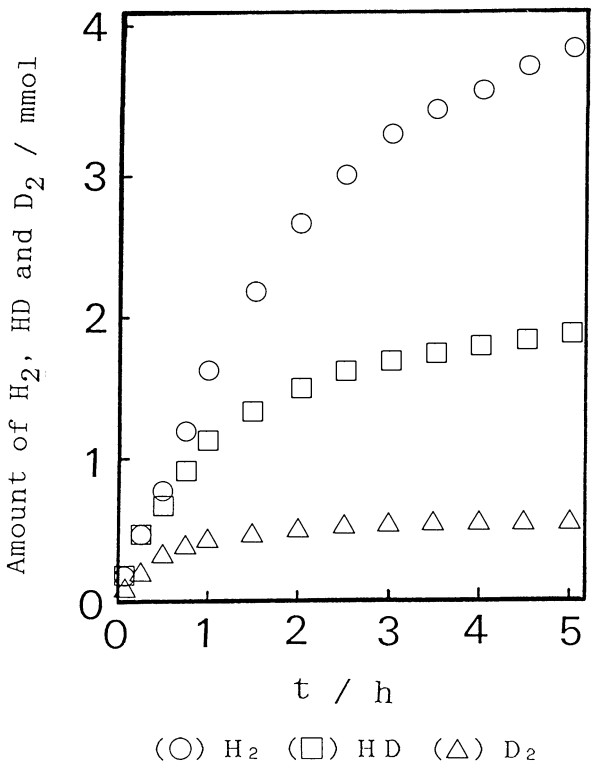

Fig. 4. Accumulation of H_2, HD, and D_2 evolved at 82.4°C from $(CH_3)_2CDOH$ under refluxing conditions (heat at 100°C) with Ru(5 wt%)/carbon catalyst.

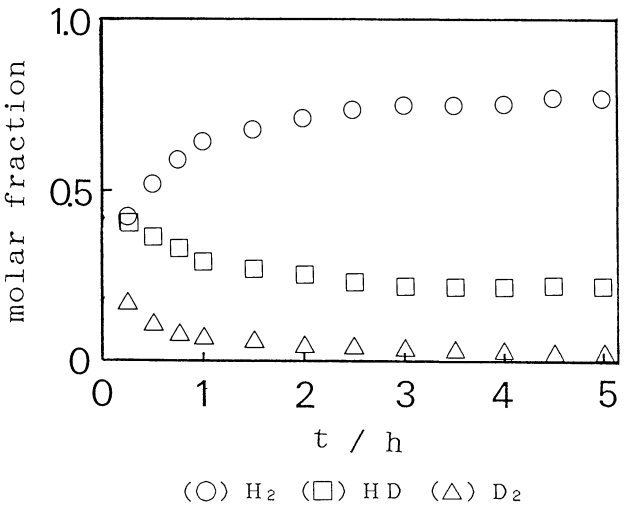

Fig. 5. Deuterium distribution among gaseous hydrogen at the time of evolution at 82.4°C from $(CH_3)_2CDOH$ under refluxing conditions (heat at 100°C) with Ru(5 wt%)/carbon catalyst.

Table 1. Deuterium Distribution in Liquid-Phase Components Obtained from $(CH_3)_2CHOD$ or $(CH_3)_2CDOH$ after 5-h Reaction under Refluxing Conditions (100°C) with Ru(5 wt%)/Carbon Catalyst

Reactant	Deuterium amount in solution	Deuterium distribution/%				
	mmol	2-Propanol			Acetone	Water
		Methyl	Methine	Hydroxyl		
$(CH_3)_2CHOD$	58.27	2.97	3.17	83.54	1.19	9.12
$(CH_3)_2CDOH$	61.61	6.16	74.48	17.62	1.17	0.47

amounted to an extent as large as 17.6% (Fig. 3B and Table 1).

The initial dehydrogenation rates of $(CH_3)_2CHOH$ and $(CH_3)_2CDOH$ gave a k_H/k_D of 1.57.

Dehydrogenation of the Mixture of 2-Propanol-d_0 and Acetone-d_6. As previously reported for a nickel fine-particle catalyst,[8] the initial rate of 2-propanol dehydrogenation on the Ru/carbon catalyst was suppressed 1/2.95 times by adding acetone (10 vol%). A mixture of $(CH_3)_2CHOH$ and $(CD_3)_2CO$ (10 vol%) gave gaseous hydrogen as mainly H_2, the molar ratios of HD/H_2 and D_2/H_2 being 0.03 and 0.02, respectively.

Most of the hydroxyl and methine groups of 2-propanol remained intact after the 1-h reaction, since the extents of deuterium exchange shown in the ^2H NMR spectrum (Fig. 6A) were only 0.78 and 0.49% of all the deuterium species in the solution, respectively. On the contrary, 75.2% of the deuterium atoms in acetone-d_6 changed to the methyl group of 2-propanol within 1 h.

The extent of hydrogen transfer from 2-propanol-d_0 to acetone-d_6, yielding 2-propan-1,1,1,3,3,3-d_6-ol within 1 h, was estimated to be 4.65 mmol from the deuterium peaks due to the two kinds of methyl groups, which was 7.15-times larger than that of hydrogen evolution (0.65 mmol).

After a reaction for 5 h, 88% of the added acetone-d_6 changed into 2-propanol (Fig. 6B and Table 2).

Effects of Gaseous Hydrogen and Hydrogen Surface Species on Deuterium Distribution. In order to ascertain the possibility of a reverse reaction between gaseous hydrogen and acetone under the dehydrogenation conditions of 2-propanol, a suspended Ru/carbon catalyst was heated in $(CH_3)_2CHOH$ as well as in $(CH_3)_2CHOH$ including $(CH_3)_2CO$ (10 vol%) under a deuterium atmosphere. After the solution was boiled for 5 h, a ^2H NMR analysis was performed at room temperature.

The amount of hydrogen evolved from the mixture of 2-propanol and acetone (10 vol%) under refluxing conditions for 5 h (2.33 mmol) was much larger than that of deuterium incorporated from the gas phase to the liquid components (0.17 mmol). The extents of H–D exchange between gaseous deuterium and the

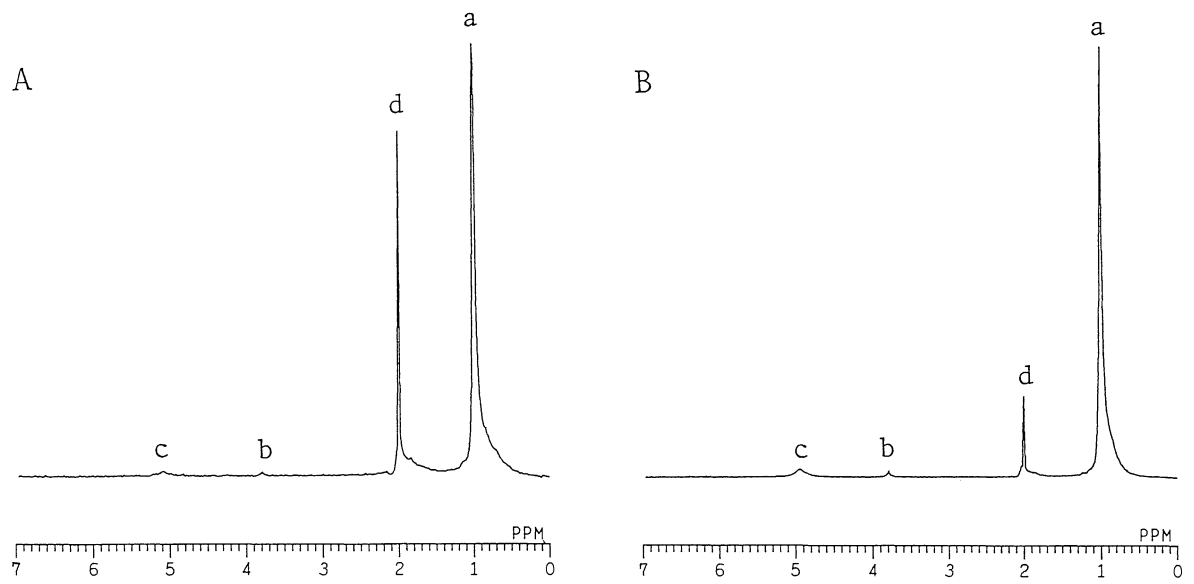

Fig. 6. ^2H NMR spectra of the mixed solution of $(CH_3)_2CHOH$ and $(CD_3)_2CO$ (10 vol%) after 1-h (A) or 5-h (B) reaction at 77.0°C under refluxing conditions (heat at 100°C) with Ru(5 wt%)/carbon catalyst. Peaks identified as 2-propanol methyl (a), methine (b) and hydroxyl (c) groups, and acetone (d).

Table 2. Deuterium Distribution in Liquid-Phase Components Obtained from the Mixture of $(CH_3)_2CHOH$ and $(CD_3)_2CO$ (10 vol%) after 1-h or 5-h Reaction at 77°C under Refluxing Conditions (100°C) with Ru(5wt%)/Carbon Catalyst

Reaction time/h	Deuterium distribution/%			
	2-Propanol			Acetone
	Methyl	Methine	Hydroxyl	
0	0.00	0.00	0.00	100.00
1	75.24	0.49	0.78	23.50
5	88.07	0.76	1.22	9.94

Table 3. Incorporation and Distribution of Deuterium from Gaseous Phase or Pre-Adsorbed State into Liquid-Phase Components as the Mixture of $(CH_3)_2CHOH$ and $(CH_3)_2CO$ (10 vol%) during the Reaction at 77.0 °C for 5 h under Refluxing Conditions (100 °C) with Ru(5 wt%)/Carbon Catalyst

Deuterium origin	Deuterium incorporated into solution	Deuterium distribution/mmol			
		2-Propanol			Acetone
	ppt	Methyl	Methine	Hydroxyl	
Gas phase	33.0	94.1	34.4	39.8	1.3
Pre-adsorbed at 130 °C	32.7	94.1	26.1	47.0	1.7

hydrogen atoms in 2-propanol or acetone were extremely small with no predominance to the methine and hydroxyl groups of 2-propanol (Table 3). The distribution and extent of deuterium incorporation in the solution of 2-propanol alone were similar to those obtained in a mixed solution of 2-propanol and acetone.

The effect of deuterium pre-adsorption on the catalyst was examined for a mixture of 2-propanol and acetone (10 vol%) at either 80 °C or 130 °C (Table 3). An extremely small amount of deuterium (0.17 mmol) was incorporated into the liquid components, irrespective of the pre-adsorption temperatures (80 °C and 130 °C) of gaseous deuterium.

Discussion

Surface Species Formed on the Ru/Carbon Catalyst during 2-Propanol Dehydrogenation. The reaction mechanism previously proposed for 2-propanol dehydrogenation (Eqs. 6—9)[7] seems to be responsible for the Ru/carbon catalyst as well.

$$(CH_3)_2CHOH \longrightarrow (CH_3)_2CHO_{ads} + H_{ads}, \quad (6)$$

$$(CH_3)_2CHO_{ads} \longrightarrow (CH_3)_2CO_{ads} + H_{ads}, \quad (7)$$

$$(CH_3)_2CO_{ads} \longrightarrow (CH_3)_2CO, \quad (8)$$

$$H_{ads} + H_{ads} \longrightarrow H_2. \quad (9)$$

As is apparent from the constitutions of the product hydrogen as the mixture of H_2, HD, and D_2, hydrogen molecules are formed irrespective of the groups to which the hydrogen atoms previously belonged.

The H/D ratio of gaseous hydrogen produced from $(CH_3)_2CHOD$ was slightly smaller than unity during the initial stage, whereas the H/D ratio from $(CH_3)_2CDOH$ exceeded unity to some extent. It is therefore conceivable that the hydroxyl group of 2-propanol is dissociated more easily than its methine group, while supplying an excess amount of isopropoxyl and hydrogen species adsorbed on the catalyst surface. A gradual increase in the H/D ratio of gaseous hydrogen indicates that the methyl and methine hydrogen atoms of either $(CH_3)_2CHOD$ or $(CH_3)_2CDOH$ exchange with the surface deuterium species directly, but slowly.

The low extent of H–D exchange between the surface hydrogen species and acetone was also confirmed by the fact that most of the gaseous hydrogen which evolved from the $(CH_3)_2CHOH/(CD_3)_2CO$ (90/10 mixed by volume) solution was H_2. The possibility of acetone adsorption in its enol form[15] is therefore unlikely on a Ru/carbon catalyst.

Hydrogen Transfer from 2-Propanol to Acetone. Acetone hydrogenation is thermodynamically more favorable than 2-propanol dehydrogenation in temperature regions as low as the boiling point of 2-propanol (82.4 °C).[4] Under boiling conditions, however, hydrogen evolution took place catalytically, even at 77.0 °C, from the 2-propanol/acetone (90/10 mixed by volume) solution.

The small extents of deuterium incorporation from pre-adsorbed deuterium or from gaseous deuterium under the reaction conditions indicate that either an intermediation of pre-adsorbed hydrogen or a dissolution and adsorption of gaseous hydrogen are insignificant for the reaction. Once expelled from the reaction medium to the gas phase, the product hydrogen becomes indifferent to the catalysis under refluxing conditions. The observed rate retardation due to acetone (1/2.95 times in the 90/10 mixed solution) would be ascribed to the following two factors: (i) occupation of sites active for 2-propanol dehydrogenation and (ii) consumption of surface hydrogen by adsorbed acetone through hydrogen transfer from 2-propanol.

As for the 2-propanol/acetone-d_6 (90/10) mixed solution, hydrogen transfer from 2-propanol to acetone is described as

$$(CH_3)_2CHOH(l) + (CD_3)_2CO_{ads} \longrightarrow (CD_3)_2CHOH(l) + (CH_3)_2CO_{ads}. \quad (10)$$

The surface hydrogen species supplied from 2-propanol is consumed not only by evolving gaseous hydrogen, but also by converting $(CD_3)_2CO$ into $(CD_3)_2CHOH$ (Eqs. 11—14):

$$(CH_3)_2CHOH \longrightarrow (CH_3)_2CO_{ads} + 2H_{ads}, \quad (11)$$

$$(CD_3)_2CO \longrightarrow (CD_3)_2CO_{ads}, \quad (12)$$

$$(CD_3)_2CO_{ads} + 2H_{ads} \longrightarrow (CD_3)_2CHOH, \quad (13)$$

and

$$(CH_3)_2CO_{ads} \longrightarrow (CH_3)_2CO. \quad (14)$$

Eq. 13 is eventually the reverse process of 2-propanol dehydrogenation(Eqs. 6 and 7).

Even through hydrogen transfer proceeded rapidly from $(CH_3)_2CHOH$ to $(CD_3)_2CO$, deuterium was incorporated into the methine and hydroxyl groups infinitesimally. As is evident from the ^2H NMR spectra shown in Fig. 6, $(CH_3)_2CO$ and $(CD_3)_2CHOH$ were yielded predominantly during the dehydrogenation of $(CH_3)_2CHOH$ in the presence of $(CD_3)_2CO$.

After the reaction of 2-propanol-d for 5 h, deuterium in the methine and methyl groups of 2-propanol-*d* amounted to 3.17 and 2.97%, respectively (Table 1). H–D exchange of the methine group proceeded more extensively than that of the methyl group per hydrogen atom (3.17/1 vs. 2.97/6), which strongly suggests that the surface deuterium species is incorporated through a transfer reaction to acetone (Eq. 15) more efficiently than through an exchange reaction with methyl hydrogen (Eq. 16):

$$(CH_3)_2CO_{ads} + 2D_{ads} \longrightarrow (CH_3)_2CDOD, \quad (15)$$

and

$$(CH_3)_2CHOD + D_{ads} \longrightarrow (CH_3)(CH_2D)CHOD + H_{ads}. \quad (16)$$

The reactions of hydrogen transfer and hydrogen evolution ought to proceed simultaneously, since the rate of either Eq. 13 or Eq. 15 is large.

Reaction Mechanism of 2-Propanol Dehydrogenation on the Ru/Carbon Catalyst. The isotope effects for hydrogen evolution from 2-propan-2-*d*-ol and 2-propanol-*d* with a suspended Ru/carbon catalyst were obtained during the initial stage as 1.57 and 1.69, respectively.

It should not be assumed that splitting the methine C–H bond is difficult, since the magnitude (1.57) is rather small as a primary isotope effect for the elimination of β-hydrogen[16] and is preceded by the magnitude obtained from 2-propanol-*d*.

Provided that the formation of molecular hydrogen from the surface hydrogen species is the slowest step, these magnitudes and tendency of the isotope effects become conceivable. More abundant deuterium species were supplied from $(CH_3)_2CHOD$ than from $(CH_3)_2CDOH$ on the catalyst surface, as indicated by the difference between 0.65 and 1.7 in the H/D ratios of molecular hydrogen formed during the initial stage. It should also be noted that the magnitudes of the k_H/k_D obtained from $(CH_3)_2CDOH$ and $(CH_3)_2CHOD$ are comparable to those for the formation of molecular hydrogen from metal hydride complexes, i. e., $Co(H)_2P(OCH_3)_3]_4^+$ (k_H/k_D=1.51 at 23 °C)[17] and $[Ir(H)_2(CO)_2(PMePh_2)_2]^+$(2.1 at 20 °C).[18]

As $(CH_3)_2CDOH$ changed appreciably into $(CH_3)_2CHOD$ on the catalyst (Table 1), the dissociation and formation processes of the methine C–H bond were facile. These distinctive characteristics of the Ru/carbon catalyst would be the reason for its superiority regarding the activity of 2-propanol dehydrogenation.[14] The splitting process of the methine C–H bond has been considered to be the most difficult step for catalytic 2-propanol dehydrogenation.[19]

New abilities for easy desorption of both acetone and hydrogen should be added to the Ru/carbon catalyst from the viewpoint of designing a catalyst most suitable for 2-propanol dehydrogenation in a chemical heat pump system.

Conclusive Remarks

The suspended Ru/carbon catalyst exhibited the following characteristics for 2-propanol dehydrogenation: i) highly selective and active performance under boiling conditions, ii) relatively small isotope effects, being larger for $(CH_3)_2CHOD$ than $(CH_3)_2CDOH$, iii) simultaneous occurrence of hydrogen evolution and hydrogen transfer from 2-propanol to acetone on the catalyst surface, and iv) the slowest step presumed not to be the splitting process of the methine C–H bond but to be the formation of molecular hydrogen from the surface hydrogen species.

Further improvements of the Ru/carbon catalyst are necessary, especially regarding easy desorption of both acetone and hydrogen.

The present work was supported by a Grant-in Aid on Priority-Area Research No. 63603007 from the Ministry of Education, Science and Culture.

Synopsis. The high-resolution solid-state cross-polarization magic-angle spinning ^{13}C NMR spectra of α, β, τ and X-form metal-free phthalocyanines (H_2pc) were investigated. Chemical shifts differed according to crystal forms. As a result of the temperature dependence of chemical shifts, we could observe the change in the spectra because of the inner protons.

Phthalocyanines are a very interesting class of organic compounds owing to their highly functional properties. In particular, metal-free phthlocyanines (H_2pcs) have specific phenomena. The H_2pc molecule has two inner protons; their locations are somewhat controversial. Cross-polarization magic-angle spinning (CP-MAS) ^{13}C nuclear magnetic resonance (NMR) has been developed as an effective method to investigate the state of a solid and its morphology. Thus, many researchers have been investigating the relationship between inner protons and phthalocyanine rings.[1,2] An especially, important theme is whether the two inner protons are directly bonded with a diagonally opposed pair of nitrogens (bonded type) or are shared by four equivalent pyrrole nitrogens (bridged type). The proton dynamics in an α-form H_2pc were observed using a two-dimensional chemical exchange in the solid-state by Meier et al.[1] They demonstrated the utility of two-dimensional exchange spectroscopy, and proposed that the way to obtain kinetic information about this system is through difficult isotope labeling. Toscano studied electrically conductive metallo-macrocyclic assemblies.[2]

This paper describes ^{13}C NMR spectroscopy that can be applied to detect and identify the difference in crystal forms of H_2pc (α, β, X, and τ-forms). Moreover, the ^{13}C NMR spectra change between -100 °C and room temperature; a peak shift, disappearance and reappearance can be found in the exchange reaction of two inner protons between the two tautomeric positions, depending upon the temperature.

Experimental

Samples. The β-H_2pc used in this work was prepared from crude H_2pc by vacuum sublimation in a zone furnace at 470 °C under a pressure of 10^{-5} Torr (1 Torr=133.322 Pa) for 8 h. Acid pasting of this β-H_2pc gave a fine powder of α-H_2pc. The X-H_2pc was prepared as previously described.[3,4] Conversion to the τ-form was achieved by a wet milling method.[5] All samples were purified by a solvent-extraction technique with methyl ethyl ketone and methanol. The individual crystal forms were checked by their powder X-ray diffraction patterns as well as infrared absorption spectra.

Spectroscopy. High-resolution CP-MAS ^{13}C NMR spectra were obtained on a JOEL GSX-270W spectrometer at a frequency of 67.5 MHz with accessories. The techniques of magic-angle spinning, cross-polarization and dipole dephasing delay were employed in order to enhance the single-to-noise ratio as well as the spectral resolution. The resolution was within 5 Hz at a spinning speed of 4.5 kHz within the temperature range used. Admantane was used for measurements of the resolution. The temperature was measured with a thermocouple positioned close to the spinner in the range the -100—25 °C. The repetition time was within 10 seconds. The ^{13}C chemical shifts were determined by using liquid tetramethyl silane (TMS) as an external reference.

Results and Discussion

H_2pc has four representative polymorphic forms: the β-form is thermodynamically stable and the α-form is metastable, while the X- and τ-forms are quite differently packed in the middle energy states between the α- and β- forms. The differences in the crystal forms found by crystallographic, spectroscopic, and photoconducting methods are attributable to a distinct stacking of phthalocyanine molecules and to the state of the inner protons.

Chemical Shifts of H_2pc at Room Temperature. The CP-MAS ^{13}C NMR spectra of H_2pcs measured at room temperature are shown in Fig. 1. The chemical shifts and their assignments are summarized in Table 1. In order to assign the quaternary carbons, the dipole dephasing delay method was used. The assignments followed the described methods by Meier et al.[5]

In the case of α-H_2pc having four equivalent central nitrogens, one resonance line comprises a contribution from four equivalent carbons (Scheme 1), due to a fast hydrogen exchange rate between the inner nitrogens. These broad lines suggest a lower regularity and a wide distribution of the crystalline structure, compar-

ed with the other three forms. We have observed four broad resonance lines of oxo(phthalocyaninato)titanium (IV) ([TiO(pc)] in CP-MAS ^{13}C spectra.[6] It is known that metallophthalocyanines possess four central nitrogen atoms equivalently bonded to the hydrogen atoms.[7,8] This result may support the fact that four resonance lines appear for α-H_2pc. The β-H_2pc actually has a much more complicated tautomerism, and the molecules tend to be packed as close as their geometry allows. Thus, the β-H_2pc have a number of chemical shifts, possibly due to the diversity of carbon atoms in the molecules. The τ-H_2pc are assigned to the eight well-split carbon atoms. The chemical shifts of the same numerals differ by approximately 5.5 ppm in relation to whether the bridge nitrogens are bonded with the inner hydrogens or not. The resonance lines, which bond with hydrogen-bonded nitrogen, appear in the lower magnetic field. Since two inner protons of τ-H_2pc are directly bonded with a diagonally opposed pair of nitrogens in a molecule, the N–H bonds may further weaken the overlapping of the π-electrons and induce differences in their chemical shifts. Though X-H_2pc has relatively similar shifts compared to the τ-form above 140 ppm, a broad shift can be seen from 120 to 130 ppm. The structures of the crystal packing of τ-H_2pc may be stable, and the distances of each molecule are in suppose to be longer than those of X-H_2pc.

Variation of the Chemical Shifts as a Function of the Temperature. The temperature dependences of the CP-MAS ^{13}C NMR spectra with H_2pcs are given in Fig. 2. These shifts are attributable to a change in the

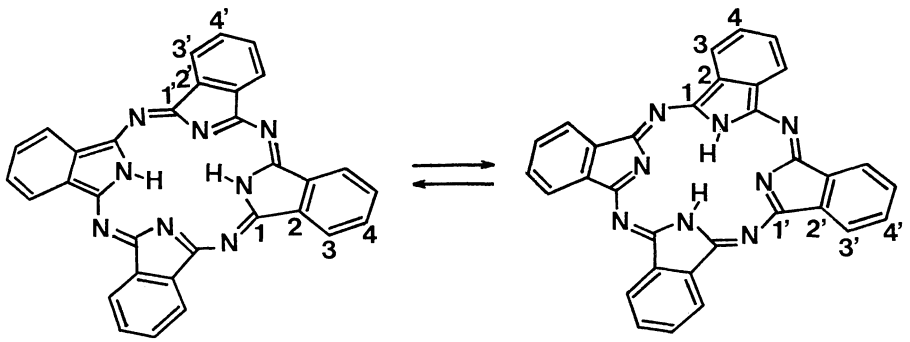

Scheme 1.

exchange limits between −30 °C and −100 °C. The chemical shifts from 130 to 150 ppm of α-H_2pc progressively decrease from room temperature to −30 °C, because of a decreasing intermolecular interaction, while the intermolecular interaction increases. Below −30 °C, these shifts increase with decreasing temperature under a smaller magnetic field (151 ppm). The temperature dependence of β-H_2pc is rather low until −100 °C. It can be concluded that a proton exchange reaction with an intramolecular interaction will occur at the same time in β-H_2pc, due to these complicated spectra. The change in the shifts of τ-H_2pc accompanied by temperature differences is remarkable. Two lines assigned to two kinds of carbons, which bond with nitrogens, shift downfield as for α-H_2pc; they disappear at −40 °C, but appear again below −60 °C. The distance of the two shifts varied at −30 °C (6.2 ppm) and −100 °C (3.0 ppm), resulting from the proton exchange velosity. The narrow distance of two equivalent spins suggests a faster exchange regime. Below −60 °C, the intermolecular interaction becomes greater due to the weakened forces of the intermolecular interaction. The influence is larger than other H_2pcs due to the high sensitivity of τ-H_2pc to the nuclear magnetic moments. Moreover, the chemical shifts of carbon in resonating benzene rings are well separated in this temperature region. The chemical shifts of resonating carbon atoms are not well separated compared with those of τ-H_2pc, and the distances of chemical shifts with carbon 2 and 2′ are 5.0 ppm at −30 °C and 4.2 ppm at −100 °C. The energy stage of X-H_2pc may be located near that of τ-H_2pc. However, the lines of the inner carbons cannot separate like those of τ-H_2pc, probably at −100 °C, because of inperfections in crystal packing.

Though the α, X and τ-H_2pcs show a changed limit at a temperature of approximately −30 °C, we can not observe this situation for the β-H_2pc. This result may be because the strong interaction of molecular packing prevents the formation of intramolecular N–H bonding, instead of the intermolecular N–H bonding with neighbor molecules.

We thank Toyo Ink Mfg. Co., Ltd. for assistance in the measurements of the NMR spectra. We also thank Mr. Deguchi, of JOEL Ltd., for his helpful discussions concerning the NMR study.

High-Pressure Fourier Transform Infrared Spectroscopy Study of the Diels-Alder Reaction of Isoprene and Maleic Anhydride in Supercritical Carbon Dioxide

Yutaka IKUSHIMA,* Norio SAITO, and Masahiko ARAI†
Government Industrial Research Institute, Tohoku, Nigatake 4-chome, Miyagino-ku, Sendai 983
† Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Aoba-ku, Sendai 980
(Received July 23, 1990)

Synopsis. A high-pressure FTIR spectroscopy was used to make an in situ study on the Diels-Alder reaction of isoprene and maleic anhydride catalyzed with aluminum chloride in supercritical carbon dioxide at 306 K and 7.45 and 7.85 MPa, suggesting a two-step mechanism and showing a pressure effect.

Considerable attension has recently been focused on the highly compressible properties of supercritical fluids (SCFs) in the near-critical region from scientific and industrial points of view.[1-5] The solvent strength varies widely with both the pressure and temperature in that region; this sensitivity can be applied to the control of chemical reaction processes. A few studies have shown that the use of SCFs as reaction media leads to significant increases in the reaction rates and the variation in product distributions.[1,2,6-8] However, detailed studies have rarely been made to examine the elementary processes involved in reactions in SCFs.[9] This is mainly because it is difficult to follow reactions in situ under supercritical conditions.

In the present work, high-pressure Fourier transform infrared (FTIR) spectroscopy was applied to a study of a chemical reaction in supercritical carbon dioxide. The reaction that we conducted was a Diels-Alder reaction of isoprene and maleic anhydride catalyzed with aluminum chloride. It was followed by examining changes in the absorption intensities for some functional groups characteristics to both the reactants and product. The present note presents information concerning the mechanism of the reaction under supercritical conditions and demonstrates that the FTIR technique used in this work is promising for the study of chemical reactions in SCFs.

Details of the experimental system used, including a high-pressure cell that can withstand high pressures and temperatures such as 50 MPa and 373 K, was described elsewhere.[10] A 2.94 g (0.03 mol) of maleic anhydride with 0.40 g (0.003 mol) of aluminum chloride was dissolved in 20 ml of benzene. A 0.35 μL portion of this solution and 0.15 μL of isoprene were simultaneously injected into the system from two injection valves. The reactants reached the high-pressure flow cell immediately after injection by stopping the flow. The reaction was conducted at 306±0.1 K and at 7.45 and 7.85 MPa. During the reaction, FTIR measurements were made at certain time intervals. Interferrograms were accumulated at a rate of 1 scan per 1.2 s and 4—5 scans were made for each measurement. A spectrum of supercritical carbon dioxide alone was used to provide the background spectrum.

Figure 1 shows the changes in the intensities of the absorption bands at 1597, 1784, and 1798 cm^{-1} during the reaction. The bands at 1597 and 1784 cm^{-1} can be

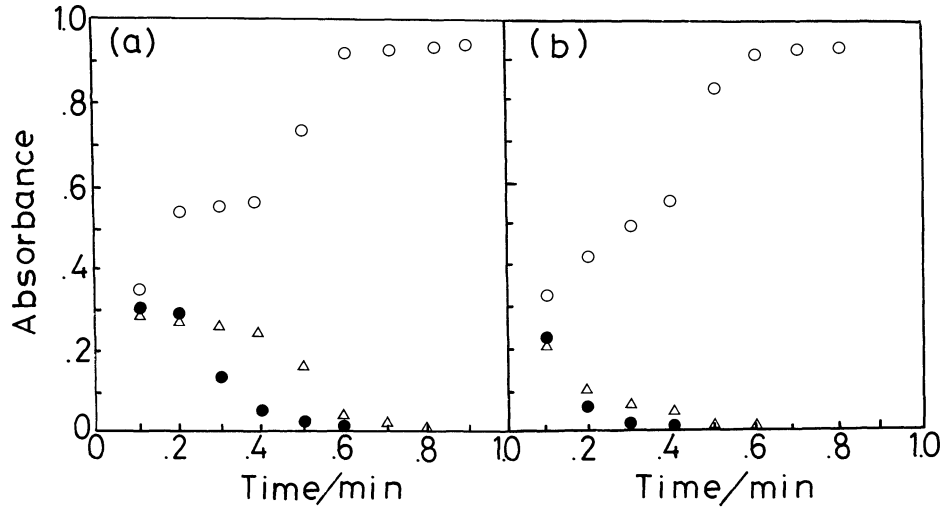

Fig. 1. Changes of the intensities of the absorption bands at 1597 (●), 1798 (○), and 1784 cm^{-1} (△) with time on the Diels-Alder reaction of maleic anhydride and isoprene catalyzed with aluminum chloride in supercritical carbon dioxide at 306 K. Pressure: (a) 7.45 MPa; (b) 7.85 MPa.

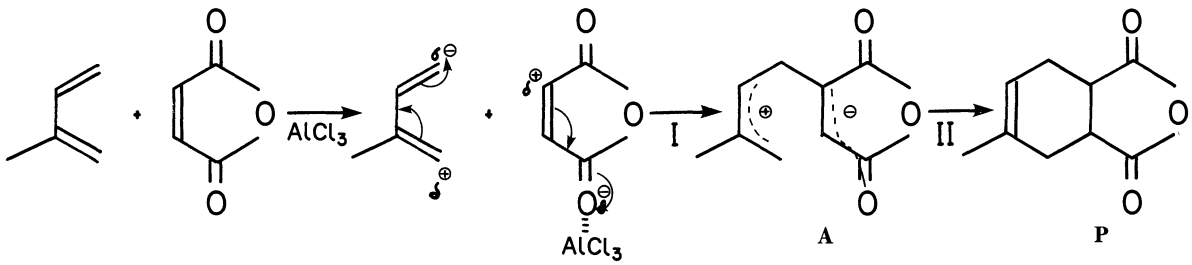

Scheme 1.

assigned to a C=C stretching of the isoprene and a C=O stretching of the maleic anhydride, respectively. From a NMR measurement, compound (**P**) shown in Scheme 1 was proved to be the only product in the present cycloaddition. The absorption at 1798 cm^{-1} is assigned to C=O stretching of this product. The formation of a cyclic adduct increases the frequency of the C=O stretching absorption band as a result of conjugation. Figure 1(a) indicates that the absorbance at 1597 cm^{-1} decreased and disappeared at about 0.6 min and that at 1784 cm^{-1} gradually decreased during a period of 0.2—0.4 min and then decreased more rapidly, disappering after about 0.6 min. The absorbance at 1798 cm^{-1} increased until 0.2 min, remained almost unchanged during the period from 0.2—0.4 min, and then increased again, reaching a constant value. The results at a higher pressure of 7.85 MPa are given in Fig. 1(b), showing some pressure effect; the absorbance at 1597 and 1784 cm^{-1} disappeared within a shorter time, and that at 1798 cm^{-1} increased throughout the reaction until about 0.5 min and attained the same constant value within a shorter time as compared with the reaction at 7.45 MPa. It follows that the overall reaction rate was enhanced by increasing the pressure from 7.45 to 7.85 MPa.

It is commonly said that Diels-Alder reactions proceed via a one-step, concerted mechanism under ordinary conditions.[11] However, the results shown in Fig. 1 strongly suggest a two-step mechanism for the present Diels–Alder reaction in carbon dioxide under supercritical conditions. The step-wise increase in the intensity of the 1798 cm^{-1} absorption during the reaction would be indirect evidence for the presence of some intermediate. One possible explanation for the changes in the absorbance shown in Fig. 1 is that the reaction proceeds via the two steps shown in Scheme 1: the formation of one σ-bond giving an intermediate (**A**), followed by a ring closure, yielding the cycloadduct (**P**). The observed step-wise increase of the 1798 cm^{-1} absorption is believed to correspond to the formation of two σ-bonds in the two steps. A gradual decrease in the C=O absorbance at 1784 cm^{-1} of maleic anhydride, as observed more clearly at 7.45 MPa, also suggests that the intermediate has two C=O bonds, similar to those of maleic anhydride and the product. One might expect that the IR carbonyl stretching frequency and band intensity for (**A**) are different from those for (**P**). The present FTIR measurements, however, did not support this idea.

In a few cases of Lewis-acid catalyzed cycloadditions, the mechanism of a [2+2] addition followed by a rearrangement, giving a [2+4] adduct, was reported in the literature.[12] Such a mechanism might be possible for the present Diels–Alder reaction. However, the intermediate that can be expected from this mechanism could not well support the FTIR results of Fig. 1. Also, the present reaction takes place with thermal energy; it is therefore natural to believe that it proceeds through a [2+4] addition mechanism. We presently believe that Scheme 1 is a possible tentative mechanism for the Diels–Alder reaction in supercritical carbon dioxide; further work is required to obtain a definite conclusion. Since the reaction is carried out under unordinary conditions, we should consider the solvent properties of carbon dioxide at supercritical conditions.

Regarding the influence of increasing pressure, the results in Fig. 1 show an enhancement in the overall reaction rate. If one can adopt the mechanism shown in Scheme 1, it is speculated that the second step depends more strongly on the pressure than does the first step, since the change of the 1798 cm^{-1} absorbance during the initial stage of the reaction seems to be little influenced by the pressure. It is a current subject of study to examine the effects of the pressure of SCFs on the reactions and to clarify the key physical/chemical properties governing the effects.

^{17}O NMR Study of Aqueous Electrolyte Solutions; Effect of KCl and NaCl on the ^{17}O NMR Parameters of Water

Akira HIGASHIYAMA, Yasuhiko YAMAMOTO, and Riichirō CHŪJŌ*
Department of Biomolecular Engineering, Tokyo Institute of Technology, O-okayama 2-chome, Meguro-ku, Tokyo 152
(Received August 1, 1990)

Synopsis. The aqueous solutions containing KCl or NaCl at various concentrations have been studied by ^{17}O NMR. The line width of the signal increases and decreases with an addition of KCl above and below 55 °C, respectivly, and these results indicate that the effect of KCl on the water structure depends on temperature.

The chemical shift changes induced on the ^{17}O NMR signal of water by an addition of salts such as KCl and NaCl have been used to study interaction between H_2O and solute molecules.[1,2] Hydrogen bonding network among water molecules and motion of water molecule have been investigated from the line width of its ^1H or ^{17}O NMR signal[3,4] and their spin-lattice (T_1) or/and spin-spin relaxation time (T_2), respectively.[5–11]

In this report, we have studied the effects of KCl and NaCl on the ^{17}O NMR parameters of water. The line width decreases with an addition of KCl below 55 °C. On the contrary, above this temperature, it increases with an addition of KCl. These results indicate that KCl acts as water structure breaking and forming salt, below and above 55 °C, respectively.

Experimental

Materials. H_2O was prepared by distillation of deionized water. D_2O was purchased from MSD Isotopes and used as received. KCl and NaCl were obtained from Sigma Chemical Co. and they were dried under reduced pressure at 150 °C for 24 h before use.

NMR Measurement. All ^{17}O NMR experiments were carried out using JEOL GSX-270 spectrometer operating at the resonance freaqency of 36.6 MHz. The spectra were recorded with proton decoupling, and the signal to noise ratio of the spectra was improved by apodization which introduced 10 Hz line broadening. The chemical shifts are given in parts per million (ppm) and the ^{17}O NMR signal of D_2O at 35 °C was used as a reference (0 ppm). T_1 values were determined by using a saturation recovery method[12] and T_2 was calculated from the line width of the signal.

Results and Discussion

Chemical Shifts. The chemical shift change for the ^{17}O NMR signal of water is plotted against the concentration of salt at 35 °C in Fig. 1. The plots for KCl and NaCl exhibit straight lines, over the salt concentration range examined, with the slope [∂(ppm)/∂(mol dm^{-3})] of 0.80 and 0.45, respectively. The ^{17}O NMR signal moves toward downfield with the addition of salt. Since K^+ and Na^+ are known to shift the signal upfield, the observed downfield shift of the signal is attributed to the large downfield shift effect of Cl^-.[1,2] Hence, the smaller slope of the plot for NaCl, compared with that for KCl, indicates that the upfield effect of Na^+ is larger than that of K^+.

Relaxation Times. Relaxation parameters measured under various conditions are summarized in Table 1. T_1 of ^{17}O NMR signal of H_2O was determined to be

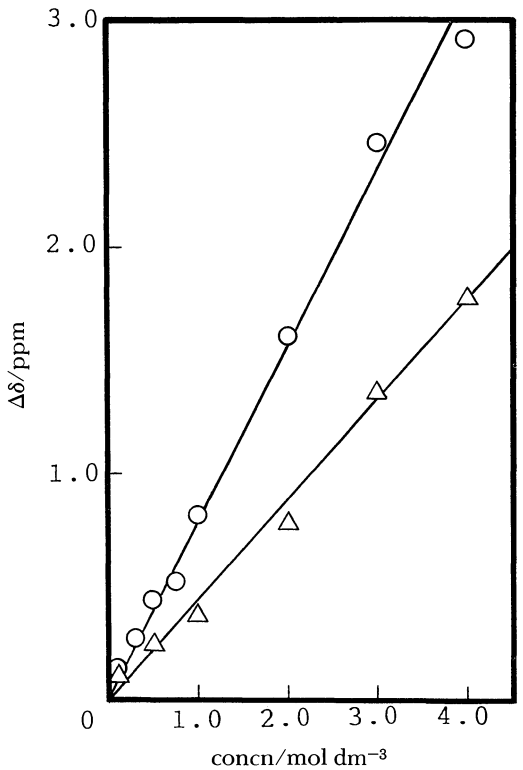

Fig. 1. Plot of observed chemical shift for the ^{17}O NMR signal of D_2O against the concentration of salt added at 35 °C. KCl (○), and NaCl (△).

T_2*/ms	6.1±0.3	4.8±0.2	9.1±0.6	5.3±0.3	8.2±0.5
τ_c/ps	2.9±0.5	2.3±0.3	1.2±0.1	2.2±0.3	1.5±0.1

a) Calculated from the observed line width. b) Estimated from the determined T_1 value with $e^2qQ/\hbar$=7.7 MHz.[7]

6.2±1.0 ms at 35 °C. This value is almost comparable to the previously reported value.[5] The apparent spin-spin relaxation time (T_2*) was calculated to be 6.1±0.3 ms from the line width of 52.5 Hz at 35 °C. Hence, T_2 is nearly equal to T_1 at this temperature. When $T_1=T_2$, i.e., a rapid motional limit, T_1^{-1} (T_2^{-1}) of ^{17}O nucleus is given by[13]

$$T_1^{-1} = T_2^{-1} = (3/125)(1 + \eta^2/3)(e^2qQ/\hbar)^2\tau_c$$

where η is an asymetric parameter of the electrical field gradient around ^{17}O nucleus and is known to be negligibly small for bulk water molecule.[14] $e^2qQ/\hbar$ is the quadrupole coupling constant of ^{17}O nucleus and τ_c is the correlation time of water molecule. The $e^2qQ/\hbar$ value for both H_2O and D_2O have been reported to be 7.7±0.1 MHz at temperature from 5 to 95 °C.[6,7] Since the $e^2qQ/\hbar$ is expected to be independent of the salt concentration, change in relaxation times is attributed to alteration of τ_c. T_1 is larger than T_2* for D_2O samples and this may be attributed to the D–O scalar coupling, although its magnitude is modulated by the dynamic process of deuterium exchange.

Effect of Salt Concentration on the Line Width. The line width of ^{17}O NMR signal of D_2O is plotted against KCl concentration in Fig. 2. At 55 °C, the line width is independent of KCl concentration. At lower temperature (35 °C), the line width decreases with increasing KCl concentration and reaches a steady-state value (ca. 59 Hz). On the contrary, at higher temperature (75 °C), the line width increases with KCl concentration and reaches another steady-state value

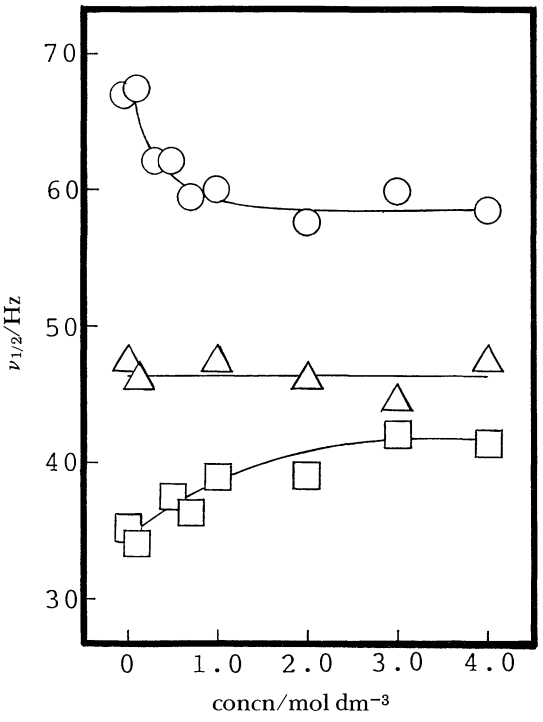

Fig. 2. Plot of the observed line width for the ^{17}O NMR resonance of D_2O against the concentration of KCl. 35 °C (○), 55 °C (△), and 75 °C (□).

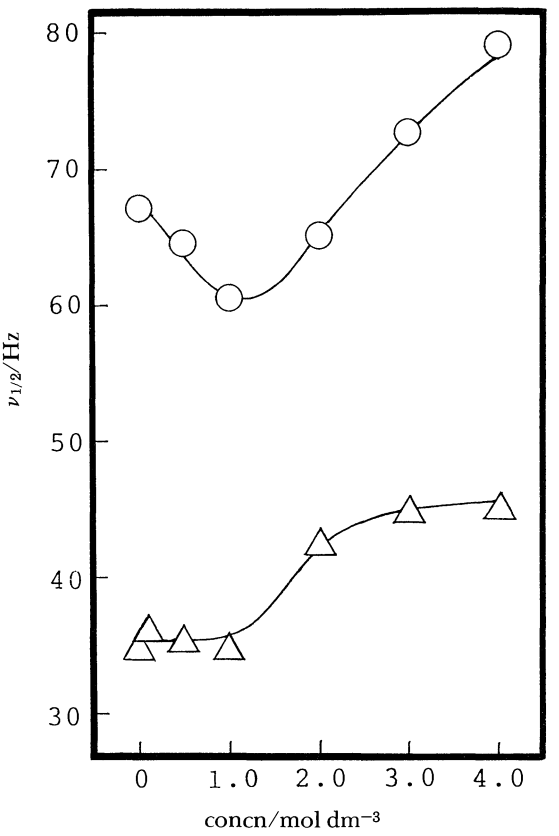

Fig. 3. Plot of the observed line width for the ^{17}O NMR resonance of D_2O against the concentration of NaCl. 35 °C (○), and 75 °C (△).

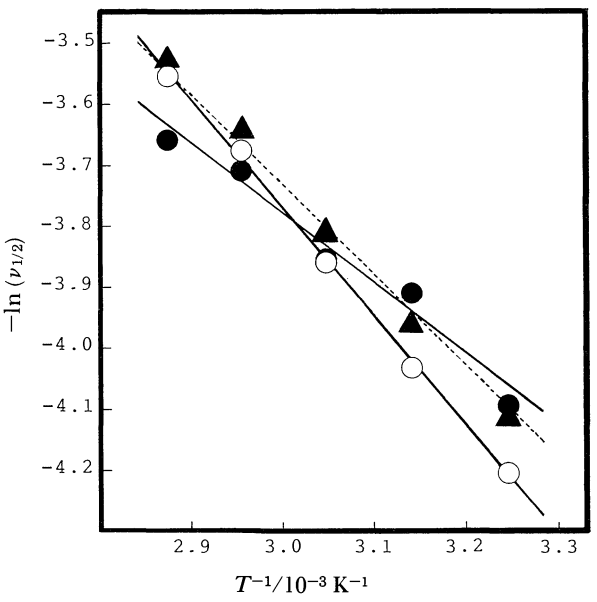

Fig. 4. Arrhenius plots for the observed line width of the ^{17}O NMR resonance of D_2O (○), D_2O containing 1.0 mol dm^{-3} of KCl (●), and NaCl (▲). The $\Delta E^{\neq}$ values determined from these plots are 10 (D_2O without salt), 15 (D_2O containing KCl), and 12 kJ mol^{-1} (D_2O containing NaCl).

(ca. 40 Hz). A similar plot for the D_2O solution containing NaCl is shown in Fig. 3. The line width of the signal at 75 °C seems to be independent of NaCl concentration below 1.0 mol dm^{-3}. But an anomalous behavior is observed above 1.0 mol dm^{-3}.

Effect of Temperature on the Line Width. Figure 4 shows the Arrhenius plots of the line width of the ^{17}O NMR signal for D_2O with and without salts in the temperature range from 35 to 75 °C. The Arrhenius plot for T_1 of ^{17}O NMR signal of water (from −14 to 180 °C) has shown to deviate from a straight line.[8] However, the plots in Fig. 4 exhibit straight lines in the temperature range studied. These two lines in Fig. 4 cross with each other at $3.0\times10^{-3}K^{-1}$ (ca. 55 °C), indicating that the line width decreases and increases below and above 55 °C, respectively, as discussed above. This result also confirms the KCl concentration independency of the line width at 55 °C. It has been reported from the ^1H NMR studies that K^+, Na^+, and Cl^- in H_2O act as water structure breaking ions at room temperature.[15] In Fig. 2, such an effect of KCl is clearly observed below 55 °C. On the contrary, above 55 °C, the increase of the line width by an addition of KCl is interpreted as an increase of τ_c, indicating that the added ions inhibit molecular motion of water, i.e., KCl acts as a water structure forming salt above 55 °C.

For NaCl solution, similar experiments were performed. The temperature where the Arrhenius plot for D_2O solution containing 1.0 mol dm^{-3} of NaCl crosses with that for D_2O is 2.9×10^{-3} K^{-1} (ca. 75 °C), reflecting that the line width is independent of NaCl concentration up to 1.0 mol dm^{-3}.

We are indebted to the central laboratry of Rengo Co., Ltd. for leaving A. Higashiyama to Tokyo Institute of Technology for this study.

(Received August 8, 1990)

Synopsis. Ultrasonic velocities of binary systems of water with 12-crown-4, 15-crown-5, and 18-crown-6 were measured and the adiabatic compressibilities were evaluated therefrom. The results indicate that the most compacted hydration structure is formed at the mole ratio, approximately 2:1, of water to oxyethylene monomer unit and that the poly(oxyethylene) chain enhances structuring of the liquid water network.

Structure of aqueous solutions of poly(oxyethylene) (POE) chains, $(-OCH_2CH_2-)_m$, is one of the important subjects in the fields not only of polymer chemistry but also of surface and colloid science, since the structural aspect of this chain is closely related to the size and shape of the micelles and the phase behavior of a number of nonionic surfactants that contain the POE chain as a hydrophilic moiety.[1] Kjellander and Florin[2] have previously discussed possible structure models for POE–water systems and indicated that water molecules form a highly linked network allowing the hydrocarbon groups to be reasonably encaged. In such a water network, hydrogen bonding between water molecules and ether oxygens of the POE chain plays an important role in forming the stable structure. Thus the hydration of the POE chain is a fundamental factor for understanding the network structure and its stability.

In an earlier study,[3] we have investigated the hydration of short model compounds of POE, namely $CH_3(OCH_2CH_2)_mOCH_3$ (m=1—4) and $CH_3(OCH_2CH_2)_m$-OH (m=2 and 3), by measuring hypersonic velocities in aqueous solutions of these compounds. This study showed that a specific hydration complex of approximately $2(H_2O):1(OCH_2CH_2)$ is formed, in agreement with the results by different experimental methods.[2,4] In the present work, we have extended the hydration study of the POE chain to cyclic oligo(oxyethylene) compounds, i.e., 1,4,7,10-tetraoxacyclododecane (12-crown-4), 1,4,7,10,13-pentaoxacyclopentadecane (15-crown-5), and 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6). In evaluating extent of hydration of the POE chain, the complexity arising from an effect of terminal groups is absent in these cyclic compounds, though there may be a possible steric effect associated with the limited conformational freedom of the ring molecules.

Experimental

The ultrasonic velocities in binary systems of water with 12-crown-4, 15-crown-5, and 18-crown-6 with various compositions were measured at 20.0±0.01 °C by the sing-around method with a model UVM-2 of Choompa Kogyo Co. at a frequency of 2 MHz. The densities of the solutions were also measured in order to evaluate the adiabatic compressibilities.

Results and Discussion

The adiabatic compressibilities, κ_S, were obtained by the relation

$$\kappa_S = 1/(\rho v^2), \quad (1)$$

where ρ is the density and v is the sound velocity in the binary mixtures. The adiabatic compressibilities obtained this way for the systems of water with the three crown ethers are shown in Fig. 1. The deviations, to be denoted by $\Delta\kappa_S$, of the observed κ_S values of the mixtures from the values based on the mole-fraction mixture law are given by

$$\Delta\kappa_S = \kappa_S - (x_1\kappa_{S1} + x_2\kappa_{S2}), \quad (2)$$

where κ_S is the observed adiabatic compressibility of the binary mixture, x_1 and x_2 are the mole fractions of the components 1 and 2 in the mixture, and κ_{S1} and κ_{S2} are the adiabatic compressibilities of the two pure components.

According to Fig. 1, the deviations $\Delta\kappa_S$ are always negative for the three systems, indicating that specific interactions exist between water molecules and POE chains. It is therefore highly suggestive of the formation of the intermolecular complexes between the crown ethers and water. The POE chain thus promotes structuring of the water network by forming hydrogen bonds between the ether oxygens and water. This implies that the ether oxygens of the POE chain are constituents of the structured water network. The close fit of the POE chain into the water lattice is geometrically favorable, since the closest oxygen–oxygen distance (0.28—0.30 nm) of POE[5] and 18-crown-6[6] with the gauche($O-CH_2-CH_2-O$) conformation is coincident with the oxygen–oxygen distance (0.285 nm) of liquid water at 25 °C.[7] Our conformational studies of POE[8] and 18-crown-6[9] have in fact indicated that these molecules in aqueous solutions much more prefer the gauche($O-CH_2-CH_2-O$) conformation with more dilution with water than the trans conformation. This consideration strongly suggests the effective incorporation of the ether oxygens of the POE chain into the structured water network around the chain. The hydrophobic CH_2CH_2 groups of the POE chain then fill out the interstitial voids of the

†† Address after October 1991: Department of Chemistry, Faculty of Science, Hiroshima University, Kagamiyama, Higashi-Hiroshima 724.

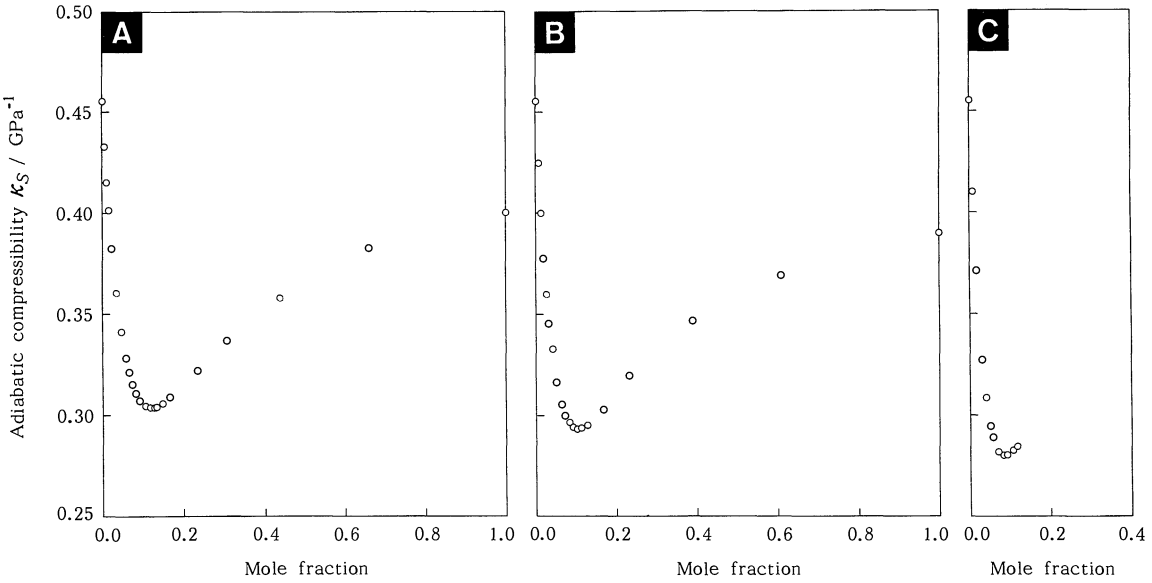

Fig. 1. Adiabatic compressibilities of the binary systems; A: water–12-crown-4, B: water–15-crown-5, and C: water–18-crown-6. Mole fraction for abscissa implies that of the crown ether. Since the water–18-crown-6 system with a large fraction of 18-crown-6 is solid at 20°C, no measurements were possible of the compressibilities in the liquid state for high concentrations.

water network, resulting in the formation of more compacted structure than the liquid structure of pure water or of the oxyethylene compounds. The observed negative values of $\Delta\kappa_S$ are thus elucidated by a model of the structured water network with the hydrophobic groups encaged.[2]

Figure 1 indicates that the absolute values of $\Delta\kappa_S$ are the largest at mole fractions of 0.113 for 12-crown-4, 0.095 for 15-crown-5, and 0.082 for 18-crown-6; the corresponding mole ratios of water to crown ether and those converted to water to oxyethylene monomer unit are shown in Table 1. The present experimental findings indicate that the most compacted hydration structure is formed at the mole ratio of approximately $2(H_2O):1(OCH_2CH_2)$ between water and the POE chain. For the compositions with more water molecules than this, the compressibility of the whole liquid mixture is increased owing to the structure of the excess bulk water, which contains a large fraction of interstitial space.[7] In more concentrated solutions than the mole ratio 2:1, on the other hand, the highly structured water network is partially broken with insufficient proton donors available to the ether oxygens of the POE chain.[2] The number of water molecules per oxyethylene unit for the most compacted hydration structure is essentially the same for the three crown ethers irrespective of the size of the POE ring. It is suggested therefore that a possible steric effect on the hydration arising from the limited conformational freedom of the ring molecule is substantially negligible.

The present work has indicated that the interstitial space of the water network is filled completely with the hydrophobic group of the POE chain with two water molecules per oxyethylene monomer unit. This result is consistent with the generally accepted hydration structure of the POE chain with two water molecules per oxyethylene unit.[2–4] A previous NMR study[10] showed, however, that three molecules of water were required for the hydration of each oxyethylene unit, but a later reexamination[4] has pointed out that the number of water molecules per oxyethylene unit is actually close to two instead of three. A recent infrared study[11] has indicated the presence of three different hydration complexes with water to oxyethylene mole ratios of 4:1, 2:1, and 1:1. The present and previous[3] studies on the cyclic and open-chain oligo(oxyethylene) compounds have demonstrated that, of these possible complexes, the 2:1 complex gives rise to the least compressible or the most elastic structure with the oxyethylene ether oxygens incorporated into the water lattice. In conclusion, the POE chain, whether it is cyclic or open-chain, enhances structuring of the liquid water network.

Table 1. Mole Ratios, at Which the Absolute Values of $\Delta\kappa_S$ are the Largest, for the Binary Systems of Water with 12-Crown-4, 15-Crown-5, and 18-Crown-6

Binary system	Mole ratios	
	H_2O:Crown ether	H_2O:OCH_2CH_2[a]
Water–12-crown-4	7.8:1	1.96:1
Water–15-crown-5	9.5:1	1.91:1
Water–18-crown-6	11.2:1	1.87:1

a) The estimated uncertainty in the number of water molecules per oxyethylene unit is ±0.1.

Surface Active Properties of Heptyl β-D-Xyloside Synthesized by Utilizing the Transxylosyl Activity of β-Xylosidase

Hirofumi SHINOYAMA,*,† Yasuo GAMA, Hisae NAKAHARA, Yutaka ISHIGAMI, and Tsuneo YASUI††
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305

(Received August 27, 1990)

Synopsis. The surface-active properties of heptyl β-D-xyloside were investigated. The critical micelle concentration of this surfactant was determined to be 30 mM (M=mol dm^{-3}). The corresponding molecular area at saturation adsorption, the micellar weight and the aggregation number were 43 Å, 20700 and 78, respectively. This surfactant was found to have a surface activity similar to that of octyl β-D-glucoside.

The nonionic surfactants, octyl β-D-glucoside (octyl glucoside), heptyl β-D-thioglucoside (heptyl thioglucoside), sucrose monodecanoate, etc., are being increasingly utilized for solubilization, reconstitution of biological membranes and the preparation of lipid vesicles.[1–7] Based on a similar point of view, we have developed a new enzymatic process to synthesize alkyl β-D-xyloside homologues by utilizing the transxylosyl activity of *Aspergillus niger* β-xylosidase.[8,9] In the present studies, the authors have tried clarify the relation between the surface activity and the hydrophile-lipophile balance of alkyl β-D-xyloside molecules, such as heptyl β-D-xyloside (heptyl xyloside). The results were compared with other detergents, such as octyl glucoside and heptyl β-D-glucoside (heptyl glucoside).

The homologues of heptyl xyloside[9] were synthesized as previously described. All other chemicals used were of the highest grade commercially available. Two typical methods were employed to determine the critical micelle concentration (cmc) of heptyl xyloside. In the first procedure the effect of the detergent concentration on the fluorescence intensity of solubilized ANS (8-anilino-1-naphthalenesulfonic acid) was measured at 50 °C. In the second procedure, cmc was determined from a break in the surface tension vs. concentration curve, as measured by Shimadzu Surface Tensiometer ST-1 at 50 °C. Light-scattering measurements were also carried out in order to estimate the micellar size at 40 °C with a wavelength of 633 nm, using a light-scattering photometer (Ootsuka Photoelectric Co. DLS-700). Scattered light was observed at 90 degrees relative to the incident beam.

Figure 1(A) shows a sudden rise of the fluorescence intensity of solubilized ANS at concentrations of heptyl xyloside higher than 30 mM, while a break appeared at 22 mM for octyl glucoside and 67 mM for heptyl glucoside. Surface tension-log concentration curves are shown in Fig. 1(B). The inflection (30 mM) in the curve corresponds to the cmc of the surfactant.[10] Thus, the two results agreed very well, and the cmc of heptyl xyloside was determined to be 30 mM. This value was higher than those obtained for sucrose monodecanoate, triton X-100 and SDS, and was similar to that for octyl glucoside (Table 1).

From the slope of the curve in Fig. 1(B), the surface

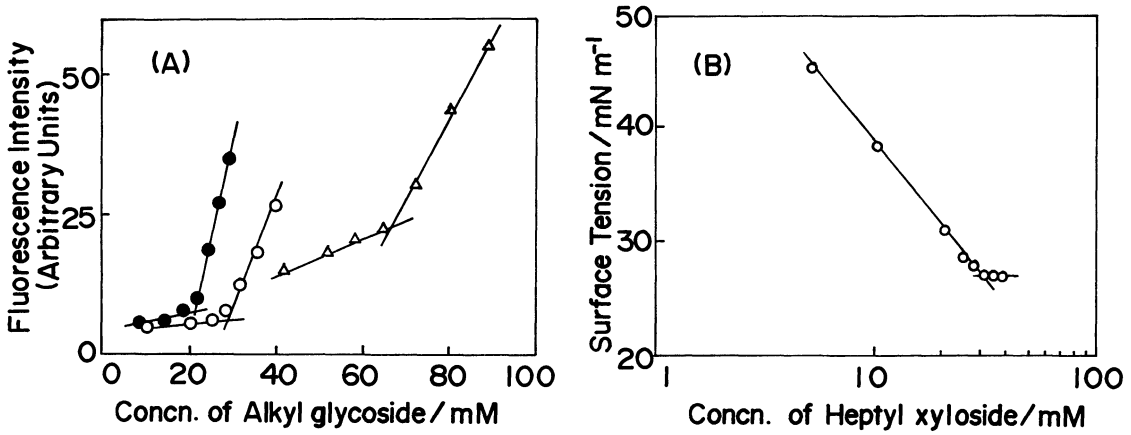

Fig. 1. Determination of cmc of heptyl xyloside. (A): Assay mixture (2.0 ml) contained 10 μM ANS and various concentrations of surfactants. Fluorescence intensity of ANS was measured at excitation wavelength of 345 nm and emission wavelength of 480 nm. (○), heptyl xyloside; (△), heptyl glucoside; (●), octyl glucoside. Table 1. Surface Active Properties of Alkyl Glycosides and Some Other Surfactants

Surfactants	cmc/mM	A/Å	Micellar wt. (Agg. Numbr.)
Heptyl xyloside	30	43	20700 (78)
Octyl glucoside	22	41**[10]	25800**[11] (87)
Sucrose monodecanoate	2.52**[5]	—	10500**[5] (22)
Triton X-100	0.25**[12]	52.4**[12]	63000**[12] (100)
SDS	8.1**[13]	45**[13]	23000**[14] (80)

**, From literatures.

excess (Γ) at saturation adsorption and the corresponding molecular area (A) were calculated by applying Gibbs adsorption isotherm, $\Gamma=-(1/RT)(\partial\gamma/\partial \ln C)_T$, where the notations used have their usual meanings. The obtained results are listed in Table 1. The A values of heptyl xyloside and octyl glucoside are almost the same. The micellar weight and the aggregation number, as obtained from light-scattering measurements for heptyl xyloside, are 20,700 and 78, respectively, which are comparable to the values for octyl glucoside (Table 1). This suggests that these compounds are similar in nature.

Among the surfactants currently used in membrane biochemistry, octyl glucoside is an excellent one[1] and has been used for the extraction and purification of the lactose carrier of *Escherichia coli*,[2] as well as for the preparation of lipid vesicles.[7] The above-mentioned applicability of heptyl xyloside to membrane biochemistry will be tested in a follow-up study. The xylose group of alkyl xyloside seems to show a fundamental difference in its properties from that of glucose in alkyl glucoside. Namely, heptyl xyloside has a Krafft point of 33.7 °C, whereas the heptyl glucoside does not show a Krafft temperature phenomena. The difference in the hydration of these compounds may cause these characteristics. A further comparison should also be made regarding the xylose and glucose groups in various glycoside.

This work was supported in part by a Grant-in-Aid for Encouragement of Young Scientists No. 01790450 from the Ministry of Education, Science and Culture.

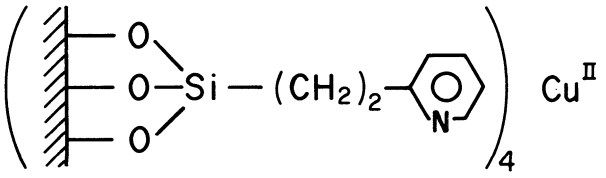
Oxidative Dimerization of 1-Propyne on a 2-Pyridylethyl Copper Complex Fixed Silica Catalyst

Yuji UKISU,*,†† Akio KAZUSAKA,*,††† and Masaharu NOMURA†
Catalysis Research Center, Hokkaido University, Supporo 060
† Photon Factory, National Laboratory for High Energy Physics, Tsukuba, Ibaraki 305
(Received August 29, 1990)

Synopsis. A 2-pyridylethyl copper complex fixed silica catalyst was applied to an oxidative-coupling dimerization reaction of 1-propyne to 2,4-hexadiyne at 100 °C, which is a typical test reaction for Cu–(N base)-complex catalyst in the homogeneous phase. It was found to be highly catalytically active for this reaction compared with a conventional CuO/SiO_2 catalyst. The reaction was deduced to proceed through a redox cycle of copper ions coordinated with the pyridine derivative.

In the presence of pyridine, CuCl has proved to be catalytically active for homogeneous oxidative-coupling reactions of acetylenes,[1] aromatic amines,[2] or phenols.[3] In a previous paper we reported the preparation and spectroscopic characterization of a novel silica-fixed copper catalyst, in which each copper ion is coordinated with four pyridine moietyies of 2-pyridylethyl group fixed on silica as:



and which was denoted as Cu–Py–SiO_2. Such copper ions were also subject to an easy reversible redox reaction under vacuum at 200 °C or with molecular oxygen.[4]

The present paper is concerned with the application of this catalyst to a heterogeneous oxidative-coupling reaction of 1-propyne, which is a typical test reaction for a Cu–(N base)-complex catalyst in the homogeneous phase, and gives a comparison of its catalytic nature with that of a conventional CuO/SiO_2 catalyst.

Experimental

The Cu–Py–SiO_2 catalyst (1.3 wt% of Cu) was prepared and characterized spectroscopically as described in a previous paper.[4] It was used after outgassing at 200 °C for 1 h and successive activation under an O_2 atmosphere at room temperature for 24 h. For a comparison, a conventional silica-supported copper catalyst (2.6 wt% of Cu) was used, which was prepared from a tetraamminecopper complex ($[Cu^{II}(NH_3)_4]$) by an ion-exchange method, and calcined with O_2 at 300 °C.[5]

A conventional closed recirculating reactor (0.7 l volume) was employed for the catalytic oxidative-coupling reaction of 1-propyne. The partial pressure of 1-propyne, O_2 or CO_2 was monitored with an on-line gas chromatograph. Analysis of the reaction product, 2,4-hexadiyne, was carried out with a Hitachi RMU-6 mass spectrometer.

The states of copper ions were monitored using an ESR or XANES (X-Ray Absorption Near-Edge Structure) spectroscopic technique. ESR spectra were obtained with a Varian E-4 spectrometer at a frequency of 9 GHz. The g-values were calculated relative to DPPH as a standard (g=2.0036). XANES spectra were measured in the transmission mode at the BL10B station of the photon Factory using sychrotron radiation from the 2.5 GeV electron storage ring.[6]

The O_2 or 1-propyne gas was of high-purity grade from Takachiho Kagaku Kogyo and was used without further purification.

Results and Discussion

Figure 1A shows the time course of the reaction between 1-propyne and O_2 on Cu–Py–SiO_2 at 100 °C. Each reactant decreased monotonously at a ratio of 4–1, respectively, indicating that this reaction proceeded catalytically within the reaction times. The 2,4-hexadiyne has found by mass spectroscopy to be

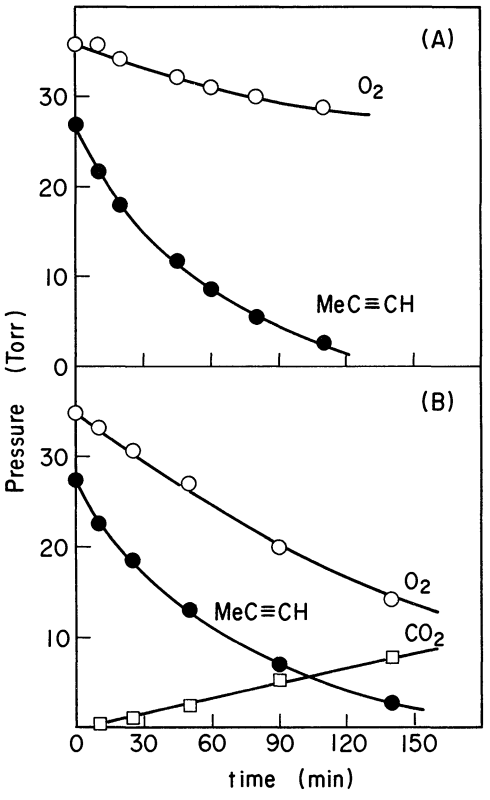


Fig. 1. Time course of reaction between 1-propyne and oxygen. (A) Cu–Py–SiO_2 at 100 °C; (●): 1-propyne; (○): O_2, (B) CuO/SiO_2 at 200 °C; (●): 1-propyne; (○): O_2; (□): CO_2.

††† Present address: Faculty of Veterinary Medicine, Hokkaido University, Sappro 060.

the main product derived from the dimerization of 1-propyne, though its amount could not be followed quantitatively because of its low vapor pressure. Neither CO_2 nor CO was detected. Therefore, the following reaction stoichiometry can be proposed:

$$2\ CH_3\text{-}C{\equiv}C\text{-}H + 1/2\ O_2 \longrightarrow CH_3\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}CH_3 + H_2O. \quad (1)$$

The activity of the CuO/SiO_2 catalyst, on the other hand, was too low to follow the reaction at 100 °C, indicating that Cu–Py–SiO_2 is specifically effective for this reaction. Fig. 1B shows the time course at 200 °C on CuO/SiO_2. As can be seen from these results, the kinetic behavior was different from that on Cu–Py–SiO_2. CO_2 was detected as one of the reaction products in addition to 2,4-hexadiyne, showing that a complete oxidation of 1-propyne proceeded other than by dimerization as:

$$CH_3\text{-}C{\equiv}C\text{-}H + 4\ O_2 \longrightarrow 3\ CO_2 + 2\ H_2O. \quad (2)$$

The Cu–Py–SiO_2 catalyst activated under an O_2 atmosphere had a dark-green color, and exhibited an ESR signal with parameters of $g_{//}$=2.24, $g_{\perp}$=2.04, $A_{//}$=170 G and A_N=15 G (Fig.2a); these are characteristic of Cu(II) ions. When the sample was exposed to 100 Torr of 1-propyne at 100 °C for 3 h (1 Torr= 133.322 Pa), it turned to a gray color and the ESR signal showed a considerably weakened intensity (Fig. 2B), indicating that 1-propyne reduced a large part of the Cu(II) ions on the catalyst. When the sample was exposed again to 100 Torr of O_2 at 50 °C after outgassing at room temperature, it turned back to a dark-green color and restored the ESR signal completely in its intensity (Fig. 2C). The copper ions were oxidized again under these conditions. This redox cycle was confirmed to be reversible by repeating the above-mentioned experiment several times.

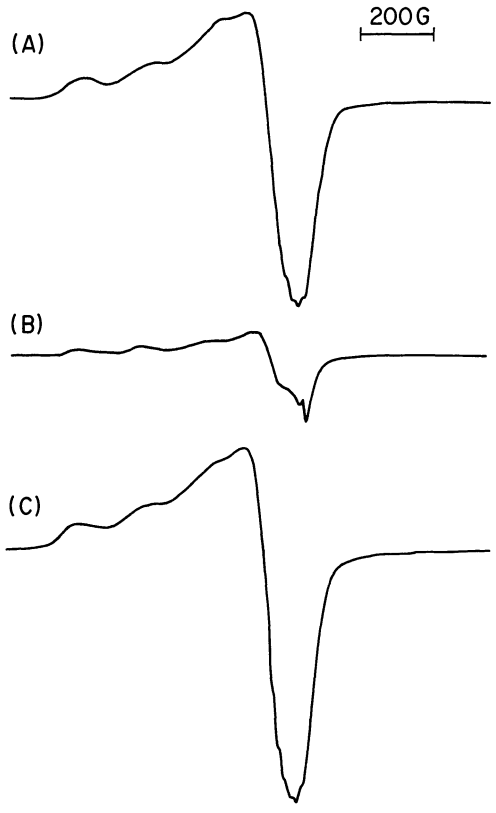

Fig. 2. ESR spectra of Cu–Py–SiO_2. (A) after activation under O_2 atmosphere, (B) after exposure to 100 Torr of 1-propyne at 100 °C for 3 h, (C) after exposure to 100 Torr of O_2 at 50 °C overnight after outgassing at room temperature. Spectra were observed at room temperature.

Such an easy reversible redox behavior was not observed for CuO/SiO_2 upon exposure to either 1-propyne or O_2. Therefore, this must be related to the low catalytic activity of CuO/SiO_2 for the above-mentioned reaction.

The following reaction mechanism has been suggested for the oxidative-coupling reaction of acetylenes in an aqueous alkaline solution,[1]

$$2\ R\text{-}C{\equiv}C\text{-}H \longrightarrow 2\ R\text{-}C{\equiv}C^- + 2\ H^+ \quad (3)$$

$$2\ R\text{-}C{\equiv}C^- + 2\ Cu^{2+} \longrightarrow 2\ R\text{-}C{\equiv}C\cdot + 2\ Cu^+ \quad (4)$$

and

$$2\ R\text{-}C{\equiv}C\cdot \longrightarrow R\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}R, \quad (5)$$

and from (3) + (4) + (5)

$$2\ R\text{-}C{\equiv}C\text{-}H + 2\ Cu^{2+} \longrightarrow R\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}R + 2\ H^+ + 2\ Cu^+. \quad (6)$$

Here, the first step consists of the ionization of acetylenic compounds, the second one is a single-electron transfer from ethynyl anions to Cu(II) ions to lead the formation of ethynyl radicals, and the last one is the dimerization of ethynyl radicals.

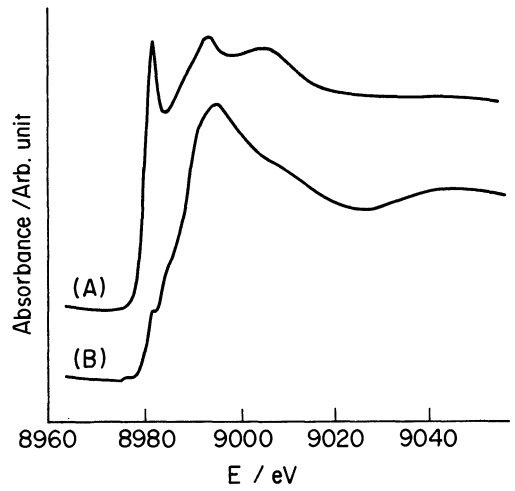

Fig. 3. XANES spectra of Cu–Py–SiO_2. (A) reduction by outgassing at 200 °C for 1 h, (B) exposure to 100 Torr of O_2 at room temperature for 24 h after observing spectrum (B).

The copper ions in Cu–Py–SiO_2 were found to be easily reduced with 1-propyne or to be oxidized with O_2, as described previously. Furthermore 1-propyne and O_2 were found to be decreased at a 4–1 ratio, as previously expressed by the stoichiometry of (1). These facts seem to indicate that the above reaction mechanism is also operative on the Cu–Py–SiO_2 catalyst, even though ethynyl radicals could not be detected by ESR spectroscopy.

Thus, the copper–pyridine derivative complex fixed on silica was proved to be active for the catalytic oxidative-coupling reaction of 1-propyne, in which the redox cycle of copper ions plays an important role.

Finally, the redox process of Cu–Py–SiO_2 was studied using XANES spectroscopy, which is usefull in distinguishing the oxidation state of copper ions; Cu(0), Cu(I) or Cu(II). In Fig.3 are shown the Cu–K edge XANES spectra of the sample. In its oxidized form, a small peak was observed around 8976 eV, which is due to the 1s→3d transition and is characteristic of Cu(II) ions. The sample which was outgassed at 200 °C, on the other hand, exhibited a quite different spectrum: the 8976 eV peak disappeared and a more intense one was observed around 8982 eV, which is due to 1s→4pπ transition and is characteristic of Cu(I) complex with a small coordination number.[7]

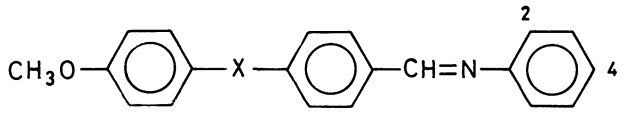
Effects of Lateral Substituents on the Mesomorphic Properties of *N*-[4-(4-Methoxybenzoyloxy)benzylidene]aniline and Its Isomeric Compound

Hiroyuki HASEGAWA, Yoshio MATSUNAGA,* and Nobuhiko MIYAJIMA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received September 27, 1990)

Synopsis. The nematic phases exhibited by the title compounds carrying a hydroxyl or cyano group at the 2-position of the aniline moiety are thermally more stable than expected on the basis of the relationship between the nematic–isotropic transition temperature of the corresponding halogeno derivatives and the van der Waals volume of the substituents.

The effects of lateral substituents on the mesomorphic properties have been the subject of extensive studies by many workers.[1] For example, Gray et al. examined the thermal behavior of 4-[(4-alkoxybenzylidene)amino]biphenyls and 4,4′-bis[(4-alkoxybenzylidene)amino]biphenyls with methyl or halogeno-substituents in the 2-position of the biphenyl core, and showed that both the smectic–nematic and the nematic–isotropic transition temperatures decrease smoothly with increasing the molecular breadth.[2,3] Moreover, Osman's recent work on 1,4-bis(4-*trans*-pentylcyclohexyl)benzenes revealed that all of the nematic–isotropic transition temperatures lie on a smooth curve when the temperature is plotted against the van der Waals volume of the lateral substituent.[4] The substituents employed by the latter author were halogens and methyl as well as cyano groups.

However, experience has shown that the effects of a substituent on the mesomorphic properties vary with the type of parent system, and also that a steric factor cannot account for all of the observed effects regarding terminal substituents; therefore, the above-mentioned relationship may not hold for other types of compounds. Indeed, we found that the nematic–isotropic transition temperatures of *N*-[4-(4-methoxybenzoyloxy)-benzylidene]-2-hydroxy and 2-cyanoanilines (**1**) deviate appreciably from a smooth curve constructed by those of the corresponding halogeno derivatives. Similarly, marked deviations were also observed with a series of isomeric compounds, 4-methoxyphenyl 4-[4-(2-substituted phenyliminomethyl)]benzoates (**2**).



(**1**) X = -CO-O- (**2**) X = -O-CO-.

Experimental

The Schiff bases were prepared and then esterification was carried out, following the procedure of Hassner and Alexanian, to obtain the desired compounds.[5] Microscopic and calorimetric examinations were made, as described in a previous paper.[6]

Results and Discussion

The van der Waals volumes of substituents at the 2- or 4-position of the aniline moiety, the transition temperatures, and the associated enthalpy changes of compounds **1** and **2** are presented in Tables 1 and 2, respectively. For a comparison, the corresponding 4-substituted compounds were included in our examination. All of the van der Waals volumes of the substituents were taken from Bondi's work, except for that of the hydrogen atom (0.7 $cm^3\ mol^{-1}$), which was calculated concerning the basis of a van der Waals radius of hydrogen of 0.100 nm, a C–H bond length of 0.110 nm, and a van der Waals radius of carbon of 0.170 nm.[7] Here, K, N, and I stand for the crystalline, nematic, and isotropic liquid phases, respectively.

As is shown in Fig. 1, plots of the N–I transition temperature of the parent compounds and their 2-halogeno derivatives against the van der Waals volume of the substituent give smooth curves. The curve for series 1 is slightly concave upwards, whereas the curve for series 2 is slightly convex upwards. Contrary to what has been reported for the above-mentioned cases, the transition temperatures of the hydroxy and cyano derivatives in the present series deviate markedly from a smooth relationship.

In the case of *N*-(2-hydroxy-4-methoxybenzylidene)-4-butylaniline, the hydroxyl group does not exert its

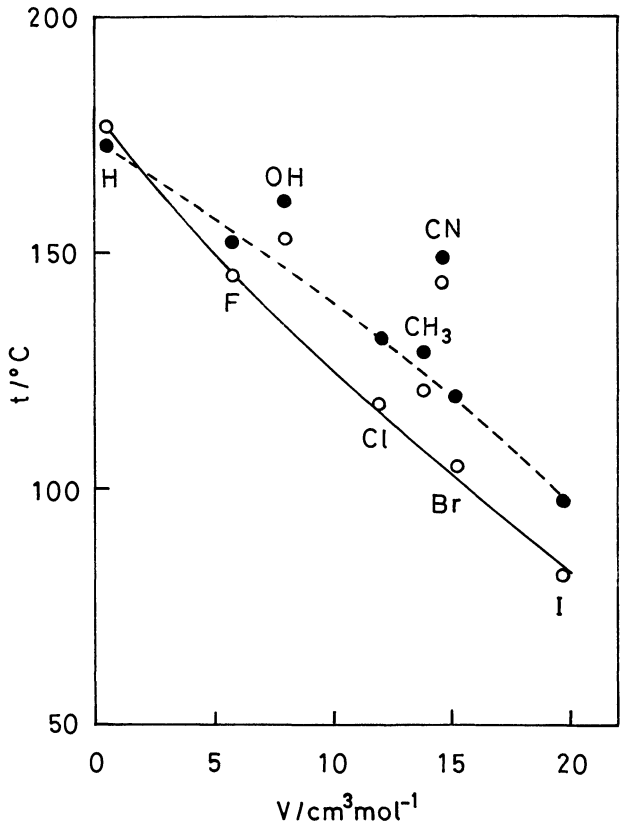

Fig. 1. Plots of the N–I transition temperature of compounds **1** (○) and of compounds **2** (●) against the van der Waals volume of substituents at the 2-position.

full breadth effect, and gives rise to an enhancement of the N–I transition temperature because it is held in the *cis*-position through intramolecular hydrogen bonding.[9] Similarly, we found that the transition temperatures of 4-(2-hydroxybenzylideneamino)phenyl 4-methoxybenzoate (193 °C) and 4-methoxyphenyl 4-(2-hydroxybenzylideneamino)benzoate (181 °C), which are isomeric with compounds **1** and **2**, are higher than those of their parent compounds (171 °C and 159 °C, respectively). For the 2-hydroxy derivatives of the present series too, an intramolecular hydrogen bonding is conceivable but stabilization of the nematic phase is clearly less significant. The same group at the 4-position is subject to intermolecular hydrogen bonding and gives rise to a promotion of the mesophase if the structural criteria for liquid crystallinity are satisfied.[10,11] The present 4-hydroxy derivative gives the highest, or the second-highest, N–I transition temperature in each series.

The terminal cyano group is well-known to give rise to an antiparallel correlation of molecular dipoles, which often results in higher N–I transition temperatures than with a comparable nonpolar substituent. As a matter of fact, the 4-cyano derivative gives the highest clearing point among compounds **1**, but the fourth among compounds **2**. The deviation of the N–I transition temperature from a smooth curve suggests that dipolar attractive forces due to a lateral cyano group cannot be ignored compared with dispersive forces in influencing the nematic thermal stability of our compounds.

A relatively small deviation of the N–I transition temperature of the methyl derivative in series 1 from a smooth curve cannot be ascribed to dipolar attractive forces and remains to be clarified.

The effects of terminal substituents on the mesomorphic behavior are certainly not simple. For example, even in the case of halogeno derivatives the nematic thermal stability increases in the order F, I, Br, Cl and cannot be explained in terms of either molecular length or van der Waals volume. It is likely that all of the factors applicable to the terminal substituents should, more or less, be considered for the lateral substituents. Apparently, the simple relationship reported by previous authors does not provide a general interpretation of the effects of lateral substituents on the N–I transition temperatures.

Synthesis and Reaction of *trans*-Dichlorobis(*o*-phenylenediamine)rhodium(III) Perchlorate with Some Oxidizing Agents

Akiko FURUHASHI,* Kunihiko ENDO, Shiro TAKAGI, and Yukichi YOSHINO
Department of Chemistry, Aoyama Gakuin University, 1-1 Morinosato-Aoyama, Atsugi 243-01
(Received May 18, 1990)

Synopsis. A new rhodium(III) complex with *o*-phenylenediamine, *trans*-$[RhCl_2\{C_6H_4(NH_2)_2\}_2]ClO_4$ was synthesized and the reaction with oxidizing agents studied. Due to coordination with the rhodium(III) ion the *o*-phenylenediamine (opd) was greatly stabilized against oxidation and the complex was oxidized slowly by periodate via intermediate radical complex to bis(*o*-benzoquinone diimine)-dichlororhodium(III) complex which decomposed to the final products.

A number of kinetic studies on the acid or base hydrolysis of various cationic rhodium(III)–amine complexes have been reported.[1–5] Even though *o*-phenylenediamine has the same bidentate function (–N–C–C–N–) as such compounds as ethylenediamine, there has been no report either on the synthesis or on the reactions of rhodium(III) complexes with *o*-phenylenediamine. The reason for this may be that the diamine possibly is oxidized by some oxidizing agents or even by the air and forms 2,4-hexadienedinitrile in the presence of some metal ions which can act as a catalyst for the oxidation reaction.[6–8] In other cases, synthesized metal complexes contain the oxidized state of the amine, *o*-benzoquinonediimine.[9,10] However, many stable complexes of bivalent metal ions such as nickel, cobalt, and so on, with opd have been reported.[11,12]

The authors tried to react rhodium(III) ion with opd in an atmosphere of nitrogen gas, and obtained the new title complex, then the oxidation process of the complex was investigated by means of spectrophotometry. Analysis of the reaction mechanism proved to be extremely difficult in the higher pH region (above 6.5) owing to the rapid and simultaneous oxidation of the coordinated diamine and the base hydrolysis of the complex. For this reason the reaction of the complex with oxidizing agents in the pH region from 5.4 to 6.2 have been focused upon.

In the pH range, reactions appeared to proceed via three steps. These may be looked upon as oxidation of the coordinated opd in the first two steps, then decomposition of the complex in the third step.

Experimental

Synthesis of The Complex. Rhodium(III) chloride trihydrate (1.5 g, 5.7 mmol) and opd (1.8 g, 17 mmol) were dissolved into hot water which had been deaerated by boiling (50 ml). The solution was then refluxed for 5 h under nitrogen gas flow. At the initial step, whitish yellow precipitate formed, but it disappeared with continuing reflux and the solution became clear and yellowish red in color. Then by adding about 5 ml of 70% perchloric acid into the hot solution, yellow crystals were obtained. The collected crystals were recrystallized repeatedly using minimal amounts of hot water.

Analysis. Found: C, 29.14; H, 3.27; N, 11.44; Cl, 21.74%. Calcd for $RhC_{12}H_{16}O_4N_4Cl_3$; C, 29.44; H, 3.29; N, 11.45; Cl, 21.73%.

Reaction Studies. The reactions were studied by measuring absorbance changes in the electronic spectra in the range from 200 to 700 nm using a Shimadzu UV-240 spectrophotometer on solutions containing 10^{-4} mol dm^{-3} of the complex in the presence of 2.12—7.1-fold excess of potassium periodate (KIO_4) as an oxidizing agent. The pH values were adjusted with acetic acid–sodium acetate buffer solutions in the range from pH 5.4 to 6.2, and the ionic strength was set at 0.3 mol dm^{-3} by using sodium perchlorate. The temperature of the solutions was controlled with an electric thermocontroller in the range of ±0.1 °C.

Results and Discussion

The spectra of the complex in aqueous solution showed a peak at 403 nm ($\log \varepsilon$=2.17) which is typical of the dichlorobis(diamine) type complex ion in a trans form.[1–5]

The spectral change of the complex solution containing potassium periodate at pH 5.85 at 50 °C is shown in Fig. 1. The increase in the absorbance at 420 nm is first order with respect to Rh(III)–opd complex in the first stage, and this may be due to oxidation of the coordinated opd when compared with the spectral change of the solution containing free opd and potassium periodate. The increase in the absorbance could be stopped by addition of hydroxylamine hydrochloride. When free opd was oxidized, formation of the radical was proved by measurements of the ESR spectra for the same solution as was used for the spectral measurements. In this case ESR spectra showed the presence of the radical and the signal disappeared with time. This change in the same as the change of the spectra at 420 nm: At 420 nm, the absorbance increased with time to a maximum, after which it steadily declined.

On the other hand, the increase in the absorbance with time at 420 nm for the complex solution with KIO_4 was much slower than that for the solution containing free opd and KIO_4, indicating the opd must be much resist to oxidation by coordination to the rhodium (k_{obsd} for opd is times greater than that for Rh–opd complex). In this case, ESR spectra did not show the presence of the radical even though the pattern of the spectral change at 420 nm was the same as opd oxidation.

It is assumed that the reaction of Rh(III)–opd with KIO_4 is initiated by a slow loss of an electron from the nitrogen atom of an opd ligand yielding an intermediate short-lived radical complex, $[RhCl_2(opd)(opd^+)]^{2+}$.[13,14] This may be followed by a rapid

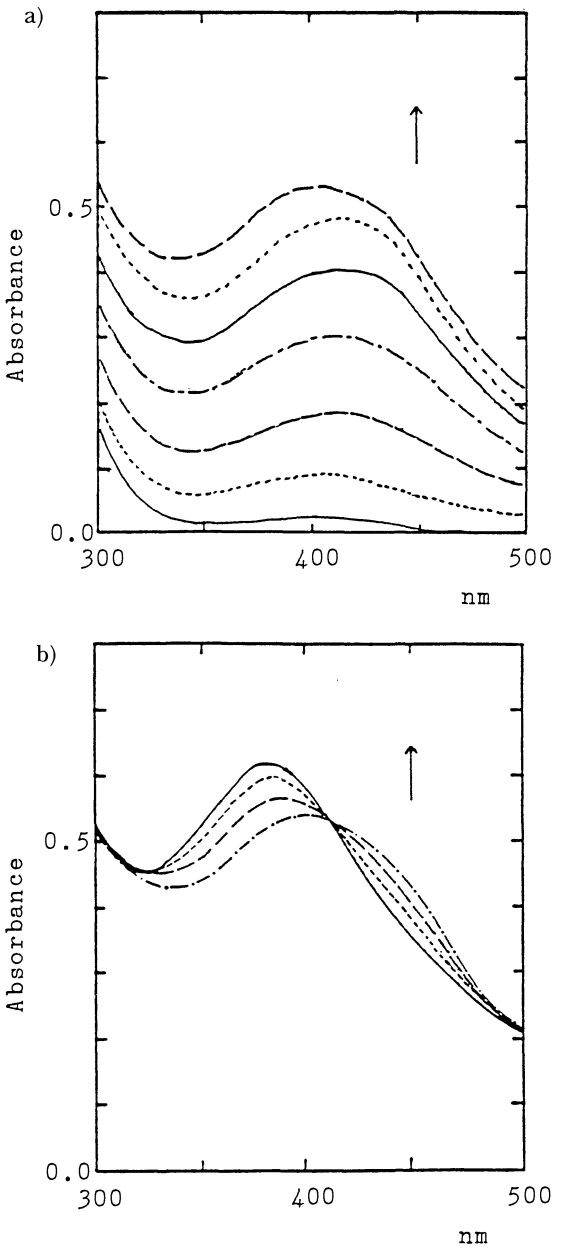

Fig. 1. The spectral change of the complex solution (1.23×10^{-4} M) containing potassium periodate (8.73×10^{-4} M) at pH 5.85 and 50 °C. (M=mol dm^{-3}). (a) From the start (bottom), curves show 20 min. intervals up to 120 min. b) From 130 min. to 180 min. 130 min. 140 min. 150 min. 180 min.

electron loss at another opd ligand in trans position thus forming $[RhCl_2(opd^+)_2]^{3+}$ (420 nm). In this intermediate radical complex, there may be two spin-coupled opd^+ radical ions coordinated to Rh(III) in trans-position, forming a diamagnetic complex as in the case of oxidation of the $Ni(opd)_2$ complex ion.[15]

As seen in Fig. 1, after the absorbance at 420 nm approached maximum, the spectra changed showing a new peak at 387 nm with an isosbestic point at 412 nm. In this stage, the color of the solution remained yellow. This step is assumed to be caused by the change of the coordinated opd radical. And this change was zeroth-order with respect to Rh(III)–opd complex. During these oxidation reactions, there may not be significant hydrolysis of the complex itself because the complex solution without the oxidizing agent showed only slight change in this pH region. This second peak at 387 nm, did not appear when free opd was oxidized. That means the second step of oxidation of opd produce a stable state only when opd is coordinated to the rhodium ion. At the last stage, the color of the solution gradually changed from yellow to dark red, implying the formation of *o*-benzoquinonediimine.[9,10,13,15,16] Then the absorbance at 387 nm decreased slowly, and finally an almost black precipitate was formed. The precipitate is thought to be a decomposed and polymerized form of the complex.

The process depends on the pH of the solution. The lower the pH, the slower the reaction rate. However, at pH 6.76, the spectral change is too complicated to analyze, indicating that overlapping of steps must occur at the same time, along with hydrolysis. In such higher pH ranges the absorbance of the peak at 420 nm decreased soon after it reached the maximum without the peak at 387 nm which was seen in the lower pH region.

The processes of the spectral change can be tentatively put as Rh–opd→A (step 1), A→B (step 2), and B→decomposed products (step 3). The examination of the effect of mole ratio of KIO_4 to the complex in the solution revealed that the higher the mole ratio KIO_4/Rh(III)–opd was, the faster the absorbance at 420 nm increased; however, the mole ratio did not much affect the rate of the step-2 change.

The absorption peak at 387 nm also can be observed with an aqueous solution of the complex which contains no other materials (buffer, $NaClO_4$ for adjusting of ionic strength, and KIO_4), although the change is too slow to follow the process quantitatively (it takes one month or more). Being such a slow process, the complex is undoubtedly oxidized even by the air.

Plots of log [A] vs. time in the step 1 change and plots of [B] vs. time in step 2 result in straight lines. From the slopes, pseudo-first-order rate constant, k^A_{obsd}, and zeroth-order rate constant, k^B_{obsd}, were evaluated. And from the Arrhenous plots, activation energies were also obtained for three different pH values. The results are shown in Table 1, and dependence of the observed rate constants on the concentration of periodate at 60 °C are given in Table 2.

The effects of other oxidizing reagents were investigated. In the case of NaClO, the previously mentioned two peaks at 420 and 387 nm could be observed, but there was no equilibrium between step 1 and step 2. $KMnO_4$ was also examined, but no fruitful results were obtained. At this time, only KIO_4 has given such quantitative results.

The same experiments were done with other Rh(III) complexes with diamines such as ethylenediamine and *cis*-1,2-cyclohexanediamine. However, similar spectral

changes for the Rh(III)–opd could not be observed.

From our experimental results, it can be concluded that the reaction of the Rh(III)–opd complex with KIO_4 is initiated by the formation of a radical of opd coordinated to Rh(III). After the formation of the opd radical complex, $[Rh^{III}Cl_2\{opd^+\}_2]^{3+}$ is completed, it easily changes to the stable state over time regardless of its concentration (step 2). The opd radical complex is apt to be oxidized by molecular oxygen to benzoquinone diimine complex, $[RhCl_2\{C_6H_4(NH)_2\}_2]^+$,[16] which eventually forms decomposed products.

The authors would like to express their gratitude to Professors Yuzo Nishida and Tatsuji Nisoku of Yamagata University for their arduous work in the ESR measurements.

Preparation and Magnetic Properties of the Copper(II) Mixed Carboxylates with Haloacetate and Ammonioacetate

Shuji EMORI* and Kayoko YOSHIDZU
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received August 28, 1990)

Synopsis. Copper(II) mixed carboxylate compounds, $CuX(X'CH_2COO)(R_3NCH_2COO)\cdot mH_2O$ (X=Cl, Br; X'=F, Cl; R=H, CH_3), were prepared, and then characterized by means of magnetic susceptibility and IR-spectroscopy. The mixed carboxylates with betaine have the copper(II) acetate-type dinuclear structures. The amount of spin-exchange coupling through betaine bridges was estimated.

A study of the ligand displacement reactions of copper(II) acetate with some carboxylate dinucleating ligands, such as the chloroacetate,[1,2] myristate,[3] and 2,6-dimethoxybenzoate anions[4] has shown that these reactions yield mixed carboxylates; an X-ray structure determination[2,4] has shown that these mixed carboxylates retain the copper(II) acetate-type[5,6] dinuclear structures with the bridging ligands of both the acetate and substituent anions. Although some carboxylic acids tend to separate the copper(II) salts characterized by weak spin-exchange couplings, their mixed carboxylates may adopt the copper(II) acetate-type dinuclear structures. We can then estimate the amounts of spin-exchange coupling through such carboxylates acting as bidentate bridging ligands. We, thus, investigated the reactions between copper(II) ammonioacetate compounds and copper(II) haloacetates, and measured the room-temperature magnetic susceptibilities and IR spectra of the obtained compounds. The effective magnetic moments were evaluated from the magnetic susceptibilities, which were corrected for the diamagnetic contribution using the Pascal constants[7] and for temperature-independent paramagnetism using the value of 60×10^{-6} emu mol^{-1} (1 emu=$4\pi\times10^{-6}$ m^3). The IR spectra of the solid compounds were recorded using nujol mulls in the 4000—600 cm^{-1} range.

The ammonioacetate compounds with copper(II) halide, $CuX_2(R_3NCH_2COO)_2\cdot nH_2O$ (X=Cl, Br; R=H, CH_3), were prepared in a way similar to that for the corresponding ω-ammoniocarboxylate compounds.[8] From the reaction mixtures of the bromides, copper(I) species were removed upon recrystallization from 0.1 mol dm^{-3} hydrobromic acid solutions. Their magnetic moments (μ_{eff}=1.75 and 1.81 BM for the betaine and glycine compounds, respectively)[9] are similar to those for the mononuclear copper(II) compounds (μ_{eff}=1.8—2.0 BM), indicating weak spin-exchange couplings between copper(II) ions. These copper(II) ammonioacetate compounds were dissolved in aqueous solutions of copper(II) haloacetates, $Cu(X'CH_2COO)_2\cdot H_2O$ (X'=F, Cl), which are well known to have the copper(II) acetate-type dinuclear structures (μ_{eff}=1.32[10,11] and 1.43[12] BM at room temperature for X'=F and Cl, respectively), in a 1:1.2 molar ratio. The resulting solutions were allowed to stand in a refrigerator until fine green crystals separated. A chemical analysis indicates that the products are mixed carboxylates, $CuX(X'CH_2COO)(R_3NCH_2COO)\cdot mH_2O$ (X=Cl, Br; R=H, CH_3; X'=F, Cl). The products are not equimolar mixtures of the reactants, since their magnetic moments differ entirely from the average of those for the reactants (Table 1).

There is a remarkable difference in the magnetic moments between the mixed carboxylates with glycine and with betaine. The former are characterized by weak spin-exchange couplings (μ_{eff}=1.73 and 1.85 BM), while the latter are characterized by strong antiferromagnetic couplings between copper(II) ions (μ_{eff}= 1.34—1.42 BM). Furthermore, the IR spectra of the latter show bands as 1605—1630 and 1410—1420 cm^{-1} characteristic of bridging carboxylate due to unsymmetric and symmetric carboxyl stretching vibrations,[13] while the bands arising from two kinds of carboxylate groups lie too close together to enable the groupings to be readily differentiated. The temperature dependence

Table 1. Analytical Data and Effective Magnetic Moments at 20°C

Compound	Found (Calcd)/%					μ_{eff}/BM
	Cu	C	H	N	Cl^-Br^-	
$CuCl(FCH_2COO)[(CH_3)_3NCH_2COO]$	21.65 (21.67)	28.65 (28.68)	4.43 (4.47)	4.79 (4.78)	12.15 (12.09)	1.35
$CuBr(FCH_2COO)[(CH_3)_3NCH_2COO]$	18.77 (18.82)	24.78 (24.90)	3.78 (3.88)	4.17 (4.15)	23.53 (23.67)	1.34
$CuCl(ClCH_2COO)[(CH_3)_3NCH_2COO]$	20.32 (20.52)	27.03 (27.15)	4.16 (4.23)	4.56 (4.52)	11.65 (11.45)	1.42
$CuBr(ClCH_2COO)[(CH_3)_3NCH_2COO]\cdot H_2O$	16.97 (17.08)	22.54 (22.60)	3.97 (4.06)	3.86 (3.76)	21.59 (21.47)	1.41
$CuCl(ClCH_2COO)(H_3NCH_2COO)\cdot H_2O$	22.42 (22.25)	16.76 (16.82)	3.04 (3.18)	4.74 (4.90)	12.67 (12.42)	1.85
$CuBr(ClCH_2COO)(H_3NCH_2COO)\cdot 3H_2O$	17.56 (17.36)	13.03 (13.12)	3.45 (3.58)	3.84 (3.83)	21.79 (21.83)	1.73

of the susceptibilities for $CuCl(X'CH_2COO)[(CH_3)_3NCH_2COO]$ (X'=F, Cl) shows the Bleaney-Bowers behavior[14] with parameters $2J=-311\ cm^{-1}$ and $g=2.18$ for X'=F and $2J=-270\ cm^{-1}$ and $g=2.19$ for X'=Cl. The magnetic and IR spectral data indicate that the mixed carboxylates with betaine have bridged dinuclear structures, similar to that of copper(II) acetate monohydrate.[5,6] The crystals may consist of a repetition of the identical dinuclear units with 2:2 mixed bridges, which are seen in copper(II) acetate 2,6-dimethoxybenzoate monohydrate,[4] or may comprise a composite of the dinuclear units with variously mixed bridges, which are seen in the copper(II) acetate chloroacetate adduct with urea.[2]

In either case, because of the additive property of spin-exchange couplings, the magnetic moment for dinuclear mixed carboxylate can be adequately approximated by the average of those for the dinuclear salts of its constituent carboxylic acids. We can thereby estimate the magnetic property of the hypothetical dinuclear betaine compound, $CuCl_2[(CH_3)_3NCH_2COO]_2$, from those for the present mixed carboxylate, chloroacetate (μ_{eff}=1.38—1.40 BM and $2J=-278\ cm^{-1}$), [15] and fluoroacetate (μ_{eff}=1.26—1.28 BM and $2J=-359\ cm^{-1}$)[16] compounds. The estimated values, μ_{eff}=1.44 BM and $2J=-262\ cm^{-1}$ are a little larger than those of the copper(II) chloroacetate compounds. This fact is consistent with the well known correlation between the magnetic properties of a series of dinuclear copper(II) (substituted acetate)s and the acidities of their parent acids,[19] since betaine is a stronger acid than chloroacetic acid (pK_a=1.8 and 2.68 for betaine and chloroacetic acid, respectively).

Complex Formation of Poly(Acrylic Acid) with Lead(II) Ion

Hiromichi HAYASHI* and Tsuyoshi KOMATSU†
Government Industrial Research Institute, Tohoku, Miyaginoku, Sendai, Miyagi 983
† Department of Polymer Science, Faculty of Science, Hokkaido University, Kitaku, Sapporo, Hokkaido 060
(Received September 10, 1990)

Synopsis. The equilibrium constants of Poly(acrylic acid)-Pb(II) complex formation reactions were evaluated from stoichiometric equations by means of pH titration with a Pb(II) ion selective electrode. The thermodynamic parameters were obtained from the temperature dependence of the equilibrium constants. The Poly(acrylic acid)-Pb(II) complexes seem to be stable due to an exothermic process.

There are many investigations on the interaction between divalent metal ions and polyelectrolytes.[1–4] Many workers have extensively discussed the stability of polyelectrolyte complexes from the equilibrium constants of complex formation reactions. Gregor and co-workers have shown that the Bjerrum method of pH titration for the evaluation of formation constants of complexes may be applied to the divalent metal–polyelectrolyte complex systems.[1]

On the other hand, the amount of complexed metal ions in aqueous solution can be evaluated from the amount of free metal ions. However, it is not so easy to determine this amount, although several methods have been proposed. Yamashita et al. showed that the potentiometric titration by use of a copper(II) ion selective electrode(Cu–ISE) is useful to investigate the complex formation in the copper(II) ion–polycarboxylic acid system. Cu–ISE is able to detect free metal ion alone. The values of equilibrium constants of complex formation reactions were evaluated from stoichiometric equations.[4]

In this paper, the complex formation in the lead(II)–poly(acrylic acid) system was investigated potentiometrically. On the basis of the data from pH titration by a lead(II) ion selective electrode(Pb–ISE), stability constants were evaluated from stoichiometric equations. Thermodynamic parameters were evaluated from the temperature dependence of stability constants for complex formation reactions.

Experimental

Materials. Poly(sodium acrylate)(PAANa) was purchased from Nakarai Chemical Co. PAANa was dissolved in distilled water and transformed to poly(acrylic acid)(PAA) by addition of excess hydrochloric acid. The aqueous solution of PAA was refined by dialysis. The molecular weight of PAA was 5.2×10^5 by viscometric measurement.[5] The other chemicals and lead(II) perchlorate used were of guaranteed reagent grade. The concentration of lead perchlorate stock solution was determined by chelatemetric titration with Xylenol Orange(XO) as the indicator.

Potentiometric Titration. The pH measurements were carried out in a nitrogen atmosphere at 15.0, 25.0, and 35.0 (±0.1)°C and ionic strength of 0.1 mol dm^{-3} $NaClO_4$ by use of a digital ion meter (Orion 801A) with glass and calomel electrodes. The activity measurements of lead(II) ion were performed with a digital ion meter (Orion Model 801A) with lead selective (Orion 948200) and calomel electrodes.

Double junction salt bridges of 1.0 mol dm^{-3} with sodium perchlorate agar and ammonium chloride-saturated agar were used between a glass (or Pb–ISE) and a reference calomel electrode in order to avoid the formation of Pb(II) chloride complex. The concentration of lead(II) ions was determined with the calibration curve obtained for the system without any polymer. The limit of detection for Pb–ISE was 10^{-6} mol dm^{-3}.

The lead perchlorate solution was added to the PAA solutions neutralized with a sodium hydroxide solution in order to avoid the precipitation. The potentiometric titration was thus carried out with a perchloric acid solution.

Results and Discussion

The average coordination number($\bar{n}$) obtained from the pH titration curve is given as follows:

$$\bar{n} = \Sigma i[PbA_i]/[Pb], \quad (1)$$

where [Pb] and [PbA_i] represent the total concentrations of lead ion and 1:i lead-carboxylate complex, respectively. Calculation of $\bar{n}$ was done by the method of reference plot contrived by Mandel et al.[2] $\bar{n}$ and the fraction of free lead ion determined with Pb–ISE are shown in Fig. 1 as two functions of the degree of dissociation of carboxyl group (α). $\bar{n}$ increased with α and reached nearly 1.8 in contrast to the decrease in fraction of free lead ion. An almost complete binding occurred above 0.3 of α. At α=0.1, 70% of lead ions was

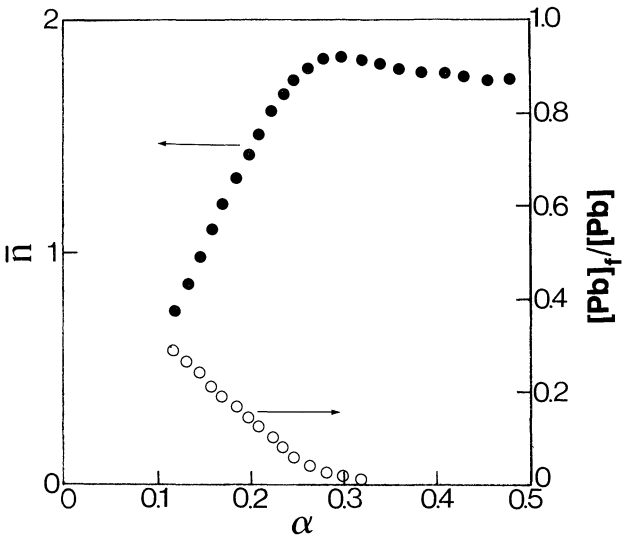

Fig. 1. Formation curve of PAA–Pb(II) complex at 25°C: ●; $\bar{n}$ (average coordination number), ○; $[Pb]_f/[Pb]$ (fraction of free lead ion). [PAA]= 1.00×10^{-2} mol dm^{-3} [Pb]=1.01×10^{-3} mol dm^{-3}.

already bound to polymer, indicating that Pb(II)–PAA complex is stable. Below 0.1 of α, the precipitation occurred.

As is shown in Fig. 1, $\bar{n}$ does not exceed 2; it indicates that 2 is the maximum number of carboxylate groups bound to a lead ion. Assuming that both monocarboxylate (1:1) and dicarboxylate complexes (1:2) are formed, the following equation holds:

$$[\mathrm{Pb}] = [\mathrm{Pb}]_f + [\mathrm{PbA}] + [\mathrm{PbA_2}], \quad (2)$$

where $[\mathrm{Pb}]_f$, [PbA], and $[\mathrm{PbA_2}]$ represent the concentrations of free lead ion, monocarboxylate complex, and dicarboxylate complex, respectively. In the present study, the concentration of free lead ion can be determined by Pb–ISE, and Eq. 1 can be rewritten as

$$\bar{n}\,[\mathrm{Pb}] = [\mathrm{PbA}] + 2[\mathrm{PbA_2}]. \quad (3)$$

The simultaneous Eqs. 2 and 3 purposely gave the concentrations of two species [PbA] and $[\mathrm{PbA_2}]$.

The fractions of PbA and $\mathrm{PbA_2}$ are shown as two functions of α in Fig. 2. The fraction of $\mathrm{PbA_2}$ increased with α in contrast to a decrease in the fraction of PbA, suggesting that each of complex formation reactions is stepwise as is in the case of the monomeric ligand. In a low α region, monocarboxylate complex predominated over dicarboxylate complex. As α increased, monocarboxylate complex changed to dicarboxylate complex under increasing carboxylate group concentration.

The stability constants of monocarboxylate and dicarboxylate Pb(II) complexes, K_1 and K_2 are given by

$$K_1 = [\mathrm{PbA}]/[\mathrm{Pb}]_f\,[\mathrm{A}] \quad (4)$$

and

$$K_2 = [\mathrm{PbA_2}]/[\mathrm{PbA}]\,[\mathrm{A}], \quad (5)$$

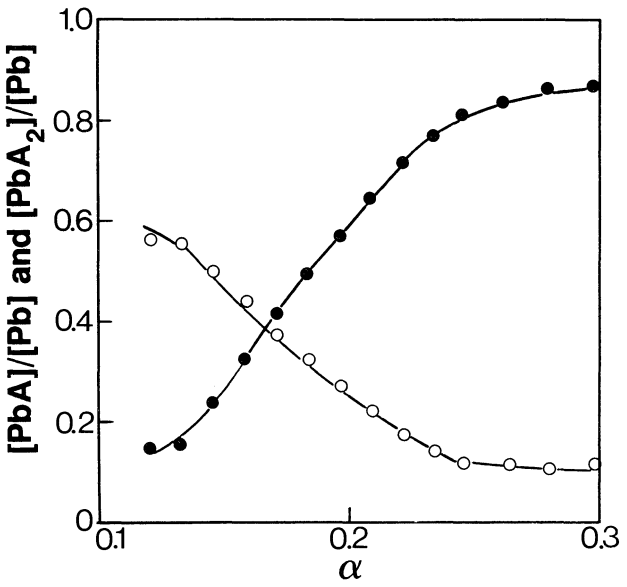

Fig. 2. Fractions of monocarboxylate and dicarboxylate Pb(II) complexes, [PbA]/[Pb] (○) and $[\mathrm{PbA_2}]$/[Pb] (●) as two functions of α.

where [A] represents the concentration of nonchelating carboxylate group determined by reference plot method proposed by Mandel and Leyte.[2] The values of K_1, K_2 calculated by the above equations in the α range of 0.1 to 0.3 are plotted in Fig. 3. The value of K_1 was nearly constant, whereas, the values of K_2 depended on α. K_2 increased with α and saturated at 0.25 of α. The behavior of K_2 is attributed to the change in negative charge density on each polymer chain, because the negative charge of carboxylate group adjacent to dicarboxylate complex raises the stability constant K_2. The stability constants of K_1 and K_2 at 0.15 of α ($\bar{n}$=1.0 in Fig. 1) were $10^{3.64}$ and $10^{3.11}$ $\mathrm{dm^3\,mol^{-1}}$, respectively.

In order to determine the change in enthalpy and entropy of the complex formation, the temperature dependence of stability constants was measured. The gross stability constant of the dicarboxylate Pb(II) complex, β_2 is given by

$$\beta_2 = K_1K_2. \quad (6)$$

The logarithmic values of β_2 were 6.86, 6.75, and 6.66 at 15, 25, and 35 °C under the conditions of 0.15 of α,

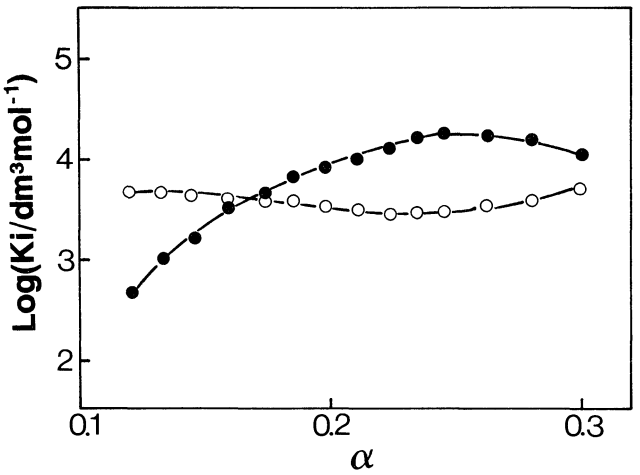

Fig. 3. Stability constants of monocarboxylate and dicarboxylate Pb(II) complexes, K_1 (○) and K_2 (●) as two functions of α.

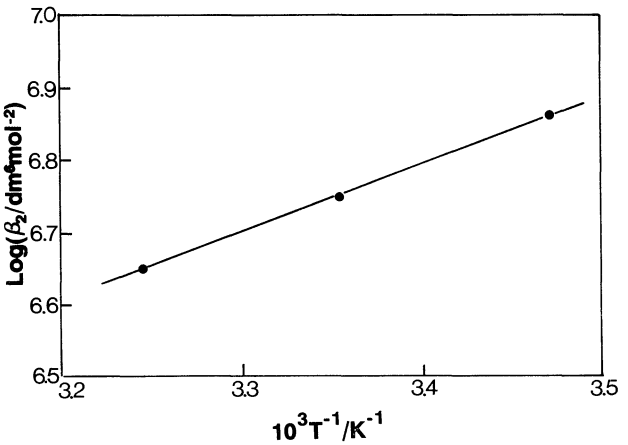

Fig. 4. Plots of log β_2 vs. T^{-1}.

Table 1. Gross Stability Constants and Thermodynamic Parameters

Metal ion	Ligand	β_2	$\Delta G^\ominus$	$\Delta H^\ominus$	$\Delta S^\ominus$
		$dm^6\ mol^{-2}$	$kJ\ mol^{-1}$	$kJ\ mol^{-1}$	$J\ mol^{-1}\ K^{-1}$
Pb^{2+}	PAA	$10^{6.75}$	−38.5	−18.0	67
Pb^{2+} [a]	Acetic acid	$10^{3.62}$	−20.5	−0.6	67
Cu^{2+} [b]	PAA	$10^{5.86}$	−33.5	2.1	117

a) Data taken from Ref. 6. b) Data taken from Ref. 7.

respectively. Figure 4 gives the plot of $\log \beta_2$ vs. T^{-1}. Log β_2 values were on the straight line between 15 and 35 °C, indicating that the enthalpy change is constant. The standard enthalpy change (ΔH) was obtained from Eq. 7:

$$\Delta H = -2.303\ R\ \mathrm{d}(\log \beta_2 / T^{-1}), \quad (7)$$

where T is the absolute temperature, and R is the gas constant. The free energy change (ΔG) obtained from the value of $\log \beta_2$ at 25 °C and the entropy change (ΔS) was calculated by $(\Delta H - \Delta G)/T$. Gross stability constants and the thermodynamic parameters obtained by the present analysis are summarized in Table 1, together with the literature values for the corresponding lead acetate,[6] and copper–PAA[7] as a comparison. The dicarboxylate complex is 10^3 times as stable as the Pb(II) acetate complex. Standard enthalpy changes for Pb(II)–PAA complex and Pb(II) acetate complex were negative, indicating that the formation of a chelate between one lead ion and two carboxylate groups is an exthothermic process. The absolute value of enthalpy change was favorable of the formation of Pb(II)–PAA complex. In the polymer–metal system, the standard enthalpy change is more negative than that in the monomeric analogue–metal ion system, so that the metal ions are more tighly bound to the polymer than to the monomeric analogue.[8]

The standard entropy change for Pb(II)–PAA complex is smaller than that for Cu(II)–PAA complex which is the most stable one among divalent metal–PAA complexes investigated, the entropy change was favorable of Cu(II)–PAA complex, whereas the enthalpy change for the former is larger than that for the latter. It is known that enthalpy change for transition divalent metal–polycarboxylate complexes are positive.[9] These comparisons show that the lead–PAA complex must be stabilized by a highly exthothermic process. It is concluded that Pb(II)–PAA complex is the most stable one of the divalent metal ion–PAA complexes which have been investigated in accord with the order of magnitude of stability constant for the divalent metal ion–monomeric carboxylate complex, that is Pb>Cu>Cd.[10]

Conjugate Reduction of 2-Butene-1,4-diones with $LiAlH_4$-$SbCl_3$

Shinsei SAYAMA* and Yutaka INAMURA
Department of Chemistry, Fukushima Medical College, Hikarigaoka, Fukushima 960-12
(Received June 15, 1990)

Synopsis. The reagent $LiAlH_4$-$SbCl_3$ was found to be more effective for a conjugate reduction of 2-butene-1,4-diones in comparison with the reagent $LiAlH_4$-other metal halides.

