
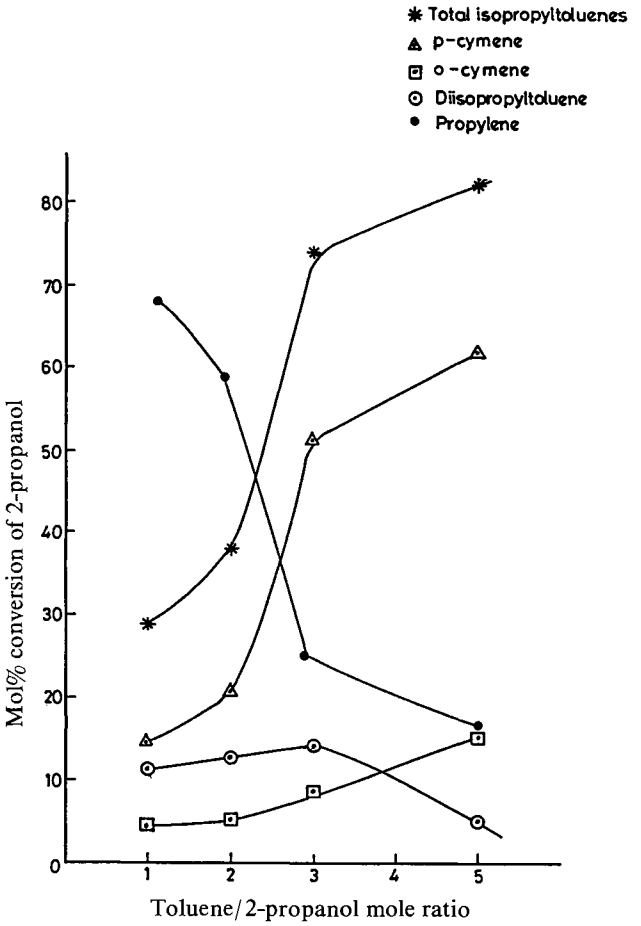

Fig. 5. Effect of toluene/2-propanol mole ratio on the conversion of 2-propanol to isopropyltoluene over Mosial-4 catalyst. Reaction conditions: Reaction temperature: 200 °C; Liquid hourly space velocity: 0.5 h^{-1}.

ene from $\overset{+}{M}$–isopropyl, causing increased conversions to isopropyltoluenes. Similarly, increased conversions to isopropylbenzene have been observed by K. H. Chandavar et al.[26] in the isopropylation of benzene at higher benzene to alcohol mole ratio.

Also the large excess of the aromatic substrate in the feed decreased the formation of diisopropyltoluene and caused marginal increase in the conversion to *o*-cymene (Fig. 5).

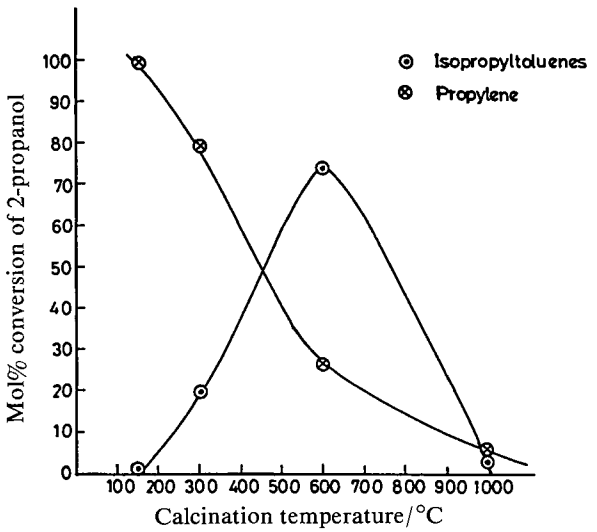

Fig. 6. Effect of calcination temperature on the alkylating activity of Mosial-4 catalyst. Reaction conditions: Reaction temperature: 200 °C; Liquid hourly space velocity: 0.5 h^{-1}; Toluene/2-propanol mole ratio: 3.

Effect of Calcination Temperature: The optimum conversion of 2-propanol to isopropyltoluenes is given by Mosial-4 samples calcined at 600 °C (Fig. 6) which has a high acid strength value and fairly large acid amount (Table 3). Even though the samples calcined at lower temperatures are less active in catalyzing the alkylation of toluene, they served as effective catlaysts in the dehydration of alcohol molecules which is evidenced by the quantity of propylene produced (Fig. 6).

The Regenerability of Mosial-4: The acidity distribution of Mosial-4 is negligibly affected by four or five successive regeneration cycles (Table 4). Correspondingly, the alkylating activity of the sample also is almost unaffected which is evidenced from (Fig. 7). However further regeneration cycles reduced alkylating activity.

Conclusion

The total acid amount of MoO_3–SiO_2–Al_2O_3 containing 9.7% by weight of MoO_3 and silica to alumina molar

ratio 16.6 is very high compared to that of SiO_2–Al_2O_3 of the same silica to alumina molar ratio. The acid strength of SiO_2–Al_2O_3 is reduced by the incorporation of MoO_3. Also the ternary oxide system coprecipitated from highly acidic solution has low acid strength and that coprecipitated from highly alkaline solution has low acid amount. The catalytic activity of MoO_3–SiO_2–Al_2O_3 for the alkylation of toluene with 2-propanol is very high compared with that of SiO_2–Al_2O_3. However reaction temperatures >200 °C, higher liquid hourly space velocity and higher alcohol content in the feed decreased the total conversion of 2-propanol to isopropyltoluenes. The acidic property and catalytic activity of MoO_3–SiO_2–Al_2O_3 are not considerably reduced up to four successive regeneration cycles.

Photocatalytic Activities of Bi_2O_3, WO_3, and Fe_2O_3: An Assessment through Decomposition of Peroxomonosulfate in Visible Radiation

Pichai MARUTHAMUTHU,* Karuppusamy GURUNATHAN, Esaikkiappan SUBRAMANIAN, and Muthupandian ASHOKKUMAR

Department of Energy, University of Madras, A. C. College Campus, Madras 600025, India

(Received August 27, 1990)

Bi_2O_3 semiconductor powder (E_g=2.8—2.9 eV) was chosen for the first time to effect photocatalysis and was found to decompose peroxomonosulfate (PMS) with visible light of $\lambda > 400$ nm. Doping of Bi_2O_3 with Cu(II)-ion considerably enhanced the photocatalytic efficiency. The effects of variation of (i) the [dopant] in Cu(II)/Bi_2O_3, (ii) the catalyst amount, and (iii) the initial [PMS] on the rate of decomposition of PMS were investigated. It was observed that (a) 4 atomic % was the optimum [dopant] for Cu(II)/Bi_2O_3, (b) the rate increased linearly with increase in catalyst amount, and (c) the decomposition of PMS followed a Langmuir kinetics in the concentration range, $[PMS]_0$=0.5—3.0×10^{-3} mol dm^{-3}. A suitable reaction mechanism is proposed for the decomposition of PMS involving all the possible reactions. A comparative analysis of the photocatalytic activities of undoped and Cu(II)-doped Bi_2O_3, WO_3, and Fe_2O_3 indicated that Cu(II)-doping enhances the activity of Bi_2O_3 to a greater extent than those observed with the other two semiconductors. This photocatalytic decomposition of PMS is one of the examples of visible light assisted reaction which otherwise takes place under UV radiation ($\lambda \leqslant 280$ nm) only.

The search for viable means of conversion of solar energy into other forms has gained momentum during the past few years and the role of semiconductors in this aspect has occupied a prominent place.[1] The oxide semiconductors, especially in the form of powders appear to be most promising for photocatalysis because of their inherent advantages such as (1) resistance to photocorrosion,[2] (2) stability in both the acidic and alkaline media, and (3) larger surface area needed for photocatalysis. Many reports on the photocatalytic activities of several oxide semiconductors, TiO_2, ZnO, SnO_2, Fe_2O_3 etc., are already available. Using WO_3, we have recently reported the photocatalytic decomposition of peroxides[3] and the photocleavage of water.[4,5]

Although the investigations with oxide semiconductors are numerous, so far only a few studies with Bi_2O_3 have been reported, despite the fact that the band-gap energy (E_g) of this semiconductor is only 2.8—2.9 eV, which absorbs more solar radiation in the visible region compared to that of either TiO_2 or $SrTiO_3$ with which numerous investigations are available. In studies conducted over the years, Bi_2O_3 has been used as a stabilizing agent and/or as a dopant in solid electrolytes. Kruidhof et al.[6,7] have prepared, characterized, and investigated the mechanical properties of Bi_2O_3-based ceramics. Winnubst and Burggraaf[8] have also prepared and studied the electrical properties of monophasic Y_2O_3-stabilized ZrO_2 doped with Bi_2O_3. In both these studies, it has been reported that the inclusion of Bi_2O_3 enhances the stability of the solid electrolyte. Only one study[9] has been carried out in detail on the photoelectrochemical properties of anodic Bi_2O_3 films. Since investigation dealing with the photocatalytic aspects of Bi_2O_3 semiconductor powder is found absent, the present work which involves the assessment of the photocatalytic activities of undoped and Cu(II)-doped Bi_2O_3 through visible light assisted decomposition of peroxomonosulfate (PMS, HSO_5^-) and comparison of the efficiencies of the above catalysts with those of undoped and Cu(II)-doped WO_3 and Fe_2O_3, are attempted. The findings of this work are significant because they brighten the possibility of Bi_2O_3 application for photocatalysis in future. This study also serves as an example for visible light assisted decomposition of PMS which otherwise happens only by UV irradiation, $\lambda \leqslant 280$ nm.

Experimental

Bi_2O_3, WO_3, and Fe_2O_3 semiconductors (99.9%) were obtained from Fluka. PMS was from E.I. du Pont de Nemours & Co., USA and was used as such. Other chemicals used were of the purest research grade available.

In catalyst preparation, a high-temperature sintering technique was used. The Cu(II)-doped (at different atomic %) semiconductor catalysts were prepared as follows: a calculated quantity of $CuCl_2$ salt (99%) was added to the aqueous slurry of the semiconductor and it was stirred magnetically for 2 hours, dried in an air oven at 110 °C and sintered at 400—500 °C for Bi_2O_3, 700—800 °C for WO_3, and 1200—1300 °C for Fe_2O_3. The sintered samples were then ground to fine powders and stored in light-proof vials. Undoped samples of Bi_2O_3, WO_3, and Fe_2O_3 were also processed in a similar manner at temperatures mentioned above. The surface areas of the catalysts were determined by Quantasorb surface area analyzer and found to be 2.0—3.0 $m^2 g^{-1}$. The catalysts were also characterized by diffuse reflectance spectra (Hitachi, Japan) and X-ray diffraction methods (Philips, Holland).

A typical procedure followed in the photocatalytic experiment is given below. 40 ml of the PMS solution ($[PMS]_0$= 0.5—3.0×10^{-3} mol dm^{-3}) in water containing 40 mg of the catalyst was irradiated with visible light of $\lambda > 400$ nm from a 150-W xenon lamp (Applied Photophysics, London), after cutting off UV and IR radiations with appropriate glass filter

and water jacket, respectively. The experiment was carried out at room temperature (ca. 25 °C) and at natural pH (ca. 6). The [PMS] was estimated iodometrically and the rate was followed by determining [PMS] at various time intervals.

Determination of Quantum Yields. Quantum yields for the PMS decomposition were determined by employing potassium tris(oxalato)ferrate(III) actinometry as described in literature.[10] A range of wavelength (400—450 nm) rather than a single wavelength was selected for this determination, because in this range, all the catalysts have maximum absorption (nearly 60%) and this was taken as an advantage in the photocatalytic experiments. A 0.006 M $K_3[Fe(C_2O_4)_3]$ solution was irradiated with the same 150-W xenon lamp mentioned above, after passing the light through a band filter for the 400—450 nm range. From the amount of Fe^{2+} formed during irradiation, the light intensity of the lamp was determined assuming $\Phi=1.11$. This experiment was repeated by keeping the semiconductor slurry in the light path and from the difference in intensities, the light intensity absorbed by the semiconductor particles was calculated. The quantum yield (Φ) for the PMS decomposition reaction was determined from the relation,

$$\Phi = \frac{\text{Number of moles of PMS decomposed per second}}{\text{Number of Einsteins absorbed per second}} \quad (1)$$

Results and Discussion

Characterization of the Catalysts. In order to get an idea about the extent of absorption of the undoped and doped semiconductors in the visible region and to know the effect of Cu(II)-dopant on the crystallinity of the semiconductors, the catalysts were characterized by diffuse absorption spectra and X-ray diffraction methods. Figure 1 shows representatively, the absorption spectra of Bi_2O_3 and Cu(II)/Bi_2O_3 catalysts. Bi_2O_3 has 55% absorption upto 410 nm, 40—20% upto 500 nm and about 15% in the remaining part of the spectrum. But when it is doped with Cu(II), the absorption ranges are increased considerably. Similar is the case with WO_3. But with Fe_2O_3, since it is of dark brown color, both Fe_2O_3 and Cu(II)/Fe_2O_3 have relatively more absorp-

tion than the other two semiconductors in the entire visible region. Thus in all these semiconductors, doping of Cu(II) increases the absorption in the visible region and this has been already explained[11] as due to the introduction of 'isolated energy levels' by the dopant in the band gap of the semiconductors.

X-Ray diffraction spectra of all undoped and Cu(II)-doped semiconductors, for example, the XRD spectra of Bi_2O_3 and Cu(II)/Bi_2O_3 shown in Fig. 2 with the corresponding 'd' spacings and intensity values given in Table 1, indicate that there is no appearance of any new peaks due to Cu(II)-doping but that the intensities of the peaks are increased, even though both the doped and undoped samples were processed at the same temperature. This observation demonstrates that Cu(II)-doping increases the crystallinity of the semiconductors without affecting the original crystal structure. Thus doping with Cu(II) produces a favorable change in the catalysts by increasing the absorption as well as the crystallinity of the semiconductors.

Decomposition of PMS with Bi_2O_3. In the photocatalytic decomposition of PMS, both Bi_2O_3 and Cu(II)/Bi_2O_3 were used as the catalysts. The rate of decomposition of PMS was studied by varying (i) the [dopant], (ii) the catalyst amount, and (iii) the initial [PMS].

Effect of Variation of [dopant]. In our previous study with WO_3,[4] it was established that Cu(II) is an efficient dopant because of its ability to scavenge e^-_{CB} and hence to prevent e^-–h^+ recombination; therefore Cu(II)/WO_3 was found to have higher efficiency than the undoped one. In order to investigate whether the increase in [dopant] continuously enhances the photocatalytic efficiency of Bi_2O_3 or not, experiments were performed with different [dopant]. Figure 3 displays the effect of variation of [dopant] on the rate of PMS decomposition. The rate is increased with increase in [dopant] upto 4 atomic % but gets decreased beyond this limit. Therefore the optimum [dopant] at which Bi_2O_3 acquires maximum photocatalytic efficiency is 4 atomic %. This observation is explicable by the fact that Cu(II) acts as e^-_{CB} scavenger at lower [dopant] but becomes e^-–h^+ recombination centers at higher [dopant], since the distance between two Cu(II) ions becomes shorter than the distance at which the image force to both e^-_{CB} and h^+_{VB} is effective.[12] This type of observation has already been made in our earlier study.[3]

Since 4 atomic % Cu(II)-doped Bi_2O_3 is found to be the most efficient catalyst, this was chosen as the representative one for further experiments to study the effect of other factors on PMS decomposition rates.

Effect of Variation of Catalyst Amount. Table 2 shows the rates observed with different amounts of the catalyst, Cu(II)/Bi_2O_3. There is a small but linear

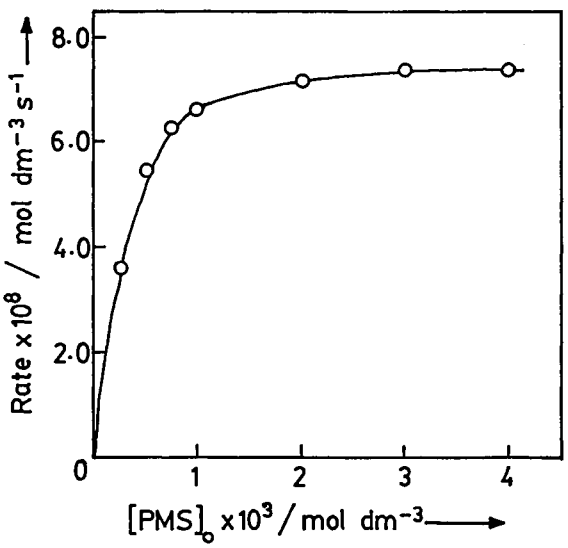

Fig. 4. Plot of rate vs. $[PMS]_0$.
Catalyst=Cu(II)/Bi_2O_3, T=298 K.

increase in the rate with increase in catalyst amount (10—40 mg) which is quite natural since with increase in catalyst amount, the number of catalyst particles coming under the irradiation region increases; in other words the effective surface area of the catalyst responsible for photocatalysis increases leading to the decomposition of more number of PMS molecules and hence the rate is increased. However, further increase of the catalyst amount only results in the saturation limit of the rates.

Effect of Initial [PMS]. The rate of decomposition of PMS was found to be affected by the initial PMS concentrations ($[PMS]_0$) employed in the experiment. From the plot of the rate vs. $[PMS]_0$ (Fig. 4), it is obvious that the rate is increased with increase in $[PMS]_0$ upto a certain range and above that it gets leveled off. This is a typical Langmuirian behavior and hence the effect of $[PMS]_0$ on rate could be described by the following relation,

$$\text{rate} = \frac{kK[PMS]_0}{1+K[PMS]_0} \quad (2)$$

Where k and K are the proportionality and equilibrium constants respectively. The reciprocal of Eq. 2 gives,

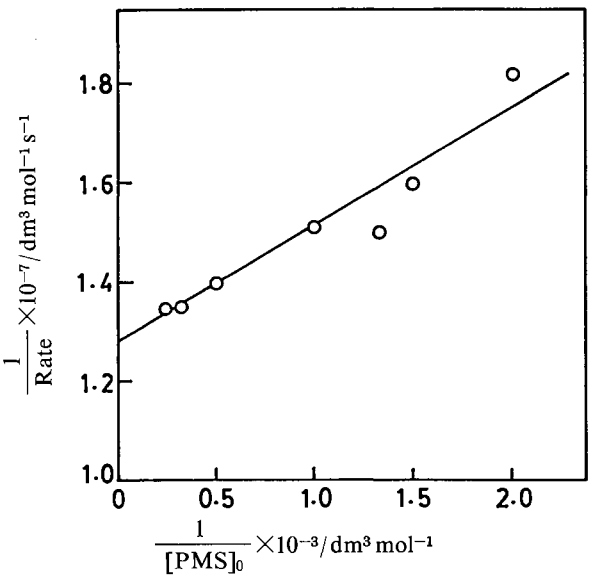

Fig. 5. Plot of $\frac{1}{\text{rate}}$ vs. $\frac{1}{[PMS]_0}$.
Catalyst=Cu(II)/Bi_2O_3, T=298 K.

$$\frac{1}{\text{rate}} = \frac{1}{kK[PMS]_0} + \frac{1}{k} \quad (3)$$

The plot of 1/rate vs. $1/[PMS]_0$ (Fig. 5) yields a straight line confirming the Eq. 3 and hence it is inferred that the reaction system under investigation obeys a Langmuir kinetics. From the intercept and slope of the plot, in Fig. 5, k and K were calculated and their values are 7.8×10^{-6} mol dm^{-3} s^{-1} and 53.4 dm^3 mol^{-1}, respectively. At lower $[PMS]_0$, since $K[PMS]_0 \ll 1$, Eq. 2 reduces to,

$$\text{rate} = kK[PMS]_0 \quad (4)$$

This is a first order equation with respect to $[PMS]_0$ and hence it explains the dependence of the rates on $[PMS]_0$ in the initial stages which is evident in Fig. 4. A similar observation on PMS decomposition has been reported.[3]

Reaction Mechanism for PMS Decomposition. PMS is a powerful oxidizing agent (E°=1.82 V). Nevertheless, it acts both as an electron acceptor and hydrogen atom donor which was confirmed by our previous study[13] on the visible-light induced decomposition of PMS with excited state $[Ru(bpy)_3]^{2+}$. Hence there is a possibility that PMS is attacked by both h^+_{VB} and e^-_{CB}. Furthermore it has been established that the hydrated electron (e^-_{aq}) reacts with PMS almost at a diffusion controlled rate.[14] Considering all the above facts, the following mechanism may be proposed for the photocatalytic decomposition of PMS in the presence of a semiconductor catalyst.

$$\text{Semiconductor} \xrightarrow[\lambda>400\text{ nm}]{h\nu} h^+_{VB} + e^-_{CB} \quad (5)$$

$$HSO_5^- \xrightarrow{\text{Catalyst}} [HSO_5^-]_{ad} \quad (6)$$

$$[HSO_5^-]_{ad} + e^-_{CB} \longrightarrow SO_4^{\cdot-} + OH^- \quad (7a)$$

$$[HSO_5^-]_{ad} + e^-_{CB} \longrightarrow SO_4^{2-} + \dot{O}H \quad (7b)$$

$$2\dot{O}H \longrightarrow 1/2\ O_2 + H_2O \quad (8)$$

$$HSO_5^- + SO_4^{\cdot-} \longrightarrow SO_5^{\cdot-} + HSO_4^- \quad (9)$$

$$HSO_5^- + \dot{O}H \longrightarrow SO_5^{\cdot-} + H_2O \quad (10)$$

$$[HSO_5^-]_{ad} + h^+_{VB} \longrightarrow SO_5^{\cdot-} + H^+ \quad (11)$$

$$2SO_5^{\cdot-} \xrightarrow{H_2O} 2HSO_4^- + 3/2\ O_2 \quad (12)$$

In these equations, $[HSO_5^-]_{ad}$ denotes the PMS molecule adsorbed onto the surface of the catalyst. The formation of $SO_5^{\cdot-}$, $SO_4^{\cdot-}$, and $\dot{O}H$ as the radical products from PMS has been identified by optical pulse radiolysis.[14] Evolution of O_2 during PMS was confirmed by oxygen sensitive electrode and this also serves

Table 3. Rates and Quantum Yields for the Decomposition of PMS with Different Catalysts.
Catalyst Amount=40 mg; [dopant]=4 Atomic % Cu(II); $[PMS]_0=1\times10^{-3}$ mol dm^{-3}

Semiconductor	Undoped Rate$\times10^8$ / mol dm^{-3} s^{-1}	Doped with Cu(II) Rate$\times10^8$ / mol dm^{-3} s^{-1}	Rate (doped) / Rate (undoped)	Φ (undoped)	Φ (doped)	Φ (doped) / Φ (undoped)
Bi_2O_3	2.3	6.6	2.86	0.9	1.7	1.8
WO_3	2.6	6.6	2.54	1.0	1.3	1.3
Fe_2O_3	3.8	8.7	2.28	0.3	0.8	2.6

as an additional proof for the above mechanism. The overall reaction could be written as:

$$HSO_5^- \xrightarrow[\lambda>400\text{ nm}]{\text{catalyst, } h\nu} 1/2\,O_2 + SO_4^{2-} + H^+ \qquad (13)$$

Efficiency Comparison with Other Catalysts: Experiments were also performed to determine the rates of decomposition of PMS with undoped and Cu(II)-doped WO_3 and Fe_2O_3. For this study, the concentration of PMS used was 1.0×10^{-3} mol dm^{-3} in all cases. Here also the Cu(II)-doped samples exhibit higher activities when compared to the undoped ones. To assign the absolute photoactivity of a particular photocatalyst, the quantum yield is a better candidate than other parameters like rate constants etc. This is because it is an activity parameter which indicates how efficiently a photocatalyst utilizes the absorbed photons for effective photochemical reaction irrespective of the light absorbing capacity of photocatalyst.

Table 3 presents the values of rates and quantum yields for the decomposition of PMS for the doped and undoped samples in the wavelength region 400—500 nm, where all the catalysts have almost equal (about 60%) absorption. By comparing the rates, we have the trend, $Bi_2O_3 \approx WO_3 < Fe_2O_3$ for both doped and undoped samples. But on comparing the quantum yields, the trend becomes, $Bi_2O_3 \approx WO_3 > Fe_2O_3$ for undoped and $Bi_2O_3 > WO_3 > Fe_2O_3$ for doped samples. On comparing the rates and quantum yields of doped and undoped samples, it is clear that both rates and quantum yields have been increased considerably by doping with Cu(II). Even though the rate is higher for Fe_2O_3 when compared with the other samples, the quantum yield seems to be lower due to the fact that the number of photons absorbed by Fe_2O_3 is greater than that absorbed by the other samples. Thus, in spite of having greater light absorbing power, Fe_2O_3 has lower quantum yield value. This is due to the fact that not all the absorbed photons are effectively utilized for PMS decomposition. But with Bi_2O_3 and WO_3, as evident from Table 3, it is the former which gets a maximum increment in activity due to Cu(II)-doping.

Since h^+_{VB} and e^-_{CB} react with PMS, the expected quantum yield for the decomposition of PMS is 2. But in all cases (Table 3) the value is less than 2, even though doping with Cu(II) considerably enhances the quantum yields of the semiconductors. The reasons may be: (i) all the photons entering into the reaction vessel are not absorbed by the catalyst and this may be due to the physical phenomena like reflection, scattering etc., (ii) recombination of a part of the e^-–h^+ pairs formed during irradiation, and (iii) the reversible formation of HSO_5^- from the $SO_4^{\cdot-}$ and $\dot{O}H$ radicals. In spite of being less than 2, the quantum yields are comparable and retain their identity.

The distinct behavior of Cu(II) with Bi_2O_3 compared to other semiconductors is interpreted as follows. The ionic radius of Cu^{2+} is closer to that of Bi^{3+} in Bi_2O_3 (ca. 0.9 Å) when compare to that of W^{6+} in WO_3 (ca. 0.6 Å). This close similarity in ionic radii of Cu^{2+} and Bi^{3+} is one more advantage which strengthens the inherent nature, i.e. the e^-_{CB} scavenging action of Cu(II). Hence the activity of Bi_2O_3 is enhanced to a greater extent by Cu(II)-doping.

The present study unequivocally reveals that although the undoped Bi_2O_3 is less efficient for photocatalysis, its activity could be improved by Cu(II)-doping to such an extent that Cu(II)/Bi_2O_3 has almost an equal activity to that of Cu(II)/WO_3 which has already found place in photocatalysis.

The authors thank the authorities of CECRI, Karaikudi and IIT. Madras for permitting to avail of the instrumental facilities. They also acknowledge the financial support from the Department of Non-conventional Energy Sources, New Delhi for this research.

Some Physico-Chemical Studies on Molecular Semiconductors Based on Charge Transfer Complexes of Substituted Phenothiazines with Iodine

Ram Adhar SINGH,* Ranjana SINGH, and Shiva Mohan VERMA*
Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi 221005, India
(Received August 27, 1990)

The synthesis, chemical and structural characterizations, and thermal, spectral, electrical, and magnetic properties of six molecular semiconductors based on the charge transfer complexes of substituted phenothiazines namely; phenothiazine, 2-chlorophenothiazine, 2-(trifluoromethyl)phenothiazine, 2-acetylphenothiazine, *N*-acetylphenothiazine, and *N*-benzoylphenothiazine with molecular iodine have been reported in this paper. These complexes have been found to have 2:3 stoichiometries. X-Ray diffraction data show that first three complexes have orthorhombic structure whereas the other three are amorphous. Thermal analysis shows that the complexes are thermally stable upto 120 °C. The existence of monomeric and dimeric cationic species of phenothiazines has been proposed on the basis of spectral data. These complexes have been found to be molecular semiconductors having moderately high electrical conductivities and activation energies. The segregated stacking of phenothiazine and iodine moieties has been proposed to be responsible for high conductivity values and a mixed conductivity mechanism accounts for temperature dependence of electrical conductivities of these complexes.

Molecular materials with remarkable physical properties have been extensively studied in the past two decades.[1-3] Potentialities offered by these materials have been tremendous in the development of molecular level electronic devices as is evident from the number of patented compounds based on organic charge transfer solids. The observation of semiconductivity in this class of materials has opened an era of developing and testing these materials for a number of technological applications. The discoveries of organic metals and organic superconductors have resulted in an interdisciplinary approach involving synthetic and physical chemists, solid state physicists, and material scientists. This upsurge of activity has its genesis in the discovery of high electrical conductivities of bromine complex of perylenes by H. Akamatu et al.[4] However, the iodine complexes with various types of electron donors have played the key role in the development of organic electronic materials, mainly because iodine is such an acceptor, which forms charge-transfer complexes from the weakest to the strongest with various electron donors.[5] The charge-transfer complexes of iodine with phenothiazines which are fairly strong donors, were reported first by Y. Matsunaga.[6,7] This complex was found to be an organic semiconductor. The ratio of donor to the acceptor was found to be 2:3 and it had a fairly high electrical conductivity. The electrical resistivity of the complex was dependent on its composition, 2:3 being the minimum resistivity composition. Similar compositional dependence of electrical and magnetic properties of some related phenothiazine–iodine complexes were reported by Matsunaga and other workers.[8-11] A complex cation radical of phenothiazine was proposed to be responsible for high conductivity of this class of compounds in which electronic conduction takes place between phenothiazines in different oxidation states. Iida[12] proposed that the X-ray diffraction studies on phenothiazine cation radical salts will help us in determining their structure and arrangement of stacking in solid state. In a study of thermoelectric power of iodine complexes of aromatic diamines and thiazines, Akamatu et al.[13,14] reported the hole conduction for phenothiazine–iodine complexes whereas *N*-methylphenothiazine–iodine complex had temperature dependent mixed conductivity mechanism, hole conduction in higher temperature region and electron conduction in the lower temperature region. The interest in the phenothiazine–iodine complexes continued and Resonance Raman and ^{129}I Mössbauer spectroscopic study of this complex was reported very recently by Sakai et al.[15] It was shown that two iodine species in this complex were present consisting of a distorted I_3^- unit and I_2 unit strongly coordinated with this I_3^- unit in which about three electrons for five phenothiazine molecules are transferred to the iodine which are delocalized on the thirteen iodine atoms. Though the single crystal of this compound has not yet been grown, the powder X-ray diffraction may yield some information about the crystal structure of this or related complexes. Electrochemical oxidation of phenothiazine in presence of different inorganic ions yielded stoichiometric complex salts of phenothiazines having 1:1, 3:2, and 2:1 compositions.[16]

The literature survey reveals that the interest in phenothiazine–iodine complexes had mainly focussed around the parent compound and some of structurally related analogues. A few complexes of ring substituted and N-substituted phenothiazines with iodine have been reported.[8,10] However, still a large number of complexes of substituted phenothiazines with iodine have not been synthesized and studied. It is, therefore, pertinent to study the role of electronic and structural modifications on the solid state properties of these complexes. We report herein six new complexes of substituted phenothiazines with iodine on which detailed X-ray diffraction, photoacoustic, electronic, and reflec-

tance, infrared and nuclear magnetic resonance spectral studies have been performed. Electrical, magnetic, and thermal studies have also been undertaken.

Experimental

Materials and Methods. Phenothiazine (PTZ), 2-chlorophenothiazine (CPZ), 2-(trifluoromethyl)phenothiazine (TPZ), and 2-acetylphenothiazine (APZ) were commercially obtained from Aldrich Chemie (F.R.G.). Further purifications were done by vacuum sublimation and fractional crystallization using cyclohexane–chloroform–ethanol mixture. Iodine obtained from E. Merck was further purified by vacuum sublimation. *N*-Acetylphenothiazine (NAPZ) was prepared by acetylation of phenothiazine with acetic anhydride according to the literature procedure.[17] The product obtained was recrystallized from ethanol. *N*-benzoylphenothiazine (NBPZ) was prepared by the reaction of phenothiazine with benzoyl chloride in a sealed tube at 100—110 °C as reported in the literature[17] and purified by recrystallization in ethanol. The purities of the compounds were checked from their melting points, elemental analyses, electronic, infrared, and NMR spectral data which were found to agree well with the literature values.

In general, the charge-transfer complexes of these phenothiazines with iodine were prepared by taking appropriate amounts of the components for 2:3 stoichiometry in suitable solvents and by mixing their dilute solutions. The dark brown colored crystalline complexes separated out when these solutions were kept for about two weeks. The resulting precipitates were collected by filtration washed three times with solvents and dried over anhydrous calcium chloride. The detailed procedures, yields, melting points, and elemental analyses for different complexes are given below:

$(PTZ)_2$-$(I_2)_3$: A dilute solution of PTZ (0.800 g, 40 mmol) in ether (50 mL) was slowly added to the dilute solution of I_2 (1.550 g, 60 mmol) in ether (50 mL). Yield: 90%, mp 175—178 °C. Elemental analysis; Found: C, 24.60; H, 1.98; N, 2.38; S, 5.34%. Calcd for $C_{24}H_{18}I_6N_2S_2$: C, 24.83; H, 1.55; N, 2.41; S, 5.52%.

$(CPZ)_2$-$(I_2)_3$: A dilute solution of CPZ (0.940 g, 40 mmol) in ether (50 mL) was slowly added to the dilute solution of I_2 (1.550 g, 60 mmol) in ether (50 mL). Yield: 91%, mp 125—128 °C. Elemental analysis; Found: C, 23.18; H, 1.77; Cl, 5.47; N, 2.12; S, 5.01%. Calcd for $C_{24}H_{16}Cl_2I_6N_2S_2$: C, 23.44; H, 1.30; Cl, 5.78; N, 2.28; S, 5.21%.

$(APZ)_2$-$(I_2)_3$: A dilute solution of APZ (0.970 g, 40 mmol) in ether (50 mL) was slowly added to the dilute solution of I_2 (1.550 g, 60 mmol) in ether (50 mL). Yield: 92%, mp 155—158 °C. Elemental analysis; Found: C, 26.79; H, 1.92; N, 2.69; S, 5.01%. Calcd for $C_{28}H_{22}I_6N_2O_2S_2$: C, 27.02; H, 1.77; N, 2.25; S, 5.15%.

$(TPZ)_2$-$(I_2)_3$: A dilute solution of TPZ (1.100 g, 40 mmol) in ether (50 mL) was slowly added to the dilute solution of I_2 (1.550 g, 60 mmol) in ether (50 mL). Yield: 90%, mp 115—118 °C. Elemental analysis; Found: C, 23.93; H, 1.29; N, 2.66; S, 4.69%. Calcd for $C_{26}H_{16}F_6I_6N_2S_2$: C, 24.08; H, 1.23; N, 2.16; S, 4.94%.

$(NAPZ)_2$-$(I_2)_3$: A dilute solution of NAPZ (0.970 g, 40 mmol) in ether (50 mL) was slowly added to the dilute solution of I_2 (1.550 g, 60 mmol) in ether (50 mL). Yield: 92%, mp more than 320 °C. Elemental analysis; Found: C, 27.31; H, 1.68; N, 2.34; S, 4.95%. Calcd for $C_{28}H_{22}I_6N_2O_2S_2$: C, 27.02; H, 1.77; N, 2.25; S, 5.15%.

$(NBPZ)_2$-$(I_2)_3$: A dilute solution of NBPZ (1.350 g, 40 mmol) in ether (50 mL) was slowly added to the dilute solution of I_2 (1.550 g, 60 mmol) in ether (50 mL). Yield: 89%, mp 190—193 °C. Elemental analysis; Found: C, 33.60; H, 1.92; N, 2.80; S, 4.38%. Calcd for $C_{38}H_{26}I_6N_2O_2S_2$: C, 33.35; H, 1.90; N, 2.05; S, 4.68%.

Measurements. All the complexes have been obtained as powdered or polycrystalline solids and attempts to grow single crystals failed. Therefore, only powder X-ray diffraction data could be obtained. The X-ray diffraction patterns were recorded on Philips X-ray diffractometer PW 1710 using Cu $K\alpha$ radiation. The electronic absorption spectra were recorded on Cary 2390 and Shimadzu UV-160A spectrophotometers. Reflectance spectra were recorded on Cary 2390 spectrophotometer. Infrared absorption spectra were recorded on Perkin–Elmer 783 spectrophotometer. ^1H NMR spectra were recorded on a JEOL FX-90 Q FT-NMR spectrometer. Electrical measurements were made on Wayne Kerr Automatic Precision Bridge B905. For electrical measurements, the pellets were prepared at a pressure ca. 15 kbar and measurements were repeated at least twice to get reproducible values of various physical properties. AC conductivities of the samples were measured at two different frequencies 1 kHz and 10 kHz at different temperatures in the range (293—403 K). The magnetic measurements were made on a Cahn–Faraday balance at 10 K gauss magnetic field. Photoacoustic spectral measurements were made on a single beam photoacoustic spectrometer designed and fabricated in the spectroscopy section, Department of Physics, B.H.U., Varanasi. Thermogravimetric analyses were done on Stanton Red Croft STA-780 series Unit. The analytical constants were: heating rate: 5 to 10 °C min^{-1}; chart speed: 1000 mm h^{-1}; reference: Al_2O_3; thermocouple: Platinum–Rhodium. The analysis was made in the atmosphere of air between room temperature and 700 °C.

Results and Discussion

Stoichiometries of the Complexes: A Thermogravimetric Analysis. All of the phenothiazine–iodine complexes reported in this paper have been obtained as dark colored solids. When these complexes are heated on a spatula over hot plate, vigorous liberation of iodine results. Thermogravimetric analyses of these complexes show two stage decompositions. A representative thermogravimetric and differential thermogravimetric curve for phenothiazine–iodine complex has been shown in Fig. 1. The phenothiazine–iodine complex shows no weight loss upto 100 °C indicating that the air-dry compound contained no residual humidity. Between 145—290 °C, the labile molecular iodine is lost, the rate of decomposition being maximum at 170 °C as indicated by its DTG curve. DTA curve indicates an exothermic peak at 170 °C. Later, all the residual material is lost between 290—700 °C. Similar curves were obtained for other complexes as well. This data led us to calculate the stoichiometry of the complexes and their decomposition characteristics. Since elemental analyses show 2:3 stoichiometries of the complexes, the relative molecular mass of the complex was calcu-

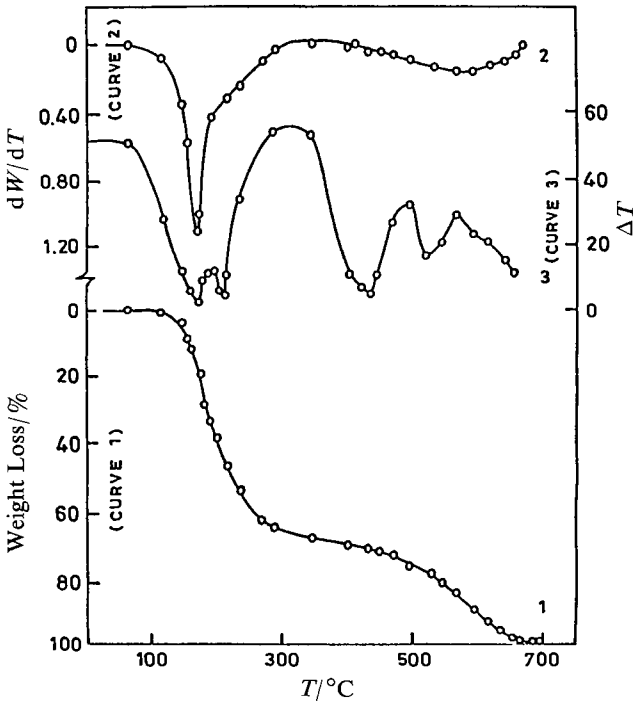

Fig. 1. Thermogravimetric (1), differential thermogravimetric (2), and differential thermal analysis (3) curves for phenothiazine–iodine complex.

lated on this basis. The decomposition steps are as follows:

$$(PTZ)_2(I_2)_3 \longrightarrow 2PTZ + 3I_2 \uparrow \quad \text{(I)}$$

$$2PTZ \longrightarrow 2(PTZ) \uparrow \quad \text{(II)}$$

Though 2:3 stoichiometries of the phenothiazine–iodine complexes have been shown to be most stable and having highest electrical conductivities, there has been a lot of controversy about the stoichiometries of this class of molecular semiconductors. Matsunaga et al.[18] proposed the structure of the complex as $(PTZ)_2^+I_5^- \cdot 1/2I_2$ in which $1/2$ I_2 is expected to be more loosely bound than those in pentaiodide. If this is so, it should result in about 10.94% loss of molecular iodine in the first stage of thermal decomposition. However, we do not observe any decomposition step corresponding to this weight loss. Similarly 2:5.2 composition proposed on the basis of Resonance Raman and Mössbauer studies can also be ruled out on the basis of thermogravimetric analysis. Thus, the phenothiazine–iodine complexes have 2:3 stoichiometries and are thermally stable upto 120 °C.

The dissociation of phenothiazine–iodine complexes in organic solvents further supports above observations. In carbon tetrachloride these complexes show intense violet color indicating the presence of molecular iodine, similar to the tetramethylammonium pentaiodides.[19] In relatively polar solvents like acetonitrile, solubility of the complexes increases indicating dative nature of these complexes. These species have been identified on the basis of their spectral data.

Spectral Data. The electronic absorption spectra of the complexes dispersed in Nujol have bands at 14.5, 20.0, 21.1, 26.7, and 30.8×10^3 cm^{-1}. The diffuse reflectance spectra showed bands at 15.1, 15.6, and 20.5×10^3 cm^{-1}. The photoacoustic spectra of solid complexes indicated bands at 12.8, 14.7, 15.6, and 18.9×10^3 cm^{-1}. The solution spectra in carbon tetrachloride and chloroform showed bands at 12.6, 19.4, 28.2, and 32.3×10^3 cm^{-1} and 11.9, 15.8, 19.7, and 33.5×10^3 cm^{-1}, respectively. Whereas in polar solvents like acetonitrile and methanol, bands at 15.5, 20.0, 21.6, 24.0, and 28.2 (sh)$\times10^3$ cm^{-1} were found. Aged solutions of the complexes in acetonitrile having lush green colors were found to have bands at 11.4, 15.2, 19.3, 24.0, and 34.5×10^3 cm^{-1}. The 11.4×10^3 cm^{-1} band on dilution by solvent, shifted to 11.9×10^3 cm^{-1}. These spectral data indicate that the phenothiazine–iodine complexes have a number of molecular species of phenothiazines in solution, which may possibly be present in solid state as well on the basis of their electronic spectra. The intense violet color of the complexes kept in nonpolar solvents having bands at 19.4×10^3 cm^{-1} indicates the presence of molecular iodine, which in polar solvents gets complexed and thus blue shifted to 21.6 and 24.0×10^3 cm^{-1}. The solvent assisted dimerization of phenothiazine cation radicals, as proposed by Foster et al.,[20] may possibly be true nature of molecular species present in polar solvents. Similar results have been obtained for DDQ complexes.[21]

The above observations are further supported from the vibrational spectra of the complexes which are identical with those reported by Matsunaga et al.[18] The sharp N–H peaks of phenothiazines between 3320—3380 cm^{-1} are replaced by broad bands in this region in the complex indicating the existence of weakly acidic N–H in the cation radical of phenothiazine, but the bands at 1560, 1590, 1050, 930, 890, and 780 cm^{-1} indicate the existence of some neutral phenothiazines in solid state. Thus, these complexes are expected to have mixed valence structures, which help in electronic conduction.

The ^1H NMR spectra of phenothiazines in $CDCl_3$ at room temperature shows two peaks at δ=1.55 and 5.84 ppm vs. TMS exchangeable with D_2O. These peaks have been attributed to two conformations of N–H protons; 'H-intra' (75%) δ=5.84, 'H-extra' (25%) δ=1.55 as reported.[22] The ^1H NMR spectra of complexes in $CDCl_3$ give exchangeable protons at δ=1.57 and 10.20. The former confirms the existence of 'H-extra' conformation as such in zero oxidation state while the later confirms the existence of acidic N–H protons. Therefore, the NMR spectra of the complexes in solution indicate the existence of mixed valence structures possibly present in solid state. The X-ray diffraction data for these complexes have been given below:

X-Ray Diffraction Data. The powder X-ray diffraction data of three complexes were indexed by Ito's method.[23] The observation of diffraction patterns in

the present set of complexes rules out the possibility of any interference by heavy halogen contents in the complexes. The lattice constants of the complexes are as follows:

(i) $(PTZ)_2$–$(I_2)_3$: *a* 4.87 Å, *b* 9.18 Å, *c* 18.51 Å.
(ii) $(CPZ)_2$–$(I_2)_3$: *a* 6.90 Å, *b* 9.07 Å, *c* 19.56 Å.
(iii) $(TPZ)_2$–$(I_2)_3$: *a* 6.93 Å, *b* 9.52 Å, *c* 24.64 Å.

The indexing of the data showed that all the phenothiazine–iodine complexes have orthorhombic crystal structures as for the parent compounds with almost similar lattice parameters.[24] Similar results have been obtained for PTZ–DDQ complexes.[25] *N*-Methylphenothiazine–iodine complex has been reported to have the orthorhombic crystal structures with lattice constants as *a* 11.4 Å, *b* 21.4 Å, *c* 21.1 Å.[11] Our values of *a*, *b*, and *c* are quite different from the above but they all have the same crystal structure. No data on crystal structure of any other complex of iodine with phenothiazines is available for comparison. The lattice constants of the parent compounds and the iodine complexes being comparable indicate that the unit cells of the complexes contain arrays of phenothiazine species in which pentaiodides occupy vacant lattice sites as speculated by Sakai et al.[15] Face to face stacking of folded phenothiazine cation radicals resulting in linear extended chain as proposed by Iida[12] may possibly be structure of high conductivity complexes.

Electrical and Magnetic Data: The electrical properties of iodine complexes of phenothiazines have been extensively studied.[26] However, the electrical conductivities of the iodine complexes of present set of substituted phenothiazines have not yet been reported. Both N-substitution and ring substitution with both electron withdrawing and electron donating group has been studied to learn about the electronic, structural, and conformational aspects of these complexes.

The logarithms of the conductivities of the complexes, plotted against the reciprocal temperatures have been shown in Figs. 2—4. The plots were nonlinear showing marked decrease at higher temperatures than at lower temperatures. Bandrauk et al.[26] proposed that the deviation from linearity was indicative of changes in conductivity mechanisms. The electrical and magnetic data of the complexes have been presented in Table 1.

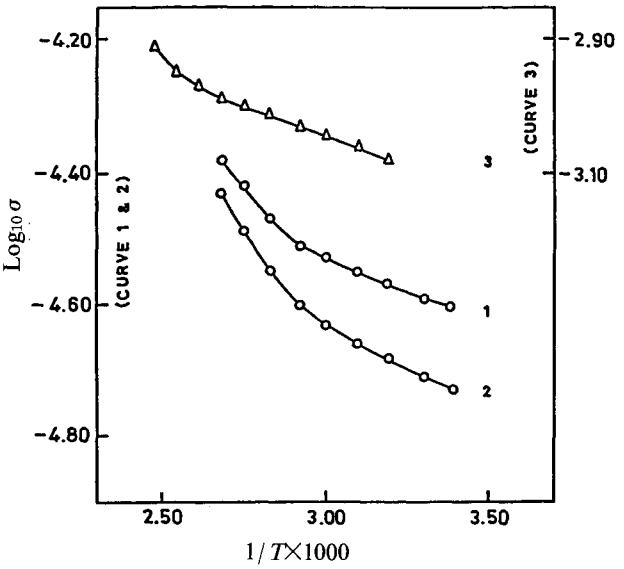

Fig. 3. The plot of logarithm of conductivities vs. T^{-1} for complexes of (1) 2-chlorophenothiazine–iodine at 10 kHz, (2) 2-chlorophenothiazine–iodine at 1 kHz, and (3) 2-acetylphenothiazine–iodine at 10 kHz.

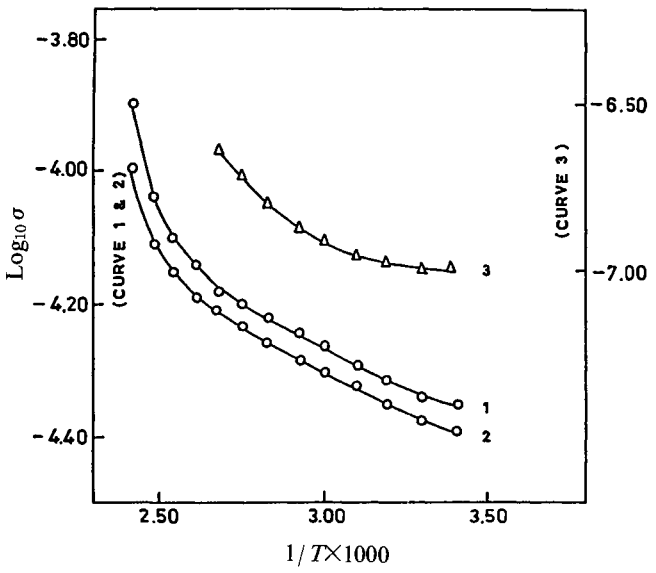

Fig. 2. The plot of logarithm of conductivities vs. T^{-1} for complexes of (1) phenothiazine–iodine at 10 kHz, (2) phenothiazine–iodine at 1 kHz, and (3) 2-(trifluoromethyl)phenothiazine–iodine at 10 kHz.

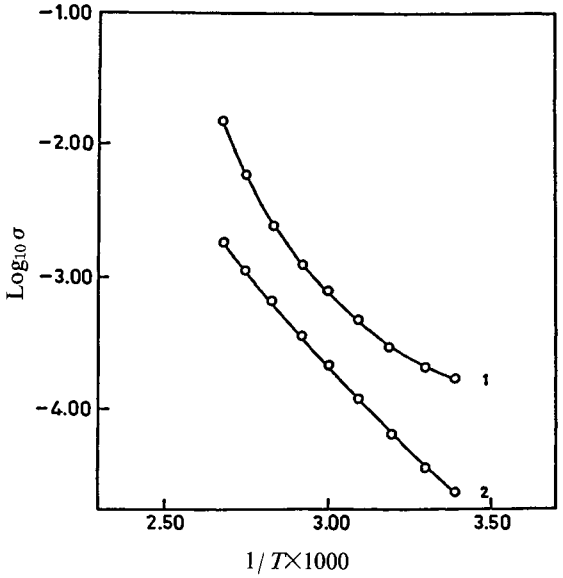

Fig. 4. The plot of logarithm of conductivities vs. T^{-1} for complexes of (1) *N*-acetylphenothiazine–iodine at 10 kHz and (2) *N*-benzoylphenothiazine–iodine at 10 kHz.

Table 1. Electrical and Magnetic Properties of Charge-Transfer Complexes of Iodine with Some Substituted Phenothiazines

Compounds	Electrical conductivity at r.t./μS cm^{-1}			Energy of activation for electrical conductivity (eV) at frequency 10 kHz		Corrected magnetic susceptibility	Magnetic moment
	10 kHz	1 kHz	100 Hz	E_{a_1}	E_{a_2}	(ml mol^{-1})$\times 10^{-6}$	BM
$(PTZ)_2$–$(I_2)_3$	44.67	40.74	—	0.15	0.04	3626.16	2.93
$(CPZ)_2$–$(I_2)_3$	24.98	18.71	15.92	0.12	0.04	3394.83	2.83
$(APZ)_2$–$(I_2)_3$	336.00	—	—	0.06	0.07	1338.73	1.78
$(TPZ)_2$–$(I_2)_3$	0.10	0.03	—	0.20	0.06	3422.41	2.84
$(NAPZ)_2$–$(I_2)_3$	174.98	144.37	127.40	0.99	0.20	—	Diamagnetic
$(NBPZ)_2$–$(I_2)_3$	24.25	19.88	17.55	0.44	—	—	Diamagnetic

Room temperate electrical conductivities of the complexes vary in the order;

$$(APZ)_2\text{–}(I_2)_3 > (NAPZ)_2\text{–}(I_2)_3 > (PTZ)_2\text{–}(I_2)_3 > (CPZ)_2\text{–}(I_2)_3 \approx (NBPZ)_2\text{–}(I_2)_3 > (TPZ)_2\text{–}(I_2)_3.$$

These values are much lower than reported for other phenothiazine–iodine complexes. This may be due to different structural factors, such as the size of crystallites, amorphous nature of some of them, and the changes due to different functional groups. The energy of activation determined from the slopes of two linear portions have also been presented in Table 1, they have been labelled as E_{a_1} and E_{a_2}. E_{a_1} has been found to be higher than E_{a_2} but both the values are characteristic of organic semiconductors. These values have been found to vary in order;

$$(NAPZ)_2\text{–}(I_2)_3 > (NBPZ)_2\text{–}(I_2)_3 > (TPZ)_2\text{–}(I_2)_3 > (PTZ)_2\text{–}(I_2)_3 > (CPZ)_2\text{–}(I_2)_3 > (APZ)_2\text{–}(I_2)_3.$$

It has been well established that the charge-transfer interaction between the ion radicals leads to a marked decrease paramagnetic susceptibilities of ion radical salts.[12] Magnetic susceptibilities and magnetic moments of the charge-transfer salts of iodine with substituted phenothiazines at room temperatures have been determined and given in Table 1. The small rise in weight of the samples of $(PTZ)_2$–$(I_2)_3$, $(CPZ)_2$–$(I_2)_3$, $(APZ)_2$–$(I_2)_3$, $(TPZ)_2$–$(I_2)_3$ on application of magnetic field of strength 10 K gauss shows that these compounds are weakly paramagnetic. The corrected molar magnetic susceptibilities yield magnetic moments of the order of about 1.78, 2.83, and 2.93 BM respectively, indicating the presence of some unpaired spins in the complexes, either on molecular or impurity sites of these partially ionized solids. $(NAPZ)_2$–$(I_2)_3$ and $(NBPZ)_2$–$(I_2)_3$ show no change in weight on application of magnetic field, therefore these compounds are diamagnetic possibly due to strong antiferromagnetic interactions.

Summary

The phenothiazine–iodine complexes reported in this paper have been found as molecular semiconductors having quite different physical properties. This highlights the importance of both electronic and structural factors on which physical properties of this class of complexes depend. Segregated stacking and mixed conductivity mechanisms have been proposed to account for electrical properties of these complexes.

We are thankful to CSIR for sanctioning a research scheme on this topic. We are grateful to Professor Suresh Chandra and Dr. S. A. Hashmi of Physics Department, B.H.U. for helping us with electrical measurements and Professor O. N. Srivastava of the same department for X-ray diffraction data. We also thank Mr. J. P. Pandey of Chemical Engineering, I.T., B.H.U. for his help in TGA measurements. We thank the referee for his fruitful comments.

Study of the Vibrational Spectra and Determination of Thermodynamic Functions of 2-Pyridone and 2-Pyridone-*N*-*d*

Kanak Chandra MEDHI
Department of Physics, Gauhati University, Guwahati 781014, India
(Received November 8, 1990)

The infrared spectra in the polycrystalline state (4000—50 cm^{-1}), in melt and in solution and the Raman spectra in the solid state and in melt of the substances have been studied for 2-pyridone and 2-pyridone-*N*-*d*. A vibrational assignment of the observed frequencies is given. Ideal gas state thermodynamic functions of the two isotopic molecules based on the observed fundamental frequencies have been determined in the temperature range 200—1500 K.

Continuing the earlier investigations on the vibrational spectra of substituted pyridines[1-4] the infrared and Raman spectra of 2-pyridone and 2-pyridone-*N*-*d* have been reported. The infrared spectrum of 2-pyridone in the solid state or in solution was measured by Gibson et al.,[5] Mason,[6] Katritzky and Jones,[7] and Albert and Spinner[8] in a limited range, and only a few bands were assigned. The incomplete simple Raman spectrum of 2-pyridone in aqueous solution was reported by Albert and Spinner.[8] No polarization of the Raman lines was studied previously. It also appears that there is no earlier report on the infrared and Raman spectra of 2-pyridone-*N*-*d*.

The present investigation was aimed at making a detailed study of the infrared and Raman spectra of 2-pyridone and 2-pyridone-*N*-*d* in the polycrystalline, liquid and solution phases. Assignments of the observed vibrational frequencies based on the polarization of the Raman lines and also on the comparison with the assignments proposed for the related molecules[4,9-12] are presented. The ideal gas state thermodynamic functions of the two isotopic molecules have been determined on the basis of the assigned fundamental frequencies.

Experimental

2-pyridone was supplied by Schuchardt, Germany. The compound was purified by repeated sublimation under reduced pressure. A sample of 2-pyridone-*N*-*d* was prepared by the exchange reaction of 2-pyridinol with D_2O. The final product used in the experiment was collected after four such

a) Solution in CS_2, CH_2Cl_2, CCl_4, or D_2O.

exchanges.

The infrared spectra of 2-pyridone and 2-pyridone-*N*-*d* in the range 4000—400 cm^{-1} were measured on a Carl-Zeiss Specord IR 75 spectrometer in the polycrystalline state as nujol or hexachlorobutadiene (HCB) mull, in the liquid state just above the melting point and in solutions in different solvents, e.g., CCl_4, CS_2, CH_2Cl_2, and D_2O. The far infrared spectra of the two compounds in the region 500—50 cm^{-1} were recorded in nujol mull on a Perkin-Elmer Model 180 spectrophotometer.

The Raman spectra were obtained in the polycrystalline state in the case of both the molecules and also in the melt of the substance in the case of 2-pyridone using a Spex 1403 Ramalog spectrometer and the 514.5 nm line as the exciting wavelength from a Spectra Physics argon ion laser. The polarization of the Raman lines of 2-pyridone was also measured using an analyser and a scrambler as described elsewhere.[1)]

Results and Discussion

The observed infrared frequencies and Raman shifts of the two isotopic molecules, their approximate relative intensities and probable assignments are given in Table 1. Tables 2 and 3 list the calculated values of the thermodynamic functions. In Fig. 1 is reproduced the laser Raman spectrum of 2-pyridone-*N*-*d* in the polycrystalline state.

Assuming the amide form for 2-pyridone[6,8,13,14)] and 2-pyridone-*N*-*d* the two isotopic molecules belong to the point group C_s and the thirty normal modes of vibration, which are active both in the infrared and Raman

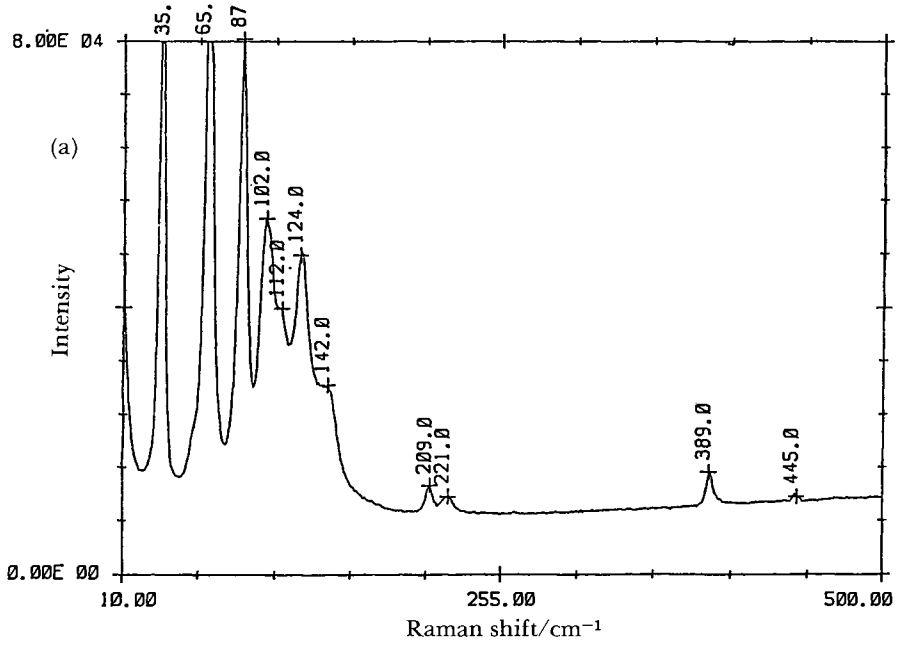
spectra, are distributed among the symmetry species as follows:

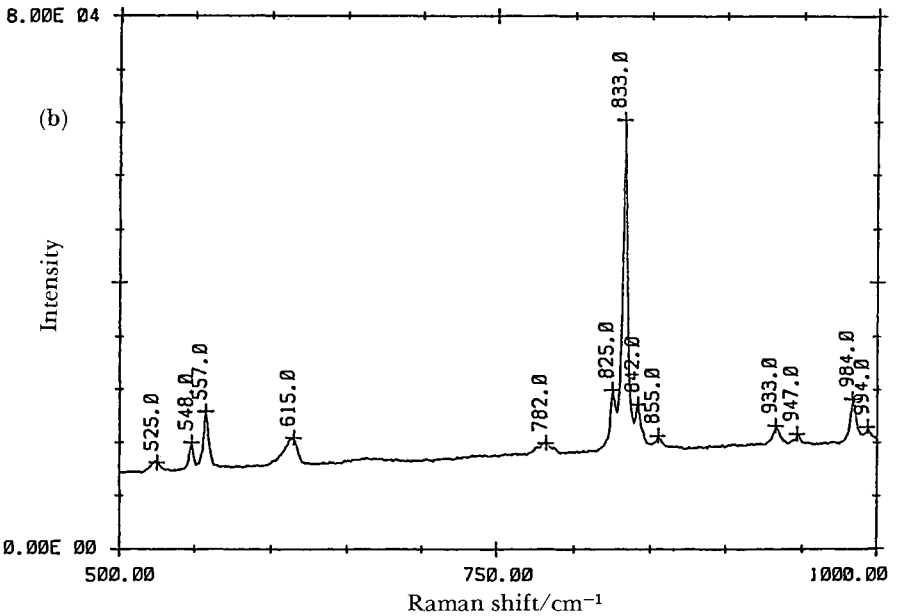
$$\Gamma = 21\ a' + 9a''$$

The species a′ gives polarized Raman lines and the species a″ depolarized Raman lines.

Species a′. The polarized Raman lines at 3091 and 3040 cm^{-1} in the case of 2-pyridone and the Raman shifts observed at 3096, 3085, and 3043 cm^{-1} in the case of 2-pyridone-*N-d* are assigned to the four C–H stretching modes. The infrared spectra of both the isotopic molecules in the liquid state show absorption at 1538 cm^{-1}, but in the polycrystalline state it is split up into two components. The Raman counterpart behaves similarly. These are attributed to both the components of the highest C–C stretching mode. The remaining ring stretching modes are identified with the polarized Raman lines at 1459, 1427, 1369, and 996 cm^{-1} in 2-pyridone and the Raman shifts observed at 1451, 1388, 994 cm^{-1} and the infrared band at 1433 cm^{-1} in 2-pyridone-*N-d*. The Raman spectrum of 2-pyridone gives polarized lines at 1248, 1157, and 1011 cm^{-1} and the infrared spectrum shows absorption of medium strength at 1099 cm^{-1}, while in the deuterated compound the Raman lines at 1242 and 1151 cm^{-1} and the infrared bands at 1098 and 1007 cm^{-1} are observed. These are assigned to the four C–H in-plane deformation modes.

Polarized Raman lines are observed at 847, 617, and 555 cm^{-1} in 2-pyridone while its deuterated analogue





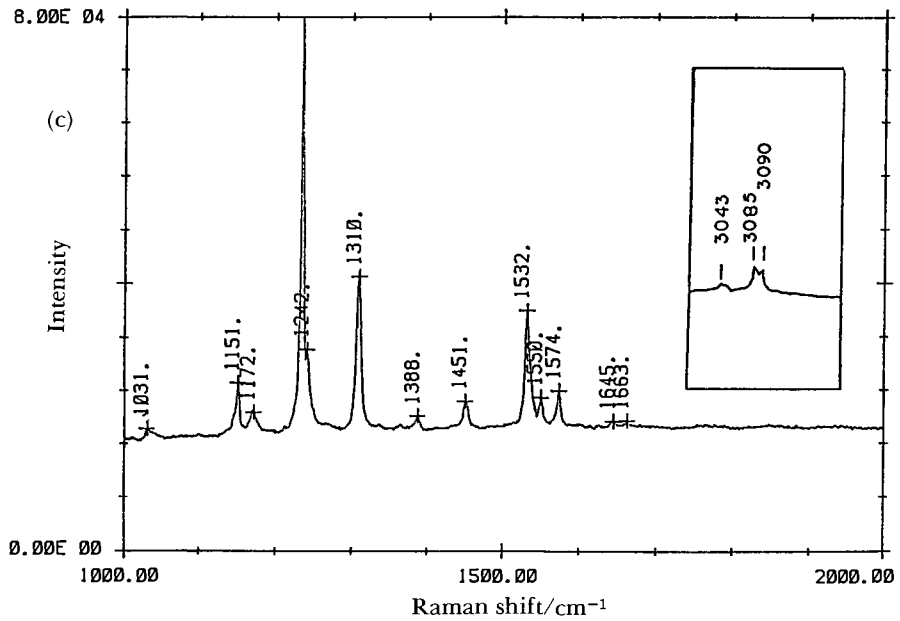


Fig. 1. (a), (b), and (c). Laser Raman spectrum of 2-pyridone-*N*-*d* in the polycrystalline state.

shows Raman shifts at 833, 615, and 548 cm^{-1}. These may be unambiguouly identified with the modes being derived primarily from the planar ring deformation.