The effect of the addition of $AlCl_3$ to $LiAlH_4$ was to produce more mild and specific reagents for reducing epoxides and halo ketones.[1] Therefore, a chemoselective reduction of polyfunctional compounds with $LiAlH_4$ in the presence of various other metal halides has been the subject of much study.[2] It was reported that the reduction of α,β-unsaturated ketones with $LiAlH_4$-Cu_2I_2 or $LiAlH_4$-metal halides (e.g., Cu_2Br_2, Cu_2Cl_2, $TiCl_3$, $FeCl_3$) gave the corresponding ketones arising from a conjugate reduction.[3,4] Since γ-keto-α,β-unsaturated ketones, such as 2-butene-1,4-diones, afforded 1,2-reduction products predominantly with $LiAlH_4$ or $NaBH_4$, there has been much interest in mild, convenient methods for a conjugate reduction of γ-keto-α,β-unsaturated ketones. The reduction of γ-keto-α,β-unsaturated ketones with $LiAlH_4$-metal halides, however, has not been carried out.[1-7] Moreover, $SbCl_3$ has not been used as a metal halide in a conjugate reduction of α,β-unsaturated ketones and γ-keto-α,β-unsaturated ketones. Since antimony is one of the representative elements which possess both metallic and nonmetallic properties and Sb^{3+} is a borderline acid in the classification of hard and soft acids,[2a,6,7] it can be expected that the reduction of carbonyl compounds with $LiAlH_4$-$SbCl_3$ has a new reactivity in comparison with $LiAlH_4$-transition metal halides. We would like to report on the results of studies concerning the selective conjugate reduction of γ-keto-α,β-unsaturated ketones, such as 2-butene-1,4-diones, with $LiAlH_4$-$SbCl_3$.

The reduction of *trans*-1-phenyl-2-pentene-1,4-dione (**1**), chosen as a representative 2-butene-1,4-dione for this study, with $LiAlH_4$ (LAH)-$SbCl_3$ in various stoichiometric ratios was carried out. The results are summarized in Table 1. At the ratio of enedione **1**, LAH, and $SbCl_3$ (1:1:1, 1:1:3, or 1:3:1), a mixture of 4-hydroxy-1-phenyl-1-pentanone, 1-phenyl-2-pentene-1,4-diol and 1-phenylpentane-1,4-diol and **1** was mainly obtained, accompanied by a small amount of 1-phenylpentane-1,4-dione (**1a**). At a stoichiometric ratio of 1:3:3 or 1:3:4, enedione **1** was reduced to give a conjugate reduction product **1a** in nearly quantitative yield. The optimum conditions for the conjugate reduction of **1** with LAH-$SbCl_3$ found in the present experiments are as follows: i) $SbCl_3$ is essential for effecting a regioselective conjugate reduction. ii) There is need to use either an equal or excess molar equivalent of $SbCl_3$ over LAH in order to suppress the reaction of 1,2-reduction with LAH. iii) There is need to use more than two molar equivalents of LAH and $SbCl_3$ over **1** for obtaining conjugate reduction products in high yield.

The results of a LAH-$SbCl_3$ reduction of other 2-butene-1,4-diones are shown in Table 2. The reductions of *trans*-3-decene-2,5-dione (**2**), ethyl 3-benzoylacrylate (**3**), *trans*- and *cis*-1,4-diphenyl-2-butene-1,4-diones (**5** and **6**), even diethyl azodicarboxylate (**4**) and 3-benzoyl-1-phenyl-2-pentene-1,4-dione (**7**) with LAH-$SbCl_3$ took place to give the corresponding conjugate reduction products in good yields.

The results of a LAH-$SbCl_3$ reduction of α,β-unsaturated carbonyl compounds are shown in Table 3. The reduction of α,β-unsaturated ketones (**9** and **10**) was not selective, as shown. Only the formyl group of **8** was reduced to a hydroxyl group in 92% yield. The chemoselective reduction of aldehydes in the presence of ketones with this reagent was also examined in the following competition experiments. Equimolar amounts of 3,7-dimethyl-6-octenal and ethyl levulinate were

a) LAH; 1.0—3.0 mmol; Solvent; 10—15 ml. b) Yield is based on the carbonyl compounds used.

allowed to compete for the reduction with three molar equivalents of LAH–$SbCl_3$. 3,7-Dimethyl-6-octenal was selectively reduced to 3,7-dimethyl-6-octene-1-ol in 70% yield and ethyl levulinate was recovered unchanged. In addition, carbonyl groups of 1-phenylbutane-1,3-dione and 1-phenylpentane-1,4-dione and ester, nitrile, and acetal groups in ethyl levulinate and 4-phenyl-4,4-ethylenedioxybutanenitrile were not affected under the above-mentioned reduction conditions.

On the other hand, the reduction of enedione **1** with LAH–other metal halides such as Cu_2I_2, $CuCl_2$, $AlCl_3$, $FeCl_3$, and $TiCl_4$ gave no 1,4-reduction products, and complex mixture of hydroxy derivatives were obtained under various ratios of LAH and metal halides.

Thus, the reagent LAH–$SbCl_3$ provides a new convenient method for a mild, selective conjugate reduction of 2-butene-1,4-diones. Further application of reduction with LAH–$SbCl_3$ to aldehyde and other functional groups is now in progress.

Experimental

IR spectra were recorded on a JASCO A-100 spectrometer. ^1H NMR spectra were taken on a Hitachi R-24B spectrometer with TMS as an internal standard. The products were identified by spectroscopic data.

General Procedure. To a suspension of LAH (113 mg, 3 mmol) in THF (8 ml) at 0 °C was added $SbCl_3$ (684 mg, 3 mmol) dissolved in THF (2 ml). The resulting mixture was stirred for 5 min at 0 °C, and then 2-butene-1,4-dione (1 mmol) in THF (2 ml) was added. After stirring for 4 h at 0—18 °C, the reaction mixture was treated with 1 M aq Na_2CO_3 and extracted with ethyl acetate. The organic layer was washed by 0.5 M aq HCl and successively saturated aq

NaCl and dried by $MgSO_4$. After removal of the solvent in vacuo, the residue was purified by column chromatography on silica gel (Wakogel C-300) with CCl_4 and $CHCl_3$ (3:1). Conjugate reduction products **1a—7a** were obtained in 64—94% yield.

2-Butene-1,4-diones were prepared according to a procedure from the literature.

trans-1-Phenyl-2-pentene-1,4-dione (**1**)[11] and *trans*-3-decene-2,5-dione (**2**) were prepared by pyridinium chlorochromate (PCC) oxidation of the corresponding 2,5-dialkylfuran derivatives.[10]

trans-1,4-Diphenyl-2-butene-1,4-dione (**5**)[11,12] was prepared by Friedel–Crafts acylation of benzene with fumaryl chloride.[14] *cis*-1,4-Diphenyl-2-butene-1,4-dione (**6**)[11,12] and 3-benzoyl-1-phenyl-2-pentene-1,4-dione (**7**) were prepared by oxidation of corresponding furan derivatives with HNO_3 in acetic acid.[15]

3-Benzoyl-1-phenylpentane-1,4-dione (7a): Mp 83—84°C (from CCl_4); IR (KBr) 1720, 1690, and 1675 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.22 (3H, s), 3.70 (2H, m), 5.30 (1H, t, J=6.0), 7.26—8.26 (10H, m).

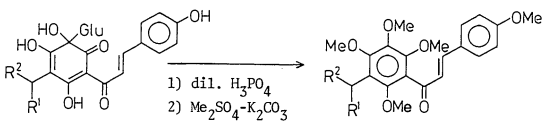
(Received July 27, 1990)

Synopsis. 5′-[1-(Methoxycarbonyl)-2-(*p*-methoxyphenyl)-ethyl]- and 5′-[2-(methoxycarbonyl)-1-(*p*-methoxypheny)-ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone were synthesized. The latter compound was completely identical with the methylated derivative of aglycone of safflomin C, a constituent of safflower (*Carthamus tinctorius L*).

Recently, we isolated a yellow pigment, safflomin C, from safflower yellow, the water soluble yellow constituent of safflower (*Carthamus tinctorius L*), and proposed the structure, **1** or **2**, for this new pigment from its spectral data and the behavior of its derivatives.[1,2]

Safflomin C was hydrolyzed with dilute phosphoric acid and methylated with dimethyl sulfate–potassium carbonate in acetone to give the methylated derivative of its aglycone which seems to have the structure **3** or **4**,[1,2] (Scheme 1).

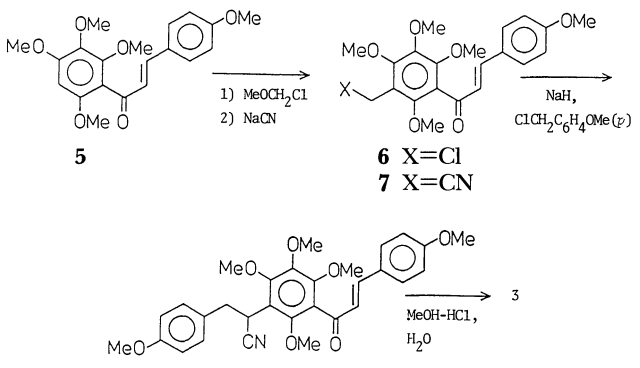


1 R^1=CH_2CO_2H, R^2=C_6H_4OH (*p*) 3 R^1=CO_2Me, R^2=$CH_2C_6H_4OMe$ (*p*)
2 R^1=CO_2H, R^2=$CH_2C_6H_4OH$ (*p*) 4 R^1=CH_2CO_2Me, R^2=C_6H_4OMe (*p*)

Scheme 1.

In this paper, we will report the synthesis of 5′-[1-(methoxycarbonyl)-2-(*p*-methoxyphenyl)ethyl]- and 5′-[2-(methoxycarbonyl)-1-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (**3** and **4**) and compare these synthetic chalcones with a natural derivative.

First, compound **3** was synthesized by the following method (Scheme 2).

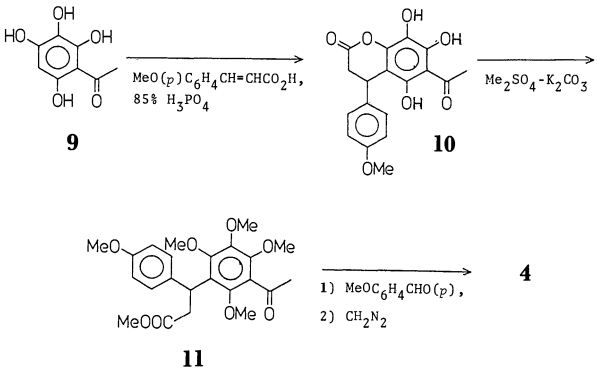


5 6 X=Cl 7 X=CN 8

Scheme 2.

Chloromethylation of 2′,3′,4,4′,6′-pentamethoxychalcone (**5**)[3] with chloromethyl methyl ether in acetic acid gave 5′-chloromethyl-2′,3′,4,4′,6′-pentamethoxychalcone (**6**) in 15% yield. Compound **6** was converted into (cyanomethyl)chalcone (**7**) in 37% yield by treating **6** with sodium cyanide in dimethyl sulfoxide. 5′-[1-Cyano-2-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (**8**) was obtained by benzylation of **7** with *p*-methoxybenzyl chloride in the presence of sodium hydride in dimethyl sulfoxide in 37% yield. Treatment of **8** with hydrogen chloride in cold methanol followed by the hydrolysis of the resulted imidate hydrochloride gave chalcone **3** in 27% yield.

On the other hand, methoxychalcone **4** was obtained by the following method (Scheme 3).



Scheme 3.

5-[2-(Methoxycarbonyl)-1-(*p*-methoxyphenyl)ethyl]-2,3,4,6-tetramethoxyacetophenone (**11**) was obtained by methylation of dihydrocoumarin(**10**) prepared by the Friedel–Crafts reaction of 2,3,4,6-tetrahydroxyacetophenone (**9**) with *p*-methoxycinnamic acid in 85% phosphoric acid in 81% yield.

Condensation of **11** with *p*-methoxybenzaldehyde in the presence of 50% aqueous sodium hydroxide solution in methanol gave 5′-[2-carboxy-1-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (**12**) which was methylated with diazomethane to give chalcone methyl ester **4** in 90% yield. The IR, ^{1}H- and ^{13}C NMR spectra of **4** were completely identical with those of a natural derivative so that the structure **1** for safflomin C was strongly supported.

Experimental

All the melting points were uncorrected. The IR spectra were recorded by a Hitachi 100-50 spectrometer. The ^{1}H-

and ^{13}C NMR spectra were measured by a Hitachi R-600 and Varian Gemini 200 spectrometer using tetramethylsilane as an internal standard, respectively. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer.

5′-Chloromethyl-2′,3′,4,4′,6′-pentamethoxychalcone (6). To a solution of 2′,3′,4,4′,6′-pentamethoxychalcone (**5**)[3] (3.0 g) in acetic acid (10 ml) was added dropwise a solution of chloromethyl methyl ether (1.5 g) in acetic acid (2 ml) with stirring under cooling with ice-water. The reaction mixture was allowed to stand for 3 days at room temperature; the mixture then poured into cold water and extracted with ethyl acetate. The extract was chromatographed on silica gel with benzene–ethyl acetate (15:1) to give **6** (0.51 g, 15%) as pale yellow crystals. Mp 82—83 °C, MS *m/z* 407 (M^+), ^1H NMR ($CDCl_3$) δ=3.80 (6H,s), 3.83, 3.92, and 4.01 (each 3H, s), 4.66 (2H, s), 6.83 and 7.34 (each 1H, d, *J*=16.0 Hz), 6.84, and 7.47 (each 2H, d, *J*=8.0 Hz), ^{13}C NMR ($CDCl_3$) δ=35.7 (t), 55.3, 60.7, 61.6, 61.7, and 63.6 (each q), 114.3 (d), 121.0, and 124.6 (each s), 126.0 (d), 127.6 (s) 130.2 (d), 142.7 (s), 145.5 (d), 151.7, 152.6, 153.9, 161.7, and 192.8 (each s). Found: C, 62.08; H, 5.74%. Calcd for $C_{21}H_{23}O_6Cl$: C, 61.99; H, 5.70%.

5′-Cyanomethyl-2′,3′,4,4′,6′-pentamethoxychalcone (7). A mixed solution of **6** (1.0 g) and sodium cyanide (0.13 g) in anhydrous dimethyl sulfoxide (40 ml) was stirred for 1 h at 35 °C. The reaction mixture was poured into cold water (250 ml) and neutralized with 10% hydrochloric acid and extracted with ethyl acetate. The extract was chromatographed on silica gel with benzene–ethyl acetate (10:1) to give **7** (0.36 g, 37%) as pale yellow crystals. Mp 102—103 °C; MS *m/z* 397 (M^+); ^1H NMR ($CDCl_3$) δ=3.63 (2H, s), 3.73, 3.78, 3.83, 3.85, and 4.03 (each 3H, s), 6.79 and 7.31 (each 1H, d, *J*=16.0 Hz), 6.83 and 7.46 (each 2H, d, *J*=8.0 Hz); ^{13}C NMR ($CDCl_3$) δ=12.5 (t), 55.3, 60.8, 61.1, 61.8, and 63.0 (each q), 113.6 (s), 114.4 (d), 118.2, and 124.2 (each s), 125.9 (d), 126.9 (s), 130.3 (d), 142.4 (s), 145.7 (d), 150.7, 151.6, 152.5, 161.8, and 192.6 (each s). Found: C, 66.56; H, 5.86; N, 3.54%. Calcd for $C_{22}H_{23}O_6N$: C, 66.49; H, 5.83; N, 3.52%.

5′-[1-Cyano-2-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (8). To a reaction mixture of **7** (0.21 g) and sodium hydride (0.018 g) in anhydrous dimethyl sulfoxide (3 ml) was added *p*-methoxybenzyl chloride (0.11 g) in anhydrous dimethyl sulfoxide (1 ml) under cooling with ice-water; the mixture was then stirred for 2 h at room temperature. The reaction mixture was poured into cold dilute hydrochloric acid and extracted with ethyl acetate. The extract was chromatographed on silica gel with benezene–ethyl acetate (15:1) and with petroleum ether–ethyl acetate (4:1) to give **8** (0.092 g, 34%) as pale yellow viscous oil. MS *m/z* 517 (M^+); ^1H NMR ($CDCl_3$) δ=3.09 (1H, dd, *J*=13.4 and 7.3 Hz), 3.33 (1H, dd, *J*=8.2 and 13.4 Hz), 3.61, 3.75, 3.84, 3.85, 3.87, and 4.02 (each 3H, s), 4.34 (1H, dd, *J*=7.3 and 8.2 Hz), 6.87 and 8.27 (each 1H, d, *J*=16.1 Hz), 6.82 and 7.50 (each 2H, d, *J*=8.8 Hz), 6.91 and 7.11 (each 2H, d, *J*=8.8 Hz); ^{13}C NMR ($CDCl_3$) δ=29.5 (d), 38.0 (t), 55.3, 55.4, 60.8, 61.1, 61.9, and 63.0 (each q), 114.0 and 114.5 (each d), 118.1, 121.1, and 123.9 (each s), 126.0 (d), 127.1, and 129.6 (each s), 130.2 and 130.4 (each d), 142.6 (s), 145.9 (d), 150.9, 151.8, 153.3, 158.8, 162.0, and 193.1 (each s). Found: C, 69.38; H, 6.18; N, 2.55%. Calcd for $C_{30}H_{31}O_7N$: C, 69.63; H, 5.99; N, 2.71%.

5′-[1-(Methoxycarbonyl)-2-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (3). To a solution of **8** (34 mg) in anhydrous methanol (10 ml), dry hydrogen chloride gas was passed under cooling with an ice-salt bath. The reaction mixture was allowed to stand for 3 days in a refrigerator; the solvent was then evaporated in vacuo. To the resulting residue was added dilute hydrochloric acid (10 ml) and allowed to stand overnight at room temperature and extracted with ethyl acetate. The extract was chromatographed on silica gel with benzene–ethyl acetate (10:1) to give **3** (10 mg, 28%) as pale yellow viscous oil. MS *m/z* 550 (M^+); ^1H NMR ($CDCl_3$) δ=3.03 (1H, dd, *J*=13.8 and 9.0 Hz), 3.45 (1H, dd, *J*=6.2 and 13.8 Hz), 3.50 (3H, s), 3.69 (6H, s), 3.79 (3H, s), 3.83 (6H, s), 3.85 (3H, s), 4.21 (1H, dd, *J*=6.2 and 9.0 Hz); 6.72 and 7.00 (each 2H, d, *J*=8.5 Hz), 6.81and 7.18 (each 1H, d, *J*=16.0 Hz), 6.91 and 7.46 (each 2H, d, *J*=8.8 Hz); ^{13}C NMR ($CDCl_3$) δ=35.9 (t), 43.3 (d), 51.8, 55.1, 55.4, 60.5, 60.7, 61.9, and 62.6 (each q), 113.4 and 114.4 (each d), 122.4 and 123.6 (each s), 126.2 (d), 127.2 (s), 130.2 and 130.4 (each d), 132.1 and 142.3 (each s), 145.8 (d), 150.5, 151.1, 153.1, 157.9, 161.8, 174.0, and 195.8 (each s). Found: C, 67.38; H, 6.05%. Calcd for $C_{31}H_{34}O_9$: C, 67.62; H, 6.22%.

6-Acetyl-3,4-dihydro-5,7,8-trihydroxy-4-(*p*-methoxyphenyl)-coumarin (10). A mixed solution of 2,3,4,6-tetrahydroxyacetophenone (**9**)[4] (1.84 g) and *p*-methoxycinnamic acid (1.78 g) in 85% phosphoric acid (60 ml) was stirred for 4 days at room temperature. The reaction mixture was poured into 5% hydrochloric acid and extracted with ethyl acetate. The ethyl acetate layer was washed with water and dried over anhydrous sodium sulfate and evaporated to give **10** (2.8 g, 81%) as pale yellow crystals. Mp 185—186 °C; MS *m/z* 344 (M^+); ^1H NMR ($CDCl_3$–DMSO-d_6) δ=2.78 (3H, s), 3.04 (2H, d, *J*=4.8 Hz), 3.77 (3H, s), 4.65 (1H, t, *J*=4.8 Hz), 6.80 (2H, d, *J*=8.0 Hz), 7.10 (2H, d, *J*=8.0 Hz), 13.58 (1H, s); ^{13}C NMR (DMSO-d_6) δ=32.5 and 33.0 (each q), 36.4 (t), 54.9 (d), 103.4 and 104.9 (each s), 113.9 and 127.5 (each d), 128.5, 132.9, 145.8, 149.1, 151.6, 157.9, 166.5, and 202.3 (each s). Found: C, 62.63; H, 4.61%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

5-[2-(Methoxycarbonyl)-1-(*p*-methoxyphenyl)ethyl]-2,3,4,6-tetramethoxyacetophenone (11). A mixed solution of **10** (1.72 g), dimethyl sulfate (12.0 g), and potassium carbonate (21.0 g) in acetone containing a small amount of water was refluxed for 30 h. The reaction mixture was filtered; the filtrate was evaporated in vacuo and the residue was poured into water (90 ml) and stirred for 6 h at room temperature and extracted with ethyl acetate. The ethyl acetate layer was washed with 10% aqueous sodium carbonate solution and with water, dried over anhydrous sodium sulfate, and then evaporated in vacuo. The residue was chromatographed on silica gel with benzene–ethyl acetate (10:1) to give **11** (1.19 g, 55%) as pale yellow viscous oil. MS *m/z* 432 (M+); ^1H NMR ($CDCl_3$) δ=2.51 (3H, s), 3.26 (2H, d, *J*=8.0 Hz), 3.58 (3H, s), 3.61 (6H, s), 3.76, 3.82, and 3.86 (each 3H, s), 4.99 (1H, t, *J*=8.0 Hz), 6.80 and 7.21 (each 2H, d, *J*=9.0 Hz); ^{13}C NMR ($CDCl_3$) δ=32.5 and 36.2 (each q), 37.8 (t), 51.5 (q), 55.2 (d), 60.5, 61.8, and 63.2 (each q), 75.3 and 77.3 (each s), 113.5 (d), 127.0 (s), 128.3 (d), 128.6, 135.2, 150.3, 153.6, 157.7, 172.9, and 201.5 (each s). Found: C, 64.06; H, 6.64%. Calcd for $C_{23}H_{28}O_8$: C, 63.88; H, 6.53%.

5′-[2-(Methoxycarbonyl)-1-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (4). To a mixed solution of **11** (2.4 g) and *p*-anisaldehyde (0.78 g) in methanol (11 ml) was added 50% aqueous sodium hydroxide solution (4.8 g) and the mixed solution was allowed to stand for 4 days at room temperature. The reaction mixture was poured into 6 M (M=mol dm^{-3}) hydrochloric acid and extracted with ethyl acetate. The ethyl acetate layer was washed with water and dried over anhydrous sodium sulfate. The ethyl acetate was evaporated in vacuo to give 5′-[2-carboxy-1-(*p*-methoxyphenyl)ethyl]-2′,3′,4,4′,6′-pentamethoxychalcone (**12**) (2.62 g, 90%) as pale yellow crystals. Mp 134—135 °C; MS *m/z* 536 (M^+); IR (KBr) ν 3450 (br.), 1705, 1624, and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.25 (2H, m), 3.48, 3.67, and 3.77 (each 3H, s), 3.82, (9H, s), 5.06 (1H, t, *J*=6.0 Hz), 6.80 and 7.52 (each 2H, d, *J*=8.5 Hz), 6.85 and 7.34 (each 1H, d, *J*=16.0 Hz), 6.90 and 7.23 (each 2H, d, *J*=8.0 Hz). To a solution of **12** in ether was added a solution of diazomethane in ether with stirring at room temperature. By evaporating

ether in vacuo **4** was obtained as pale yellow viscous oil in quantitative yield. MS *m/z* 550 (M^+); IR (CCl_4) ν 1740, 1645, and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3,24 (2H, m), 3.52, 3.62, 3.66, 3.77, 3.83, 3.84, and 3.85 (each 3H, s), 5.02 (1H, t, J=7.9 Hz), 6.83 and 6.90 (each 2H, d, J=9.0 Hz), 6.89 and 7.32 (each 1H, d, J=16.2 Hz), 7.22 and 7.51 (each 2H, d, J=8.5 Hz); ^{13}C NMR ($CDCl_3$) δ=36.3 (d), 37.8 (t), 51.8, 55.4, 55.6, 60.8, 62.0, and 63.1 (each q), 113.8 and 114.7 (each d), 124.6 (s), 126.4 (d), 127.1 and 127.7 (each s), 128.7 and 130.8 (each d), 132.8 and 135.8 (each s), 143.4 (d), 146.5, 150.6, 151.6, 154.1, 158.3, 162.3, 173.7, and 194.7 (each s). Found: C, 67.50; H, 6.09%. Calcd for $C_{31}H_{34}O_9$: C, 67.62; H, 6.22%.

The IR, ^1H-, and ^{13}C NMR spectra of this compound were completely identical with those of natural derivative **4**.

The authors express their thanks to Dr. Masanobu Suzuki of Nippon Kayaku Co., Ltd., for the measurement of ^1H- and ^{13}C NMR spectra. We are also grateful to Mr. Kazuaki Sato for elemental analyses.

Oxidation of Primary Alcohols over Hydrous Zirconium(IV) Oxide

Hideyuki KUNO,* Makoto SHIBAGAKI, Kyoko TAKAHASHI, and Hajime MATSUSHITA
Life Science Research Laboratory, Japan Tobacco Inc., 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227
(Received July 31, 1990)

Synopsis. The oxidation of primary alcohols with quinone or benzophenone was carried out by catalysis with hydrous zirconium(IV) oxide in both batch and flow reaction systems. As a result, it was elucidated that a lot of primary alcohols can be efficiently oxidized over hydrous zirconium(IV) oxide.

In the oxidation of alcohols with carbonyl compounds by catalysis with metal alkoxide, which is known as an Oppenauer-type oxidation, it has been difficult to apply primary alcohols as the reactants. This is because an aldol condensation easily occurs between an aldehyde of the product and a carbonyl compound of the hydrogen acceptor. Recently, the oxidation of some primary alcohols was reported to proceed efficiently using bis(cyclopentadienyl)zirconium(IV) dihydride as a complex catalyst.[1] However, the oxidation of the primary alcohol over a solid catalyst has never been achieved.

In a previous paper,[2] we reported that the Oppenauer-type oxidation of secondary alcohols with ketones proceeded efficiently over hydrous zirconium(IV) oxide. Several ketones, for example, acetone, diethyl ketone, and cyclohexanone, could be used as a hydrogen acceptor. However, primary alcohols were not efficiently converted to the corresponding aldehydes. As reported in our previous paper,[3] the ability of primary alcohols to provide a hydrogen donor is less than that of secondary alcohols. Further, the aldehydes produced from primary alcohols were easily condensed with ketones when the ketones which have a hydrogen atom at the α-position of the carbonyl group were used as the hydrogen acceptor. Thus, compounds which could not undergo the aldol condensation were used as the hydrogen acceptor for the oxidation.

In this paper we report that the Oppenauer oxidation of primary alcohols proceeds efficiently using *p*-benzoquinone or benzophenone as the hydrogen acceptor over hydrous zirconium(IV) oxide. The Oppenauer oxidation is the best method for the preparation of aldehydes from primary alcohols, since further oxidation of the aldehydes does not theoretically occur. Furthermore, the following advantages are expected in our method; (1) easy product isolation, (2) a lack of the need to maintain water-free conditions, (3) reusability of the catalyst, and (4) durability of the catalytic activity. These oxidations could be carried out in both batch and flow reaction systems.

Experimental

Catalyst and Materials. Hydrous zirconium(IV) oxide was prepared in the manner described in a previous paper.[3] The calcination of the catalyst was performed at 300°C for 5 h. Comercial reagents were used for the reaction without any further purification.

General Procedure in the Batch Reaction System. The following were placed in a 20 cm^3 round-bottomed flask equipped with a reflux condenser: hydrous zirconium oxide (24—60 mesh; 0.1 or 0.3 g), an alcohol (0.1 or 0.25 mmol), a ketone (20 mmol) or *p*-benzoquinone (1.5 mmol), and a hydrocarbon as an internal standard. The contents were then heated under gentle reflux. The reaction mixture was collected at an appropriate time after refluxing, and the products were analyzed by GLC (a capillary column PEG 20 M 30 m or OV101 30 m) and GC-MS (Shimadzu QP1000).

General Procedure in the Flow Reaction System. Catalytic oxidation was carried out in a glass-flow reactor (6.5 mm in diameter) with a fixed-bed catalyst: flow rate of nitrogen=60 $cm^3\ min^{-1}$; catalyst=1.5—2.0 g, 24—60 mesh; reaction temperature=200°C; A xylene solution (10 mmol cm^{-3}) of an alcohol, a ketone (2 mol cm^{-3}), and a hydrocarbon as an internal standard was fed into the reactor (5 $cm^3\ h^{-1}$) by means of a microfeeder. The yields of the products were analyzed in a similar manner to that described above after a steady state condition had been reached.

Results and Discussion

tion of the alcohols was carried out in the batch reaction system. The results are listed in Table 1. Benzyl alcohol was efficiently oxidized to give benzaldehyde in high yield; most of the alcohols were converted to the corresponding aldehydes without aldol condensations, even though the yields were relatively low. The low reactivity in these systems can be explained as being due to the catalyst being inactivated by the strong adsorption of *p*-benzoquinone.

Oxidation of Alcohols with Several Ketones. The oxidation of benzyl alcohol and 1-octanol with several ketones was carried out in the batch reaction system. In the case of acetone, both benzyl alcohol and 1-octanol could not be converted to the corresponding aldehyde. The aldol condensation of the compound produced from the primary alcohol occured with acetone. Since the oxidizing ability of diisopropyl ketone is much smaller than that of acetone,[2)] the oxidation of the primary alcohol does not occur. Compared with these ketones, benzophenone has a high ability for oxidizing the alcohols and resisting aldol condensation. Accordingly, it was elucidated that benzophenone is the best hydrogen acceptor for the oxidation of the primary alcohol among these ketones.

Oxidation of Alcohols with Benzophenone in the Batch Reaction System. All of the alcohols could be oxidized in this system, as shown in Table 2. These yields were almost the same as those when using *p*-benzoquinone as the hydrogen acceptor. Compared with benzyl alcohol and its derivative, the other alcohols were never efficiently convereted to the corresponding aldehydes. The Oppenauer oxidation was believed to proceed via a hydride transfer from the alcohol to ketone, and the reactivity of alcohol was affected by the electron density of the hydrogen on the α-carbon of the hydroxyl group. Compared with aliphatic alcohols, the derivertives of benzyl alcohol had a high ability to provide a hydrogen donor, because of a π-electron donation from the phenyl group.

Oxidation of Alcohols with Benzophenone in the Flow Reaction System. The results of the oxidation of primary alcohols in the flow reaction system are listed in Table 3. Most of the alcohols were efficiently converted to the coresonding aldehydes. In particular, it was noteworthy that the aliphatic alcohols were efficiently oxidized in comparison with the batch reaction system.

In conclusion, it was elucidated that the oxidation of primary alcohols with benzophenone in a flow reaction system proceeds efficiently by catalysis with hydrous zirconium(IV) oxide.

Synopsis. Triaminosulfoxonium salts were synthesized by the oxidation of triaminosulfonium salts with sodium perbenzoate. The reaction of these salts with nucleophiles was carried out.

Heteroatom substituted sulfoxonium salts are interesting compounds for their anomalous reactivity.[1] Monoaminosulfoxonium salts were prepared by Johnson and Schroek, which acted as good methylene transfer agents.[2] Previously, we synthesized diaminosulfoxonium salts and examined their reactivities.[3] However, to our knowledge, there is no report on the synthesis of triaminosulfoxonium salts (CA Index name; (triamide)-oxosulfur(1+) salts). Recently, we proposed an excellent method for the preparation of sulfoxonium salts from the corresponding sulfonium salts.[4] We also described the general synthesis of triaminosulfonium salts (**1**) by the reaction of thiobisamines with *N*-chlorobenzotriazole followed by the addition of secondary amines.[5] These findings prompted us to investigate the direct formation of triaminosulfoxonium salts (**2**) from **1** by oxidation reaction. In this paper, we would like to report a convenient synthesis of **2**.

Results and Discussion

Triaminosulfonium salts were prepared from 4,4′-thiodimorpholine with *N*-chlorobenzotriazole followed by the addition of secondary amines as mentioned before.[5] Treatment of trimorpholinosulfonium chlorides (CA Index name; tris(morpholino-N⁴)sulfur(1+) chloride) with 3 equiv of sodium perbenzoate in water afforded a pale yellow solution of trimorpholinosulfoxonium chloride (**2a**). Other triaminosulfonium chlorides (**1b—f**) were also oxidized under similar conditions. The triaminosulfoxonium chlorides obtained from **1b—f** were very hygroscopic, which were, therefore, isolated by transferring into the corresponding tetraphenylborates (**2b—f**). These results are summarized in Table 1. When equal amount of sodium perbenzoate was used, only 30 % of **1** were oxidized. Generally, more than 3 equiv of perbenzoate was required for improving the yields of **2**. However, dimethylaminodimorpholinosulfonium chloride (**1g**) could not be oxidized under these conditions. Even if 10 equiv of sodium perbenzoate was used, **1g** could not be oxidized. It is interesting that relatively hindered sulfonium salts (**1a**, **1b**, and **1e**) could be easily oxidized under these conditions.

The ^{1}H NMR spectra of **2** clearly show that sulfur bears a high degree of positive charge which significantly deshields the *N*-methylene protons, thereby shifting the signals downfield to 3.5 ppm around. The *N*-methylene protons of ethyldimorpholinosulfonium tetrafluoroborate were observed at 3.2 ppm.[6] The downfield shift of *N*-methylene protons is characteristic of triaminosulfoxonium salts compared to triaminosulfonium salts. The ^{13}C NMR spectrum of **2c** also shows that the *N*-methylene carbons are shifted to downfields (**1c**; 46.4 and 49.3 ppm→**2c**; 46.9 and 49.8 ppm).

Previously, Noyori and co-workers reported the formation and reaction of tris(diethylamino)sulfonium difluorotrimethylsiliconate with enol silyl ethers to give the corresponding sulfonium enolates and which

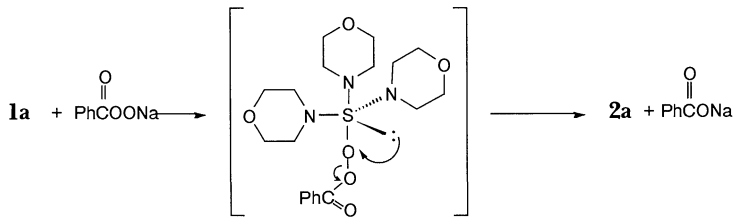
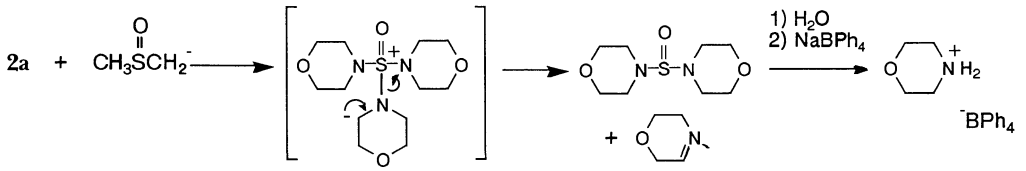


Scheme 2.



Scheme 3.

did not form covalent sulfuranes.[7] In contrast to their results, we found that triaminosulfonium salts were easily oxidized by attack of the perbenzoate anion. The difference in the reactivity might be owing to the leaving ability of the benzoate anion. The oxidation of sulfonium salt with sodium perbenzoate in aqueous solution may proceed via an S-O sulfurane intermediate to afford a sulfoxonium salt by nucleophilic attack of perbenzoate anion on the cationic sulfur atom of the sulfonium salt as show in Sheme 2.

Then, we studied the reactivity of these sulfoxonium salts. We first tried the reaction of sulfoxonium chloride **2a** with 1-cyclohexenyl silyl ether in THF. However, no reaction was observed and **2a** was recovered almost quantitatively. The reaction of **2a** with other nucleophiles such as butyllithium (room temperature), sodium phenoxide (60 °C), and CH_3SOCH_2Na (120 °C) also gave the same results. We then compared the reactivity of sulfoxonium salts with those of sulfonium salts. The reaction of **1a** with CH_3SOCH_2Na at 100 °C recovered the starting salts in 85% yield. A similar result was obtained by use of **2a**. However, treatment of **2a** with CH_3SOCH_2Na followed by the addition of sodium tetraphenylborate at 150 °C gave morpholinium tetraphenylborate in 66% yield. The reaction is accounted for by the abstraction of α-proton of morpholino group with CH_3SOCH_2Na to afford 5,6-dihydro-2*H*-1,4-oxazine and 4,4′-sulfinyldimorpholine which degradates into morpholinium salt as shown in scheme 3. A similar result is reported by Richards and Tarbel in the reaction of ethyldimorpholinosulfonium salt with butyllithium.[6]

Another heteroatom-substituted sulfoxonium salts, aryloxysulfoxonium salts, have different reactivity toward nucleophiles. Whiting reported that the reaction of aminodiaryloxysulfoxonium salts with primary amines afforded the corresponding sulfoximides in good yields.[8] Still also reported that aryloxydimethylsulfoxonium salts reacted with $NaBH_4$ to afford dimethyl sulfoxide.[9] We also tried the reaction of **2a** with $NaBH_4$ in methanol. However, starting **2a** was recovered almost quantitatively. Thus, triaminosulfoxonium salts were found to react only under drastic conditions as mentioned above and to be quite stable compounds.

In conclusion, triaminosulfoxonium salts were prepared by oxidation of corresponding triaminosulfonium salts. These salts are very stable toward nucleophiles.

Experimental

Melting points were determined on a Shibata-Büchi Model 510 and uncorrected. ^1H NMR spectra were measured on a JEOL PMX 60 spectrometer using TMS as internal standard.

Preparation of Trimorpholinosulfoxonium Chloride (2a). To a solution of sodium perbenzoate (4.8 g, 30 mmol) in water (50 cm^3) was added a solution of trimorpholinosulfonium chloride (**1a**) (3.3 g, 10 mm ol) in water (25 cm^3) at room temperature. After stirring for 12 h, the resulting

suspension was filtered off. The water of filtrate was evaporated to give pale yellow crystals, which were recrystallized from methanol to give trimorpholinosulfoxonium chloride (**2a**) (1.9 g, 5.6 mmol) in 56% yield; mp 91—93 °C. Elemental analysis was carried out after converting this chloride salt into the corresponding tetraphenylborate salt. Anal. Calcd for $C_{36}H_{44}BN_3O_4S$: C, 69.11; H, 7.09; N, 6.71%. Found: C, 68.68; H, 7.14; N, 6.52%.

Preparation of 2b. To a solution of sodium perbenzoate (4.8 g, 30 mmol) in water (50 ml) was added a solution of dimorpholinopiperidinosulfonium chloride (3.3 g, 10 mmol) in water (25 cm^3) at room temperature. After stirring for 12 h, the resulting suspension was filtered off. To this filtrate was added a solution of sodium tetraphenylborate (3.4 g, 10 mmol) in water (25 cm^3). Immediately, colorless fine crystals of **2b** were precipitated. Crude **2b** was collected by filtration and recrystallized from methanol to give colorless crystals (4.2 g, 6.6 mmol, 66%); Anal. Calcd for $C_{37}H_{46}BN_3O_3S$: C, 71.26; H, 7.43; N, 6.77%. Found: C, 71.75; H, 7.01; N, 6.95%.

Compounds **2c**, **2d**, and **2e** were prepared in a similar manner.

2c; (3.5 g, 5.8 mmol, 58%); Anal. Calcd for $C_{36}H_{44}BN_3O_3S$: C, 70.93; H, 7.27; N, 6.89%. Found: C; 70.63; H, 7.51; N, 6.59%.

2d; (3.4 g, 5.4 mmol, 54%); mp 207—208 °C; Anal. Calcd for $C_{36}H_{44}BN_4O_3S$: C, 69.33; H, 7.11%. Found: C, 69.47; H, 7.28%.

2e; (3.8 g, 5.8 mmol, 58%); mp 228—229 °C; Anal. Calcd for $C_{38}H_{52}BN_3O_4S$: C, 69.39; H, 7.97; N, 6.39%. Found: C, 69.05; H, 7.65; N, 6.62%.

Reaction of Trimorpholinosulfonium Chloride (1a) with CH_3SOCH_2Na. Sodium hydride (0.50 g, 5.3 mmol, 50% dispersion) was washed with dry hexane (10 cm^3) for three times. Dimethyl sulfoxide (10 cm^3) was added at 60 °C for 1 h and trimorpholinosulfonium chloride (**1a**) (1.6 g, 5 mmol) was added in one portion to this solution. After stirring at 160 °C for 16 h, the reaction mixture was poured into water (100 cm^3) and a solution of sodium tetraphenylborate (1.7 g, 5 mmol) was added to this solution. Pale yellow crystals were precipitated and collected by filtration. Recrystallization from MeOH/ether afforded colorless crystals of morpholinium salts (1.2 g, 3 mmol, 60%); mp 159—161 °C.

Reaction of Trimorpholinosulfoxonium Chloride (2a) with CH_3SOCH_2Na. Sodium hydride (0.50 g, 5.3 mmol, 50% dispersion) was washed with dry hexane (10 cm^3) for three times. Dimethyl sulfoxide (10 cm^3) was added and warmed up to 60 °C for 1 h. Trimorpholinosulfoxonium chloride (**2a**) (1.7 g, 5 mmol) was added in one portion to this solution. After stirring at 150 °C for 16 h, the reaction mixture was poured into water (100 cm^3) and a solution of sodium tetraphenylborate (1.7 g, 5 mmol) was added to this solution. Pale yellow crystals were precipitated and collected by filtration. Recrystallization from MeOH/ether afforded colorless crystals of morpholinium salts (1.3 g, 3.3 mmol, 66%); mp 159—161 °C.

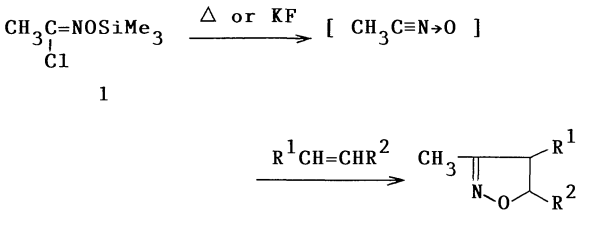
O-Ethoxycarbonyl Hydroximoyl Chloride as Nitrile Oxide Precursor

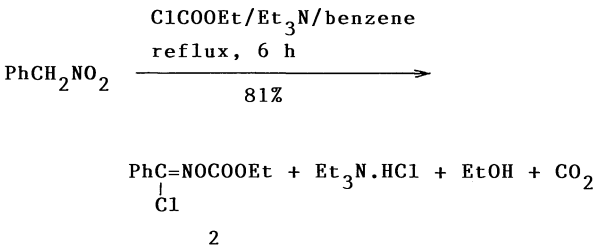
Tomio SHIMIZU,* Yoshiyuki HAYASHI, Nobuhiro FURUKAWA, and Kazuhiro TERAMURA
Department of Chemistry and Materials Technology, Faculty of Engineering and Design,
Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received August 20, 1990)

Synopsis. *O*-Ethoxycarbonyl hydroximoyl chloride serves as a stable precursor for nitrile oxide and is converted into the 1, 3-dipole when heated under reflux in pyridine.

2-Isoxazoline and isoxazole derivatives show various biological activities,[1] and are often found in natural products.[2] They are synthetically versatile heterocycles since they are readily converted into γ-amino alcohols and β-hydroxy ketones by reductive cleavage of the ring.[3,4] The most general synthetic approach to these heterocycles is the cycloaddition of olefins or acetylenes with nitrile oxides which have been generated by a variety of methods.[5,6] Of these the most widely used method is the dehydrochlorination of hydroximoyl chloride with base. Recently, an *O*-substituted hydroximoyl chloride has been employed as nitrile oxide precursor, i. e., *O*-(trimethylsilyl)acetohydroximoyl chloride (**1**) undergoes the thermolysis in refluxing toluene to generate acetonitrile oxide.[7]



We report here a unique method for the generation of benzonitrile oxide from *O*-ethoxycarbonyl hydroximoyl chloride, *O*-ethoxycarbonylbenzohydroximoyl chloride (**2**), that can be prepared in high yield (81%) by the reaction of (nitromethyl)benzene with ethyl chloroformate in the presence of triethylamine.[8]

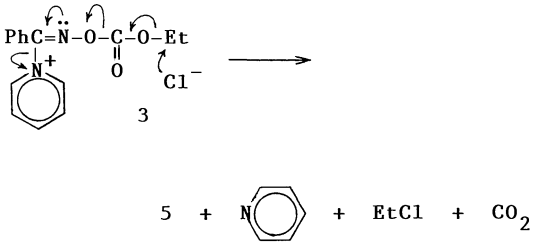


Results and Discussion

The thermal decomposition of **2** was carried out in pyridine at the refluxing temperature for 3 h in the presence of olefin. 2-Isoxazolines (**6a—i**) were isolated from the reaction mixture in good yields as shown in Table 1. During the reaction, evolution of carbon dioxide and ethyl chloride was observed. From these evidences, a probable mechanism of the formation of the cycloadducts may be as follows (see Scheme 1); i) the formation of pyridinium chloride (**3**), ii) the nucleophilic substitution at the carbon atom of carbonate group by chloride ion giving the betaine (**4**), iii) the generation of benzonitrile oxide (**5**) and pyridine in an equiliblium with **4**, and iv) 1,3-dipolar cycloaddition reaction of the nitrile oxide with olefins would give 2-isoxazolines (**6**). This mechanism is in accoord with that reported on the generation of nitrile oxides by the reaction of *O*-unsubstituted hydroximoyl chloride with tertiary amines.[14] It is known that **4** attains an equiliblium with **5** and pyridine.[15]

It is known that ethyl chloroformate decomposes to carbon dioxide and ethyl chloride on refluxing in pyridine.[16] Trapping of carbon dioxode and ethyl chloride in our reaction suggests the formation of ethyl chloroformate.

Another mechanism involving direct formation of **5** from **3** by E2 type elimination shown below would also be supposed.



We also investigated the reaction of **2** with pyridine in the absence of dipolarophile and obtained ethyl *N*-phenylcarbamate and benzonitrile in 17% and 20% yields, respectively. These yields were not so varied when the reaction was carried out in the presence of a small amont of water or ethanol. The formation of benzonitrile may be ascribed to the thermal fragmentation[17] of 3,6-diphenyl-1,4,2,5-dioxadiazine (**7**) from (**3**+**3**) head-to-tail dimerization[18] in the presence of pyridine. Although we have no definite evidences for a plausible mechanism of the formation of the carbamate, Beckmann rearrangement of **2** may be involved in the formation during which benzonitrile may be formed as a side product.

Using phenylacetylene as a dipolarophile, 3,5-diphenylisoxazole was obtained in 62% yield.

3-Methoxycarbonylisoxazolines (**9**) were obtained in poor yields (5—30%) from the similar reaction using methyl 2-chloro-2-(ethoxycarbonyloxyimino)acetate (**8**) instead of **2**. On the other hand, no cycloadducts were

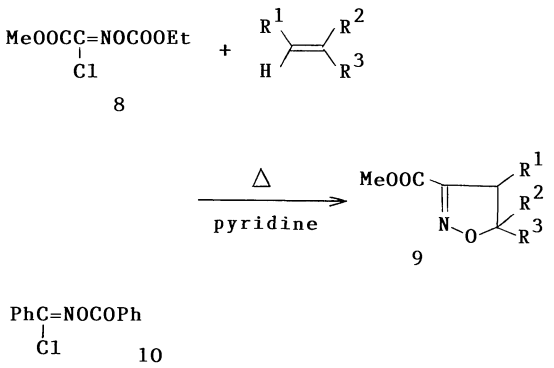
obtained by the reaction using *O*-benzoyl derivative (**10**) of benzohydroximoyl chloride as the nitrile oxide precursor.



Compared with conventional nitrile oxide precursors, hydroximoyl chlorides [RC(Cl)=NOH] and their *O*-trimethylsilyl derivatives (**1**), our new precursor (**2**) gave more satisfactory results from the standpoints of simple preparative method and the stability of the precursor [in fact, this reagent is so stable to be distilled in vacuo (115°C/0.3 mmHg, 1 mmHg=133.322 Pa) and is stable during the storage for a long time at ambient temperature even in the presence of moisture].

Experimental

Measurements and Materials. All melting and boiling points are uncorrected. *O*-Ethoxycarbonylbenzohydroximoyl chloride (**2**) was prepared similarly according to the method in literature[8] except for the usage of the substrates, (nitromethyl)benzene, ethyl chloroformate, and triethylamine, in 1:3:3 molar ratio [the yield of **2** was improved to 81% yield based on (nitromethyl)benzene by this modification]. Methyl 2-chloro-2-(ethoxycarbonyloxyimino)acetate (**8**) was prepared according to the method in literature.[8] The other reagents were of commercial origin and were used without further purification.

Preparation of 3-Phenyl-2-isoxazolines (6) and 3, 5-Diphenylisoxazole: General Procedure: An equimolar mixture of **2** (1.14 g, 5 mmol) and olefin (5 mmol) in pyridine (30 ml) was heated to reflux for 3 h. Gradual evolution of carbon dioxide (trapped as $CaCO_3$) and ethyl chloride (captured by a chilled trap and identified by ^1H NMR spectral analysis) was observed in the course of the reaction. After evaporation of pyridine, the residue was treated with water and extracted with chloroform. The chloroform layer was dried over anhydrous sodium sulfate and the solvent was evaporated to give crude products. Crystalline crude products were recrystallized from appropriate solvent to give pure cycloadducts (**6a—f** and **6h**) in yields shown in Table 1. 3,5-Diphenylisoxazole was ob-

tained in crystalline state from the reaction of **2** with phenylacetylene; yield; 600 mg (62%); mp 139—141 °C (methanol) (lit,[19] mp 141—142 °C). Oily products obtained from the reaction using butyl vinyl ether or methyl methacrylate as dipolarophile were distilled in vacuo to give pure isoxazolines (**6g** and **6i**) in yields shown in Table 1. All the melting and boiling points of the cycloadducts are well agreed with those appeared in literatures.[8–13,19] ^{1}H NMR spectra of **6a—c**,[9] **6d—f**,[20] **6g**,[8] **6h**,[9] and **6i**[20] appeared in literatures are fully agreed with those of specimens prepared here.

Thermal Treatment of 2 in Pyridine. A solution of **2** (1.14 g, 5 mmol) in pyridine was heated to reflux for 3 h. The reaction mixture was treated according to the procedure described above. Oily residue, thus obtained, was distilled in vacuo to give two fractions, bp 75 °C/15 mmHg and 110 °C/2 mmHg. The former fraction was found to be benzonitrile (0.20 g, 20% yield) and the latter one found to be ethyl phenylcarbamate (0.28 g, 17% yield) by comparison with authentic specimens.

Redox Photochromism of Arylviologen Crystals

Hiroyoshi KAMOGAWA* and Shigeki SATO
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received September 4, 1990)

Synopsis. Reversible color development induced by near UV light (photochromism) was observed for some crystalline powder of 1,1′-diaryl-4,4′-bipyridinium bis(*p*-toluenesulfonate). Redox mechanism by the electron transfer from the sulfonate anion to viologen dication is claimed.

In previous papers,[1,2] we have reported for the first time that some 1,1′-disubstituted 4,4′-bipyridinium salts (4,4′-viologens), in the crystalline solid state without any additives, exhibit reversible intense *blue or pink* color development with irradiation of near-UV light (photochromism).

In the present study, we wish to report another class of 4,4′-viologens, some members of which are also susceptible to near-UV light in the crystalline state to exhibit reversible *green* color development.

The viologens synthesized and investigated for photochromic behavior in this study were 1,1′-diaryl-4,4′-bipyridinium bis(*p*-toluenesulfonate) (to be abbreviated below as "arylviologen"), as shown in Table 1.

Results and Discussion

Arylviologens (**V**) were prepared by the anion-exchange reaction of the corresponding viologens having the chloride counter ion (**IV**) with *p*-toluenesulfonate anion (PTS^-), using an anion-exchange resin loaded with PTS^-. Compounds **IV** were synthesized, in its turn, starting with 4,4′-bipyridine (**I**) via its diquaternary pyridinium salt (**III**) with 2,4-dinitrochlorobenzene (**II**), followed by the amine-exchange reaction of **III**, as is indicated in Eq. 1.[3]

V-1	H	**V-4**	F
V-2	Me	**V-5**	Cl

a) 1,1′-Diphenyl-4,4′-bipyridinium dichloride.

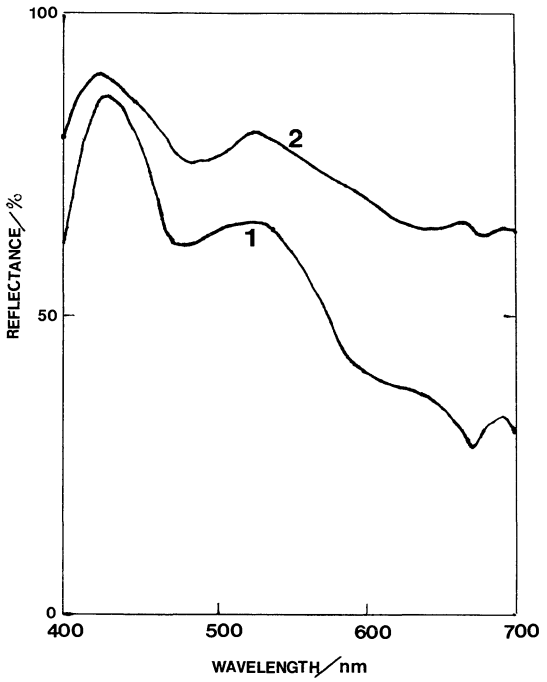

Fig. 1. Typical visible reflection spectra of the colors developed on viologen crystals with irradiation of near-UV light. Ordinate indicates values against those for the unirradiated sample. Curve 1: immediately after 10 s irradiation in air; curve 2: 10 min standing in the dark after irrad., each for 1,1′-bis(*p*-methylphenyl)-4,4′-bipyridinium bis(*p*-toluenesulfonate)(viologen No. **V-2**).

Fig. 1 indicates typical reflectance changes for crystalline powder of arylviologens upon irradiation and subsequent standing in dark.

Thus, with irradiation of light including the near-UV region, reflectances particularly at 600—700 nm decreased rapidly with simultaneous decrease of those at 400—500 nm. Since the viologen crystalline powder before irradiation showed some absorptions at 400—500 nm, the visual color was deep green for the sample during and immediately after the irradiation (curve 1).

It can be also recognized from this Figure that

V-5	90	94	100	660	Greenish Yellow	75	80	83	660	Green

a) % Values (based on those for unirradiated viologens) in 0, 10, and 30 min after 10 s irradiation. b) Absorption peak newly developed above 600 nm as a result of irradiation. Reflectance was measured at this wavelength. c) Visual color developed upon irradiation. d) No new peak. The reflectances indicated are those throughout the whole visible range.

reflectance for the irradiated sample was recovered significantly on standing for 10 min in dark (curve 2) [Photochromism].

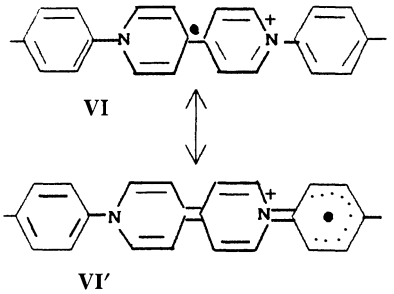
Table 2 also summarizes the results obtained for the crystalline powder of various arylviologens irradiated and let stand in air or under vacuum.

It can be known from this Table that, in the case of arylviologen, all samples investigated are susceptible to near-UV light, except viologen No. IV-1 bearing the chloride counter anion. This behavior differs notably from that in the previous study,[2] in which only limited numbers of viologens with sulfonate anions showed photochromism in crystals.

The fact that the arylviologens bearing the PTS^- counter anion in the present study exhibit photochromic behavior generally might indicate that the electron transfer to viologen dication from the counter anion induced by light and vice versa in dark (redox photochromism) are allowed in the crystal lattice.

The generation of the radical cation from the viologen dication as a result of photoreduction was demonstrated by the EPR change corresponding to reflectance change. This electron transfer to viologen dication from the sulfonate counter anion has also been observed on the transparent and isotropic films made singly of viologens bearing a long alkyl group in the counter anion part.[4]

In the present case, however, the dication part of the arylviologen molecule is wholly conjugated, so that the whole part of it might participate in radical cation formation, as exemplified in Eq. 2.



(2)

This whole conjugation may be the cause of a remarkable red shift of a reflectance peak around 600 nm for the radical cations derived from the conventional viologens[1,2] to that at 660 nm or so in this case, with simultaneous shift of that around 400 nm to a yellow region (blue→green color).

High photosensitivities observed in the present type of viologen crystals might also be caused, to some extents, by this extension of conjugation, which might lower the potential barrier of this photoinduced redox reaction.

Table 2 also indicates that the presence of air oxygen promotes the bleaching of the color developed by light considerably due to oxidation of the radical cation (**VI**-VI') back to original dication. Bleachings become very slow mostly at intermediate stages even in air, presumably because some or the major part of the radical cations (VI–VI') within crystal lattices are untouchable with air oxygen.

The stability of VI-VI' confined in crystal lattices may be dependent on temperature and other factors including the kind of the counter anion. Bleaching was complete when crystals were heated above 100°C for 10 min or so, indicating that the back reaction took place by the application of heat energy.

Judging from the results so far obtained, including those in previous studies,[1,2] it can be said safely that the 4,4'-viologens bearing the sulfonate counter anion should exhibit redox photochromism in the solid crystalline state, in case various requisites, especially as the occurrence of the electron transfer within the crystal lattice, are satisfied.

Experimental

Infrared (IR), ^1H NMR, and elemental analyses were conducted using a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Perkin–Elmer 240 instrument, respectively. Visible reflectance and EPR were taken with a Hitachi C-1020 color sensor and a JES-FE1XG spectrometer, respectively.

1,1'-Bis(2,4-dinitrophenyl)-4,4'-bipyridinium Dichloride (III). A solution of 4,4'-bipyridine (1.6 g, 10 mmol) and 2,4-dinitrochlorobenzene (7.0 g, 35 mmol) in anhydrous acetonitrile (30 mL) was refluxed for 72 h with exclusion of moisture. The reaction mixture was diluted with acetonitrile (30 mL) to afford yellowish precipitate in 95% yield.

Found: C, 47.17; H, 2.71; N, 14.67%. Calcd for

$C_{22}H_{14}N_6O_8C_{12}$: C, 46.91; H, 2.50; N, 14.92%. IR (KBr) 1510, 1330 (NO_2) cm^{-1}.

1,1′-Diphenyl-4,4′-bipyridinium Dichloride (IV-1). Compound **III** (1.1 g, 2 mmol) was dissolved in 50% ethanol (40 mL) by the application of heat. To the stirred resulting solution was then added dropwise a solution of aniline (0.9 mL, 9 mmol) in ethanol (50 mL), followed by stirring at 20°C for 24 h. The red solution was evaporated to dryness on a rotary evaporator, followed by stirring the residue in ether (100 mL) for 30 min. The resulting residue was stirred in water (50 mL) at 100°C for 24 h. Upon cooling, the mixture was filtered and the filtrate was freeze dried to provide crude product, which was recrystallized from ethanol–ethyl acetate (yield, 86%).

Found: C, 69.08; H, 4.82; N, 7.05%. Calcd for $C_{22}H_{18}N_2Cl_2$: C, 68.94; H, 4.73; N, 7.31%. NMR (D_2O) δ=7.9 (s, 10H, 2 phenyl), 8.8 (d, 4H, pyridinium), 9.5 (d, 4H, pyridinium).

1,1′-Diphenyl-4,4′-bipyrdinium Bis(*p*-toluenesulfonate) (V-1). An anion-exchange resin (Diaion SA 10A; 20 g) loaded with *p*-toluenesulfonate anion in the conventional manner was added to a solution of **V** (1.0 g) in water (50 mL). The mixture was stirred gently overnight, filtered, and the filtrate was freeze dried to provide crude product, which was recrystallized from methanol–ether (yield, 60%).

IR (KBr) 1190 (SO_3^-) cm^{-1}. NMR (D_2O) δ=2.3 (s, 6H, 2Me), 7.1—8.0 (18H, Aryl), 8.8 (d, 4H, Pyridinium), 9.1 (d, 4H, Pyridinium).

V-2, **V-3**, and **V-5** were prepared in the same manner as that for **V-1**, except that, in the **III—IV** step, *p*-toluidine, *p*-anisidine, and *p*-chloroaniline were employed instead of aniline, respectively. In the case of **V-4**, stirring with *p*-fluoroaniline at 80°C for 24 h was effected at the first stage of the **III—IV** step, instead of stirring with aniline at 20°C for 24 h, other procedures being equal to those for **V-1**. Analytical results for these viologens synthesized were also satisfactory.

Measurement of Reflection Spectra. Viologen crystals finely powdered (0.2 g) were packed tightly in a glass tube for 5 mL use, which, if necessary, was evacuated carefully under 0.1 mmHg for 30 min and sealed off. The tube was then subjected to the light reflectance measurement using a color sensor covering 400 to 700 nm in approximately one second. Light irradiation to the tube was carried out at a distance of 10 cm from a 75W high-pressure Hg lamp (Toshiba SHLUV-2) for 10 s.

Synthesis of 2,6-Dihydronaphth[1,2,3-*cd*]indol-6-ones[1)]

Sadao Arai,* Sigeaki Yamauchi, Takamichi Yamagishi, and Mitsuhiko Hida*
Department of Industrial Chemistry, Faculty of Technology,
Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received September 10, 1990)

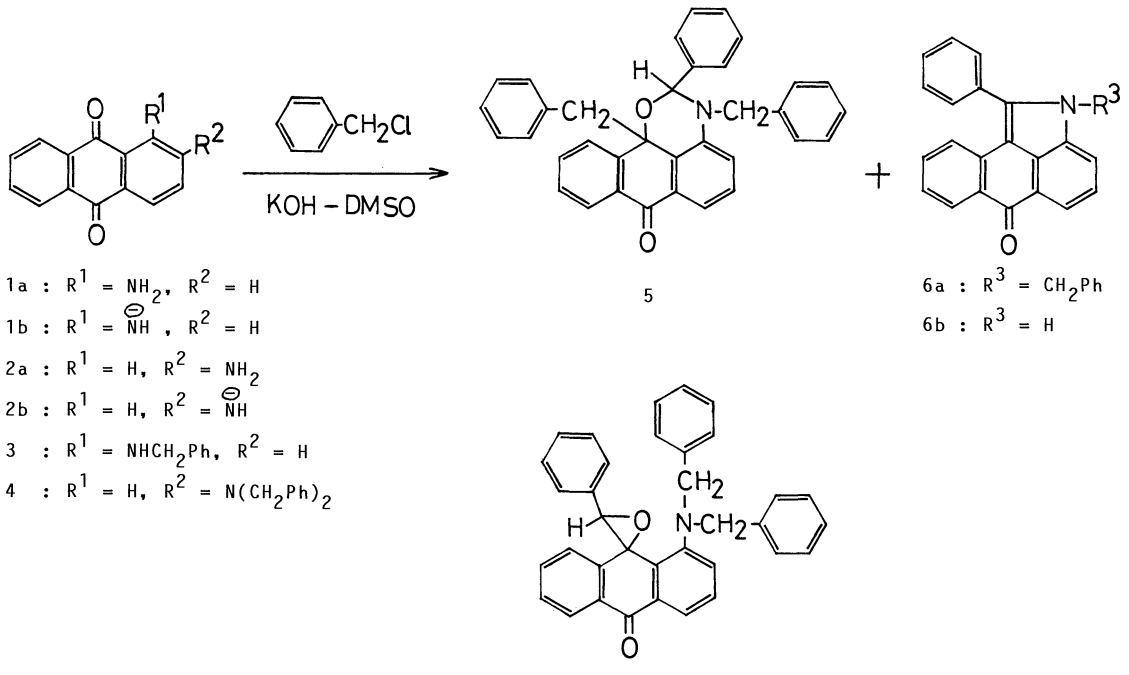
Synopsis. The reaction of 1-aminoanthraquinone with benzyl chloride in KOH–DMSO system afforded 3,11b-dibenzyl-2-phenyl-2,3,7,11b-tetrahydroanthra[1,9-*de*][1,3]-oxazin-7-one (**5**; 78% yield), whose structure was determined by single-crystal X-ray diffraction. The reaction of compound **5** with aluminium chloride gave 1-phenyl-2,6-dihydronaphth[1,2,3-*cd*]indol-6-one (52% yield) having strong fluorescence.

In our previous paper we reported that amide ions were formed by the loss of a proton from the amino group of aminoanthraquinones in the presence of powdered potassium hydroxide (KOH) in dimethyl sulfoxide (DMSO).[1,2)] The amide ion of 1-aminoanthraquinone (**1a**) reacted with excess alkyl halides such as 1-iodobutane and 1-bromohexadecane to yield red 1-alkylaminoanthraquinones, while the *N*-alkylation of 2-aminoanthraquinone (**2a**) afforded 2-dialkylaminoanthraquinones in good yields.[2)] The reaction of **1a** with benzyl chloride, however, produced not a predicted red 1-benzylaminoanthraquinone (**3**) but yellow product together with a trace amount of highly fluorescent compound. These unexpected results prompted us to examine the reaction of aminoanthraquinones with benzyl chloride in KOH–DMSO system. In this paper we will report a new method for the preparation of 2,6-dihydronaphth[1,2,3-*cd*]indol-6-ones having strong fluorescence.

Results and Discussion

Reaction of Aminoanthraquinone (1a or 2a) with Benzyl Chloride in KOH–DMSO System. The compound **1a** or **2a** was first converted to its amide ion by treating it with powdered KOH in DMSO. Then excess benzyl chloride was added to the green amide ion solution (**1b** or **2b**). In the reaction of **2a**, 2-dibenzylaminoanthraquinone (**4**) was obtained in 93% yield. The reaction of **1a**, however, unexpectedly afforded a yellow product with a trace amount of strongly fluorescing compound.

The yellow product shows an M^+ ion at m/z 493. Its IR spectrum shows the presence of carbonyl group but no N–H group. The ^1H NMR shows two remarkable features: AB quartet at around 3.46 and 4.32 ppm, and a singlet at 6.28 ppm. The quartets wre assigned to two sets of benzylic protons caused by restricted rotation. From these results and analytical data we have given this yellow product an oxirane structure (**7**), 1-dibenzylamino-3′-phenylspiro[anthracene-9(10*H*), 2′-oxiran]-10-one in our previous communication.[1)] However, after further examination, we came to a view that 1,3-dihydrooxazine structure (**5**) was more plausible than the previously-proposed **7**. The ^{13}C NMR spectrum displays two benzyl methylene carbons at 49.3 and 51.6 ppm, and



Scheme 1.

carbonyl carbon at 184.0 ppm. These results indicate that two benzyl groups are placed at different positions. Since spiro[anthracene-9(10*H*), 2′-oxiran]-10-one was reported to easily react with boron trifluoride to yield 10-formyl-10-phenylanthrone,[3] oxirane **7** would be expected to afford a formyl compound. In the reaction of the yellow product with excess boron trifluoride in diethyl ether, however, the starting compound was recovered and no formyl compound was observed. These results suggest that the yellow product would not be oxirane **7**. The molecular structure was finally established by X-ray crystal analysis, and the Oak Ridge Thermal Ellipsoid Program (ORTEP) drawing is illustrated in Fig. 1. Figure 1 unequivocally shows that the yellow product is not oxirane **7** but 3,11b-dibenzyl-2-phenyl-2,3,7,11b-tetrahydroanthra[1,9-*de*][1,3]oxazin-7-one (**5**). Figure 1 also suggests that the rotation of the benzyl group is restricted mainly by the steric hindrance in the structure.

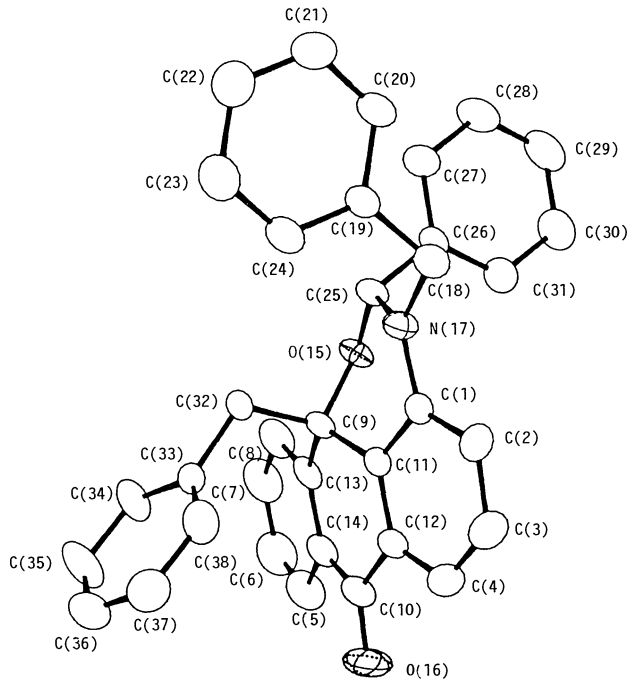


Fig. 1. ORTEP drawing of **5** showing 50% probability ellipsoids for all nonhydrogen atoms.

The structure of the strongly fluorescing compound was determined from both spectroscopic and analytical data to be 2-benzyl-1-phenyl-2, 6-dihydronaphth[1,2,3-*cd*]indol-6-one (**6a**).

Synthesis of 2,6-Dihydronaphth[1,2,3-*cd*]indol-6-ones. The compound **6a** was formed in a trace amount by the reaction of **1a** with benzyl chloride in KOH–DMSO system as described above. In fact the treatment of **5** with KOH in DMSO gave **6a** in very low yield (3%) and **5** was recovered in 85% yield. It was found that **5** was transformed more easily into **6** under acidic conditions. Table 1 shows that both Brønsted and Lewis acids were effective for the transformation. It is interesting to note that in the reaction of **5** with aluminium chloride compound **6b** was obtained together with **6a** and the total yield of **6** was increased, while other Lewis acids ($ZnCl_2$, $FeCl_3$, and $TiCl_4$) did not afford **6b**. The compound **6b** would be obtained by debenzylation of **6a**, because **6b** was obtained in 84% yield by the treatment of **6a** with $AlCl_3$ (see Table 2). The ratio of $AlCl_3$ to **5** was found to be important for the conversion of **5** to **6b**. In the case of 1:1 ratio, **6a** was obtained in 44% yield and **6b** was not formed. The best result (**6b**; 73% and **6a**; 11%) was obtained by the successive addition of $AlCl_3$: the reaction mixture was refluxed at 4:1 ratio for 1 h, then at 6:1 ratio for 2 h. The dealkylation was examined for **6a** and alkylaminoanthraquinones. Table 2 demonstrats that $AlCl_3$ was effective for the debenzylation, though **1a** was obtained in 14% yield in the case of 1-cyclohexyl-

aminoathraquinone.

Dihydronaphthindolones have been known to be good fluorophores[4] and our procedure is a facial and useful one for the preparation of 2,6-dihydronaphth-[1,2,3-*cd*]indol-6-ones, though some synthetic methods have been reported.[5]

Experimental

Materials. All commercial compounds were reagent grade and used without further purification. Dimethyl sulfoxide was distilled twice under reduced pressure and stored under a nitrogen atmosphere. Benzyl chloride was distilled under a nitrogen atmosphere. Aminoanthraquinones were purified as described previously.[2]

Instruments. Melting points were obtained on a Yamato melting point apparatus MP-21 and are uncorrected. UV and visible spectra were recorded with a Hitachi 220A spectrometer. ^{1}H and ^{13}C NMR data were recorded on a Hitachi R-24 (60 MHz) or JEOL FX90Q (90 MHz) spectrometers using Me_4Si as internal standard. IR spectra were measured on a JASCO IRA-1 spectrometer. Mass spectra were recorded with a JEOL JMS-DX 300 spectrometer by the electron impact (EI) ionizing technique at 70 eV. Elemental analyses were performed on a Yanaco MT2 CHN corder.

Reaction of Aminoanthraquinone with Benzyl Chloride in KOH–DMSO System. A typical procedure is described for the reaction with 1-aminoanthraquinone (**1a**). The compound **1a** (446 mg, 2 mmol) was treated with powdered KOH (1.12 g, 20 mmol) in DMSO (60 cm^3) for 30 min at 30°C and the mixture rapidly turned from red to green. Then, benzyl chloride (2.53 g, 20 mmol) was added and the solution was stirred for 1 h at 30°C. The resulting brown solution was poured into water (1000 cm^3) and then extracted with benzene. After evaporation of the extract, the residue was chromatographed on a silica-gel column with benzene eluent. The yellow fractions (R_f=0.49 by SiO_2 TLC, benzene as eluent) together with a trace amount of orange fractions (R_f=0.23) fluorescing in intense yellowish green were isolated. The yellow fractions were concentrated, and recrystallized from ethanol to afford 3,11b-dibenzyl-2-phenyl-2,3,7,11b-tetrahydroanthra[1,9-*de*][1,3]oxazin-7-one (**5**) (769 mg, 78%) as yellow crystals: Mp 202.0—202.8°C; UV (C_2H_5OH) 259 (log ε 4.32), 275 (sh), and 394 nm (3.17); IR (KBr) 1670 (C=O), 1245, 1150, 830, and 820 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.46 (2H, ABq, J=12 Hz, CH_2), 4.32 (2H, ABq, J=16 Hz, CH_2), 5.9—6.2 (2H, m, ArH), 6.28 (1H, s, CH), and 6.7—8.0 (20H, m, ArH); ^{13}C NMR ($CDCl_3$) δ=49.3, 51.6, 87.5, 115.5, 116.5, 126.4—144.6, and 184.0.

Found: C, 85.13; H, 5.42; N, 2.85%; *m/z* 493.2054. Calcd for $C_{35}H_{27}NO_2$: C, 85.16; H, 5.51; N, 2.83%; M, 493.2042.

The fluorescing fractions were concentrated and recrystallized from ethanol to give 2-benzyl-1-phenyl-2,6-dihydronaphth[1,2,3-*cd*]indol-6-one (**6a**) (23 mg, 3%) as orange crystals: Mp 228.5—230.0°C; UV (C_2H_5OH) 245 (log ε 4.42), 276 (4.23), 306 (4.09), 356 (3.61), and 426 nm (4.16); IR (KBr) 1630, 1610, 1595, 1550, 1180, and 970 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.20 (2H, s, CH_2) and 6.8—8.6 (17H, m, ArH); ^{13}C NMR ($CDCl_3$) δ=47.8, 107.9, 115.4—141.8, 184.0.

MS *m/z* 358 (M^+); Found: C, 87.25; H, 4.69; N, 3.41%. Calcd for $C_{28}H_{19}NO$: C, 87.25; H, 4.97; N, 3.63%.

2-(Dibenzylamino)anthraquinone (4): Mp 144.5—145.5°C; IR (KBr) 3075, 3040, 1670, 1590, 1405, 1300, 943, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.82 (4H, s, CH_2) and 6.9—8.4 (17H, m, ArH).

MS *m/z* 403 (M^+); Found: C, 83.57; H, 5.18; N, 3.37%. Calcd for $C_{28}H_{21}NO_2$: C, 83.35; H, 5.25; N, 3.47%.

The Conversion of 5 into 6. A typical procedure is described for the reaction of **5** with concd HCl. A mixture of **5** (200 mg, 0.4 mmol) and concd HCl (5 cm^3) in ethanol (35 cm^3) was refluxed for 3 h. The mixture was concentrated and chromatographed on silica gel column with benzene as eluent to afford **6a** (81 mg, 51%).

Dealkylation. A typical procedure is described for the debenzylation of compound **6a.** A mixture of compound **6a** (62 mg, 0.16 mmol) and $AlCl_3$ (106 mg, 0.80 mmol) in benzene was refluxed for 3 h. The mixture was poured into ice-water. The benzene extract was evaporated and chromatographed on a silica-gel column with benzene as eluent to afford 1-phenyl-2,6-dihydronaphth[1,2,3-*cd*]indol-6-one (**6b**) (40 mg, 84%): Mp 321—322°C; UV (C_2H_5OH) 248 (log ε 4.45), 277 (4.12), 305 (4.03), 359 (3.63), and 430 nm (4.08); IR (KBr) 3260, 3050, and 1630 (C=O) cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=7.3—8.5 (12H, m, ArH) and 12.3 (1H, s, NH); ^{13}C NMR (DMSO-d_6) δ=105—141 and 182.4 (C=O).

MS *m/z* 295 (M^+); Found: C, 85.51; H, 4.32; N, 4.67%. Calcd for $C_{21}H_{13}NO$, C, 85.40; H, 4.44; N, 4.74%.

X-Ray Crystallographic Analysis of 5. A large, well-shaped triclinic crystal of **5** was obtained by slow evaporation of an ethanol solution: $C_{35}H_{27}NO_2$=493.2; space group $P\bar{1}$; a=10.043(5), b=15.665(9), c=8.454(4) Å; β=83.02(4)°; V=1270.1 Å^3; Z=2. Lattice constants and intensity data of **5** were measured by using graphite-monochromated Cu$K\alpha$ radiation on a Rigaku AFC-5 diffractometer. A total of 4202 unique reflections with $F_o > 4\sigma(F_o)$ were obtained by using the ω–2θ scanning method with a 2θ scan speed of 4° min^{-1} to 2θ=145°. The structure was solved by the RASA-II system (Rigaku Corp.) on the basis of the direct method and refined to a final R value of 0.073. Further crystallographic details were deposited as Document No. 9094 at the Office of the Editor of Bull. Chem. Soc. Jpn.

The authors wish to express their thanks to Dr. Keiichi Yamaguchi and Professor Masataka Yokoyama of Chiba University for measurement of single-crystal X-ray diffraction.

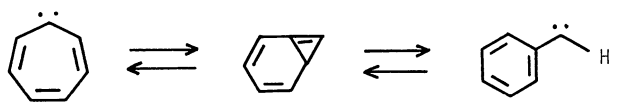
Flash Vacuum Pyrolysis of 5-Diazodibenzo[*ad*]cycloheptene. Some Insights into Aromatic Carbene-Arylcarbene Rearrangement

Hideo Tomioka* and Noriyuki Kobayashi
Department of Industrial Chemistry, Faculty of Engineering,
Mie University, Tsu, Mie 514
(Received September 14, 1990)

Synopsis. Flash vacuum pyrolysis of the title diazo compound gives 4*H*-cyclopenta[*def*]phenanthrene, which is interpreted as indicating that dibenzo[*ad*]cycloheptatrienylidene (**13**) undergoes the carbene–carbene rearrangement to generate 4-phenanthrylcarbene. The reactivities of **13** are compared with those of other benzoannulated cycloheptatrienylidenes and discussed in terms of the effect of the benzo ring to the activation energy for the rearrangement.

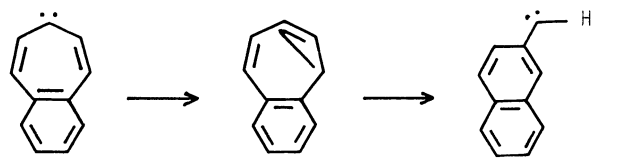
Interconversion of aromatic carbenes (e.g., cycloheptatrienylidene, **1**) and arylcarbenes (e.g., phenylcarbene, **3**) had been attracting continued attention since its discovery not only from the synthetic viewpoint but also from the standpoint of mechanism.[1,2] The rearrangement has permitted the straightforward synthesis of many useful organic compounds which are otherwise not readily obtained, and the mechanism of rearrangement still continues to plague organic chemists.

Although phenylcarbene and cycloheptatrienylidene rapidly interconvert in the gas phase at moderate to high temperatures, this is not a typical reaction of these carbenes in solution. The mechanism involves initial closure of a singlet carbene onto the π system of the aromatic ring to give a cyclopropene intermediate



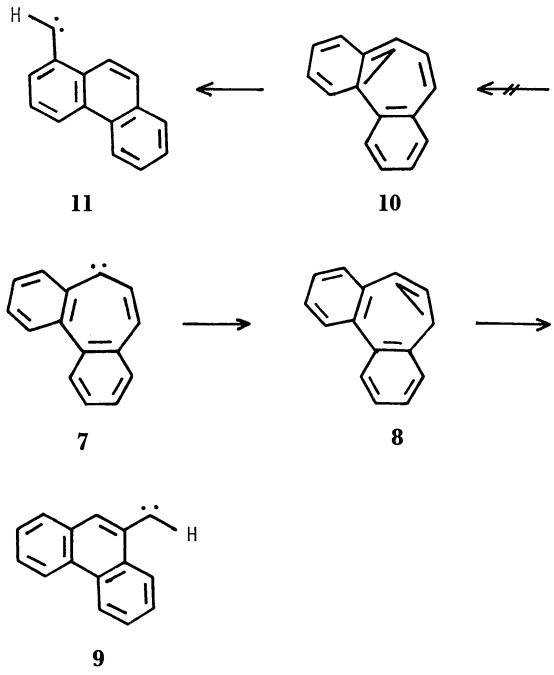
1 2 3

(**2**) that then opens to the new carbene (**3**). It is apparent that the interconversion of aromatic and arylcarbenes should be favored by perturbations that reduce the activation energy for the rearrangement presumably by accelerating closure to **2**. This is supported by the findings[3] that 7*H*-benzocyclohepten-



4 5 6

7-ylidene (**4**) gives the products expepcted from the rearranged carbene (**6**) even in solution at −30°C, suggesting that the benzannelation reduces the loss of aromaticity when the ring closes to the nonaromatic tricyclo[5.4.0.0^{4,6}]undeca-2,4,7(1),8,10-pentane **5**. More interestingly, dibenzo[*ac*]cyclohepten-5-ylidene (**7**) also rearranges in solution but only products from 9-phenanthrylcarbene (**9**) are formed and no trace of those expepcted from 1-phenanthrylcarbene (**11**) are



11 10

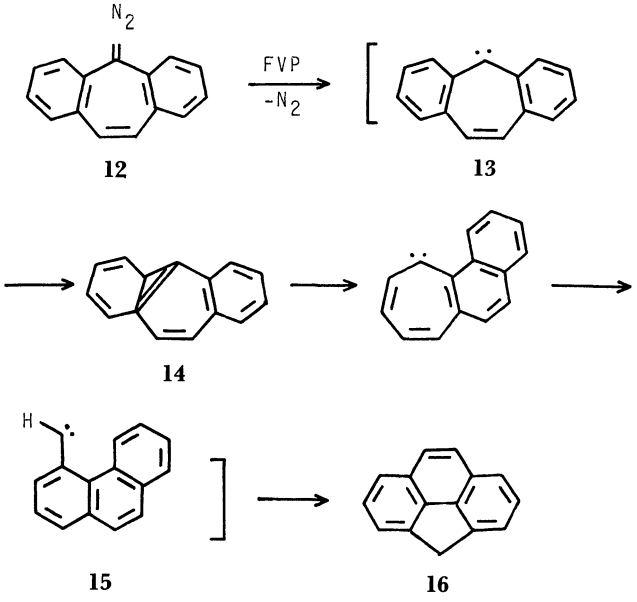
7 8

9

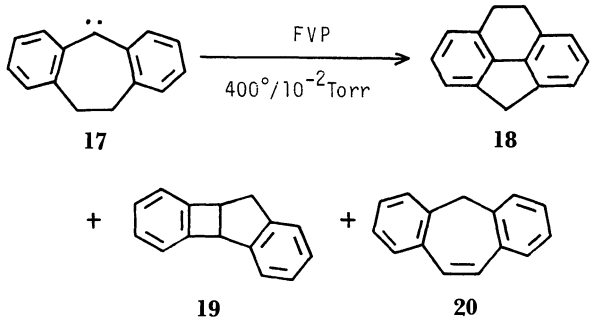
detected.[4] This is reasonably understood as indicating that the ring closure onto the 2, 3 π system forming **10** and then **11** will result in the destruction of aromaticity of one of the benzocyclic systems. In order to ascertain the mechanism of the rearrangement, we examined the reactivities of dibenzo[*ad*]cyclohepten-5-ylidene (**13**), whose rearrangement will be forced to cause the loss of aromaticity of either of the benzene rings and therefore is expected to be highly unfavorable.

Results and Discussion

Flash vacuum pyrolysis (450°C/10^{-5} Torr, 1Torr= 133.322 Pa) of 5-diazodibenzo[*ad*]cycloheptene (**12**) produced 4*H*-cyclopenta[*def*]phenanthrene (**16**) as a main volatile product in 17% yield along with dibenzo[*ad*]cyclohepten-5-one and dibenzo[*ad*]cycloheptene. The formation of **16** is interpreted as indicating that 4-phenanthrylcarbene (**15**) must be generated presumably by the rearrangement of the carbene (**13**) through tetracyclo intermediate (**14**), since it has been reported[5] that 9-phenanthrylcarbene (**9**) generated by FVP (590°C/0.1Torr) also produces **16**



via **15** generated through the repeated carbene rearrangements. The reaction is very similar to that of 10,11-dihydrodibenzo[*ad*]cyclohepten-5-ylidene (**17**), a dihydro analogue of **13**. Thus **17** generated in the gas phase produces 8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene (**18**) along with two $C_{15}H_{12}$ hydrocarbons (**19**, **20**).[5] The formation of **18** is explicable in terms of the



rearrangement forming 1-(9,10-dihydrophenanthryl)carbene, while **19** and **20** can be formed by the transannular insertion reaction in **17**. Apparently, transannular interaction is not feasible in **13** due to the increased strain.

The reactions of **13** in fluid solution or in rigid matrix have been investigated[6,7] to show that it is trapped by trapping reagents before it undergoes the rearrangement. For example, photolysis of **12** in the presence of alkenes at room temperature results in the formation of spirocyclopropanes by the addition of **13** to the alkenes.[6a] This is in a marked contrast with that observed[4] for the isomeric dibenzocycloheptenylidenes (i.e., **7**) which undergoes the rerrangement leading to arylcarbenes (i.e., **9**) in solution even at −60°C. The contrasting difference in the behavior between these two isomeric dibenzannulated aromatic carbenes (i.e., **7** and **13**) can be ascribed to the difference in the activation energy for the rearrangement as advanced above.

The present results coupled with those reported by the others suggest that, although the rearrangement of dibenzo[*ad*]cycloheptenylidene is not observed at low temperature obviously due to the introduction of benzo ring in an improper position, it does undergo the rearrangement at much higher temperature in spite of the destruction of aromaticity of one of the benzocyclic systems during the rearrangement. It is very interesting then to know to what extent the rearrangement will be disfavored by these two benzocyclic groups. The simplest way to estimate this is to determine roughly the lowest temperature at which the rearrangement products form. Thus, we decomposed **12** at various temperatures from 450 to 150°C at 50°C intervals in the gas phase and estimated the lowest temperature required for the rearrangement to be 250°C. For comparison purposes, similar experiments were done with cycloheptatrienylidene (**1**) which produces stilbenes and heptafulvalene, the former being formed as a result of cycloheptatrienylidene–phenylcarbene rearrangement. Stilbenes were not detected when the pyrolysis was carried out at <250°C.

Table 1. Effect of Benzannulation on Carbene–Carbene Rearrangement

Carbenes	Temp/°C[a]	Conditions	Ref.
1	300	Δ at 10^{-4} Torr	This work
4	−30	*hν* in PhH	3)
7	−60	*hν* in THF	4)
13	250	Δ at 10^{-4} Torr	This work

a) The lowest temperature required for rearrangement.

In Table 1, we summarize the lowest temperature required for carbene-carbene rearrangement for a series of isomeric mono-(**4**) and dibenzocycloheptenylidene (**7**, and **13**) as well as the parent carbene (**1**). The results suggest that, although the rearrangement in **13** is highly unfavorable compared to that in **4** and **7**, it is not unduly disfavored compared with that of **1**. Presumably, carbenes generated in the gas phase are forced to undergo multiple rearrangements if possible until they are quenched by a proximate reactive center leading to stable final products. It is very interesting to note here in this connection that tolylmethylenes generated photolytically in the vaper phase produce benzocyclobutene and styrene as a result of rearrangement even at 30°C.[8]

Experimental

Instrumentation. The IR spectra were determined with a JASCO A-100 spectrometer, while the ^{1}H NMR spectra were measured on a JEOL JNM-MH-100 and JNM-GX-400 spectrometer with Me_4Si as the internal reference. The mass spectra were recorded on a Shimadzu QP-1000 mass spectrometer. The GC analyses were performed on a Yanagimoto instrument, Model G-80. The GC column A was prepared from 5% SE-30 on Diasolid L (5.0 mm×2.0 m): column B consisted of 5% PEG-20M on Diazolid L (5.5 mm× 1.0 m).

Materials. The diazo compound (**12**) was prepared according to the methods described.[6]

Flash Vacuum Pyrolysis. The apparatus used for the FVP consisted of a quartz tube (30 mm i.d.×35 cm long)

maintained at the desired temperature by resistance wire. The tube was fitted with a loose plug of quartz wool 10 cm below the top of the heated zone. At the top of the tube, provision was made for the introduction of solid reactants via a solid addition tube. The lower end of the tube was fitted with consecutive U-tubes which were immersed in liquid nitrogen. The pyrolysis tube was bent near the bottom such that the pyrolysis zone was angled about 35° from the vertical.

The carbene precursor was introduced into the hot tube either by subliming at 10^{-4} Torr or by adding the precursor coated on inert support such as powdered quartz. Solvent-assisted sublimation recently advanced by Fowler[9] was also used especially for non-volatile precursors. Products were collected in the U-tubes at −196°C and analysed by MS and NMR.

FVP of 12. In a typical experiment, 50 mg of **12** was dissolved in pentane, quartz powder (ca. 1 ml) was added and the pentane was removed under reduced pressure leaving the diazoalkene coated on the support. The sample was continuously added from the top of the tube at an operating pressure of 10^{-5} Torr. The volatile products were collected in a trap cooled with liquid nitrogen and chromatographed on the preparative TLC over Merck Kiselgel 60 PF_{254} eluting with pet. ether to give a white solid (mp 114—115°C), with NMR and MS spectra identical with those of an authentic sample[10] of 4*H*-cyclopenta[*def*]phenanthrene (**16**).

We thank Professor M. Minabe of Utsunomiya University for the supply of the authentic phenanthrene (**16**). This work was supported by the Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, which is gratefully asknowledged.

The Effect of Hydrogen Sulfide on Acridine Hydrodenitrogenation on a Sulfided NiMo/Al_2O_3 Catalyst

Masatoshi NAGAI
Department of Chemical Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received June 14, 1990)

Synopsis. The effect of hydrogen sulfide on acridine hydrodenitrogenation over a sulfided NiMo/Al_2O_3 catalyst at 280—380 °C and 10.1 MPa total pressure was studied. The result showed that the presence of H_2S depressed the total C–N hydrogenolysis at a low P_{H_2S}/P_{H_2} ratio of 1.1—79×10^{-5}, but that it rarely affected the C–N hydrogenolysis at a ratio above 0.003.

Previous studies[1,2] have shown that the presence of various sulfur compounds depressed the C–N hydrogenolysis reactions in the hydrodenitrogenation of acridine and carbazole on the Mo/Al_2O_3 catalysts at 10.1 MPa total pressure. Satterfield *et al.*[3,4] reported, however, that the presence of hydrogen sulfide increased the overall rate of hydrodenitrogenation of pyridine or quinoline on sulfided NiMo/Al_2O_3 catalysts. Recently, Yan *et al.*[5] reported the promoting effect on quinoline hydrodenitrogenation over a sulfided CoMo/Al_2O_3 catalyst. Nickel- or cobalt-promoted molybdenum catalysts might be more active for the C–N hydrogenolysis of nitrogen compounds in the presence of H_2S, as well as the C–S hydrogenolysis. Moreover, the presence of H_2S at a high H_2S/H_2 ratio not only changed the sulfided state of the catalyst's surface[6] but also caused the reduction of organic compounds on MoS_2.[7] In the present work, the effect of the presence of H_2S on acridine hydrodenitrogenation on a sulfided NiMo/Al_2O_3 catalyst is discussed on basis of changes in the ratio of P_{H_2S}/P_{H_2} and the reaction temperature.

Experimental

The study was carried out in a continuous-flow fixed-bed reactor, using the NiMo/Al_2O_3 catalyst and procedures described previously.[1] The catalyst was preheated in air at 450 °C in the reactor before pretreatment. Sulfiding was accomplished *in situ* in a flowing 10 vol% H_2S/H_2 atmosphere (6 $dm^3\ h^{-1}$) at 400 °C for 3 h after the oxidized catalyst was reduced at 400 °C and 10.1 MPa pressure for 3 h. The experiment was performed at 280—380 °C and 10.1 MPa total pressure. A solution of xylene containing 0.25 wt% acridine was fed at a rate of 20 $cm^3\ h^{-1}$ into the reactor with flowing hydrogen at 30 $dm^3\ h^{-1}$. Ethanethiol (0.1 kPa) was added to the feed in order to maintain the sulfided state of the catalyst during the reaction. Ethanethiol was readily decomposable to form H_2S at 10.1 MPa total pressure. No ethanethiol was observed in the reaction products. The reaction reached a steady state in about 3 h. The liquid reaction products were analyzed by FID gas chromatography.

Results and Discussion

The major denitrogenated product was dicyclohexylmethane with a small amount of benzylcyclohexane. Acridine was completely hydrogenated to yield perhydroacridine through *cis*- and *trans*-1,2,3,4,4a,9,9a,10-octahydroacridines, even at 280 °C, while 1,2,3,4,5,6,7,8-octahydroacridine was formed preferentially rather than the 1,2,3,4,4a,9,9a,10-octahydro compounds above 300 °C.

The effect of H_2S on acridine hydrodenitrogenation on the sulfided catalyst at 330 °C is shown in Fig. 1. The presence of H_2S decreased the concentration of dicyclohexylmethane and increased those of octahydroacridine and perhydroacridine. This result showed that the presence of H_2S depressed the C–N hydrogenolysis of perhydroacridine to dicyclohexylmethane at 330 °C. The concentration of dicyclohexylmethane was decreased to 0.18 wt% from 0.2 wt% by the addition of P_{H_2S} of 7.0 kPa from 0.10 kPa at 330 °C, which corresponded to a ratio of P_{H_2S}/P_{H_2} varying from 7.9×10^{-4} to 1.1×10^{-5}. Figure 2 shows, however, that at 280 °C the presence of H_2S decreased the concentrations of perhydroacridine and dicyclohexylmethane and increased that of octahydroacridine. The presence of H_2S depressed the hydrogenation of octahydroacridine to perhydroacridine and resulted in a reduced

Table 1. The Effects of H_2S on Hydrodenitrogenation

Compound	Catalyst	Reaction temperature °C	H_2S pressure kPa	H_2S/H_2 ratio	Effect[a]	Reference

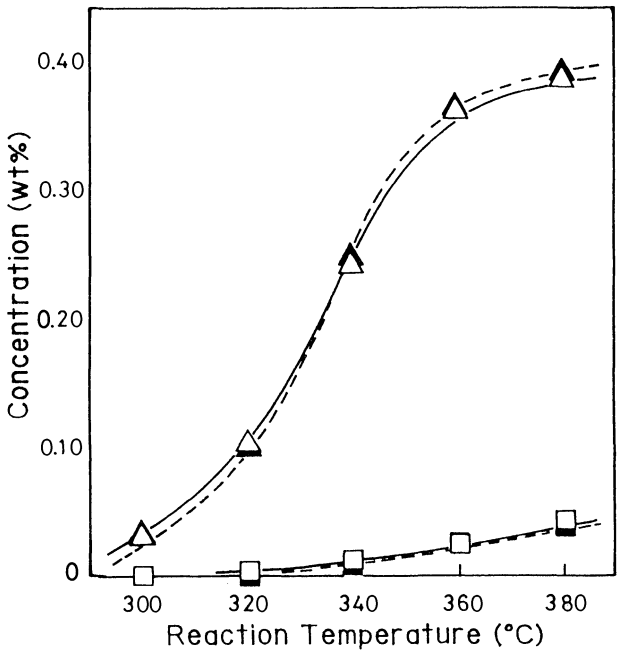

Fig. 3. The hydrodenitrogenation of acridine on the sulfided $NiMo/Al_2O_3$ catalyst at 10.1 MPa total pressure when 0.3 kPa (3×10^{-5} P_{H_2S}/P_{H_2}) (---) and 17.8 kPa (0.003 P_{H_2S}/P_{H_2} ratio) (—) of H_2S were added to the feed; See Fig. 1 for symbols.

C–N hydrogenolysis at lower temperature. These results suggest that the stability of the surface of the sulfided catalyst is probably changed at the reaction temperature.

In order to determine the effect of H_2S on C–N hydrogenolysis at a high ratio of P_{H_2S}/P_{H_2}, the study was carried out at 10.1 MPa total pressure and an H_2S/H_2 ratio of 0.003. The concentration of dicyclohexylmethane was slightly increased at 380°C and remained unchanged up to 360°C. In this case, the presence of H_2S slightly increased the C–N hydrogenolysis at high temperature, but remained unchanged at low temperature. This observation is in agreement with the results obtained by Satterfield and coworkers[3,4] in studies of the hydrodenitrogenation of pyridine and quinoline at 6.9 MPa total pressure and the P_{H_2S}/P_{H_2} ratio of 0.002. Yan et al.[5] reported the promoting effect of H_2S on quinoline hydrodenitrogenation at a H_2S/H_2 ratio of 0.052. Hirschon and Lain[8] also reported the promoting effect on SRCII hydroliquefaction over a $CoMo/Al_2O_3$ catalyst at a H_2S/H_2 ratio of 0.1. Moreover, Itabashi et al.[7] found that the presence of H_2S extremely enhanced the reduction of carbonyl compounds to hydrocarbons over a MoS_2 catalyst at 200°C and about 7.5 MPa H_2S pressure. The promoting effect on the hydrodenitrogenation was carried out at a high ratio of H_2S/H_2 (above 0.003). Consequently, the presence of H_2S depressed the C–N hydrogenolysis at a low P_{H_2S}/P_{H_2} ratio of below 7.9×10^{-4}, but promoted C–N hydrogenolysis at a higher ratio. The total C–N hydrogenolysis remains unchanged at a ratio of about 0.003,

though the effect of H_2S depends on the reaction temperature. The stability of the sulfided catalyst is probably changed thermodynamically in an H_2S/H_2 atmosphere and at the reaction temperature.

Waseda University, 3-4-1 Okubo, Shinjuku-ku, Tokyo 169
(Received August 20, 1990)

Synopsis. Ultrafine particles (UFP) of Cu were prepared by reduction in a w/o emulsion system, in which Cu(II) ions dissolved in aqueous droplets were reduced by a reducing agent. This method gave a very narrow particle size distribution. Moreover, the average size of UFP could be controlled by choosing the concentration of Cu ions.

Many studies to prepare metallic UFP have been carried out. Although a liquid-phase reduction method[1–3] in which metal ions dissolved in a solution are reduced by a reducing agent is one of these techniques, the conventional liquid-phase reduction method often produces nonreproducible results. The primary objective of this study was to develop a method to prepare UFP having a narrow distribution of particle size. A w/o (water-in-oil) type emulsion system is applied to the conventional liquid-phase reduction method, in which metal ions are dissolved in aqueous droplets in the emulsion.

Experimental

Cu UFP were prepared by reducing Cu(II) ions in an emulsion system. A mixture of a predetermined amount of a $CuCl_2$ aqueous solution, toluene and glycerol monooleate as an emulsifier was vigorously shaken by hand to make an emulsion. The Cu(II) ions were dissolved in water in a w/o-type emulsion as droplets. An excess amount of a $NaBH_4$ aqueous solution was added to the emulsion. A dark-brown "solution" was obtained and then stirred for 1 h. After dilution of the precipitate in the solution with methanol for convenience of subsequent handling, the precipitate was filtered and washed with methanol. The resulting particles were dried in vacuo.

The UFP of Cu were also prepared differently by a conventional liquid-phase reduction method for a comparison. An aqueous solution of $NaBH_4$ was added to the aqueous solution of $CuCl_2$. After being well stirred, the resulting precipitate was first washed with water and then with methanol. The precipitate was dried in vacuo.

All of the procedures were carried out in a nitrogen atmosphere in order to prevent the product from being oxidized.

The average size of aqueous droplets in the emulsion was measured using an optical microscope. The obtained UFP were analyzed by inductively coupled plasma emission spectrometry regarding the chemical composition and by X-ray diffraction method regarding the crystal structure and crystallite size. The particle size distribution was determined by the use of a transmission electron microscope. The size of the UFP was obtained according to a method of Feret,[4] which is one of the methods used to measure the size of irregularly shaped particles. The particle size was defined as being the perpendicular distance between parallel tangents touching opposite sides of the profile.

Results and Discussion

Emulsions. The emulsion prepared by the above-mentioned procedure remained stable upon standing for several hours. An optical micrograph of a typical emulsion is shown in Fig. 1. The sizes of droplets in the emulsion were distributed widely. It is obvious from Fig. 1 that the droplets of the aqueous phase stuck together. The droplet size distributions for emulsions containing the $CuCl_2$ aqueous solution in various concentrations are shown in Fig. 2. It was found that the size of the droplets in the emulsion was independent of the $CuCl_2$ concentration. The mean volumetric diameters of the droplets were determined to be about 15 μm for all of the emulsions used in this study.

Particles. The results of the chemical analysis and the X-ray diffraction analysis are given in Table 1 and Fig. 3, respectively. These results show that the powders obtained in this work were composed of metallic copper and a small amount of Cu_2O. It is not apparent whether the oxide was formed in the course of preparation or during subsequent handling.

Transmission electron micrographs of the UFP prepared in the emulsion system showed sphere-shaped particles, as can be seen in Fig. 4. Similar shaped particles were also observed on the UFP obtained by the conventional method. Figure 5(B) gives the particle size distribution, the mean volumetric diameter (D_v) and the standard deviation of the particle size (SD) of Cu powder prepared in the emulsion system. The particles had a size range from 5 to 40 nm, with a maximum at around 20 nm. The

size distribution of the particles obtained according to this method was very narrow, when compared with that obtained by the conventional method (Fig. 5(A)).

The formation of particles in the emulsion system was followed by an optical microscope observation, which suggested that the formation of particles or the reduction of Cu ions proceeded according to the following steps, as shown in Fig. 6: (1) initiation of reduction in aqueous droplets, (2) evolution of

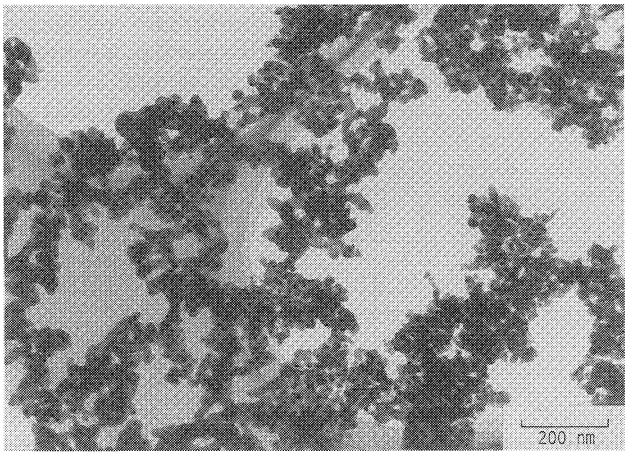

Fig. 4. Transmission electron micrograph of Cu UFP prepared in the emulsion system.

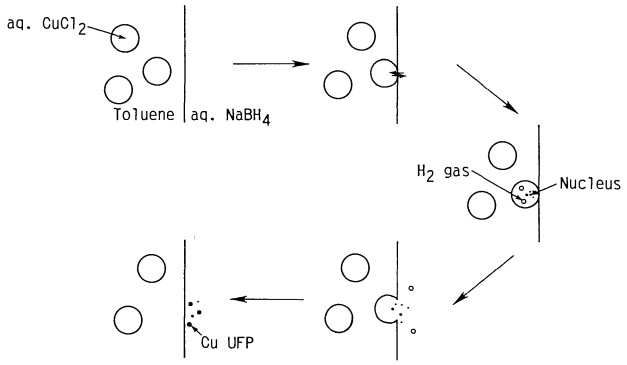

Fig. 6. Model for particle formation in emulsion system.

hydrogen and rupture of the droplets, (3) mixing of the content in droplets with the bulk of the solution of the reducing agent resulting in a further reduction to completion.

From these presumptions, the difference between the powder prepared in the emulsion system and that prepared by the conventional method regarding their particle size distribution is interpreted as being due to a homogeneous reduction of Cu ions: In the case of the conventional method, Cu ions were immediately reduced when the reducing agent was added. Consequently, a local inhomogeneity was unavoidable. On the other hand, in the case of preparation using the emulsion system, the reduction of Cu ions was retarded by toluene, which prevented the Cu ions dissolved in the aqueous droplets from the action of reducing agent. As the aqueous droplets ruptured, reduction took place independently at every droplet. Therefore, homogeneous reduction leading to a narrow particle size distribution was achieved by the use of the emulsion system.

Figure 7 summarizes the effect of the concentration of Cu ions dissolved in aqueous droplets in the emulsion. It is obvious from Fig. 7 that the average particle size was reduced, and that the particle size distribution became narrow with decreasing concentration of Cu ions.

The results presented in this study show that the preparation method using the emulsion system produces UFP having a narrow size distribution. Moreover, the average size of UFP could be controlled by the concentration of Cu ions. It is expected that this method can be used for preparing UFP composed of other materials.

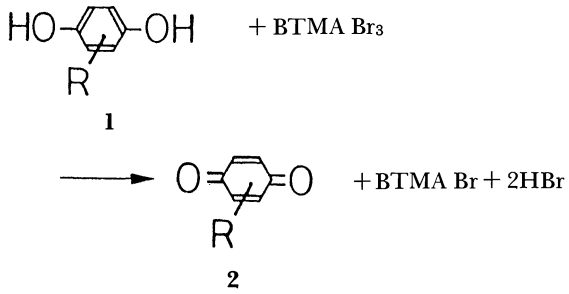
Synopsis. The reaction of 1,4-benzenediols with 1.1 equiv of benzyltrimethylammonium tribromide in dichloromethane in the presence of aqueous sodium acetate at room temperature gave 2,5-cyclohexadiene-1,4-diones in good yields. On the other hand, the reaction of 1,4-benzenediols with a large excess of the reagent in aqueous acetic acid at 40—60°C gave polybromo-substituted 2,5-cyclohexadiene-1,4-diones in good yields.

In general, 1,2- and 1,4-benzenediols are easily oxidized to 3,5-cyclohexadiene-1,2-diones (*o*-benzoquinone derivatives) and 2,5-cyclohexadiene-1,4-diones (*p*-benzoquinone derivatives), respectively. Either or both hydroxyl groups can be replaced by amino groups to give the same quinones. A number of oxidizing agents such as sodium dichromate–sulfuric acid,[2] manganese dioxide,[3] nitrous acid,[4] nitric acid,[5] iron(III) chloride,[6] lead dioxide,[7] nitrosodisulfonate,[8] (diacetoxyiodo)benzene,[9] and salcomin–oxygen[10] have been used. Halogens or their compounds, such as chlorine–hydrochloric acid,[11] bromine–pyridine,[12] chlorine–sodium hypochlorite,[13] sodium hypochlorite,[14] sodium chlorate–vanadium oxide–sulfuric acid,[15] and *N*-bromosuccinimide–water,[16] have also been used.

In previous papers, we have reported that the reaction of 1,4-benzenediol (**1a**) with BTMA Br_3 (2 equiv) in dichloromethane–methanol gave 2,5-dibromo-1,4-benzenediol, electrophilic substitution product, in good yield.[17] In our further investigation regarding the synthetic utility of quaternary ammonium polyhalides, we have now found that benzyltrimethylammonium tribromide (BTMA Br_3) is a useful oxidizing agent.[18] In this paper we wish to report on the oxidation of 1,4-benzenediols (hydroquinone derivatives) (**1**) to 2,5-cyclohexadiene-1,4-diones (**2**) by the use of BTMA Br_3.

Results and Discussion

The reaction of **1** with 1.1 equiv of BTMA Br_3 in dichloromethane in the presence of aqueous sodium acetate at room temperature gave **2** in good yields. The results are summarized in Table (Procedure **A**). The reaction scheme can be represented as follows:



Scheme 1.

Generated hydrogen bromide should be removed with sodium acetate. Otherwise, disodium hydrogenphosphate (equimolar amount for BTMA Br_3) was also used insead of sodium acetate. When aqueous sodium hydroxide was used, a black oil was obtained and the desired benzoquinone derivatives could not be isolated. The end point of the reaction was detected by a decolorization of the initial orange color of the reagent.

Incidentally, when the quantity of the reagent used was less than equivalent weight for **1**, a mixture of **2** and quinhydrone derivatives, dark green needles, was obtained.

The reaction of **1** with BTMA Br_3 (1.1 equiv) in aqueous acetic acid at room temperature also gave **2** in good yields (Table: Procedure **B**). When the reaction of **1** was carried out with a large excess (4.0—7.5 equiv) of the reagent at 40—60°C, polybromo-substituted 2,5-cyclohexadiene-1,4-diones (**3**) were obtained in good yields (Table: Procedure **B**). Products **3** might be derived from **1** through the sequential reactions shown in Scheme 2.

The reaction of 2,5-di-*t*-butyl-1,4-benzenediol (**1b**) with 4—5 equiv of BTMA Br_3 gave only 2,5-di-*t*-butyl-2,5-cyclohexadiene-1,4-dione (**2b**). It can be assumed that 1,4-addition of hydrogen bromide to **2b** does not occur because of the steric hindrance of the bulky *t*-butyl group.

Attempts to prepare 3,5-cyclohexadiene-1,2-diones by the oxidation of 1,2-benzenediols (catechol derivatives) with BTMA Br_3 failed.

We believe that, although many other procedures for the oxidation of **1** to **2** or **3** have been reported, our methods using BTMA Br_3 are characterized by simple operation, mild conditions, and good product yields.

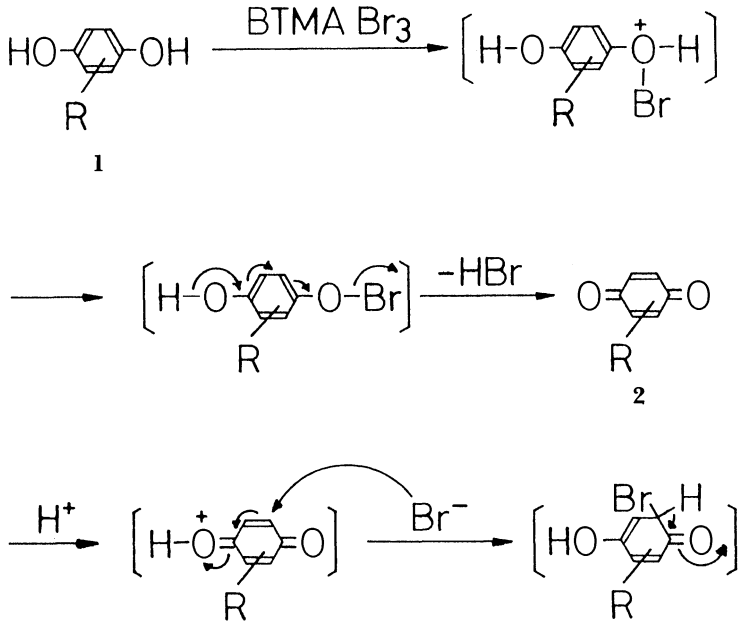

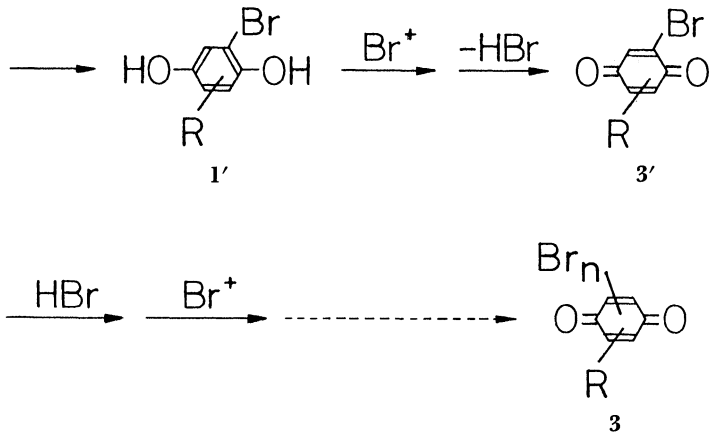

Scheme 2.

Experimental

Oxidation of 1,4-Benzenediol (1a) with BTMA Br_3-CH_3COONa aq. Representative procedures are as follows. To a solution of sodium acetate hydrate ($CH_3COONa \cdot 3H_2O$) (0.82 g, 6 mmol) in water (20 ml) was added **1a** (0.22 g, 2 mmol) and a solution of BTMA Br_3 (0.86 g, 2.2 mmol) in dichloromethane (10 ml). The mixture was stirred at room temperature for only 2 min until the initial orange color faded. Then, the water layer was filtered through wet filter paper. The separated organic layer was washed with water and dried over $MgSO_4$, filtered, and evaporated in vacuo give 2,5-cyclohexadiene-1,4-dione (*p*-benzooquinone) (**2a**) as a yellow needles; yield 0.22 g (quant.); mp 113—115 °C (lit,[19] mp 114.6—115.6 °).

Oxidation of 2,5-Di-*t*-buty-1,4-benzenediol (1b) with BTMA Br_3-AcOH aq. BTMA Br_3 (0.86 g, 2.2 mmol) was added into a solution of **1b** (0.44 g, 2 mmol) in acetic acid (5 ml)-water (10 ml). The mixture was stirred at room temperature for 10 min until the initial orange red color faded. The reaction mixture was extracted with dichloromethane (10 ml×3) and the organic layer was washed with water and dried over $MgSO_4$, filtered, and evaporated in vacuo to give 2,5-di-*t*-butyl-2,5-cyclohexadine-1,4-dione (**2b**) as yellow needles; yield 0.44 g (quant.) mp 153—154 °C (lit,[20] mp 153 °C).

Preparation of 3,5,6-Tribromo-2-methyl-2,5-cyclohexadiene-1,4-dione (3c). BTMA Br_3 (4.68 g, 12 mmol) was added into a solution of 2-methyl-1,4-benzenediol (**1c**) (0.25 g, 2 mmol) in acetic acid (5 ml)-water (10 ml). The mixture was stirred at 60 °C for 5 h, and then allowed to stand at room temperature. Water (100 ml) was added into the reaction mixture and the mixture was cooled in an ice bath. Deposited yellow solids were filtered and washed with water. The filtrate and washings were combined and extracted with ether (20 ml). The ether solution was evaporated in vacuo to give **3c** as yellow plates; yield 0.68 g (94%); mp 243—245 °C (lit,[21] mp 233 °C).

The crystal structures of polymorph II of diisothiocyanatobis(2,2′-bipyridine)iron(II), $[Fe(bpy)_2(NCS)_2]$, in the high- (298 K) and low-spin states (175, 110 K) were determined by an X-ray diffraction method. The crystal is orthorhombic, space group *Pcnb* and $Z=4$ over the entire temperature range. At 298 K, $a=13.2044$ (6), $b=16.4820$ (7), $c=10.1086$ (7) Å, $U=2200.0$ (2) Å^3, $D_c=1.462$ g cm^{-3} and at 110 K, $a=12.9842$ (9), $b=16.1067$ (12), $c=9.8938$ (8) Å, $U=2069.1$ (3) Å^3, $D_c=1.555$ g cm^{-3}. The structures were refined to $R=0.047$, 0.044, and 0.042 at 298, 175, and 110 K, respectively. The difference in the average Fe-N bond lengths between high- and low-spin states is 0.17 Å. The pressure dependence of the absorption spectra was also measured up to 8.5 GPa using a diamond anvil cell. These results indicate that with increasing pressure the high-spin state at 1 atm starts to change to the low-spin state at 0.3 GPa and that its low-spin state reverts again to the high-spin state at around 3.3 GPa.