Species a″. A depolarized Raman line is observed at 393 cm^{-1} in 2-pyridone in the liquid state, while the corresponding Raman shift is observed at 389 cm^{-1} in the case of 2-pyridone-*N*-*d*. This may be associated with one component of the nonplanar ring angle deformation, the other component being substituent sensitive may be identified with the infrared band of medium intensity observed at 220 cm^{-1} in the case of both the isotopic molecules. The other fundamental frequencies belonging to a″ class may be assigned to the infrared bands at 981, 926, 780, 731, and 525 cm^{-1} in 2-pyridone and 982, 934, 782, 731, and 522 cm^{-1} in 2-pyridone-*N*-*d*. These assignments are in close agreement with those proposed for other monosubstituted pyridines.[1,3,4,9,10]

The Internal Vibrations of the NH and CO Group. If the molecule of 2-pyridone exists in the amide form[15] due to tautomerism, it should exhibit the N–H stretching band near 3400 cm^{-1} in the infrared spectrum. Since there is strong intermolecular hydrogen bonding which exists not only in the crystalline state[16] but also in the liquid and solution phases (as evident from the

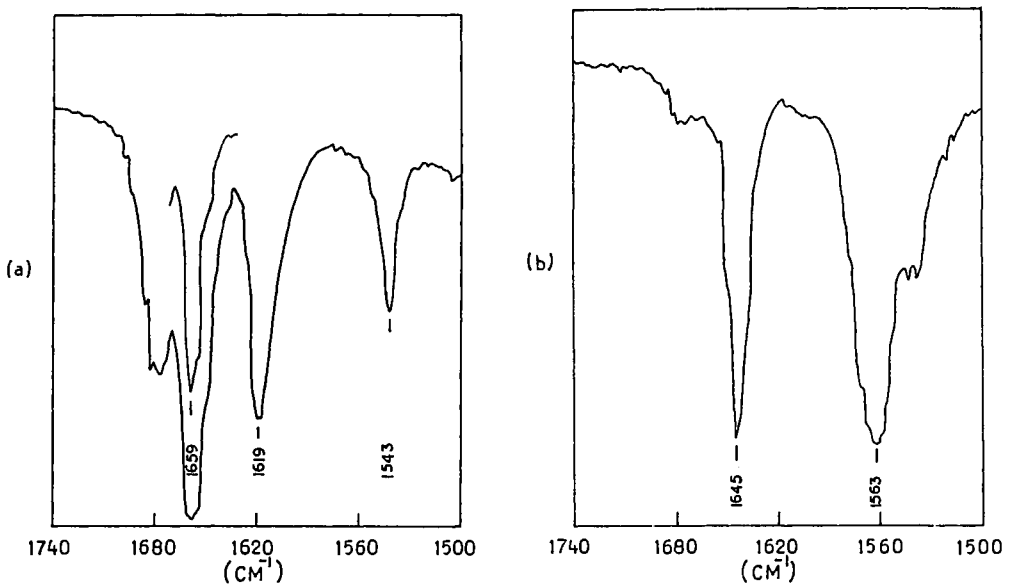

Fig. 2. Portions of the infrared spectra of (a) 2-pyridone in methylene chloride, and (b) 2-pyridone-*N*-*d* in D_2O.

spectrum) the N–H stretching frequency may decrease to about 3200 cm^{-1} and it is, therefore, probably submerged in the broad absorption region covering the range 3300—2500 cm^{-1}, and as such this frequency cannot be located with certainty. Mason[6] reported the N–H stretching band at 3404 cm^{-1} in a very dilute solution in CCl_4 and at 3198 cm^{-1} in the solid state in the case of 2-pyridone. The present study shows that the infrared band at 3197 cm^{-1} (present value) persists in solid 2-pyridone-*N*-*d*. So the band at 3197 cm^{-1} cannot be assigned to the N–H stretching mode. But in the case of 2-pyridone-*N*-*d* a strong infrared band is observed at 2282 cm^{-1} which is absent in the spectrum of the normal 2-pyridone molecule. It is, therefore, assigned to the N–D stretching mode.

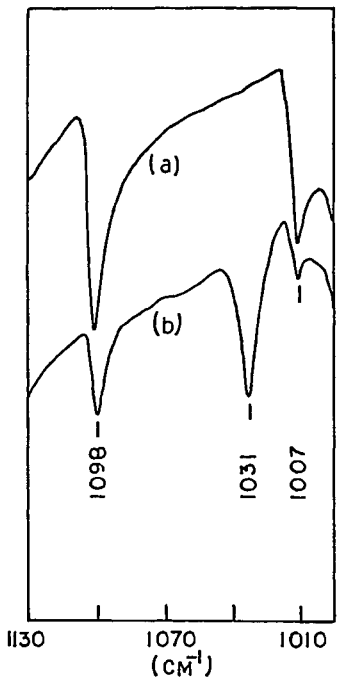

Fig. 3. Portions of the infrared spectra of (a) 2-pyridone in nujol, and (b) 2-pyridone-*N*-*d* in nujol.

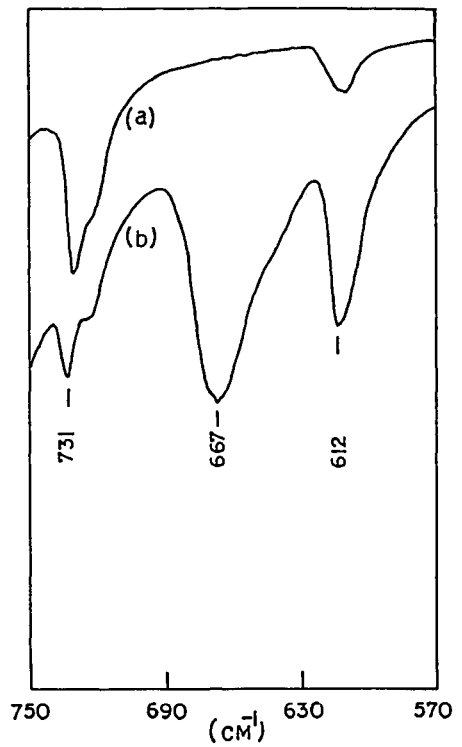

Fig. 4. Portions of the infrared spectra of (a) 2-pyridone in nujol, and (b) 2-pyridone-*N*-*d* in nujol.

A polarized Raman line at 1599 cm^{-1} with a very strong infrared counterpart at 1605 cm^{-1} is observed in 2-pyridone. This band is found to disappear on N–H deuteration (Fig. 2) and a new band of medium strength at 1031 cm^{-1} is observed in both the infrared (Fig. 3) and Raman spectra of 2-pyridone-*N*-*d*. The former band must therefore be assigned to the N–H in-plane deformation mode[1] against the previous assignment of this frequency to a C–C stretching mode[7] and the latter (1031 cm^{-1}) to the N–D in-plane bending mode.

It is observed that in 2-pyridone an infrared band of medium intensity at 1099 cm^{-1}, which has already been assigned to a C–H in-plane deformation mode, decreases in intensity on N–H deuteration. This is indicative of the fact that two fundamentals are overlapping at this position. Moreover, the Raman line at the same frequency which appears to be depolarized in 2-pyridone is missing in the Raman spectrum of 2-pyridone-*N*-*d*. This shows that the band at 1099 cm^{-1} must have some contribution from the N–H out-of-plane deformation mode. On the other hand, an infrared band of medium intensity at 667 cm^{-1} is observed on N–H deuteration (Fig. 4). This band is attributed to the N–D out-of-plane deformation mode.

The highly intense infrared bands at 1643 and 1637 cm^{-1} in 2-pyridone and 2-pyridone-*N*-*d*, respectively, are assigned to the C=O stretching frequency.[1] The C=O in-plane and out-of-plane deformation frequencies are identified with the observed infrared bands at 559 and 473 cm^{-1} respectively in 2-pyridone and at 556 and 471 cm^{-1} respectively in the case of 2-pyridone-*N*-*d*.[17]

Teller–Redlich product rule applied to the present assignment gives the following result:

$$\text{For the a' species} \quad \Gamma'_{exp} = \prod_i \frac{\nu_i^D}{\nu_i^H} = 0.445, \quad \Gamma'_{cal} = 0.510$$

$$\text{For the a'' species} \quad \Gamma''_{exp} = \prod_i \frac{\nu_i^D}{\nu_i^H} = 0.613, \quad \Gamma''_{cal} = 0.728$$

Thermodynamic Functions: Assuming a rigid rotator and harmonic oscillator approximation ideal gas state thermodynamic functions of 2-pyridone and 2-pyridone-*N*-*d* have been calculated in the temperature range 200—1500 K using the standard expressions[18] and the wavenumbers of the fundamental frequencies.

Remarks

It is seen from the vibrational analysis given above

that the spectral behavior of the two isotopic molecules corroborates to the fact that 2-pyridone and 2-pyridone-*N-d* exist predominantly in the amide form due to tautomerism in the solid, liquid, and solution phases.

The author is thankful to Professor I. Haque for his kind permission to use the infrared spectrophotometer. Thanks are also due to the Department of Science and Technology, Government of India for financial support to the project work.

A Combined Solvent Extraction-Spectrophotometry for the Determination of Bismuth(III)

Ganesh Shantilal DESAI and Vijay Malhar SHINDE*
Analytical Laboratory, The Institute of Science, 15 Madam Cama Road, Bombay 400032, India
(Received September 5, 1990)

A method has been proposed for the extraction of bismuth(III) at microgram level from bromide media using mesityl oxide as an extractant. The bismuth–bromo complex formed in the concentration range of 0.05—0.3 mol dm^{-3} hydrobromic acid showed quantitative extraction into mesityl oxide. Various experimental conditions such as acid concentration, mesityl oxide concentration, period of equilibration, stripping agents, and diverse ions have been studied. Bismuth ion after stripping is determined by thiourea spectrophotometrically. The method is applicable to the analysis of pharmaceutical samples, alloy samples, and synthetic mixtures.

Bismuth is an important element because of its intermediate or metalloid character. It is chiefly employed for the preparation of hard and easily fusible alloys which are useful as safety plugs in boilers, electrical fuses, solders, and type metal for printing. Trivalent bismuth salts are used medicinally to control diarrhoea and other gastrointestinal distresses. Bismuth salts are also used as radio-contrast agents. In view of this separation of bismuth from associated elements for the determination is desired.

Literature survey reports a very few extraction methods for bismuth(III). Amongst the ion-association systems, polar solvents such as tributyl phosphate (TBP), methyl isobutyl ketone (MIBK), isopentyl alcohol, isopentyl acetate, and diethyl ether have been used for the extraction of bismuth from iodide, perchlorate and thiocyanate media.[1–5] High molecular weight amines have also been used for extraction of bismuth from iodide, chloride, thiocyanate, bromide, and succinate media.[6–11] *N*-*m*-Tolyl-*p*-chlorobenzohydroxamic acid has been used to extract bismuth.[12] However the existing methods suffer from limitations such as longer extraction time,[3,12] critical pH,[12] centrifugation,[11] and large number of interferences.[2,3,6] The proposed method is free from these limitations and affords separation for the determination of bismuth in some samples. The method is reproducible and rapid.

Experimental

Apparatus and Reagents. Mesityl oxide (bp 128 °C, Fluka) was used after double distillation.

Thiourea; 10% solution was used for the determination of bismuth.[13]

The stock solution of bismuth(III) was prepared by dissolving 0.58 g of bismuth nitrate (AR grade) in distilled water containing 2 cm^3 of concentrated nitric acid and diluting to 250 cm^3. The solution was standardised by known method[14] and diluted as required for working solution. All other reagents used were of analytical reagent grade.

Absorbance measurements were made on a Unicam SP 500 spectrophotometer with 1 cm (silica) cells.

General Extraction Procedure. To an aliquot of solution containing 200 μg of bismuth(III), hydrobromic acid was added so that its concentration is 0.2 mol dm^{-3} in a total volume of 10 cm^3. The solution was transferred into a separatory funnel and extracted with 5 cm^3 of undiluted mesityl oxide for 30 s. After separating the aqueous layer, bismuth from the organic layer was stripped with two 5 cm^3 portions of 0.2 mol dm^{-3} nitric acid and determined with thiourea spectrophotometrically at 460 nm.[12]

Results and Discussion

Extraction Conditions. The concentration of hydrobromic acid was varied from 0.05 to 1.0 mol dm^{-3} and that of mesityl oxide from 50 to 100% (v/v) by dilution

Table 1. Extraction of Bismuth(III) as a Function of Hydrobromic Acid Concentration and Mesityl Oxide Concentration. Bi(III)=200 μg

Mesityl oxide concn/%	[HBr] mol dm^{-3}	Extraction %	Distribution ratio, D
50	0.2	13.8	0.32
60	0.2	25.0	0.67
70	0.2	42.6	1.48
80	0.2	58.7	2.84
90	0.2	72.6	5.30
100	0.05—0.3	99.9	1998
100	0.4	83.7	10.26
100	0.5	73.1	5.43
100	1.0	57.5	2.70

with toluene. The results (Table 1) showed that the quantitative extraction of bismuth occurs with undiluted mesityl oxide from the solution containing 0.05 to 0.3 mol dm^{-3} hydrobromic acid. Variation of shaking time from 5 to 60 s showed that an equilibration for 30 s was enough for complete extraction of bismuth into organic phase. However prolonged shaking had no adverse effect on the extraction of bismuth.

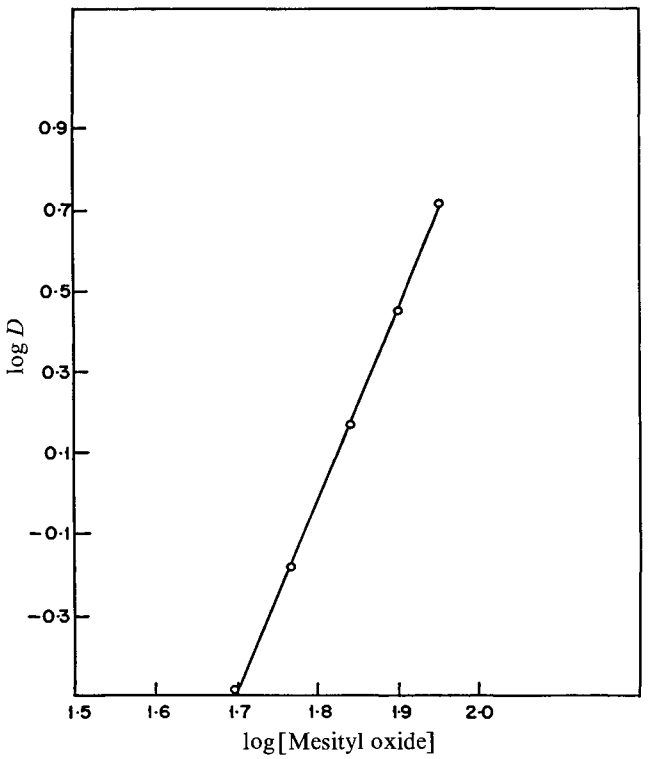

Fig. 1. Plot of log(distribution ratio, D) vs. log(Mesityl oxide concentration, %) at 0.2 mol dm^{-3} hydrobromic acid concentration.

Nature of the Extracted Species. The nature of the extracted species was established using log–log plot. A plot of log of distribution ratio (D) versus log of mesityl oxide concentration (at 0.2 mol dm^{-3} hydrobromic acid concentration) gave a slope of 2.3 indicating a molar ratio of 1 : 2 with respect to the extractant (Fig. 1).

Effect of Strippng Agents. Different stripping agents were tried for back extraction of bismuth. Nitric acid was suitable stripping agent because with other agents such as hydrochloric acid, perchloric acid, sulphuric acid, ammonium hydroxide, and sodium hydroxide the recovery of bismuth was not quantitative. Water do not strip bismuth from the organic phase. The results are reported in Table 2.

Effect of Foreign Ions. Varying amounts of foreign ions were added to a fixed amount of bismuth (200 μg) to study interference in the recommended procedure. The tolerance limit was set at the amount required to cause ±1% error in bismuth recovery. There was no interference from 8000 μg each of Cu(II), Zn(II), Fe(III), Mn(II), and Ni(II); 6000 μg each of Mo(VI), Co(II), Mg(II), citrate, and tartrate; 4000 μg each of Be(II), Pb(II), Th(IV), As(III), and fluoride; 2000 μg each of W(VI), Sb(III), V(V), Ba(II), Ti(IV), U(VI), thiourea, oxalate, sulfate, nitrate, nitrite, phosphate, chloride, and ascorbic acid; 1000 μg each of Cd(II), Hg(II), Sn(II), Cr(VI), Au(III), Ag(I), and Pd(II); 400 μg of thiosulfate and 200 μg of EDTA.

Analysis of Synthetic Mixture. The proposed method was applied for the extraction and determination of

bismuth in different synthetic mixtures. The results showed that the recovery of bismuth was $\geqslant$99%. The results are reported in Table 3.

Analysis of Alloys. A known amount of bismuth was added to leaded brass (BCS 385), leaded bronze (BCS 364), and leaded gunmetal (BCS 183/4) and bismuth was recovered by the proposed method. The procedure is detailed below.

Weigh accurately 100 mg each of leaded brass, leaded bronze, and leaded gunmetal, add 3 cm^3 of concentrated nitric acid and evaporate to almost dryness. The residue is taken up with water and the precipitate of metastannic acid is filtered off. The precipitate is first washed with hot dilute nitric acid and then thoroughly with hot water. To the filtrate add solution containing 2.5 mg of bismuth and dilute to 25 cm^3. 2 cm^3 of this solution is taken for extraction and determination of bismuth by the proposed method. The results are reported in Table 4.

40 mg of Woods alloy was taken and dissolution was carried out as described above. Then the filtrate was diluted to 100 cm^3 and 1 cm^3 of this solution was taken for extraction and determination of bismuth by the proposed method. The result is reported in Table 4.

Analysis of Pharmaceutical Samples. Bismuth containing drugs such as Denol were analysed by the proposed method. A Denol tablet was dissolved in 10 cm^3 of perchloric acid, evaporated to almost dryness, taken up in water, filtered and the filtrate was diluted to 500 cm^3. Agrawal and Bhatt have determined bismuth in

a) Average of triplicate analysis.

Pectomycin suspension[12] (Manufactured by Lyka Labs, India). The sample of Pectomycin available in the Bombay market, however does not contain bismuth and hence 2.5 mg of bismuth was added to 5 cm^3 of Pectomycin suspension and dissolved in 10 cm^3 of 2.5 mol dm^{-3} H_2SO_4 the solution was filtered and diluted to 50 cm^3. 1 cm^3 and 4 cm^3 aliquot of Denol and Pectomycin suspension were respectively taken for extraction and determination of bismuth by the proposed method. The results are reported in Table 5.

The method is selective and permits a rapid separation and determination of a microgram amount of bismuth. The average recovery of bismuth was 99.0±1%. Each determination took a total of 20—25 min.

The authors are grateful to the University of Bombay for awarding "The Pandit Bhagwandin Dube and Mrs. Ramdulari Dube Scholarship in Science" to one of them. (G.S.D.)

Dynamics of Autoxidation of Aqueous Sulfur Dioxide in Aqueous Suspensions of Cadmium Oxide

Ashu RANI, D. S. N. PRASAD, Rachna BHARGAVA, and Krishna Swarup GUPTA*
Atmospheric Chemistry Laboratory, Department of Chemistry, University of Rajasthan, Jaipur 302004, India
(Received September 12, 1990)

Autoxidation of S(IV), in buffered solutions,conforms the rate law (1). The increase in buffer concentration has a

$$R_{obsd} = k_5[CdO][S(IV)]^2[H^+]^{-1.22} \quad (1)$$

rate decreasing effect. On the other hand, in unbuffered solutions the kinetics obey a different rate law (2).

$$R_{obsd} = (k_{10} + k_{11}[CdO])[S(IV)][H^+]^{-0.5} \quad (2)$$

In both situations, the dissolution of CdO accompanies the autoxidation. A heterogeneous catalytic mechanism involving adsorption of both dioxygen and sulfur(IV) on the surface of CdO particle has been proposed.

While investigating heterogeneous photocatalytic oxidation of sulfite in aqueous suspensions of semiconductor powders, Frank and Bard (1977)[1] observed that zinc oxide, in dark, displayed a significant catalysis in suspensions containing 1×10^{-2} mol dm^{-3} acetic acid although the autoxidation was accompanied by a dissolution of ZnO and as a sequel neutralization of the solution also took place, and the experiments with ZnO were not persued further. In view of the fact that cadmium belongs to Zn-subgroup and CdO is more basic than ZnO, it may be expected that surface-pH of CdO particles would be higher than the former and as a consequence CdO would exhibit a stronger catalytic activity, as surface pH is reported to be a dominant factor in determining rates and capacities of SO_2 removal by several metal oxides in systems; aerosol–SO_2(g)–water (Judeikis et al., 1978).[2]

Additional points of interest in studying CdO catalysis were as follows. CdO is found, to a small extent, in suspended particulate matter.[3,4] In an earlier study, the photocatalytic autoxidation of S(IV) in CdS-suspensions has been reported by Gutierrez and Henglein (1983).[5] In this paper, the kinetics of the autoxidation of S(IV), in aqueous suspensions of CdO, is being reported.

Experimental

Materials and Methods. Cadmium oxide in powder form was of Arbha IM make and of 99.5% purity. All other chemicals were of reagent grade and used as received. For obtaining aqueous S(IV) solution, sodium sulfite was used. For study at constant pH, CH_3COOH–CH_3COONa buffer was used. In case of study in unbuffered solutions, the desired initial pH was obtained by adding dilute perchloric acid.

The experimental procedure was essentially the same as used by Brodzinsky et al.[6] The reactions were conducted in an open Erlenmayer flask, which was maintained at desired temperature by circulating thermostated water around it. The reaction was initiated by first adding temperature equilibrated sodium sulfite solution to the buffer solution maintained at the same temperature, followed by the addition of weighed CdO. The reaction mixture was stirred continuously at 1600±100 rpm using a magnetic bar. At this stirring speed, the reaction was shown not to be oxygen mass transfer controlled.

Table 1. Estimation of Sulfate in Final Product Solution, [CdO]=0.3 mol dm^{-3}, pH=5.06

[S(IV)]×10^3 mol dm^{-3}	[Sulfate]×10^3 mol dm^{-3}	[Sulfate]/[S(IV)]	% Recovery as sulfate
2.0	1.94	0.97	97
3.0	2.89	0.96	96
4.0	3.91	0.98	98

The kinetics were followed by withdrawing 5 ml aliquot, filtering of the solid rapidly with glass wool and analyzing the filterate iodometrically.

The initial rates for kinetics runs were calculated and as the reaction is accompanied by a dissolution of CdO, the initial rates had a slightly higher uncertainty, nevertheless, the rate measurements were reproducible within ±15%. All calculations were done on Apple IIe Computer using Curve Fitter and Scientific Plotter programmes of Interactive Microwave Inc. U.S.A. In the presentation of rate data later, the statistical parameters have been abbreviated as follows: correlation coefficient=CC; coefficient of determination=CD; standard error of estimate=SEE.

Product Analysis. The quantitative analysis, performed on the final product solution, showed sulfate to be the only product. It was quantitatively estimated in solutions having different initial sulfite concentrations using the standard procedure. The results are given in Table 1. Thus, the stoichiometry of the reaction could be written as,

$$\text{Sulfur(IV)} + 1/2O_2 \xrightarrow{CdO} \text{Sulfate}.$$

Results

To begin with, the effect of stirring speed on the reaction rate was examined by varying rpm from 300—1800. It was found that the rate increased with increase in rpm attaining a maximal value around 1200 rpm. Hence, all the experiments were carried out at 1600±100 rpm, as at this rpm, reaction is not oxygen mass transfer-controlled.

The initial kinetics experiments, both in buffered and in unbuffered solutions, indicated that CdO has a significant catalytic activity and the standard S(IV) disappearance curves are normal in this case. However, a disturbing and complicating factor, that the reaction is accompanied by a dissolution of CdO powder, also came to light. The same observation was made by Frank and Bard[1] in case of ZnO-catalyzed reaction. The dissolution was apparent from a visual examination of the reaction mixture and it was observed to be higher in buffered solution than in unbuffered reaction mixtures, presumably owing to the reaction of CdO with CH_3COOH in the former. In case of unbuffered solutions, some CdO was left undissolved at the end of a kinetics run (60% completion). Despite CdO dissolution, the pH in buffered solutions remained effectively constant throughout the course of a kinetics run. This is probably due to interplay of two opposing factors. CdO dissolution tends to increase the pH, while sulfite ion oxidation into sulfate tends to decrease pH and thus, these two factors counter-balance each other leaving pH of the reaction mixtures almost unchanged.

The dissolution of CdO and consequent production of Cd^{2+} ions made us to look for the cause of the catalysis; whether it was due to homogeneous catalysis perpetuated by Cd^{2+} ions or due to CdO particles or due to both. For this reason, influence of 1—2.4×10^{-3} mol dm^{-3} cadmium acetate, $Cd(OAc)_2$, and 2—5×10^{-3} mol dm^{-3} cadmium chloride, in the absence of CdO, was examined. For comparison, the uncatalyzed reaction was also studied under exactly similar conditions. The results given in Table 2 indicate that the rate of autoxidation, in presence of added Cd-salts, is no different than the rate in their absence. This rules out Cd^{2+} being the cause of catalysis.

It may be mentioned that the cadmium acetate used in aforesaid experiments was prepared by dissolving same CdO in acetic acid, as was used in preparing aqueous suspensions for kinetics work. In view of the dissolution of the CdO, the treatment of kinetics results obtained in this study, was based on initial rates, as the initially most of CdO will remain undissolved.

Kinetics in Buffered Suspensions. Influence of Buffer Concentration: The effect of buffer concentration on the reaction rate was studied with twin objectives of finding out a suitable buffer concentration required for maintaining pH for the range of CdO employed, and for examining its influence on the rate itself. The rate increases with decreasing buffer concentrations, while maintaining the ratio $[CH_3COONa]/[CH_3COOH]$ and hence, pH same. However, at buffer concentrations less than $[CH_3COOH]=6\times10^{-2}$ mol dm^{-3} and $[CH_3COONa]=1.4\times10^{-1}$ mol dm^{-3}, the pH could not be maintained constant. This led us to select these concentrations of acetic acid and sodium acetate for buffering reaction mixtures. When it was desired to vary pH, $[CH_3COONa]$ was held constant at 1.4×10^{-1} mol dm^{-3}, and $[CH_3COOH]$ was varied.

Table 2. The Influence of $Cd(OAc)_2$ and $CdCl_2$ on S(IV) Autoxidation. $[S(IV)]=2\times10^{-3}$ mol dm^{-3}, pH=5.16, t=30 °C

CdO-Dependence: Using initial rates, R_{obs}, for CdO variation an order of 0.98±0.02 was determined for CdO. The plots of R_{obsd} vs. [CdO] (Fig. 1) are linear with small intertepts in agreement with the rate law (1). R_{buff} and k_1 values obtained from this figure are collected in Table 3.

$$R_{obsd} = R_{buff} + k_1[CdO], \quad (1)$$

where R_{buff} is the rate of uncatalyzed reaction in buffered suspensions. k_1 values are seen to vary with S(IV) in accordance with Eq. 2.

$$k_1 = k_2[S(IV)]^2. \quad (2)$$

From a plot of k_1 and $[S(IV)]^2$, k_2 was determined to be

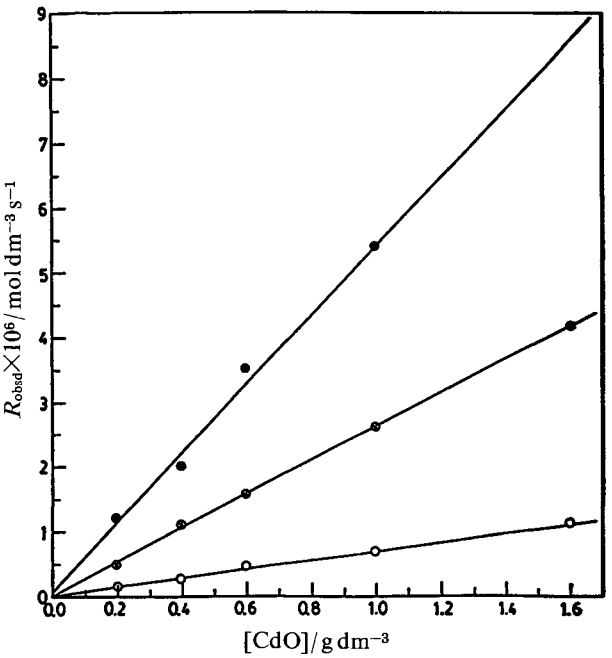

Fig. 1. Variation of CdO at three different S(IV) in buffered solutions at pH 5.06 and 30 °C. [S(IV)]; ○=2.5×10^{-3}, ⊗=5×10^{-3}, ●=7.5×10^{-3} mol dm^{-3}.

Table 3. The Values of R_{buff} and k_1 at Different [S(IV)] at pH=5.06 and 30 °C

$[S(IV)]\times10^3$/mol dm^{-3}	2.5	5.0	7.5
$k_1\times10^7$/mol g^{-1} s^{-1}	7.1	26.2	53.8
$R_{buff}\times10^8$/mol dm^{-3} s^{-1}	0.2	0.4	6.2

$(8.6\pm0.2)\times10^{-2}$ $dm^6\,mol^{-1}\,g^{-1}\,s^{-1}$. The uncatalyzed rate, R_{buff}, is negligible in comparison to catalyzed rate and contribution of the former to the total rate does not exceed more than 6% at the highest [S(IV)], which is well within the uncertainty of present rate measurements and R_{buff} can, therefore, be neglected. In the light of Eq. 2, Eq. 1 then can be modified as Eq. 3.

$$R_{obsd} = k_2[CdO][S(IV)]^2. \quad (3)$$

Sulfur(IV)-Dependence: R_{obsd} values for sulfur(IV) variations yielded an order of 2.05 ± 0.07, in conformity with the rate law (4).

$$R_{obsd} = k_4[S(IV)]^2. \quad (4)$$

The values of k_4, given in Table 4, were determined at various [CdO] from R_{obsd} vs. $[S(IV)]^2$ plots which are given in Fig. 2. A comparison of Eqs. 4 and 3 shows,

$$k_4 = k_2[CdO]. \quad (5)$$

Thus, the results of variation of S(IV) also conform Eq. 3. Using Eq. 2, the values of k_2 from sulfur(IV) variations at 0.2, 0.6, and 1.0 $g\,dm^{-3}$ [CdO] were determined to be 0.12 ± 0.02, 0.08 ± 0.01, and 0.07 ± 0.01 $dm^6\,mol^{-1}\,g^{-1}\,s^{-1}$ respectively at pH 5.06 and 30 °C. Similarly, at same pH and temperature, k_2 values of 0.11 ± 0.01, 0.11 ± 0.01, and 0.10 ± 0.01 $dm^6\,mol^{-1}\,g^{-1}\,s^{-1}$ were determined by varying [CdO] at 2.5×10^{-3}, 5.0×10^{-3}, and 7.5×10^{-3} $mol\,dm^{-3}$ [S(IV)], respectively. Some variation is seen in these values which fall in the range 0.07—0.12 $dm^6\,mol^{-1}\,g^{-1}$.

It must be admitted that under varying reaction conditions, such as [S(IV)], [CdO] and pH, the rate of dissolution of CdO will not be same and is likely to vary from one reaction condition to another. Perhaps, this is the reason for variation in k_2 values, although the values fit the same rate law (11) and one gets nearly same values if extracted from a particular variation. We, therefore, ascribe the variation in k_2 values to the phenomenon of differential dissolution.

pH-Dependence: The results of pH variation in the range 4.8—5.9, given in Table 5, show the rate to increase with increase in pH. From a log-log plot between R_{obsd} and $[H^+]$, an order of -1.22 in $[H^+]$ was obtained. The complete rate law, including [CdO], [S(IV)] and $[H^+]$-dependences can, therefore, be written as Eq. 6.

$$R_{obsd} = k_5[CdO][S(IV)]^2[H^+]^{-1.22}. \quad (6)$$

Rate laws (3) and (6) are equivalent through $k_2 = k_5[H^+]^{-1.22}$.

Temperature-Dependence: The values of R_{obsd}, determined at 25, 30, and 35 °C (Table 6), yielded an energy of activation of 322 kJ mol^{-1}.

Kinetics in Unbuffered Suspensions. for studying kinetics in unbuffered solutions, initial pH was adjusted to desired value with the help of dilute perchloric acid. In all these experiments, pH varied with the progress of the reaction. The reaction profiles at different pH values are shown in Fig. 3. For investigating [CdO] and [S(IV)] dependences, a pH value of 5.06±0.02 was selected.

CdO-Dependence: [CdO] was varied from 0.05 to 0.30 g dm^{-3} at [S(IV)]=2×10^{-3} mol dm^{-3}, pH=5.06 and 30 °C and order in CdO was determined to be 0.6. The fractional order in CdO probably indicates the presence of a term independent of [CdO] in the rate law. In all likelihood, this term corresponds to uncatalyzed reaction. Indeed, the rate measurements, in the absence of CdO, yielded an uncatalyzed rate of 6×10^{-7} mol dm^{-3} s^{-1} under similar reaction conditions. On this premise, a plot between R_{obsd} and [CdO] was drawn and found to be linear (Fig. 4) in agreement with the rate law (7).

$$R_{obsd} = R_{un} + k_6[CdO], \quad (7)$$

where R_{un} is the rate of uncatalyzed reaction in unbuffered suspensions. R_{un} and k_6 values were found to be (6.8±2.1)×10^{-7} mol dm^{-3} s^{-1} and (8.0±1)×10^{-6} mol g^{-1} s^{-1} (CC=0.99; CD=0.99; SEE=3.18×10^{-8}). The presence of uncatalyzed rate term in unbuffered suspensions and its near absence in buffered suspensions deserves an

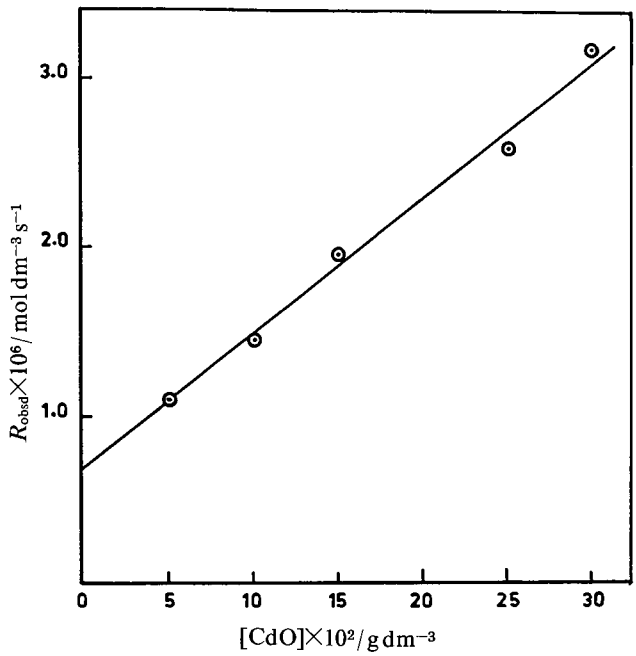

Fig. 4. Variation of R_{obsd} with CdO in unbuffered solutions at [S(IV)]=2×10^{-3} mol dm^{-3}, pH=5.06, t=30 °C.

explanation. The uncatalyzed rate has its origin in trace metal ion catalysis.[7,8] In buffered solutions, the acetate ions render these metal ions less reactive by forming complexes with them and, therefore, suppress the uncatalyzed path. Indeed, Cohen et al. (1981)[9] found the autoxidation of S(IV) in fly ash slurries, which incidentally is catalyzed by trace metal ions, is completely seized in acetate buffers, presumably due to masking of trace metal ion catalysts.[9] Moreover, trace organics are also known to inhibit the S(IV) autoxidation and their presence in acetic acid sample used by us can not be denied.[9,10]

S(IV)-Dependence: At a fixed [CdO] of 0.1 g dm^{-3}, pH 5.06 and 30 °C, [S(IV)] was varied from (1—5)×10^{-3} mol dm^{-3} (Table 7) and order in S(IV) was found to be 0.97 in agreement with Eq. 8,

$$R_{obsd} = k_7[S(IV)]. \quad (8)$$

In view of the fact that a first order dependence of uncatalyzed reaction is well established,[11] it shows the catalyzed reaction to be also of first order in [S(IV)]. On combining Eqs. 7 and 8, one obtains Eq. 9. Comparison of rate laws (7) and (9), and (8) shows,

$$R_{obsd} = (k_8 + k_9[CdO])[S(IV)], \quad (9)$$
$$k_7 = k_8 + k_9[CdO], \quad (10)$$
$$R_{un} = k_8[S(IV)], \quad (11)$$
$$k_6 = k_9[S(IV)]. \quad (12)$$

The values of R_{un}, k_6, and k_7 are collected in Table 8 and these values were used for obtaining k_9. The validity of the proposed rate law was tested by calculating the values of k_7 at [CdO]=0.1 g dm^{-3} using Eq. 10. The calculated value of 7.4×10^{-4} s^{-1} is in good agreement

with the experimental value of $(9.7\pm2.6)\times10^{-4}$ s^{-1} obtained from Fig. 5, based on Eq. 10 under similar conditions.

pH-Dependence: A variation in initial pH showed the rate to increase on increasing pH (Table 7). From a log–log plot between rate and $[H^+]$, an order of -0.5 in $[H^+]$ was extracted. On including $[H^+]$-dependence, the rate law (11) is modified to

$$R_{obsd}=(k_{10}+k_{11}[CdO])[S(IV)][H^+]^{-0.5}, \quad (13)$$

where,

$$k_8=k_{10}[H^+]^{-0.5} \text{ and } k_{11}=k_9[H^+]^{-0.5}.$$

Discussion

The most complicating aspect of this study is the dissolution of cadmium oxide, which accompanies the autoxidation of sulfur(IV), as the reaction progresses. However, the observation, that $CdCl_2$ and $Cd(OAc)_2$ do not possess any catalytic activity, is a redeeming feature which renders the system amenable to explanation. It should be mentioned here that the $Cd(OAc)_2$ solution, used for detecting any homogeneous catalysis by Cd^{2+} ions, was prepared by dissolving the same CdO in acetic acid, as was used in aqueous suspensions for studying heterogeneous catalysis. This firmly rules out the possibility of the impurities present in the CdO-sample as a possible cause of catalysis.

Having ruled out the possibility of catalytic activity of CdO-suspensions being due to Cd^{2+} ion, it is attractive to apportion it to the surface provided by CdO-particles. There are two strong points in favor of the heterogeneous nature of the catalysis in the present case. First is the order of two in [S(IV)], as has been found in glass,[12] silica,[13] and ceramic[13] catalyzed reactions. Second is the lack of an alternative explanation.

However, before presenting a mechanism, it is necessary to discuss the apparent difference in $[H^+]$ dependencies in buffered (Eq. 6) and unbuffered (Eq. 13) suspensions. Since, the uncatalyzed reaction, for

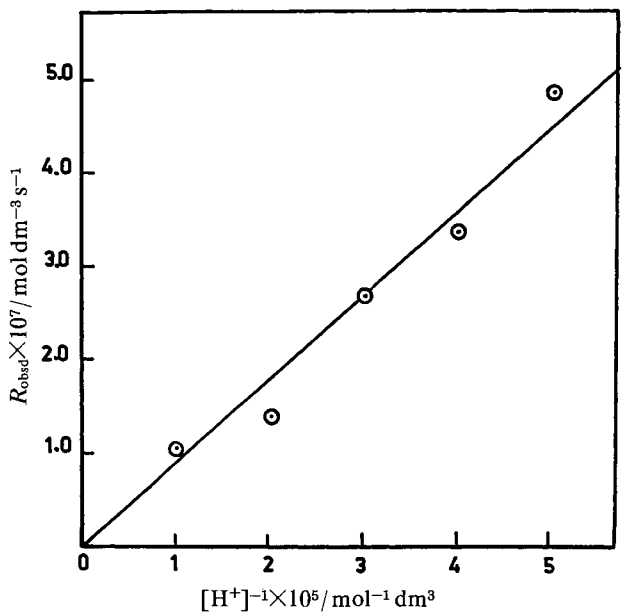

Fig. 6. Variation of R_{obsd} with $[H^+]$ in unbuffered solutions at [S(IV)]=2×10^{-3} mol dm^{-3}, [CdO]=0.2 g dm^{-3}, t=30 °C.

which rate is known to vary as $[H^+]^{-1}$ makes a substantial contribution to overall rate, it is likely that the order of −0.5 in $[H^+]$ in unbuffered study is largely due to this path and the CdO-catalyzed might be $[H^+]$-independent. On this premise, the rate law (13) if written as Eq. 14 fully accounts for observed $[H^+]$-dependence. The plot of R_{obsd} vs. $[H^+]^{-1}$ is straight line with a non-zero intercept (Fig. 6),

$$R_{obsd} = k_{12}[S(IV)][H^+]^{-1} + k_{13}[S(IV)][CdO]. \quad (14)$$

It yielded k_{12} and k_{13} values of $(2.2\pm0.4)\times10^{-9}$ s^{-1} and $(2.5\pm0.5)\times10^{-3}$ dm^3 g^{-1} s^{-1} respectively at 30 °C.

In buffered study, the uncatalyzed rate is negligible and, therefore, $[H^+]$-dependence can not be ascribed to this path, except nominally. An interpretation in terms of reaction mechanism via involvement of HSO_3^- and SO_3^{2-} ions would be vitiated and obscurred by the fact that the variation in $[H^+]$ also entails a variation in the ratio $[CH_3COONa]/[CH_3COOH]$. Obviously, with increase in pH, $[H^+]$ and $[CH_3COOH]$ both decrease and there is no way to discern whether the rate increases on increasing pH is due to decrease in $[H^+]$ or due to decrease in $[CH_3COOH]$ or both. It should be mentioned that a decrease in $[CH_3COOH]$ would result in decreasing the rate of dissolution of CdO (loc cit) and will thus have a rate increasing effect. CH_3COOH may affect the reaction in another way by getting adsorbed onto particle surface and thus by inhibiting the heterogeneous reaction. In view of this it is best not to consider the $[H^+]$-dependence in the construction of the reaction mechanism.

The kinetics order of unity in bulk [CdO] would result in an order of 1.5 in surface CdO provided all particles are of same radius and the situation would be much more complicated if the particles are not of uniform size as is usually the case.# The interpretation of kinetics results obtained in this study is based on bulk concentration of CdO, which is similar to mechanistic treatment resorted to by earlier workers in respect of similar systems.[6]

Now, the results obtained in the present study can be explained by proposing that both S(IV) and O_2 are adsorbed on CdO surface. Subsequently, the reaction is accomplished via interaction between these. Although oxygen dependence could not be studied, it is implicated to account for the observation that no reaction occurs in the absence of O_2 and that if O_2 is not allowed to diffuse rapidly in the suspension, as is evident from the influence of stirring speed on the reaction rate, the rate of autoxidation is quite slow. The kinetics orders of one in bulk [CdO], of two in [S(IV)] in buffered study and of one in unbuffered study would require the formation of at least two activated complexes having the gross compositions—$CdO\cdot O_2\cdot S(IV)$ and $CdO\cdot O_2\cdot(S(IV))_2$ for an unified treatment. The observed kinetics in both types of studies can be explained by the following general mechanism for the CdO-catalyzed path.

$$CdO + O_2 \underset{}{\overset{K_1}{\rightleftharpoons}} CdO\cdot O_2, \quad (15)$$

$$CdO\cdot O_2 + S(IV) \overset{K_2}{\rightleftharpoons} CdO\cdot O_2\cdot S(IV), \quad (16)$$

$$CdO\cdot O_2\cdot S(IV) + S(IV) \overset{K_3}{\rightleftharpoons} CdO\cdot O_2\cdot (S(IV))_2, \quad (17)$$

$$CdO\cdot O_2\cdot S(IV) \xrightarrow{k_{14}} \text{Products}, \quad (18)$$

$$CdO\cdot O_2\cdot (S(IV))_2 \xrightarrow{k_{15}} \text{Products}. \quad (19)$$

Assuming that the equilibria (Eqs. 15—17) are rapidly established and that the values of K_1, K_2, and K_3 are low, the rate expression (Eq. 20), at constant atmospheric pressure, can be derived.

$$R_{CdO} = A[CdO][S(IV)]^2 + B[CdO][S(IV)], \quad (20)$$

where R_{CdO} is the rate of CdO-catalyzed path and $A=k_{15}K_1K_2K_3[O_2]$ and $B=k_{14}K_1K_2[O_2]$. It appears that in buffered suspensions path A is dominant and B makes a negligible contribution. The reverse appears to be true in unbuffered suspensions. It is interesting to recall that in carbon-catalyzed sulfur(IV) autoxidation[6] and in nitrite–sulfur(IV)[14] reactions, order in sulfur(IV) was found to vary from zero to two.

An alternative mechanism may also be proposed. CdO due to its basic nature is likely to become hydrated to form $Cd(OH)_2$ and this species may react further with S(IV) and O_2. It may be mentioned here that in Fe(III)-catalyzed reaction above pH 5, and in Cu(II)-catalyzed reaction in alkaline solutions, the possibility of involvement of $Fe(OH)_3$[15] and $Cu(OH)_2$[16] has been indicated. Dyson and Quon,[17] while studying the reaction between ZnO fume and SO_2, found that in presence of water vapors $Zn(OH)_2$ is formed. Based on reactive $Cd(OH)_2$, a mechanism similar to (Eq. 15—19) can be written which will reproduce the observed kinetics. The autoxidation in surficial complexes,[18] $CdO_2\cdot O_2\cdot S(IV)$ and $CdO_2\cdot O_2\cdot(S(IV))_2$, is likely to proceed through the formation of peroxomonosulfate[19] and disulfate[20] species. It should be pointed out that in the present study an initial rapid drop in [S(IV)] has not been observed as was the case with carbon particles.[6] This phenomenon was taken as an evidence of adsorption of O_2 on particle surface in a primary step i.e. in Eq. 15 by Brodzinsky et al.[6] So, in the absence of any initial rapid fall in S(IV) in this case, it is possible to formulate the proposed mechanism in an alternative way, which involves the adsorption of S(IV) on CdO first, followed by adosrption or reaction with O_2. At pH=5.06, $[S(IV)]=2\times10^{-3}$ mol dm^{-3}, $[CdO]=0.2$ g dm^{-3}, and $t=30$ °C. R_{obsd} values of 1.3×10^{-7} and 2.35×10^{-6} mol dm^{-3} s^{-1} have been determined in buffered and unbuffered suspensions respectively. This shows the rate in unbuffered solution to be much faster than in buffered solutions. This could possibly be linked to the difference in the solubility of CdO in two situations. In unbuffered solutions, the solubility of CdO is compara-

This was pointed by the referee.

tively low and a large amount of solid CdO particles is available for surface catalysis and probably this explains the higher rate in unbuffered solutions.

It is interesting to speculate the possible cause of CdO-catalysis. In our laboratory several transition metal oxides such as CuO,[12] CoO,[13] Co_2O_3,[13] and Ni_2O_3[13] have been found to be effective catalyst for S(IV) autoxidation. However, in all these cases it is possible to ascribe the catalytic activity to the ease of availability of multiple oxidation states and their easy interconvertibility (for example Co(II)/Co(III) in CoO) and adsorption of S(IV) and O_2. In case of CdO, such an explanation does not seem plausible. On the basis of the fact that like CdO, other basic oxides like MgO and ZnO also catalyze the S(IV) autoxidation, the most probable reason for the catalytic activity possessed by CdO particles is its relatively high surface-pH due to its basis nature, which helps in accomplishment of the reaction between sulfur(IV) and O_2.[21]

In the light of the present work, it is desirable that the catalytic activity of other metal oxides, which are found in suspended particulate matter, should also be investigated.

The authors are grateful to Dr. R. E. Huie, National Institute of Standards and Technology, Gaithersburg, MD, USA. The work was supported by Indo-US Subcommission Research Project CE-2.

Separation of Scandium Using Liquid-Liquid Extraction with Macrocyclic Polyether(s) from Picrate Media

N. V. DEORKAR and Shnpad M. KHOPKAR*
Department of Chemistry, Indian Institute of Technology, Bombay 400076, India
(Received October 11, 1990)

Scandium was quantitatively extracted at pH 2.5—4.5 with 4.0×10^{-2} mol dm^{-3} 18-crown-6 in dichloromethane from 4.0×10^{-2} mol dm^{-3} solution of picric acid. It was stripped with 0.1 mol dm^{-3} nitric acid and determined spectrophotometrically at 650 nm as its complex with Arsenazo-III. It was separated from yttrium, lanthanides, zirconium, hafnium, vanadium, niobium, and uranium in multicomponent mixtures. Scandium from rock sample was also analysed.

Solvent extraction of scandium(III) with oxygenated solvents[1] is not quantitative, although, in the presence of salting out agent scandium can be extracted completely with tributyl phosphate.[2-5] Long chain amines were effective for its extraction.[6-7] The study of 15-crown-5, DB-18-crown 6, and DB-24-crown-8 indicated complexation is due to weak ion-dipole interaction.[8-11] However, systematic investigations on solvent extraction separation of scandium with crown ethers are lacking. Such studies are reported in this paper.

Experimental

Apparatus and Reagents: Apparatus used was similar to one described earlier.[12]

A stock solution of scandium was prepared by dissolving 0.850 g of its oxide (Merck, Germany) in 25 cm^3 of concentrated nitric acid and made upto 250 cm^3 with deionized water. The solution was standardized[13] complexometrically. It contained 2.20 mg cm^{-3} of scandium. A dilute solution containing 25 μg cm^{-3} of scandium was prepared by appropriate dilution. Picric acid (0.05 mol dm^{-3}) solution, benzo-15-crown-5 (B15C5), 12-crown-4 (12C4), 15-crown-5 (15C5), 18-crown-6 (18C6), dibenzo-18-crown-6 (DB18C6), and dicyclohexyl-18-crown-6 (DC18C6) (Merck, Germany) were used without further purification.

General Procedure: To an aliquot of solution containing scandium (25 μg) picric acid was added so as to have its concentration as 4.0×10^{-2} mol dm^{-3} in total volume of 10 cm^3. Then pH of the solution was adjusted to 2.5—4.5 with 0.05 mol dm^{-3} picric acid or lithium hydroxide solution. The solution was transferred to a separatory funnel and 10 ml of 4.0×10^{-2} mol dm^{-3} of 18C6 in dichloromethane was added to it and it was shaken on wrist action shaker for 10 min. The two phases were allowed to settle and separate. Scandium from the organic phase was stripped with 0.1 mol dm^{-3} nitric acid and it was determined spectrophotometrically as its complex with Arsenazo-III.[14] The concentration of scandium was calculated from the calibration curve.

Results and Discussion

Extraction as the Function of pH: Scandium was extracted at different pH to ascertain optimum pH for quantitative extraction. The phase volume ratio was maintained as 1 : 1. The extraction commenced at pH 1.5 and was complete at pH 2.5—4.5 only with 18C6. With other extractants it was not quantitative. Hence, 18C6 was used in subsequent studies (Fig. 1).

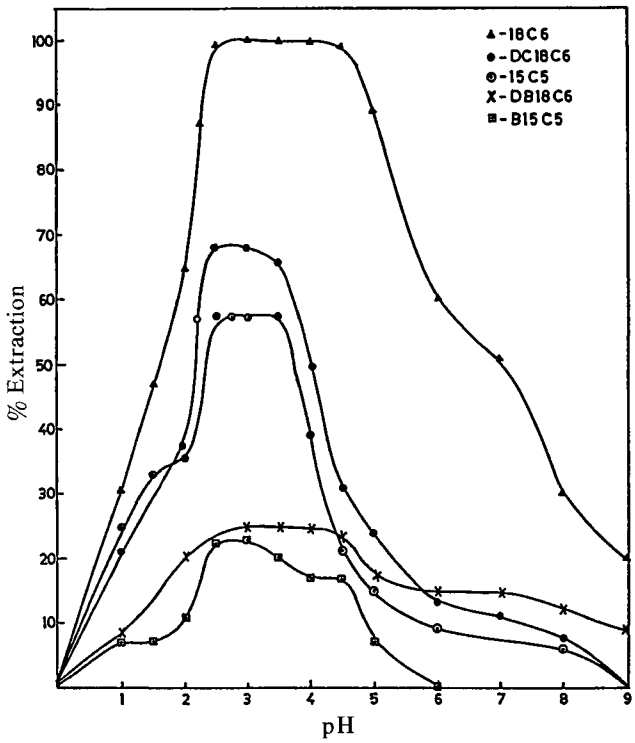

Fig. 1. Extraction of the scandium as the function of pH.

Extraction as the Function of 18C6 Concentration: Scandium was extracted at pH 2.5—4.5 with varying concentration of crown ether in dichloromethane (Table 1). The extraction was incomplete below 3.5×10^{-2} mol dm^{-3} 18C6 while it was quantitative with 4.0×10^{-2}

Table 1. Effect of 18-Crown-6 Concentration on Extraction of Scandium(III)

[18C6]/10^{-2} mol dm^{-3}	% E	D
0.5	9.1	0.10
1.0	32.0	0.47
1.5	50.3	1.01
2.0	64.2	1.79
2.5	75.0	3.0
3.0	88.0	7.33
3.5	95.0	19.0
4.0—10	>99.9	999

Table 2. Effect of Picric Acid Concentration on Extraction of Scandium(III)

[Picric acid]/10^{-2} mol dm^{-3}	% E	D
0.5	5.0	0.05
0.70	15.2	0.17
1.5	33.2	0.49
2.0	55.0	1.22

3.8—5.0	99.9	999

mol dm^{-3} 18C6 in dichloromethane.

Extraction as the Function of Picric Acid Concentration: Among the various counter ions such as eosin, tropeolin 00, dipicrylamine, Metanil Yellow, and picric acid, only picric acid was most suitable as it was capable of forming stable ion pair complex. Scandium was extracted with various concentrations of picric acid in concentration range of 0.5×10^{-2}—5.0×10^{-2} mol dm^{-3}. The extraction was quantitative above 4.0×10^{-2} mol dm^{-3} picric acid (Table 2).

Effect of on Diluent on Extraction: Benzene, toluene, xylene, carbon tetrachloride, chloroform, dichloromethane, dichloroethane, nitrobenzene, and cyclohexane were tested as the diluents (Table 3). Dichloromethane, dichloroethane, and nitrobenzene were effective as the diluents whereas all other diluents showed incomplete extraction.

Effect of Stripping Agents: Scandium was stripped with hydrochloric, nitric, sulfuric, perchloric, and acetic acid. Hydrochloric and acetic acid were effective from 2.0—7.0 mol dm^{-3} while other stripping agents were good from 0.1—0.7 mol dm^{-3}. 0.1 mol dm^{-3} nitric acid was used as the stripping agent in this work (Table 4).

Table 3. Effect of Diluents

Solvents	Dielectric constant E	% E	D
Cyclohexane	2.0	87.0	6.69
Benzene	2.28	17.5	0.21
Toluene	2.30	8.7	0.10
Xylene	2.38	5.6	0.06
Carbon tetrachloride	2.24	21.0	0.265
Chloroform	5.8	89.1	8.17
Dichloromethane	9.08	100.0	∞
Dichloroethane	10.5	100.0	∞
Nitrobenzene	34.8	100.0	∞

Table 4. Effect of Stripping Agents[a)]

CH_3COOH	23.1	37.0	53.0	76.1	100

a) 1 M=1 mol dm^{-3}.

Effect of Shaking Period on Extraction: The extraction was carried out for various time of shaking from 2 to 20 min. Beyond 8 min shaking the extraction attained equilibrium. In order to ensure complete extraction 10 min shaking was employed.

Nature of Extracted Species: The composition of extracted species was ascertained by plotting a log D vs. log[18C6] at fixed picric acid concentration and a graph of log D vs. log[picric acid] at fixed 18C6 concentration. The corresponding slopes were 1.96 and 2.87 respectively. Hence the probable composition of extracted species was scandium : 18C6 : picric acid=1 : 2 : 3 i.e. $[Sc(pic)_3\cdot(18C6)_2]$. These findings were in agreement with those of earlier workers.[10)]

Separation from Binary Mixtures: Scandium was extracted in the presence of several ions. The tolerance limit was set as the amount of foreign ion and not salt which is causing an error of less than ±0.5% in the recovery of scandium. Since pH for extraction of scandium and alkali metals are different under condition of extraction of scandium, alkali and alkaline earths are not extracted. Alkali and alkaline earths were tolerated in the ratio of 1 : 6 to 1 : 80 except lithium tolerated in the ratio of 1 : 200. Yttrium, titanium, zirconium, hafnium, and uranium were tolerated in the ratio of 1 : 40 while thorium was tolerated in the ratio of 1 : 4.

Table 5. Separation of Scandium from Binary Mixtures Sc=25 μg, picric acid=4.0×10^{-2} M, 18C6=4.0×10^{-2} M, pH=2.5

The common anions were tolerated in the ratio of 1 : 200 (Table 5).

Separation from Multicomponent Mixtures: A mixture of scandium, cerium(III), and yttrium was separated by first extracting scandium with 4.0×10^{-2} mol dm^{-3} 18C6 from 4.0×10^{-2} mol dm^{-3} picric acid at pH 2.5. Then cerium(III) was extracted with 5.0×10^{-2} mol dm^{-3} 15C5 at pH 6.0. Scandium and cerium were stripped with 0.1 mol dm^{-3} nitric acid and 1 mol dm^{-3} perchloric acid respectively. Since yttrium was not extracted, it was determined directly from the aqueous phase. Since size of the hydrated scandium species is large, it readily reacts with 18-crown-6 to form complex in comparison with that of yttrium in the presence of picrate anion.

Scandium was separated from mixture of scandium, lanthanum, and yttrium by extracting it with 4.0×10^{-2} mol dm^{-3} 18C6 followed by extraction of lanthanum at pH 4.5 with 1.0×10^{-1} mol dm^{-3} 18C6 from 4.0×10^{-2} mol dm^{-3} picric acid. Since yttrium was not extracted, it was determined directly from the aqueous phase.

A mixture of lead, scandium, and aluminium was resolved by first extracting lead with 2.0×10^{-2} mol dm^{-3} DB18C6 at pH 3.0 from 1.0×10^{-2} mol dm^{-3} picric acid followed by extraction of scandium with 4.0×10^{-2} mol dm^{-3} 18C6 from 4.0×10^{-2} mol dm^{-3} picric acid when aluminium was not extracted and it remained unextracted in the aqueous phase.

A mixture of scandium, iron(III), zirconium, and titanium was separated by first extracting scandium with 4.0×10^{-2} mol dm^{-3} 18C6 from 4.0×10^{-2} mol dm^{-3} picric acid. Iron(III) was latter extracted with 1.0×10^{-2} mol dm^{-3} DB18C6 from 7.0 mol dm^{-3} hydrochloric acid followed by extraction of zirconium with 2.5×10^{-2} mol dm^{-3} DC18C6 from 8.5 mol dm^{-3} hydrochloric acid. Titanium remained in the aqueous phase as unextracted species.

Similarly scandium was separated from niobium(V)/uranium(VI), hafnium, and vanadium(IV) by extracting first scandium with 4.0×10^{-2} mol dm^{-3} 18C6 from 4.0×10^{-2} mol dm^{-3} picric acid. The niobium/uranium was extracted with 2.0×10^{-2} mol dm^{-3} DC18C6 from 7.0 mol dm^{-3} hydrochloric acid, finally, hafnium was extracted with 7.0×10^{-2} mol dm^{-3} DC18C6 from 9.0 mol dm^{-3} hydrochloric acid. The unextracted vanadium remained in the aqueous phase (Table 6).

Analysis of Scandium from Real Samples: About 0.5 g of rock sample was dissolved in a mixture of hydrofluoric and nitric acid (1 : 1) and was evaporated to dryness. The solution after filtration was diluted to 250 ml. An aliquat of solution containing barium, iron, zirconium, hafnium, yttrium, vanadium and aluminium was taken and first barium was extracted with 1.0×10^{-2} mol dm^{-3} DB18C8 in nitrobenzene from 1.0×10^{-2} mol dm^{-3} picric acid at pH 6.0 then scandium was extracted with 4.0×10^{-2} mol dm^{-3} 18C6 from 4.0×10^{-2} mol dm^{-3} picric acid at pH 2.5. From the organic phase scandium was stripped with 0.1 mol dm^{-3} nitric acid and determined spectrophotometrically. All other elements did not interfere during the extraction of scandium. The amount of scandium in the rock sample was 3.43% against the standard value of 3.5% which was determined by atomic absorption spectrometer.

The proposed method is simple, rapid, and selective. The total time required for extractive separation and determination is about 2 h. The relative standard deviation was ±1.9%. The separation of scandium from yttrium, lanthanum, cerium, uranium, zirconium, hafnium, and niobium was significant.

Thanks are due to the Council of Scientific and Industrial Research for sponsoring this project and awarding a senior research fellowship to one of the authors (NVD).

Reaction of Amidine Phenylogous with *p*-Benzoquinones

Ahmed M. Nour EL-DIN,* Aboul-Fetouh E. MOURAD, Alaa A. HASSAN, and Mohsen A. GOMAA

(Received October 20, 1990)

N-(4-Dimethylaminobenzylidene)anilines and N^1-(4-dimethylaminophenyl)-N^1,N^2-diphenylformamidine reacted with tetrachloro-, tetrabromo,- and tetrafluoro-*p*-benzoquinones via charge-transfer complexes formation giving 2-monoarylamino-3,5,6-trihalo-*p*-benzoquinones and 2,5-bis(arylamino)-3,6-dihalo-*p*-benzoquinones. The course of the reaction leading to the formation of the products has been interpreted.

Recently, we have shown that azomethines,[1] azomethine *N*-oxides[2] (nitrones), as well as heteroaromatic *N*-oxides[3] form charge-transfer complexes (CTC) with different electron-deficient π-systems as *p*-benzoquinones, tetracyanoethylene, and tetracyanoquinodimethane.

In the previous work[1] concerning the study of the CTC of aryl substituted azomethines with electron-poor *p*-benzoquinones, tetrachloro-*p*-benzoquinone (chloranil, CHL), tetrabromo-*p*-benzoquinone (bromanil, BRL), and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), we found that, the presence of dimethylamino group on the benzylidene ring increases the donor ability of the azomethine compound enough for immediate reaction with the *p*-benzoquinones. This behavior prompted us to study the chemical interaction between different *N*-(4-dimethylaminobenzylidene) anilines (**1a—i**) (Fig. 1), and the electron-deficient *p*-benzoquinones CHL, BRL and tetrafluoro-*p*-benzoquinone (fluoranil, FRL).

On addition of equimolar amounts of *p*-benzoquinones CHL, BRL, and FRL to azomethines (**1a—i**) in ethyl acetate, with admission of air at room temperature, a green color of the transient CTC was observed, which immediately changed to brown color and a solid product precipitated. When the reaction was followed spectrophotometrically, absorption maxima were observed in the range 620—728 nm, and were assigned to the CTC, since both the azomethines (**1a—i**) and the

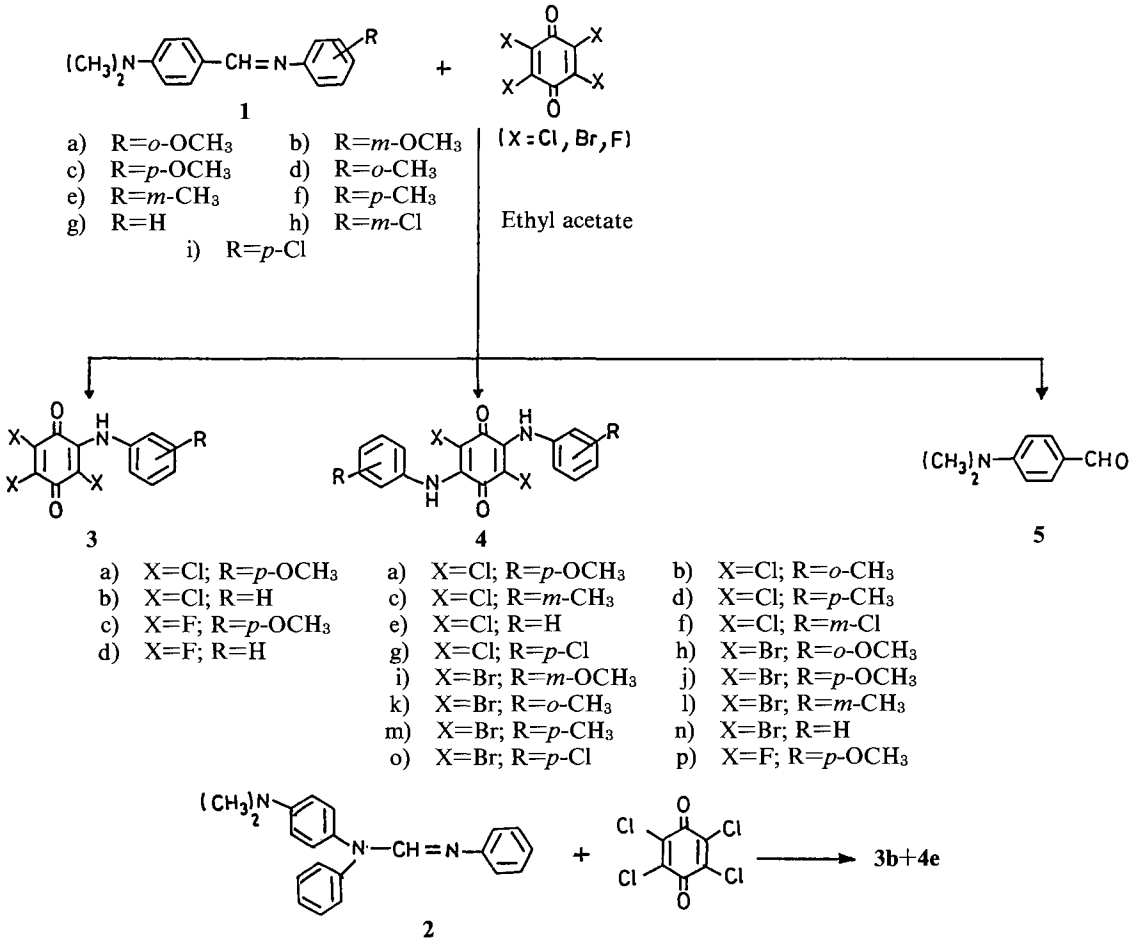

Fig. 1.

p-benzoquinones alone did not absorb in this region[4] (Table 1). The chromatographic separation of the reaction mixtures yielded the 2-arylamino-3,5,6-trihalo-*p*-benzoquinones (**3a—d**) as minor products (10—16%), the 2,5-bis(arylamino)-3,6-dihalo-*p*-benzoquinones (**4a—p**) (41—61%) as major products,[5] and 4-dimethylaminobenzaldehyde (**5**) (Fig. 1).

However, the reactions of other azomethines, which bear methoxy or methyl substituents instead of a dimethylamino group on the benzylidene ring led to the formation of relatively stable CTC and did not give the expected mono- and/or di-arylaminohalo-*p*-benzoquinone products. This result indicates that the presence of dimethylamino group on the benzylidene ring plays an important role in this reaction and is essential for the azomethine **1a—i** to be capable of undergoing this chemical reaction. On the other hand, the structures of the products **3a—d** and **4a—p** show that the active center of the azomethines **1a—i** is the nitrogen atom of the imino group. Thus, it may be assumed that the presence of the good electron-donating dimethylamino group in para position on the benzylidene ring, and consequently in conjugation with it, makes Schiff's bases (**1a—i**) to behave like amidines[6] (⩾N–CH=N–) or phenylogous amidines. This assumption could be rationalized through the formation of both the 2-arylamino- (**3b**) and the 2,5-bis-arylamino- (**4e**) derivatives (Fig. 1) from the reaction of the amidine **2** with chloranil under the same conditions.