Some iron(II) and iron(III) complexes exhibit spin transitions induced by temperature or pressure between different spin multiplicities.[1-4] Especially in iron(II) complexes, a drastic change was observed in the metal-ligand bond distance between high- and low-spin states[5-12] It is interesting to study the ligand field as well as the mechanism of spin transitions, since changes of ligand substituents, counter anions, solvent molecules, complex geometries, crystal forms, and states (solid or solution) cause various types of conversions between different spin states. Several theoretical models, a cooperative Jahn-Teller interaction,[13,14] the coupling to lattice vibrations[15] and the elastic interaction between high- and low-spin ions via an image pressure,[16] have been introduced in order to lead to a cooperative nature of the spin transitions. In order to understand the nature and the mechanism of spin transitions, it is necessary to investigate the difference among molecular geometries and molecular interactions between low- and high-spin states. The $[Fe(\alpha\text{-pic})_3]^{2+}$ system (α-pic=α-picolylamine) is one of the interesting ionic spin crossover complexes, since the effective magnetic moments depend on the nature of the counter anions or solvent molecules.[17-21] We determined the crystal structures of the $[Fe(\alpha\text{-pic})_3]Cl_2 \cdot EtOH$ compound at 298, 150, and 90 K and found that the average bond distance contracted by 0.18 Å upon making a transition from the high- to the low-spin state.[6,7] On the other hand, $[Fe(phen)_2(NCS)_2]$ (phen=1,10-phenanthroline) and $[Fe(bpy)_2(NCS)_2]$ complexes without solvent molecules are typical molecular spin crossover complexes showing discontinuous spin transitions; they have been investigated in detail by various means.[22-28] König et al.[24] reported on the magnetic susceptibility and Mössbauer spectra for three polymorphs of the $[Fe(bpy)_2(NCS)_2]$ complex as well as the preliminary results of the crystal structure ($R=0.19$—0.20) of polymorph II determined by a photographic method.[5] The difference in the Fe-N bond lengths (0.12 Å) between the high- and low-spin states observed by them appears to be small compared with those observed in other iron(II) spin crossover complexes.[6,7,11] We redetermined the crystal structures of the polymorph II of $[Fe(bpy)_2(NCS)_2]$ at 298, 175, and 110 K by a diffractometer method in order to gain more accurate information and to interpret the nature of the phase transitions and different magnetic behaviors between polymorphs I and II in the temperature range from 273 to 220 K. The change in the absorption spectra was also measured with increasing pressure up to 8.5 GPa in order to investigate the pressure effects for spin states.

Experimental

X-Ray Structure Analysis. Crystals were deep red and thin hexagonal (0 1 0) plates. The crystal specimens used for X-ray data collection were sealed in Lindemann-glass capillaries, since they are rather sensitive to air exposure. Oscillation and Weissenberg photographs taken at room temperature showed the crystal to be polymorph II. The crystal was cooled in a cold N_2 gas flow and kept constant at 175±1 and 110±1 K. The unit cell dimensions were refined by least-squares methods based on the values of 31, 19, and 16 reflections at 298, 175, and 110 K, respectively. The intensities were measured on an automated four-circle diffractometer with Mo$K\alpha$ radiation ($\lambda=0.71069$ Å) monochromated by graphite plate. Three standard reflections were recorded every fifty reflections. Though Lorentz and polarization corrections were applied, no correction was made for either absorption or extinction. Crystal data are summarized in Table 1.

The structure was solved by the conventional heavy-atom method. After several refinement cycles, difference syntheses showed an orientational disorder of an S atom on the

NCS ligand at room temperature. Full-matrix least-squares refinements including a population of this disordered S atom were carried out by using a program called RADIEL.[29] In the low-spin state (175 and 110 K) the NCS group takes a regular position. Anisotropic thermal parameters were applied, except for H atoms and disordered S atom with a low population. Scatterring factors for Fe^{2+}, S, N, and C atoms were taken from International Tables for X-ray Crystallography[30] and for H atom from Stewart, Davidson, and Simpson.[31] The unit weight was used for all of the reflections. The final refinements for reflections corresponding to $|F_o|\geq 3\sigma(|F_o|)$ led to convergences of R=0.047, 0.044, and 0.042 at 298, 175, and 110 K, respectively. Final atomic parameters are given in Tables 2, 3, and 4.[32]

Absorption Spectra Measurements at High Pressures. The absorption spectra of a single crystal of $[Fe(bpy)_2(NCS)_2]$ were measured under high pressure up to 8.5 GPa in the wavelength region 450—800 nm. A diamond anvil cell was used to generate high pressure.[33] Measurements were carried out by using a microscopic optical measurement system comprising a Nikon G250 spectrometer. A mixed solvent of pentane and isopentyl alcohol (1 : 1) was used for the pressure medium, since crystals are soluble to methyl or ethyl alcohol. A pressure calibration was made based on a shift of the ruby luminescence peaks. A He-Cd laser was employed for ruby excitation; its beam was 10 μm in diameter. Changes in the crystals were visually observed under the microscope and a TV monitor.

Results and Discussion

Crystal Structure. A projection of the crystal structure along the c-axis in the high-spin state is given in Fig. 1 and those along b-axis in both spin states are shown in Figs. 2(a) and (b). An iron atom of $[Fe(bpy)_2(NCS)_2]$ molecule lies on a crystallographic two-fold axis along the c-axis and is octahedrally coordinated by two N atoms of isothiocyanate ligands in the cis-configuration and four N atoms of bidentate bipyridine ligands. The molecular symmetry of the structure remains the same in both high- and low-spin states. The general feature of the structure is the same as that reported by König and Watson.[5] However, remarkable structural changes according to the electronic configuration of two spin states including some orientational disorder of the NCS ligand were revealed from the present results. No crystallographic change was observed in the temperature range from 175 to 110 K, although a thermal anomaly at 145 K was observed in the heat-capacity measurements by Takahashi et al.,[34] besides a thermal anomaly at 213 K associated with the spin transition. The bond lengths and angles at 175 and 110 K are in good agreement within twice the esd's. They are listed in Table 5 together with those at 298 K. The average Fe-N value is 2.133 Å (298 K) in the high-spin state, while 1.962 (3) Å (175 K) and 1.959 (3) Å (110 K) in the low-spin state. The Fe-N bond difference of 0.17 Å between low- and high-spin states is consistent with that (0.18 Å) observed in $[Fe(\alpha\text{-pic})_3]Cl_2 \cdot EtOH$[6,7] and that (0.20 Å) observed between bis[hydrotris-(1-pyrazolyl)borato]iron(II) in the low-spin state and bis[hydrotris(3,5-dimethyl-1-pyrazolyl)borato]iron(II) in the high-spin state.[11] When looked into with more detail, the Fe-N bond distances were found to shorten by 0.207 Å for the bipyridine ligand and by 0.106 Å for the NCS ligand upon transition from the high- to low-spin state. The considerable $Fe\text{-}N_{(bpy)}$ shortening in the low-spin state appears to show large increase of back-donation of the $d\pi$ electron of the Fe atom to an empty π^* orbital of the bipyridine ligand, as was observed in $Fe\text{-}N_{(py)}$ of $[Fe(\alpha\text{-pic})_3]Cl_2 \cdot EtOH$ compound.[6,7]

The distortion on the FeN_6 core from an octahedron is smaller in the low-spin state than in the high-spin state. The twist angle between two triangles, which are defined by three N atoms on the planes perpendicular to the pseudo three-fold axis, is 45° in the high-spin state and 49° in the low-spin state. The tilt angle between two triangular faces is 8.2° at 298 K and 1.1° at 110 K. The N(1)-Fe-N(3) angle decreases from 100.4(2)° to 91.6(1)° upon going from the high- to the low-spin state, while N(1)-Fe-N(2′) and N(3)-Fe-N(3′) became closer to a linear configuration. Though the increases of the angle in N(2)-Fe-N(2′) and N(2)-Fe-N(3′) are in opposite directions, it seems to be related to a relative detachment of two bipyridine ligands with respect to each other in the low-spin state. This possibly occurs through a repulsion

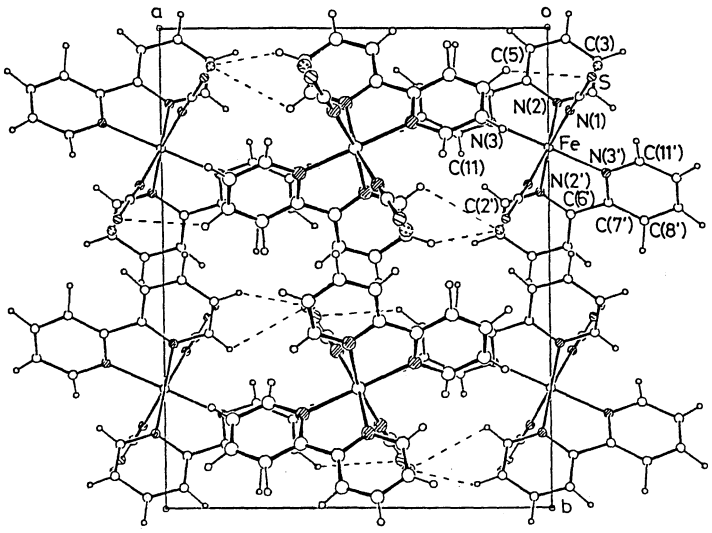

Fig. 1. A projection of $[Fe(bpy)_2(NCS)_2]$ in the high-spin state (298 K) along c-axis.

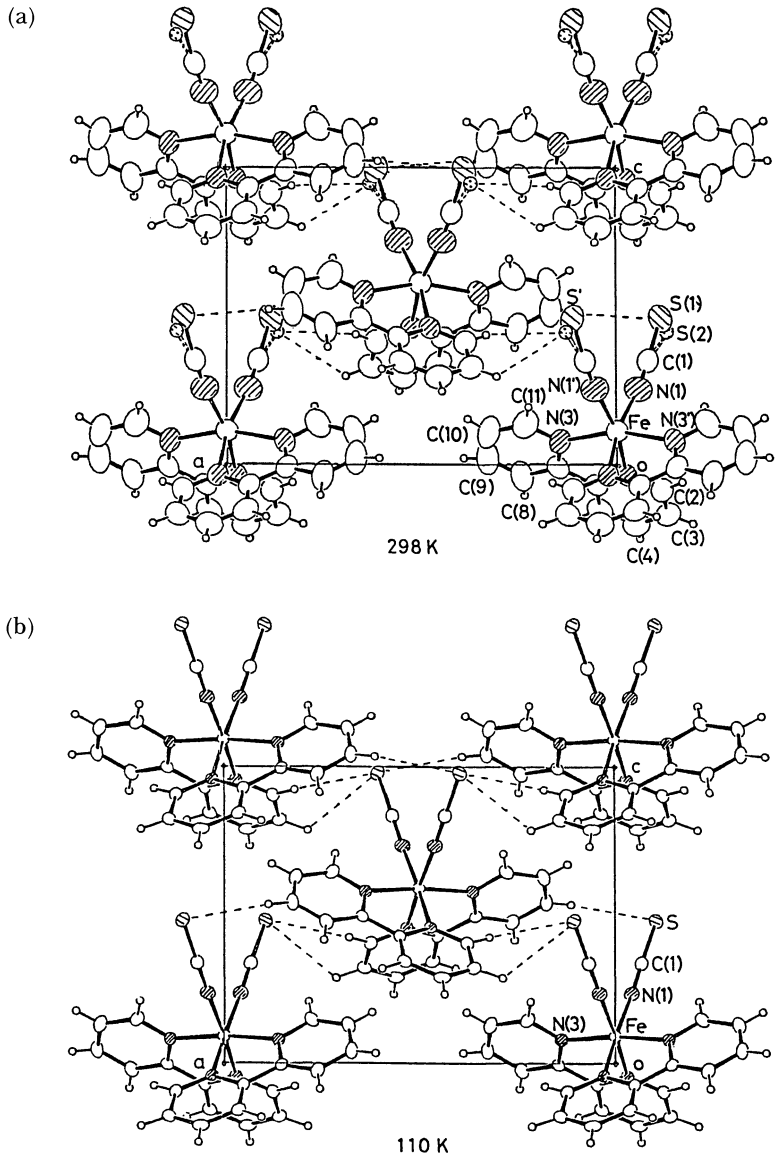

Fig. 2. Projections of $[Fe(bpy)_2(NCS)_2]$ along b-axis. (a) in the high-spin state (298 K), (b) in the low-spin state (110 K). Broken lines show short contacts between S and H atoms.

between an anti-bonding π^* orbital of bipyridine ligands, which has increased occupancy in the low-spin state due to the back-donation.

In the high-spin state the NCS ligands exhibit an orientational disorder of the S atoms at two sites with a population ratio ca. 7 : 1; in the low-spin state the NCS ligand takes a regular position. The S atom with a lower population contacts to H(3) with a short distance of 2.80(6) Å, indicating a weak hydrogen-bond between them. The interatomic distance between the S atom with a higher population and H(9) is 2.95(6) Å. On the other hand, in the low-spin state the NCS ligand takes the same arrangement as that of higher occupancy in the high-spin structure. A short contact between adjacent molecules is found between the S and H(9) with an interatomic distance of 2.89 (4) Å.

The bond distances and angles of the NCS ligand show that it resonates between the $Fe\text{-}N^-\text{=}C\text{=}S$ and $Fe\text{-}N\text{-}C\equiv S^-$ structures. The N(1)-C(1) bond distance is 1.139 (7) and 1.153 (4) Å at 298 and 110 K, respectively, indicating that the bond order is almost triple. The C(1)-S(1) bond length appears to be constant in both the high- and low-spin states and the average value of 1.638 Å seems to suggest that the bond order is between double and single, being much closer to the former. The larger occupation in the $Fe\text{-}N^-\text{=}C\text{=}S$ configuration brings about a larger deviation from 180° regarding the Fe-N-C bond angle owing to the sp^2 configuration of the N atom. The Fe-N(1)-C(1) angle is

a) Primed and unprimed atoms are related by a two-fold axis along the c-axis through the iron atom of the molecule.

165.3 (4)° at 298 K and 164.4 (3)° at 110 K, both of them shifting from linear coordination. A deviation of the M-N-C angle from 180° is usually found in octahedral coordination of the NCS ligand;[35,36] in tetrahedrally coordinated complex, however, $Co(NCS)_4Hg$, Co-N-C was observed to be linear.[37]

Two pyridine rings within a bipyridine ligand are slightly bent with respect to a five-membered ring in the opposite direction. As shown in Fig. 1, two pyridine rings of neighboring complexes related by a symmetry center are parallel and overlap each other with an interplanar distance of 3.503 Å (298 K) in the high-spin state and 3.495 Å (175 K) and 3.457 Å (110 K) in the low-spin state. There seems to be a charge-transfer interaction between these rings. The change of the interplanar distance upon a spin transition is small compared to the value expected from thermal expansion, suggesting that the occupation of the π^* orbital of the bipyridine ligand due to a back-donation in the low-spin state weakens the π-π^* charge transfer interaction between them.

Absorption Spectra at High Pressure. The absorption maximum was observed around 540 nm for the spectra of $[Fe(bpy)_2(NCS)_2]$ in the high-spin state at 1 atm; this was in good agreement with the results reported by Takahashi et al.[38] When the crystal was pressed to 0.4 GPa, the color darkened from deep red to dark red and the spectra exhibited a fine structure with two maxima at 545 and 570 nm. This indicates that the spin state had started to change from the high-spin to the low-spin state at 0.3 GPa, since the low-spin state spectra at 77 K/1 atm has two maxima at 538 and 595 nm.[38] The absorption edge of the spectra showed a remarkable red shift with increasing pressure and intensity saturation was observed in the wavelength region less than 600 nm. The intense visible absorption band around 600 nm can be assigned to a charge-transfer transition of t_{2g} to the π^* orbital in

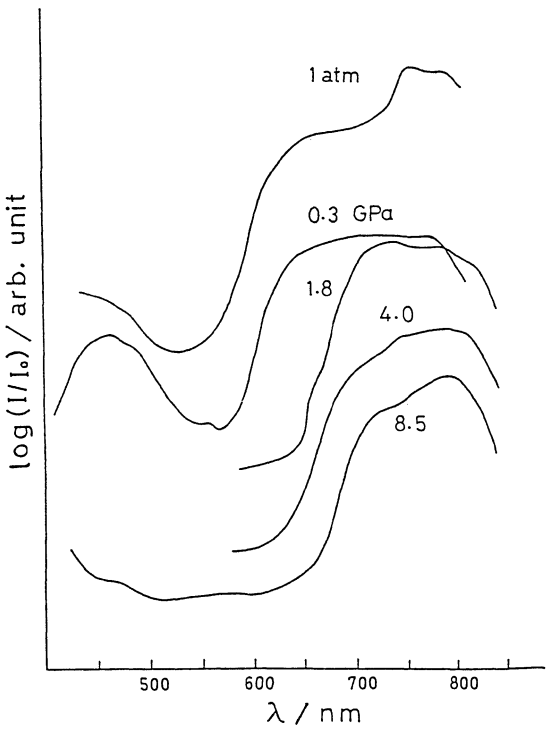

Fig. 3. Absorption spectra of $[Fe(bpy)_2(NCS)_2]$ under high pressure.

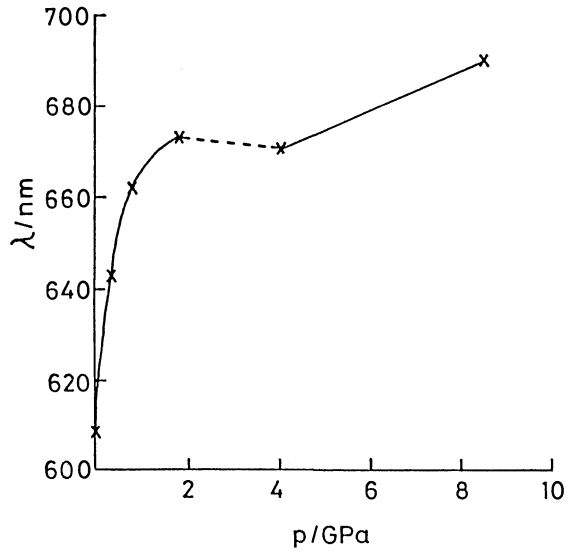

Fig. 4. Variation of absorption edge of $[Fe(bpy)_2(NCS)_2]$ under high pressure.

analogy with the case of $[Fe(phen)_2(NCS)_2]$.[23] At a pressure of 3.3 GPa a microscope observation showed that the crystal made a drastic change, displaying net-like boundaries on the surface, changing at every momemt, which seems to reflect something like a domain structure. Such movement continued for a few minutes; when it settled, the crystal color had lightened and once again became uniform. At that time, the absorption edge shifted back to a shorter wavelength region, as illustrated in Fig. 4. The iron(II) spin crossover complexes are known to exhibit pressure-induced spin transitions of the high- to the low-spin state under rather low pressure (up to ca. 2 GPa) and inversion of the low- to the high-spin state in the higher pressure range based on a ligand field calculation of the electronic states of both spin states.[3] The change around 3.3 GPa can be interpreted as being a latter conversion of the low- to the high-spin state. At 8.5 GPa, however, the spectra showed an entirely different feature from that of either the high- or the low-spin states. When the pressure was slowly reduced to 1 atm, the position of the small absorption maxima was slightly shifted by about 10 nm from the original position. One interpretation for this phenomenon is that the crystals changed from polymorph II to polymorph I by imposing pressure, since polymorph I has a larger density compared to polymorph II, their specific gravity being 1.482 and 1.462 $g\,cm^{-3}$, respectively. This can be understood structurally as being a small rotation of complex molecules, just like propellers facing in a certain direction systematically.

The authors are grateful to Professor Keisuke Suzuki and Jun Takahashi at the Faculty of Science of Kwansei Gakuin Univesity for the single crystals. Thanks are also due to Professor Takehiko Yagi of Institute for Solid State Physics, the University of Tokyo for all the facilities made available for measurements of the absorption spectra under high pressure. This work was carried out under the joint research in the Institute for Solid State Physics, the University of Tokyo.

Ion Pairing of Radical Ions of Aromatic Alkenes and Alkynes Studied by Pulse Radiolysis

Satoshi YAMAMOTO, Yukio YAMAMOTO,* and Koichiro HAYASHI
The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567
(Received June 28, 1990)

Pulse radiolysis of 1,2-dichloroethane solutions of *trans,trans*-1,4-bis(2-phenylethenyl)benzene and 1,4-bis(2-phenylethynyl)benzene was undertaken in the presence of Bu_4NPF_6 (Bu=butyl) to investigate the effect of ion pairing of the solute radical cations with PF_6^-. It was also undertaken for the tetrahydrofuran solutions of the above compounds in the presence of Bu_4NPF_6 and $NaBPh_4$, where the solute radical anions are generated and form ion pairs with Bu_4N^+ and Na^+. The decay of the radical ions, which is due to neutralization, is retarded by the ion pairing. The rate constants for the neutralization reactions in the free-ion and ion-paired states were determined. Also presented are the data for the radical ions of *trans*-stilbene, diphenylacetylene, *trans,trans*-1,4-diphenyl-1,3-butadiene, and diphenylbutadiyne. The radical ions of the aromatic alkynes are less stabilized by the ion pairing than those of the aromatic alkenes having the same carbon skeletons probably because of more extensive charge delocalization of the former radical ions. Spectral shifts to shorter wavelengths caused by the ion pairing are appreciable for the radical anions. Dependence of the spectral shifts on the size of the radical anions is described.

Extensive spectrophotometric studies of ion pairing have been undertaken for aromatic radical anions formed by alkali-metal reduction.[1,2] The absorption maxima of the anionic species are shifted to shorter wavelengths when they form contact ion pairs with the alkali-metal cations. The magnitude of the spectral shifts decreases as the interionic separation, or the radius of the cations, increases. Thus, the absorption maxima of solvent-separated ion pairs are essentially the same as those of free anions. The effect of ion pairing has also been studied for negatively charged species generated by pulse radiolysis. The rate constants for the reactions of solvated electrons, aromatic radical anions, and carbanions have been determined for the free-ion and ion-paired states.[3-7]

We have previously reported pulse radiolysis studies of salt effects for aromatic radical cations and anions, which are formed in 1,2-dichloroethane and tetrahydrofuran (THF) solutions, respectively.[8-12] In the solutions containing Bu_4NPF_6 (Bu=butyl) and $NaBPh_4$ (Ph=phenyl) the radical ions form ion pairs with the counter ions derived from the salts, such as PF_6^-, Bu_4N^+, and Na^+. The decay of the radical ions, which is due to neutralization, was retarded by the ion pairing. Spectral shifts to shorter wavelengths by the ion pairing were appreciable for the radical anions. For the radical anions of all-*trans* α,ω-diphenyl-substituted polyenes, $Ph(CH{=}CH)_nPh$ (n=1—4), the magnitude of the spectral shifts varied with the value of n depending on the kind of the counter ions, Bu_4N^+ and Na^+.[12] As the value of n increased, the magnitude of the spectral shift increased for the ion pairs with Bu_4N^+ and decreased for the ion pairs with Na^+. Small spectral shifts were also observed for the radical cations of $Ph(CH{=}CH)_nPh$, when paired with PF_6^-.[11] We are interested in the ion pairing of the radical ions having long conjugated π-electron systems.

The present pulse radiolysis study has been undertaken for the radical ions of *trans,trans*-1,4-bis(2-phenylethenyl)benzene (DStBz) and 1,4-bis(2-phenylethynyl)benzene (DPEBz). Also presented are the data for the radical ions of other aromatic alkenes

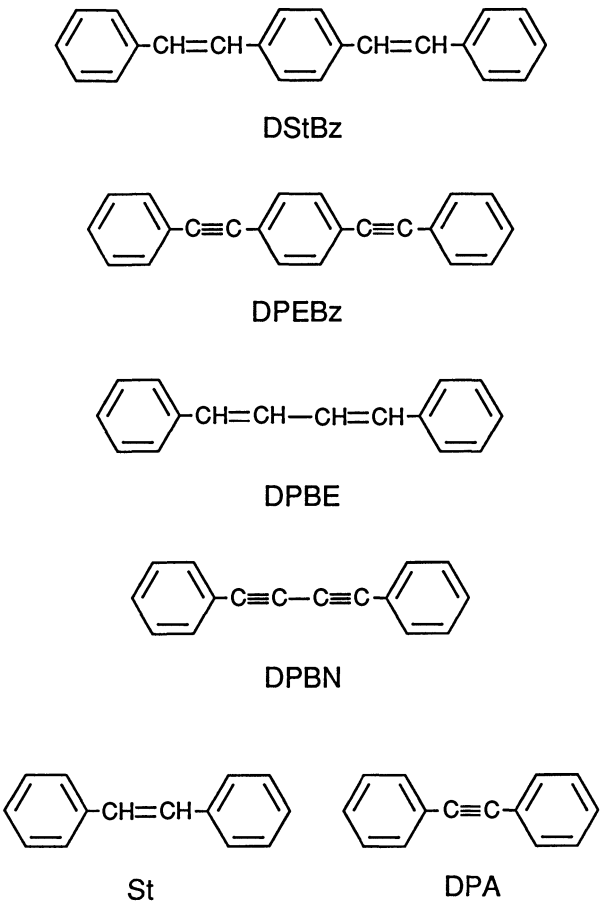

Fig. 1. Structures of the aromatic alkenes and alkynes.

and alkynes such as *trans*-stilbene (St), diphenylacetylene (DPA), *trans,trans*-1,4-diphenyl-1,3-butadiene (DPBE), and 1,4-diphenylbutadiyne (DPBN). The structures of these compounds are shown in Fig. 1. The second-order rate constants for the neutralization reactions of the radical ions were determined in the absence and presence of the salts. The effect of the ion pairing is compared between the radical ions of the aromatic alkenes and alkynes having the same carbon skeletons. The results of the previous studies on the ion pairing of the various aromatic radical ions are summarized in the present paper.

Experimental

1,2-Dichloroethane, THF, Bu_4NPF_6, and $NaBPh_4$ were the same as those used in the previous studies.[8-12] DStBz and DPEBz were prepared by literature procedures[13,14] and recrystallized from benzene and a benzene-hexane mixture, respectively. DPA (Tokyo Kasei) and DPBN (Aldrich) were purified by recrystallization from hexane. The experimental procedures and the techniques of pulse radiolysis have been described in the previous paper.[8] The pulse radiolysis experiments were carried out by using 8 ns electron pulses and at room temperature. The molar extinction coefficients of the radical ions were determined by comparing the absorption intensities based on the values of the St radical ions as in the previous studies.[8-12]

Results

The pulse radiolysis of 1,2-dichloroethane solutions of the aromatic alkenes and alkynes was carried out at a solute concentration of 3×10^{-3} mol dm^{-3} in the presence of 6×10^{-2} mol dm^{-3} biphenyl as in the previous studies.[8-12] The solute radical cations are produced by charge transfer from the biphenyl radical cation initially formed. The decay of the radical cations, $S^{+\cdot}$, is due to neutralization with Cl^-, a product of electron attachment to the solvent.

$$S^{+\cdot} + Cl^- \longrightarrow \text{neutral product}, \quad (1)$$

where S denotes the aromatic solute.

Figures 2 and 3 show the transient absorption spectra measured for the solutions of DStBz and DPEBz, respectively, in the absence of the salt. The absorption spectra did not change during the decay, and all observed peaks are assigned to $DStBz^{+\cdot}$ and $DPEBz^{+\cdot}$. When 6×10^{-3} mol dm^{-3} Bu_4NPF_6 was added, the peaks of the absorption spectra were slightly shifted to shorter wavelengths, and the decay of the absorption was retarded. The absorption spectra measured in the absence and presence of the salt are those of the free-radical cations and their ion pairs with PF_6^-, respectively.

The pulse radiolysis was also carried out for the solutions of DPA and DPBN. The absorption spectra of $DPA^{+\cdot}$ and $DPBN^{+\cdot}$ agreed with those reported in literature.[15] The absorption maxima of the radical cations and the magnitudes of the spectral shifts caused by the ion pairing are listed in Table 1 together with those of $St^{+\cdot}$ and $DPBE^{+\cdot}$ measured in the previous studies.[10,11]

The decay of the absorption of the radical cations obeyed second-order kinetics, suggesting that it is due exclusively to the neutralization. The rate constants, k_1 and k_2, for the neutralization reactions were determined in the absence and presence of the salt, respectively. The data are listed in Table 2. In the presence of the salt the neutralization reactions occur

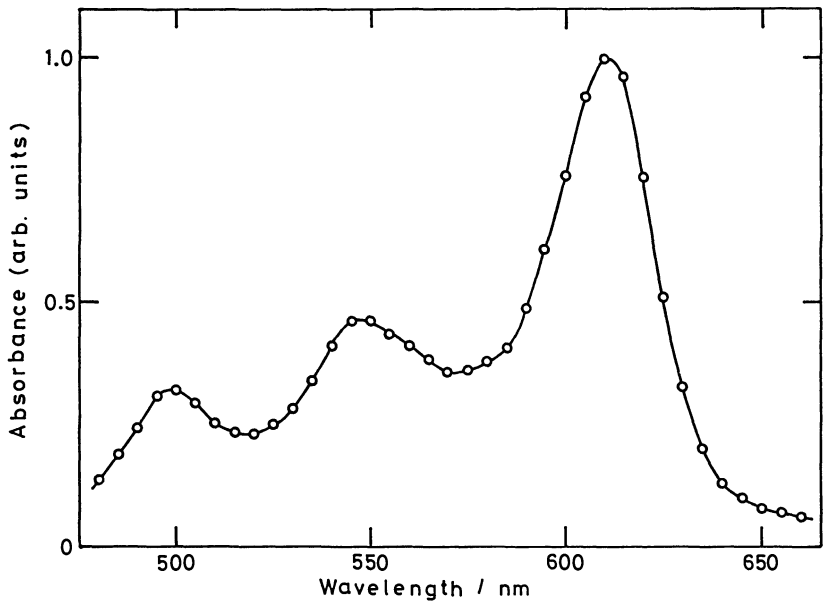

Fig. 2. Transient absorption spectrum of $DStBz^{+\cdot}$ in 1,2-dichloroethane (at 400 ns).

Table 1. Positions of Absorption Maxima of the Free-Radical Cations and Spectral Shifts Caused by Ion Pairing with PF_6^-

Cation	λ_{max}	$\Delta\lambda$	ε_{max}
	nm	nm	$dm^3\,mol^{-1}\,cm^{-1}$
$St^{+\cdot}$	480	<2	6.5×10^4
$DPBE^{+\cdot}$	546	4	1.2×10^5
$DStBz^{+\cdot}$	610	2	1.1×10^5
$DPA^{+\cdot}$	422	0	3.9×10^4
$DPBN^{+\cdot}$	482	0	1.7×10^4
$DPEBz^{+\cdot}$	515	3	7.1×10^4

Table 2. Rate Constants for the Neutralization Reactions of the Radical Cations in the Free-Ion (k_1) and Ion-Paired (k_2) States

Cation	Rate constant/$dm^3\,mol^{-1}\,s^{-1}$		k_1/k_2
	k_1	k_2	
$St^{+\cdot}$	$(1.6\pm0.2)\times10^{11}$	$(3.3\pm0.2)\times10^{10}$	5.0
$DPBE^{+\cdot}$	$(1.6\pm0.1)\times10^{11}$	$(2.9\pm0.1)\times10^{10}$	5.5
$DStBz^{+\cdot}$	$(8.9\pm0.7)\times10^{10}$	$(1.7\pm0.2)\times10^{10}$	5.2
$DPA^{+\cdot}$	$(1.2\pm0.2)\times10^{11}$	$(4.4\pm0.5)\times10^{10}$	2.7
$DPBN^{+\cdot}$	$(1.5\pm0.2)\times10^{11}$	$(6.4\pm0.4)\times10^{10}$	2.3
$DPEBz^{+\cdot}$	$(1.4\pm0.1)\times10^{11}$	$(4.3\pm0.2)\times10^{10}$	3.3

between the ion pairs.

$$S^{+\cdot}/PF_6^- + Bu_4N^+/Cl^- \longrightarrow \text{neutral product.} \quad (2)$$

The k_1/k_2 ratios are presented as a measure of the salt effect. It can be seen that the k_1/k_2 ratios of the radical cations of the aromatic alkynes are small compared with those of the aromatic alkenes having the same carbon skeletons.

Table 3. Positions of Absorption Maxima of the Free-Radical Anions and Spectral Shifts Caused by the Ion Pairing with Bu_4N^+ and Na^+

Anion	λ_{max}	$\Delta\lambda$/nm ($\Delta\bar{\nu}/10^2\,cm^{-1}$) Counter ions		ε_{max}
	nm	Bu_4N^+	Na^+	$dm^3\,mol^{-1}\,cm^{-1}$
$St^{-\cdot}$	500	5 (2)	20 (8)	6.1×10^4
$DPBE^{-\cdot}$	573	9 (3)	18 (6)	1.1×10^5
$DStBz^{-\cdot}$	634	14 (4)	6 (2)	1.5×10^5
$DPA^{-\cdot}$	449	5 (3)	13 (7)	5.6×10^4
$DPBN^{-\cdot}$	494	6 (2)	14 (6)	1.1×10^5
$DPEBz^{-\cdot}$	519	7 (3)	3 (1)	1.1×10^5

Similar experiments were carried out for the THF solutions of DStBz and DPEBz containing 6×10^{-2} mol dm^{-3} biphenyl, where the solute radical anions are produced by electron transfer from the biphenyl radical anion and are neutralized by the solvent cation.

$$S^{-\cdot} + THF(H^+) \longrightarrow \text{neutral product.} \quad (3)$$

When 6×10^{-3} mol dm^{-3} Bu_4NPF_6 and $NaBPh_4$ were added, the absorption maxima of the radical anions were appreciably shifted to shorter wavelengths. Figures 4 and 5 show the transient absorption spectra measured for the solutions of DStBz and DPEBz, respectively, in the absence and presence of Bu_4NPF_6. The absorption spectra did not change during the decay. The pulse radiolysis was also carried out for the solutions of DPA and DPBN. The absorption spectra of $DPA^{-\cdot}$ and $DPBN^{-\cdot}$ in the absence of the salts agreed with those reported in literature.[15] The absorption maxima of the radical anions are listed in

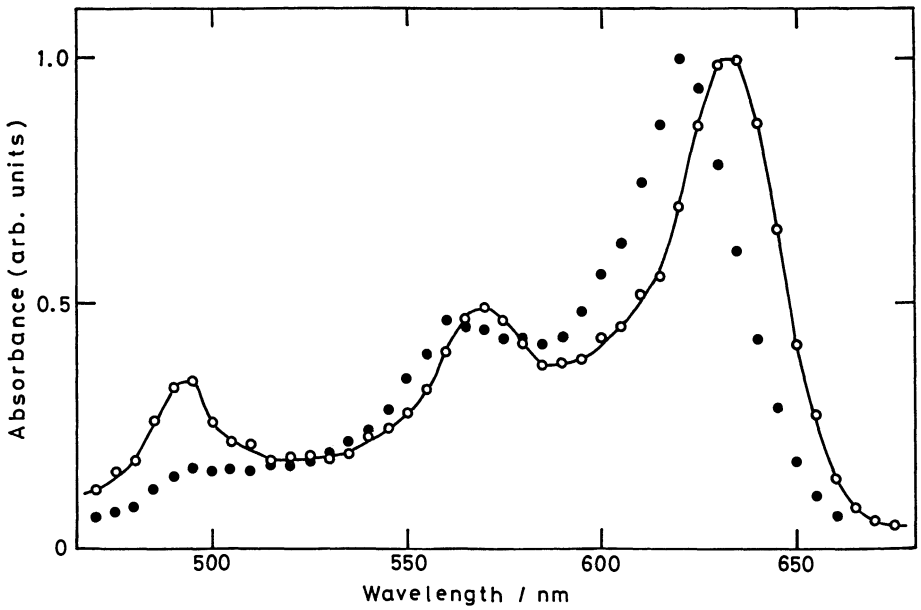

Fig. 4. Transient absorption spectra of DStBz$^{-\cdot}$ in the absence (○) and presence (●) of 6×10^{-3} mol dm^{-3} Bu_4NPF_6 (at 400 ns).

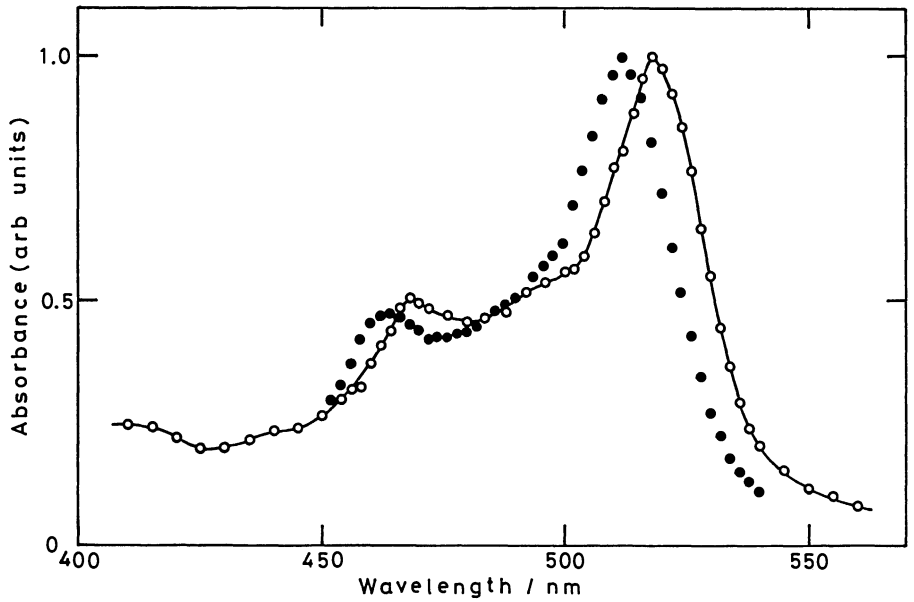

Fig. 5. Transient absorption spectra of DPEBz$^{-\cdot}$ in the absence (○) and presence (●) of 6×10^{-3} mol dm^{-3} Bu_4NPF_6 (at 400 ns).

Table 3 together with those of St$^{-\cdot}$ and DPBE$^{-\cdot}$ measured in the previous studies.[9,12]

The rate constants for the neutralization reactions of the radical anions are listed in Table 4. The k_3 and k_4 values were determined in the absence and presence of 6×10^{-3} mol dm^{-3} Bu_4NPF_6, respectively. The k_4 values are the rate constants for the reactions between the ion pairs.

$$S^{-\cdot}/Bu_4N^+ + THF(H^+)/PF_6^- \longrightarrow \text{neutral product.} \quad (4)$$

Table 4. Rate Constants for the Neutralization Reactions of the Radical Anions

Anion	Rate constant/dm^{-3} mol^{-1} s^{-1}		k_3/k_4
	k_3	k_4	
St$^{-\cdot}$	$(4.0\pm0.3)\times10^{11}$	$(8.2\pm0.3)\times10^{9}$	49
DPBE$^{-\cdot}$	$(3.4\pm0.2)\times10^{11}$	$(9.0\pm0.4)\times10^{9}$	38
DStBz$^{-\cdot}$	$(2.5\pm0.1)\times10^{11}$	$(5.4\pm0.2)\times10^{9}$	47
DPA$^{-\cdot}$	$(2.9\pm0.1)\times10^{11}$	$(7.9\pm0.2)\times10^{9}$	37
DPBN$^{-\cdot}$	$(3.3\pm0.1)\times10^{11}$	$(1.0\pm0.1)\times10^{10}$	33
DPEBz$^{-\cdot}$	$(1.7\pm0.1)\times10^{11}$	$(5.3\pm0.2)\times10^{9}$	32

The k_3/k_4 ratios of the radical anions are much larger than the k_1/k_2 ratios of the radical cations. The rate constants determined in the presence of $NaBPh_4$ were intermediate between the k_3 and k_4 values.

It can be seen for the absorption spectra of $DStBz^{-\cdot}$ that the peak at 495 nm becomes smaller in the presence of Bu_4NPF_6 (Fig. 3). This was also observed in the case of $NaBPh_4$. Furthermore, the intensity of the 500-nm band of $DStBz^{+\cdot}$ was decreased by 20% in the presence of Bu_4NPF_6. However, the extinction coefficients of $DStBz^{+\cdot}$ and $DStBz^{-\cdot}$ at the main absorption peaks were not affected by the addition of the salts.

Discussion

The interaction between oppositely charged species of ion pairs, or the magnitude of spectral shifts caused by the ion pairing, decreases as the ion size increases.[1,2] The charge distribution of the large aromatic radical ions is considered to be responsible for the effect of the ion pairing rather than the apparent size of the charged species. The retardation of the neutralization reactions and the spectral shifts caused by the ion pairing are considered to be the measure of the interaction between the radical ions and the counter ions derived from the salts. Here the ion pairing of the radical ions of the aromatic alkenes and alkynes is discussed by considering the charge distribution and the length of the conjugated π-electron systems.

Radical Cations. The neutralization reactions of the radical cations of the aromatic alkenes and alkynes with Cl^- in the free-ion state are considered to be diffusion controlled and be accelerated by Coulombic attraction between the oppositely charged reactants. This is similar to the case of the radical cations of biphenyl, anthracene, triphenylethylene, and $Ph(CH{=}CH)_nPh$ (n=1—4).[10,11] The rate constants, k_1, of these radical cations are close to each other, lying in the range $(8.6—19)\times10^{10}$ $dm^3\,mol^{-1}\,s^{-1}$. In general, k_1 decreases as the ion size increases because of the slow rate of diffusion of the large radical cations.[10,11] A similar trend is observed for k_3 of the radical anions.[9,12]

In the presence of the Bu_4NPF_6, the rate constants of the radical cations of the aromatic alkenes decrease by a factor of about 5: the k_1/k_2 ratios are in the range 5.0—5.5. On the other hand, the k_1/k_2 ratios of the radical cations of the aromatic alkynes are in the range 2.7—3.3. It is suggested that the alkyne radical cations are less stabilized by the ion pairing with PF_6^- than the alkene radical cations having the same carbon skeletons. This can be explained as follows. The positive charge of the alkyne radical cations is cylindrically distributed around the triple bonds, whereas the charge distribution of the alkene radical cations is restricted to the direction perpendicular to the molecular planes. The charge of the alkyne radical cations may be spread over the aromatic rings more extensively than that of the alkene radical cations, for which the aromatic rings and the olefinic moieties are not completely coplanar. The charge delocalization of the alkyne radical cations results in a lowering of the interaction with PF_6^-.

As reported previously,[10,11] the neutralization reactions of the radical cations of pyrene, perylene, and tetraphenylethylene in the free-ion state are not diffusion controlled: the k_1 values are 9.4×10^9, 7.2×10^9, and 2.8×10^9 $dm^3\,mol^{-1}\,s^{-1}$, respectively, and are one order of magnitude smaller than those of the other radical cations. Furthermore, the salt effect is negligibly small for these radical cations: the k_1/k_2 ratios are nearly unity.[10,11] It can be said that these radical cations have smaller reactivities or interactions with the anions, Cl^- and PF_6^-, than the other radical cations. The result for the tetraphenylethylene radical cation has been interpreted in terms of steric crowding of the phenyl groups, which surround the positive charged center located on the olefinic double bond. For the radical cations of pyrene and perylene the charge delocalization over the large condensed-ring aromatics may be responsible for the small reactivities or interactions with the anions. Formation of a complex has been proposed for the slow neutralization reactions of the radical cations of pyrene and perylene, $P^{+\cdot}$.[10,11]

$$P^{+\cdot} + Cl^- \underset{k_d}{\overset{k_c}{\rightleftarrows}} P^{+\cdot}/Cl^- \xrightarrow{k_n} \text{neutral product.} \qquad (5)$$

The k_1 values correspond to k_nk_c/k_d.

Although both the radical cations and Cl^- are paired with the counter ions from the salt, the retardation of the neutralization is due largely to the ion pairing of the radical cations as reported previously.[10,11] This is based on the result that the k_1/k_2 ratios depend on the kind of the radical cations and are close to unity for the radical cations of pyrene, perylene, and tetraphenylethylene.

Spectral shifts by the ion pairing are observed only for the radical cations having long π-electron systems, such as $DStBz^{+\cdot}$, $DPEBz^{+\cdot}$, and $Ph(CH{=}CH)_nPh^{+\cdot}$ (n=2—4), although very small spectral shifts, <2 nm, are also observed for $St^{+\cdot}$ and the triphenylethylene radical cation.[10,11] An explanation for the spectral shifts of these large radical cations may be the charge localization induced by PF_6^- in the long π-electron systems, resulting in formation of contact ion pairs.[11] It is also possible that the absorption spectra of the radical cations having long π-electron systems are sensitive to the counter ion and are shifted without forming contact ion pairs.

Radical Anions. The appreciable spectral shift by the ion pairing is characteristic of the radical anions. The magnitude depends on the size of the radical anions and on the kind of the counter ions. A

dependence of the spectral shift on the size of the radical anions, similar to that for $Ph(CH=CH)_n$-$Ph^{-\cdot}$,[12] can be seen in Table 3, although the trend is not clear when the magnitude is small. It is suggested that a large radical anion has a strong interaction with a large counter ion while a small one does with a small counter ion. This may be particular to the radical anions having long π-electron systems.

The neutralization reactions of the radical anions with $THF(H^+)$ in the free-ion state are considered to be diffusion controlled. The rate constants, k_3, are in the range $(1.7—4.0)\times10^{11}$ $dm^3\,mol^{-1}\,s^{-1}$, including k_3 of the radical anions of biphenyl, anthracene, pyrene, perylene, triphenylethylene, and $Ph(CH=CH)_nPh$ (n=1—4).[9,12] They are larger than k_1 for the diffusion controlled reactions of the radical cations in 1,2-dichloroethane. This is due mainly to the difference in the solvent viscosity as reported previously.[10] The viscosities of 1,2-dichloroethane and THF at 22 °C are 0.0081 and 0.0048 Pa s, respectively. Corrected for the solvent viscosities, k_1 and k_3 become almost the same.

Contrary to the radical cations, the radical anions of pyrene and perylene have k_3 comparable to those of the other radical anions.[9,12] It has been suggested that the neutralization reactions of the radical anions with $THF(H^+)$ are less selective than those of the radical cations with Cl^- because of the strong electrophilicity of $THF(H^+)$, which is essentially a proton.

The neutralization reactions of the radical anions are significantly affected by the addition of Bu_4NPF_6. The k_3/k_4 ratios are one order of magnitude larger than the k_1/k_2 ratios of the radical cations. It has already been demonstrated that the salt effect on the neutralization reactions is due mainly to the ion pairing of $THF(H^+)$ with PF_6^- rather than to that of the radical anions with Bu_4N^+.[8] Therefore, the large retarding effect for the radical anions can be attributed to the strong interaction of the charge-localized $THF(H^+)$ with PF_6^-.

The k_3/k_4 ratios of the radical anions of the aromatic alkynes are slightly smaller than those of the aromatic alkenes having the same carbon skeletons. This shows that the alkyne radical anions are less stabilized by the ion pairing than the alkene radical anions. This is similar to the radical cations paired with PF_6^-. The dependence of k_4 on the kind of the radical anions suggests that the ion pairing of the radical anions with Bu_4N^+ is partly responsible for the retardation of the neutralization reactions but to a less extent compared to the ion pairing of $THF(H^+)$ with PF_6^-.

We thank the members of the Radiation Laboratory of this Institute for help with the pulse radiolysis experiments and Professor S. Takahashi of this Institute for useful suggestions for the synthesis of DPEBz.

Photoelectron Emission Study of Iron(II) and Cobalt(II) Complexes in Aqueous Solution. Reorganization Energies

Iwao WATANABE,* Kaori ONO, and Shigero IKEDA†
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
†Faculty of Science and Technology, Ryukoku University, Otsu, Shiga 520-21
(Received July 11, 1990)

The photoelectron emission threshold energies of Fe^{II} and Co^{II} complexes in aqueous solutions have been determined. The values could be successfully used for obtaining the reorganization energies in the one-electron oxidation reaction of these complexes. The obtained reorganization energies were found to be correlated with the rate constants of the electron-self-exchange reactions of Fe^{II}/Fe^{III} and Co^{II}/Co^{III}.

A new spectroscopic technique, Photoelectron Emission Spectroscopy (PEES) of solution,[1-5] provides the photoelectron emission threshold energies, E_t, of molecules or ions in solution. The E_t values for organic molecules in solutions have been found to be linearly correlated with their ionization potentials, I_p, in the gas phase or the oxidation potentials, E_{ox}, in solutions.[4,5] The E_{ox} values used, however, are not of the equilibrium values but the peak potentials in cyclic voltammetry. Since E_{ox} is thermodynamically less meaningful than the standard redox potential, E°, it is essential to measure the E_t values of any samples for which the E° values are accurately known in order to study the correlation between E_t and E°. Iron(II) and cobalt(II) with various ligands or chelates are suitable for this purpose since it is easy to find a variety of E° values from these complexes.

The E_t and E° for a one-electron redox reaction pertain to the energy changes of the following reactions:

$$X^{nz} \rightarrow {}^*X^{nz+1} + e^-(\text{vacuum}) \qquad E_t \quad (1)$$

$$X^{nz} \rightarrow X^{nz+1} + e^-(\text{electrode at the potential of NHE})^{6)} \qquad E^\circ \quad (2)$$

Since the $^*X^{nz+1}$ in Eq. 1 is the product of an optical process (the Franck-Condon transition), the $^*X^{nz+1}$ has a geometrical structure which is exactly the same as that of the X^{nz} with respect to the geometries both in the inner- and the outer-sphere regions, and is in a vibrationally excited state. The vibrational relaxation energy of the $^*X^{nz+1}$, or the reorganization energy, ΔG_r, in the one-electron oxidation reaction of X^{nz}, is defined by

$$^*X^{nz+1} \rightarrow X^{nz+1} \qquad \Delta G_r \quad (3)$$

and given as follows:

$$\Delta G_r = (E^\circ + \Delta G_H) - E_t \qquad (4)$$

where $\Delta G_H (\approx 4.5\text{eV})$[7] is the potential energy of the vacuum level with respect to NHE.

In the Marcus theory for outer-sphere electron transfer reactions, the ΔG_r is a key parameter closely related to the activation energy.[8] Its evaluation is thus essential for the study of the kinetics. Considering the importance of ΔG_r, the potentiality of the PEES of solution providing the ΔG_r value must be fully explored.

Only a few studies have taken place in which ΔG_r values have been obtained from PEES experiments,[9-11] or the values so obtained treated in discussions concerning electron transfer kinetics.[12-16] In the present study, the experimentally obtained ΔG_r values for iron(II)/(III)[17] and cobalt(II)/(III) complexes are compared with the values calculated with the following equations, which are considered to be the only practical method for estimating the ΔG_r values:

$$\Delta G_r = \Delta G_r(\text{in}) + \Delta G_r(\text{out}), \qquad (5)$$

$$\Delta G_r^{calc}(\text{in}) = -(1/2) N f_o (\Delta r)^2, \qquad (6)$$

and

$$\Delta G_r^{calc}(\text{out}) = -(e^2/2a)(\varepsilon_{op}^{-1} - \varepsilon_s^{-1}), \qquad (7)$$

where ΔG_r(in) and ΔG_r(out) are the inner- and outer-sphere components of the reorganization energy, respectively; N is the coordination number of the complex (6 in this study), f_o the force constant for the bond between the central metal and its coordinating atom for the oxidized species (X^{nz+1}), Δr the difference in the coordination bond distances for the X^{nz} and X^{nz+1}, a the mean radius of the assumed boundaries between the inner- and outer-sphere regions for the X^{nz} and X^{nz+1}, and ε_{op} and ε_s the optical and the static dielectric constants of water.

Experimental

Photoelectron Emission Spectrometer for Solution. Details concerning the spectrometer have been described elsewhere.[3,4] Since this technique is extremely sensitive to any surface contamination of a sample solution, a surface scratcher was newly provided to the rotating glass disk. The scratcher is made of a thin plastic film and presses the glass surface very lightly at a few millimeters above the sample solution; it thus prevents organic contaminants floating on the surface of the solution from entering the photoionization region. This greatly improved the cleanliness of the observing surface. Therefore, the slower rotation rate of the glass disk could be utilized, resulting in

smaller capacitive noise currents and better S/N ratios.

Samples. The reagents used to prepare the solutions were of guaranteed reagent grade and were used without further purification. The abbreviations used in this paper are: edta=*N,N,N',N'*-ethylenediaminetetraacetate, pdta=1,2-diaminopropane-*N,N,N',N'*-tetraacetate, cydta=1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetate, bpy=2,2'-bipyridine, dmbpy=4,4'-dimethyl-2,2'-bipyridine, phen=1,10-phenanthroline, tmp=3,4,7,8-tetramethyl-1,10-phenanthroline, Cl-phen=5-chloro-1,10-phenanthroline, tpy=2,2':6',2''-terpyridine, N4=1,4,8,11-tetraazacyclotetradecane.

The constituents of the solutions measured were: $[Fe(H_2O)_6]^{2+}$; 2M(M=mol dm^{-3}), 1M, 0.5M in 3M H_2SO_4, $[Fe(edta)]^{2-}$; 0.2M, 0.1M, 0.05M, $[Fe(CN)_6]^{4-}$; 0.2M in 0.1M KOH, $[Fe(bpy)_3]^{2+}$; 0.8M, 0.4M, 0.2M, $[Fe(dmbpy)_3]^{2+}$; 0.05M, 0.025M, $[Fe(phen)_3]^{2+}$; 0.8M, 0.4M, 0.2M, $[Fe(tmp)_3]^{2+}$; 0.05M, 0.025M, $[Fe(tpy)_2]^{2+}$; 0.05M, 0.025M, $[Co(H_2O)_6]^{2+}$; 0.2M in 2M H_2SO_4, $[Co(NH_3)_6]^{2+}$; saturation in 4M ammonia water, $[Co(edta)]^{2-}$; 0.2M, 0.1M, $[Co(pdta)]^{2-}$; 0.2M, 0.1M, $[Co(cydta)]^{2-}$; 0.2M, 0.1M, $[Co(bpy)_3]^{2+}$; 0.2M, 0.1M 0.02M, $[Co(dmbpy)_3]^{2+}$; 0.2M, 0.1M, $[Co(phen)_3]^{2+}$; 0.2M, 0.1M, 0.04M, $[Co(Cl\text{-}phen)_3]^{2+}$; 0.05M, 0.01M, $[Co(tpy)_2]^{2+}$; 0.025M, 0.0125M, $[Co(N4)]^{2+}$; 0.1M.

The solutions containing edta or its analogues were prepared from $FeSO_4\cdot 7H_2O$, or $CoSO_4\cdot 7H_2O$, and $Na_2H_2edta\cdot 2H_2O$, H_4pdta, or H_4cydta, and the acidities were adjusted to pH ca. 7 with $NaHCO_3$. The solutions containing the bpy, phen, N4 or their analogues were prepared by adding excess amounts of the metal ions so that the free ligands would not exist in the solutions. If a ligand exists in excess of the metal ion, it is possible that the free ligand molecules can coagulate on the solution surface, while perturbing photoelectron emission from the solute.

The $[Co(NH_3)_6]^{2+}$, $[Fe(edta)]^{2-}$ and some others are extremely sensitive to oxidation by air. These samples were therefore prepared under a nitrogen gas atmosphere.

The solutions were cooled to around +1 °C, except for aqueous ammonia solutions, which were cooled to −15 °C since the vapor pressure of ammonia was too high at +1 °C.

Determination of E_t Values. The photoelectron emission yield Y is a function of the exciting photon quantum energy $h\nu$ and the E_t as follows:[1)]

$$Y=A(h\nu-E_t)^n, \tag{8}$$

where A is a proportional constant and n is known to be either 2 or 2.5. A plot of $Y^{1/n}$ gives a straight line and its extrapolation to $Y=0$ gives the E_t value. In this study, after testing both n values, that which gave better statistics to be fitted on a straight line was chosen. Consequently, a value of 2 was used for $[Fe(dmbpy)_3]^{2+}$, $[Co(bpy)_3]^{2+}$, $[Co(phen)_3]^{2+}$, and $[Co(tpy)_2]^{2+}$, and 2.5 was used for the other samples. The E_t values obtained with this extrapolation method are considered to correspond to the energy change of the reaction given in Eq. 1.

The E_t values were reproducible within 0.1 eV or less, irrespective of the concentrations of the metal complexes.

Results and Discussion

The E_t values obtained are listed in Table 1 together with the E° values for the X^{nz}/X^{nz+1} couples. Since both the E_t and E° values pertain to the energy necessary for removing an electron from X^{nz} (cf. Eqs. 1 and 2), one may well expect that they are related with each other. No correlation, however, was observed between them. This is because the complexes presently studied had quite different ΔG_r values. This is in contrast with the results concerning the organic molecules which have been reported.[4,5)]

The ΔG_r values determined by the PEES technique with Eq. 4 are plotted as ΔG_r^{exp} in Fig. 1 against the ΔG_r^{calc} values given by Eqs. 5—7.

The values of Δr in Eq. 6 were collected from reports concerning the X-ray diffraction and EXAFS (Extended X-ray Absorption Fine Structure). The values of a in Eq. 7 are determined according to

$$a=d_{X-L}+r_L, \tag{9}$$

where d_{X-L} is the distance between the central metal atom X and an atom L in the ligand at the most distant position from X, and r_L is the van der Waals radius of L. The values of Δr and a are included in Table 1.

As shown in Fig. 1, the experimental ΔG_r values are in excellent agreement with the calculated ones. The line in the figure indicates the position where both values are the same. It should be noted that both ΔG_r values are the result of a number of approximations and simplifications, as follows. In the derivation of Eq. 6, (1) only the bond length between the metal and the atom directly coordinating to the metal is taken into account; thus, the other differences in geometries of the X^{nz} and X^{nz+1} are neglected. (2) A harmonic potential is adopted for the bond deformation. (3) In Eq. 7, the outer-sphere component is calculated by using the Born model, i.e. the spherical conductor of radius a in a continuous medium with dielectric constants of ε_{op} and ε_s. In the derivation of Eq. 4, there exists (4) the uncertainty in ΔG_H, and (5) the double layer potential or the surface potential at the solution/gas interface is neglected. In Eq. 8, there is (6) the uncertainty in the value of n, and (7) the density of states for the ion solvated is represented by a delta function; thus, the concept of adiabatic and vertical ionization energies is abandoned.[18)] However, considering the excellent agreement between the experimental and calculated ΔG_r values, it seems that the approximations used here are adoptable within the present experimental accuracy.

Due to a spin-state change during the oxidation process for many of the cobalt complexes, i.e. the high-spin state for Co^{II} to the low-spin state for Co^{III}, these complexes have the large bond differences, Δr, and thus large ΔG_r values compared to the iron complexes whose spin states remain high. It is now important to note that the electronic state of cobalt complexes just after photoionization is not of the low-spin cobalt(III)(^1A: t_{2g}^6, e_g^0) but of a ^3T state as expressed by

Table 1. Standard Redox Potentials $E°$, Photoelectron Emission Threshold Energies E_t of M^{II}, Parameters to Calculate Reorganization Energies ΔG_r^{calc}, and Experimentally Determined Reorganization Energies ΔG_r^{exp} for Iron and Cobalt Complexes in Aqueous Solutions

Some are estimated from the data for the complexes having similar structure. a) Estimated from the data for $[Fe(edta)]^-$. b) The parameters for equatorial bonds, and c) for axial bonds.

$$Co(II)(^4T: t_{2g}^5, e_g^2) \rightarrow {}^*Co(III)(^3T: t_{2g}^5, e_g^1) + e^-(vacuum). \quad (10)$$

Therefore, the ΔG_r^{exp} value for this process must be expressed as

$$\Delta G_r^{exp} = -(1/2)Nf_o(\Delta r)^2 - (e^2/2a)(\varepsilon_{op}^{-1} - \varepsilon_s^{-1}) + \Delta E_{spin}, \quad (11)$$

where ΔE_{spin} is the energy difference between the two spin states as follows and is regarded as having a positive value:

$${}^*Co^{III}(^3T: t_{2g}^5, e_g^1) \rightarrow {}^*Co^{III}(^1A: t_{2g}^6, e_g^0). \quad \Delta E_{spin} \quad (12)$$

The structure of the product with * in Eq. 12 still remains the same as that of Co^{II}. The present study

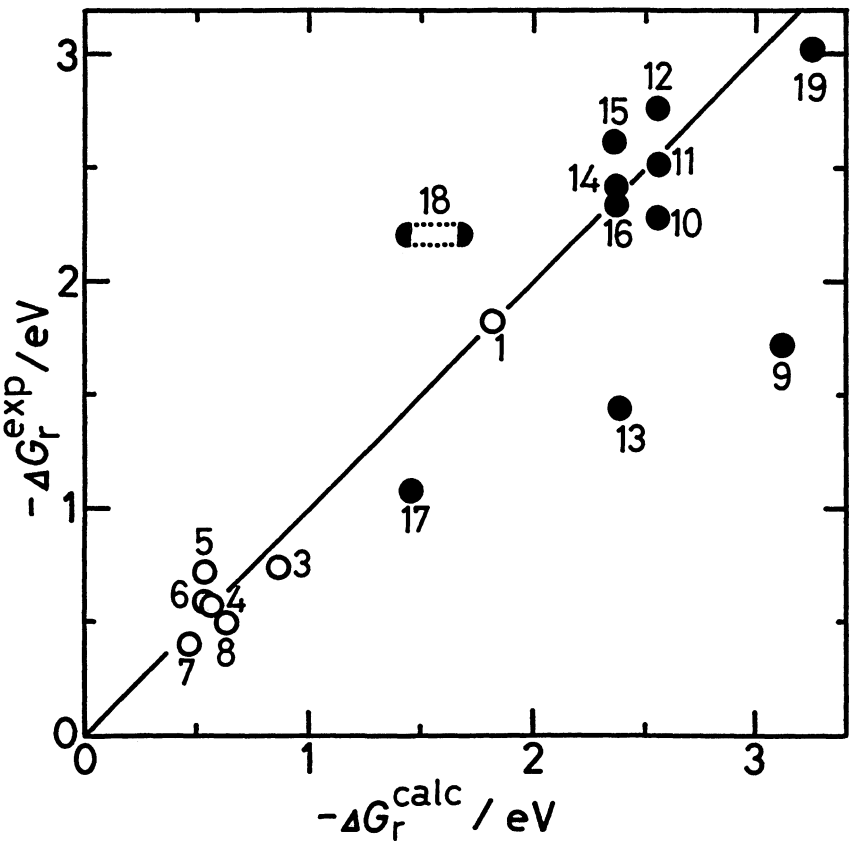

Fig. 1. Plot of the reorganization energies ΔG_r^{exp} determined by the photoelectron emission technique against the ΔG_r^{calc} values calculated by using Eqs. 5—7 for iron (○) and cobalt (●) complexes. The numbers are the same as those in Table 1.

provides the value of ΔE_{spin} as the difference of $(\Delta G_r^{exp} - \Delta G_r^{calc})$. The results shown in Fig. 1 indicate that the ΔE_{spin} values are rather small for most of the cobalt complexes studied here. One exception is $[Co(H_2O)_6]^{2+/3+}$ the value of which is very large (ca. 1.6 eV). The abnormal behavior of this couple concerning the rate of the electron-self-exchange reaction (which has been known for long time[19]) will be studied elsewhere by taking into account their spin states.

The other two samples for which the ΔG_r values do not agree are $[Co(bpy)_3]^{2+/3+}$ and $[Co(N4)(H_2O)_2]^{2+/3+}$. The disagreement for the case of $[Co(bpy)_3]^{2+/3+}$ is not understandable since other complexes which are quite similar to this one give excellent agreement. For the case of $[Co(N4)(H_2O)_2]^{2+/3+}$, the shape of the complex is not spherical since ligand N4 is a flat ring molecule. The equatorial a value used for the calculation of ΔG_r may be too large and the Δr value used here too small, which is regarded as being the same as that of the $[Co(H_2O)_6]^{2+/3+}$.

The relatively small ΔG_r values for $[Co(tpy)_2]^{2+/3+}$ are in accordance with the fact that both ionic states of this complex have a low-spin electron configuration.[20]

It is almost impossible to estimate the ΔG_r value for $[Fe(edta)]^{2-/-}$. The $[Fe(edta)]^-$ is considered to take the heptacoordinate structure of $[Fe(edta)(H_2O)]^-$ in aqueous solution[21] and is too complex to be handled with Eq. 6 (all the metal-ligand atom bond lengths are different in crystals[22]). In addition, the structure in solution is not known for $[Fe(edta)]^{2-}$. In any case, it should be noted that the ΔG_r value (=2.44 eV) for this complex is the largest among the iron complexes. The fact that the $[Fe(edta)]^{2-}$ is an extremely stronger reductant than the $[Fe(H_2O)_6]^{2+}$ (cf. E°=0.117 and 0.77 V, respectively) can be understood as being caused by a large stabilization free energy (2.44 eV) gained after (vertical) one-electron oxidation. This is concluded from the experimental fact that removing an electron vertically from $[Fe(edta)]^{2-}$ requires the same enegy as that from $[Fe(H_2O)_6]^{2+}$ (E_t=7.09 and 7.06 eV, respectively).

It is interesting to compare the ΔG_r^{exp} values obtained by the PEES technique with the rate constants, k_{exch}, of electron-self-exchange reactions in solution. According to the Marcus-Hush theory, the ΔG_r value is closely related to the activation energy, ΔG^*, for the thermal electron-exchange reaction and, thus, to its rate constant. In the simplest model,

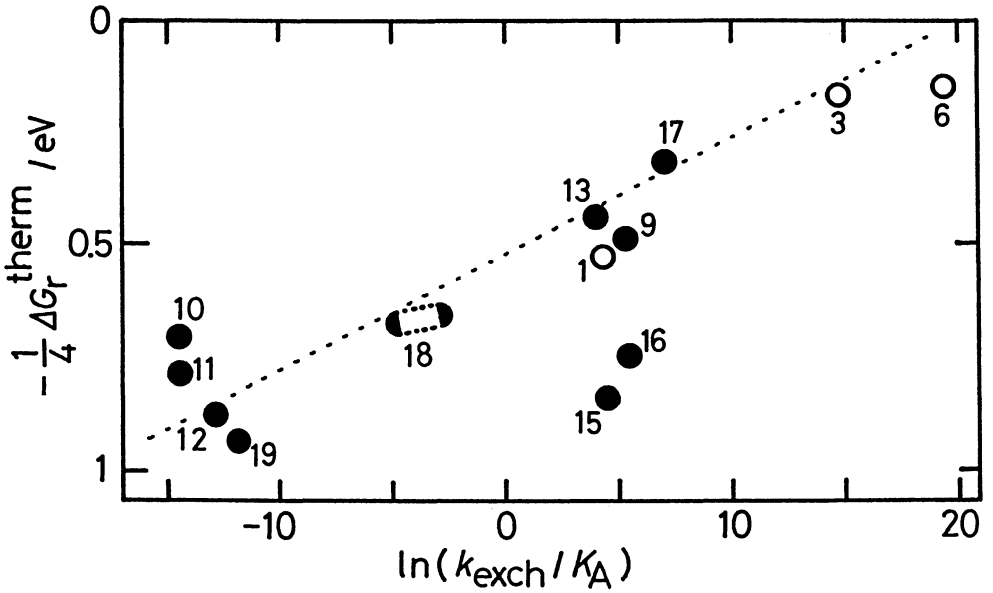

Fig. 2. Correlation between the logarithm of the rate constant k_{exch} for the electron-self-exchange reaction corrected for the formation constant K_A of the precursor complex and a quarter of the thermal reorganization energy ΔG_r^{therm} derived from the ΔG_r^{exp} determined by the photoelectron emission technique for iron (○) and cobalt (●) complexes. The numbers are the same as those in Table 1. The dotted line indicates the slope of RT(=25.7 meV). The k_{exch} and K_A values are collected from Ref. 23.

$\Delta G_r = -4\Delta G^{\ddagger}$. By using many transition metal(II)/(III) couples, Brunschwig and co-workers showed a linear correlation between $(\Delta r)^2$ and ΔG_r(in), as determined by the following equation:[23]

$$\Delta G_r(\text{in}) = 4RT \ln(k_{exch}/K_A) - \Delta G_r^{calc}(\text{out}), \quad (13)$$

where K_A is the equilibrium constant for the formation of the precursor complex for the electron exchange reaction and the ΔG_r^{calc}(out) was obtained by using Eq. 7. Their results support the classical model for evaluating the ΔG_r(in) from Δr, as described in Eq. 6.

The ΔG_r^{exp} determined in the present work is of the optical transition and is different from the ΔG_r^{therm} for the thermal one, like an electron-transfer reaction in solution. For the calculation of ΔG_r in an optical transition, only the force constant, f_o, for X^{nz+1} is used as in Eq. 6, while the f for ΔG_r^{therm} must be evaluated by using the mean value of f_o and f_r for X^{nz}.

According to the Delahay's treatment,[24,1]

$$\Delta G_r^{therm} = \Delta G_r^{opt} + \Delta G_r^{opt}(\text{in}) \cdot [(3f_r - f_o)/(f_r + f_o)], \quad (14)$$

where ΔG_r^{opt} is the reorganization energy pertaining to the optical electron-transfer reaction, i.e. the ΔG_r^{exp} determined by the PEES technique. It is then possible to evaluate ΔG_r^{therm} using $\Delta G_r^{opt}(\text{in}) = \Delta G_r^{exp} - \Delta G_r^{calc}(\text{out})$. The values of the term $(3f_r - f_o)/(f_r + f_o)$ were calculated and found to be almost constant (0.37) for the complexes studied here.

The ΔG_r^{therm}, thus obtained, is obviously related to the k_{exch} corrected for the K_A, as shown in Fig. 2, with an expected slope of RT, which is indicated by the dotted line.

It is worth noting that the anomalous behavior of the $[Co(H_2O)_6]^{2+/3+}$ observed by Brunschwig and co-workers that the experimental k_{exch} value is several orders greater than the predicted value from the classical model,[23] now disappears in the k_{exch} vs. ΔG_r^{exp} relation (the point 9 in Fig. 2). The present results indicate that the thermal electron-transfer reaction proceeds not via the $Co^{III}(^1A)$ state, but via a state which is optically accessible and lies fairly below the $Co^{III}(^1A)$ state when the $[Co(H_2O)_6]^{2+}$ complex deforms its geometry in order to transfer its electron.

6) The E° is commonly defined as the potential of an electrode in equilibrium with equi-activity X^{nz} and X^{nz+1} ions with respect to NHE (Normal Hydrogen Electrode). This means that the free energy of X^{nz} in solution is the same as that of the system consisting of X^{nz+1} in solution plus e^- in the electrode having the potential of E°, and that no energy is necessary to transfer an electron from X^{nz} to the electrode at E°. Thus, the transfer of the electron from X^{nz} to NHE requires the energy of $-eE^\circ$, where e is the charge of an electron. Equation 2 is the expression for this process.

Hydrates of Organic Compounds. XV. The Formation of Clathrate-Like Hydrates of Tetraisopentylammonium Alkanoates and Alkanedioates

Haruo NAKAYAMA,* Kayoko NAKAMURA, Yukio HAGA, and Yōji SUGIURA
Division of Materials Science and Chemical Engineering, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received September 26, 1990)

The solid–liquid phase diagrams of binary mixtures of water with tetraisopentylammonium alkanoates, $[(i\text{-}C_5H_{11})_4N]C_nH_{2n+1}COO$ (n=0—9), and with bis(tetraisopentylammonium) alkanedioates, $[(i\text{-}C_5H_{11})_4N]_2[OOC(CH_2)_nCOO]$ (n=0—10), were examined in order to confirm the formation of clathrate-like hydrates. The results are summarized as follows: (1) For all the compounds examined the formation of a clathrate-like hydrate is newly confirmed; (2) the melting points of these hydrates are fairly high (lie between 10 and 28 °C); (3) typical hydrates formed by the alkanoates have hydration numbers around 38 and those formed by the alkanedioates around 80; and (4) hydrates with hydration numbers around 14 and larger than 40 are also found for the alkanoate hydrates and around 30 and larger than 80 for the alkanedioate hydrates. The effects of the alkyl chain length of the alkanoate anion and of the methylene chain length of the alkanedioate anion on the stability of the hydrates are not marked, suggesting that a hydrogen-bonded framework of water molecules around a $(i\text{-}C_5H_{11})_4N^+$ cation is fairly stable.

Since the formation of unusual hydrates of tetrabutylammonium alkanoates and aromatic carboxylate like formate, acetate, propionate, and benzoate, which have a large number of water molecules per one ammonium ion (hydration numbers), was reported by Kraus et al.[1] in 1940, the formation of similar kind of alkanoate hydrates has extensively been studied.[2-5]

A single-crystal X-ray examination by Jeffrey and his co-workers on these hydrates[2-3] showed that they were clathrate-like hydrates similar to the so-called gas hydrates:[6] The water structure is a hydrogen-bonded framework and is essentially a regular arrangement of polyhedra-like pentagonal dodecahedra; tetrakaidecahedra and oxygen atoms of the carboxylate anion are incorporated into the water lattice, making an anionic host structure.

Recently, in our phase-diagrammatic studies[7-12] it was concluded that tetrabutylammonium alkanoates or alkanedioates having various alkyl chains or methylene chains could also form a clathrate-like hydrate. Judging from the hydration numbers and melting points of these hydrates, it was assumed that their crystal structure is isostructural with that of a well known $(n\text{-}C_4H_9)_4NF\cdot 30H_2O$ hydrate[13] and that the alkyl group of the alkanoate anions and a methylene chain of the alkanedioate anions is accommodated in a vacant pentagonal dodecahedra.

On the other hand, although some tetraisopentylammonium salts, such as $(i\text{-}C_5H_{11})_4NF$ and $(i\text{-}C_5H_{11})_4NCl$, are known to form similar type hydrates,[2,14,15] no information concerning the formation of a clathrate-like hydrate of tetraisopentylammonium alkanoates or alkanedioates has been reported, except for formate[1] and benzoate.[4] Thus, in this work, phase-diagrammatic studies regarding binary mixtures of tetraisopentylammonium alkanoates or alkanedioates with water were carried out in order to confirm the formation of clathrate-like hydrates. Tetraisopentylammonium alkanoates and alkanedioates are expected to form more stable hydrates than those of tetrabutylammonium alkanoates or alkanedioates since (1) the water frameworks surrounding a $(i\text{-}C_5H_{11})_4N^+$ cation are, in general, more stable than those surrounding a $(n\text{-}C_4H_9)_4N^+$ cation[16] and (2) in a $(i\text{-}C_5H_{11})_4NF$ hydrate,[14] there exists an extended layer structure of connected pentagonal dodecahedra which are suitable to accommodate either an alkyl chain of an alkanoate anion or a methylene chain of an alkanedioate anion.

Experimental

Aqueous solutions of tetraisopentylammonium alkanoates, except for formate and acetate, were prepared by a reaction between tetraisopentylammonium iodide and the corresponding silver alkanoates in water, followed by filtration of silver iodide precipitate. Tetraisopentylammonium iodide was synthesized by allowing a reaction of triisopentylamine with isopentyl iodide in ethyl acetate and purified by repeated recrystallization from ethyl acetate. Each silver alkanoate was obtained as a precipitate by mixing an aqueous solution of silver nitrate with an aqueous solution of sodium alkanoate, followed by repeated washing with water in order to remove the resultant sodium nitrate. Aqueous solutions of tetraisopentylammonium formate, acetate and of all the bis(tetraisopentylammonium) alkanedioates, were obtained by neutralization of tetraisopentylammonium hydroxide solution with the corresponding acids. The hydroxide solution was obtained by treating tetraisopentylammonium iodide with freshly prepared silver(I) oxide in water. The wet silver(I) oxide was prepared by reacting a silver nitrate solution with a sodium hydroxide solution, followed by filtration and repeated washing with water. Triisopentylamine, isopentyl iodide and all the carboxylic acids and some of the dicarboxylic acids were reagent grade commercial materials and used without further purification. Seven dicarboxylic acids, $HOOC(CH_2)_nCOOH$ with n=3—8 and 10, which were purchased from Tokyo Kasei Kogyo Co., Ltd., were recrystallized from water.

The solid-liquid phase diagrams of the binary tetraisopentylammonium alkanoate (or alkanedioate)-water systems were determined in the following manner. A sample solution (about 1.0—1.5 g) of known concentration was prepared by weighing out water and a concentrated mother solution of each alkanoate (or alkanedioate), and was sealed in a small glass ampoule. The concentration of the mother solution was determined by a titration method using a sodium tetraphenylborate solution.[9] Each ampoule was gradually cooled until the solid phase appeared and was annealed for at least 24 h at a temperature several degrees lower than the temperature at which the solid phase completely disssolved. After that, the ampoule was slowly warmed (at the rate of about 0.3—0.5 °C per hour) with shaking in a constant temperature bath and the temperature at which the solid phase completely dissolved was accurately determined.

Results and Discussion

(1) The Formation of Hydrates of Tetraisopentylammonium Alkanoates. The solid-liquid phase diagrams for the binary systems, water-[(i-C_5H_{11})$_4$N]n-$C_nH_{2n+1}COO$, where n=2—5, are shown in Fig. 1. The logarithm of the concentration expressed as the mole fraction, X, is plotted against the reciprocal of the absolute temperature. The temperature expressed in ordinary Celsius units is shown on the upper side of the figure. The phase diagrams of two binary systems, water-[(i-C_5H_{11})$_4$N]HCOO and water-[(i-C_5H_{11})$_4$N]CH_3COO, are not shown in Fig. 1 since the phase diagram of the former system resembles the one of the water-[(i-C_5H_{11})$_4$N]C_2H_5COO system and the latter system the one of the water-[(i-C_5H_{11})$_4$N]n-C_3H_7COO system. The phase diagrams of these systems exhibit congruent melting points at concentrations near X=0.025—0.026, indicating that these carboxylates form a hydrate with hydration numbers around 38. It is interesting to note that (1) these hydrates are fairly stable: the melting points are 22—28 °C; and (2) they can be in equilibrium with very dilute solutions: For

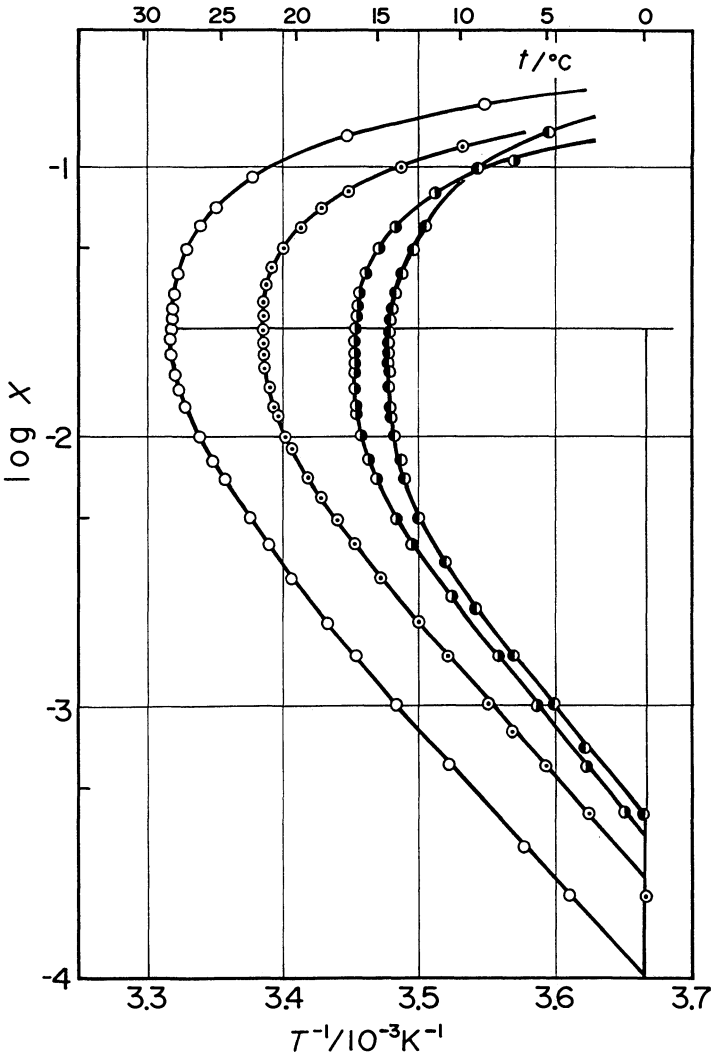

Fig. 1. Solid-liquid phase diagrams for the [(i-C_5H_{11})$_4$N]-RCOO-water systems. ○: R=C_2H_5; ⊙: R=n-C_3H_7; ◑: R=n-C_4H_9; ◐: R=n-C_5H_{11}.

example, the most stable $[(i\text{-}C_5H_{11})_4N]C_2H_5COO$ hydrate is formed in such a dilute solution as $X=1\times10^{-4}$ (0.206 wt%).

The phase diagrams of the two systems with $n=4$ and $n=5$ also exhibit congruent melting points at about 15 °C. However, all the solid phases which are formed in the solutions in the concentration range between $X=0.020$ and $X=0.024$ for $n=4$ salt and between $X=0.018$ and 0.024 for $n=5$ salt dissolve at very narrow temperature range: Between a maximum dissolution temperature and the one only 0.1 °C lower than that. Therefore, exact hydration numbers cannot be determined for these hydrates. A probable reason for this behavior is that some hydrates with different hydration numbers between 40 and 55 are formed simultaneously, depending upon the concentration of the solution. The fact that the slope $-\partial \log X/\partial(1/T)$ in dilute solutions, $X=0.001$ for example, for the above-mentioned two systems, is slightly steeper than that of the systems of $n=2$ and $n=3$ indicates that salts with $n=4$ and $n=5$ form a hydrate with hydration numbers larger than those of $n=2$ and 3 hydrates (around 38), since it has been verified that the slope $-\partial \log X/\partial(1/T)$ is approximately proportional to the hydration numbers of a hydrate.[16]

The solid-liquid phase diagrams for binary systems water-$[(i\text{-}C_5H_{11})_4N]n\text{-}C_nH_{2n+1}COO$ with long alkyl chains as $n=6$ and 9 are shown in Fig. 2. For a comparison, Fig. 2 includes the phase diagram of the $n=2$ system shown in Fig. 1. The phase diagram of a system with $n=7$ is omitted because of the similarity in the data with those of the $n=6$ system. This figure shows the existence of congruent melting points near $X=0.026$, just as in the case of $n=2$, indicating that salts with such long alkyl chains as $n=6$, 7, and 9 can also form a hydrate with hydration numbers around 38, although their melting points (11—16 °C) are

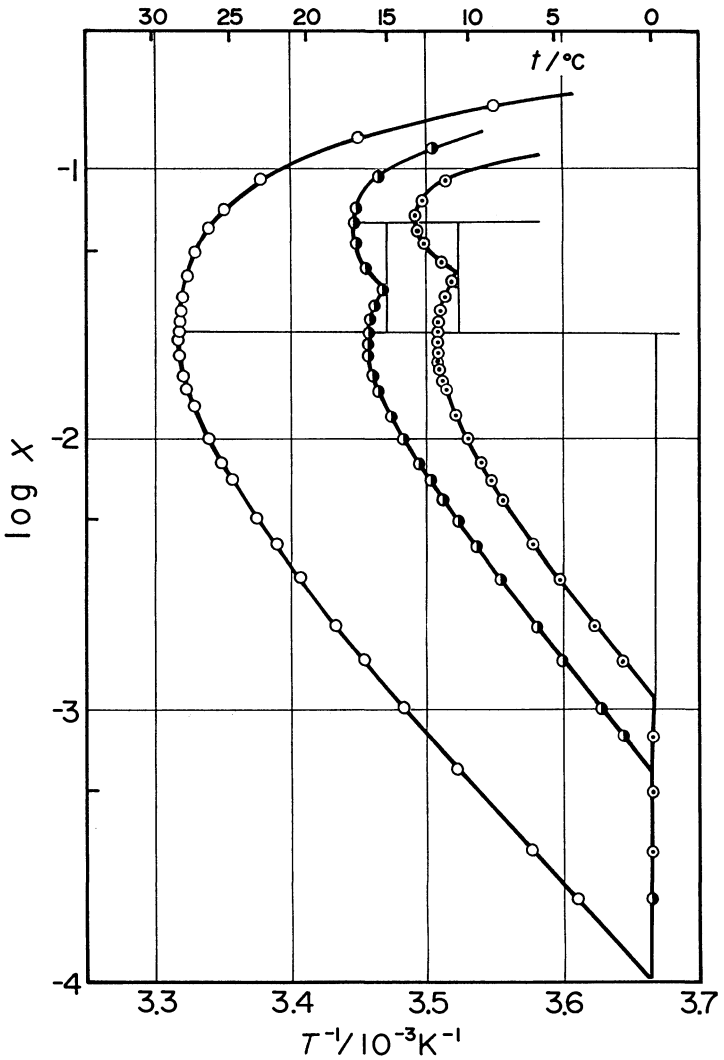

Fig. 2. Solid-liquid phase diagrams for the $[(i\text{-}C_5H_{11})_4N]$-RCOO-water systems. ○: R=C_2H_5; ⊙: R=n-C_6H_{13}; ◑: R=n-C_9H_{19}.

lower than those of the salts with short alkyl chains like n=0—3 (Fig. 1). Furthermore, Fig. 2 indicates that systems with n=6, 9 (and n=7) have another congruent melting point around X=0.067. This means the formation of hydrate with hydration numbers around 14. It is interesting to note that these hydrates have slightly higher melting points than those with hydration numbers around 38.

All of the melting points and hydration numbers, determined from each congruent melting point and congruent composition, are summarized in Table 1.

Table 1. Melting Points and Hydration Numbers of the Clathrate-Like Hydrates Formed by a Series of Tetraisopentylammonium Alkanoates, $[(i\text{-}C_5H_{11})_4N]RCOO$

R	Melting point t_m/ °C	Hydration numbers
H	22.4	37±3
CH_3	24.5	37±2
C_2H_5	28.3	39±2
n-C_3H_7	22.3	39±2
n-C_4H_9	16.5	40—50
n-C_5H_{11}	14.3	40—55
n-C_6H_{13}	11.9	40±2
	13.4	14±1
n-C_7H_{15}	10.7	37±2
	13.1	14±2
n-C_9H_{19}	16.1	37±3
	17.1	15±2

The existence of these hydrates, except for the formate hydrate, has been newly confirmed in this study. However, the melting point 15—20 °C and hydration numbers 50 of the formate hydrate reported by Kraus et al.[1] are fairly different from our values. From Table 1 it is clear that the most typical hydrate is one with hydration numbers around 38. This hydrate is formed regardless of the chain length of the alkyl group in the alkanoate anion and the effect of the chain length of the $C_nH_{2n+1}COO^-$ anion on the melting points of the hydrates is not so marked. Judging from the values of the hydration numbers and the melting points, these hydrates seem to be isostructural clathrate-like hydrates with a well known $(i\text{-}C_5H_{11})_4NF \cdot 39H_2O$ hydrate.[14] Other hydrates found in Table 1 are the ones with hydration numbers larger than 40 and around 14. The former is formed for the salts of n=4 and 5 and the latter for the salts with a longer alkanoate than n=6. Although there is no information concerning the structure of these hydrates, it seems probable that one of the former hydrates has some connection with a tetraisopentylammonium benzoate hydrate, $[(i\text{-}C_5H_{11})_4N]C_6H_5COO \cdot (48\pm2)H_2O$, which was found in a preliminary experiment. This hydrate is fairly unstable with a melting point of about 6.3 °C.

In Fig. 3 the relationship between the melting points of the hydrates and the number of carbon atoms of the alkyl group in the carboxylate anion (n) is shown for the two series of salts, $[(i\text{-}C_5H_{11})_4N]$-$n$-$C_nH_{2n+1}COO$ and $[(n\text{-}C_4H_9)_4N]n$-$C_nH_{2n+1}COO$.[7]

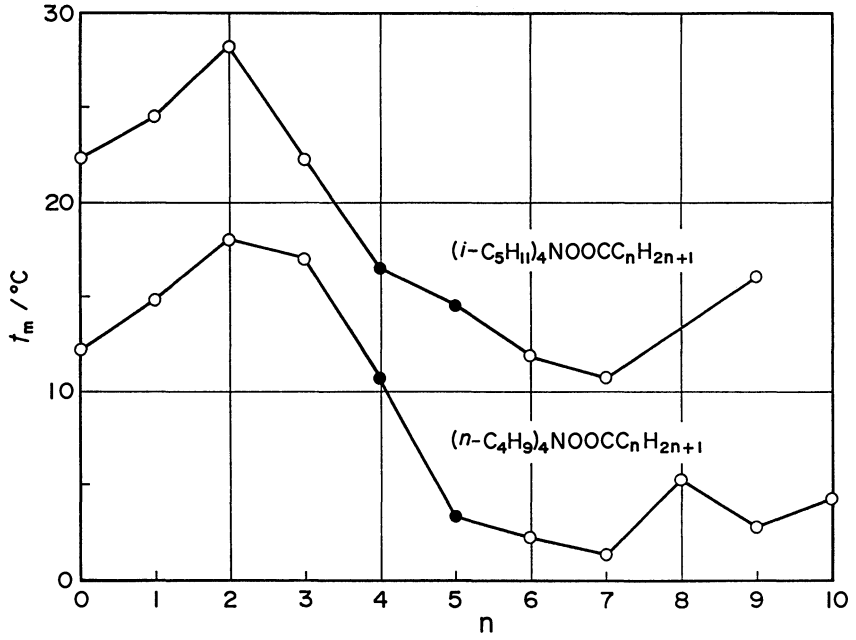

Fig. 3. Relationships between the melting points, t_m, of the tetrabutylammonium and of the tetraisopentylammonium alkanoate hydrates and the chain length of the alkanoate anion. Filled circle indicates a hydrate with somewhat larger hydration numbers as compared with the other hydrates shown by open circles.

The latter series form hydrates with hydration numbers around 30 and only when n=4 and 5, just as in the case of the former salt hydrates, hydrates with hydration numbers larger than 30 are formed.[7] It is interesting to note that both series of hydrates behave almost in a similar manner, except that the melting points of a series of $[(i\text{-}C_5H_{11})_4N]n\text{-}C_nH_{2n+1}COO$ hydrates are about 10 °C higher than those of a series of $[(n\text{-}C_4H_9)_4N]n\text{-}C_nH_{2n+1}COO$ hydrates irrespective of the values of n, coinciding with a general trend that the water frameworks surrounding a $(i\text{-}C_5H_{11})_4N^+$ cation are more stable than those surrounding a $(n\text{-}C_4H_9)_4N^+$ cation.[12,16] The similar behavior of the two series of hydrates leads the conclusion that the same arguement can be applied regarding the way to accommodate an alkyl group, $n\text{-}C_nH_{2n+1}$, of the alkanoate anion within the $[(i\text{-}C_5H_{11})_4N]n\text{-}C_nH_{2n+1}COO$ hydrates as in the $[(n\text{-}C_4H_9)_4N]n\text{-}C_nH_{2n+1}COO$ hydrates:[7-10] (1) Such short alkyl groups as CH_3, C_2H_5, and $n\text{-}C_3H_7$ are encaged in a vacant pentagonal dodecahedron, which exists in a gap between the arrangement of larger polyhedra (tetrakaidecahedra and/or pentakaidecahedra) filled by one of the isopentyl group of a tetraisopentylammonium cation and the highest melting point of the propionate hydrate coincide with the best fitness of the $CH_3CH_2COO^-$ anion to a pentagonal dodecahedron; (2) long alkyl chains like $n\text{-}C_4H_9$—$n\text{-}C_9H_{19}$ penetrate through two (or three) vacant pentagonal dodecahedra forming a hydrogen-bonded anionic host structure with water.

(2) The Formation of Hydrates of Bis(tetraisopentylammonium) Alkanedioates. The solid-liquid phase diagrams for the binary systems, water-$[(i\text{-}C_5H_{11})_4N]_2OOC(CH_2)_nCOO$, where n=0—2 are shown in Fig. 4 in the same manner as in Figs. 1 and 2. All three systems exhibit congruent melting points (20—25 °C) at concentrations around X=0.0125, indicating

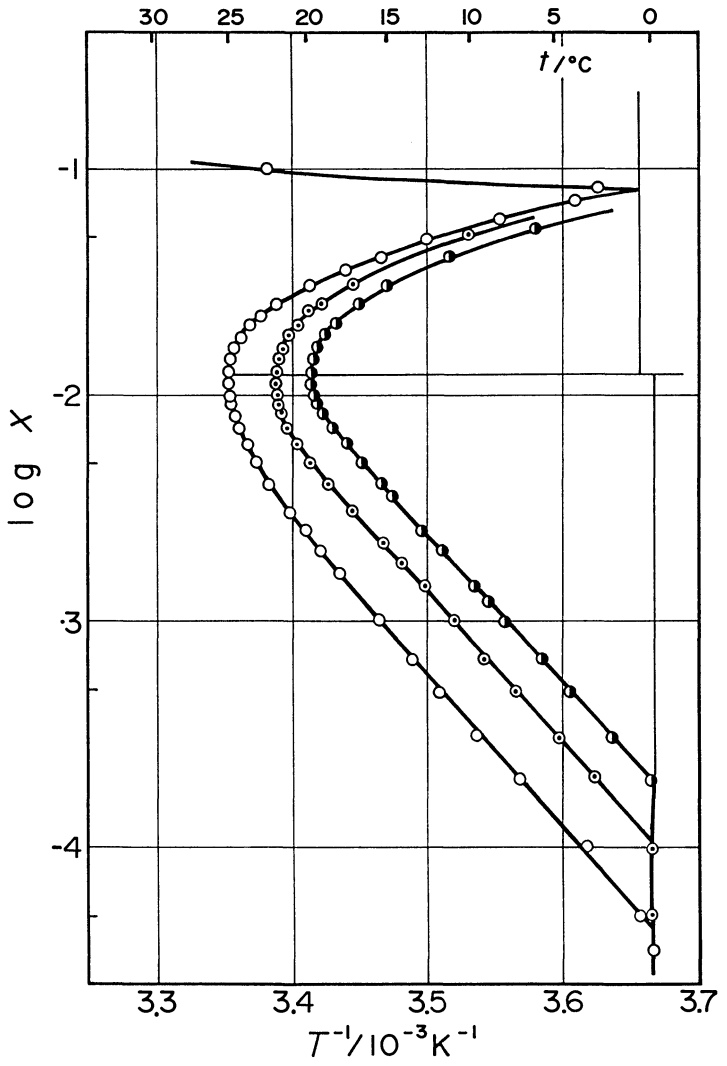

Fig. 4. Solid-liquid phase diagrams for the water-$[(i\text{-}C_5H_{11})_4N]_2OCC(CH_2)_nCOO$ systems. ○: n=0; ⊙: n=1; ◑: n=2.

that these salts form a fairly stable hydrate with hydration numbers of about 80. The melting points of the hydrates decrease with increasing the number of n. The solid-liquid phase diagrams for the other three systems with n=3—5 show similar behaviors as shown in Fig. 4, except that the most stable hydrate is formed by the salt of n=4; its melting point is 27.5 °C.

On the other hand, the solid-liquid phase diagrams, which are shown in Fig. 5, for the binary systems, water-[(i-C_5H_{11})$_4$N]$_2$OOC(CH_2)$_n$COO, where n=6—10, exhibit a somewhat complicated behavior, as compared with the case of n=0—5. The characteristic features of Fig. 5 are summarized as follows: (1) Although there is a maximum dissolution temperature around X=0.0125 for the salts of n=6—8, solid phases formed from the solutions in the concentration range of X=0.012—0.013 for the n=6 salt, X=0.012—0.014 for n=7, and X=0.010—0.0125 for n=8, dissolve at very narrow temperature range around the maximum dissolution temperatures just as in the case of the alkanoate hydrates with n=4 and n=5 (Fig. 2). This indicates that exact hydration numbers of the hydrates cannot be determined. (2) There are incongruent melting points about 1 °C below the maximum dissolution temperature. These temperatures are 18.3 °C for the n=6 salt, 17.2 °C for the n=7 salt and two or three incongruent melting points between 17 and 19 °C for the n=10 salt. The existence of incongruent compositions smaller than X=0.012 clearly indicates the formation of hydrates with hydration numbers larger than 80. (3) For the systems of n=8 and n=10, another congruent melting point is found around X=0.032; this means the formation of a hydrate with hydration numbers around 30.

The melting points and hydration numbers found for the hydrates of a series of bis(tetraisopentylammonium) alkanedioate are summarized in Table 2. All of these hydrates were newly confirmed in this study.

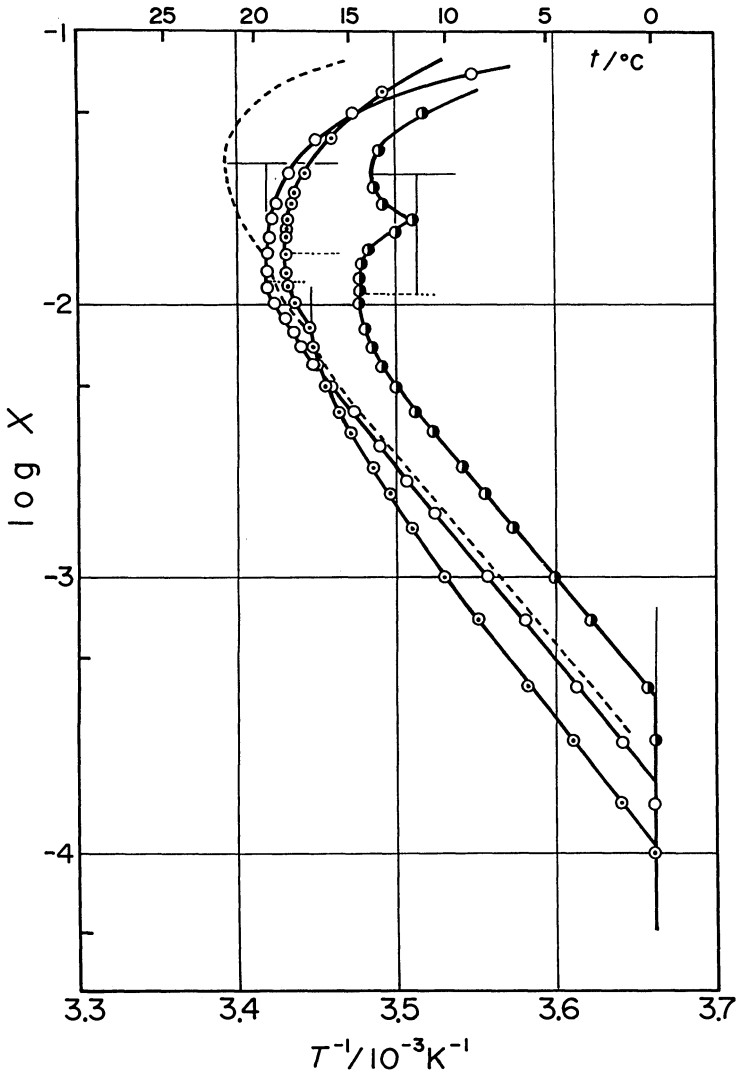

Fig. 5 Solid-liquid phase diagrams for the water-[(i-C_5H_{11})$_4$N]$_2$ OOC(CH_2)$_n$COO systems. ○: n=6; ⊙: n=7; ◑: n=8; broken line: n=10.

As can be seen in Table 2, the most typical hydrate is one with a hydration number around 80. This hydrate is considered to be isostructural with the alkanoate hydrates of hydration numbers around 38 (Table 1), since the hydration number, 80, is about twice of 38. Other hydrates are those with hydration numbers around 30 and larger than 80. As mentioned above, the exact hydration numbers of the latter hydrates cannot be determined owing to the complexity of the phase diagrams. It is not certain whether there is any structural relation between these hydrates and the alkanoate hydrates having hydration numbers larger than 40 (Table 1). The hydrate of the hydration numbers around 30 is formed for alkanedioates with n larger than 8 and, eventually, its hydration numbers are almost twice that (14—15, Table 1) of the alkanoate hydrates which are formed by the alkanoates with n larger than 6. Both hydrates seem to be isostructural with each other.

Table 2. Melting Points and Hydration Numbers of the Clathrate-Like Hydrates Formed by a Series of Bis(tetraisopentylammonium) Alkanedioates, $[(i\text{-}C_5H_{11})_4N]_2OOC(CH_2)_nCOO$

n	Melting point t_m/ °C	Hydration numbers
0	25.1	80±2
1	22.1	80±2
2	19.8	82±2
3	23.7	79±3
4	27.5	80±3
5	19.8	80±3
6	19.4	75—85
	18.3 (incong.)	
7	18.4	70—85
	17.2 (incong.)	
8	14.5	80—100
	13.9	32±3
10	21.5	30±5

The relationship between the melting points, t_m, of the alkanedioate hydrates and the methylene chain length, n, of the alkanedioate anions is shown in Fig. 6 for two series of alkanedioates, $[(i\text{-}C_5H_{11})_4N]_2OOC(CH_2)_nCOO$ and $[(n\text{-}C_4H_9)_4N]_2OOC(CH_2)_nCOO$.[11] In general, the t_m's vary with n in a similar manner for both series of hydrates. Just as in the case of alkanoate hydrates (Fig. 3), the melting points of the tetraisopentylammonium dicarboxylate hydrates are about 10 °C higher than those of the tetrabutylammonium alkanedioate hydrates, though this difference becomes larger when n is larger than 6. The maximum t_m is found in the case n=4 for the bis(tetraisopentylammonium) alkanedioate hydrates whereas n=3 for the bis(tetrabutylammonium) alkanedioate hydrates. This discrepancy will not be essential since the melting point of the hydrate of bis(tetrabutylammonium) alkanedioate with n=4 is also fairly high.

It is interesting to note that the melting points initially decrease with increasing n from 0 to 2 then increase with increasing n from 2 to 4. This can be explained by the fact that the hydrates of salts with such small n as 0—2 are constructed with two kinds of units, $[[(i\text{-}C_5H_{11})_4N]OOC(CH_2)_nCOO]^-$ and (*i*-

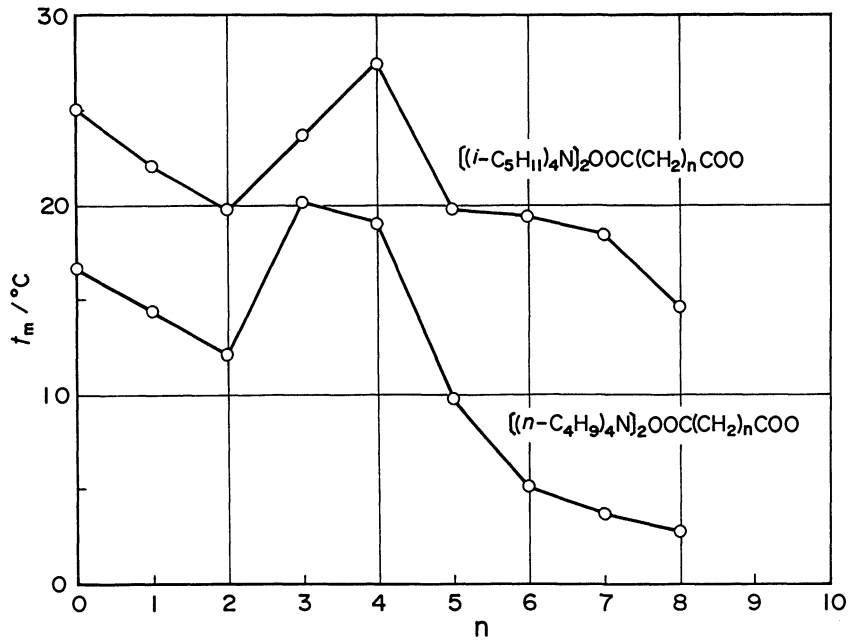

Fig. 6. Relationships between the melting points, t_m, of the bis(tetrabutylammonium) and of the bis(tetraisopentylammonium) alkanedioate hydrates and of the chain length of the methylene chain in the alkanedioate anion.

$C_5H_{11})_4N^+$; then, the distortion effect of the $^-OOC(CH_2)_nCOO^-$ anion on the hydrogen-bonded water network surrounding a $(i\text{-}C_5H_{11})_4N^+$ cation increases with increasing n, leading to a lowering of the melting points of the hydrates. On the other hand, the hydrates of the salts with n larger than 3 can be considered to be constructed by a sequence of $(i\text{-}C_5H_{11})_4N^+ \cdots {}^-OOC(CH_2)_nCOO^- \cdots (i\text{-}C_5H_{11})_4N^+$; the central $^-OOC(CH_2)_nCOO^-$ anion is surrounded by vacant pentagonal dodecahedron or connected pentagonal dodecahedra, leading to the formation of fairly stable hydrate, as is found in the case of tetraisopentylammonium alkanoate hydrates.

(Received June 20, 1990)

The photoamination of 1,1-diphenylpropene (**1a**) with ammonia and some primary alkylamines in the presence of *p*-dicyanobenzene gave the corresponding *N*-substituted 2-amino-1,1-diphenylpropane (**2a—e**) along with the formation of 3-methyl-4,4-diphenylbutanenitrile (**3a**), 1,1-diphenylpropane (**4a**), 3,3-diphenylpropene (**5**), and diphenylmethane (**6**). In the case of 1,1-diphenylethene (**1b**), *N*-substituted 1-amino-2,2-diphenylethane (**2f—h**), 4,4-diphenylbutanenitrile (**3b**), and 1,1-diphenylethane (**4b**) were produced. In photoamination with *t*-butylamine in acetonitrile, **3a** and **3b** were mainly formed as a consequence of the incorporation of acetonitrile to **1a** and **1b**. The photoamination of 1-phenyl-3,4-dihydronaphthalene (**1c**) with isopropylamine or *t*-butylamine gave *cis*- and *trans*-*N*-substituted 1-phenyl-2-amino-1,2,3,4-tetrahydronaphthalenes (**15** and **16**) in a ratio of ca. 8:2. The mechanism of photoamination is discussed in terms of a photochemical electron transfer of **1** to *p*-dicyanobenzene followed by a nucleophilic addition of the amine to the cation radical of **1**.

Photoinduced nucleophilic additions in the presence of electron acceptors have been investigated for a variety of electron-donating substances (D) involving aryl-substituted alkenes, strained compounds, and arenes from mechanistic and synthetic points of view.[1] In general, a key pathway for photoinduced nucleophilic additions is the addition of nucleophiles (NuH) to the cation radicals of D ($D^{+\cdot}$) generated from a photochemical electron transfer from D to electron acceptors (A), as shown in Scheme 1. While extensive studies on photoadditions using alcohols, water, and cyanide ion as nucleophiles have accumulated, little is known about the photoaddition of ammonia and amines, except for our reports on the photoamination of arenes with ammonia and alkylamines.[2] Since amines serve as both a nucleophile and a base, their photoaddition is expected to show different features from other nucleophiles. Herein we wish to report on the photoaddition of ammonia and alkylamines to aryl-substituted alkenes (**1**) using *p*-

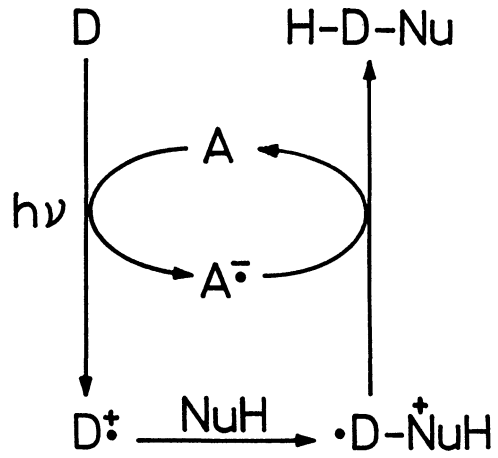

Scheme 1.

dicyanobenzene (DCNB) as A.

Results

The photoamination of diphenylalkene (**1**) was carried out by irradiating a deaerated acetonitrile solution of **1**, DCNB, and ammonia or alkylamines through a Pyrex filter with a high-pressure mercury lamp; incident light was absorbed by both **1** and DCNB under these conditions. The results are summarized in Table 1 and Scheme 2. The photoamination of 1,1-diphenylpropene (**1a**) with ammonia, isopropylamine, 2-methoxyethylamine, and 2-aminoethanol gave the *N*-substituted 2-amino-1,1-diphenylpropanes (**2a—e**) accompanied by the formation of considerable amounts of 3-methyl-4,4-diphenylbutanenitrile (**3a**), 1,1-diphenylpropane (**4a**), 3,3-diphenylpropene (**5**), and diphenylmethane (**6**). Similarly, *N*-substituted 1-amino-2,2-diphenylethanes (**2f—h**), 4,4-diphenylbutanenitrile (**3b**), and 1,1-diphenylethane (**4b**) were formed from the photoamination of 1,1-diphenylethene (**1b**) with ammonia, isopropylamine, and *t*-butylamine. The photoamination of **1b** with 2-methoxyethylamine gave *N*-(2-methoxyethyl)-2,2-diphenylethylamine (**2i**) along with the formation of 1-(2-aminoethoxy)-3,3-diphenylpropane (**8**), **3b**, and **4b** (Scheme 3). In all cases, DCNB was mostly

recovered after photoamination. It was confirmed that the photoamination which takes place to afford the aminated products (**2**) does not occur in the absence of an electron acceptor; e.g. the photoreaction of **1b** with isopropylamine in the absence of DCNB gave **3b**, **4b**, and 1,1-dimethyl-3,3-diphenylpropylamine (**9**) (Scheme 4).

Photoamination with isopropylamine gave both **2a** and **2b** from **1a**, and **2f** and **2g** from **1b** in addition to other products. Figure 1 shows plots of the yields of **2f**, **2g**, **3b**, and **4b** vs. the irradiation time for the photoamination of **1b** with isopropylamine; the yields of **3b** and **4b** increased with an increase in the conversion of **1b**, whereas the yield of **2f** gradually increased

at the expense of **2g**.

Although acetonitrile has been found to be an excellent solvent for the photoamination of arenes,[2] the photoamination of **1a** and **1b** in acetonitrile gave considerable amounts of acetonitrile-incorporated products (**3a,b**). It is noteworthy that the photoamination of **1a** and **1b** with *t*-butylamine gave **3a,b** as the major product. It was also found that the photoamination of **1a** with *t*-butylamine occurred in propanenitrile to give **2c** without photoreaction with the nitrile group of the solvent. No photoamination of **1b** occurred in *N,N*-dimethylformamide (DMF), 1,2-dimethoxyethane, or benzene; the photoreaction of **1b** in DMF gave adducts (**10**, **11**, and **12a,b**) of DMF with either **1b** or DCNB (Scheme 5).[3] In the photoamination of **1b** with ammonia in acetonitrile–water (9 : 1), 2,2-diphenylethanol (**7**) was produced in consequence to the photoaddition of water to **1b** along with the formation of **2f**.

Since electron-transfer photosensitization by 9,10-dicyanoanthracene (DCA)[4,5] and 1-naphthonitrile (CNN)[6] or redox-photosensitization[7] by aromatic hydrocarbons have provided useful tools for the photoaddition of alcohols to a variety of aryl-substituted alkenes, these methods were attempted in the present photoamination. However, no photoamination of **1b** with isopropylamine occurred by DCA- or CNN-photosensitization. The redox-photosensitized reaction of **1b** with isopropylamine in the presence of DCNB using phenanthrene as a sensitizer gave **2g**, **3b**, and **4b** accompanied by the formation of *N*-isopropyl-9-amino-9,10-dihydrophenanthrene (**13**). When triphenylene was used as a sensitizer, the photoamination proceeded along with the consumption of triphenylene. Thus, the redox-photosensitized amination of **1b** using phenanthrene or triphenylene are inefficient because of the consumption of sensitizers.

In order to elucidate the stereochemistry of the addition of amines, the photoamination of 1-phenyl-3,4-dihydronaphthalene (**1c**) was performed. The photoamination of **1c** with ammonia, isopropylamine, and *t*-butylamine gave the corresponding *cis*- and *trans*-*N*-substituted 1-phenyl-2-amino-1,2,3,4-tetrahydronaphthalene (**14**, **15**, and **16**) (Scheme 6). The stereochemistries of **14**, **15**, and **16** were determined by their ^{1}H NMR spectra. The signal for the methine proton (H_A) on the C_1 of trans isomers appeared at 0.35—0.50 ppm higher in field than that of cis isomers. The upfield shift of H_A of trans isomers may be due to a shielding effect of lone-pair electrons on the adjacent nitrogen atom. Further support is that the vicinal coupling constants (J=5.0—5.5 Hz) between H_A and H_B in cis isomers were smaller than those in trans isomers (J=7.7—9.0 Hz). Though the ratio of the trans to cis isomer was dependent on the bulkiness of amine, the cis isomers (**15a** and **16a**) were

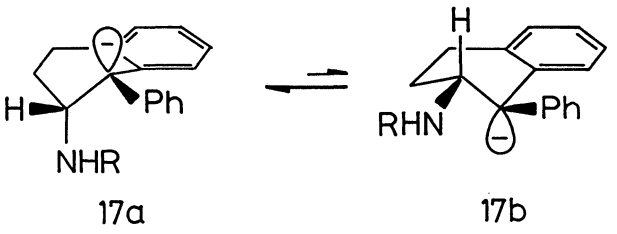
mainly produced in the cases of photoamination with isopropylamine and *t*-butylamine (Table 2).

Discussion

The photochemical electron transfer reaction from electron-rich substances to aromatic nitriles has been well known to occur in polar solvents.[1] It is proposed that such photoamination is initiated by a photochemical electron transfer from **1** to DCNB, since no photoamination of **1** occurred in the absence of A (Eq. 1). The cation radicals of **1**, thus formed, react with RNH_2 to give aminated cation radicals which are reduced with the anion radical of DCNB and then protonated to afford **2** (Eq. 2).

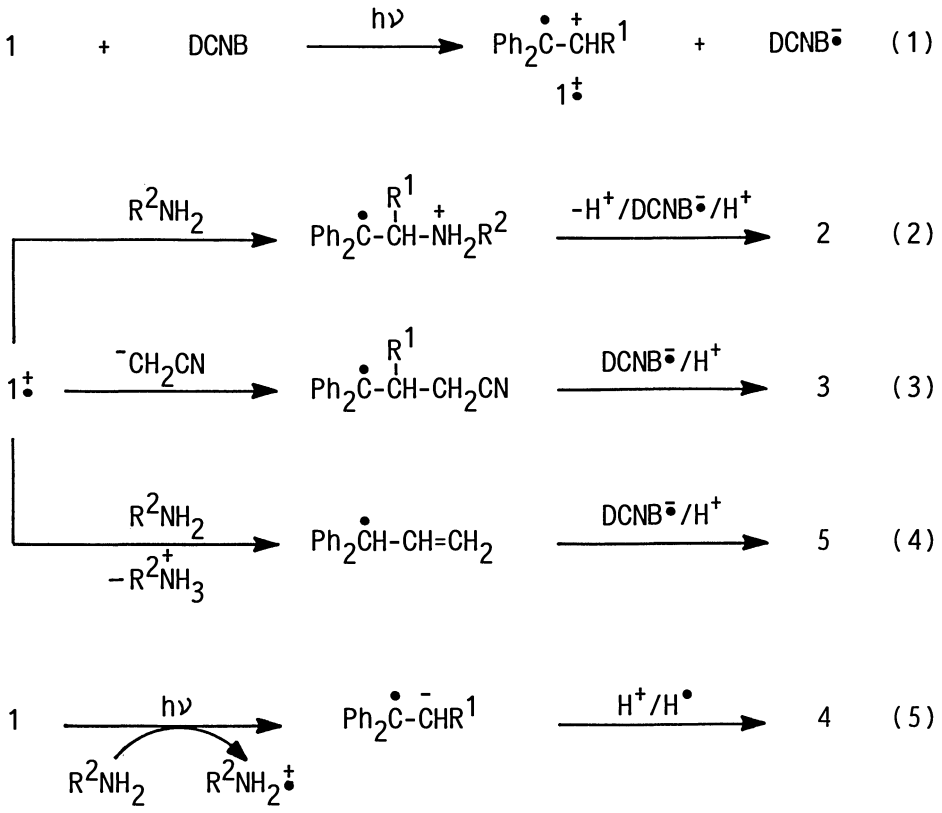
In the case of **1c**, the resulting aminated anion (**17**) takes both **17a** and **17b** conformations, depending on the bulkiness of the amine, as shown in Scheme 7.

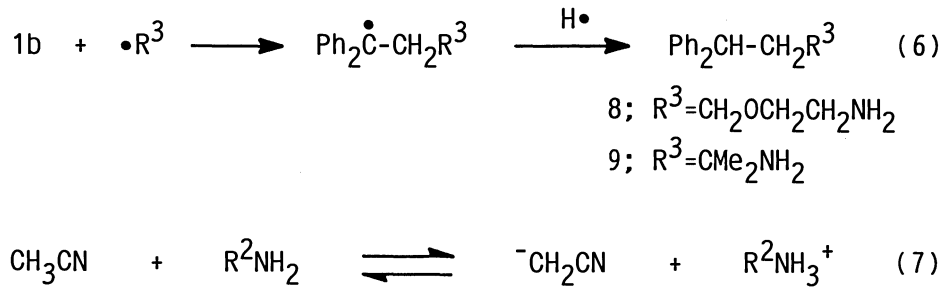


Scheme 7.