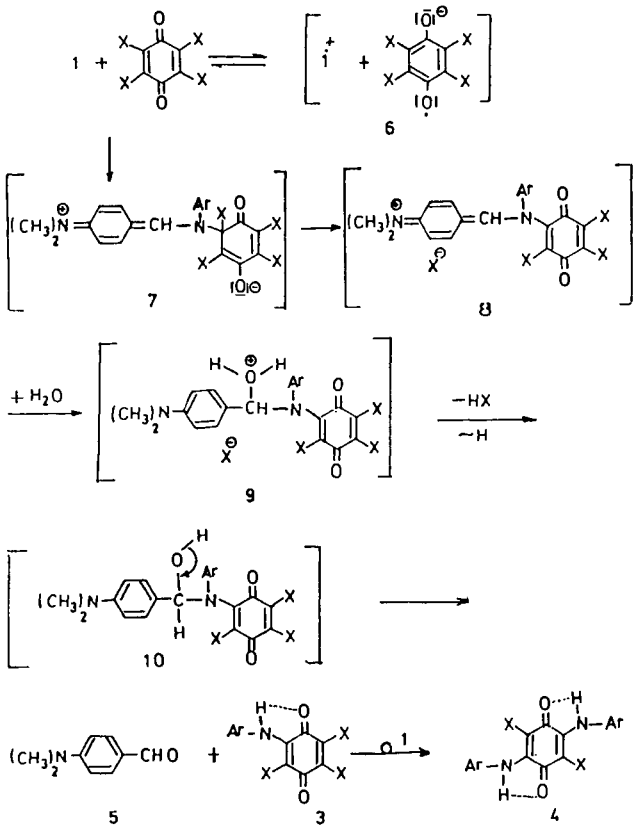

Fig. 2.

Table 1. Absorption (λ_{max}) of the Charge-Transfer Complexes of *p*-Benzoquinones with Various Donors in Dichloromethane at Room Temperature (25 °C)

Donor	Acceptor	λ_{max}/nm	Donor	Acceptor	λ_{max}/nm
1a	CHL	670	**1a**	BRL	710
1b	CHL	695	**1b**	BRL	714
1c	CHL	711	**1c**	BRL	728
1d	CHL	695	**1d**	BRL	717
1e	CHL	693	**1e**	BRL	710
1f	CHL	705	**1f**	BRL	721
1g	CHL	690	**1g**	BRL	707
1h	CHL	686	**1h**	BRL	700
1i	CHL	688	**1i**	BRL	705
1a	FLR	648(sh)	**1b**	FLR	632
1c	FLR	650	**1d**	FLR	641(sh)
1e	FLR	628	**1f**	FLR	640
1g	FLR	625	**1i**	FLR	620
2	CHL	586			

These findings can be interpreted according to Fig. 2. The mixing of the electron-deficient *p*-benzoquinones CHL, BRL, or FRL with each of the donors **1a—i** would lead initially to the formation of CTC **6**, which exists in equilibrium with the two reactants: Then the activation of the nitrogen atom of the imino group through the electron-pair of the dimethylamino group enables their nucleophilic attack on the *p*-benzoquinone forming **7**, which gives the salt **8**. The addition of H_2O molecule to the intermediate **8** followed by dehydrohalogenation, deprotonation on oxygen and protonation on the arylated nitrogen affords the 2-arylamino-*p*-benzoquinones (**3**) and 4-dimethylaminobenzaldehyde (**5**). Hydrolysis of the Schiff's base (which should generate the aldehyde and the free amine Ar–NH_2, which in turn would attack the quinone) prior to reaction with the quinone is considered unlikely, because there is no change in the Schiff's base under the similar conditions where a *p*-benzoquinone is absent. On the other hand, the salt **8** may be attacked by moisture faster than the free Schiff's base. The reaction of **3** with another molecule of amidine phenylogous **1** should lead to the formation of the major product **4** (Fig. 2). Proofs of the structures of the products were based firmly on elemental analysis, UV, IR, ^{1}H NMR, and the mass spectra, chemical reactions, or comparison with authentic samples (Tables 1—4).

Experimental

Melting points are uncorrected. UV-vis spectra were measured on a Perkin-Elmer Lambda 2 spectrophotometer using 1.0 cm stoppered silica cells. IR spectra were measured on a Shimadzu 408 spectrophotometer (KBr). The ^{1}H NMR spectra were recorded on Bruker Wp 80 (80 MHz), and the chemical shifts were expressed as δ (ppm) with TMS as the internal standard. The MS spectra were recorded on Finnigan MAT 8430 spectrometer at 70 eV. Elemental analyses were performed by microanalytical unit at Duisburg University, FRG, using Carlo ERBA strumentazione elemental analyzer Model 1106.

Preparative Layer Chromatography. Air dry 1.0 mm layers of silica gel Merck pf 254 on plates were employed for preparative TLC and bands were detected by indicator fluorescence quenching upon exposure to 254 mm UV-light.

Compounds: 2,3,5,6-Tetrachloro-*p*-benzoquinone (chloranil, CHL, Aldrich) and 2,3,5,6-tetrabromo-*p*-benzoquinone (bromanil, BRL, Merck) were recrystallized several times from benzene before use. 2,3,5,6-Tetrafluoro-*p*-benzoquinone (Fluoranil, FRL, Aldrich) was used without purification. Azomethines **1a—i** were prepared by the usual condensation reaction of 4-dimethylaminobenzaldehyde with substituted aromatic amines.[7,8] The amidine **2** was prepared according to the literature.[9] Ethyl acetate used as a solvent, was purified according to Vogel[10] and Organikum,[11] dried and distilled.

The Reaction of *p*-Benzoquinones, (BRL, CHL, FRL) with Azomethines 1a—i and Amidine[#] 2. General Procedure: To a solution of tetrahalo-*p*-benzoquinone (0.001 mol) in 20 ml dry ethyl acetate, the azomethine (0.001 mol) which was dissolved in 10 ml dry ethyl acetate was added dropwise with stirring at room temperature. The reaction mixture became deep green which turned immediately into brown color. The stirring was continued for 48 h with admission of air to complete the reaction.

The reaction mixture was filtered and the precipitate was washed several times with cold ethyl acetate until the mother liquor became clear. The filtrate was concentrated and the residue was chromatographed on thin-layer plates using toluene as eluent to give two zones; the first contained compound **3** which is characterized by a deep blue color, and the second the 4-dimethylaminobenzaldehyde.

The two zones were extracted with acetone and the products recrystallized from the suitable solvent to afford the pure compounds (see Table 2).

The precipitate was recrystallized from acetone to give a pure compounds of 2,5-bis(arylamino)-3,6-dihalo-*p*-benzoquinone **4**.

We thank DAAD (F.R.G) for the financial support of this work. Thanks are also due to Professor Dr. D. Döpp, Fachbereich Organische Chemie, Duisburg Uni-

[#] In the case of reaction with amidine **2**, the corresponding aldehyde could not be isolated in apure form.

versität, F.R.G, for providing laboratory facilities and for valuable discussions.

Crystalline 1:1 Inclusion Complexes between a Roof-Shaped Diamide Host and Methanol or Propionic Acid. Crystal Structures and Modes of Interaction

Ingeborg CSÖREGH,* Stephan FINGE,† and Edwin WEBER*,†
Department of Structural Chemistry, Arrhenius Laboratory, Stockholm University, S-106 91 Stockholm, Sweden
†Institut für Organische Chemie und Biochemie der Universität Bonn, Gerhard-Domagk-Straße 1, D-5300 Bonn-1, FR-Germany
(Received November 26, 1990)

The crystal structures of two inclusion complexes between *anti-N,N'*-di-*t*-butyl-9,10-dihydro-9,10-ethanoanthracene-11,12-dicarboxamide host and methanol [a=11.8893(4), b=18.0943(7), c=12.6322(4) Å, β=108.47(3)°, $P2_1/c$, Z=4] or propionic acid [a=11.4580(8), b=11.7614(9), c=12.4675(8) Å, α=95.37(3), β=109.70(3), γ=113.26(3)°, $P\bar{1}$, Z=2] as guests have been studied by X-ray diffraction. Closed loops of different sizes, formed via hydrogen-bond interactions between host and guest or between the hosts only, characterize both structures. The crystals with the propionic acid guest consist of hydrogen-bonded host : guest associates with 2 : 2 stoichiometry, while the methanol inclusion gives rise to infinite hydrogen-bonded chains.

Carboxylic acids have been noted as powerful crystalline hosts.[1] Due to their distinct hydrogen bonding properties,[2,3] they make possible crystalline complex formation with a wide range of guests.[4–6] Amides corresponding to the carboxylic acids are also crystalline hosts[7] but show different complexation behavior. An example is the diamide **1** which yielded a crystalline 1 : 1 inclusion compound with methanol (**2**) in a highly selective manner,[8] while the corresponding diacid[9] gave crystalline inclusion complexes with higher alcohols only.[8] Apart from this difference, the inclusion ability of the diacid is much more pronounced.[8] Nevertheless, **1** also yields a crystalline inclusion compound with propionic acid (**3**) which has the same stoichiometric ratio (1 : 1) as the corresponding propionic acid complex

a) Weights of the structure factors in SHELX[12] are estimated as $w=\text{const}/(\sigma^2(F)+g\cdot F^2)$

formed by the mentioned diacid host.[8] Analogs of **1** with less bulky groups than *t*-butyl are inefficient.[8]

For a better understanding of the inclusion properties of **1**, and to learn the general modes of interaction between host amide and different guest functions,[9] we studied the crystal structures of the 1 : 1 complexes of **1** with methanol (**2**) and propionic acid (**3**).

Experimental

Crystals of the inclusion complexes **2** [**1**·methanol (1 : 1)] and **3** [**1**·propionic acid (1 : 1)] were obtained as described earlier.[8] In order to protect the crystals from possible solvent evaporation during the measurements, each selected single crystal of both **2** and **3** was sealed in a glass capillary.

X-Ray Data Collection and Processing. X-Ray diffraction data were collected on a STOE/AED2 diffractometer at room temperature, using the ω–2θ scan technique. Five reference reflections for the crystal of **2** were measured at intervals of about 1 h. No systematic variation of intensity was detected. The six monitor reflections, measured approximately every 45 min for **3**, however, showed a decrease in intensity of about 7%. Moreover, despite the low absorption coefficients of the present crystals (cf. Table 1), significant absorption effects were detected in the case of compound **3**, in all probability due to the mother liquor content of the capillary. Accordingly, the net intensities were corrected for Lorentz and polarization effects, and in the case of **3** also for decay and absorption effects. The absorption correction was based upon ψ scans of eight reflections within the limits $76<\chi<85°$ and $25<2\theta<71°$. The transmission factor varied between 50 and 83%.

The unit cell parameters, listed in Table 1, were refined by least-squares fit to θ values of 57 [$37<2\theta<57°$] and 58 [$16<2\theta<53°$] accurately centered reflections.

Structure Analysis and Refinement

The positions of the non-hydrogen atoms were derived by direct methods [SHELXS][11] and refined by full-matrix least-squares treatment according to Sheldrick.[12] The carbon-bonded hydrogen positions

were calculated after each refining cycle, using geometric evidence. The amide H atoms in both structures, together with the hydroxyl H in **2** and the carboxylic one in **3**, were located from difference electron density maps and were held riding on their respective 'mother' atoms during the subsequent calculations.

In the last stage of the refinements, the C, O, and N atoms were allowed to vibrate anisotropically, while isotropic temperature factors were refined for the H positions. The methyls were treated as rigid groups with three rotation parameters refined for each of them. The final R values together with the crystal data and some details of the refinement calculations are shown in Table 1.

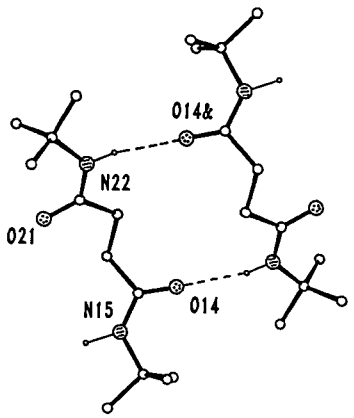

Fig. 2. Diagram of the hydrogen-bonded host–host unit present in the inclusion compounds **2** and **3**. Excerpts of the host molecules including the bridge C-atoms and functional groups only. Hydrogen bonds are indicated by broken lines.

Results and Discussion

The final fractional coordinates and the hydrogen bond dimensions for **2** and **3** are listed in Tables 2 and 3, respectively. The crystallographic labelling of the atoms of the host is shown in Fig. 1. Figure 2 is a schematic representation of the H-bonded host-host interaction found in the complexes. Figures 3 and 4 illustrate the H-bonded host-guest units in **2** and **3**, while the respective crystal packings are shown in Figs. 5 and 6. Intramolecular bond distances and angles and the thermal parameters of the non-hydrogen atoms are collected in Tables 4, 5, and 6.[13]

Molecular Structures. The dihydroanthracene moiety of the diamide host **1**, in both structures, shows the expected roof-shaped form with bond lengths and bond angles in agreement with the data published earlier for related carboxylic host molecules.[8,14,15] Accordingly, the elongated C(9)–C(10) and C(11)–C(12) bonds

Individual cases of zones with host–host and host–guest hydrogen bond contacts are indicated by hatched and dotted areas, respectively.

of the ethano bridge in the present structures have the average length values of 1.577 and 1.562 Å, respectively; the mean C(10)–C(11) bond distance is 1.540 Å, and the dihedral angles[16] between the two aromatic ring planes are 121.0(1)° in **2** and 122.8(2)° in **3**. The bond dimensions in the amide groups, with the calculated mean values of 1.336 Å for N–$C_{(sp^2)}$, 1.486 Å for N–$C_{(sp^3)}$ and 1.231 Å for C=O, also conform to the common values for such bonds.[17] The guest molecules, (methanol in **2** and propionic acid in **3**) have ordered structures with acceptable bond dimensions.

Packing Relations and Host-Guest Interactions. The host **1** as well as the guests (methanol and propionic acid) in the present inclusion complexes are equipped with functional groups (carbamoyl, hydroxyl or carboxyl) possessing both proton donor and proton acceptor ability. Consequently, hydrogen bonds are expected to play an important role in these structures. There are hydrogen bonds between the amide moieties of symmetry-related host molecules (Table 3). These relatively weak N(–H)···O bonds form 14-membered (including the hydrogen atoms) closed loops when linking the hosts pairwise in both compounds (Fig. 2). The 1 : 1 clusters of hosts comprise two proton donor (NH)

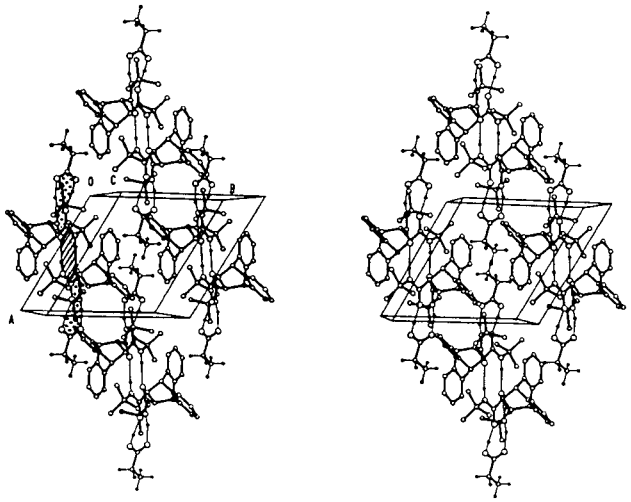

Fig. 6. Stereoscopic view of the crystal packing of **3** (inclusion complex with propionic acid). The nonrelevant hydrogen atoms of the host are omitted for clarity. Hydrogen bonds as thin lines. Individual cases of zones with host–host and host–guest hydrogen bond contacts are indicated by hatched and dotted areas, respectively.

and two proton acceptor sites (C=O) for potential H bond interaction with the guests (see Fig. 2).

Although both guest molecules have typical proton donor and acceptor functions, the H bond interactions between host and guest show different topologies in the present two complexes. In **2**, each methanol is H-bonded to two different host molecules (or host–host clusters), and the two amide moieties of the host are involved in H-bonding with two different guests. Accordingly, a large, 18-membered (including the H atoms) loop is formed around the center of symmetry via two O–H···O and two N–H···O interactions (Fig. 3). In the case of **3**, however, an 11-membered loop is closed via H-bond interactions involving the two amide moieties of one host and the carboxyl group of the guest molecule (Fig. 4).

Thus, in the methanol inclusion crystal, the total hydrogen bonding scheme results in a framework which is infinite in one dimension. It includes 'double chains' of opposite O–H···O and N–H···O hydrogen-bonded strings, running in the crystallographic *a* direction (Fig. 5). By way of contrast, in the propionic acid inclusion, discrete hydrogen-bonded host–guest associates with 2 : 2 stoichiometry are created (Fig. 6). They include a large 24-membered ring with O–H···O and N–H···O hydrogen bonds. Both the supramolecular strings in **2** and the discrete clusters of host–guest units in **3** are shielded by a smooth cover of lipophilic groups, which makes possible a quite dense packing in the crystal. The host–guest associates are held together by van der Waal's forces.

Conclusions

Elucidations of the crystal structures in the present

study provides a rationale for the host properties of **1** and analogous compounds. Normally, amide molecules use their self-complementary hydrogen bonding functionality to form dimers (8-membered hydrogen-bonded rings) in the crystal.[10] Obviously, this causes severe sterical problems for the bulky molecules **1**, both in the intra- and intermolecular sense, except for the extended dimer formation specified in Fig. 2. On the other hand, it is a general rule[10] that good proton donors and acceptors, such as provided by the amide function, are always involved in hydrogen bonding in a crystal structure. Consequently, **1** makes use of suitably shaped proton donor and acceptor guest molecules to accomplish hydrogen bonding in a densely packed host–guest co-crystal. The analogues of **1** with substituents less bulky than *t*-butyl are different.[8] They do not need the aid of a guest molecule for crystallization, and they make no space available for guest molecules. Thus, the present inclusion structures are determined primarily by the bonding characteristics between host and guest and steric requirements in the crystal structure. On the same line, other host molecules with amide functions for selective crystal inclusion may be designed, and the observed interaction patterns are also a promising approach for engineering organic solids.[18]

I.C. is indebted to Professor P. Kierkegaard (Stockholm University) for his continuous interest and encouragement. Financial support from the Swedish Natural Research Council (NFR), and the Deutsche Forschungsgemeinschaft (SFB 334), and the Fonds der Chemischen Industrie is gratefully acknowledged.

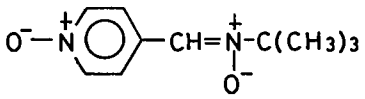
Spin-Trapping of Selenium-Containing Inorganic Radicals in Aqueous Solutions

Toshihiko OZAWA* and Akira HANAKI
National Institute of Radiological Sciences, 9-1, Anagawa-4-chome, Chiba 260
(Received January 9, 1991)

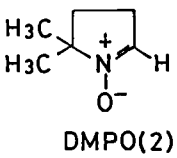
Synopsis. The selenite radical anion, $SeO_3^{\cdot-}$, can be detected by ESR spectroscopy using water-soluble spin-traps, *N*-(4-pyridylmethylene)-*t*-butylamine *N,N'*-dioxide (POBN) and 3,5-dibromo-4-nitrosobenzenesulfonate (DBNBS), but selenate radical anion, $SeO_4^{\cdot-}$, cannot be trapped by POBN or DBNBS.

In continuation of our works[1-4] on the spin-trapping of short-lived inorganic radicals, we have investigated the spin-trapping of selenium-containing inorganic radicals. Selenium is being increasingly recognized as biochemical importance.[5] It is now recognized to be an essential nutrient and is present, for example, in glutathione peroxidase, an enzyme important in the metabolism of hydroperoxides. It also has come out as a significant anticarcinogen. However, the chemistry *per se* is still not understood.[6] Selenium can exist as selenide (Se^{2-}), elemental selenium (Se^0), selenite (SeO_3^{2-}), and selenate (SeO_4^{2-}). Each oxidation state exhibits different chemical behavior. Metal selenides, Se-sulfides, and elemental Se are insoluble, and therefore biologically unavailable. For the pH and redox conditions of aquatic environments, SeO_3^{2-} and SeO_4^{2-} should be dominant forms of Se. Consequently, it is imperative to know the chemical reactivities of these ions. If these ions are oxidized by one electron oxidation, these may produce radical intermediates. However, at present there have been no reports concerning the spin-trapping of radical intermediates formed during the oxidation of the selenium-containing inorganic compounds, the lifetime of which is too short to be detected by conventional ESR measurements. It has been reported that spin-trapping is a technique to detect short-lived free radicals in solutions. That is, this technique involves the ability of spin-trap to react with short-lived free radicals to yield a spin adduct having a longer lifetime, the ESR spectrum of which gives information specially identifying the original radical species.

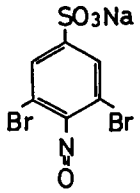
It is known that Ce(IV) is a strong oxidizing agent in acidic aqueous solutions. Then, using this ion as an oxidizing agent, we have examined the spin-trapping of selenium-containing inorganic radicals. We now first report herein selenium-containing inorganic radicals trapped by water-soluble spin-trap.



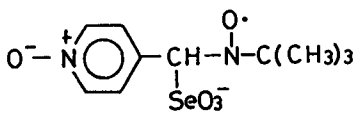
POBN(1)



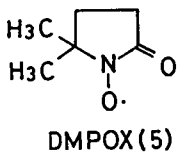
DMPO(2)



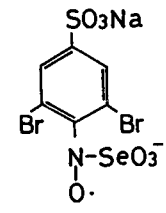
DBNBS(3)



POBN-SeO_3^- (4)



DMPOX(5)



DBNBS-SeO_3^- (6)

Experimental

Materials. Water-soluble spin-traps, *N*-(4-pyridylmethylene)-*t*-butylamine *N,N'*-dioxide (POBN, **1**) and 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO, **2**), were purchased from Sigma Chemical Co. and used without further purification, because no ESR signal was observed when these spin-traps were dissolved in an acidic aqueous solution. Other water-soluble spin-trap, sodium 3,5-dibromo-4-nitrosobenzenesulfonate (DBNBS, **3**) was synthesized as described previously.[7] The selenium compounds, sodium selenite (Na_2SeO_3) and sodium selenate (Na_2SeO_4) were obtained from Wako Pure Chemical Ind., Ltd. and used as received. $Ce(NO_3)_4 \cdot 2NH_4NO_3$ was purchased from Wako Pure Chemical Ind., Ltd. and used as a source of Ce(IV). Other reagents were commercially available. All reaction solutions were prepared from deionized and triply distilled water and their pHs were adjusted to be 2.0 by sulfuric acid.

Measurements. ESR measurements were carried out on a JEOL JES-RE-1X ESR spectrometer (X-band) with 100 kHz field modulation. ESR spectra were recorded at room temperature in a JEOL flat quartz cell. ESR parameters were calibrated by comparison with a standard Mn^{2+}/MgO marker and 1,1-diphenyl-2-picrylhydrazyl (DPPH, g=2.0036). Further, magnetic field was calibrated with NMR field meter (JEOL ES-FC5).

Results and Discussion

Spin-Trapping with POBN. When Ce(IV) solution (1 mmol dm^{-3}) was mixed with the aqueous solution of selenite ion (SeO_3^{2-}) (10 mmol dm^{-3}) containing POBN (10 mmol dm^{-3}), ESR spectrum as shown in Fig. 1 was

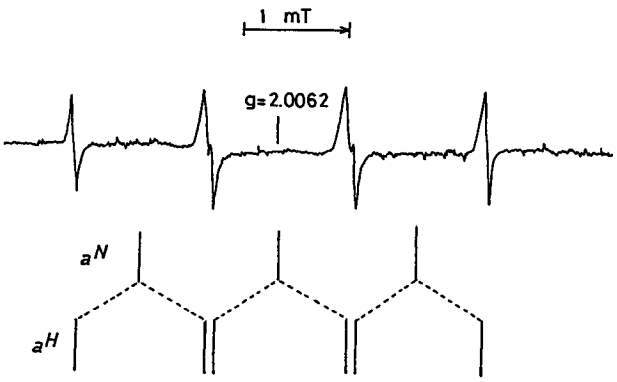


Fig. 1. ESR spectrum observed during the oxidation of SeO_3^{2-} with Ce(IV) in the presence of POBN. Conditions: Ce(IV), 1 mmol dm^{-3}; SeO_3^{2-}, 10 mmol dm^{-3}; POBN, 10 mmol dm^{-3}.

observed. The ESR spectrum could be analyzed as shown by the stick diagram in Fig. 1 and ESR parameters obtained were as follows: $a^N(1)=1.49$ mT, $a^H(1)=1.39$ mT, $g=2.0062$. When either Ce(IV) or SeO_3^{2-} ion was omitted from the solution, no ESR spectrum was observed. Further, Ce(IV) is used as an one-electron oxidant. The potential of Ce(IV)/Ce(III) couple in 1 M H_2SO_4 (1 M=1 mol dm^{-3}) solution is as follows:[8]

$$Ce(IV)+e=Ce(III) \qquad E^0=+1.44\ V \qquad (1)$$

Therefore, the observed radical species is assigned to SeO_3^- adduct of POBN (**4**). The formation of (**4**) can be expressed as follows:

$$Ce(IV)+SeO_3^{2-} \longrightarrow Ce(III)+SeO_3^{\cdot-} \qquad (2)$$

$$SeO_3^- + POBN \longrightarrow (\mathbf{4}) \qquad (3)$$

In this case, hyperfine splitting from ^{75}Se ($I=1/2$, natural abundance 7.50%) was not observed.

On the other hand, no ESR spectrum was observed from selenate ion (SeO_4^{2-}) by oxidation with Ce(IV). The yellow color of aqueous Ce(IV) solutions, however, changed to colorless immediately after additon of selenate solutions, suggesting that Ce(IV) was reduced to Ce(III). Therefore, this result may be considered that POBN cannot form the stable adduct with selenate anion radical, $SeO_4^{\cdot-}$.

Spin-Trapping-with DMPO. ESR spectrum was observed as shown in Fig. 2, when Ce(IV) solution (1 mmol dm^{-3}) was mixed with aqueous solutions of selenite ion (10 mmol dm^{-3}) containing DMPO (10 mmol dm^{-3}). The ESR spectrum could be analyzed as shown by the stick diagram in Fig. 2 and ESR parameters obtained were as follows: $a^N(1)=0.74$ mT, $a^H(2)=0.41$ mT, and $g=2.0070$. ESR spectrum shown in Fig. 2 could not be observed, when either Ce(IV) or selenite ion was omitted from the reaction solution. This ESR spectrum was identical with that of 5,5-dimethyl-2-oxol-1-pyrrolidinyloxyl (DMPOX, **5**)[9] which was generated by the oxidation of DMPO with α-cumyl hydroperoxide–hematin system. Thus, the radical species giving ESR spectrum shown in Fig. 2 can be assigned to DMPOX. The same ESR spectrum as

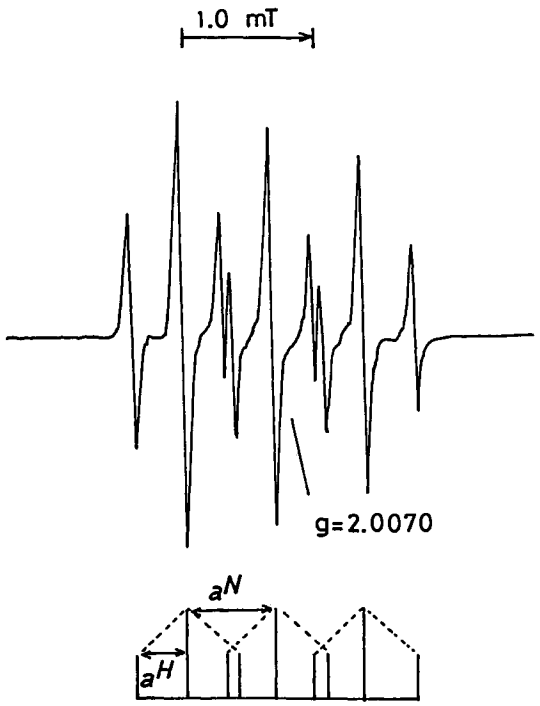

Fig. 2. ESR spectrum obtained during the oxidation of SeO_3^{2-} by Ce(IV) in the presence of DMPO. Conditions: Ce (IV), 1 mmol dm^{-3}; SeO_3^{2-}, 10 mmol dm^{-3}; DMPO, 10 mmol dm^{-3}.

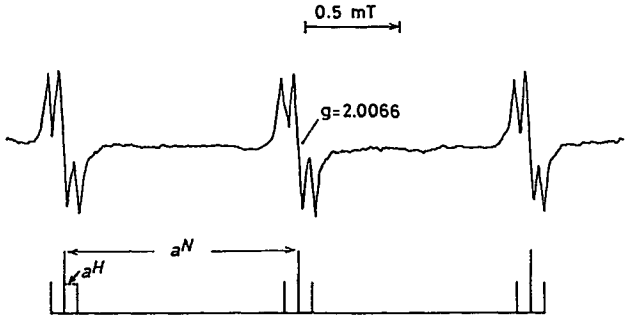

Fig. 3. ESR spectrum observed from the oxidation of SeO_3^{2-} by Ce(IV) in the presence of DBNBS. Conditions: Ce(IV), 1 mmol dm^{-3}; SeO_3^{2-}, 10 mmol dm^{-3}; DBNBS, 10 mmol dm^{-3}.

shown in Fig. 2 was observed when the selenate ion was oxidized by Ce(IV) in the presence of DMPO. Rosen et al. suggsted that DMPOX arises by spin-trapping α-cumyldioxyl radicals followed by base-catalyzed rearrangement.[10] Thus, according to their suggestion, DMPOX may arise by spin-trapping selenite anion radical or selenate anion radical followed by base-catalyzed rearrangement. However, since it is known that the formation mechanism of DMPOX is very complicated,[11] at present the exact reaction scheme is not explained.

Spin-Trapping with DBNBS. When Ce(IV) solution (1 mmol dm^{-3}) was mixed with the aqueous solution of selenite ion (SeO_3^{2-}) (10 mmol dm^{-3}) including DBNBS (10 mmol dm^{-3}), ESR spectrum was observed as shown in Fig. 3. The ESR spectrum could be analyzed as

shown by the stick diagram in Fig. 3 and ESR parameters obtained were as follows: $a^{N}(1)=1.24$ mT, $a^{H}(2)=0.07$ mT, $g=2.0066$. This ESR spectrum could not be observed, when either Ce(IV) or selenite ion was ommited from the reaction solution. Further, the hyperfine splitting constants are similar to the spin adducts of DBNBS with sulfur-containing inorganic radicals such as $SO_3^{\bar{\cdot}}$,[1] $S_2O_3^{\bar{\cdot}}$, and $S^{\bar{\cdot}}$.[4] These results suggest that the radical species observed here are assignable to the spin adduct of DBNBS with $SeO_3^{\bar{\cdot}}$ radical (**6**). In this case, hyperfine splitting due to ^{75}Se was not observed.

On the other hand, no ESR spectrum was obtained from selenate ion (SeO_4^{2-}) by oxidation with Ce(IV). Since Ce(IV) is reduced by SeO_4^{2-} to Ce(III) as described previously, $SeO_4^{\bar{\cdot}}$ radical may be formed. Thus, DBNBS may not give a stable spin adduct with $SeO_4^{\bar{\cdot}}$.

In our experiments, $SeO_4^{\bar{\cdot}}$ radical could not be trapped by water-soluble spin-traps used here. In this case, it is very difficult to distinguish whether $SeO_4^{\bar{\cdot}}$ radical was not generated from the oxidation of SeO_4^{2-} ion with Ce^{4+} or the spin adducts of $SeO_4^{\bar{\cdot}}$ radical was too unstable to be detected by ESR. To elucidate this problem it will be needed to use the some radical scavenger for $SeO_4^{\bar{\cdot}}$ radical, although we can not find out such radical scavenger at present time.

In conclusion, selenite anion radical, $SeO_3^{\bar{\cdot}}$, was first observed by ESR using water-soluble spin-traps, POBN and DBNBS. But, $SeO_4^{\bar{\cdot}}$ cannot be trapped by both spin-traps. Using DMPO as a spin-trap for both $SeO_3^{\bar{\cdot}}$ and $SeO_4^{\bar{\cdot}}$ radicals, oxidation product, DMPOX was formed instead of spin adduct of DMPO.

Synopsis. The complex formation of α- and β-cyclodextrins (CyDs) with *p*-(chloro, bromo, and iodo)fluorobenzenes has been studied in aqueous medium at 25 °C. Formation constants are compared with those of CyD–monohalobenzene systems.

The concept of microscopic binding constant (MBC concept) has been proposed by Connors and Pendergast.[1] They applied the concept to α-cyclodextrin (CyD) complex formations with various 1,4-disubstituted benzenes. In a system consisting of a guest substrate having two sites, X and Y, and a host with a single binding site (α-CyD), two isomeric 1 : 1 complexes can exist, X′Y and XY′, where the superscript prime indicates the binding site. The observed 1 : 1 formation constant, K_{11}^{XY}, is related to microscopic binding constants, $K_{X'Y}$ and $K_{XY'}$, as $K_{11}^{XY}=K_{X'Y}+K_{XY'}$. If the two substrate sites are identical, the equation becomes $K_1^{XX}=2K_{X'X}$.

We studied host–guest associations using α-, β-, and γ-CyDs as hosts and four monohalobenzenes,[2] X–C_6H_5, where X refers to a halogen atom, and four symmetrical *p*-dihalobenzenes,[3] X–C_6H_4–X, as guests. Based on a comparison of their 1 : 1 formation constants, we discussed the validity of the MBC concept.[3] It turned out that the equation, $K_{11}^{XX}=2K_{X'X}$, holds for chloro- and bromobenzene, but this is not the case for fluoro- and iodobenzene. We concluded therefore that the concept does not necessarily apply to α-CyD complex formations with all of symmetrical *p*-disubstituted benzenes.

The present work is concerned with α- and β-CyD complex formations with *p*-dihalobenzenes, X–C_6H_4–Y, where X and Y refer to different halogen atoms. One of the aimes of the present study is to discuss the validity of the MBC concept. There are many possible XY combinations. The formation constants of α- and β-CyD with monohalobenzenes and symmetrical *p*-dihalobenzenes increase with an increase in the size of the halogen atom.[2,3] It is therefore preferable to use either fluoro- or iodobenzene derivatives in order to make clear the difference of another halogen atom. Here we chose *p*-halofluorobenzenes.

In the case of β-CyD complex formations, where the MBC concept cannot be applied, it is of interest to see if there is any relationship between the 1 : 1 association constant of X–C_6H_4–Y and that of X–C_6H_5 and Y–C_6H_5. This is another incentive of the present study.

The method used in this work to determine the association constant is the same as that employed in our previous works,[2–4] and is based on the volatility of guest in aqueous solutions. Volatile guest molecules are driven out to the gas phase by introducing an inert gas at a constant flow rate into the aqueous solution. The volatilization rate is measured with and without addition of CyD; the rate decreases as a result of the association with CyD.

Experimental

Materials and Preparation of Sample Solutions. Deionized distilled water was used throughout the experiments. An appropriate amount of α- or β-CyD of guaranteed grade (Nakarai Chemical Co.), dried over phosphorus pentoxide under vacuum, was weighed and dissolved in water to prepare CyD stock solutions of desired concentrations. Three guest substances, (*p*-chloro-, *p*-bromo-, and *p*-iodo-)fluorobenzenes, were used as received; the minimum purities are 99.0, 98.0, and 98.0%, respectively, as claimed by the manufacturer (Tokyo Kasei Kogyo Co.). An aqueous stock solution of each guest was prepared by adding an excess of each *p*-dihalobenzene to water and stirring for at least 24 h in the dark. After leaving the mixture standing for at least 24 h, a portion of the saturated guest solution was transferred to a separatory funnel and the absorbance of its cyclohexane extract was measured to determine the guest concentration at the following wavelengths: *p*-chloro- at 270 (or 263), *p*-bromo- at 270, and *p*-iodo-fluorobenzene at 271.8 nm.

A portion of the saturated guest solution was transferred into a 2.5φ×25 cm cylindrical glass tube. An appropriate fraction of the CyD stock solution was then added, and the solution was diluted with water to 80 cm³. The concentration ranges of host and guest are given in the footnote of Table 1.

Apparatus and Procedures. The apparatus and the experimental procedure were the same as those described in previous papers.[2,3] Nitrogen gas was bubbled into the aqueous guest solution with or without CyD placed in the cylindrical glass tube immersed in a bath thermostated at 25.0±0.1 °C, at a constant flow rate suitable for each guest volatility: *p*-chloro- at 50, *p*-bromo- at 80, and *p*-iodofluorobenzene at 100 cm³ min⁻¹. The N_2 gas leaving the sample solution was passed through a glass column of 0.5 φ×23 cm filled to 8 cm in length with XAD-2 resin beads (80—150 mesh). The guest adsorbed on the resin within a fixed time was eluted out with 4 cm³ of cyclohexane, and the amount of guest, ΔQ_ϕ, was determined by UV absorption measurements.

Results and Discussion

Determination of Formation Constants. The equation derived in a previous paper[4] was used to estimate the 1 : 1 and 2 : 1 (host : guest) association constants, K_1 and K_2:

$$\ln(C_\phi - Q_\phi V^{-1}) = -kt/(1+K_1C_{CyD}+K_1K_2C^2_{CyD}) + \ln C_\phi = -k't + \ln C_\phi, \quad (1)$$

where C_{CyD} and C_ϕ refer to the total concentration of host and that of guest, respectively, Q_ϕ is the sum of ΔQ_ϕ from time 0 to t, V is the volume of the aqueous solution, k is the rate constant for transfer of guest molecules from the aqueous to gas phase, and

$$K' = k/(1+k_1C_{CyD}+K_1K_2C^2_{CyD}). \quad (2)$$

Rearrangement of Eq. 2 yields

$$1/k' = K_1K_2C^2_{CyD}/k + K_1C_{CyD}/k + 1/k. \quad (3)$$

The plots according to Eq. 1 for all the *p*-halofluorobenzene–CyD systems examined in this work gave straight lines over the whole aeration time, during which ca. 70% of the guest molecules present initially in the sample solutions were purged. Slopes of the resulting straight lines, k' (and k), were evaluated by the least-squares method. Typical $1/k'$ vs. C_{CyD} plots are shown in Figs. 1 and 2. The plots exhibit upward curvatures for α- and β-CyDs, indicating formations of both 1 : 1 and 2 : 1 (host : guest) complexes. The K_1 and K_2 values were determined by the curve-fitting method and are summarized in Table 1. Concerning the present host–guest systems, there are no data available in the literature.

α-Cyclodextrin Complex Formation. According to the MBC concept,[1] the 1 : 1 formation constant is to be 134 for *p*-chlorofluorobenzene (abbreviation; Cl–F), 544 for *p*-bromofluorobenzene (Br–F), and 1134 M^{-1} for *p*-iodofluorobenzene (I–F), where 1 M=1 mol dm^{-3}. The expected value for each guest, however, is not in agree-

Table 1. Formation Constants, K_1 (1 : 1) and K_2 (2 : 1) of (Cyclodextrin: *p*-Halofluorobenzene) Complexes at 25 °C[a]

Guest (*p*-Halofluorobenzene)	Host (Cyclodextrin)	Formation constant	
		K_1	K_2
		M^{-1}	M^{-1}
p-Chlorofluorobenzene	α-CyD	65±4	29±6
	β-CyD	120±2	30±10
p-Bromofluorobenzene	α-CyD	250±7	9±2
	β-CyD	180±40	50±50
p-Iodofluorobenzene	α-CyD	980±30	50±30
	β-CyD	510±20	50±10

a) The total concentration of guest and that of host are as follows: *p*-chlorofluorobenzene ((4.53—4.68)×10^{-4} M) –α-CyD ((1.06—2.51)×10^{-2} M) and –β-CyD ((2.01—5.09)×10^{-3} M); *p*-bromofluorobenzene (2.70—2.82)×10^{-4} M) –α-CyD ((3.01—19.2)×10^{-3} M) and –β-CyD ((1.00—8.03)×10^{-3} M); *p*-iodofluorobenzene ((1.69—2.32)×10^{-6} M) –α-CyD ((0.258—2.04) ×10^{-3} M) and –β-CyD ((1.01—3.02)×10^{-3} M).

ment with the corresponding experimental value.

Of halogen atoms, iodine with the van der Waals radius of 2.2 Å best fits to the cavity of α-CyD. The van der Waals contact area within the cavity decreases in going from iodine to fluorine atom. This is the reason that the K_1 of iodobenzene is much larger than that of fluorobenzene.[2] When α-CyD associates with the I–F guest, the host molecule is expected to associate preferentially with the iodine atom of this guest. Under the present experimental conditions where CyD molecules are always in large excess of guest molecules, there are many chances for CyD molecules to come into contact with the fluorine atom side of I–F. Nevertheless, it does not seem that the association with the fluorine atom contributes to the K_1 of I–F, because this value is almost equal to the K_1 of iodobenzene itself.

It is noteworthy that the K_1 of Cl–F or Br–F is considerably smaller than that of chlorobenzene or bromobenzene itself. This is in conflict with the MBC concept and is difficult to explain even if the association with the fluorine atom of Cl–F or Br–F is assumed not to occur. Here we postulate that the fluorine atom has a negative contribution to α-CyD complex formations, that is, the presence of this atom reduces the K_1 of Cl–F or Br–F (or I–F) that would be expected from the corresponding mono(chloro, bromo, or iodo)benzene. This assumption is made based on the fact that symmetrical *p*-difluorobenzene has a much smaller K_1 value than that of monofluorobenzene itself. The addition of an F atom to the para-position of the benzene ring might render the guest molecule somewhat hydrophilic (not the guest molecule as a whole, but locally, probably at around the F atom), which is unfavorable to the association with CyD.

When a substituent is the methyl group, a typical hydrophobic group, the MBC concept holds. For instance, as was pointed out in a previous paper,[3] the toluene (K_1=33±3)–*p*-xylene (K_1=72±7 M^{-1})[4] system supports the concept.

Connors and Pendergast derived an equation which correlates 2:1 (host:guest) formation constants to microscopic binding constants.[1] In the present paper, however, we are not concerned with this point, because K_2 values are in general less reliable than K_1 values.

β-Cyclodextrin Complex Formation. Since β-CyD can include a benzene ring as a whole, the MBC concept is not applicable to 1,4-disubstituted benzenes unless the substituent groups are not so large as to hinder the approach of a β-CyD molecule to the benzene ring.

We see an interesting relationship between the K_1 of Cl–F, Br–F, or I–F and that of the corresponding monohalobenzene. Namely, the K_1 of Cl–F, Br–F, or I–F is neary equal to half the sum of the K_1 of fluorobenzene and that of chloro-, bromo-, or iodobenzene, respectively. It should be mentioned here that this relationship does not hold for the toluene (K_1=140±10) –*p*-xylene (K_1=240±10 M^{-1})[4] system; in this case, the K_1 of *p*-xylene is approximately twice that of toluene. A further study is necessary using various kinds of both symmetrical and unsymmetrical 1,4-disubstituted benzenes as guests to see whether this arithmetic mean is a general rule for unsymmetrical guests or only applicable to the *p*-dihalobenzene series.

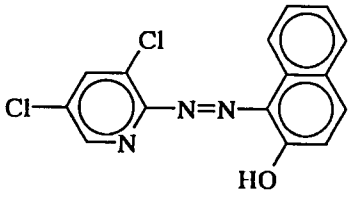
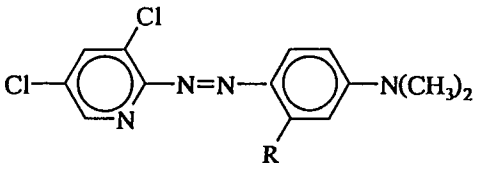
Synopsis. New ligands, 1-(3,5-dichloro-2-pyridyl-azo)-2-naphthol, 2-(3,5-dichloro-2-pyridyl-azo)-5-(dimethylamino) phenol, and 2-(3,5-dichloro-2-pyridyl-azo)-5-(dimethylamino)benzoic acid, were synthesized. Changes in the reduction potentials and electronic spectra of the ligands upon complexation with Ni(II), Zn(II), and Cd(II) were studied. The dissociation constants of the ligands and the stability constants of their metal(II) complexes are discussed.

It is well known for pyridylazo compounds that introduction of halogen or dimethylamino groups on appropriate aromatic ring enhances the sensitivity of photometric determination of a given metal ion, and these substituents are advantageous for metal determination because the absorption peak wavelengths of ligands themselves and those of the complexes are shifted from the ultraviolet to visible region.[1] In view of this, 1-(3,5-dichloro-2-pyridyl-azo)-2-naphthol (abbr. as $Cl_2\beta$PAN), 2-(3,5-dichloro-2-pyridyl-azo)-5-(dimethylamino)phenol (Cl_2DMPAP) and 2-(3,5-dichloro-2-pyridyl-azo)-5-(dimethylamino)benzoic acid (Cl_2PAMB) were newly synthesized in the present work, and their complexing equilibria with Ni(II), Zn(II), and Cd(II) were studied both polarographically and spectrophotometrically.



$Cl_2\beta$PAN



R=OH : Cl_2DMPAP
R=COOH : Cl_2PAMB

Experimental

Preparation of Ligands. $Cl_2\beta$PAN was prepared by coupling 2-naphthol with 3,5-dichloro-2-pyridyldiazonium salt synthesized according to a previous paper.[1c] Yield, 10.8%; mp 191—192 °C. Found: C, 56.83; H, 3.08; N, 13.49%. Calcd for $C_{15}H_9N_3OCl_2$: C, 56.63; H, 2.85; N, 13.21%. IR ($\nu_{N=N}$) 1365 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=6.60 (1H, d, J=9.90 Hz, H-8), 7.40—7.63 (3H, m, H-4, H-5, H-6), 7.66 (1H, d, J=9.90 Hz, H-7), 7.76 (1H, d, J=1.8 Hz, H-4'), 8.41 (1H, d, J=1.8 Hz, H-8'), 8.53 (1H, dd, J=6.3 and 1.4 Hz, H-3), 16.32 (1H, br, s, OH). Cl_2DMPAP was synthesized in a similar manner. Yield, 12.1%; mp 189—191 °C. Found: C, 49.90; H, 4.00; N, 17.80%. Calcd for $C_{13}H_{12}N_4OCl_2$: C, 50.18; H, 3.99; N, 18.01%. IR ($\nu_{N=N}$) 1300 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=3.32 (6H, s, 2×CH_3), 6.05 (1H, d, J=2.4 Hz, H-6), 6.60 (1H, dd, J=10.2 and 2.4 Hz, H-4), 7.62 (1H, d, J=10.2 Hz, H-3), 7.86 (1H, d, J=3.0 Hz, H-4'), 8.47 (1H, d, J=3.0 Hz, H-6'), 16.11 (1H, br, s, OH). Cl_2PAMB was obtained by a similar procedure. Yield, 5.9%; mp 198—202 °C. Found: C, 49.48; H, 3.45; N, 16.20%. Calcd for $C_{14}H_{12}N_4O_2Cl_2$: C, 49.58; H, 3.57; N, 16.52%. IR ($\nu_{N=N}$) 1296 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=3.23 (6H, s, 2×CH_3), 6.85 (1H, dd, J=9.0 and 3.0 Hz, H-4), 7.68 (1H, d, J=3.0 Hz, H-6), 7.87 (1H, d, J=2.4 Hz, H-4'), 8.06 (1H, d, J=9.0 Hz, H-3), 8.40 (1H, d, J=2.4 Hz, H-6'), 14.35 (1H, br, s, OH). These compounds are slightly soluble in water, methanol, and ethanol, and readily soluble in dioxane, benzene, and chloroform. All the solutions of the ligands and the metal (II) complexes were prepared with aqueous 60% (v/v) dioxane.

Measurements. ^{1}H NMR spectra were recorded on a JEOL JNM-EX90 FT NMR spectrometer. IR spectra were recorded on a JASCO A-102 spectrometer (KBr disk). Electronic spectra were recorded on a Hitachi 220A recording spectrophotometer. Polarograms were obtained on a Yanaco Polarographic Analyzer P-1100 as described previously,[2] in an aqueous 60% (v/v) dioxane solution.

Results and Discussion

Protonation Constants of Ligands. All of the dissociation constants of the ligands were obtained by the Hildebrand-Reilly's method.[3] The values are summarized in Table 1 together with those of analogous ligands for comparison. The larger pK_{ai} values of hydroxyl groups in $Cl_2\beta$PAN and Cl_2DMPAP than

Table 1. Dissociation Constants of the Ligands

Aq 60% (v/v) dioxane soln, μ=0.1 (KNO_3), 25.0± 0.5 °C. All the experimental errors are within ±0.05 in pK_a unit in this work. The dissociations of proton are from: a) nitrogen atom in pyridine moiety; b) HO- in naphthol moiety; c) nitrogen atom in dimethylamino group; d) HO- in phenol moiety; e) HOOC-. βN=2-naphthol; AP=3-aminophenol; MAB=4-dimethylaminobenzoic acid.

those of βNS and AP indicate the presence of strong intramolecular hydrogen bonding[2] between the azo and hydroxyl groups in Cl_2βPAN and Cl_2DMPAP. The ^{1}H NMR data for these ligands are in line with this speculation, namely, the signal of the proton of the hydroxyl groups in these ligands appears in very low magnetic fields (δ=16.32 for Cl_2βPAN and 16.11 for Cl_2DMPAP). On the other hand, the pK_{ai} value of the carboxyl group in Cl_2PAMB is lower than that of MAB. This may reflect a strong electron-attractive ability of the dichloropyridylazo group rather than weak intramolecular hydrogen bonding between the azo and carboxyl group in Cl_2PAMB, which has a highly distorted six-membered ring by forming the intramolecular hydrogen bonding as speculated from a molecular model.

Coordination Modes in Metal (II) Complexes. Figure 1 shows the relation between the pH and the reduction potential of the azo group. For Cl_2βPAN and Cl_2DMPAP, it is particularly noteworthy that the half-wave potentials are markedly shifted toward positive potentials region at pH=10.9 and 11.3, respectively, where the proton in the hydroxyl group at an ortho position to the azo group will be dissociated (see Table 1). This means that a very strong hydrogen bond formed between the proton of the hydroxyl group and the N atom in the azo group is abruptly destroyed at this pH; the azo group is thus easily reduced at this pH by a positive shift effect.[4] In Cl_2PAMB, however, the reduction potential of the azo group is only dependent on pH, but independent of the kinds of the ligand species, since the hydrogen bonding is very weak. The reduction potentials of the ligands in Ni(II) complexes are markedly negative of those of free ligands at the same pH, showing stabilization by a negative shift effect.[5,6] This means that, for these complexes, stable chelate rings involving the azo group are formed. The magnitude of the shift for the metal (II) complexes was in the order of Ni(II)>Zn(II)>Cd(II).

It is seen in Fig. 2 that the absorption for the $\pi\rightarrow\pi^*$ transition[7] in the metal (II) complexes markedly shift to lower wavenumbers compared with those of the HL species. In addition, the absorption band of the complexes is split into two peaks, although this splitting is not very clear for the Cl_2PAMB complexes. Similar shifts upon complexation were reported in metal (II) complexes of analogous ligands forming *N,N,O*-terdentate chelate rings.[7] Accordingly, the above mentioned changes in the reduction potentials and absorption spectra of the azo group by complexation strongly suggest that these ligands coordinate to metal (II) ions with *N,N,O*-(N atom in the pyridine ring, N atom in the

azo group adjacent to the naphthol, phenol, or benzoic acid ring, O atom of the naphtholate, phenolate, or benzoate)terdentate. In these ligands, no formation of tetrahedral complexes is anticipated in view of the steric restriction since the three coordination sites (*N,N,O*) lie on the same plane. The structure of these complexes may be a six-coordinated octahedron. In the case of 1 : 1 complexes three water molecules as solvent would be coordinated as $ML(H_2O)_3$, and in 1 : 2 complexes two *N,N,O*-terdentate ligands coordinated to a metal (II) ion.

Stability Constants of Metal (II) Complexes. For all the metal (II)-ligand combinations, pH variation of the complex solution led to a spectral change with a clear isosbestic point due to the presence of an equilibrium. The complexing equilibria could thus be analyzed as described previously.[2]

Table 2 summarizes the results. The complexes formed were very stable in a wide pH range up to about pH=12. The maximum molar absorptivity exceeds 10^5 for the Ni(II) complexes with Cl_2DMPAP and Cl_2PAMB, and the Zn(II) complex with Cl_2PAMB. Therefore Cl_2DMPAP and Cl_2PAMB are useful as highly sensitive spectrophotometric reagents. The stability constants, after a final correction for the side-reaction coefficients of ligands using the values in Table 1 and the values for metal (II) ions,[8] are listed in Table 2. The β_1 values of Zn(II) and Cd(II), having filled *d* shells, with $Cl_2\beta$PAN and Cl_2DMPAP are significantly larger than those of other complexes with inorganic or amino acid ligands[8] having no π conjugated system. Namely, this can be contributed to the strong π back-donation in these complexes, since all the ligands have conjugated system which is formed between the pyridine ring and the phenol, naphthol, or benzoic acid ring via the azo group. On the other hand, the magnitude of β for the Cl_2PAMB complex is very small. This probably reflects the situation that Cl_2PAMB forms a metal (II) complex involving a five-membered ring and a highly distorted six-membered ring as suggested by molecular model. As noted in Table 1, the pK_a (4.59) of Cl_2PAMB is much smaller than those of the other two ligands (10.91 for $Cl_2\beta$PAN and 11.29 for Cl_2DMPAP).

Effects of Six-Membered Chelate Rings in the Oxidant Cobalt(III) Complexes on the Stereoselective Oxidation of $[Co(en)_3]^{2+}$

Akira TATEHATA* and Hiromi AKITA
Department of Chemistry, Faculty of Science, Shizuoka University, Ohya, Shizuoka 422
(Received January 28, 1991)

Synopsis. The stereoselectivities in the oxidation of $[Co(en)_3]^{2+}$ by chiral cobalt(III) complexes containing six-membered chelate ligands, such as malonate, β-alaninate, and acetylacetonate ions, were examined. All of the oxidant complexes with the Δ-configuration studied here, like the corresponding oxalato and glycinato complexes containing five-membered chelate rings, led to an excess of Λ-$[Co(en)_3]^{3+}$, with the exception of Δ-$[Co(ox)(acac)_2]^-$.

There have been some studies on stereoselective electron-transfer reactions between cobalt(II) and cobalt(III) complexes.[1-4] Most of them, however, were limited to the oxidation of cobalt(II) amine complexes by $[Co(edta)]^-$ and its derivatives. Then, as shown for the $[Co(en)_3]^{2+}$-$[Co(edta)]^-$ system (en=ethylenediamine and edta=ethylenediaminetetraacetate ion), it was thought that the ion-pairing stereoselectivity must play a dominant role in the electron-transfer stereoselectivity. Recently, we reported that even the Δ-$[Co(ox)_2(en)]^-$, Δ-C_2-*cis(N)*- and Δ-*trans(N)*-$[Co(ox)(gly)_2]^-$ (ox=oxalate ion and gly=glycinate ion), which form favorable pairs with Λ-$[Co(en)_3]^{3+}$, oxidized $[Co(en)_3]^{2+}$ to produce an excess of Λ-$[Co(en)_3]^{3+}$.[5] This indicates that there exist systems in which the observed stereoselectivity in the electron-transfer reaction is different from the ion-pairing stereoselectivity. Thus, in order to obtain more detailed information about the stereoselective reaction mechanisms, it is important to know what kinds of factors affect the electron-transfer stereoselectivity between metal complexes. In this paper, the influence of six-membered chelate rings in the chiral oxidant cobalt(III) complexes are examined.

Experimental

Preparation of Complexes. $K_3[Co(mal)_3]\cdot 3H_2O$ (mal=malonate ion) was prepared and resolved according to a method by Butler and Snow,[6] with Λ-lel$_3$-$[Co(+pn)_3]Cl_3$ (+pn=(S)-1,2-propanediamine) used as a resolving agent. Several Δ anionic complexes ($[Co(mal)_2(gly)]^{2-}$,[7] $[Co(mal)_2(\beta\text{-ala})]^{2-}$,[7] $[Co(ox)_2(\beta\text{-ala})]^{2-}$,[7] $[Co(ox)_2(acac)]^{2-}$,[8] $[Co(ox)(acac)_2]^-$,[8] $[Co(mal)_2(en)]^-$,[9] and C_1-*cis(N)*-,[10] C_2-*cis(N)*-,[10] and *trans(N)*-[11]$[Co(ox)(\beta\text{-ala})_2]^-$ (β-ala=β-alaninate ion and acac=acetylacetonate ion)) were prepared according to methods described in the literature, and were isolated as their sodium or potassium salts. *fac*-[12] and *mer*-[13]$[Co(\beta\text{-ala})_3]$ were resolved by the chromatographic methods of Yoneda and co-workers. All of the complexes presently obtained were confirmed by the absorption and circular dichroism (CD) spectra, and were then used as the oxidant in electron-transfer reactions with $[Co(en)_3]^{2+}$.

Electron-Transfer Stereoselectivity. Measurements of electron-transfer stereoselectivity were made in the same manner as in a previous study.[5] The maximum absorbance and CD spectrum in the first absorption region of the $[Co(en)_3]^{3+}$ product collected in 1.5 M HCl (1 M=1 mol dm^{-3}) were measured by a Jasco Uvidec-320 spectrophotometer and a Jasco J-500 spectropolarimeter, respectively, using 2 cm cells. The stereoselectivity was expressed in terms of enantiomeric excess (%ee) by evaluating the optical purity of the $[Co(en)_3]^{3+}$ product. Each standard deviation of %ee in this study was smaller than ±0.2%ee for at least triplicate runs.

Ion-Pairing Stereoselectivity. A column (φ 1.0 cm×55 cm) of SP-Sephadex C-25 cation exchanger, saturated with chiral $[Co(en)_3]^{3+}$, was prepared. When the anionic or neutral complex (3 cm^3 of 10—15 mmol dm^{-3}) was passed through the column with water, a partial resolution took place. The enantiomer which interacts favorably with the chiral $[Co(en)_3]^{3+}$ anchored to the ion exchanger can be expected to be eluted later from the column. Thus, favorable pairs between $[Co(en)_3]^{3+}$ and the complexes used as the oxidant were chromatographically determined by examining the late-eluted enantiomer.

Results and Discussion

In Table 1 are summarized the enantiomeric excesses of $[Co(en)_3]^{3+}$ produced by electron-transfer reactions of $[Co(en)_3]^{2+}$ with Δ-anionic or neutral complexes containing six-membered chelate rings and the enantiomers of $[Co(en)_3]^{3+}$ which form favorable pairs with the Δ-oxidant complexes, together with previous results for complex systems containing the corresponding five-membered chelate rings. It has been pointed out that the oxidation of $[Co(en)_3]^{2+}$ by chiral $[Co(mal)_3]^{3-}$ leads to a much lower stereoselectivity than that by chiral $[Co(ox)_3]^{3-}$.[4,5] A similar trend has been observed for bis(malonato) complexes such as $[Co(mal)_2gly]^{2-}$ and $[Co(mal)_2(\beta\text{-ala})]^{2-}$, although the differences in magnitude of stereoselectivity between bis(malonato) and the corresponding bis(oxalato) complexes are considerably smaller than that between the tris complexes. The complexes of the type $[Co(ox\text{ or }mal)_2(gly\text{ or }\beta\text{-ala})]^{2-}$ possess a pseudo-C_3 carboxylate face capable of forming hydrogen bonds with N–H protons of $[Co(en)_3]^{3+}$ and, therefore, were classified as the C_3^- group by Miyoshi and Yoneda.[14] This group of anionic complexes shows the same stereoselectivity in the electron-transfer reaction as that in ion-pairing reaction (ΛΔ preference). On the other hand, $[Co(mal)_2en]^-$ showed a more enhanced electron-transfer stereoselectivity than did $[Co(ox)_2en]^-$, and the electron-transfer (ΛΔ preference) and the ion-pairing stereoselectivities (ΔΔ preference) by $[Co(mal)_2en]^-$ were opposite to each other, unlike the above C_3^- group complexes, in direction in the same manner as those by $[Co(ox)_2en]^-$. These anionic complexes were expected to interact with $[Co(en)_3]^{3+}$ along their C_2 axes and, thus, were classified as the C_2^- group;[14] the above results, therefore, indicate that bis(malonato) chelates lead to either a lower or higher electron-transfer stereoselectivity than do the corresponding bis(oxalato) chelates according as they belong

Table 1. Electron-Transfer and Ion-Pairing Stereoselectivities

Erroneously given in Ref. 5 and thus corrected here. e) Very small stereoselectivity. f) Virtually no detectable stereoselectivity. g) Also reported in Ref. 14.

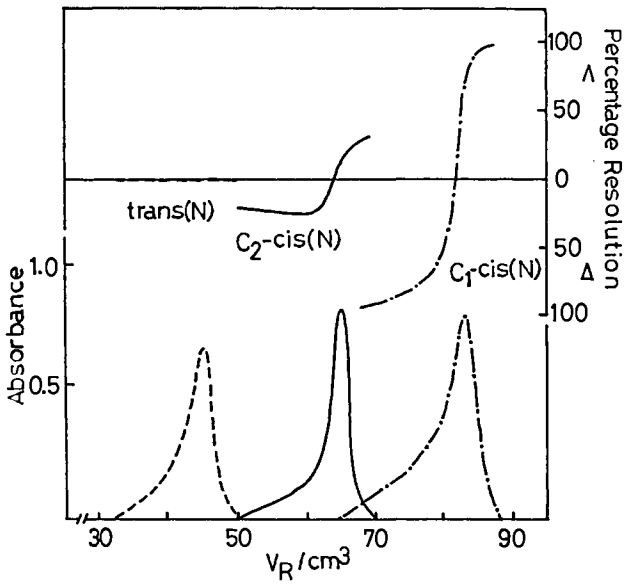

Fig. 1. Elution curves and percentage resolutions for *trans(N)*-, C_2-*cis(N)*-, and C_1-*cis(N)*-$[Co(ox)(\beta\text{-ala})_2]^-$ by Δ-$[Co(en)_3]^{3+}$ form SP-Sephadex column using H_2O as an eluent.

to either the C_3^-or C_2^- group. This suggests that the interaction mode of malonato complexes with $[Co(en)_3]^{2+}$ plays an important role regarding the magnitude of electron-transfer stereoselectivity.

For β-alaninato complexes, apart from *trans(N)*-$[Co(ox)(\beta\text{-ala})_2]^-$, which show virtually no detectable stereoselectivities in both the electron-transfer and the ion-pairing reactions (Fig. 1), all of the β-alaninato complexes with the Δ-configuration used here produced excess Λ-$[Co(en)_3]^{3+}$, although the electron-transfer and ion-pairing stereoselectivities by tris(β-alaninato) complexes were inverted in same manner as those by $[Co(ox)_2en]^-$ and $[Co(mal)_2en]^-$. Thus, in spite of large size and conformational lability of the six-membered chelate ring, it may be concluded that the observed electron-transfer stereoselectivity by the malonato and β-alaninato complexes was the same in direction as that by the corresponding oxalato and glycinato complexes containing five-membered chelate rings.

Finally, for the acetylacetonato complexes, the mono(acetylacetonato) complex, $[Co(ox)_2(acac)]^{2-}$ showed essentialy the same electron-transfer stereoselectivity as did $[Co(ox)_2gly]^{2-}$ and $[Co(ox)_2(\beta\text{-ala})]^{2-}$. However, the bis(acetylacetonato) complex, Δ-$[Co(ox)(acac)_2]^-$, was the only oxidant complex which produced an excess of Δ-$[Co(en)_3]^{3+}$ in the present study. The favorable ion pair of $[Co(en)_3]^{3+}$ with $[Co(ox)(acac)_2]^-$ was $\Lambda\Delta$, similar to that with $[Co(ox)_2acac)]^{2-}$. At present, it is difficult to explain the unique phenomenon caused by $[Co(ox)(acac)_2]^-$. The selectivities in the oxidation reactions by various acetylacetonato complexes need to be examined further.

Solvent Bulkiness Effect on *N,N*-Dimethylformamide Exchange of the *o*-Phenylenediamine-*N,N,N',N'*-tetraacetatoferrate(III) Complex as Studied by a High-Pressure NMR Method

Masafumi MIZUNO, Shigenobu FUNAHASHI,* Noriyuki NAKASUKA, and Motoharu TANAKA
Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464-01
(Received February 1, 1991)

Synopsis. Activation parameters for solvent exchange of the title complex in *N,N*-dimethylformamide (DMF) have been determined as follows: k (25 °C)=(3.4±0.2)×10^7 s^{-1}, $\Delta H^{\ddagger}$=18±3 kJ mol^{-1}, $\Delta S^{\ddagger}$=−40±10 J K^{-1} mol^{-1}, and $\Delta V^{\ddagger}$=10±2 cm^3 mol^{-1}. The positive value of $\Delta V^{\ddagger}$ indicates that the DMF exchange proceeds via a dissociative interchange mechanism.

Rates for the complexation of d^5 iron(III) ion have been found to be greatly affected by the electron donecity of the bound ligand and the bulkiness of coordinated solvent molecules in several solvents.[1-3] The purpose of this work is to demonstrate the effects of the bound multidentate ligand and the solvent bulkiness on the solvent exchange of iron(III) complexes in terms of activation parameters. Recently we have reported the bound ligand effect on the water exchange of the iron(III) complex with *o*-phenylenediamine-*N,N,N',N'*-tetraacetate (phdta^{4-}) in aqueous solution.[4] In order to investigate the solvent bulkiness effect on solvent exchange rate, we selected *N,N*-dimethylformamide (DMF) as a bulky solvent.