The electron pair of **17** may exist in the axial position, which is favorable for a maximum orbital overlap of the electron pair with the aromatic ring. When an amino group has a bulky alkyl group, a steric interaction between the amino group on C-2 and the phenyl group on C-1 may be expected to favor **17a**, in which the amino group is axial and phenyl group is equatorial. Therefore, the protonation of **17** affords mainly the cis isomer (**15a** and **16a**) in the photoamination of **1c** with isopropylamine or *t*-butylamine. This result is in accord with the results reported for the photoaddition of methanol to **1c**.[5]

The fact that 4,4-diphenyl-2,2-dideuterio-1-butanenitrile was formed from the photoamination of **1b** in acetonitrile-d_3 reveals that the cyanomethyl group of **3** can undoubtedly be attributed to acetonitrile. Figure 1 shows that **3b** is the primary product from the photoreaction of **1b**. On the other hand, it has been reported that **3** was not formed at all from the photoaddition of water and alcohols to **1a** or **1b** in the





Equation 1—7.

presence of electron acceptors.[5,6] Indeed, when DCNB was used as an electron acceptor, the photoaddition of water to **1b** in the absence of amines in acetonitrile gave only **7** in 41% yield without the formation of **3b**. This fact shows that the presence of amines is requisite for the formation of **3b**. These observations, therefore, suggest that $\mathbf{1}^{+\cdot}$ reacts with the cyanomethyl anion which is generated from the deprotonation of acetonitrile by the amine. The reduction of cyanomethylated radicals by the anion radical of DCNB gives **3** after protonation (Eqs. 3 and 7). Thus, $\mathbf{1}^{+\cdot}$ can undergo Eq. 3 competitively with Eq. 2, depending on the nature of RNH_2. *t*-Butylamine operates more effectively for the formation of **3** compared with other primary alkylamines since the bulky substituent may slow down the nucleophilic addition and/or the strong basicity may facilitate the deprotonation of acetonitrile. Also, amines operate as a base for the isomerization of **1a** to **5**, which proceeds by deprotonation from $\mathbf{1a}^{+\cdot}$ with RNH_2 according to Eq. 4.

The photoreaction of **1b** with isopropylamine in the absence of DCNB would be initiated by a photochemical electron transfer from isopropylamine to **1b** to give a cation radical of the amine and the anion radical of **1b**, as discussed in previous reports.[8,9,11] The protonation of the anion radical of **1b** and the subsequent hydrogen abstraction from such hydrogen sources as isopropylamine gave **4b** (Eq. 5). Equation 5 would take place to some extents, even for photoamination in the presence of DCNB, since a considerable amount of **4b** was produced.

The formation of **9** would occur by the reaction of **1b** with the 2-amino-2-propyl radical which is generated by deprotonation from the cation radical of isopropylamine or by hydrogen abstraction from isopropylamine with a radical species, as shown in Eq. 6. Similarly, the formation of **8** would occur by the reaction of **1b** with the 2-aminoethoxymethyl radical formed by hydrogen abstraction from 2-methoxyethylamine (Eq. 6). The formation of **3b** from the photoreaction in the absence of DCNB would occur by the reaction of **1b** with the cyanomethyl radical formed by hydrogen abstraction from acetonitrile by a radical species in reaction systems; this mechanism is in accord with that for photochemical incorporation of acetonitrile to norbornene.[11]

Degradation of secondary amines (**2b** and **2g**) to primary amines (**2a** and **2f**) can be attributed to be the consequence of secondary reactions, as is shown in Fig. 1. It was confirmed that the photoreaction of isolated **2g** with DCNB gave **2f**. Degradation would occur through an electron transfer reaction from **2b** or **2g** to the excited singlet state of DCNB.[9] Also, the formation of **6** occurred as a secondary reaction which proceeds by C-C bond cleavage of the cation radicals of **2a—e** generated by a photochemical electron transfer to DCNB. This is in agreement with a mechanism which has been reported for the cleavage of tertiary amines[12] and 2,2-diphenylethyl alkyl ethers.[13]

Neither DCA- nor CNN-photosensitization was a useful method for the photoamination of **1**. From the fluorescence quenching of DCA or CNN with **1** or amines, it was found that the excited singlet state of DCA or CNN was efficiently quenched by ammonia and primary amines, as well as by **1**. No occurrence of the DCA- or CNN-sensitized photoamination is caused by the more efficient quenching of the excited singlet state of DCA or CNN by RNH_2 than that by **1** under the reaction conditions.

Experimental

^1H and ^{13}C NMR spectra were taken on a Bruker AC 250P for $CDCl_3$ solutions with tetramethylsilane used as an internal standard. The fluorescence and IR spectra were taken on a Hitachi MPF-4 and a JASCO A-302, respectively. A JEOL JMS-D300S was used for analyzing the mass spectra. GLC analysis was carried out on a Shimadzu GC-14A or a Hitachi 163 with flame-ionization detectors using a capillary column (CBP1-M25-025) or a 50 cm×4 mm column of 2% silicone OV-17 on Chromosorb WAW DMCS.

Spectral grade acetonitrile was distilled from P_2O_5 and then from CaH_2. 1,1-Diphenylethene, *p*-dicyanobenzene, and amines were commercially available. 1,1-Diphenylpropene was prepared from the acid-fragmentation of 2,2-diphenyl-3-methyloxetane prepared from the photoaddition of benzophenone with 2-butene.[14] 1-Phenyl-3,4-dihydronaphthalene was prepared according to a method described in the literature.[15]

Photoamination of 1a,b with Amines. Into a pyrex vessel was introduced an acetonitrile solution (150 ml) containing **1** (5.6 mmol) and DCNB (16 mmol). The amine (73

mmol) was added to the solution after argon bubbling for 50 min, whereas an ammonia solution was obtained by dissolving gaseous ammonia into the solution. The solutions were irradiated for 8—50 h with an Eikosha PIH-300 high-pressure mercury lamp through Pyrex. After evaporation of the solvent, cool methanol was added to the residue and then unreacted DCNB was filtered off. The filtrate was chromatographed on silica gel with hexane to give **1**, **4**, **5**, and **6**. Further elution with hexane-benzene (4:1) gave **3**. The aminated products (**2a—i**) were obtained by elution with benzene-ethyl acetate (4:1) or acetone. Purification was carried out by either recrystallization from hexane-benzene or vacuum distillation. The recrystallization of **2c** and **2h**, however, could not be achieved owing to a failure regarding their acetylation. The structures of **2b**, **2d**, and **2e** were determined by comparisons of the ^{1}H and ^{13}C NMR spectra with authentic samples prepared from the reaction of 1,1-diphenyl-3-propanone with the corresponding amines in the presence of sodium cyanoborohydride.[16] The structures of **4a**, **4b**, **5**,[17] **6**, **7**, and **13**[2a] were determined by direct comparisons with authentic samples.

1-Methyl-2,2-diphenylethylamine (2a). ***N*-(2-Hydroxyethyl)-(1-methyl-2,2-diphenylethyl)amine (2e):** Mp 83.5—84.0 °C; ^{1}H NMR δ=1.05 (3H, d, J=6.1 Hz), 2.63—2.72 (1H, m), 2.74—2.89 (3H, m), 3.46—3.57 (3H, m), 3.78 (1H, d, J=10.3 Hz), and 7.13—7.38 (10H, m); ^{13}C NMR δ=18.5, 48.1, 55.9, 59.0, 60.6, 126.5, 126.8, 128.0, 128.1, 128.6, 128.9, 142.2, and 142.8; MS m/z 255 (M^+).

2,2-Diphenylethylamine (2f). The acetamide: Mp 89.5—90.0 °C; ^{1}H NMR δ=1.82 (3H, s), 3.84 (1H, d, J=7.9 Hz), 3.86 (1H, d, J=7.9 Hz), 4.17 (1H, d, J=7.9 Hz), 5.67 (1H, br s), and 7.16—7.33 (10H, m); ^{13}C NMR δ=23.2 43.9, 50.5, 126.8, 128.0, 128.7, 141.9, and 170.2; MS m/z 239 (M^+). The acetamide of **2f** was unambiguously identified by a direct comparison with an authentic sample.

***N*-Isopropyl-2,2-diphenylethylamine (2g).** The acetamide: Mp 104.5—105.0 °C; ^{1}H NMR δ=0.78 and 1.18 (6H, d J=6.8 and 6.9 Hz), 1.58 and 2.10 (3H, s), 3.78 and 3.87 (2H, d, J=7.5 and 7.0 Hz), 3.74—3.82 and 4.11—4.20 (1H, m), 4.14 and 4.69 (1H, t, J=7.0 and 7.5 Hz), and 7.13—7.39 (10H, m); ^{13}C NMR δ=20.3 and 20.9, 22.3 and 22.6, 47.3 and 49.1, 48.4 and 51.6, 49.6 and 52.5, 126.3 and 126.9, 128.2 and 128.7, 128.6 and 132.7, 142.3 and 143.1, and 171.2; MS m/z 281 (M^+); IR ($CHCl_3$) 1620 cm^{-1}; Found: C, 80.79; H, 8.51; N, 5.07%. Calcd for $C_{19}H_{23}O$: C, 81.10; H, 8.24; N, 4.98%.

***N*-*t*-Butyl-2,2-diphenylethylamine (2h):** ^{1}H NMR δ=1.14 (9H, s), 3.28 (2H, d, J=8.0 Hz), 4.30 (1H, t, J=8.0 Hz), 4.70 (1H, br s), and 7.19—7.35 (10H, m); ^{13}C NMR δ=27.4, 46.9, 50.5, 52.1, 126.8, 128.0, 128.7, and 142.0; MS m/z 253 (M^+).

***N*-(2-Methoxyethyl)-2,2-diphenylethylamine (2i):** A colorless oil, ^{1}H NMR δ=2.81 (2H, t, J=5.3 Hz), 3.25 (2H, d, J=7.7 Hz), 3.30 (3H, s), 3.42 (2H, t, J=5.3 Hz), 4.21 (1H, t, J=7.7 H), and 7.14—7.38 (10H, m); ^{13}C NMR δ=49.1, 51.1, 54.5, 58.6, 71.7, 126.5, 127.9, 128.6, and 142.8; MS m/z 255 (M^+). The acetamide: Found: C, 76.98; H, 7.58; N, 4.98%. Calcd for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.80; N, 4.71%.

3-Methyl-4,4-diphenylbutanenitrile (3a): Mp 55.0—55.5 °C; ^{1}H NMR δ=1.07 (3H, d, J=6.5 Hz), 2.10 (1H, dd, J=16.7 and 7.0 Hz), 2.33 (1H, dd, J=16.7 and 3.8 Hz), 2.62—2.79 (1H, m), 3.65 (1H, d, J=11.4 Hz), and 7.12—7.31 (10H, m); ^{13}C NMR δ=18.3, 23.5, 34.2, 57.6, 118.5, 126.6, 126.9, 127.6, 127.8, 128.7, 129.0, 142.5, and 142.6; MS m/z 235 (M^+); IR ($CHCl_3$) 2220 cm^{-1}.

4,4-Diphenylbutanenitrile (3b): ^{1}H NMR δ=2.20 (2H, t, J=7.5 Hz), 2.30—2.45 (2H, m), 4.03 (1H, t, J=7.9 Hz), and 7.10—7.31 (10H, m); ^{13}C NMR δ=15.7, 31.0, 49.8, 119.3, 126.8,127.7, 128.8, and 142.8; MS m/z 221 (M^+); IR ($CHCl_3$) 2190 cm^{-1}. The structure of **3b** was determined by a comparison with an authentic sample prepared from the cyanation of 3,3-diphenyl-1-propanol according to a reported method.[18]

1-(2-Aminoethoxy)-3,3-diphenylpropane (8). The acetamide: Mp 64.5—65.0 °C (from hexane-benzene); ^{1}H NMR δ=1.95 (3H, s), 2.28—2.36 (2H, m), 3.34—3.39 (6H, m), 4.09 (1H, t, J=7.9 Hz), 5.89 (1H, br s), and 7.15—7.37 (10H, m); ^{13}C NMR δ=23.2, 35.2, 39.3, 47.5, 69.1, 69.3, 126.3, 127.8, 128.5, 144.4, and 170.1; MS m/z 297 (M^+); IR ($CHCl_3$) 3440 and 1660 cm^{-1}; Found: C, 76.73; H, 7.63; N, 4.66%. Calcd for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.80; N, 4.71%.

1,1-Dimethyl-3,3-diphenylpropylamine (9). The acetamide: Mp 120.5-121.0 °C (from hexane-benzene); ^{1}H MMR δ=1.29 (6H, s), 1.44 (3H, s), 2.53 (2H, d, J=7.1 Hz), 4.05 (1H, t, J=7.0 Hz), 5.38 (1H, br s), and 7.18—7.29 (10H, m); ^{13}C NMR δ=23.4, 27.3, 44.1, 47.2, 53.2, 125.6, 126.7, 128.1, 145.0, and 169.1; MS m/z 255 (M^+). IR ($CHCl_3$) 3440 and 1660 cm^{-1}; Found: C, 81.26; H, 8.46; N, 4.82%. Calcd for $C_{19}H_{23}NO$: C, 81.10; H, 8.24; N, 4.98%.

Photoreaction of 1b in *N,N*-Dimethylformamide. After irradiation, the photolysates were dissolved in 150 ml of benzene; then, *N,N*-dimethylformamide was extracted with six 50 ml portions of water. After evaporation of benzene, the residue was chromatographed on silica gel with hexane to give **1b** and **4b**. Further elution with benzene gave **10** and **11**. **12a** and **12b** were obtained by elution with benzene-ethyl acetate (8:1). **11** and **12b** could not be purified from the mixture of either **10** and **11** or **12a** and **12b**.

***N*-(3,3-Diphenylpropyl)-*N*-methylformamide (10):** Mp 60.0—61.0 °C (from hexane-benzene); ^{1}H NMR δ=2.30 and 2.33 (2H, m), 2.85 and 2.86 (3H, s), 3.17 and 3.28 (2H, t,

J=6.9 and 7.7 Hz), 3.86 and 3.94 (1H, t, J=7.9 and 7.8 Hz), 7.14—7.33 (10H, m), 7.60 and 7.98 (1H, s); ^{13}C NMR δ=29.4 and 32.5, 33.5 and 34.7, 43.5 and 47.6, 48.0 and 49.1, 126.4 and 126.7, 127.6 and 127.7, 128.6 and 128.8, 143.5 and 144.1, 162.4 and 162.8; MS m/z 253 (M^+); IR ($CHCl_3$) 1665 cm^{-1}; Found: C, 80.65; H, 7.53; N, 5.79%. Calcd for $C_{17}H_{19}NO$: C, 80.57; H, 7.56; N, 5.53%.

***N,N*-Dimethyl-3,3-diphenylpropanamide (11):** ^{1}H NMR δ=2.86 (6H, s), 3.04 (2H, d, J=7.5 Hz), 4.68 (1H, t, J=7.4 Hz), and 7.13—7.32 (10H, m); ^{13}C NMR δ=35.5, 37.2, 39.3, 47.2, 126.3, 127.8, 128.8, 144.3, and 171.2; MS m/z 253 (M^+); IR ($CHCl_3$) 1645 cm^{-1}.

***N*-(4-Cyanobenzyl)-*N*-methylformamide (12a):** A colorless oil, ^{1}H NMR δ=2.80 and 2.91 (3H, s), 4.49 and 4.58 (2H, s), 7.35—7.38 (2H, d, J=8.0 Hz), 7.64—7.69 (2H, d, J=8.0 Hz), 8.20 and 8.26 (1H, s); ^{13}C NMR δ=29.7 and 34.3, 47.6 and 53.0, 111.6 and 112.2, 118.3 and 118.6, 128.0 and 128.7, 132.5 and 132.8, 141.5 and 141.7, 162.78 and 162.82; MS m/z 174 (M^+); IR ($CHCl_3$) 2230 and 1660 cm^{-1}; Found: C, 68.84; H, 5.89; N, 16.26%. Calcd for $C_{10}H_{10}N_2O$: C, 68.94; H, 5.79; N, 16.08%.

***N*-(3-Cyanobenzyl)-*N*-methylformamide (12b):** ^{1}H NMR δ=2.83 and 2.96 (3H, s), 4.64 and 4.77 (2H, s), 7.27—7.50 (2H, m), 7.57—7.74 (2H, m), 8.20 and 8.34 (1H, s); ^{13}C NMR δ=29.6 and 34.5, 45.8 and 51.4, 112.1 and 112.3, 116.9 and 117.4, 128.3 and 128.8, 128.9 and 132.6, 132.8 and 133.4, 139.5 and 139.9, 162.9 and 163.0; MS m/z 174 (M^+); IR ($CHCl_3$) 2230 and 1660 cm^{-1}.

Photoamination of 1c. In a similar manner to the case of **1a**, the photoamination of **1c** was performed for an acetonitrile solution (50 ml) containing **1c** (2.5 mmol), DCNB (2.5 mmol), and the amine (25 mmol). After irradiation, aminated products were obtained by extraction with dilute hydrochloric acid. The acidic aqueous layer was basified with saturated $NaHCO_3$ followed by extraction with diethyl ether. Evaporation of the ether left crude aminated products. **1c** and DCNB were recovered from benzene solutions and were chromatographed on silica gel with hexane and benzene. A mixture of **14a** and **14b** was acetylated with Ac_2O, and recystallized from hexane-benzene to give the acetamide of **14a**. Also, **15a** was obtained in the same way, though the acetamide of **16** was not purified by recrystallization.

***cis*-2-Amino-1-phenyl-1,2,3,4-tetrahydronaphthalene (14a):** ^{1}H NMR δ=1.62 (2H, br s), 2.03—2.15 (2H, m), 2.88—3.12 (2H, m), 3.32 (1H, ddd, J=8.1, 5.4, and 5.2 Hz), 4.22 (1H, d, J=5.2 Hz), and 6.68—7.40 (9H, m); ^{13}C NMR δ=28.3, 31.0, 51.7, 56.1, 125.9, 126.3, 126.5, 127.9, 128.5, 130.6, 130.8, 136.3, 138.3, and 141.7.

Synthesis of Substituted Pyridines by a Cycloaddition Route Using Nitrile Oxides and Homoallyl Alcohols

Shuji KANEMASA,* Yoshihiko ASAI,† and Junji TANAKA
Institute of Advanced Material Study, Kyushu University, Kasugakoen, Kasuga 816

(Received August 13, 1990)

Cycloadditions of nitrile oxides with unprotected homoallyl alcohols, followed by Swern oxidations, lead to 5-(2-oxoalkyl)-2-isoxazolines. Subsequent Raney Ni reduction of the resulting heterocycles in ethanol in the presence of excess tetrafluoroboric acid affords substituted pyridine derivatives.

Cycloadditions of nitrile oxides with terminal olefins take place readily and regioselectively to produce 5-substituted 2-isoxazolines in high yields;[1] the nitrogen-oxygen bond of cycloadducts is reductively cleaved to lead to β-imino alcohol intermediates, which are further hydrolyzed into β-hydroxy ketones and related functionalities.[2] Since the synthetic application of β-imino alcohol functionality is quite limited, we planned to open a new entry to the synthesis of pyridine nuclei by utilizing this unusual functional group.

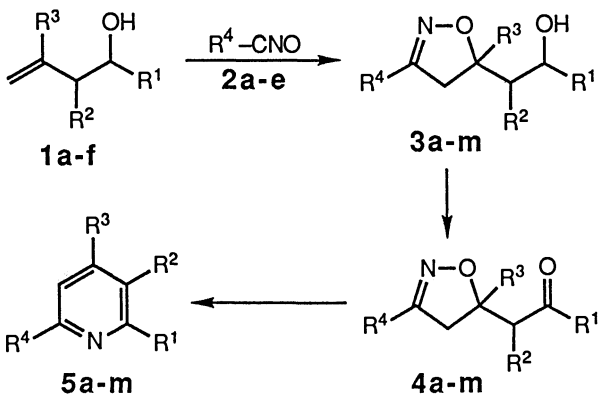
Our synthetic plan of pyridine synthesis consists of the combination of β-imino alcohol and carbonyl functionalities. Dehydrative cyclization of β-hydroxy-δ-imino ketones would offer a convenient construction route of pyridine skeletons, and the shortest access to the requisite β-hydroxy-δ-imino ketone functionality would be the nitrile oxide cycloaddition with β,γ-unsaturated ketones. However, the availability of β,γ-unsaturated ketones is quite narrow due to their susceptibility toward double bond migration.[3,4] Accordingly, we examined the nitrile oxide cycloadditions with homoallyl alcohols.

Nitrile oxides **2a—e** were found to react smoothly with a variety of homoallyl alcohols **1a—f** without protecting the hydroxyl group to give 5-(2-hydroxyalkyl)-2-isoxazolines **3a—m** in satisfactory yields (Scheme 1 and Table 1). These reactions make a striking contrast with the nitrile oxide cycloadditions with allyl alcohols where the use of unprotected dipolarophiles gave cycloadducts in poor yields.[5] Since homoallyl alcohols **1a—f** can be prepared in high yields by the reactions of readily available allyl bromides with aldehydes according to the Akiba's method,[6] this cycloaddition route is synthetically useful to construct pyridine skeletons.

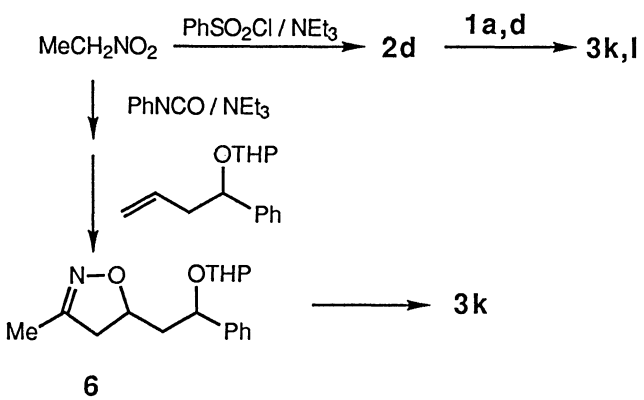
Nitrile oxides **2a—c** and **2e** were generated from the corresponding hydroximoyl halides by dehydrohalogenation with triethylamine, and ethanenitrile oxide (**2d**) was generated from nitroethane and benzenesulfonyl chloride/triethylamine (Scheme 2).[7] An effective generation method of **2d** by the Mukaiyama procedure[8] could not be successfully employed since phenyl isocyanate reacted with **1**.

Although the cycloaddition of **2d**, generated by the Mukaiyama's procedure, with the tetrahydropyranyl (THP) ether of **1a** produced the corresponding cycloadduct **6** in 76% yield, one further deprotection step (73%) was required; the overall yield of **3k** being 55%.

The secondary hydroxyl group of **3a—m** was oxidized according to the Swern oxidation procedure[9] to give ketones **4a—m** in almost quantitative yields (Table 1).

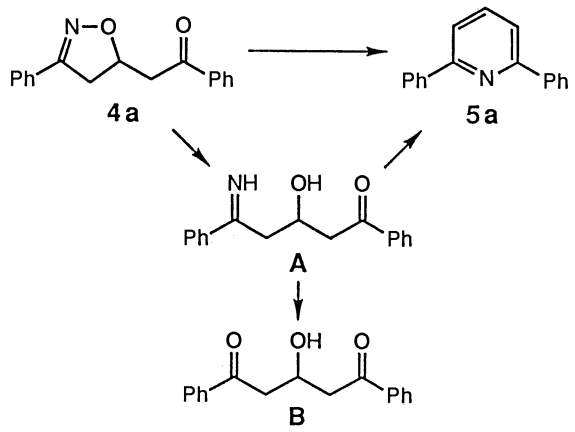


Scheme 1.



Scheme 2.

Reductive cleavage of the nitrogen-oxygen bond of 5-(2-oxoalkyl)-2-isoxazolines **4a—m** was carried out by use of Raney Ni (W-2). The Raney-Ni reduction of **4a** in the presence of boric acid in aqueous ethanol (ethanol/water=6 : 1 v/v)[10] gave the expected pyridine **5a** in only 19% yield (Scheme 3 and Table 2). In this case, a complex mixture of unidentified products was accompanied.[11]



Scheme 3.

It is likely that β-hydroxy-δ-imino ketone intermediate **A** undergoes either dehydrative cyclization to give pyridine **5a** or hydrolysis leading to 3-hydroxy-1,5-diphenyl-1,5-pentanedione (**B**) (Scheme 3). An acid would catalyze both the reactions, and presence of water is not favored for the pyridine formation. Several reaction conditions were examined on these basis, and we found that the Raney Ni reduction of **4a** in ethanol in the presence of tetrafluoroboric acid (42% aqueous solution) took place very cleanly to provide a satisfactory yield of **5a** (82%). Amount of tetrafluoroboric acid is not so important.

Under these reaction conditions, other 5-(2-oxoalkyl)-2-isoxazolines **4a—m** were reduced with Raney Ni to give pyridines **5a—m** (Scheme 1 and Table 1). The very poor yield of pyridine **5e** is in part due to its ready chelate formation with Raney Ni.[12]

In conclusion, substituted pyridines are synthesized by a sequence of the cycloaddition of nitrile oxides with homoallyl alcohols, Swern oxidation, and Raney Ni reduction. Since a variety of nitrile oxides and homoallyl alcohols are readily accessible, this method becomes a useful synthetic method of substituted pyridine derivatives.

Table 1. Pyridine Synthesis by Nitrile Oxide Cycloaddition Route

Experimental

Melting points were recorded on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or an A-702 spectrometer. ^{1}H and ^{13}C NMR spectra were measured on a Hitachi R-40 (^{1}H NMR: 90 MHz) or a JEOL GSX-270 (270 MHz for ^{1}H NMR and 67.94 MHz for ^{13}C NMR) instrument. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra and high-resolution mass spectra (HRMS) were taken with a JEOL-01SG-2 spectrometer where the ionization energy of 70 eV was employed unless otherwise stated. Elemental analyses were performed on a Hitachi 026 CHN analyzer. For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silica gel 60 (Merck) were employed.

General Procedure for Cycloadditions of Homoallyl Alcohols 1a—f with Nitrile Oxides 2a—e Leading to 3a—m. Some typical procedures employing methods A—D for the nitrile oxide generation are described:

Method A: Triethylamine (0.404 g, 4 mmol) was added dropwise to a solution of benzohydroximoyl chloride (0.6 g, 3.85 mmol) and **1a** (0.57 g, 3.85 mmol) in dry diethyl ether (20 ml), and the mixture was stirred at room temperature for 15 h. The triethylammonium chloride was filtered off and the filtrate was evaporated in vacuo. The residue was chromatographed on silica gel by using hexane-ethyl acetate (4:1 v/v) to give **3a** (0.693 g, 67%).

Method B: Triethylamine (1.01 g, 10 mmol) in diethyl ether (14 ml) was added, at 0 °C in a period of 2 h, to a solution of ethyl chloro(hydroxyimino)acetate (1.212 g, 8 mmol) and **1a** (0.592 g, 4 mmol) in diethyl ether (20 ml), and the mixture was stirred at room temperature for 15 h. Similar workup mentioned above and subsequent column chromatography on silica gel using hexane-ethyl acetate (4:1 v/v) gave **3i** (0.92 g, 87%).

Method C: Benzenesulfonyl chloride (1.77 g, 10 mmol) was added dropwise to a solution of nitroethane (0.375 g, 5 mmol), **1a** (0.74 g, 5 mmol), and triethylamine (1.01 g, 10 mmol) in chloroform (25 ml), and the mixture was stirred at room temperature for 17 h. Water (30 ml) was added and the mixture was extracted with dichloromethane (30 ml×3). The combined extract was washed with water (20 ml×3), dried over magnesium sulfate, and the solvent was evaporated in vacuo. The residue was chromatographed on silica gel with hexane-ethyl acetate (2:1 v/v) to give **3k** (0.407 g, 40%).

Method D: To a solution of (diethoxyphosphinyl)acetaldehyde oxime (0.975 g, 5 mmol) in dry *N*,*N*-dimethylformamide (DMF, 10 ml) was added dropwise at −20 °C a DMF solution (10 ml) of *N*-bromosuccinimide (NBS, 2.1 g, 10 mmol). The mixture was stirred at −20 °C for 1 h and then at 0 °C for 30 min. Diethyl ether (10 ml), triethylamine (0.505 g, 5 mmol), and an ether solution (10 ml) of **1a** (1.48 g, 10 mmol) were added dropwise in this order, and the mixture was stirred overnight at room temperature. Water (50 ml) was added and the mixture was extracted with dichloromethane (30 ml×3). The combined extract was washed with water (30 ml×3), dried over magnesium sulfate, and the solvent was evaporated in vacuo. The residue was chromatographed on silica gel with ethyl acetate to give **3m** (1.2 g, 70%). Products **3a—m** were submitted to the Swern oxidation procedure. Spectral data for some of these compounds are given as follows and yields are summarized in Table 1:

3a: Solid (a 3:2 diastereomeric mixture (^{1}H NMR)); ^{13}C NMR ($CDCl_3$) δ=40.62, 40.64 (each C-4), 44.48, 44.62 (each 5-CH_2), 71.14, 72.47 (each C-5), 78.40, 79.67 (each CH(OH)Ph), 125.58, 125.96, 126.68, 126.71, 127.61, 128.58, 128.71, 128.74, 130.09, 130.16, 143.78, 144.36 (each Ph), 156.90, and 156.93 (each C-3). MS *m*/*z* (rel intensity) 267 (M^+, 12), 148 (9), 146 (10), 120 (9), 119 (28), 105 (18), and 104 (100).

3c: Solid (a roughly 1:1 diastereomeric mixture (^{1}H NMR)); IR (KBr) 3320, 1440, 1350, 750, and 690 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=8.22, 9.16 (each Me), 38.10, 38.21 (each C-4), 44.58, 44.87 (each 5-CH), 73.32, 75.40 (each C-5), 83.24 (CH(OH)Ph), 125.96, 126.22, 126.62, 127.02, 127.31, 128.12, 128.25, 128.66, 129.57, 129.97, 130.05, 143.02, 143.26 (each Ph), 156.73, and 157.04 (each C-3).

3d: Solid (a 1:1 diastereomeric mixture (^{13}C NMR)); IR (KBr) 3380, 1440, 1350, 890, 755, and 690 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=9.78, 9.85 (each Et), 30.34, 30.74 (each Et), 40.59, 40.65 (each C-4), 41.74, 42.26 (each 5-CH_2), 69.92, 71.24 (each each C-5), 78.77, 80.34 (each CH(OH)Ph), 126.65, 126.68, 128.68, 129.53, 129.67, 130.02, 130.10 (each Ph), 156.96, and 157.08 (each C-3). MS *m*/*z* (rel intensity) 219 (M^+, 27), 147 (10), 146 (100), 145 (23), 144 (13), and 118 (11).

3g: Solid (a 1:1 diastereomeric mixture (^{13}C NMR)); IR (KBr) 3280, 1600, 1240, 1010, 890, and 820 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=40.81, 40.85 (each 5-CH_2), 44.43, 44.58 (each C-4), 55.32 (MeO), 71.06, 72.41 (each C-5), 78.10, 79.35 (each CH(OH)Ph), 114.11, 114.14, 122.04, 122.17, 125.58, 125.96, 127.50, 127.68, 128.19, 128.22, 128.51, 143.85, 144.44 (Ph and Ar), 156.50, 156.52 (each C-3), 161.03, and 161.09 (each Ar).

3h: Solid (a 1:1 diastereomeric mixture (^{13}C NMR)); IR (KBr) 3320, 1600, 1240, 1015, 890, and 820 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=9.81, 9.88 (each Et), 30.35, 30.78 (each Et), 40.86, 40.89 (each 5-CH_2), 41.76, 42.27 (each C-4), 55.32 (MeO), 69.95, 71.26 (each C-5), 78.53, 80.08 (each CH(OH)Et), 114.11, 114.14, 122.11, 122.29, 128.17, 128.22 (each Ar), 156.54, 156.65 (each C-3), 161.00, and 161.07 (each Ar).

3i: Oil (a 1:1 diastereomeric mixture (^{13}C NMR)); IR (neat) 3400, 1715, 1250, 930, and 760 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=14.11 (COOEt), 38.93, 39.08 (each 5-CH_2), 43.99, 44.62 (each C-4), 62.06 (COOEt), 70.73, 71.75 (each C-5), 81.02, 81.90 (each CH(OH)Ph), 125.53, 125.90, 127.79, 127.97, 128.64, 128.66, 143.48, 144.13 (Ph), 151.77, 151.80 (each C-3), and 160.76 (COOEt); MS *m*/*z* (rel intensity) 263 (M^+, 9), 190 (26), 172 (19), 157 (44), 129 (31), 115 (23), 111 (27), 108 (13), 107 (100), 105 (52), 104 (54), and 79 (26).

3j: Oil (a 1:1 diastereomeric mixture (^{13}C NMR)); IR (neat) 3420, 1720, 1590, 1250, 1130, and 930 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=9.75 (Et), 14.13 (COOEt), 30.44, 30.81 (each Et), 38.96, 39.21 (each 5-CH_2), 41.58, 42.27 (each C-4), 62.06, 62.10 (each COOEt), 69.66, 70.68 (each C-5) , 81.44, 82.72 (each CH(OH)Et), 151.79, 151.92 (each C-3), 160.83, and 160.86 (each COOEt); MS *m*/*z* (rel intensity) 215 (M^+, 12), 186 (11), 183 (12), 157 (20), 142 (100), 129 (12), 124 (12), 114 (47), 111 (14), 96 (10), and 59 (11).

3k: Oil (a 1:1 diastereomeric mixture (^{13}C NMR)); IR (neat) 3380, 1435, 1325, 1040, 760, and 700 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=13.12, 13.16 (each Me), 44.28, 44.35, 44.42, 44.52 (C-4 and 5-CH_2), 70.87, 72.31 (each C-5), 77.28, 78.60 (each CH(OH)Ph), 125.57, 125.93, 127.38, 127.58, 128.43, 143.94,

144.57 (each Ph), and 155.85 (C-3); MS *m/z* (rel intensity) 205 (M^+, 5), 120 (12), 107 (23), 105 (20), 104 (100), 99 (25), 79 (11), and 57 (29).

3l: Oil (a 1 : 1 diastereomeric mixture (^{13}C NMR)); IR (neat) 3420, 1440, 1335, and 870 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ=9.73, 9.86 (each Et), 13.22, 13.29 (each 3-Me), 30.32, 30.68 (each Et), 41.80, 41.97 (each 5-CH_2), 44.42, 44.65 (each C-4), 70.06, 71.66 (each C-5), 77.69, 79.67 (each CH(OH)Et), 155.79, and 155.91 (each C-3).

General Procedure for the Swern Oxidation of 3a—m Leading to 4a—m. The oxidation of **3a** is described as a typical example. To a solution of oxalyl dichloride (0.14 ml, 1.5 mmol) in dry dichloromethane (3.5 ml) was added dropwise, at −78 °C under nitrogen, a dichloromethane (3 ml) solution of dimethyl sulfoxide (0.24 ml, 3 mmol). After 5 min, a solution of **3a** (0.36 g, 1.35 mmol) in dichloromethane (3 ml) was added, and the stirring was continued for 20 min. Triethylamine (0.682 g, 6.8 mmol) was added. After 10 min, the mixture was warmed to room temperature, and poured into water (50 ml). The mixture was extracted with dichloromethane (30 ml×2). The combined extract was washed with saturated aqueous sodium chloride (30 ml×3), dried over magnesium sulfate, and the solvent was evaporated in vacuo. The residue was chromatographed on silica gel by using hexane–ethyl acetate (1 : 1 v/v) to give **4a** (0.351 g, 98%).

Results are summarized in Table 1.

5-(2-Oxo-2-phenylethyl)-3-phenyl-2-isoxazoline (4a): Colorless needles (ethyl acetate–hexane); mp 141—143 °C; IR (KBr) 1670, 1430, 1205, 910, 760, and 685 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.08 (1H, dd, J_{gem}=16.9 and $J_{4,5}$=7.7 Hz, one of H-4), 3.26 (1H, dd, J_{gem}=17.4 and $J_{CH,5}$=8.5 Hz, one of 5-CH_2), 3.66 (1H, dd, J_{gem}=17.4 and $J_{CH,5}$=4.6 Hz, the other of 5-CH_2), 3.67 (1H, dd, J_{gem}=16.9 and $J_{4,5}$=10.3 Hz, the other of H-4), 5.25 (1H, dddd, $J_{4,5}$=10.3, 7.7, $J_{5,CH}$=8.5, and 4.6 Hz, H-5), 7.4—7.7 (8H, m, Ph), and 7.9—8.0 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=40.73 (C-4), 43.87 (5-CH_2), 77.46 (C-5), 126.69, 128.09, 128.71, 128.74, 129.53, 130.10, 133.57, 136.51 (each Ph), 156.93 (C-3), and 197.36 (CO); MS *m/z* (rel intensity) 265 (M^+, 12), 160 (11), 147 (11), 146 (100), and 120 (26). Found: C, 77.01; H, 5.92; N, 5.34%. Calcd for $C_{17}H_{15}NO_2$: C, 76.96; H, 5.70; N, 5.28%.

5-(2-Oxo-2-phenylethyl)-5-methyl-3-phenyl-2-isoxazoline (4b): Pale yellow prisms (diethyl ether–hexane); mp 68—70 °C; IR (KBr) 1780, 1450, 1360, 920, 760, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.60 (3H, s, 5-Me), 3.32, 3.48 (each 1H, d, J_{gem}=17.2 Hz, H-4), 3.44, 3.59 (each 1H, J_{gem}=16.9 Hz, 5-CH_2), and 7.2—8.0 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.92 (5-Me), 45.44 (C-4), 47.69 (5-CH_2), 85.63 (C-5), 126.59, 128.16, 128.68, 128.71, 129.92, 129.97, 133.52, 136.99 (each Ph), 157.26 (C-3), and 197.46 (CO); MS *m/z* (rel intensity) 279 (M^+, 6), 161 (12), 160 (100), and 120 (9). Found: C, 77.77; H, 6.16; N, 4.88%. Calcd for $C_{18}H_{17}NO_2$: C, 77.40; H, 6.13; N, 5.01%.

5-(2-Oxo-1-methyl-2-phenylethyl)-3-phenyl-2-isoxazoline (4c): Obtained as a 1 : 1 mixture of diastereomers (^1H NMR); pale yellow liquid; IR (neat) 1670, 1440, 1215, 890, 760, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23, 1.43 (each 1/2×3H, d, J=7.0 Hz, Me), 2.99, 3.26 (each 1/2H, dd, J_{gem}=17.2 and $J_{4,5}$=8.1 Hz, one of H-4), 3.42, 3.52 (each 1/2H, dd, J_{gem}=17.2 and $J_{4,5}$=11.3 Hz, the other of H-4), 3.77 (1/2H, dq, $J_{CH,Me}$=7.0 and $J_{CH,5}$=6.6 Hz, 5-CH), 3.95 (1/2H, quint, $J_{CH,Me}$=$J_{CH,5}$=7.0 Hz, 5-CH), 5.02 (1/2H, dt, $J_{5,4}$=11.3 and $J_{5,4}$=$J_{5,CH}$=8.1 Hz, H-5), 5.13 (1/2H, ddd, $J_{5,4}$=11.3, 8.1, and $J_{5,CH}$=6.6 Hz, H-5), 7.3—7.7 (8H, m, PH), and 7.9—8.0 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=12.30, 15.93 (each Me), 36.85, 39.42 (each C-4), 44.35, 46.09 (each 5-CH), 82.01, 82.89 (each C-5), 128.45, 128.56, 128.66, 128.71, 128.76, 128.79, 129.48, 130.05, 130.09, 133.37, 133.49, 136.08, 136.27 (each Ph), 156.64, 156.99 (each C-3), 201.43, and 202.46 (each CO); MS *m/z* (rel intensity) 279 (M^+, 5), 146 (47), and 134 (100). Found: C, 77.49; H, 5.95; N, 5.20%. Calcd for $C_{18}H_{17}NO_2$: C, 77.38; H, 6.14; N, 5.02%.

5-(2-Oxobutyl)-3-phenyl-2-isoxazoline (4d): Colorless needles (diethyl ether–hexane); mp 81—82.5 °C; IR (KBr) 1700, 1435, 910, 750, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08 (3H, t, J=7.3 Hz, Et), 2.50, 2.52 (2H, each q, J=7.3 Hz, Et), 2.71 (1H, dd, J_{gem}=16.5 and $J_{CH,5}$=7.5 Hz, one of 5-CH_2), 2.99 (1H, dd, J_{gem}=16.7 and $J_{4,5}$=8.1 Hz, one of H-4), 3.04 (1H, dd, J_{gem}=16.5 and $J_{CH,5}$=5.7 Hz, the other of 5-CH_2), 3.56 (1H, dd, J_{gem}=16.7 and $J_{4,5}$=10.3 Hz, the other of H-4), 5.0—5.1 (1H, dddd, $J_{5,4}$=10.3, 8.1, $J_{5,CH}$=7.5, and 5.7 Hz, H-5), 7.3—7.4 (3H, m, Ph), and 7.6—7.7 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=7.56, 36.84 (each Et), 40.47 (C-4), 47.32 (5-CH_2), 77.07 (C-5), 126.69, 128.72, 129.50, 130.15 (each Ph), 156.78 (C-3), and 208.68 (CO); MS *m/z* (rel intensity) 217 (M^+, 11), 147 (10), 146 (100), and 57 (15). Found: C, 71.98; H, 7.10; N, 6.32%. Calcd for $C_{13}H_{15}NO_2$: C, 71.87; H, 6.96; N, 6.45%.

5-[2-Oxo-2-(2-pyridyl)ethyl]-3-phenyl-2-isoxazoline (4e): Colorless needles (diethyl ether–hexane); mp 81—83 °C; IR (KBr) 1690, 1435, 910, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.13 (1H, dd, J_{gem}=16.5 and $J_{4,5}$=7.3 Hz, one of H-4), 3.52 (1H, dd, J_{gem}=17.6 and $J_{CH,5}$=7.7 Hz, one of 5-CH_2), 3.62 (1H, dd, J_{gem}=16.5 and $J_{4,5}$=10.2 Hz, the other of H-4), 3.91 (1H, dd, J_{gem}=17.6 and $J_{CH,5}$=5.9 Hz, the other of 5-CH_2), 5.33 (1H, dddd, $J_{4,5}$=10.2, 7.3, $J_{5,CH}$=7.7, and 5.9 Hz, H-5), 7.3—7.4, 7.6—7.7 (3H and 2H, m, Ph), 7.55, 7.84, 8.05, and 8.68 (each 1H, m, Py); ^{13}C NMR ($CDCl_3$) δ=40.52 (C-4), 43.44 (5-CH_2), 77.41 (C-5), 121.78, 126.71, 127.48, 128.69, 129.69, 130.03, 136.97 (Ph and Py), 149.11, 152.95 (C-2 and C-6 of Py), 156.68 (C-3), and 198.97 (CO); MS *m/z* (rel intensity) 266 (M^+, 2), 163 (10), 122 (9), 121 (100), 93 (14), and 79 (11). Found: C, 72.31; H, 5.45; N, 10.44%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.17; H, 5.30; N, 10.52%.

5-[2-Oxo-2-(3-pyridyl)ethyl]-3-phenyl-2-isoxazoline (4f): Colorless needles (ethyl acetate–hexane); mp 138.5—139 °C; IR (KBr) 1675, 1570, 1210, 890, 790, and 755 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.12 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=7.7 Hz, one of 5-CH_2), 3.28 (1H, dd, J_{gem}=17.6 and $J_{4,5}$=8.1 Hz, one of H-4), 3.68 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=5.1 Hz, the other of 5-CH_2), 3.71 (1H, dd, J_{gem}=17.6 and $J_{4,5}$=9.9 Hz, the other of H-4), 5.29 (1H, dddd, $J_{5,4}$=9.9, 8.1, $J_{5,CH}$=7.7, and 5.1 Hz, H-5), 7.4—7.5, 7.6—7.7 (3H and 2H, m, Ph), 7.45, 8.25, 8.81, and 9.18 (each 1H, m, Py); ^{13}C NMR ($CDCl_3$) δ=40.72 (C-4), 44.12 (5-CH_2), 76.99 (C-5), 123.74, 126.73, 128.76, 129.31, 130.28, 131.77, 135.42 (Ph and Py), 149.69, 153.96 (C-2 and C-6 of Py), 156.93 (C-3), and 196.35 (CO); MS *m/z* (rel intensity) 266 (M^+, 18), 160 (9), 146 (54), 121 (100), and 106 (18). Found: C, 72.36; H, 5.49; N, 10.65%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.17; H, 5.30; N, 10.52%.

5-(2-Oxo-2-phenylethyl)-3-(4-methoxyphenyl)-2-isoxazoline (4g): Colorless needles (ethyl acetate–hexane); mp 146—147 °C; IR (KBr) 1670, 1600, 1255, and 890 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.05 (1H, dd, J_{gem}=16.8 and $J_{4,5}$=9.6 Hz, one of H-4), 3.25 (1H, dd, J_{gem}=17.6 and $J_{CH,5}$=8.5 Hz, one of 5-CH_2), 3.65 (1H, dd, J_{gem}=16.8 and $J_{4,5}$=10.3 Hz, the other of

H-4), 3.68 (1H, dd, J_{gem}=17.6 and $J_{CH,5}$=4.7 Hz, the other of 5-CH_2), 3.82 (3H, s, OMe), 5.23 (1H, dddd, $J_{5,4}$=10.3, 9.6, $J_{5,CH}$=8.5, and 4.7 Hz, H-5), and 6.9—7.9 (9H, m, Ph and Ar); ^{13}C NMR ($CDCl_3$) δ=41.02 (C-4), 43.93 (5-CH_2), 55.35 (MeO), 77.18 (C-5), 114.15, 122.10, 128.12, 128.25, 128.75, 133.57, 136.57 (Ph and Ar), 156.52 (C-3), 161.12 (Ar), and 197.50 (CO); MS *m/z* (rel intensity) 295 (M^+, 19), 177 (11), 176 (100), 175 (65), 147 (10), 120 (14), 105 (38), and 77 (29). Found: C, 73.48; H, 5.89; N, 4.42%. Calcd for $C_{18}H_{17}NO_3$: C, 73.19; H, 5.81; N, 4.74%.

5-(2-Oxobutyl)-3-(4-methoxyphenyl)-2-isoxazoline (4h): Colorless leaflets (diethyl ether-hexane); mp 111—112.5 °C; IR (KBr) 1690, 1595, 1380, 1240, 880, and 815 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (3H, t, J=7.3 Hz, Et), 2.49 (2H, q, J=7.3 Hz, Et), 2.69 (1H, dd, J_{gem}=16.5 and $J_{4,5}$=8.0 Hz, one of H-4), 2.95 (1H, dd, J_{gem}=16.5 and $J_{CH,5}$=7.8 Hz, one of 5-CH_2), 3.02 (1H, dd, J_{gem}=16.5 and $J_{CH,5}$=6.5 Hz, the other of 5-CH_2), 3.51 (1H, dd, J_{gem}=16.5 and $J_{4,5}$=10.5 Hz, the other of H-4), 3.81 (3H, s, MeO), 5.03 (1H, dddd, $J_{5,4}$=10.5, 8.0, $J_{5,CH}$=7.8, and 6.5 Hz, H-5), 6.89, and 7.56 (each 2H, d, J=7.8 Hz, Ar); ^{13}C NMR ($CDCl_3$) δ=7.53, 36.74 (each Et), 40.63 (C-4), 47.31 (5-CH_2), 55.32 (MeO), 76.76 (C-5), 114.12, 122.06, 128.19 (each Ar), 156.32 (C-3), 161.09 (Ar), and 208.73 (CO); Found: C, 68.22; H, 6.95; N, 5.56%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

Ethyl 5-(2-Oxo-2-phenylethyl)-2-isoxazoline-3-carboxylate (4i): Colorless prisms (diethyl ether-hexane); mp 74—75.5 °C; IR (KBr) 1710, 1680, 1215, 935, and 755 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.36 (3H, t, J=7.3 Hz, EtO), 2.96 (1H, dd, J_{gem}=18.0 and $J_{4,5}$=8.4 Hz, one of H-4), 3.26 (1H, dd, J_{gem}=17.5 and $J_{CH,5}$=8.0 Hz, one of 5-CH_2), 3.53 (1H, dd, J_{gem}=18.0 and $J_{4,5}$=11.0 Hz, the other of H-4), 3.65 (1H, dd, J_{gem}=18.0 and $J_{CH,5}$=7.1 Hz, the other of 5-CH_2), 4.34 (2H, q, J=7.3 Hz, EtO), 5.33 (1H, dddd, $J_{5,4}$=11.0, 8.4, $J_{5,CH}$=8.0, and 7.1 Hz, H-5), and 7.4—8.0 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.11 (EtO), 39.32 (C-4), 43.57 (5-CH_2), 62.03 (EtO), 79.93 (C-5), 128.07, 128.79, 133.80, 136.32 (each Ar), 151.96 (C-3), 160.57 (COOEt), and 196.52 (CO); MS *m/z* (rel intensity) 262 (M^++1, 2), 188 (23), 162 (13), 120 (97), and 105 (100). Found: 64.57; H, 5.84; N, 5.02%. Calcd for $C_{14}H_{15}NO_4$: C, 64.36; H, 5.79; N, 5.36%.

Ethyl 5-(2-Oxobutyl)-2-isoxazoline-3-carboxylate (4j): Pale yellow liquid; IR (neat) 1710, 1250, 1115, and 925 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.07 (3H, t, J=7.3 Hz, Et), 1.36 (3H, t, J=7.1 Hz, EtO), 2.49 (2H, q, J=7.3 Hz, Et), 2.73 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=7.0 Hz, one of 5-CH_2), 2.88 (1H, dd, J_{gem}=17.6 and $J_{4,5}$=8.2 Hz, one of H-4), 3.03 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=5.9 Hz, the other of 5-CH_2), 3.43 (1H, dd, J_{gem}=17.6 and $J_{4,5}$=11.0 Hz, the other of H-4), 4.33 (2H, q, J=7.1 Hz, OEt), and 5.16 (1H, m, H-5); ^{13}C NMR ($CDCl_3$) δ=7.47 (Et), 14.11 (EtO), 36.69 (Et), 38.97 (C-4) , 46.91 (5-CH_2), 62.03 (EtO), 79.54 (C-5), 151.80 (C-3), 160.53 (COOEt), and 207.84 (CO); MS *m/z* (rel intensity) 214 (M^++1, 3), 205 (9), 184 (23), 169 (18), 168 (9), 157 (9), 142 (98), 140 (45), 114 (65), 96 (12), 84 (15), 72 (23), and 57 (100). Found: C, 56.20; H, 6.91; N, 6.48%. Calcd for $C_{10}H_{15}NO_4$: C, 56.32; H, 7.09; N, 6.57%.

5-(2-Oxo-2-phenylethyl)-3-methyl-2-isoxazoline (4k): Colorless needles (diethyl ether-hexane); mp 97—98 °C; IR (KBr) 1670, 1435, 1380, 1320, and 1210 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s, 3-Me), 2.68 (1H, br dd, J_{gem}=17.2 and $J_{4,5}$=7.7 Hz, one of H-4), 3.17 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=8.0 Hz, one of 5-CH_2), 3.25 (1H, br dd, J_{gem}=17.2 and $J_{4,5}$=9.9 Hz, the other of H-4), 3.58 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=5.1 Hz, the other of 5-CH_2), 5.07 (1H, m, H-5), and 7.4—8.0 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.22 (3-Me), 43.86, 44.42 (C-4 and 5-CH_2), 76.40 (C-5), 128.09, 128.74, 133.55, 136.55 (each Ph), 155.82 (C-3), and 197.49 (CO); MS *m/z* (rel intensity) 203 (M^+, 1), 162 (7), 121 (9), 120 (100), 105 (84), and 84 (67). Found: C, 70.62; H, 6.51; N, 6.86%. Calcd for $C_{12}H_{13}NO_2$: C, 70.90; H, 6.45, N, 6.89%.

5-(2-Oxobutyl)-3-methyl-2-isoxazoline (4l): Colorless liquid; bp 115 °C/27 Pa (bulb-to-bulb); IR (neat) 1695, 1375, 1115, and 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (3H, t, J=7.3 Hz, Et), 1.99 (3H, s, 3-Me), 2.49 (2H, q, J=7.3 Hz, Et), 2.60 (1H, dd, J_{gem}=17.2 and $J_{4,5}$=9.6 Hz, one of H-4), 2.63 (1H, dd, J_{gem}=16.9 and $J_{CH,5}$=7.0 Hz, one of 5-CH_2), 2.94 (1H, dd, J_{gem}=16.9 and $J_{CH,5}$=5.9 Hz, the other of 5-CH_2), 3.15 (1H, dd, J_{gem}=17.2 and $J_{4,5}$=10.2 Hz, the other of H-4), and 4.90 (1H, dddd, $J_{5,4}$=10.2, 9.6, $J_{5,CH}$=7.0, and 5.9 Hz, H-5); ^{13}C NMR ($CDCl_3$) δ=7.53 (Et), 13.16 (3-Me), 36.86 (Et), 44.13 (C-4), 47.30 (5-CH_2), 76.05 (C-5), 155.61 (C-3), and 208.85 (CO); MS *m/z* (rel intensity) 155 (M^+, 5), 126 (12), 84 (100), 72 (11), 57 (34), and 43 (10). HRMS Found: *m/z* 155.0944. Calcd for $C_8H_{13}NO_2$: M, 155.0946.

3-[(Diethoxyphosphinyl)methyl]-5-(2-oxo-2-phenylethyl)-2-isoxazoline (4m): Pale yellow liquid; IR (neat) 1670, 1230, 1015, and 950 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.34 (6H, dd, J=7.2 and J_{HP}=4.0 Hz, OEt), 2.86 (1H, ddd, J_{gem}=17.6, $J_{4,5}$=7.3, and J_{HP}=3.7 Hz, one of H-4), 2.98 (2H, d, J_{HP}=22.4 Hz, CH_2P), 3.19 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=7.8 Hz, one of 5-CH_2), 3.40 (1H, ddd, J_{gem}=17.6, $J_{4,5}$=10.3, and J_{HP}=3.7 Hz, the other of H-4), 3.58 (1H, dd, J_{gem}=17.2 and $J_{CH,5}$=5.1 Hz, the other of 5-CH_2), 4.15 (4H, dq, J=7.2 and J_{HP}=7.0 Hz, OEt), 5.16 (1H, dddd, $J_{5,4}$=10.3, 7.3, $J_{5,CH}$=7.8, and 5.1 Hz, H-5), and 7.4—8.0 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.39 (d, J_{CP}=5.9 Hz, OEt), 26.31 d, J_{CP}=141.8 Hz, CH_2P), 42.97 (C-4), 43.64 (5-CH_2), 62.54 (d, J_{CP}=6.8 Hz, OEt), 77.22 (C-5), 128.06, 128.72, 133.56, 136.51 (each Ph), 151.93 (C-3), and 197.17 (CO); MS *m/z* (rel intensity) 339 (M^+, 1), 221 (9), 220 (100), and 192 (10). HRMS Found: *m/z* 339.1233. Calcd for $C_{16}H_{22}NO_5P$: M, 339.1235.

General Procedure for the Reductive N-O Bond Cleavage of 4a—m Leading to Pyridines 5a—m. The conversion of **4a** into **5a** is described as a typical example. To a solution of **4a** (0.068 g, 0.26 mmol) in ethanol (12 ml) were added tetrafluoroboric acid (42% aqueous solution, 0.269 g, 1.29 mmol) and Raney Ni (W-2 in ethanol, 0.8 ml). The mixture was stirred under a hydrogen atmosphere (1 atm) at room temperature for 16 h. The catalyst was removed by filteration and an aqueous solution of sodium hydroxide was added to the filtrate which was then extracted with dichloromethane (30 ml×3). The combined extract was dried over magnesium sulfate and the solvent was evaporated in vacuo. The residue was chromatographed on silica gel by using hexane-ethyl acetate (5 : 1 v/v) to give **5a** (0.049 g, 82%). Mp 82 °C (lit,[13] mp 81—82 °C).

In the case of **5e**, the filtrate from which the catalyst had been filtered off was evaporated in vacuo. The residue was treated with aqueous ethylenediaminetetraacetic acid, extracted with dichloromethane (30 ml×3), and the purification procedure was continued.

Yields of **5a—m** are summarized in Table 1. The following pyridines are all known: 2,6-diphenylpyridine (**5a**);[13,15] 4-methyl-2,6-diphenylpyridine (**5b**);[13] 3-methyl-2,6-diphenylpyridine (**5c**);[14] 2-phenyl-6-(2-pyridyl)pyridine (**5e**);[15] 2-(4-

methoxyphenyl)-6-phenylpyridine (**5g**);[16] 2-methyl-6-phenylpyridine (**5k**);[17] 2-ethyl-6-methylpyridine (**5l**).[18]

2-Ethyl-6-phenylpyridine (5d): Colorless liquid; IR (neat) 1565, 1440, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.36 (3H, t, J=7.7 Hz, 2-Et), 2.88 (2H, q, J=7.7 Hz, 2-Et), and 7.0—8.0 (8H, m, Ph and Py); ^{13}C NMR ($CDCl_3$) δ=13.85, 31.56 (each 2-Et), 117.65, 120.31, 126.98, 128.64, 136.90, 139.88, 156.73 (Ph and Py), and 163.36 (C-2 and C-6 of Py); MS m/z (rel intensity) 184 (M^++1, 12), 183 (M^+, 90), 182 (100), 155 (20), 154 (22), 127 (13), and 77 (18). HRMS Found: m/z 183.1047. Calcd for $C_{13}H_{13}N$: M, 183.1047.

2-Phenyl-6-(3-pyridyl)pyridine (5f): Pale yellow liquid; IR (neat) 3000, 1550, 1430, and 750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.3—8.7 (11H, m, Ph and Py) and 9.30 (1H, br s, Py); ^{13}C NMR ($CDCl_3$) δ=118.66, 119.35, 123.57, 126.95, 128.76, 129.24, 134.41, 137.75, 139.03 (Ph and Py), 148.35, 149.87, 154.26, and 157.26 (Py); MS m/z (rel intensity) 232 (M^+, 100), 231 (42), 206 (8), 204 (8), and 77 (8). HRMS Found: m/z 232.1002. Calcd for $C_{16}H_{12}N_2$: M, 232.1000.

2-Ethyl-6-(4-methoxyphenyl)pyridine (5h): Colorless liquid; IR (neat) 1570, 1445, 1250, 1035, and 845 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.36 (3H, t, J=7.8 Hz, Et), 2.86 (2H, q, J=7.8 Hz, Et), 3.82 (3H, s, MeO), 6.93 (2H, d, J=9.2 Hz, Ar), 7.0—7.6 (3H, m, Py), and 7.95 (2H, d, J=9.2 Hz, Ar); ^{13}C NMR ($CDCl_3$) δ=13.82, 31.53 (each Et), 55.25 (MeO), 114.01, 116.83, 119.58, 128.48, 136.80, 156.31, 160.28, and 163.15 (Ar and Py); MS m/z (rel intensity) 214 (M^++1, 16), 213 (M^+, 100), 212 (84), 185 (10), and 170 (12). HRMS Found: m/z 213.1150. Calcd for $C_{14}H_{15}NO$: M, 213.1154.

Ethyl 6-Phenyl-2-pyridinecarboxylate (5i): Pale yellow needles; mp 44—45 °C; IR (KBr) 1720, 1580, 1435, 1280, 1225, 1160, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.46 (3H, t, J=7.2 Hz, COOEt), 4.47 (2H, q, J=7.2 Hz, COOEt), and 7.3—8.1 (8H, m, Ph and Py); ^{13}C NMR ($CDCl_3$) δ=14.31, 61.78 (each COOEt), 123.25, 123.42, 127.18, 128.79, 129.41, 137.62, 138.50, 148.36 (Ph and Py), 157.60 (C-5 of Py), and 165.47 (COOEt); MS m/z (rel intensity) 227 (M^+, 14), 156 (13), 155 (100), 154 (29), 127 (18), and 77 (10). Found: C, 74.25; H, 5.83; N, 6.18%. Calcd for $C_{14}H_{13}NO_2$: C, 73.98; H, 5.77; N, 6.17%.

Ethyl 6-Ethyl-2-pyridinecarboxylate (5j): Pale yellow liquid; IR (neat) 1715, 1460, 1300, 1175, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.34 (3H, t, J=7.7 Hz, 5-Et), 1.43 (3H, t, J=7.0 Hz, COOEt), 2.94 (2H, q, J=7.7 Hz, 5-Et), 4.47 (3H, q, J=7.0 Hz, COOEt), 7.36 (1H, br d, J=7.7 Hz, H-5 of Py), 7.74 (1H, t, J=7.7 Hz, H-4 of Py), and 7.94 (1H, br d, J=7.7 Hz, H-3 of Py); ^{13}C NMR ($CDCl_3$) δ=14.04 (5-Et), 14.33 (COOEt), 31.43 (5-Et), 61.78 (COOEt), 122.46, 125.31, 137.17, 147.79, 164.18 (each Py), and 165.52 (COOEt); MS m/z (rel intensity) 180 (M^++1, 15), 179 (M^+, 100), 178 (11), 133 (19), 107 (85), 106 (33), 105 (75), 104 (26), 79 (27), 78 (13), and 77 (25). HRMS Found: m/z 179.0946. Calcd for $C_{10}H_{13}NO_2$: M, 179.0946.

2-[(Diethoxyphosphinyl)methyl]-6-phenylpyridine (5m): Pale yellow liquid; IR (neat) 1570, 1450, 1240, and 1020 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.26 (6H, t, J=7.2 Hz, EtO), 3.51 (2H, d, J_{HP}=21.6 Hz, CH_2P), 4.11 (4H, dq, J_{HP}=7.7 and J=7.2 Hz, EtO), and 7.3—8.0 (8H, m, Ph and Py); ^{13}C NMR ($CDCl_3$) δ=16.34 (d, J_{CP}=6.8 Hz, OEt), 36.68 (d, J_{CP}=134.0 Hz, CH_2P), 62.22 (d, J_{CP}=6.8 Hz, OEt), 118.50, 118.54, 122.56, 122.63, 126.86, 128.68, 128.97, 137.29, 139.12, 152.46, and 156.96 (Py and Ph); MS m/z (rel intensity) 306 (M^++1, 10), 305 (M^+, 48), 256 (12), 181 (11), 170 (14), and 169 (100). HRMS Found: m/z 305.1185. Calcd for $C_{16}H_{20}NO_3P$: M, 305.1181.

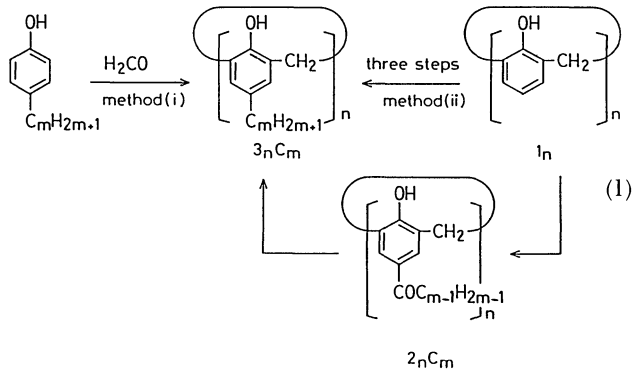
(Received September 12, 1990)

Calix[*n*]arenes (n=4, 6, and 8) bearing long *p*-alkyl groups (R=hexyl and dodecyl) have been synthesized by "direct" acylation of the *p*-position followed by silane reduction. The method is convenient and the yields are higher than those reported so far. Among them, *p*-hexanoylcalix[4]arene showed a curious phase transition behavior; with raising the temperature it changed as crystal A→liquid→crystal B→liquid. It was found on the basis of the solid ^{13}C NMR spectra that this behavior is ascribed to a conformational change from "cone" (crystal A) to "partial cone" (crystal B).

Calix[*n*]arenes having long aliphatic chains at *p*-position have been of increasing concern in host-guest chemistry and Langmuir monolayer formations.[1-3] They are synthesized by two different methods: (i) one-step synthesis by condensation of *p*-alkylphenols with formaldehyde[1,2,4,5] and (ii) three-step synthesis going from O-acylation of calix[*n*]arenes ($\mathbf{1}_n$) to the Fries rearrangement[6,7] followed by the Wolff-Kishner reduction[3] (Eq. 1). Method (i) is a convenient one-step synthesis, but one has to optimize the reaction conditions by himself so that one can obtain desired *n*-meric *p*-alkylcalix[*n*]arenes: that is, one has to look for the appropriate solvent, temperature, and separation conditions. Furthermore, attempts to synthesize *p*-alkylcalix[4]arenes failed.[3,5] In contrast, method (ii) involves three steps, but one can use well-characterized $\mathbf{1}_n$ as starting materials. Thus, these two methods have both merit and demerit.



(1)

It occurred to us that if the acyl group could be "directly" introduced into the *p*-position of $\mathbf{1}_n$, one could shorten the reaction route for method (ii). In this paper we report "direct" acylation of $\mathbf{1}_n$ (n=4, 6, and 8) to *p*-acylcalix[*n*]arenes ($\mathbf{2}_n\mathrm{C}_m$) followed by reduction with triethylsilane to *p*-alkylcalix[*n*]arenes ($\mathbf{3}_n\mathrm{C}_m$). In addition, we found that some of these calix[*n*]arenes show very interesting solid and solution properties.

Experimental

Materials. Preparations of $\mathbf{1}_n$ were described previously.[8,9] We studied the Friedel-Crafts reaction of $\mathbf{1}_n$ with $\mathrm{C}_{m-1}\mathrm{H}_{2m-1}\mathrm{COCl}$ (m=6 and 12).

***p*-Hexanoylcalix[4]arene ($\mathbf{2}_4\mathrm{C}_6$).** Hexanoyl chloride (1.4 g; 10 mmol) and $AlCl_3$ (1.4 g; 10 mmol) was mixed in 30 ml of nitrobenzene, and after stirring for 30 min at room temperature under a nitrogen stream $\mathbf{1}_4$ (1.1 g; 2.5 mmol) was added. The reaction mixture was stirred at 50 °C for 10 h and then at 70 °C for 3 h. This operation afforded a homogeneous, brown solution. After cooling, the solution was poured into a 0.1 M# HCl solution (200 ml) and extracted with chloroform (200 ml). The organic layer was separated, washed with 1 M NaCl solution and dried over $MgSO_4$. The solution was concentrated to dryness, the resultant solid being reprecipitated from chloroform to methanol. Finally, the yellow solid product was recrystallized twice from benzene: white powder, mp 94—98 °C, yield 80%; IR (Nujol) ν_{OH} 3600—2500 cm^{-1}, $\nu_{C=O}$ 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$, 30 °C) δ_H=0.6—2.0 (9H, C_4H_9), 2.6—3.0 (2H, CH_2CO), 3.7—4.2 (2H, broad, $ArCH_2Ar$), 7.70 (2H, ArH), 9.5—10.5 (1H, broad, OH).

Other $\mathbf{2}_n\mathrm{C}_m$'s were synthesized in a manner similar to that for $\mathbf{2}_4\mathrm{C}_6$. The reaction conditions, yields, and mp's are summarized in Table 1. The elemental analysis data are recorded in Table 2.

***p*-Hexylcalix[4]arene ($\mathbf{3}_4\mathrm{C}_6$).** Compound $\mathbf{2}_4\mathrm{C}_6$ (0.50 g; 0.60 mmol) was dissolved in 20 ml of trifluoroacetic acid, and triethylsilane (0.70 g; 6.0 mmol) was added dropwise to this solution. The exothermic reaction was initiated immediately after the addition of triethylsilane. After stirring for 10 h at room temperature, the solution was concentrated in vacuo. The residue was dissolved in chloroform and the solution was washed with aqueous $NaHCO_3$. The organic layer was separated and dried over Na_2SO_4. The chloroform solution was concentrated to dryness, the residue being recrystallized from ethanol: white plates, mp 108—109 °C, yield 66%; IR (Nujol) ν_{OH} 3500—2500 cm^{-1}, no $\nu_{C=O}$; ^{1}H NMR ($CDCl_3$, 30 °C) δ_H=0.6—1.9 (11H, C_5H_{11}), 2.2—2.6 (2H, CH_2Ar), 3.2—3.4 (2H, broad, $ArCH_2Ar$), 6.80 (2H, ArH), 10.10 (1H, OH).

1 M=1 mol dm^{-3}.

Other $\mathbf{3}_n\mathrm{C}_m$'s were synthesized in a manner similar to that for $\mathbf{3}_4\mathrm{C}_6$. Compounds $\mathbf{2}_n\mathrm{C}_{12}$ were less reactive than $\mathbf{2}_n\mathrm{C}_6$ and required the more drastic reaction conditions (e.g., reflux for 100 h). The reaction conditions, yields, and mp's are summarlzed in Table 3. The products were recrystallized either from ethanol or ethanol-$CHCl_3$ (or CCl_4). The elemental analysis data are recorded in Table 4.

25,26,27,28-Tetrapropoxy-*p*-hexanoylcalix[4]arene (with a Partial Cone Conformation: $\mathbf{4}_4\mathrm{C}_6$). Compound $\mathbf{2}_4\mathrm{C}_6$ (200 mg; 0.245 mmol) and propyl bromide (1.21 g; 9.81 mmol) were dissolved in 30 ml of DMF and the solution was stirred at 50 °C for 6 h in the presence of Cs_2CO_3 (3.47 g; 9.81 mmol). The HPLC analysis showed that the product contains 90% of partial-cone-$\mathbf{4}_4\mathrm{C}_6$ and 10% of another isomer (probably, cone-$\mathbf{4}_4\mathrm{C}_6$). The solution was filtered, the filtrate being diluted with water. The aqueous solution was extracted with chloroform. The chloroform solution was concentrated to dryness. The residue was viscous oil. This was subjected to preparative TLC separation (silica gel, chloroform-hexane): caramel-like solid (an attempt to crystallize this solid failed), yield 50%, single peak on HPLC; ^{1}H NMR ($CDCl_3$, 30 °C) δ=0.9—1.2 (56H, m, CH_3CH_2 in *n*-Pr and $CH_3(CH_2)_3$), 3.02, 3.61, 3.81 (4H, 2H, 2N (respectively), q each, OCH_2), 2.26, 2.54, 3.87 (2H, 4H, 2H (respectively), t each, $COCH_2$), 3.19, 3.73, 3.78, 4.07 (2H each, d each, $ArCH_2Ar$), 6.84, 7.60, 7.81, 7.94 (2H each, d, d, s, s (respectively), ArH). Found: C, 77.53; H, 9.01%. Calcd for $(C_{16}H_{22}O_2)_4$: C, 78.00; H, 9.00%.

A partial cone conformation results in three different phenol units. The situation is reflected by OCH_2 and $COCH_2$ which appear as three peaks in an integral intensity ratio of 2:1:1. The $ArCH_2Ar$ protons in a partial cone conformation feature two pairs of doublets:[10] one pair with the large chemical shift difference (3.19 and 4.07 ppm in $\mathbf{4}_4\mathrm{C}_6$) is ascribed to those flanked by two syn phenol units (H_{exo} and H_{endo}, respectively) and another pair with the small chemical shift difference (3.73 and 3.78 ppm in $\mathbf{4}_4\mathrm{C}_6$) is ascribed to those flanked by two anti phenol units. These results consistently support the partial cone conformation. The peaks for OCH_2 appear as quartets. This is probably due to the rotational restriction of the OCH_2 group.

^{13}C NMR Spectra. The solid-state ^{13}C NMR spectra were measured with a Bruker PC-250. The ^{13}C cross polarization-magic angle spinning NMR spectra were recorded at 30 °C with a CP-MAS method: the crystalline powder sample was contained in a bullet-type rotor and spun at 3.5 kHz. Contact time was 3 ms and repetition time was 5 s. The ^{13}C chemical shifts were calibrated indirectly through external TMS.

Results and Discussion

As mentioned in Introduction, *p*-alkylcalix[4]arenes cannot be synthesized from formaldehyde and *p*-alkylphenols.[3,5] Thus, they have been synthesized through three steps: that is, tetra-O-acylation, Fries rearrangement, and reduction. According to Gutsche and Lin,[10] acetylation and benzoylation of $\mathbf{1}_n$ occur in 23—38% yields. We could enhance the yields for acylation (using hexanoyl chloride and 2-methylbutanoyl chloride) up to 50—51%.[7] On the other hand, Fries rearrangement occurs in 29—64% yields.[6,7] This means that the total yields of these two steps are at most 30%. As shown in Table 1, on the other hand, "direct" acylation of the *p*-position results in $\mathbf{2}_n\mathrm{C}_m$ in 30—88% yields. Thus, the present method is much superior to the previous method.

It is known that O-acylation of $\mathbf{1}_n$ can be effected even at 0 °C whereas Fries rearrangement proceeds at 70—100 °C.[6,7,10] In the present "direct" acylation method, the products were yielded when the solution was heated at 70 °C. When the reaction temperature was not raised, the product gave the $\nu_{C=O}$ band at 1760 cm^{-1} which is assigned to the ester group. This suggests that the present "direct" acylation actually occurs via O-acylation followed by Fries rearrangement. These two steps proceed in one pot.

According to Nakamoto et al.,[3] $\mathbf{2}_4\mathrm{C}_8$ could be reduced to $\mathbf{3}_4\mathrm{C}_8$ by the Wolff-Kishner method in 70% yield. We found, however, that this method is troublesome because in the reducetion of $\mathbf{2}_4\mathrm{C}_m$ the solution foamed over in the flask. As an alternate

method, we employed the silane reduction method. Although the yields (55—81%) are not significantly higher than those for the Wolff-Kisher method, the operation is very simple and convenient.

$\mathbf{2}_n\mathrm{C}_m$ and $\mathbf{3}_n\mathrm{C}_m$ thus synthesized showed several interesting physical properties. First, $\mathbf{2}_8\mathrm{C}_{12}$ gellated when recrystallized from benzene, toluene, hexane, heptane, etc.: that is, the solution was apparently solidified. Thus, this compound was recrystallized from ethanol-chloroform (3 : 1 v/v). Such gelation was not found for other $\mathbf{2}_n\mathrm{C}_m$.

More interesting is a phase transition phenomenon of $\mathbf{2}_4\mathrm{C}_6$. As shown in Scheme 1, crystal A (K_A) obtained by recrystallization from benzene melts at 95 °C. From the isotropic liquid phase (I_1) new crystals (K_B) grow up rapidly, which finally melt at 194 °C. When the final isotropic liquid (I_2) is cooled, crystal B results. Only when crystal B is recrystallized from benzene, crystal A is reproduced.

Figure 1 shows a DSC thermogram of $\mathbf{2}_4\mathrm{C}_6$. It is

seen from Fig. 1 that an endothermic change occurs at 95 °C, which is immediately followed by an exothermic change. These changes correspond to melting of K_A at 95 °C followed by recrystallization to K_B. An endothermic peak at 194 °C corresponds to melting of K_B to I_2. We attempted the preparation of single crystals for X-ray analysis from K_A and K_B but failed. We thus evaluated the structures of these crystals using the solid-state ^{13}C NMR spectroscopy.

Basically, calix[4]arenes can exist in four different conformations; they are cone, partial cone, 1,2-alternate, and 1,3-alternate (Fig. 2). X-ray studies of *p-t*-butylcalix[4]arene and some clathrates show the calixarene moiety to be present in a cone conformation with C_{4v} symmetry.[11-13] Since each phenol unit is equivalent around a 4-fold axis, the CP-MAS ^{13}C NMR should result in a single set of ^{13}C peaks for the phenol unit. Other three conformations have never been found for unmodified calix[4]arenes not only in solution but also in the solid state.[14] One can predict on the basis of their symmetry that partial cone, 1,2-alternate, and 1,3-alternate should give three sets, a single set (but two sets for the $ArCH_2Ar$ methylene carbons), and a single set (including the $ArCH_2Ar$ methylene carbons) of ^{13}C peaks for four phenol units, respectively. To test this hypothesis, we prepared tetra-O-propyl derivative ($\mathbf{4}_4C_6$) with a partial cone conformation from $\mathbf{2}_4C_6$ (Eq. 2).[14] It has been established that being different from unmodified calix[4]-arenes, the propyl group is bulky enough to suppress the oxygen-through-the-annulus rotation and thus tetra-O-propylated calix[4]arene results in conformationally-immobile isomers.[15] As shown in Fig. 3, the ^{13}C NMR spectrum for partial-cone-$\mathbf{4}_4C_6$ is very complex. It is clearly seen from Fig. 3, however, that there appear three peaks for CO (C-6 in Fig. 3) and O-C (in phenyl: C-10 in Fig. 3). This establishes that as predicted from its symmetry, ^{13}C NMR for the partial

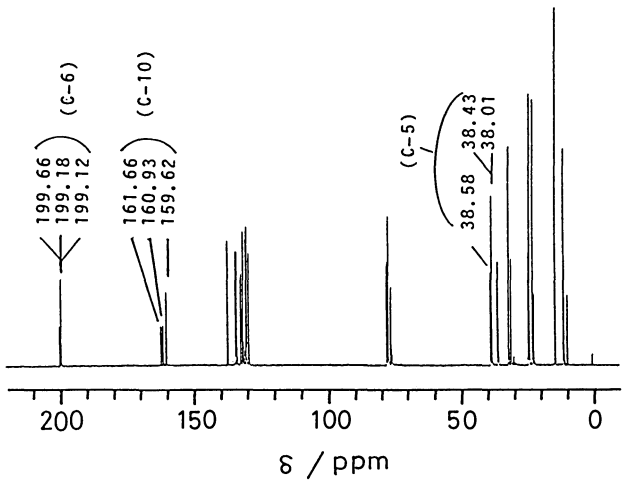

Fig. 3. ^{13}C NMR spectrum of partial-cone-$\mathbf{4}_4C_6$ ($CDCl_3$, 30 °C).

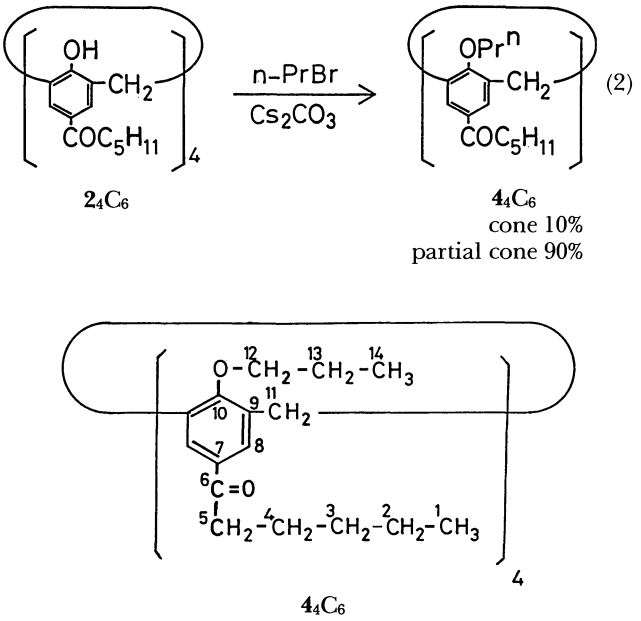

$\mathbf{4}_4C_6$

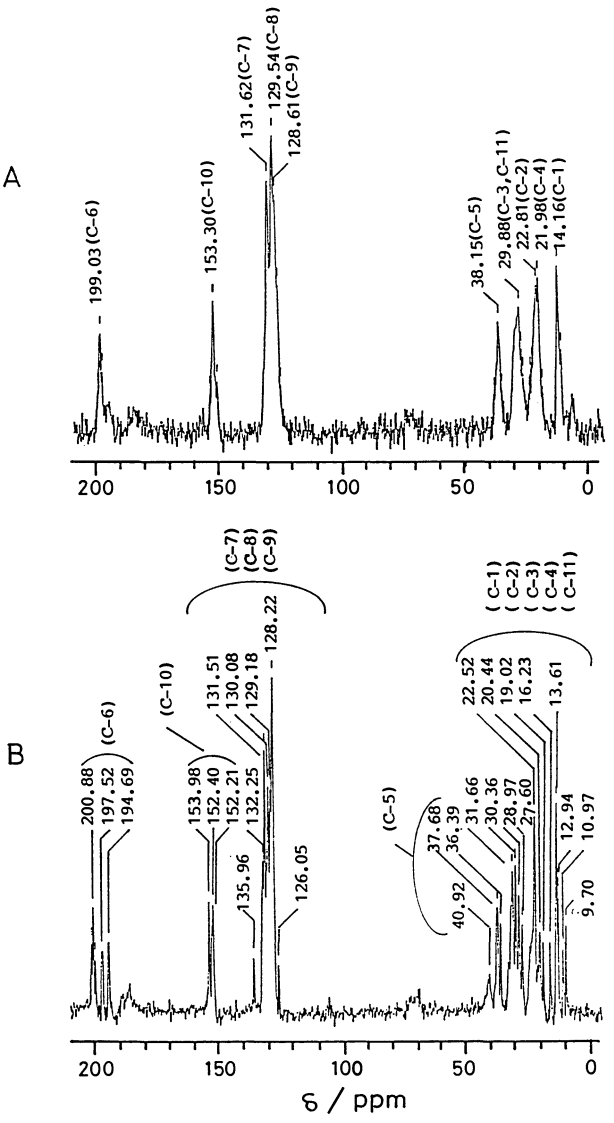

Fig. 4. CP-MAS ^{13}C NMR spectra of (A) crystal A and (B) crystal B. The numbering system is the same as that in Fig. 3.

cone isomer features three sets of ^{13}C peaks.

In Fig. 4, CP-MAS ^{13}C NMR spectra for crystals A and B are illustrated. As expected, crystal A, crystallized from benzene solution, gave a single set of ^{13}C peaks for C-6 and C-10. This provides evidence that crystal A adopts a cone conformation. In contrast, crystal B, which crystallized above 95 °C, gave three sets of ^{13}C peaks for C-6 and C-10. This split pattern is basically commensurate with a partial cone conformation. In the solid state, however, one has to take the presence of noncongruent molecules into consideration: for example, the asymmetry in the solid-state ^{13}C NMR spectra may result from noncongruence in the crystal lattice or from slight distortion of the calix[4]arene ring.[16] Thus, we further confirmed the difference between crystals A and B through IR measurements which possibly reflect the intramolecular structural difference rather than the intermolecular one. Unmodified calix[4]arenes (that is, those having four OH groups) adopt a cone conformation not only in solution but also in the solid state.[10-13,17-19] The exception against this conclusion has never been found. This is due to a large stabilization effect brought forth by intramolecular hydrogen-bonding interactions among OH groups. Hence, compounds $\mathbf{2}_4C_n$ should adopt a cone conformation in the solid state. The FT-IR spectra (KBr, at room temperature) of these compounds showed only one $\nu_{C=O}$ band at around 1680 cm^{-1}: for instance, the $\nu_{C=O}$ for crystal A appeared at 1675 cm^{-1}. In contrast, crystal B showed three $\nu_{C=O}$ bands at 1670, 1679, and 1684 cm^{-1}. This indicates that compound $\mathbf{2}_4C_6$ in crystal B has three different C=O groups which are commensurate with a partial cone conformation. Partial-cone-$\mathbf{4}_4C_6$, synthesized as a reference compound for crystal B also showed three $\nu_{C=O}$ bands at 1671, 1679, and 1689 cm^{-1}. The results, together with those of the ^{13}C NMR spectra, consistently support the view that $\mathbf{2}_4C_6$ in crystal B is a partial-cone conformer.

As described above, calix[4]arenes favorably adopt a cone conformation because of strong intramolecular hydrogen-bonding interactions.[10,17-19] This view is supported not only by X-ray studies[11-13] but also by recent computational studies.[20] To isomerize to other conformers, one or two hydrogen bonds must be cleaved, which causes destabilization of the calix[4]arene ring.[20] Above 95 °C the stabilization effect through hydrogen bonds becomes less important because of a vigorous molecular motion and a cone isomer can isomerize to a partial cone isomer. In the partial cone isomer, one phenol unit is inversed and the hydrogen-bonding interaction with this OH group is disrupted. Instead, the partial cone isomer acquires a flexible seesaw motion around the inversed phenol unit. Probably, this motional freedom is more important than the stabilization by hydrogen bonds above 95 °C. According to the molecular mechanics calculations about *p*-*t*-butylcalix[4]arene, total E values for the cone isomer and the partial cone isomer are -2.0 and 5.7 kcal mol^{-1}, respectively.[20] This supports the view that the concentration of the partial cone isomer increases with raising the temperature. Anyhow, this is the first example for a partial cone isomer of unmodified calix[4]arenes found in the solid state.

In conclusion, the present paper demonstrated new syntheses of *p*-alkylcalix[4]arenes and their interesting physical properties. In particular, the finding of partial-cone-$\mathbf{2}_4C_6$ in the solid state is noteworthy. Further applications of these calixarenes to T_1 measurements, monolayer formations, etc. are currently investigated in these laboratories.

This research was supported by the Grant-in-Aid from the Ministry of Education, Science and Culture.

Asymmetric Diels-Alder Reactions of an Acrylic Acid Derivative Using a Chiral Titanium Catalyst

Koichi NARASAKA,* Hiroko TANAKA, and Fumihiko KANAI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 26, 1990)

Asymmetric Diels-Alder reactions of an acrylic acid derivative using a catalytic amount of a chiral titanium reagent were performed with several dienes. The titanium catalyst was prepared by the alkoxy exchange between dichlorodiisopropoxytitanium(IV) and a chiral 1,4-diol derived from (2*R*,3*R*)-tartrate. By the use of the titanium catalyst, the reaction between 3-acryloyl-1,3-oxazolidin-2-one and dienes proceeded in a toluene-petroleum ether mixture in the presence of Molecular Sieves 4A to afford the Diels-Alder adducts in 72—100% yields and 88—>96% enantioselectivity. This reaction can be applied to a diene containing a hetero atom such as 2-ethylthio-1,3-butadiene, which affords the Diels-Alder adduct in a high optical purity. In this paper are also described the methods for determining the optical purities of the obtained 4-substituted 3-cyclohexenecarboxylic acid derivatives.

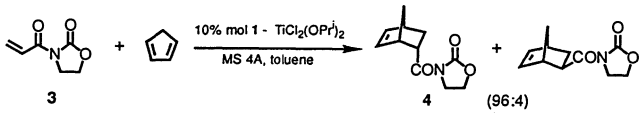
Diels-Alder reaction is one of the most important reaction for the formation of carbon frameworks in a variety of organic compounds, and has been widely used as a key step in the synthesis of many kinds of natural products. Development of asymmetric Diels-Alder reaction has been in active research,[1] however, the catalytic reaction with a wide applicability and a high enantioselectivity is scarce.

In our laboratory, the exploration of asymmetric reactions, including asymmetric Diels-Alder reaction, has been investigated using a chiral titanium catalyst prepared by an alkoxy exchange between a tartrate derived 1,4-diol (**1**) and dichlorodiisopropoxytitanium(IV) (Eq. 1).[2]

1 2 (1)

We have already found that when 3-(2-alkenoyl)-1,3-oxazolidinone derivatives were used as dienophiles, the reaction with several dienes proceeded in a toluene-petroleum ether (P.E.) mixture in the presence of a catalytic amount of the titanium catalyst and Molecular Sieves (MS) 4A to yield the Diels-Alder adducts in more than 90% enantiomeric excess (ee).[3]

The Diels-Alder adducts of acrylic acid derivatives constitute an important class of compounds as key intermediates for the total synthesis of a variety of natural products.[4] The catalytic asymmetric Diels-Alder reaction was also performed with 3-acryloyl-1,3-oxazolidin-2-one (**3**). However, the only result obtained so far was the reaction carried out in toluene, which afforded the Diels-Alder adduct **4** with cyclopentadiene in only 65% ee[5] and the reaction had never been carried out in the mixed solvent (toluene-petroleum ether (P.E.)) which has been found to be the most suitable solvent in the reaction of other α,β-unsaturated carboxylic acid derivatives.[3] Therefore some modifications in the reaction conditions have to be made to obtain synthetically useful 4-substituted 3-cyclohexenecarboxylic acid derivatives in high optical purities.

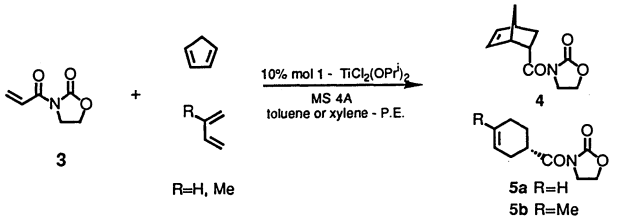


3 4 (96:4) 65% ee (2)

At the same time there arose a need for the development of a method for determining the accurate optical purities of the obtained Diels-Alder adducts, the 4-substituted 3-cyclohexenecarboxylic acid derivatives, since the method for the determination of the optical purities of these products was limited to transforming them to some compounds whose optical rotations are known.[6,7] Such a method lacks in accuracy especially when the enantioselectivities are very high.

In this paper, the reaction conditions using an acrylic acid derivative **3** were optimized to give the Diels-Alder adducts in good to high enantioselectivity, and the method for determining accurate optical purities of the adducts has been developed.

First, the reactions of **3** and several dienes were performed in a mixed solvent of toluene or xylene and P.E. in the presence of MS 4A. (Eq. 3) The results are



3 R=H, Me 4 5a R=H 5b R=Me (3)

Table 1. Diels-Alder Reaction Using a Catalytic Amount of **1**

Diene	Solvent	Temp, θ/°C	Time	Yield/%	Opt. purity/%ee
Cyclopentadiene	Toluene-P.E.(1 : 1)	−23	24 h	81(12)[a]	88
	p-Xylene-P.E.(1 : 1)	0	3 h	96	75
	m-Xylene-P.E.(1 : 1)	0	12 h	Quant	82

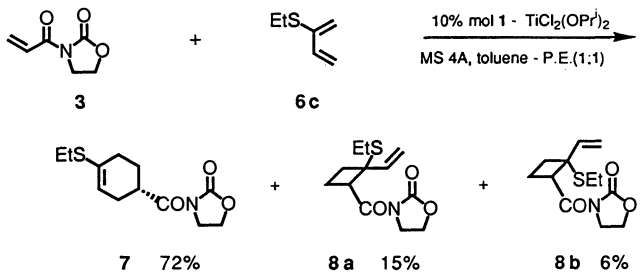
	m-Xylene-P.E.(1 : 1)[c]	RT	2 d	67	89

a) Amount of the recovered **3** is shown in ( ). b) 10 mol% catalyst was used. c) 20 mol% catalyst was used.

listed in Table 1.

By the use of a mixed solvent, toluene-P.E. (1 : 1), the reaction of **3** with cyclopentadiene proceeded at −23 °C in the presence of 10% mol of the chiral titanium reagent and MS 4A to give the cycloadduct **4**. Only the endo isomer **4** was obtained and the optical purity of the obtained adduct was found to be greatly enhanced from 65 to 88% ee. In the reaction with 1,3-butadiene, the best result was observed when the reaction was carried out at room temperature in a *p*-xylene-P.E. (1 : 1) mixed solvent using 20% mol of the chiral catalyst, and the optical purity of the adduct **5a** was 93% ee. The reaction with isoprene proceeded at 0 °C using 10% mol of the chiral catalyst and the optical purity of the adduct **5b** was over 96% ee in either toluene-P.E. or xylene-P.E. mixed solvent. In this case too, the obtained cycloadduct consisted of a single isomer and none of the other regio-isomer could be detected. After all, the use of toluene or xylene in the mixed solvent made little or no influence on the optical purity of the obtained product. When 2 molar amounts of the chiral titanium catalyst were used, the reaction proceeded at lower temperatures, but that does not alter the enantioselectivity to a great extent. Next, to obtain a masked cyclohexanone derivative, which is an important synthetic intermediate, the reactions of dienes with a hetero atom were examined. 2-*t*-Butyldimethylsiloxy-1,3-butadiene (**6a**)[8] and 2-methoxy-1,3-butadiene (**6b**)[9] were employed as dienes, but the reaction did not proceed well. With **6a**, the titanium seemed to exchange with the silyl part of the diene and therefore the reaction did not proceed. With **6b**, decomposition of the diene took place prior to the Diels-Alder reaction. 2-Ethylthio-1,3-butadiene (**6c**)[10] containing a sulfur atom instead of an oxygen atom was then examined. With **6c**, the acryloyloxazolidinone **3** reacted smoothly at 0 °C within 2 h in a toluene-P.E. (1 : 1) mixed solvent to afford the adduct **7** in 72% yield and in 91% optical purity along with cyclobutanes **8a** and **8b** (Eq. 4). The *trans* **8a** and *cis* **8b** isomers of the cyclobutane were obtained in 15 and 6% yields, respectively,

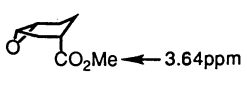


(4)

which are the [2+2] cycloaddition products as we have already reported in the cycloaddition reaction between α,β-unsaturated carbonyl compounds and a ketene dithioacetal, an alkenyl sulfide and an alkynyl sulfide.[11] The obtained Diels-Alder adduct **7** has a vinyl sulfide group, which is easily transformed to some other functional groups.

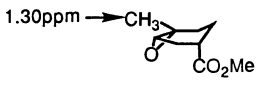
As mentioned in the beginning, the precise optical purity of the obtained Diels-Alder products, 4-substituted 3-cyclohexenecarboxylic acid derivatives, had never been determined. The optical purities of the cyclohexenecarboxylic acid derivatives **5a** and **5b** prepared above were determined after transformation to the epoxy derivative **12** based on the following Scheme 1.

First the adducts **5a** and **5b** were hydrolyzed to the corresponding carboxylic acids after they were transformed into their methyl esters. The iodolactonization of the carboxylic acids followed by the treatment with sodium methoxide gave the corresponding *cis*-epoxy carboxylic esters (**12a,b**). The optical purities were determined by adding a chiral shift reagent Eu(hfc)$_3$[12] and analyzing their NMR. The methoxyl



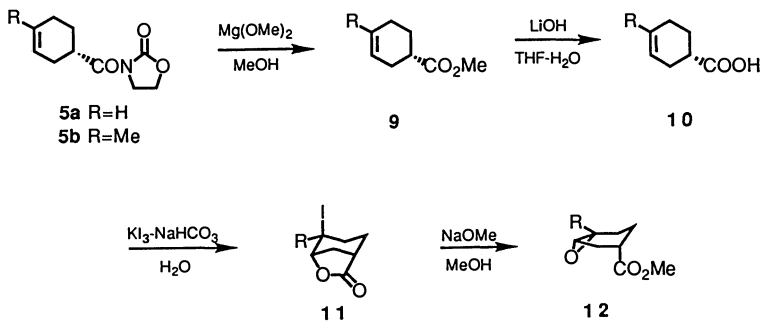
12a

Fig. 1.



12b

Fig. 2.

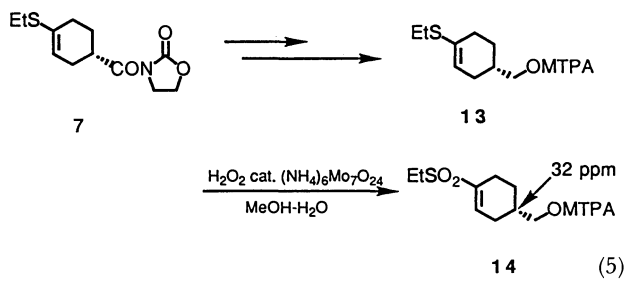


Scheme 1.

peak (δ=3.64) of **12a** (Fig. 1), and the methyl peak (δ=1.30) of **12b** (Fig. 2) were used to determine the optical purities.

The optical purity of the norbornene derivative **4**, was determined by the Mosher's method[13] after the adduct was esterified and reduced with $LiAlH_4$.

In the case of **7**, the product was first transformed into its (+)-trifluoromethylmethoxyphenylacetic acid (MTPA) ester and then the sulfide **13** was oxidized to the sulfone **14** by hydrogen peroxide and $(NH_4)_6Mo_7O_{24}$ catalyst (Eq. 5).[14] Its optical purity was determined by measuring the ^{13}C NMR spectrum. The peak of the chiral center of the cyclohexene ring (δ=32)[15] separated completely.



(5)

The absolute configuration of the norbornene derivative **4** was determined by the comparison of its optical rotation with those of the literatures.[3] For the cyclohexene derivatives **5a** and **5b** the obtained adducts were transformed to their benzyl (in the case of **5a**) or methyl (in the case of **5b**) esters and their optical rotations were measured and compared with those of the literatures.[6,7]

Combined with the results of the previous paper,[3] the absolute stereoselection of the Diels-Alder reaction is predictable without any exceptions according to the transition model as depicted in Fig. 3. The chiral titanium species is thought to form a six-membered chelate with 3-acyl-1,3-oxazolidin-2-one, which exists in a pseudo C_2 symmetrical twist chair conformation. The axial phenyl groups in the seven-membered ring orient to the reaction site and restrict the approach of a diene. Therefore, *re*-face of the α-carbon of the unsaturated acid moiety is attacked preferentially in both of the possible transition states shown in Fig. 3, when the (2*R*,3*R*)-1,4-diol is employed as a chiral auxiliary.

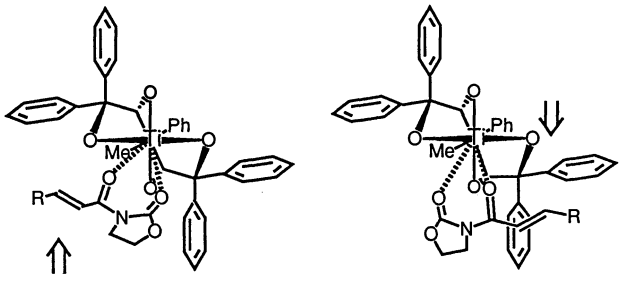


Fig. 3.

In summary, the Diels-Alder reaction of acrylic acid derivative using a catalytic amount of the chiral titanium reagent proceeded to produce the adducts in good yields and in good enantioselectivities. The reaction was carried out in a toluene-P.E.(1 : 1) mixed solvent in the presence of MS 4A. This catalytic asymmetric Diels-Alder reaction totally offers a practical and a convenient method for the preparation of variously substituted 3-cyclohexenecarboxylic acids via 3-alkenoyl-1,3-oxazolidin-2-one in general.

Experimental

General. NMR spectra were recorded on a Hitachi R24B or Bruker AM 500 spectrometer using tetramethylsilane as the internal standard. IR spectra were recorded on a Horiba FT-300S. Optical rotation was measured with a Nippon Bunko DIP-370. Mass spectra were obtained with a JEOL JMS-D300 mass spectrometer.

Dichlorodiisopropoxytitanium was prepared from titanium(IV) chloride and titanium(IV) isopropoxide according to the literature method.[16] Toluene was distilled and dried over MS 4A. Xylenes were distilled from CaH_2 and stored over MS 4A. Tetrahydrofuran was freshly distilled from sodium diphenylketyl.

(2*R*,3*R*)-1,1,4,4-tetraphenyl-2,3-*O*-(1-phenylethylidene)-1,2,3,4-butanetetrol (**1**) and 3-acryloyl-1,3-oxazolidin-2-one (**3**) were prepared according to the literature procedures.[3,7]

Preparation of 2-Ethylthio-1,3-butadiene (6c). 2-Ethylthio-1,3-butadiene was synthesized according to the literature procedure.[10] The crude product was purified by

column chromatography using pentane as an eluent (37% yield). ^{1}H NMR ($CDCl_3$) δ=1.31 (t, 3H, J=7.4 Hz), 2.77 (q, 2H, J=7.4 Hz), 5.02 (s, 1H), 5.17 (d, 1H, J=10.0 Hz), 5.33 (s, 1H), 5.54 (d, 1H, J=17.2 Hz), and 6.44 (dd, 1H, J=10.0, 17.2 Hz).

Asymmetric Diels-Alder Reaction. General Procedure for the Reaction Using a Catalytic Amount of the Titanium Reagent. The reaction of 3-acryloyl-1,3-oxazolidin-2-one (**3**) with isoprene is outlined. To a toluene (4 ml) solution of dichlorodiisopropoxytitanium (145 mg, 0.611 mmol) was added the chiral diol **1**, (325 mg, 0.615 mmol) at room temperature under an argon atmosphere and the mixture was stirred for 1 h. This toluene solution of the chiral titanium catalyst (1 ml, 0.153 mmol) was added to powdered MS 4A under an argon atmosphere, and the mixture was cooled to −78 °C. A toluene (4 ml) solution of 3-acryloyl-1,3-oxazolidin-2-one (**3**) (216 mg, 1.53 mmol) was added to the mixture. Then P.E. (5 ml) and isoprene (1.5 ml) were added. The mixture was stirred overnight at 0 °C, and then pH 7 buffer was added to the mixture. The organic materials were extracted with ethyl acetate and the combined extracts were dried over anhydrous Na_2SO_4. After the evaporation of the solvent, the crude product was purified by thin-layer chromatography (silica gel, AcOEt : hexane=1 : 1) to give the pure product **5b** in 89% yield.

By the same procedure described above, the cycloaddition products **4**, **5a**, and **5b** were obtained.

Spectral data and physical properties of the cycloadducts are as follows:

3-[(1*S*,2*S*,4*S*)-Bicyclo[2.2.1]hept-5-en-2-ylcarbonyl]-1,3-oxazolidin-2-one (4). ^{1}H NMR and IR spectra agreed with those of the literatures.[2] $[\alpha]_D^{25}$ −132.5° (*c* 0.898, CH_2Cl_2), 88% ee, lit, $[\alpha]_D$ −65° (*c* 1.5, CH_2Cl_2), 38% ee.[3]

3-[(1*R*)-3-Cyclohexen-1-ylcarbonyl]-1,3-oxazolidin-2-one (5a). IR (KBr) 1776, 1695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.14—2.74 (m, 6H), 3.45—4.61 (m, 5H), and 5.65 (s, 2H); $[\alpha]_D^{23}$ −20.2° (*c* 1.75, CH_2Cl_2), 89% ee. HRMS Found: *m/z* 195.0890. Calcd for $C_{10}H_{13}NO_3$: M, 195.0896.

3-[(1*R*)-4-Methyl-3-cyclohexen-1-ylcarbonyl]-1,3-oxazolidin-2-one (5b). IR (KBr) 1776, 1689 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.68 (s, 3H), 1.75—2.40 (m, 6H), 3.72—4.95 (m, 5H), and 5.36 (br, 1H); $[\alpha]_D^{23}$ −38.8° (*c* 2.55, CH_2Cl_2), 96% ee. Anal. Calcd for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%. Found: C, 63.15; H, 7.18; N, 6.71%.

3-[(1*R*)-4-Ethylthio-3-cyclohexen-1-ylcarbonyl]-1,3-oxazolidin-2-one (7). IR (KBr) 1776, 1695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.26 (t, 3H, J=7.5 Hz), 1.77 (ddd, 1H, J=24.0, 11.0, 5.7 Hz), 2.01—2.06 (m, 1H), 2.20—2.25 (m, 1H), 2.30—2.39 (m, 3H), 2.68 (dq, 1H, J=12.5, 7.2 Hz), 2.71 (dq, 1H, J=12.5, 7.2 Hz), 3.73 (dddd, 1H, J=2.7, 5.8, 9.0, 15.0 Hz), 4.03 (t, 2H, J=8.3 Hz), 4.42 (t, 2H, J=8.3 Hz), and 5.61—5.63 (br, 1H); $[\alpha]_D^{26}$ −44.3° (*c* 0.859, CH_2Cl_2), 91% ee. HRMS Found: *m/z* 255.0902. Calcd for $C_{12}H_{17}NO_3S$: M, 255.0930.

Transformation of 5a and 5b into Their Epoxy Derivatives 12a and 12b. Formation of the Methyl Ester 9b. A few drops of carbon tetrachloride was added to magnesium (80.1 mg, 3.30 mmol). Then dry methanol (6.6 ml) was added under an argon atmosphere at 0 °C to generate magnesium methoxide. When all the magnesium dissolved, an ether (5 ml) solution of the Diels-Alder adduct **5b** (263 mg, 1.26 mmol) was added. The reaction was immediately quenched with saturated ammonium chloride and the methyl ester was extracted with ether. The organic layers were washed with brine and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the crude product **9b** was directly used for further transformations.

Hydrolysis of 9b to the Carboxylic Acid 10b. A THF-water (10 : 1) mixture was added to the methyl ester **9b** (93.1 mg, 0.603 mmol) at room temperature until the ester completely dissolved. Then 2.5 equiv of lithium hydroxide monohydrate (62.9 mg, 1.50 mmol) was added to this solution at room temperature and the mixture was stirred for 8 h. After the evaporation of the solvent, 1M sodium hydroxide solution was added and the water layer was washed with ether. The water layer was made acidic with concd hydrochloric acid, and extracted with ether. The combined organic layers were dried over anhydrous sodium sulfate. After the evaporation of the solvent, the crude carboxylic acid was directly used for further transformations.

Iodolactone 11b. The carboxylic acid **10b** (40.0 mg, 0.285 mmol) was dissolved in 0.5M sodium hydrogencarbonate solution (1.7 ml). To this, an aqueous solution (4 ml) of iodine (148.0 mg, 0.583 mmol) and potassium iodide (285.0 mg, 1.72 mmol) was added and the mixture was stirred overnight at room temperature in the dark. The reaction mixture was diluted with water. Then aqueous $Na_2S_2O_3$ was added and the organic compounds were extracted with CH_2Cl_2. The combined organic layers were washed with saturated sodium hydrogencarbonate solution and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the crude product (**11b**) (76.1 mg) was directly used for obtaining the epoxy derivative **12b**.

Epoxy Derivative 12b. NaOMe (17.1 mg, 0.317 mmol) was dissolved in dry methanol (3 ml) at 0 °C under an argon atmosphere. To this, a THF (3 ml) solution of the iodolactone **11b** (69.6 mg, crude) was added and the mixture was stirred overnight. The reaction mixture was quenched with a pH 7 phosphate buffer after the evaporation of methanol. The epoxy compound was extracted with ether and the combined organic layers were washed with water and brine successively, and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the epoxy derivative **12b** was purified by TLC (hexane : AcOEt=4 : 1). (23.0 mg, 52% yield). The epoxy compound was analyzed by NMR with the addition of a chiral shift reagent, (Eu(hfc)$_3$).[12]

Spectral data of the epoxy compounds are as follows.

Methyl 3,4-Epoxycyclohexane-1-carboxylate (12a). **5a** was transformed to its epoxy derivative **12a** in the same manner. ^{1}H NMR ($CDCl_3$) δ=1.52—1.62 (m, 2H), 1.70—1.77 (m, 2H), 2.10—2.12 (m, 2H), 2.15—2.22 (m, 2H), 3.08 (s, 1H), and 3.64 (s, 3H).

Methyl 4-Methyl-3,4-epoxycyclohexane-1-carboxylate (12b). ^{1}H NMR ($CDCl_3$) δ=1.30 (s, 3H), 1.54—1.71 (m, 4H), 2.02—2.25 (m, 3H), 2.96 (d, 1H), and 3.64 (s, 3H).

Preparation of the MTPA Ester 13. The Diels-Alder adduct **4** was transformed to its benzyl ester by the literature method.[7] To reduce the benzyl ester to the corresponding alcohol, the THF (3 ml) solution of the benzyl ester was added to the mixture containing THF (1 ml) and $LiAlH_4$ (13.8 mg, 0.364 mmol) at 0 °C under an argon atmosphere. After 1 h, the reaction was quenched with saturated aqueous sodium sulfate and the organic materials were extracted with ether by decantation, and dried over anhydrous sodium sulfate. Filtration and evaporation of the solvent afforded the crude product, which was purified by thin layer chromatography (benzene : ether=2 : 1, ×2) to give the pure product

(84% yield). The obtained alcohol was transformed to its MTPA ester **13** by the Mosher's method.[13]

Oxidation of the MTPA Ester to 14.[14] Methanol was added to (1*S*)-4-ethylthio-3-cyclohexen-1-ylmethyl (+)-trifluoromethylmethoxyphenylacetate (**13**) (9.2 mg, 0.024 mmol) until all of **13** had dissolved at 0 °C. Then 30% hydrogen peroxide (1 ml) and $(NH_4)_6Mo_7O_{24}$ (10 mg) were added and the mixture was stirred for 3.5 h. The sulfone (**14**) was extracted with CH_2Cl_2 and the combined organic layers were washed with brine and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the crude product (10.1 mg) was analyzed by ^{13}C NMR without further purification. ^1H NMR ($CDCl_3$) δ=1.25 (t, 3H), 1.26—1.37 (m, 1H), 1.89—2.09 (m, 2H), 2.24—2.50 (m, 3H), 2.89 (dq, 1H), 2.91 (dq, 1H), 3.51 (s, 3H), 4.16 (dd, 1H), 4.30 (dd, 1H), 6.72—6.76 (br, 1H), 7.37—7.43 (m, 3H), and 7.47—7.50 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=7, 23, 25, 28, 30, 31, 32, 47, 56, 69, 122, 128, 129, 130, 139, and 167.

On the Reaction of *N*-(Diphenylphosphinyl)-1-phenylethanimine with Aromatic Aldehydes Giving 4-Aryl-2,6-diphenylpyridine Derivatives

Tomoshige KOBAYASHI,* Hidetaka KAKIUCHI, and Hiroshi KATO*
Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390
(Received October 1, 1990)

N-(Diphenylphosphinyl)-2-phenyl-1-azaallyl anion (**1**), generated from *N*-(diphenylphosphinyl)-1-phenylethanimine, reacted with aromatic aldehydes in a 2 : 1 molar ratio to give 4-aryl-2,6-diphenylpyridines in moderate yields. The intervention of *N*-phosphinyl-1-azadiene intermediates is proposed on the basis of the independent synthesis of an *N*-phosphinyl-1-azadiene and its conversion into a pyridine by the reaction with **1**.

In the previous paper, we described a novel route to phenyl-substituted pyridines by the reaction of α,β-unsaturated carbonyl compounds with *N*-phosphinyl-1-azaallyl anions, which are easily generated from the corresponding *N*-phosphinylimine and enamine.[1] The *N*-phosphinyl-1-azaallyl anions have shown bidentate reactivity at the β-carbon and the nitrogen atoms to behave as a synthetic equivalent of primary vinylamines, which are labile even at low temperature.[2] The primary vinylamines[2] and their synthetic equivalents such as an *N*, *N*-bis(trimethylsilyl) enamine,[3] 1-amino-2-hydroxyalkylsilanes,[4] and *N*-vinyliminophosphoranes[5] have been reported to provide 2-azadienes upon treatment with aldehydes. Our attention, therefore, turned to the reaction of the *N*-phosphinyl-1-azaallyl anion **1** with aromatic aldehydes **3** to investigate the chemo-selectivity of **1** towards simple carbonyl compounds with the result that the unexpected formations of 4-aryl-2,6-diphenylpyridines was observed.

Results and Discussion

In a preliminary study, *N*-(diphenylphosphinyl)-1-phenylethanimine (**2**)[1,6] was treated with an equimolar amount of benzaldehyde **3a** in the presence of potassium *t*-butoxide to afford 2,4,6-triphenylpyridine **4a** in 8% yield, instead of the presumed 2-azadiene (**2-AD**, Scheme 2). Since the two phenyl groups at the 2- and 6-positions of **4a** seemed to arise from two molecules of **2**, the reaction of **2** and **3a** in a 2 : 1 molar ratio in the presence of potassium *t*-butoxide at ambient temperature was investigated to give the pyridine **4a** in 52% yield along with diphenylphosphinic acid (**5**) and diphenylphosphinic amide (**6**) in 58 and 18% yield, respectively. Similarly, the reactions of the imine **2** with substituted benzaldehydes **3b—h** as well as 2-thiophenecarbaldehyde **3i** also resulted in the regioselective formation of pyridine derivatives **4b—i** in which the aryl groups derived from the aldehydes are located exclusively at the 4-position of the pyridine ring. The use of ortho-substituted benzaldehydes **3g** and **3h** obviously decreases the yields of the pyridines **4g** and **4h**. All the pyridines except **4i** have been reported. Pyridines **4a—f** were characterized by comparison of their spectral data and melting points with those described in the literatures for **4a—f**, and **4g** and **4h** were identified by independent syntheses.

The present reaction can be best explained as shown in Scheme 2. Upon treatment with an aromatic aldehyde **3**, the 1-azaally anion **1** undergoes the condensation reaction on the β-carbon atom to give *N*-phosphinyl-1-azadiene **7**. The 1-azadiene **7** further reacts with **1** to lead to a dihydropyridine **9** via elimination of the phosphinic amide **6** from **8**. Since the phosphinic acid **5** was isolated from the reaction of **2** and **3a**, a route involving release of the phosphinic acid **5** from **9**, followed by dehydrogenation is likely for the formation of the pyridine **4**. However, an alternative route through direct elimination of diphenylphosphine oxide (**11**) from **9** can not be excluded, as **11** was easily converted to the phosphinic acid **5**

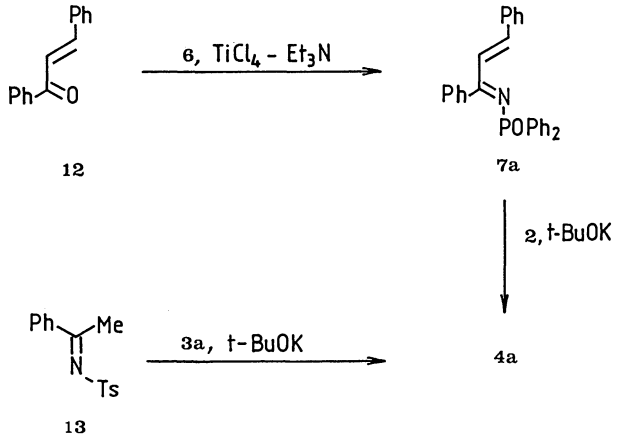

Scheme 3.

under the reaction conditions (see Experimental).

Some efforts were devoted to the isolation and capture of the *N*-phosphinyl-1-azadiene intermediate **7**. The azadiene **7a** could not be formed among the products of the reaction of the imine **2** with two fold excess amount of benzaldehyde **3a**, while the reaction gave the pyridine **4a** in 7% yield. Further, the reaction of **2** and **3a** in the presence of 1-(1-pyrrolidinyl)-1-cyclohexene, 1-trimethylsiloxy-1-cyclohexene, or ethyl vinyl ether did not afford the expected adducts.[7] Thus, an independent synthesis of the azadiene **7a** was performed in 78% yield by treatment of 1,3-diphenyl-2-propen-1-one (**12**) with the phosphinic amide **6** in the presence of titanium tetrachloride and triethylamine in refluxing toluene.[8] Upon treatment with **2** and potassium *t*-butoxide in benzene at ambient temperature, the propenimine **7a** provided the pyridine **4a** in 52% yield, and this outcome agrees with the mechanism shown in Scheme 2 including both an intervention of the 1-azadiene intermediate **7** and its sequential reaction with **1**.

Finally, it should be noted that the phosphinyl group seems to be essential for the present transformation, because a similar reaction of benzaldehyde **3a** with *N*-(*p*-tolylsulfonyl)-1-phenylethanimine (**13**)[9] gave only a trace amount of the pyridine **4a**.

In conclusion, the reaction of *N*-phosphinyl-2-phenyl-1-azaallyl anion **1** with aromatic aldehydes has been found to give 4-aryl-2,6-diphenylpyridines probably via *N*-phosphinyl-1-azadiene intermediate. It is surprising to observe nucleophilic attack exclusively by the anionic carbon of the 1-azaallyl anion **1**. This result sharply contrasts with the behavior of primary vinylamines and their synthetic equivalents known so far.[2-5] Although the yields of the pyridines are modest, the present reaction has shown a novel reactivity of the azaallyl anion **1**.

Experimental[10]

General Procedure for the Reaction of N-(Diphenylphosphinyl)phenylethanimine (2) and Aromatic Aldehydes (3) (2:1 molar ratio). To a solution of the imine **2**[1,6] (160 mg, 0.5 mmol) in anhydrous benzene (5 ml) was added potassium *t*-butoxide (56 mg, 0.5 mmol). The mixture was stirred at ambient temperature for 10 min, and a solution of aromatic aldehyde **3** (0.25 mmol) in anhydrous benzene (3 ml) was added to the mixture. Stirring was continued for 2 h at the same temperature. The mixture was washed with water, dried over Na_2SO_4, and concentrated. The residue was purified on TLC (silica gel, benzene) to give the pyridine **4**. In the reaction of **2** and **3a**, the base line portion on the TLC plate was developed again with benzene–methanol (3:1) to yield diphenylphosphinic amide **6** in 18% yield, and acidification of the aqueous phase with hydrochloric acid provided diphenylphosphinic acid **5** in 58% yield. The yields of the pyridine derivatives **4** are based on the amount of aromatic aldehydes. The spectra of the pyridines **4a**, **4b**, **4c**, and **4e** were previously described.[1] The reactions of the imine **2** and benzaldehyde **3a** in molar ratios of 1:1 and 1:2 were carried out in similar manners.

2,4,6-Triphenylpyridine (4a): 52%; mp and mixed mp 134—135 °C (methanol) (lit,[11] mp 137 °C).

4-(*p*-Methylphenyl)-2,6-diphenylpyridine (4b): 57%; mp

and mixed mp 124.5—125 °C (methanol) (lit,[12] mp 118—119 °C.

4-(*p*-Chlorophenyl)-2,6-diphenylpyridine (4c): 41%; mp and mixed mp 129—130 °C (methanol) (lit,[13] mp 129—130 °C).

4-(*p*-Nitrophenyl)-2,6-diphenylpyridine (4d): 37%; mp 202—203 °C (benzene–hexane=1 : 1) (lit,[14] mp 188 °C); IR ($CHCl_3$) 1590, 1540, 1380, 1350, 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.20—7.66 (6H, m), 7.85 (2H, s), 7.87 (2H, d, J=9.0 Hz), 8.08—8.25 (4H, m), 8.36 (2H, d, J=9.0 Hz); MS m/z (rel intensity) 352 (M^+, 100), 322 (14), 306 (37). 4-[*p*-(Dimethylamino)phenyl]-2,6-diphenylpyridine(4f): 28%; mp 142—143 °C (methanol) (lit,[14] mp 138 °C); IR ($CHCl_3$) 1590, 1520, 1360, 1180, 1120 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.99 (6H, s), 6.80 (2H, d, J=8.7 Hz), 7.20—7.60 (6H, m), 7.66 (2H, d, J=8.7 Hz), 7.84 (2H, s), 8.14—8.24 (4H, m); MS m/z (rel intensity) 350 (M^+, 100), 333 (5), 306 (6).

4-(*o*-Methylphenyl)-2,6-diphenylpyridine (4g): 7%; mp and mixed mp 122—123 °C (methanol) (lit,[15] mp 116-117 °C); IR (KBr) 1610, 1580, 1536, 1490, 1400 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.36 (3H, s), 7.20—7.60 (10H, m), 7.66 (2H, s), 8.12—8.28 (4H, m); MS m/z (rel intensity) 321 (M^+, 75), 320 (100). Found: C, 89.39; H, 5.95; N, 4.44%. Calcd for $C_{24}H_{19}N$: C, 89.68; H, 5.96; N, 4.36%.

4-(*o*-Chlorophenyl)-2,6-diphenylpyridine (4h): 11%; mp and mixed mp 114—115 °C (methanol) (lit,[12] mp 112—113 °C); IR (KBr) 1600, 1551, 1478, 1405 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.20—7.64 (10H, m), 7.76 (2H, s), 8.08—8.28 (4H, m); MS m/z (rel intensity) 343 (M^++2, 31), 341 (M^+, 100), 306 (51). Found: C, 80.48; H, 4.75; N, 3.81%. Calcd for $C_{23}H_{16}NCl$: C, 80.81; H, 4.72; N, 4.10%.

2,6-Diphenyl-4-(2-thienyl)pyridine (4i): 31%; mp 165—166 °C (methanol); IR (KBr) 1600, 1580, 1560, 1500, 1410, 1250, 1080, 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.00—7.62 (9H, m), 7.83 (2H, s), 8.02—8.25 (4H, m); MS m/z (rel intensity) 313 (M^+ 100); HR-MS Found: 313.0928. Calcd for $C_{21}H_{15}NS$: 313.0925. Found: C, 80.38; H, 4.75; N, 4.32%. Calcd for $C_{21}H_{15}NS$: C, 80.48; H, 4.82; N, 4.47%.

Diphenyphosphinic Acid (5): Mp and mixed mp 196—198 °C (lit,[16] mp 190—192 °C); IR (KBr) 3450, 1421, 1180, 1138 cm^{-1}.

Diphenylphosphinic Amide (6): Mp and mixed mp 170—171 °C (lit,[17] mp 168 °C); IR (KBr) 3250, 1440, 1190, 1126 cm^{-1}.

Independent Synthesis of the Pyridine 4g.[18] A mixture of 3-(*o*-methylphenyl)-1-phenyl-2-propen-1-one[19] (2.123 g, 9.5 mmol), acetophenone (0.916 g, 7.6 mmol), and $BF_3 \cdot OEt_2$ (3.336 g, 22.8 mmol) was heated at 115 °C for 7 h. The solution was cooled to room temperature, and the product was crystallized from benzene to give 4-(*o*-methylphenyl)-2,6-diphenylpyrylium tetrafluoroborate (1.142 g, 37%) as yellow powders: Mp 113—115 °C (decomp). Found C, 70.58; H, 4.78%. Calcd for $C_{24}H_{19}OBF_4$: C, 70.27; H, 4.67%.

To a suspension of the pyrylium salt (1.076 g, 2.6 mmol) in ethanol (3 ml) was added 25% aq NH_3 (5 ml) and stirring was continued for 24 h at ambient temperature. The product was extracted with dichloromethane prior to drying over Na_2SO_4. After removal of the solvent, recrystallization of the resulting solid from methanol gave the pyridine **4g** (515 mg, 62%).

Independent Synthesis of the Pyridine 4h.[18] By a similar procedure for **4g**, a mixture of 3-(*o*-chlorophenyl)-1-phenyl-2-propen-1-one[19](3.191 g, 13.1 mmol), acetophenone (1.221 g, 10 mmol), and $BF_3 \cdot OEt_2$ (4.346 g, 30 mmol) was heated at 115 °C for 7 h to afford 4-(*o*-chlorophenyl)-2,6-diphenylpyrylium tetrafluoroborate (1.102 g, 26%) as yellow powders: Mp 114—116 °C (decomp). Found: C, 64.15; H, 3.74%. Calcd for $C_{23}H_{16}OClBF_4$: C, 63.63; H, 3.75%. The pyrylium salt was used without further purification.

A similar treatment of the pyrylium salt (1.028 g, 2.4 mmol) gave the pyridine **4h** (610 mg, 67%).

Reaction of Diphenylphosphine Oxide (11) under Basic Conditions.[20] A mixture of the phosphine oxide **11** (89 mg, 0.44 mmol) and potassium *t*-butoxide (62 mg, 0.55 mmol) in benzene was stirred for 3 h at ambient temperature under nitrogen atmosphere. The organic phase was washed with aq $NaHCO_3$, and the aqueous phase was acidified with hydrochloric acid. The product was extracted with dichloromethane prior to drying over $MgSO_4$. Removal of the solvent gave the phosphinic acid **5** (57 mg, 59%).

Independent Synthesis of (2*E*)-*N*-(Diphenylphosphinyl)-1,3-diphenyl-2-propenimine (7a). A mixture of the propenone **12** (2.083 g, 10 mmol), the phosphinic amide **6** (2.384 g, 11 mmol), and triethylamine (3.03 g, 30 mmol) in toluene (20 ml) was heated at 70 °C. To this mixture was slowly added $TiCl_4$ (0.60 ml, 5.5 mmol), and the mixture was heated under reflux for 6 h. Insoluble material was removed by filtration and the filtrate was concentrated. The residue was chromatographed on silica gel using benzene–ethyl acetate (1 : 1) as an eluent to give an oily product, which was crystallized from ether to give **7a** (3.17 g, 78 %) as colorless powders: Mp 120—121 °C; IR (KBr) 3090, 1610, 1590, 1560, 1430, 1300, 1180, 1120, 1100, 1020, 990, 980, 910 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.99 (1H, d, J=16.4 Hz), 7.21—8.11 (20H, m), 8.28 (1H, dd, J=16.4, 1.4 Hz); ^{13}C NMR ($CDCl_3$) δ=124.2—146.4, 180.3 (J_{P-C}=8.5 Hz, C=N); ^{31}P NMR ($CDCl_3$) δ=19.0; MS m/z (rel intensity) 407 (M^+, 60), 206 (86), 77 (100); HR-MS Found: 407.1426. Calcd for $C_{27}H_{22}NOP$: 407.1439. Found: C, 79.74; H, 5.51; N, 3.33%. Calcd for $C_{27}H_{22}NOP$: C, 79.59; H, 5.44; N, 3.44%.

Reaction of the Ethanimine 2 and the Propenimine 7a. A mixture of the ethanimine **2** (191 mg, 0.6 mmol), the propenimine **7a** (204 mg, 0.5 mmol), and potassium *t*-butoxide (67 mg, 0.6 mmol) in benzene (5 ml) was stirred for 4 h at ambient temperature. The mixture was washed with aq $NaHCO_3$ and water, then dried over Na_2SO_4. Purification on TLC (silica gel, benzene) gave 2,4,6-triphenylpyridine **4a** (80 mg, 52%): Mp and mixed mp 139—140 °C.

Synthesis of *N*-(*p*-Tolylsulfonyl)-1-phenylethanimine (13).[9] To a cooled solution (−35 °C) of acetophenone oxime (16.23 g, 0.12 mol) and triethylamine (12.14 g, 0.12 mol) in petroleum ether–dichloromethane (160 ml, 1 : 1) was added *p*-toluenesulfinyl chloride[21] (20.96 g, 0.12 mol). The mixture was warmed up to room temperature and stirring was continued for 1 h. Insoluble material was filtered and the filtrate was concentrated. The residue was crystallized from ether to give **13** (4.048 g, 12%): Mp 71.5—73.5 °C; IR (KBr) 1605, 1600, 1570, 1313, 1301, 1280 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.42 (3H, s), 2.96 (3H, s), 7.12—7.58 (5H, m), 7.80—8.00 (4H, m); ^{13}C NMR ($CDCl_3$) δ=21.1 (q), 21.5 (q), 127.1, 128.2, 128.6, 129.4, 133.1, 137.5, 138.8, 143.5, 179.8 (s); MS m/z (rel intensity) 273 (M^+, 26), 209 (24), 155 (95), 91

(100). HR-MS Found: 273.0809. Calcd for $C_{15}H_{15}O_2S$: 273.0823.

Reaction of the *N*-Sulfonylimine (13) with Benzaldehyde (3a). A solution of the *N*-sulfonylimine **13**[9] (547 mg, 2 mmol) and potassium *t*-butoxide (226 mg, 2 mmol) in benzene (5 ml) was stirred at ambient temperature for 10 min. To the mixture was added benzaldehyde **3a** (106 mg, 1 mmol) and stirring was continued for 24 h. The mixture was washed with aq $NaHCO_3$ and dried over $MgSO_4$. Separation on TLC (silica gel, benzene) afforded only a trace amount of the pyridine **4a**, which was detectable only by the ^1H NMR spectrum.

Association Characteristics of Amphiphilic α-Helices Connected by Flexible Links

Hisayuki MORII,* Shinya HONDA, Kunihiro ICHIMURA, and Hatsuho UEDAIRA
Research Institute for Polymers and Textiles, 1-1-4 Higashi, Tsukuba, Ibaraki 305
(Received October 2, 1990)

Amphiphilic helical peptides interlinked with sequences bearing a flexible mobility were designed and synthesized. The sequences containing glycine and/or cystine were adopted for the linkage parts. The secondary structure of the peptides was investigated by circular dichroism(CD) and the super-secondary structure was estimated. The CD spectra and their pH dependence show that the peptides have almost the same α-helix contents as designed and that the helices associate to be "coiled-coil" at neutral pH. The apparent helix contents increase at low pH and some of helices are subject to denaturation at high pH. The denaturation of α-helix bundles by guanidine hydrochloride is contemplated to be three-state transition. It is proposed that the peptides construct α-helix bundles with both loose and tight contacts between helices. Two kinds of folded structure constructed with 2 or more helices are also suggested.

The construction of artificial proteins is a very attractive field. Several new designs[1-5] of proteins have been presented in the last several years.

In nature there exist "coiled-coil"[6] and "4-helix bundle"[7] structures which are formed by 2 and 4 α-helices, respectively. Amphiphilicity of cylindrical helices is characteristic of these structures. The contact faces of associated helices are rich in hydrophobic residues and the opposite faces are often hydrophilic. Nishino et al.[8] investigated the association of amphiphilic helices by means of a size exclusion chromatography (SEC). They tested the effect of hydrophobic and hydrophilic amino acids in helices on the association. DeGrado et al.[9,10] revealed an association free energy and the number of association by measuring the concentration dependence of CD intensity. Mutter et al.[11] proposed a new design of peptides and the structure was analyzed with CD and SEC. In these studies the linked helices were found to form more stable aggregates than single helices.

In this work, we designed and synthesized several amphiphilic helical peptides interlinked with flexible connections. The important characteristic of our designed peptides is flexible linkage of amphiphilic helices. The flexible links are expected to play an important role in arranging helices in a stable packing. Moreover, the peptides may be useful as "induced fitting" host molecules. The formation of a bundle structure by amphiphilic helices is already known, however, the folding course and the influence of temperature and pH on a folded structure are not investigated well. In order to make clear the super-secondary structure as well as the folding behavior of linked α-helices the CD spectra were analyzed in detail.

Experimental

Materials. *t*-Butoxycarbonyl-protected amino acids and 4-(bromomethyl)phenylacetic acid were purchased from Kokusan Chemical Works and used without further purification. The other reagents were trifluoroacetic acid (TFA), dicyclohexylcarbodiimide (DCC), ninhydrin, diethyl phosphorocyanidate (DEPC), triethylamine (Et_3N), cesium carbonate (Cs_2CO_3), trifluoromethanesulfonic acid (TFMSA), dichloromethane, *N*,*N*-dimethylformamide (DMF) distilled over CaH_2, and dimethyl sulfoxide (DMSO), which were purchased from Wako Pure Chemical. The solvents were dried over molecular sieve 4A.

Peptide Synthesis and Purification. The peptides P2, P3, P4x, P4w and P6, of which the sequences are shown in Fig. 1 with one letter abbreviations,[12] were synthesized manually by a solid-phase method. The initial Boc-protected amino acid was anchored onto copoly(styrene-1%-divinylbenzene) (Bio-beads S-X1, Bio-Rad) intermediated with 4-(hydroxymethyl)phenylacetamidomethyl group by the method of Mitchell et al.[13] The second and the third residues from C-terminus were introduced in one time with DEPC-Et_3N[14] in order to be free from 2,5-piperazinedione formation.[15] The subsequent residues were coupled stepwise. The side-chain-protecting groups used were Glu(OBzl), Lys(ClZ), and Cys(Acm)[16] (Bzl, benzyl; ClZ, 2-chlorobenzyloxycarbonyl; Acm, acetamidomethyl). The double couplings were carried out for each step by means of DEPC-Et_3N and symmetrical carboxylic anhydride methods.[17] Finally the peptide was deprotected and cleaved from the resin by TFMSA-Me_2S-*m*-cresol system[18] at 0 °C for 28h. For the peptides P4x, P4w, and P6, Cys(Acm) was deprotected and oxidized to be cystine with 0.01 M (1 M=1 mol dm^{-3}) iodine in water-acetic acid (1 : 4) at 20 °C for 1 h.

Each crude peptide was desalted by gel filtration with Sephadex G-15 using 0.1 M acetic acid. The crude yields of the peptides P2, P3, P4x, P4w, and P6 were 24, 17, 29, 30, and 17%, respectively. The collected peptide solution was then applied to a column of CM-Sephadex C-25(1.7 cm by 70 cm) and eluted with a linear gradient 0.01 to 0.60 M ammonium acetate, pH 6.5, using a total volume of 1000 ml (Fig. 2). Two peaks were obtained for peptide P2, however they were found to be the same composition by means of amino acid analysis. The later peak seems to correspond to a dimer. Reversed-phase HPLC's with columns of octadecyl or 2-cyanoethyl silica gel were attempted but resulted in strong adsorption to column packings. The adsorption also occurred in the chromatography with CM-Toyopearl

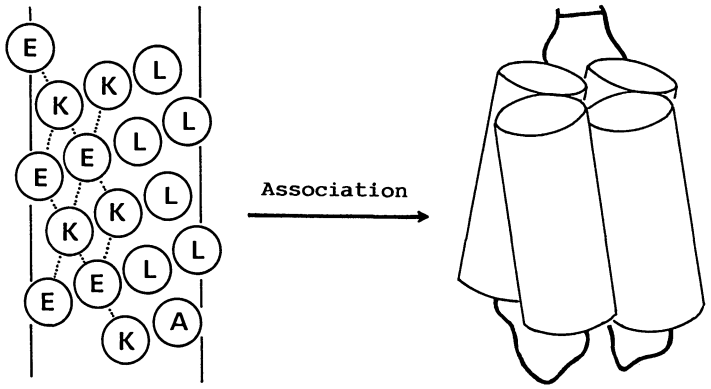

Fig. 1. Primary structures of the peptides represented with one letter abbreviations (upper) and drawing of a helical part to form bundle structure (lower). The peptides were named P2, P3, P4x, P4w, and P6 as shown in parentheses. The underlined sequences are α-helix parts predicted with the method of Chou and Fasman.[28] Cystine bonds are indicated with vertical line segments.

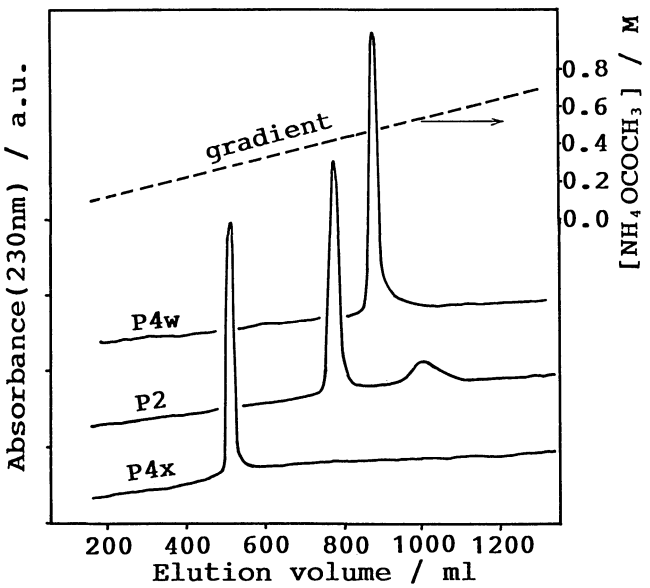

Fig. 2. Ion-exchange chromatography on CM-Sephadex C-25 with linear gradient.

650M and TSKgel G3000PW, and delayed elution was observed. Finally, the peptide was desalted by gel filtration and lyophilized to a fluffy powder.

The formation of a cystine linkage was confirmed by means of iodine titration[19] and quantitation of cysteine with di-(2-pyridyl) disulfide.[20] The amino acid compositions are listed in Table 1. The observed values have good agreements with the theoretical ones.

Table 1. Amino Acid Analyses of the Peptides[a]

Amino acid	P2	P3	P4x /2	P4w /2	P6 /2
Glu	8.91(9)	13.34(13)	8.97(9)	9.03(9)	13.38(13)
Gly	5.09(5)	7.35(8)	4.71(5)	4.82(5)	8.29(9)
Ala	1.75(2)	1.21(1)	(0)	1.00(1)	1.13(1)
Leu	13.26(13)	19.10(19)	13.31(13)	13.16(13)	19.20(19)
Lys	9.80(10)	14.32(15)	9.00(10)	9.33(10)	14.36(15)
Pro	0.93(1)	1.69(2)	0.86(1)	0.90(1)	1.81(2)

a) The values for peptides P4x, P4w, and P6 are related to their half-peptides. The values in parentheses are theoretical.

Measurement. Amino acid analyses were performed on a Hitachi 835 amino acid analyzer. Quantities of peptides were determined from amino acid analyses after hydrolysis[21] in 10 M HCl-TFA mixture (2:1, v/v) for 50 min at 165 °C. The total of the molar ratios of accurately measurable amino acids was used to calculate the peptide concentrations.

CD spectra from 195—205 nm to 260 nm were recorded using a JASCO J600 spectropolarimeter with 10 mm path length cells at a controlled temperature. Peptide concentrations were 6.0×10^{-4} M (for residue) for the measurements

of temperature and pH dependence. The denaturation with guanidine hydrochloride (GuHCl) was measured for 1.2×10^{-3} M (for residue) solution in a 1 mm cell. Mean residue molar ellipticity($[\theta]$) were reproducible within 3%. Sodium phosphate buffer (0.015 M) containing 0.15 M NaCl was used in the pH range from 2.00 to 11.00 where the pH values were adjusted with HCl or NaOH. For the solutions with pH 1.30 and pH 11.50, HCl-NaCl and NaOH-NaCl buffer were used, respectively. GuHCl solutions were prepared with stock buffer solutions of 0.015 M 3-morpholino-1-propanesulfonic acid with and without 8.0 M GuHCl. Each solution of 0—8.0 M GuHCl was adjusted to pH 7.00.

Results and Discussion

Design of Peptides. The peptides were designed to fold in helix-bundle structures (Fig. 1). The peptides P2, P3, P4x, P4w, and P6 contain 2, 3, 4, 4, and 6 helical parts, respectively. P4x and P4w are respectively cross-linked at different positions with disulfide bonds.

The principles for constructing the helical parts are proper choice of residues which tend to form α-helix and arrangement of hydrophobic and hydrophilic residues on opposite sides of a helix cylinder. The hydrophilic residues, Glu and Lys, were arranged to form a salt-bridge between positions i and $i+3$ or $i+4$ which is favored in nature.[22] The sequences of α-helical region are aligned in the order of Lys-Lys-Leu-Glu-Glu-Leu-Leu or Glu-Glu-Leu-Lys-Lys-Leu-Leu. Each helical part contains 14—17 residues and is possible to form a helix winding 4—5 times.

A loop with 5 residues or a cystine bond were used as the linkage part connecting two α-helical parts. The former is -Gly-Lys-Pro-Gly-Gly- and the latter is -Cys-Lys-, Cys-Gly- or Cys-Gly-Gly- coupled by disulfide bond. Glycine residue was chosen because it tends to form turn structures and has flexible mobility compared with α-substituted amino acid. Proline was chosen because of its specific tendency to terminate α-helix chain.[23] These residues widely occur in loop regions. As a loop region seemed to be exposed to water, lysine was added to the sequence as a hydrophilic residue.

The possible conformations of these peptides were examined with computer graphics, which showed us that the helices could associate and form a bundle structure with only a small distortion energy at a loop region. The stable association of the helices may be possible because their linkage parts have high flexibility.

CD Spectra of Peptides. The CD spectra of the peptides are shown in Fig. 3. A typical pattern of α-helix was observed for each peptide. In this condition the peptides seem to undergo little denaturation as shown later (Fig. 5). Generally, three classes, i.e. α-helix, β-sheet, and remainder, are most often used for secondary structures. However, it was pointed out that more splitted classes[24] of β-sheet are necessary

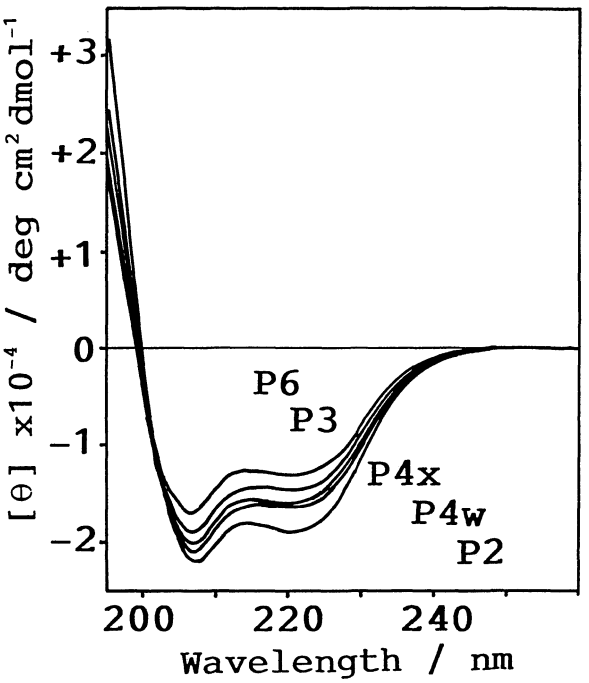

Fig. 3. CD spectra of the peptides in sodium phosphate buffer, pH 7.00, at 20 °C.

in order to obtain an improved accuracy in the analysis of CD spectra. In addition, the CD spectra of poly(amino acid)'s forming β-sheet were related to no single reference spectrum.[25] From these results, the CD analysis of β-sheet seems to be somewhat vague. The remainder structure is also vague because it has no defined structures. On the other hand, α-helix contents appears to be determinable more quantitatively than the other structures.

Chen et al.[26] introduced an empirical chain length dependent factor for a helix and obtained a good agreement with theoretical CD intensity. In Chen's equation, $[\theta]_H=[\theta]_H^\circ\cdot(1-k/n)$, mean residue ellipticity of a helix is a function of chain length, n. The parameters, $[\theta]_H^\circ$ and k, are listed in the literature.[26] According to this equation, the number, n, was calculated on the assumption that $[\theta]_{222}$ for nonhelical residues are from 1000 to 5000 deg cm^2 dmol^{-1} which are the values reported for remainder structures.[27] This leads to the results that the numbers n are smaller by about 3 to 5 per helix than the numbers predicted with the method of Chou and Fasman.[28] The helix contents with this method, which is named here "method-A", are almost consistent with the values obtained with CONTIN program[29] as listed in Table 2. The stabilization of helices with hydrophobic interaction between helices is so significant that it is difficult to interpret these reduced helix contents.

Then, we applied another method which is named "method-B" to determine helix contents. As reference data the method-B adopts the $[\theta]$ values of tropomyosin and its model peptide[30] which form "coiled-

Table 2. The Helix Contents Calculated with Various Methods

Peptide	Designed[a]	CONTIN[b]	Method-A[c]	Method-B[c]
	%	%	%	%
P2	78	60	63	82
P3	78	48	54	69
P4x	74	50	56	73
P4w	78	56	57	74
P6	75	38	49	63

a) The values were calculated with the prediction method of Chou and Fasman.[28] b) The program version 2DP(1984) of CONTIN[29] was used. c) The helix contents were determined with the method described in the text on the assumption that $[\theta]$ values for nonhelical structures were 3000 deg cm^2 dmol^{-1} at 222 nm.

coil", while the method-A and CONTIN are based on the data of familiar globular proteins. The reference $[\theta]_H^\circ$ values for method-B are −1.52, −2.45, −2.57, −2.46, −2.54, −2.67, −2.77, −2.68, −2.11, −1.38, −0.93, −0.56, −0.29, and -0.09×10^4 deg cm^2 dmol^{-1} at every 3 nm from 204 to 243 nm. In a similar manner as above, the differences between the number n and the designed number are estimated to be about −1 to 2 per helix. Thus, the helix contents with method-B are almost consistent with the designed helix contents as listed in Table 2.

Consequently, it may be concluded that the helices of our peptides are coiled-coil structure rather than "general" α-helix found in globular proteins. The peptides containing more than two helices, P3—P6, would have certain helix bundle structures constructed with coiled-coil structural units. These structures are discussed precisely in following sections. The coiled-coil structure has small distortion in comparison with "general" α-helix. This seems to cause the difference in $[\theta]_H^\circ$ values between coiled-coil and "general" α-helix.

In order to estimate the secondary structures of nonhelical parts the calculated spectra for helical regions were subtracted from the observed spectra. The subtracted spectra are converted to mean residue ellipticity and shown in Fig. 4. The spectra have large negative CD peaks at less than 205 nm and resemble the spectra of random-coiled poly(amino acid)'s which have negative peaks with the intensity about −5.0 to -2.5×10^4 deg cm^2 dmol^{-1} at 196—202 nm.[31] As the β-sheet shows positive $[\theta]$ value at this wavelength region, the nonhelical parts of our peptides are considered to have not a β-sheet but a remainder structure which is specific for our designed sequences.

Thermal Transition of the Peptides. The temperature dependence of $[\theta]_{222}$ is shown in Fig. 5. Each peptide undergoes gradual thermal transition. The slope of transition curves is not steep compared with CM-tropomyosin but similar to that of Hodges' peptide.[30] The helices of the peptides are not fully denatured even at 90 °C. The peptide P2 is the most stable and its transition curve is different from the others. It is suggested that the peptide with two amphiphilic helices make a stable folded structure while more than two helices results in somewhat different folded structure containing a helix associated by weaker interac-

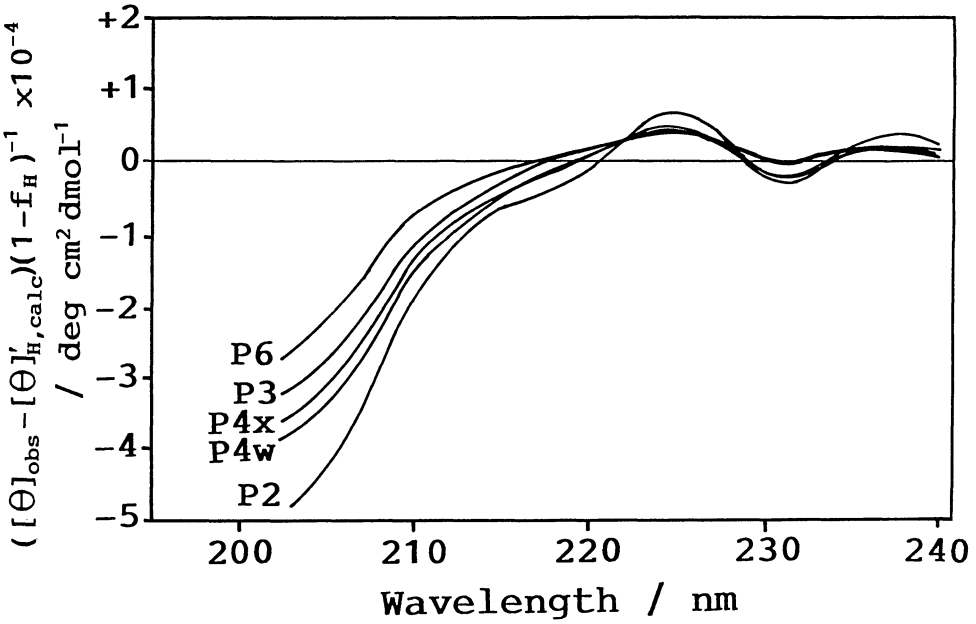

Fig. 4. Remained CD spectra after subtracting those of α-helical parts. $[\theta]_{obs}$, $[\theta]_{H,calc}$ are mean residue ellipticities which are observed and calculated for helical parts, respectively and f_H is a mole fraction of helical residue.

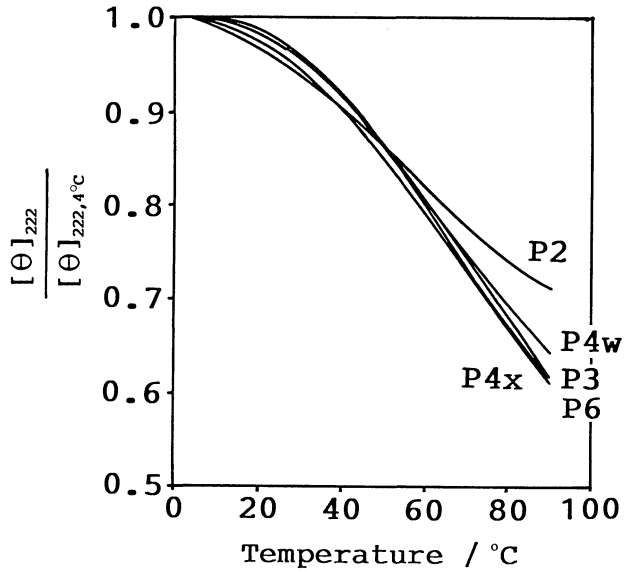

Fig. 5. Temperature dependence of mean residue ellipticity at 222 nm in phosphate buffer, pH 7.00. The values of $[\theta]_{222}$ are normalized at 4 °C.

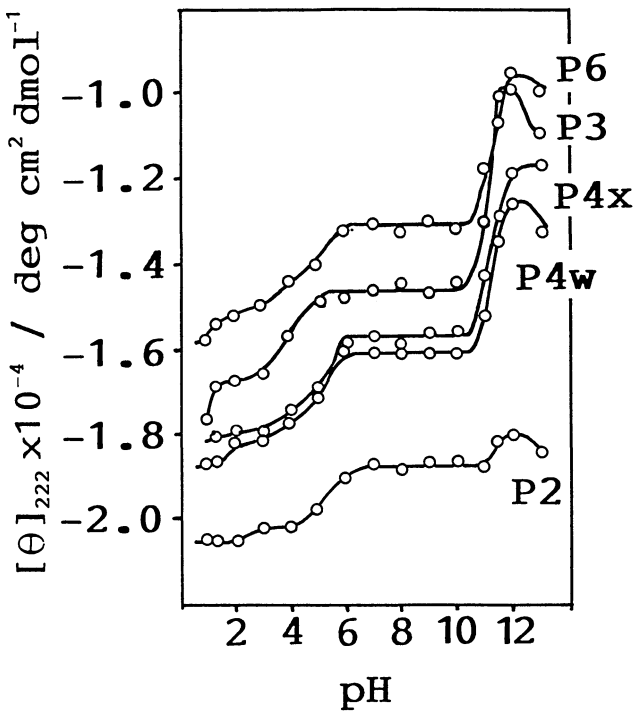

Fig. 6. The pH dependence of mean residue ellipticity at 222 nm.

tion. The disulfide bond does not appear to make a major contribution to the stability.

pH Dependence. The pH dependence of $[\theta]_{222}$ are shown in Fig. 6. For each peptide the intensity at 222 nm is constant at pH 6 to 11. These five peptides have a common tendency that the negative intensity increases in acidic conditions and decreases in basic conditions. The pH regions of the both transitions are consistent with pK_a of Glu and Lys side chains. At pH 12 the spectra are characteristic pattern of α-helix. Though only Glu side chains dissociate in this basic conditions, the denaturation of helices is restricted to some extent. Some denaturation may be attributed to weakened amphiphilicity because the Glu residues exist only at every two turns of helix.

In contrast to the basic conditions, the acidic ones cause a negative shift of $[\theta]_{222}$. The intensity increases by about 20%. If this is due to the increase of a helix content, the linkage region of the peptide will be shortened and become difficult to make a helix bundle. Therefore, it is reasonable to consider that the helix contents are constant but the type of helix changes from coiled-coil to otherwise "general" helix found in globular proteins. This change seems to result in the increase of the intensity of $[\theta]_H^0$ as discussed in the previous section.

As mentioned by Eisenberg et al.,[32] apolar carbon atoms of hydrophilic residues such as Lys and Glu have significant contributions to the stability of the folded structure of proteins. So, even if hydrophilicity is reduced in acidic or basic solutions, where either Lys or Glu is ionized, the helices of these peptides may not be necessarily denatured. The experimental results suggest that the helices of these peptides are susceptible to denaturation only at basic pH. As Lys has a long methylene side chain, non-protonated Lys at basic pH play a role as more hydrophobic residue

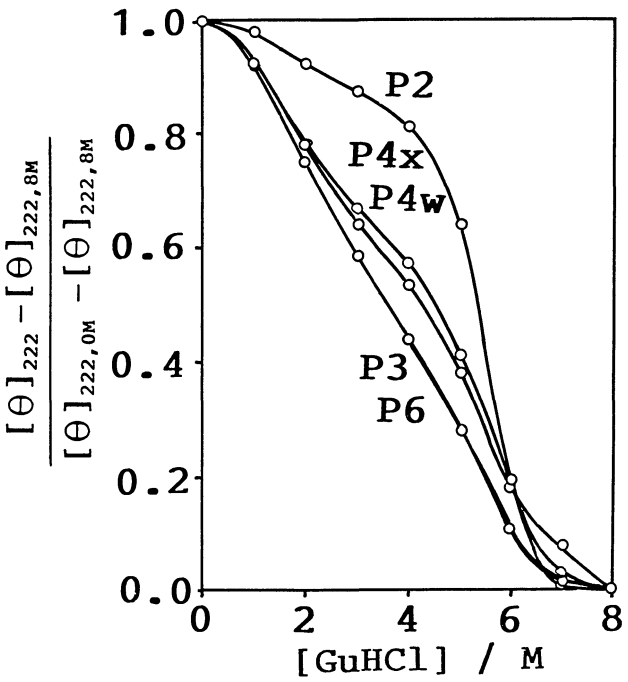

Fig. 7. Guanidine denaturation curves. The values of $[\theta]_{222}$ are normalized to be 1.0 in 0 M GuHCl and 0.0 in 8 M GuHCl. The ellipticities of these peptides in 8 M GuHCl were about 500—900 deg cm^2 dmol^{-1}.

than Glu at acidic pH, which is exposed to water and make α-helix unstable. Insufficient amphiphilicity would cause partial denaturation of helices in basic solutions. Thus, amphiphilicity is important in stabilizing α-helices.

Denaturation with Guanidine Hydrochloride. The helix structures were denatured with the increase of GuHCl concentration and $[\theta]_{222}$ values became about 1000 deg cm^2 dmol^{-1} in 8 M GuHCl. The relative changes of $[\theta]_{222}$ are shown in Fig. 7. The denaturation of P2 is a very steep transition in comparison with those of the other peptides. The midpoint of denaturation for P2 was shifted to a little higher GuHCl concentration when the peptide concentration was increased. This means that intermolecular association occurs in addition to intramolecular association of helices.

Each denaturation curve shows the fine structure that the first transition occurs at 2—3 M of GuHCl and the second at 5—6 M. For the peptide P2 the second transition is a major one, however for the other peptides almost the half of helices is subject to the first transition. It is reported that the peptide containing single amphiphilic α-helical strand takes α-helix form in associating with each other but that it can not form α-helix when isolated in a dilute solution.[9] Therefore, in our conditions no isolated α-helices exist. As all helices are not destroyed in the first denaturation step, the association of helices would exist even up to the second denaturation. So, both transitions relate to changes in association forms. These two types of transition can be explained by two types of interaction constructing a bundle structure. One of these interactions is relatively weak attractive force and the combined helices are susceptible to denaturation.

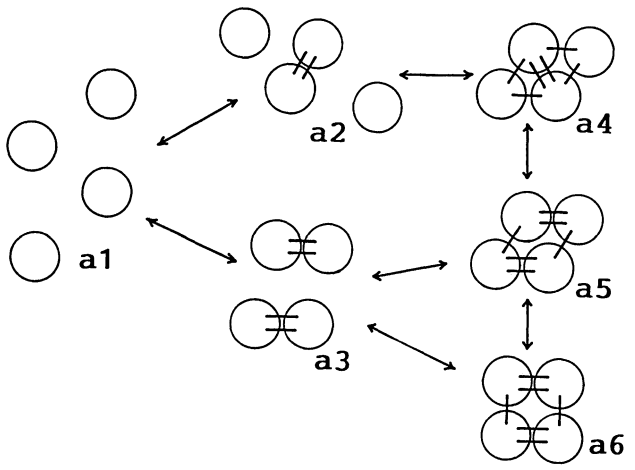

Fig. 8. Probable folded structures and defolding course. An example of 4-helix bundle is illustrated. Each circle represents α-helix as an axial view. Loose and tight contacts are represented with single (-) and double (=) line segments, respectively.

Another interaction brings about close contact of helices like coiled-coil structures.

Defolding Model of Linked Helices. In summarizing the results of denaturation experiments we can assume preliminary model for defolding as drawn in Fig. 8. It is considered that the association of helices is constructed with both loose and tight contacts. Most of P2 molecules take a folded structure with a tight contact, whereas some helices of the other peptides make a loose contact.

The experimental results of GuHCl denaturation are interpreted as follows. As described in the previous section, P2 takes an associated form such as $(P2)_2$. Most of P2 molecules take structures of **a5** or **a6** and turn to **a3** through the first denaturation point at 2—3 M GuHCl. In this course the helices are not subjected to deformation. On the other hand, not a minor molecules of P4x and P4w seem to take structures of **a4**. Through the first denaturation point they turn to **a2** and two helices among four undergo a denaturation, so that the total helix content decreases. The second denaturation point at about 6 M GuHCl is assumed to be related to a destruction of tight contact of helices like **a3** which results in entire transition to random coils. The denaturation of P3 and P6 is explained similarly to P4x and P4w but the number of associated helices could not be determined by only these experiments. It is interesting that the fractions corresponding to the first transition of P3 and P6 are a little larger than those of P4x and P4w. P3 and P6 may have more complicated association forms with loose contact.

The denaturation in basic solution can be explained by a similar consideration. As shown in Fig. 6, $[\theta]_{222}$ of P2 does not change largely in comparison with the others in a condition from neutral to basic. This course is assumed to be a denaturation of a loose contact. As most of P2 is related to a tight contact, the change of $[\theta]_{222}$ seems to result in a small change.

Richmond[33] gave the geometrical data for a packing of helices, that is, the inter-axial distance between helices is 1.05 nm and the outermost surface of leucine residue is 0.74 nm apart from a helix axis. These data lead to a consideration that on the average almost one residue contained in a winding pitch of α-helix contributes to hydrophobic interaction between two helices. As our helices contain -Leu- and -Leu-Leu- alternately in winding pitches, one of serial Leu residues may participate in a loose contact of helices.

It is interesting that our peptide P4w and peptide α4 designed by DeGrado et al.[1] show different GuHCl denaturation curves from each other nevertheless both are made of 4 helical parts. This means that the linkage parts play a significant role to array helices. The flexible mobility of our linkage parts results in two steps of denaturation. The design of linkage parts will be important for specific functions of artificial proteins.

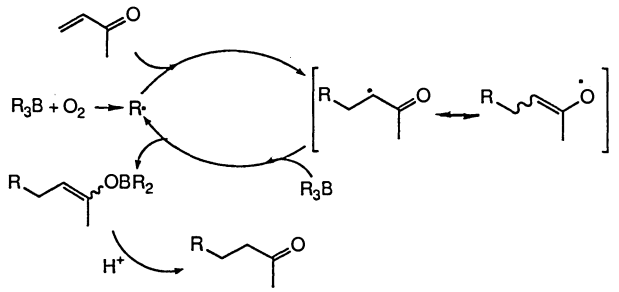
Trialkylborane as an Initiator and Terminator of Free Radical Reactions. Facile Routes to Boron Enolates via α-Carbonyl Radicals and Aldol Reaction of Boron Enolates

Kyoko NOZAKI, Koichiro OSHIMA,* and Kiitiro UTIMOTO*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 29, 1990)

A variety of trialkylborane-induced reactions were examined for the preparation of the α-carbonyl radicals: (1) addition of alkyl radical to methyl vinyl ketone, (2) reduction of α-halo ketone, and (3) intramolecular radical addition to α,β-unsaturated carbonyl moiety. Trialkylborane reacted with α-carbonyl radicals to give boron enolates. The resulting boron enolates were efficiently trapped by carbonyl compounds to give β-hydroxy ketones in good yields.

For the past two decades, there have been much effort to develop the utility of organoborane compounds in organic synthesis. Radical reaction is one of the most important synthetic methods in organoborane chemistry.[1] The 1,4-addition of R_3B to α,β-unsaturated carbonyl compounds was reported by Suzuki et al. in 1967.[2] Generally, trialkylboranes react with neither carbonyl compounds nor carbon-carbon unsaturated bonds. The unusual reactivity of α,β-unsaturated carbonyl compounds was originally explained by six-membered ring transition state. Further investigation by Suzuki and Brown[3] proved this reaction to proceed via radical mechanism by the fact that 5 mol% of galvinoxyl free radical (2,6-di-*t*-butyl-α-(3,5-di-*t*-butyl-4-oxo-2,5-cyclohexadien-1-ylidene)-*p*-tolyloxyl free radical) completely interrupted the reaction (Scheme 1).[4]



Scheme 1.

The structure of the intermediate boron enolate was confirmed with ^1H NMR by Köster et al.[5,6] We came to be interested in this radical trapping step where α-carbonyl radical reacted with trialkylborane to give boron enolate. In this paper we would like to report radical reactions in which trialkylborane acts as an initiator of radical reactions and, at the same time, works as a terminator to trap the α-carbonyl radical.[7]

First, addition of other radicals than R group of trialkylborane (R_3B) to α,β-unsaturated carbonyl compounds was investigated as a method to obtain α-carbonyl radicals. It is known that trialkylborane reduces active halides, such as benzyl bromide, via radical mechanism. Alkyl radical generated by the reaction of trialkylborane with oxygen abstracts the bromine atom of benzyl bromide to give benzyl radical.[1] We treated *t*-butyl iodide with triethylborane in the hope that *t*-butyl radical would be formed by the action of ethyl radical and that *t*-butyl radical would react with α,β-unsaturated carbonyl compound prior to ethyl radical. In fact, treatment of *t*-butyl iodide (3.0 mmol) with triethylborane[8] (1.0 mmol) in benzene in the presence of methyl vinyl ketone (1.0 mmol) and benzaldehyde (1.0 mmol) gave the three component coupling product **4a** (63% yield as a 66/34 diastereomeric mixture) along with the compound **4e** (2% yield) derived from the reaction of ethyl radical instead

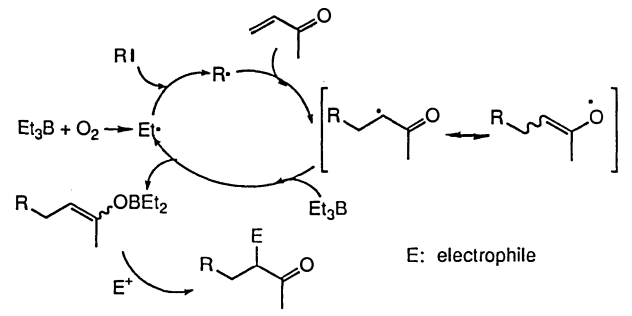
Scheme 2.



Scheme 3.

of *t*-butyl radical (Scheme 2). We are tempted to assume the following radical cycle reaction mechanism (Scheme 3).

The success of the reaction is ascribed to the characteristics of Et_3B which plays critical two roles: (1) initiation of the radical reaction generating *t*-butyl radical from *t*-butyl iodide and (2) trapping the formed α-carbonyl radical as a boron enolate. Primary iodide such as methyl iodide did not give satisfactory results because ethyl radical from triethylborane competed with primary alkyl radical from alkyl iodide and a mixture of two products were obtained. Not only secondary or tertiary alkyl iodide but also diiodide or perfluoroalkyl iodide such as diiodomethane, perfluorohexyl iodide gave the corresponding adducts in good yield. In the case of Suzuki-Brown's or Köster's work, the nature of the alkyl radicals adding to methyl vinyl ketone are limited because they have to be attached on boron atom directly and therefore hydroboration was mainly used for the preparation of radical sources as trialkylboranes. Meanwhile, in our method, variety of radicals can be used for this purpose taking advantage of the reductive nature of trialkylborane. Methanol worked as an electrophile so efficient as aldehydes affording β-alkylated ketones. The results are summarized in Table 1. In the reaction of diiodomethane, methyl vinyl ketone, and methanol, the use of trioctylborane instead of Et_3B gave octyl iodide indicating the reduction of diiodomethane by octyl radical.

Second, one-electron reduction of α-halo ketones with Ph_3Sn radical was employed to produce α-carbonyl radicals. Recently we have shown that Et_3B is an effective initiator to give triaryltin or triarylgermanium radical from their corresponding hydride in the presence of trace amount of oxygen,[9,10] and that the new system, R_3SnH-Et_3B, enabled us to provide highly selective free radical reactions at lower temperature, e.g. −78 °C.[10,11] Here, this R_3SnH-Et_3B system was utilized for the reductive enolization of α-halo ketones.[12]

The Reformatsky type reaction was carried out as follows. Triethylborane (1.1 mmol) was added to a solution of α-bromo ketone (1.0 mmol) and aldehyde (1.0 mmol) in benzene at 25 °C under an argon atmosphere. To this mixture was slowly added Ph_3SnH (1.0 mmol) to afford β-hydroxy ketone in good yield. In this reaction Et_3B worked as (1) an initiator of the radical reaction generating triphenyltin radical and (2) a terminator trapping the α-carbonyl radical as a boron enolate. The representative results are shown in Table 2. The reaction proceeded chemoselectively so that only formyl group reacted in the presence of ketone (Entries 2 and 14 in Table 2). Whereas the reaction of 7-bromo-6-dodecanone with benzaldehyde gave a mixture of *erythro*- and *threo*-β-hydroxy carbonyl compound (Entry 12 in Table 2), α-bromocyclopentanone or α-bromocyclohexanone provided *threo* adducts with high stereoselectivities.[13] The presence of 5 mol% of galvinoxyl effectively stopped the reaction of α-bromoacetophenone and benzaldehyde. This reaction can be explained by the following radical cycle (Scheme 4).

The reaction of α-iodo ketones with carbonyl compounds proceeded without Ph_3SnH. For instance, an addition of Et_3B to a solution of α-iodoacetophenone and benzaldehyde in benzene gave 1,3-diphenyl-3-hydroxy-1-propanone in 86% yield.[14] The results are also shown in Table 2. The *erythro/threo* ratios of the products were exactly the same as those obtained from the reaction of α-bromo ketones. In this reaction Et_3B also worked as (1) an initiator of the radical reaction generating α-carbonyl radical from α-iodo ketone and (2) a terminator trapping this radical as a boron enolate. The presence of 5 mol% of galvinoxyl also interrupted the reaction of α-iodoacetophenone and benzaldehyde effectively.

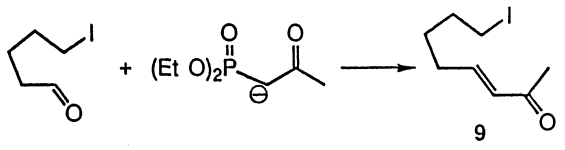
Third, we synthesized 8-iodo-3-octen-2-one (**9**) expecting the intramolecular cyclization under reductive conditions to give an α-carbonyl radical. Treatment of **9** and benzaldehyde with Ph_3SnH-Et_3B gave the cyclized aldol adduct (**10**) in 70% (a mixture of *erythro/threo* or *threo/erythro*=63/37).

To the best of our knowledge, there had been no practical method for this one step cyclization-aldol condensation reaction. 8-Iodo-3-octen-2-one was synthesized from 5-iodopentanal by Horner-Wadsworth-Emmons reaction.[15]



Experimental

Distillation of the products was performed by the use of Kugelrohr (Büchi), and boiling points are indicated by an air bath temperature without correction. All melting points were obtained on a Yanaco MP-50929 melting points apparatus and are uncorrected. The IR spectra were determined on a JASCO IR-810 spectrometer, the mass spectra on a Hitachi M-80 machine, the ^1H and ^{13}C NMR spectra on a Varian XL-200 spectrometer. The chemical shifts of the ^1H NMR are given in δ with Me_4Si as an internal standard, and those of the ^{13}C NMR are given in δ with $CDCl_3$. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyls. Purification of products was performed by column chromatography or preparative thin-layer chromatography (TLC) on silica gel.

General Procedure for Three Component Coupling Reaction of Alkyl Iodide, Methyl Vinyl Ketone, and Carbonyl Compound. The reaction of t-BuI and methyl vinyl ketone with benzaldehyde is representative. A benzene solution of methyl vinyl ketone (70 mg, 1.0 mmol) was added to a solution of t-butyl iodide (0.55 g, 3.0 mmol), Et_3B (1.0 M hexane solution, 1 M=1 mol dm^{-3}, 1.0 ml, 1.0 mmol), and benzaldehyde (0.11 g, 1.0 mmol) in benzene at 25 °C under an argon atmosphere. After stirring for 5 min, concentration of the resulting mixture in vacuo followed by purification by preparative TLC gave 3-(α-hydroxybenzyl)-5,5-dimethyl-2-hexanone (**4a**, 0.15 g) in 63% yield (*erythro/threo*=71/29) along with 3-(α-hydroxybenzyl)-2-hexanone (**4e**, 5 mg, 2%, *erythro/threo*=70/30). Assignment of the stereochemistry of *erythro*- and *threo*- isomers was based on the chemical shift and coupling constant of the carbinol proton (PhCH (OH)R). Heathcock et al. have reported that *threo*-isomers exhibited signals of larger coupling

constant at higher field than those for protons in *erythro*-isomers for the aldol type adduct PhCH(OH)CH(Me)C(=O)R.[16]

erythro-3-(α-Hydroxybenzyl)-5,5-dimethyl-2-hexanone (*erythro*-**4a**): Mp 87.8—88.0 °C (hexane); R_f=0.38 (hexane/ethyl acetate=3/1); IR (neat, before crystallization) 3426, 3024, 2934, 1686, 1466, 1390, 1364, 1055, 743, 699 cm^{-1}; ^{1}H NMR δ=0.74 (s, 9H), 1.60 (dd, *J*=1.4, 14.1 Hz, 1H), 1.87 (dd, *J*=9.7, 14.1 Hz, 1H), 2.02 (s, 3H), 2.42 (d, *J*=2.6 Hz, 1H, -OH), 2.95 (ddd, *J*=1.4, 5.5, 9.7 Hz, 1H, RCHC(=O)Me), 4.75 (dd, *J*=2.6, 5.5 Hz, 1H, PhCH(OH)R), 7.37 (bs, 5H). Found: C, 76.88; H, 9.46%. Calcd for $C_{15}H_{22}O_2$: C, 76.87; H, 9.68%.

threo-3-(α-Hydroxybenzyl)-5,5-dimethyl-2-hexanone (*threo*-**4a**): Bp 150 °C (bath temp, 1.0 Torr, 1 Torr=133.322 Pa); R_f=0.31 (hexane/ethyl acetate=3/1); IR (neat) 3404, 3028, 2954, 2864, 1701, 1474, 1365, 1156, 699 cm^{-1}; ^{1}H NMR δ=0.77 (s, 9H), 1.20 (dd, *J*=2.2, 14.2 Hz, 1H), 1.79 (dd, *J*=9.4, 14.2 Hz, 1H), 2.15 (s, 3H), 2.68 (bs, 1H, -OH), 3.05 (ddd, *J*=2.2, 7.4, 9.4 Hz, 1H, RCHC(=O)Me), 4.62 (bd, *J*=7.4 Hz, 1H, PhCH(OH)R). Found: C, 76.60; H, 9.46%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

erythro-3-(α-Hydroxybenzyl)-2-hexanone (*erythro*-**4e**): R_f=0.42 (hexane/ethyl acetate=3/1); IR (neat) 3340, 2956, 2928, 2870, 1701, 1458, 1356, 700 cm^{-1}; ^{1}H NMR δ=0.85 (t, *J*=7.2 Hz, 3H), 1.10—1.40 (m, 2H), 1.55—1.80 (m, 2H), 2.00 (s, 3H), 2.74 (d, *J*=2.5 Hz, 1H, -OH), 2.90 (m, 1H), 4.88 (dd, *J*=2.5, 5.8 Hz, 1H, PhCH(OH)R), 7.40 (s, 5H). ***erythro*-3-(α-Hydroxybenzyl)-5-iodo-2-pentanone (*erythro*-4c):** The title compound quickly decomposed at room temperature under air. R_f=0.27 (hexane/ethyl acetate=3/1); IR (neat, for a mixtire of *erythro*/*threo*=61/39) 3382, 2920, 1702, 1492, 1453, 1356, 1175, 1051, 1025, 762, 700 cm^{-1}; ^{1}H NMR δ=2.08 (s, 3H), 2.15 (m, 1H), 2.45 (m, 1H, -OH), 3.00 (m, 2H), 4.98 (d, *J*=5.6 Hz, 1H, PhRCHOH), 7.35 (bs, 5H).

***threo*-3-(α-Hydroxybenzyl)-5-iodo-2-pentanone (*threo*-4c):** The title compound also quickly decomposed at room-temperature under air. R_f=0.27 (hexane/ethyl acetate=3/1); ^{1}H NMR δ=2.20 (s, 3H), 2.15 (m, 1H), 2.45 (m, 1H, -OH), 3.00 (m, 2H), 4.79 (d, *J*=7.3 Hz, 1H, PhRCHOH), 7.35 (bs, 5H).

The structures of *erythro*- and *threo*-3-(α-hydroxybenzyl)-5-iodo-2-pentanones were confirmed by the reduction of the compounds with *n*-Bu_3SnH–Et_3B to give the corresponding aldol adduct. Tributyltin hydride (0.26 g, 0.90 mmol) and Et_3B (1.0 M in hexane, 0.10 ml, 0.10 mmol) were added to a mixture of *erythro*-**4c**/*threo*-**4c** (161 mg, 0.51 mmol/104 mg, 0.32 mmol) in benzene at 25 °C under an argon atmosphere. After stirring for 1 day to this mixture were added KF (100 mg) and water (1.0 ml). The resulting heterogeneous mixture was stirred vigorously. Filtration, concentration of the organic layer, and purification by silica-gel column chromatography gave 76 mg (0.48 mmol) of *erythro*-3-(α-hydroxybenzyl)-2-pentanone (78% yield) and 48 mg of its *threo*-isomer (78% yield).

erythro-3-(α-Hydroxybenzyl)-2-pentanone: Bp 100 °C (1.0 Torr, bath temp); R_f=0.40 (hexane/ethyl acetate=3/1); IR (neat) 3402, 2964, 2876, 1702, 1456, 1359, 1026, 764, 701 cm^{-1}; ^{1}H NMR δ=0.86 (t, *J*=7.5 Hz, 3H), 1.60—1.85 (m, 2H), 2.02 (s, 3H), 2.75 (bs, 1H, -OH), 2.84 (m, 1H), 4.90 (d, *J*=6.0 Hz, 1H, RPhCHOH), 7.35 (bs, 5H). Found: C, 74.97; H, 8.46%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

threo-3-(α-Hydroxybenzyl)-2-pentanone: Bp 100 °C (1.0 Torr, bath temp); R_f=0.40 (hexane/ethyl acetate=3/1); IR (neat) 3412, 2964, 2932, 2876, 1703, 1455, 1358, 1213, 1169, 767, 701 cm^{-1}; ^{1}H NMR δ=0.83 (t, *J*=7.5 Hz, 3H), 1.30—1.75 (m, 2H), 2.16 (s, 3H), 2.78 (bs, 1H, -OH), 2.87 (m, 1H), 4.80 (d, *J*=7.9 Hz, RPhCHOH), 7.35 (bs, 5H). Found: C, 74.75; H, 8.56%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

***erythro*-5,5,6,6,7,7,8,8,9,9,10,10,10-Tridecafluoro-3-(α-hydroxybenzyl)-2-decanone (*erythro*-4d):** R_f=0.47 (hexane/ethyl acetate=3/1); white solid; IR (neat before crystallization, for a mixture of *erythro*/*threo*=77/23) 3406, 1714, 1364, 1240, 1194, 1145, 1107, 1044, 766, 731, 701 cm^{-1}; ^{1}H NMR δ=2.17 (s, 3H), 2.64 (d, *J*=5.5 Hz, 1H, -OH), 2.75 (m, 2H), 2.70 (m, 1H, R^1R^2CHC(=O)Me), 4.76 (dd, *J*=5.5, 7.2 Hz, 1H, PhCH(OH)R), 7.33 (m, 5H). ***threo*-5,5,6,6,7,7,8,8,9,9,10,10,10-Tridecafluoro-3-(α-hydroxybenzyl)-2-decanone (*threo*-4d):** R_f=0.47 (hexane/ethyl acetate=3/1); ^{1}H NMR δ=1.89 (s, 3H), 2.40 (d, *J*=2.5 Hz, 1H, -OH), 2.70 (m, 2H), 3.29 (m, 1H, R^1R^2CHC(=O)Me), 4.75 (dd, *J*=2.5, 7.0 Hz, 1H, PhCH(OH)R), 7.36 (m, 5H).

Methanol Quenching of the Boron Enolates Generated by the Radical Addition of Alkyl Iodide to Methyl Vinyl Ketone in the Presence of Triethylborane. The reaction of *t*-BuI and methyl vinyl ketone is representative. A benzene solution of methyl vinyl ketone (70 mg, 1.0 mmol) was added to a solution of *t*-butyl iodide (0,55 g, 3.0 mmol), Et_3B (1.0 M hexane solution, 1.0 ml, 1.0 mmol), and methanol (0.08 ml, 2.0 mmol) in benzene at 25 °C under an argon atmosphere. After stirring for 5 min, concentration of the resulting mixture and purification by preparative TLC gave 5,5-dimethyl-2-hexanone[17] (**5a**, 0.10 g, 79% yield) along with 2-hexanone (**5e**, 5 mg, 5%).

5-Methyl-2-hexanone (5b): The compound was identical with the sample purchased from Aldrich Chemical Co.[18]

5-Iodo-2-pentanone (5e): The compound slowly decomposed under air at room temperature. R_f=0.47 (hexane/ethyl acetate=5/1); IR (neat) 2956, 1711, 1453, 1420, 1364, 1221, 1176, 701 cm^{-1}; ^{1}H NMR δ=2.07 (tt, *J*=6.7, 7.0 Hz, 2H), 2.17 (s, 3H), 2.60 (t, *J*=7.0 Hz, 2H), 3.23 (t, *J*=6.7 Hz, 2H).

Found: C, 28.49; H, 4.45%. Calcd for C_5H_9OI: C, 28.32; H, 4.28%.

5,5,6,6,7,7,8,8,9,9,10,10,10-Tridecafluoro-2-decanone (5d): Bp 83 °C (bath temp, 20 Torr), R_f=0.53 (hexane/ethyl acetate=5/1); IR (neat) 2922, 2852, 1723, 1364, 1238, 1194, 1144, 1020 cm^{-1}; ^1H NMR δ=2.23 (s, 3H), 2.42 (m, 2H), 2.78 (t, J=7.5 Hz, 2H). Found: C, 30.55; H, 1.81%. Calcd for $C_{10}H_7OF_{13}$: C, 30.79; H, 1.81%.

Methanol Quenching of the Boron Enolates Generated by the Radical Addition of Diiodomethane to Methyl Vinyl Ketone in the Presence of Trioctylborane. A benzene solution of methyl vinyl ketone (70 mg, 1.0 mmol) was added to a solution of diiodomethane (0.80 g, 3.0 mmol), Oct_3B (1.0 M THF solution, 1.0 ml, 1.0 mmol), and methanol (0.08 ml, 2.0 mmol) in benzene at 25 ° under an argon atmosphere. After stirring for 5 min, concentration of the resulting mixture and purification by preparative TLC gave 5-iodo-2-pentanone (**5a**, 0.11 g, 54% yield) and 0.11 g (48%) of octyl iodide.

Triethylborane Mediated Reformatsky Type Reaction of α-Bromo Ketones[19] (or α-Iodo Ketones[20]) and Carbonyl Compounds. The reaction of α-bromoacetophenone and benzaldehyde is representative. A hexane solution of Et_3B (1.0 M, 1.1 ml, 1.1 mmol) was added to a solution of α-bromoacetophenone (0.20 g, 1.0 mmol) and benzaldehyde (0.11 g, 1.0 mmol) in benzene (3.0 ml) at 25 °C under an argon atmosphere. To the mixture was added slowly a benzene solution of Ph_3SnH (0.2 M, 5.0 ml, 1.0 mmol) and the resulting mixture was stirred for 5 min at 25 °C. Then 100 mg of KF and 1.0 ml of water were added and the mixture was stirred vigorously. Filtration and purification by preparative TLC on silica gel gave 1,3-diphenyl-3-hydroxy-1-propanone (**8a**, 0.20 g, 88% yield).[21] In the case of α-iodoacetophenone, the reaction proceeded without an addition of Ph_3SnH.

3-Hydroxy-1-phenyl-1,12-tridecanedione (8b): Mp 50.2—50.5 °C (hexane); R_f=0.29 (hexane/ethyl acetate 5/1); IR (neat, before crystallization) 3400, 2910, 2846, 1706, 1681, 1449, 1379, 1270, 1166, 1079, 752, 688 cm^{-1}; ^1H NMR δ=1.25—1.70 (m, 16H), 2.14 (s, 3H), 3.03 (dd, J= 8.6, 17.7 Hz, 1H), 3.20 (dd, J=3.1, 17.7 Hz, 1H), 3.24 (bs, 1H, -OH), 4.20—4.35 (m, 1H, R^1R^2CHOH), 7.50—7.70 (m, 3H), 8.00—8.03 (m, 2H). Found: C, 74.78, H, 9.27%. Calcd for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27%.

1-(2-Oxo-2-phenylethyl)cyclohexanol (8c): Mp 77.0—77.2 °C (hexane); R_f=0.70 (hexane/ethyl acetate=3/1); IR (neat, before crystallization) 3510, 3050, 2934, 2854, 1675, 1448, 1380, 749, 687 cm^{-1}; ^1H NMR δ=1.25—1.90 (m, 10H), 3.12 (s, 2H), 4.00 (s, 1H, -OH), 7.45—7.75 (m, 3H), 7.96—8.07 (m, 2H). Found: C, 77.02; H, 8.32%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%.

***erythro*-2-(1-Hydroxyheptyl)cyclohexanone (*erythro* 8i):** R_f=0.48 (hexane/ethyl acetate=5/1); IR (neat, for a mixture of *erythro*/*threo*=2/98) 3446, 2930, 2856, 1701, 1451, 1312, 1131 cm^{-1}; ^1H NMR δ=0.84 (t, J=6.9 Hz, 3H), 1.15—2.45 (m, 19H), 3.90 (m, 1H), 4.12 (m, 1H); Found (for a mixture of *erythro*/*threo*=2/98): C, 73.32; H, 11.56%. Calcd for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39%.

***threo*-2-(1-Hydroxyheptyl)cyclohexanone (*threo* 8i):** R_f=0.48 (hexane/ethyl acetate=5/1); ^1H NMR δ=0.84 (t, J=6.9 Hz, 3H), 1.15—2.45 (m, 20H), 3.73 (m, 1H).

***erythro*-7-(Hydroxyphenylmethyl)-6-dodecanone (*erythro*-8l):** R_f=0.55 (hexane/ethyl acetate=5/1); IR (for a mixture of *erythro*/*threo*=65/35) 3340, 2922, 2852, 1702, 1458, 1376, 699 cm^{-1}; ^1H NMR δ=0.75—0.95 (m, 6H), 1.05—1.80 (m, 14H), 2.08—2.48 (m, 2H), 2.78—3.06 (m, 2H), 4.88 (dd, J=2.5, 6.0 Hz, 1H), 7.35 (bs, 5H). Found (for a mixture of *erythro*/*threo*=65/35): C, 78.35; H, 10.67%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%.

***threo*-7-(α-Hydroxybenzyl)-6-dodecanone (*threo*-8l):** ^1H NMR δ=0.75—0.95 (m, 6H), 1.05—1.80 (m, 14H), 2.08—2.48 (m, 2H), 2.78—3.06 (m, 2H), 4.80 (d, J=6.9 Hz, 1H), 7.45—7.60 (m, 3H), 7.68—7.77 (m, 2H).

Triethylborane-Mediated Reformatsky Type Reaction of α-Bromoacetophenones and Benzaldehyde in the Presence of Garvinoxyl. A hexane solution of Et_3B (1.0 M, 1.1 ml, 1.1 mmol) was added to a solution of α-bromoacetophenone (0.20 g, 1.0 mmol), benzaldehyde (0.11 g, 1.0 mmol), and Garvinoxyl (42 mg, 0.10 mmol) in benzene (3.0 ml) at 25 °C under an argon atmosphere. To the mixture was added slowly a benzene solution of Ph_3SnH (0.2 M, 5.0 ml, 1.0 mmol) and the resulting mixture was stirred for 5 min at 25 °C. Then 100 mg of KF and 1.0 ml of water were added and the mixture was stirred vigorously. Filtration and purification by preparative TLC on silica gel gave 1,3-diphenyl-3-hydroxy-1-propanone (**8a**, 80 mg, 36% yield) and complex mixture.

Preparation of 8-Iodo-3-octen-2-one. 5-Iodo-1-pentanol (0.80 g, 3.7 mmol) was added dropwise to a dispersion of PDC (pyridinium dichromate, 2.0 g, 5.3 mmol) in CH_2Cl_2 (40 ml) at room temperature under air. After stirring for 1 h, the liquid phase of the resulting mixture was filtered through silica gel. The precipitate was washed with ether (10 ml, twice) and poured on the silica gel. The combined organic layers were concentrated and purified by silica-gel column chromatography to give 0.38 g (1.8 mmol) of 5-iodopentanal in 48% yield. This aldehyde was quite unsta-

ble under air at room tempareture and it was required to carry out the next step immediately. (Diethyloxyphosphinyl)acetone (0.37 g, 1.9 mmol) was added to a generally prepared THF solution of LDA (lithium diisopropylamide, 0.5 M, 3.8 ml, 1.9 mmol) at 0 °C under an argon atmosphere. After stirring for 1 h at 0 °C this yellow brown mixture was transferred into a THF solution of 5-iodopentanal (0.5 M, 3.6 ml, 1.8 mmol) by syringe. The resulting mixture was stirred for 15 min at 0 °C, 15 min at room temperature, and 30 min at THF reflux. After cooling, the reaction mixture was poured into water and extracted by ethyl acetate (10 ml, twice). The combined organic layers were washed with brine. Concentration and purification by silica-gel column chromatography gave 0.20 g (0.77 mmol, 43%) of 8-iodo-3-octen-2-one (**9**): R_f=0.29 (hexane/ethyl acetate=5/1); IR (neat) 2930, 2854, 1697, 1672, 1626, 1426, 1361, 1254, 1206, 1180, 976 cm^{-1}; ^1H NMR δ=1.52—1.75 (m, 2H), 1.78—1.97 (m, 2H), 2.22—2.36 (m, 2H), 2.25 (s, 3H), 3.20 (t, J=6.7 Hz, 2H), 6.10 (d, J=15.9 Hz, 1H), 6.79 (dt, J=15.9, 6.8 Hz, 1H). Found: C, 38.25; H, 5.23%. Calcd for $C_8H_{13}OI$: C, 38.12; H, 5.20%.

Cyclization-Aldol Condensation of 8-Iodo-3-octen-2-one and Benzaldehyde. A benzene solution of Ph_3SnH (0.18 M, 3 ml, 0.55 mmol) was added dropwise to a mixture of 8-iodo-3-octen-2-one (0.13 g, 0.50 mmol), benzaldehyde (58 mg, 0.55 mmol), and Et_3B (1.0 M in hexane, 0.55 ml, 0.55 mmol) in benzene (7 ml) at room temperature under an argon atmosphere. After stirring for 30 min at room temperature, 50 mg of KF and 2 ml of water were added and stirred vigorously. The resulting mixture was filtered through Celite 545 and washed with brine. The aqueous layer was extracted by ethyl acetate (10 ml, twice). Combined organic layers were concentrated and purified by preparative TLC. 81 mg of 3-cyclopentyl-4-hydroxy-4-phenyl-2-butanone (**10**, 0.35 mmol, 70% yield, *erythro/threo* or *threo/erythro*=55/45) was obtained. **10**: R_f=0.37 (hexane/ethyl acetate=5/1); IR (neat, for a mixture of *erythro/threo* or *threo/erythro*=63/37) 3424, 2950, 2868, 1701, 1453, 1353, 760, 731, 700 cm^{-1}; ^1H NMR (for major) δ=1.07—1.40 (m, 2H), 1.40—2.07 (m, 6H), 1.94 (s, 3H), 2.08—2.40 (m, 1H), 2.68 (bs, 1H, -OH), 2.98 (dd, J=6.5, 8.3 Hz, 1H, R^1R^2CHC(=O)Me), 4.97 (m, 1H, PhRCHOH), 7.35 (m, 5H); ^1H NMR (for minor) δ=1.07—1.40 (m, 2H), 1.40—2.07 (m, 6H), 1.86 (s, 3H), 2.08—2.40 (m, 1H), 2.81 (dd, J=4.4, 9.9 Hz, 1H, R^1R^2CHC(=O)Me), 3.92 (bs, 1H, -OH), 4,97 (m, 1H, PhRCHOH), 7.35 (m, 5H). Found (for a mixture of *erythro/threo* or *threo/erythro*=63/37): C, 77.26; N, 8.68%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

Micellar Accelerated Reduction of Ethylenediaminetetraacetatocobaltate(III) by 1-Benzyl-1,4-dihydronicotinamide

Kohichi YAMASHITA, Masahiro CHIBA, Hitoshi ISHIDA, and Katsutoshi OHKUBO*
Department of Applied Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860
(Received October 8, 1990)

The electrostatic and hydrophobic effects of ionic micelles on the reduction of ethylenediaminetetraacetato cobaltate(III) ([Co(edta)]$^-$) by 1-benzyl-1,4-dihydronicotinamide (BNAH) were investigated with dodecyltrimethylammonium chloride (DTAC) and/or sodium dodecyl sulfate (SDS). Cationic DTAC accelerated the reduction of [Co(edta)]$^-$, while anionic SDS retarded the reaction. The micellar effects of DTAC on the present reaction at 30 °C were kinetically analyzed by using the ion-exchange model and the Berezin's approach: the evaluated rate constant, $(1.0\pm0.1—1.1\pm0.4)\times10^{-4}$ mol^{-1} dm^3 s^{-1}, for the micellar-phase reaction was ten times smaller than that, 1.46×10^{-3} mol^{-1} dm^3 s^{-1}, for the aqueous-phase one. This fact was well-explained by the electron-transfer rate constant calculated with the experimentally determined redox potentials of BNAH and [Co(edta)]$^-$. The cationic DTAC micelles, however, resulted in considerably larger value (3.58×10^{-3} mol^{-1} dm^3 s^{-1}) of overall reaction rate constant than that (1.46×10^{-3} mol^{-1} dm^3 s^{-1}) of nonmicellar one, because the apparent concentrations of the reactants in the micellar phase increased remarkably by condensation of BNAH and [Co(edta)]$^-$ to the micelles through the hydrophobic interaction and the electrostatic interaction, respectively.

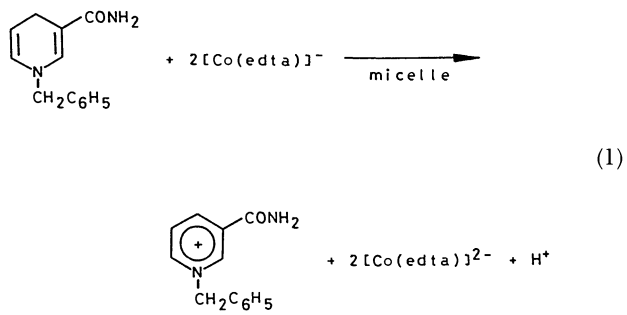
The hydride-transfer reactions from a reduced nicotinamideadenine dinucleotide (NAD(P)H) and its model compounds have been shown to proceed through the sequential electron-proton-electron transfer.[1,2] Since the first electron-transfer step plays a significant role in the reaction of NADH model compounds,[1,2] the reduction of one-electron oxidants such as transition metal complexes by NADH model compounds is useful to evaluate the reactivity of NADH model compounds.[3-9]

Although biochemical processes involving NAD(P)H proceed in a microheterogeneous system composed of an aqueous phase and a lipophilic phase, less attention has been paid to the study of microenvironmental effects on the reaction of NADH model compounds. Since the micellar systems represent a convenient simple model of enzymes to provide important information about the microenvironmental effects on the reaction,[10,11] it is of interest to study the micellar effects on the redox reactions of NADH model compounds.

In a previous paper,[12] we investigated the effects of ionic surfactants on the reduction of hydrophobic and nonionic tris(acetylacetonato)cobalt(III) by 1-benzyl-1,4-dihydronicotinamide (BNAH). The micelles retarded the reaction rates by incorporation of the reactants through the hydrophobic interaction because low polar environments in the micellar phase destabilized the transition states of the reaction.

The reduction of hydrophilic and ionic substrates like ethylenediaminetetraacetatocobaltate(III) ([Co(edta)$^-$] by BNAH might give further information about the micellar effects on the reaction of NADH model compounds, since the ionic micelles can concentrate the ionic substrate by electrostatic interaction.

In this paper, we describe the micellar promoted reduction of [Co(edta)]$^-$ by BNAH in the presence of cationic dodecyltrimethylammonium chloride (DTAC) and anionic sodium dodecyl sulfate (SDS).



(1)

Experimental

The materials and the procedure of reaction were the same as used in the previous work,[12] except that potassium ethylenediaminetetraacetatocobaltate(III) (K[Co(edta)]·2H$_2$O) were prepared according to the literature.[13] The cyclic voltammetry measurements were performed on a Hokuto Denko HA-301 potentiostat/galvanostat by using a glassy carbon working electrode and a saturated calomel reference electrode. The ion-exchange constant for the equilibrium between [Co(edta)]$^-$ and the surfactant counter ion (Cl$^-$) was determined by employing a molecular sieve filtration on Sephadex G-15.[14] A column (diameter=3 cm and bed-height=30 cm) was maintained at 30±0.1 °C with an outer jacket by circulating water. The void volume (V_o) of the packed column was estimated to be 29.0 cm^3 by using Blue Dextran 2000. Before run the column was equilibrated with 1000 cm^3 of 4%(v/v)methanol-borate buffer (pH 9.0, μ=0.02 mol dm^{-3}) containing the surfactants (0—9.0×10^{-2} mol dm^{-3}). The each run was started by the addition of 1.0 cm^3 of 2×10^{-3}mol dm^{-3} K[Co(edta)]·2H$_2$O. Elution with the appropriate eluent was followed at a rate of 1.0 cm^3 min^{-1}. Fractions (0.5—1.0 cm^3) were collected employing an automatic fraction collector and were monitored at 275

nm spectrophotometrically. The elution volume was given by the total volume of the eluent until the fraction gave the maximum absorbance peak of [Co(edta)]$^-$.

Results and Discussion

When BNAH (5.0×10^{-4} mol dm^{-3}) and [Co(edta)]$^-$ (1.0×10^{-3} mol dm^{-3}) were thermally reacted in 4%(v/v)methanol-0.02 mol dm^{-3} H_3BO_3-NaOH buffer (pH 9.0, μ=0.02 mol dm^{-3} with KCl) containing the surfactants of DTAC or SDS (0—6.0×10^{-2} mol dm^{-3}), both absorptions of BNAH (λ_{max}=360 nm) and [Co(edta)]$^-$ (λ_{max}=540 nm) decreased with time. The spectral changes indicated that 2 moles of [Co(edta)]$^-$ were consumed by 1 mole of BNAH. All the present reactions followed by monitoring the absorbance change of [Co(edta)]$^-$ at 540 nm were found to obey the second-order rate law (Eq. 2).

$$-\frac{d[[Co(edta)]^-]}{dt}=2k_{obsd}[BNAH][[Co(edta)]^-]. \quad (2)$$

Therefore, the following mechanism (Eqs. 3a—c) seems appropriate for the reduction of [Co(edta)]$^-$ by BNAH as reported in other systems.[3,12]

$$BNAH+[Co(edta)]^- \longrightarrow BNAH^{\cdot+}+[Co(edta)]^{2-}, \quad (3a)$$

$$BNAH^{\cdot+} \longrightarrow BNA^{\cdot}+H^+, \quad (3b)$$

$$BNA^{\cdot}+[Co(edta)]^- \longrightarrow BNA^+ +[Co(edta)]^{2-}. \quad (3c)$$

Since the reduction potential (E_{red}^0) of [Co(edta)]$^-$ and the oxidation potential (E_{ox}^0) of BNAH in 4%(v/v)methanol-borate buffer were estimated to be -0.53 ± 0.1 and -0.01 ± 0.1 V vs. SCE, respectively, the first electron-transfer reaction (Eq. 3a) is endothermic. The subsequent deprotonation (Eq. 3b) and the second electron-transfer reaction (Eq. 3c) might proceed very quickly as can be seen from the pK_a value of BNAH$^{\cdot+}$ (3.6)[2] and the oxidation potential of BNA$^{\cdot}$ (-1.08 V vs. SCE).[2] Therefore, the first-electron-transfer step (Eq. 3a) may be a rate-determining step, which might suffer micellar effects.

Figure 1 depicts the micellar effects of SDS and DTAC on the second-order rate constant (k_{obsd}) observed for the reduction of [Co(edta)]$^-$ by BNAH under [surfactant]>cmc. The reaction rate was enhanced remarkably by cationic DTAC and was maximized at [DTAC]=4.0×10^{-2} mol dm^{-3}, while anionic SDS retarded the reaction rate. (The broken line in Fig. 1 will be discussed later.)

Since these micellar effects could result from distribution of the reactants between a micellar phase and an aqueous phase,[10,11] the incorporation of BNAH and [Co(edta)]$^-$ into the micelles were evaluated by using the binding constants and the ion-exchange constants, respectively.[15] The binding constants (K_{BNAH}) of BNAH to SDS and DTAC in 4%(v/v)methanol-borate buffer (pH 9.0, μ=0.02 mol dm^{-3}) at 30 °C were determined to be 236 ± 15 and 102 ± 13 mol^{-1} dm^3, respectively, in our previous work.[12]

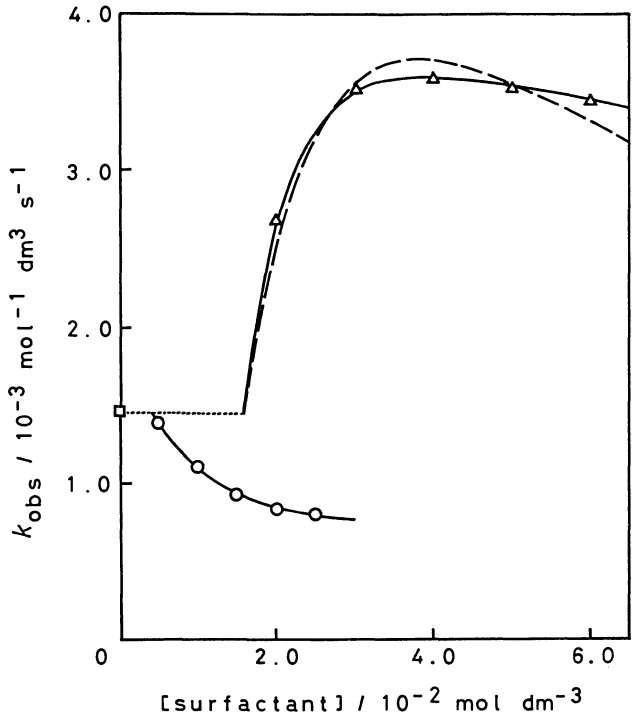


Fig. 1. Micellar effects on second-order rate constants obtained for thermal reduction of [Co(edta)]$^-$ by BNAH with SDS (○) or DTAC (△). The broken line represents the rate constants calculated by Eq. 10.

The ion-exchange constant for the equilibrium between [Co(edta)]$^-$ and the surfactant counter ion was estimated by using a gel filtration chromatography.[14,15] The elution volume (V_e) and the ion-exchange constant (K_1) are related as follows;

$$\frac{1}{V_e-V_o}=\frac{1}{V_i k' K_D}\left(1+K_1\frac{[\overline{Cl^-}]_m}{[\overline{Cl^-}]_w}\right)(1-C_m v), \quad (4)$$

$$k'=(kV_g+V_i)/V_i$$

where V_o and V_i are the void volume and the imbibed (stationary) volume, respectively, V_g is the total volume of a gel matrix, v is the partial molar volume of a surfactant molecule in the micelles, K_D is the molecular sieving constant, C_m, (C_m=[surfactant]—cmc) is the concentration of micelles, k is the constant of proportionality between [Co(edta)]$^-$ absorbed per unit volume of a gel matrix and the equilibrium concentration of [Co(edta)]$^-$ in a liquid phase, $[\overline{Cl^-}]$ is the stoichiometric (bulk) concentration of Cl$^-$, and subscripts w and m refer to an aqueous phase and a micellar phase, respectively.

The concentrations of Cl$^-$ in the micellar phase and in the aqueous phase are calculated by the following equations.[15]

$$[\overline{Cl^-}]_m=(1-\alpha)C_m-[\overline{[Co(edta)]^-}]_m-[\overline{H_2BO_3^-}]_m, \quad (5)$$

$$[\overline{Cl^-}]_w=\alpha C_m+cmc+[\overline{[Co(edta)]^-}]_m+[\overline{H_2BO_3^-}]_m+[\overline{Cl^-}]_{add}, \quad (6)$$

$$K_1=\frac{[\overline{[Co(edta)]^-}]_m\,[\overline{Cl^-}]_w}{[\overline{[Co(edta)]^-}]_w\,[\overline{Cl^-}]_m}, \tag{7}$$

$$K_2=\frac{[\overline{[Co(edta)]^-}]_m\,[\overline{H_2BO_3^-}]_w}{[\overline{[Co(edta)]^-}]_w\,[\overline{H_2BO_3^-}]_m}, \tag{8}$$

$$A\,[\overline{[Co(edta)]^-}]_m^3+B\,[\overline{[Co(edta)]^-}]_m^2+C\,[\overline{[Co(edta)]^-}]_m+D=0, \tag{9}$$

$$A=(1-K_1)(1-K_2),$$

$$B=E(1-K_2)+(K_1[[Co(edta)]^-]_t+[H_2BO_3^-]_t)(1-K_1),$$

$$C=[EK_1+K_1\{[[Co(edta)]^-]_t-(1-\alpha)C_m(1-K_1)\}][[Co(edta)]^-]_t,$$

$$D=-(1-\alpha)C_mK_1K_2[[Co(edta)]^-]_t^2,$$

$$E=\alpha C_m+\mathrm{cmc}+[\overline{Cl^-}]_{add}+K_1[[Co(edta)]^-]_t+(1-\alpha)C_mK_1,$$

where α is the degree of ionization of the micelle, $[\overline{[Co(edta)]^-}]$ and $[\overline{H_2BO_3^-}]$ are the stoichiometric (bulk) concentrations of $[Co(edta)]^-$ and $H_2BO_3^-$, $[\overline{Cl^-}]_{add}$ is the concentration of Cl^- added as KCl, and the subscript t refer to the total concentration. Thus, the $(V_e-V_o)^{-1}$ value is calculated at a given C_m value by using Eqs. 4—9.

When the values of $\alpha=0.2$ and $v=0.256$ mol^{-1}dm^3 were used,[15,16] the data experimentally obtained for the gel filtration chromatography with DTAC were quite adequately simulated by Eq. 4 with values of $K_1=1.2\pm0.1$ and $K_2=0.2\pm0.1$ as shown by the broken line in Fig. 2. On the other hand, the $(V_e-V_o)^{-1}$ values decreased with increasing the SDS micellar concentration. The fact indicates that $[Co(edta)]^-$ is not distributed to the SDS micellar phase due to the electrostatic repulsion between $[Co(edta)]^-$ and anionic SDS. Thus, the anionic SDS micelles retarded the reaction rates by suppressing the reaction of BNAH in the micellar phase with $[Co(edta)]^-$ in the aqueous phase. The K_{BNAH}, K_1, and K_2 values are summarized in Table 1.

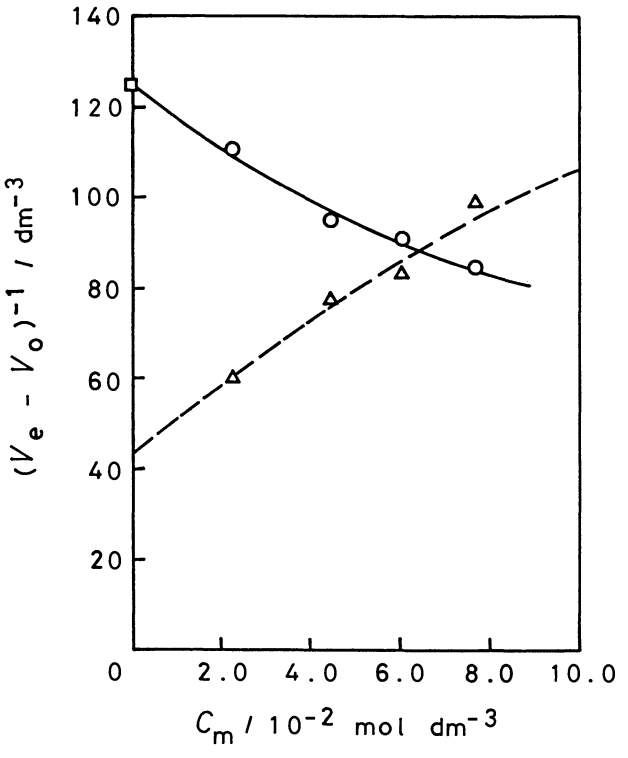

Fig. 2. Plots of $(V_e-V_o)^{-1}$ vs. C_m for elution of $[Co(edta)]^-$ on column of Sephadex G-15 in the presence of SDS (○) or DTAC (△) at 30 °C. The broken line represents the $(V_e-V_o)^{-1}$ values calculated by Eq. 4.

The following reaction scheme can be depicted for the reduction of $[Co(edta)]^-$ by BNAH in the presence of DTAC micelles.[15]

$$\begin{array}{ccc} BNAH_m+[Co(edta)]^-_m & \longrightarrow & \text{products} \\ \uparrow\downarrow K_{BNAH} \quad\quad \uparrow\downarrow K_1 & & \\ BNAH_w+[Co(edta)]^-_w & \longrightarrow & \text{products} \end{array}$$

According to the ion-exchange model, the observed second-order rate constants (k_{obsd}) can be given by Eq. 10.[15]

$$k_{obsd}=\frac{(k^m/v)K_{BNAH}K_1\dfrac{[\overline{Cl^-}]_m}{[\overline{Cl^-}]_w}+k^w}{(1+K_{BNAH}C_m)\left(1+K_1\dfrac{[\overline{Cl^-}]_m}{[\overline{Cl^-}]_w}\right)}, \tag{10}$$

where k^m and k^w are the rate constants of reactions in the micellar phase and the aqueous phase, respectively. The broken line depicted in Fig. 1 shows the second-order rate constants calculated from Eqs. 5—10 by using the above mentioned values of $K_1=1.2\pm0.1$ and $K_2=0.2\pm0.1$, and $\alpha=0.2$. Thus, the rate constants (k^m) of the reaction in the DTAC micellar phase was evaluated to be $(1.0\pm0.1)\times10^{-4}$ mol^{-1}dm^{3}s^{-1} as listed in Table 1. The k^m value obtained by the ion-exchange model was confirmed by comparing with that ($k^m=(1.1\pm0.4)\times10^{-4}$ mol^{-1}dm^{3}s^{-1}) estimated by using the following equations of Berezin's approach in stead of Eqs. 4 and 10.[17]

Table 1. Binding Constants of BNAH to DTAC and SDS (K_{BNAH}), Ion-Exchange Constants for $[Co(edta)]^-$ (K_1 and K_2), and Second-Order Rate Constants (k^w for the Aqueous Phase and k^m for the DTAC Micellar Phase) in 4%(v/v)Methanol-Borate Buffer (pH 9.0) at 30 °C

Surfactant	K_{BNAH}[a] / mol^{-1}dm^3	K_1	K_2	k^w or k^m / 10^{-4} mol^{-1}dm^{3}s^{-1}

SDS	236±15			

a) Ref. 12.

$$\frac{1}{V_e-V_o}=\frac{K_{Co}}{V_i k' K_D}C_m+\frac{1}{V_i k' K_D}, \quad (11)$$

$$k_{obsd}=\frac{(k^m/v)K_{BNAH}K_{Co}C_m+k^w}{(1+K_{BNAH}C_m)(1+K_{Co}C_m)}, \quad (12)$$

where K_{Co} (=15.3±2.8 mol^{-1}dm^3) is the binding constant of [Co(edta)]$^-$ to the micelles.

The second-order rate constant (k^m) in the DTAC micellar phase was ten times as small as that (k^w=(1.46±0.06)×10^{-3} mol^{-1}dm^{3}s^{-1}) in the aqueous phase. This fact suggests that the reactivities of BNAH and [Co(edta)]$^-$ were affected by the microenvironments in the micellar phase. In this regard, the present micellar system including BNAH was not so effective for the formation of substrate-micelle complex and the activation of the substrate as compared with the native enzymatic system including NADH, because the former excludes the functional parts such as histidine, cysteine, and metal ions.

To elucidate the microenvironmental effects of the micelles on the reactivity of BNAH, the oxidation potential (E_{ox}^0) of BNAH and the reduction potential (E_{red}^0) of [Co(edta)]$^-$ were determined with or without DTAC by cyclic voltammetry measurements.[18] The oxidation and reduction peak potentials (E^p) of BNAH and [Co(edta)]$^-$ are related to the transfer coefficient (β) as Eqs. 13—15 based on Rehm-Weller, Marcus, and Marcus-Levine free energy relationships, respectively.[18]

$$E^p=E^0+\frac{1-2\beta}{[\beta(1-\beta)]^{1/2}}\Delta G_0^{\neq}, \quad (13)$$

$$E^p=E^0+4(1-2\beta)\Delta G_0^{\neq}, \quad (14)$$

$$E^p=E^0+\frac{\ln(\beta^{-1}-1)}{\ln 2}\Delta G_0^{\neq}. \quad (15)$$

The transfer coefficient (β) is calculated from Eq. 16 by using the width of the wave ($|E^p-E^{p/2}|$).

$$\beta=\frac{1.857RT}{F|E^p-E^{p/2}|}. \quad (16)$$

Figure 3 depicted the plots according to Eqs. 13—15 for BNAH oxidation with or without 5.0×10^{-2} mol dm^{-3} DTAC in 4%(v/v)methanol-borate buffer. The E_{ox}^0 values of BNAH in the aqueous solution and micellar solution were estimated to be −0.01±0.1 and 0.14±0.1 V vs. SCE, respectively, from the intercepts of the linear plots.[19] On the other hand, the cyclic voltammetry for [Co(edta)]$^-$ in the presence of DTAC was complicated probably due to the electrostatic interaction between [Co(edta)]$^-$ and DTAC. Therefore, the reduction potentials of [Co(edta)]$^-$ were determined in 4%(v/v) and 30%(v/v)methanol-borate buffer (Fig. 4) because the reaction circumstances in the micellar phase have been reported to be akin to those in solution of 30—50%(v/v)methanol-borate buffer.[12] The E_{red}^0 value (−0.44±0.1 V vs. SCE) obtained for [Co(edta)]$^-$ in 30%(v/v)methanol-borate

Table 2. Oxidation Potentials (E_{ox}^0) of BNAH and Reduction Potentials (E_{red}^0) of [Co(edta)]$^-$ with or without 5.0×10^{-2} mol dm^{-3} DTAC in 4%(v/v)Methanol-Borate Buffer (pH 9.0) at 30 °C

[DTAC]	E_{ox}^0	E_{red}^0
10^{-2} mol dm^{-3}	V vs. SCE	V vs. SCE
0	−0.01±0.1	−0.53±0.1
5.0	0.14±0.1	−0.44±0.1[a]

a) Determined in 30%(v/v)methanol-borate buffer without DTAC.

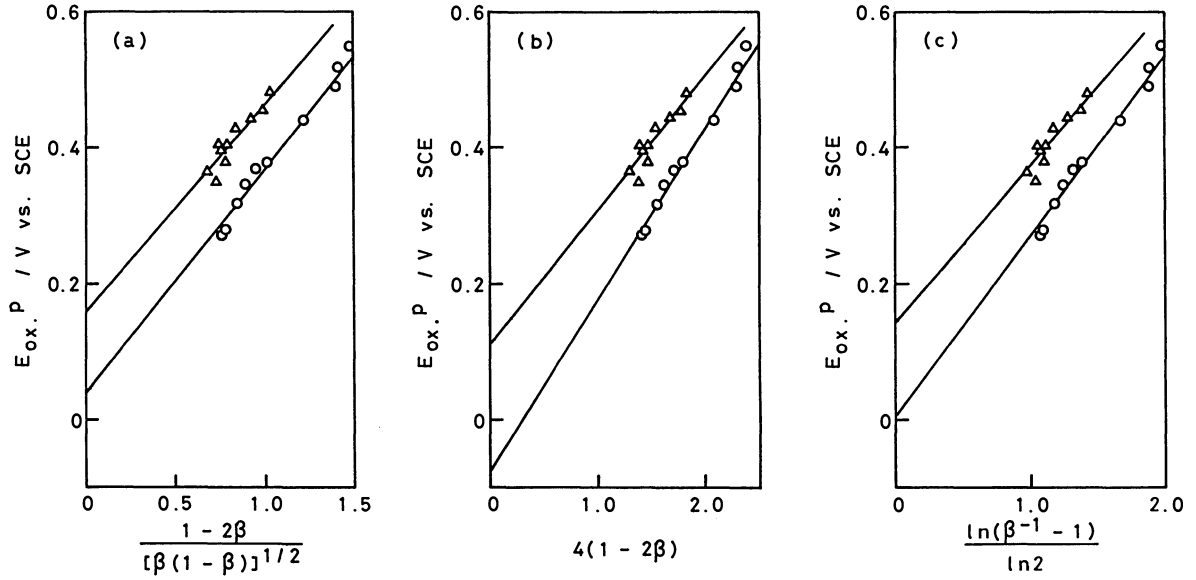

Fig. 3. Plots of E_{ox}^p vs. (a) $(1-2\beta)/[\beta(1-\beta)]^{1/2}$, (b) $4(1-2\beta)$, and (c) $\ln(\beta^{-1}-1)/\ln 2$ for BNAH without surfactants (○) or with 5.0×10^{-2} mol dm^{-3} DTAC (△) in 4% (v/v) methanol-borate buffer.

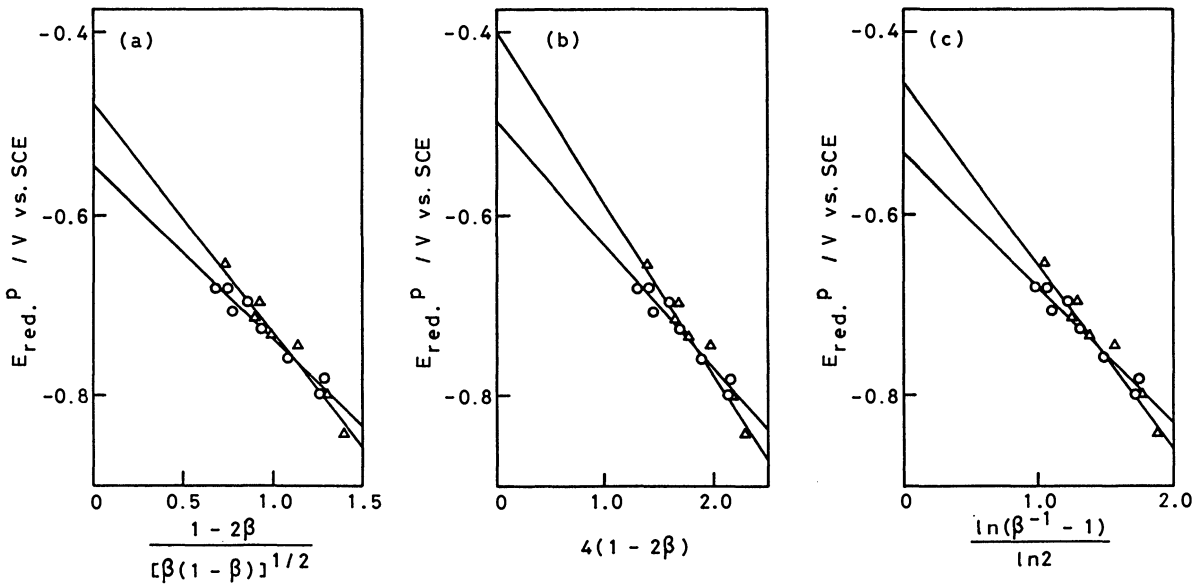

Fig. 4. Plots of E_{red}^{p} vs. (a) $(1-2\beta)/[\beta(1-\beta)]^{1/2}$, (b) $4(1-2\beta)$, and (c) $\ln(\beta^{-1}-1)/\ln 2$ for $[Co(edta)]^-$ in 4% (v/v)- (○) and 30% (v/v) methanol-borate buffer (△).

buffer was slightly positive than that (−0.53±0.1 V) obtained in 4%(v/v)methanol-borate buffer. The E_{ox}^{0} and E_{red}^{0} values were summarized in Table 2.

According to Marcus theory, the rate constant (k_e) of the electron transfer from BNAH to $[Co(edta)]^-$ is related to the E_{red}^{0} and E_{ox}^{0} values by Eq. 17.[21,22]

$$RT \ln k_e = RT \ln K_e k_d + (E_{red}^{0} - E_{ox}^{0}) - (w_p - w_r), \quad (17)$$

where K_e is the equilibrium constant for the formation and the dissociation of the encounter complex ([BNAH $Co(edta)^-$]), k_d is the rate constant for the dissociation of the successor complex ([$BNAH^+$ $Co(edta)^{2-}$]) to $BNAH^{\cdot+}$ and $[Co(edta)]^{2-}$, and w_r and w_p are the work terms required to bring together the reactants and the products, respectively. When the $K_e k_d$ and $(w_p - w_r)$ values were assumed to be constant both in the micellar phase and in the aqueous phase, the k_e value in the micellar phase was calculated to be $k_e = 1.5\times10^{-4}$ $mol^{-1}dm^3s^{-1}$ from Eq. 17 by using the above-mentioned E_{red}^{0}, E_{ox}^{0}, and k^w values. Since the rate constant (k_e) estimated for the reaction between BNAH and $[Co(edta)]^-$ in the micellar phase were very close to that ($k^m = (1.0\pm0.1 — 1.1\pm0.4)\times10^{-4}$ $mol^{-1}dm^3$ s^{-1}) obtained experimentally, the small k^m value in the micellar phase compared with the k^w value in the aqueous phase was attributable to weak reducing ability of BNAH in the micellar phase. That is, low polar microenvironments in the micellar phase are unfavorable for production of ionic species such as $BNAH^{\cdot+}$ and BNA^+. Furthermore, the cationic charge of the DTAC micellar surface suppresses the formation of a positive charge on the nicotinamide ring of BNAH (or BNA·) and the charge separation of produced $[Co(edta)]^{2-}$. Thus, the electron-transfer reaction from BNAH to $[Co(edta)]^-$ was retarded in the DTAC micellar phase. However, the total reaction rate was accelerated by DTAC micelles because $[Co(edta)]^-$ and BNAH were considerably concentrated to the DTAC micellar phase through the electrostatic force and the hydrophobic force, respectively.

Oxidative Cleavage of Diselenide by *m*-Nitrobenzenesulfonyl Peroxide. Novel Method for the Electrophilic Benzeneselenenylations of Olefins and Aromatic Rings

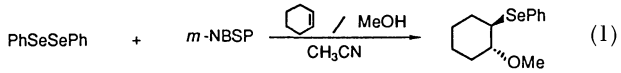
Masato YOSHIDA,* Shuichi SASAGE, Kyoko KAWAMURA, Takashi SUZUKI, and Nobumasa KAMIGATA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received October 23, 1990)

Diphenyl diselenide was found to be readily converted into benzeneselenenyl *m*-nitrobenzenesulfonate ($PhSeOSO_2C_6H_4NO_2$-*m*) by treating with *m*-nitrobenzenesulfonyl peroxide. When the selenenyl sulfonate thus formed was allowed to react in situ with olefins, such as cyclohexene, 1-octene, or styrene, in the presence of various nucleophiles, the adducts of benzeneselenenyl group and a nucleophile were obtained. As the nucleophiles water, methanol, acetic acid, phenol, and anisole could be employed; oxyselenenylated (PhSe-C-C-OR: R=H, Me, Ac, and Ph) and arylselenenylated (PhSe-C-C-C_6H_4OR: R=H and Me) adducts were afforded. Phenol gave oxyselenenylated products in cyclohexene or 1-octene and arylselenenylated products in styrene. Efficient intramolecular cyclizations of unsaturated alcohols and carboxylic acids were similarly performed by the selenenyl sulfonate to afford corresponding benzeneselenenylated cyclic ethers and lactones. The selenenyl sulfonate was also found to be a highly reactive benzeneselenenylating reagent for aromatic rings, such as anisole, phenol, acetanilide, toluene, and benzene.

Organoselenium reagents can be used as nucleophiles, electrophiles, and radicals according to the conditions. Electrophilic selenenylating reagents are usually prepared from oxidative cleavage of diselenide, which is stable and easy to prepare and handle, by halogens,[1] metal ions,[2] electrolytic oxidation,[3] and photoelectron transfer.[4] We are currently interested in the conversion of stable substrates into electrophilic reagents using nitrobenzenesulfonyl peroxides (NBSP).[5] In the course of the study, we found that diphenyl diselenide could be readily converted into electrophilic selenenylating reagent by treating with *m*-nitrobenzenesulfonyl peroxide (*m*-NBSP), and a preliminary communication has appeared.[6] Since we further investigated the electrophilic selenenylations of olefins and aromatic rings using a combination of diphenyl diselenide with *m*-NBSP in detail under various conditions, we report the results as full account.

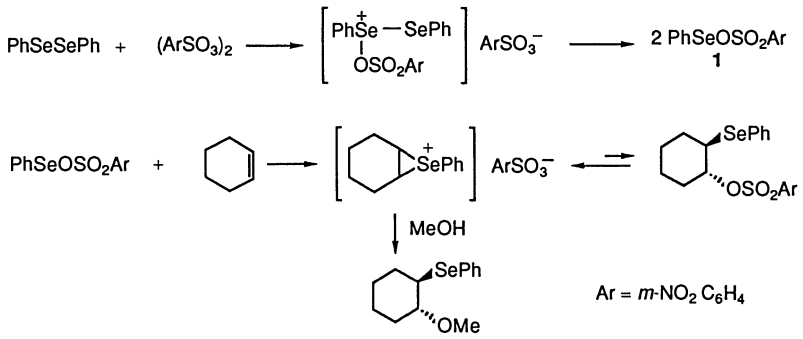
Results and Discussion

Diphenyl diselenide (0.5 mmol) was treated with *m*-NBSP (0.5 mmol) in 20 ml acetonitrile at 0 °C, and then to the resulting solution cyclohexene (1.1 mmol) in 5 ml methanol was added. The anti-adduct of benzeneselenenyl and methoxyl groups to cyclohexene was obtained in 92% yield.



(1)

A plausible mechanism is shown in Scheme 1. Methoxyselenenylations are well-known to occur by the reactions of electrophilic selenenylating reagents with olefins in the presence of methanol,[7] so the formation of cationic benzeneselenenyl species is suggested in the reaction of diphenyl diselenide with *m*-NBSP. We propose benzeneselenenyl *m*-nitrobenzenesulfonate (**1**) as the electrophilic intermediate as shown in Scheme 1. The lone pair on the selenium atom of the diselenide attacks the O-O bond of *m*-NBSP to produce the selenonium salt, and then the cleavage of Se-Se bond gives two moles of benzenesele-



Scheme 1.

nenyl sulfonate.[8] *m*-NBSP is known to behave as a good electrophile in the presence of π- and n-electron donors.[9]

The formation of selenenyl sulfonate **1** was confirmed by ^{13}C NMR studies. Diphenyl diselenide was treated with *m*-NBSP or *p*-NBSP in chloroform-*d*, and ^{13}C NMR was measured to compare with those of benzeneselenenyl trifluoromethanesulfonate. The chemical shifts of the benzeneselenenyl group in benzeneselenenyl *m*-nitrobenzenesulfonate were 130.7, 130.7, 132.5, and 135.8 ppm from internal TMS, and those of bezeneselenenyl *p*-nitrobenzenesulfonate were 130.8, 130.8, 133.2, and 135.6 ppm. The observed chemical shifts were quite similar to those in benzeneselenenyl trifluoromethanesulfonate reported in the literature.[10] Benzeneselenenyl trifluoromethanesulfonate has been prepared from benzeneselenenyl chloride with silver trifluoromethanesulfonate[10,11] or trifluoromethanesulfonic acid.[11]

Electrophilic benzeneselenenylating reagents are known to react with olefins to give episelenonium salts.[7] Although episelenonium salts usually exists in equilibrium with their adducts,[7] the episelenonium nitrobenzenesulfonate did not give adduct, probably because the counter anion, *m*-nitrobenzenesulfonate, is a very stable and weak nucleophile. Therefore, when methanol exists in the reaction system of olefin with **1**, the episelenonium salt thus formed reacts with the methanol to give the adduct of benzeneselenenyl and methoxyl groups (Scheme 1). The anti addition observed in methoxyselenenylation of cyclohexene supports the formation of episelenonium ion. Selenenyl chlorides and bromides have been most widely used for electrophilic selenenylation, however the halide anions act as nucleophiles and often cause an addition of halogen.[7] If it is desired to favor introduction of methanol, the counter anion of episelenonium salt is preferable to be as weak nucleophile as possible. For this purpose it was attempted that selenenyl halides were converted into other selenenylating reagents possessing weak nucleophilic counter anions, such as *N*-phenylselenophthalimide or succinimide.[12] Benzeneselenenyl sulfonates are also expected to be good reagents for oxyselenenylations due to the weak nucleophilicity of sulfonate.[13]

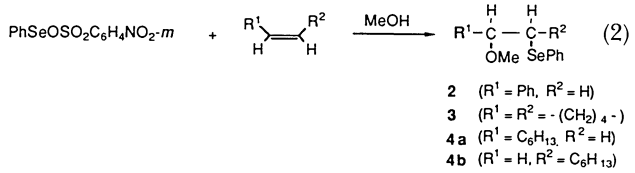
So we investigated the various benzeneselenenylations of styrene, cyclohexene, and 1-octene with **1** in the presence of oxygen nucleophile such as methanol, acetic acid, water, or phenol. Diphenyl diselenide (0.5 mmol) was reacted with *m*-NBSP (0.5 mmol) in a freshly distilled solvent (20 ml), such as dichloromethane, acetonitrile, or nitromethane, and olefin and then nucleophile were added. The results are sum-

Table 1. Reactions of Selenenyl Sulfonate **1** with Olefins in the Presence of Oxygen Nucleophiles

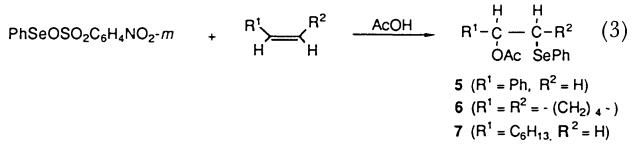
Olefin	Nucleophile		Solvent	Products (Yield/%)[a]
Styrene	MeOH	(5 ml)	CH_3CN	**2** (98)[b]
Cyclohexene	MeOH	(5 ml)	CH_3CN	**3** (92)[b]
1-Octene	MeOH	(5 ml)	CH_3CN	**4a**+**4b** (83)[b,c]
Cyclohexene	MeOH	(5 ml)	CH_2Cl_2	**3** (81)
Cyclohexene	AcOH	(5 ml)	CH_2Cl_2	**6** (trace)
Cyclohexene	AcOH	(5 ml)	CH_3CN	**6** (25)
Cyclohexene	AcOH	(5 ml)	CH_3NO_2	**6** (70)
Styrene	AcOH	(5 ml)	CH_3NO_2	**5** (11)
1-Octene	AcOH	(5 ml)	CH_3NO_2	**7** (73)
Styrene	H_2O	(5 ml)	CH_3CN	**8** (99)
Cyclohexene	H_2O	(5 ml)	CH_3CN	**9** (77), **12** (16)
1-Octene	H_2O	(5 ml)	CH_3CN	**13a**+**13b** (22)[d]
Styrene	H_2O	(5 mmol)	CH_3CN	**8** (61), **11** (Trace)
Cyclohexene	H_2O	(5 mmol)	CH_3CN	**9** (33), **12** (64)
1-Octene	H_2O	(5 mmol)	CH_3CN	**10a** (43),[e] **13a**+**13b** (54)[f]
Styrene	H_2O	(5 ml)	CH_3NO_2	**8** (77)
Cyclohexene	H_2O	(5 ml)	CH_3NO_2	**9** (72)
1-Octene	H_2O	(5 ml)	CH_3NO_2	None
Styrene	PhOH	(10 mmol)	CH_3CN	**16** (78)[b]
Cyclohexene	PhOH	(10 mmol)	CH_3CN	**14** (38)[b]
1-Octene	PhOH	(10 mmol)	CH_3CN	**15** (25)[b]
Styrene	PhOH	(10 mmol)	CH_3NO_2	**16** (82)
Cyclohexene	PhOH	(10 mmol)	CH_3NO_2	**14** (64)
1-Octene	PhOH	(10 mmol)	CH_3NO_2	**15** (62)

a) Products were isolated and the yields were determined based on **1** evaluated from diselenide. b) Data from Ref. 6. c) The products were obtained as a mixture of **4a** and **4b** (80 : 20 by NMR). d) The products were obtained as a mixture of **13a** and **13b** (88 : 12 by NMR). e) A small amount of regioisomer **10b** was contained. f) The products were obtained as a mixture of **16a** and **16b** (84 : 16 by NMR).

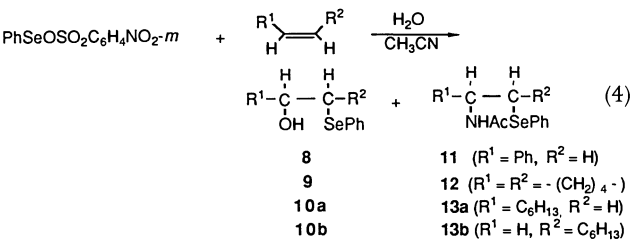
marized in Table 1. Methoxyselenenylation (Eq. 2) proceeded in good to excellent yields regardless of olefins and solvents employed.



On the other hand, the yields of acetoxyselenenylation (Eq. 3) depended on both solvents and olefins employed. Acetoxyselenenylation of cyclohexene proceeded in nitromethane in good yield, however, in dichloromethane the reaction proceeded only to a small extent. The results mean that selenenyl sulfonate **1** is formed in dichloromethane, acetonitrile, and nitromethane, but the acetoxyselenenylation with **1** is extremely influenced by solvents. Thus, acetoxyselenenylations of styrene and 1-octene were examined in nitromethane; although 1-octene afforded **7** in good yield, the yield of acetoxyselnenylated product of styrene (**5**) was only 11%.

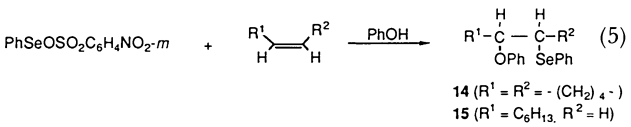


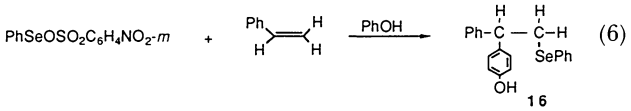
When excess of water (5 ml) was added in acetonitrile, hydroxyselenenylation occurred in good to excellent yields in styrene and cyclohexene to afford **8** and **9**. Hydroxyselenenylation of 1-octene did not occur under similar conditions, but amidoselenenylated product (**13**) was obtained in 22% yield. On the other hand, when small amount of water (5 mmol) was used in acetonitrile, amidoselenenylation of cyclohexene and 1-octene occurred prior to hydroxyselenenylation, but amidoselenenylation of styrene proceeded only in a small yield.



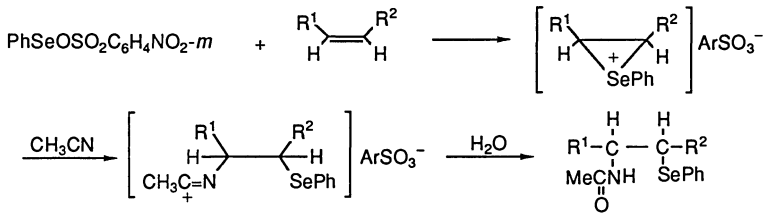
The amidoselenenylation is explained by the reaction of episelenonium ion with acetonitrile as shown in Scheme 2. Amidoselenenylations of olefins have been known to proceed in the reaction of electrophilic benzeneselenenylating reagents with olefin in acetonitrile in the presence of trifluoromethanesulfonic acid and water.[14,15] By the use of nitromethane as a solvent hydroxyselenenylated products of styrene **8** and cyclohexene **9** could be obtained selectively in good yields, however, hydroxyselenenylation of 1-octene did not occur.

Since the nucleophilicity of nitrobenzenesulfonate is very weak, the oxyselenenylation is expected to occur even in the presence of weak oxygen nucleophiles, which are inapplicable with benzeneselenenyl halides. Thus, we investigated the reaction of **1** with olefins in the presence of phenol. Phenoxyselenenylation of cyclohexene and 1-octene occurred in moderate yields in acetonitrile and in good yields in nitromethane (Eq. 5). An unexpected product (**16**) was obtained in the reaction of styrene as shown in Eq. 6. The episelenonium ion produced from the reaction of styrene with **1** electrophilically attacked on the aromatic ring of phenol, whereas those from cyclohexene and 1-octene reacted at oxygen atom of phenol.





The arylselenenylation is interesting as Friedel-Crafts type C-C bond formation. The electrophilic aromatic substitutions of the episelenonium ion with



Scheme 2.

anisole were also observed.[6] When anisole was added to the reaction mixture of diselenide with *m*-NBSP and olefin, the adduct of benzeneselenenyl group and anisole to styrene was obtained in excellent yield in acetonitrile (Eq. 7). *p*-Methoxyphenylselenenylations of cyclohexene and 1-octene also occurred in moderate yields in nitromethane (Eq. 7), but not in acetonitrile. Acetonitrile reacted as nucleophile prior to anisole to give amidoselenenylated products **12** and **13** in 51% and 43% yields, respectively. The aromatic substitutions of the episelenonium ion did not occur in benzene and toluene under similar conditions.

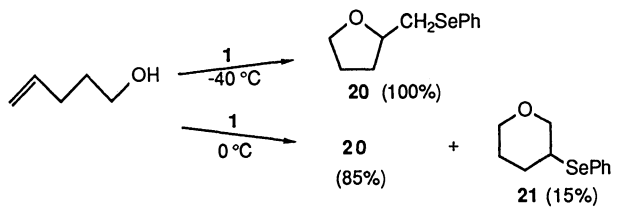
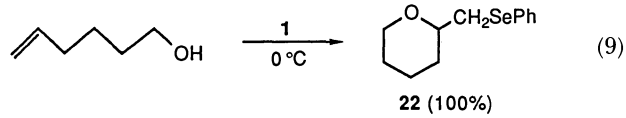
17 (R^1 = Ph, R^2 = H), 96% in CH_3CN
18 (R^1 = R^2 = -$(CH_2)_4$-), 33% in CH_3NO_2
19 (R^1 = C_6H_{13}, R^2 = H), 53% in CH_3NO_2

Intramolecular ring closure by electrophilic activation of an unsaturated alcohol or carboxylic acid is a useful synthetic methodology for the synthesis of complex natural products. The reagents composed of reactive electrophiles and weak nucleophiles are expected to have the particular advantage of being applicable for cyclofunctionalization, and benzeneselenenyl sulfonates were shown to be good reagents for cycloselenenylations.[10,16,17] We have also examined cyclizations of 4-penten-1-ol, 5-hexen-1-ol, 4-pentenoic acid, and 5-hexenoic acid using our method for preparation of selenenyl sulfonate. To the resulting solution of diphenyl diselenide (0.5 mmol) with *m*-NBSP (0.5 mmol) in acetonitrile (20 ml) 4-penten-1-ol was added at −40 °C, and the solution was further allowed to react at −40 °C for 2 h to give cyclic ether **20** almost quantitatively. When the reaction was carried out at 0 °C, small amoumt of the isomer **21** was obtained in addition to **20**. On the other hand, the cyclic ether **22** was obtained as a sole product at 0 °C from 5-hexen-1-ol.

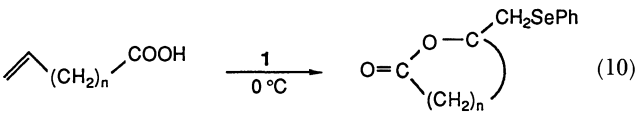


(8)



(9)

Similary, lactones **23** and **24** were obtained from 4-pentenoic acid and 5-hexenoic acid in excellent yields, respectively (Eq. 10).