Experimental

Oxygen-17-enriched DMF was synthesized according to the reference method.[5] The ^{17}O-enriched DMF was purified by distillation over the 4A Molecular Sieves. PhDTA and its iron(III) complex were prepared by the procedures previously described.[4] The preparation of the sample solution for variable-temperature NMR measurement was carried out by the freeze-thaw technique under vacuum. Transfer of the sample solution into a high-pressure NMR tube (o.d. 7 mm) was performed under nitrogen gas in a dry box.[6,7] The concentration of Fe(III)-PhDTA in sample solutions ($C_{\mathrm{Fe(III)\text{-}PhDTA}}$) is given in the Figure caption.

Variable-temperature Fourier-transform ^{17}O NMR spectra were measured with JEOL JNM-FX100 and JNM-GX270 NMR instruments operating at 13.50 and 36.63 MHz, respectively. Variable-pressure FT oxygen-17 NMR spectra were obtained with a JEOL-FX100 NMR spectrometer equipped with a high-pressure NMR probe.[6] Temperature and pressure were measured by the same methods as reported previously.[4]

The structure of Fe(III)-PhDTA in the DMF solution should be similar to that in water: The central iron(III) ion is seven-coordinate, with one DMF molecule being solvated.[4] Thus the DMF exchange at the iron(III) complex is expressed by Eq. 1.

$$[\mathrm{Fe(dmf^*)(phdta)}]^- + \mathrm{dmf} \rightleftarrows [\mathrm{Fe(dmf)(phdta)}]^- + \mathrm{dmf^*}. \quad (1)$$

The exchange rate of solvent molecules between the bulk and the coordination site of a paramagnetic metal ion has been estimated from the transverse relaxation time (T_{2P}) of the bulk solvent nuclei. The solvent ^{17}O NMR line broadening, $(T_{2P}P_M)^{-1}$, due to the paramagnetic iron(III) complex is expressed as $(T_{2P}P_M)^{-1}=\pi(\Delta\nu_{obsd}-\Delta\nu_{solv})P_M^{-1}$, where $\Delta\nu_{obsd}$ and $\Delta\nu_{solv}$ are the half-height widths of the ^{17}O NMR spectra of DMF in the bulk in the presence and absence, respectively, of Fe(III)-PhDTA. P_M is the ratio of the number of DMF molecule bound to the iron(III) complex to that of DMF molecules in the bulk. NMR line broadening data were analyzed on the basis of the modified Swift-Connick equation.[4,8]

Results and Discussion

Figure 1 shows the temperature dependence of $(T_{2P}P_M)^{-1}$ for the Fe(III)-PhDTA complex in DMF over the range from −58 to 72 °C. Since the transverse relaxation rate due to the bound DMF in the absence of exchange, T_{2M}^{-1}, is small enough compared with the other relaxation terms over the observable temperature region for the present system, the modified Swift-Connick equation is reduced to Eq. 2:

$$(T_{2P}P_M)^{-1} = 1/(\tau_M^{-1}\Delta\omega_M^{-2} + \tau_M), \quad (2)$$

where τ_M is the residence time of the solvent molecule in the inner sphere of the iron(III) complex and $\Delta\omega_M$ is the shift between bulk and bound DMF resonances when no exchange occurs. The temperature dependence of $\Delta\omega_M$ is assumed to be $\Delta\omega_M=-C_\omega/T$.[9,10] A nonlinear least-squares analysis of the data led to the following parameters by fitting to Eq. 2: $\Delta H^{\ddagger}$/kJ mol^{-1}, $\Delta S^{\ddagger}$/

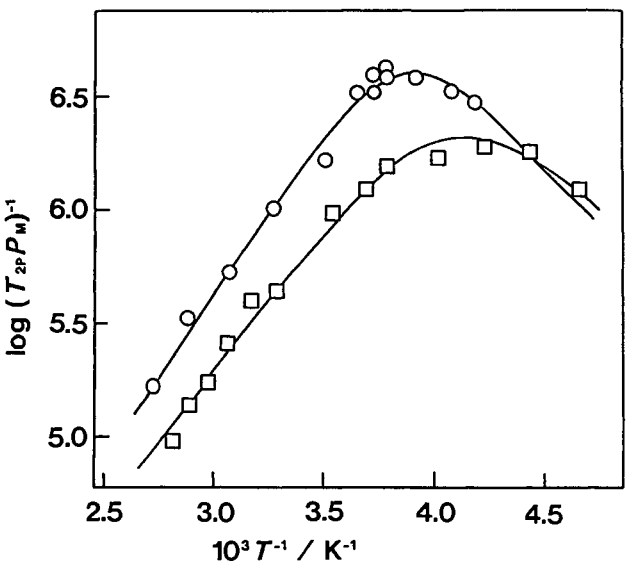

Fig. 1. Variation of the solvent DMF oxygen-17 relaxation rates $(T_{2P}P_M)^{-1}$ with temperature for Fe(III)-PhDTA in DMF solution. $C_{\mathrm{Fe(III)\text{-}PhDTA}}$= 4.50×10^{-3}, 7.03×10^{-3}, and 1.85×10^{-2} mol kg^{-1}. ○: 36.63 MHz ^{17}O; □: 13.50 MHz ^{17}O.

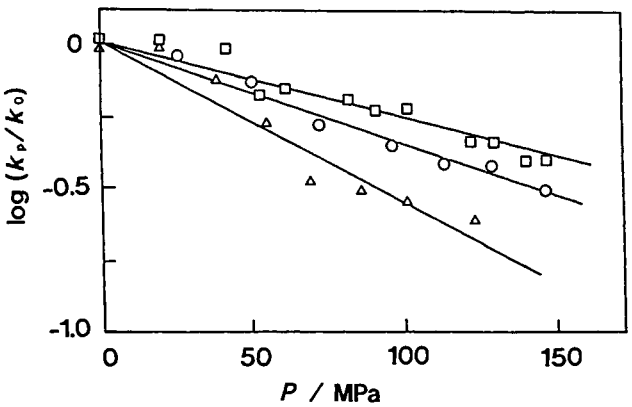

Fig. 2. Pressure dependence of logk_P for DMF exchange of the Fe(III)–PhDTA complex at −23.4 °C (△), 27.0 °C (○), and 61.3 °C (□). $C_{Fe(III)\text{-}PhDTA}=2.16\times10^{-2}$ mol kg^{-1}.

J K^{-1} mol^{-1}, and C_ω/K rad s^{-1} are 16.1±0.8, −51±3, and (1.03±0.06)×10^9 for 13.50 MHz and 20.9±0.9, −33±3, and (2.05±0.09)×10^9 for 36.63 MHz, respectively. These values obtained were used for drawing the solid curves in Fig. 1. The enthalpy and entropy of activation for DMF exchange on Fe(III)–PhDTA were determined to be 18±3 kJ mol^{-1} and −40±10 J K^{-1} mol^{-1}, respectively, taking experimental errors into account.

Since the definite chemical exchange region was not observed, we estimated the activation volume according to the following procedure. The solvent electrostriction acting on the primary coordination sphere may result in a large compression, typically of the order of gigapascals,[11] so that an externally applied pressure of about 150 MPa will not produce any noticeable changes in bond lengths. Therefore, the scalar coupling constant (A)[12] which depends on the distance between the iron(III) ion and the oxygen nucleus is not expected to vary to an appreciable extent in the present pressure experiments. Consequently, we calculated the k_P values at various pressures at three different temperatures, assuming that $\Delta\omega_M$ is independent of pressure as has been demonstrated by Merbach et al.[13] Values of ln (k_P/k_0) are plotted against P in Fig. 2. The activation volume at the respective temperature was obtained as follows: $\Delta V^{\ddagger}$=11.9±2.6 (−23.4 °C), 8.7±1.0 (27.0 °C), and 8.6±1.1 cm^3 mol^{-1} (61.3 °C). Taking into account experimental errors, the mean value of $\Delta V^{\ddagger}$ should be 10±2 cm^3 mol^{-1}.

The exchange of DMF on the Fe(III)–PhDTA complex is much faster than the solvent exchange on the hexa(solvento)iron(III) ion in water and DMF (see Table 1). This fact comes mainly from the difference in activation enthalpy. The values of $\Delta V^{\ddagger}$ for the solvent exchange on the hexa(solvento)iron(III) ion are negative, while those of the Fe(III)–PhDTA complex are positive both in water and DMF: The solvent exchange proceeds via an associative interchange mechanism for the former, while a dissociative interchange mechanism is operative for the latter. Since a ligand with electron donecity such as phdta^{4-} binds to the iron(III) ion, the electron density of the iron(III) atom should increase and the bond between the metal ion and a coordinated DMF molecule may be weakened (the bound ligand effect). The solvent exchange of the Fe(III) complex with electron-donating ligand proceeds much faster and more dissociatively than that on the hexa(solvento)-iron(III) ion. The more positive activation volume for the DMF exchange may be attributed to the bulkiness of a DMF molecule compared with a water molecule. In bulkier solvents, a coordinated leaving solvent molecule may be forced to leave partly the inner sphere of the central metal ion due to steric hindrance before an entering solvent starts to coordinate (solvent bulkiness effect). In conclusion, this study has clearly demonstrated that both the bound ligand effect and the solvent bulkiness effect make the activation mode less associative for the solvent exchange of Fe(III)–PhDTA in DMF.

Effects of Halide Ions on Micelle-Enhanced Chemiluminescence Reaction of Lucigenin with Adrenaline

Tamio KAMIDATE,* Tetsutoshi KANEYASU, Tadashi SEGAWA, and Hiroto WATANABE
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received February 13, 1991)

Synopsis. A remarkable lowering of chemiluminescence (CL) emitted from the CL reaction of lucigenin (Luc) with adrenaline (AD) was observed in cationic micellar assemblies containing halide ions, when their concentrations were above 5×10^{-3} mol dm^{-3}. These results could be explained in terms of the quenching of the Luc CL reaction by halide ions. The quenching by chloride ions was dependent on the carbon number in the alkyl group of surfactant reagents.

The use of appropriate aqueous micellar solutions has been shown to enhance the chemiluminescence (CL) intensity from CL reaction systems involving lucigenin (10,10′-dimethyl-9,9′-biacridinium dinitrate, Luc). Micelle-enhanced Luc CL reactions have been employed in order to improve the sensitivity of the determination of hydrogen peroxide and biological reductants.[1,2]

We previously proposed the Luc CL method for the determination of such catecholamines (CAs) as dopamine, noradrenaline and adrenaline (AD).[3] In addition, we have shown that cationic surfactant micelles are superior to nonionic and anionic surfactant micelles with respect to the enhancement effect on the CL intensity.[4] In this paper we describe the effects of such halide ions as bromide and chloride on the CL intensity emitted from the Luc CL reaction with AD in cationic micellar solutions.

Experimental

Reagents. Hexadecyltrimethylammonium hydroxide (CTAOH), hexadecyltrimethylammonium chloride (CTAC), hexadecyltrimethylammonium bromide (CTAB), tetradecyltrimethylammonium chloride(TTAC) and dodecyltrimethylammonium chloride (DTAC) were used without further purification. All of the solutions used were prepared as described previously.[4]

Apparatus. All CL measurements were performed by use of a fluorometer (Farrand Optical Co., Type Ratio-2) equipped with an automatic injector which had two flow lines (Ohtsuka Denshi Co., Type MX-7). A strip-chart recorder was used to record the CL intensity–time profiles.

Procedure. A 250 μl portion of surfactant solution and a 250 μl portion of a 0.2 M (1 M=1 mol dm^{-3}) NaOH solution were added using an Eppendorf pipet into a 1-cm glass cell in the fluorometer. Next, a 250 μl portion of 6.0×10^{-5} M Luc solution and a 250 μl portion of 1.0×10^{-4} M AD solution were injected simultaneously through Teflon tubing into the cell by using an automatic injector. Thus, the CL reaction was initiated and light emission was detected by a photomultiplier tube. The resultant photocurrent was converted to a voltage and displayed on a chart recorder. The maximum light emission was corrected using the light emission of a blank containing no AD. These background-corrected CL values were referred to as the CL intensities.

Results and Discussion

The CL measurements were carried out using different counterion-types of such cationic surfactants as CTAOH, CTAC, and CTAB. Figure 1 shows the CL intensity-surfactant concentration profiles. When the surfactant concentrations were well below the critical micelle concentrations (cmc) (results not shown), the CL intensity was about the same as that in water. The increase in the CL intensity commenced at surfactant concentrations near cmc, which were 9×10^{-4} M for CTAOH, 1.3×10^{-3} M for CTAC and 9.2×10^{-4} M for CTAB, respectively.[5] The CL intensities were maximal at 5×10^{-3} M and were about the same, regardless of the cationic micellar assemblies used. However, the CL intensities were dependent on the counterion types and concentrations of cationic surfactants used, when their concentrations were above 5×10^{-3} M. The relative effectiveness of these cationic micelles at enhancing the CL intensity followed the order CTAOH>CTAC> CTAB, thus indicating that the micelle-enhanced Luc CL reaction was affected by the concentrations of halide ions.

In order to elucidate the effect of halide ions on the Luc CL reaction, a 250 μl portion of NaCl solution or that of NaBr solution was added to the reaction mixture instead of surfactant micellar solutions. The results

shown in Fig. 2 indicate that halide ions play the roll as a quencher for the Luc CL reaction with AD when their concentration are above 1×10^{-2} M. Quenching by bromide ions was greater than that by chloride ions. Therefore, the remarkable decrease of the CL intensity in the micellar assemblies containing halide ions is probably attributable to quenching of the Luc CL reaction by halide ions. However, the degree of lowering the CL intensity in micellar assemblies was greater than that in water alone at the same concentration of haliden ions. These results may be interpreted as follows. Halide ions interact electrostatically with and bind to a cationic micelle pseudophase. Consequently, the local halide concentration on the micelle surface is greater than the stoichiometric concentration in bulk water alone. Thus, quenching by halide ions is greater in micellar assemblies compared to that in water alone.

We then examined the effect of chloride ions on the micelle-enhanced CL using DTAC, TTAC, and CTAC with different carbon numbers in an alkyl group of surfactant reagents. Figure 3 shows the CL intensity–surfactant concentration profiles for the respective surfactants. The CL intensity increased with an increase in the carbon number of the alkyl group. The degree of quenching by chloride ions was dependent on the carbon number in the alkyl group of the surfactant reagents used. This is ascribable to their cmc, which are 1.3×10^{-3} M for CTAC, 4.5×10^{-3} M for TTAC,[6] and 2.0×10^{-2} M for DTAC,[7] respectively. Along with a decrease in the carbon number of the alkyl group, the cmc, and thus the concentration of surfactant micelles, increased, resulting in an effective enhancement of the CL intensity in micellar assemblies. The concentration of chloride ions increases simultaneously under these conditions.

Consequently, the degree of the quenching by chloride ions may increase with a decrease in the carbon number of the alkyl group of surfactant reagents. On the other hand, the maximum CL intensities in such C_{16} surfactants as CTAOH, CTAC, and CTAB, were not affected by the counterions of the surfactant reagents. This result may be interpreted by taking into acount their cmc. That is, the CL intensity reached a maximum value without suffering from the quenching effect of halide ions on the CL intensity, since the cmc for CTAC and CTAB are well below the concentrations required for quenching by halide ions.

As described above, CTAOH is very useful as a micellar medium for enhancing the CL intensity of Luc CL with AD. On the other hand, the optimum concentrations of CTAC and CTAB are within a very limited range, thus precluding their use.

Epoxidation of 2-Butene-1,4-diones with Hydrogen Peroxide in the Presence of a Catalytic Amount of Quaternary Ammonium Iodide

Shinsei SAYAMA* and Yutaka INAMURA
Department of Chemistry, Fukushima Medical College, Hikarigaoka, Fukushima 960-12
(Received December 13, 1990)

Synopsis. The epoxidation of 1,4-disubstituted 2-butene-1,4-diones with 30% aq H_2O_2 in the presence of a catalytic amount of quaternary ammonium iodide afforded 2,3-epoxy-1,4-butanediones in high yield.

The epoxidation of α,β-unsaturated ketones was carried out with nucleophilic reagents, such as hydrogen peroxide or *t*-butyl hydroperoxide, in alkaline solution.[1-3] These available methods are not applicable to base-sensitive substrates.[7] There have therefore been many studies of an epoxidation reaction to overcome the problem without employing a strong base.[4-9] It was reported that the epoxidation reaction of α,β-unsaturated ketones using 30% aq H_2O_2–Bu_4NF gave the corresponding epoxy ketones.[7] Also reported was a direct and stereospecific epoxidation of 2-butene-1,4-diones with $MoO_5 \cdot H_2O \cdot HMPA$, based on approaches to the synthesis of antibiotic cerulenin.[8-10] Although 30% aq H_2O_2 was a convenient and inexpensive reagent for the oxidation reactions, in comparison with other peroxides, the epoxidation of 1,4-disubstituted 2-butene-1,4-diones with H_2O_2 under the non-basic reaction conditions, has not been examined. We would like to report on the results of studies concerning the chemoselective epoxidation of 1,4-disubstituted 2-butene-1,4-diones with H_2O_2 in the presence of a catalytic amount of quaternary ammonium iodides.

The epoxidation of *trans*-1,4-diphenyl-2-butene-1,4-dione (**1**), chosen as a representative 2-butene-1,4-dione for this study, with 30% aq H_2O_2–quaternary ammonium halides in various stoichiometric ratios, was carried out. The results are summarized in Table 1. At an appropriate ratio of enedione **1**, H_2O_2, and Bu_4NI (1 : 26 : 1, 1 : 28 : 0.5, or 1 : 29 : 0.1), *cis*-2,3-epoxy-1,4-diphenyl-1,4-butanedione (**1b**) was predominantly obtained (Entries 1—3).[15] The yield of *trans*- and *cis*-epoxides **1a** and **1b** was determined by the recrystallization of crude products from ethyl acetate as follows.

trans-2,3-Epoxy-1,4-diphenyl-1,4-butanedione (**1a**) was obtained in 10—18% yield as the first crop of crystals; *cis*-epoxide **1b** was then afforded by recrystallization of the filtrates. The stereochemistries of *trans*- and *cis*-epoxides (**1a** and **1b**) were determined by a direct comparison of the spectral data with that of *trans*-epoxide **1a**, which was alternatively prepared by the epoxidation of **1** with alkaline hydrogen peroxide. The spectral data of **1a** and **1b** were also identical with those of known compounds reported in the literature.[8,9] In addition, the catalytic amount of Bu_4NI (0.1 equiv) and a slight excess molar equivalent of H_2O_2 (5 equiv) gave a similar result (Entry 5). On the other hand, the epoxidation of enedione **1** with H_2O_2 and other common quaternary ammonium halides (Bu_4NF, Me_4NCl, Bu_4NBr, and $PhCH_2N(Et)_3Br$) did not give *trans*- and *cis*-epoxides **1a** and **1b** in high yield (less than 15%), and a complex mixture of hydroxy derivatives was obtained

under various ratios of H_2O_2 and quaternary halides (Entries 9—12). These results suggest that the iodide ion acts as a base while promoting the conjugate addition of hydroperoxide to the carbon–carbon double bond of enedione **1**.[7,11,12] The epoxidation of enedione **1** with H_2O_2 in the presence of another quaternary ammonium iodide ($PhCH_2N(Me)_3I$) also gave epoxides in good yield (Entry 13).

The results of the epoxidation of other 2-butene-1,4-diones with 30% aq H_2O_2–quaternary ammonium iodide (Bu_4NI or $PhCH_2N(CH_3)_3I$) are shown in Tables 2 and 3. *cis*-1,4-Diphenyl-2-butene-1,4-dione (**2**) also afforded *cis*-epoxide **1b** predominantly as well as *trans*-enedione **1**. *trans*-1-Phenyl-2-pentene-1,4-dione (**4**), *trans*-3-decene-2,5-dione (**5**), and ethyl 4-oxo-4-phenyl-2-butenoate (**3**) afforded the corresponding *trans*-2,3-epoxy derivatives (**3a**, **4a**, and **5a**). The stereochemistries of *trans*-epoxides of **3a**, **4a**, and **5a** were assigned based on the ^1HNMR spin–spin coupling constants between the epoxy ring protons; **3a**—**5a** showed coupling constants of 2 Hz. This coupling constant was in good agreement with the reported value for *trans*-vicinal coupling in epoxides.[8,9] 3-Benzoyl-1-phenyl-2-pentene-1,4-dione (**6**) also afforded the corresponding epoxide (**6a**)[14] in good yield.

On the other hand, the epoxidation of α,β-unsaturated ketones such as 5-isopropenyl-2-methyl-2-cyclohexen-1-one, 4-(2,6,6-trimethyl-2-cyclohexen-1-yl)-3-buten-2-one, 3-methyl-2-cyclohexen-1-one, 4,4-dimethyl-2-cyclohexen-1-one, and chalcone with H_2O_2–Bu_4NI did not give corresponding epoxides in high yield (less than 10%). α,β-Unsaturated ketones were recovered unchanged in 61—98% yield.

Thus, the reagent 30% aq H_2O_2-quaternary ammonium iodides provides a new convenient method for mild and chemoselective epoxidation of 2-butene-1,4-diones without using a strong base. Further application of epoxidation with this method to *cis*-2-butene-1,4-diones and other functional unsaturated compounds is now in progress.

Experimental

IR spectra were recorded on a JASCO FT-IR 5000 spec-

trometer. ^{1}H NMR spectra were taken on a Hitachi R-24B spectrometer with TMS as an internal standard. MS spectra were taken on a JEOL-HX 110 spectrometer at 70 eV. The products were identified by spectroscopic data.

General Procedure. To a solution of 2-butene-1,4-dione (1 mmol) and Bu_4NI or $PhCH_2N(Me)_3I$ (0.1 mmol) in THF (10 ml) at 0 °C was added dropwise 30% aq H_2O_2 (5—30 mmol) dissolved in THF (3 ml). After stirring for 20—96 h at 0—23 °C, the reaction mixture was poured into 0.5 M aq KI. The resulting mixture was treated with 0.5 M aq $Na_2S_2O_3$ and extracted with ethyl acetate. The organic layer was washed by 0.5 M aq $Na_2S_2O_3$ and successively saturated aq NaCl and dried by $MgSO_4$. After removal of solvent in vacuo, the residue was purified by recrystallization or column chromatography on silica gel (Wakogel C-200) with CCl_4 and $CHCl_3$ (1 : 1, v/v). Epoxy diketones **1a**—**6a** were obtained in 53—91% yield.

2-Butene-1,4-diones were prepared according to the literature procedure.[13]

trans-1,4-Diphenyl-2-butene-1,4-dione (**1**) was prepared by Friedel-Crafts acylation of benzene with fumaroyl dichloride. *cis*-1,4-Diphenyl-2-butene-1,4-dione (**2**) and 3-benzoyl-1-phenyl-2-pentene-1,4-dione (**6**) were prepared by oxidation of corresponding furan derivatives with HNO_3 in acetic acid.

trans-1-Phenyl-2-pentene-1,4-dione (**4**) and *trans*-3-decene-2,5-dione (**5**) were prepared by pyridinium chlorochromate (PCC) oxidation of corresponding 2,5-dialkylfuran derivatives.

(Received January 24, 1991)

Synopsis. The 2-styrylbenzo[*a*]quinolizinium salt was photocyclized to afford 12a-azoniabenzo[*ghi*]perylene salt in 66% yield. The 2a-azoniabenzo[*a*]coronene salt was obtained by the photocyclization of 2-[2-(4-biphenylyl)vinyl]benzo[*a*]-quinolizinium salt and 2-styryl-10-phenylbenzo[*a*]quinolizinium salt in 80% and 75% yields, respectively.

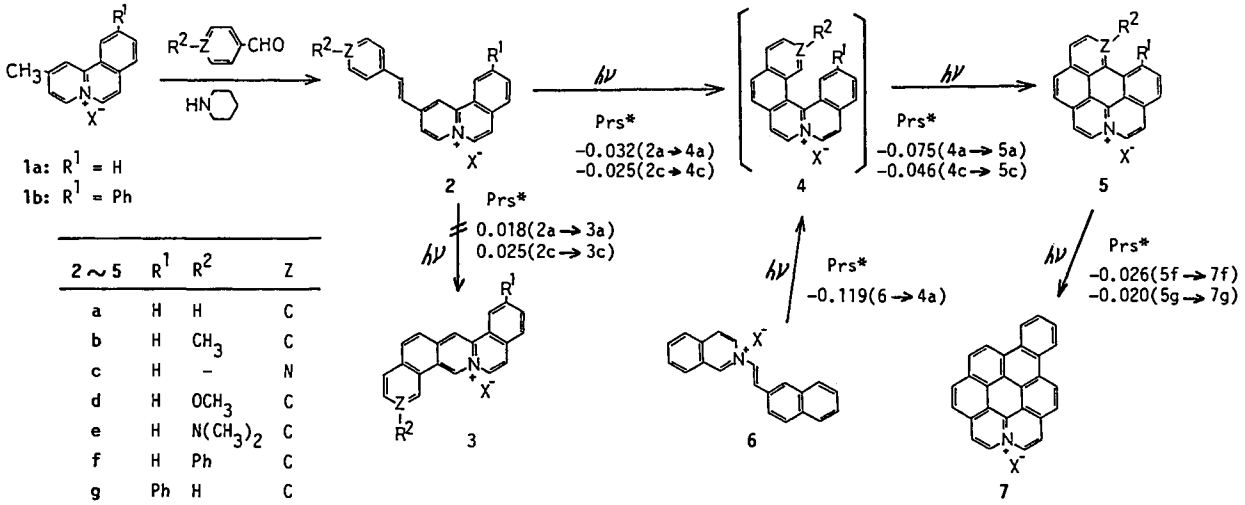
Recently we reported that the photocyclization of *N*-styrylpyridinium-type molecules provided a good route to construct new fused polycyclic azonia aromatic compounds.[1] In these reactions it was demonstrated that the bond formation via a conrotatory photocyclization is possible when the bond order (*Prs**) between the atoms *r* and *s*, involved in the cyclization in the excited state, has a negative value.[1] Compounds 2-(2-arylvinyl)-benzo[*a*]quinolizinium salts (**2**), which was obtained by the reaction of 2-methylbenzo[*a*]quinolizinium salt (**1a**) with benzaldehyde derivatives in the presence of piperidine,[2,3] would be an ideal precursor of fused polycyclic azonia aromatic compounds. We report herein the synthesis of azonia derivatives of benzoperylene and benzocoronene by oxidative photocyclization of compounds **2**.

Results and Discussion

The Knoevenagel condensation of 2-methylbenzo-[*a*]quinolizinium salt (**1a**) or 2-methyl-10-phenylbenzo-[*a*]quinolizinium salt (**1b**) with benzaldehyde derivatives in the presence of piperidine afforded the corresponding *trans*-arylvinyl derivatives **2a**—**g** in good yields. Compound **2a** was irradiated with a Pyrex-filtered light (λ>280 nm) in ethanol in the presence of iodine. The photocyclization of **2a** could, hypothetically, give 6a-azoniadibenzo[*a*,*h*]anthracene salt (**3a**) and 2a-azoniadibenzo[*c*,*g*]phenanthrene salt (**4a**). The values of *Prs**, however, predicted that out of the two possible cyclization products **3a** (*Prs**=0.018) and **4a** (*Prs**=−0.032) only **4a** should be formed. The fast-atom bombardment (FAB) mass spectrum of the isolated product (66% yield) using *m*-nitrobenzyl alcohol as a matrix showed that the ion at highest *m*/*z* value (278) did not correspond to the intact cation (C^+) of **4a** (*m*/*z* 280) predicted but to that of 12a-azoniabenzo[*ghi*]-perylene salt (**5a**) (C^+, *m*/*z* 278), formed by further photocyclization of **4a**. This structure was confirmed by the fact that the spectral data were identical with those of the photocyclization product[1] of 2-[2-(2-naphthyl)vinyl]isoquinolinium salt (**6**). The *Prs** value (−0.075) shows that the photocyclization of **4a** is possible to give **5a**.[1] The methyl derivative **2b**[3] was also photocyclized to afford 7-methyl-12a-azoniabenzo[*ghi*]-perylene salt **5b** in 40% yield.

The *Prs** value predicted that **2c** could be photocyclized by two succesive oxidative photocylization via 9-aza-2a-azoniabenzo[*c*,*g*]phenanthrene salt (**4c**) to afford 7-aza-12a-azoniabenzo[*ghi*]perylene salt **5c**. The irradiation of **2c** in ethanol or methanol, however, caused decomposition. Compound **2c** was successfully photocyclized to give **5c** in acetonitrile in 42% yield.

The cyanine-type compounds **2d**[2] and **2e**,[3] however, failed to undergo photocyclization: the irradiation with or without iodine in ethanol or acetonitrile leads to only



2～5	R^1	R^2	Z

Scheme.

decomposition.

In the photocyclization of **2f**, the values of *Prs** predicted that three succesive photocyclizations should take place to give 2a-azoniabenzo[*a*]coronene salt (**7**). A methanol solution of **2f** in the presence of iodine was irradiated with a Pyrex-filtered light. The FAB mass spectrum of the product (80% yield) showed the presence of a peak at *m/z* 352 (C^+): this pointed to the loss of six mass units from **2f** (C^+ 358). The FAB mass spectrum of the photocyclization-product (75% yield) from **2g** also exhibited the intact cation at *m/z* 352. The ^1H NMR and UV spectral data of the photoproduct from **2f** was identical with those of the photoproduct from **2g**. These results indicate that photocyclization of both **2f** and **2g** afforded **7** as predicted from *Prs** values.

Experimental

Melting points were determined with a Yamato melting point apparatus (MP21) and are uncorrected. IR spectra were recorded on a JASCO IRA-1 spectrometer. ^1H NMR spectra were recorded on a Hitachi R-24 (60 MHz) or a JEOL FX90Q (90 MHz) spectrometer with Me_4Si as an internal standard. ^1H NMR (400 MHz) and ^{13}C NMR (100.40 MHz) spectra were obtained on a JEOL GSX-400 spectrometer. UV spectra were obtained with a Hitachi 220A spectrophotometer. Fast-atom bombardment (FAB) mass spectra were obtained with a JEOL JMS-DX 300 using *m*-nitrobenzyl alcohol as a matrix. Elemental analyses were performed by Mr. Hirokatsu Suzuki at Department of Chemistry, Tokyo Metropolitan University. An Eikosha 300 W high-pressure mercury lamp was used as the irradiation source.

The bond orders (*Prs**) were obtained by Hückel MO calculations using the parameters suggested by Streitwieser, Jr.[4]

2-Methylbenzo[*a*]quinolizinium salt (**1a**) was prepared by photocyclization of 1-styryl-4-methylpyridinium salt according to our previous paper.[2] **1a** (X=Br): Found: C, 61.14; H, 4.47; N, 4.99%. **1a** (X=ClO_4): Found: C, 57.23; H, 3.94; N, 4.64%. **1a** (X=PF_6): Found: C, 49.51; H, 3.71; N, 4.15%.

2-Methyl-10-phenylbenzo[*a*]quinolizinium Perchlorate (1b: X=ClO_4): Compound **1b** was prepared in a four-step process according to the method[2] described for **1a**. The reaction of 4-methylpyridine with 1-(4-biphenylyl)-2-bromoethanone gave 2-(4-methyl-1-pyridinio)-1-(4-biphenylyl)ethanone bromide (79% yield): Pale yellow crystals from ethanol; mp 240—242 °C (decomp); ^1H NMR (60 MHz, CF_3CO_2H) δ=2.79 (3H, s, CH_3), 6.32 (2H, s, CH_2), and 7.2—8.7 (13H, m, ArH). Found: C, 64.98; H, 4.81; N, 3.78%. Calcd for $C_{20}H_{18}NOBr$: C, 65.23; H, 4.98; N, 3.80%.

The pyridinium salt was reduced with $NaBH_4$ in water to afford 1-[2-hydroxy-2-(-4-biphenylyl)ethyl]-4-methylpyridinium bromide (54%): Pale yellow crystals from ethanol–benzene; mp 226—228 °C (decomp); ^1H NMR (60 MHz, CF_3CO_2H) δ=2.66(3H, s, CH_3), 4.7—5.2 (2H, m, CH_2), 5.25—5.6 (1H, m, CH), and 7.2—8.6 (13H, m, ArH). Found: C, 64.94; H, 5.39; N, 3.66%. Calcd for $C_{20}H_{20}NOBr$: C, 64.87; H, 5.44; N, 3.78%. The reaction between the alcohol with phosphorus tribromide gave 1-[2-(4-biphenylyl)vinyl]-4-methylpyridinium bromide (51%): Yellow crystals from 1-pentanol; mp 215—218 °C (decomp); ^1H NMR (60 MHz, CF_3CO_2H) δ=2.56 (3H, s, CH_3) and 7.1—8.8 (15H, m, CH=CH and ArH). Found: C, 68.33; H, 5.30; N, 3.76%. Calcd for $C_{20}H_{18}NBr$: C, 68.19; H, 5.15; N, 3.98%.

2-Methyl-10-phenylbenzo[*a*]quinolizinium perchlorate (**1b**: X=ClO_4) was obtained by photocyclization of the olefin, followed by anion exchange (33% yield): White crystals from ethanol–acetonitrile; mp 290—293 °C (decomp); IR (KBr) 1643, 1480, 1312, 1122, 850, and 764 cm^{-1}; ^1H NMR (90 MHz, DMSO-d_6) δ=2.81 (3H, s, CH_3) and 7.4—9.7 (15H, m, ArH); FABMS *m/z* 270 $(M-ClO_4)^+$. Found; C, 65.23; H, 4.27; N, 3.91%. Calcd for $C_{20}H_{16}NClO_4$; C, 64.96; H, 4.36; N, 3.79%

2-(2-Arylvinyl)benzo[*a*]quinolizinium salts **2a—g** were prepared by the reaction of **1a** or **1b** with benzaldehyde derivatives in the presence of piperidine in methanol, according to our previous paper.[2,3]

2-Styrylbenzo[*a*]quinolizinium Hexafluorophosphate (2a: X=PF_6; 69%): Yellowish green crystals from methanol–acetone; mp 239.7—240.5 °C; UV (C_2H_5OH) 401 nm (log ε 4.58); IR (KBr) 3040, 1660, 1640, 1482, 1210, 1162, and 980 cm^{-1}; ^1H NMR (60 MHz, CF_3CO_2H) δ=7.3—9.6 (m, ArH); FABMS *m/z* 282 $(M-PF_6)^+$. Found: C, 59.02; H, 3.78; N, 3.28%. Calcd for $C_{21}H_{16}NPF_6$: C, 59.02; H, 3.89; N, 3.32%.

2-[2-(4-Methylphenyl)vinyl]benzo[*a*]quinolizinium Perchlorate (2b: X=ClO_4 74%):[3] Found: C, 66.55; H, 4.53; N, 3.72%.

2-[2-(4-Pyridyl)vinyl]benzo[*a*]quinolizinium Hexafluorophosphate (2c: X=PF_6; 68%): Yellowish green crystals from methanol; mp 244—247 °C; UV (C_2H_5OH) 388 nm (log ε 4.57); IR (KBr) 3080, 1660, 1640, 1481, and 981 cm^{-1}; ^1H NMR (90 MHz, 7.6—9.7 (m, ArH); FABMS *m/z* 283 $(M-PF_6)^+$. Found: C, 55.99; H, 3.56; N, 6.69%. Calcd for $C_{20}H_{15}N_2PF_6$: C, 56.08; H, 3.54; N, 6.54%.

2-[2-(4-Methoxyphenyl)vinyl]benzo[*a*]quinolizinium Perchlorate (2d: X=ClO_4; 99%):[2] Found: C, 64.25; H, 4.30; N, 3.23%.

2-[2-(4-Dimethylaminophenyl)vinyl]benzo[*a*]quinolizinium Bromide (2e: X=Br; 62%):[3] Found: C, 68.06; H, 5.34; N, 6.87%.

2-[2-(4-Biphenylyl)vinyl]benzo[*a*]quinolizinium Bromide (2f: X=Br; 88%): Yellowish green needles from methanol: mp >300 °C; UV (C_2H_5OH) 272 (log ε 4.41), 290 (4.34), 338 (4.16), 354 (4.29), and 407 nm (4.82); IR (KBr) 1620, 1484, 1195, 1162, 979, and 782 cm^{-1}; ^1H NMR (90 MHz, DMSO-d_6) δ=7.4—9.6 (m, ArH); FABMS *m/z* 283 $(M-Br)^+$. Found: C, 73.81; H, 4.56; N, 3.23%. Calcd for $C_{27}H_{20}NBr$: C, 73.98; H, 4.60; N, 3.20%.

2-Styryl-10-phenylbenzo[*a*]quinolizinium Perchlorate (2g: X=ClO_4; 65%): Yellow crystals from methanol; mp 260—263 °C (decomp); UV (CH_3OH) 290 (4.51), 336 (4.30), 348 (4.46), and 410 nm(4.58); IR (KBr) 1618, 1472, 1445, 1120, 975, and 690 cm^{-1}; ^1H NMR (90 MHz, DMSO-d_6) δ=7.4—9.7 (m, ArH); FABMS *m/z* 358 $(M-ClO_4)^+$. Found: C, 71.06; H, 4.36; N, 3.10%. Calcd for $C_{27}H_{20}NClO_4$: C, 70.82; H, 4.40; N, 3.06%.

Photocyclization of compounds **2a—g** was carried out according to our previous paper.[1]

12a-Azoniabenzo[*ghi*]perylene Hexafluorophosphate (5a: X=PF_6; 66%): Yellowish green crystals from methanol–acetone; mp >320 °C; IR (KBr) 1650, 1440, and 1315 cm^{-1}; ^1H NMR (90 MHz, CD_3CN) δ=8.3—9.4 (m, ArH); FABMS *m/z* 278 $(M-PF_6)^+$. Found; C, 59.45; H, 2.83; N, 3.50%. Calcd for $C_{21}H_{12}NPF_6$: C, 59.59; H, 2.86; N, 3.31%.

7-Methyl-12a-azoniabenzo[*ghi*]perylene Perchlorate (5b: X=ClO_4; 40%): Pale orange crystals from acetonitrile; mp >300 °C; UV (CH_3OH) 316 (log ε 4.41), 402 (4.09), and 431 nm (4.24); IR (KBr) 1655, 1608, 1404, 1350, 1095, 870, and 742 cm^{-1}; ^1H NMR (90 MHz, DMSO-d_6) δ=3.01 (3H, s, CH_3) and 7.9—9.5 (m, 11H, ArH); FABMS *m/z* 292 $(M-PF_6)^+$. Found; C, 67.21; H, 3.50; N, 3.37%. Calcd for $C_{22}H_{14}NClO_4$; C, 67.44 ; H, 3.60; N, 3.58%.

7-Aza-12a-azoniabenzo[*ghi*]perylene Hexafluoroposphate (5c: X=PF_6; 43%): Brown crystals from methanol–acetonitrile; mp >320 °C; UV (C_2H_5OH) 435 (log ε 4.25), 410 (3.99), 388 (3.57), and 373 nm (3.83); IR (KBr) 1640, 1430, and 1340 cm^{-1}; ^1H NMR (90 MHz, CD_3CN) δ=8.4—9.9 (m, ArH);

FABMS m/z 280 $(M-PF_6)^+$. Found; C, 56.76; H, 2.63; N, 6.59%. Calcd for $C_{20}H_{11}N_2PF_6$; C, 56.62; H, 2.61; N, 6.60%.

2a-Azoniabenzo[*a*]coronene Bromide (7: X=Br; 80%): An orange powder from *N,N*-dimethylformamide–ethanol; mp >300 °C; UV (CH_3OH) 279 (log ε 4.46), 339 (4.56), 420 (3.99), and 446 nm (3.98); IR (KBr) 1640, 1342, 856, and 752 cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=7.55 (1H, s, ArH), 7.6—7.7 (3H, m, ArH), 7.87 (1H, s, ArH), 7.9—8.1 (5H, m, ArH), 8.2—8.4 (2H, m, ArH), 8.99 (1H, d, J=4.9 Hz, ArH), and 9.19 (1H, d, J=5.4 Hz, ArH); ^{13}C NMR (100.40 MHz, DMSO-d_6) 113.8—133.7 (27 lines); FABMS m/z 352 $(M-Br)^+$. Found; C, 74.75; H, 3.00; N, 2.98%. Calcd for $C_{27}H_{14}NBr$; C, 75.01; H, 3.26; N, 3.24%.

2a-Azoniabenzo[*a*]coronene Perchlorate (7: X=ClO_4; 75%): An orange powder from *N,N*-dimethylformamide–ethanol; mp >300 °C; UV (CH_3OH) 278 (log ε 4.45), 338 (4.55), 420 (4.00), and 446 nm (3.99); FABMAS m/z 352 $(M-ClO_4)^+$. Found; C, 71.50; H, 3.00; N, 2.85%. Calcd for $C_{27}H_{14}NClO_4$; C, 71.77; H, 3.12; N, 3.10%.

The authors are grateful to Dr. Masashi Kikuchi of Shiseido Laboratories for obtaining the NMR spectra (400 MHz).

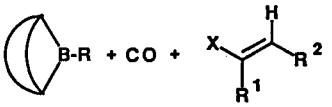
Palladium-Catalyzed Carbonylative Cross-Coupling Reaction of 1-Halo-1-alkenes with 9-Alkyl-9-BBN Derivatives. A Direct Synthesis of α,β-Unsaturated Ketones

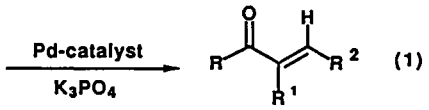
Tatsuo ISHIYAMA, Norio MIYAURA, and Akira SUZUKI*
Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received February 12, 1991)

Synopsis. The synthesis of α,β-unsaturated ketones by means of the palladium-catalyzed cross-coupling reaction between 9-alkyl-9-borabicyclo[3.3.1]nonanes (9-R-9-BBN) and 1-halo-1-alkenes under carbon monoxide atmosphere is described.

Carbonylative cross-coupling of organic halides with organometallic compounds, such as organotin,[1] boron,[2] aluminum,[3] and zinc[4] compounds has been extensively studied and reported to provide a good method for the synthesis of unsymmetrical ketones. Among a variety of organometallic reagents, organoboron compounds were first examined by Kojima and his co-workers[2a] for the synthesis of alkyl aryl ketones. Due to the low nucleophilicity of alkyl group on boron, the transmetallation between organoboranes and acylpalladium(II) species generated in catalytic cycles is anticipated to be a step of retarding for the coupling of organoboron compounds. They found that bis(acetylacetonato)zinc(II) accelerates the transmetallation and the palladium-catalyzed carbonylative coupling of organoboranes with aryl and benzyl halides to give the corresponding ketones. However, when we applied the procedure in the reaction with 1-halo-1-alkenes, it was found that no expected α,β-unsaturated ketones are obtained. Thus, we have reinvestigated such a carbonylative cross-coupling reaction of organoboranes, and observed that the cross-coupling reaction of 9-R-9-BBN, with carbon monoxide and 1-iodo-1-alkenes is effectively induced with K_3PO_4 at room temperature in the presence of Pd-catalyst (Eq. 1). The reactions with aryl or benzyl halides proceed nicely under similar conditions to give the corresponding products, respectively.



1



(1)

2

The effects of such conditions on the reaction of 9-octyl-9-BBN with (*E*)-1-hexenyl, phenyl, and benzyl halides are listed in Table 1. The addition of bis(acetylacetonato)zinc(II) never accelerates the reaction with 1-iodo-1-alkene (Entry 1). When we use K_3PO_4 as a base, 1-iodo-1-hexene is effectively carbonylated and couples with 9-octyl-9-BBN in the presence of 5 mol% of $Pd(PPh_3)_4$ to give (*E*)-5-pentadecen-7-one in almost quantitative yields (Entries 2—4). Both $Pd(PPh_3)_4$ and $PdCl_2(PPh_3)_2$ are effective as catalysts for the present carbonylative coupling reaction (Entries 4 and 5). However, dichloro[1,1′-bis(diphenylphosphino)ferrocene]palladium(II), $PdCl_2$(dppf), gives a lower yield of ketone (Entry 6) whereas this catalyst has been reported to be a good catalyst for the carbonylative coupling reaction of aryl triflates[1e] with organostannanes. The carbonylation of 1-bromo-1-octene gives a mixture of products, (*E*)-7-heptadecen-9-one and (*E*)-7-hexa-

Table 1. Carbonylative Cross-Coupling Reaction of 9-Octyl-9-BBN with Organic Halides[a]

a) The 9-alkyl-9-BBN derivatives obtained by hydroboration of alkenes (1.1 equiv) with 9-BBN (1.1 equiv) were directly used for the next coupling reaction with haloalkenes (1.1 equiv). b) Method A: The reaction was conducted in benzene at room temperature for 5 h under 1 atm CO in the presence of K_3PO_4 (3 equiv) and $Pd(PPh_3)_4$ (5 mol%); Method B: The same conditions with A, except in dioxane under 3 atm CO. c) GLC yields based on organic iodides and isolated yields are in parentheses. d) $PdCl_2(PPh_3)_2$ (5 mol%) was used as a catalyst. e) TBDMS; *t*-butyldimethylsilyl, MOM; methoxymethyl.

decene, in a ratio of 2:1 even under 3 atmospheric pressure of carbon monoxide (Entry 7), the yield of which can be improved to 69% by running the reaction in the presence of powdered potassium iodide (Entry 8). Iodobenzene and benzyl bromide are also carbonylated and coupled with 9-octyl-9-BBN in good yields under the same reaction conditions (Entries 9 and 11).

In Table 2, the representative results obtained by a sequence of hydroboration of alkenes, followed by coupling with 1-iodo-1-alkenes under carbon monoxide atmosphere in the presence of $Pd(PPh_3)_4$ (5 mol%) and K_3PO_4 (3 equiv) are summarized. In Method A, the reaction is carried out under relatively mild conditions by using 1 atm of carbon monoxide at room temperature, whereas Method B is performed under 3 atm of carbon monoxide. Although the carbonylative coupling proceeds especially smoothly when iodoalkenes substituted with alkyls are used, the presence of electron-withdrawing substituents[5] leads to a mixture of carbonylated and uncarbonylated coupling products. For example, the carbonylation of 3-iodo-2-cyclohexenone and 1-iodo-1-octen-3-one mainly gives direct coupling products without the CO insertion, together with small amounts of the desired α,β-unsaturated ketones.

As shown in the last column of Table 2, the hydroboration-carbonylative coupling sequence can be readily extended to intramolecular reaction to afford cyclic ketones.

The reaction may proceed by a pathway similar to that of the palladium-catalyzed carbonylative coupling reaction of organometallics[1-4] which involves (a) oxidative addition of haloalkene to Pd(0) complex, (b) insertion of carbon monoxide to give acylpalladium(II) halide, (c) transfer of alkyl group on boron to acylpalladium(II) halide with the aid of K_3PO_4, and (d) reductive elimination to ketone. Although the carbonylation[6] of 9-alkyl-9-BBN with carbon monoxide to provide ketones is known, we have not observed any evidence that acylboron species are participated in a catalytic cycle.

In a course of our study on the palladium-catalyzed reaction[7a] of organoboranes, we reported the direct coupling reactions of aryl,[7b] 1-alkenyl,[7a,c] and alkylboron[7d] compounds with organic halides. The present reaction can make it possible for the extension of such coupling reactions to the synthesis of ketones.

Experimental

IR spectra were recorded on a Hitachi Perkin-Elmer Model 125 spectrometer. ^1H NMR spectra were obtained with a Hitachi-R-90H Fourier transform NMR spectrometer (90 MHz) and are recorded in δ values using tetramethylsilane as an internal standard. Mass spectra were taken on a JEOL JMS-D300 for a high resolution analysis and Finnigan ITD 800. GLC analyses were performed on a Hitachi 163 instrument using Silicone OV-17 on Uniport B (2 m).

Material and Reagents. Benzene and dioxane were dried and distilled before use. 9-Borabicyclo[3.3.1]nonane (9-BBN) in THF from Aldrich Chemical Co. was used directly. $Pd(PPh_3)_4$ and $PdCl_2(PPh_3)_2$ were commercial products. $PdCl_2(dppf)$ was prepared by the reported procedure.[8] (*E*)-

1-Iodo-1-hexene,[9] (*E*)-1-bromo-1-octene,[10] (*E*)-3,3-dimethyl-1-iodo-1-butene,[9] (*E*)-β-iodostyrene,[9] 1-iodocyclohexene,[11] and (*E*)-3-(*t*-butyldimethylsiloxy)-1-iodo-1-octene[12] were prepared by reported procedures. 1-(2,6,6-Trimethyl-1-cyclohexenyl)-3-methyl-1,3-butadiene[13] and 3β-acetoxy-20-methylene-5-pregnene[14] were prepared from the corresponding ketones by Wittig olefination. 1-Iodo-2-(1-methoxy-methoxy-2-propenyl)-1-cycloheptene was prepared[7d] as follows. Treatment of 2-chloro-1-cycloheptenecarbaldehyde obtained by Vilsmeier reaction of cycloheptanone with NaI in acetonitrile in the presence of 1 equivalent of chlorotrimethylsilane at room temperature for 24 h gave 2-iodo-1-cycloheptenecarbaldehyde in a yield of 54% (bp 95—100 °C/0.1 mmHg; 1 mmHg=133.322 Pa). This was treated with vinylmagnesium bromide (1 equiv) in THF, followed by the reaction with chloromethyl methyl ether (1.2 equiv) to afford the compound in an 83% yield.

General Procedure for the Carbonylative Cross-Coupling Reaction. A 50 ml pressure bottle equipped with a magnetic stirring bar was charged with an alkene (1.1 mmol) in THF (0.5 ml). A 0.5 M (1M=1 mol dm^{-3}) solution of 9-BBN in THF (1.1 mmol) was added slowly at 0 °C, and then the reaction mixture was warmed up slowly to room temperature. After stirring for 5 h, dioxane or benzene (6 ml), $Pd(PPh_3)_4$ (5 mol%), K_3PO_4 (3 mmol), and iodoalkene (1 mmol) were added. The flask was flushed with carbon monoxide (1 or 3 atmospheric pressure) and the mixture was stirred for 5 h at room temperature. Water (20 ml) was added and stirred for 30 min. The product was extracted with benzene, washed with brine, and finally dried over $MgSO_4$. Chromatography over silica gel with hexane–ethyl acetate gave the ketone.

The following ketones were obtained by this procedure.

(*E*)-5-Pentadecen-7-one: n_D 1.4531; IR (film) 1700, 1680, 1635, 1470, and 985 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92 (t, 6H, *J*=6.0 Hz), 1.28 (m, 16H), 2.22 (dt, 2H, *J*=7.2 Hz), 2.52 (t, 2H, *J*=7.4 Hz), 6.08 (d, 1H, *J*=15.6 Hz), and 6.82 (dt, 1H, *J*=15.8 and 6.6 Hz); MS *m/z* (rel intensity) 28 (27), 41 (53), 55 (97), 111 (53), 126 (22), 167 (13), and 225 (100); High resolution MS, Found: *m/z*, 224.2163. Calcd for $C_{15}H_{28}O$: M, 224.2140.

Methyl (*E*)-15,15-Dimethyl-12-oxo-13-hexadecenoate: n_D 1.4853; IR (film) 1740, 1700, 1680, 1625, 1460, 1440, 1360, 1165, and 980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.09 (s, 9H), 1.28 (m, 16H), 2.30 (t, 2H, *J*=7.2 Hz), 2.53 (t, 2H, *J*=7.2 Hz), 3.66 (s, 3H), 6.00 (d, 1H, *J*=16.0 Hz), and 6.81 (d, 1H, *J*=16.0 Hz); MS *m/z* (rel intensity) 41 (47), 55 (52), 111 (100), 126 (26), 221 (11), 253 (20), 279 (25), and 311 (33); High resolution MS, Found: *m/z*, 310.2510. Calcd for $C_{19}H_{34}O_3$: M, 310.2508.

(*E*)-12-Oxo-14-phenyl-13-tetradecenonitrile: Mp 64 °C; IR (Nujol) 2250, 1695, 1610, 1580, 1470, 1380, and 1080 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.31 (m, 16H), 2.32 (t, 2H, *J*=6.6 Hz), 2.66 (t, 2H, *J*=6.9 Hz), 6.72 (d, 1H, *J*=16.3 Hz), and 7.49 (m, 6H); MS *m/z* (rel intensity) 41 (13), 55 (10), 77 (18), 103 (35), 131 (100), 146 (79), 159 (7), 188 (3), and 297 (4); High resolution MS, Found: *m/z*, 297.2083. Calcd for $C_{20}H_{27}ON$: M, 297.2093.

(1*E*,6*E*)-8-(*t*-Butyldimethylsiloxy)-3-methyl-1-(2,6,6-trimethyl-1-cyclohexenyl)-1,6-tridecadien-5-one: n_D 1.4805; IR (film) 1705, 1685, 1640, 1470, 1365, 1260, 1100, 980, 840, and 780 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=−0.03 (s, 6H) , 0.88 (s, 18H), 1.04 (d, 3H, *J*=6.4 Hz), 1.23 (m, 8H), 1.44 (m, 4H), 1.58 (s, 3H), 1.91 (m, 2H), 2.56 (s, 2H), 2.73 (m, 1H), 4.25 (m, 1H), 5.24 (dd, 1H, *J*=15.8 and 7.0 Hz), 5.81 (d, 1H, *J*=16.0 Hz), 6.19 (d, 1H, *J*=15.8 Hz), and 6.73 (dd, 1H, *J*=15.8 and 4.8 Hz); MS *m/z* (rel intensity) 73 (74), 95 (37), 107 (34), 121 (45), 161 (31), 177 (73), 215 (46), 269 (25), 337 (10), 403 (8), and 460 (26); High resolution MS, Found: *m/z* 460.3731. Calcd for $C_{29}H_{52}O_2Si$: M, 460.3736.

1-(1-Cyclohexenyl)nonan-1-one: n_D 1.4777; IR (film) 1670, 1640, 1460, 1440, 1385, 1205, and 1185 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, 3H, *J*=5.6 Hz), 1.28 (m, 12H), 1.62 (m, 4H), 2.23 (m, 4H), 2.61 (t, 2H, *J*=6.7 Hz), and 6.87 (s, 1H); MS *m/z* (rel intensity) 29 (22), 41 (47), 53 (22), 81 (74), 109 (100), 124 (57), and 222 (89); High resolution MS, Found: *m/z* 222.1974. Calcd for $C_{15}H_{26}O$: M, 222.1948.

Steroid: Mp 83 °C; IR (Nujol) 1745, 1715, 1690, 1640, 1260, and 1055 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.73 (s, 3H), 0.94 (d, 3H, *J*=4.6 Hz), 0.96 (t, 3H, *J*=4.8 Hz), 1.02 (s, 3H), 2.02 (s, 3H), 0.9—2.5 (m, 29H), 4.3—4.8 (m, 1H), 5.35 (d, 1H, *J*=4.1 Hz), 6.01 (d, 1H, *J*=15.8 Hz), and 6.75 (dt, 1H, *J*=15.8 and 6.8 Hz); MS *m/z* (rel intensity) 43 (65), 55 (100), 81 (50), 105 (38), 145 (29), 161 (23), 282 (86), 390 (4), 434 (2), and 469 (2); High resolution MS, Found: *m/z*, 468.3623. Calcd for $C_{31}H_{48}O_3$: M, 468.3604.

11-(Methoxymethoxy)bicyclo[5.4.0]undec-1(7)-en-8-one: n_D 1.5045; IR (film) 1660, 1440, 1280, 1140, 1080, 1020, 910, 870, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.60 (m, 8H), 2.10 (m, 2H), 2.47 (m, 4H), 3.43 (s, 3H), 4.18 (m, 1H), 4.67 (d, 1H, *J*=6.8 Hz), and 4.81 (d, 1H, *J*=7.0 Hz); MS *m/z* (rel intensity) 45 (100), 79 (12), 91 (9), 120 (5), 133 (5), 163 (13), and 224 (3); High resolution MS, Found: *m/z*, 224.1402. Calcd for $C_{13}H_{20}O_3$: M, 224.1413.

Molecular Structure and Carbonylation of Ethyl(benzenethiolato)-palladium(II) Complex, *trans*-PdEt(SPh)(PMe_3)$_2$

Kohtaro OSAKADA,* Youichi OZAWA, and Akio YAMAMOTO*,†
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,

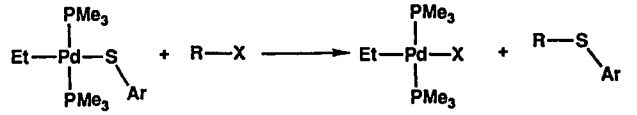
(Received February 22, 1991)

Synopsis. X-Ray crystallography of ethylpalladium thiolato complex, *trans*-PdEt(SPh)(PMe_3)$_2$, shows the detailed features of the Pd–C and Pd–S bonding. Reaction of the complex with CO at 5 atm gives *S*-phenyl thiopropionate. The NMR spectrum of the reaction mixture under 1 atm of CO shows the presence of *trans*-Pd(COEt)(SPh)(PMe_3)$_2$ formed through CO insertion into the Pd–C bond.

Recently attention has been paid to organotransition metal thiolato complexes which are regarded as key intermediates in the metal complex-catalyzed synthetic organic reactions such as desulfurization of organosulfur compounds[1–4] and coupling reaction of organic halides with thiolate anion to give dialkyl sulfides.[5–7] In the course of our study on chemical properties of organonickel and -palladium thiolato complexes[8] we found that the palladium complexes, *trans*-PdEt(SAr)(PMe_3)$_2$ (Ar=Ph, *p*-MeC_6H_4, and *p*-$MeOC_6H_4$), reacted with various organic halides to give sulfides through selective coupling of the thiolato ligand with the alkyl or acyl group of the substrates.[9]



(R–X = MeCOCl, MeI, CH_2=$CHCH_2Cl$, $PhCH_2Br$)

Although various interesting properties of thiolato complexes of transition metals were already revealed, there have been few reports on the alkylpalladium thiolato complexes. We carried out further investigation on the structure and reactivities of *trans*-PdEt(SPh)(PMe_3)$_2$. Here we report the results of the X-ray crystallography and of the study on the reaction with CO.

Results and Discussion

Structure. Figure 1 shows the molecular structure of *trans*-PdEt(SPh)(PMe_3)$_2$ (**1**) determined by X-ray crystallography. The bond distances and angles of the non-hydrogen atoms are summarized in Table 1. The molecule has a square-planar coordination around the palladium center. The phenyl plane of the thiolato ligand is almost perpendicular to the coordination plane similarly to the phenoxide ligand of the already reported methylpalladium phenoxide complexes with PMe_3 ligands.[10] The methyl carbon atoms of the two PMe_3 ligands are staggered with respect to the P–Pd–P axis. The molecule of the already reported *trans*-PdEt(Br)(PMe_3)$_2$ has an eclipsed conformation regarding with the carbon atoms in the PMe_3 ligands, and has a pseudo-mirror plane that includes Pd, Br, and the car-

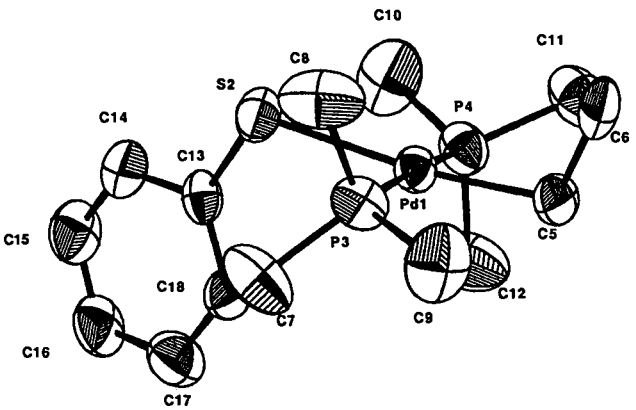

Fig. 1. The molecular structure of *trans*-PdEt(SPh)-(PMe_3)$_2$ (**1**) with the atomic numbering scheme. Non-hydrogen atoms are shown by thermal ellipsoids at 50% probability levels. Hydrogen atoms are omitted for simplicity.

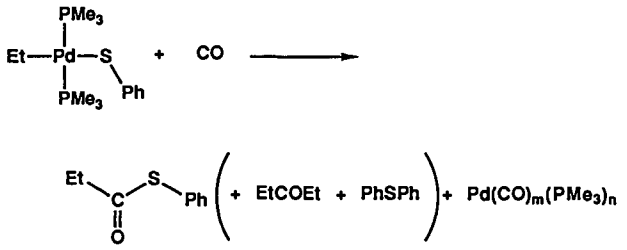
bon atoms in the ethyl ligand.[9] The Pd–C bond distance [2.098(9) Å] in the present ethylpalladium thiolato complex is longer than that in *trans*-PdEt(Br)(PMe_3)$_2$ [2.063(5) Å], suggesting a larger trans influence of the thiolato ligand than the bromo ligand. The Pd–S bond distance [2.384(2) Å] is somewhat longer than the Pd–S bond of the terminal thiolato ligand in [Pd(SC_6F_5)-(PPh_3)(μ-SC_6F_5)]$_2$.[11]

A recent review on the structures of transition metal thiolato complexes indicated that the M–S–C bond angles of the benzenethiolato complexes are in the range 103—118°.[12] The Pd–S–C angle in the title compound (109.2(3)°) is within the range.

Reaction of 1 with CO. Reaction of complex **1** with CO at 5 atm for 3 h gives *S*-phenyl thiopropionate in 62% yield accompanied by formation of small amounts of diethyl ketone and diphenyl sulfide. The resulting palladium complexes consisted of a mixture of several palladium(0) carbonyl complexes Pd(CO)$_m$(PMe_3)$_n$[13] as deduced on the basis of the IR spectrum. The NMR



study of the reaction mixture was carried out in CD_2Cl_2 under 1 atm of CO. NMR spectra (^{1}H, ^{13}C, and ^{31}P) indicated the presence of *trans*-Pd(COEt)(SPh)(PMe_3)$_2$ as the major palladium complex. Signals due to unreacted **1** are also observed, while the signals due to the *S*-thioester are not observed under the conditions. The above carbonylation of **1** under 5 atm of CO seems to proceed through formation of a propionyl palladium complex through CO insertion into the Pd–C bond in **1** followed by reductive elimination of the propionyl and thiolate ligands.[14]

Previously we have reported carbonylation of similar organonickel and -palladium alkoxide complexes. PdMe($OCH(CF_3)_2$)(dppe) (dppe=1,2-[bis(diphenylphosphino)ethane]) reacts with CO easily to give PdMe($COOCH(CF_3)_2$)(dppe) through selective CO insertion into the Pd–O bond.[15] On the other hand, *trans*-PdMe(OAr)L_2 (L=PEt_3) undergoes CO insertion into the Pd–C bond to give Pd(COMe)(OAr)L_2.[16] In the present case it is noted that CO insertion occurs into the Pd–C bond rather than into the Pd–S bond.

Experimental

trans-PdEt(SPh)(PMe_3)$_2$ (**1**) was prepared by the method reported previously.[9] GC-MS measurement was preformed on a Hitachi M-80 mass spectrometer. GC was measured on a Shimadzu 3BT gas-chromatograph using a 1-m column packed with Silicone OV-1. NMR spectra were recorded at −40 °C on a JEOL FX-100 spectrometer.

Crystallography. The single crystals suitable for crystallography were grown in acetone at −20 °C.

Crystald Data: $C_{14}H_{28}P_2SPd$, M=396.55, triclinic, $P\bar{1}$, a=9.613(7), b=12.204(6), c=8.419(4) Å, α=91.10(4), β=101.85(5), γ=94.82(5)°, U=962.5(9) Å^3, Z=2, D_c=1.369 g cm^{-3}, μ(Mo$K\alpha$)=12.1 cm^{-1}, F(000)=408.

Data Collection and Structure Refinement: A crystal with approximate dimensions of 0.45×0.50×0.50 mm sealed in a glass capillary under argon was mounted on a Rigaku AFC-5 automated four-cycle diffractometer. Unit cell parameters were determined by the least-squares calculation of 2θ values of 25 reflections with 19°<2θ<22°. Intensity data collection was carried out using Mo$K\alpha$ radiation (λ=0.71069 Å) by the ω–2θ mode. The scan speed and range were 4° min^{-1} in 2θ and $\Delta(2\theta)$=(1.40+0.7 tanθ)°, respectively. Among 2516 unique reflections (3°<2θ<45° and $-10 \leqslant h \leqslant 10$, $-13 \leqslant k \leqslant 13$, $0 \leqslant l \leqslant 8$), 2407 reflections with $F_o \geqslant 3\,\sigma(F_o)$ were used in the structure calculation. No absorption correction was applied.

Calculations were carried out on a FACOM A-70 computer. The position of palladium was determined by a direct method (SAPI85).[17] The other non-hydrogen atoms were found in the subsequent Fourier procedure. A full-matrix least-squares refinement was carried out applying anisotropic thermal factors for the non-hydrogen atoms. Hydrogen atoms were located in the difference Fourier map or at the idealized positions, and included in least-squares calculations without refinement of their parameters. Atomic coordinates are listed in Table 2. The weighting scheme, $w=1/\{\sigma^2(F_o)+[0.009(F_o)]^2\}$, with $\sigma(F_o)$ from counting statistics, gave satisfactory agreement analyses. Final R and R_w values were 0.059 and 0.064, respectively.**

Reaction of 1 with CO. To a tetrahydrofuran (3 cm^3) solution of **1** (36 mg, 0.091 mmol) in a glassware autoclave was introduced CO at 5 atm at room temperature. The orange yellow solution soon changed into deep red. After stirring for 3 h GC and GC-MS analyses of the solution indicated formation of *S*-phenyl thiopropionate (9.4 mg, 62%); MS (70 eV) m/z (rel intensity) 166 (M^+; 29), 110 (81), 109 (36), 57 (100), and 29 (87). Formation of small amounts (<10%) of diethyl ketone and diphenyl sulfide was also observed in the reaction mixture. IR spectrum of the reaction mixture after removal of the solvent showed strong broad peaks near 1700

** The complete F_o—F_c data, temperature factors of the non-hydrogen atoms, and bond distances and angles of the hydrogen atoms are deposited as Document No. 9117 at the Office of the Editor of Bull. Chem. Soc. Jpn.

cm^{-1} which are assigned to the CO stretching vibrations of palladium carbonyl complexes with the phosphine ligands.