(10)

23 : n = 2 (93%)
24 : n = 3 (96%)

Although electrophilic selenenylating reagents easily react with olefins, electrophilic aromatic substitutions by benzeneselenenyl group have been scarecely reported in the literature. Most methods for the introduction of areneselenenyl group into aromatic rings were nucleophilic displacement of selenium reagents on halobenzenes bearing an electron-withdrawing group.[18–20] Benzeneselenenyl chloride reacted with electron-rich benzenes as a reagent for chlorination rather than selenenylation.[21] Benzeneselenenyl chloride was converted in situ into benzeneselenenyl hexafluorophosphate, which reacted with anisole to give *p*-methoxyphenyl phenyl selenide and bis(*p*-methoxyphenyl)phenylselenonium hexafluorophosphate.[22] Dimethyl(phenylseleno)sulfonium tetrafluoroborate formed from benzeneselenenyl bromide was reported to be a highly reactive selenenylating reagent for electron-rich aromatic compounds, however, aromatic rings were limited to aromatic amines, phenols, and aromatic ethers.[23] Selenenyl sulfonate **1** also electrophilically reacted with aromatic rings to afford aryl phenyl selenides. To the resulting solution of diphenyl diselenide (0.5 mmol) with *m*-NBSP (0.5 mmol) in dichloromethane or acetonitrile, substituted benzene was added, and the solution was allowed to react at room temperature for 1 h and then refluxed for 2 h. Benzeneselenenyl group was introduced into aromatic rings, and the results are summarized in Table 2.

(11)

The electrophilic aromatic substitutions with **1** described herein proceeded in good to excellent yields for electron-rich benzenes such as anisole, phenol, and acetanilide, selectively at the *p*-position, and also could be applied to even toluene and benzene. Thus, benzeneselenenyl group in **1** was found to act as very reactive electrophile to react not only with olefins but also with aromatic rings.

In conclusion, diphenyl diselenide could be readily converted into very reactive electrophilic selenenylating reagents, benzeneselenenyl arenesulfonate, by the oxidative cleavage of Se-Se bond with *m*-NBSP.

Table 2. Benzeneselenenylation of Aromatic Rings with Selenenyl Sulfonate **1**

ArH/mmol		Solvent	Yield[a)]	Isomer ratio para/ortho[a)]
PhOMe	1.1	CH_2Cl_2	94	98/ 2

a) Yields and isomer ratio were determined by GC.

m-NBSP is readily synthesized from *m*-nitrobenzenesulfonyl chloride with 30% hydrogen peroxide and relatively stable for handling and storage.[24] Thus, the method for electophilic benzeneselenenylation described in this paper is expected to be very attractive and potentially useful in general organic synthesis.

Experimental

^1H NMR spectra were taken with a JEOL JNM PMX 60SI (60 MHz) spectrometer. ^{13}C NMR spectra were taken with a JEOL JNM FX90Q FTNMR spectrometer. IR spectra were recorded on a Hitachi 260-10 spectrometer. Gas chromatography was performed by a Hitachi 263-30 gas chromatograph with SE-30 (10%) 2-m stainless steel column. Gel-permeation chromatography was performed by means of a JAI Model LC-08 liquid chromatograph equipped with two JAIGEL-1H columns (20ϕ×600 mm) with chloroform as eluent. Mass spectra were obtained with a JEOL JMS DX-300 spectrometer by an electron-impact (EI) ionization technique at 70 eV.

Materials. Diphenyl diselenide was obtained from Nacalai Tesque and recrystallized prior to use. *m*-Nitrobenzenesulfonyl peroxide was synthesized from *m*-nitrobenzenesulfonyl chloride and 30% hydrogen peroxide according to the method described in the literature[24] (mp 107 °C (decomp) lit, 112 °C (decomp)). Dichloromethane and acetonitrile were refluxed over calcium hydride and distilled prior to use. Nitromethane was dried over phosphorus pentaoxide and distilled prior to use.

General Procedure for the Preparation of Selenenyl Sulfonate 1. Diphenyl diselenide (0.5 mmol) was dissolved in freshly distilled solvent (20 ml), and solid *m*-NBSP (0.5 mmol) was added to the solution in small portions at 0 °C. The color of the solution turned reddish brown at once, and the resulting solution was further allowed to stir for 10 min at 0 °C and used for reactions in situ.

The Reactions of 1 with Olefins in the Presence of Methanol. Olefin (1.1 mmol) dissolved in methanol (5 ml) was added to the solution of **1** prepared in acetonitrile, and the reaction mixture was allowed to stir at room temperature for 3 h. Ether (20 ml) was added to the reaction mixture, and the solution was washed twice with 20 ml of water, 5% aqueous solution of sodium hydrogencarbonate (20 ml) and then water (20 ml). The separated organic layer from aqueous layer was dried over anhydrous magnesium sulfate, and the solvent was evaporated to give yellow oil, which was subjected to column chromatography on silica gel (Wakogel C-60) to give methoxyselenenylated products (hexane–ethyl acetate 5:1 as eluent). 2-Methoxy-2-phenylethyl phenyl selenide (**2**), 2-methoxycyclohexyl phenyl selenide (**3**) was isolated as pure forms, but 2-methoxyoctyl phenyl selenide (**4a**) could not be separated from a small amount of its regioisomer (**4b**), and these products were identified by comparison of the spectral data with those described in the literature.[25]

The Reaction of 1 with Olefins in the Presence of Acetic Acid. Olefin (1.1 mmol) dissolved in nitromethane and then acetic acid (1 ml) was added to the solution of **1** prepared in nitromethane, and the reaction mixture was allowed to stir for 3 h at room temperature. Ether (20 ml) was added to the reaction mixture, and the solution was washed with 5% aqueous solution of sodium hydrogencarbonate (100 ml) and water (100 ml) twice in order to remove acetic acid and *m*-nitrobenzenesulfonic acid. The organic layer was separated from the aqueous layer and dried over anhydrous magnesium sulfate. The reactions in acetonitrile were similarly performed. When dichloromethane was used as solvent, the reaction mixture was washed with aqueous solution of sodium hydrogencarbonate and water without addition of ether. The evaporation of the solvent left a yellow oil which was subjected column chromatography on Wakogel C-60 to give diphenyl diselenide (hexane as eluent) and acetoxyselenenylated product (hexane–ethyl acetate 5:1). 2-Acetoxy-2-phenylethyl phenyl selenide (**5**), 2-acetoxycyclohexyl phenyl selenide (**6**), and 2-acetoxyoctyl phenyl selenide (**7**) were isolated as almost pure forms and identified by comparison of the spectral data with those described in the literature.[2]

Reactions of 1 with Olefins in the Presence of Water. To the solution of **1** prepared in acetonitrile, olefin (1.1 mmol) and then water (5 mmol) dissolved in acetonitrile was added, and the solution was allowed to react at room temperature for 3 h. After working up the products were separated by column chromatography on Wakogel C-60 using hexane and hexane–ethyl acetate (5:1) as eluent. Amidoselenenylated products (**11**, **12**, **13**)[14] and hydroxyselenenylated products (**8**, **9**, **10**)[26] were identified by comparison of the spectral data with those described in literatures. The reactions in the presence of water (5 ml) in nitromethane and acetonitrile were similarly performed.

The Reaction of 1 with Olefins in the Presence of Phenol. To the solution of **1** prepared in nitromethane or acetonitrile, olefin (1.1 mmol) and then phenol (10 mmol) were added. The reaction mixture was allowed to stir for 3 h at room temperature and worked up as in the case of acetoxyselenenylations. Column chromatography on Wakogel C-60 afforded pure products (hexane–ethyl acetate 5:1 as eluent).

2-(4-Hydroxyphenyl)-2-phenylethyl phenyl selenide (**16**): Yellow oil; ^1H NMR ($CDCl_3$) δ=3.40 (d, J=7.9 Hz, 2H), 4.25 (t, J=7.9 Hz, 1H), 4.63 (s, 1H), 6.44 and 6.88 (ABq, J=9.6 Hz, 4H), and 6.9—7.3 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=34.1, 50.8,

115.5, 126.7, 126.9, 127.8, 128.6, 129.1, 129.1, 129.2, 132.8, 136.0, 144.0, and 154.2; IR (neat) 3340 cm^{-1} (OH); MS *m/z* 354 (M^+); Exact MS 354.0523 (Calcd for $C_{29}H_{18}OSe$: 354.0570).

2-Phenoxycyclohexyl phenyl selenide (**14**): Yellow oil; ^1H NMR ($CDCl_3$) δ=1.0—2.5 (m, 8H), 3.3 (m, 1H), 4.2 (m, 1H), and 6.6—7.7 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=22.9, 25.3, 30.2, 31.2, 46.4, 78.4, 116.3, 121.0, 127.6, 128.4, 128.9, 129.5, 135.4, and 157.7; MS *m/z* 332 (M^+); Exact MS 332.0671 (Calcd for $C_{18}H_{20}OSe$: 332.0678).

2-Phenoxyoctyl phenyl selenide (**15**): Yellow oil; ^1H NMR ($CDCl_3$) δ=0.6—2.3 (m, 13H), 3.05 (d, *J*=6.0 Hz, 1H), 3.10 (d, *J*=3.6 Hz, 1H), 4.27 (m, 1H), and 6.5—7.6 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=14.0, 22.5, 25.3, 29.2, 31.7, 31.8, 34.0, 77.5, 116.1, 120.9, 127.2, 129.0, 129.4, 130.0, 133.3, and 158.0; MS *m/z* 362 (M^+), Exact MS 362.1159 (Calcd for $C_{20}H_{26}OSe$: 362.1158).

The Reaction of 1 with Olefins in the Presence of Anisole. To the solution of **1** prepared in acetonitrile, styrene (1.1 mol) dissolved in anisole (5 ml) was added. The reaction mixture was allowed to stir at room temperature for 3 h, and worked up according to the same procedure described in the case of methoxyselenenylations. The solvent and excess anisole was distilled off in vacuo, and the residue was almost pure 2-(*p*-methoxyphenyl)-2-phenylethyl phenyl selenide (**17**), which was further purified by column chromatography on Wakogel C-60; yellow oil; ^1H NMR ($CDCl_3$) δ=3.49 (d, *J*=7.9 Hz, 2H), 3.70 (s, 3H), 4.25 (t, *J*=7.9 Hz, 1H), 6.74 and 7.05 (ABq, *J*=7.8 Hz, 4H), and 7.1 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=34.1, 50.8, 55.3, 113.9, 126.6, 126.9, 127.7, 128.6, 128.8, 129.1, 130.9, 132.8, 133.0, 135.7, 144.0, and 158.4; MS *m/z* 368 (M^+); Exact MS 368.0679 (Calcd for $C_{21}H_{20}OSe$: 368.0694). Cyclohexene or 1-octene was also allowed to react in nitromethane and worked up as in the case of styrene. The products were separated by preparative layer chromatography (Merck Silica Gel 60 PF) using hexane–chloroform (5 : 1) as eluent. 2-(*p*-Methoxyphenyl)cyclohexyl phenyl selenide (**18**) and 2-(*p*-methoxyphenyl)octyl phenyl selenide (**19**) were further purified by medium-pressure column chromatography (Kusano Kagakukikai Co. CIG Pre-Packed Column CPS-HS-221-05).

2-(*p*-Methoxyphenyl)cyclohexyl phenyl selenide: Mp 136—138 °C (from hexane); ^1H NMR ($CDCl_3$) δ=1.0—2.5 (m, 8H), 2.8 (m, 1H), 3.3 (m, 1H), 3.76 (s, 3H), and 6.8—7.6 (m, 9H), coupling constant between H^1 and H^2 of cyclohexyl group was determined to be 10.0 Hz by spin decoupling technique; ^{13}C NMR ($CDCl_3$) δ=26.5, 27.6, 35.7, 37.1, 49.1, 50.4, 55.2, 113.8, 127.3, 128.2, 128.6, 129.2, 135.7, 137.6, and 158.2; MS *m/z* 346 (M^+); Exact MS 346.0801 (Calcd for $C_{19}H_{22}SeO$: 346.0836).

2-(*p*-Methoxyphenyl)octyl phenyl selenide: Yellow oil; ^1H NMR ($CDCl_3$) δ=0.7—2.1 (m, 13H), 2.5—3.5 (m, 3H), 3.76 (s, 3H), 6.7—7.7 (m, 9H); ^{13}C NMR ($CDCl_3$) δ=14.0, 22.6, 27.5, 29.2, 31.7, 35.9, 36.4, 45.5, 55.2, 113.9, 126.6, 128.4, 128.9, 132.5, 132.7, 136.5, and 158.3; MS *m/z* 376 (M^+); Exact MS 376.1333 (Calcd for $C_{21}H_{28}OSe$: 376.1306).

Reactions of 1 with Unsaturated Alcohols or Carboxylic Acids. To the solution of **1** prepared in acetonitrile 4-penten-1-ol (1.1 mmol) was added at 0 °C or −40 °C. The reaction mixture was allowed to stir at 0 °C for 2 h or −40 °C for 2.5 h and worked up as in the case of methoxyselenenylations. The separated organic layer was dried over anhydrous magnesium sulfate, and the solvent was evaporated. Almost pure tetrahydro-2-(phenylselenomethyl)furan (**20**) was obtained from the reaction mixture at −40 °C. The furan (**20**)[27] was further purified by GPC and identified on the basis of the spectral data. Tetrahydro-3-(phenylseleno)-pyran (**21**),[28] which was obtained from the reaction at 0 °C, could not be separated as pure form. Similarly, the reactions of 5-hexen-1-ol, 4-pentenoic acid, and 5-hexenoic acid were carried out. Tetrahydro-2-(phenylselenomethyl)-pyran (**22**),[27] dihydro-5-(phenylselenomethyl)-2-furanone (**23**),[29] and tetrahydro-6-(phenylselenomethyl)-2-pyranone (**24**)[29] were identified on the basis of spectral data.

Reactions of 1 with Substituted Benzenes. Substituted benzene dissolved in dichloromethane was added to the solution of **1** prepared in dichloromethane, and the solution was allowed to stir at room temperature for 1 h and then refluxed for 2 h. The reaction mixture was washed with 5% aqueous solution of sodium hydrogencarbonate and water, and the organic layer was dried over magnesium sulfate. The products were analyzed by GC-MS and the yields were determined by GC using diphenyl sulfide as an internal standard. The aryl phenyl selenides were isolated by column chromatograpy on Wakogel C-60 and Gel-permeation chromatography. 4-Methoxyphenyl phenyl-selenide,[17] 4-hydroxyphenyl phenyl selenide,[23] 2-hydroxyphenyl phenyl selenide,[23] 4-acetamidophenyl phenyl selenide,[21] 4-methylphenyl phenyl selenide,[20] and diphenyl selenide[30] were identified by their ^1H NMR, ^{13}C NMR, and MS.

Time Courses of the Numbers of Spins from a Single or Two Organic Compounds on a Decationated Y-Type Zeolite

Hiroshi KASHIWAGI
Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani, Toyama 930-01
(Received July 30, 1990)

The time courses of the number of organic radicals produced on the surface of a decationated Y-type zeolite (HY) were followed with electron paramagnetic resonance spectroscopy after the removal of heptane (a solvent). Regardless of the presence of the heptane, the relationship between the amount of adsorption and the number of spins for a binary system of HY and a single organic compound was linear and reversible, suggesting the significance of the presence of an adsorption equilibrium. On the surface of HY, there are two kinds of active sites possessing different times required for attaining constant numbers of spins. Cation radicals from a strong donor (perylene) adsorbed in advance on HY were gradually replaced by those from a weak donor (naphthalene), while a small number of cation radicals from naphthalene adsorbed in advance on HY remained after contact with a sufficiently large quantity of perylene. The coexistence of both donor and acceptor molecules on HY increased the number of both cations and anion radicals, which were significantly dependent on the order of adsorption.

The charge-transfer interaction, resulting in the formation of either cation radicals on solid acid sites or anion radicals on solid base sites on the surfaces of zeolites, was frequently studied using electron paramagnetic resonance (EPR) spectroscopy up to the early 1970's.[1-4] The majority of EPR spectroscopic investigations on the charge-transfer interaction between zeolites and organic compounds were carried out at adsorption equilibrium.[1] These results have been applied, for example, to an evaluation of the activity of zeolites as solid acid or base catalysts and to the construction of a model of active sites.[1]

In general, the content of an organic compound adopted in a mechanistic study of a contact reaction is usually much smaller than that employed in a practical catalytic synthesis. Provided that the spectroscopic studies were carried out with multicomponent systems comprising an aluminosilicate and relatively large quantities of adsorbate molecules, it was observed that some new phenomena occurred only in a complicated system, but disappeared in a simple system. These results might be applicable, for example, to a quantitative evaluation of the activity of practical catalysts.

The time courses of the number of spins induced in a binary system comprising silica-alumina and a large quantity (10%) of glycolic acid after the removal of a solvent were considered quantitatively from both pharmaceutical and mechanochemical points of view.[5] In this case, the number of spins (NOS) was initially small, gradually increased, attained a constant number of spins (CNS), and then decreased from CNS during the final stage.[5] The values of CNS and the duration of CNS (a measure of the oxidation rate or polymerization of glycolic acid) were dependent on the calcination temperature of silica-alumina, on the mechanical energy (shaking or compressing) applied during or after mixing, on the conditions for storing the mixed systems (temperature, atmosphere, or humidity), and on the time interval between mixing and ultraviolet irradiation.[5]

From the viewpoint of surface or catalytic chemistry, we attempted to follow by EPR spectroscopy the time courses of the number of radicals produced from a single or two organic compounds (0.1—10 times the maximal amount of adsorbate molecules/g-HY (A_{max})) adsorbed on the surface of a decationated Y-type zeolite (HY). Since the formation of radicals on HY is attributable to a charge-transfer interaction,[1] the behaviors of radicals from perylene (PE) as a strong donor (ionization potential=6.90 eV),[6] naphthalene (NA) as a weak donor (ionization potential=8.13 eV),[6] tetracyanoethylene (TCNE) as a strong acceptor (electron affinity=2.3 eV),[7] or 1,3-dinitrobenzene (DNB) as a weak acceptor (electron affinity $<$0.7 eV) on HY were compared.

A long time was required for a Hammett indicator adsorbed on an aluminosilicate to attain equilibrium.[8] In the case of HY, the time courses of NOS have not been paid much attention. However, it took a long time for the NOS of an HY-organic system to attain a constant value, suggesting the significance of the presence of nonequilibrium states when HY is applied, for example, to practical contact reactions.

Regardless of the presence of a solvent, the dependence of NOS on the amount of adsorption was found to be linear and reversible in the case of a binary system of HY and a single organic compound, suggesting the significance of adsorption equilibrium. Qualitatively, however, rapid heating or vigorous stirring of this HY-organic system in contact with heptane resulted in an irreversible dependence of NOS on the amount of adsorption. However, the NOS values of ternary systems comprising HY and two organic compounds after the removal of the solvent were suitable for quantitative considerations on this irreversibility. Eventually, cation radicals from a strong donor (PE) adsorbed in advance were gradually replaced by

those from a weak donor (NA), while cation radicals from NA adsorbed in advance remained even after subsequent contact with PE. Further, the coexistence of donor and acceptor molecules on HY increased the number of both the cation and anion radicals, which were considerably dependent on the order of adsorption. Thus, the NOS values of binary (HY-organic) systems behave like being in equilibrium, while those of some ternary (HY-two organic) systems were dependent on the adsorption processes.

The main object of this report is to describe the time courses of NOS with zeolite-organic systems after removing the solvent and to try to search for some new factors necessary for considering NOS of slightly complicated systems, both quantitatively and reproducibly. The obtained results may be available, at least, for improving the reproducibility of some physicochemical data of slightly complicated systems. They may be expected in the future to provide a technique for supplying an HY possessing constant and the desired efficiency or a model of active sites.

Experimental

Materials. An HY was obtained by calcining an NH_4^+-exchanged Y-type zeolite (Si/Al=4.8) at 400 or 650 °C. PE or DNB was recrystallized from toluene or 1/1 (v/v) ethanol/water, respectively. NA and TCNE were purified by sublimation. Freshly distilled heptane was used as a solvent.

Procedure. A binary system of HY and a single organic compound was obtained by impregnating HY with a given volume of a heptane solution (0.1 mol dm^{-3}) of PE, NA, TCNE, or DNB (containing the A_{max} of the organic compound), followed by drying under reduced pressure (ca. 300Pa).

A ternary system of HY and two electron donors or HY and two electron acceptors was obtained by impregnating HY with a given volume of a heptane solution (0.01 mol dm^{-3}) of the first organic compound (containing therein 0.1 times the A_{max} of the organic compound), followed by drying under reduced pressure, soaking again with a given volume of a heptane solution (0.1 mol dm^{-3}) of the second organic compound (containing therein 10 times the A_{max} of the organic compound), and drying again in vacuo. A ternary system arranged in the order HY-TCNE or DNB (A_{max})-PE or NA (A_{max}) or HY-PE or NA (A_{max})-TCNE or DNB (A_{max}) was prepared similarly.

Determination of the Number of Molecules Adsorbed on HY from Heptane Solutions. The number of organic molecules adsorbed when HY (20—50 mg) was brought in contact with a heptane solution (1.0×10^{-4}—3.0×10^{-1} mol dm^{-3}) of an organic compound for a given time of contact (0—72 h) at 25 °C was determined spectrophotometrically.

EPR Measurement. The EPR spectra of the binary and ternary systems were obtained in dry nitrogen at 25 °C with a JEOL JES-FE3X type spectrometer (X band, 100 kHz modulation) at a microwave power of 0.2 mW and a modulation amplitude of 3.2×10^{-3} mT. The NOS values, expressed as spins per gram of dry HY, were estimated by a comparison with standard carbon samples which had previously been calibrated with solutions of 2,2-diphenyl-1-picrylhydrazyl in benzene.[3] The experimental errors in NOS and the amount of organic molecules adsorbed/g-HY were less than 10%.

Results and Discussion

EPR Spectra of Radicals on HY. A fairly well-resolved hyperfine structure was obtained in the EPR spectrum of the PE or NA cation radical or of the DNB anion radical, whereas the spectrum of the TCNE anion radical was unresolved. The EPR spectra of PE, NA, TCNE, and DNB adsorbed on HY were analogous to those reported by Stamires and Turkevich,[2] Flockhart et al.,[3] Hirota et al.,[4] and so on.

An EPR spectrum of a ternary system of HY and two organic compounds was almost the superposition of the spectra of two binary (HY-organic) systems. In addition, one or more band(s) was observed separately from the spectrum of each ion radical. Therefore, the NOS values of two radical species on HY could be determined independently.

Adsorption Equilibrium for Binary Systems during Contact with Heptane Solutions. The adsorption isotherm of PE or TCNE from heptane solutions at 25 °C is shown in Fig. 1. In the low-concentration region of the isotherm, the amount of adsorption is proportional to the number of PE or TCNE molecules in contact with HY, decreasing its increase, and

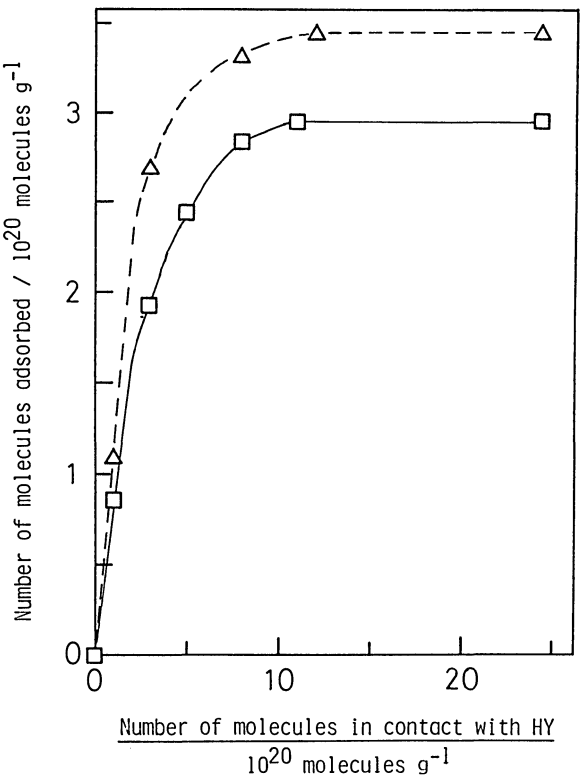

Fig. 1. Room temperature isotherm of PE (□) or TCNE (△) adsorption from heptane solutions on HY calcined at 650 °C.

finally reaching a plateau. Similar results were obtained for the adsorption of NA or DNB.

Figure 2 shows the dependence of the amount of adsorption on the contact time from immediately after bringing HY into contact with heptane solutions (0.1 mol dm^{-3}). During the initial stage, the amount of molecules adsorbed increased linearly with the contact time, decreasing its increase, and finally reaching a plateau. Similar results were confirmed at a PE or TCNE concentration from 0.001 to 0.3 mol dm^{-3} or with the adsorption of NA or DNB. Independent of the calcination temperature of HY (T_{ca}), the time required for reaching the plateau for PE, NA, TCNE, or DNB was ca. 45, 60, 50, or 50 h, respectively.

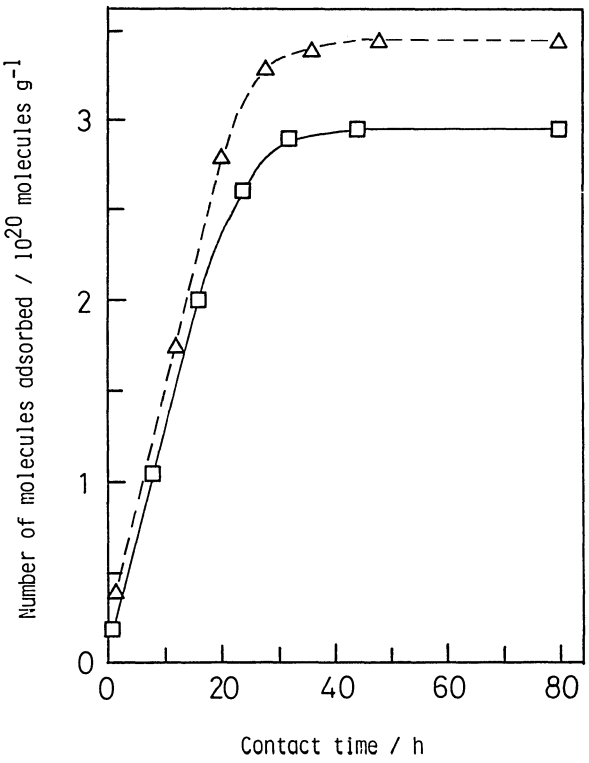

Fig. 2. Time courses of the numbers of PE (□) or TCNE (△) molecules adsorbed on HY calcined at 650 °C from heptane solutions (0.1 mol dm^{-3}) at 25 °C.

Figure 3 illustrates the increase of NOS obtained at the plateau with the adsorption of PE or TCNE from heptane. In agreement with the results of Stamires and Turkevich,[2] NOS increases linearly with an increase in the amount of adsorption, finally reaching the maximal number of spins (g-HY)$^{-1}$ (MNS) at the amount of adsorption of A_{max}. Similar results were obtained with the adsorption of NA or DNB on HY.

The values of A_{max} and MNS as well as g are summarized in Table 1. As shown from Table 1, A_{max} and g are independent of T_{ca}, while MNS is significantly dependent on T_{ca}.

It can be seen from Fig. 3 that the ratio of NOS to the amount of adsorption is independent of the concentrations of the solutions. This suggests the absence of specific parts of HY surfaces advantageous either for the adsorption or for radical formation. That is, both adsorption and radical formation occur

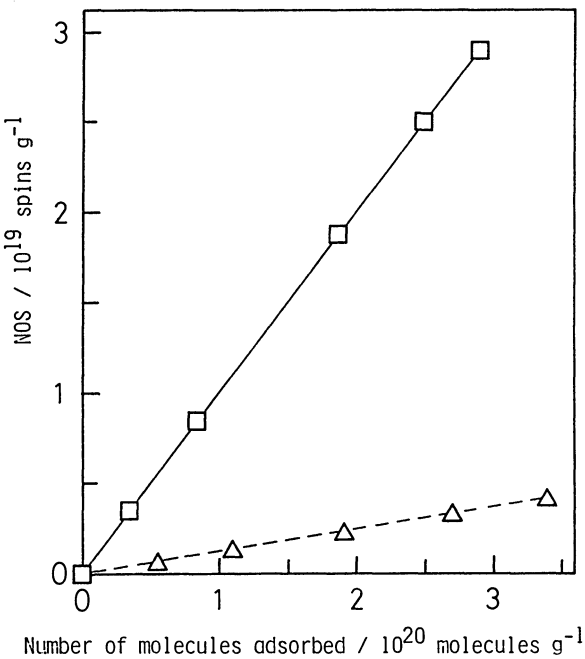

Fig. 3. Increase in NOS with adsorption of PE (□) or TCNE (△) from heptane solutions on HY calcined at 650 °C.

Table 1. Values of g, A_{max}, and MNS for PE, NA, TCNE, or DNB Adsorbed on the Surface of HY

Organic compound	T_{ca} / °C	g	A_{max} / 10^{20} molecules g^{-1}	MNS / 10^{18} spins g^{-1}
PE	650	2.0026	2.9	29
	400	2.0026	2.9	4.1
NA	650	2.0024	6.0	5.4
	400	2.0024	6.0	1.1
TCNE	650	2.0027	3.4	4.2
	400	2.0027	3.4	0.85
DNB	650	2.0041	2.1	2.9
	400	2.0041	2.1	0.26

uniformly on the surface of HY.

When PE or TCNE was desorbed with a large excess of heptane, NOS decreased with a decrease in the number of molecules adsorbed along the same straight line shown in Fig. 3. This reversible relation between NOS and the amount of adsorption may indicate the significance of the presence of an equilibrium upon the adsorption of PE or TCNE on HY from heptane solutions. Though qualitatively, this linear and reversible relationship disappeared when the HY-organic systems were stirred vigorously or heated rapidly during contact with heptane.

Time Courses of NOS for Binary (HY-Organic) Systems Free from Heptane. Figure 4 depicts the time courses of NOS for PE, NA, TCNE, or DNB on HY from immediately after the removal of heptane. NOS is initially small, increases with the passage of time, and finally reached a constant number of spins. CNS increased with an increase in the amount of organic molecules in contact with HY up to A_{max} along the same straight line shown in Fig. 3. The values of CNS were almost identical with those of MNS given in Table 1.

The EPR spectra of these binary systems were unchanged after attaining CNS. A considerable amount of adsorbate molecules were recovered unchanged by desorbing them with a large excess of heptane. CNS decreased with a decrease in the number of adsorbate molecules along the same straight line shown in Fig. 3. This linear and reversible dependence of CNS on the amount of adsorption may support the importance of adsorption equilibrium, even in a heptane-free binary system. Since HY is composed of abundant but relatively weak active sites,[1] radicals produced on HY can possibly remain unchanged for a long time.

The time required for attaining CNS (t_{CNS}) for the HY-organic system in contact with heptane was 45—60 h. The t_{CNS} for a heptane-free system, however, ranges from 1 h (PE on HY calcined at 650 °C) to 140 h (DNB on HY calcined at 400 °C). The rapid diffusion of PE or TCNE molecules may be due to the heat of radical formation on the surface of HY, which might be effectively removed by solvent molecules. CNS increases, while t_{CNS} decreases when a weak donor (NA), weak acceptor (DNB), or HY calcined at a low temperature (400 °C) was employed.

Table 2 shows the dependence of t_{CNS} on the amount of adsorption from 0.1 to 1.0 times A_{max}. The t_{CNS} value for PE or TCNE is independent of the amount of adsorption over the entire region examined. Whereas, the value of t_{CNS} for NA or DNB is near to that for PE or TCNE, respectively, at an adequately decreased amount of adsorption, it increases stepwise, and then remains unchanged at a further increased amount of adsorption. This suggests the coexistence of both an active site possessing a large t_{CNS} and one having a small t_{CNS} on the HY surface. The former may correspond to a weak active site, because a weak donor or acceptor is related to its occurrence.

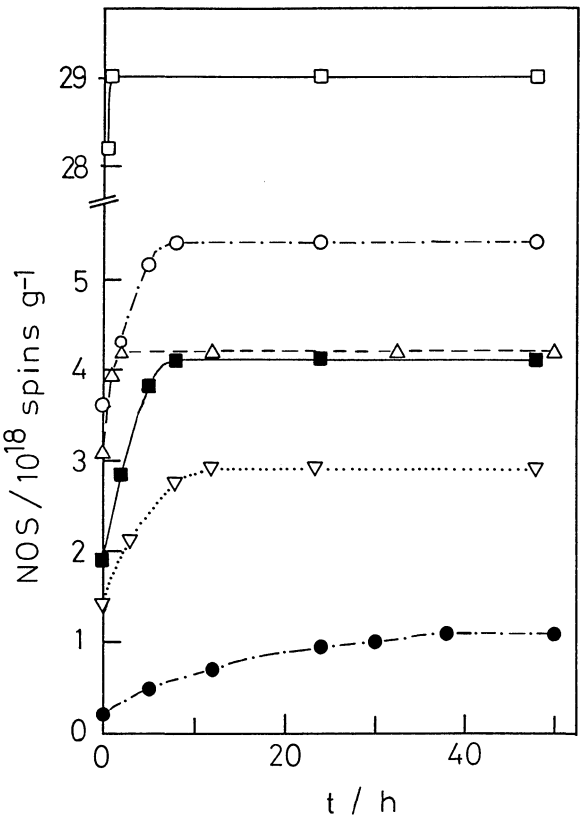

Fig. 4. Time course of the number of PE cation radicals on HY calcined at 650 (□) or 400 (■) °C, of NA cation radicals on HY calcined at 650 (○) or 400 (●) °C, or of TCNE (△) or DNB (▽) anion radicals on HY calcined at 650 °C from immediately after drying HY having been impregnated with a heptane solution (containing A_{max} of the organic compound) under reduced pressure.

Table 2. Dependence of t_{CNS} on the Amount of Adsorption

Organic compound	T_{ca}	t_{CNS}/h				
	°C	A[a)]=0.1	A=0.2	A=0.3	A=0.5	A=1.0
PE	650	1	1	1	1	1
	400	8	8	8	8	8
NA	650	1	1	8	8	8
	400	10	10	40	40	40
TCNE	650	2	2	2	2	2
	400	12	12	12	12	12
DNB	650	2	10	10	10	10
	400	12	120	120	120	120

a) Amount of organic molecules adsorbed divided by A_{max}.

Time Courses of NOS for Two Electron Donors Coexisting on HY. Figure 5 demonstrates a decrease in the number of PE cation radicals and an increase in that of NA cation radicals up to their CNS values, when HY was first adsorbed by PE (0.1 times A_{max}) and

then by NA (10 times A_{max}). The CNS value of the NA cation radicals is almost identical with MNS (shown in Table 1), while that of the PE cation radicals is considerably small.

If a base is gradually added to an aqueous solution containing several acids, the base reacts preferentially with one particular acid possessing the strongest acidity until it is exhausted; it then reacts with another acid having the second strongest acidity. In the case of two donors on HY, however, even cation radicals from a strong electron donor (PE) adsorbed in advance were mostly replaced by those from a weak donor (NA), eventually reaching a new equilibrium. The coexistence of two cation radicals, however, were also qualitatively observed when HY was impregnated with a heptane solution containing both PE and NA.

The t_{CNS} value of PE or NA for this ternary system is considerably greater than that obtained with the corresponding binary system (Fig. 4). CNS for each cation radical increases, while t_{CNS} decreases with an increase in T_{ca}.

A decrease in the number of NA cation radicals and an increase in that of PE cation radicals up to their CNS was obtained with a ternary system adsorbed in the order HY (T_{ca}=650 or 400 °C)-NA (0.1 times A_{max})-PE (10 times A_{max}). Table 3 summarizes CNS and t_{CNS} for two coexisting radical species for this order of adsorption. The CNS value for PE is identical with MNS (Table 1), while a small amount of NA cation radicals remains on HY, even during the final stage.

Different from an acid or base dissolved in a solution, a significant amount of radicals from a weak donor (NA) adsorbed in advance remained at a stationary state attained after subsequent contact with a sufficient quantity of a strong donor (PE).

The t_{CNS} value for NA or PE for this ternary system is much greater than that for the binary system (Fig. 4). CNS increases, while t_{CNS} decreases with an increase in T_{ca}.

Time Courses of NOS for Two Electron Acceptors Coexisting on HY. Figure 6 depicts one curve showing the decrease in the number of TCNE anion radicals and another the increase in the number of DNB anion radicals with a ternary system adsorbed in the HY-TCNE (0.1 times A_{max})-DNB (10 times A_{max})

Table 3. Values of CNS and t_{CNS} for Each Cation Radical[a)]

T_{ca} / °C	Cation radical	CNS / 10^{18} spins g^{-1}	t_{CNS} / h
650	NA	0.06	30
	PE	29	22
400	NA	0.014	95
	PE	4.1	120

a) Order of adsorption: HY (calcined at 650 or 400 °C)-NA (0.1 times the A_{max})-PE (10 times the A_{max}).

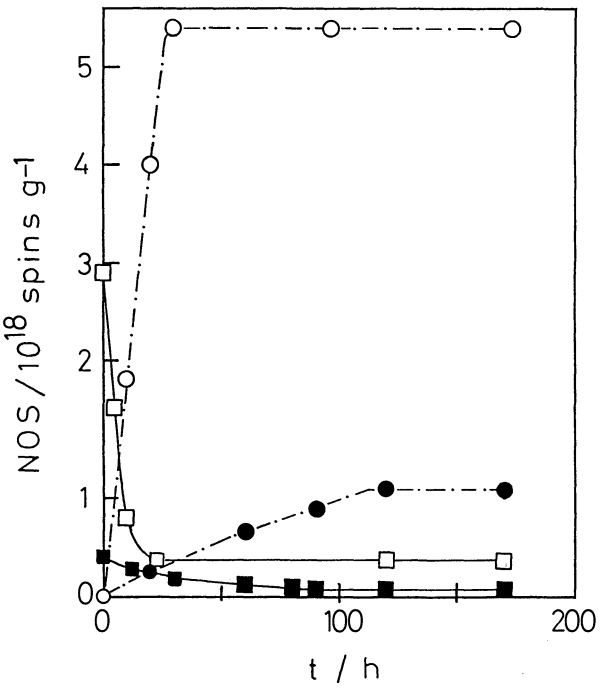

Fig. 5. Time courses of the numbers of PE (□) and NA (○) cation radicals on HY calcined at 650 °C and of PE (■) and NA (●) cation radicals on HY calcined at 400 °C. Order of adsorption: HY-PE (0.1 times the A_{max})-NA (10 times the A_{max}).

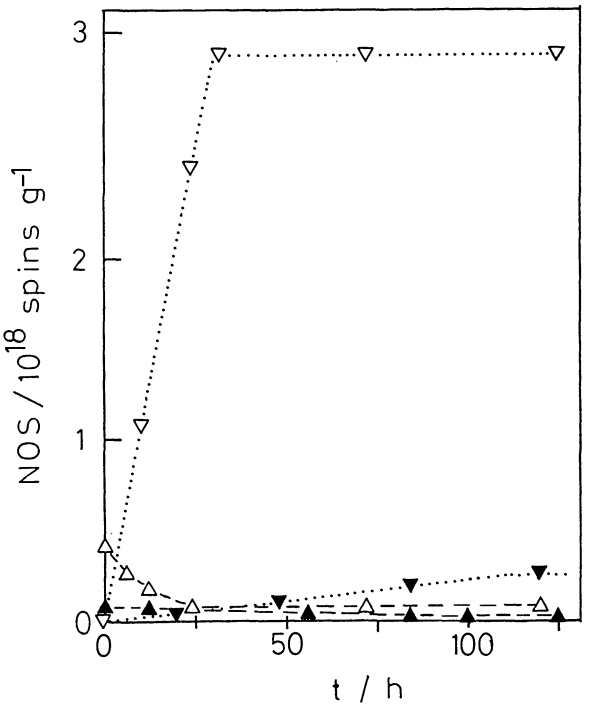

Fig. 6. Time courses of the numbers of TCNE (△) and DNB (▽) anion radicals on HY calcined at 650 °C and of TCNE (▲) and DNB (▼) anion radicals on HY calcined at 400 °C. Order of adsorption: HY-TCNE (0.1 times the A_{max})-DNB (10 times the A_{max}).

Table 4. Values of CNS and t_{CNS} for Each Anion Radical[a)]

T_{ca} °C	Anion radical	CNS 10^{18} spins g^{-1}	t_{CNS} h
650	DNB	0.040	32
	TCNE	4.2	24
400	DNB	0.012	120
	TCNE	0.85	100

a) Order of adsorption: HY (calcined at 650 or 400 °C)-DNB (0.1 times the A_{max})-TCNE (10 times the A_{max}).

Table 5. Values of CNS and t_{CNS} for Coexisting Cation and Anion Radicals on HY[a)]

Order of adsorption	Ion radical	CNS 10^{18} spins g^{-1}	t_{CNS} h
HY-PE-DNB	PE	31.5	6
	DNB	8.0	6
HY-NA-DNB	NA	7.9	10
	DNB	6.4	10

a) Order of adsorption: HY (calcined at 650 °C)-PE or NA (A_{max})-DNB (A_{max}).

order. Table 4 lists the CNS and t_{CNS} of coexisting DNB and TCNE anion radicals in the case of the order of adsorption of HY (T_{ca}=650 or 400 °C)-DNB (0.1 times A_{max})-TCNE (10 times A_{max}). In these cases, anion radicals from a strong acceptor (TCNE) adsorbed in advance were replaced by those from a weak acceptor (DNB), while anion radicals from DNB adsorbed in advance remained even after subsequent contact with a sufficiently large quantity of TCNE.

Time Courses of NOS for Both Donor and Acceptor Molecules Coexisting on HY. Figure 7 shows the time courses of the number of both DNB anions and either PE or NA cation radicals with a ternary system adsorbed in the order HY-DNB-PE or NA. The number of both anions and cation radicals increase with the passage of time up to their CNS. The values of CNS for both anions and cation radicals are much greater than those of MNS shown in Table 1. The ratio of CNS (Fig. 7) to MNS (Table 1) was significant when a weak donor (NA), weak acceptor (DNB), or HY calcined at 400 °C was employed. For example, the ratios for coexisting DNB (A_{max}) and NA (A_{max}) on HY calcined at 400 °C were 3.7 and 4.6, respectively, while those for coexisting DNB (A_{max}) and PE (A_{max}) on HY calcined at 650 °C were 2.4 or 1.1, respectively. Apparently, an increase in the number of solid base sites gives rise to an increase in the number of coexisting solid acid sites, or vice versa.

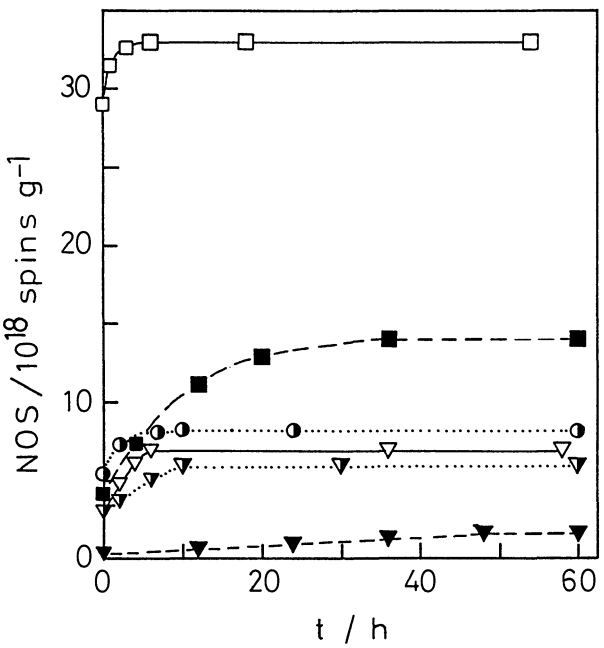

Fig. 7. Time courses of NOS for DNB (▽) and PE (□) on HY calcined at 650 °C, for DNB (▼) and NA (◑) on HY calcined at 650 °C, and for DNB (▼) and PE (●) on HY calcined at 400 °C. Order of adsorption: HY-DNB (A_{max})-PE or NA (A_{max}).

Comparing the time courses of NOS shown in Fig. 7 with those shown in Fig. 4, t_{CNS} for PE or NA in the ternary system increases, while the corresponding t_{CNS} for DNB decreases remarkably. In the neighborhood of CNS, NOS increases rather steeply in the case of DNB, while it increases slowly in the case of coexisting PE or NA. A similar tendency was observed with a ternary system adsorbed in the order HY-TCNE (A_{max})-PE or NA (A_{max}).

Similar time courses of NOS were obtained with a ternary system adsorbed in the order HY (T_{ca}=650 °C)-PE or NA (A_{max})-DNB (A_{max}). Table 5 summarizes CNS and t_{CNS} for two coexisting radical species for this adsorption order.

Dependence of CNS on the Order of Adsorption. In general, a physicochemical property obtained at an equilibrium is independent of the process for reaching equilibrium. Actually, the relationship between CNS and the amount of adsorption for a binary (HY-organic) system was linear and reversible, supporting the importance of equilibrium. As can be seen from Fig. 7 and Table 5, however, the CNS values of a ternary system comprising HY (T_{ca}=650 °C), DNB (A_{max}), and either PE or NA (A_{max}) are significantly dependent on the order of adsorption. On the other hand, the CNS values of this ternary system in contact with heptane were dependent only on the concentrations of two organic compounds, but independent of the order of adsorption.

The dependence on the adsorption order was pronounced for solvent-free systems. The results described above may be applicable to practical catalytic reactions in the solid or gaseous phase. Although it was difficult to observe quantitatively, it occurred in complicated solutions.

The NOS value of a binary system comprising glycolic acid and silica-alumina without a solvent depended on the method of applying mechanical energy (shaking or compressing) or on the time interval between mixing and ultraviolet irradiation.[5] Chemical modifications of the surface energy[9] and mechanochemical transformation of the surface structure or surface property[10] have already been investigated. Then, the dependence of NOS on the order of adsorption may result from either the heat of adsorption or the heat of radical formations.[5] Though this heat may be effectively removed from the surface of HY to the solvent molecules, it may cause a local augmentation in surface energy or a local variation in the surface property in the absence of a solvent.[5,9,10] Other causes of the dependences on the adsorption order will be presented in a subsequent publication.

Interaction between Cation and Anion Radicals Coexisting on HY. Very little radical formation in a mixture of PE and DNB without HY suggests the formation of radicals only on HY. In the case of a ternary system adsorbed in the HY-DNB-PE order at a constant DNB content (A_{max}), CNS for the DNB anion radical increased with an increase in the PE content from 0 (2.9×10^{18} spins/g) to 0.23 times the A_{max} (6.9×10^{18} spins/g), and became unchanged at a further increased PE content. However, CNS for PE (0, 11, or 33×10^{18} spins/g, respectively, at a PE content of 0, 0.23, or 1.0 times the A_{max}) increased, even in the region where CNS for DNB was independent of the PE content. In addition, an observation of the superimposed spectra of the DNB anion and the PE cation radicals suggests little interaction between the anion and cation radicals on HY. Therefore, the formation of anions and cation radicals may occur at different sites.

Practical Application. Probably the most important factor necessary for a quantitative, reproducible consideration concerning the physicochemical properties of slightly complicated systems may be t_{CNS}. A great t_{CNS} usually obtained with an HY-organic system suggests a significant role of nonequilibrium states when HY is used as a practical catalyst. As shown in Fig. 4, the t_{CNS} of PE or TCNE is much smaller than that of NA or DNB. Then, the difference in the spin-generating ability between PE and NA or between TCNE and DNB determined soon after adsorption may be considerably greater than the corresponding difference obtained at equilibrium.

The second factor may be the order of adsorption. Thermodynamically, a physicochemical property obtained at equilibrium is independent of the process to reach equilibrium. Regardless of the presence of heptane, the dependence of CNS of a binary (HY-organic) system on the amount of adsorption was linear and reversible, suggesting the significance of equilibrium. The CNS values of the ternary systems of HY and two organic compounds in contact with heptane was independent of (while those of the ternary system without heptane were dependent on) the adsorption order. The dependence became pronounced when the number of components or the amount of adsorption increased.

The cation radicals formed from two donors or anion radicals from two acceptors on HY exhibited peculiar acid-base characteristics. Further, the CNS of a donor was enhanced by the coexistence of an acceptor. At least, a quantitative consideration of this enhanced radical formation would prompt an improvement in controlling the reproducibility of some physicochemical properties (e. g., the activities of HY as a practical catalyst) of complicated zeolite-organic systems. In the future, a technique for forcing HY to exhibit a constant, desired efficiency might be obtained.

A few results which are probably available for constructing a model of active sites were obtained. As shown in Table 2, there coexist two kinds of active sites on the surface of HY. These exhibit different t_{CNS}. An active site having a small t_{CNS} may correspond to a strong active site, since the PE cation or the TCNE anion radicals on HY calcined at 650 °C is concerned. An active site possessing a large t_{CNS}, however, may correspond to a weak active site, since a weak donor (NA) or acceptor (DNB) on HY calcined at 400 °C is concerned for its occurrence. The latter may play a role in enhanced radical formation in the presence of both a donor and an acceptor or in the dependence on the adsorption order.

Spin-generating sites of HY have been attributed to Lewis acid or base sites, which are known to be produced from Brönsted acid or base sites at a T_{ca} greater than 500 °C.[1,2] However, radicals were produced on HY calcined at 400 °C, especially when HY was in contact with both donor and acceptor molecules. Apparently, an increase in the number of anion radical-generating sites gives rise to an increase in the number of coexisting cation radical-generating sites, or vice versa. Other results necessary for constructing a model of active sites will be described in a subsequent publication.

Exciplex Formation between Perylene and *N,N*-Dimethylaniline in a Ternary Inclusion Compound with γ-Cyclodextrin in H_2O-Ethanol (7:3) Mixture

Sanyo HAMAI
Department of Physics, Miyazaki Medical College, Kiyotake, Miyazaki 889-16
(Received August 1, 1990)

Inclusion compounds in the system of γ-cyclodextrin (γ-CD)-*N,N*-dimethylaniline (DMA)-perylene (Pe) have been studied in an H_2O-ethanol (7:3) mixture by means of absorption and fluorescence spectral measurements. A ternary 1:1:1 inclusion compound of γ-CD-ethanol-Pe is formed by the addition of γ-CD to an H_2O-ethanol solution of Pe. In the presence of γ-CD, a further addition of DMA results in the formation of a γ-CD-DMA-Pe inclusion compound followed by association with a 1:1 γ-CD-DMA inclusion compound to form a ternary 2:2:1 inclusion compound of γ-CD-DMA-Pe. The exciplex fluorescence of Pe-DMA within the γ-CD cavity has been observed from the ternary inclusion compound. Equilibrium constants for the formation of these inclusion compounds have been evaluated.

Cyclodextrins (CDs) are cyclic oligosaccharides consisting of at least six glucose residues which are joined by α-(1→4) linkages. Commercially available α-, β-, and γ-CD have six, seven, and eight glucose units, respectively, and are shaped like a truncated cone having a narrower and a wider end, which has the cavity capable of accommodating many kinds of organic and inorganic substances in aqueous solutions.[1] Among these CDs, γ-CD possessing the largest cavity has been suggested to form 1:2 and 2:2 host-guest inclusion compounds,[2-8] and ternary inclusion compounds.[9-15]

From an induced circular dichroism study, an inclusion of two chlorpromazine molecules entering the single γ-CD cavity has been pointed out.[16] Pyrene and sodium 1-naphthylacetate excimer emissions have been observed in γ-CD aqueous solutions.[7,8,11,17] The 1-naphthylacetate excimer emission has been ascribed to an excimer arising from a ground-state dimer of the guest within the single γ-CD cavity. For the pyrene excimer, however, it has been revealed that the ground-state dimer of pyrene is formed within two γ-CD cavities associating with each other.[8] Owing to the ground-state dimer formation of substrates, themselves, within the γ-CD cavity, it is difficult to investigate the interaction of substrates with other kinds of organic substances within the γ-CD cavity. Until now, there have been few studies on the interaction between different kinds of organic substances bound to the γ-CD cavity in solutions. Thus, as a guest molecule, we selected perylene (Pe), which seems to be too large to form a ground-state dimer within the cavity of a single γ-CD molecule. Because Pe is insoluble in water, an H_2O-ethanol (7:3) mixture was used as the solvent. Although, in general, the formation of inclusion compounds of CDs is unfavored in organic solvents, an alcohol molecule in water associates with 1:1 inclusion complexes of β-CD with pyrene, acenaphthene, fluorene, and 1-naphthonitrile to produce ternary 1:1:1 inclusion compounds.[12,13,15,18-21] In addition, for aromatics such as pyrene, an alcohol molecule included in the β-CD cavity promotes the formation of ternary inclusion compounds formed among β-CD, alcohol, and aromatics. With γ-CD, 1-butanol enables a ground-state pyrene dimer that is positioned inside the γ-CD cavity to dissociate, resulting in the formation of a γ-CD-1-butanol-pyrene inclusion compound.[11] The formation of ternary inclusion compounds of γ-CD-pyrene-alcohol (including ethanol) has also been confirmed.[12-15] Consequently, ethanol as a solvent is anticipated to inhibit the formation of the ground-state Pe dimer within the γ-CD cavity. In this respect, the use of a mixture containing ethanol simplifies the investigation of the interaction between different kinds of guests entering the γ-CD cavity.

Experimental

Perylene (Pe) was purchased from Aldrich and purified by column chromatography. γ-CD (Nakarai) and ethanol (Wako) were used as received. Benzene (Wako) was distilled. Aniline (Wako), *N,N*-Dimethylaniline (Tokyo Kasei), and *N,N*-diethylaniline (Tokyo Kasei) were distilled under reduced pressure.

The absorption spectra were recorded on a Shimadzu 260 spectrophotometer with which spectral data accumulation was repeated 20 times. The fluorescence spectra were obtained with a Shimadzu RF-501 spectrofluorometer equipped with a cooled Hamamatsu R-943 photomultiplier, and were corrected for the wavelength dependence of the sensitivity of the fluorometer. Aerated sample solutions were employed throughout this study, and measured at 25±0.1 °C. A water-ethanol (7:3) mixture was used as the solvent. The concentration of Pe was 3.0×10^{-7} mol dm^{-3}, unless otherwise stated.

Results and Discussion

Inclusion Compound of γ-CD with Pe. Figure 1 shows the absorption spectra of Pe solutions contain-

ing various concentrations of γ-CD. The absorption peaks are red shifted and sharpened accompanied by isosbestic points at 392, 397, 413, 423, and 437 nm, indicating the formation of an inclusion compound consisting of at least γ-CD and Pe. The red shift of the 0-0 band peak from 435 to 445 nm amounts to an energy gap of 520 cm^{-1}, which is comparable to those of 440 and 640 cm^{-1} for the absorption peaks between 1 : 1 : 1 inclusion compounds of β-CD-alcohol-pyrene and -fluorene and free pyrene and fluorene in water, respectively.[18,20] The red shifts are only 90 and 200 cm^{-1} for the peaks of 1 : 1 inclusion compounds of pyrene and fluorene, respectively. In contrast to 1 : 1 inclusion compounds of these aromatics, sharp vibronic bands are characteristic of ternary inclusion compounds containing alcohol, except for a β-CD-alcohol-acenaphthene inclusion compound. This is the case of the inclusion compound of Pe. Furthermore, considerable quantities of ethanol exist in the solvent used in this work. Consequently, the most plausible species responsible for the absorption spectral change shown in Fig. 1 is a ternary inclusion compound comprising γ-CD, ethanol, and Pe. Figure 2 exhibits the absorption spectra of Pe solutions with a fixed concentration of γ-CD (1.0×10^{-3} mol dm^{-3}) and varying amounts of cyclohexane. The addition of cyclohexane results in an enhancement of the 445-nm band at the expense of the 435-nm band. This spectral change resembles that shown in Fig. 1 where the γ-CD concentration is increased. In Fig. 2, cyclohexane acts as if it is γ-CD in Fig. 1. For pyrene solutions with β-CD, cyclohexane or hexane was found to induce an absorption spectral change similar to those observed for the addition of alcohols, indicating the formation of a 1 : 1 : 1 inclusion complex of β-CD with cyclohexane (hexane) and pyrene. Since cyclohexane is much more hydrophobic than ethanol, cyclohexane is expected to readily associate with γ-CD, thereby forming a γ-CD-cyclohexane-Pe inclusion compound analogous to the γ-CD-ethanol-Pe inclusion compound. This explains the effect of added cyclohexane on the absorption spectrum of Pe shown in Fig. 2. The finding of the effect of cyclohexane provides additional evidence for the ternary inclusion compound of γ-CD-ethanol-Pe. As revealed for the β-CD-alcohol-pyrene,[18] -acenaphthene,[19] -fluorene,[20] and -1-naphthonitrile systems,[21] it is most likely that the γ-CD-ethanol-Pe inclusion compound (PEC) comprises a single γ-CD, a single ethanol, and a single Pe molecule:

$$\mathrm{Pe} + \mathrm{EtOH} + \gamma\text{-CD} \overset{K_1}{\rightleftarrows} \mathrm{PEC}, \qquad (1)$$

where EtOH is ethanol, and K_1 is an equilibrium constant for the formation of PEC.

Figure 3 depicts the fluorescence spectra of Pe in the absence and presence of γ-CD. When γ-CD is added to a Pe solution, the fluorescence maxima are red shifted, and isoemissive points are observed at 445, 473, 494, and 506 nm. The spectral change in the fluorescence by the addition of γ-CD is also due to the 1 : 1 : 1 inclusion compound of γ-CD-ethanol-Pe.

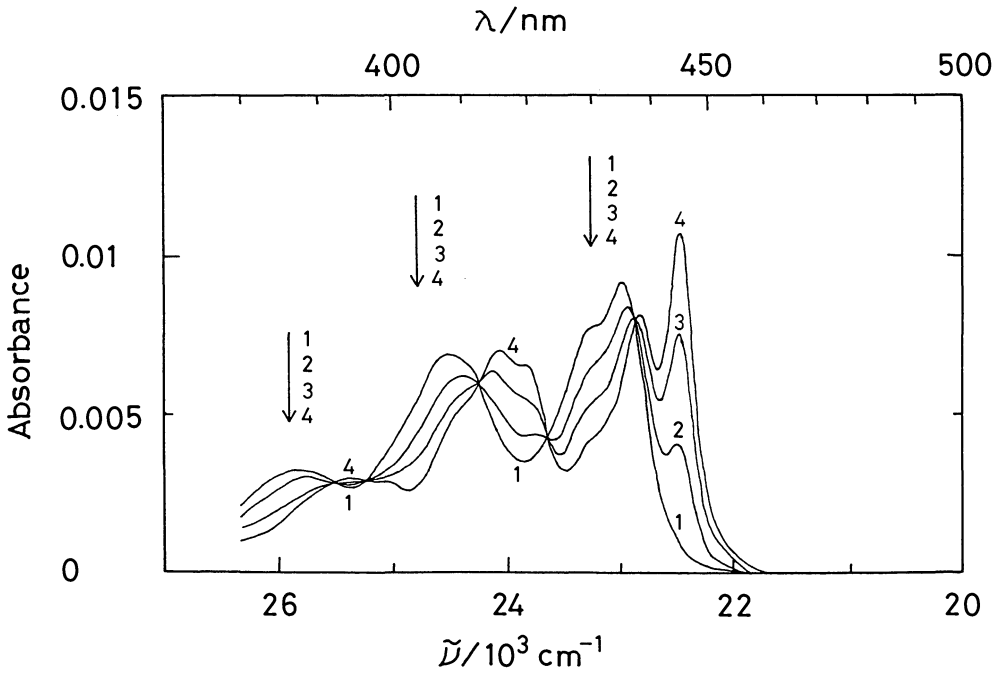

Fig. 1. Absorption spectra of Pe (3.0×10^{-7} mol dm^{-3}) in H_2O-ethanol (7 : 3) containing varying concentrations of γ-CD. Concentration of γ-CD: (1) 0, (2) 1.0×10^{-3}, (3) 2.0×10^{-3}, and (4) 4.0×10^{-3} mol dm^{-3}.

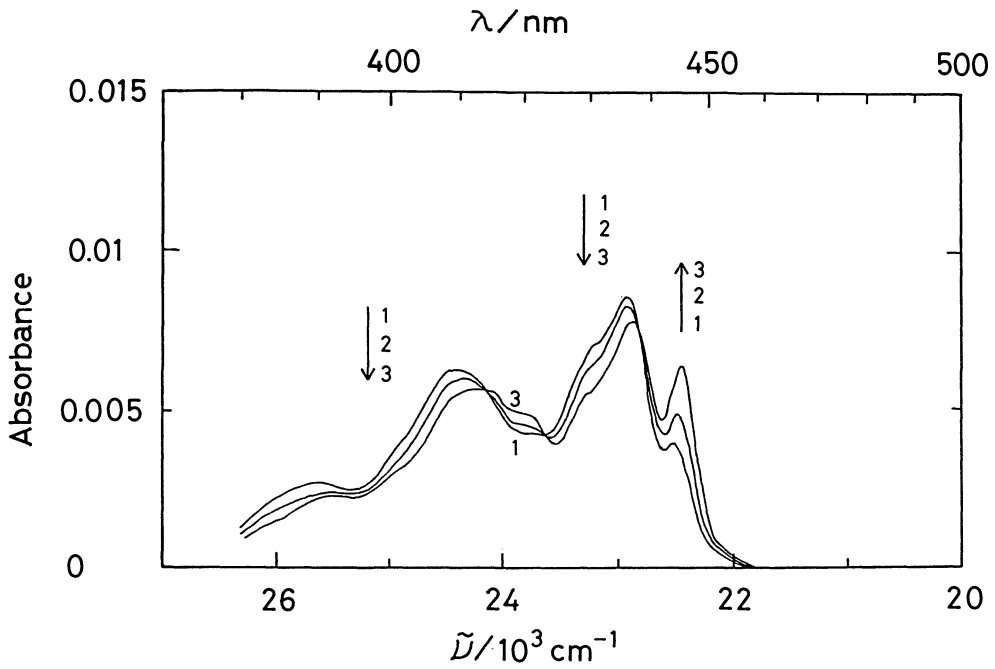

Fig. 2. Absorption spectra of Pe (3.0×10^{-7} mol dm^{-3}) in H_2O–ethanol (7 : 3) containing a fixed concentration of γ-CD (1.0×10^{-3} mol dm^{-3}) and varying concentrations of cyclohexane. Concentration of cyclohexane: (1) 0, (2) 1.85×10^{-3}, and (3) 4.63×10^{-3} mol dm^{-3}.

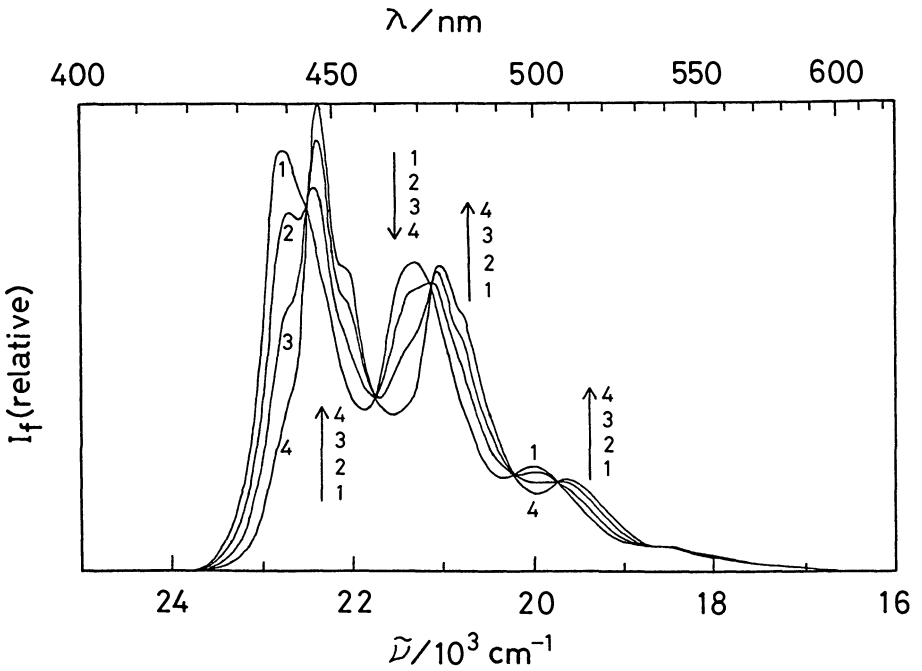

Fig. 3. Fluorescence spectra of Pe (3.0×10^{-7} mol dm^{-3}) in H_2O–ethanol (7 : 3) containing varying concentrations of γ-CD. Concentration of γ-CD: (1) 0, (2) 1.0×10^{-3}, (3) 2.0×10^{-3}, and (4) 4.0×10^{-3} mol dm^{-3}. λ_{ex}=413 nm.

For the equilibrium represented by Eq. 1, the following equation holds:

$$1/\Delta I_f = 1/a + 1/aK_1[\mathrm{EtOH}]_0[\gamma\text{-CD}]_0, \quad (2)$$

where ΔI_f is the difference in the integrated fluorescence intensity between a Pe solution with γ-CD and that without γ-CD, a is a constant, subscript 0 stands for the initial concentration, and $[EtOH]_0$ is 5.11 mol dm^{-3}. According to Eq. 2, K_1 was evaluated to be 37 ± 10 mol^{-2}dm^6. Upon the addition of cyclohexane

to a γ-CD solution of Pe, the Pe fluorescence spectrum shows a change similar to that shown in Fig. 3 where γ-CD is added to a Pe solution without cyclohexane. This spectral change for the fluorescence upon adding cyclohexane corresponds to that for the absorption change shown in Fig. 2.

Inclusion Compound of γ-CD with *N,N*-Dimethylaniline (DMA). DMA was confirmed to form an inclusion compound with γ-CD from the absorption and fluorescence spectral changes. Although there is a possibility that a ternary inclusion compound of γ-CD-ethanol-DMA is formed, we could not obtain evidence for its existence from spectroscopic measurements. Therefore, it is most likely that the spectral change is due to a 1 : 1 inclusion compound of γ-CD-DMA (DC) which is formed according to the equation

$$\text{DMA} + \gamma\text{-CD} \overset{K_2}{\rightleftarrows} \text{DC}, \tag{3}$$

where K_2 is an equilibrium constant for the formation of DC. A fluorometric method was used to determine K_2:

$$1/\Delta I_f = 1/b + 1/bK_2[\gamma\text{-CD}]_0, \tag{4}$$

where b is a constant. From an analysis based on Eq. 4, 27±14 $mol^{-1}dm^3$ was obtained as K_2.

Inclusion Compound of γ-CD with *N,N*-Dimethylaniline (DMA) and Pe. In the DMA concentration range below ca. 1×10^{-3} mol dm^{-3}, addition of DMA to a γ-CD (4.0×10^{-3} mol dm^{-3}) solution of Pe results in red shifts of the absorption maxima accompanied by isosbestic points at 421, 429, and 447 nm (Fig. 4). The absorption change can be attributed to the formation of an inclusion compound consisting of γ-CD, DMA, and Pe. It is most likely that the spectral change at low DMA concentrations is caused by the formation of a 1 : 1 : 1 inclusion compound of γ-CD-DMA-Pe. Above ca. 1×10^{-3} mol dm^{-3} of DMA, however, isosbestic points disappear with further red shifts of the absorption maxima. The absorption bands are broadened as the DMA concentration is raised. Because, as is described later, any benzene that cannot form an electron donor-acceptor complex with Pe causes an absorption spectral change similar to that produced by DMA, this change in the absorption is not due to a charge-transfer interaction between Pe and DMA but, rather, due to a kind of microscopic solvent effect exerted by neighboring DMA. Figure 5 illustrates the fluorescence spectrum of a Pe solution containing γ-CD (4.0×10^{-3} mol dm^{-3}) and DMA (3.16×10^{-3} mol dm^{-3}). Upon the addition of DMA, the Pe monomer band (447-nm band) is quenched. At the same time, a broad emission that is located at longer wavelengths appears with a maximum at 599 nm. For the Pe solution with γ-CD and DMA, the excitation spectrum observed at 580 nm was almost identical to the absorption spectrum. This broad emission is assigned to an exciplex fluorescence of Pe and DMA which enter the γ-CD cavity. If a Pe ground-state dimer within the γ-CD cavity exists in

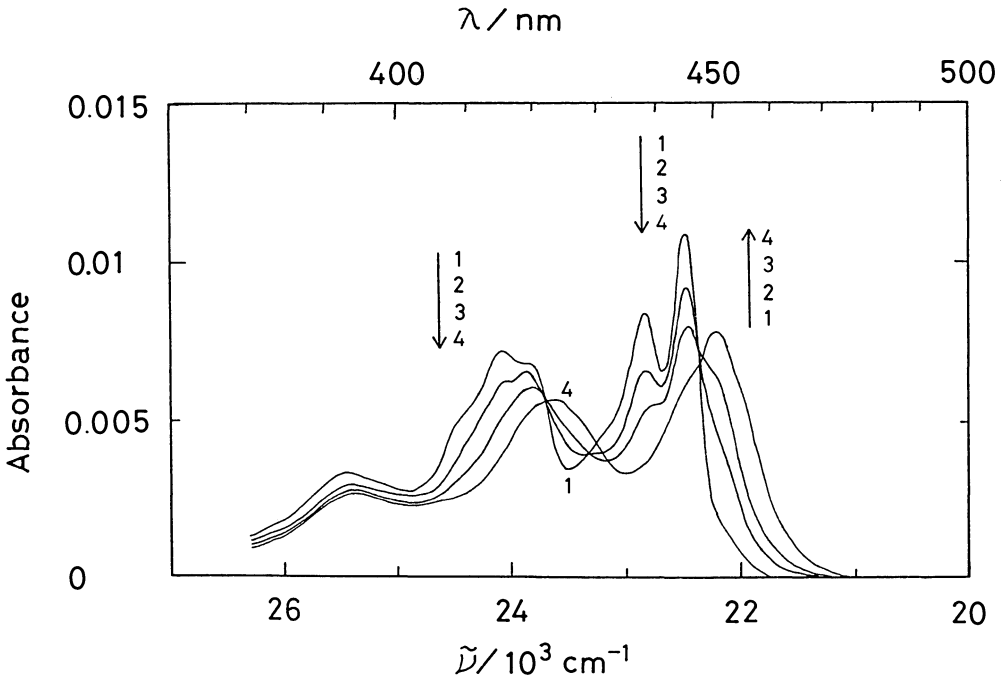

Fig. 4. Absorption spectra of Pe (3.0×10^{-7} mol dm^{-3}) in H_2O-ethanol (7 : 3) containing a fixed concentration of γ-CD (4.0×10^{-3} mol dm^{-3}) and varying concentrations of DMA. Concentration of DMA: (1) 0, (2) 3.16×10^{-4}, (3) 7.89×10^{-4}, and (4) 3.16×10^{-3} mol dm^{-3}.

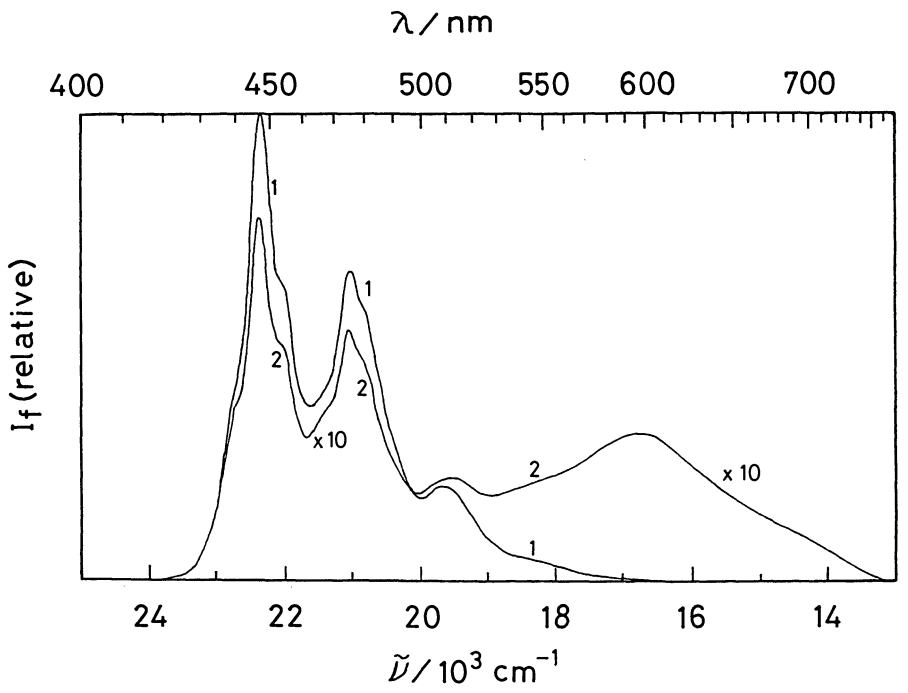

Fig. 5. Fluorescence spectra of Pe (3.0×10^{-7} mol dm^{-3}) in H_2O-ethanol (7 : 3) containing γ-CD (4.0×10^{-3} mol dm^{-3}) in the absence (Spectrum 1) and presence (Spectrum 2) of DMA (3.16×10^{-3} mol dm^{-3}). The fluorescence intensity of a Pe solution with DMA is multiplied by 10. λ_{ex}=402 nm.

H_2O-ethanol (7 : 3), it might be responsible for the broad emission. However, this possibility is excluded due to the following result. Nitrobenzene, which has been found to form an inclusion compound similar to that for DMA, only quenches the Pe monomer band, and does not induce the longer-wavelength emission, as does DMA.

For a Pe solution with both γ-CD (4.0×10^{-3} mol dm^{-3}) and DMA (3.16×10^{-3} mol dm^{-3}), an experiment on the concentration dependence of Pe was performed. The normalized absorption spectrum for 3.0×10^{-7} mol dm^{-3} Pe was identical to that for 1.0×10^{-7} mol dm^{-3} Pe, indicating that only one Pe molecule is included in the inclusion compound responsible for the exciplex fluorescence. A continuous variation plot of the absorbance at 437 nm, which is an isosbestic point for γ-CD-Pe solutions without DMA, against the molar fraction of γ-CD ($[\gamma\text{-CD}]_0/([\gamma\text{-CD}]_0+[\text{DMA}]_0)$) was made in order to identify the relevant inclusion compound under the condition of $[\gamma\text{-CD}]_0+[\text{DMA}]_0=2.0\times10^{-3}$ mol dm^{-3}. The result that the absorbance passes through a minimum at a molar fraction of 0.5 (not shown) revealed that the inclusion compound has a 1 : 1 stoichiometry concerning γ-CD and DMA. Combined with no concentration effect of Pe on the absorption spectrum, both the absorption change shown in Fig. 4 and the exciplex fluorescence in Fig. 5 are evidently due to a complex that includes a single Pe molecule, with a 1 : 1 stoichiometry of γ-CD and DMA. Therefore, as candidates responsible for the exciplex fluorescence, there are a 1 : 1 : 1 inclusion compound of γ-CD-DMA-Pe (PDC) and an inclusion compound (PDC · DC) formed by the association between PDC and DC:

$$\text{PEC}+\text{DMA}\overset{K_3}{\rightleftarrows}\text{PDC}+\text{EtOH}, \quad (5)$$

and

$$\text{PDC}+\text{DC}\overset{K_4}{\rightleftarrows}\text{PDC}\cdot\text{DC}, \quad (6)$$

where K_3 and K_4 are equilibrium constants for the formation of PDC and PDC · DC, respectively. Because the exciplex fluorescence intensity is proportional to the concentration of the emitting species under our experimental conditions, the exciplex fluorescence intensities which are a function of DMA concentration were compared with the concentration curves of the candidates in order to clarify the inclusion compound emitting the exciplex fluorescence. The concentrations of PDC and PDC · DC were calculated from the following equations:

$$[\text{PDC}]=K_1K_3[\text{DMA}][\gamma\text{-CD}]_0[\text{Pe}]_0/(1+K_1[\gamma\text{-CD}]_0([\text{EtOH}]_0+K_3[\text{DMA}])), \quad (7)$$

with $[\text{DMA}]=[\text{DMA}]_0/(1+K_2[\gamma\text{-CD}]_0)$

and

$$[\text{PDC}\cdot\text{DC}]=K_1K_2K_3K_4[\text{DMA}]^2[\gamma\text{-CD}]_0^2[\text{Pe}]_0/(1+K_1[\gamma\text{-CD}]_0([\text{EtOH}]_0+K_3[\text{DMA}]+K_2K_3K_4[\text{DMA}]^2[\gamma\text{-CD}]_0)). \quad (8)$$

The results are given in Fig. 6 together with the

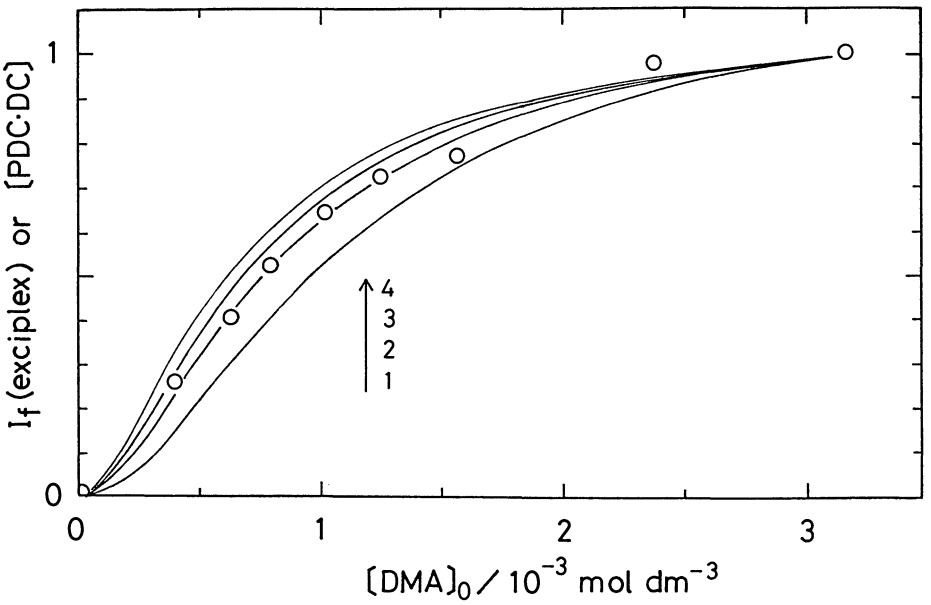

Fig. 6. Comparison of intensities of the Pe-DMA exciplex fluorescence in H_2O-Ethanol (7:3) containing both γ-CD (4.0×10^{-3} mol dm^{-3}) and DMA with calculated curves which are obtained with assumed K_3 and K_4 (20000 mol^{-1} dm^3). The exciplex fluorescence intensities and the curves are normalized to unity at the highest DMA concentration, respectively. Assumed K_3 value: (1) 10000, (2) 20000, (3) 30000, and (4) 40000. $[Pe]_0=3.0\times10^{-7}$ mol dm^{-3}. λ_{ex}=402 nm.

observed intensities of the exciplex fluorescence as a function of DMA concentration. Under the condition that $[\gamma\text{-CD}]_0=4.0\times10^{-3}$ mol dm^{-3}, a calculated curve for PDC·DC with assumed values of K_3=20000 and K_4=20000 mol^{-1} dm^3 was in good agreement with the observed data points, whereas a best-fit curve for PDC afforded K_3=10000. Because these comparisons could not identify the relevant inclusion compound, we next compared the data with calculated curves as a function of γ-CD concentration, keeping the initial DMA concentration at 3.16×10^{-3} mol dm^{-3}. The fitting procedure for PDC·DC gave K_3=20000 and K_4=15000 mol^{-1} dm^3 (not shown), which well agreed with the values evaluated from the previous simulation as a function of DMA concentration. From a similar procedure for PDC, on the other hand, K_3 was estimated to be 2000, which was in disagreement with the K_3 value obtained above for the mechanism of PDC formation. Therefore, we conclude that the exciplex fluorescence is due to PDC·DC. Upon diluting the initial concentration of DMA from 3.16×10^{-3} to 7.89×10^{-4} mol dm^{-3}, the same simulation method for PDC·DC in which comparisons were made as a function of γ-CD concentration afforded K_3=20000 and K_4=20000 mol^{-1} dm^3, which were in excellent agreement with the values already obtained, while the procedure for PDC could not give any K_3 value. These results provide additional evidence that PDC·DC is responsible for the exciplex fluorescence.

The inclusion compound PDC·DC closely resembles in form an association complex of a β-CD-aniline-sodium 1-pyrenesulfonate (or -pyrene) 1:1:1 inclusion compound with a β-CD-aniline 1:1 inclusion compound in the system of β-CD-aniline-sodium 1-pyrenesulfonate (or -pyrene), although a different CD (β-CD) is used.[22] In addition, the charge-transfer fluorescence of sodium 1-pyrenesulfonate- or pyrene-aniline has been observed from the β-CD association complexes. At low DMA concentrations (below ca. 1×10^{-3} mol dm^{-3}), PDC may exist predominantly in a Pe solution with γ-CD, since, as stated previously, there are isosbestic points in the low DMA concentration range. Inclusion compounds similar in form to PDC have also been suggested for the systems of β-CD-aniline-sodium 1-pyrenesulfonate and -pyrene.[22] In contrast to 2:2:1 inclusion compounds, such as PDC·DC, exciplex or charge-transfer emissions are not detected for the 1:1:1 inclusion compounds, such as PDC, probably because the polarity around an excited species within the CD cavity is very high, owing to the smaller degree of shielding from the aqueous phase, compared with the 2:2:1 inclusion compounds including two CD molecules.

Effects of Benzene, Aniline, and *N,N*-Diethylaniline on the Absorption and Fluorescence Spectra of Pe Solutions with γ-CD. When benzene was added to a Pe solution containing γ-CD, the Pe absorption spectrum changed in a fashion similar to that for DMA. This finding shows the formation of an inclusion compound, being of the PDC·DC type, which con-

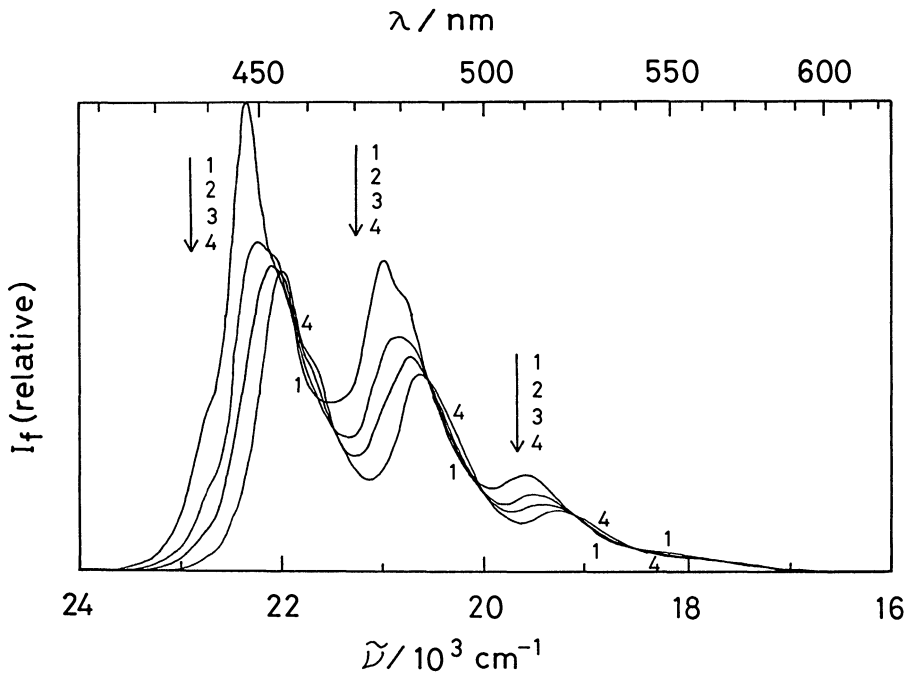

Fig. 7. Fluorescence spectra of Pe (3.0×10^{-7} mol dm^{-3}) in H_2O-ethanol (7 : 3) containing a fixed concentration of γ-CD (4.0×10^{-3} mol dm^{-3}) and varying concentrations of benzene. Concentration of benzene: (1) 0, (2) 5.63×10^{-3}, (3) 1.13×10^{-2}, and (4) 2.25×10^{-2} mol dm^{-3}. λ_{ex}=413 nm.

tains benzene instead of DMA. As the benzene concentration is increased, the fluorescence spectrum exhibits red shifts of peaks accompanied by a slight broadening of bands (Fig. 7). No appearance of long-wavelength emission is observed. In this case, benzene within the γ-CD cavity accommodating Pe exerts microscopic solvent effects, in which, depending on the strength of the interaction with Pe, a microscopic medium (neighboring benzene) influences the band position and band width, etc. Aniline as well as benzene showed similar effects on the absorption and fluorescence spectra, although the Pe monomer fluorescence was relatively efficiently quenched. For aniline, the exciplex fluorescence of Pe was not observed in 1-propanol and ethyl acetate. Consequently, no observation of the Pe-aniline exciplex fluorescence is reasonable for an inclusion compound including Pe and aniline. However, the behavior of *N,N*-diethylaniline towards the Pe fluorescence is intermediate between that of aniline and DMA. That is, both spectral shifts of the Pe monomer fluorescence and the weak exciplex fluorescence of Pe-*N,N*-diethylaniline are observed. In this case, owing to a bulkier diethylamino group in *N,N*-diethylaniline than a dimethylamino group in DMA, a smooth reorientation within the lifetime of excited Pe may be sterically hindered for Pe and *N,N*-diethylaniline molecules inside the γ-CD cavities, resulting in both the exertion of a kind of microscopic solvent effect (the spectral shifts of the monomer fluorescence bands, etc.) and the appearance of the weak exciplex fluorescence.

Polarity of the Interior of the γ-CD Cavities. In order to investigate the polarity within the γ-CD cavities, the exciplex fluorescence maximum (599 nm) was compared with the maxima of the Pe-DMA exciplex fluorescence in organic solvents. This examination has revealed that the dielectric constant around the Pe-DMA exciplex within the γ-CD cavities is close to that of 1-pentanol (ε=13.9), in which the exciplex fluorescence is centered at 600 nm. This value is rather greater than the dielectric constants obtained previously from charge-transfer emissions of a 2-methoxynaphthalene-phthalonitrile complex within the β-CD cavities and 1-pyrenesulfonate- and pyrene-aniline complexes within the β-CD cavities,[22,23] but less than that from a 1-naphthonitrile-anisole exciplex emission in the β-CD-anisole-1-naphthonitrile system.[21] Such differences are, of course, unlikely to be attributed to the differences in property between β- and γ-CD. There have been several studies concerning the polarity of the interior of the CD cavity:[21,22-29] The dielectric constants experienced by fluorescent probes have been reported to be in the very wide range from 2.2 to 55. These results imply that the intrinsic dielectric constant of the CD cavity interior is close to that of 1,4-dioxane (ε=2.2). As pointed out by Cox et al.,[25] the location of a probe molecule inside the cavity is quite critical for the evaluation of the dielectric constants of CDs. A probe molecule does not neces-

sarily totally enter the cavity, since the interior of the CD cavity is not so wide and deep for probes usually used. The polarity sensed by a probe molecule varies from point to point within the cavity. Consequently, the polarity determined from such a probe technique conversely indicates the location of a probe incorporated into the cavity.[21] If the estimated dielectric constant is large, the probe molecule inside the cavity seems to reside near the aqueous phase or to be in contact with water.

The author thanks Professor Fumio Hirayama for his valuable discussion.

Anisochrony in Rotatable Ligands and Symmetry Non-Equivalence Characterized by Subduction of Coset Representations

Shinsaku FUJITA
Research Laboratories, Ashigara, Fuji Photo Film Co., Ltd., Minami-Ashigara, Kanagawa 250-01
(Received September 27, 1990)

A general method of characterizing symmetry equivalence and non-equivalence in a molecule is developed on the basis of the one-one correspondence between an orbit and a coset representation. This method provides us with a theoretical foundation to understand anisochrony in rotatable ligands. A given molecule is regarded as a combination of a three-dimensional skeleton and ligands. The ligand is referred to as a segment or a fragment according to its environment. Thus, the fragment is defined as a ligand-in-isolation; and the segment denotes a ligand built into a molecule. The symmetry of the ligand as a fragment is restricted to the local symmetry. This restriction is examined by using methyl and methylene ligands as examples. A methyl fragment has a homospheric $\mathbf{C}_{3v}(/\mathbf{C}_s)$ orbit that consists of three hydrogen atoms. On the other hand, a methylene fragment has an enantiospheric $\mathbf{C}_s(/\mathbf{C}_1)$ orbit that contains two hydrogen atoms. Such an orbit is incorporated into various molecules to afford restricted orbits, which are characterized by subduction of coset representations. The restricted orbits are discussed in terms of global and local orbits. This discussion provides a general approach to rationalize various types of anisochronies.

Relationship between global and local symmetries in a molecule has been investigated in order to clarify stereochemical behaviors of the molecule.[1] In particular, chemical shift equivalence (isochrony) and non-equivalence (anisochrony) of nuclei have been discussed in the light of such stereochemical relationships.[2,3]

Anisochrony of methyl protons has been observed in several molecules at low temperatures. Nakamura et al.[4] reported that the bridgehead methyl segment of 1,2,3,4-tetrachloro-5,8,9-trimethyltriptycene (**1**) exhibited three chemical shifts at −90 °C. Anderson and Rawson[5] observed split methyl signals (2:1) in the NMR spectrum of **2** at −141 °C.

2

On the other hand, anisochrony of geminal groups in an appropriate intramolecular environment was observed independent of temperature.[6] One of such anisochronies was observed in molecules having the general formula ($XYC(CU_2R)_2$). According to Jenning's review,[7] this type of anisochronies can be rationalized by combining the prochirality concept of Hanson[8] with the topic relationships of Mislow and Raban.[2] Eliel reviewed nuclear magnetic resonances with reference to prochiralities.[9] However, since the conventional prochirality concept is not based on a mathematical formulation, rather tedious procedures are required for judging such anisochronies.

Flanzen and Binsch[10] pointed out two general possibilities for realizing another type of anisochrony of geminal groups: Class A is characterized by the general formula $RU_2C\text{-}CX_3^*$, with X* being a chiral substituent; Class B conforms to the general formula $(RU_2C)_3C\text{-}CXYZ$. Reisse et al.[11] added another class $(RU_2C)_3C\text{-}CX_3^*$ to this classification. These phenomena were also analyzed in terms of topic relationships.[1,2] Reisse et al.[11] concluded that anisochronies of diastereotopic and constitutional heterotopic groups stemmed from a single source: symmetry non-equivalence of nuclei. However, such symmetry non-equivalence has been investigated by applying Newmann's projections or other diagrams to every molecule; and there has appeared no comprehensive understanding on this issue.

We recently discussed several applications of coset representations (CRs) and of their subductions.[12-14] These applications are based on the one-one correspondence between a CR and a set (an orbit) of equivalent atoms (or objects). We have clarified that such topic relationships should be used subsidiarily to sphericities (chirality fittingnesses) of such CRs, since diastereotopic and heterotopic relations cannot provide equivalence classes from a mathematical point of view.[14] In other words, the terms "diastereotopic" and "heterotopic" indicate that two objects are different; but are incapable of clarifying how different they are. On the other hand, the chirality fittingness characterizes an orbit as being *homospheric, enantiospheric,* or *hemispheric.* This classification clarifies how different (or how equivalent) such two objects are. In the present paper, we deal with another application of such CRs, which aims at providing a general approach to symmetry (non-)equivalence as well as at rationalizing various types of anisochronies.

1. Orbits of Ligands

An orbit is an equivalence class whose members can be any kind of objects. For discussing stereochemical relationships, such objects may be atoms, bonds, or faces. Moreover, a ligand, which is a set of one or more atoms, can also be such an object. Thereby, a set of equivalent ligands is regarded as an orbit.[15]

The term "ligand" has been used in various meanings, which depend upon how to manipulate the three-dimensional (3D) structure of the ligand. This fact has attracted little attention of organic chemists, inasmuch as such different usages have provided no confusion in most cases. For the purpose of discussing stereochemical relationships in detail, however, we should use this term in a stricter fashion. There are at least three ways to treat the 3D structure of a ligand according to the fact that the ligand has three kinds of attributes: (1) chirality/achirality, (2) a point group, and (3) an internal 3D structure, in ascending order of concreteness. In order to make our discussion clearcut, we here introduce a new term "proligand"; this takes account of the chirality/achirality. The term "ligand" is used for discussing (2) and (3).

A Set of Equivalent Proligands as an Orbit. The molecule **1** (or **2**) is regarded as a combination of a triptycene skeleton and a methyl ligand.[16] These examples contain only one methyl ligand to be examined. However, we should discuss a more general case in which two or more equivalent ligands are taken into consideration.

Before we manipulate such ligands directly, we begin with equivalence and non-equivalence of proligands. A *proligand* is defined as a point ligand that is structureless but has chirality; such a proligand is either chiral or achiral. The term proligand has been introduced in order to explicate a logical standpoint that primarily takes neither the point group nor the internal structure of ligand into consideration. In the present discussion, the proligand concept is coupled with the concept of local symmetry. Although several predecessors of the present cencept (proligand) have been reported for discussing stereochemistry,[8,17] they pay little attention on such implications that are revealed by the proligand term. For simplicity's sake, we here deal with achiral proligands, which apparently behave like atoms. A more general approach will be discussed elsewhere.[18]

We then define a *promolecule* as a three-dimensional (3D) object that consists of a skeleton and proligands. We differentiate such promolecules from molecules, since this differentiation simplifies discussions on stereochemical relationships.

A set of equivalent proligands is regarded as an *orbit*, which is characterized by a coset representation (CR). For illustrating this relationship, we depict several promolecules derived from adamantane skeletons (Fig. 1). Each A is an achiral proligand; the remaining part of each promolecule is regarded as a skeleton without losing generality.[19] Table 1 indicates properties of each orbit concerning the proligands (A's), where other orbits are not taken into account.

Let **G** be the symmetry of a promolecule, which is referred to as a *global symmetry*. Then, a CR for an orbit is represented by $\mathbf{G}(/\mathbf{G}_i)$, where $\mathbf{G}_i$ is an appropriate subgroup of **G**. This CR indicates that $\mathbf{G}_i$ is the *local symmetry* for each member of the orbits.[14] The number of the members is equal to the length of the orbit, which is calculated to be $|\mathbf{G}|/|\mathbf{G}_i|$, where $|\mathbf{G}|$ and $|\mathbf{G}_i|$ denote the orders of **G** and $\mathbf{G}_i$, respectively. For example, the orbit of four equivalent A's of **3** is assigned to the CR, $\mathbf{T}_d(/\mathbf{C}_{3v})$.[20] This assignment is accomplished by using a table of marks for $\mathbf{T}_d$ point group.[13,14] In terms of the CR ($\mathbf{T}_d(/\mathbf{C}_{3v})$), the local symmetry of each A in this molecule is concluded to be $\mathbf{C}_{3v}$, which appears in the parentheses of the symbol of the CR. The achiral proligand (A) is presumed implicitly to have $\mathbf{C}_{\infty v}$ symmetry in isolation; but is restricted to the $\mathbf{C}_{3v}$ local symmetry in this promolecule. The local symmetries in the other promolecules are listed in Table 1, in which they are placed by

Table 1. Coset Representations for Orbits of Proligands

Promolecule	Member(s) of an orbit	Local symmetry	Coset representation	Chirality fittingness (Sphericity)
3	A_4	$\mathbf{C}_{3v}$	$\mathbf{T}_d(/\mathbf{C}_{3v})$	Homospheric
4	A_4	$\mathbf{C}_s$	$\mathbf{D}_{2d}(/\mathbf{C}_s)$	Homospheric
5	A	$\mathbf{C}_{3v}$	$\mathbf{C}_{3v}(/\mathbf{C}_{3v})$	Homospheric
6	A_3	$\mathbf{C}_s$	$\mathbf{C}_{3v}(/\mathbf{C}_s)$	Homospheric
7	A_6	$\mathbf{C}_1$	$\mathbf{C}_{3v}(/\mathbf{C}_1)$	Enantiospheic
8	A_4	$\mathbf{C}_1$	$\mathbf{D}_2(/\mathbf{C}_1)$	Hemispheric
9	A_2	$\mathbf{C}_s$	$\mathbf{C}_{2v}(/\mathbf{C}_s)$	Homospheric
10	A_4	$\mathbf{C}_1$	$\mathbf{S}_4(/\mathbf{C}_1)$	Enantiospheric
11	A	$\mathbf{C}_3$	$\mathbf{C}_3(/\mathbf{C}_3)$	Hemispheric
12	A_3	$\mathbf{C}_1$	$\mathbf{C}_3(/\mathbf{C}_1)$	Hemispheric
13	A	$\mathbf{C}_s$	$\mathbf{C}_s(/\mathbf{C}_s)$	Homospheric
14	A_2	$\mathbf{C}_1$	$\mathbf{C}_s(/\mathbf{C}_1)$	Enantiospheric
15	A_2	$\mathbf{C}_1$	$\mathbf{C}_2(/\mathbf{C}_1)$	Hemispheric

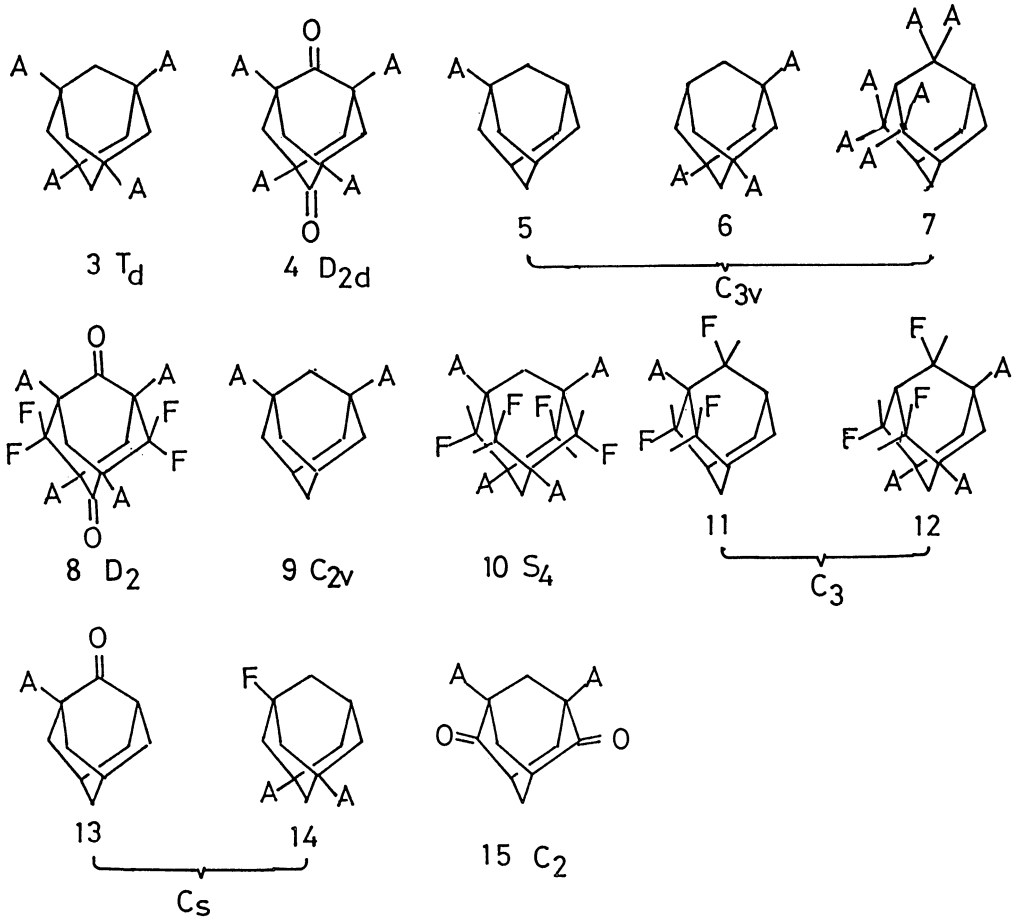

Fig. 1. Promolecules based on adamantane skeletons.
Capital A's in each promolecule denote achiral proligands. The remaining part of the promolecule is regarded as a skeleton. A capital F denotes a fluorine atom, which is here considered to be a component of a skeleton.

the sides of the corresponding CRs.

A proligand in a promolecule is called a *segment* and a proligand in isolation is referred to as a *fragment*. The segment may be different from the corresponding fragment in their symmetries. The promolecules (**5** to **7**) belong to the same C_{3v} symmetry; however, they have different types of orbits concerning A's (Table 1). Thus, one A of **5** constructs a $C_{3v}(/C_{3v})$ orbit; three A's of **6** belong to a $C_{3v}(/C_s)$ orbit; and six A's of **7** build a $C_{3v}(/C_1)$ orbit. The respective local symmetries are C_{3v}, C_s and C_1, as found in the parentheses of the symbols.

A Set of Equivalent Ligands as an Orbit. We now discuss symmetry changes that take place when proligands are replaced by achiral ligands having a 3D structure. The treatment described in this section is concerned with the symmetries of the ligands to such a limited extent that only their point groups are taken into consideration; but without considering their internal structures. Suppose that the achiral proligand (A) in the promolecule (**5**) of C_{3v} symmetry is replaced by a methyl ligand. The resulting molecule (**22**) retains the global C_{3v} symmetry, because the C_{3v} symmetry of the methyl fragment is equal to the local C_{3v} symmetry due to the $C_{3v}(/C_{3v})$ CR (Table 1). Thereby, the methyl segment has the same C_{3v} symmetry as the fragment. Thus, this operation gives rise to no restriction of the fragment symmetry. We also use the terms *segment* and *fragment* for discussing properties of ligands.[21]

In the case of the promolecule (**6**), the replacement of each A by a methyl ligand produces a molecule (**23**) that has a global C_{3v} symmetry equal to that of **6**. However, this conservation of the global symmetry is different from that of **22** described above, because the C_{3v} point group (for the methyl as a fragment) involves the C_s point group (for the local symmetry) as a subgroup. In contrast with the global symmetry, each of the resulting methyl segments has a C_s local symmetry, to which the original C_{3v} symmetry of the methyl ligand (as a fragment) is restricted.

These facts can be generalized as follows: If the symmetry of a fragment is equal to or involves the local symmetry of a promolecule, the resulting molecule has the same symmetry (point group) as does the promolecule; and the segment derived from the frag-

ment is restricted so as to have the symmetry equal to the local symmetry.

Chirality Fittingness of an Orbit. In order to discuss the chirality/achirality of a molecule (or a promolecule), we have introduced the concept "chirality fittingness" (sphericity) in a previous paper.[14] Thus, any $\mathbf{G}(/\mathbf{G}_i)$ orbit is classified into one of the three categories according to $\mathbf{G}$ vs. $\mathbf{G}_i$.

Global symmetry	Local symmetry	Chirality fittingness	Number of orbits	
$\mathbf{G}$	$\mathbf{G}_i$	(Sphericity)	$\downarrow\mathbf{G}$	$\downarrow\mathbf{G}^{max}$
Achiral	Achiral	Homospheric	1	1
Achiral	Chiral	Enantiospheric	1	2
Chiral	Chiral	Hemispheric	1	1

Table 1 collects coset representations and chirality fittingness. For illustrating the chirality fittingness, let us examine homospheric and enantiospheric orbits. For example, the two proligands (A_2) in the promolecule (**9**) (or equivalently the two hydrogen atoms in difluoromethane (CH_2F_2) construct a $\mathbf{C}_{2v}(/\mathbf{C}_s)$ orbit, which is homospheric because both of the $\mathbf{C}_{2v}$ and $\mathbf{C}_s$ point groups are achiral. The two members (A_2) of the orbit are interchangeable by the proper rotations (I and C_2) and the improper rotations ($\sigma_{v(1)}$ and $\sigma_{v(2)}$) contained in the $\mathbf{C}_{2v}$ group. In other words, the homospheric orbit remains unchanged even if we restrict the $\mathbf{C}_{2v}$ into $\mathbf{C}_2=\{I, C_2\}$. As a result, the number of orbits is 1 under the action of $\mathbf{C}_{2v}$ (no restriction) and is unchanged to be 1 under the action of $\mathbf{C}_2$ (restriction denoted by $\downarrow\mathbf{C}_2$). Let $\mathbf{G}^{max}$ be such a subgroup of $\mathbf{G}$ that is composed of all of the proper rotations of $\mathbf{G}$. Then, this case can be generalized as follows. The restriction to the $\mathbf{G}^{max}$ (denoted by $\downarrow\mathbf{G}^{max}$) produces no division of a homospheric $\mathbf{G}(/\mathbf{G}_i)$ orbit.

On the other hand, the two proligands (A_2) in the promolecule (**14**) (or equivalently the two hydrogen atoms in chlorofluoromethane (CH_2ClF)) belong to a $\mathbf{C}_s(/\mathbf{C}_1)$ orbit. This orbit is enantiospheric, because the $\mathbf{C}_s$ is achiral and the $\mathbf{C}_1$ is chiral. The two members (A_2) of the orbit are interchangeable by the improper rotation (σ) but not interchangeable by the proper rotation (I) contained in the $\mathbf{C}_s$ group. As a result, the number of orbits is 1 under the action of $\mathbf{C}_s$ (no restriction) but the orbit is divided into two orbits under the action of $\mathbf{C}_1$ (restriction denoted by $\downarrow\mathbf{C}_1$). This case can be generalized as follows. The restriction to the $\mathbf{G}^{max}$ (denoted by $\downarrow\mathbf{G}^{max}$) divides an enantiospheric $\mathbf{G}(/\mathbf{G}_i)$ orbit into two parts.

Enantiospheric Orbit under a Chiral Environment. Several symmetrical properties of a segment can be discussed in terms of coset representations and chirality fittingnesses (sphericities) collected in Table 1; thus, these determine behaviors of the segment (A) under chiral environments (such as actions of chiral shift reagents and of chiral solvents). The following general theorem is important throughout the present discussions:

Theorem 1 (Fujita[14]). An enantiospheric orbit is capable of separating into two hemispheric orbits of the same length under a chiral environment, whether the change is reversible or irreversible.

This general theorem stems from the difference in the behavior of the enantiospheric orbit toward $\mathbf{G}$ and $\mathbf{G}^{max}$. The theorem can be applied to the orbits of proligands and of ligands. For example, since the six A's (or achiral ligands) of **7** belong to an enantiospheric orbit governed by $\mathbf{C}_{3v}(/\mathbf{C}_1)$, Theorem 1 predicts that they are divided into two sets of three equivalent (hemispheric) segments if **7** is placed under an external chiral environment (e.g, by the action of a chiral shift reagent). If the resulting anisochrony is large enough to determine, there emerge two sets of signals of equal intensities for A's. Similar predictions are obtained with respect to **10** and **14**, since they have an enantiospheric orbit (Table 1). To the best of our knowledge, no example has been reported for such splittings that concern four or more ligands, although several anisochronies concerning two ligands have been observed by the actions of chiral solvents.[22]

Each of the other promolecules (or the corresponding molecules) collected in Table 1 has a homospheric (or hemispheric) orbit only; such an anisochronous effect is predicted not to be observed.

2. Local Orbits and Global Orbits

In the preceding section, we have discussed an orbit of ligands, where we took no account of the internal structure of each ligand. The latter issue is a matter we aim at in this section. Figure 2 illustrates the fundamental principle of formulating a ligand that has an internal 3D structure. Suppose that a ligand-in-isolation (fragment) belongs to **F**-point group. It consists of several atoms, which construct its own orbits. The orbits in the fragment are referred to as *infraorbits*. Each of the infraorbits are govorned by a coset representation ($\mathbf{F}(/\mathbf{F}_p)$), where $\mathbf{F}_p$ is an appropriate subgroup of $\mathbf{F}$. Each $\mathbf{F}(/\mathbf{F}_p)$ infraorbit has the length of $|\mathbf{F}|/|\mathbf{F}_p|$, where $|\mathbf{F}|$ and $|\mathbf{F}_p|$ are the orders of $\mathbf{F}$ and $\mathbf{F}_p$ respectively.

Let us next incorporate this fragment into a molecule. Just as the fragment symmetry ($\mathbf{F}$) of the ligand is restricted into a local symmetry ($\mathbf{F}_q$) when incorporated as a segment, so the infraorbits ($\mathbf{F}(/\mathbf{F}_p)$'s) are restricted to the same local symmetry. The resulting orbits are called *local orbits*. The generation of the local orbits is controlled by the subduction, $\mathbf{F}(/\mathbf{F}_p)\downarrow\mathbf{F}_q$.[12] If we now inspect the whole molecule, we find that an appropriate set of such local orbits, each of which belongs to a segment, constructs an orbit of the molecule. We call the latter orbit a *global orbit*.

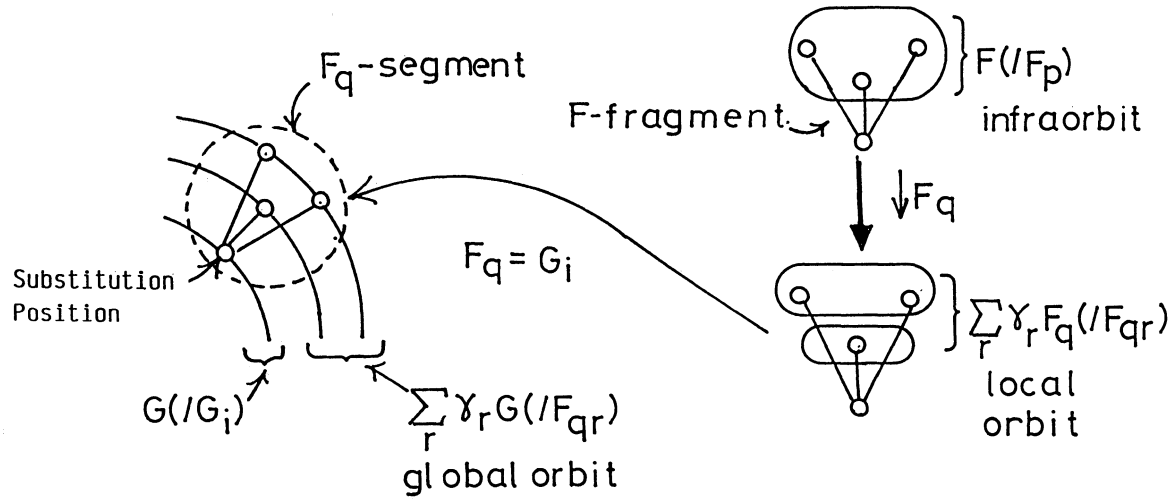

Fig. 2. Infraorbits, local orbits, and global orbits.

Since global orbits and local orbits characterize the same objects from different points of view, there is a close relationship between them.

This relationship is described by means of the following theorems, which can be proved by a slight modification of a mathematical treatment reported elsewhere.[15]

Theorem 2. Suppose that a promolecule has a $\mathbf{G}(/\mathbf{G}_i)$ orbit with $|\mathbf{G}|/|\mathbf{G}_i|$ achiral proligands; and that each of the achiral proligands in the orbit is replaced by an achiral ligand having an $\mathbf{F}(/\mathbf{F}_p)$ infraorbit ($\mathbf{F} \not\geqslant \mathbf{G}_i$). Then, the resulting molecule belongs to $\mathbf{G}$ symmetry. The $|\mathbf{F}|/|\mathbf{F}_p|$-membered infraorbit is divided according to $\mathbf{F}(/\mathbf{F}_p)\downarrow\mathbf{F}_q$, where $\mathbf{G}_i=\mathbf{F}_q$.

The resulting local and global orbits are represented by

Theorem 3. a) If the infraorbit ($\mathbf{F}(/\mathbf{F}_p)$) is restricted in the light of Theorem 2, the restriction is represented by

$$\mathbf{F}(/\mathbf{F}_p)\downarrow\mathbf{F}_q = \sum_{r=1}^{c_q} \gamma_r \mathbf{F}_q(/\mathbf{F}_{qr}), \tag{1}$$

wherein each $\mathbf{F}_{qr}$ is a subgroup of $\mathbf{F}_q$; c_q is the number of representative subgroups; and γ_r is the multiplicity of the $\mathbf{F}_{qr}$ subgroup. The resulting orbits ($\mathbf{F}_q(/\mathbf{F}_{qr})$'s) in the right-hand side are local orbits. Each $\mathbf{F}_q(/\mathbf{F}_{qr})$ orbit has the length of $|\mathbf{F}_q|/|\mathbf{F}_{qr}|$.

b) The corresponding global orbits are represented by

$$\sum_{r=1}^{c_q} \gamma_r \mathbf{G}(/\mathbf{F}_{qr}), \tag{2}$$

wherein c_q is the number of representatives of conjugate subgroups appearing in $\mathbf{F}_q$. Each $\mathbf{G}(/\mathbf{F}_{qr})$ orbit has the length of $|\mathbf{G}|/|\mathbf{F}_{qr}|$. Note that

$$\frac{|\mathbf{G}|}{|\mathbf{G}_i|} \times \left(\sum_{r=1}^{c_q} \frac{\gamma_r |\mathbf{F}_q|}{|\mathbf{F}_{qr}|} \right) = \sum_{r=1}^{c_q} \frac{\gamma_r |\mathbf{G}|}{|\mathbf{F}_{qr}|}, \tag{3}$$

since $\mathbf{G}_i$ is identical with $\mathbf{F}_q$.

It should be noted that Theorems 2 and 3 concern the highest attainable symmetry. These theorems determine symmetry equivalence and non-equivalence in a general fashion. Theorems 2 and 3 are true for any cases; but we hereafter bear special cases in mind: each ligand has an additional $\mathbf{F}(/\mathbf{F})$ orbit at which the ligand is linked to a member of the $\mathbf{G}(/\mathbf{G}_i)$ orbit, so that a free bond rotation at the linking position is allowed.

Comparison between Eqs. 1 and 2 indicates no increase in the number of orbits. In addition, Eqs. 1 and 2 afford a splitting ratio:

$$\begin{aligned}
&\underbrace{\frac{|\mathbf{F}_q|}{|\mathbf{F}_{q1}|}}_{\gamma_1} : \cdots : \underbrace{\frac{|\mathbf{F}_q|}{|\mathbf{F}_{q2}|}}_{\gamma_2} : \cdots : \cdots : \underbrace{\frac{|\mathbf{F}_q|}{|\mathbf{F}_{qc_q}|}}_{\gamma_{c_q}} : \cdots \\
&= \underbrace{\frac{|\mathbf{G}|}{|\mathbf{F}_{q1}|}}_{\gamma_1} : \cdots : \underbrace{\frac{|\mathbf{G}|}{|\mathbf{F}_{q2}|}}_{\gamma_2} : \cdots : \cdots : \underbrace{\frac{|\mathbf{G}|}{|\mathbf{F}_{qc_q}|}}_{\gamma_{c_q}} : \cdots \\
&= \underbrace{\frac{1}{|\mathbf{F}_{q1}|}}_{\gamma_1} : \cdots : \underbrace{\frac{1}{|\mathbf{F}_{q2}|}}_{\gamma_2} : \cdots : \cdots : \underbrace{\frac{1}{|\mathbf{F}_{qc_q}|}}_{\gamma_{c_q}} : \cdots
\end{aligned}$$

These facts mean that non-equivalence can be discussed in terms not only of global orbits but also of local orbits. When two atoms belong to the same global (or local) orbit, they are symmetrically equivalent; otherwise, they are symmetrically non-equivalent. Moreover, such expressions as Eq. 1 can be preestimated in the form of tables of subduction (see below), which simplify our discussions on symmetry equivalence to a great extent. The present methodology, obviously, does not require terms concerning topic

relationships, such as enantiotopic and diastereotopic. In the subsequent sections, we will apply these theorems to several cases and reveal merits of the present approach.

3. Methyl Segments in Various Molecules

Global and Local Orbits for Methyl Segments. Figure 3 illustrates the same concepts as shown in Fig. 2 more concretely by using a D_{2d} skeleton and methyl ligands. In this case, we start from the skeleton (**16**) of D_{2d} symmetry. For simplicity's sake, we use a schematic top view (right) in place of a usual structural diagram (left). Each position of **16** (belonging to $D_{2d}(/C_s)$) is replaced by an achiral proligand (A) to produce the promolecule (**4**). Then the replacement of A's of **4** by methyl ligands produces the molecule (**17**), which has D_{2d} symmetry in a conformation of the highest attainable symmetry. In this conformation, the twelve hydrogen atoms in **17** are split into two orbits (H_4^a and H_8^b), which are governed by $D_{2d}(/C_s)$ and $D_{2d}(/C_1)$, respectively. These orbits are global orbits concerning these twelve hydrogens.

Let us now focus our attention on one of the four methyl ligands in **17**. Each of these methyl ligands is decided to be a C_s segment on the basis of the local symmetry determined by the $D_{2d}(/C_s)$ CR concerning the A_4 of **4**. This C_s segment contains atoms (H^a and H_2^b), which are subject to $C_s(/C_s)$ and $C_s(/C_1)$ if the labeling with a and b is taken into account. These orbits are local orbits concerning the methyl segment.