A CD_2Cl_2 (ca. 0.3 cm^3) solution of **1** (32 mg, 0.081 mmol) was introduced to an NMR tube (5 mmϕ) which was then capped with a rubber septum under argon atmosphere. After removal of the argon in the system with a needle connected with a vacuum line, CO (1 atm) was charged with a syringe. After setting the solution at room temperature for 6 h the NMR spectra indicated formation of *trans*-Pd(COEt)(SPh)-$(PMe_3)_2$ in ca. 80% yield. Signals due to unreacted **1** were also observed. ^1H NMR (CD_2Cl_2) δ=0.99 (t, CH_3, J(HH)=7 Hz), 1.21 (t, $P(CH_3)_3$, J=4Hz),[18] 2.55 (q, CH_2, J(HH)=7 Hz), and 6.8—7.5 (m, C_6H_5); $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ=149.7 (s, C_6H_5), 132.0 (s, C_6H_5), 127.3 (s, C_6H_5), 120.3 (s, C_6H_5), 49.6 (t, CH_2, J(PC)=16 Hz), 13.9 (t, $P(CH_3)_3$, J=15 Hz),[18] 8.4 (s, CH_3); $^{31}P\{^1H\}$ NMR (CD_2Cl_2, chemical shift referred to external H_3PO_4) −20.4 ppm.

Reaction of **1** with ^{13}CO in an NMR tube was carried out similarly. $^{13}C\{^1H\}$ NMR spectrum of the reaction mixture showed a singlet at 250.1 ppm due to the carbonyl carbon atom of *trans*-Pd(COEt)(SPh)$(PMe_3)_2$. The signals of the ethyl ligand in the ^1H and $^{13}C\{^1H\}$ NMR spectra showed splitting due to the C–C and C–H coupling. The obtained coupling constants ^1J(CC), ^2J(CH), and ^3J(CH) are 33, 5, and 7 Hz, respectively.

Association Behavior of Protoporphyrin IX in Water and Aqueous Poly(*N*-vinylpyrrolidone) Solutions. Interaction between Protoporphyrin IX and Poly(*N*-vinylpyrrolidone)

Isamu INAMURA* and Kazutomo UCHIDA
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690
(Received December 25, 1990)

Synopsis. The association behavior of protoporphyrin IX was investigated at different pH by absorption spectroscopy and gel chromatography. Protoporphyrin IX existed as monomer in acidic water, as aggregate in neutral water, and as dimer in basic water. Poly(*N*-vinylpyrrolidone) tended to suppress dimerization and aggregation of protopophyrin IX.

Protoporphyrin IX is a metal-free porphyrin of the same structure as hemin. It has both the acid and base properties due to two pyrrole nitrogens capable of accepting protons and two propionic acid residues. In addition to these ionizable groups, this molecule contains a wide hydrophobic region. Tough hemin has been widely studied by many investigators,[1,2] there are only a few reports on the association behavior of protoporphyrin IX. Savitski et al.[3] reported that protoporphyrin IX was solubilized as monomer in the micelles of Triton X-100. Gallagher et al.[4] observed spectral changes of hematoporphyrin and protoporphyrin IX reflecting the dimer-to-monomer conversion. Except for these works, the association behavior of protoporphyrin IX has not been elucidated.

We recently succeeded in solubilizing hemin as monomer in both neutral and acidic water by complexing with poly(*N*-vinylpyrrolidone)] (PVP).[5] In view of this, we got interested in clarifying the interaction between PVP and protoporphyrin IX, and its influence on the association behavior of protoporphyrin IX.

In the present work, we measured at different pH the absorption spectra of protoporphyrin IX both in water and in aqueous PVP solutions. Some of the solution were examined by gel chromatography. Three types of absorption spectra were observed, and assigned to monomer, dimer, and aggregate of protoporphyrin IX. The effects of pH and PVP on the association behavior of protopophyrin IX are discussed on the basis of the structure of protoporphyrin IX.

Experimental

Materials. Protoporphyrin IX disodium salt was purchased from Nacalai Tesque, Inc. PVP (molecular weight 40000) was from Kishida Chemical Co., Ltd, and was purified by reprecipitation in water–acetone.

Preparation of Aqueous Protoporphyrin IX/PVP Solution. Protoporphyrin IX disodium salt (2 mg) and PVP (1.32 g) were dissolved in water to obtain 80 ml of an aqueous solution (pH 4.8). The pH of the solution was adjusted with HCl or NaOH. Aqueous protoporphyrin IX solutions were prepared in a similar way.

Gel Chromatography. Gel chromatography of aqueous protoporphyrin IX and protoporphyrin IX/PVP solutions was performed as follows. Two milliliters of the sample (pH 4.8 or 10) was applied onto a column (0.8×40 cm) of Toyopearl HW-55 equilibrated with water adjusted to pH of the sample. Then it was eluted with water (pH 4.8 or 10) at a flow rate of 0.13 ml min^{-1}. Concentrations of samples applied to the column were 2.5×10^{-4} mol dm^{-3} for protoporphyrin IX, and 10% wt/vol-solution for PVP. The content of protoporphyrln IX in the eluted fraction (4 ml) was monitored by measuring the maximum absorbance in a wavelength range of 350 nm to 800 nm. The amount of PVP was monitored by weighing the fraction after evaporation, which usually contained a negligible content of protoporphyrin IX.

Analytical Method. Absorption spectra at room temperature were measured with a double beam spectrophotometer UVIDEC-510 (Japan Spectroscopic Co., Ltd.).

Results

Figure 1 shows the absorption spectra of protoporphyrin IX in different states. At pH 1.0, protopor-

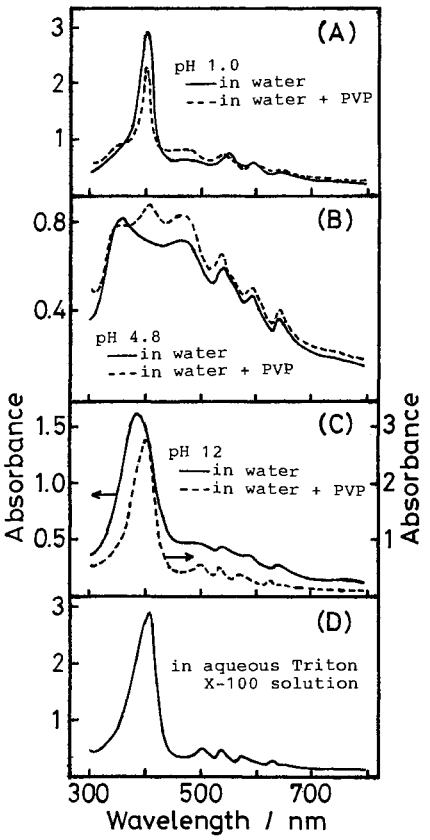

Fig. 1. Absorption spectra of protoporphyrin IX in different states.
Protoporphyrin IX in water (——) and in aqueous PVP solution (------) at pH 1.0 (A), 4.8 (B) and 12 (C). Protoporphyrin IX in aqueous Triton X-100 (1.5%) solution at pH 5.4 (D). Concentrations of protoporphyrin IX and PVP are 4.12×10^{-5} mol dm^{-3} and 1.65×10^{-2} g cm^{-3}, respectively.

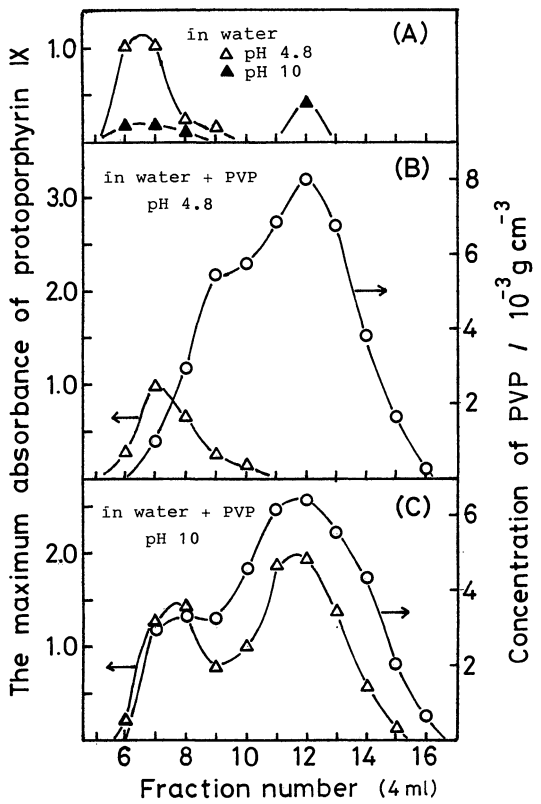

Fig. 2. Elution patterns of gel chromatography.
(A) aqueous protoporphyrin IX solution at pH 4.8 and 10, (B) aqueous protoporphyrin IX/PVP solution at pH 4.8, (C) aqueous protoporphyrin IX/PVP solution at pH 10.

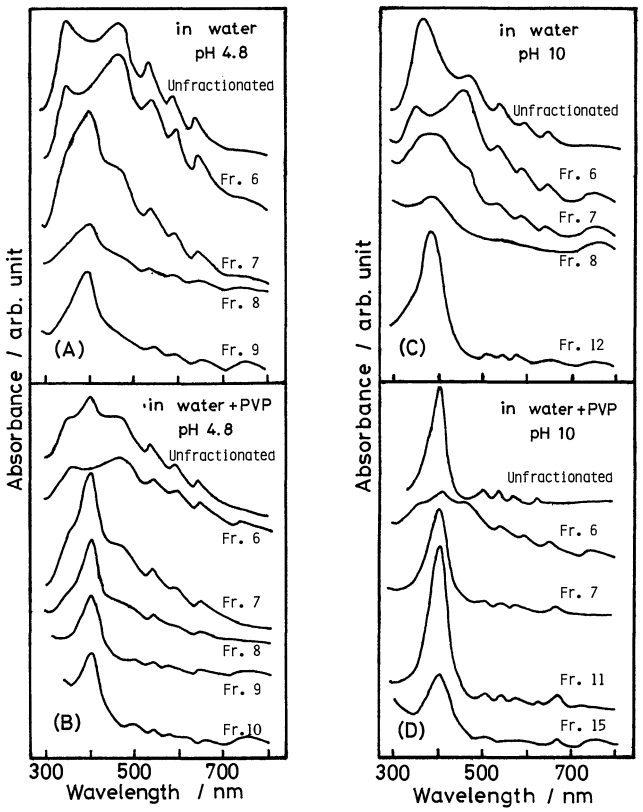

Fig. 3. Absorption spectra of protoporphyrin IX in unfractionated and fractionated solutions in gel chromatography.
(A) protoporphyrin IX in water at pH 4.8, (B) protoporphyrin IX in aqueous PVP solution at pH 4.8, (C) protoporphyrin IX in water at pH 10, (D) protoporphyrin IX in aqueous PVP solution at pH 10. Fraction numbers are the same as those in Fig. 2. The absorption spectra of fractions 8—10 and 12—14 for sample (D) are not shown, because they changed successively as the fraction number grew.

phyrin IX in water and in aqueous PVP solution had a sharp Soret band at 405 nm and four weak Q-bands. Protoporphyrin IX in water at pH 4.8 exhibited a weak Soret band at about 350 nm and four weak Q-bands; on interacting with PVP, a new Soret band appeared at 406 nm. Protoporphyrin IX in water at pH 12 showed a sharp Soret band at 388 nm and four weak Q-bands; on interacting with PVP, the Soret band shifted to 404 nm and its intensity increased about 1.7 times, resulting in the same intensity as the Soret band at pH 1.0.

Thus, the following three types of absorption spectra were observed for protoporphyrin IX in water and aqueous PVP solutions. Type 1—a weak Soret band at about 350 nm and four weak Q-bands, Type 2—a sharp Soret band at 388 nm and four weak Q-bands, Type 3—a sharp Soret band at about 405 nm and four weak Q-bands.

Figure 2 shows the elution patterns of gel chromatography. Each plot in this figure gives the amount of protoporphyrin IX or PVP contained in each fraction. The elution curves of protoporphyrin IX and PVP were remarkably dependent on pH.

Figure 3 shows the absorption spectra of protoporphyrin IX in unfractionated (sample applied onto the column) and fractionated solutions. For each sample, Fr. 6 showed the Type 1 absorption spectrum. As the fraction number increased, the Soret bands shifted from about 350 nm to 398 nm (Fig. 3-A), 403 nm (Fig. 3-B), 381 nm (Fig. 3-C), or 405 nm (Fig. 3-D), and their intensities became much higher as compared with Q-bands. These absorption spectra were classified into Types 2 and 3 as follows. The absorption spectra of later fractions in water at pH 4.8 (Fig. 3-A), and in aqueous PVP solutions at pH 4.8 (Fig. 3-B) and at pH 10 (Fig. 3-D) belonged to Type 3, since the Soret bands were at 398—405 nm. On the other hand, the absorption spectrum of a later fraction, Fr. 12, in water at pH 10 (Fig. 3-C) belonged to Type 2 with the Soret maximum at 381 nm.

Discussion

Effect of pH. Since protoporphyrin IX is an amphoteric electrolyte, it is considered to dissociate into ions in acidic and basic water. This explains the result that the intensity of the Soret band of protoporphyrin IX in water increased in the order at pH 4.8< at pH 12< at pH 1.0 (Fig. 1). At pH 4.8, the solubility of protoporphyrin IX was substantially small due to the low degree of electrolytic dissociation.

Assignment of Three Types of Absorption Spectra. In

gel chromatography, it is expected that as the fraction number increased, the molecular weight was lower. Therefore, Type 1 observed in the earliest fraction, Fr. 6, may represent a bulky species of protoporphyrin IX. On the other hand, Types 2 and 3 observed in later fractions may be due to a small species. Based on these, we assigned the three types of absorption spectra of protoporphyrin IX as follows.

Type 1 was supposed to arize from a large species. The molecular weight of this species was inferred to be larger than 700000, because as specified by the manufacturer, Toyopearl HW-55 excludes proteins of molecular weight larger than 700000. A most probable candidate for Type 1 is thus an aggregate of protoporphyrin IX. The lowest intensity of the Soret band of Type 1 in water at pH 4.8 (Fig. 1-B) was consistent with this assignment. Savitski et al.[3] reported a similar absorption spectrum for protoporphyrin IX in water at pH 8.0.

Type 2 was observed in basic water of pH 10 and 12 (Figs. 1-C and 3-C), and the gel chromatographic elution time suggested that it was a small species. The spectral feature of Type 2 was similar to that of a hematoporphyrin dimer in 0.02 M NaOH (1 M=mol dm^{-3}), reported by Gallagher et al.[4] The dimer of hematopophyrin had a Soret band at about 375 nm and four weak Q-bands, and on dilution the Soret band shifted to 395 nm and its intensity increased about 1.5 times, due to disintegration of dimer to monomer. They also described that a similar spectral change was observed for protoporphyrin IX under the same conditions.[4] Therefore, Type 2 was assigned to a dimer of protoporphyrin IX.

Type 3 was also suggested to reflect a small species from gel chromatography. It should be noted that this type was also observed in an aqueous Triton X-100 solution (Fig. 1-D). Savitski et al.[3] reported that protoporphyrin IX was solubilized as monomer in Triton X-100 micelles, on the basis of fluorescence spectra. Therefore, Type 3 was assigned to the monomer of protoporphyrin IX. The highest intensity of the Soret band of type 3 (Fig. 1) supports this assignment.

From the assignments of three types of absorption spectra, it can be concluded that protoporphyrin IX was dissolved as monomer in acidic water, as aggregate in neutral water, and as dimer in basic water, though a small amount of other species was involved in some cases.

Model for Dimerization and Aggregation. It is interesting to note that protoporphyrin IX is dissolved as monomer in acidic water whereas as dimer in basic water, though the ionization occurs in both media. This fact seems to suggest that ionization of two pyrrole nitrogens at nearly the center of the porphyrin ring under acidic conditions, is more effective in inhibiting dimerization than that of two propionic acid residues outside the ring under basic conditions. This interpretation is in line with the "face-to-face" or "ring stacking" model[2] for dimerization and aggregation of protoporphyrin IX. Furthermore, the blue shift of the Soret band of protoporphyrin IX due to conversion of monomer to dimer (Fig. 1-C) also supports this model for dimerization.[2,6,7]

Interaction between PVP and Protoporphyrin IX. When PVP was present, protoporphyrin IX tended to show Type 3 assigned to a monomer, even in neutral and basic water (Figs. 1—3). Therefore, we could conclude that PVP tends to suppress dimerization and aggregation of protoporphyrin IX. This effect of PVP was more conspicuously observed at pH 10 and 12 than at pH 4.8. Since the protoporphyrin IX molecule has a wide hydrophobic region, PVP probably binds the molecule within its random coil chain through a hydrophobic interaction, thereby preventing dimerization and aggregation of protoporphyrin IX.

Synthesis of 2,2,2-Trifluoroethylated Onium Salts of Nitrogen, Sulfur, and Phosphorus with (2,2,2-Trifluoroethyl)phenyliodonium Triflate

Teruo UMEMOTO* and Yoshihiko GOTOH
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received January 25, 1991)

Synopsis. Various 2,2,2-trifluoroethyl onium triflates were synthesized by treating tertiary amines, pyridines, quinoline, a triazole, sulfides, and a phosphine with (2,2,2-trifluoroethyl)phenyliodonium triflate. Sulfoxides and N-oxide were converted to the corresponding trifluoroethylated salts. As an application, CsF-treatment of (2,2,2-trifluoethyl)triphenylphosphonium triflate with an aldehyde was shown to produce a trifluoromethylated olefin.

Much attention has been directed to trifluoromethyl or 2,2,2-trifluoroethyl-containing organic compounds for developing new medicines, agricultural chemicals and other materials since trifluoromethyl and trifluoroethyl groups are considered to be importantly involved in biological activity and physical properties of materials in consideration of their own unique features.[1] The onium salts of nitrogen, sulfur, and phosphorus are important particularly for their use as reagents in synthetic organic chemistry.[2] No effective methods are presently available for preparing trifluoroethylated onium salts and only a few 2,2,2-trifluoroethylated salts are known.[3] We successfully developed (2,2,2-trifluoroethyl)phenyliodonium triflate (**1**), the smallest in a series of (1*H*,1*H*-perfluoroalkyl)phenyliodonium triflates (FMITS reagents), as the most reactive source of 2,2,2-trifluoroethyl cation.[4,5] The present study was conducted to establish an effective means for preparing 2,2,2-trifluoroethylammonium, pyridinium, quinolinium, sulfonium, and phosphonium triflates with **1**. One application of the phosphonium salt obtained is discussed.

Results and Discussion

Table 1 shows modes for the synthesis of various kinds of 2,2,2-trifluoroethyl onium triflates using **1**. Salt **1** reacted readily with tertiary amines, pyridine and its derivatives, quinoline and benzothiazole in dichloromethane at room temperature to give 2,2,2-trifluoroethyl onium triflates **2**—**10** in high yields. Both bulky 2,4,6-collidine or 2,6-lutidine and the less nucleophilic ethyl nicotinate were well-trifluoroethylated with **1** under the same conditions. Salt **1** was clearly shown as the most reactive in a series of (1*H*,1*H*-perfluoroalkyl)phenyliodonium triflates, since (1*H*,1*H*-perfluoropropyl, -perfluorobutyl and -perfluorooctyl)-phenyliodonium triflates (**15**, **16**, and **17**) failed to react with 2,4,6-collidine, due possibly to bulkiness about the pyridine nitrogen. Pyridine reacted with **15**, **16**, and **17** in dichloromethane to give the corresponding pyridinium triflates[6] in 93, 92, and 74% yields, respectively, but this required increase in reaction temperature and/or time. The high reactivity of **1** greatly facilitated converting sulfides to trifluoroethylsulfonium salts so that diphenyl and dimethyl sulfides smoothly reacted with **1** at room temperature to give the trifluoroethylsulfonium triflates, **11** and **12**, in high yields. The reaction of dibenzothiophene, however, was quite slow and the yield of **13** was low, owing possibly to the great decrease in the reactivity of the latter sulfide. Salts **11** and **13** are stable crystals, while those of **12** are unstable due to their highly hygroscopic nature. The reaction of triphenylphosphine with **1** was successfully conducted using benzene as the solvent to obtain trifluoroethylphosphonium triflate **14**, nonhygroscopic and stable crystals, in 95% yield. Previously, (2,2,2-trifluoroethyl)triphenylphosphonium iodide could be obtained only in 9% yield by treating triphenylphosphine with 2,2,2-trifluoroethyl iodide for 9 months at room temper-

a) Dichloromethane was used as a solvent for Runs 1—12 and benzene for Run 13. All the reactions were carried out at room temperature. b) Minute, unless otherwise noted.

ature with northern exposure.[3b]

Diphenyl sulfoxide and dimethyl sulfoxide were each found to react smoothly with **1**. Isolating the resulting salts in pure form, however, was difficult owing to their extremely hygroscopic nature. The ^{19}F NMR spectra of the crude products showed a peak of the trifluoroethyl group at −72.8 ppm for the product from diphenyl sulfoxide and at −73.9 ppm for dimethyl sulfoxide. These chemical shifts appeared in considerably high magnetic fields compared with those of sulfonium salts **11** (−60.0) and **12** (−61.1). However, structural assignments for *O*- or *S*-trifluoroethyl salts **18** or **19** could not

$R_2S{=}O + \mathbf{1} \longrightarrow R_2S^+{-}OCH_2CF_3\ {}^-OTf$

a; R=Ph **18, b**

b; R=Me

or $R_2S^+{-}CH_2CF_3\ {}^-OTf$ (O double-bonded to S)

19a,b

be determined. Pyridine *N*-oxide smoothly reacted with **1** under the same conditions to give *N*-(2,2,2-trifluoroethoxy)pyridinium triflate (**20**) in a quantitative yield.

As an application of trifluoroethyl onium salts in synthetic organic chemistry, phosphonium triflate **14** was treated with benzaldehyde using cesium fluoride as a base in *N,N*-dimethylformamide at room temperature to give β-(trifluoromethyl)styrene in 43% yield (*E*-/*Z*-isomer=46/54). When sodium hydride was used as the base, there was no product formation.

Experimental

Melting points were uncorrected. ^{1}H and ^{19}F NMR spectra were recorded with a Varian EM 390 NMR and a Hitachi R-20 B NMR spectrometer, respectively. Unless otherwise noted, acetone-d_6 was used as a solvent. ^{19}F NMR chemical shifts were reported in ppm downfield from trichlorofluoromethane as an internal standard. The IR spectra were measured on a JASCO A-202 diffraction grating infrared spectrometer. Mass spectra were recorded on a Hitachi RMU-6MG spectrometer at 70 eV. (2,2,2-Trifluoroethyl)-phenyliodonium triflate (**1**) was prepared according to a reported method.[4c] Cesium fluoride was dried at 140 °C for 3—12 h in vacuo.

Preparation, of 2,2,2-Trifluoroethyl Onium Triflates with 1. General Procedure; Into a solution of 1 mmol of a substrate (shown in Table 1) in 2 ml of dry dichloromethane was added 436 mg (1 mmol) of **1** under an argon atmosphere. The reaction mixture was stirred for the time shown in Table 1 at room temperature. The results are summarized in Table 1. In the case of triphenylphosphine as a substrate, benzene was used as a solvent. Isolation of products **2**—**10** was carried out by preparative thin-layer chromatography on silica gel. Products **11**—**14** each appeared as crystals upon adding pentane to the reaction mixture, and were collected by filtration. Analytically pure samples of **2** and **4** could not be obtained, probably due to changing hydrate formation for the former and the oily nature for the latter. For **12**, only ^{1}H and ^{19}F NMR were measured, since pure crystals of **12** were not obtained because of lability.

Benzyldimethyl(2,2,2-trifluoroethyl)ammonium triflate (**2**): mp 99—100 °C; ^{1}H NMR δ=3.48 (6H, s, 2×CH_3), 4.65 (2H, q, *J*=9 Hz, CH_2CF_3), 5.00 (2H, s, CH_2), 7.43—7.86 (5H, m); ^{19}F NMR δ=−60.8 (3F, t, *J*=9 Hz, CF_3), −77.6 (3F, s, SCF_3); Mass *m/z* 218 (M^+ −OTf). *N,N*-Dimethyl-*N*-(2,2,2-trifluoroethyl)anilinium triflate (**3**): mp 82—84 °C; ^{1}H NMR δ=4.10 (6H, s, 2×CH_3), 5.25 (2H, q, *J*=9 Hz, CH_2), 7.56—7.83 (3H, m), 8.06—8.26 (2H, m); ^{19}F NMR δ=−62.3 (3F, t, *J*=9 Hz, CF_3), −78.0 (3F, s, SCF_3); Mass *m/z* 204 (M^+ −OTf). Found; C, 36.84; H, 3.87; N, 4.14%. Calcd for $C_{11}H_{13}F_6NO_3S \cdot 1/2H_2O$; C, 36.47; H, 3.89; N, 3.87%. *N*-(2,2,2-Trifluoroethyl)pyridinium triflate (**4**):[7] oil; ^{1}H NMR δ=5.81 (2H, q, *J*=8 Hz, CH_2), 8.28—8.53 (2H, m), 8.80—9.40 (3H, m); ^{19}F NMR δ=−70.7 (3F, t, *J*=8 Hz, CF_3), −77.9 (3F, s, SCF_3); IR (neat) 3070, 1640, 1500, 1400, 1260, 1170, 1030, 840, 780, 695, 640, 600, 520 cm^{-1}; Mass *m/z* 162 (M^+ −OTf). *N*-(2,2,2-Trifluoroethyl)-3,5-lutidinium triflate (**5**): mp 162—164 °C (1,2-dichloroethane); ^{1}H NMR δ=2.70 (6H, s, 2×CH_3 5.72 (2H, q, *J*=8 Hz, CH_2), 8.60 (1H, br.s), 9.02 (2H, br.s); ^{19}F NMR δ=−70.4 (3F, t, *J*=8 Hz, CF_3), −77.9 (3F, s, SCF_3); Mass *m/z* 190 (M^+ −OTf). Found: C, 35.31; H, 3.33, N, 4.07%. Calcd for $C_{10}H_{11}F_6NO_3S$: C, 35.40; H, 3.27; N, 4.13%. *N*-(2,2,2-Trifluoroethyl)-2,6-lutidinium triflate (**6**): mp 188—189 °C (1,2-dichloroethane); ^{1}H NMR δ=2.97 (6H, s, 2×CH_3), 5.68 (2H, q, *J*=8 Hz, CH_2), 7.8—8.6 (3H, m); ^{19}F NMR δ=−65.4 (3F, t, *J*=8 Hz, CF_3), −77.6 (3F, s, CF_3S); Mass *m/z* 190 (M^+ −OTf). Found: C, 35.31; H, 3.33, N, 4.07%. Calcd for $C_{10}H_{11}F_6NO_3S$; C, 35.40; H, 3.27; N, 4.13%. Found; C, 35.30; H, 3.33; N, 4.02%. *N*-(2,2,2-Trifluoroethyl)-2,4,6-collidinium triflate (**7**): mp 146—148 °C (chloroform); ^{1}H NMR δ=2.59 (3H, s, CH_3), 2.96 (6H, s, 2×CH_3), 5.68 (2H, q, *J*=8 Hz, CH_2);7.89 (2H, br.s); ^{19}F NMR δ=−65.6 (3F, t, *J*=8 Hz, CF_3), −77.3 (3F, s, SCF_3); Mass *m/z* 204 (M^+ −OTf). Found: C, 32.40; N, 1.75; N, 3.65%. Calcd for $C_{10}H_7F_6NO_3S$: C, 32.70; H, 1.92; N, 3.81%. (2,2,2,-Trifluoroethyl)diphenylsulfonium triflate (**11**): mp 138—140 °C (acetonitrile–ether); ^{1}H NMR (acetonitrile-d_3) δ=5.21 (2H, q, *J*=9 Hz, CH_2), 7.66—7.98 (6H, m), 7.98—8.23 (4H, m); ^{19}F NMR (acetonitrile-d_3) δ=−60.0 (3F, t, *J*=9 Hz, CF_3), −78.0 (3F, s, SCF_3); Mass *m/z* 186 (Ph_2S^+). Found: C, 42.93; H, 2.93%. Calcd for $C_{15}H_{12}F_6O_3S_2$: C, 43.06; H, 2.89%. (2,2,2-Trifluoroethyl)dimethylsulfonium triflate (**12**): ^{1}H NMR (acetonitrile-d_3) δ=3.10 (6H, s, 2×CH_3), 4.30 (2H, q, *J*=9 Hz, CH_2); ^{19}F NMR (acetonitrile-d_3) δ=−61.1 (3F, t, *J*=9 Hz, CF_3), −78.1 (3F, s, SCF_3). (2,2,2-Trifluoroethyl)dibenzothiophenium trilfate (**13**): mp 168 °C (acetonitrile–ether); ^{1}H NMR (acetonitrile-d_3) δ=4.80 (2H, q, *J*=9 Hz, CH_2), 7.78—8.11 (4H, m), 8.34—8.48 (4H, m); ^{19}F NMR (acetonitrile-d_3) δ=−59.4 (3F, t, *J*=9 Hz, CF_3), −78.4 (3F, s, SCF_3); Mass (SIMS method) *m/z* 267 (M^+ −OTf), 184 (267−CH_2CF_3). Found: C, 43.05; H, 2.69%. Calcd for $C_{15}H_{10}F_6O_3S_2$: C, 43.27; 2.42%. (2,2,2-Trifluoroethyl)-

triphenylphosphonium trilfate (**14**): mp 208 °C (acetonitrile–ether); ^{1}H NMR (acetonitrile-d_3) δ=4.42—4.96 (2H, m, CH_2), 7.60—8.00 (15H, m, 3×Ph); ^{19}F NMR (acetonitrile-d_3) δ=−52.5 (3F, dt, J=7, 9 Hz, CF_3), −78.0 (3F, s, SCF_3); ^{31}P NMR (acetonitrile+acetonitrile-d_3, Ph_3P as an standard) δ=22.6 (q, J=7 Hz); Mass m/z 220 (M^+ −OTf). Found: C, 51.05; H, 3.46%. Calcd for $C_{21}H_{17}F_6O_3PS$: C, 51.02; H, 3.47%.

Reaction of Pyridine with (1*H*,1*H*-Perfluoropropyl, -Perfluorobutyl, or -Perfluorooctyl)phenyliodonium Triflate (15, 16, or 17). The procedure was the same as that mentioned above. The reaction time and temperature were as follows: 30 min, room temperature for **15** and **16**; 1 h, reflux temperature for **17**. After each reaction, the solvent was evaporated and the residue recrystallized from 1,2-dichloroethane. Spectral data and elemental analysis of new compounds are as follows. *N*-(1*H*,1*H*-Perfluoropropyl)pyridinium triflate: mp 84—86 °C; ^{1}H NMR δ=6.05 (2H, t, J=15 Hz, CH_2), 8.30—8.66 (2H, m), 8.90—9.50 (3H, m); ^{19}F NMR δ=−77.6 (3F, s, SCF_3), −82.7 (3F, s, CF_3), −119.3 (2F, t, J=15 Hz, CF_2); Mass m/z 262, 242. Found: C, 29.89; H, 1.77; N, 3.80%. Calcd for $C_9H_7F_8NO_3S$: C, 29.93; H, 1.95; N, 3.88%. *N*-(1*H*,1*H*-Perfluorobutyl)-pyridinium triflate: mp 126—127 °C; ^{1}H NMR δ=6.02 (2H, t, J=15 Hz, CH_2), 8.33—8.60 (2H, m), 8.90—9.50 (3H, m); ^{19}F NMR; δ=−77.6 (3F, s, SCF_3), −79.7 (3F, t, J=15 Hz, CH_2CF_2), −116.3 (2F, m, CF_2), −125.3 (2F, m, CF_2); Mass m/z 212, 192. Found: C, 29.07; H, 1.73, N, 3.28%. Calcd for $C_{10}H_7F_{10}NO_3S$: C, 29.21; H, 1.72; N, 3.41%.

Preparation of 18a,b or 19a,b and 20. The procedure was the same as that described above using diphenyl sulfoxide, dimethyl sulfoxide, and pyridine N-oxide as substrates. The reaction time and temperature were as follows: 4 h, room temperature for **18a** or **19a**; 5 h, room temperature for **18b** or **19b**; 3 h, room temperature for **20**. The spectral data and elemental analyasis are shown in the following: **18a** or **19a**: ^{1}H NMR (acetonitrile-d_3) δ=5.15 (2H, q, J=9 Hz, CH_2), 7.35—8.13 (10H, m, 2×Ph); ^{19}F NMR (acetonitrile-d_3) δ=−72.8 (3F, t, J=9 Hz, CF_3), −78.0 (3F, s, SCF_3). **18b** or **19b**: ^{1}H NMR (acetonitrile-d_3) δ=3.41 (6H, s, 2×CH_3), 4.82 (2H, q, J=9 Hz, CH_2); ^{19}F NMR (acetonitrile-d_3) δ=−73.9 (3F, t, J=9 Hz, CF_3), −78.0 (3F, s, SCF_3). Salt **20** was purified by washing the oily product, which was obtained by adding pentane to the reaction solution, with pentane. **20**: oil; ^{1}H NMR (acetonitrile-d_3) δ=5.26 (2H, q, J=9 Hz, CH_2), 8.06—8.40 (2H, m, 4-H), 8.58—8.80 (1H, m, 3-H), 9.00—9.28 (2H, m, 2-H); ^{19}F NMR (acetonitrile-d_3) δ=−72.0 (3F, t, J=9 Hz, CF_3), −78.0 (3F, s, SCF_3); Mass m/z 178 (M^+ −OTf). Found: C, 28.36; H, 2.23; N, 4.16%. Calcd for $C_8H_7F_6NO_4S \cdot 1/2H_2O$: C, 28.58; H, 2.40; N, 4.17%.

Reaction of 14 with Benzaldehyde. Into a mixture of 5 mmol of dry cesium fluoride in 5 ml of dry *N,N*-dimethylformamide were added 1 mmol of **14** and 1 mmol of benzaldehyde. The reaction mixture was stirred at room temperature for 8 h, poured into water, and extracted with pentane. The pentane layer was washed with water, dried with magnesium sulfate, and concentrated. The product yields were determined by ^{19}F NMR analyses of the concentrated solution. Structural assignments were carried out by spectral analyses of the isolated products. β-(Trifluoromethyl)styrene: ^{19}F NMR (chloroform-*d*) δ=−58.3 (d, J=9.0 Hz, CF_3, *Z*-isomer), −64.1 (dd, J=7.0, 2.0 Hz, CF_3, E-isomer).

Formation of Acyclic *cis*-Azobenzene without Light

Nobuyuki TAMAOKI,* Sawako YOSHIMURA, and Tsuguo YAMAOKA
Department of Image Science and Technology, Faculty of Engineering, Chiba University, 1-33 Yayoi-cho, Chiba 260
(Received February 2, 1991)

Synopsis. Reduction mixture of bis(4-nitrobenzyl) ether contained a considerable amount of *cis*-4,4′-dimethylazobenzene.

Although several chemical syntheses of *trans*-azobenzene derivatives are known,[1] chemical syntheses of *cis* isomers are known only in the case of cyclic azobenzene derivatives.[2] The only method to synthesize acyclic *cis*-azobenzene derivatives ever known is a photochemical one, namely, exposing the corresponding *trans*-azobenzene derivatives to UV light.[3] This is probably due to the fact that the intermediates in the chemical formations of azo linkages energetically favor *trans* conformations about the N–N bonds. In this note we describe the one-pot chemical formation of *cis*-4,4′-dimethylazobenzene, **3**, without using light.

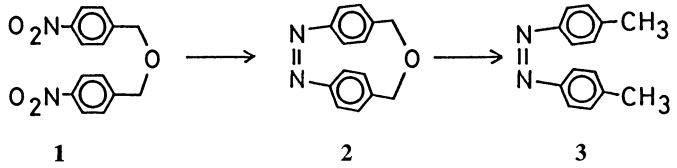
Bis(4-nitrobenzyl) ether, **1**, was reduced with $LiAlH_4$ in dry THF by a high-dilution method. It was found by TLC that the reaction mixture contained several orange products. The mixture was then separated by column chromatography. Two main orange compounds which were eluted together during the early stage of chromatography were further separated by preparative GPC and crystallized by slow evaporation of the solvent under atmospheric pressure at room temperature. One of the fractions was identified as being *trans*-4,4′-dimethylazobenzene by comparing the ^{1}H NMR and retention time on reversed-phase HPLC with an authentic sample# which was synthesized by the reduction of 4-nitrotoluene. Identification of the fraction was further confirmed by FD-MS. The detected mass was 210, which corresponds to 4,4′-dimethylazobenzene. The other fraction of the preparative GPC showed two peaks on reversed-phase HPLC after crystallization. This means that the compound in this fraction of GPC is slowly changed to another compound in the dark. On the ^{1}H NMR chart there exist four kinds of doublets (each two peaks of which is coupled) and two kinds of singlets. By a comparison of ^{1}H NMR and the retention time on reversed-phase HPLC with an authentic mixture prepared by the UV irradiation of *trans*-4,4′-dimethylazobenzene in solvent, the second isolated fraction was identified as being a mixture of *trans*- and *cis*-4,4′-dimethylazobenzene.

Since we performed the entire process under yellow light (<500 nm), it is certain that *cis*-4,4′-dimethylazobenzene is formed chemically, not photochemically. This interesting phenomenon is explained as below (scheme). Bis(4-nitrobenzyl) ether was first reduced to form 2-oxa-10,11-diaza[3.2]paracyclophan-10-ene, **2** in which the azo linkage is fixed to the *cis* form due to a ring restriction. The cyclophane is destabilized by ring strain and is thus very easily further reduced to form an acyclic azobenzene derivative, **3**, while maintaining the azo configuration in the *cis* form. Another possible route, in which the ether linkage of **1** is first decomposed to form 4-nitrotoluene and then converted to **3**, is excluded by the following observation. A reduction of 4-nitrotoluene under similar conditions did not produce *cis*-4,4′-dimethylazobenzene, but produced *trans*-4,4′-dimethylazobenzene only.

This proposed reaction process to form the *cis*-azobenzene derivative is also interesting fields involving the synthesis of cyclophanes which contain hetero atoms. The synthesis of 10,11-diaza[3.2]paracyclophane-10-enes has not yet succeeded, in spite of the intensive efforts by Funke and Grützmacher.[4] Although we have not yet isolated 10,11-diaza[3.2]paracyclophane-10-enes, we believe that 1,3-bis(4-nitrophenyl)propane will be stably converted to 10,11-diaza[3.2]paracyclophan-10-ene under the same reduction conditions as described in this study.

Experimental

Synthesis of Bis(4-nitrobenzyl) Ether, 1: **1** was synthesized by a bimolecular condensation of 4-nitrobenzyl alcohol, **4**. 6 ml of concd H_2SO_4 was added to 25 g of **4** in 150 ml of benzene. The solution was heated under reflux for 4 h. After that, H_2SO_4 was further added until **4** completely disappeared. After 25 h the solution was cooled to room temperature and washed four times with 100 ml (each) of water. A small portion of **1** appeared as a white solid two or three days after removing the benzene from the solution by evaporation. Additional **1** appeared after removing (4-nitrophenyl)-



1 **2** **3**

Scheme 1.

#^{1}H NMR (270 MHz) *trans*-4,4-dimethylazobenzene ($CDCl_3$) δ=2.43 (s, 6H), 7.30 (d, J=8.2 Hz, 4H, Ar), 7.81 (d, J=8.2 Hz, 4H, Ar); *cis*-4,4′-dimethylazobenzene ($CDCl_3$) δ=2.30 (s, $-CH_3$), 6.77 (d, J=7.2 Hz, 4H, Ar), 7.05 (d, J=7.2 Hz, 4H, Ar).

phenylmethane[5] from the remaining solution by distillation. The product was combined and recrystallized from ethanol. 3.82 g (16.2%), mp 97—98 °C (lit,[6] 97—98 °C), ^{1}H NMR ($CDCl_3$) δ=4.72 (s, 4H, CH_2OCH_2), 7.55 (d, 4H, Ar), 8.24 (d, 4H, Ar).

Reduction of 1: A solution of 5.0 g of **1** in 100 ml of dry THF was added dropwise for 3 h to a suspension of 3.4 g of $LiAlH_4$ in 140 ml of dry THF under a nitrogen atmosphere. After 20 h of stirring, a small amount of water was carefully added to the reaction mixture in order to destroy the remaining any $LiAlH_4$. O_2 was then passed through the reaction mixture for 4.5 h in order to oxidize any hydrazo compounds to the corresponding azo compounds. The solid was filtered off and the filtrate evaporated. The residue was extracted by chloroform. A condensed chloroform solution was transferred to a silica gel column and eluted with hexane–chloroform (1:1 v/v). The first eluent was further purified by preparative GPC (Waters, ULTRASTYRAGEL 500 Å+100 Å/chloroform). *cis*- and *trans*-4,4′-Dimethylazobenzene was eluted at retention volumes of 95.5 and 99.6 ml, respectively. By slowly evaporating of chloroform parts of the first fraction (8.07 mg, 0.21%) and second fraction (0.196 g, 5.1%) were isolated.

We are grateful to Mr. Madoka Yasuike and Mr. Yasumasa Toba of Toyo Ink M.F.D. Co., Ltd., Japan for FD mass spectra.

Efficient Transformation of Methyl Propargyl Ethers into α,β-Unsaturated Ketones

Yukitoshi FUKUDA† and Kiitiro UTIMOTO*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Yoshida, Kyoto 606
(Received February 13, 1991)

Synopsis. Methyl propargyl ethers, obtained from carbonyl compounds by successive treatment with an acetylide and MeI, were easily converted to the corresponding α,β-unsaturated ketone by regioselective hydration of acetylenic moiety followed by elimination of methanol under the catalytic action of Au(III).

Hydration of an acetylenic moiety has been utilized for the preparation of ketones from easily accessible alkynes. Various transition metal catalysts have been employed for the hydration of unactivated alkynes.[1-14] As a propargylic alcohol **1** is a suitable precursor of α-hydroxy ketone **2** or α,β-unsaturated ketone **4** by the regiocontrolled hydration, generally applicable methodologies have been needed. We have disclosed the regioselective formation of **2** (R=Ac) from acetate **1** (R=Ac) under the catalytic action of Au(III).[15] As for selective formation of **4**, Hg(II) catalysts are applied in strongly acidic conditions, other effective catalysts are needed for the transformation in mild conditions.

During the continuous studies on selective hydration of the derivatives of propargyl alcohols **1**, we have observed the highly regioselective hydration of methyl ethers to give **4** exclusively. This paper describes Au(III) catalyzed regioselective hydration of **1** (R=Me) under mild conditions.

Internal methyl propargyl ethers **1** (R=Me, R^1 and/or $R^2 \neq H$, $R^3 \neq H$) were treated with $NaAuCl_4$ (5 mol%) in refluxing aqueous methanol to give α,β-unsaturated ketones by regioselective hydration followed by elimination of methanol. A propargyl methyl ether **1f** (R=Me, $R^1=R^2=H$, $R^3=n$-C_5H_{11}), on the other hand, afforded β-methoxy ketone **3f** (R=Me, $R^1=R^2=H$, $R^3=n$-C_5H_{11}) in an excellent yield. Results are summarized in Table 1.

Although the hydration of internal propargyl methyl ethers afforded α,β-unsaturated ketone **4** mainly, small amount of methoxy ketone **3** was obtained as a by-product. Pure **4** was obtained by column chromatography. An attempt to obtain **4** in pure state by employing nonalcoholic solvent was unsuccessful; the reaction of 4-methoxy-2-nonyne (**1b**) in aqueous tetrahydrofuran or acetonitrile resulted in quantitative recovery of the starting material.

The stereochemistry around the double bond was exclusively *trans* in the cases of disubstituted olefins (Entry 1—3). It should be noted that alkynes bearing a methoxyl substituent on the propargylic position were regioselectively hydrated as described above, whereas no regioselectivity was observed in the hydration of simple alkynes catalyzed by Au(III) salt.[12,15] This regioselectivity might be realized both by electron withdrawing effect of the methoxyl group or by the interaction of oxygen with Au(III) at transition state; the reverse regioselectivity was observed for acetoxy alkynes where anchimeric interaction of carbonyl oxygen with Au(III) could control the regioselectivity.[10,12,13]

In contrast to the regioselective hydration giving **3** or **4** from methyl propargyl ethers (**1**, R=Me, $R^3 \neq H$), a methyl ether of α-ethynyl alcohol (**1g**, R=Me, $R^1=n$-

C_5H_{11}, R^2=R^3=H) afforded α-methoxyketone **2g** (Table 1, Entry 7).

The conversion of propargyl alcohols into, α,β-unsaturated ketones has been known as Meyer–Schuster rearrangement.[16] This rearrangement, however, requires strongly acidic conditions, and aliphatic propargyl alcohols were not applicable to the reaction.

Compared with reported procedures, the Au(III) catalyzed reaction described above produces α,β-unsaturated ketones in good yields under mild and neutral conditions. Since methyl propargyl ethers are easy accessible by the etherification of propargyl alcohols,[17,18] the above described hydration would find practical uses in organic synthesis.

Experimental

IR spectra were obtained on a JASCO IR-810 spectrometer. ^{1}H NMR (200 MHz) were measured on a Varian XL-200. Elemental analyses were performed at Elemental Analysis Center of Kyoto University.

Preparation of Methyl Propargyl Ethers 1: Methyl propargyl ethers were prepared from 1-alkyne, aldehyde or ketone, and methyl iodide described in the literature.[18] Alternatively, they were synthesized by the reaction of propargyl alcohols, whose easy synthesis is known as Favorskii–Babayan synthesis,[19] with methyl iodide in the presence of solid potassium hydroxide in DMSO (dimethyl sulfoxide).[17]

Hydration of Methyl Propargyl Ethers 1 to α,β-Unsaturated Ketones 4 (General Procedure): Methyl propargyl ether (**1**, 1 mmol) was dissolved in a mixture of methanol (10 ml) and water (1 ml) and $NaAuCl_4 \cdot 2H_2O$ (20 mg, 0.05 mmol, 5 mol%) was added to this solution. The reaction mixture was heated at reflux for 2—10 h and then concentrated under reduced pressure. The residue was diluted with ether and washed with 1 : 1 mixture of brine and aqueous ammonia. The ethereal solution was dried over Na_2SO_4 and concentrated to give the crude product, which was purified by column chromatography (silica gel; hexane–ethyl acetate).

7-Methoxy-5-dodecyne (1a): ^{1}H NMR ($CDCl_3$), δ=0.89 (3H, t, *J*=7.0 Hz), 0.92 (3H, t, *J*=7.0 Hz), 1.22—1.74 (12H, m), 2.23 (2H, td, *J*=6.8, 2.0 Hz), 3.39 (3H, s), 3.91 (1H, tt, *J*=6.3, 2.0 Hz); IR (neat) 2220, 1378, 1337, 1186, 1143, 1121, 1097, 984, 925, 899, 728 cm^{-1}; Found: C, 79.35; H, 12.42%. Calcd for $C_{13}H_{24}O$: C, 79.53; H, 12.32%.

4-Methoxy-2-nonyne (1b): ^{1}H NMR ($CDCl_3$), δ=0.89 (3H, t, *J*=6.4 Hz), 1.23—1.52 (8H, m), 1.87 (3H, d, *J*=2.0 Hz), 3.39 (3H, s), 3.89 (1H, tq, *J*=6.9, 2.0 Hz); IR (neat) 2250, 1021, 1095, 927, 900 cm^{-1}; Found: C, 77.60; H, 11.96%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%.

3-Methoxy-1-phenyl-1-pentyne (1c): ^{1}H NMR ($CDCl_3$), δ=1.08 (3H, t, *J*=7.2 Hz), 1.84 (2H, quint, *J*=7.2 Hz), 3.49 (3H, s), 4.12 (1H, t, *J*=7.2 Hz), 7.34 (3H, m), 7.46 (2H, m); IR (neat) 3075, 3050, 2220, 1595, 1490, 1464, 1444, 1338, 1128, 1105, 1085, 755, 690 cm^{-1}; Found: C, 82.58; H, 8.17%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

2-Methoxy-2-methyl-3-decyne (1d): ^{1}H NMR ($CDCl_3$), δ=0.90 (3H, t, *J*=6.7 Hz), 1.24—1.58 (8H, m), 1.42 (6H, s), 2.19 (2H, t, *J*=6.9 Hz), 3.35 (3H, s); IR (neat) 2225, 1376, 1359, 1225, 1172, 1150, 1079 cm^{-1}; Found: C, 78.85; H, 12.27%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

1-Methoxy-1-(1-propynyl)cyclohexane (1e): ^{1}H NMR ($CDCl_3$), δ=1.18—1.93 (10H, m), 1.88 (3H, s), 3.35 (3H, s); IR (neat) 1294, 1185, 1146, 1094, 926 cm^{-1}; Found: C, 78.71; H, 10.84%. Calcd for $C_{10}H_{16}O$: C, 78.89; H, 10.59%.

6-Dodecen-5-one (4a): ^{1}H NMR ($CDCl_3$), δ=0.90 (3H, t, *J*=6.7 Hz), 0.93 (3H, t, *J*=7.2 Hz), 1.29—1.67 (10H, m), 2.23 (2H, tdd, *J*=7.3, 7.3, 1.6 Hz), 2.53 (2H, t, *J*=7.5 Hz), 6.10 (1H, dt, *J*=16.0, 1.6 Hz), 6.83 (1H, dt, *J*=16.0, 7.3 Hz); IR (neat) 3050, 1699, 1676, 1631, 1378, 1192, 983 cm^{-1}; Found: C, 78.86; H, 12.35%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

Pure **3a** was obtained in 6% yield: ^{1}H NMR ($CDCl_3$), δ=0.90 (3H, t, *J*=6.9 Hz), 0.92 (3H, t, *J*=7.0 Hz), 1.25—1.72 (12H, m), 2.44 (1H, dd, *J*=16.1, 5.1 Hz), 2.46 (2H, t, *J*=7.3 Hz), 2.68 (1H, dd, *J*=16.1, 7.7 Hz), 3.32 (3H, s), 3.45 (1H, m); IR (neat) 1714, 1128, 1093 cm^{-1}; Found: C, 72.69; H, 12.44%. Calcd for $C_{13}H_{26}O_2$: C, 72.84; H, 12.23%.

3-Nonen-2-one (4b): ^{1}H NMR ($CDCl_3$), δ=0.89 (3H, t, *J*=6.8 Hz), 1.24—1.55 (6H, m), 2.22 (2H, tdd, *J*=6.2, 6.2, 1.6 Hz), 2.23 (3H, s), 6.02 (1H, dt, *J*=16.0, 1.6 Hz), 6.83 (1H, dt, *J*=16.0, 7.0 Hz); IR (neat) 3050, 3000, 1698, 1675, 1624, 1360, 1254, 980 cm^{-1}; Found: C, 76.82; H, 11.80%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

1-Phenyl-2-penten-1-one (4c): ^{1}H NMR ($CDCl_3$), δ=1.16 (3H, t, *J*=7.2 Hz), 2.36 (2H, qdd, *J*=7.2, 6.2, 1.6 Hz), 6.87 (1H, dt, *J*=16.0, 1.6 Hz), 7.12 (1H, dt, *J*=16.0, 6.2 Hz), 7.50 (3H, m), 7.95 (2H, m); IR (neat) 3050, 1671, 1648, 1621, 1283, 1215, 990, 972, 691 cm^{-1}; Found: C, 82.31; H, 7.52%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%.

2-Methyl-2-decen-4-one (4d): ^{1}H NMR ($CDCl_3$), δ=0.88 (3H, t, *J*=6.7 Hz), 1.22—1.71 (8H, m), 1.89 (3H, d, *J*=2.0 Hz), 2.14 (3H, d, *J*=2.0 Hz), 2.40 (2H, t, *J*=7.4 Hz), 6.08 (1H, septi, *J*=2.0 Hz); IR (neat) 1689, 1622, 1378, 1132, 730 cm^{-1}; Found: C, 78.69; H, 12.01%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

1-Cyclohexylidene-2-propanone (4e): ^{1}H NMR ($CDCl_3$), δ=1.52—1.75 (6H, m), 2.12 (2H, m), 2.13 (3H, s), 2.81 (2H, br-t, *J*=6.0 Hz), 6.02 (1H, s); IR (neat) 3000, 1687, 1620, 1173, 960 cm^{-1}; Found: C, 77.99; H, 10.05%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

Hydration of 1-Methoxy-2-octyne (1f): **1f** was prepared from commercially available 2-octyn-1-ol by the reaction with methyl iodide according to the procedure described above.

1-Methoxy-2-octyne (1f): ^{1}H NMR ($CDCl_3$), δ=0.90 (3H, t, *J*=7.0 Hz), 1.25—1.63 (6H, m), 2.23 (2H, tt, *J*=7.2, 2.4 Hz), 3.37 (3H, s), 4.08 (2H, t, *J*=2.4 Hz); IR (neat), 2170, 1184, 1131, 1096, 1000, 905 cm^{-1}; Found: C, 77.02; H, 11.44%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

1-Methoxy-3-octanone (3f): ^{1}H NMR ($CDCl_3$), δ=0.88 (3H, t, *J*=6.8 Hz), 1.20—1.72 (6H, m), 2.44 (2H, t, *J*=7.2 Hz), 2.65 (2H, t, *J*=6.4 Hz), 3.34 (3H, s), 3.65 (2H, t, *J*=6.4 Hz); IR (neat) 1716, 1119 cm^{-1}; Found: C, 68.01; H, 11.55%. Calcd for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

3-Methoxy-1-octyne (1g): **1g** was obtained by the methylation of commercially available 1-octyne-3-ol. ^{1}H NMR ($CDCl_3$), δ=0.90 (3H, t, *J*=6.5 Hz), 1.25—1.80 (8H, m), 2.46 (1H, d, *J*=2.0 Hz), 3.40 (3H, s), 3.95 (1H, td, *J*=6.3, 2.0 Hz); IR (neat) 3300, 2100, 1120, 1096, 940, 917 cm^{-1}; Found: C, 76.80; H, 11.69%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

Hydration of Methyl Ether of α-Ethynyl Alcohol (1g): 3-Methoxy-1-octyne (**1g**, 140 mg, 1 mmol) was dissolved in a mixture of methanol (10 ml) and water (1 ml) and

$NaAuCl_4 \cdot 2H_2O$ (8 mg, 0.025 mmol, 2 mol%) was added to this solution. The reaction mixture was heated at reflux for 1 h, concentrated in vacuo and then diluted with ether. The ethereal solution was washed with 1:1 mixture of brine and aqueous ammonia, dried (Na_2SO_4) and concentrated. Column chromatographical purification gave 3-methoxy-2-octanone (**2g**, 143 mg, 0.91 mmol, 91% yield).

3-Methoxy-2-octanone (2g): ^1H NMR ($CDCl_3$), δ=0.89 (3H, t, J=6.2 Hz), 1.18—1.67 (8H, m), 2.15 (3H, s), 3.36 (3H, s), 3.59 (1H, t, J=7.0 Hz); IR (neat) 1717, 1354, 1123, 1100 cm^{-1}; Found: C, 68.32; 11.63%. Calcd for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

Reduction of Carbon Dioxide to Give Unstable Carbon Oxides. An Attempt of Capture of Unstable Carbon Oxides Formed by the Reduction of Carbon Dioxide with Benzoin Carbanion Using Phenyliodonium Bis(phenylsulfonyl)methylide

Fuminori AKIYAMA
Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Sendai 980
(Received March 11, 1991)

Synopsis. Capture of unstable carbon oxides formed by the reduction of carbon dioxide (CO_2) with benzoin carbanion using phenyliodonium bis(phenylsulfonyl)methylide (**1**) was tried. In this reaction decomposition of the ylide **1** by the unstable carbon oxides was observed to give phenylsulfonylcarbene : $CH(SO_2Ph)$.

The reaction of CO_2 is receiving much attention in view of the use of resources. In most of many reactions of CO_2 reported, CO_2 combines with organic compounds keeping CO_2 unit to give carboxylic acids, carbonates, lactones, carbamates, substituted 5(2*H*)-oxazolones, and substituted 2-oxazolidinones as described in the preceding papers.[1] In a previous paper[2] of this study, a hypothesis that CO_2 can be converted to unstable carbon oxides by the reduction with mild reducing reagent such as benzoin carbanion and that the unstable carbon oxides formed have special reactivities, has been proposed. The preceding papers have shown that the reduction products of CO_2 with benzoin carbanion, which was formed using LDA, had special reactivities with sydnones,[3] and that carbon atom of unstable carbon oxides was captured by sodium dithionites.[1]

Unstable carbon oxides formed by the reduction of CO_2 with benzoin carbanion was considered to have the structure : $C\frac{}{n}C=O$.[1] Various sorts of unstable carbon oxides such as C_2O,[4] C_3O,[5] C_4O,[6] and C_6O[6] have been reported to have the structure : $C\frac{}{n}C\frac{}{n}C=O$.[1] Since unstable carbon oxides are considered to have carbene and cumulene structures, it seems to be preferable to use substances having ability to eject carbene in order to capture such carbon oxides. Recently, it has been reported that phenyliodonium bis(phenylsulfonyl)-methylide $PhI^+-C^-(SO_2Ph)_2$ (**1**) are able to eject carbene under mild conditions.[7] In the present report it will be shown that unstable carbon oxides formed by the reduction of CO_2 with benzoin carbanion show specific reaction behavior to phenyliodonium bis(phenylsulfonyl)methylide (**1**).

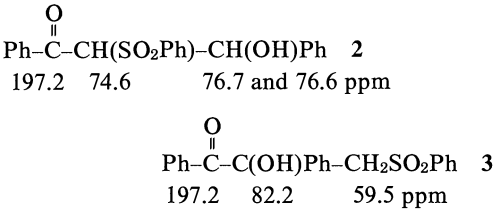
Results and Discussion

Benzoin carbanion was formed by the reaction of benzoin with lithium metal (see Experimental).[8] After treating of the THF solution of benzoin carbanion with CO_2 gas, the ylide **1** was added to this solution and the products were separated as described in Experimental. In this reaction mixture, besides benzoin, benzil, hydrobenzoin, and lithium benzoate, the insertion products of the carbene derived from the ylide **1** to benzoin were observed. The insertion products consisted of two isomers. Because of close R_f values of two isomers, relatively low solubilities, and a little instabilities of these isomers,[1] separation of two isomers were unsuccessful. However, analyses of a mixture of two isomers and trimethylsilylation and acetylation of these two isomers showed that the mixture consisted of isomer **2** and **3** (vide infra).

Mass spectroscopy indicated following peaks; m/z 366 (M^+, rel intensity 3), 259 ($M^+ - CH(OH)Ph$, 58), 125 (PhSO, 13), 118 (CHC(O)Ph, 31), and 105 (PhCO, 100). Measurement of molecular weight by means of vapor phase osmometry also showed that molecular weight of the mixture was 366. IR spectrum of the mixture indicated the absorptions at 3475 (OH), 1683 (C=O), 1302 and 1153 (SO_2), 1083 (C–O), 746 and 700 cm^{-1} (Ph).

^1H NMR spectrum of the mixture of two isomers indicated that the isomer **2** had signals at 7.0—8.0 ppm (Ph), 5.85—5.89 ppm (two doublets combined to give a triplet, HC(OH)(Ph) for two diastereomers of **2**), 4.30—4.51 ppm (two doublets, $HC(SO_2Ph)$ for two diastereomers of **2**). Double irradiation at 5.85—5.89 ppm converted two doublets at 4.30—4.51 ppm into two singlets. ^1H NMR spectrum of the mixture also indicated that isomer **3** had signals at 7.0—8.0 ppm (Ph) and 4.25—4.29 ppm (s,[10], CH_2SO_2Ph). Double irradiation technique for this case did not give any change in this apectrum.

^{13}C NMR of the two isomers were assigned reasonably as following (absorptions for phenyl groups appear at 124—141 ppm)



Trimethylsilylation of a mixture of **2** and **3** using trimethylchlorosilane, hexamethyldisilazane, and pyridine gave a rearranged silylated compound and a small amount of decomposition product, in addition to silylated products of **2** and **3**. R_f values of two silylated products of **2** and **3** were almost same and that of a rearranged silylated compound was slightly smaller than those of two silylated products of **2** and **3**. It was impossible to isolate the silylated product of **2** and **3** from a mixture of these compounds having similar R_f values by TLC or HPLC. Acetylation of a mixture of **2** and **3** by a mixture of acetic anhydride and pyridine showed disappearance of ^1H NMR absorption at 4.30—4.51 and 5.85—5.89 ppm, which are attributed to those

of isomer **2** (vide ante), and appearrance of ^{1}H NMR absorption (singlet) at 6.72 ppm. Presumably the isomer **2** was dehydrated to give an olefin. By this acetylation the isomer **3** was converted to an acetylated product which showed ^{1}H NMR absorption at 4.29 ppm (2H, CH_2SO_2Ph) and 2.2 ppm (3H, CH_3CO). Unfortunately R_f values of an acetylated product of **3** and this decomposition product of **2** were almost same. Therefore, isolation of the acetylated product of **3** from this mixture by means of TLC or HPLC was impossible. However, this acetylation experiment indicated that ^{1}H NMR absorptions at 4.30—4.51 and 5.85—5.89 ppm can be attributed to one isomer **2** and a singlet at 4.25—4.29 ppm can be attributed to another isomer **3**.

Yields of **2** and **3** were 10 and 8 mol% based on ylide **1** used, respectively. Although the yields of the products **2** and **3** are relatively low, formation of **2** and **3** indicates that unstable carbon oxides formed by the reduction of CO_2 with benzoin carbanion decomposes ylide **1** to give a carbene and the carbene formed inserts to benzoin to give **2** and **3**.

One might suppose that ylide **1** is decomposed by the compounds which is present in the solution. In order to exclude this possibility, six sorts of control experiments were undertaken. The reactions of ylide **1** with following six mixtures were carried out at room temperature for 0.5 h. (a) Benzoin and THF; (b) Benzoin, Li, and THF; (c) Benzoin, benzaldehyde, and THF; (d) Benzoin, hydrobenzoin (see Experimental), THF; (e) Benzoin, benzil, and THF; (f) Benzoin, lithium benzoate, lithium carbonate, and THF. These six experiments gave only disulfone $CH_2(SO_2Ph)_2$ but did not give product **2** and **3**. Presumably ylide **1** abstracts hydrogen atom from THF to give disulfone. In the control expertiments the ylide **1** was remained as a powder at first and gradually dissolved in the THF solution by the reaction with THF in 0.5 h. On the other hand, ylide **1** decomposed in a few minutes when **1** was added to the solution containing reduction products of CO_2. These control experiments exclude the possibility that compounds in the solution other than reduction products of CO_2 (C_xO_y) decompose the ylide **1**. Therefore, it is probable that C_xO_y decompose the ylide **1**.

Reaction scheme is tentatively shown as following.

$$\mathrm{Ph{-}\overset{O}{\overset{\|}{C}}{-}CH(OH)Ph} + 2\mathrm{Li} \longrightarrow \mathrm{Ph{-}\overset{O}{\overset{\|}{C}}{-}\overset{OLi}{\overset{|}{C}}{-}Ph} \xrightarrow{CO_2} C_xO_y \quad (1)$$

$$C_xO_y + \underset{\mathbf{1}}{PhI^+{-}C^-(SO_2Ph)_2} \longrightarrow PhI^+{-}C^{\mp}(SO_2Ph) \quad (2)$$

$$PhI^+{-}C^{\mp}(SO_2Ph) \xrightarrow[\text{from THFor -OH}]{+H} \longrightarrow :CH(SO_2Ph) \quad (3)$$

$$\text{Benzoin} + :CH(SO_2Ph) \xrightarrow{\text{C-H insertion}} \mathbf{3} \quad (4)$$

$$\text{Benzoin} + :CH(SO_2Ph) \longrightarrow \mathrm{Ph{-}\overset{O^-}{\overset{|}{C}}{-}CH(OH)Ph} \longrightarrow \mathbf{2} \quad (5)$$

$$\mathrm{HC(SO_2Ph)}$$

Such a characteristic decomposition reaction of **1** has not been reported.[7] Forbus et al. have reported the preference of C_2O for attack on oxygen over C–H insertion.[4h] In preceding paper carbon atom of unstable carbon oxide was captured by sulfur atom.[1] The fact that C_xO_y showed characteristic behavior to sydnones[3] can be explained by similar tendency of them. Presumably such a tendency of a preferential attack of C_xO_y on heteroatom such as sulfur atom over carbon atom of the ylide brings about elimination of a sulfonyl group as shown in the reaction (2). Although phenylsulfonylcarbene is considered to be formed as shown in reaction (3), detailed interpretation of this reaction can not be given in the present stage of this study. Insertion of phenylsulfonylcarbene to C–H bond of benzoin gives the isomer **3** as is shown in reaction (4). Attack of carbene to a carbon atom of C=O bond of ketones has been proposed to give dipolar intermediate[11] as is shown in reaction (5). Rearrangement of an alkyl group in such a dipolar adduct does not seem to occur to so much extent in the reaction of simple ketones. However, rearrangement of CH(OH)Ph group to carbon atom of $CH(SO_2Ph)$ group seems to occur to some extent to give isomer **2**.

Although capture of carbon atom from unstable carbon oxides by ylides **1** was unsuccessful in the present report, the present results indicated that benzoin carbanion formed using Li metal reduced CO_2 to give C_xO_y, and that C_xO_y formed had special reactivity.

Experimental

General Procedures. The ^{1}H NMR spectra were recorded on JEOL Fourier transform NMR spectrometer operating at 89.55 MHz and Brooker AC 250T NMR spectrometer operating at 250 MHz. The ^{13}C NMR were recorded on a Brooker AC 250T NMR spectrometer. Mass spectra were recorded on JEOL JMS-DX-300 mass spectrometer. Other procedures and instruments were described in the previous paper.[2]

Formation of Benzoin Carbanion and the Reaction of the Carbanion Formed with CO_2. Into the nitrogen containing 100 ml two-necked flask, in which 0.009 g atom of lithium powder was placed, 10 ml of THF, which was refluxed over $LiAlH_4$ under nitrogen atmosphere and distilled just before use, was injected through a serum cap using a syringe. To this mixture 16 ml of THF solution containing 0.0045 mol of benzoin was injected through a serum cap using a syringe, and the resulting mixture was stirred for 3 h at room temperature. The resulting dark red mixture was immersed in a cooling bath maintained at −78 °C. To this solution CO_2 was bubbled as gas through a delivery tube for 20 min. During the introduction of CO_2 a part of CO_2 escapes from a needle which is attached to a serum cap. After the reaction THF was evaporated and the residue was analyzed by same procedure as described in the previous paper.[2] Yields of the reaction products were benzoin 55, benzil 20, hydrobenzoin 11,[12] and lithium benzoate 3% based on benzoin used.[13]

Reaction of the Reduction Products of CO_2 with Ylide 1. After the reaction of benzoin carbanion with CO_2 was finished as described above, a serum cap was put off and 0.0018 mol of ylide **1** was added at −78 °C as a powder through one neck of the flask. The resulting mixture was warmed to room temperature. A few minutes after warming up to room temperature the ylide seemed to decompose. The mixture was stirred for one hour at room temperature. THF was evaporated and the residue was separated by means of TLC using chloroform as an eluent. Crude mixture of **2** and **3** was again separated by means of TLC using a mixture of chloroform and ethyl acetate as an eluent. Yields of **2** and **3** were determined to be 10 and 8 mol% based on the ylide used from ^{1}H NMR spectrum. Although a mixture of **2** and **3** was slightly contaminated with decomposition products or hydro-

benzoin because of difficulty of separation as mentioned above, satisfactory analytical result was obtained. Calcd for $C_{21}H_{18}O_4S$; M^+, 366.0926. Found: m/z 366.0930. This molecular formula of **2** and **3** and the fact shown by acetylation experiment that one isomer **2** has ^1H NMR absorptions at 4.30—4.51 and 5.85—5.89 ppm and another isomer **3** has a singlet at 4.25—4.29 ppm, together with fact shown by double irradiation technique that one isomer **2** consists of two diastereomers and another isomer **3** consists of one structure, indicate that structures of **2** and **3** are correct. Although disulfone was formed, quantitative analysis of it was not undertaken.

Author thanks to Dr. Hisahiro Hagiwara of this institute for measurement of mass spectra and helpful discussion.

7) L. Hatjarapoglou, A. Varvoglis, N. W. Alcock, and G. A. Pike, *J. Chem. Soc., Perkin Trans. 1*, **1988**, 2839.
8) When ylide **1** was added to the reaction mixture of CO_2 with benzoin carbanion formed using LDA, totally decomposition of the ylide **1** was observed to give disulfone. Presumably diisopropylamine decomposes ylide to give disulfone. Therefore, lithium was used to make benzoin carbanion.
9) During the separation procedure of a mixture of **2** and **3** by means of TLC or HPLC, decomposition of the isomers was observed to occur to some extent. During the separation procedure by means of HPLC elution time became very longer because of stuffing of the column.
10) Although this signal was observed as a singlet in the measurement by 90 MHz ^1H NMR this signal separated to a multiplet in the measurement by 250 MHz ^1H NMR. Presumably this separation can be attributed to a slight barrier for rotation around C–C bond since OH group locates between carbony and sulfonyl groups.
11) W. Kirmse, "Carbene Chemistry," 2nd ed, Academic Press, New York (1971), Chap. 11, p. 434.
12) Hydrobenzoin has been reported to be prepared by the reaction of benzoin with basic compound. For example, see A. Breuer and T. Zinke, *Liebigs Ann. Chem.*, **198**, 151 (1879). Therefore, hydrobenzoin is presumably formed during the reaction of benzoin with lithium at room temperature (vide ante).
13) Small amounts of benzaldehyde was formed. Since benzaldehyde was lost during evaporation procedure of THF, quantitative analyses of it was not undertaken. An unknown compound, which was found in near R_f range with hydrobenzoin, was obtained in a few wt% yield. It showed very low solubility, high melting point (220 °C). NMR spectra indicated that this compound had PhCH(OH) and PhC(OH) groups. Since this compound showed very peculiar behavior in NMR analyses including 2D NMR, which has not ever been reported in the literatures, structure can not be determined at present. Since this compound has same functional group with benzoin and it exists in small amount, it certainly has nothing to do with decomposition of the ylide **1**. Therefore, determination of the structure of this compound was postponed.

Urea Sensitive Field Effect Transistors Based on Dithio Group-Containing Langmuir-Blodgett Membranes

Shouryu LEE, Jun-ichi ANZAI, and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received December 21, 1990)

Synopsis. 2-(Octadecyldithio)pyridine (**1**) and 5-(octadecyldithio)-2-nitrobenzoic acid (**2**) were synthesized in order to prepare Langmuir–Blodgett (LB) membranes which possess reactive dithio groups on the surface for further modification with enzymes. The monolayer membrane, composed of **1** or **2**, was deposited successfully on an ion-sensitive field effect transistor, and the membrane surface was modified with urease covalently by a thiol–disulfide exchange reaction. The LB membrane-based sensor **2** showed a better potentiometric response to urea than that of the membrane-based sensor **1**. The results are discussed on the basis of the reactivity of the dithio groups to urease at the membrane surface.

Recently, much attention has been devoted to the development of biosensors based on Langmuir–Blodgett (LB) membranes, because of the advantages they offer in the form of thinness, uniform thickness, and controlled molecular orientation.[1] We have already reported that a penicillin sensor can be constructed by immobilizing penicillinase through adsorption on the surface of LB membrane deposited on the gate surface of an H^+-ion-sensitive field effect transistor (pH-ISFET).[2,3] Penicillinase, fortunately, can be tightly adsorbed, through electrostatic and/or hydrophobic force of attraction, to the surface of the LB membrane. However, it is not always possible for enzymes to be adsorbed to the LB membrane surface without deactivation. In fact, we have observed poor reproducibility in potentiometric responses of the pH-ISFETs covered with LB membranes adsorbing urease, trypsin, and α-chymotrypsin, presumably on account of the desorption or deactivation of the enzymes. For these reasons, we have developed the reactive LB membranes which can bind enzymes covalently.[4,5] Watanabe et al. also used reactive LB membranes for enzyme sensor preparation.[6]

The present paper reports the preparation of dithio group-containing reactive LB membranes and their application to the ISFET urea sensors.

Experimental

Materials. 1-Octadecanethiol, di-(2-pyridyl)disulfide, and 6,6-dinitro-3,3′-dithiodibenzoic acid were purchased from the Tokyo Kasei Co. Urease (EC 3.5.1.5) was obtained from the Sigma Co. The amphiphile **1** was prepared by a coupling reaction of 1-octadecanethiol (2 g) and di-(2-pyridyl)disulfide (1.6 g) in dichloromethane (20 ml) at room temperature for 16 h. The crude product was washed twice with water and then applied to a silica-gel column chromatograph with dichloromethane as the eluent. It was finally purified by repeated recrystallization from methanol–water. Yield: 1.2 g (44%). Mp 42—43 °C. Found: C, 69.73; H, 10.40; N, 3.47; S, 16.36%. Calcd for $C_{23}H_{41}NS_2$: C, 69.83; H, 10.54; N, 3.54; S, 16.18%. For the synthesis of **2**, a chloroform solution (30 ml) of 1-octadecanethiol (3 g), 6,6′-dinitro-3,3′-dithiodibenzoic acid (4.2 g), and triethylamine (5 ml) was stirred for 5 h. The amphiphile **2** was purified by column chromatograph and recrystallization. Yield: 2.4 g (47%). Mp 62—63 °C. Found: C, 62.08; H, 8.55; N, 2.90; S, 13.23%. Calcd for $C_{25}H_{41}NO_4S_2$: C, 61.85; H 8.49; N, 2.83; S, 13.20%.

Sensor Fabrication. A benzene solution (0.1 w/v%) of **1** or **2** was spread on a pure water subphase in a Langmuir trough (Kyowa Kaimenkagaku Co.) at 17 °C, and the surface monolayer was compressed at the rate of 0.4 $cm^2 min^{-1}$ up to a surface pressure of 20 $mN m^{-1}$ for **1** or 30 $mN m^{-1}$ for **2**. Monolayer **1** or **2** was deposited on the gate surface of the pH-ISFET precoated with an octadecanoic acid LB membrane (1, 3, or 5 layers), according to the reported procedure,[3] by dipping the probe vertically through the monolayer at a rate of 0.4 $cm min^{-1}$. After the remaining surface monolayer had been removed from the water subphase, the probe was raised. By this kind of treatment, the dithio groups should be located at the uppermost surface of the deposited LB layer. Thus, the surface will be reactive to protein containing free mercapto groups such as urease (Fig. 1). The deposition ratios of **1** and **2** LB membranes were elucidated by the use of glass plates precoated with a 1-layer octadecanoic acid LB membrane, since the small size of the pH-ISFET inhibited precise measurement of the deposition ratio.

The LB membrane-coated pH-ISFET prepared in the above manner, was immersed in a 0.01 mM (1 M=1 mol dm^{-3}) urease solution (100 mM tris(hydroxymethyl)aminomethane–HCl buffer containing 100 mM KCl and 1 mM EDTA, pH 7.2) for 1 h at 23 °C, in order to immobilize urease on the LB membrane surface. The ISFET urea sensors so prepared were rinsed thoroughly with the working buffer before use.

The procedures for the fabrication and the electric property of the bare pH-ISFET used in this study are described elsewhere.[7]

Results and Discussion

Figure 2 shows surface pressure/area isotherms (π–A isotherms) of **1** and **2** spread on a pure water subphase at 17 °C. Both **1** and **2** gave condensed phase monolayers at the air/water interface, with the occupied area of ca. 29 Å²/molecule for **1** and ca. 35 Å²/molecule for **2**. The bulky head group (nitrobenzoic acid) in **2** may be responsible for the larger value of its occupied area. The monolayer **2** gave a higher collapse pressure than

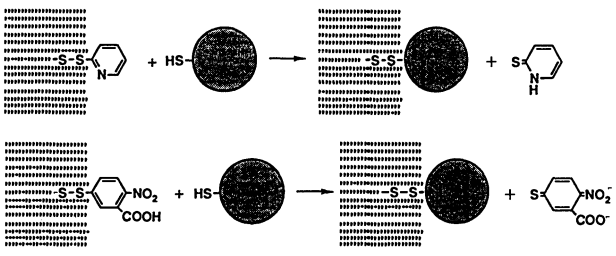

Fig. 1. A schematic illustration of enzyme immobilization on the surface of LB membranes composed of disulfide amphiphiles.

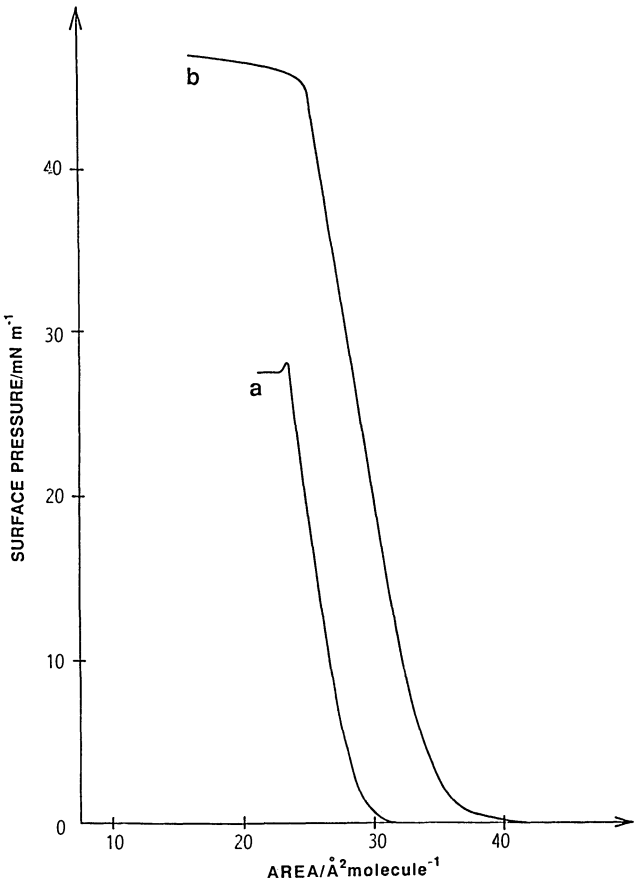

Fig. 2. The π–A isotherms of the **1** (a) and **2** (b) monolayers on pure water at 17 °C.

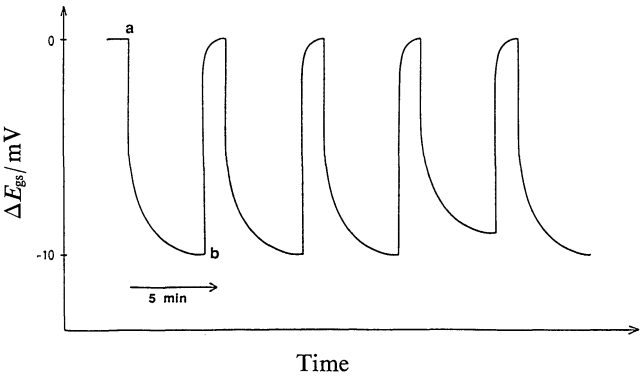

Fig. 3. A typical response curve of the urea sensor prepared with the LB membrane **2**. The prove was immersed in the urea solution (10 mM) at (a) and in the buffer solution at (b). 2 mM KH_2PO_4 buffer containing 1 mM EDTA (pH 6.0) was used.

monolayer **1**, probably as a result of the stabilizing effect of hydrogen bonding between carboxyl groups in the nitrobenzoic acid moieties.

The deposition ratios of the monolayers **1** and **2** were measured by dipping the glass plate with hydrophobic surface into the pure water subphase through the monolayer at 20 mN m^{-1} for **1** and 30 mN m^{-1} for **2**. The deposition ratios, thus measured, were ca. 1.0 for both the monolayers **1** and **2**. This result suggests that the monolayers **1** and **2** can be deposited successfully with the dithio groups located at the uppermost surface on the gate of the pH-ISFET precoated with the octadecanoic acid LB membrane.

Figure 3 shows a typical response curve for the ISFET urea sensor prepared with the LB membrane **2** by the use of an ISFET precoated with a 1-layer octadecanoic acid LB membrane. The sensor exhibited a potentiometric response, ΔE_{gs}, to urea, confirming that the urease was immobilized without deactivation and catalyzed the hydrolysis of urea, while changing the pH value at the gate surface of the pH-ISFET as follows:

$$(NH_2)_2CO + 2H_2O + H^+ \xrightarrow[\text{urease}]{} 2NH_4^+ + HCO_3^-$$

During five successive measurements, the potentiometric response was fairly reproducible, demonstrating clearly the effectiveness of the thiol–disulfide exchange reaction to immobilize urease covalently. However, the sensor response was deteriorated gradually after ten successive measurements.

The ISFET probes precoated with 3- and 5-layer octadecanoic acid LB membranes were also used for urea sensor fabrication. The potentiometric response was suppressed by increasing the thickness of the LB layer. The response of the sensor depended significantly on the buffer capacity of the sample solution. The useful calibration graphs could be obtained in the buffers of lower than 10 mM KH_2PO_4. These properties of the LB membrane-based sensors are the common case for the potentiometric enzyme sensors reported so far.[1,3,8]

It is interesting to clarify the effects of the different chemical structures of the hydrophilic head groups in **1** and **2** on the potentiometric and enzyme-binding properties of the LB membranes. Firstly, it was checked

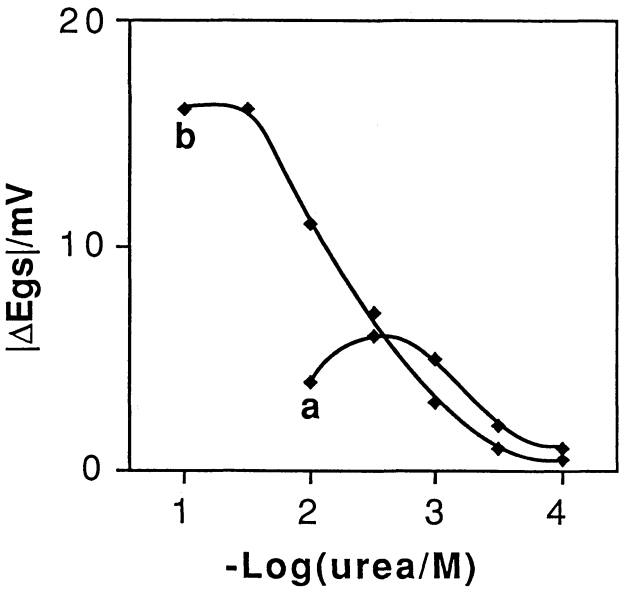

Fig. 4. Typical calibration graphs of the urease-immobilized pH-ISFETs to urea. The sensors were prepared with LB membranes **1** (a) or **2** (b), deposited on the 1-layer octadecanoic acid LB membrane. 2 mM KH_2PO_4 buffer containing 1 mM EDTA (pH 6.0) was used.

that the LB membrane-coated ISFETs with both **1** and **2** show almost the same pH response with each other (45—50 mV/pH). Figure 4 shows the typical calibration graphs for the ISFET urea sensors based on LB membranes **1** and **2**. The potentiometric response of the sensor prepared with LB membrane **2** was higher than that for **1**-based sensor. The dynamic range of the **2**-based sensor was 0.3—30 mM urea. This range is comparable to those of the urea sensors based on a urease–albumin crosslinked membrane.[8,9] The low response of the membrane sensor **1** may stem from the low enzyme loading on the gate surface, which, in turn, probably results from the limited reactivity of LB membrane **1** with mercapto groups in urease.

Thus, we have shown that 5-(octadecyldithio)-2-nitrobenzoic acid is a useful material for the preparation of a reactive LB membrane and it can bind an enzyme covalently to its surface, and so is useful as a biosensor application.

This work was supported in part by Grant-in-Aid for International Joint Research "SUPRAMOL" from New Energy and Industrial Technology Development Organization.

Preparation and Crystal Data of the New Compounds Ag_7MS_6 (M=Ta and Nb)

Hiroaki WADA
National Institute for Researches in Inorganic Materials, Namiki 1-1, Tsukuba, Ibaraki 305
(Received December 14, 1990)

Synopsis. The compounds Ag_7TaS_6 and Ag_7NbS_6 were prepared by a sealed silica tube method at 500 °C for 4 d. They crystallize in the face-centered cubic system with the unit-cell dimensions of a=10.5139±0.0003 Å and a=10.5001 ±0.0006 Å, respectively. From the density measurements, it has been clarified that the unit cell contains four formula units.

In recent years there has been great interest in ternary silver sulfides with the general formula $Ag^{+}_{(12-n)}M^{n+}S_6$ (M=Al, Ga, Si, Ge, Sn, P, As, and Sb) which are usually called 'Argyrodite' compounds. Many works have been done on their crystal structures and physical properties.[1-13] A common feature of these compounds is the presence of tetrahedrally closed-packed S sublattice forming the interpenetraiting, centered, distorted icosahedra, and the highly ionic motion of Ag atoms in a 'liquid-like manner' within the rigid framework of S lattice. Hitherto, however, preparative studies reported of this type have been limited only to the compounds associated with M=group 3 (IIIB), group 4 (IVB), and group 5 (VB) cations. A similar $Ag^{+}_{(12-n)}M^{n+}S_6$ compound could be expected for other metal systems. In this connection group 5 (VA) transition metals were selected as candidates for M cations and the possibility of preparing analogous compounds was examined. In the course of the investigation of the Ag–Ta–S system, the new compound Ag_7TaS_6 whose crystal structure is face-centered cubic has been recently discovered besides $AgTaS_3$.[14] Furthermore, the analogous new compound Ag_7NbS_6 has been obtained successfully. This note is concerned with the X-ray powder diffraction studies of the compounds, Ag_7TaS_6 and Ag_7NbS_6.

Results and Discussion

For the preparation of Ag_7MS_6 (M=Ta and Nb), tantalum (3N6), niobium (3N6), sulfur (6N), and Ag_2S (3N) powders were used as starting materials. Initially TaS_2 and NbS_2 were produced from these elements at 600 °C. The title compounds were prepared by using TaS_2, NbS_2, Ag_2S, and S in the stoichiometric proportions. The materials were mixed in an agate mortar in the glove box under pure N_2 atmosphere, pressed into pellets (radius: 7 mm), and sealed in evacuated silica tubes. The heat treatments were performed at 500 °C for 4 d. At the end of runs the tubes were quenched into water. The final volume of pellet became about 2 times larger than the initial one owing to the expansion through the reaction process.

Black-colored products obtained were identified by means of X-ray powder diffraction methods. A Rigaku diffractometer (Geigerflex, RAD-B system) with graphite-monochromated Cu $K\alpha$ radiation was used. The lattice constants were calculated by least-squares method. All peaks in X-ray diffraction patterns of Ag_7TaS_6 and Ag_7NbS_6 could be indexed by means of the cubic lattice with the unit cell dimension of

a=10.5137±0.0003 Å and a=10.5001±0.0006 Å, respectively. Both X-ray patterns were very similar except for the slight difference in diffraction intensities. The systematic extinction (*hkl*: $h+k=2n+1$, $k+l=2n+1$, $l+h=2n+1$) is indicative of the face centered cubic and leads to the possible space groups $F23$, $Fm3$, $Fm3m$, $F\bar{4}3m$, and $F432$. In order to determine the number of formula units per cell, density measurements were carried out by immersion method, using CCl_4. The values d_m=6.55 g cm^{-3} and d_m=5.90 g cm^{-3} were obtained for Ag_7TaS_6 and Ag_7NbS_6, respectively. These results suggest clearly that the unit cell contains four formula units (Z=4). In the analogy of other cubic Argyrodites compounds the space group $F\bar{4}3m$ could be considered to be most probable. The *d*-spacings, *hkl* indecies and relative intensities of both compounds are listed in Table 1. Based on the close similarity of data it can be concluded that Ag_7TaS_6 and Ag_7NbS_6 are isotypic to each other. In order to examine the transporting phenomena of these compounds, conductivity measurements were carried out on disk-shaped, cold pressed polycrystalline samples (thickness: 1.0—1.6 mm). Direct current methods were employed with Solartron 1286 electrical interface. The cell arrangement was $Ag/RbAg_4I_5/Ag_7MS_6/RbAg_4I_5/Ag$ (M=Ta or Nb), in which $RbAg_4I_5$ served as an electron blocking layer. The experiment was made by sending a constant current (less than 30 μA) and measuring the voltage drop across the specimen. The silver ionic conductivity $\log \sigma_{Ag^+}$ of Ag_7TaS_6 is −4.9 at 27 °C and rises linearly to −3.5 at 144 °C with an activation energy of 0.33 eV. This compound becomes more conductive above 144 °C based on some of the phase transition and the curvature changes rapidly. The value of $\log \sigma_{Ag^+}$ reaches −1.8 at 200 °C with an activation energy of 1.13 eV. Similarly the silver ionic conductivity of Ag_7NbS_6 is −4.6 at 27 °C and increases linearly to −3.6 at about 119 °C with an activation energy of 0.25 eV. After that the value of $\log \sigma_{Ag^+}$ rises rapidly to +0.1 at 135 °C. However, the results of preliminary experiments on the ionic transport number indicated clearly that both compounds are the mixed conductors like Ag_2S.[15] Detailed studies on their crystal structure and physical properties are now in progress.

Partition Coefficient of 21*H*,23*H*-Porphine and Its Metal(II) Complexes between Heptane and Nonaqueous Polar Solvents

Yoshito WAKUI,*,† Hisanori IMURA,†† and Nobuo SUZUKI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received January 5, 1991)

Synopsis. The partition coefficients of 21*H*,23*H*-porphine (H_2por) and its copper(II) (Cu(por)) and zinc(II) (Zn(por)) complexes were determined in nonaqueous two-phase systems. A linear free-energy relationship was observed between the partition coefficients of H_2por and Cu(por). The partition coefficient of Zn(por) was suppressed by coordination bonding with the polar solvent molecules.

Porphyrin and its related compounds are important substances in biochemistry and geochemistry. Porphyrin and metal-porphyrin compounds occur extensively in nature as well-known chlorophylls, hemoglobins, and petroporphyrins, which usually contain magnesium, iron, vanadium, and nickel as central metals. In relation to chemical separation and natural migration of these porphyrin compounds, a systematic study on the solution behavior of porphyrins, and their metal complexes is desirable. However, little is known about the solubility and the liquid–liquid partition of these porphyrin compounds. The liquid–liquid partition coefficient is an important equilibrium constant which governs the behavior of organic substances and metal complexes in both solvent extraction and liquid chromatography.

In previous work[1] we prepared a mother compound of porphyrins, 21*H*,23*H*-porphine, and investigated the liquid–liquid partition behavior between various nonpolar organic solvents and an acidic aqueous solution. In the present work we determine the liquid–liquid partition coefficients of 21*H*,23*H*-porphine (H_2por) and its copper(II) (Cu(por)) and zinc(II) (Zn(por)) complexes in a nonaqueous partition system, i.e., heptane as a nonpolar solvent and acetonitrile (AN), nitromethane (NM), dimethyl sulfoxide (DMSO), and methanol (MeOH) as polar solvents. The solvent effect and role of the central metals in the partition coefficient is discussed.

Experimental

Materials. 21*H*,23*H*-Porphine was synthesized and purified in the same manner as that described previously.[1] Porphinatocopper(II) was synthesized by refluxing 0.014 mmol of purified 21*H*,23*H*-porphine and 0.042 mmol of bis(acetylacetonato)copper(II) in chloroform (200 cm^3) for 270 min. The chloroform solution obtained was passed through an alumina column (Merck, 200—400 mesh). The porphinatocopper(II) was eluted with chloroform and recrystallized from chloroform–methanol.

Porphinatozinc(II) was synthesized by mixing 0.014 mmol of purified 21*H*,23*H*-porphine in chloroform (50 cm^3) with 0.10 mmol of anhydrous zinc(II) acetate in methanol (20 cm^3) and heating for 45 min at 60 °C. The porphinatozinc(II) was purified in a similar manner as that for the copper(II) complex.

The purity of the metal complexes synthesized was ascertained by high-performance liquid chromatography (column, LiChrosorb RP-18, 250 mm×4 mm (i.d.); mobile phase, acetonitrile: acetone=70:30; detection wavelength, 388 nm for the copper(II) complex and 397 nm for the zinc(II) complex). Each metal complex gave a single peak on the chromatogram.

Heptane and polar organic solvents such as acetonitrile, nitromethane, dimethyl sulfoxide, and methanol were purified by fractional distillation after appropriate chemical treatment and dehydration.[2]

Procedure. Heptane and a polar organic solvent were presaturated with each other before use. A certain volume of the solution of porphine, or its metal(II) complex, was shaken with the other phase for 5—60 min and centrifuged. The partition coefficient, P, which is defined as the ratio of the concentration in the heptane phase to that in the polar phase, was determined from the absorbance of the initially prepared phase and the equilibrated phase.

The wavelengths used for the absorbance measurements in different solvents are shown in Table 1.

The quartz cuvette and such glasswares as extraction vials, volumetric flasks, and pipettes were treated with dimethyldichlorosilane prior to use in order to prevent the adsorption of porphine and its metal(II) complexes onto the wall. All of the experiments were carried out in a thermostated room at 25 °C.

Table 1. Wavelength(nm) Used for the Absorbance Measurement of Porphine and Its Copper(II) and Zinc(II) Complex

Solvent	H_2por		Cu(por)	Zn(por)	
	λ_{max} [a]	λ_{max} [b]	λ_{max} [a]	λ_{max} [a]	λ_{max} [b]

MeOH	388.8	486.4	388.2	397.4	530.3

a) Soret band. b) Q band.

Results and Discussion

Partition equilibrium was completely attained within 5 min. A constant partition coefficient was obtained within the experimental error when the porphine concentration was altered in the concentration range 10^{-6} to 10^{-5} M (1 M=1 mol dm^{-3}). This demonstrates that a single species of porphine is present in both the heptane and polar phases under the experimental conditions. Measurements of the partition coefficient of porphinatocopper(II) and porphinatozinc(II) were also performed in a similar manner as that for porphine. The mean values and the standard deviations of the obtained partition coefficients are summarized in Table 2.

Polar solvent	H_2por	Cu(por)	Zn(por)
AN	$(1.01\pm0.04)\times10^{-1}$	$(2.65\pm0.08)\times10^{-1}$	$(2.23\pm0.02)\times10^{-2}$
NM	$(5.54\pm0.20)\times10^{-2}$	$(1.38\pm0.03)\times10^{-1}$	$(4.74\pm0.12)\times10^{-2}$
DMSO	$(3.06\pm0.42)\times10^{-3}$	$(6.46\pm0.12)\times10^{-3}$	$(5.17\pm0.31)\times10^{-5}$
MeOH	$(2.65\pm0.20)\times10^{-1}$	$(7.04\pm0.12)\times10^{-1}$	$(9.11\pm0.23)\times10^{-2}$

a) Mean value±standard deviation.

The Gibbs free energy for the partition of a solute (denoted by the subscript 2) from a polar solvent to heptane is represented by the difference in the Gibbs free energy ($\Delta\bar{G}_s$) for the dissolution of the solute in both phases,

$$-RT\ln P_2=\Delta\bar{G}_{s,n}-\Delta\bar{G}_{s,p}, \quad (1)$$

where subscripts p and n denote the polar and nonpolar solvent, respectively. The dissolution process can be divided into two steps: the formation of a cavity to accommodate the solute molecule in the solvent, followed by an interaction of the surrounding solvent molecules with the solute introduced into the cavity. Equation (1) can be rewritten as

$$RT\ln P_2=(\bar{G}_{c,p}-\bar{G}_{c,n})+(\bar{G}_{i,p}-\bar{G}_{i,n})$$
$$=\Delta\bar{G}_c+\Delta\bar{G}_i, \quad (2)$$

where $\Delta\bar{G}_c$ and $\Delta\bar{G}_i$ denote the cavity-formation energy and interaction energy, respectively. The solute–solvent interaction of porphine is probably dominated by the van der Waals interaction, since a specific solute–solvent interaction is not notable for porphine with not only nonpolar solvents (such as heptane, carbon tetrachloride, and benzene), but somewhat polar hydrogen bonding solvents (such as chloroform and 1-octanol), as we pointed out previously.[1)]

By applying Eq. 2 to the partition of both porphine and its metal complex, the following relation is obtained:

$$RT\ln P_M-RT\ln P_H=(\Delta\bar{G}_{c,M}-\Delta\bar{G}_{c,H})$$
$$+(\Delta\bar{G}_{i,M}-\Delta\bar{G}_{i,H}), \quad (3)$$

where subscripts H and M denote porphine and its metal complex, respectively. It would be reasonable that the molecular diameter of porphine is approximately equal to that of porphinatometal(II) and, hence, the cavity formation energy ($\Delta\bar{G}_c$) for those compounds can be considered to be equal to each other. Therefore, the following equation is given:

$$\log P_M=\log P_H+\frac{(\Delta\bar{G}_{i,M}-\Delta\bar{G}_{i,H})}{2.303\,RT}. \quad (4)$$

Plots of $\log P_M$ against $\log P_H$ for porphinatocopper(II) and porphinatozinc(II) are shown in Fig. 1. Almost

The numbers correspond to those in Fig. 1.

linear plots were observed for the copper(II) complex; they fall almost along a straight line with a slope of unity passing through the origin. The observed linear free-energy relationship (LFER) indicates that the value of the interaction term, $\Delta\bar{G}_{i,M}-\Delta\bar{G}_{i,H}$, in Eq. 4 should be small and nearly constant. This result means that the solute–solvent interaction for the copper(II) complex is quite similar to that for the ligand, itself. Accordingly, the central copper(II) ion in the complex can be concluded to have no specific interaction with the polar solvents used.

On the other hand, the plot of the zinc(II) complex is located in a region lower than the solid line, except for the nitromethane system. Additionally, the degree of deviation from the solid line is very different for each polar solvent; LFER is not observed. This means that the interaction term, $\Delta\bar{G}_{i,M}-\Delta\bar{G}_{i,H}$, in Eq. 4 has negative values and is fairly different with the polar solvents used.

Figure 2 shows the correlation between $-(\log P_M-\log P_H)$ and the donor number of the polar solvents, which is a measure of the coordination efficiency of solvent molecules. The value of $-(\log P_M-\log P_H)$, corresponding to the interaction term in Eq. 4, for the zinc(II) complex increases with an increase in the donor number; that for the copper(II) complex, however, is nearly constant. This result suggests that the partition coefficient of the zinc(II) complex is strongly influenced by specific interactions, such as the coordination bond with the polar solvents.

In studies of the solvent effect on the absorption spectrum of tetraphenylporphinatozinc(II),[3–6] the red shift of the absorption peak at the Soret and Q bands has been reported and ascribed to the axial coordination of solvent molecules to the central metal in the zinc(II) complex. Figure 3 shows plots of $-(\log P_{Zn}-\log P_H)$ against the wavenumber $\tilde{\nu}$ at the absorption peak of porphinatozinc(II) (Table 1). A good correlation is observed; the absorption peak is shifted to the lower energy region as the interaction term for the zinc(II) complex becomes larger. Therefore, the specific interaction of porphinatozinc(II) with the polar organic solvents should be attributed to the axial coordination of the solvent molecules to the central metal in the zinc(II) complex.

Equilibrium and Kinetic Studies on Complex Formation Reaction between Crown Ethers and Bivalent Transition Metal Ions

Hideto MATSUYAMA,* Takeo ARIMURA, Yoshikazu MIYAKE, and Masaaki TERAMOTO
Department of Chemistry and Materials Technology, Faculty of Engineering and Design, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received January 5, 1991)

Synopsis. The complex formation reaction between crown ethers and bivalent transition metal ions was investigated. Although the obtained equilibrium constants were generally small, there was a case where the constant was larger than that for the crown ether–alkali metal system. From kinetic studies the reactions were found to obey the Eigen's mechanism.

It is well known that crown ethers can stably capture various metal ions in their cavities. A number of studies on such complex formations were carried out for an interest in the reaction itself, or for the purpose of metal separation or analysis.[1] However, the target metal has been restricted mostly to alkali and alkaline earth metals so far. Further, relatively few studies have been reported on the kinetics of complex formation reaction although they are important to elucidate the reaction mechanism.

In this work we attempted to investigate both equilibria and kinetics of the complex formation reaction between crown ethers, not containing N or S, and bivalent transition metal ions, for which little information is available in the literature.

Experimental

Materials. Benzo-15-crown-5 (B15C5) and dibenzo-18-crown-6 ($B_2$18C6), purchased from Nacalai Tesque, Inc., were employed in this work. The metal ions used were Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}. Metal solutions were prepared by dissolving their perchlorates in acetonitrile or methanol.

Equilibrium and Kinetic Experiments. Equilibrium constants were determined spectrophotometrically. An example of the metal-induced spectral change is shown in Fig. 1. In the case of reactions of Zn^{2+} or Co^{2+} with B15C5 in acetonitrile, the equilibrium constants were directly determined by using the molar absorption coefficients of the complexes since the equilibrium constants were large enough to evaluate these coefficients accurately. In other cases where the equilibrium constants were small, they were determined as follows. The metal concentration was adjusted to be much higher than the crown ether concentration so that the former was approximately constant before and after the complex formation. Thus, the absorbance (Abs) obtained by substracting the metal ion absorbance from the total absorbance is given by

$$Abs=\varepsilon_1[C]+\varepsilon_2[MC^{2+}] \quad (1)$$

Here [C] and $[MC^{2+}]$ are the concentrations of crown ether and the complex, respectively, and ε_1 and ε_2 are molar absorption coefficients. The total concentration of crown ether, $[C]_t$, and the equilibrium constant, K_M, are given by Eqs. 2 and 3.

$$[C]_t=[C]+[MC^{2+}] \quad (2)$$

$$K_M=[MC^{2+}]/([C][M^{2+}]) \quad (3)$$

where M^{2+} denotes a metal ion. Combination of Eqs. 1—3 gives the following formula:

$$\frac{-1}{Abs/[C]_t-\varepsilon_1}=\frac{1}{\varepsilon_1-\varepsilon_2}+\frac{1}{K_M(\varepsilon_1-\varepsilon_2)}\cdot\frac{1}{[M^{2+}]} \quad (4)$$

K_M can hence be determined from a plot of $-1/(Abs/[C]_t-\varepsilon_1)$ against $1/[M^{2+}]$. An example of such plots is shown in Fig. 2. Linear relations were observed in all cases: this ensures the formation of 1 : 1 complexes assumed in Eq. 3. Almost the same equilibrium constants were obtained at two or three wavelengths near 280 nm in every case.

The rate of complex formation was measured with a stopped flow apparatus (Otsuka Electronics Co., Ltd., RA-401) by following the temporal change in absorbance at 280 nm. To simplify the analysis, the metal concentration was

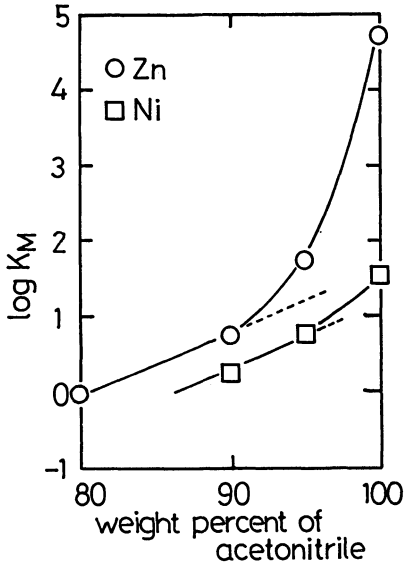

Fig. 3. Equilibrium constant in various acetonitrile–water mixtures. Crown ether: B15C5.

always sufficiently higher than that of crown ether. All the experiments were carried out at 298 K.

Results and Discussion

Equilibrium Constant. The equilibrium constants obtained are listed in Table 1. The values of K_M with B15C5 in methanol are three orders-of-magnitude smaller than that for the Na^+–B15C5 system in methanol.[2] One of the reasons for this result is that "soft" transition metal ions do not easily form a complex with "hard" crown ether.[3] The sequence of K_M, $Co^{2+}<Ni^{2+}<Cu^{2+}>Zn^{2+}$, follows the Irving–Williams order,[4] which generally holds for the equilibrium constants of transition metals. A similar tendency was observed also with $B_2$18C6 in acetonitrile.

However, the sequence of K_M for B15C5 in acetonitrile is quite different from those in the above two systems. The value of K_M for Zn^{2+} is especially large and is larger than that of Na^+–B15C5 system (3.5×10^4 at 295 K[5]). The ionic radius of Zn^{2+} is the largest among the four metal ions[6] and is closest to the 15C5 cavity radius.[1] One of the causes for the unusual K_M sequence in this solvent may be the metal–crown ether size fitting. However, further investigation is necessary to settle this problem.

Figure 3 shows the values of K_M in various acetonitrile–water mixtures. The value of K_M decreases as the water content increases. This suggests that an increase in the water content leads to an increase in the hydration number of the metal ion, thereby enhancing the total strength of the metal ion solvation and suppressing the complex formation. In the region of higher water content, the variation of $\log K_M$ for Zn^{2+} was found to parallel that for Ni^{2+}, though the number of data points is limited. This indicates that the linear free energy relationship[7] holds between the complex formation of Zn^{2+} and that of Ni^{2+}. On the other hand, as the water content decreases, the $\log K_M$ value for Zn^{2+} gradually deviates from the parallel relation, probably in accordance with the anomaly for the complex formation of Zn^{2+} in pure acetonitrile mentioned above.

Rate of Complex Formation. The reaction between a crown ether and a metal ion is expressed as Eq. 5.

$$M^{2+}+C \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} MC^{2+} \quad (5)$$

The pseudo-first-order rate constant, k_p with respect to [C] is given by

$$k_p=k_1[M^{2+}]+k_1/K_M \quad (6)$$

The relations between k_p and the metal concentration are shown in Fig. 4. In line with Eq. 6, linear relations were obtained. The obtained complex formation rate constants, k_1, and K_M thus obtained are listed in Table 2. Good agreement is seen between the K_M values obtained from this kinetic study and those from the equilibrium study mentioned above.

If the reaction obeys the Eigen's mechanism,[8] the complex formation rate constant, k_1, is given by $K_{os}k_{sol}$ (K_{os}: equilibrium constant of the outer complex, k_{sol}: rate constant of solvent exchange). Since the value of

Table 1. Equilibrium Constants, K_M/dm³ mol⁻¹

Crown ether	Solvent	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}

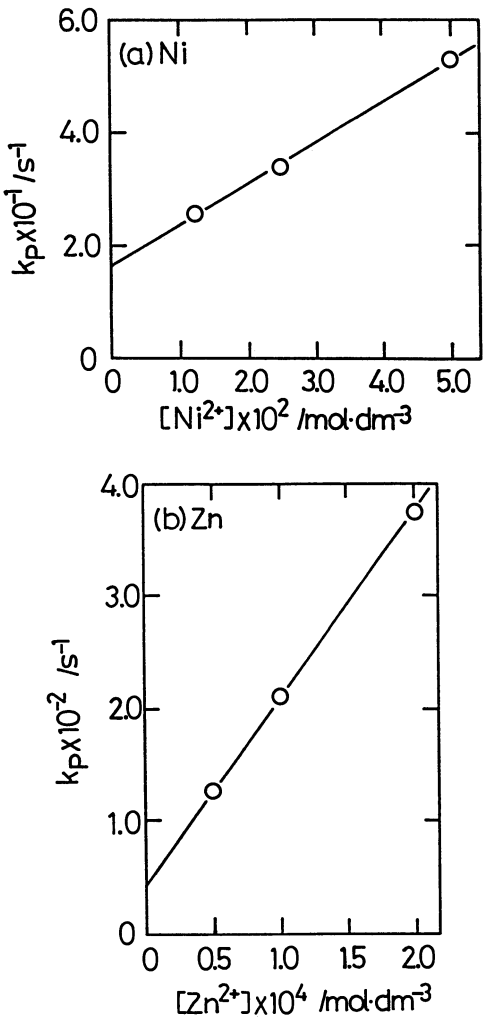

Fig. 4. Relation between k_p and metal concentration. Crown ether: B15C5, Solvent: acetonitrile.
(a) [B15C5]$=2.0\times10^{-3}$ mol dm^{-3}, (b) [B15C5]$=7.0\times10^{-6}$ mol dm^{-3}.

k_1/K_{os} for Ni^{2+} is almost in accord with the rate constant for acetonitrile exchange,[9] we conclude that the reaction obeys the Eigen's mechanism. As far as we know, the rate of exchange of acetonitrile molecules coordinated to Zn^{2+} in the bulk of the solution has not been reported. Although the value of k_1/K_{os} for Zn^{2+} is somewhat smaller than the rate constant of water exchange,[10] it is presumed that the reaction for Zn^{2+} also obeys the Eigen's mechanism because the rates of water exchange are 3—16 times those of acetonitrile exchange for other bivalent transition metals.[11]

Maynard et al.[13] studied the 18-crown-6 ether complexation of alkali metal ions in nonaqueous solvents, and speculated that the reactions consisted of succesive steps involving both ion desolvation and ligand rearrangement, and also that the rearrangement of the macrocyclic ligand was the slowest step. However, the reaction in the present case obeyed the Eigen's mechanism and therefore an ion desolvation should be the rate-determining step. Because the ion desolvation rates for bivalent transition metals are much slower than those for alkali metals, the rate of ligand rearrangement may become faster relatively.

Dielectric Relaxation Studies of Oligether of Ethylene Glycol at Microwave Frequencies

Hari Dutt PUROHIT and Ram Jeewan SENGWA*
Microwave Research Laboratory, Department of Physics, University of Jodhpur, Jodhpur 342001, India
(Received September 19, 1990)

Synopsis. Dielectric relaxation studies of dialkyl ethers of ethylene glycol and of diethylene glycol have been carried out at microwave frequencies in benzene solutions. Dipole moment and relaxation times corresponding to overall and group rotations and their weight factors have been determined. The configuration of these molecules and the mechanism of the rotation of end alkoxyl groups have been discussed.

Several[1-3] attempts have been made to study the configuration of oligethers of ethylene glycol by carrying out measurements of dipole moments in solutions. So far these studies have been made with ethers, R-$(OCH_2CH_2)_m$-OR with different values of m but keeping same end alkoxyl groups. All these studies concluded the preference of the trans positions in the chain.

In this paper dipole moments of dialkyl ethers of ethylene glycol and of diethylene glycol with different end alkoxyl groups in benzene solutions have been determined, using Higasi[4] equation (Table 1). The dielectric measurements of these molecules in benzene solutions have also been carried out at microwave frequencies with a view to study the group rotations of the end alkoxyl groups and configurations of these molecules.

Experimental

The dielectric permittivity ε' and dielectric loss ε'' at four microwave frequencies viz. 9.83, 18.26, 24.50, and 30.20 GHz and static permittivity ε_0 at 1 MHz and permittivity at high frequency $\varepsilon_\infty = n_D^2$ in benzene solutions were determined using the method described in an earlier paper.[5] All measurements were made at 35 °C.

Linear slopes a_0, a', a'', and a_∞ (ε_0, ε', ε'', and ε_∞ vs. wt fraction of solute) have been used for complex plane plots (a'' vs. a') and analysis of data. Average relaxation time τ_0 and distribution parameter α have been calculated from these plots.[6] Data have been analyzed for the relaxation time of overall rotation τ_1, group rotation τ_2 and their corresponding weight factors, using Budo[7] equation (Table 2).

The compounds were obtained from Riedel-de Haën, E. Merck, Germany and Messrs Fluka A.G., Switzerland of purum grade and used as such. Benzene Analar (B.D.H., India) was used as solvent after double distillation.

Results and Discussion

The dipole moment of these compounds are in good agreement with those reported earlier[1-3] (Table 1). The dipole moment of the molecule decreases with increase in the size of two end alkoxyl groups. This is the characteristic behavior of all homologous series in which increase in the size of the alkoxyl groups decreases the polarity at the two ends of the chain, hence there is a decrease in the dipole moment. The dipole moment of dialkyl ether of diethylene glycol is greater than the corresponding dialkyl ether of ethylene glycol because of the increase in the separation of the end polar alkoxyl groups resulting in an increase in the dipole moment. Dipole moment of monoalkyl ether[8,9] is greater than the corresponding dialkyl ether because of the higher group moment of the hydroxyl group in comparison to that of the alkoxyl group (Table 1).

The complex plane plots obeyed the Cole-Cole arcs which show the symmetrical distribution of relaxation time in these molecules. The value of τ_0 increases with increase in the size of the molecule which is in agreement with that of the other homologous series.[8,9] Small values of τ_0 and large values of α indicate that besides

the overall rotation, there is considerable contribution of group rotations. It has been observed that the presence of polar end alkoxyl groups in the polymers of lower molecular weight results in proportionately higher rigidity in the polymer chain, consequently there is practically no twisting or coiling of the chain. In case of these molecules central portion may be regarded as a rigid rod, at the two ends of which the alkoxyl groups rotate. The situation can be compared with 1,4-dimethoxybenzene[10] in which there is internal rotation of the alkoxyl groups about the C–O axes, the angle of rotation of two groups at the upper and lower end being different and hence these molecules have two distinct relaxation processes viz., due to overall rotation as well as to internal rotations. The weight factor for group rotations C_2 is considerably large indicating the possibility of the trans positions of the end groups. In this model if the two alkoxyl groups would have been in gauche form with respect to the central portion of the chain, the freedom of rotation of end groups would have been restricted. Value of C_2 decreases with increase in the size of the alkoxyl group in the same series which indicates that the freedom of the rotation of alkoxyl groups decreases and hence τ_2 increases. The values of C_2 for dialkyl ethers of diethylene glycol are less as compared to the dialkyl ethers of ethylene glycol because with the increase in the size of the chain, the flexibility of the chain increases causing the end alkoxyl groups to be closer thereby decreasing the freedom of rotation of the end alkoxyl groups. The values of τ_2 of methoxyl group presented in this paper compares favorably with that reported earlier.[8,10,11] The value of τ_1 is found to decrease with the increase in the size of the alkoxyl groups because of the decrease in the dipole moment with increase in the size of the alkoxyl group.

The authors wish to express their appreciation to Professor N. K. Mathur, Department of Chemistry of this University for many fruitful discussions. One of the authors (R. J. S.) is also thankful to Council of Scientific and Industrial Research, New Delhi for providing financial assistance.

Synthesis and Reactions of Some New Pyridazinones

Essam Abdel GHANI†
Chemistry Department, Faculty of Science, Zagazig University, Zagazig, Egypt
(Received August 1, 1990)

Synopsis. 3-(*p*-Ethoxybenzoyl)acrylic acid (**1**) reacts with 3-methyl-1-phenyl-2-pyrazolin-5-one to give an addition compound **2**. The condensation of **2** with hydrazine hydrate affords 4,5-dihydro-3(2*H*)-pyridazinone (**3a**). Reaction of **3a** with dimethyl sulfate, diethyl sulfate, ethyl bromoacetate, $POCl_3$, and P_2S_5 gave the N-substituted pyridazinones **3b**—**d**, a dichloro derivative **5a**, and a dithione **7**. The behavior of the dichloro and the dithione derivatives was studied toward different reagents. The *in vitro* antibacterial screening reveals moderate activity against Gram-positive for compounds **3a** and **3c** while **4** and **7** are inactive.

A large number of pyridazinones are reported to exhibit bactericidal activities.[1-4] Direct methods for introduction of oxygenated substituents into aromatic rings are often quite limited. Anodic oxidation is potentially an excellent procedure for direct introduction of oxygen functionalities into aromatics.[5] In addition, efficiency of the anodic oxidation of para-substituted aromatic ethers[6] prompted the author to synthesize a new series of pyridazinones, through the nucleophilic addition of 3-methyl-1-phenyl-2-pyrazolin-5-one to 3-(*p*-ethoxybenzoyl)acrylic acid followed by cyclization of the adduct to give the corresponding dihydropyridazinone. The synthesis of various compounds (**2**—**9**) are outlined in Scheme 1.

Thus, the reaction of 3-(*p*-ethoxybenzoyl)acrylic acid[7] (**1**) with 3-methyl-1-phenyl-2-pyrazolin-5-one[8] in dry benzene gave 4,5-dihydro-α-[2-(4-ethoxyphenyl)-2-oxoethyl]-3-methyl-5-oxo-1-phenyl-1*H*-pyrazole-4-acetic acid (**2**). Structure[a] of the acid **2** was derived from its infrared spectrum which showed ν C=O (acid) at 1700, ν C=O at 1675 and ν C=N at 1605. The reaction of the acid **2** with hydrazine hydrate in boiling ethanol yielded 6-(*p*-ethoxyphenyl)-4-(5-oxo-2-pyrazolin-4-yl)-4,5-dihydro-3(2*H*)-pyridazinone (**3a**). The IR spectrum of **3a** showed ν C=O at 1655, ν C=N at 1605 and ν NH at 3430. Reaction of **3a** with dimethyl sulfate, diethyl sulfate, and ethyl bromoacetate gave the N-substituted products **3b**—**d**. The IR spectra of **3b**—**d** showed ν C=O at 1660—1630, ν C=N 1600—1585, and additional band at 1740 for **3d** attributable to ν C=O (ester). Condensation of **3a** with *p*-anisaldehyde in the presence of ethanolic KOH took place at the 5-position[9] to give 4,5,6-trisubstituted pyridazin-3(2*H*)-one (**4**). The IR specrum of **4** showed bands at 1650 (ν C=O), 1600 (ν C=N), and 3390 (ν NH).

This work reports on the behavior of the pyridazinone derivative towards nucleophilic reagents like phosphoryl chloride. Treatment of **3a** with $POCl_3$ gave the dichloro derivative **5a**. The IR spectrum of **5a** was devoid of ν C=O and showed ν C=N at 1605. The ^{1}H NMR (DMSO-d_6) of **5a** showed signals at δ=8.1—6.9 (9H, m, Ar-H), 3.9—2.7 (5H, m, CH_2CH+CH_2 of ethyl), 2.30 (3H, s, CH_3) and 1.32 (3H, t, CH_3 of ethyl). The dichloro derivative **5a** reacted with sodium methoxide to give the dimethoxy derivative **5b**. The IR spectrum showed ν C=N at 1610. Reaction of **5a** with hydrazine hydrate in ethanol gave the dihydrazino derivative **5c**. The IR spectrum showed ν C=N at 1600 and ν NH at 3170. Compound **5c** condensed with aromatic aldehydes namely benzaldehyde, *p*-anisaldehyde, and *p*-tolualdehyde and yielded the bis (hydrazone) derivatives **5d**—**f** which showed ν C=N at 1605—1600 and ν NH at 3420—3400. The reaction of the dichloro derivative **5a** with sodium azide gave compound **6**. The IR spectrum of **6** showed ν C=N at 1590. ^{1}H NMR (DMSO-d_6) of **6** showed signals at δ=8.08—7.2 (9H, m, Ar-H), 3.8—2.7 (5H, m, CH_2-, CH, $+CH_2$ of ethyl), 2.20 (3H, s, CH_3), and 1.32 (3H, t, CH_3 of ethyl). An alternative route for the preparation of compound **6** was the reaction of the dihydrazino derivative **5c** with nitrous acid to give the same compound **6**. The similarity of these compounds were identified by IR spectra and by mixed melting point determination with the sample prepared before.

Compound **3a** reacted with P_2S_5 in dry xylene to give the dithioxo derivative **7**. Compound **7** evidently exists in the mercapto–thioxo equilibrium. The IR spectrum exhibited bands for ν N–C=S at 1470, ν C=S at 1385, ν C=N at 1600 and band at 3420 evidently for ν SH. The ^{1}H NMR (DMSO-d_6) of **7** showed signals at δ= 8.0—7.7 (10H, m, Ar-H+pyridazine proton), 3.43 (2H, q, CH_2 of ethyl), 3.30 (1H, s, pyrazolethione proton), 2.29 (3H, s, CH_3), and 1.34 (3H, t, CH_3 of ethyl). Treatment of **7** with dimethyl sulfate, diethyl sulfate, and/or methyl acrylate in dry acetone yielded the corresponding S-substituted derivatives **8a**—**c**, respectively. The IR spectra of **8** showed bands at 1605 (ν C=N) in addition to a strong band at 1725 of the ν C=O (ester) for compound **8c**. Compound **7** was easily oxidized to the cyclic disulfide **9** by iodine solution and the IR spectrum of **9** showed ν C=N at 1600.

Screening for an Antibacterial Activity. The prepared compounds **3a**, **3c**, **4**, and **7** were tested for *in vitro* antibacterial activity using the method described by Heatly.[6] The medium for screening was composed of (g 11000 ml) "Lab-lemco" beef extract, 1.0; yeast extract (Oxoid 120), 20; peptone (Oxoid L 37), 5.0; sodium chloride, 2.0, and agar, 15.0 (pH 7.0). Cylinders of known volume (0.1 ml) were placed on the solid medium seeded with a Gram-positive and Gram-negative test organism. A known constant volume (0.05 ml) of the compounds **3a**, **3c**, **4**, and **7** dissolved in SDS was introduced into each cylinder and allowed to diffuse through the agar at room temperature for 1 h and finally incubated at 37 °C for about 18—20 h. Clear circular zones of inhibition of the test organisms were formed around the holes containing compounds **3a** and **3c**. It

is suggested that compounds **3a** and **3c** possess moderate activities against Gram-positive as shown in Table 1.

Experimental

All melting points are uncorrected. The IR spectra (KBr discs) were recorded on a Unicam SP 1200 spectrophotometer. The ^{1}H NMR spectra were obtained on a JEOL FX-100 Fourier transform instrument using tetramethylsilane as internal standard. Physical data of **2**—**9** are summarized in Table 2.

Preparation of Compound 2. To a solution of **1**[7] (0.01 mol) in dry benzene (20 ml), 3-methyl-1-phenyl-2-pyrazolin-5-one[8] (0.01 mol) was added and the reaction mixture refluxed for 10 h. The solid that separated on cooling was crystallized from ethanol to give **2**.

Preparation of Compounds 3a, 5c, and 5d—f. To a solution of **2**, **5a**, or **5c** (0.01 mol) in ethanol (20 ml), hydrazine hydrate, benzaldehyde, *p*-anisaldehyde, or *p*-tolualdehyde (0.01 or 0.02 mol) was added and the reaction mixture refluxed for 5 h. The solid that separated on cooling was crystallized from a suitable solvent to give **3a**, **5c**, and **5d**—**f**, respectively.

Preparation of Compounds 3b—d and 8a,b. A mixture of **3a** or **7** (0.01 mol), anhydrous potassium carbonate (0.03 mol), dimethyl sulfate, diethyl sulfate, or ethyl bromoacetate (0.03 mol), and dry acetone (50 ml) was refluxed for 20 h. After removing the excess solvent the products were crystallized from the proper solvent to give compounds **3b**—**d** and **8a,b**.

Preparation of Pyridazinone 4. A warm solution of **3a** (0.01 mol) in ethanol (20 ml) was treated with an ethanolic KOH solution (25 ml, 4%) and *p*-anisaldehyde (0.01 mol) was added portionwise with continuous shaking. The reaction mixture was refluxed for 2 h, cooled, poured into cold water and the solid obtained crystallized from the proper solvent to give **4**.

Preparation of Dichloro Derivative 5a. A mixture of **3a** (0.01 mol) and $POCl_3$ (10 ml) was gently refluxed for 30 min, cooled, and treated with crushed ice. The precipitated solid was filtered and crystallized from a suitable solvent to give **5a**.

Preparation of Dimethoxy Derivative 5b. The dichloro compound **5a** (0.01 mol) was added to sodium methoxide solution [from sodium (0.02 mol) in absolute methanol (50 ml)]. The mixture was refluxed for 2 h, then evaporated under reduced pressure. To the residue was added water (10 ml) and insoluble matter was filtered off and crystallized from suitable solvent to give **5b**.

Formation of Compound 6. (a) A mixture of **5a** (1.0 g), sodium azide (2.0 g), water (5 ml), and *N*,*N*-dimethylformamide (20 ml) was boiled for 2 h and cooled. The solid obtained upon dilution with water was filtered and crystallized from a suitable solvent to give **6** (in 55% yield).

(b) An aqueous solution of $NaNO_2$ (0.03 mol in 10 ml H_2O) was added dropwise with stirring to a solution of **5c** (0.01 mol) in 4 M (M=mol dm^{-3}) acetic acid (10 ml) and stirring was continued for 1 h. The solid formed was filtered and crystallized from a suitable solvent to give **6** (in 49% yield).

Preparation of Dithione 7. A solution of **3a** (0.01 mol) and P_2S_5 (0.03 mol) in dry xylene (50 ml) was boiled under reflux for 6 h. The reaction mixture was filtered while hot and then concentrated. The product which separated on cooling was crystallized from a suitable solvent to give **7**.

Preparation of Compound 8c. A solution of **7** (0.01 mol) and methyl acrylate (0.02 mol) in ethanol (20 ml) was treated with a few drops of 10% aqueous sodium hydroxide solution and the mixture heated under reflux for 12 h. The solid formed after cooling was crystallized from a suitable solvent to

(Received September 4, 1990)

Synopsis. It has been established that phosphorus containing alkylammonium salts obtained by alkylation of primary amines with bis(2-chloroethyl) phosphonate or alkyl 2-chloroethyl phosphonate can be transformed into corresponding compounds with aziridine ring.

Physiologically active polymers replace successfully in recent years well known low-molecular therapeutic compounds. Advantages of such drug forms, lower toxicity, prolongated action, higher selectivity etc.[1,2] are due to the unique combination between the polymer character of the drug carrier and the physiological action of the low-molecular medicine.

This work is a continuation of our previous studies on the reaction of *N*-alkylation of compounds containing amino groups with esters of phosphorous acids.[3]

Polycations are effective anticancer agents. They create some level of selectivity regard to malignant cells, which possess greater negative charge and greater endocytic ability compared to normal cells.

The purpose of the present research is the synthesis of polymers with potential biological activity containing an ethyleneimine ring in its side chain.

Results and Discussion

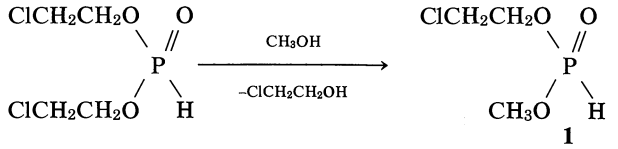
It is well known[4,5] that ethyleneimine is obtained by treating 2-bromoethylamine with potassium hydroxide:

$$H_2N\text{-}CH_2CH_2Br + KOH \longrightarrow \underset{\diagdown\ \diagup}{\overset{}{CH_2\text{-}CH_2}} + KBr + H_2O$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad NH$$

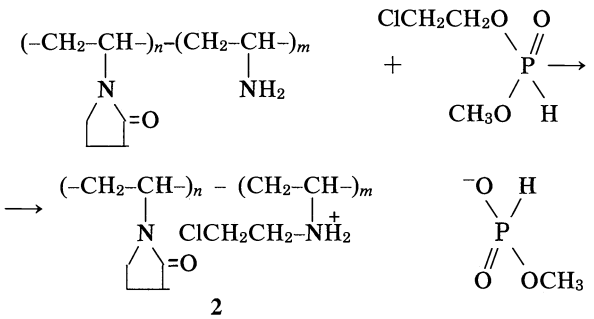
This reaction is fundamental in our studies on the synthesis of phosphorus containing polymers with aziridine ring.

We used two polymers containing amino groups—a glucomacropeptide (GMP), and a vinylpyrrolidone—vinylamine copolymer (VP-VA). The fragments containing amino groups with reaction ability are different for them.

In the GMP the amino group is included in the amino acid lysine (ε-amino group) $-HN-\underset{\displaystyle (CH_2)_4}{\overset{\displaystyle |}{\underset{\displaystyle |}{CH}}}-CO-$ while in the $\qquad\qquad\qquad\qquad\qquad\qquad

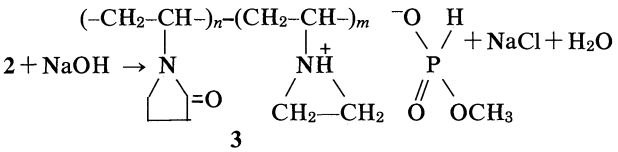


The reaction of transesterification at that temperature 50 °C, is possible as it takes place in a base environment which accelerates the reaction. The obtained methyl 2-chloroethyl phosphonate alkylates the copolymer following the scheme:



In the IR spectra of product **2** (Table 2) the bands for P=O and P–H groups are bathochromically shifted. This proves the ionic character of the bonds.[6]

A. II. Treating of Product 2 with NaOH. Further treatment of the reaction mixture by equimolar amount of 0.1 M NaOH leads to the final product **3** containing an aziridine ring.



The structure is proven by the disappearance of both triplets in the ^{1}H NMR spectra. The singlet at δ=2.71 for the aziridine ring can not be observed (Table 1) because of overlapping with the polymer signals.

B. Reaction of GMP with Bis(2-chloroethyl) Phosphonate. Dimethyl sulfoxide was used as a solvent in this case. The reaction takes place without the isolation of the intermediate product **4** and follows the equation:

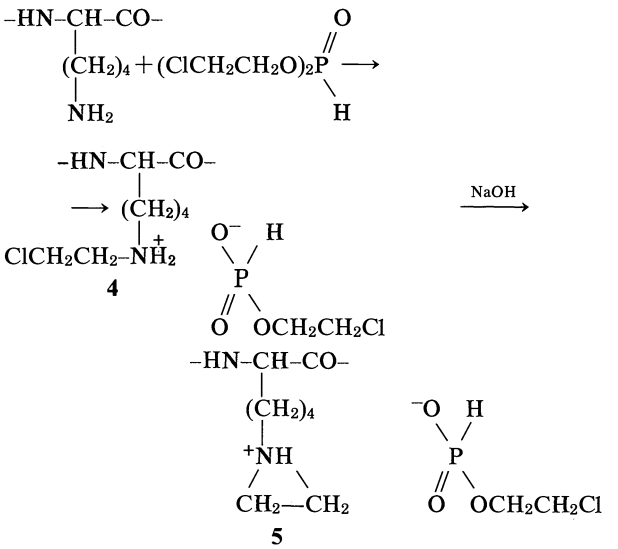


Table 2. IR Spectral Data for Products **2** and **5**

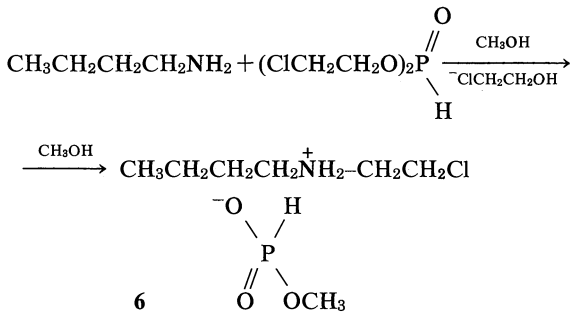
Compound	P=O/cm^{-1}		P–H/cm^{-1}	
	Starting ester	Product	Starting ester	Product
2	1268	1213	2444	2348
5	1268	1214	2444	2319

There is a singlet at δ=2.72 for the aziridine ring in the ^{1}H NMR spectrum of product **4**. The bathochromic shift of P–H and P=O group bands in the IR spectrum is a further proof for the ionic character of the bonds.

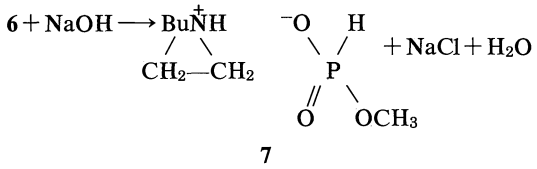
The structure of product **3** obtained from the reaction of the VP–VA copolymer with bis(2-chloroethyl) phosphonate is confirmed also by the model reaction between *n*-BuNH$_2$ and bis(2-chloroethyl) phosphonate. Methanol is used as a solvent.

In the first stage of the reaction a transesterification of the phosphonate takes place. It is followed by the *N*-alkylation of the amine by the methyl 2-chloroethyl phosphonate:

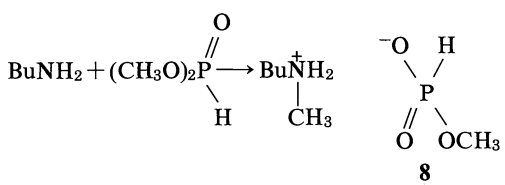


The process is followed by means of ^{1}H NMR spectroscopy. The characteristic doublets for P–H and P–OCH$_3$ protons at δ=6.66 and $^1J_{P-H}$=634.6 Hz, and δ=3.554 $^3J_{P-OCH}$=11.9 Hz, respectively are observed. At δ=3.67 and δ=3.84 two triplets appear for $\overset{+}{N}$–CH$_2$ and CH$_2$Cl protons.