It should be noted that an object can exhibit simultaneous memberships of several distinct orbits that are presumed from different points of view. Thus, H^a is

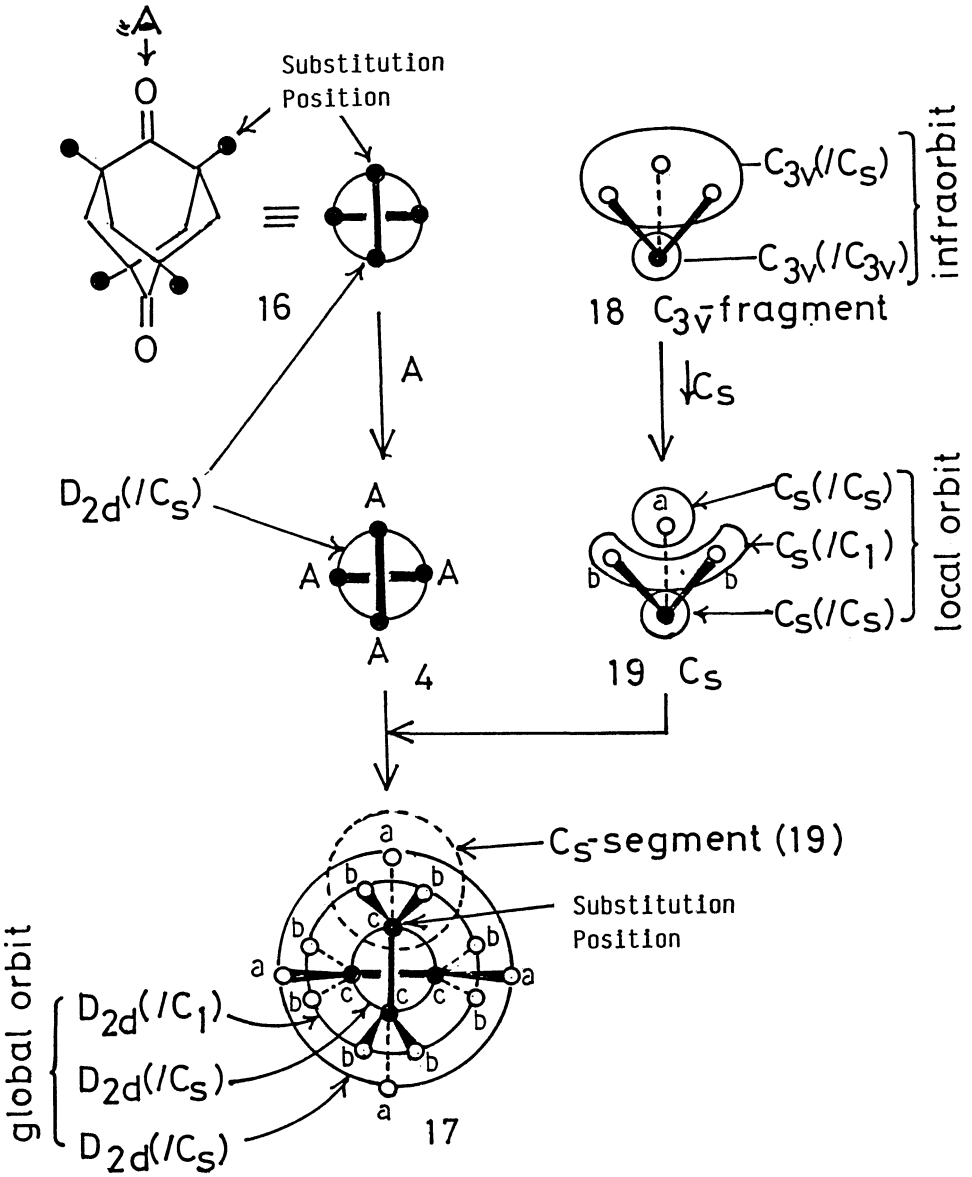

Fig. 3. Infraorbits, local orbits, and global orbits in **17**.

a member of the 4-membered global orbit denoted by $\mathbf{D}_{2d}(/\mathbf{C}_s)$, and, at the same time, belongs to the one-membered local orbit governed by $\mathbf{C}_s(/\mathbf{C}_s)$. Similarly, H^b belongs to the 8-membered $\mathbf{D}_{2d}(/\mathbf{C}_1)$ global orbit and to the 2-membered $\mathbf{C}_s(/\mathbf{C}_1)$ local orbit. The global orbit and the local orbit are linked with each other through the CR $\mathbf{D}_{2d}(/\mathbf{C}_s)$ of the substitution positions.

The local orbit concerning a methyl segment can be interpreted otherwise. This treatment is a direct application of Theorem 3. Let us begin with a methyl ligand in isolation (fragment). The methyl fragment (**18**) has an infraorbit of three hydrogen atoms that is subject to the CR, $\mathbf{C}_{3v}(/\mathbf{C}_s)$. Since this infraorbit is homospheric, it coincides with itself by the rotations and rotoreflections of the $\mathbf{C}_{3v}$ point group. When the methyl ligand is incorporated into **4** in place of A, its infraorbit is restricted to the $\mathbf{C}_s$ local symmetry. This restriction producing **19** is represented by the symbol, $\mathbf{C}_{3v}(/\mathbf{C}_s)\downarrow\mathbf{C}_s$, which is referred to as a *subduced representation* (SR) of the CR. Such a subduced representation is intransitive and can be further reduced into a set of CRs for $\mathbf{C}_s$ point group. For the purpose of such reduction, it is important to prepare a table of subduction of CRs.[12] Table 2 lists the subduction of CRs for $\mathbf{C}_{3v}$ point group. From this table, we obtain an expression:

$$\mathbf{C}_{3v}(/\mathbf{C}_s)\downarrow\mathbf{C}_s = \mathbf{C}_s(/\mathbf{C}_1) + \mathbf{C}_s(/\mathbf{C}_s), \quad (4)$$

which is an explicit form of Eq. 1 denoting this case. Equation 4 indicates that there emerge two orbits; the one (H_2^b) is a two-membered orbit subject to $\mathbf{C}_s(/\mathbf{C}_1)$ and the other (H^a) is a one-membered orbit subject to $\mathbf{C}_s(/\mathbf{C}_s)$. This splitting corresponds to the local orbits depicted in Fig. 3. Theorem 3 indicates that the sum $(\mathbf{C}_s(/\mathbf{C}_1)+\mathbf{C}_s(/\mathbf{C}_s))$ in the right-hand side of Eq. 4 corresponds to the sum $(\mathbf{D}_{2d}(/\mathbf{C}_1)+\mathbf{D}_{2d}(/\mathbf{C}_s))$. This fact agrees with the global orbits described above.

In general, local orbits are deduced from subduction of an infraorbit. Furthermore, global orbits are deduced form the local orbits in terms of Theorem 3. Table 3 lists local and global orbits that are created by the subduction of $\mathbf{C}_{3v}(/\mathbf{C}_s)$ infraorbit of a methyl ligand incorporated in **3** to **15**. These data are easily obtained from Table 2 by restricting $\mathbf{C}_{3v}(/\mathbf{C}_s)$ into the respective local symmetries that are listed in Table 1 and in the CR-for-ligand column of Table 3.

Anisochrony in Methyl Ligands. Symmetry equivalence is ascribed to the membership of the same orbit (local and global); and symmetry non-equivalence stems from the membership of distinct orbits. Then, we ascribe anisochrony to such symmetry non-equivalence. This criterion is mathematically stricter than that of Reisse et al.,[11] in which anisochrony is ascribed to diastereotopism by external or internal comparison.

According to the local-orbit column of Table 3, we can predict isochronies for the methyl segments of **21**, **22**, and **28**, since there appears no splitting of the 3-membered infraorbits. However, the former two (**21** and **22**) are different from **28** in their behaviors. In the cases of **21** (from **3**) and **22** (from **5**), the local symmetry of $\mathbf{C}_{3v}$ provides no restriction to the methyl group. On the other hand, the $\mathbf{C}_3(/\mathbf{C}_3)$ CR restricts the proligand (A) of the promolecule (**11**) so as to

Table 2. Subduction of Coset Representations for $\mathbf{C}_{3v}$ Group

Coset representation	Subduction			
	$\downarrow\mathbf{C}_1$	$\downarrow\mathbf{C}_s$	$\downarrow\mathbf{C}_3$	$\downarrow\mathbf{C}_{3v}$
$\mathbf{C}_{3v}(/\mathbf{C}_1)$	$6\mathbf{C}_1(/\mathbf{C}_1)$	$3\mathbf{C}_s(/\mathbf{C}_1)$	$2\mathbf{C}_3(/\mathbf{C}_1)$	$\mathbf{C}_{3v}(/\mathbf{C}_1)$

belong to C_3 local symmetry. When a methyl ligand is incorporated in **11** to afford **28**, this restriction to the local symmetry results in a subduction: $C_{3v}(/C_s)\downarrow C_3=C_3(/C_1)$. Although this equation indicates no discrimination between three methyl protons of **28**, the methyl ligand is restricted to the C_3 symmetry.

The other molecules collected in Table 3 exhibit a division of the infraorbit of each methyl fragment, which stems from a restriction to the corresponding local symmetry. This division causes an anisochrony of three protons of each methyl ligand. The present restriction is concerned with a conformation having the highest attainable symmetry, which is possible to exist when a sufficient energy barrier is realized under an appropriate condition (e.g., at low temperature). Otherwise, we should take account of bond rotations concerning the methyl segment. The CR ($C_{3v}(/C_s)$) in the left-hand side of Eq. 4 predicts that a free rotation equalizes three methyl protons in **17**. On the other hand, the right-hand side indicates that, if the rotation is slow on the NMR time scale, two anisochronous methyl proton signals (intensity ratio 2:1) can be observed. Note that $|C_s|/|C_1|$ is equal to 2 and $|C_s|/|C_s|$ is equal to 1. Among the molecules listed in Table 3, **23** (from **6**), **26** (from **9**), and **30** (from **13**) involve A's of the same situation as does **17** (from **4**). Thereby, the same prediction can be made for each of these molecules.

The equalization of the methyl protons under free bond rotation can be explained more logically. This process is equivalent to considering CH_3B, where the symbol B denotes an achiral proligand. This hypothetical promolecule belongs to C_{3v} symmetry. Hence, the carbon atom of the CH_3B constructs a $C_{3v}(/C_{3v})$ orbit. By using the C_{3v} local symmetry in place of C_s, we have $C_{3v}(/C_s)\downarrow C_{3v}=C_{3v}(/C_s)$ for the three protons. This equation indicates the equivalence of the methyl protons under free bond rotation.

The methyl protons of **2** are characterized in a similar way. The corresponding promolecule can be obtained by substituting an achiral proligand (A) for the methyl group of **2**. It belongs to C_s symmetry; the A constructs a one-membered orbit governed by C_s ($/C_s$). Since the local symmetry is determined to be C_s, the methyl segment in **2** is also restricted according to Eq. 4. Therefore, the same prediction as above can be obtained, although **4** has D_{2d} and **2** has C_s, as their global symmetries. Since $|C_s|/|C_1|=2$ and $|C_s|/|C_s|=1$, splitting of 2:1 intensity ratio is predicted to be observed in its low-temperature NMR spectrum. This prediction has already been verified experimentally.[5]

Each methyl segment in **24** (from **7**) is restricted to C_1 local symmetry. The subduction represented by $C_{3v}(/C_s)\downarrow C_1=3C_1(/C_1)$ (Table 2) indicates the symmetry non-equivalence of the three methyl protons in a conformation of the highest attainable symmetry. Hence, the three protons can be anisochronous if a bond rotation about a methyl segment is slow on the NMR time scale. If the rotation is fast, an average chemical shift is predicted to be observed because of the CR ($C_{3v}(/C_s)$). This example contains six methyl ligands and indicates an advantage of the present method over conventional ones which use Newmann's projections. In the cases in which so many ligands participate, it would be very tedious task to determine sterochemical non-equivalence in terms of Newmann's projections.

The same prediction is obtained with respect to **27** (from **10**) and **31** (from **14**), which are also characterized by C_1 local symmetry, although the global symmetry of the three molecules are different from each other. It should be noted that the global symmetries of these molecules are achiral (i.e., contain proper and improper rotations); but the local symmetries are chiral (i.e., contain proper rotations only).

A local symmetry of a chiral molecule is always chiral. Since the local symmetry of the ligand (A) in **8** is C_1 the corresponding subduction is represented by $C_{3v}(/C_s)\downarrow C_1=3C_1(/C_1)$. Hence, we can predict non-equivalence of three methyl protons in **25** (from **8**). We can obtain the same prediction about **29** (from **12**) and **32** (from **15**) in the same line, since they have C_1 local symmetries. Note that this type of anisochrony is observed only in a fixed conformation; the free rotation of a methyl ligand equalizes the three methyl protons. Anisochrony observed in the molecule (**1**) is rationalized in a similar way.[4]

The equalization under free bond rotation is equivalent to considering CH_3* where * denotes a chiral proligand. This hypothetical promolecule belongs to C_3 symmetry. Hence, the carbon atom constructs a $C_3(/C_3)$ orbit. By using the C_3 local symmetry in place of the C_1, we have $C_{3v}(/C_s)\downarrow C_3=C_3(/C_1)$ for the three protons. This equation means the equality of the three protons under free bond rotation.

4. CH_2X Segments in Various Molecules

Global Orbits and Local Orbits for CH_2X Segments. Suppose that A's of **3** to **15** are replaced by CH_2X ligands in place of methyl ligands described in the preceding section. The two protons of the CH_2X ligand construct an infraorbit governed by $C_s(/C_1)$. Table 4 collects the results of applying Theorems 2 and 3 to the present cases, where only orbits of the two protons are listed.

Table 5 lists the subduction of CRs for C_s point group. These data control restrictions of ligand symmetries, as collected in the local-orbit column of Table 4. The resulting global orbits are also collected in Table 4.

The case of **33** should be mentioned in contrast with **21**.[23] Although they are derived from the same promolecule (**3**), they are different in their resulting symmetries. Since the condition $\mathbf{F} \gtrdot \mathbf{G}_i$ is true for the case of the methyl ligands applied to **3**, Theorem 2

Table 4. Local Orbits and Global Orbits in **3**—**15** Substituted by CH_2X Ligands

Molecule	Structure	CR for ligands[a]	Local orbits	Global orbits
33	**3** (A=CH_2X)	$\mathbf{D}_{2d}(/\mathbf{C}_s)$*	$\mathbf{C}_s(/\mathbf{C}_1)$	$\mathbf{D}_{2d}(/\mathbf{C}_1)$
34	**4** (A=CH_2X)	$\mathbf{D}_{2d}(/\mathbf{C}_s)$	$\mathbf{C}_s(/\mathbf{C}_1)$	$\mathbf{D}_{2d}(/\mathbf{C}_1)$
35	**5** (A=CH_2X)	$\mathbf{C}_s(/\mathbf{C}_s)$*	$\mathbf{C}_s(/\mathbf{C}_1)$	$\mathbf{C}_s(/\mathbf{C}_1)$
36	**6** (A=CH_2X)	$\mathbf{C}_{3v}(/\mathbf{C}_s)$	$\mathbf{C}_s(/\mathbf{C}_1)$	$\mathbf{C}_{3v}(/\mathbf{C}_1)$
37	**7** (A=CH_2X)	$\mathbf{C}_{3v}(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{C}_{3v}(/\mathbf{C}_1)$
38	**8** (A=CH_2X)	$\mathbf{D}_2(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{D}_2(/\mathbf{C}_1)$
39	**9** (A=CH_2X)	$\mathbf{C}_{2v}(/\mathbf{C}_s)$	$\mathbf{C}_s(/\mathbf{C}_1)$	$\mathbf{C}_{2v}(/\mathbf{C}_1)$
40	**10** (A=CH_2X)	$\mathbf{S}_4(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{S}_4(/\mathbf{C}_1)$
41	**11** (A=CH_2X)	$\mathbf{C}_1(/\mathbf{C}_1)$*	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$

43	**13** (A=CH_2X)	$\mathbf{C}_s(/\mathbf{C}_s)$	$\mathbf{C}_s(/\mathbf{C}_1)$	$\mathbf{C}_s(/\mathbf{C}_1)$
44	**14** (A=CH_2X)	$\mathbf{C}_s(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{C}_s(/\mathbf{C}_1)$
45	**15** (A=CH_2X)	$\mathbf{C}_2(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{C}_2(/\mathbf{C}_1)$

a) The structure marked by an asterisk is desymmetrized in a mismatched fashion.

Table 5. Subduction of Coset Representations $\mathbf{C}_s$ Group

Coset representation	Subduction	
	$\downarrow\mathbf{C}_1$	$\downarrow\mathbf{C}_s$
$\mathbf{C}_s(/\mathbf{C}_1)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$\mathbf{C}_s(/\mathbf{C}_1)$
$\mathbf{C}_s(/\mathbf{C}_s)$	$\mathbf{C}_1(/\mathbf{C}_1)$	$\mathbf{C}_s(/\mathbf{C}_s)$

indicates that the symmetry ($\mathbf{T}_d$) of **3** retains in **21**. On the other hand, the condition is not satisfied in the substitution of CH_2X ($\mathbf{C}_s$ symmetry), since $\mathbf{F}=\mathbf{C}_s$ and $\mathbf{G}_i=\mathbf{C}_{3v}$. Hence, the symmetry of **3** is restricted into $\mathbf{D}_{2d}$ so as to satisfy the conditions $\mathbf{F} \gtrdot \mathbf{G}_i$ (i.e., $\mathbf{F}=\mathbf{G}_i=\mathbf{C}_s$).[24] This restriction produces **33** of $\mathbf{D}_{2d}$ symmetry, for which Theorem 2 holds. The cases of **35** and **41** (marked with an asterisk in Table 4) are explained in a similar way.

Anisochrony in CH_2X Ligands. Two methylene protons in a CH_2X ligand (fragment) construct a $\mathbf{C}_s(/\mathbf{C}_1)$ orbit. Since this infraorbit is enantiospheric, the two protons are equivalent in isolation; they coincide with each other by improper rotations only, not by proper rotations. Under *any* chiral environment, they are split to construct two hemispheric orbits in terms of Theorem 1. The chiral environment required in Theorem 1 may come from a local symmetry. From the data of Table 4 (the CR-for-ligand column), we can select **37**, **38**, **40**, **41**, **42**, **44**, and **45** as examples of such chiral local symmetries. Note that **37**, **40**, and **44** are achiral; on the other hand, **38**, **41**, **42**, and **45** are chiral. The restriction of such a CH_2X ligand is expressed by the subduction,

$$\mathbf{C}_s(/\mathbf{C}_1)\downarrow\mathbf{C}_1 = 2\mathbf{C}_1(/\mathbf{C}_1), \quad (5)$$

which is selected from Table 5. The two members of the $\mathbf{C}_s(/\mathbf{C}_1)$ orbit are presumed to coincide with each other only by a reflection concerning a mirror plane, if they are isolated hypothetically. However, since they are restricted to the $\mathbf{C}_1$ local symmetry in terms of Eq. 5, they are not superposed even if a free rotation is permitted. Thus, these molecules are predicted to show anisochronies of the geminal protons.

Anisochrony of $XYC(CU_2R)_2$ is obviously ascribed to the same effect as operating in **44**; $RU_2C\text{-}CX_3^*$ is explained in the same line as **41**; and anisochrony of $(RU_2C)_3C\text{-}CXYZ$ is equivalent to that of **42**. Other cases can be rationalized by the same rule. Some of these examples have once been discussed in terms of "intrinsic assymetry".[9] However, Reisse et al.[11] have concluded that continued use of the term is no longer justified. The present analysis strengthens their conclusion; but has an advantage over their method. While the Reisse method requires internal and external comparison for determining diastereotopism, the present method does not require such operations that are based on stereoisomerism; in other words, stereochemical non-equivalence (diastereotopism) is ascribed to membership of distinct orbits.

To the best of our knowledge, such anisochrony has never been reported that concerns four or more CH_2X ligands, probably because there have existed no methods effective to design complicated cases. The present method is capable of predicting anisochronies of such complicated compounds. Experimental verification will be challenging and is open to further investigation.

5. Criteria for Judging Symmetry Equivalence and Non-Equivalence

Our principal idea is here restated as follows: When a fragment is incorporated in a molecule, the CR of its infraorbit is restricted to the corresponding local symmetry; the restriction is represented by a subduction of the CR to the local symmetry. This idea has been exemplified by the discussions in the preceding sections. Thereby, it is generalized in the form of the following criteria.

a) Suppose that, in Theorem 3, the $\mathbf{F}(/\mathbf{F}_p)$ infraorbit is homospheric (for example, in a methyl ligand). The local symmetry $\mathbf{F}_q$ may be achiral or chiral.

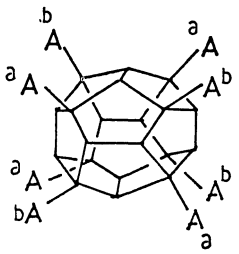
- If $\mathbf{F}(/\mathbf{F}_p)\downarrow\mathbf{F}_q$ produces a subdivision of the $\mathbf{F}(/\mathbf{F}_p)$ in terms of Eq. 1, the nuclei in the $\mathbf{F}(/\mathbf{F}_p)$ infraorbit are capable of exhibiting anisochrony due to $\mathbf{F}(/\mathbf{F}_p)\downarrow\mathbf{F}_q$. This anisochrony is observed at such a low temparature as affording slow bond rotations on the NMR time scale; otherwise, it exhibits an average chemical shift.
- If $\mathbf{F}(/\mathbf{F}_p)\downarrow\mathbf{F}_q$ provides no subdivision, there emerges no anisochronies.

b) Suppose that, in Theorem 3, an $\mathbf{F}(/\mathbf{F}_p)$ infraorbit is enantiospheric (for example, in a CH_2X ligand) and that the local symmetry $\mathbf{F}_q$ is achiral. The conclusion for the case a) holds for this case.

c) Suppose that, in Theorem 3, an $\mathbf{F}(/\mathbf{F}_p)$ infraorbit is enantiospheric (for example, in a CH_2X ligand) and

that the local symmetry $\mathbf{F}_q$ is chiral. Equation 1 provides the splitting of the enantiospheric orbit so as to yield two hemispheric orbits. Since this splitting is inherent, split signals can be observed with no respect to the NMR time scale.

These criteria indicate guidelines for determining anisochronies of nuclei; more detailed discussions should be based on concrete forms of SRs. In order to show the scope of these criteria, we examine more complicated molecules (**47**—**49**). The corresponding promolecule (**46**) has a $\mathbf{T}_h(/\mathbf{C}_3)$ orbit that consists of A_8. Since this orbit is enantiospheric, these eight A's are capable of splitting into two 4-membered hemispheric orbits (A_4^a and A_4^b) under an external chiral condition (Theorem 1).



46 A=proligand
47 A=CH_3
48 A= 49 A=CH_2OH $\mathbf{D}_{2h}$

The local symmetry of the proligands (A's) is $\mathbf{C}_3$ (chiral) in **46**. The $\mathbf{C}_3$ point group is a subgroup of the $\mathbf{C}_{3v}$ group of a methyl fragment. Hence, when each A is replaced by a methyl ligand, the resulting molecule (**47**) retains $\mathbf{T}_h$ symmetry. The incorporated methyl segment is restricted to the local symmetry in terms of

$$\mathbf{C}_{3v}(/\mathbf{C}_s)\downarrow\mathbf{C}_3=\mathbf{C}_3(/\mathbf{C}_1). \tag{6}$$

This equation indicates that, under any condition, there occurs no splitting of three protons in each methyl segment. In contrast with this, the methyl symmetry is lowered from $\mathbf{C}_{3v}$ to $\mathbf{C}_3$. This effect results in splitting of 8 methyl segments into two sets of equivalent methyl segments (A_4^a and A_4^b in **47**; A=CH_3) under an external chiral condition (e,g., by the action of a chiral shift reagent).

When a ligand has an enantiospheric $\mathbf{C}_{3v}(/\mathbf{C}_1)$ infraorbit as shown in **48**, the criterion c) is satisfied. Thus, we obtain

$$\mathbf{C}_{3v}(/\mathbf{C}_1)\downarrow\mathbf{C}_3=2\mathbf{C}_3(/\mathbf{C}_1). \tag{7}$$

This equation is selected from the $\mathbf{C}_{3v}(/\mathbf{C}_1)$ row of Table 2. Equation 7 means that we can observe two ^{13}C signals for methylene carbons (C_3^a and C_3^b) independent of temperature, if this splitting provides chemical shifts different enough to determine. Experimental verification regarding such a general type of anisochronies predicted here is open to further investigation.

When the same ligand as for **48** is incorporated in **3** ($\mathbf{T}_d$ symmetry), the resulting molecule exhibits a different nature. Since the local symmetry is $\mathbf{C}_{3v}$ (Table 1), the ligand suffers no restriction, i.e., $\mathbf{C}_{3v}(/\mathbf{C}_1)\downarrow\mathbf{C}_{3v}=\mathbf{C}_{3v}(/\mathbf{C}_1)$. Hence, there emerges no anisochrony. If this ligand is applied to any one of the promolecules listed in Fig. 1, its respective behavior can be explained by the $\mathbf{C}_{3v}(/\mathbf{C}_1)$ row of Table 2.

The criterion c) determines the fate of enantiospheric infraorbits incorporated into a chiral local symmetry in any case. When the achiral proligand (A) is substituted by CH_2X, the resulting molecule (**49**) no longer retains $\mathbf{T}_h$ symmetry; but is restricted to $\mathbf{D}_{2h}$ symmetry. Since the $\mathbf{C}_s$ symmetry of CH_2X is incompatible with the local symmetry ($\mathbf{C}_3$) of **46**, this desymmetrization occurs so that the local symmetry is created by $\mathbf{C}_3\cap\mathbf{C}_s=\mathbf{C}_1$. According to this restriction, the original $\mathbf{T}_h(/\mathbf{C}_3)$ orbit is converted into $\mathbf{D}_{2h}(/\mathbf{C}_1)$ orbit.[25] Note that the length of the $\mathbf{T}_h(/\mathbf{C}_3)$ orbit ($|\mathbf{T}_h|/|\mathbf{C}_3|=24/3=8$) is equal to that of the $\mathbf{D}_{2h}(/\mathbf{C}_1)$ orbit ($|\mathbf{D}_{2h}|/|\mathbf{C}_1|=8/1=8$). As a result, the resulting molecule (**49**) of the $\mathbf{D}_{2h}$ global symmetry exibits a $\mathbf{C}_1$ local symmetry at the $\mathbf{D}_{2h}(/\mathbf{C}_1)$ orbit. Thereby, the CH_2X ligand is controlled by

$$\mathbf{C}_s(/\mathbf{C}_1)\downarrow\mathbf{C}_1=2\mathbf{C}_1(/\mathbf{C}_1), \tag{8}$$

which is selected from the $\mathbf{C}_s(/\mathbf{C}_1)$ row of Table 5. This equation satisfies the criterion c); hence, the two protons of the CH_2X in **49** show anisochrony independent of NMR time scale. The corresponding global orbits are concluded to be $2\mathbf{D}_{2h}(/\mathbf{C}_1)$ in terms of Theorem 3. It is important to recognize that such an enantiosphericity of an infraorbit is by no means referred to as "prochirality". The prochirality should concern the enantiosphericity of a global orbit or of its equivalents.

6. Conclusion

A ligand is chracterized as a fragment when isolated and as a segment when incorporated in a molecule. The symmetry of the ligand-in-isolation (fragment) is restricted into the symmetry of the ligand-in-molecule (segment) in accord with the local symmetry of the molecule. As a result, any orbit in the ligand (an infraorbit) is restricted into local orbits. The relationship between such local orbits and global orbits is discussed in terms of subduction of coset representations. This discussion provides a general approach to rationalize various types of anisochronism.

3) Convensional usages of the terms "isochrony" and "anisochrony" have been criticized by Fulea.[26] However, his criticism proves to be simply based on the difference between his definition and the convensional one. According to his

definition, the terms are used to refer to a relationship between *states* of two nuclei; hence, any nuclei can be isochronous under one condition and anisochronous under another condition. On the other hand, the terms are conventionally used to refer to a relationship between *properties* (attributes) of two nuclei, though this standpoint has never been mentioned explicitly. Our usage in the present paper restates such an convensional usage more explicitly: Isochronous (chemical-shift equivalent) nuclei are defined as the ones that exhibit equal chemical shifts independent of any environments; anisochronous (chemical-shift non-equivalent) nuclei are defined as the ones that exhibit different chemical shifts but are capable of showing equal chemical shifts under an appropriate condition.

18) S. Fujita, *Tetrahedron*, **47**, 31 (1991).

19) The selection of a skeleton depends upon the purpose of our discussion. For example, adamantane ($C_{10}H_{16}$) itself can be selected to generate a skeleton, $C_{10}\pi_{16}$, where π denotes a substitution position. Thereby, the promolecule (**10**) is produced as a result of an $H_8F_4A_4$ substitution; on the other hand, the promolecule (**14**) comes from an $H_{13}FA_2$ substitution. In these processes, the original symmetry ($\mathbf{T}_d$) of the skeleton is restricted to $\mathbf{S}_4$ for **10** and to $\mathbf{C}_s$ for **14**. When we further replace the A's by ligands, we can start from such proligands as having $\mathbf{S}_4$ and $\mathbf{C}_s$ symmetries. If we do not introduce the concept of promolecule, we should go back to the original $\mathbf{T}_d$ symmetry in every examination. This is the reason for introducting the concept of promolecule in additon to the concept of skeleton.

20) For a concrete form of the CR, see Ref. 12.

21) The term "(imprimitive) block" used Ref. 14 denotes a geometical object that meets mathematical requirements only; hence, such a block is not always equivalent to a ligand. On the other hand, the term "segment" used in this paper designates a ligand-in-molecule, which has a chemical meaning as well as a mathematical one. In other words, a segment is a set of blocks selected so as to possess a chemical meaning.

22) W. H. Pirkle, S. D. Beare, and R. L. Muntz, *J. Am. Chem. Soc.*, **91**, 4575 (1969).

23) The molecules with an asterisk are called mismatched molecules, since the condition $\mathbf{F} \geqslant \mathbf{G}_i$ is not true for these cases. On the other hand, molecules satisfying this condition are called matched molecules. More detailed discussions is reported in Ref. 18.

24) This desymmetrization can be discussed in terms of a subduction table of $\mathbf{T}_d$.[14] It corresponds to the subduction: $\mathbf{T}_d(/\mathbf{C}_{3v})\downarrow\mathbf{D}_{2d}=\mathbf{D}_{2d}(/\mathbf{C}_s)$.

25) This desymmetrization can be expressed by $\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{D}_{2h}=\mathbf{D}_{2h}(/\mathbf{C}_1)$. A subduction table for $\mathbf{T}_h$ will be reported elsewhere.

Ion-Exchange Reaction on Cubic Ammonium Molybdate in Acidic and Alkaline Media—Exchange of Structural NH_4^+

Abdul Jabbar KHAN, Mitsuo ABE,* Yasushi KANZAKI, and Masamichi TSUJI
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology,
2-12-1 Ookayama, Meguro-ku, Tokyo 152
(Received July 6, 1990)

The alkali metal ion exchange reaction on cubic ammonium molybdate (CAM) cation exchanger was studied in acidic as well as alkaline media. The ion-exchange reaction and TPD-Mass thermogram of CAM indicated the presence of structural NH_4^+ as interstitial solid solution. The stuctural NH_4^+ in the H^+ form of CAM (H-CAM) was efficiently exchanged with K^+ as compared with other alkali metal ions in the equilibrated solutions. The exchanger was observed to be stable in acid medium, however structural transformations were observed at high pH. The presence of K^+ and Cs^+ at high pH could act as "Structure Building Ions" for CAM or H-CAM.

The ammonium or alkali metal tungstates have been reported by different authors.[1,2] Such type of materials are of interest because of their conductor properties with high ionic mobility due to existence of atomic sized tunnels within their crystal structure. The ionic mobility of NH_4^+ in ammonium tungstate investigated through NMR study, has been reported by Clark et al.[3] The existence of alkali metal ions (e.g. Rb^+) in tunnel structures of niobium and tantalum oxides have been discussed by Fallon and Gatehouse.[4]

The isopolymolybdates contain zigzag rows of MoO_6 octahedra which share corners in two directions forming MoO_4^{2-} layers.[5,6] The interstices of these layers provide channels for transport of cations (monovalent ions). These cations exist as solid solution in metal oxide structure.[7] The displacement of NH_4^+ or exchange of alkali ions (especially K^+) with NH_4^+ in heteropolyacid salts has been extensively reviewed by Amphlett[8] and Clearfield et al.[9] However less interest has been devoted to the study of mobility or transport of cations (e.g. NH_4^+) in the tunnel structure of molybdenum oxides, particularly through ion-exchange investigations.

The synthesis, characterization, and ion-exchange behavior of CAM along with the chromatographic separations of alkali metal ions have already been reported.[10,11] The present work was carried out to investigate the ion-exchange process of structural NH_4^+ in H-CAM through the maximum exchange capacity for alkali metal ions with respect to the crystal system of H-CAM. Ion-exchange equilibria, thermal analyses and X-ray diffractometry were employed for these investigations.

Experimental

Reagents. All the reagents used were analytical grade chemicals of Wako Pure Chemical Ind., Japan. Rubidium hydroxide and cesium hydroxide solutions were prepared through anion-exchange reaction by eluting the corresponding metal chloride solution through a column of Dowex 2-X8 anion exchanger in OH^- form. The N_2 gas was incorporated to avoid the CO_2 contamination in the resulting solutions.

Preparation of CAM and Conversion to H-CAM and A-CAM The cubic ammonium molybdate (CAM) $[(NH_4)_{0.78}(NH_4)_2]O_{1.39}\cdot 14.16MoO_3\cdot 6.08H_2O$ cation exchanger was prepared by the reaction of hexaammonium heptamolybdate and HNO_3 at 60 ±0.5 °C following the previously reported procedure.[10] CAM was converted to its H^+ form (H-CAM) $[(H)_{0.68}(NH_4)_2]O_{1.34}\cdot 14.16MoO_3\cdot 6.92H_2O$ by conditioning with 0.5 mol dm^{-3} HNO_3, using a column. H-CAM (100—200 mesh) was used throughout this work unless otherwise stated. The H-CAM when conditioned with 0.5 mol dm^{-3} NH_4NO_3 solution was converted to NH_4^+-form (A-CAM) $[(NH_4)_{0.68}(NH_4)_2]O_{1.34}\cdot 14.16MoO_3\cdot 5.26H_2O$.

X-Ray Diffractions. X-ray diffractions were taken with a JEOL JDX-7E and a Rigaku Denki Co. (Japan), model CN-5320 A-1/CN-2155 D-5 X-ray diffractometers. The crystal structures were deduced by using SANDMAN computer programs.[12—14]

Thermal Analyses and TPD-Mass Spectra. A Rigaku Denki Thermoflex, model 8001, was used for thermogravimetry (TG) and differential thermal analysis (DTA) at a heating rate of 10 °C min^{-1} using α-Al_2O_3 as a reference material.

The Temperature Programmed Desorption-Mass (TPD-Mass) spectrometry for investigating the desorption of structural ammonia and water in H-CAM was performed on a Quadrupole Mass Analyser MSQ-300 ULVAC. The sample was heated in an evacuated tube in the heating system provided with the said analyzer, at the same heating rate mentioned above. Each component was determined under an appropriate mass number. An adequate quantity of NH_3-gas was used as a reference for the investigation of ammonia in H-CAM.

Ion Selectivity, Maximum Exchange Capacity, and pH Titration. The distribution coefficients (K_d) were determined batchwise by equilibrating H-CAM (0.1 g) with 10 cm^3 solutions of 10^{-4} mol dm^{-3} alkali metal ions in different concentrations of HNO_3 at 30±0.5 °C with intermittent shaking.

The maximum exchange capacity for alkali metal ions on H-CAM was determined by batch experiment using 0.1 mol dm^{-3} MNO_3 (M=Li^+, Na^+, K^+, Rb^+, or Cs^+) solution in

10^{-4} mol dm^{-3} HNO_3. H-CAM (0.25 g) was equilibrated at 30±0.5 °C by the successive addition of each 25 cm^3 of the above solution, till no further uptake of respective metal ion. Similarly the topotactic K^+/NH_4^+ exchange was investigated by equilibrating A-CAM with KNO_3 solution.

The pH titration experiments were conducted by equilibrating H-CAM (0.1 g) with 10 cm^3 solution of a constant ionic strength of 0.1, containing different ratios of MNO_3/MOH or NH_4NO_3/NH_3 aq, at 30±0.5 °C with intermittent shaking.

The pH of the supernatant solutions were determined by a Toa Dempa HM-5B pH meter, the metal ion concentrations by an atomic absorption spectrophotometer, NH_4^+ by Nessler's method and the Mo(VI) cocentration by an Inductively Coupled Plasma (ICP) Spectrometer SPS-7000, Seiko Instruments, Japan.

Results and Discussion

Characteristics of CAM. The X-ray diffraction patterns, IR-spectra, and thermal analysis for CAM and H-CAM or A-CAM were observed to be the same as reported.[10] A-CAM was observed to possess two types of NH_4^+, the H^+-exchangeable NH_4^+ (EA-NH_4^+) and structural NH_4^+ (SA-NH_4^+). A reversible NH_4^+/H^+ exchange reaction was also studied on H-CAM.[10] However the present study showed that beside EA-NH_4^+, H-CAM was capable of exchanging SA-NH_4^+ too, with different selectivity for alkali metal ions. Hence A-CAM showed to possess two types of exchange sites i.e. H^+-exchangeable NH_4^+-site (EA-site) and structural NH_4^+-site (SA-site).

Selectivity of Alkali Metal Ions. The log-log plot (Fig. 1) of K_d vs. [HNO_3] was linear with a slope of −1 indicating an ideal ion-exchange reaction for all alkali metal ions except K^+. The selectivity sequence was observed to be $Cs^+>Rb^+>K^+>Na^+>Li^+$, in proportion to the increasing order of ionic radii (Table 1). The slope for K^+ was >−1 showing greater uptake irrespective of increase in HNO_3 concentration. These observations indicated that even though the exchange reaction for alkali metal ions at low metal ion concentration (i.e. 10^{-4} mol dm^{-3}) was preferred at EA-site, K^+ was more selective for SA-site (the release of NH_4^+ to the equilibrated solution by the uptake of K^+ was the experimental evidence for the exchange reaction).

TPD-Mass Spectroscopy. The TPD-Mass analysis (Fig. 2) showed two step loss of ammonia (solid-line peaks) and water (dashed-line peaks). The peaks around 120 °C indicated the loss of adsorbed ammonia and water on H-CAM, whereas the peaks at 200—350 °C corresponded to the presence of structural NH_4^+ and H_2O. Two peaks for structural H_2O were

H-CAM: 0.0053 g; Heating: 10 °C min^{-1}; B. K. Press: 4×10^{-7} Torr (1 Torr =133.322 Pa); Init. Intensity: 20×10^{-8} (NH_3 m/z=17), 20×10^{-7} (H_2O m/z=18), 10×10^{-9} (NO m/z=30 and NO_2 m/z=46), 10×10^{-8} (N_2O_3 m/z=76); Heating atm.: vacuum.

observed at temperature >250 °C. The former peak indicated the loss of structural H_2O whereas the latter one stood for the H_2O formed as a result of oxidation of structural NH_4^+ by MoO_3 into NO_x (broken-line peaks). This fact was supported by change in color of the product to black by heating H-CAM upto 600 °C in TPD-Mass experiment. The increase in the NO-peak with the rise of temperature may be attributed to the desorption of the adsorbed nitrogen oxide on molybdenum oxide, in accordance with the observations of Schiavello et al, on WO_3.[15]

The coexistence of structural NH_4^+ and H_2O, made it clear that structural NH_4^+ might stay as an interstitial solid solution in H-CAM lattice. The structural H_2O is probably the water molecules coordinated to Mo(VI) within the layers as noticed by Kerbs,[16] forming the adsorption centers (exchange sites) for NH_4^+ (or K^+ etc.). These observations signified the probability of SA-site being active for K^+ uptake. The presence of intervening NH_4^+ and H_2O molecules have also been reported by Matsumoto et al.[17] in ammonium pentamolybdodisulfate trihydrate.

Ion Exchange Capacity and Thermal Analysis. The maximum ion exchange capacity on H-CAM for all alkali metal ions in HNO_3 medium, ionic radii, and lattice constants of metal ion-exchanged forms of H-CAM i.e. M-CAM (M=Li, Na, K, Rb, or Cs) are given in Table 1. The maximum exchange capacity of H-CAM was observed to be in the order $Li^+<Na^+<Cs^+<Rb^+<K^+$. The equivalents of NH_4^+ released were equal to the equivalents of metal ions uptaken. In the view of experimental maximum

exchange capacity for K^+, the theoretical capacity of H-CAM could be calculated equal to 1.2 mequiv g^{-1}.

The change in the lattice constant of H-CAM after metal ions uptake is shown in Table 1. Almost no change was indicated with the uptake of Li^+. An increase in the lattice constant (a) of H-CAM was observed in Na^+ and Cs^+ exchanged forms ($a_{Na} > a_{Cs} > a_{H\text{-}CAM}$), whereas decrease in lattice constant was indicated by the uptake of K^+ and Rb^+ ($a_K \leqslant a_{Rb} < a_{H\text{-}CAM}$). However no transformation of H-CAM was observed in acid medium. The ion-exchange reaction on H-CAM especially at SA-site

Table 2. Percent Water Contents of H-CAM and Its Metal Ions Exchanged Forms (M-CAM). Data Calculated from Thermogravimetric (TG) Analyses

Samples	H_2O Contents
	%
H-CAM	5.30

Na-CAM	6.45
K-CAM	5.53
Rb-CAM	4.66
Cs-CAM	4.47

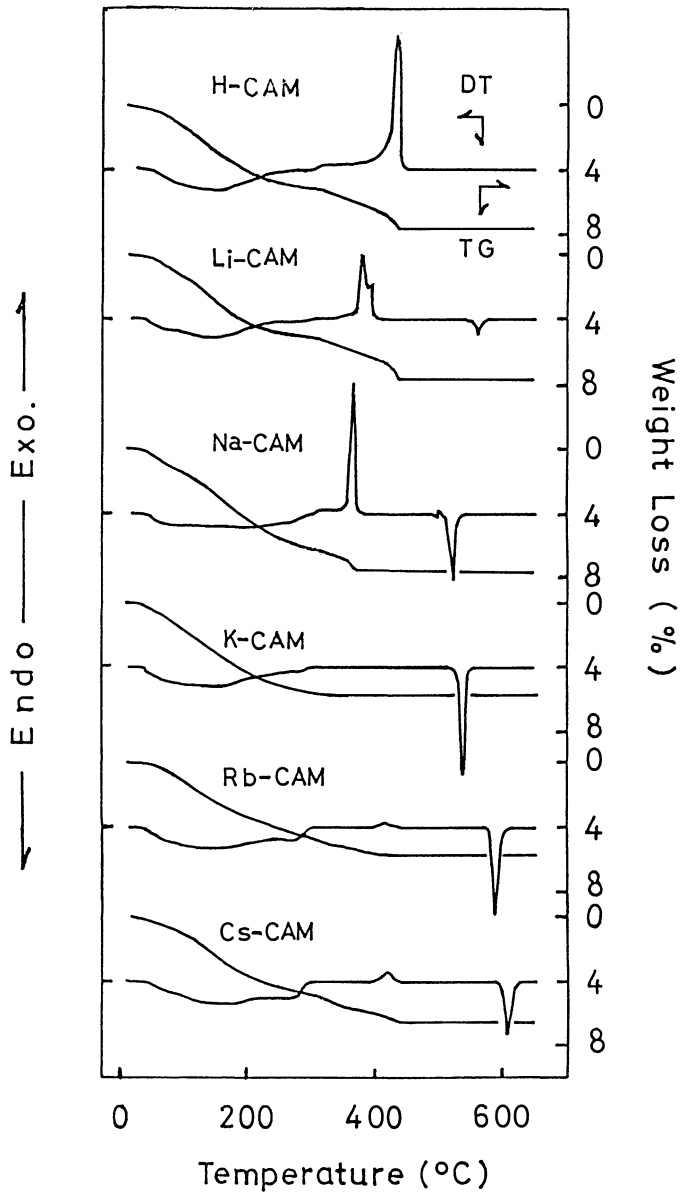

Fig. 3. The differential thermal (DT) and thermogravimetric (TG) curves of H-CAM and alkali metal ion-exchanged forms (M-CAM).
H-CAM or M-CAM: 0.0482 g; Heating: 10 °C min^{-1}; Heating atm.: ordinary.

seemed to be dependent on hydration of M^+ ions. The change in lattice with the uptake of M^+ ions may be attributed to the arrangement or size of hydration sphere (water molecules) around the respective ion in the tetrahedral layers (exchange sites). According to Diamond and Whitney,[21] the arrangement or size of the hydration sphere (water molecules) in the exchanger depends on the kind of metal ions.

Table 2 indicates the percent water contents of H-CAM and M-CAM samples. The water contents were observed to decrease in Rb and Cs forms (Cs-CAM<Rb-CAM<H-CAM) whereas increased in Li, Na, and K forms (Na-CAM>Li-CAM>K-CAM>H-CAM). The alteration (or arrangement) in the water contents brings alteration in the hydration sphere causing free energy (or entropy) changes which results in lattice change of the exchanger. The changes in water contents of M-CAM samples (Table 2) may correspond to the changes in water molecules of hydration sphere (at exchange site) brought about by the uptake of alkali metal ions on H-CAM. Greater free energy change caused by greater disturbance of hydration sphere resulted in greater change of lattice constants (e.g. a_{Na} and a_{Cs}).

The TG/DTA curves of H-CAM and M-CAM are shown in Fig. 3. The rise in DTA curve of H-CAM at >300 °C ending in a sharp exothermic peak at >430 °C indicated the existence of structural ammonia and

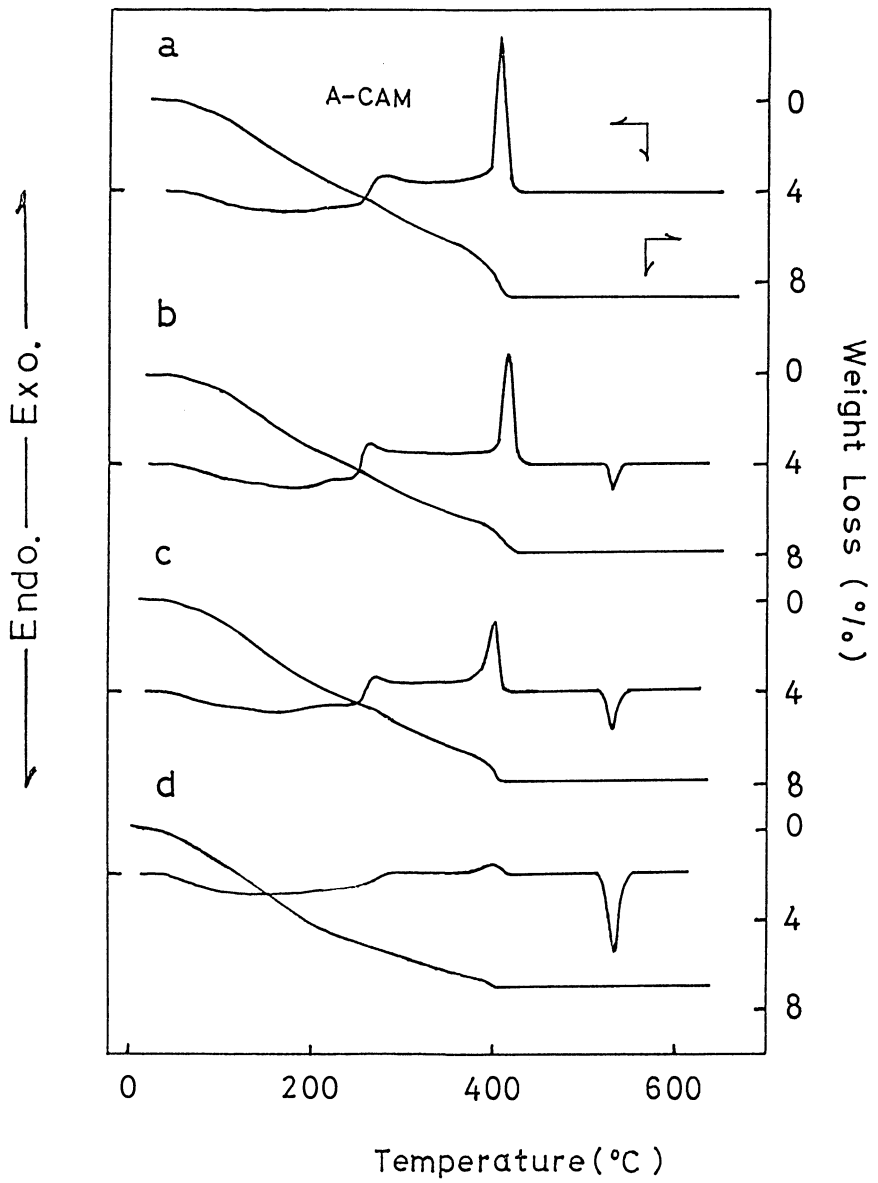

Fig. 4. The differential thermal (DT) and thermogravimetric (TG) curves of A-CAM (a) and K^+-exchanged forms (b—d) at different loadings. A-CAM: 0.0482 g K^+ mequiv g^{-1}: 0.2224 (b), 0.370 (c), 0.9760 (d); Heating: 10 °C min^{-1}; Heating atm.: ordinary.

water.[10] The DTA curves showed the presence of almost same ammonia contents of H-CAM in Li-CAM and Na-CAM indicating almost no exchange of structural ammonia (SA-NH_4^+) for Li^+ and Na^+ might be due to their selectivity preference for H^+-site or EA-site. In case of K^+ no exothermic peak due to structural ammonia was observed i.e. K^+ had replaced all the SA-NH_4^+ in H-CAM. This preference of K^+/NH_4^+ exchange was consistent with the selectivity of K^+ for SA-site in H-CAM. All of the NH_4^+ in H-CAM was not exchanged with Rb^+ and Cs^+ because of steric effect for their larger ionic radii. The very small exothermic peaks in DTA of Rb and Cs-CAM indicated the presence of unexchanged or remaining ammonia in H-CAM. The TG curves of the respective M-CAM were in accordance with the changes in DTA curves. The endothermic peaks in DTA curves at 500—620 °C indicated the fusion of M-CAM samples in the presence of alkali metal ions. No change in the TG curves was indicated at temperature >500 °C.

Exchange Sites and Metal Ion Uptake. The experimental results from K_d, maximum exchange capacity of alkali ions, and thermal analysis of M-CAM were in consistency for the exchange reaction at EA and SA-sites. Li^+ and Na^+ exchange reaction was favored at EA-site and K^+, Rb^+, and Cs^+ at SA-site in H-CAM. However to investigate the exchange reaction of K^+-Cs^+ at EA-site, the topotactic uptake of K^+ versus the apparent change in ammonia at EA/SA-sites was studied on A-CAM with different loadings of K^+. Figure 4a indicates the TG/DTA of A-CAM. The exothermic peaks at around 270 and 400 °C correspond to the loss of NH_4^+ at EA and SA-sites, respectively. Figure 4b,c indicated that the decrease in SA-NH_4^+ was proportional to the loading of K^+ at SA-site. However near the completion of K^+ uptake (maximum capacity), the exchange at both EA and SA-sites was favored (Fig. 4d). These results also provided an evidence for the discrepancy from slope −1 of K_d values for K^+. The cubic structure of both H-CAM and A-CAM was strictly retained after exchange of metal ions.

pH Titrations. The pH titration of H-CAM for alkali metal ions indicated apparently a monobasic acid, showing a large difference in blank and sample titration curves (Fig. 5). However dissolution of H-CAM occurred at pH >4.0 with a sharp increase in pH in NH_4NO_3/NH_3 aq medium. The equilibrium uptake of Li^+, Na^+, and NH_4^+ was observed to increase with increase in pH upto pH>4.0, whereas K^+, Rb^+, and Cs^+ showed a maximum uptake around

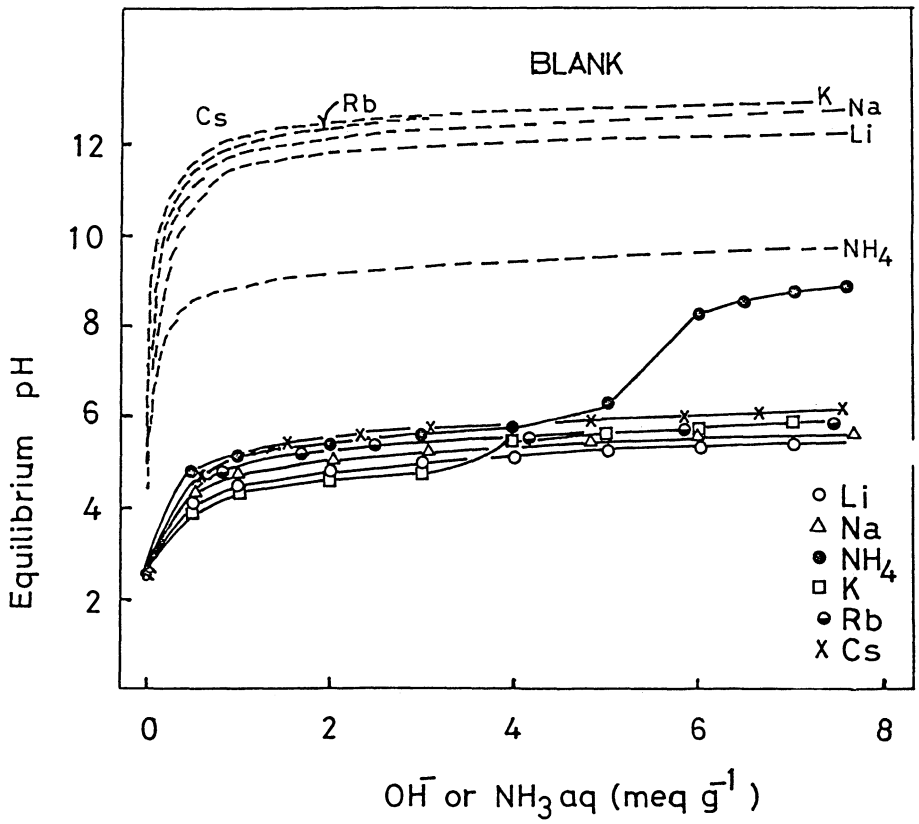

Fig. 5. pH titration curves of H-CAM.
H-CAM: 0.10 g; Soln vol.: 10.0 cm^3; Concn: 0.10 mol dm^{-3} (MCl+MOH) or (NH_4NO_3+NH_3 aq); Temp: 30±0.5 °C.

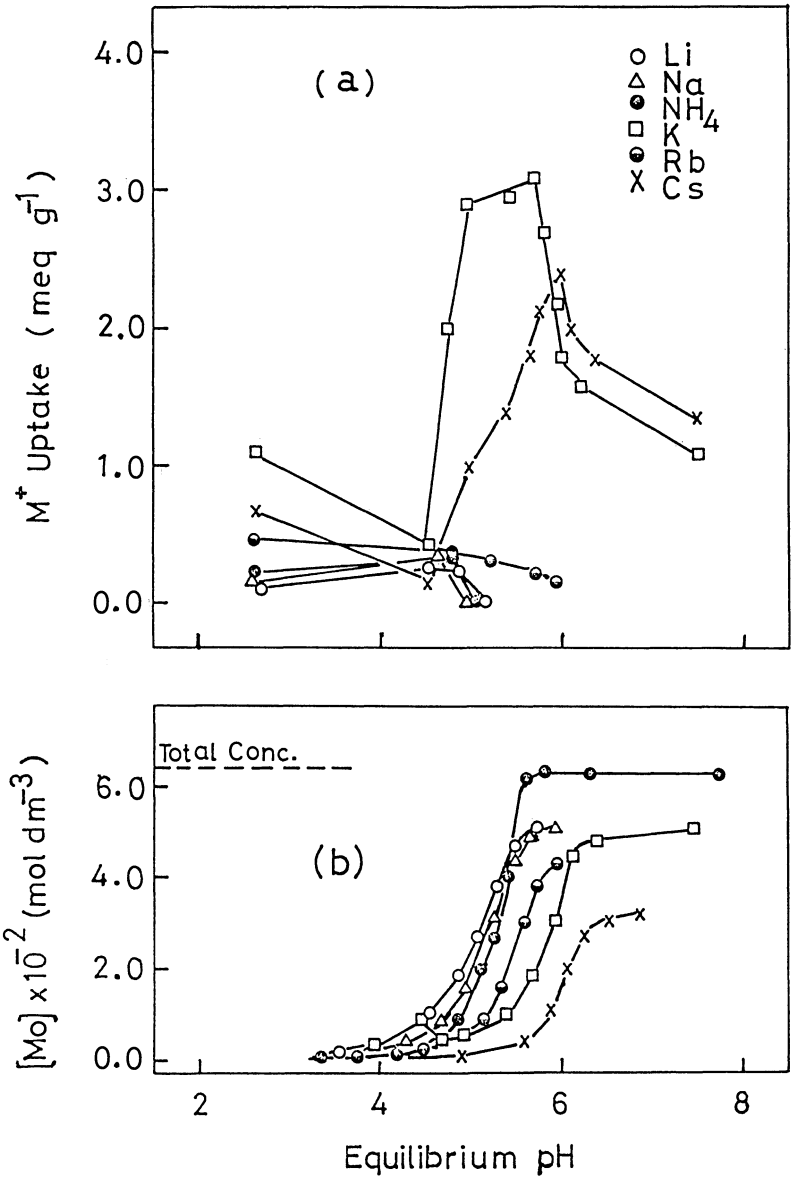

Fig. 6. Uptake of monovalent ions vs. equilibrium pH (a) and [Mo] in the supernatant solutions (b), after pH determination. H-CAM: 0.10 g; Soln vol: 10.0 cm^3; Concn: 0.10 mol dm^{-3} (MCl+MOH) or (NH_4NO_3+NH_3 aq); Temp: 30±0.5 °C.

pH 3 and decreased with increase in pH (Fig. 6a). The increase in the K^+ and Cs^+ uptake curves at pH>4.5 did not correspond to the uptake of these ions by H-CAM through ion-exchange reaction. Figure 6b indicates the dissolved amount of H-CAM {as [Mo(VI)]} in supernatant solutions at higher pH. The K^+ uptake (Fig. 6a) and [Mo(VI)] in the supernatant solutions (Fig. 6b) showed irregular curves with a break point around pH>4.5. The decrease in the K^+ uptake was due to the dissolution of H-CAM at high pH, however further increase in the uptake curve and an inflexion in the [Mo(VI)] curve at pH>4.5 indicated the complexation of K^+ with the dissolved H-CAM. The X-ray diffractions of the precipitates formed indicated the phase transformation of H-CAM to orthorhombic crystal system (with a totally different composition from H-CAM or K-CAM) at pH around 6.0 (Fig. 7). Almost similar observations were noticed for Cs^+ with a complete structural change to a triclinic form at pH around 6.17. The increase in amount (mequiv g^{-1}) of K^+ and Cs^+ (Fig. 6a) at pH>4.5 indicated the amount of these ions complexed with dissolved H-CAM (i.e. Mo(VI)) at higher pH. In the case of Li^+, Na^+, and Rb^+, no structural transformation or recomplexation was observed, though a slight change in the crystal lattice of H-CAM occurred after the uptake of metal ions, with no much difference in case of Rb^+ due to its

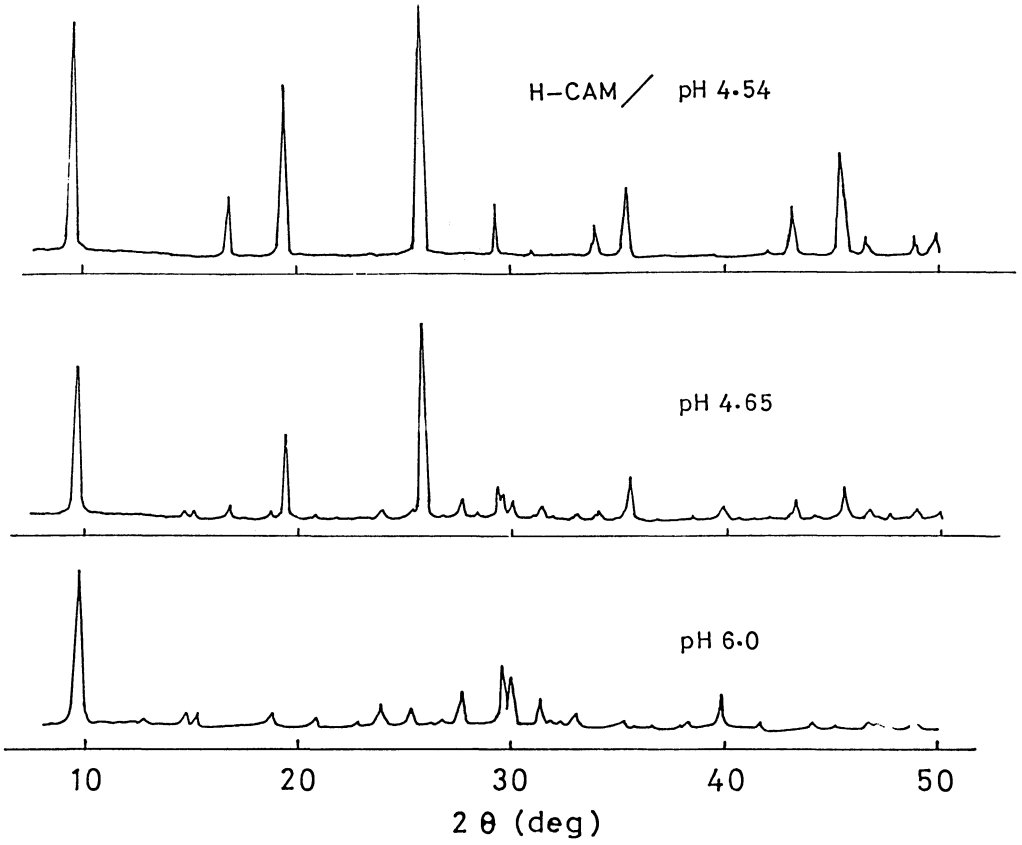

Fig. 7. X-Ray diffraction patterns indicating the pH dependent transformation of H-CAM to orthorhombic K-molybdenum oxide hydrate (KMO) formed (at pH 6.0) during the pH-titration of H-CAM.

nearly similar ionic radius as of NH_4^+.[18,19]

Conclusion

The cubic ammonium molybdate (CAM) cation exchanger possesses two different exchange sites, EA and SA-sites. Both sites were active for exchange of alkali metal ions with different selectivities. The order of selectivity at SA-site and maximum exchange capacity on H-CAM or A-CAM was $K^+ > Rb^+ > Cs^+$. The exchange of these ions for the structural NH_4^+ indicated that the NH_4^+ at SA-sites were mobile (i.e. not fixed up or trapped in the structure), however not accessible for the hydrated H^+ or H_3O^+ to be exchanged with. No change in cubic structure of CAM even with the loss of NH_4^+ indicated that the NH_4^+ seems to be existing in the atomic sized tunnels or layers within the crystal structure and is easy to exchange with ions of greater ionic radii without any alteration in the crystal structure. At high pH, the transformation of CAM or H-CAM to orthorhombic and triclinic-forms of molybdenum oxide in the presence of K^+ and Cs^+ respectively, lead to new concept—"The stucture building of metal oxides by metal ions," for preparation of new inorganic ion-exchange materials.

The help of Mr. K. Honda (a member of our group) in computer programs for X-ray diffraction analyses is hereby acknowledged.

Metal Complexes of Peptides. V. Cobalt(III) Complexes with *N*-β-Alanyl-(*S*)-aspartate

Tomoharu AMA,* Ritsuko MAKI, Hiroshi KAWAGUCHI, and Takaji YASUI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received August 10, 1990)

Three cobalt(III) complexes containing *N*-β-alanyl-(*S*)-aspartic acid (H_3L), [Co(L)(en)] (en: ethylenediamine), [Co(L)(dien)] (dien: diethylenetriamine), and $[Co(HL)(dien)]^+$, were newly prepared and characterized on the basis of their ^{13}C NMR, UV-visible absorption, and circular dichroism spectra. The dipeptide L functions as a quadridentate ligand in [Co(L)(en)] and as terdentate ligands in [Co(L)(dien)] and $[Co(HL)(dien)]^+$. The structures of these complexes are discussed in connection with those of $[Co((S)\text{-asp})(dien)]^+$ (H_2(*S*)-asp: (*S*)-aspartic acid) and $[Co(edma)(dien)]^{2+}$ (Hedma: ethylenediamine-*N*-acetic acid).

Many reports on the preparation and characterization of the cobalt(III) complexes containing dipeptides have been published.[1-17] In most of these complexes, the coordinated dipeptides function as terdentates in a meridional form with respect to the peptide backbones. In the previous paper,[1,2] we reported the novel coordination mode of dipeptide in $[Co(Hcar)(en)(OH_2)]^{2+}$ (H_2car: H_2β-ala-(*S*)-his, carnosine, or *N*-β-alanyl-(*S*)-histidine; en: ethylenediamine), where the carnosine coordinates to cobalt(III) as a facial terdentate with an uncoordinated amino group. This complex was prepared from $[Co(CO_3)_2(en)]^-$ and H_2car in an acidic aqueous solution. On the other hand, $[Co(car)(en)]^+$ complex containing a quadridentate dipeptide was prepared from the same materials in a basic aqueous solution.[1]

Replacement of the imidazolyl group in carnosine with a carboxyl group gives *N*-β-alanyl-(*S*)-aspartic acid (H_3L or H_3β-ala-(*S*)-asp), and it is expected that the latter exhibits similar coordination behavior to that of the former. In the present paper, the preparations of some cobalt(III) complexes with the ligand L will be described, and the coordination modes of the peptide will be discussed in detail on the basis of spectroscopic data of the complexes.

Experimental

Preparation of the Complexes. [Co(L)(en)] (Abbreviation: AA1): $K[Co(CO_3)_2(en)]\cdot H_2O$[18] (1.3 g) was dissolved in 30 cm^3 of water, and the pH of the solution was adjusted to 3 with 1 M (M=mol dm^{-3}) $HClO_4$. After the solution was stirred at room temperature for about 30 min, a solution containing 1.0 g of H_3L in 20 cm^3 of water was added to the solution. The pH of the combined solution was adjusted to 9 with 1 M NaOH, and then the solution was stirred at 65 °C for 8 h. The resultant solution was filtered and poured on an SP-Sephadex column (K^+ form, 4.7 cm×90 cm), and the adsorbed band was developed with water. The red band separated was eluted out, and the solution was concentrated to about 10 cm^3. The concentrated solution was again chromatographed on a QAE-Sephadex column (Cl^- form, 4.7 cm×90 cm). The adsorbed band was separated into pink and red parts by recycle-development with water on the same column. The solution eluted from the red band was concentrated under reduced pressure to a few milliliters, and methanol was added to the concentrated solution to obtain a crude complex. The crude complex was recrystallized from water by addition of methanol. Found: C, 32.94; H, 5.70; N, 16.94%. Calcd for $[Co(L)(en)]\cdot 0.5H_2O=C_9H_{18}N_4O_{5.5}Co$: C, 32.84; H, 5.51; N, 17.02%.

[Co(HL)(dien)]Br (AA2): The pH of a solution containing $[CoCl_3(dien)]$ (1.0 g)[19] (dien: diethylenetriamine) and H_3L (0.83 g) in 65 cm^3 of water was adjusted to 5 with 1 M NaOH. This solution was stirred for 48 h at 60 °C, keeping the pH of the solution to about 5. The reactant solution was cooled to room temperature, filtered, and then charged on an SP-Sephadex column (K^+ form). After the column was swept with 0.5 dm^3 of water, the adsorbed band was developed with 0.2 M KCl to separate a dark-orange band. The solution eluted from dark-orange band was concentrated to small volume under reduced pressure at 35—40 °C. Methanol was added to the concentrated solution, and potassium chloride deposited was removed by filtration. The filtrate was concentrated to about 10 cm^3 and treated with a QAE-Sephadex column (Br^- form). The treated solution was concentrated to small volume. A crude complex was obtained by addition of ethanol to the concentrate, which was recrystallized from water-ethanol solution. Found: C, 27.57; H, 5.88; N, 14.43%. Calcd for $[Co(HL)(dien)]Br\cdot 2H_2O=C_{11}H_{37}N_5O_7CoBr$: C, 27.51; H, 5.67; N, 14.58%.

[Co(L)(dien)] (AA3): A solution containing H_3L (0.83 g) in 15 cm^3 of water was added to the solution of $[CoCl_3(dien)]$ (1.0 g) in 50 cm^3 of warm water. After the pH of the solution was adjusted to 9 with 1 M NaOH, the solution was stirred for 24 h at 60 °C. The reactant solution was cooled to room temperature and filtered. The filtrate was poured onto an SP-Sephadex (K^+ form) column. The orange solution which was eluted with water was concentrated to ca. 20 cm^3 and loaded on a QAE-Sephadex column. Developing with water, the adsorbed band was separated into two parts; an earlier-eluted orange band and a later-eluted red band. The solution eluted from the later-eluted band was concentrated by using a vacuum evaporator and filtered. Crude complex obtained by addition of ethanol to the filtrate was recrystallized from water-ethanol solution. Found: C, 33.17; H, 6.64; N, 17.58%. Calcd for $[Co(L)(dien)]\cdot 2H_2O=C_{11}H_{26}N_5O_7Co$: C, 33.09; H, 6.56; N, 17.54%.

Isomers of [Co((*S*)-asp)(dien)]Cl and [Co(edma)(dien)]Cl_2: The geometrical isomers of $[Co((S)\text{-asp})(dien)]Cl$ (H_2(*S*)-asp: (*S*)-aspartic acid) and $[Co(edma)(dien)]Cl_2$ (Hedma: ethylenediamine-*N*-acetic acid) were obtained according to the

methods described in the previous papers.[20-21]

Absorption and Circular Dichroism Spectral Changes with pH. **AA1** (100 mg) was dissolved in 2 cm^3 of water, and 2 cm^3 of the solution was placed in a measuring flask (10 cm^3). A prescribed volume of 2 M HCl was added to the solution. The volume of the acidic solution was adjusted to 10 cm^3 with water. By the same procedure, nine solutions were prepared at different pH's (0.5—6.0). Absorption and CD spectra and pH of each solution were recorded at room temperature. In the same manner, the spectral changes with pH's were examined for **AA2** and **AA3**.

Measurements. The absorption and CD spectra were measured by a Hitachi 557 spectrophotometer and a JASCO J-22 spectropolarimeter, respectively. The ^{13}CNMR spectra were recorded on a Hitachi R-90H spectrometer. The chemical shifts in ^{13}CNMR were measured relative to internal dioxane (δ=67.40).

Results and Discussion

Structural Assignments of the Complexes. [Co(L)(en)] (AA1): Figure 1 shows the ^{13}CNMR shift patterns of free (uncoordinated) L and its complexes, together with those of the related compounds. The numbering of the carbons in L is also given in Fig. 1.

The carbon resonances of the free ligand L show a considerable difference in chemical shift with the

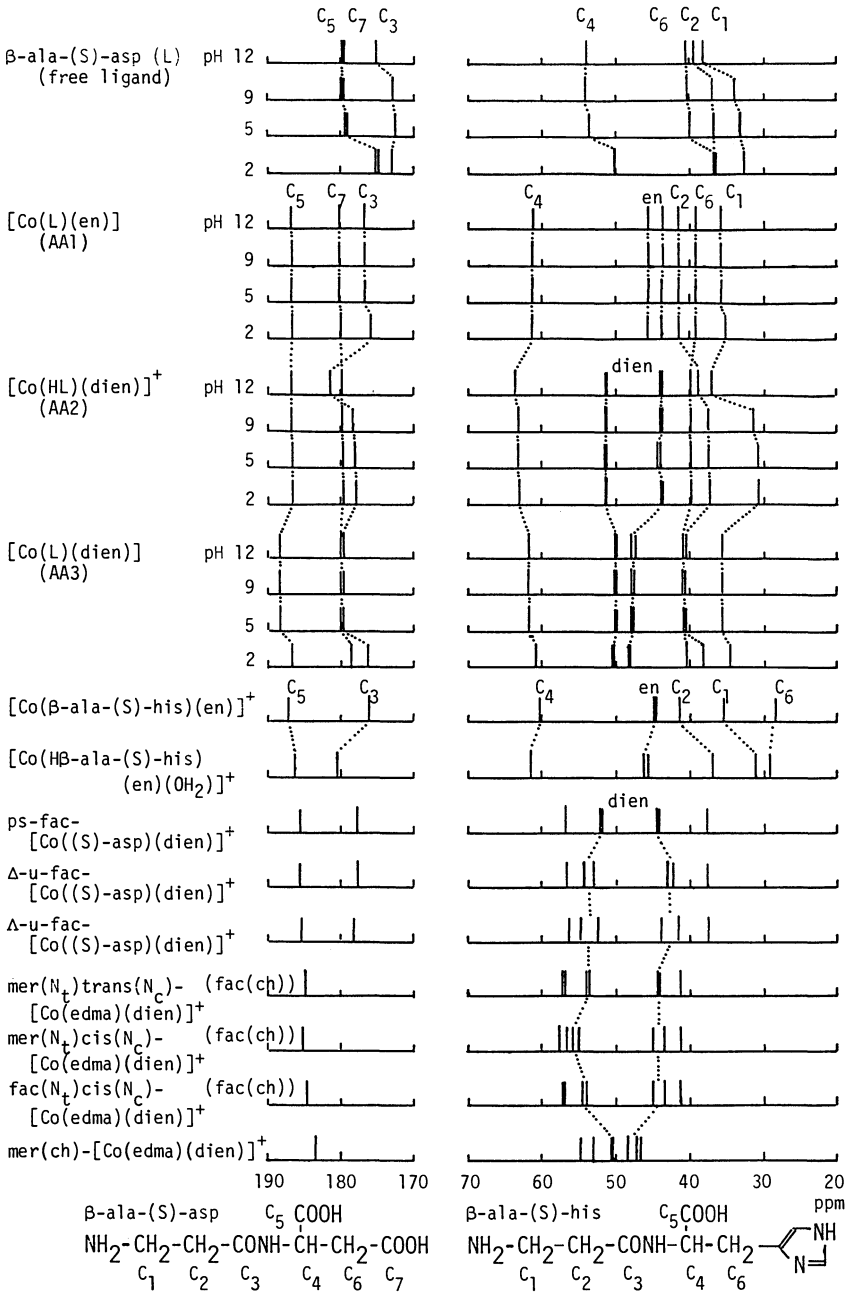

Fig. 1. ^{13}CNMR spectral patterns of β-ala-(*S*)-asp and the cobalt(III) complexes at various pH.

change of pH (12 to 2). The down-field shifts observed for the C_1, C_2, and C_3 carbons at pH 12 are due to the deprotonation of the terminal amino group ($-NH_3^+$). On the other hand, the up-field shifts of the C_4, C_5, C_6, and C_7 carbon resonances at pH 2 are due to the protonation to the α- and β-carboxylate anions. However, such the shift changes with pH as observed in the free ligand L are not observed in the ^{13}C shift pattern of **AA1**. This result suggests that the amino and two carboxyl groups of the peptide L in **AA1** coordinate to cobalt(III).

The chemical shifts of C_1, C_2, C_3, C_4, and C_5 in **AA1** are almost equal to those of the corresponding carbons of β-ala-(*S*)-his in [Co(β-ala-(*S*)-his)(en)]$^+$ at pH 5, in which the β-ala-(*S*)-his coordinates to cobalt(III) as a quadridentate.[1] This result suggests that the coordination mode of L in **AA1** is similar to that of β-ala-(*S*)-his in [Co(β-ala-(*S*)-his)(en)]$^+$. Accordingly, we propose that the ligand L in **AA1** coordinates to cobalt(III) in the quadridentate mode (Fig. 2(A)).

[Co(HL)(dien)]$^+$(AA2): The ^{13}C chemical shift behavior of the (*S*)-asp moiety (C_5, C_6, and C_7) in **AA2** resembles well to that in **AA1**. On the other hand, the shift behavior of the β-ala moiety (C_1 and C_2) in **AA2** is much different from that in **AA1**, but similar to that in [Co(Hβ-ala-(*S*)-his)(en)(OH_2)]$^+$ where Hβ-ala-(*S*)-his coordinates to cobalt(III) as a facial terdentate with free $-NH_3^+$ group.[1,2] These results suggest that L in **AA2** coordinates to cobalt(III) in the coordination mode similar to that of β-ala-(*S*)-his in [Co(Hβ-ala-(*S*)-his)(en)(OH_2)]$^+$; the ligand L coordinates with amide-N and two carboxyl-O's, and amino group is free. The down-field shifts of the β-ala moiety carbons (C_1 and C_2) at pH 12 compared with the shifts at pH 5 are due to the deprotonation from uncoordinated $-NH_3^+$.

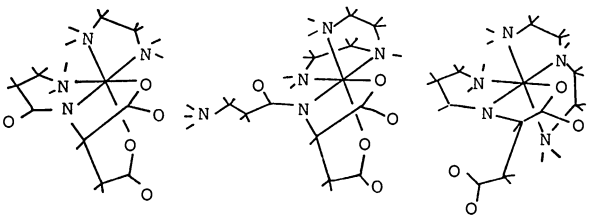

Fig. 2. Proposed structures of the cobalt(III) complexes containing β-ala-(*S*)-asp.

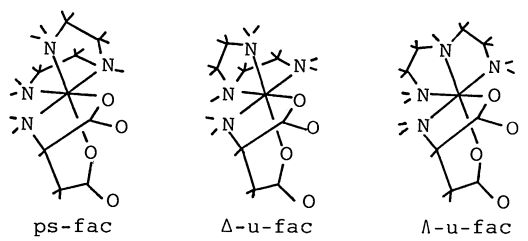

Fig. 3. Structures of the isomers of [Co((*S*)-asp)(dien)]$^+$.

Although the coordination mode of the HL in **AA2** is clarified as mentioned above, three geometries are possible for the structures of **AA2** in the same manner as shown for [Co((*S*)-asp)(dien)]$^+$ in Fig. 3. The geometrical structure of the isolated **AA2** can be assigned in comparison with its ^{13}C NMR spectrum with those of the [Co((*S*)-asp)(dien)]$^+$ isomers; the ^{13}C NMR signals of dien in **AA2** appear in shift pattern similar to that in ps-*fac*-[Co((*S*)-asp)(dien)]$^+$, but not in *Δ*-u-*fac* or *Λ*-u-*fac* (Fig. 3). On the basis of the above mentioned recognition, we propose the structure shown in Fig. 2 (B) for **AA2**.

Whereas the ps-*fac* type isomer of [Co(HL)(dien)]$^+$ was isolated in the preparation of **AA2**, the yields of *Δ*- and *Λ*-u-*fac* type isomers were so little that we did not succeeded to isolate them. The steric repulsion between β-ala moiety in HL and dien $-CH_2-$ may decrease the yields of the *Δ*- and *Λ*-u-*fac* type isomers.

[Co(L)(dien)] (AA3): The ^{13}C NMR signal of **AA3** shows the shift pattern characteristic to the complexes containing meridionally coordinated dien,[22,23] such as mer(ch)-[Co(edma)(dien)]$^{2+}$ (Fig. 1), and it obviously differs from those of the facial isomers of [Co((*S*)-asp)(dien)]$^+$ and of [Co(edma)(dien)]$^{2+}$. This observation suggests that dien in **AA3** coordinates to cobalt(III) in meridional form as a terdentate, and that the ligand L occupies the remaining meridional coordination sites.

The shift behavior of the β-ala moiety (C_1 and C_2) in **AA3** is similar to those in **AA1** at pH 5—12. Such a shift behavior suggests that the $-NH_2$ group of the β-ala moiety in **AA3** coordinates to cobalt(III). In addition, the chemical shifts of β-carbon (C_6) and β-carboxyl-carbon (C_7) in the (*S*)-asp moiety are in up-field at pH 2 compared with its chemical shifts at pH 5. These up-field shifts arise from protonation on the free β-carboxyl group. From these results we propose the structure shown in Fig. 2(C) for **AA3**.

The Absorption and CD Spectral Changes with pH: The absorption and CD spectra of **AA1**, **AA2**, and **AA3** in the neutral aqueous solutions are shown in Fig. 4. All of these complexes exhibited the absorption and CD spectral changes with pH in an aqueous solution. Figure 5 shows the CD spectral change of **AA2** over the pH range 0.63 to 6.08. The iso-circular dichroism points (iso-CD points) appear at 402, 498, and 529 nm, and the isosbestic points in the absorption spectra were observed at 429 and 494 nm. The pK_a value estimated from these changes was ca. 0.7. This value indicates that the spectral changes are related to the protonation on the coordinating amide group of L.[1,4,24] Similar spectral changes were also observed for **AA1** over the pH range 1.10 to 5.67 (iso-CD point: 414 nm; isosbestic point: 432 nm; pK_a value: ca. 0.9).

AA3, which has two proton acceptable groups

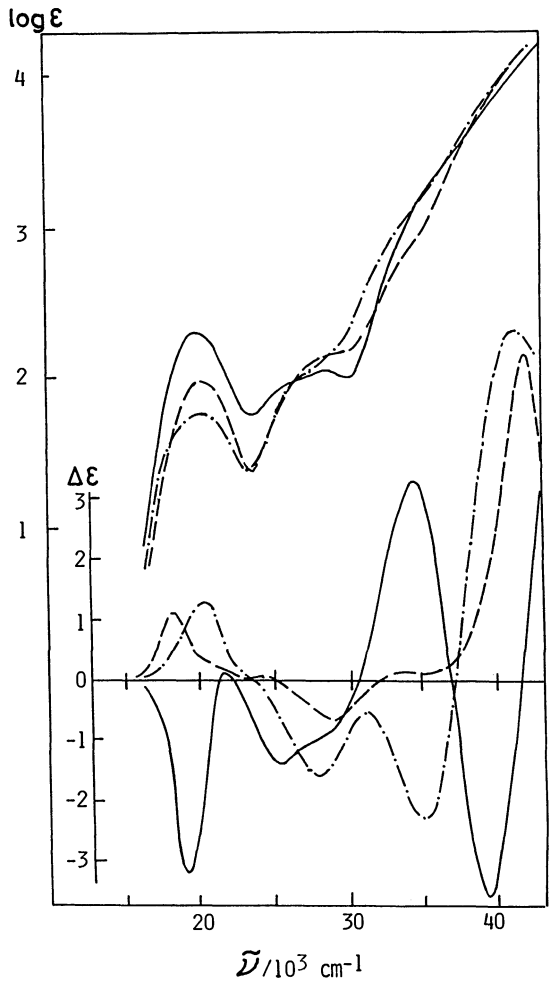

Fig. 4. Absorption and circular dichroism spectra of the complexes containing β-ala-(*S*)-asp: **AA1** (— · —), **AA2** (----), and **AA3** (——). ε and Δε values are given in $mol^{-1}dm^3cm^{-1}$.

(amide and free β-carboxyl), exhibited more complicated CD spectral change in the pH range 6.48—0.88 compared with those of **AA1** and **AA2**. That is, there was no iso-CD point over the pH range 6.48 to 2.0. However, the pK_a value for the amide group was calculated to ca. 1.5 from the CD spectral change in the pH range 2.0—0.88, where iso-CD points appeared at 433 and 507 nm.

Comparing the pK_a values of the coordinating amide groups in **AA1**, **AA2**, and **AA3**, the following result is noteworthy; the pK_a value of **AA3**, in which the peptide backbone is flat and free from the strain caused by the coordination of the β-carboxyl group of L-asp moiety, is larger than those of **AA1** and **AA2**, in which the peptide backbones are bended and strained by the coordination of the β-carboxyl groups in (*S*)-asp moieties.

AA1 did not show obvious spectral changes with time in the pH range 6.0—1.0, but it showed slowly spectral change with time in a strong acidic (2 M HCl) solution, accompanying with lower energy shifts and intensity decreases of the first and second absorption bands. This spectral change with time may be attributed to the fission of the β-carboxyl-cobalt(III) bond.

AA2 showed slowly spectral change with time in a strong acidic (2 M HCl) solution similarly to **AA1**. On the other hand, **AA3**, in which the β-carboxyl group of L does not coordinate to cobalt(III), did not show obvious spectral change with time in 2 M HCl solution. Such a fission of the β-carboxyl-cobalt bond occurring in **AA1** and **AA2** can be attributed to the strained coordination of the β-carboxyl group with six-membered chelate ring.[25]

The pH of the Reaction Solution Controlling the Coordination Mode of Peptide: The reaction between

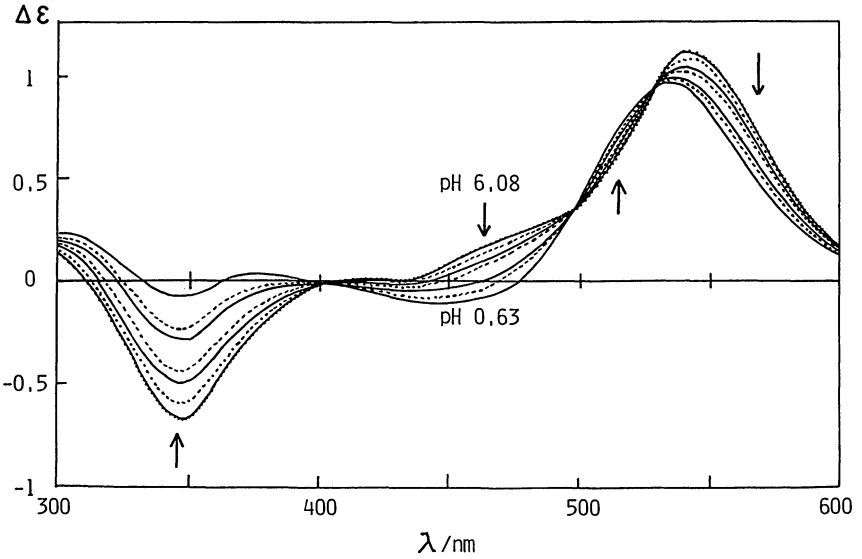

Fig. 5. CD spectral change with pH for the **AA2** complex. pH 6.08, 2.07, 1.60, 1.31, 1.18, 0.95, 0.85, and 0.63. Δε values are given in mol^{-1} dm^3cm^{-1}.

[$CoCl_3$(dien)] and H_3L yielded mainly **AA3** (the peptide functions as a meridional terdentate with uncoordinated β-carboxyl group) in a weakly basic aqueous solution (pH 9) and **AA2** (the peptide functions as a facial terdentate with uncoordinated amino group) in a weakly acidic aqueous solution (pH 5). These results suggest that the coordination modes of peptides can be controlled by the pH of the reaction solution. That is, the amino group on the peptide can not easily coordinate to cobalt(III) in a weakly acidic solution because of the protonation on the amino group, but the carboxyl group can easily coordinate in the weakly acidic solution. Accordingly, the β-ala-(*S*)-asp ligand coordinates to cobalt(III) with the α-carboxyl O, β-carboxyl O, and amide N in the facial terdentate mode (**AA2**; the meridional terdentate mode with α-carboxyl O, β-carboxyl O, and amide N is sterically impossible). However, in a basic aqueous solution, the amino group on the β-ala-(*S*)-asp can be coordinated to cobalt(III) more easily than in an acidic solution. Consequently, when the β-ala-(*S*)-asp is forced into terdentates in the basic solution, the β-ala-(*S*)-asp ligand coordinates to cobalt(III) in the meridional terdentate mode with amino N, α-carboxyl O, and amide N (**AA3**), which is preferable to the facial mode for dipeptides.[1,4,5]

One of the important subjects in bioinorganic chemistry is to control the coordination modes of a peptide on a metal ion. The present results provide useful clues for this subject in the manner different from those obtaind for labile complexes such as copper(II) ones.[26,27] Though the coordination modes of a dipeptide in the labile complexes are controlled by the stability (thermodynamics) rather than by the reaction rates (kinetics) of the ligands in the labile complexes, those in the present cobalt(III) complexes are controlled by the reaction rate of the amino group on the dipeptide. The present cobalt(III) complexes are stable and do not show the structural changes in the skeltons in the wide pH range 1—11 for several hours, even though deprotonation or protonation on the coordinated dipeptide is observed.

Extraordinary Coordination of Acetonitrile to Square-Planar, 1,4,8,11-Tetraazacyclotetradecanenickel(II) and (1*R*,4*R*,8*S*,11*S*)-1,4,8,11-Tetramethyl-1,4,8,11-tetraazacyclotetradecanenickel(II) Cations

(Received August 22, 1990)

Coordination of dipolar aprotic solvents to the square-planar complexes of nickel(II) was investigated in nitrobenzene (NB) spectrophotometrically. Compared with *N*,*N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO), it was observed that acetonitrile (AN) was strongly coordinated to $[NiL]^{2+}$ (L=1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane). The stepwise coordination constants K_{NiS1} and K_{NiS2} (mol^{-1} dm^3) for (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ were found to be (1.6, 0.5), (1.0, 0.1), (3.4, 6.7), and (0.4, 1.9) for DMSO, DMF, AN, and benzonitrile, respectively. The K_{NiS2} values for nitriles are larger than the K_{NiS1} values, showing that nitriles are coordinated to the metal ion through π-back donation.

$[NiL]^{2+}$ (L=1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) has two stable isomer of 1*R*,4*R*,8*S*,11*S*-nitrogen and 1*R*,4*S*,8*R*,11*S*-nitrogen configuration.[1-9] [Ni(cyclam)]$^{2+}$ (cyclam=1,4,8,11-tetraazacyclotetradecane), (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ and (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$ are described in Scheme (1). (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ and [Ni(cyclam)]$^{2+}$ form the six-coordinated complexes where two solvent molecules are attached to the central nickel.[9,10] However, (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$ forms the five-coordinated complex where only one solvent molecule is attached to the nickel.[7] The rate constants for exchange reaction of the coordinated solvent have been reported in H_2O, acetonitrile(AN), and *N*,*N*-dimethylformamide (DMF).[11-14] Accordingly, the observed values of enthalpy of activation for (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ were about twice as large as those for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$. It was also found that the coordination of the AN molecule to both isomers of $[NiL]^{2+}$ is stronger than that of other basic solvents.[14]

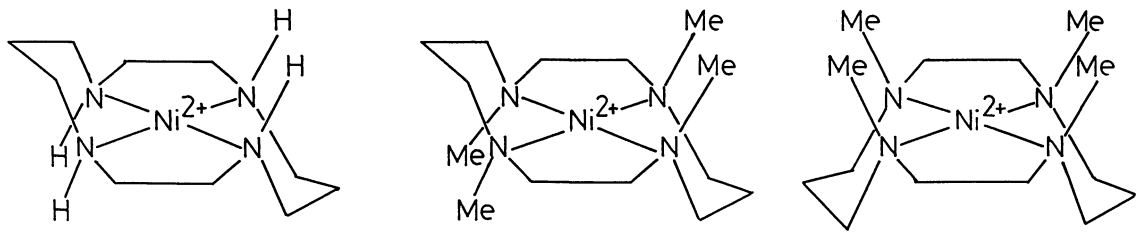
The axial coordination constants for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$ in various binary mixed solvents using nitrobenzene (NB) as a diluent were reported previously,[15] and the values obtained were decreased in the order DMF (5.4 mol^{-1} dm^3)>dimethyl sulfoxide (DMSO) (3.8)>AN (3.1)>benzonitrile (BzN) (0.4), while in pure solvents, the order was AN (13.4)>DMF (10.8)>DMSO (3.5)>BzN (2.4)>H_2O (1.8).[16] In these cases, the coordination constant of AN molecules is larger than that expected from Gutmann's donor number (DN), because DN of the solvents is decreased in the order DMSO>DMF>H_2O>AN>BzN, thus suggesting π-back donation.[15] The first and second coordination constants (K_{NiS1} and K_{NiS2}) for (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ have not been reported yet. An investigation of K_{NiS1} and K_{NiS2} might help in understanding the strong coordination of AN. Therefore, the stepwise coordination constants for (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ and a comparison with the results for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$ and [Ni(cyclam)]$^{2+}$ in NB mixtures are reported.

Experimental

NB, DMF, DMSO, AN, and BzN were purified as described previously.[15,17] $[Ni(cyclam)](ClO_4)_2$, $[Ni(cyclam)](BPh_4)_2$ (BPh_4=tetraphenylborate) and (1*R*,4*R*,8*S*,11*S*)-$[NiL](ClO_4)_2$ were prepared according to the published methods.[7-9,15,18] The purities were confirmed by the elemental analyses of the respective complexes. The instrumentation and procedure used for measurements of conductances and spectra are as reported previously.[15,18,19]

Results and Discussion

NB was selected as the diluent for the donor solvents



(a) [Ni(cyclam)]$^{2+}$ (b) (1R,4R,8S,11S)-[NiL]$^{2+}$ (c) (1R,4S,8R,11S)-[NiL]$^{2+}$

Scheme 1.

because polar NB dissolves (1*R*,4*R*,8*S*,11*S*)-[NiL]$(ClO_4)_2$ enough to permit measurements of the molar absorptivities spectrophotometrically. As NB has a weak basicity, NB is not coordinated to both (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and [Ni(cyclam)]$^{2+}$, and furthermore larger coordination constants of donor solvents were obtained in NB rather than in nitromethane and propylene carbonate.[15,17] Figures 1 (A) and (B) show variations of the visible spectra for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and [Ni(cyclam)]$^{2+}$ with AN concentration in NB. The wavelength of absorption maximum is 500 and 450 nm for the square-planar species (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and [Ni(cyclam)]$^{2+}$, respectively. In both Figs. 1 (A) and (B) the absorbance decreases with increasing donor solvent concentration.

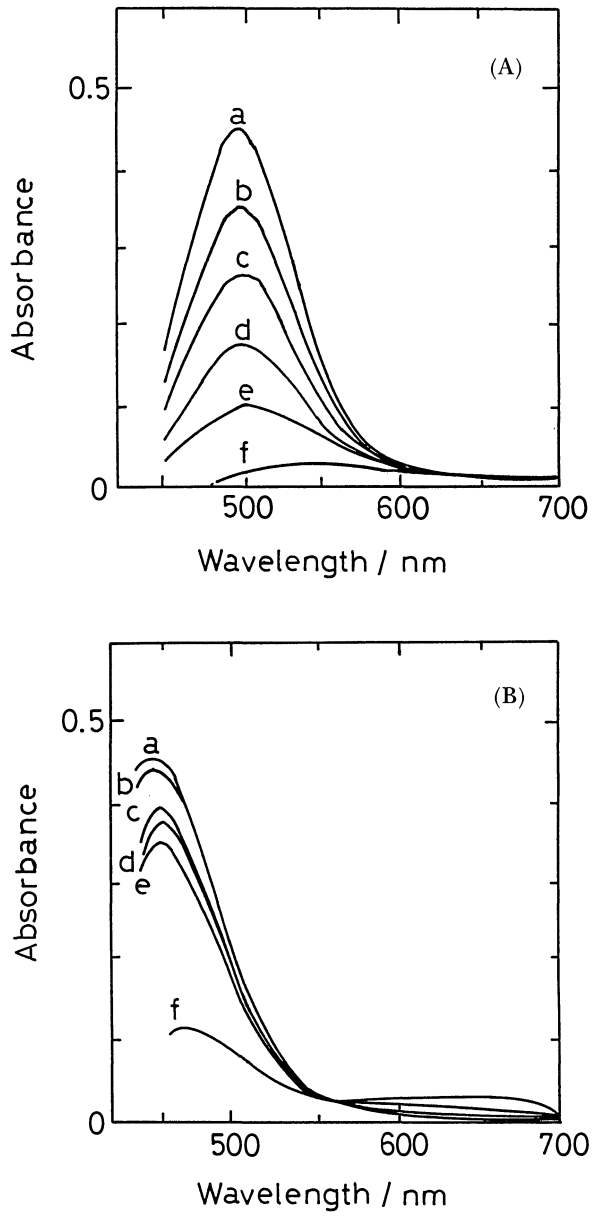


Fig. 1. (A) Variation of the visible spectrum with AN concentration for a solution of (1*R*,4*R*,8*S*,11*S*)-[NiL]$(ClO_4)_2$ (1×10^{-3} mol dm^{-3}) in NB at 25 °C. AN concentration (mol dm^{-3}): (a) 0.0, (b) 0.067, (c) 0.13, (d) 0.19, (e) 0.33, (f) neat; (B) for [Ni(cyclam)]$(ClO_4)_2$. AN concentration (mol dm^{-3}): (a) 0.0, (b) 0.32, (c) 0.54, (d) 0.71, (e) 1.0, (f) neat.

Figures 2 and 3 show variations of the molar absorptivities for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and [Ni(cyclam)]$^{2+}$ with the concentration of the donor solvents, respectively. The molar absorptivities for both complexes decreased with increasing donor solvent concentration. It should be noted that the decreasing ratio of AN is larger than those of DMF and DMSO for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$, but the reverse is true for [Ni(cyclam)]$^{2+}$. For [Ni(cyclam)]$^{2+}$ a small variation in the molar absorptivities was observed. The plots for BzN in which there is no variation in the molar absorptivities for [Ni(cyclam)]$^{2+}$, are omitted.

Equations 1 and 2 show the stepwise equilibria for the coordination of a solvent to the square-planar complexes,

$$(1R,4R,8S,11S)\text{-}[NiL]^{2+} + S \overset{K_{NiS1}}{\rightleftarrows} (1R,4R,8S,11S)\text{-}[NiL(S)]^{2+}, \quad (1)$$

$$(1R,4R,8S,11S)\text{-}[NiL(S)]^{2+} + S \overset{K_{NiS2}}{\rightleftarrows} (1R,4R,8S,11S)\text{-}[NiL(S)_2]^{2+}, \quad (2)$$

where S stands for the donor solvent. The molar absorptivities of the complexes are correlated to the

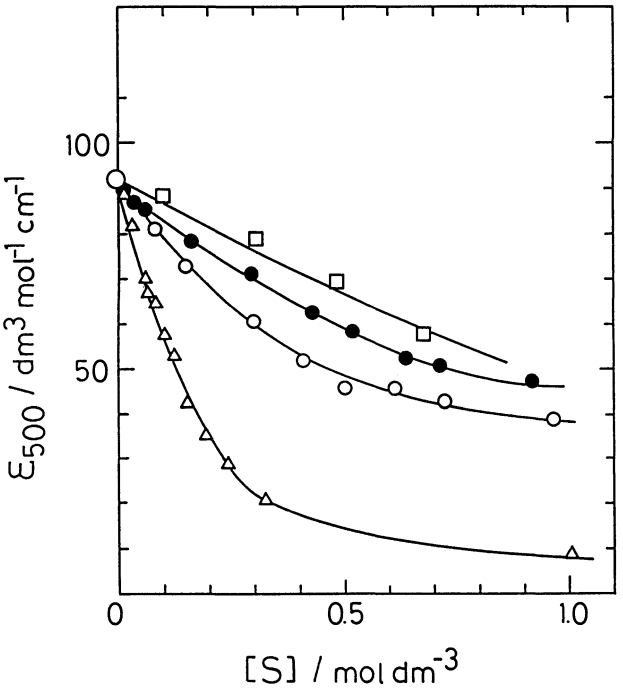

Fig. 2. Variation of molar absorptivities for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ with the donor solvent concentration in NB at 25 °C. ○, DMSO; ●, DMF; △, AN; □, BzN.

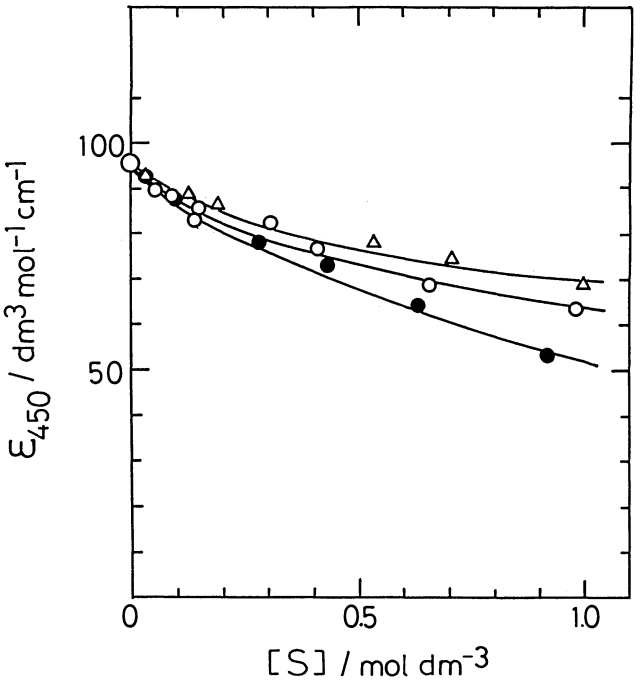

Fig. 3. Variation of molar absorptivities for [Ni(cyclam)]$^{2+}$ with the donor solvent concentration in NB at 25 °C. ○, DMSO; ●, DMF; △, AN.

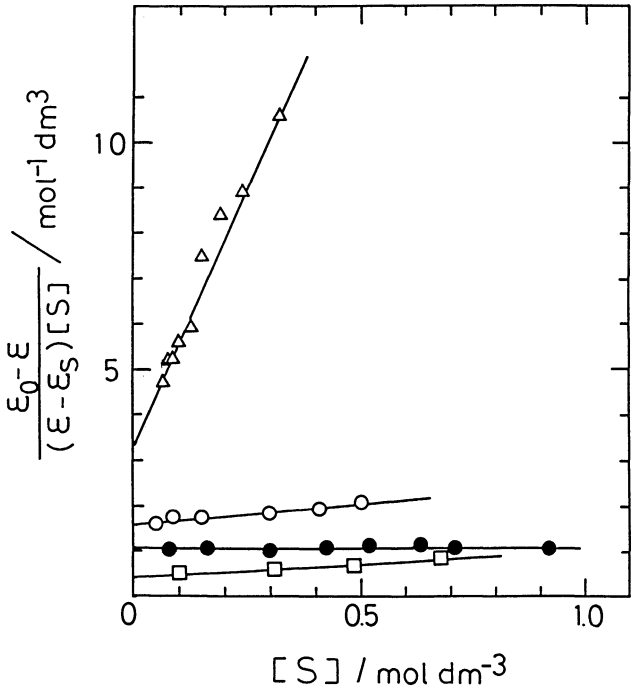

Fig. 4. Plots of $(\varepsilon_o-\varepsilon)/(\varepsilon-\varepsilon_s)$[S] for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$. ○, DMSO; ●, DMF; △, AN; □, BzN.

axial coordination constants by Eq. 3.

$$(\varepsilon_o-\varepsilon)/(\varepsilon-\varepsilon_s)[S]=K_{NiS1}+K_{NiS1}K_{NiS2}[S]. \quad (3)$$

The molar absorptivity, ε_o of square-planar species for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and for [Ni(cyclam)]$^{2+}$ is 92.2 dm^3 mol^{-1} cm^{-1} at 500 nm and 94.9 at 450 nm, respectively. The symbol ε is the apparent molar absorptivity, and ε_s is the combined molar absorptivity for five- and six-coordinated species and is 1.0 dm^3 mol^{-1} cm^{-1} at 500 nm for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and 14.2 at 450 nm for [Ni(cyclam)]$^{2+}$. A typical plot of Eq. 3 for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ is shown in Fig. 4 where a good linear relationship is obtained for all solvents used. In all the plots of Fig. 4, the concentration of S bonded to the cation is negligible compared with that of unbonded S, since the complex cation concentration used for measurements is 1×10^{-3} mol dm^{-3}. The K_{NiS1} and K_{NiS2} values can be obtained from the intercept and slope, and the results obtained are summarized in Table 1.

The overall coordination constants for [Ni(cyclam)](ClO$_4$)$_2$ and (1*R*,4*R*,8*S*,11*S*)-[NiL](ClO$_4$)$_2$ in NB are decreased in the order DMF (0.24)>AN (0.22)>DMSO (0.021) and AN (23)>DMSO (0.80)>BzN (0.76)>DMF (0.11), respectively. In pure solvents the overall coordination constants for [Ni(cyclam)](ClO$_4$)$_2$ are decreased in the order DMF (27.15)>AN (8.85)>DMSO (2.13)>H$_2$O (0.43, 0.38).[20,21]

Coordination ability of DMSO and H$_2$O as pure solvents is less than that expected from their basicity. This is attributed to the self-association which masks the donor oxygen atom: DMSO forms a cyclic dimer and water forms a three dimensional polymer.[17]

From Table 1, it is obvious that the coordination constants for [Ni(cyclam)](ClO$_4$)$_2$ are smaller than those for (1*R*,4*R*,8*S*,11*S*)-[NiL](ClO$_4$)$_2$. This can be

Table 1. K_{NiS1} and K_{NiS2} for (1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$ and [Ni(cyclam)]$^{2+}$, and K_{NiS} for (1*R*,4*S*,8*R*,11*S*)-[NiL]$^{2+}$ in NB at 25 °C

Solvent	(1*R*,4*R*,8*S*,11*S*)-[NiL]$^{2+}$		[Ni(cyclam)]$^{2+}$		(1*R*,4*S*,8*R*,11*S*)-[NiL]$^{2+}$[a]

a) Ref. 15. b) [Ni(cyclam)](BPh$_4$)$_2$.

explained, first, through the phenomenon of hydrogen bonding of the four N-H protons of $[Ni(cyclam)]^{2+}$. Effects of hydrogen bonding of N-H protons on ionic association in NB were studied.[18] The ionic association constants K_a obtained by the Fuoss-Edelson method,[22] were 0, 1190, and 11000 mol^{-1} dm^3 for $[Ni(cyclam)](BPh_4)_2$, (1*R*,4*S*,8*R*,11*S*)-$[NiL](ClO_4)_2$, and $[Ni(cyclam)](ClO_4)_2$, respectively, indicating that $[Ni(cyclam)](ClO_4)_2$ greatly associative.[15,18] The difference in K_a between BPh_4^- and ClO_4^- for $[Ni(cyclam)]^{2+}$ is slightly reflected on the K_{NiS1} values: the ClO_4^- complex gives a little smaller K_{NiS1} value compared with BPh_4^-. The basic donor solvents can be also hydrogen-bonded to the N-H protons, and their attack on the central nickel is hampered.

Secondly, the stability of square-planar configuration for $[Ni(cyclam)]^{2+}$ is considered. The logarithm of the stability constant is 8.6 for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$ and 20.1 for $[Ni(cyclam)]^{2+}$.[23] The absorption wavelength of the d-d transition observed is 450, 500, and 520 nm for $[Ni(cyclam)]^{2+}$, for (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$, and for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$, respectively, indicating that the stability for the square-planar configuration decreases in the order $[Ni(cyclam)]^{2+}$>(1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$> (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$. Cyclam is the secondary amines while L is the tertiary ones. As the coordination of the tertiary amine is stronger than the secondary one, the stability for $[NiL]^{2+}$ must be larger than that for $[Ni(cyclam)]^{2+}$.[23] However, the repulsion between the methyl groups of $[NiL]^{2+}$ leads to less stability for the square-planar configuration. In other words, it is easy for $[NiL]^{2+}$ to change its configuration from the square-planar into the square-pyramidal or the octahedral. Therefore, $[NiL]^{2+}$ easily receives the attack of the solvent.

Table 1 also compiles the coordination constants obtained together with K_{NiS} for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$. The K_{NiS1} values of DMF and DMSO are less than K_{NiS}, but those of AN and BzN are the same as K_{NiS}. The calculation of the strain energy showed that each coordination site for (1*R*,4*R*,8*S*,11*S*)-$NiL]^{2+}$ is more sterically crowded than the coordination site for (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$.[3,4] It is likely that coordination of DMF and DMSO molecules with $-N(CH_3)_2$ and two $-CH_3$, respectively, is sterically hindered, and the rod-like cyano group receives little steric hindrance.

Cyano groups show a striking and different trend from other solvents. K_{NiS2} for AN is twice as large as K_{NiS1}, although K_{NiS2} for DMF is only one tenth of K_{NiS1}. This anomalous behavior of AN may refer to π-back donation. Evidence has been reported for the π-back bonding of AN: the increase of the CN stretching frequency for copper halide adducts with AN,[24] the large stability constant of bis (α-furil dioximato)-diiodocobaltate(III) in AN,[25] the large ratio of $10Dq'$ (nickel bromide AN complex)/$10Dq'$ (nickel chloride AN complex),[26] the dependence of the coordination power value (relative Gibbs free energy change for solvation of the nickel ion) on other parameters,[27] and the deviation of ν_{max} for the copper complexes in AN from a correlation of ν_{max} with solvent donor number.[28] In all these cases, AN is strongly bonded to the complex than expected from its basicity. The coordination of one AN molecule via π-back donation makes another axial trans-coordination site active (a trans-effect). On receiving the electron-pair of AN, the nickel atom loses the positive charge slightly, but when the electrons of the nickel atom flow in the AN molecule via π-back donation, the density of positive charge on nickel increases. Therefore, the larger the π-back donation becomes, the stronger the second coordination, resulting in K_{NiS2}>K_{NiS1} for nitriles. The activation enthalpy for the loss of a single solvent molecule from (1*R*,4*R*,8*S*,11*S*)-$[NiL(AN)_2]^{2+}$ and (1*R*,4*R*,8*S*,11*S*)-$[NiL(DMF)_2]^{2+}$ are 41.5 and 38.3 kJ mol^{-1}, respectively.[14] This indicates that the coordination of AN to (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ is stronger than that of DMF, thus supporting π-back donation. In addition, the wavelength of the absorption maximum is 349 and 373 nm for the octahedral species (1*R*,4*R*,8*S*,11*S*)-$[NiL(S)_2]^{2+}$ in AN and in DMF, respectively, and indicates blue-shifts in AN compared with DMF.[15]

X-Ray crystallographic data showed that the deformation in the square-planar configuration of (1*R*,4*S*,8*R*,11*S*)-$[NiL]^{2+}$ is larger for one AN molecule coordination than that of DMF,[5,29,30] hence supporting the above view. The Ni-N (ring) bond lengths for the non-coordinated, DMF-coordinated, and AN-coordinated species are 0.1960, 0.2105, and 0.2143 nm, respectively. For DMF-coordinated species the distance of nickel atom displaced from the N_4 plane is 0.029 nm, while for the AN-coordinated it is 0.034 nm. The trans non-coordinating axial site of (1*R*,4*S*,8*R*,11*S*)-$[NiL(AN)]^{2+}$ is also activated, but the solvent cannot be coordinated because of the steric hindrance of methylene groups.

Influence of the ligand trans to O_2 on the O_2 adduct formation for the square-planar complex has already been reported.[31-33] The coordination constants of O_2 (K_{O_2}) increases in the order H_2O<pyridine (Py)< imidazole (Im)<NH_3<CN^- for $[Co(cyclam)]^{2+}$, Cl^-< ClO_4^-<Br^-<Py<Im for $[Co(Me_6(14)4,11\text{-dien}\ N_4)]^{2+}$, and ClO_4^-<Cl^-<SCN^- for $[Co(C\text{-meso-}Me_6[14]\text{-}aneN_4)]^{2+}$. As a matter of fact, when the axial ligand trans to O_2 is coordinated to the cobalt atom by π-back donation (e.g. CN^-), the K_{O_2} is large. A correlation between axial ligand basicity and oxygen affinity is stronger for a fully saturated macrocycle than that for unsaturated ones.[31] It is likely that the π-electrons of the macrocycle interrupt the approaching ligand through repulsion, resulting in a large K_{NiS2} for (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ which has a saturated macro-

cyclic ligand.

Conclusion

The introduction of AN into the coordination sphere of (1*R*,4*R*,8*S*,11*S*)-$[NiL]^{2+}$ is supported by π-back donation and hence AN is strongly bonded to the nickel atom. Coordination of nitriles by π-back donation activates the opposite axial trans-site of the square-planar complexes, contrary to DMF and DMSO, where no influence on its trans position is observed. The fact that K_{NiS2} is larger than K_{NiS1} for AN in AN–NB mixture, provides conclusive evidence for π-back donation to the nickel atom.

Different Kinetic Behavior of Zinc(II), Cadmium(II), and Lead(II) Porphyrins in the Ligand-Substitution Reaction with Ethylenediaminetetraacetic Acid

Masaaki TABATA* and Kazuhisa SUENAGA
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received September 14, 1990)

Kinetics and mechanism of the ligand-substitution reaction of Zn-, Cd-, and Pb(tpps)$^{4-}$ (H_2tpps^{4-}= 5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin) with ethylenediaminetetraacetic acid (EDTA) have been studied at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$). The rate equation for the decrease of M(tpps)$^{4-}$ is expressed as $-d[M(tpps)^{4-}]/dt=(k_1[edta^{4-}]+k_2[Hedta^{3-}]+k_3k_4[H]^2(k_{-3}+k_4[H^+])^{-1})[M(tpps)^{4-}]$, where M=$Zn^{2+}$, Cd^{2+}, and Pb^{2+}, and edta^{4-} denotes the fully deprotonated form of EDTA, respectively. The values of k_1 were found to be 0 for all of the metalloporphyrins studied, and k_2=0 mol^{-1}dm^3 s^{-1}; $k_3k_4(k_{-3})^{-1}$=8.7±0.2 mol^{-2} dm^6 s^{-1} for Zn(tpps)$^{4-}$, k_2=4.1±0.2 mol^{-1} dm^3 s^{-1}; $k_3k_4(k_{-3})^{-1}$=(8.3±0.4)×10^{12} mol^{-2} dm^6 s^{-1} for Cd(tpps)$^{4-}$ and k_2=2.0±0.1 mol^{-1} dm^3 s^{-1}; k_3(5.4±0.1)×10^7 mol^{-1} dm^3 s^{-1}; $k_3k_4(k_{-3})^{-1}$=2.0±0.1 mol^{-2} dm^6 s^{-1} for Pb(tpps)$^{4-}$, respectively. Hedta^{3-} directly attacks Cd- or Pb(tpps)^4 to form its metal complex, whereas Hedta^{3-} can not bind Zn(tpps)$^{4-}$. Zn(tpps)$^{4-}$ dissociates to aquazinc(II) by proton attack, then the aquazinc(II) reacts with Hedta^{3-}. Therefore, the ligand-substitution reaction of Zn(tpps)$^{4-}$ with EDTA is so slow that the reaction can be negligible compared with those of Cd- and Pb(tpps)$^{4-}$ in an alkaline solution. The reaction mechanism of the ligand substitution reaction and the different reactivities of the metalloporphyrins in it are discussed in detail.

Since zinc(II), cadmium(II), and lead(II) have filled d shell, they, especially zinc(II) and cadmium(II), are very similar in their chemical properties. For example, the formation constants of their metal complexes with ethylenediaminetetraacetic acid (EDTA) are $10^{16.44}$, $10^{16.36}$, and $10^{17.88}$.[1] Therefore it is difficult to determine these metal ions separately. However, the chemical properties of metalloporphyrins are different considerably. Formation constant of the metalloporphyrin of 5,10,15,20-tetrakis(4-sulfonatophenyl)-porphyrin (H_2tpps^{4-}) with zinc(II) is about 10^9 times larger than that of cadmium(II) or lead(II),[2,3] and the acid-dissociation rate of Cd(tpps)$^{4-}$ is 10^{12} times as fast as that of Zn(tpps)$^{4-}$. These large differences have been applied to the determination of zinc(II) in a large amount of cadmium(II) or lead(II) using the acid-dissociation reaction of their metalloporphyrins or the ligand-substitution reaction with EDTA.[3-5]

It has been believed that metalloporphyrins are very stable and they are hard to be replaced with EDTA.[6-8] In addition, only a few papers concerning the formation constants of metalloporphyrins have been published.[2,9-11] Because of the slow reaction rate of metalloporphyrin formation, it will take a few months or years to reach the equilibrium at room temperature except for some metalloporphyrins of such as mercury(II), cadmium(II), and lead(II). For that reason, it is ambiguous whether thermodynamically or kinetically metalloporphyrins are not replaced with EDTA. We have succeeded in determining the formation constant of Zn(tpps)$^{4-}$ using a catalytic effect of mercury(II) on the formation rate of Zn(tpps)$^{4-}$.[2] Comparing the formation constant of Zn(tpps)$^{4-}$ with that of Zn(edta)$^{2-}$, we have noticed that the conditional formation constant of Zn(tpps)$^{4-}$ is comparable to that of Zn(edta)$^{2-}$ at a neutral pH and that Zn(tpps^{4-}) should be replaced with EDTA thermodynamically in large excess of EDTA.

The present study was undertaken to clarify the reaction mechanism on the replacement of Zn(tpps)$^{4-}$ with EDTA and to get the detailed information on the large differences in the reactivities of Zn-, Cd- and Pb(tpps)$^{4-}$ which have been applied to the determination of zinc(II) in the presence of a large amount of cadmium(II) or lead(II).

Experimental

Reagents. 5,10,15,20-tetrakis(4-sulfonatophenyl)-porphyrine (TPPS) was synthesized and its sodium salt (Na_4H_2tpps) was purified by a previous method.[12] The purity was checked by thin-layer chromatography and ^{1}H NMR. Solutions of zinc(II), cadmium(II), and lead(II) were prepared from their nitrates, and the concentrations in these stock solutions were determined by EDTA titration using Xylenol Orange or Eriochrome Black T as indicators. The ionic strength of the sample solutions was held constant (0.1 mol dm^{-3}) with sodium nitrate. Sodium acetate (1×10^{-2} mol dm^{-3}) or sodium borate (1×10^{-2} mol dm^{-3}) containing nitric acid or sodium hydroxide was used as buffer solution. All reagents were of analytical reagent grade and all solutions were prepared in water deionized and then distilled from alkaline permanganate. The solutions of the metalloporphyrins were prepared just before the kinetic measurements in volumetric flasks covered with aluminum foil to shield from light. The formation of the metalloporphyrins was confirmed spectrophotometrically.