In the second stage, after the treatment of product **6** with NaOH these triplets disappear while a singlet at δ=2.71 for the aziridine ring protons is observed.



Together with these signals the spectra of products **6** and **7** display another doublet at δ=6.78 with J=641.9 Hz and a singlet at δ=2.68 of very low intensity. It may be that under the conditions of the reaction part of bis(2-chloroethyl) phosphonate is transesterified to di methyl phosphonate which takes part further in the *N*-alkylation of butylamine:



The ratio between this component **8** and the main product **7** is 1 : 8.5 or 11.8% : 88.2% calculated from the integral intensity of the peaks.

These two signals are absent in the case of the reaction between the VP-VA copolymer and bis(2-chloroethyl) phosphonate in the presence of CH_3OH. It is probable that the ability for transesterification also of the *s*-alkoxyl group is a function of the basicity of the amines in use.

Experimental

Materials. We used two type of polymers:

A. Synthetic polymer—a copolymer of vinylpyrrolidone with vinylamine (VP-VA) was prepared according the literature[7] with molar ratio of 9:91 and molecular weight 80000±1000.

B. Natural polymer—a glucomacropeptide (GMP) isolated from milk[8] with molecular weight 6000. Galactose, galactosamine, neuraminic acid and 58 anino acids take part in its composition.

Bis(2-chloroethyl) phosphonate (Fluka product) purified by distillation under vacuum was used as an alkylating agent.

The solvents—methanol and dimethyl sulfoxide were purified and dried according the literature.[9]

Procedure. A. Reaction between the Copolymer VP-VA and Bis(2-chloroethyl) Phosphonate. The reaction is carried out in a flask equipped with a stirrer and a capillary for purging with argon. The copolymer is solved in methanol and the phosphonate is added. The temperature of the reaction is t=50 °C. After reaching pH=7 an equimolar amount of 0.1 M NaOH is added and the mixture is heated at 50 °C for 11 h. The product is isolated by precipitation in ether and is dried under vacuum. Elem. Anal. P=2.10%.

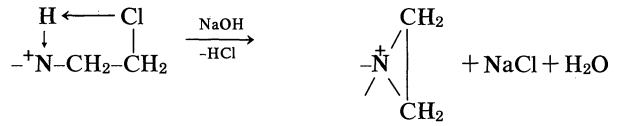
B. Reaction between GMP and Bis(2-chloroethyl) Phosphonate. The reaction is carried out in a flask equipped with a stirrer and a capillary for purging with argon. The GMP is solved in DMSO and the bis(2-chloroethyl) phosphonate is added. The mixture is stirred for 4 h at t=50 °C after which an equimolar amount of 0.1 M NaOH is added. After the reaction has taken place the polymer is precipitated in acetone (0 °C) and is dried under vacuum. Elem. Anal. P=3.14%.

C. Reaction between *n*-Butylamine with Bis(2-chloroethyl) Phosphonate. In a flask equipped with a stirrer and a capillary for purging with argon equimolar quantities of *n*-$BuNH_2$ and bis(2-chloroethyl) phosphonate are mixed. The mixture is heated at t=50 °C until reaching pH=7 after which 0.1 M NaOH is added. The reaction takes place at t=50 °C until once again pH=7 is reached. The final product is isolated by evaporating the methanol under vacuum.

The structure of the final products is proved by IR spectroscopy (PE 983) and ^{1}H NMR spectroscopy (BRUKER WP 250).

Conclusion

The presence of positive charge at the quaternary nitrogen atom probably will accelerate the reaction of forming an aziridine ring because the synthesis is accompanied by release of HCl. The positive charge at the nitrogen atom will provide for higher acidity of the proton associated with it and in this way will accelerate the acid-base reaction:



These results show that polymers containing amino groups *N*-alkylated by bis(2β-chloroethyl) phosphonate may be transformed into *N*-alkylated polymers with aziridine ring.

Classification of Phenothiazine Complexes by Structure and Electronic Properties

Kozo Kozawa,* Taketoshi Hoshizaki, and Tokiko Uchida
Department of Industrial and Engineering Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278
(Received September 21, 1990)

Donor-acceptor complexes were prepared, and their structures and electronic properties were observed. Donors were phenothiazine and its four derivatives, and acceptors were metallic chlorides (Lewis acids), iodine, and two π-type acceptors. By the absorption edge of diffuse reflection spectra (λ_E) and crystal structure, the complexes were classified into four groups. Groups I, II, and III correspond to the complexes with Lewis acids or iodine, and group IV consists of complexes with π-type acceptors. The summarized characteristics of each group are as follows. Group I: $\lambda_E \leqslant 950$ nm, complete charge transfer, insulator, and alternate arrangement of cations and anions. Group II: 1200 nm$\leqslant\lambda_E\leqslant$1700 nm, complete charge transfer, semiconductive behavior, and oligomeric or columnar arrangement of cation radicals. Group III: $\lambda_E > 2500$ nm, partial charge transfer, metallic conductor or semiconductor with small activation energy, and columnar arrangement. Group IV: $\lambda_E \geqslant 1700$ nm, and semiconductive behavior. Based on these classifications, we have proposed a mechanism for controlling the aggregate manner of cation radicals.

Recently, functional organic solid materials have attracted attention due to their potential for practical applications. These materials include organic conductors (or superconductors), photosensitive materials used for information recording, and substances having nonlinear optical properties. In designing these organic functional materials, it should be noted that not only their molecular structure but also their aggregate manner (i.e., crystal structure) plays a very important role, since the interactions (such as electron transfer or energy transfer) between neighboring molecules closely depend on their arrangements in the crystal. For instance, the magnitude of the electrical conductivity of organic conductors is greatly affected by the arrangement of the molecules in the crystal.[1] However, it has not been elucidated what rules determine the arrangement of molecules in the solid state, especially the formation of segregated stacks of molecules, though several authors have tried to define these rules.[2]

5

We have been studying solid complexes of the electron donor–acceptor type, relating their electronic properties to their crystal structures. This report describes the results of our studies of phenothiazine (hereafter PT) and its derivatives (hereafter PT derivatives) as electron donors.

PT derivatives used in this study were the following five substances: phenothiazine (PT, **1**), 10-methylphenothiazine (MPT, **2**), benzo[*a*]phenothiazine (B[*a*]PT, **3**), benzo[*b*]phenothiazine (B[*b*]PT, **4**), and benzo[*c*]phenothiazine (B[*c*]PT, **5**). Acceptors used in this study were various metal chlorides (Lewis acids): $SbCl_3$ (**6**), $SbCl_5$ (**7**), $SnCl_4$ (**8**), $TeCl_4$ (**9**), and $CuCl_2$ (**10**), iodine (**11**) and two typical π-acceptors: 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ, **12**) and 7,7,8,8-tetracyanoquinodimethane (TCNQ, **13**). Many complexes, possessing a variety of both structures and electronic properties, were prepared by the combination of these donors and acceptors. The purpose of this research was to describe the determining factor of molecular arrangements in the solid state through the classification of the complexes obtained, and to search for a method to control the molecular arrangement.

Experimental

Materials. PT (Wako Junyaku Co.) was purified by sublimation in vacuo after repeated recrystallization from benzene. MPT was prepared by the method described in the literature,[3] and purified by recrystallization from hexane. B[*a*]PT, B[*b*]PT, and B[*c*]PT were also synthesized according to the literature[4] and purified by sublimation in vacuo. $SbCl_3$ and $TeCl_4$ were purified by sublimation in vacuo and I_2 was sublimed by the usual method.

Each complex was prepared by slow evaporation of solvent from a solution of a suitable donor and an acceptor. Single

a) Complexes are presented by their numbering hereafter. The first and second numbers indicate the donor and acceptor, respectively. A letter represents a different crystal from the same combination of donor and acceptor. b) Mole ratio of a solution. c) DCE: 1,2-dichloroethane; BZ: benzene; DCM: dichloromethane; ETH: diethyl ether; AN: acetonitrile. d) DCPT: 3,7-dichlorophenothiazine (PT was substituted). e) Ref. 18.

crystals were also obtained by a similar method. Table 1 shows the preparative conditions of the complexes along with their numbering.

Electrical Resistivity. For a single crystal of **4-11**, resistivity was measured along its three axes by direct current with the four probe method from −170 °C to room temperature.[5] Resistivities of other single crystals of **1-6b**, **5-6a**, and **2-7** were measured by direct current with the two probe method from room temperature to 100 °C, from −65 °C to room temperature, and only at room temperature, respectively. For other complexes, direct current with the two probe method was applied to a compressed polycrystalline pellet of 3 mm diameter. The electric potential generator used was a Takedariken (Advantest) TR6142 or a Yokogawa Electric Co. 2853, 2861. A Takedariken TR8651 was used for current measurements. Probes were 100 μmϕ Pt wires. Specimens and probes were connected with Dotite XC-12 paint (Fujikurakasei carbon series). Measurements were carried out in a dry nitrogen atmosphere.

Diffuse reflectance spectra of powder crystalline complexes were measured with a Hitachi 330 spectrometer with a 60 mmϕ integral sphere and an Al_2O_3 plate as a reference. Although the nominal measurable ranges of this sphere were 250—800 nm and 900—1500 nm, absorption was observed in the ranges 800—900 nm and 1500—2500 nm. Hence, measurements were carried out in the range 250—2500 nm.

In order to determine the oxidation state of the PT derivatives in the solid state, solution spectra of the complexes, dissolved in 1,2-dichloroethane, were measured with a Hitachi 330 spectrometer. Although the donors do not always remain in the same oxidation state when dissolved, a stable oxidized state might be confirmable by this procedure.

The X-ray structure determinations were carried out for several complexes, of which appropriate single crystals were obtained.

Results and Discussion

Classification of the PT Complexes. PT is readily oxidized to a cation radical which is fairly stable in solution and in the solid state.[6,7] Figure 1 shows a typical solution spectra of neutral PT and $PT^{+\cdot}$. The characteristic λ maxima of each cation radical are presented in Table 2.

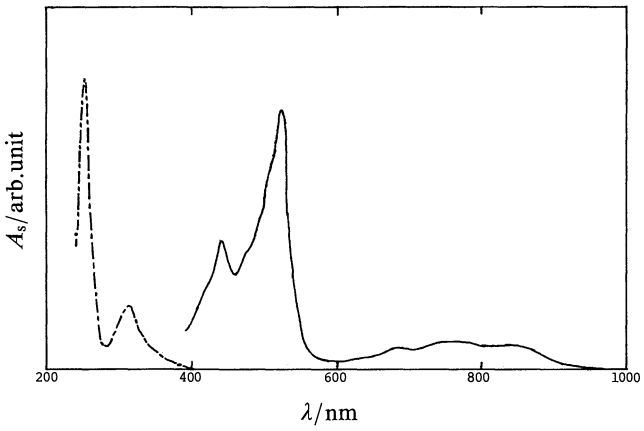

Fig. 1. Absorption spectra of PT (——·——) and PT–$SbCl_6$ (**1–7a**) (———), in 1,2-dichloroethane solution.

Table 2. Characteristic Absorption Maxima of the Cation Radical of Phenothiazine Derivatives

Cation radical	Absorption maximum λ/nm					
$PT^{+\cdot}$ [a]		271,	435,	480, 500,	515,	
$MPT^{+\cdot}$ [b]		271,	450,		518

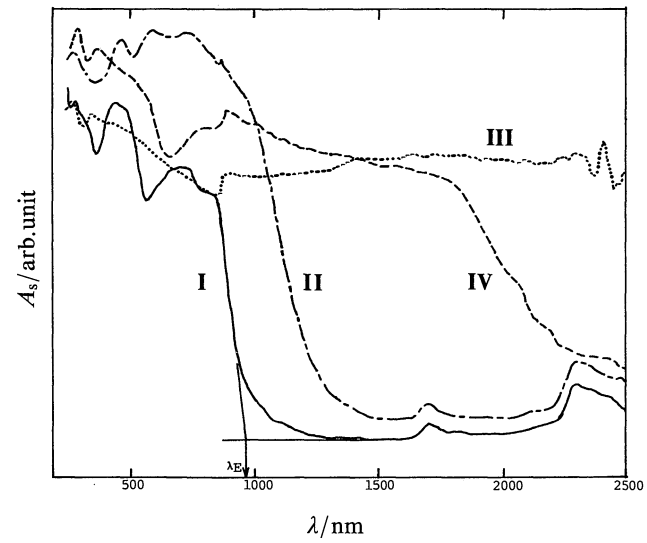

Fig. 2. Diffuse reflection spectra of **2–7**(I), **5–6a**(II). **4–11**(III), and **1–13**(IV). The manner for evaluation of λ_E is shown in the curve of **2–7**.

Figure 2 shows four typical diffuse reflectance spectra, in which reflectance is converted to absorbance by Kubelka–Munk's equation. The wavelengths of the absorption edge (λ_E) are defined by the intersection of tangent lines of the absorption edge and the baseline, as shown in Fig. 2.

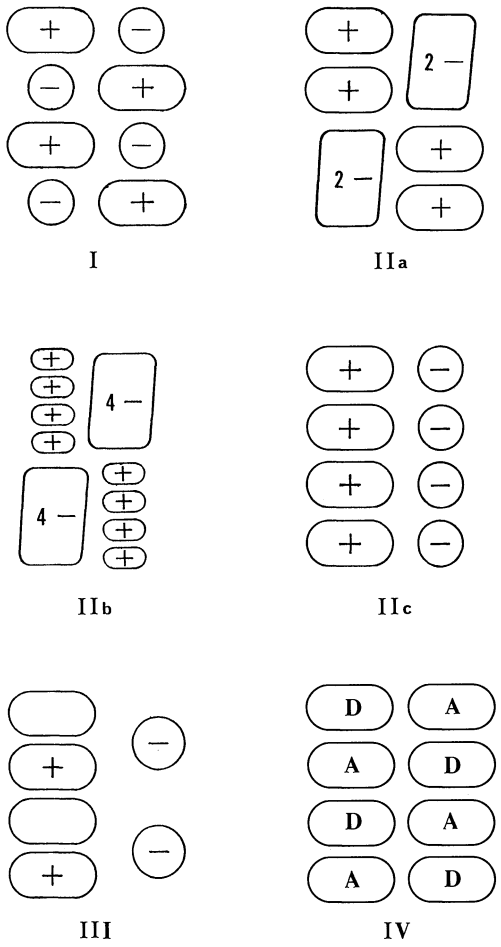

Fig. 3. Classification of crystal structure of the complexes of PT derivatives. I: Simple ionic crystal type; IIa: dimer; IIb: tetramer; IIc: segregated stack of donors with unit charge per molecule; III: segregated stack of donors with fractional charge per molecule; IV: mixed stack of π–π type CT complex.

We found that the physical properties and crystal structures of PT complexes were closely correlated if we classified them into four groups. The classification was made based on the value of λ_E as defined above. Namely, Group I: $\lambda_E \leqslant 950$nm, Group II: 1200 nm$\leqslant \lambda_E \leqslant$1700 nm, Group III: $\lambda_E > 2500$ nm, those complexes mainly between PT derivatives and iodine, and Group IV: complexes between PT derivatives and π-acceptors. Table 3 presents the physical properties of the complexes along with the crystal structures so far determined. Schematic structures for each group of complexes are shown in Fig. 3.

Group I: Substances classified in this group possess very high electrical resistivity (actually unobservable), and their absorption edges are in a shorter wavelength range than those of the other three groups. The commonly observable absorption band with its edge at 900 nm can be assigned to the intramolecular transition of the corresponding cation radical by reference to its

solution spectra (Table 2).[7] All the crystal structures so far determined of the substances belonging to this group are simple ionic crystal types similar to NaCl. They are almost spherical anions and plate-like cation radicals arranged alternately without any overlap between the donor planes (see Fig. 3). This is the reason why the substances belonging to Group I are good insulators.

A typical example of this group is **1-7a**. Polarized absorption spectra, observed with its single crystal, and observation of ESR absorption clearly indicate the existence of stable cation radicals in the crystal.[7]

Group II: As illustratively shown in Fig. 3, there are various kinds of crystal structures in this group, namely, dimers(IIa), tetramers(IIb), or segregated stacks of donors(IIc). In these solids, plate-like cation radicals overlap each other in a face-to-face manner. However, attractive interactions between donors can not be very large because of the Coulomb repulsion between fully ionized donors. It is obvious that the mean interplanar distance of 3.47 Å in **1-6b** is rather large in spite of its structure of segregated stacks.[8]

Anions in Group II crystals also exist as dimers, tetramers or polyanions, having a unit negative charge per one chemical unit (see Fig. 3). Since all the complexes so far studied in this group had a donor/acceptor mole ratio of 1:1, donors also should have a unit positive charge per molecule. Consequently, the absorption bands ranging from 950 nm to 1700 nm,

between the λ_E's of Group I and Group II, can be interpreted as a charge transfer absorption band between the cation radicals.

Measurement of electrical resistivity, performed with single crystals of **1-6b** and **5-6a**, proved that they were semiconductors with anisotropy. The observed rather high resistivity and comparatively large spacing in the column, in spite of its one-dimensional structure, can be understood by considering that the amount of charge transfer is very close to unity. Since other complexes of this group possess electrical resistivity of a similar magnitude, their structures should be similar to those already determined.

Group III: As shown in Table 3, most iodine complexes of PT derivatives belong to this group. The crystal structure determination of the complexes of this group has been successful with only one complex: **4-11**, though it is not yet complete.[5] Its structure (Fig. 4) and characteristics are briefly described below.

The crystal structure of **4-11**, $(B[b]PT)_2(I_3^-)(I)_2$, consists of infinite stacks of B[*b*]PT molecules (stack direction is parallel to the *c* axis), separated by univalent I_3^- anions, and linear polyiodide chains (also parallel to the *c* axis). Though the electronic state of the polyiodide has not yet been precisely determined, the amount of charge transfer from B[*b*]PT to the iodine species is probably less than unity. This presumption is supported by the observation of metallic conduction along the *c* axis, and a plasma-edge-like dispersion of reflection spectra in the near-IR region with polarized light parallel to the *c* axis. The observations of ESR spectra and electronic absorption spectra indicate the existence of B[*b*]PT cation radicals.

All the Group III complexes, except **4-11**, are semiconductors. Though they have not yet been structurally analyzed, their structures and electronic states in the solid state are thought to be very similar to those of **4-11**. The structural feature common to Group III complexes is probably an infinite stack of PT derivatives with a fractional charge as shown in Fig. 3 III. Our observations, such as an absorption band extending to the near infrared range, fairly good electrical conductivity with small activation energy, positive Seebeck coefficients etc., support this assumption. Moreover, we propose that all of the Group III iodine complexes have the possibility of possessing metallic conduction, which is hidden by the semiconductive behavior in the observable room temperature range, namely, by the existence of the metal–insulator transition point at a higher range than room temperature.

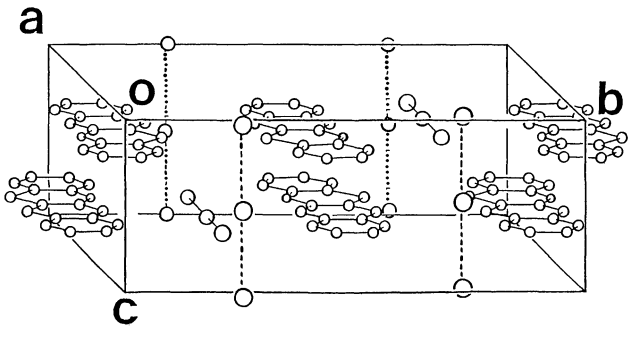

Fig. 4. Perspective view of the crystal structure of **4-11**.

Next, we compare the infinite donor stacks of Group II and Group III. Since the charge on PT derivatives per molecule is fractional in Group III, they have a smaller Coulomb repulsion than those of Group II. In fact, an observed interplanar distance of 3.22 Å between B[*b*]PT moieties in **4-11** is smaller than the value of the Group II complex cited above.

Group IV: Since both donor and acceptor molecules have a π-electron system in this group, both mixed column structure and segregated column structure are possible in the solid state. In the former structure, charge transfer interaction occurs between the donor and acceptor species, and in the latter structure, charge transfer interactions are of the donor–donor or acceptor–acceptor type. Several structural studies have been published describing the complexes between PT and π-acceptors: PT–pyromellitic dianhydride (PMDA),[9] PT–$(PMDA)_2$,[10] PT–trinitrobenzene,[11] and PT-*cis*-bis(trifluoromethylene-1,2-dithiolato)nickel.[12] All of these structures, including **1-13**[13] and **2-13**,[14] are made up of mixed stacks, as shown in Fig. 3 IV, in which PT molecules and flat acceptors stack alternately. The observed absorption band in the near infrared region is probably caused by some intermolecular interaction as cited above, though its precise assignment was not performed at this stage of our research.

The electrical resistivities of this group are in the range of "organic semiconductors". However, the variety of ρ values suggests that there are some possible crystal structures other than a 1:1 mixed column or a simple segregated column; for example, $(perylene)_3(DDQ)_2$,[15] $(perylene)_3(TCNQ)$,[16] and TTF·TCNQ.[17] More structural information should be accumulated for further investigation of this group.

Configuration and Arrangement of PT Derivatives. Since a thiazine ring has an S atom as a member of the ring, PT and its derivative molecules are consequently folded in two planes with creasing through the N and S atoms, in their neutral state. However, we found that these molecules were easily flattened by incorporating their thiazine rings into conjugated systems, such as being oxidized to their cation radicals. Such enlargement of a conjugated system onto the whole molecule is favorable for stabilizing the cation radicals in the solid state, and the flattened molecules can be stacked easily to make dimers or tetramers or segregated columns. In Groups I and II, where all the PT derivatives are flattened cation radicals, their aggregate manner probably depends on the characteristics of the anions. Namely, PT derivatives combined with hexa-coordinated globular anions, such

as $SbCl_6^-$ in Group I, exist as monomers. In Group II, the aggregate manner of PT derivatives are the same as those of the anions; dimeric pairs with dimer anions (**3-9**), tetrameric stacks with tetramer anions (**1-6a**), and infinite stacks with infinite polyanions (**1-6b**). By analogy with **4-11**, we presume that the crystals in Group III are composed of segregated columns of fractionally charged donors, which are also flattened.

In conclusion, the aggregate manner of PT derivatives in solids can be somewhat controlled by choosing Lewis acids which form polyanions.

(Received January 21, 1991)

According to the propagation theory of a conductive zone for the electrochemical doping process of conducting polymer films, an oxidized conductive zone works as an electrode for oxidizing the reduced non-conductive region and is propagated throughout the film under charge transfer control. This theory was verified for polypyrrole films by tracing the temporal and spatial variations of conductive regions in a film. An exhaustively reduced polypyrrole film was laid on an insulating glass plate and connected electrically to an ITO electrode at the marginal part. The film absorbance to a monochromatic light beam was monitored with a photodiode array detector at 14 segments of the film. When the potential of the ITO electrode was stepped to an oxidation potential of the film, an electrochemically oxidized conductive zone was propagated through the film with a manifest phase boundary. The distance from the edge of the ITO electrode to the front of the conductive zone increased linearly with time. The logarithmic slope of the propagation speed exhibited a linear relation to the applied potential.

A conducting polymer film deposited on an electrode can be switched between a highly conductive oxidized (doped) state and a resistive (or insulating) reduced (undoped) state by controlling the electrode potential. This electrochemical conversion involves mass and charge transport in the film and heterogeneous charge transfer at the underlying electrode. Therefore, the composition of the film is non-uniform and varies with time during the process of conversion.

In order to predict the temporal and spatial variations in composition, we have proposed the propagation model of a conductive zone under charge transfer control.[1-4] This model is available when supporting electrolytes permeate sufficiently into the film and so mass transport of the supporting electrolyte does not limit the conversion rate. This model consists of the following processes: Initially the film is resistive or in the reduced state. When the potential of the underlying electrode was set more anodic than the oxidation potential of the film, first the film is oxidized only in a region very close to the underlying electrode and becomes locally conductive. This conductive region works as a new electrode for oxidizing the reduced non-conductive region on it. Then a reduced region very close to this new 'electrode' is subsequently oxidized and converted into the conductive to yield an additional new electrode. Through the repetition of this process, the conductive zone is propagated up to the top of the polymer film. The conversion rate is controlled by charge transfer at the interface between the conductive zone and the reduced region. This concept has been introduced by Lacroix and Diaz.[5]

We have verified this model for the electrochemical doping process of polypyrrole films by analyzing linear sweep voltammograms,[1] in situ spectroscopic voltammograms,[2] and chronoamperometric responses.[3] This model differs on the time dependence of current from the reported models; models for charge transport due to diffusion-like electron hopping[6-10] and due to both diffusion and migration,[11] a model analogous to a porous electrode which yields charging current,[12] a capacity model including deeply and shallowly trapped ions,[13] an RC time constant model,[14] and a film resistance model.[15]

An aspect of the propagation of the conductive zone can be seen from the temporal and spatial analysis of a distribution of conductive species in the film. In our previous paper,[4] a polypyrrole film was coated onto an addressable microband array electrode in the reduced state, and oxidized from the margin of the film by applying an oxidation potential only to the marginal electrode. The potentials of the other microband electrodes were expected to reflect the distribution of the conductive species on the basis of the Nernst equation. Unfortunately, these potentials were overlapped by the applied potential because the electrochemically generated conductive zone conducted the potential of the marginal electrode. In order to obtain the precise distribution of the conductive species, a non-electric measurement is required.

Polypyrrole shows great spectral change in visible and near-infrared regions with the conversion between the reduced and the oxidized states.[2,16] Therefore, the extent of oxidation or the concentration of the conductive species can be estimated from the absorbance at a wavelength at which it is sufficiently different between the two states. The distribution of such species which absorb the light with a particular wavelength can be measured with a photodiode array detector, a linear arrangement of small photodiode elements with a multichannel detector.[17,18] In this study, an exhaustively reduced polypyrrole film was laid on an insulating glass plate and connected electrically to an ITO electrode at the margin of the film. The film was

oxidized by applying an oxidation potential to the ITO electrode, and variations in absorbance at 14 segments of the film were measured with the photodiode array detector. The relation between the distance from the ITO electrode to each segment and the time at which each absorbance begin to change gives the intuitive evidence of the propagation of the conductive zone.

Experimental

Chemicals. Pyrrole (Tokyo Kasei Ltd.) was distilled under reduced pressure (at 1.07×10^4 Pa) and stored in a sealed vessel at N_2 atmosphere. Acetonitrile was distilled successively with molecular sieves, 4A 1/16 (Wako, Tokyo), and with calcium hydride (Tokyo Kasei Ltd.) at N_2 atmosphere and stored in a sealed vessel at N_2 atmosphere. Lithium perchlorate anhydrous (Wako, Tokyo) was of analytical grade and was used as received.

Apparatus and Procedure. Polypyrrole was formed by applying a potential of 1.2 V (vs. SCE) to an ITO electrode (15 mm×8 mm) for 40 s in an acetonitrile solution containing 0.06 mol dm^{-3} pyrrole, 0.1 mol dm^{-3} $LiClO_4$ and 1% H_2O at N_2 atmosphere at 25 °C. The ITO electrode was a glass plate coated on one side with In-Sn oxide (ITO) and supplied by ULCOAT (Saitama, Japan). The resistance of the electrode was 12 Ω cm^{-2}. A potentiostat was HA-301 (Hokuto Denko Ltd., Tokyo). Current vs. time curves for the polymerization were recorded with a *x–t* recorder, RW-21T (Rikadenki, Tokyo). The charge, *Q*, consumed in the polymerization was evaluated by integrating the current vs. time curve and was 0.133 C cm^{-2}. From the equivalence of 1 C cm^{-2} to 6.85 μm,[2] the film was 0.91 μm thick. The film was covered with a platinum plate so that is was sandwiched between the platinum and the ITO electrodes. The film was reduced exhaustively by applying a potential of −1.0 V (vs. SCE) to both the electrodes for 15 min in an N_2 saturated acetonitrile solution containing 0.1 mol dm^{-3} $LiClO_4$. Then the film turned uniformly yellow. Without the platinum plate, the film was not completely reduced and looked green. The reduced film was stripped

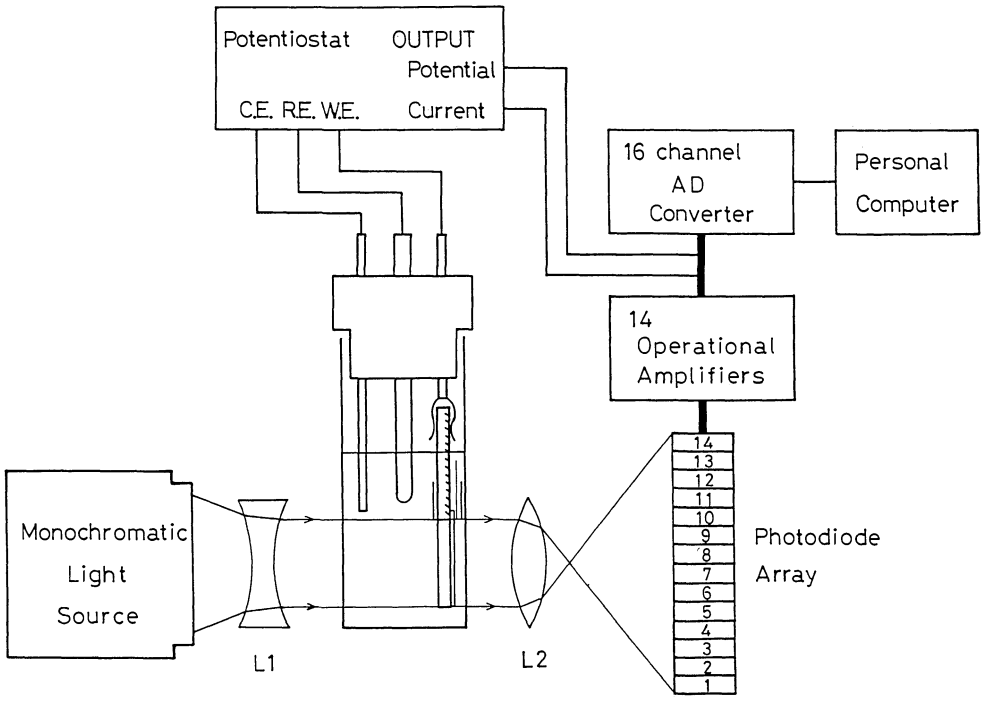

Fig. 2. Schematic diagram of optical apparatus. L1 is a concave lens (*f*=29 mm). L2 is a convex lens (*f*=28 mm).

from the ITO substrate and cut into a rectangle (6 mm×2 mm). It was laid on an insulating glass plate which was joined to an ITO electrode, so that the marginal part of the film (1 mm long) was on the ITO electrode (see Fig. 1). For electrical contact, the marginal part was pressed to the ITO electrode with a thin glass plate and a stainless steel holder. All these procedures were done at N_2 atmosphere in a glove box.

An optical apparatus is shown in Fig. 2. A rectangular (1 cm×1 cm) quartz cell with a teflon holder was used as an electrochemical cell. The top of the ITO electrode was clipped with a stainless steel holder so that the polypyrrole film was immersed into an N_2 saturated acetonitrile solution containing 0.1 mol dm^{-3} $LiClO_4$. A counter electrode was a platinum plate. A reference electrode was a saturated calomel electrode (SCE) which was connected to the electrochemical cell through a salt bridge filled with acetonitrile containing 0.1 mol dm^{-3} $LiClO_4$. Excitation light of a fluorescence spectrophotometer, Hitachi 650-40, was used as a monochromatic light source. A beam from the monochromatic light source was collimated with a concave lens L1 and passed through the polypyrrole film on the glass plate perpendicularly. The beam was then magnified by 2.8 times with a convex lens L2 and imaged onto 14 elements of a photodiode array, S2311-35Q (Hamamatu, Shizuoka, Japan), located on the image plane of the film. The photodiode elements were 0.94 mm wide and lined up at intervals of 0.05 mm. Since the image of the film was magnified by 2.8 times, the spatial resolution to the film was 0.36 mm. The 14 photodiode elements were connected to operational amplifiers through which photocurrent signals were converted to voltage signals. Deterioration in the spatial resolution by scattering of the excitation beam was negligible, which was confirmed by measuring the 14 photocurrents with attaching a narrow grid to the polymer film.

The polypyrrole film was oxidized by stepping the potential of the ITO electrode from −1.0 to 0.2 V (vs. SCE) or more anodic potentials. According to the result from the conductivity measurements of polypyrrole films reported by Feldman et al., polypyrrole is insulating at potentials more cathodic than −0.4 V (vs. SSCE) and highly conductive at potentials more anodic than 0.0 V.[19] Therefore, the films exhaustively reduced at −1.0 V (vs. SCE) and the films oxidized at 0.2 V or more anodic potentials can be considered as resistive and highly conductive, respectively. The stepped potential was limited up to the polymerization potential of the film, 1.2 V (vs. SCE), in order to avoid irreversible over-oxidation of the film which lead to the destruction of the polymer structure. The films oxidized at potentials between 0.2 V and 1.2 V (vs. SCE) could be reversed to the exhaustively reduced state by sandwiching the film between an ITO and a platinum electrodes and applying a potential of −1.0 V (vs. SCE) to both the electrodes.

After the potential of the ITO electrode was stepped, the 14 photocurrents measured with the photodiode array detector were recorded every 25 ms on a personal computer, PC-9801 (NEC, Tokyo), with potential and current outputs of the potentiostat through a 12 bits A/D converter, AZI-204 (Interface, Tokyo). Each photocurrent, i_p, was converted to the absorbance, A, at the corresponding segment of the film through the following equation:

$$A = -\log(i_p/i_p^\circ) \quad (1)$$

where i_p° is the photocurrent measured without setting the film on the glass plate.

Absorption spectra of the polypyrrole film at various potentials were measured with a multichannel photodetector system, MCPD-1000 (Photal, Tokyo), sufficiently after the potential of the ITO electrode was stepped to each potential.

Time-sequence photographs were taken every 0.4 s with a single-lens reflex camera, Olympus OM-2, equipped with a lens, Zuiko Auto Macro 50 mm F3.5, and a motor-drive unit, Winder 2.

Results and Discussion

Figure 3 shows absorption spectra of the polypyrrole film in the exhaustively reduced state (at −1.0 V vs. SCE) and in the oxidized states (at 0.0, 0.4, and 0.8 V). The spectrum at −1.0 V showed a prominent absorption band centered at 420 nm. There was no peak at wavelengths longer than 500 nm, indicating that the film was in the completely reduced state. When the film was oxidized at 0.0 V, the band at 420 nm decreased and two broad bands appeared around 520 nm and in the near-infrared region (700—1000 nm). As the oxidation of the film proceeds (at 0.4 and 0.8 V), the band around 520 nm slightly decreased with shifting to the shorter wavelength and the band in the near-infrared region increased monotonically.

Figure 4 shows a chronoamperometric curve for the oxidation of the polypyrrole film when the potential of the ITO electrode was stepped from −1.0 to 0.8 V (vs. SCE). Immediately after the potential was stepped, large current flowed for a short period (t<0.1 s). After this pulsed current, the curve showed a plateau up to 5.8 s. Exhibition of the plateau is consistent with the theoretical chronoamperometric curve for a very rapid heterogeneous rate at the underlying electrode.[3] After showing the plateau, the curve decreased exponentially.

The absorbance vs. time curves simultaneously measured with the chronoamperometric curve (Fig. 4)

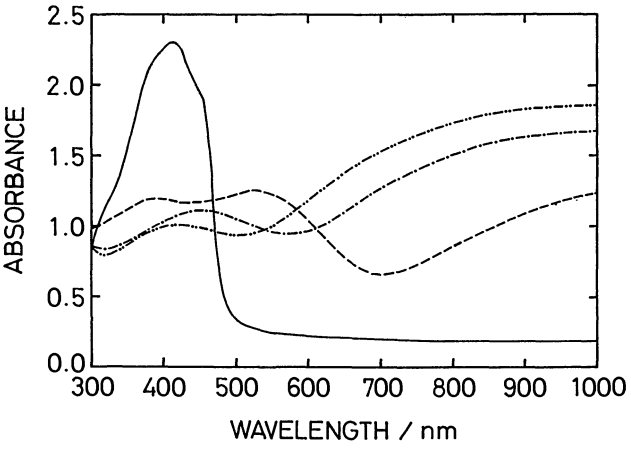

Fig. 3. Absorption spectra of a polypyrrole film at −1.0 (———), 0.0 (– – –), 0.4 (–·–·–), and 0.8 V (vs. SCE) (–··–··–··–).

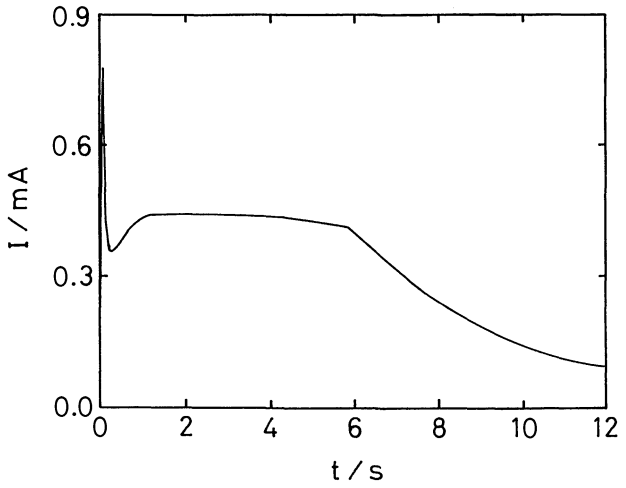

Fig. 4. Chronoamperometric curve of the polypyrrole film when the potential of the ITO electrode was stepped from −1.0 to 0.8 V (vs. SCE).

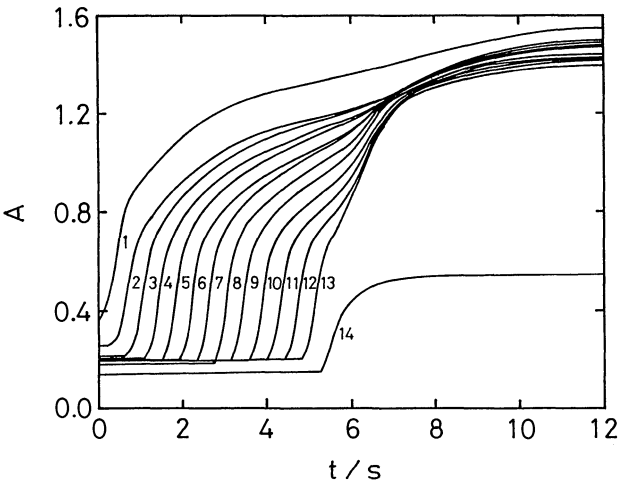

Fig. 5. Variations in the absorbance at 800 nm with time. The number marked beside the curves corresponds to the number of the photodiode element in Fig. 2.

are shown in Fig. 5. The monitored wavelength was 800 nm. Curve 1 represents the absorbance at the segment closest to the ITO electrode, and curve 14 represents the furthest segment. The higher absorbance in curve 1 was caused by scattering of the excitation beam at the joint between the glass plate and the ITO electrode. The lower absorbance in curve 14 was due to a shortage in length of the film. The further from the ITO electrode the segment was, the slower the absorbance began to change, indicating that the conversion proceeded from the electrode/film interface towards the end of the film.

The amount of charge, q, evaluated by integrating the chronoamperometric curve in Fig. 4, was 40 mC cm^{-2}. The efficiency of the oxidation, q/Q, was 0.30, being much greater than the value, 0.17, calculated from the maximum doping level (0.33) of polypyrrole perchlorate on the assumption that both q and Q did not include non-faradaic components. This large q/Q value suggests that the chronoamperometric cuve includes large capacitive components as observed in ordinary potential step experiments.

The initial pulsed current (t<0.1 s) in Fig. 4 can be ascribed to a capacitive current at the interface between the ITO electrode and the reduced film. The other source of the capacitive current is the interface between the conductive zone and the solution or the reduced region in the film. The conductive zone can be considered as a series connection of a resistor, R, and a capacitor, C. When a potential is applied to such a series connection of R and C, the capacitive current shows an exponential decay according to the product, RC (RC time constant). As the conductive zone is propagated in the film, both R and C should increase because they are proportional to the length (amount) of the conductive zone. Unfortunately, these capacitive components have not been separated mathematically from the faradaic current.[3] When the chronoamperometric curve began to decrease from the plateau (t=5.8 s), the absorbance vs. time curve 14 (in Fig. 5) had passed a half of the transition, namely, the top of the oxidized zone had reached the end of the film. Thus, the decreasing portion of chronoamperometric curve is mainly attributed to the capacitive current with a large RC time constant rather than the faradaic current.

Every absorbance vs. time curve in Fig. 5 changed at two stages; a steep rise from the initial value (0.18—0.25 for curves 2—13) to the intermediate value (0.67—0.68) and the following gradual increase to the final steady state value (1.4—1.5). Absorbance vs. time curves at 400 nm showed a precipitous fall from the initial value to the final steady state value. At 550 nm, they showed a steep rise from the initial value to a intermediate value followed by a gradual decrease to the final steady-state value.

The change at two stages observed at 800 and 550 nm indicates the presence of an intermediate state between the exhaustively reduced state and the final oxidized state. The intermediate state in polypyrrole has been found by in situ spectroscopic voltammetry[2] and ESR measurements.[20-23] Simultaneous ESR and electrochemical measurements[21-23] have demonstrated the participation of polaron (radical cation) as an intermediate between the neutral form in the reduced state and bipolaron (dication) in the sufficiently oxidized state. Therefore, the intermediate state may correspond to the polaron, and the final oxidized state to the bipolaron. The intermediate state is not observed when the conversion from the intermediate to the final state is much faster than that from the initial to the intermediate state. Therefore, the conversion from the polaron to the bipolaron is considered to be slower than that from the neutral form to the polaron.

Both the regions in the intermediate state and in the

final oxidized state can be considered as conductive because both polaron and bipolaron have been considered as conductive species.[23,24] Therefore, the rapid change in the absorbance vs. time curves from the initial value to the intermediate value indicates the presence of a distinctive conductive zone rather than a vague boundary as observed in diffusion. A diffusional process such as charge transfer by electron hopping or electron exchange in the film might provide more gradual change with an increase in distance from the ITO electrode.

Since the film absorbance increased monotonically with the extent of oxidation at a wavelength in the near-infrared region, we can estimate the concentration of oxidized species, C_O, (and reciprocally the concentration of reduced species, C_R,) from it. When it is assumed that $C_O=0$ in the exhaustively reduced state and $C_R=0$ in the final oxidized state, the ratio of C_O to C_O+C_R is estimated from the absorbance, A, through the following equation:

$$C_O/C^* = (A - A_0)/(A_\infty - A_0), \quad (2)$$

where $C^*=C_O+C_R$, A_0 is the absorbance in the exhaustively reduced state, and A_∞ is that in the final oxidized state. If we apply Eq. 2 to the result of the spatially resolved spectral measurement, we obtain concentration vs. distance profiles of the oxidized species in the film.

Figure 6 shows the concentration vs. distance profiles of the oxidized species in the film at various times calculated from the absorbance vs. time curves in Fig. 5. A representative distance from the ITO electrode to the each monitored segment is the distance, d, from the edge of the ITO electrode to the center of the each segment. The small circles in Fig. 6 represent the center of the 14

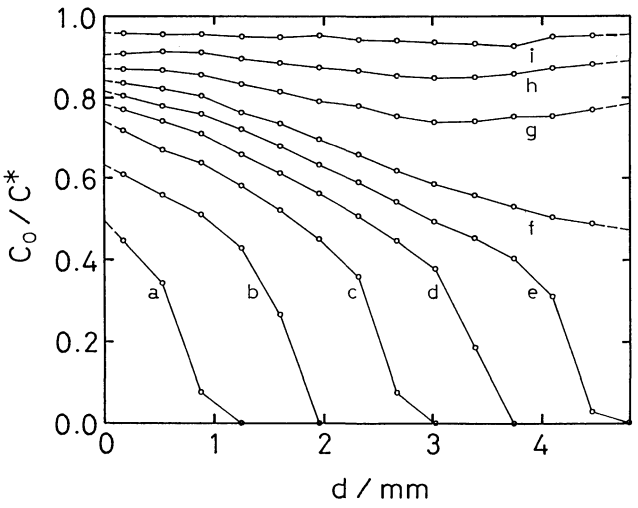

Fig. 6. Concentration vs. distance profiles of the oxidized species in the film at t=(a) 1.0, (b) 2.0, (c) 3.0, (d) 4.0, (e) 5.0, (f) 6.0, (g) 7.0, (h) 8.0, (i) 10.0 s. Dashed lines represents the extrapolation.

monitored segments of the film. Both C_O/C^* at a given d and d at a given C_O/C^* increased with time. These concentration profiles are similar to the theoretical ones derived from the propagation theory.[3] Since the intermediate state, at which A=0.67—0.68 for curves 2—13 in Fig. 5, corresponds to C_O/C^*=0.37, the segment in which $C_O/C^*>0.37$ can be considered as the conductive region. Therefore, the steep concentration gradients below C_O/C^*=0.37 indicate the presence of a manifest phase boundary between the conductive zone and the resistive region.

Figure 6 obviously shows that the conversion proceeded from the electrode/film interface towards the end of the film. For conducting polymer films deposited on ordinary solid electrodes, the relation between the rate-limiting process and the conversion direction has been considered as follows: When the conversion rate is limited by charge transfer in the film, the conversion occurs from the electrode/film interface towards the solution/film interface:[25] When the conversion rate is limited by mass transport of supporting electrolytes in the film, the conversion occurs in the reverse direction.[26] In our experimental condition, the direction of the ion transport is perpendicular to the direction of the film length. Therefore, if conversion proceeded with the mass transport being the rate-limiting process, the conversion has occurred from the upper layer of the film and seemed to occur from the whole of the film without depending on the distance from the electrode. Therefore, the conversion from the electrode/film interface indicates that the conversion proceeded with the charge transfer being the rate-limiting process.

In some previous papers, however, conversion with the mass transport being the rate-limiting process has been reported for polypyrrole films.[26-29] The reason why different rate-limiting processes have been observed for the same kind of polymer film may be attributed to the difference in permeability and porosity of the film which effects mobility of dopant ions in the film. Slow conversion from the fringe (solution/film interface) was also observed in our experimental condition when the film was sandwiched with two glass plates, in which the supporting electrolyte was supplied only by capillary action through the gap between the two glass plates and so the conversion might occur with the mass transport being the rate-limiting process.

The distance, d_{CF}, from the edge of the ITO electrode to the front of the conductive zone is an intercept of the abscissa in the concentration vs. distance profiles. However, they sometimes deviate from the real profiles especially at the conductive front, because the 14 measuring points is insufficient to describe the steep concentration gradient at the conductive front. Consequently, curves a, c, and d in Fig. 6 seemed to lean back in $C_O/C^*<0.1$. Therefore, the d_{CF} was estimated approximately with d at C_O/C^*=0.1. In Fig. 7, the d_{CF} was plotted against t at various stepped potentials, E's.

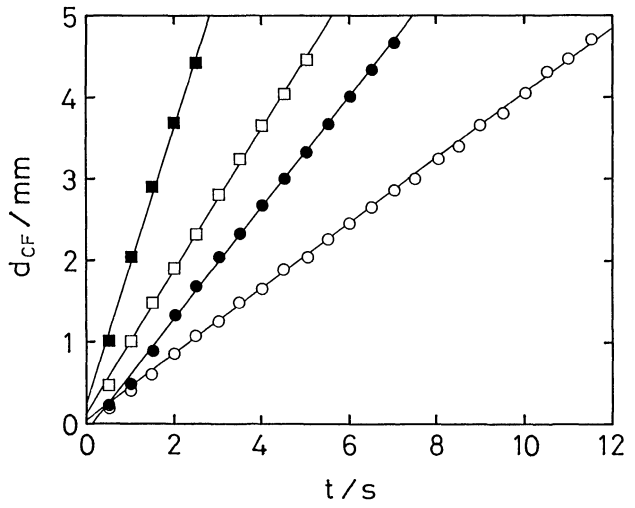

Fig. 7. Plots of d_{CF} against t at E=(○) 0.2, (●) 0.4, (□) 0.8, and (■) 1.2 V (vs. SCE).

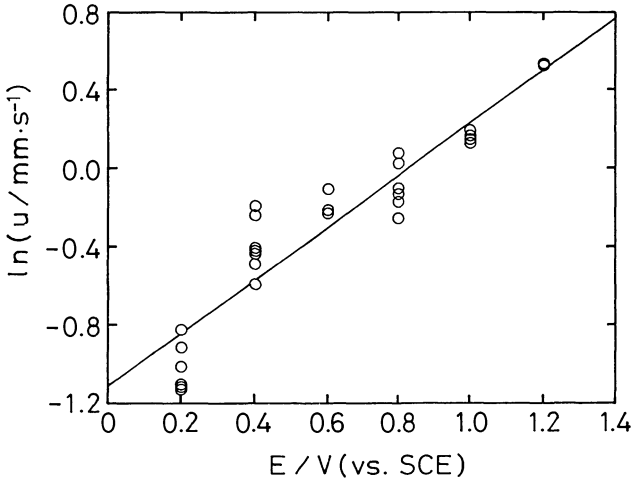

Fig. 8. Dependence of u on E. Values of u are the slope in Fig. 7.

These plots fell on the each straight line, indicating that the conductive zone was propagated in the film at a constant speed according to the applied potential. The propagation speed, u, is the slope of each line. A typical speed was 1.0 mm s^{-1} at E=0.8 V (vs. SCE). The linear relation of d_{CF} with t has been predicted from the propagation theory of a conductive zone in which the charge transfer at the interface between the conductive zone and the resistive region being the rate-limiting process.[3] This linear relation does not support any diffusional charge transfer process such as charge transport by electron hopping or electron exchange in the film. In such diffusional process, d_{CF}, which corresponds to the thickness of the diffusion layer, should have increased with $\sqrt{t}$.

The logarithm of the propagation speed (u) was plotted against E in Fig. 8. They exhibit a linear relation, i.e. the propagation speed varies exponentially with the applied potential. This exponential relation indicates that the propagation is controlled by a charge transfer process of the Tafel type.

An aspect of the propagation could be seen in time-sequence photographs (Fig. 9) taken after the potential of the ITO electrode was stepped from −1.0 to 0.8 V (vs. SCE). Initially, the polypyrrole film was in the exhaustively reduced state and was uniformly yellow (Fig. 9a). After stepping the potential, the purple conductive zone grew, invading the yellow reduced domain (Figs. 9b and c). The distinctive phase boundary does not support the diffusive propagation but suggests the propagation under the charge transfer control as at a conventional electrode/solution interface. The distinctness of the boundary was independent of applied potentials in the range from 0.2 to 1.2 V (vs. SCE). It has been reported that a rapid charge transfer rate makes the boundary vague.[30] Thus the rate constant belongs to the totally irreversible case.[30] The purple zone was followed by a blue-black zone with a vague phase boundary (Figs. 9 c and d). The purple and

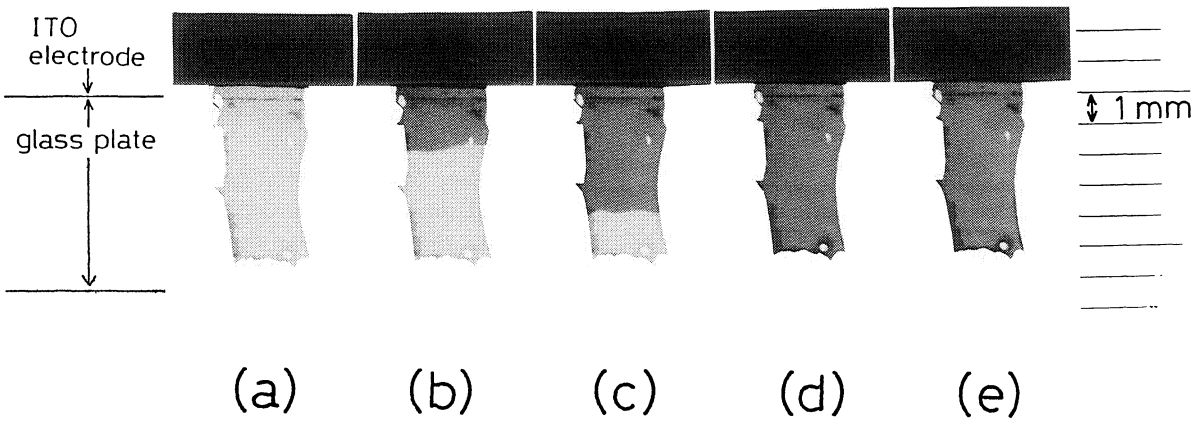

Fig. 9. Time-sequence photographs of a polypyrrole film at t=0 (a), 1.6 (b), 3.2 (c), 4.8 (d), 9.6 (e) s.

the blue-black zones were observed when the potential was more anodic than 0.2 V (vs. SCE). The film finally turned uniform in the blue-black state (Fig. 9 e).

Apparently, the purple zone corresponds to the intermediate state and the blue-black zone to the final oxidized state, therefore, they may correspond to the polaron and the bipolaron, respectively. The transient appearance of the intermediate state (polaron) is consistent with the transient ESR responses in polypyrrole films reported by Zhong et.al.,[23] in which the intensity of the ESR signal initially increased to a maximum and afterwards decreased to a steady state when the potential was stepped to 0.2 V (vs. SCE) or more anodic potentials.

In conclusion, the oxidation of resistive polypyrrole films obeyed the propagation theory of a conductive zone under charge transfer control in that (1) the distinctive phase boundary was observed; (2) the propagated distance was linear to the time of the electrolysis; (3) the propagation speed exhibited the exponential dependence on the applied potential.

Pressure-Induced Neutral-Ionic Phase Transition of a Tetrathiafulvalene-Iodanil Crystal

Susumu MATSUZAKI,* Toshihiro HIEJIMA, and Mizuka SANO†
Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860
† Division of Natural Sciences, International Christian University, Mitaka, Tokyo 181
(Received March 4, 1991)

The pressure dependence of IR spectra measured for a mixed-stack neutral charge-transfer (CT) crystal, tetrathiafulvalene–iodanil (TTF-IA), showed an occurrence of a neutral–ionic (N–I) transition at 1.9 GPa. The N–I transition is accompanied by gradual dimerization of the crystal lattice and a small ionicity jump, in contrast to the case of TTF–chloranil (TTF–CA). Such a quasi-continuous N–I transition is attributable to stronger electron–lattice interaction in TTF–IA than that in TTF–CA.

Organic charge-transfer (CT) crystals with mixed-stack structures are classified into two types with a neutral and an ionic ground electronic states. The occurrence of either ground state is determined by a balance between energy gain by the electrostatic Madelung energy (E_M) of an ionic crystal lattice and energy cost on ionization of a donor–acceptor pair ($I_D - E_A$) in a neutral crystal lattice, where I_D is ionization potential of a donor (D) and E_A is electron affinity of an acceptor (A). When a transfer integral "t" determined by an orbital overlap between the D–A pairs is negligibly small, the neutral–ionic interface is sharp; i.e., degree of ionicity (ρ) takes one of the extreme values, zero or one.[1] The interface diffuses with an increase in "t", and ρ comes to take a value between zero and one. In such a case, the CT crystals are labeled as quasi-neutral ($\rho<0.5$) and quasi-ionic ($\rho>0.5$) compounds.[2]

It has recently been found[3] that application of pressure or lowering of temperature generates a phase transition accompanying an increase in ρ from quasi-neutral to quasi-ionic i.e., N–I transition, for several mixed-stack CT crystals near the neutral–ionic interface. In particular, a mixed-stack CT crystal of tetrathiafulvalene (TTF) and chloranil (CA), TTF–CA, has attracted much attension of physicists and chemists for the pressure-induced[4,5] and temperature-induced[6,7] N–I transitions. Many experimental and theoretical works on TTF–CA have revealed that an increase in E_M with a contraction of the crystal lattice and electron–lattice interaction play important roles in the N–I transition. On the other hand, there are only a few reports on the N–I transition of other CT crystals.[8,9] Experimental studies on various CT crystals are necessary to draw a complete scheme of N–I transitions.

TTF–tetrahalo-*p*-benzoquinones are known to give several CT crystals with segregated- or mixed-stack structure and neutral or ionic ground state;[10,11] e.g., mixed-stack crystals of TTF–FA[12] (FA, fluoranil), TTF–CA,[12] and TTF–IA[11] (IA, iodanil) are neutral, and the crystal of TTF–BA[13] (BA, bromanil) is ionic. We are interested in an effect of halogen-substitution on the ionicity and N–I transition in the TTF–tetrahalo-*p*-benzoquinone crystals. Here, we report a pressure-induced N–I transition in a mixed-stack CT crystal of TTF and iodanil (TTF–IA) and compare the results with those of TTF–CA.

Experimental

Tetrathiafulvalene (Tokyo Kasei Co.) was purified by sublimation in vacuo. Iodanil (tetraiodo-*p*-benzoquinone) synthesized from bromanil and potassium iodide by the method of Torrey and Hunter[14] was purified by repeated recrystalizations from ethyl acetate to give deep purple needle-like crystals. They were identified by elemental analyses and IR spectra.

Charge-transfer complexes of TTF and IA were prepared by mixing of the hot ethyl acetate solutions of each component. When the mixed solution was cooled, two kinds of crystals were simultaneously obtained: One is an orange needle and another is a dark brown plate. The former is a 1:1 CT complex (TTF–IA) and the latter is a 2:1 CT complex, $(TTF)_2IA$. Compositions of these complexes were determined by elemental analyses and X-ray crystal-structure analyses.[15] The results for $(TTF)_2IA$ will be published elsewhere. A potassium salt of IA, K·IA, was prepared from IA and potassium iodide in acetone. Crystals of TTF–CA and TTF–BA were prepared by mixing of the hot acetonitrile solutions of each component.

IR spectra of powder samples were recorded on a JASCO FT/IR-7000 Fourier-transform infrared spectrometer in the pressure region up to 6.3 GPa by use of a diamond anvil cell (DAC). A stainless steel foil 0.03 mm thick was used as a gasket which had a hole of 0.6 mm in diameter. Nujol was used as a pressure medium and the applied pressure was calibrated by use of the R_1 fluorescence line of ruby. Raman spectra of powder samples were recorded on a JASCO R-800 spectrometer equipped with an NEC GLG-3200 Ar^+ laser as an excitation light source at ambient pressure to determine frequencies of totally symmetric vibrations. The fluorescence line of ruby was also recorded on the Raman spectrometer. All the measurements were performed at ambient temperature.

Results and Discussion

Ionicity at Ambient Pressure. Figure 1a shows an IR-spectrum of a TTF–IA powder sample at ambient pressure. A spectrum of TTF–CA obtained in this study is shown in Fig. 1b for comparison. Frequencies and assignment of the IR bands are given in Table 1 with those of IA^0 and IA^-.[11] The frequencies of K·IA are

a) Frequencies of TTF^0 and TTF^+ are from Ref. 16.

used as those of IA^-, and frequencies and assignment of TTF^0 and TTF^+ have been reported in the literature.[16] The spectrum of TTF–IA (Fig. 1a) is reasonably explained as a superposition of the spectra of neutral donor (TTF^0) and neutral acceptor (IA^0), as in the case of TTF–CA (Fig. 1b);[17] i.e., TTF–IA is a neutral CT crystal. The degree of ionicity at ambient pressure (ρ_0) is estimated at 0.08 for TTF–IA from the C=O stretching IR frequency (1647 cm^{-1}) of IA on the assumption of a linear relation between the frequency and ρ.[17]

Metzger and Torrance[18] and Girlando, et al.[13] discussed on the difference in ionicity between two mixed stack CT crystals, TTF–CA and TTF–BA: the former is neutral and the latter is ionic. They claimed that BA has larger polarizability than CA and the resulting large polarization energy plays an important role in stabilizing the ionic ground state in TTF–BA. However, their claim appears to be inconsistent with the fact found in this study that TTF–IA has a neutral ground state. Iodanil has larger polarizability than BA as reported by Sato, et al.[19]. They have estimated that the molecular polarizability of IA is about twice as large as that of BA, on the basis of the difference in ionization energy between the gaseous and solid states. The electron affinity of IA, on the other hand, is not so different from the electron affinities of CA and BA.[20] These factors are expected to advantage the ionic ground state also in the case of TTF–IA. Therefore, the neutral ground state found in this study suggests that other factors should be considered to explain the difference in the ionicity of TTF–tetrahalo-*p*-benzoquinone crystals.

Large polarizability of the component molecules in CT crystals stabilizes the energy of D^+ and A^-. This effect decreases the energy difference, I_D-E_A, and is favorable for the ionic ground state. On the other hand, the large polarizability simultaneously increases dielectric constant (ε) of the crystals, according to Clausius–Mossotti relation. The increased dielectric constant reduces the Madelung energy, $E_M=\alpha e^2/\varepsilon r$, where α, e, and r are Madelung constant, electron charge, and intermolecular distance, respectively; therefore, this effect is favorable for the neutral ground state. Ionicity of the CT crystals is expected to be dominated by the relative importance of these two effects, so that large polarizability of the component molecules does not necessarily produce the ionic ground state.

There is another factor to be taken into consideration, i.e., a packing motif of donor and acceptor molecules in the crystal. The packing motif is expected to affect the ionicity through a change of E_M. Among all the CT crystals of TTF–tetrahalo-*p*-benzoquinones with the mixed stack structure, only TTF–BA is ionic and the others are neutral. The neutral CT crystals, TTF–FA,[12] TTF–CA,[12] and TTF–IA,[15] have packing motifs similar to each other: The crystals are composed of a single mixed stack. On the other hand, the crystal of TTF–BA is composed of two mutually orthogonal mixed stacks; i.e., the packing motif is quite different from those of the three neutral CT crystals. The results suggest that the difference in the molecular packing motif must also play an important role in the occurrence of the ionic ground state of TTF–BA in addition to the polarization effect.

The value of ρ_0 is estimated at 0.18 for TTF–CA[5,17] by use of the C=O stretching frequencies of the complex (1657 cm^{-1}), CA^0 (1693 cm^{-1}), and CA^{-1} (1518 cm^{-1}). The ionicity estimated for TTF–IA (0.08) is considerably smaller than that of TTF–CA. The small value is attributed to the effect of the substitution of large iodine atoms into the acceptor. An interplanar distance between TTF and IA (3.57 Å)[15] is 0.18 Å longer than that of TTF–CA (3.39 Å),[12] because of the larger atomic

radius of iodine than that of chlorine. The large interplanar distance in TTF–IA should be responsible for the small value of ρ_0. The ionicity is approximately expressed by the relation, $\rho \propto t^2/(h\nu_{CT})^2$, where t is a transfer integral and $h\nu_{CT}$ is energy of charge-transfer absorption. The value of $h\nu_{CT}$ observed for TTF–IA in a KBr disk is 6300 cm^{-1}, which is not so different from the value for TTF–CA (5300 cm^{-1}).[21] Therefore, the small ρ_0 value of TTF–IA is attributed to a small transfer integral, which results from the large interplanar distance, i.e., a small overlap between π molecular orbitals of donors and acceptors in comparison with TTF–CA.

Pressure Dependence of Ionicity and N–I Transition. Figure 2 shows pressure dependence of the IR spectra for TTF–IA. The IR band A of an IA C=O stretching vibration (b_{1u} ν_{10}) shows a large low-frequency shift with increasing pressure. At 1.9 GPa (Fig. 2c), a new band A′ appears as a shoulder on the low-frequency side of band A. On further compression, intensity of band A′ increases and band A disappears as shown in Fig. 2e. The crystals of TTF–IA were found to decompose gradually when storaged in a desiccator to give neutral iodanil. The decomposition is probably attributed to sublimation of TTF molecules which leaves IA^0 molecules on the crystal surface. An IR band of the IA^0 molecules is marked with an asterisk in the figure. The rate of decomposition was so slow that no spectral change induced by the decomposition was observed during the measurements of pressure dependence.

Pressure dependence of the IR frequencies (Fig. 3) shows that band A changes to band A′ at 1.9 GPa with a slight frequency jump. The degrees of ionicity are estimated at 0.36 and 0.42 for bands A and A′, respectively, at 1.9 GPa. With further compression, the frequency of band A′ gradually decreases and the degree of ionicity increases up to 0.57 at 6.3 GPa which is the highest pressure in this study. The C=O stretching frequencies of IA and K·IA are practically independent of applied pressure as shown in Fig. 3. Therefore, ionicity at every pressure was estimated by use of the frequencies of IA and K·IA at ambient pressure.

Even at the highest pressure, the R_1 fluorescence line of ruby showed only small inhomogeneous broadening. The broadening is known as a measure of non-hydrostatic compression in a pressure medium.[22] Small inhomogeneous broadening observed shows negligible pressure distribution in the gasket hole of the DAC. Such negligible pressure distribution is also demonstrated by absence of inhomogeneous broadening of bands A and A′ of which widths are expected to be sensitive to the non-hydrostatic compression because of the large frequency shifts by pressure. (See Fig. 2.)

An increase in ρ at P_c is also indicated by frequency

shifts of TTF C–S stretching vibrations (bands E, F, and G) in Fig. 4. Bands E, F, and G are assigned to b_{2u} ν_{25}, b_{1u} ν_{16} and b_{1u} ν_{17}, respectively, as given in Table 1.

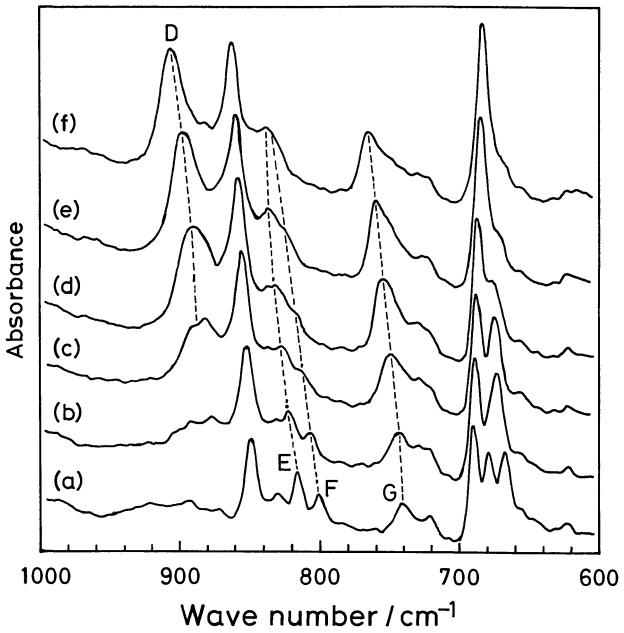

Fig. 4. IR spectra of TTF–IA in thee region of C–S stretching vibrations at high pressures. (a) 1.2; (b) 1.7; (c) 1.9; (d) 2.3; (e) 2.7; (f) 3.5 GPa.