Measurement. The ligand-substitution reaction of M(tpps)$^{4-}$ (M=Zn^{2+}, Cd^{2+}, and Pb^{2+}) with EDTA was studied in a pH range 3—4.5 for Zn(tpps)$^{4-}$ and 8.0—9.3 for Cd- and Pb(tpps)$^{4-}$ at the concentrations of EDTA (1.0×10^{-3}—5.0×10^{-2} mol dm^{-3}), metal ions (Zn^{2+}, Cd^{2+}, Pb^{2+}; each at 4.0×10^{-6}—1.0×10^{-4} mol dm^{-3}) and H_2tpps^{4-} (1.0×10^{-6}—2.0×10^{-6} mol dm^{-3}). The reaction was started by mixing a

$M(tpps)^{4-}$ solution with an EDTA solution using a sample mixing device (Union Giken, MX7). The change in absorbance at Soret bands of the metalloporphyrins (421 nm for $Zn(tpps)^{4-}$, 430 nm for $Cd(tpps)^{4-}$, and 465 nm for $Pb(tpps)^{4-}$) was monitored as a function of time on a Hitachi 323 spectrophotometer. The kinetic studies for the acid-dissociation rate of Zn-, Cd-, and $Pb(tpps)^{4-}$ were carried out in a pH range of 1.2—2.0 for $Zn(tpps)^{4-}$ and that of 4.5—5.5 (acetate buffer, 10^{-2} mol dm^{-3}) for $Cd(tpps)^{4-}$ and $Pb(tpps)^{4-}$, respectively. The change in absorbance at Soret band of the metalloporphyrins was followed by a Uniongiken RA401 stopped-flow spectrophotometer at 25 °C.

The pH values were determined by a Radiometer Ion 85 Ion Analyzer with a combined electrode (GK2401C). A 1.000×10^{-2} mol dm^{-3} nitric acid solution containing 0.09 mol dm^{-3} sodium nitrate was employed as a standard hydrogen ion concentration ($-\log[H^+]=2.000$). From pH meter readings in various hydrogen ion concentrations at 0.1 mol dm^{-3} ionic strength (HNO_3-$NaNO_3$), the pH meter and electrode system was calibrated in terms of $-\log[H^+]$.

Results

Ligand-Substitution Reaction of Zn-, Cd-, and $Pb(tpps)^{4-}$ with EDTA. The reaction of $M(tpps)^{4-}$ ($M=Zn^{2+}$, Cd^{2+}, and Pb^{2+}) with EDTA was studied in large excess of EDTA at pH 3—4.5 for the reaction of $Zn(tpps)^{4-}$ and at pH 8—9.3 for that of Cd- and $Pb(tpps)^{4-}$. Under the present experimental conditions, the porphyrin is in its protonated and free base forms: H_4tpps^{2-}, H_3tpps^{3-}, and H_2tpps^{4-}, since the protonation constants for $[H_3tpps^{3-}][H^+]^{-1}[H_2tpps^{4-}]^{-1}$ and for $[H_4tpps^{2-}][H^+]^{-1}[H_3tpps^{3-}]^{-1}$ are $10^{4.99}$ and $10^{4.76}$, respectively.[2] Furthermore, the chemical species of EDTA are in the forms of H_3edta^-, H_2edta^{2-}, $Hedta^{3-}$, and $edta^{4-}$. Thus the reaction of $M(tpps)^{2-}$ with EDTA is written as

$$M(tpps)^{2-} + edta' \rightleftarrows M(edta)^{2-} + tpps', \quad (1)$$

where edta' and tpps' are all chemical species of EDTA and TPPS not bound to metal ions, respectively. The equilibrium of metalloporphyrin formation is generally given by

$$M^{2+} + H_2tpps^{4-} \rightleftarrows M(tpps)^{4-} + 2H^+, \quad (2)$$

with the equilibrium constant defined by

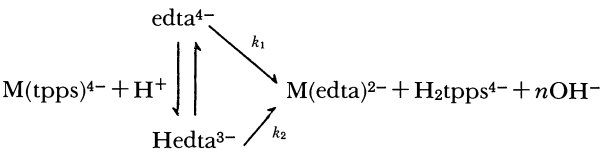
$$K_{MP} = \frac{[M(tpps)^{4-}][H^+]^2}{[M^{2+}][H_2tpps^{4-}]}, \quad (3)$$

and the values of K_{MP} have been found to be $10^{-0.43}$, $10^{-9.94}$, $10^{-9.97}$ for Zn-, Cd-, and $Pb(tpps)^{4-}$, respectively at 25 °C and I=0.1 mol dm^{-3}.[2,3] Moreover, the formation constants of $M(edta)^{2-}$ are respectively $10^{16.44}$, $10^{16.36}$, and $10^{17.88}$ for $M=Zn^{2+}$, Cd^{2+}, and Pb^{2+}, while the stepwise protonation constants of $edta^{4-}$ are $10^{10.17}$, $10^{6.18}$, and $10^{2.68}$.[1] Thus the equilibrium constants of Eq. 1 are calculated to be $10^{2.39}$ at pH 4 for $Zn(tpps)^{4-}$, $10^{8.13}$ at pH 8 for $Cd(tpps)^{4-}$, and $10^{8.16}$ at pH 8 for $Pb(tpps)^{4-}$, respectively. The metalloporphyrins, therefore, are completely replaced with EDTA and the reverse reaction of Eq. 1 can be neglected in large excess of EDTA compared with that of TPPS.

Thus, the pseudo-first-order kinetics was observed for the reaction of Eq. 1:

$$-d[M(tpps)^{4-}]/dt = k_0[M(tpps)^{4-}], \quad (4)$$

where k_0 denotes the conditional rate constant containing concentrations of edta', hydrogen ion, and metal ion. The k_0 values for the reactions of Cd- and $Pb(tpps)^{4-}$ increased with the edta' (Fig. 1), and this result shows that the reaction is first-order in edta'. In contrast, the k_0 values for the reaction of $Zn(tpps)^{4-}$ were independent of edta' even at its concentration of 0.05 mol dm^{-3} (Fig. 2). Figure 3 shows the dependence of rate constant on hydrogen ion concentration for the reaction of Cd- and $Pb(tpps)^{4-}$ with EDTA. The k_0 values increased with hydrogen ion concentrations and reached a plateau at pH 8, where main chemical species of EDTA is in the form of $Hedta^{3-}$. Thus the reaction mechanism to account for the kinetic data is shown in Scheme 1:



Scheme 1.

This leads to the rate equation of Eq. 5

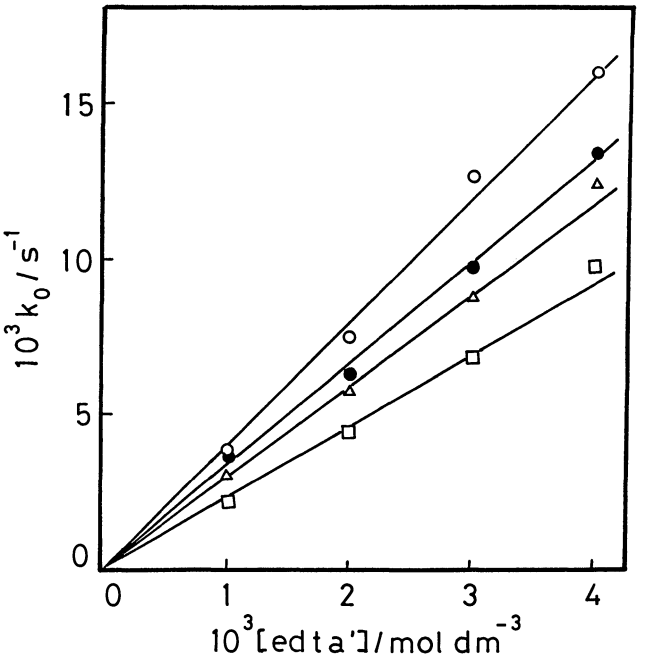


Fig. 1. Dependence of rate constants on the concentrations of edta' for the reaction of $Cd(tpps)^{4-}$ with EDTA in pH 8.01 (○), 8.48 (●), 8.69 (△), and 9.09 (□) at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$).

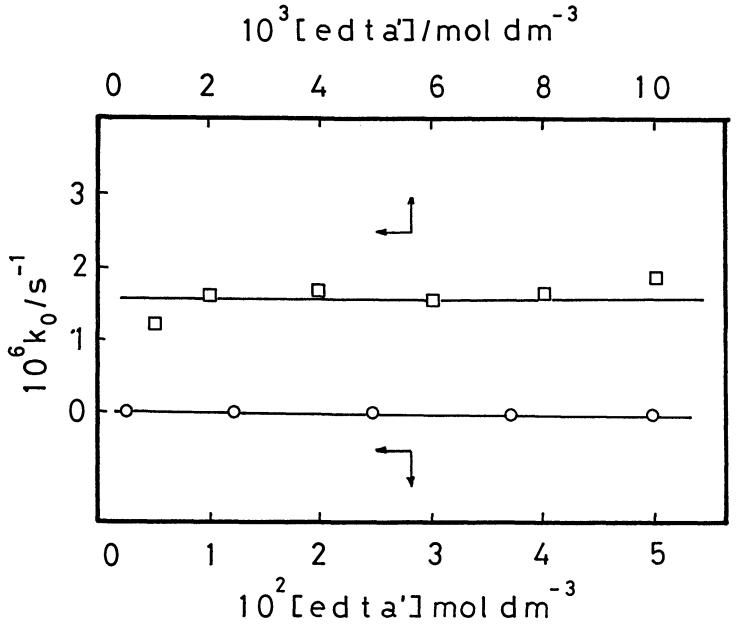

Fig. 2. Dependence of rate constants on the concentrations of edta' for the reaction of $Zn(tpps)^{4-}$ with EDTA in pH 3.30 (□) and 4.50 (○) at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$).

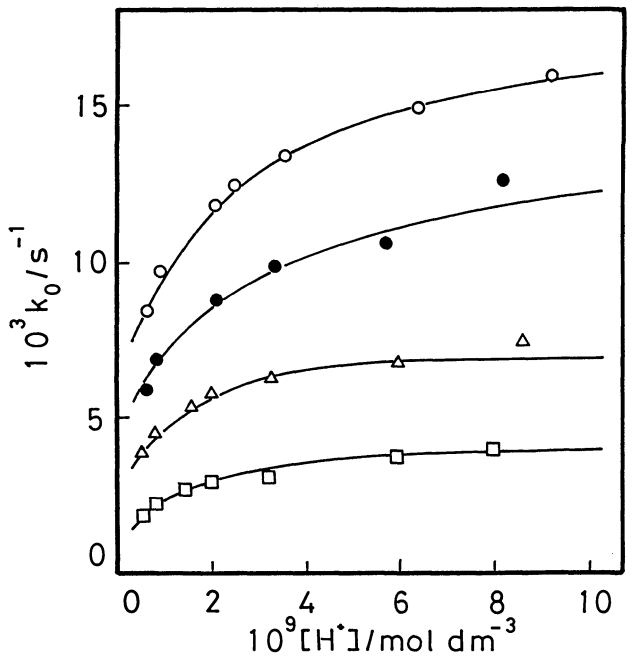

Fig. 3. Dependence of rate constants on the concentrations of hydrogen ion for the reaction of $Cd(tpps)^{4-}$ with EDTA at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$). [edta']/mol dm^{-3}=1.00×10^{-3} (□), 2.00×10^{-3} (△), 3.00×10^{-3} (●), and 4.00×10^{-3} (○).

$$k_0 = k_1[\text{edta}^{4-}] + k_2[\text{Hedta}^{3-}] \quad (5)$$

$$= \frac{(k_1 + k_2K^{H}[H^+])[\text{edta'}]}{1 + K^{H}[H^+]}, \quad (6)$$

where [edta']=[edta^{4-}]+[Hedta^{3-}]. Equation 6 is rearranged to

$$k_0(1 + K^{H}[H^+])[\text{edta'}]^{-1} = k_1 + k_2K^{H}[H^+] \quad (7)$$

where K^{H} is the protonation constant of edta^{4-}: $K^{H}=10^{10.17}$. The plots of the left-hand side of Eq. 7 against [H$^+$] give straight lines with zero intercept for Cd- and $Pb(tpps)^{4-}$ (Fig. 4). The values were found to be k_1=0 mol^{-3} dm^3 s^{-1} both for Cd- and $Pb(tpps)^{4-}$, k_2=4.1±0.2 mol^{-1} dm^3 s^{-1} for $Cd(tpps)^{4-}$ and k_2= 2.02±0.1 mol^{-1} dm^3 s^{-1} for $Pb(tpps)^{4-}$. In Fig. 5, the k_0 values are plotted against the concentrations of cadmium(II) or lead(II). The results show that the k_0 values are independent of the concentrations of these metal ions, and suggest that the metalloporphyrins do not dissociate before the attack of EDTA to Cd- or $Pb(tpps)^{4-}$.

Acid-Dissociation of Zn-, Cd-, and $Pb(tpps)^{4-}$. Protolytic demetallation of Zn-, Cd, and $Pb(tpps)^{4-}$ was studied in acidic medium. Cd- and $Pb(tpps)^{4-}$ easily dissociate in a dilute acid solution of pH 4—6 and $Zn(tpps)^{4-}$ dissociates at lower pH than 2. The observed first-order rate constants were plotted against [H$^+$]^2. The plots for Zn- and $Cd(tpps)^{4-}$ were straight lines, while those for $Pb(tpps)^{4-}$ were proportion to[H$^+$]^2 at the low concentration of hydrogen ion but suppressed at the high concentrations of hydrogen ion. This indicates that the rate for the second-proton attack to $Pb(Htpps)^{3-}$ which is formed in the first-protonation of $Pb(tpps)^{4-}$ as shown in Scheme 2 becomes comparable to that for the dissociation $Pb(Htpps)^{3-}$.

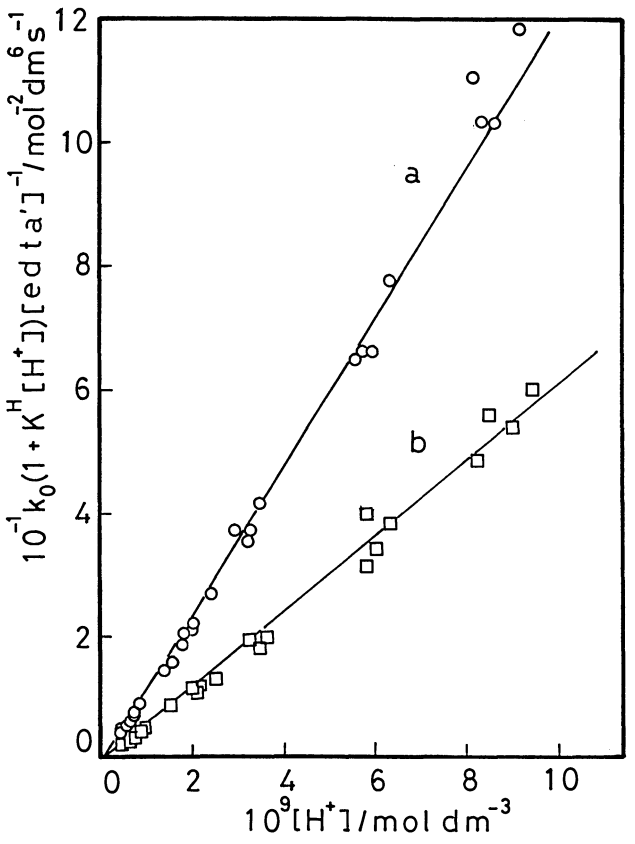

Fig. 4. Plots of 10^{-1} k_0 $(1+K^H[H^+])/[edta']$ vs. $[H^+]$ for the reaction of $Cd(tpps)^{4-}$ (a) and $Pb(tpps)^{4-}$ (b) with EDTA at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$).

$$M(tpps)^{4-} + H^+ \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} M(Htpps)^{3-} \quad (8)$$

$$M(Htpps)^{3-} + H^+ \xrightarrow{k_4} M^{2+} + H_2tpps^{4-} \quad (9)$$

$$H_2tpps^{4-} + 2H^+ \xrightarrow{fast} H_4tpps^{2-} \quad (10)$$

Scheme 2.

Applying the steady-state approximation for $M(Htpps)^{3-}$, we have Eq. 11

$$k_0 = \frac{k_3k_4[H^+]^2}{k_{-3}+k_4[H^+]}. \quad (11)$$

The equation agrees with the observed kinetic results. That is, $k_{-3} \gg k_4[H^+]$ for Zn- and $Cd(tpps)^{4-}$, and $k_{-3} \approx k_4[H^+]$ for $Pb(tpps)^{4-}$ at the high concentration of hydrogen ion. Equation 11 is rearranged to

$$[H^+]^2k_0^{-1} = k_{-3}(k_3k_4)^{-1} + k_3^{-1}[H^+]. \quad (12)$$

The plots of $[H^+]^2k_0^{-1}$ vs. $[H^+]$ are shown in Fig. 6. For Cd- and $Zn(tpps)^{4-}$, only $k_3k_4(k_{-3})^{-1}$ was found, while for $Pb(tpps)^{4-}$ both k_3 and $k_3k_4(k_{-3})^{-1}$ were determined.

Combining the rate equations both for the ligand-substitution reaction of $M(tpps)^{4-}$ with EDTA (Eq. 5) and the acid-dissociation reaction of $M(tpps)^{4-}$ (Eq. 11), we have Eq. 13 for the the rate of the decrease of $M(tpps)^{4-}$

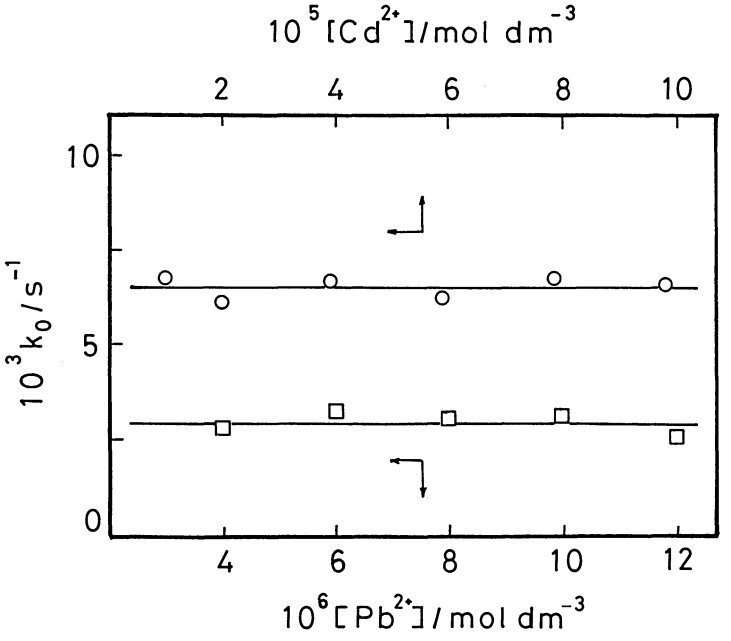

Fig. 5. Dependence of rate constants on the concentrations of cadmium(II) (○) and lead(II) (□) for the reaction of Cd- and $Pb(tpps)^{4-}$ with EDTA at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$). Concentrations of edta' (mol dm^{-3}) and pH are 2.00×10^{-3} and 8.26 for $Cd(tpps)^{4-}$, and 4.00×10^{-3} and 8.69 for $Pb(tpps)^{4-}$, respectively.

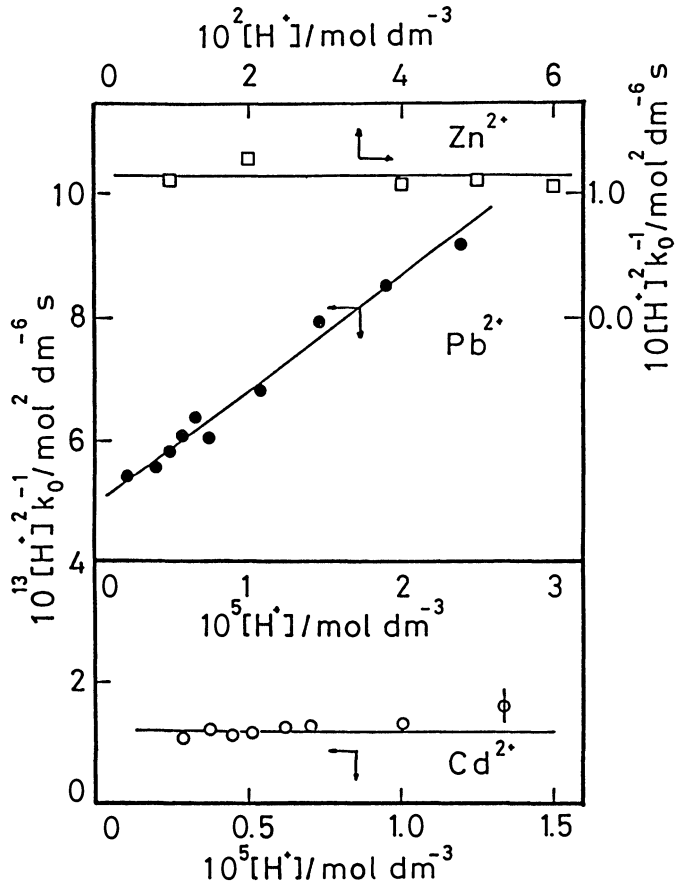

Fig. 6. Plots of $[H^+]^2(k_0)^{-1}$/mol^2 dm^{-6} s vs. $[H^+]$ for the acid-dissociation of Zn(tpps)$^{4-}$ (□), Pb(tpps)$^{4-}$ (●), and Cd(tpps)$^{4-}$ (○) at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$).

Table 1. Kinetic Parameters for the Reaction of Zn-, Cd-, and Pb(tpps)$^{4-}$ with EDTA and the Acid-Dissociation Reaction of the Metalloporphyrins at 25 °C and I=0.1 mol dm^{-3} ($NaNO_3$)

	Zn(II)	Cd(II)	Pb(II)
k_2 / mol^{-1} dm^3 s^{-1}	0.00	4.1±0.2	2.0±0.1
k_3 / mol^{-1} dm^3 s^{-1}	—	—	(5.4±0.3)×10^7
$k_3k_4(k_{-3})^{-1}$ / mol^{-2} dm^6 s^{-1}	8.7±0.2	(8.3±0.4)×10^{12}	(2.0±0.1)×10^{12}
K_{MP} / mol dm^{-3}	10$^{-0.43}$	10$^{-9.94}$	10$^{-9.97}$

$$-d[M(tpps)^{4-}]/dt = (k_1[edta^{4-}] + k_2[Hedta^{3-}] + k_3k_4[H^+]^2 \times (k_{-3} + k_4[H^+])^{-1})\,[M(tpps)^{4-}]. \quad (13)$$

In Table 1, the kinetic and the equilibrium parameters are summarized for the ligand-substitution and the acid-dissociation reactions of Cd-, Pb-, and Zn(tpps)$^{4-}$, where the values of k_1 are not shown as they were 0 for all the M(tpps)$^{4-}$.

Discussion

We can see the followings from Table 1. 1. Zn(tpps)$^{4-}$ is hard to be replaced with EDTA, whereas Cd- and Pb(tpps)$^{4-}$ are easily substituted with EDTA. 2. Acid-dissociation rate of Cd- and Pb(tpps)$^{4-}$ is 10^{12} times faster than that of Zn(tpps)$^{4-}$. 3. The formation constant of Zn(tpps)$^{4-}$ is about 10^9 times as large as those of Cd- and Pb(tpps)$^{4-}$. These large differences are discussed below.

Reaction with EDTA. The rate of the ligand-substitution reaction of Cd- or Pb(tpps)$^{4-}$ with EDTA increased linearly along with the concentrations of edta', while that of Zn(tpps)$^{4-}$ was independent of edta'. The kinetic difference between zinc(II) and cadmium(II) or lead(II) can be ascribed to their ionic radii: 109 pm for Cd^{2+}; 132 pm for Pb^{2+}; 89 pm for Zn^{2+}. Large metal ions such as cadmium(II) and lead(II) can not incorporate well into porphyrin core and just sit on the porphyrin plane. Barkigia et al. called lead(II) porphyrin a "roof complex" after X-ray

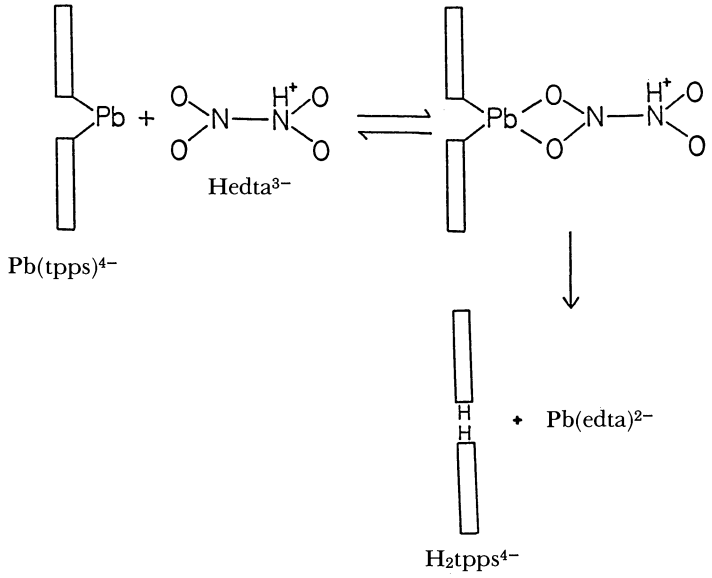

Fig. 7. Reaction mechanism for the reaction of $Pb(tpps)^{4-}$ with EDTA. ▭ H-H ▭ denotes H_2tpps^{4-}.

analysis of tetrapropylporphyrinato lead(II).[13] The roof metalloporphyrin, therefore, can be bound with a segment of $Hedta^{3-}$: two carboxylato and nitrilo groups, and then is easily replaced with $Hedta^{3-}$ (see Fig. 7). On the other hand, zinc(II) incorporates well into porphyrin core to form stable $Zn(tpps)^{4-}$.[14-16] Thus, $Hedta^{3-}$ can not pull zinc(II) away from $Zn(tpps)^{4-}$ by means of an axial ligation of $Hedta^{3-}$.

Dependence of rate constant on pH for the reaction with EDTA indicates that $Hedta^{3-}$ is more reactive than $edta^{4-}$. Similar results were also observed for the reaction of $Gd^{III}(tpps)^{4-}$ with EDTA.[17] A proton-transfer pathway might contribute to the dissociation of metalloporphyrin as in the case of the ligand-substitution reaction of metal-peptide complexes.[18-20] First, the carboxylato and the nitrilo groups of $Hedta^{3-}$ coordinate to lead(II) or cadmium(II), then the proton bound to the other nitrilo nitrogen of $Hedta^{3-}$ transfers to the pyrrole nitrogen of the porphyrin. Binding of the proton to the pyrrole nitrogen makes the demetallation of Cd- or $Pb(tpps)^{4-}$ easier (vide infra).

Proton-Assisted Demetallation. The metalloporphyrins of Cd-, Pb-, and $Zn(tpps)^{4-}$ were demetallated in acidic solution. The rate for the acid dissociation of $Cd(tpps)^{4-}$, is only four times as fast as that for $Pb(tpps)^{4-}$, while the dissociation rate for $Zn(tpps)^{4-}$ is about 10^{12} times slower than those for $Cd(tpps)^{4-}$ and $Pb(tpps)^{4-}$. The large kinetic difference also results from the ionic radii as described before. In the case of the demetallation of $Pb(tpps)^{4-}$, the present kinetic data clearly indicate that hydrogen ion attacks the

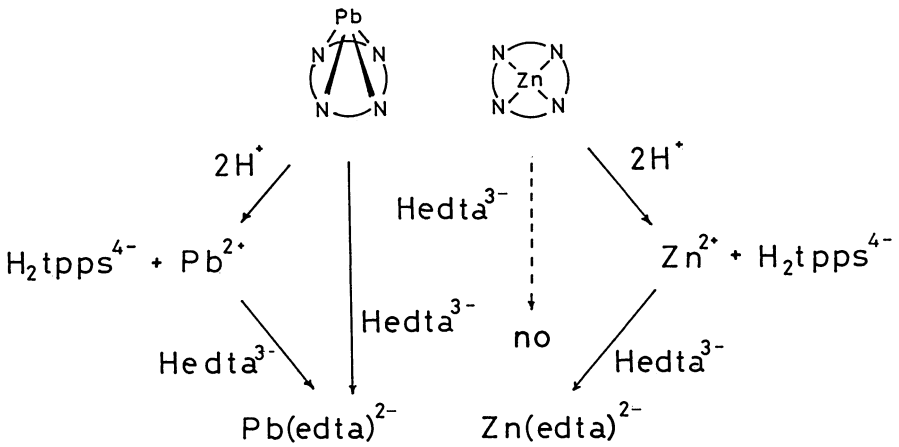

Fig. 8. Summary of the reaction pathways for the reaction of Pb- and $Zn(tpps)^{4-}$ with EDTA. $Cd(tpps)^{4-}$ goes through the same reaction pathway as $Pb(tpps)^{4-}$.

porphyrin core step by step to bind the pyrrole nitrogens. The first step is the formation of $Pb(Htpps)^{3-}$ through the protonation, and the second step is the dissociation of the metalloporphyrin after the formation of the diprotonated metalloporphyrin: $Pb(H_2tpps)^{2-}$.

Proposed reaction mechanism is shown in Fig. 8. $Hedta^{3-}$ directly attacks Pb- or $Cd(tpps)^{4-}$ to form its metal complex. On the other hand, $Hedta^{3-}$ can not bind $Zn(tpps)^{4-}$. Therefore, $Zn(tpps)^{4-}$ dissociates to aquazinc(II) and the free-base porphyrin after the proton attack, then the aquazinc(II) reacts with $Hedta^{3-}$ to form $Zn(edta)^{2-}$. Pb- and $Cd(tpps)^{4-}$ also dissociate to their aqua ions in an acidic medium. The rate-determining step for Pb- and $Cd(tpps)^{4-}$ is the $Hedta^{3-}$ attack at pH 8—9.3, which shifts to the proton attack at pH 4—6.

Present paper clearly shows the different behavior of Zn-, Cd-, and $Pb(tpps)^{4-}$ in their reaction mechanism and rate constants. $Zn(tpps)^{4-}$ is replaced with EDTA although the reaction is very slow compared with Cd- and $Pd(tpps)^{4-}$, and the rate-determining step for $Zn(tpps)^{4-}$ is the proton attack. The differences in the kinetic behavior of Zn-, Cd-, and $Pb(tpps)^{4-}$ also strongly support the experimental results in the previous analytical methods for the determination of zinc(II) in large excess of cadmium(II) and lead(II) using the ligand substitution reaction with EDTA or the acid-dissociation rate of these metalloporphyrins.

The present study was partly supported by Grant-in-Aid for Scientific Research (No. 01470030) and a Grant-in-Aid for Scientific Research (No. 02245212) on Priority Area of "Molecular Approaches to Nonequilibrium Processes in Solutions" from the Ministry of Education, Science and Culture Japan. We also wish to express our thanks for the support from Ito Foundation.

Solvent Extraction of Dansyl-Amino Acid Anions by Dicationic Extractants

Akira OHKI,* Hiroyuki DOHMITSU, and Shigeru MAEDA
Department of Applied Chemistry, Faculty of Engineering, Kagoshima University,
1-21-40, Korimoto, Kagoshima 890
(Received September 25, 1990)

The extraction of dansyl-amino acid anions from an alkaline aqueous medium was studied by the use of dicationic anion-exchange extractants, polymethylenebis(trioctylphosphonium)s (abbreviated as C_nBPs; n=2—12). As for the extraction of dianionic species, such as dansyl-aspartic acid anion (Dns-Asp^{2-}) and dansyl-glutamic acid anion (Dns-Glu^{2-}), the dicationic extractants were greatly superior to a monocationic extractant, butyltrioctylphosphonium (BuMP). However, regarding the extraction of monoanionic species, such as dansyl-serine anion, dansyl-phenylalanine anion, and dansyl-valine anion, the extraction abilities of the dicationic extractants and the monocationic extractant were similar to one another. The extraction ability of dicationic extractants was remarkably dependent on the length of their bridge-chain, which connects the two ionic centers. For extractants having short bridge-chain (C_2BP—C_4BP), Dns-Asp^{2-} was more extracted than Dns-Glu^{2-}. On the contrary, for extractants with long bridge-chain (C_8BP—$C_{12}BP$), Dns-Glu^{2-} was more extracted than Dns-Asp^{2-}. The solvent effect on the extraction of Dns-Asp^{2-} and Dns-Glu^{2-} was also studied.

Solvent extraction using anion-exchange extractants (liquid anion-exchangers) is widely used in separation processes of analytical chemistry.[1] Not only the extraction of metal complex anions, but also that of organic anions, have been studied by many researchers. However, as for the extraction of organic anions, 1 : 1 ion-pair formation between an extractant and an extracted anion has been most extensively discussed. Few studies have been concerned with multi-point ion-pair formation within a complex. Most of the liquid anion-exchange extractants hitherto reported are monoonium salts, i.e., long-chain quaternary ammonium ions and protonated long-chain tertiary amines have been used.

In recent years, we have developed dicationic anion-exchange extractants, which are lipophilic diphosphonium ions bearing two cationic centers within a molecule.[2-5] In our previous paper,[6] the extraction of phthalate isomer dianions (phthalate, isophthalate, and terephthalate) from an alkaline aqueous medium was studied by the use of such dicationic extractants, polymethylenebis(trioctylphosphonium)s (abbreviated as C_nBPs; n=2—12; Fig. 1). Two-point ion-pair formation within a complex between the dicationic extractant and the dianionic species caused some peculiar phenomena.

In the present study we investigated the extraction of dansyl-amino acid anions by use of the dicationic extractants (C_nBPs) and a monocationic extractant, butyltrioctylphosphonium (BuMP). Dansyl-amino acids have frequently been used in the field of chromatography. However, the extraction of dansyl-amino acids from alkaline media has not yet been sufficiently studied in detail. Especially, regarding the extraction of dicarboxylates, Dns-Asp^{2-} and Dns-Glu^{2-} (Fig. 1), two-point ion-pair formation within a complex has not yet been studied.

The effect of extracting solvent is one of the important factors in anion-exchange extractions. However, this effect has not yet been studied regarding the extractions using dicationic extractants. We found and analyzed a peculiar solvent effect when the dicationic extractants were used.

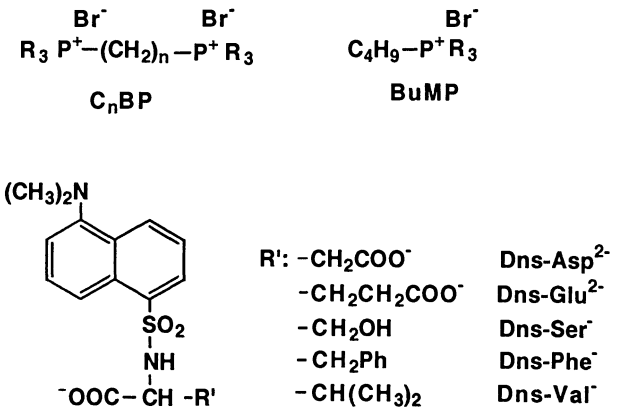

Fig. 1. Anion-exchange extractants, C_nBPs and BuMP (R=octyl; n=2—12), and dansyl-amino acid anions. The all carboxyl groups of dansyl-amino acids act as carboxylate anions under the relevant pH conditions (pH 10). Therefore, dansyl-aspartic acid, dansyl-glutamic acid, dansyl-serine, dansyl-phenylalanine, and dansyl-valine are abbreviated as Dns-Asp^{2-}, Dns-Glu^{2-}, Dns-Ser^{-}, Dns-Phe^{-}, and Dns-Val^{-}, respectively.

Experimental

Reagents. The synthesis of C_nBPs and BuMP was described in our previous paper.[5] Dansyl-amino acids (Sigma) and other chemicals were of reagent grade and used without further purification.

Extraction Procedure. An aqueous solution (10 ml) containing a 0.1 mM (1 M=1 mol dm^{-3}) dansyl-L-amino acid, sodium bromide, and 10 mM $Na_2B_4O_7$–NaOH buffer (pH 10) was shaken with an organic solution (10 ml) containing a 0.2 mM C_nBP (or 0.4 mM BuMP) in a stoppered centrifuge tube at 25 °C for 30 min. After phase separation, the con-

centration of the dansyl-amino acid anion remaining in the aqueous phase was determined by spectrophotometry using a Hitachi 228 instrument (λ_{max}=328 nm). The amount of the dansyl-amino acid anion extracted into the organic phase was taken as the difference between the amount initially added and that remaining in the aqueous phase after equilibrium. In some runs, the material balance on the distribution of dansyl-amino acid anions between the aqueous and organic phases was confirmed by back-extraction experiments.[2)]

Results and Discussion

Extraction of Dansyl-Amino Acids. The extraction of dansyl-amino acids by various anion-exchange extractants is summarized in Table 1. The concentration of the monocationic extractant (BuMP) initially added to the organic phase was twice that of the dicationic extractants (C_nBPs). Therefore, the cationic charge concentration in the aqueous phase was the same for both the monocationic and dicationic extractants.

It is reasonable to consider that the dansyl-derivatives of neutral amino acids (Dns-Ser$^-$, Dns-Phe$^-$, and Dns-Val$^-$) serve as monoanions under the relevant pH conditions (pH 10). When these dansyl-amino acids were extracted, the extraction abilities of the monocationic extractant (BuMP) and the dicationic extractants (C_4BP and $C_{10}BP$) were similar to each other.

However, when the dansyl-derivatives of acidic amino acids (Dns-Asp^{2-} and Dns-Glu^{2-}) were extracted, which serve as dianions, the extraction ability of the dicationic extractants greatly surpassed that of the monocationic extractant. These results suggest that the compatibility of the charge number between the extractant and the extracted anion greatly affects the extractability. We observed such a concept in the extraction of dianionic species including anionic metal complexes[2,4,5)] and phthalates;[6)] we call this concept "multiple charge compatibility."

A commercially available monocationic extractant, Capriquat (methyltrioctylammonium), showed a similar extraction behavior to that of BuMP in the extraction of the monoanionic dansyl-amino acids, as well as in the extraction of the dianionic dansyl-amino acids.

Table 1. % Extraction of Dansyl-Amino Acids[a)]

Dansyl-amino acid	[NaBr][b)]	Extractant		
	mM	BuMP	C_4BP	$C_{10}BP$
Dns-Asp^{2-}	1.2	3.9	57.3	26.2
Dns-Glu^{2-}	1.2	2.7	41.8	30.2
Dns-Ser$^-$	50	30.0	25.7	27.3
Dns-Phe$^-$	200	79.6	76.3	79.6
Dns-Val$^-$	200	44.3	46.7	39.1

a) Extracting Solvent: 1,2-dichloroethane. b) Sodium bromide was initially added in the aqueous phase.

Extraction Equilibrium of Dianionic Dansyl-Amino Acids. The extraction of dianionic dansyl-amino acids, Dns-Asp^{2-} and Dns-Glu^{2-}, was investigated in detail. One can assume that the extraction of the dianion (A^{2-}) by the dicationic extractant (C_nBP) involves the formation of a 1:1 ion-pair complex between C_nBP and A^{2-}. The reaction and the extraction constant (K_{ex}) can be defined as follows:

$$(Q\cdot Br_2)_o + (A^{2-})_w \rightleftarrows (Q\cdot A)_o + 2(Br^-)_w,$$

and

$$K_{ex} = [Q\cdot A]_o[Br^-]_w^2/[Q\cdot Br_2]_o[A^{2-}]_w, \quad (1)$$

where $Q\cdot Br_2$ represents C_nBP, and subscripts w and o denote the aqueous and organic phases, respectively. It can also be expressed logarithmically:

$$\log [Q\cdot A]_o/[Q\cdot Br_2]_o[A^{2-}]_w = \log K_{ex} - 2\log [Br^-]_w. \quad (2)$$

The $Q\cdot Br_2$ and the complex, $Q\cdot A$, are highly lipophilic and do not appreciably dissolve in the aqueous phase. Thus, the values of $\log [Q\cdot A]_o/[Q\cdot Br_2]_o[A^{2-}]_w$ and $\log [Br^-]_w$ in Eq. 2 can be easily obtained experimentally.

With the monocationic extractant (BuMP) calibrations were carried out in such a way that $[Q\cdot Br_2]_o$ and $[Q\cdot A]_o$ in Eq. 2 were taken as $2\times[BuMP^+\cdot Br^-]_o$ and $[(BuMP^+)_2\cdot A^{2-}]_o$, respectively.

Figure 2 shows a plot of $\log [Q\cdot A]_o/[Q\cdot Br_2]_o[A^{2-}]_w$

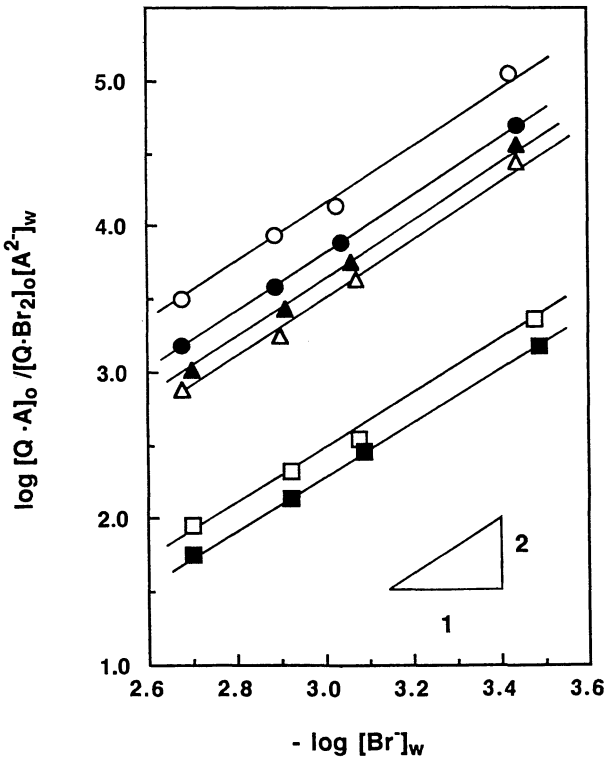

Fig. 2. Extraction of Dns-Asp^{2-} (○, C_4BP; △, $C_{10}BP$; □, BuMP) and Dns-Glu^{2-} (●, C_4BP; ▲, $C_{10}BP$; ■, BuMP) (extracting solvent: 1,2-dichloroethane).

against $-\log[Br^-]_w$ in the extractions of Dns-Asp^{2-} and Dns-Glu^{2-}; the extractants (C_4BP, $C_{10}BP$, and BuMP) were used and 1,2-dichloroethane was used as an extracting solvent (diluent). All of the plots in Fig. 2 are straight lines with a slope of 2. These results suggest that the extraction reaction proceeds via the formation of a 1 : 1 ion-pair complex between C_nBP^{2+} and A^{2-} (or a 2 : 1 complex between $BuMP^+$ and A^{2-}). These results again indicate that the dansyl-amino acids serve as dianions, so that the dissociation of the sulfonamide proton in dansyl-amino acids is negligibly small under the present conditions.

Figure 3 (a and b) shows graphical representations of the extraction constants ($\log K_{ex}$) as a function of the length of "bridge-chain" of C_nBPs; the "bridge-chain" is defined as the bridging chain connecting the two ionic centers of the extractant (or extracted anion). The bridge-chain length greatly affects the extraction ability of C_nBPs, and the plots possess maximum values at n=4 for the Dns-Asp^{2-} extraction and around n=4—6 for the Dns-Glu^{2-} extraction. Therefore, such a extraction behavior cannot be explained simply in terms of the change in the lipophilicity of C_nBPs via the change in the length of the methylene unit. We have proposed a concept called "geometrical charge distribution compatibility" regarding the extraction of phthalates; the compatibility between the ionic center distance of the dicationic extractants and that of the dianionic phthalates has fundamental significance regarding the extractability of the phthalates.[6] Obviously, the concept is at work as well concerning the present dansyl-amino acid extractions.

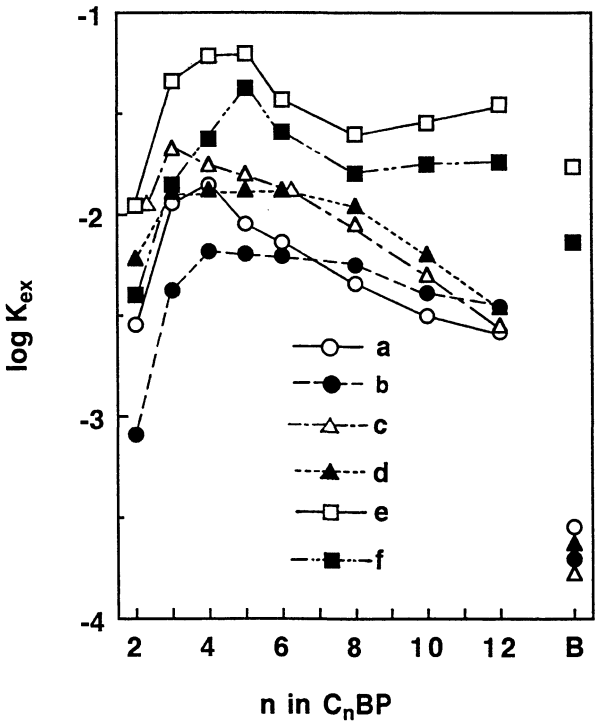

Fig. 3. Extraction constants ($\log K_{ex}$) obtained in the cases of 1,2-dichloroethane (a, Dns-Asp^{2-}; b, Dns-Glu^{2-}), 1-pentanol (c, Dns-Asp^{2-}; d, Dns-Glu^{2-}), and toluene (e, Dns-Asp^{2-}; f, Dns-Glu^{2-}). B represents BuMP.

It is noted that Dns-Asp^{2-} was more extracted than Dns-Glu^{2-} in the cases of C_2BP—C_6BP, whereas conversely Dns-Glu^{2-} was more extracted in the cases of C_8BP—$C_{12}BP$. The bridge-chain of Dns-Glu^{2-} is longer by one methylene unit than that of Dns-Asp^{2-}. Therefore, the short bridge-chain extractants (the C_nBPs possessing short bridge-chain) prefer the Dns-Asp^{2-} extraction, whereas the long bridge-chain extractants prefer the Dns-Glu^{2-} extraction.

Extranction of Dianionic Dansyl-Amino Acids with Various Extracting Solvents. 1-Pentanol and toluene were used as extracting solvents instead of 1,2-dichloroethane. Figure 3 again indicates plots of $\log K_{ex}$ vs n in C_nBP by the use of these solvents (Fig. 3, c—f). In all cases, the extraction equilibrium, Eq. 1, was confirmed to hold.

When 1-pentanol was used (Fig. 3, c and d), the order of the extractabilities of Dns-Asp^{2-} and Dns-Glu^{2-} was reversed at n=6; the short bridge-chain extractants preferred Dns-Asp^{2-} and the long bridge-chain extractants preferred Dns-Glu^{2-}. When 1-octanol was used, the extraction ability of the extractants was systematically larger than that in the extraction using 1-pentanol (see Table 2). However, the

Table 2. Extraction Constants ($\log K_{ex}$) by Use of Various Extracting Solvents

Extracting solvent	ε[a]	Dns-Asp^{2-}			Dns-Glu^{2-}		
		BuMP	C_4BP	$C_{10}BP$	BuMP	C_4BP	$C_{10}BP$
Toluene	2.4	−1.76	−1.22	−1.54	−2.14	−1.62	−1.75
Chlorobenzene	5.6	−2.78	−1.51	−1.67	−3.09	−2.06	−1.78
o-Dichlorobenzene	9.9	−3.06	−1.49	−2.01	−3.45	−2.07	−2.15
1-Octanol	10.3	−3.06	−1.23	−1.45	−2.96	−1.37	−1.33
1,2-Dichloroethane	10.4	−3.55	−1.85	−2.51	−3.71	−2.17	−2.38
1-Pentanol	13.9	−3.78	−1.75	−2.29	−3.63	−1.88	−2.19
$\Delta \log K_{ex}$[b]		2.02	0.53	0.75	1.49	0.26	0.44

a) Dielectric constant. b) $\Delta \log K_{ex}$ is defined as the difference between the $\log K_{ex}$ in the case of toluene and that in the case of 1-pentanol (see text).

extractability order of the dansyl-amino acids was similarly reversed at n=6.

When toluene was used (Fig. 3, e and f), the extractability of Dns-Asp^{2-} was greater than that of Dns-Glu^{2-} in all cases concerning the extractants. The uses of chlorobenzene and *o*-dichlorobenzene as extracting solvents resulted in a similar behavior regarding the extractability order of Dns-Asp^{2-} and Dns-Glu^{2-}; Dns-Asp^{2-} was more extracted than Dns-Glu^{2-}.

The extraction constants ($\log K_{ex}$), in terms of the use of various extracting solvents, are summarized in Table 2. The extraction ability of BuMP was remarkably dependent on the polarity of the extracting solvents. Low polar solvents, such as toluene, promote both the extractions of Dns-Asp^{2-} and Dns-Glu^{2-}. It is noted that when C_4BP was used as an extractant, the dependence of $\log K_{ex}$ on the polarity of the solvents became relatively small compared to the extractions by BuMP.

The value of $\Delta \log K_{ex}$ is defined as the difference between $\log K_{ex}$ in the case of toluene and that in the case of 1-pentanol; the former is the least polar solvent of all indicated in Table 2, while the latter is the most polar solvent. As shown in Table 2, the value of $\Delta \log K_{ex}$ decreased in the order BuMP$\gg$$C_{10}BP>$$C_4$BP in both Dns-Asp^{2-} and Dns-Glu^{2-} extractions.

"Multiple charge compatibility" can be at work when the dicationic extractants are used, and "geometrical charge distribution compatibility" can be more effectively at work in the case of C_4BP than in the case of C_{10}BP. Therefore, especially in the case of C_4BP, two-point ion-pair formation can be smoothly and compatibly carried out, so that the ion-pair is considered to be very tight. Thus, the instabilization for the ion-pair by polar solvents may be relaxed to a considerable extent, since the insertion of the solvent molecule between the cation and anion composing the complex is retarded. Such a situation leads to a lowering of the dependence of $\log K_{ex}$ on the polarity of the solvents in the case of C_4BP. The polarity and/or other solvent properties may complicatedly affect the stability of the ion-pair and, thus, the solvent effects cannot be elucidated sufficiently.

In conclusion, two-point ion-pair formation within a complex causes some unique phenomena in the extraction of Dns-Asp^{2-} and Dns-Glu^{2-}. The concepts presented in this study can be applied to chromatographic separation systems including ion-pair chromatography, and may offer a new possibility in the separation among dansyl-amino acids.

Association of Symmetrical *p*-Dihalobenzenes with Cyclodextrins in Aqueous Medium

Tatsuyoshi TAKUMA, Toshio DEGUCHI, and Isao SANEMASA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received October 3, 1990)

The complex formation of cyclodextrin (CyD, host) with symmetrical *p*-difluoro-, dichloro-, dibromo-, and diiodobenzenes (guests) has been studied in aqueous medium at 25 °C by making use of the volatilization rate of guest molecules from the aqueous into gaseous phase. In the excess of the host, α- and β-CyDs form 1 : 1 and 2 : 1 (host : guest) complexes, while γ-CyD forms 1 : 1 complexes. The association constants, especially for α- and β-CyDs, increased with an increase in the size of the halogen atom. A linear relationship between the logarithm of the 1 : 1 association constant and the total surface area of guest molecule was found for CyD–monohalobenzenes and CyD–*p*-dihalobenzenes. The van der Waals force seems to be the main factor in stabilizing the associated complexes. The validity of the concept of microscopic binding constant is discussed.

We studied host-guest associations using α-, β-, and γ-cyclodextrins (CyDs) as hosts and four monohalobenzenes as guests.[1] The present work is concerned with symmetrical *p*-dihalobenzenes as analogous guests. Although complex formations of α-CyD with *p*-dichloro-, dibromo-, and diiodobenzenes have been reported,[2] there are no literature data published on other CyDs and *p*-difluorobenzene. The object of this study is to compare the association constants of monohalobenzenes with those of *p*-dihalobenzenes and to discuss the mechanism of CyD-halobenzene complexations.

Several methods are available to approach CyD-guest complexations. Of these, UV absorption and fluorescence spectroscopies are generally used; the former is based on the shift of absorption spectrum by association, and the latter on the enhancement of guest fluorescence intensity in the presence of host. These methods, however, cannot be satisfactorily applied to guests of high volatility and low aqueous solubility, because in aqueous medium it is difficult to prepare CyD-guest associated species in an appreciable amount and to maintain its concentration constant during measurements. To such guests the solubility method can be applied, which makes use of an increase in the guest solubility in water as a consequence of association with CyD. This method is usually based on a "shake-flask technique:" an excess quantity of a guest substance is added to water containing CyD of known concentration, the mixture is mechanically shaken, and then the excess guest, which may be present in water as a liquid or solid phase, is separated. The solubility method is simple and versatile, but there are some essential problems. It is difficult to separate the excess guest phase while maintaining the temperature of the aqueous solution constant. The presence of an excess guest phase is particularly troublesome: CyD (host) molecules will be adsorbed on the surface of the liquid or solid guest phase or, in an extreme case, can penetrate into the guest phase to cause modification of its physicochemical properties and consequently its aqueous solubility.

The method used in this work to determine the association constant is the same as that employed in our previous works.[3,4] This method is based on the volatility of guest in aqueous solutions. Volatile guest molecules are driven out to the gas phase by introducing an inert gas at a constant flow rate into the aqueous solution. The volatilization rate is measured with and without addition of CyD; the rate decreases as a result of the association with CyD. The method is applicable to host-guest association systems where (a) the guest molecule is volatile, (b) the concentration of host is sufficiently high in comparison with that of guest, and (c) the rate of association is rapid compared with the volatilization rate. This method has been applied to CyD associations with such guests as iodine,[5] benzene and alkyldenzenes,[3] naphthalene and its methyl derivatives,[6] polynuclear aromatic hydrocarbons,[4] carbon tetrachloride, chloroform, and dichoromethane,[7] monohalobenzenes,[1] and normal alkanes,[8] and proved to give satisfactory association constants in reasonable agreement with the literature data.

Experimental

Materials and Preparation of Sample Solutions. Deionized distilled water was used throughout the experiments. An appropriate amount of α-, β-, and γ-CyD of guaranteed grade (Nakarai Chemical Co.), dried over phosphorus pentoxide under vacuum, was weighed and dissolved in water to prepare CyD stock solutions of desired concentrations. Four guest substances, *p*-difluoro-, *p*-dichloro-, *p*-dibromo-, and *p*-diiodobenzene, were used as received; the minimum purities are 95, 98, 99, and 98%, respectively, as claimed by the manufacturers (Tokyo Kasei Kogyo Co. for the first three and Kanto Kagaku Co. for the last one). An aqueous stock solution of each guest was prepared by adding an excess of each *p*-dihalobenzene to water and stirring for at least 24 h in the dark. After leaving the mixture standing for at least 24 h, a portion of the saturated guest solution was transferred to a separatory funnel and the absorbance of its cyclohexane extract was measured to determine the guest

concentration at the following wavelengths: *p*-difluoro- at 272.4, *p*-dichloro- at 273, *p*-dibromo- at 273, and *p*-diiodobenzene at 241 nm.

A portion of the saturated guest solution was transferred into a 2.5ϕ×25 cm cylindrical glass tube for *p*-difluoro- and dichlorobenzenes, or into a round-bottom flask of 500 cm^3 capacity for the other two guests. An appropriate fraction of the CyD stock solution was then added, and the solution was diluted with water to 100 cm^3 for the former two guests or to 500 cm^3 for the latter two guests. The concentration ranges of host and guest are given in Table 1.

Apparatus and Procedures. The apparatus and the experimental procedure were the same as those described in a previous paper.[1] Nitrogen gas was bubbled into the aqueous guest solution with or without CyD placed in the cylindrical glass tube, or in the round-bottom flask immersed in a bath thermostated at 25.0±0.1 °C, at a constant flow rate suitable for each guest volatility: *p*-difluoro- at 30, *p*-dichloro- at 50, *p*-dibromo- at 400, and *p*-diiodobenzene at 400 cm^3 min^{-1}. The N_2 gas leaving the sample solution was passed through a glass column of 0.5ϕ×23 cm filled by 8 cm in length with XAD-2 resin beads (80—150 mesh). The guest adsorbed on the resin within a fixed time was eluted out with 4 cm^3 of cyclohexane, and the amount of guest, ΔQ_ϕ, was determined by UV absorption measurements.

Results

The equation derived in previous papers[3,4] was used to estimate the 1 : 1 and 2 : 1 (host : guest) association constants, K_1 and K_2:

$$\ln(C_\phi - Q_\phi V^{-1}) = -kt/(1 + K_1 C_{CyD} + K_1 K_2 C^2_{CyD}) + \ln C_\phi = -k't + \ln C_\phi, \quad (1)$$

where C_{CyD} and C_ϕ refer to the total concentration of host and that of guest, respectively, Q_ϕ is the sum of ΔQ_ϕ from time 0 to t, V is the volume of the aqueous solution, k is the rate constant for transfer of guest molecules from the aqueous to gas phase, and

$$k' = k/(1 + K_1 C_{CyD} + K_1 K_2 C^2_{CyD}). \quad (2)$$

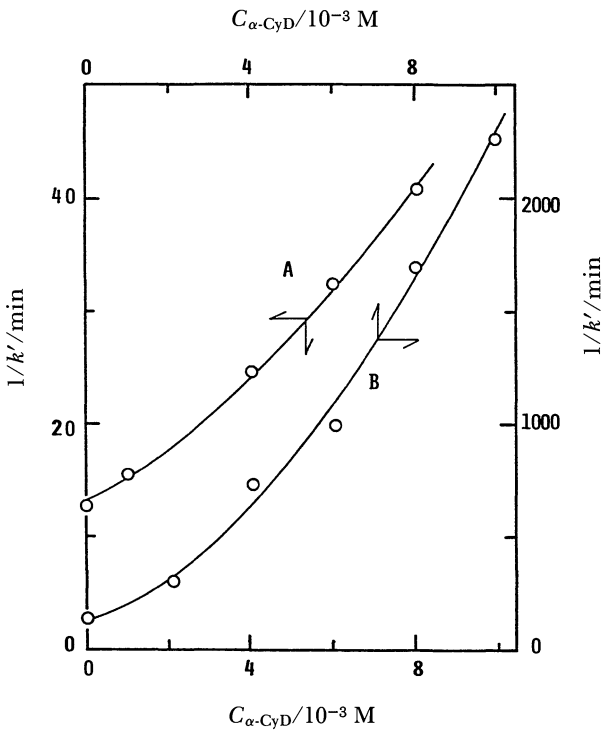

Fig. 1. Plots of $1/k'$ vs. C_{CyD}. α-CyD-*p*-difluorobenzene(A), -*p*-diiodobenzene (B).

Table 1. Concentration Ranges of Host and Guest and the Formation Constants, K_1 (1 : 1) and K_2 (2 : 1) of (Host : Guest) Complexes at 25 °C

	Concentration		Formation constant (Literature value)[a]			
	C_ϕ[b]	C_{CyD}[c]	K_1		K_2	
	10^{-5} M	10^{-2} M	M^{-1}		M^{-1}

γ-CyD	11.6—15.7	1.00—3.00	28±9		—[d]	
p-Dichlorobenzene:						
α-CyD	21.7—27.7	1.00—5.00	225±8	(232±16)	42±3	(90±12)
β-CyD	25.2—27.7	0.201—0.703	320±20		90±30	
γ-CyD	21.3—27.7	1.00—3.00	43±1		—[d]	
p-Dibromobensene:						
α-CyD	4.61—5.86	0.100—0.500	1020±60	(913±22)	100±40	(397±14)
β-CyD	5.34—6.50	0.0604—0.230	940±20		100±20	
γ-CyD	5.34—6.40	0.500—2.00	48±8		—[d]	
p-Diiodobenzene:						
α-CyD	0.132—0.295	0.0204—0.100	4200±900	(5060±940)	2000±1000	(6255±1270)
β-CyD	0.132—0.239	0.0203—0.0807	1500±200		1500±400	
γ-CyD	0.132—0.414	0.362—1.50	81±8		—[d]	

a) Literature values given in the parentheses are from Ref. 2. b) Total concentration of guest. c) Total concentration of cyclodextrin. d) K_2 was not evaluated because $1/k'$ vs. C_{CyD} plots gave a nearly straight line.

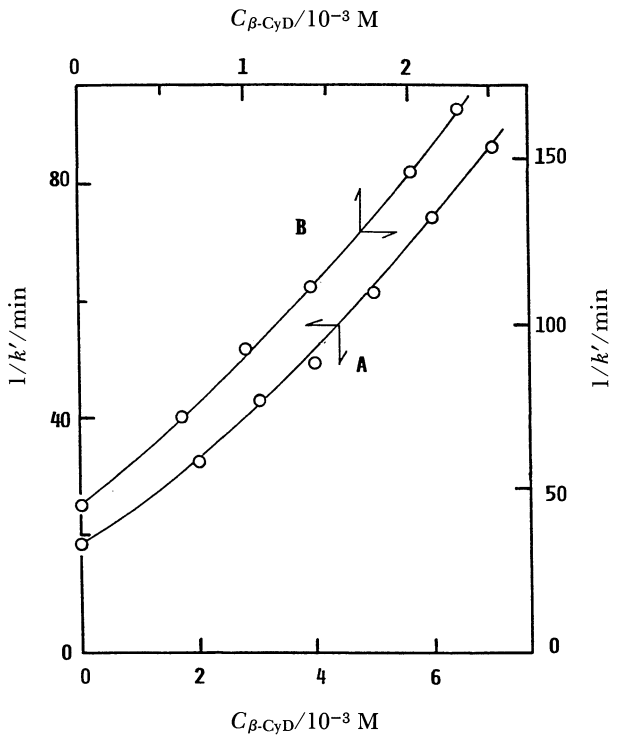

Fig. 2. Plots of $1/k'$ vs. C_{CyD}. β-CyD–*p*-dichlorobenzene (A), -*p*-dibromobenzene (B).

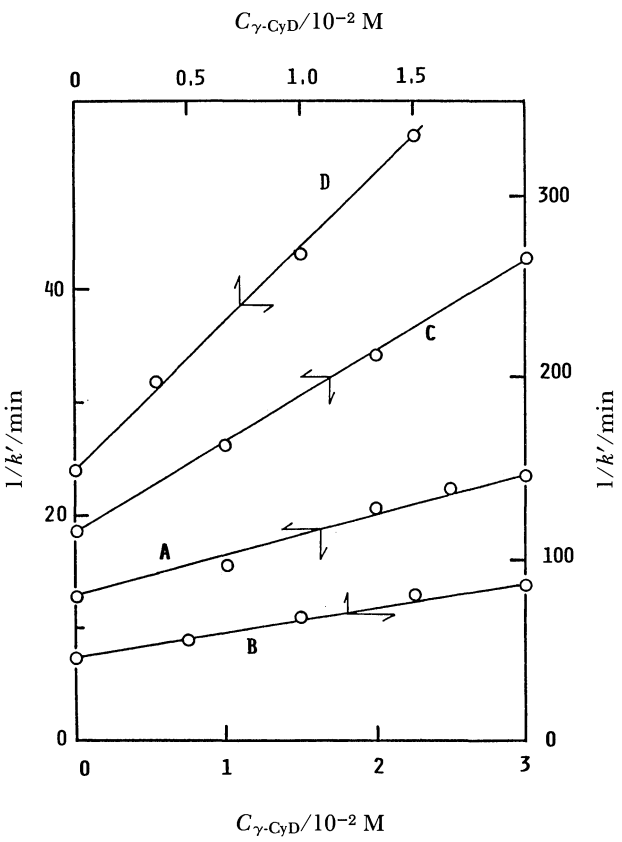

Fig. 3. Plots of $1/k'$ vs. C_{CyD}. γ-CyD–*p*-difluorobenzene (A), -*p*-dichlorobenzene (B), -*p*-dibromobenzene (C), -*p*-diiodobenzene (D).

Rearrangement of Eq. 2 yields

$$1/k' = K_1K_2C^2_{CyD}/k + K_1C_{CyD}/k + 1/k. \quad (3)$$

The plots according to Eq. 1 for all the symmetrical *p*-dihalobenzene-CyD systems examined in this work gave straight lines over the whole aeration time, during which ca. 50 to 70% of the guest molecules present initially in the sample solutions were purged. Slopes of the resulting straight lines, k' (and k), were evaluated by the least-squares method. Typical $1/k'$ vs. C_{CyD} plots are shown in Figs. 1 through 3. The plots display upward curvatures for α- and β-CyDs, indicating the formation of 1 : 1 and 2 : 1 (host : guest) complexes, whereas those for γ-CyD are linear, indicating only 1 : 1 complex formation. The K_1 and K_2 values were determined by the curve-fitting method and are summarized in Table 1, where the data obtained by solubility measurements by Connors and Pendergast[2] are also listed.

The agreement between the present and the literature K_1 values is good, in spite of an essential difference in the methods employed. As for the K_2 value, however, considerable discrepancies are noted; we have no criterion at the present stage to claim that the literature data are overestimated.

Discussion

The concept of microscopic binding constant has been proposed by Connors and Pendergast.[2] They used various kinds of symmetrical *p*-disubstituted benzenes, X-C_6H_4-X, as guests and α-CyD as host, and predicted that the 1 : 1 association constant, K_{11}^{xx}, is just twice the microscopic binding constant, $K_{x'x}$ (the binding site is indicated by a superscript prime). The concept seems reasonable when we consider that a guest molecule with two equivalent binding sites is to be accepted by a host molecule which associates with the guest at a single site (α-CyD, in the present case). There have been reported, however, few data to support directly this idea. An example which seems to support the concept is the α-CyD complex with toluene (K_1=33±3)—*p*-xylene (K_1=72±7 M^{-1})[3] (1 M=1 mol dm^{-3}). It is interesting to compare our previous data on monohalobenzenes with the present data on symmetrical *p*-dihalobenzenes and to examine whether the concept of microscopic binding constant is valid for the halobenzene series. If K_1 of a symmetrical *p*-dihalobenzene is twice that of the corresponding monohalobenzene, the concept is acceptable.

We use the following K_1 in M^{-1} for α-CyD—monohalobenzene: fluorobenzene (34±1), chlorobenzene (100±10), bromobenzene (510±10), and iodobenzene (1100±100).[1] Comparing with the corresponding K_1 value listed in Table 1, the microscopic binding concept seems to hold for chloro- and bromobenzene, but this is not the case for fluoro- and iodobenzene. The K_1 of *p*-difluorobenzene is smaller than that of mono-

fluorobenzene itself, while the K_1 of *p*-diiodobenzene is much larger than the doubled K_1 of monoiodobenzene. Although the data available at the present stage are scanty, we conclude that the microscopic binding concept does not necessarily apply to α-CyD complexations with all of symmetrical *p*-disubstituted benzenes. The physicochemical properties of the substituent such as size, polarity, and affinity to water should be taken into consideration.

If the size of the guest relative to the host cavity is considered, the microscopic binding concept seems not to be applicable to β- and γ-CyD associations with mono- and *p*-dihalobenzenes. When we compare these association constants,[1] however, the concept appears to hold for some host-guest association systems. Namely, for β-CyD, the K_1 of chlorobenzene (160±10) is just half that of *p*-dichlorobenzene, and this is also the case for the iodobenzene (K_1=800±100)—*p*-diiodobenzene combination. As for γ-CyD, in view of the range of experimental error, the K_1 of fluorobenzene (14±6), bromobenzene (39±8), and iodobenzene (30±10) are almost half that of the corresponding *p*-dihalobenzenes. These observations rather deteriorate than reinforce the validity of the concept of microscopic binding constant, because γ-CyD forms only 1 : 1 associated complexes with both mono- and *p*-dihalobenzenes.

In preceding papers,[1,3] dealing with polyaromatic hydrocarbons and monohalobenzenes as guests, we concluded that the van der Waals interaction of these guests with the CyD inner wall is the main factor to stabilize the CyD complexes. Our conclusion came from the finding that the 1 : 1 complex formation constant K_1 for the homologous guest series decreases with increasing the guest hydrophobicity estimated from the Henry's law constant, and that $\log K_1$ increases almost linearly with the surface area of guest molecule.

In Fig. 4 are plotted $\log K_1$ vs. the total surface area (TSA) of *p*-dihalobenzenes; the plots for monohalobenzenes are also shown for comparison. Linear positive relationships between $\log K_1$ and TSA are observed for the three CyDs. In analogy with monohalobenzenes, association constants of *p*-dihalobenzenes for α-CyD are most sensitive to the size of halogen atom. For γ-CyD, $\log K_1$ vs. TSA plots of mono- and *p*-dihalobenzenes fall within a single line. This means that the cavity size of γ-CyD is wide enough to allow the guest molecule to orient itself in the cavity to get as

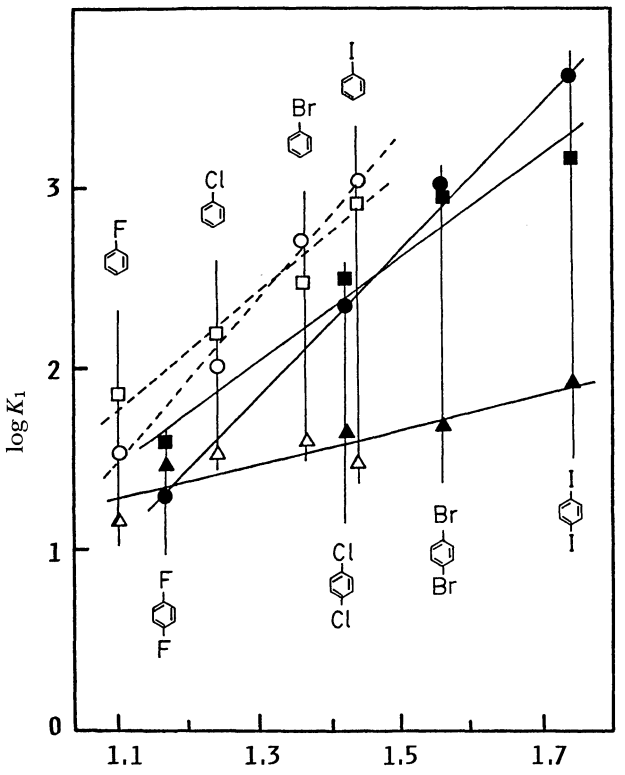

Fig. 4. Dependence of association constant on the total surface area of guest molecule. α-CyD (○, ●), β-CyD (□, ■), γ-CyD (△, ▲). Data of total surface area are from Ref. 9.

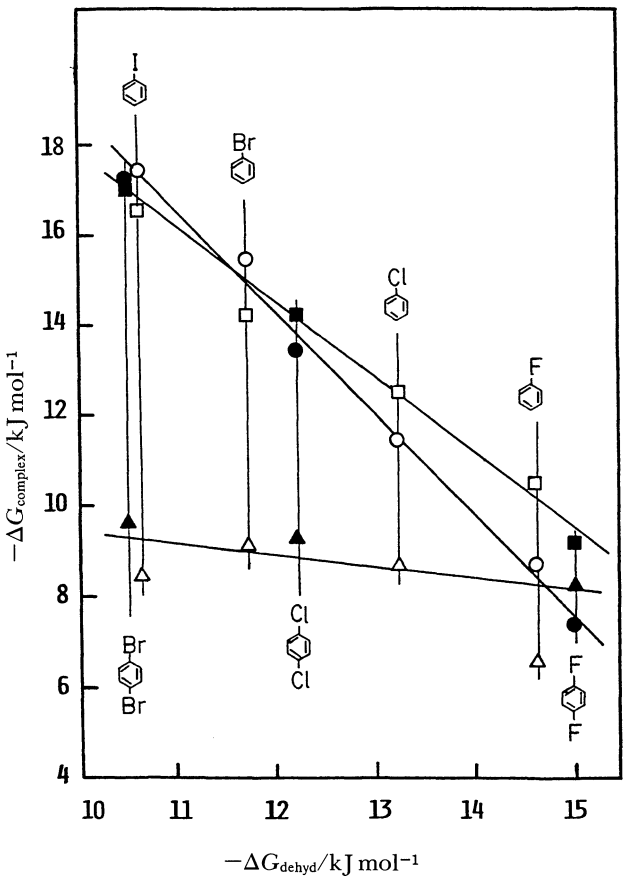

Fig. 5. Free energy changes of CyD-guest complexation, $\Delta G_{complex}$ ($=-RT \ln K_1$), and that of dehydration, ΔG_{dehyd} ($=-RT \ln K_H$) of guest. Symbols are the same as in Fig. 4.

large a contact area as possible. On the other hand, for either α- or β-CyD, the linear plot of *p*-dihalobenzenes, compared with that of monohalobenzene, shifts to the lower $\log K_1$ side. This is probably due to a difference in the 1 : 1 CyD-guest association model between mono- and *p*-dihalobenzenes, or to the affinity for water of another halogen atom substituted to monohalobenzene.

In the case of *p*-dihalobenzene, the benzene ring is situated just in the center of the cavity of β-CyD and two halogen atoms extrude equally outside the host cavity to some extent depending on the size of a particular halogen atom, whereas in the case of monohalobenzene the center of the cavity of β-CyD shifts to the halogen atom side. As for α-CyD, its cavity size is too small to include the benzene ring as a whole, but nearly equal to the diameter of the iodine atom. When the 1:1 complex is formed between *p*-dihalobenzene and α-CyD, an unassociated halogen atom might have some influence on the complex formation. That is, iodine, the most hydrophobic among halogen atoms, promotes, whereas fluorine, the most hydrophilic, depresses the association which occurs on the opposite side. This idea is not accepted in general at present, but helps us explain why the microscopic binding concept fails in the two cases mentioned above.

We previously proposed that the most reasonable parameter for the hydrophobicity of volatile solutes is the Henry's law onstant, K_H.[1,3,4] The K_H value is a measure how easily the solute is transferred from the aqueous to gas phase; a solute with the larger K_H is more hydrophobic. The free energy change in the 1 : 1 complex formation, $\Delta G_{complex}$ ($=-RT \ln K_1$), is plotted against ΔG_{dehyd} ($=-RT \ln K_H$) in Fig. 5; because of the lack of the vapor pressure data available for *p*-diiodobenzene, we cannot estimate ΔG_{dehyd} of this guest. In analogy with polyaromatic hydrocarbons,[4] almost linear relationships are observed for the three types of CyD. There are still two points to be noted.

First, as is the case of monohalobenzenes,[1] the hydrophobic interaction as a driving force of CyD complex formation is not significant for *p*-dihalobenzenes, because $-\Delta G_{complex}$ does not increase with $-\Delta G_{dehyd}$ but the situation is just the reverse. The van der Waals force seems to govern the associations of CyD with both mono- and *p*-dihalobenzenes. On an assumption that the positive relationship between $-\Delta G_{complex}$ and $-\Delta G_{dehyd}$ indicates the association being governed by the host-guest hydrophobic interaction, the negative slope of the linear plot may be taken as a measure of nonhydrophobic interaction. Namely, there is some contribution from hydrophobic interaction to γ-CyD complexations, but the least to α-CyD complexations. Secondly, regardless of the type of CyD, the plots for the two different halobenzene homologous series fall on the same linear line. We cannot elucidate this observation at the present stage.

Studies on Ferrocene Derivatives. VII.[1] Solvent Effect on the Oxidation Reaction of *t*-Butylferrocenes

Takatoshi HAYASHI, Yutaka OKADA,* and Tetsurou YAMASHITA†
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received September 7, 1990)

The oxidation reactivity of *t*-butylferrocenes with air was measured in 1,2-dichloroethane or 1,4-dioxane. Their reactivity in 1,2-dichloroethane was increased with increasing the number of the substituents. It was considered that the oxidation proceeds through air oxidation with catalytic proton. On the other hand, in 1,4-dioxane, the conversion amount to oxidized form of ferrocene or *t*-butylferrocene suddenly incresed in the course of the reaction. In this solvent, the ferrocene nucleus was decomposed to give Fe^{3+} ion. It seems that the substrate was oxidized by Fe^{3+} ion formed.

Ferrocene (Fc) is very stable in air, so that the oxidation from Fe(II) to Fe(III) is difficult. However, in an acidic solution, Fc is readily oxidized to ferrocenium ion[2] with air.

The oxidation reaction of ferrocene derivatives with air (or oxygen gas) in acidic solution has been investigated by several workers.[3,4] The reaction mechanism was considered as follows:[4] ferrocenonium ion[2] is formed by coordination of a proton to iron atom of Fc, and is converted continuously to ferrocenium ion with loss of hydrogen atom by the attack of oxygen (Eq. 1).

$$\mathrm{Fc} \xrightarrow{H^+} \underset{\text{ferrocenonium ion}}{[\mathrm{Fc\text{-}H}]^+} \xrightarrow{O_2} \underset{\text{ferrocenium ion}}{\mathrm{Fc}^+} \quad (1)$$

In our previous paper,[5] the oxidation reaction of (substituted phenyl)ferrocenes was discussed. It was clarified that the reactivity of (substituted phenyl)ferrocenes is influenced by a coordination facility of proton to iron atom. The coordination facility is governed by both the I-effect and the steric effect of the substituent. That is to say, the oxidation reaction proceeds through Eq. 1. In the present work, the oxidation reaction of *t*-butylferrocenes was carried out in the presence of trichloroacetic acid. The reactivity of *t*-butylferrocenes in 1,2-dichloroethane increased with the number of *t*-butyl substituents, and was governed by the coordination facility of proton to iron atom. No steric hindrance by *t*-butyl groups was observed, and the reactivity was controlled by the I-effect of *t*-butyl groups. However, in 1,4-dioxane, the order of the reactivity was different from that in 1,2-dichloroethane. In 1,4-dioxane, the reactivity of ferrocene or *t*-butylferrocene suddenly increased in the course of the reaction. In this paper, we will discuss the mechanism of the oxidation reaction of these ferrocenes in 1,4-dioxane.

Experimental

Preparation of Materials. t-Butylferrocenes were prepared by well known methods[6-9] and the method developed in our laboratory.[10]

$$\mathrm{Fc} \xrightarrow{(CH_3CO)_2O} \mathrm{Fc\text{-}COCH_3} \xrightarrow{CH_3MgI+I_2} \mathrm{Fc\text{-}C(CH_3)_3}$$

$$\mathrm{Fc} \xrightarrow{CH_3COCl} \mathrm{Fc(COCH_3)_2} \xrightarrow{2CH_3MgI+I_2} \mathrm{Fc[C(CH_3)_3]_2}$$

$$\mathrm{Fc} \xrightarrow{(CH_3)_3CCl} \mathrm{Fc[C(CH_3)_3]}_n \quad (n=3,4).$$

† Present address: Dainippon Screen Mfg. Co., Ltd., Rakusai Plant, 322 Furukawa-cho, Hazukashi, Fushimi-ku, Kyoto 612.

The compounds were identified by melting point and ^{1}H NMR, and the purity was determined by HPLC. The melting point data and ^{1}H NMR chemical shifts are shown in Tables 1 and 2.

Measurements of Oxidation Reactivity. The oxidation reaction and analysis were carried out as described in the previous paper.[5] In the case of the reaction in 1,4-dioxane, HPLC analysis was carried out as follows: after water was added to a sample, unreacted material and internal standard (nitrobenzene) were extracted with 1,2-dichloroethane from a mixture of the reaction solution and water. The extract was analyzed by HPLC as mentioned in the previous paper.[5]

Results and Discussion

Oxidation Reaction in 1,2-Dichloroethane. The conversion of the oxidation of ferrocene and *t*-butylferrocenes in 1,2-dichloroethane is shown in Fig. 1. The order of the reactivity was as follows:

Fc<*t*-Bu-Fc<1,1′-di-*t*-Bu-Fc<1,1′,3-tri-*t*-Bu-Fc
<1,1′,3,3′-tetra-*t*-Bu-Fc.

The reactivity increased with increase in the number of the substituents. The reason was considered as follows: the electron density of iron atom of ferrocene molecule increases with an increase in the number of the electron-releasing substituents (*t*-butyl groups). It seems that the coordination of catalytic proton to iron atom is accelerated by higher electron density of iron atom. It was considered that the oxidation reaction in this solvent is not controlled by the steric hindrance of *t*-butyl groups and proceeds through Eq. 1.

Oxidation Reaction in 1,4-Dioxane. The conversion of the oxidation of *t*-butylferrocenes in 1,4-dioxane is shown in Fig. 2. The reactivity of ferrocene or *t*-butylferrocene suddenly increased in the course of the reaction. The conversion amount of ferrocene was zero in 1,2-dichloroethane, but the reactivity in 1,4-dioxane was higher. The color of the reaction solution will be noticed. When no remarkable increase of the conversion amount was observed, the solution was green of ferrocenium ion. Whereas, after the conversion amount increased, the solution changed to red-violet. Therefore, it was considered that the sudden increase of the conversion amount did not proceed through Eq. 1, and another mechanism is necessary to explain this reaction.

When sodium hydroxide was added to the red-violet solution, red precipitates were produced. By the addition of potassium thiocyanate (confirmatory reagent for Fe^{3+}) and 1,10-phenanthroline (confirmatory reagent for Fe^{2+}), the solution became orange-red and red, respectively. From these results, both F^{3+} and Fe^{2+} ions must be contained in the red-violet solution after sudden increase of the conversion amounts.[11] On the other hand, in the green solution, where the remarkable increase of the conversion amounts was absent, there were neither Fe^{3+} nor Fe^{2+} ions. Therefore, it seems that the ferrocene nucleus was decom-

posed in the red-violet solution.

The increase of the conversion amounts was not recognized in 1,2-dichloroethane, but it was found in 1,4-dioxane. Another ethereal solvent, dibutyl ether, was used instead of 1,4-dioxane. In a mixed solvent (dibutyl ether: 1,2-dichloroethane=1 : 9 (molar ratio)), which included only 10% ethereal solvent, it seems that the dielectric constant of the solvent is not different from that of pure 1,2-dichloroethane. As shown in Fig. 3, the increase of the conversion amounts was recognized. That is to say, the increase of the conversion amounts is recognized in the presence of ethereal solvents as 1,4-dioxane or dibutyl ether.

Trichloroacetate anion is stable in nonpolar solvent such as 1,2-dichloroethane. However, it was reported that the anion is decomposed to CCl_3^- ion with decarboxylation in aprotic polar solvent such as 1,4-dioxane.[12,13]

$$CCl_3COO^- \longrightarrow CCl_3^- + CO_2 \quad (2)$$

CCl_3^- ion is carbanion, and is a very strong nucleophilic reagent.[14] On the other hand, ferrocenium ion is decomposed by the attack of nucleophilic reagent.[15] Therefore, it seems that CCl_3^- ion is effective species for the decomposition of ferrocenium ion. It was considered that ferrocenium ion was decomposed by CCl_3^- ion.

The oxidation was carried out in methanol. The remarkable increase of the conversion amounts was not recognized as in 1,2-dichloroethane. The reason was considered as follows: CCl_3^- ion was produced even in methanol. However, the ion was converted to chloroform by the attack of methanol proton,[12] and did not act as nucleophilic reagent for ferrocenium ion. The decomposition process of ferrocenium ion by CCl_3^- ion was supported by this phenomenon observed in methanol.

The decomposition of ferrocene nucleus was confirmed by the following facts. As shown in Fig. 2, the remarkable increase of the conversion amounts was detected only for ferrocene and *t*-butylferrocene. Whereas, for 1,1′-di-, 1,1′,3-tri-, and 1,1′,3,3′-tetra-*t*-butylferrocene, such an increase was not observed. The reason was considered as follows: the Cp(cyclopentadienyl)-Fe bond is relatively strong for di-, tri-, and tetra derivatives and the steric hindrance is increased by *t*-butyl groups. Therefore, the decomposition of ferrocene nucleus of these compounds is difficult, so that the increase of the conversion amount was not remarkable for these three derivatives. The Cp-Fe bond force and the steric hindrance of ferrocene are weakest in all the ferrocenes examined in this study, and the remarkable increase occurred within 1 h from the start of the reaction. Whereas, on *t*-butylferrocene, the increase was observed after 3 h. These phenomena were explained by a similar reason to that mentioned above.

Fe^{3+} ion was formed by the decomposition of ferrocene nucleus. Fe^{3+} ion was a very strong oxidizing reagent for ferrocenes. Ferrocene and *t*-butylferrocenes examined in this study were oxidized perfectly by iron(III) chloride. Hence, when the remarkable increase of the conversion amount was recognized, the oxidation reaction by Fe^{3+} ion seems to proceed as Eq. 3.

$$Fe^{3+} + Fc \longrightarrow Fe^{2+} + Fc^+ \quad (3)$$

Furthermore, in order to block the oxidizing ability of Fe^{3+} ion, the following reaction was carried out: salicylic acid, which forms a complex between Fe^{3+} ion,[16] was added to the reaction solution together with trichloroacetic acid. No remarkable increase of the conversion amounts was recognized, and the reaction proceeded slowly (Fig. 3). (By the addition of acetic acid possessing no complex-forming ability, the increase of the conversion amounts was not stopped.) The reaction solution was washed with water, and UV spectra of the washings (light violet) showed a sharp absorption at 305.5 nm. The solution of iron(III) chloride and salicylic acid absorbed at the same position. From these results, it seems that Fe^{3+} ion formed by the decomposition of ferrocene nucleus was masked as a complex of salicylic acid in the presence of salicylic acid.

It was considered that the remarkable increase of the conversion amounts for ferrocene or *t*-butylferrocene was caused by the following mechanism: ferrocene nucleus was attacked by CCl_3^- ion formed by the decomposition of trichloroacetate ion in 1,4-dioxane. The nucleus was decomposed to form Fe^{3+} ion. Fe^{3+} ion oxidized ferrocenes, and the increase of the conversion amounts was remarkable. As mentioned above, the reaction solution contains Fe^{2+} and Fe^{3+} ions. It seems that Fe^{3+} ion was reduced to Fe^{2+} through Eq. 3 or by the action of Cp^- ion[15] formed by the decomposition of ferrocene nucleus.

Conclusion

In 1,4-dioxane, the oxidation of ferrocene or *t*-butylferrocene proceeds as follows:

1. CCl_3^- ion is produced by the decomposition of trichloroacetate ion.
2. The ferrocene nucleus is decomposed by CCl_3^- ion to form Fe^{3+} ion.
3. The substrate is oxidized faster by Fe^{3+} ion than ferrocenonium ion is oxidized by air.

Consequently, in 1,4-dioxane, the conversion amount of ferrocene or *t*-butylferrocene suddenly increases in the course of the reaction.

(Received September 19, 1990)

Phosphorylation of nucleotides (nucleoside 3′- and 5′-monophosphates, and 2′-deoxynucleoside 5′-monophosphates) with inorganic sodium cyclo-triphosphate (P_{3m}) was studied in aqueous solutions under various conditions (mixing ratio of P_{3m} to nucleotides, pH, reaction temperature, and time). (1) Unprotected nucleoside 5′-monophosphates (5′-NMP's) were easily phosphorylated at the *cis*-2′,3′-diol by P_{3m} to form selectively nucleoside 2′,5′-bis(monophosphate) (2′,5′-NDP's), nucleoside 3′,5′-bis(monophosphate) (3′,5′-NDP's), and nucleoside 2′,3′-cyclic 5′-bis(monophosphate) (cNDP's). (2) The phosphorylation of 5′-NMP's was strongly dependent on mixing ratio, pH, reaction temperature, and time. Under conditions of high mixing ratios of P_{3m} to 5′-NMP's (5 : 1—10 : 1), high pH (12), and room temperature, 92—98% of 5′-NMP's was converted into 3′,5′-NDP's and 2′,5′-NDP's in roughly equimolar quantities. (3) Small quantities (5—8%) of cNDP's were formed at the initial stage of reaction of 5′-NMP's with P_{3m} but in the course of the reaction for a long period, cNDP's were hydrolyzed to 2′,5′-NDP's and 3′,5′-NDP's. (4) Nucleoside 3′-monophosphates (3′-NMP's) and 2′-deoxynucleoside 5′-monophosphates (dNMP's) could not be phosphorylated by P_{3m}, which indicates that the presence of hydroxyl groups at both 2′- and 3′-positions on nucleotides is indispensable for the phosphorylation of nucleotides with P_{3m}. (5) The mechanism of the formation of 2′,5′-NDP's, 3′,5′-NDP's, and cNDP's in the phosphorylation of 5′-NMP's with P_{3m} is discussed.

Phosphoryl chloride,[1,2] organic phosphorus compounds,[1,3,4] and polyphosphoric acid[5-8] have so far been used as phosphorylating agents of organic compounds, nucleosides, and bioorganic compounds. Since the phosphorylation with these phosphorylating agents is accompanied by various side reactions, introduction of protective groups is often required. In addition, the experimental operation of phosphorylation is extremely complicated because of its character of multi-stage reaction in organic solvents. Simple and selective phosphorylating agents have always been required.

In 1965—1969, Feldmann demonstrated that inorganic cyclo-triphosphate (P_{3m}) phosphorylated selectively some functional groups on organic compounds such as alkylamines,[9,10] alcohols,[11] sugars,[11] amino acids,[12] and phenol[13] without complicated handling. After Feldmann's work, several authors have tried to extend this technique to the phosphorylation of nucleosides.

Saffhill[14] reported that a treatment of unprotected adenosine with P_{3m} produced adenosine 2′- and 3′-monophosphates in high yield. On the other hand, Etaix and Orgel[15] reported that the reaction of 2′-deoxynucleosides with P_{3m} gave 2′-deoxynucleoside triphosphates in substantial yield, whereas a small amount of adenosine triphosphate and a large amount of adenosine 2′- and 3′-monophosphates were obtained by the reaction of adenosine with P_{3m}. There are some discrepancies in the kind and yield of products between the experimental results of Saffhill and those of Etaix and Orgel, because of some differences in their reaction conditions. Schwartz[16] produced a small amount of a mixture of 2′-deoxyadenosine 3′- and 5′-monophosphates by phosphorylating 2′-deoxyadenosine with P_{3m}.

The present authors[17] have extensively studied the phosphorylation of unprotected nucleosides with P_{3m} and its reaction mechanism. We reported that the hydroxyl groups at the 2′- and 3′-positions of ribonucleosides were selectively phosphorylated by the reaction of ribonucleosides with P_{3m} in an aqueous solution to form nucleoside 2′-, 3′-, and 2′,3′-cyclic monophosphates in high yield (80—90%). We concluded on the basis of this mechanistic study that nucleoside 2′- and 3′-triphosphates as well as nucleoside 2′,3′-cyclic monophosphates were produced as reaction intermediates.

The present authors have tried to phosphorylate nucleic acids and their related compounds with inorganic sodium cyclo-triphosphate (P_{3m}) to develop a selective phosphorylating agent for single-stage reaction in aqueous solution. In the present study, therefore, phosphorylation of nucleotides with P_{3m}, structures of reaction products, yields, and reaction mechanisms were investigated using HPLC and ^{31}P NMR.

Experimental

Chemicals. Sodium cyclo-triphosphate hexahydrate (P_{3m}), $Na_3P_3O_9 \cdot 6H_2O$, was prepared by the procedure described in our previous paper[18] and recrystallized twice from an aqueous solution. Guaranteed grade adenosine 5′-monophosphate (5′-AMP), adenosine 3′-monophosphate (3′-AMP), 2′-deoxyadenosine 5′-monophosphate (dAMP), cytidine 5′-monophosphate (5′-CMP), cytidine 3′-monophosphate (3′-CMP), 2′-deoxycytidine 5′-monophosphate (dCMP), guanosine 5′-monophosphate (5′-GMP), guanosine 3′-monophosphate (3′-GMP), uridine 5′-monophosphate (5′-UMP), uridine 3′-monophosphate (3′-UMP), and thymidine 5′-monophosphate(dTMP) were purchased from Yamasa Shoyu Co., Ltd. (Tokyo, Japan) and Sigma

Chemical Company.

Phosphorylation of Nuceotides with Inorganic Cyclotriphosphate (P_{3m}). The initial concentration of P_{3m} was fixed at a constant value of 0.5 mol dm^{-3} and those of nucleotides were varied from 0.5 to 0.05 mol dm^{-3}. Values of pH of mixed solutions were adjusted to desired values (14, 12, 10, 7, and 5) with 6 mol dm^{-3} sodium hydroxide solution or hydrochloric acid. Mixed solutions were allowed to react at room temperature (20—25 °C) or at specified temperatures (50 and 70 °C) by use of a thermostated bath controlled within ±2 °C. As the pH of the mixtures handled would gradually decrease with progress of reaction, it was kept at the prescribed value using sodium hydroxide solution during reaction.

HPLC Measurement. HPLC analysis was carried out with a JASCO HPLC-800 system (Tokyo, Japan). A column (250×4.6 mm i. d.) was packed with an anion exchanger (MCI gel, CDR-I0, Mitsubishi Chemical Industry, Tokyo, Japan), and the column temperature was maintained at 40 °C.

The linear gradient elution techique was used for the adenosine (5′-AMP, 3′-AMP, and dAMP) and cytidine (5′-CMP, 3′-CMP, and dCMP) systems, whereas the isocratic elution technique was used for the separation of guanosine (5′-GMP and 3′-GMP), uridine (5′-UMP and 3′-UMP), and dTMP systems. All eluents contained ammonium sulfate, dipotassium hydrogenphosphate, and 4% (v/v) acetonitrile. The eluent pH was kept at 10. The UV absorbance of an effluent was monitored continuously at 260 nm for the adenosine, guanosine, and uridine systems, 270 nm for the dTMP system, and 280 nm for the cytidine system.

^{31}P NMR Measurement. Pulse FT ^{31}P NMR spectra were recorded at room temperature by use of Varian XL-VX 300 (121 MHz) and Varian XL-200 (81 MHz) spectrometers. Orthophosphoric acid (85%) was used as an external standard.

Results and Discussion

Phosphorylation of 5′-AMP with P_{3m}. An aqueous reaction mixture of P_{3m} (0.5 mol dm^{-3}) and 5′-AMP (0.05 mol dm^{-3}) was allowed to react at pH 12 and room temperature. The pH of the mixed solution decreased gradually and reached about 9.9 after 1 d. Thus, the pH of the mixture was kept at 12 using sodium hydroxide solution during reaction.

Figure 1 shows the results of HPLC of the reaction products in the phosphorylation of 5′-AMP with P_{3m} at mixing ratio 10:1 (0.5 mol dm^{-3}:0.05 mol dm^{-3}), pH 12, and room temperature. With progress of reaction, the peak of 5′-AMP (retention time about 9 min) was reduced and the three peaks of the reaction products were observed at the retention times of about 26,

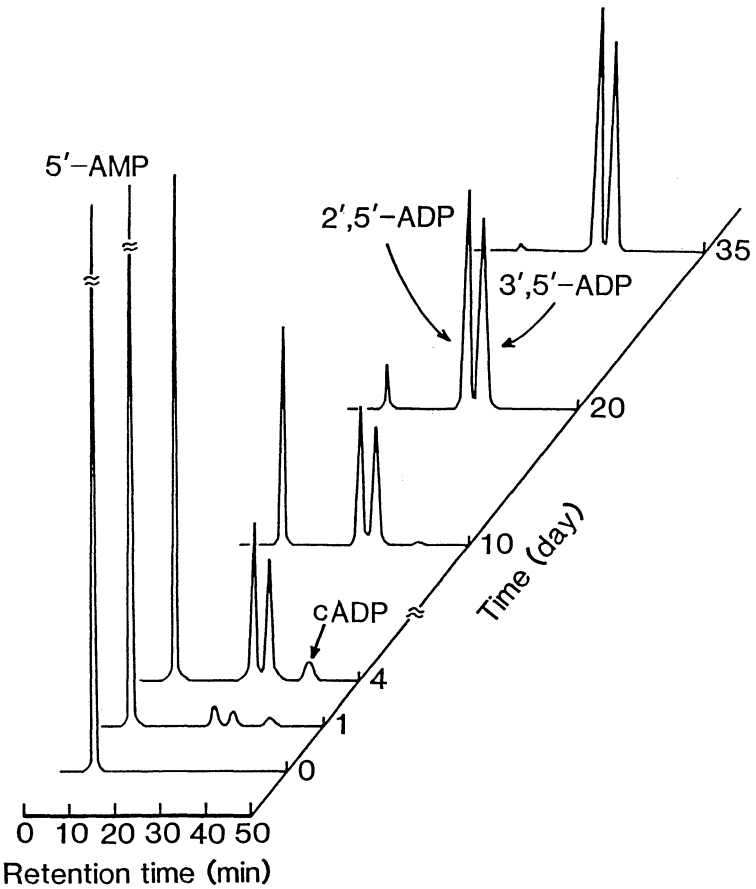

Fig. 1. Phosphorylation of 5′-AMP with P_{3m}.
P_{3m}: 5′-AMP=10:1 (0.5 mol dm^{-3}: 0.05 mol dm^{-3}), pH 12, room temperature.

30, and 38 min, respectively. These reaction products were identified to be adenosine 2′,5′-bis(monophosphate) (designated as 2′,5′-ADP), adenosine 3′,5′-bis(monophosphate) (3′,5′-ADP), and adenosine 2′,3′-cyclic 5′-bis(monophosphate) (cADP) by comparing with results of HPLC and ^{31}P NMR analyses of the authentic samples. As can be seen from the result of HPLC, two main products (2′,5′-ADP and 3′,5′-ADP) and a by-product (cADP) were produced in the phosphorylation of 5′-AMP with P_{3m} in an aqueous solution. cADP was produced at the initial stage of reaction, and it gradually decreased with reaction time and finally disappeared after 13 d. On the other hand, the amounts of 2′,5′-ADP and 3′,5′-ADP increased with elapse of reaction time and reached 46.1 and 46.3% after 20 d, respectively. Under any reaction conditions, the amounts of 2′,5′-ADP and 3′,5′-ADP were nearly equal to each other.

To establish the structure of phosphorylated products, ^{31}P NMR spectra were measured. Figure 2 shows the ^{31}P NMR spectra for the reaction mixture of P_{3m} and 5′-AMP at molar ratio 10 : 1, pH 12, and room temperature. In the ^{1}H-decoupling spectrum, four peaks due to the reaction products were observed at δ=+4.9, +4.7, +4.6, and +4.4. By comparing with the chemical shifts of the authentic samples, the peaks at δ=+4.9 and +4.7, and at δ=+4.6 and +4.4 were attributed to 3′,5′-ADP and 2′,5′-ADP, respectively. The peaks at δ=+4.9 and +4.7 split into a doublet and a triplet, respectively, in the ^{1}H-coupling spectrum. Thus, it was found that the peaks at δ=+4.9 and +4.7 were attributable to the phosphorus atoms at the 3′- and 5′-positions of ribose in 3′,5′-ADP, respectively, and the peaks at δ=+4.4 and +4.6 were attributable to the phosphorus atoms at the 2′- and 5′-positions in 2′,5′-ADP, respectively. A singlet peak corresponding to the 2′,3′-cyclic phosphate of cADP was observed at δ=+20.5 and split into a triplet due to the two protons of 2′- and 3′-positions of ribose in the ^{1}H-coupling. The singlet peak at δ=−21.4 corresponds to the starting material, P_{3m}, the peaks at δ=−4.0 and −4.3 were assigned to the terminal phosphorus atoms of triphosphate (P_3) produced by the hydrolysis of P_{3m} and those at δ=−18.2, −18.4, and −18.6 to the middle phosphorus atom of P_3. The singlet peaks at δ=+5.4 and −4.6 were attributed to ortho (P_1) and pyrophosphates (P_2), respectively.

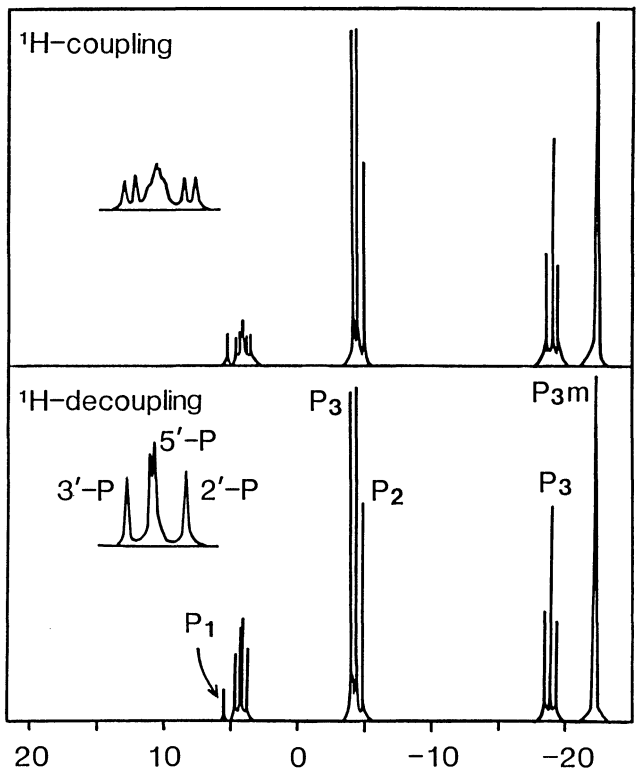

Fig. 2. ^{31}P NMR of the reaction products.
P_{3m}: 5′-AMP=10 : 1 (0.5 mol dm^{-3}: 0.05 mol dm^{-3}), pH 12, room temperature, after 30 d.

In Fig. 3, the amounts of 2′,5′-ADP, 3′,5′-ADP, and cADP, formed in the reaction of P_{3m} with 5′-AMP at mixing ratio 10 : 1, pH 12 and room temperature, are plotted as a function of time. While the starting material (5′-AMP) decreased with reaction time, each amount of 2′,5′-ADP and 3′,5′-ADP gradually increased up to the same constant value of approximately 47%. The yield of 2′,5′-ADP was nearly equal to that of 3′,5′-ADP at any reaction times. The yield of cADP reached about 5% after 1 d and decreased to zero after 13 d.

The influence of pH on the reaction of P_{3m} with 5′-AMP is shown in Fig. 4. The phosphorylation of 5′-AMP with P_{3m} proceeded faster in a high alkaline region, e.g., at pH 12, than at pH 10 and less. The phosphorylation did not proceed in an acidic medium (pH 5) at all. This fact may be explained in terms of

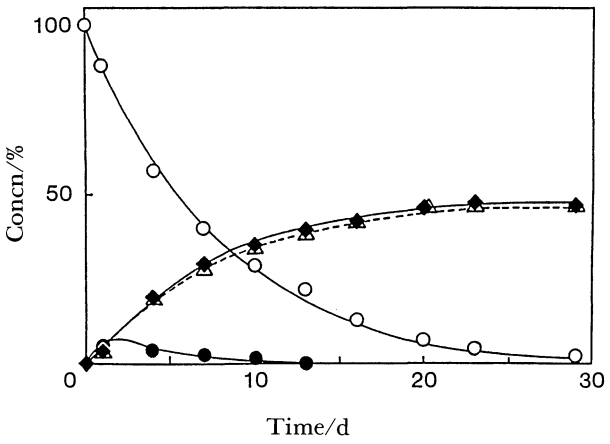

Fig. 3. Changes of the amounts of products in the reaction of P_{3m} with 5′-AMP.

such a sequence that the hydroxyl group (-OH) at the 2′- or 3′-position of ribose in 5′-AMP[19] is partially dissociated into O^- which nucleophilically attacks the phosphorus atom of P_{3m}.

We have further studied the phosphorylation of 5′-AMP at varying temperatures and mixing ratios, with the pH of reaction mixture maintained at pH 12. The yields of the 2′,5′-ADP, 3′,5′-ADP, and cADP thus obtained are summarized in Table 1. The effect of reaction temperature on maximum yield was examined for the reaction of 5′-AMP with P_{3m} at a mixing ratio of 5 : 1. As can be seen in Table 1, the best yield was obtained at room temperature after 40 d. Due to the hydrolysis of the reaction products, the maximum yield obtained at higher temperatures is lower than that obtained at room temperature. The effect of the mixing ratio of P_{3m} to 5′-AMP was tested as listed in Table 1. The ratio of P_{3m} to 5′-AMP of 10 : 1 (0.5 mol dm^{-3} : 0.05 mol dm^{-3}) is better than that of 1 : 1 (0.5 mol dm^{-3} : 0.5 mol dm^{-3}). The yield at a mixing ratio of 10 : 1 was, however, not so much different from that at 5 : 1.

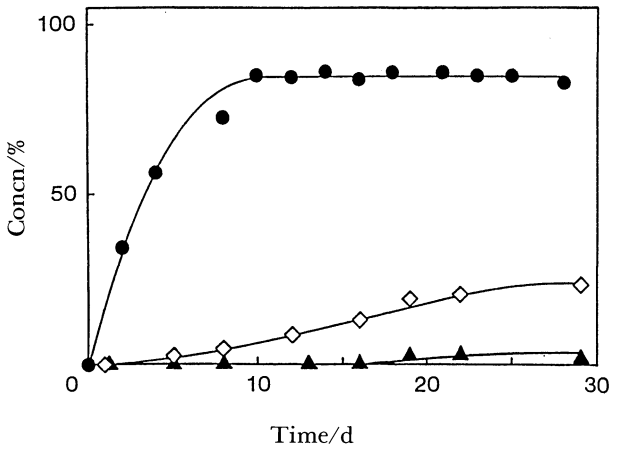

Fig. 4. Changes of the amounts of products in the reaction of P_{3m} with 5′-AMP.
P_{3m}: 5′-AMP=5 : 1 (0.5 : 0.1 mol dm^{-3}), 50 °C, ●; pH 12, ◇; pH; 10, ▲; pH 7.

The optimum conditions for the phosphorylation of 5′-AMP with P_{3m} are found to be mixing ratio 5 : 1—10 : 1, pH 12, room temperature, and reaction period 35—41 d. The total yields of 2′,5′-ADP and 3′,5′-ADP under the optimum condition were about 96.5%. On the other hand, cADP was produced only at the initial stage of reaction under any reaction conditions and its yield was about 5—6% which was much lower than those of 2′,5′-ADP and 3′,5′-ADP. The amount of cADP gradually decreased with elapse of reaction time. This is because cADP is easily hydrolyzed to give 2′,5′-ADP and 3′,5′-ADP.

The phosphorylation of 3′-AMP or dAMP with P_{3m} was also investigated under various conditions. However, these compounds could not be phosphorylated with P_{3m} at all under any conditions. This fact may suggest that the presence of the hydroxyl groups at both the 2′- and 3′-positions of ribose in 5′-AMP is required for the phosphorylation of nucleotides with P_{3m}.

Phosphorylation of 5′-CMP with P_{3m}. HPLC separations of the reaction products in the phosphorylation of 5′-CMP with P_{3m} gave the three peaks due to cytidine 2′,3′- cyclic 5′-bis(monophosphate) (designated as cCDP), cytidine 2′,5′-bis(monophosphate)

(2′,5′-CDP), and cytidine 3′,5′-bis(monophosphate) (3′,5′-CDP). The main reaction products were identified to be 2′,5′-CDP and 3′,5′-CDP by comparing with the results of HPLC and ^{31}P NMR of the authentic samples. Although a small amount (about 5—8%) of cCDP was produced at the initial stage of reaction, it decreased rapidly with reaction time. The formation of 2′,5′-CDP and 3′,5′-CDP increasingly predominated with progress of reaction.

Table 2 lists the yields of 2′,5′-CDP, 3′,5′-CDP, and cCDP under various reaction conditions. In the reaction of 5′-CMP with P_{3m} at mixing ratio 5:1 (0.5 mol dm^{-3} : 0.1 mol dm^{-3}), pH 12, and room temperature for long time (48 d), about 92% of 5′-CMP was phosphorylated to form 2′,5′-CDP (40%) and 3′,5′-CDP (52%). The yield of 3′,5′-CDP was always a little more than that of 2′,5′-CDP, though both yields were nearly equal to each other. The phosphorylation proceeded for a short time (5 h) at 70 °C and high pH (14), and the total yields of 2′,5′-CDP, and 3′,5′-CDP reached about 66% at 5 h. The amounts of these products, however, gradually decreased with time, because they were easily hydrolyzed at pH 14 and 70 °C. The reaction rate was decreased by lowering the pH of the mixed solution. The reaction did not proceed at all in acidic medium (pH 5). Neither 3′-CMP, nor dCMP could be phosphorylated with P_{3m} under the same conditions as the phosphorylation of 5′-CMP with P_{3m}.

The experimental results indicate that the optimum conditions for the phosphorylation of 5′-CMP with P_{3m} are mixing ratio 5:1, pH 12, and room temperature.

Phosphorylation of 5′-GMP with P_{3m}. The phosphorylation of 5′-GMP with P_{3m} was carried out by the same method as that of the 5′-AMP and 5′-CMP systems. Figure 5 shows an example of HPLC analysis of the reaction products in the phosphorylation of 5′-GMP with P_{3m}. The products were guanosine 2′,5′-bis(monophosphate) (2′,5′-GDP) and guanosine 3′,5′-bis(monophosphate) (3′,5′-GDP). No guanosine 2′,3′-cyclic 5′-bis(monophosphate) (cGDP) was obtained in the phosphorylation of 5′-GMP with P_{3m} unlike those of the 5′-AMP and 5′-CMP systems. It is not clear yet whether cGDP was not formed originally or the cGDP once formed at the initial stage of the reaction was so unstable as to be immediately hydrolyzed to form 2′,5′-GDP and 3′,5′-GDP. However, it may be reasonable to consider that the latter is more probable, similarly to the case of the 5′-AMP and 5′-CMP systems.

Table 3 shows amounts of 2′,5′-GDP and 3′,5′-GDP obtained under various reaction conditions. The optimum conditions for the phosphorylation of 5′-GMP with P_{3m} are found to be mixing ratio 5:1—10:1, pH 12, room temperature, and long reaction period (28 d). The yields of the reaction products (2′,5′-GDP and 3′,5′-GDP) under the optimum conditions were approximately 97%. Also, the yield of 2′,5′-GDP was nearly equal to that of 3′,5′-GDP under any conditions. On the other hand, 3′-GDP was not phosphorylated with P_{3m} at all.

Phosphorylation of 5′-UMP with P_{3m}. In the phosphorylation of 5′-UMP with P_{3m}, the reaction

products were identified to be uridine 2',5'-bis(monophosphate) (2',5'-UDP), uridine 3',5'-bis(monophosphate) (3',5'-UDP), and uridine 2',3'-cyclic 5'-bis(monophosphate) (cUDP) by comparing with the data of HPLC and ^{31}P NMR of the authentic samples. Although cUDP was produced at the initial stage of the reaction, it disappeared with reaction time and the formation of 2',5'-UDP and 3',5'-UDP predominated instead.

Yields of 2',5'-UDP, 3',5'-UDP, and cUDP under various reaction conditions are summarized in Table 4. The optimum conditions for the phosphorylation of 5'-UMP with P_{3m} are mixing ratio 5 : 1—10 : 1, pH 12, and room temperature. The total yields of 2',5'-UDP and 3',5'-UDP under the optimum conditions were about 93% at the highest. 3'-UMP was not phosphorylated with P_{3m} at all, similarly to 3'-AMP, 3'-CMP, and 3'-GMP.

ation of 5′-NMP's with P_{3m} are shown in Table 5. The measurements of ^{31}P NMR were made at pH 12.

Mechanism of Phosphorylation of 5′-NMP's with P_{3m}. In the reaction of P_{3m} and 5′-NMP's, cis-2′,3′-diol on nucleotides is phosphorylated to form 2′,5′-NDP's, 3′,5′-NDP's, and cNDP's. Considering that dNMP's and 3′-NMP's are not phosphorylated, the presence of hydroxyl groups at both 2′- and 3′-positions is indispensable for the phosphorylation of 5′-NMP's with P_{3m}.

From the above-mentioned experimental results, the authors propose the reaction mechanism shown in Fig. 6. The hydrogen bond is first formed between the hydroxyl group at the 2′- or 3′-position on nucleotides and an oxygen atom of P_{3m}, e.g., the hydrogen bond of 3′-OH with P_{3m} in Fig. 6. Closely related hydrogen-bonded intermediates have been postulated.[13,17] Then, the lone electron pair on the oxygen atom of another hydroxyl group (2′-OH in Fig. 6) nucleophilically attacks the phosphorus atom of P_{3m} to generate nucleoside 2′-triphosphates as an unstable intermediate, via the ring opening of P_{3m}. The roles of the 2′- and 3′-hydroxyl groups in hydrogen bonding and nucleophilic attack could equally be reversed, of course. An intramolecular attack of unphosphorylated hydroxyl group (3′-OH in Fig. 6) on a phosphorus atom of nucleoside 2′-triphosphates occurred to produce cNDP's as an intermediate. The cNDP's thus formed are quickly hydrolyzed to give 2′,5′-NDP's and 3′,5′-NDP's. The yields of 2′,5′-NDP's were nearly equal to those of 3′,5′-NDP's, which shows that the rate of hydrolysis at the 2′-position of cNDP's is almost the same as that at the 3′-position. Such a fact is well-known in the hydrolysis of RNA in an alkaline solution.[20]

In the 5′-GMP system, however, guanosine 2′,3′-

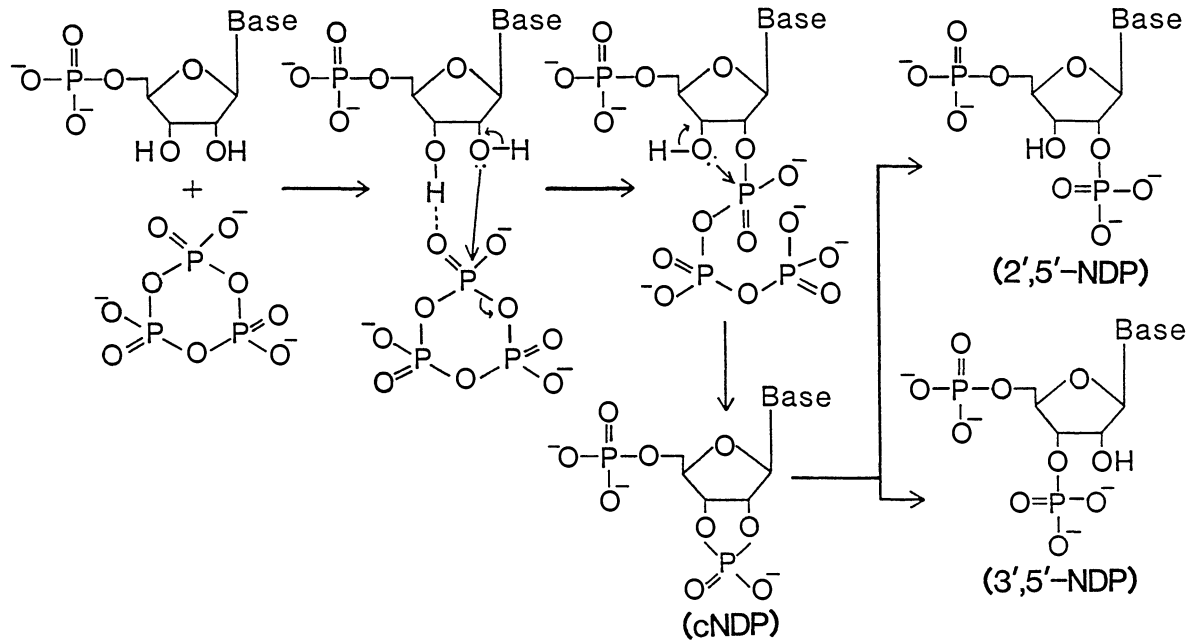

Fig. 6. Mechanism of phosphorylation of nucleotides with P_{3m}.

cyclic 5′-bis(monophosphate) (cGDP) could not be detected by HPLC or ^{31}P NMR. It is considered that cGDP is so unstable in alkaline aqueous solution that it is easily hydrolyzed to 2′,5′-GDP and 3′,5′-GDP.

Fluctuation of Local Field and Depolarization Ratio of the ν_1 Raman Line of Carbon Tetrachloride in Carbon Disulfide Solution

Shi-aki Hyodo
Toyota Central Research and Development Labs., Inc., Nagakute-cho, Aichi-gun, Aichi 480-11
(Received March 3, 1990)

The depolarization ratio of a molecule having T_d symmetry has been expressed in terms of the mean-square fluctuation of the local field which is felt by a molecule in the condensed phase. The fluctuation of the polarizability at each position in the scattering volume was found to dominantly affect local-field fluctuation. The concentration dependence of the depolarization ratio for the ν_1 Raman line of carbon tetrachloride in a carbon disulfide solution could be well described by this expression.

The depolarization ratio of Raman spectra, ρ, for linear polarized incident light sources is defined as

$$\rho=\frac{3\,\gamma^2}{45\,\bar{\alpha}^2+\gamma^2}, \tag{1}$$

where

$$\bar{\alpha}\equiv\frac{1}{3}(\alpha'_{xx}+\alpha'_{yy}+\alpha'_{zz})$$

and

$$\gamma^2\equiv[(\alpha'_{xx}-\alpha'_{yy})^2+(\alpha'_{yy}-\alpha'_{zz})^2+(\alpha'_{zz}-\alpha'_{xx})^2].$$

Here, $\alpha'_{\sigma\rho}$ is the $\sigma\rho$-component of the Raman scattering tensor. Using this relation, ρ can supply much useful information concerning molecular structure. It is easy to imagine that ρ also includes information about intermolecular interactions and/or the aggregation structure of molecules in condensed phases. The depolarization ratio of the ν_1 Raman line of liquid carbon tetrachloride is an example of such phenomena. This depolarization ratio should be exactly zero in an isolated molecule, since the relation $\alpha'_{xx}=\alpha'_{yy}=\alpha'_{zz}$ is satisfied. However, it has been reported by many authors[1-6] that the depolarization ratio has an experimental value that is not exactly zero. The isotropic effects of chlorine atoms were quantitatively analyzed and were found to contradict information regarding the origin of this finite value of ρ.[7,8] This ρ value came to be considered to originate from some intermolecular interactions. Its detailed mechanism, however, had not been discussed until a report concerning the fluctuation of the local field[9] appeared.