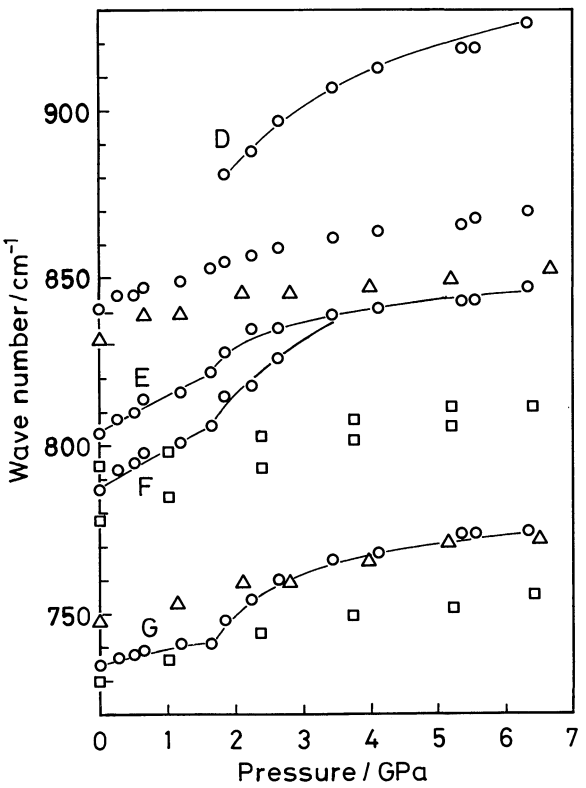

Fig. 5. Pressure dependence of IR frequencies of TTF–IA in the region of C–S stretching vibrations. (○) TTF–IA; (□) TTF^0; (△) TTF^+.

These bands show considerable high-frequency shifts (20—40 cm^{-1}) on ionization of TTF as shown in the table, and can be used as indicators for ionicity of TTF. Figure 5 shows the pressure dependence of the three bands. The corresponding frequencies of TTF^0 and TTF^+ are also plotted versus applied pressure in the figure: frequencies of TTF–BA are used as those of TTF^+. The figure shows that the pressure dependence of the frequencies clearly changes at P_c and the frequencies gradually approach to those of TTF^+ above P_c: band F comes to be concealed by band E. However, ionicity of TTF could not be precisely estimated because of the nonlinear relations between the frequencies and ionicity, which were found by use of the frequencies of TTF^0, $TTF{\cdot}Br_{0.76}$ and TTF^+.

A new band B appears around 1560 cm^{-1} at P_c, as shown in Fig. 2c. This band is assigned to the totally-symmetric C=O stretching vibration of IA (a_g ν_1) from its frequency value. Band B shows a low-frequency shift with an increase in pressure as shown in Fig. 3 and is concealed by the band C of an IA C=C stretching vibration (b_{2u} ν_{18}) at ca. 3 GPa. Another new band D appears around 880 cm^{-1} at P_c, as shown in Fig. 4c. This band is assigned to a totally-symmetric ring-deformation vibration of IA (a_g ν_3) from its frequency value. Figure 5 shows that the frequency of band D increases with an increase in pressure. This is consistent with an observed high-frequency shift of the a_g ν_3 Raman band of IA on ionization: 870 cm^{-1} for IA^0 and 935 cm^{-1} for IA^-.

IR activation of these bands B and D, which are intrinsically IR-inactive, is attributed to a kind of vibronic interaction, i.e., electron–molecular vibration (e–mv) interaction, between TTF and IA.[23] The appearance of vibronically-activated IR bands demonstrates dimerization of a crystal lattice, because such IR activation is not expected to occur in CT crystals with regular mixed-stack structures.[23] Such dimerization of a crystal lattice is the same as that observed in the N–I transition of TTF–CA,[5] and is produced by electron–lattice interaction. Consequently the anomaly observed for the IR spectra of TTF–IA at 1.9 GPa is attributed to a pressure-induced N–I transition accompanied by dimerization of the crystal lattice. Upon this transition, a yellow sample of TTF–IA was found to turn red, which is attributable to a change in the electronic state of the complex at P_c. The state of the high-pressure phase should rather be labeled as "quasi-ionic" in spite of the result that ionicity of the high-pressure phase is less than 0.5 at P_c as mentioned above. Such a "quasi-ionic" phase is theoretically suggested to exist in the case of strong electron–lattice interaction.[24]

There is another possible assignment of the C=O stretching IR bands A′ and B: band A′ is assigned to a_g ν_1 and band B to b_{1u} ν_{10}. The frequencies of bands A′ and B are 1591 and 1557 cm^{-1} at P_c, respectively. If this assignment is accepted, the phase transition of TTF–IA should be accompanied by a large ionicity jump from

0.36 to 0.64, which is almost equal to that of TTF-CA. However, this assignment is unacceptable because of the following reason. The two C=O stretching vibrations of IA^0 are almost equal to one another: 1656 cm^{-1} (a_g ν_1) and 1659 cm^{-1} (b_{1u} ν_{10}). Furthermore, magnitudes of the low frequency shifts on ionization are also almost equal to one another: 171 cm^{-1} (a_g ν_1) and 161 cm^{-1} (b_{1u} ν_{10}). Therefore, frequencies of the two vibrations are expected to be almost equal to one another at every ionicity if the frequencies are not affected by the e-mv interaction. In fact, frequencies of totally-symmetric vibrations are decreased by the e-mv interaction. On the other hand, non-totally symmetric vibrations are free from any influence by the interaction.[23] Consequently, the frequency of a_g ν_1 must be less than that of b_{1u} ν_{10}.

Comparison of N-I Transitions between TTF-IA and TTF-CA. In the pressure-induced N-I transition of TTF-CA at room temperature, IR bands as well as visible bands of the ionic species appear at pressures considerably lower than P_c. The bands of the neutral and ionic phases are both observed in the pressure region between 0.7 and 1.1 GPa.[5] On the other hand, in the temperature-induced N-I transition of TTF-CA at 81 K, such coexistence of the two phases is not observed.[7]

Table 2. Comparison of N-I Transitions in TTF-IA and TTF-CA

Complex	ρ_0	P_c / GPa	$\Delta\rho$	IR intensity of totally symmetric vibrations above P_c
TTF-IA	0.08	1.9	0.06 (0.36→0.42)	Gradual increase
TTF-CA[a]	0.18	1.1	0.30 (0.34→0.64)	Abrupt increase

a) Refs. 5 and 6.

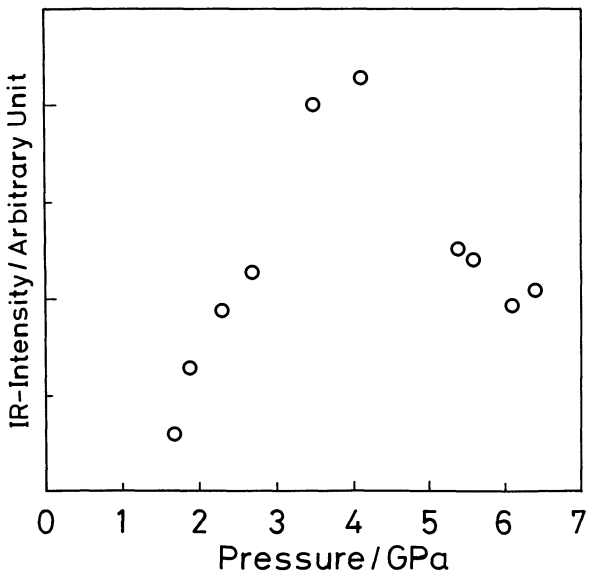

Fig. 6. Pressure dependence of IR intensity observed for a totally-symmetric vibration (IA a_g ν_3) of TTF-IA.

The coexistence is attributed to thermal excitation of the ionic state which has an energy not far off the neutral state near the transition point.[24] Also in the case of TTF-IA, such coexistence is observed as shown in Figs. 2 and 3. The N-I transitions of TTF-IA and TTF-CA are similar to one another on this point but there are a few remarkable differences between the two CT crystals.

Characteristic features of the N-I transition in the two systems are shown in Table 2. In the case of TTF-CA, a large ionicity jump of 0.3 (from 0.34 to 0.64) is observed at the transition pressure (1.1 GPa): The average of ρ for the neutral and ionic phases at P_c is almost equal to 0.5. On the other hand, in the case of TTF-IA, the ionicity shows only a slight jump of 0.06 (from 0.36 to 0.42) at the transition pressure (1.9 GPa): The average of ρ is clearly less than 0.5. There is a difference also in the IR activation of the totally symmetric vibrations between the two CT crystals. An abrupt increase is observed for the IR intensity of CA (a_g ν_3) in TTF-CA at P_c.[5] In the case of TTF-IA, on the other hand, intensity of the corresponding IR band of IA (a_g ν_3) gradually increases with an increase in pressure above P_c, as shown in Fig. 6. The intensity of the vibronically-activated totally symmetric vibrations is known as a measure of dimerization of crystal lattice,[23] so that Fig. 6 demonstrates gradual dimerization in TTF-IA.

According to a quantum Monte Carlo simulation by Nagaosa,[24] the N-I transition of the mixed-stack CT crystal changes from the discontinuous transition of the first order to the continuous one of the second order with an increase in the electron-lattice interaction, which is due to a variaton of a transfer integral with a change in the interplanar distance between the donor and acceptor. The quasi-continuous transition observed for TTF-IA, i.e., the small ionicity jump and the gradual dimerization of the crystal lattice, are characteristic to the case of large electron-lattice interaction in comparison with TTF-CA. The simulation, on the other hand, predicts a decrease in the transition pressure for the case of large electron-lattice interaction if other conditions are unchanged. This disagrees with the increased transition pressure in TTF-IA compared with TTF-CA as shown in Table 2. This disagreement may be due to the large interplanar distance between TTF and IA[15] and the large polarizability of IA.[19] These two factors decrease the electrostatic Madelung energy and are expected to push up the transition pressure.

(Received January 14, 1991)

The solvatochromism of the first ligand field absorption bands and/or the solvent dependence of ^{13}C and ^{59}Co NMR shifts for *trans*- and *cis*-$[M(N)_2(O)_4]$ type complexes of cobalt(III) or chromium(III) with various kinds of polyamine-*N*-polycarboxylato ligands was elucidated in terms of the angular overlap model (AOM) parametrization. On the basis of the difference in the solvent-dependence of spectroscopic data of the complexes studied in various solvents, it was found that the solvatochromism could result from variations of the metal-ligand σ and/or π bond interactions (expressed by the $e_\sigma(O)$, $e_\sigma(N)$, and anisotropic $e_\pi(O)$ AOM parameter values) due to the preferential solvation toward the oxygen p_π orbitals coplanar with the $M(O)_2$ coordinate planes.

There have been a few reports on the solvent dependence of the ligand field d–d transitions of inert complexes with the saturated coordination numbers in comparison with a number of investigations on remarkable solvatochromism in the charge transfer transitions of metal complexes.[1] For Co(III) and Cr(III) complexes with ethylenediaminetetraacetate (edta) type ligands, the first d–d absorption band maxima were found to shift to the shorter wavelength with increasing acceptor numbers,[2] which were defined as a quantitative empirical electron pair acceptor number for solvents by Gutmann et al.[3] on the basis of the ^{31}P NMR chemical shifts of triethylphosphine oxide in various kinds of solvents. Nevertheless, there has been no systematic study on the elucidation for the solvent dependence of the ligand field bands of this type of complexes. Though Taura proposed the preferential solvation model toward the σ electrons of the carboxylato oxygens for *cis*-$[Co(ox)_2(NH_3)_2]^-$ in terms of EHMO calculations,[2d] this approach could not necessarily account for the blue shift of the first ligand field band. For the higher symmetry complexes of *trans*-$[CrX_2(N)_4]$ type, on the other hand, it has recently been reported that the solvent dependent ligand field band and ^2H NMR shifts can be elucidated in terms of the ligand field or the angular overlap model (AOM) parametrization.[4] A notable ligand field variability and the interligand cooperative effect due to the selective solvation toward electronegative ligating atoms has been revealed. These findings might make feasible to account for the solvatochromism of the edta type complexes with multiple (at most triple) d–d transition components due to much lower symmetry than tetragonal or octahedral, and could provide a basis for more plausible solvation models than Taura's one.[2d]

In this article, we will examine the solvent-dependence of the ligand field absorption spectra for *trans*- and *cis*-$[M(N)_2(O)_4]$ type complexes of Co(III) and Cr(III) together with ^{13}C and ^{59}Co NMR spectra for the Co(III) complexes and analyze them on the basis of the AOM parametrization. Assuming that the polyamine-*N*-polycarboxylato ligands are nonlinear ligators with the anisotropic π interaction between metal d orbitals and ligating oxygen p_π orbitals perpendicular to the chelate plane, it has been revealed that preferential (additional) solvations toward a pair of two neighboring oxygen p_π orbitals coplanar with the $M(O)_2$ plane play an important role in the solvatochromism and that the solvatochromic behavior reflects the difference in the topological arrangements of the ligating oxygen p_π orbitals in the carboxylato groups.

Experimental

Materials. The complexes used in this study are given in Table 1 together with numbering (**1**—**37**) for short. The ligands' abbreviations are as follows: ida=iminodiacetate; mida=*N*-methyliminodiacetate; eida=*N*-ethyliminodiacetate; bida=*N*-butyliminodiacetate; nta=nitrilotriacetate; β-alada=β-alanine-*N*,*N*-diacetate; edta=ethylenediaminetetraacetate; (*S*)-pdta=(*S*)-1,2-propanediaminetetraacetate; 1,3-pdta=1,3-propanediaminetetraacetate; eddda=ethylenediamine-*N*,*N*′-diacetate-*N*,*N*′-dipropionate; (*S*,*S*)-edds=(*S*,*S*)-ethylenediamine-*N*,*N*′-disuccinate; edtp=ethylenediaminetatrapropionate; (*S*)-pdtp=(*S*)-1,2-propanediaminetetrapropionate; dmedda=*N*,*N*′-dimethylethylenediamine-*N*,*N*′-diacetate; edda=ethylenediamine-*N*,*N*′-diacetate; aeida=*N*-(2-aminoethyl)iminodiacetate or ethylenediamine-*N*,*N*-diacetate.

Preparation of Complexes. Most complexes except **11**, **12**, **16**, **32**, **33**, and **36** complexes in Table 1 were prepared by the literature methods; **1**,[5] **2**,[6] **3**,[7] **4**,[7] **5**,[7], **6**,[8] **7**,[9] **8**,[9] **9**,[10] **10**,[11] **13**,[12] **14**,[13] **15**,[12] **17**,[14] **18**,[15] **19**,[15] **20**,[16] **21**,[17] **22**,[18a] **23**,[19] **24**,[20] **25**,[19b] **26**,[21] **27**,[17] **28**,[22] **29**,[23] **30**,[22] **31**,[23] **34**,[8] **35**,[9] **37**.[25] These complexes were identified by the absorption spectra.

***trans*(*N*)-K[Co(mal)(gly)$_2$]·2H$_2$O.** The reaction mixture was obtained by the same method as that for the corresponding oxalato complex[10] by using potassium malonate instead of potassium oxalate. The separation of three isomers, *trans*(*N*),

§ Present address: Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560.

Table 1. Solvatochromic Data of $[M(N)_2(O)_4]$ Type Complexes

	Complexes	Absorption			^{59}Co NMR

The symbols, *sym*- and *unsym*-, denote symmetrical and unsymmetrical geometrical structures, respectively. The asterisked (*) complexes (**22**—**25**) take a *trans*-(O_5) geometrical structure in which the five-membered acetate rings occupy *trans*-axial sites while the propionate rings lie in the equatorial plane with two nitrogen atoms.

C_1-*cis*(*N*), C_2-*cis*(*N*), was chromatographically performed by a method similar to that for the oxalato complex. The *trans*(*N*) isomer was first eluted and was isolated as crystals from its eluate. The geometrical structure of the *trans*(*N*) isomer was determined on the basis of the presence of a shoulder at the lower energy region in the first absorption band as found for the corresponding oxalato complex.[10] Found: C, 22.02; H, 3.76; N, 7.21%. Calcd for $K[Co(mal)(gly)_2]\cdot 2H_2O$:C, 21.88; H, 3.67; N, 7.29%.

***trans*(*N*)-K[Co(mal)(β-ala)$_2$]·2.5H$_2$O·KCl.** This complex was prepared and characterized by a similar method to that for the corresponding glycinato complex. Found: C, 22.10; H, 3.80; N, 5.68%. Calcd for $K[Co(mal)(\beta\text{-ala})_2]\cdot 2.5H_2O\cdot KCl$: C, 21.80; H, 3.86; N, 5.65%.

Na[Cr(mal)$_2$(en)]·0.5H$_2$O. Five grams of *cis*-$Na[Cr(mal)_2(H_2O)_2]\cdot 3H_2O$ was dissolved in 400 cm^3 of hot *N*,*N*-dimethylformamide (DMF) at 90 °C. To the resulting dark blue solution was added 1.2 g of ethylenediamine in 25 cm^3 of DMF. The color of the mixture changed to be light violet. After this solution was allowed to stand for a while at 90 °C, it was cooled to room temperature. By the addition of a large amount of ether to the reaction solution, red precipitate was obtained. The aqueous solution of this precipitate was poured onto a QAE-Sephadex C-25 anion-exchange column (ϕ 3.5×40 cm). After washing the column with water, the chromatography was carried out by eluting with 0.04 M (1 M=1 mol dm^{-3}) aqueous NaCl solution. The column gave three bands. The first eluate was collected and evaporated to dryness. By the repetition of the extraction of the red complex with methanol, sodium chloride was removed. This was recrystallized from water and acetone. Calcd for $Na[Cr(mal)_2(en)]\cdot 0.5H_2O$: C, 27.58; H, 3.73; N, 8.04%. Found: C, 27.59; H, 3.55; N, 7.95%.

***sym-cis*-K[Co(dmedda)(ox)]·0.5H$_2$O.** This complex was

prepared according to the literature method for the corresponding sodium salt[24] by using potassium oxalate instead of sodium oxalate. Found: C, 30.20; H, 3.69; N, 7.14%. Calcd for K[Co(ox)(dmedda)]·0.5H_2O: C, 30.23; H, 3.44; N, 7.05%.

***sym-cis*-K[Co(dmedda)(mal)]·1.5H_2O.** This complex was prepared by the same method as that for the corresponding oxalato complex by using potassium malonate instead of potassium oxalate. Found: C, 30.90; H, 4.35; N, 6.54%. Calcd for K[Co(dmedda)(mal)]·1.5H_2O: C, 30.78; H, 4.46; N, 6.53%. The *sym-cis* structure with a C_2 symmetry was confirmed by the ^{13}C NMR spectroscopy.

***sym*-K[Co(aeida)(ox)].** This complex could be prepared using *unsym*-K[Co(NO_2)$_2$(aeida)]·H_2O as a starting material. Potassium salt of the dinitro complex was prepared according to the literature method for the corresponding sodium salt[26] by using potassium nitrite instead of sodium nitrite. Found: C, 18.95; H, 3.24; N, 14.45%. Calcd for K[Co(NO_2)$_2$(aeida)]·H_2O: C, 18.85; H, 3.16; N, 14.65%.

To a solution containing 5 g of the dinitro complex and 5.32 g of potassium oxalate in 50 cm^3 of water was added 0.3 g of activated charcoal. The mixture was stirred at 60 °C for 1 h. Then, the dinitro complex was almost quantitatively converted to a mixture of the *sym* and *unsym* isomers of the oxalato complex. After the charcoal was removed, the *unsym* and *sym* isomers were separately obtained by means of fractional crystallization; the former complex being less soluble than the latter one. Found: C, 26.65; H, 2.90; N, 7.75%. Calcd for *sym*-K[Co(aeida)(ox)]: C, 26.68; H, 2.80; N, 7.78%.

Measurements. The ligand field absorption spectra were obtained by a Shimadzu UV-240 spectrophotometer at room temperature. ^{13}C and ^{59}Co NMR spectra were measured by a JEOL GX-270 FT-NMR spectrometer at 20 °C and 25 °C, respectively, at Nara Women's University. ^{13}C NMR shifts were determined by using dioxane (66.6 ppm) as an external standard, whereas [Co(edta)]$^-$, *fac*-[Co(β-ala)$_3$], *cis*(*N*)-[Co(nta)(gly)]$^-$, and [Co(ox)$_3$]$^{3-}$ were taken as the external standards for ^{59}Co NMR shifts according to the chemical shift range of the complexes with the down field positive convention. The chemical shifts of the complexes were converted as δ(Co)=10300 ppm for the edta complex relative to external aqueous [Co(CN)$_6$]$^{3-}$ (δ(Co)=0). In order to obtain the sufficient concentrations for these spectroscopic measurements (0.001—0.01 M, 0.2 M, and 0.005—0.02 M for absorption, ^{13}C and ^{59}Co NMR, respectively) in aprotic solvents, cryptand 222 was used as a solubilizing agent.

The solvents used for the measurements were of spectrograde or reagent grade. The abbreviations for the solvents in parentheses and their acceptor numbers in square brackets as found in the literature[3] are as follows: *N*,*N*-dimethylacetamide (DMA) [13.6]; *N*,*N*-dimethylformamide (DMF) [16.0]; dimethyl sulfoxide (DMSO) [19.3]; *N*-methylformamide (NMF) [31.0]; formamide (FA) [39.8]; methanol (MeOH) [41.3]; H_2O [54.8].

Results and Discussion

Since the present complexes are so stable or inert to be isolated from aqueous solutions as described in the Experimental section, it is unlikely that the solvatochromism is associated with the ligand dissociation. There exists to be fairly good linear correlation between the ligand field band maxima and the solvents' acceptor numbers for the present complexes including those bearing the N–H protons. This fact indicates that the solvatochromism is accompanied by the acceptor properties of the solvents, but not by the donor properties. In view of the extent of the solvatochromism and/or the solvation sites, the trans and cis type complexes are classified into two and three groups, respectively, as below.

***trans*-[M(N)$_2$(O)$_4$] Type Complexes.** In general, *trans*-[Co(N)$_2$(O)$_4$] type complexes give two components in the first ligand field absorption band region. These components are assigned to the holohedrized tetragonal (D_4) $^1A_2$ and ^1E state in the $^1T_1 \leftarrow {}^1A_1$ transition region from the longer wavelength side. As found for [Co(edta)]$^-$ and the analogous complexes,[2] the absorption band maxima corresponding to the transition $^1E \leftarrow {}^1A_1$ of the trans type complexes also give linear correlations with Gutmann's acceptor numbers[3] as

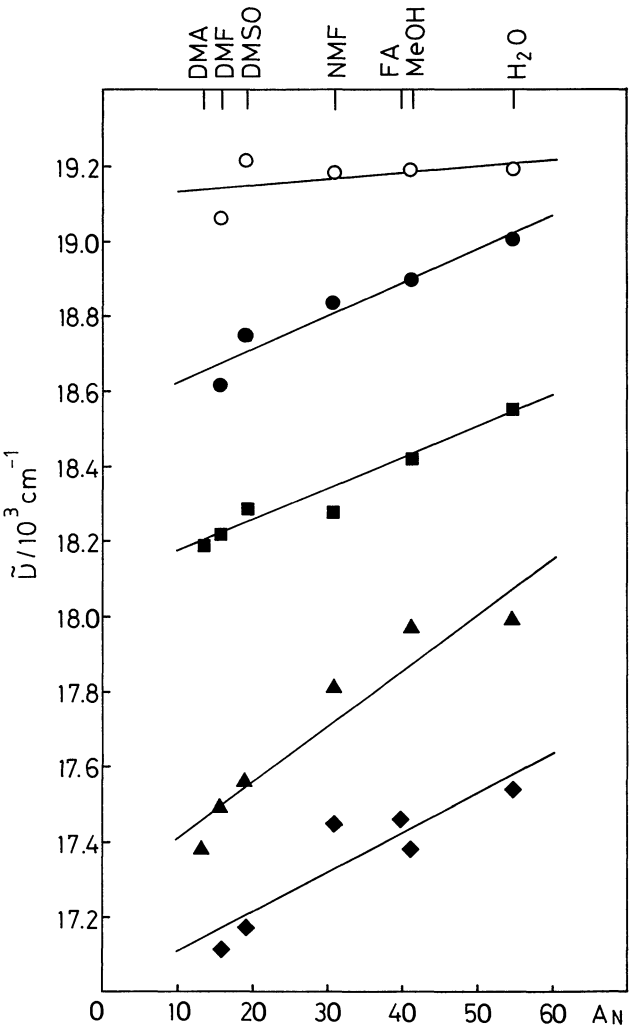

Fig. 1. Plots of the absorption band maxima ($\nu/10^3$ cm^{-1}) vs. the acceptor numbers (A_N): ○ *trans*(*N*)-[Co(mida)$_2$]$^-$ (A group); ● *trans*(*N*)-[Co(ox)(gly)$_2$]$^-$ (B group); ■ [Co(ox)$_2$(en)]$^-$ (C group); ▲ [Co(edtp)]$^-$ (D group); ◆ *cis*(*N*)-[Co(nta)(gly)]$^-$ (E group).

shown in Fig. 1. However, the extent of the solvent-dependence varies from one group of the complexes to the other. That is, for *trans*(*N*)-[Co(ida)$_2$]$^-$ type complexes which are classified as the A group (**1**—**8**), the slopes of the plots of the shorter wavelength absorption band maxima (the ^{1}E component near 20000 cm^{-1}) with the acceptor numbers are smaller by about one half than those for *trans*(*N*)-[Co(ox)(gly)$_2$]$^-$ type complexes which are classified as the B group (**9**—**12**) as shown in Fig. 1 and Table 1. In other words, the former A group complexes show negligible solvent-dependence, whereas the latter B group complexes exhibit considerable solvatochromism. Such solvatochromic behavior of the ^{1}E component together with that for the ^{1}A$_2$ one is also substantiated by the ^{59}Co NMR shifts as in Table 1. The A group complexes give little dependence of the ^{59}Co NMR shifts on the acceptor numbers, whereas the ^{59}Co NMR shifts of the B group complexes are more dependent on the acceptor number. These ^{59}Co NMR shifts behave in a manner similar to the solvatochromism for the ^{1}E component and reflect the solvent change of both the tetragonal split components in the first band region more directly than the solvatochromism, since the ^{59}Co NMR shifts are related with the sum of the reciprocal of the transition energy of each split component in the ^{1}T$_1$←^{1}A$_1$ transition.[27] Such a remarkable difference in the solvatochromism can be accounted for by considering the AOM parametrization including the anisotropic π interaction between metal d orbitals and the ligating oxygen p_π orbitals perpendicular to the chelate planes rather than the isotropic one as in Fig. 2. The transition energies of the first ligand field band components for two groups of *trans*-[Co(N)$_2$(O)$_4$] type complexes with holohedrized tetragonal (D$_4$) symmetry are given in terms of the AOM parameters on the assumption of the orthoaxial coordination by taking account of only the anisotropic π metal–oxygen p_π interaction perpendicular to the chelate planes for the carboxylato groups as follows:

$$E(^1\mathrm{E}) = 3/2e_\sigma(\mathrm{N}) + 3/2e_\sigma(\mathrm{O}) + 4B \quad (1)$$

$$E(^1\mathrm{A}_2) = 3e_\sigma(\mathrm{O}) - 4e_\pi(\mathrm{O}) + 4B \quad (2)$$

for *trans*(*N*)-[Co(ida)$_2$]$^-$ type complexes of the A group. The same formulations of the transition energies are given for *trans*(*N*)-[Co(nta)(gly)]$^-$ type complexes assuming the identical topological arrangements of the ligating oxygen p_π orbitals of the carboxylato groups unless three kinds of the ligating oxygen atoms of the different carboxylato groups were discriminated.

$$E(^1\mathrm{E}) = 3/2e_\sigma(\mathrm{N}) + 3/4e_\sigma(\mathrm{O}) + 3/4e_\sigma(\mathrm{O}') - e_\pi(\mathrm{O}') + 4B \quad (3)$$

$$E(^1\mathrm{A}_2) = 3/2e_\sigma(\mathrm{O}) + 3/2e_\sigma(\mathrm{O}') - 2e_\pi(\mathrm{O}) + 4B \quad (4)$$

for *trans*-[Co(ox)(gly)$_2$]$^-$ type complexes of the B group

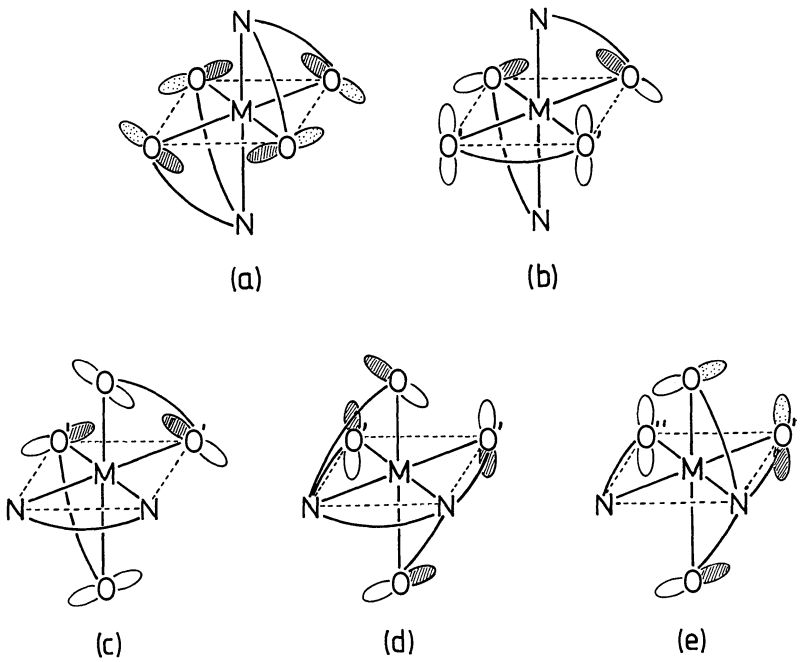

Fig. 2. Topological arrangements of the ligating oxygen p_π orbitals for which a pair of the shaded and/or dotted lobes at the octahedral edge is directed toward the solvents; implying the preferential (additional) solvation for the following types of complexes: (a) *trans*(*N*)-[M(ida)$_2$]; (b) *trans*(*N*)-[M(ox)(gly)$_2$]; (c) [M(ox)$_2$(en)]; (d) [M(edta)]; (e) *cis*(*N*)-[M(nta)(gly)].

where O and O′ denote the coordinated oxygen atoms of the amino acidato and oxalato ligands, respectively, as in Fig. 2(b). The last term B in Eqs. 1—4 is the Racah interelectronic repulsion parameter. It is plausible that this parameter is almost solvent independent as mentioned previously.[4]

Although the absorption bands and ^{59}Co NMR shifts of the A group complexes are little altered with variation of the solvents' acceptor numbers as in Fig. 1 and Table 1, ^{13}C NMR signals of the carboxylato carbons shift to the lower field with increasing the acceptor numbers; the slope of the plots with the acceptor numbers is +0.1. This suggests the solvation toward the ligating oxygens of the carboxylato groups as claimed from the ^{13}C NMR behavior of [Co(edta)]$^-$ by Taura,[28] leading to the change of the AOM parameter values in each energy term in Eqs. 1 and 2. It is likely that the highly preferential (additional) solvation occurs toward pairs of the ligating oxygen p_π orbitals coplanar with the $M(O)_4$ plane of the A group complexes as shown in Fig. 2(a). This may give the decrease in the AOM e_π(O) parameters. As a result, both the AOM e_π(O) and e_σ(O) values decrease with increasing the acceptor numbers. This variation in the AOM parameter values results in the negligible change of the $^1A_2$ transition energy; the term $3e_\sigma(O)-4e_\pi(O)$ keeping almost constant with change of the solvents as found for $3e_\sigma(F)-4e_\pi(F)$ of *trans*-[CrF_2(3.2.3-tet)]$^+$ complex.[4] On the other hand, the e_σ(N) value increases with increasing the acceptor numbers due to a cis electronic effect, followed by the decrease in the e_σ(O) or e_π(O) value as revealed for *trans*-[CrF_2(3.2.3-tet)]$^+$ complex.[4] The solvent dependent ^{13}C NMR shifts of the methyl carbons in *trans*(*N*)-[Co(mida)$_2$]$^-$ lend support to the solvent variation of the e_σ(N) values, since the slope (−0.025) of the plots of these shifts with the acceptor numbers is opposite to that (+0.1) of the carboxylato carbons. Thus, the ^{1}E transition energy is little affected by the solvents' acceptor properties owing to the cancellation between the e_σ(N) and e_σ(O) values within the energy terms, whereas the parallel change of the e_σ(O) and e_π(O) values gives a small alternation of the $^1A_2$ transition energy. This is the finding for the solvatochromism of the A group complexes (**1**—**8**), though the solvatochromism cannot clearly be seen for the latter $^1A_2$ component of most *trans*(*N*) type complexes, because this component is usually observed only as the shoulders or poorly defined band maxima at the longer wavelength side of the ^{1}E component.

For *trans*(*N*)-[Co(ox)(gly)$_2$]$^-$ (the B group), however, ^{13}C NMR chemical shifts of the carboxylato carbons for the glycinato ligands is more largely solvent dependent than that for the oxalato ones; the slopes of the plots for ^{13}C NMR shifts with the acceptor numbers of the solvents are +0.12 and +0.065 for the carboxylato carbons of the glycinato and oxalato ligands, respectively. This suggests the preferential (additional) solvation toward a pair of the p_π orbitals of the glycinato oxygens coplanar with the $M(O)_4$ plane in support of the proposed solvation mode for the A group complexes as shown in Fig. 2(b). In this case, the observed solvatochromism may be explained by grouping the AOM parameters into the braces in the following equations for the transition energies (Eqs. 3 and 4) of each component:

$$E(^1E) = 3/4e_\sigma(N) + 3/4\{e_\sigma(N) + e_\sigma(O)\} + 1/4\{3e_\sigma(O') - 4e_\pi(O')\} + 4B \quad (5)$$

$$E(^1A_2) = 3/2e_\sigma(O') + 1/2\{3e_\sigma(O) - 4e_\pi(O)\} + 4B \quad (6)$$

The terms $\{e_\sigma(N)+e_\sigma(O)\}$ and $\{3e_\sigma(O)-4e_\pi(O))\}$ and/or $\{(3e_\sigma(O')-4e_\pi(O')\}$ are almost solvent independent as revealed for the A group complexes, whereas the remaining e_σ(N) and e_σ(O) parameters may be more susceptible to the solvent dependence as revealed from the following consideration. The preferential solvation toward a pair of the p_π orbitals for two glycinato coordinated oxygens (O in Fig. 2(b)) causes shortening both the Cr–N and Cr–O′ bond or increasing both the e_σ(N) and e_σ(O′) values, followed by the lengthening of the Cr–O bonds or the decrease in the e_σ(O) or e_π(O) owing to a cis electronic effect or the electroneutrality principle. Accordingly, it is plausible that the band maxima of two components in the first band region shift to the higher frequency side with increasing the acceptor numbers. This indeed accounts for the fact that the solvatochromism for the B group complexes is significantly larger than that for the A group complexes.

For the corresponding Cr(III) complexes, the transition energies of two tetragonal split components in the $^4T_2 \leftarrow {}^4A_2$ transition are given by the same AOM parametrization as for the Co(III) complexes except for the use of the irreducible representation $^4B_2$ instead of the $^1A_2$ and the exclusion of the Racah parameter B. Therefore, it is expected that the solvatochromism for *trans*(*N*)-[Cr(mida)$_2$]$^-$, -[Cr(eida)$_2$]$^-$, and -[Cr(bida)$_2$]$^-$ complexes occurs as similarly to the corresponding cobalt(III) complexes. This is the finding as in Table 1.

***cis*-[M(N)$_2$(O)$_4$] Type Complexes.** On the basis of the AOM parametrization, the cis type complexes are also classified into three groups. That is, the C group is represented by [M(ox)$_2$(en)] type complexes (**13**—**16**) and the others D and E are the edta type (**17**—**33**) and the *cis*(*N*)-(nta)(gly) type complexes (**34**—**37**), respectively.

The transition energies of each tetragonal split component in the first ligand field transition of the C and D group complexes of Co(III) are given by the AOM parameters as follows:

$$E(^1A_2) = 3/2e_\sigma(N) + 3/2e_\sigma(O') - 2e_\pi(O') + 4B \quad (7)$$

$$E(^1E) = 3/4e_\sigma(N) + 3/4e_\sigma(O') + 3/2e_\sigma(O) - e_\pi(O) + 4B \quad (8)$$

for the C group complexes, and

$$E(^1A_2) = 3/2e_\sigma(N) + 3/2e_\sigma(O') + 4B \quad (9)$$

$$E(^1E) = 3/4e_\sigma(N) + 3/2e_\sigma(O) - e_\pi(O) + 3/4e_\sigma(O') - e_\pi(O') + 4B \quad (10)$$

for the D group complexes. For both cases, the O and O′ denote the carboxylato ligating oxygens cis and trans to the amine nitrogens, respectively, as shown in Fig. 2. The same situation of the AOM parameters is encountered with Cr(III) complexes where the Racah parameter is excluded. The absorption band maxima of both the Co(III) and Cr(III) complexes and ^{59}Co NMR chemical shifts of the Co(III) complexes are linearly correlated with the acceptor numbers as shown in Table 1.

For the C group complexes, the preferential solvation is expected to occur toward a pair of two oxygen p_π orbitals on the $M(N)_2(O)_2$ plane (Fig. 2(c)), as in the cases of the A and B group complexes. Then, the Co–N and Co–O bond distances become shorter or the $e_\sigma(N)$ and $e_\sigma(O)$ values increase, followed by the decrease in the $e_\sigma(O')$ and $e_\pi(O')$ values or the lengthening of the Co–O′ bonds. On the other hand, the transition energies in terms of the AOM parameters (Eqs. 7 and 8) are reformulated by grouping almost solvent-independent terms into the braces in Eqs. 11 and 12.

$$E(^1A_2) = 3/2e_\sigma(N) + 1/2\{3e_\sigma(O') - 4e_\pi(O')\} + 4B \quad (11)$$

$$E(^1E) = 3/4e_\sigma(N) + 3/4\{e_\sigma(O) + e_\sigma(O')\} + 1/4\{3e_\sigma(O) - 4e_\pi(O)\} + 4B \quad (12)$$

The first terms $3/2e_\sigma(N)$ and $3/4e_\sigma(N)$ for the $^1A_2$ and ^1E components are solvent dependent, respectively. Thus, the $e_\sigma(N)$ values or both the tetragonal split components are predicted to increase the transition energies or to shift to the higher frequency side with increasing the acceptor numbers. This predicted tendency is in accordance with the finding for the C group complexes (**13**—**16**) as in Fig. 1 and Table 1, although the observed band maxima correspond to the position of either one of the split components or the weighted average of two components.

For the D group complexes including the *sym-cis*-[M(edda)(ox)] type, each transition energy of two tetragonal components contains only almost solvent independent terms in the braces as in Eqs. 13 and 14.

$$E(^1A_2) = 3/2\{e_\sigma(N) + e_\sigma(O')\} + 4B \quad (13)$$

$$E(^1E) = 3/4\{e_\sigma(N) + e_\sigma(O)\} + 1/4\{3e_\sigma(O) - 4e_\pi(O)\} + 1/4\{3e_\sigma(O') - 4e_\pi(O')\} + 4B \quad (14)$$

In contrast with the C group complexes, there are two preferential solvation sites for the D group complexes as in Fig. 2(d). It is assumed that the extent of the bond length variation due to the solvation per one solvation site does not change so much on going from the C group complexes with one solvation site to the D group complexes with two solvation sites in view of the similarity of the slopes of the plots for the ^{13}C NMR shifts of the carboxylato carbons with the acceptor numbers; +0.083 for $[Co(edta)]^-$ [28] and +0.08 for $[Co(mal)_2(en)]^-$. This situation is analogous to the case for ruthenium(III) ammine complexes where the correlation of the donor solvent dependent solvatochromism with the numbers of the ammine protons has been claimed.[29] Thus, the increase in the $e_\sigma(N)$ value due to the solvation for the D group complexes may be about twice as large as that for the C group complexes and the decrease in the $e_\sigma(O')$ and $e_\sigma(O)$ values owing to the electroneutrality principle. As a result, $3/2\{e_\sigma(N)+e_\sigma(O')\}$ and $3/2\{e_\sigma(N)+e_\sigma(O)\}$ terms in Eqs. 13 and 14 are not necessarily solvent independent as for the A, B, and C group complexes, but are expected to change in a similar manner to the variation of the $e_\sigma(N)$ which increase with increasing the acceptor numbers. Since the other remaining terms are almost solvent independent, the transition energies of two components increase with increasing the acceptor numbers. This is the finding for the D group complexes (**17**—**33**) as in Fig. 1 and Table 1.

For the E type complexes exemplified by *cis*(*N*)-$[Co(nta)(gly)]^-$ with two solvation sites, three components in the holohedrized D_2 field of the $^1T_1 \leftarrow {}^1A_1$ transition are different in energy from each other. The following transition energies for *cis*(*N*)-$[Co(nta)(gly)]^-$ are given in terms of the AOM parameters.

$$E(^1A_2) = 3/4e_\sigma(N) + 3/2e_\sigma(O) + 3/4e_\sigma(O'') - e_\pi(O'') + 4B \quad (15)$$

$$E(^1B_1) = 3/4e_\sigma(N) + 3/2e_\sigma(O) + 3/4e_\sigma(O') - e_\pi(O') - 2e_\pi(O) + 4B \quad (16)$$

$$E(^1B_2) = 3/2e_\sigma(N) + 3/4e_\sigma(O') + 3/4e_\sigma(O'') + 4B \quad (17)$$

where O, O′, and O″ denote two equivalent in-plane carboxylato oxygens (O), one out-of-plane carboxylato oxygen (O′) of the nta, and glycinato oxygen (O″), respectively, as in Fig. 2(e). For *sym*- and *unsym*-$[Co(aeida)(ox)]^-$, the same expressions for the transition energies are given by disregarding the difference in the carboxylato oxygens in view of the identical topological arrangements of the ligating oxygen p_π orbitals in the carboxylato groups. By grouping $3e_\sigma(X)-4e_\pi(X)$ (X=O, O′, and O″) and comparing the increasing $e_\sigma(N)$ and $e_\sigma(O'')$ values with the decreasing $e_\lambda(X)$ values($\lambda=\sigma$ and π; X=O and O′) as a result of the preferential solvation toward the O and O′ ligating oxygens, three components for the E group complexes are expected to shift to the higher frequency side with increasing the acceptor numbers, assuming that $e_\sigma(N)$ and $e_\sigma(O'')$ variation due to the solvation is about twice as large as

the e_σ(O) and e_σ(O′) ones as in the case of the D group complexes with two solvation sites. This is the finding for the E group complexes (**34**—**37**) as in Table 1.

These elucidations of the solvatochromism seem to be in accordance with the difference in the observed solvent dependence of the absorption band maxima from complex to complex, depending on the topological arrangements of the ligating oxygen p_π orbitals perpendicular to the chelate plane. The slopes of the plots of the absorption band maxima with the solvents' acceptor numbers for the C and D group complexes with six-membered malonato or amino acidato chelates are larger than those with five-membered ones as shown in Table 1. This behavior may arise from the difference in the displacement from the regular octahedral vertices; i.e., the ligating oxygens of the six-membered chelate rings are in general located closer to the regular octahedral vertices (90°) than those of the five-membered ones. Such a displacement may result in the mismatch of the coordinated oxygen p_π orbitals with the donor sites of the solvents. This appears to be responsible for the difference in the extent of the solvent dependence between the complexes with five- and six-membered rings.

In the edta type complexes of the D group, the solvent dependence is larger by more than 30% for the chromium(III) complexes than for the cobalt(III) complexes with the identical ligands as shown in Table 1 (**17**—**31**). Thus, the ligand field for the chromium(III) complexes may be more susceptible with variation of solvents than that for the cobalt(III) complexes; suggesting the more ligand field variability or the higher electronegativity of the coordinated oxygen in the chromium(III) complexes than in the cobalt(III) complexes as claimed from a comparison of the solvatochromism for *trans*-[CrX_2(3.2.3-tet)]$^+$ complexes with various halide ligands.[4)]

(Received February 7, 1991)

A family of titanoxycarbene-metal carbonyl complexes of formula $Cp^*_2TiOC(=ML_n)CH_2CH_2$ (**3**), where $Cp^*=\eta^5$-C_5Me_5 and ML_n=$Cr(CO)_5$, $Mo(CO)_5$, $W(CO)_5$, $Mn_2(CO)_9$, and $Re_2(CO)_9$, has been prepared by the treatment of titanocene-ethylene complex **1** with metal carbonyls of group 6 and 7. Complex **3b** crystallizes in space group $P2/a$ (Z=8) with cell constants a=30.401(1), b=9.251(1), c=27.561(5) Å, β=105.73(1)°, and V=7460(2) Å^3 (data taken at −40 °C, 6715 reflections, R=0.069). Two independent molecules of **3b** in crystal make an enantiomorphic pair. A notable feature of the structure is the long distance of Ti–O bond coupled with the short distance of C(2)–O bond, which is characterized by a large contribution of zwitterionic canonical form **7**. Thermal decomposition of **3** affords ethylene and the corresponding metal carbonyls, indicating that the C(carbenic)–C(3) bond fission occurred selectively, which is rather unusual for conventional Fischer-type carbene complexes. Complexes **3** react rapidly with atmospheric pressure of carbon monoxide below −30 °C to produce cyclic acyltitanium complexes **12**. The reverse reactions occur even below −30 °C upon replacement of carbon monoxide by argon. Complex **3b** also reacts with *t*-butyl isocyanide with a cleavage of the Ti–O bond to give 1:2 adduct **17**, whose molecular structure has been elucidated by X-ray crystallography [$P2_1/n$ with cell constants a=14.964(2), b=26.207(4), c=14.719(3) Å, β=100.30(1)°, and V=5679(2) Å^3 (measured at −120 °C, 5311 reflections, R=0.068)], revealing that it has a novel zwitterionic structure possessing (η^2-imidoyl)titanium cation and anionic acyldirhenium carbonyl moieties linked by an ethylene bridge. The controlled experiments show that complex **16** in which acyl ligand is trans to the Re–Re bond is the precursor of complex **17**. Complex **18**, a tungsten analogue of **17**, has also been prepared. Reactions of **3b** and **3e** with acetylenes are also described.

Activation of carbon monoxide by coordination to transition metals has been actively investigated.[1] Fischer and his co-workers in their pioneering works accomplished synthesis of so-called Fischer-type carbene-metal complexes by the reaction of carbon monoxide coordinated to transition metals of group 6 and 7 with nucleophiles followed by alkylation.[2,3] Recently a new entry to a synthesis of Fischer-type carbene complexes has been developed, which is based on the reaction of early transition metal or actinoid metal complexes such as (1,3-diene)zirconocene, (η^2-aryne)zirconocene, (dinitrogen)zirconocene, and so on with a variety of metal carbonyls to form carbene-metal complexes.[4,5] We have found that titanocene-ethylene complex **1** reacts readily with metal carbonyl complexes of group 6 and 7 to afford new cyclic titanoxycarbene-metal carbonyl complexes and revealed their characteristic features in molecular structures and chemical properties.[6]

Results and Discussion

Preparation of Cyclic Titanoxycarbene-Metal Carbonyl Complexes 3. The reaction of titanocene-ethylene complex **1** with decacarbonyldirhenium (**2b**) in toluene-d_8 was monitored by ^{1}H NMR measurement. Above −30 °C, resonances due to complex **1** disappeared slowly and a new set of two triplets assignable to complex **3b** appeared reaching to 84% yield. Above −10 °C, however, amount of **3b** decreased gradually and ethylene was formed, which indicates that the product **3b** starts to decompose even at −10 °C. Therefore, a mixture of complexes **1** and **2b** in toluene was stirred at −20 °C for 48 h and then the reaction mixture was diluted with hexane to afford after cooling to −80 °C titanoxycarbene-dirhenium carbonyl complex **3b** as orange red prisms in 57% yield (Eq. 1). The isolated **3b** is relatively stable and decomposes at 95—99 °C. Similar reaction of **1** with decacarbonyldimanganese (**2a**) gave complex **3a** in 30% isolation yield. This approach can also be applied to the reaction of **1** with metal carbonyls of group 6 transition metals. Thus, complexes **3c** and **3e** were isolated as orange solids in 26% and 34% yields, respectively. The molybdenum derivative **3d** was also formed

	^{13}C	83.59 (124)	67.56 (127)	328.36	12.02 (127)	201.07[c] 205.2 (broad)

a) All spectra were recorded in toluene-d_8 at −30 °C using solvent absorptions at δ=2.31 (^{1}H) and δ=137.70 (^{13}C) as internal standards. b) Coupling constants are given in parentheses (Hz). c) $J_{C\text{-}W}$=125 Hz.

from **1** and $Mo(CO)_6$, but it was too unstable to be isolated in pure form and characterized based solely on NMR spectra. Similar tendency in stability has been observed for the carbene complexes of the type $(CO)_5M{=}C(OCH_3)R$ (M=Cr, Mo, W; R=CH_3 and C_6H_5).[3]

The structures of titanoxycarbene-metal carbonyl complexes **3a**—**e** were assigned based mainly on the elemental analyses and spectroscopic data. The NMR spectral data of complexes **3** are summarized in Table 1. The absorptions due to C(3) methylene protons (δ= 4.02—4.35) appear at a little lower field than those due to methylene protons α to the carbenic carbon of Fischer-type carbene complexes [e.g. δ=3.22 for $(CO)_5W{=}C(OCH_3)CH_2CH_3$].[7] $^{13}C\{^{1}H\}$ NMR spectra exhibited absorptions due to carbenic carbons in the range of 290—350 ppm which are comparable with the chemical shift values of carbenic carbons reported for Fischer-type carbene complexes.[8] The chemical shift values of C(4) methylene protons and ^{13}C resonances due to C(4) are also comparable with those of titanacyclopentanes.[9-11]

The trans structure of dinuclear metal carbonyl moieties in **3a** and **3b** were determined based on $^{13}C\{^{1}H\}$ NMR spectra, which exhibited three absorptions for **3a** and two for **3b** due to coordinated carbon monoxide. In the ordinary syntheses of Fischer-type carbene complexes of dinuclear group 7 metal carbonyls, nucleophiles are known to attack initially equatorial CO which has lower electron density than axial ones, while, in the present reaction, electrophilic titanium atom reacts with axial CO having a higher electron density. Moreover, in the trans complexes **3a** and **3b**, the steric interaction between CO on rhenium atom and Cp* ligands on titanium is minimized.

When NMR spectra of complexes **3a**—**c** and **3e** were monitored over a temperature range of 0—30 °C, quantitative formations of ethylene and the corresponding metal carbonyls were observed. The fate of titanocence moiety has not been revealed. Clear first-order disappearance of these complexes was observed. Plots of these observed first-order rate constants were made as shown in Fig. 1 for complex **3a**, which gave activated parameters summarized in Table 2. The results show that the complexes **3a** and **3b** derived from **1** and group 7 metal carbonyls are more stable than those obtained from group 6 transition metal carbonyls. The C(2)–C(3) bond of 1-oxa-5-titanacyclopentane moiety in complex **3** was selectively cleaved during the thermolysis. This corresponds to the reverse reaction of the formation of **3** [Eq. 1], where a concerted pericyclic $[2_s+2_s]$-type

3b	24.2	11.6	−21.1	223 (30°C)
3c	21.2	16.8	−8.2	73 (0°C)
3e	23.4	18.5	−8.2	64 (30°C)

reaction via a transition state **4** is proposed.[12] Such fission of C(carbenic)–C bond is rarely observed for conventional Fischer-type carbene complexes,[13] while this fission is rather common in the thermolysis of 5-membered titanacycles such as titanacyclopentane **5**[9-12] and 1-oxa-5-titanacyclopentane complexes **6**.[14] This shows that the complexes **3** have thermal behaviors characteristic of five-membered metallacycles, rather than those of Fischer-type carbene complexes.

Crystal Structure of Titanoxycarbene-Dirhenium Complex 3b. For further elucidation of the molecular structure of **3**, a single crystal X-ray diffraction study has been done for the most stable complex **3b**. Selected data on the molecular geometry are listed in Table 3. The molecular structure of **3b** with numbering scheme is shown in Fig. 2. Two molecules of **3b–I** and **3b–II** with

Table 3. Selected Bond Distances (Å) and Angles (Degree) of Complex **3b–I** and **3b–II**[a]

	3b–I	**3b–II**
	Bond distances	
Re1–Re2	3.057 (2)	3.054 (2)
Re1–C2	2.12 (3)	2.12 (2)
Ti–O	2.02 (2)	2.04 (2)
Ti–C4	2.25 (2)	2.26 (2)
O–C2	1.26 (3)	1.28 (3)
C2–C3	1.57 (4)	1.56 (4)
C3–C4	1.52 (4)	1.60 (3)
	Angles	
Re2–Re1–C2	176.7 (7)	176.5 (7)
O–Ti–C4	79.1 (9)	79.5 (8)
Ti–O–C2	121.6 (18)	120.4 (17)
Re1–C2–O	125.2 (22)	124.1 (21)

a) Two molecules **3b–I** and **3b–II** are crystallographically independent and make an enantiomorphic pair.

different conformations of the metallacyclic five-membered ring are crystallographically independent and make an enantiomorphic pair. A stereoview of crystal packing of **3b–I** and **3b–II** is shown in Fig. 3.

The Ti–C(4) bond distances, 2.25(2) Å for molecule **I** and 2.26(2) Å for molecule **II**, are normal as a single covalent Ti–C bond. The C(2)–O bond distances of 1.26(3) Å for molecule **I** and 1.28(3) Å for molecule **II** are considerably shorter than that of usual covalent C–O bond (1.43 Å), while Ti–O bond distances of 2.02(3) Å for **I** and 2.04(2) Å for **II** are much longer than those of

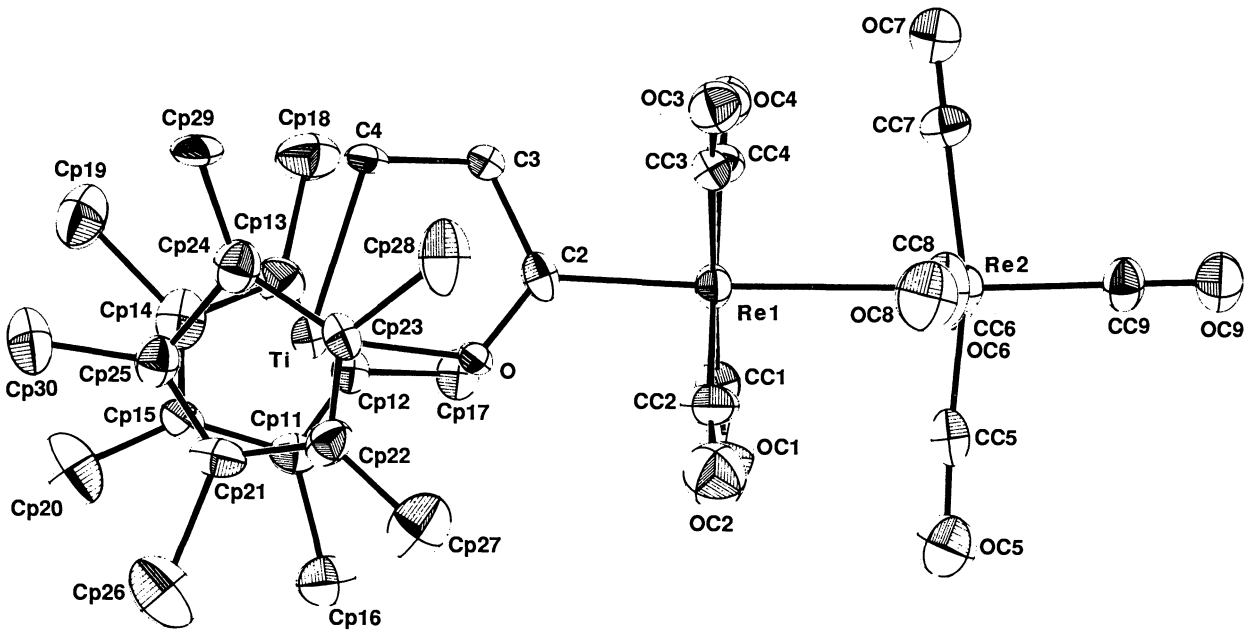

Fig. 2. ORTEP drawing of a molecule of complex **3b–I** showing the atom-labeling scheme. Ellipsoids represent 30% probability. Hydrogen atoms are omitted.

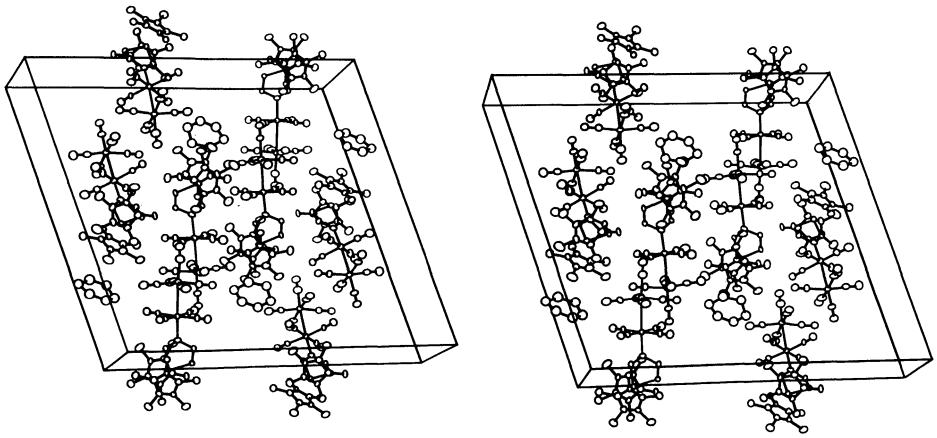

Fig. 3. Stereoview of crystal packing of complex **3b**. Two molecules are crystallographically independent and make an enantiomorphic pair. Methyl carbon of crystalline solvent toluene was not located.

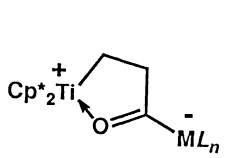
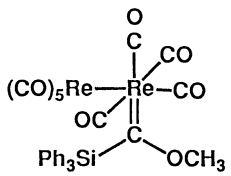
$Cp_2TiCl(OC_2H_5)$ [1.855(2) Å][15] and complex **6** [1.866 (3) Å].[14a] These results contrast with the fact that Ti–O bond of titanacyclopentanes such as **6** has a double bond character due to the considerable degree of donation from the pπ orbital of oxygen to the laterally-directed dπ acceptor orbital of titanocene. The C(2)–C(3) bond distances, 1.57(4) Å for **I** and 1.56(4) Å for **II**, are almost comparable with 1.493(11) Å reported for *cis*-$Mn(CO)_5$-$Re(CO)_4$=$C(OCH_3)CH_3$.[16] Thus, complex **3b** has a characteristic Fischer-type carbene structure[17] and there is an important contribution of a dipolar resonance structure **7**. Such contribution of dipolar resonance structures has been already pointed out for many zirconoxy-carbene complexes.[5]

Titanium atom in complex **3b** has a monomeric pseudo tetrahedral configuration defined by two η^5-C_5Me_5, methylene carbon, and an oxygen ligands. The angles C(4)–Ti–O, 79.1(9)° for molecule **I** and 79.5(8)° for molecule **II**, are comparable with that of **6** [80.9(2)°].[14a]

Angles of C(2)–Re(1)–Re(2) for **I** and **II** are 176.7(7)° and 176.5(7)°, respectively. The carbenic ligand is *trans* to Re–Re bond which contrasts with the complexes derived from $Re_2(CO)_{10}$ by conventional Fischer method where the carbene is *cis* to the Re–Re bond as is seen in complex **8**.[18] The Re(1)–C(2) bond distances of 2.12(3) and 2.12(2) Å for molecules **I** and **II**, respectively, are comparable with the reported values of 2.094(7) Å for *cis*-$Mn(CO)_5Re(CO)_4$=$C(OCH_3)CH_3$[16] and 2.09(2) Å for **8**,[18b] but longer than that of *trans* C(carbenic)–Re bond of 1.85(3) Å.[18b] Carbonyl groups on one rhenium atom occupy the staggered position relative to those on the another rhenium metal. Similar staggered geometry is commonly observed for the complexes such as $Re_2(CO)_{10}$[19] and $Re_2(CO)_9(CNCMe_3)$.[20] The Re–Re bond distances of 3.057(2) Å for **I** and 3.054(2) Å for **II** are comparable with those of carbene complexes such as **8** [3.052(1) Å] and *cis*-$Re(CO)_5Re(CO)_4$=$C(SiPh_3)(OEt)$ [3.050(3) Å],[18b] but are longer by 0.013—0.016 Å than that of $Re_2(CO)_{10}$ [3.041(1) Å].[19]



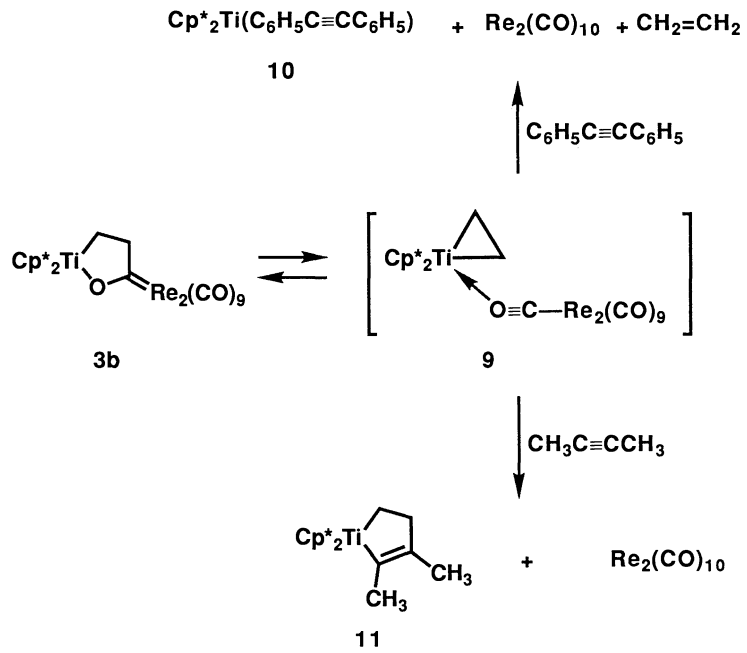
7



8

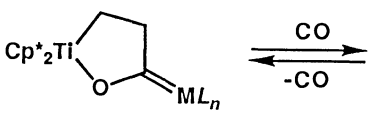
Reactions of 3b and 3e with Alkynes. Reaction of complex **3b** with diphenylacetylene was monitored by NMR spectroscopy. The addition of diphenylacetylene to a solution of **3b** in toluene-d_8 at room temperature induced rapid change in color from orange to deep red. ^1H and $^{13}C\{^1H\}$ NMR spectra indicated the formation of ethylene, $Re_2(CO)_{10}$ (**2b**), and titanocene–diphenylacetylene complex **10**[9b] (Scheme 1). Reaction of **3e** with diphenylacetylene afforded the same complex **10**, ethylene, and $W(CO)_6$. On the other hand, reaction of **3b** with 2-butyne afforded $Re_2(CO)_{10}$ and titanacyclopentene complex **11**.[9b] By contrast, reaction of **3e** with 2-butyne afforded no metallacyclic compounds, but ethylene, $W(CO)_6$, and unidentified titanocene species as detected by NMR. The complex **9** in which carbon monoxide of metal carbonyl coordinates to titanium may be an intermediate. In fact, similar complexes, $Cp^*_2Ti(CH_3)OCW(CO)_2Cp$,[21a] $Cp_2Ti(THF)OCMo(CO)_2Cp$,[21b] $Cp_2Zr(\eta^2\text{-}COCH_3)OCMo(CO)_2Cp$,[21c,21d] and $Cp^*_2Yb(THF)OCCo(CO)_3$[21e] have been prepared and characterized. No products arising from the reaction of carbene moiety and alkynes have been detected.

Reaction of 3 with Carbon Monoxide. Complex **3b**

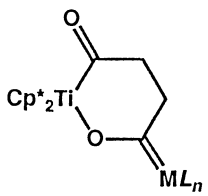


Scheme 1.

was allowed to react with atmospheric pressure of CO in a sealed NMR tube, and the reaction was monitored by ^{1}H NMR spectroscopy, showing that the carbonylation reaction was completed in a few minutes at −30 °C. Absorptions due to **3b** were rapidly replaced by those due to acyltitanium complex **12b**, which indicates that the yield is quantitative. On allowing the solution to warm up to room temperature, however, complex **12b** decomposed gradually to give ethylene, $Re_2(CO)_{10}$, and unidentified titanocene species, the same product obtained by the thermal reaction of **3b**. Interestingly when the CO was replaced by argon, complex **12b** liberated CO to give **3b**. Similar decarbonylation has been found in the reaction of dialkyl derivatives of zirconocene and hafnocene, but not reported for titanium analogues.[22] The carbonylations of other titanoxycarbene complexes **3a**, **3c**, and **3e** afforded the corresponding acyltitanium complexes **12a**, **12c**, and **12e** in quantitative yields, though they are too unstable to be isolated. These results contrast with the reported fact that 1-oxa-5-oxo-6-titanacyclohexanes, structurally related complexes to **12**, are thermally stable.[14a] For stabilization of cyclic η^1-acyltitanium(IV) complexes, π-donation from the p_π orbital of O(1) to the acceptor $1a_1$ orbital of titanocene is considered to be important. As can be easily deduced from the molecular structure of carbene complex **3** determined by X-ray analysis, such π-donation from O(1) will not be significant for complex **12** due to the presence of electron-accepting carbene moiety adjacent to the O(1) atom.



3



(2)

12a, $ML_n = Mn_2(CO)_9$
12b, $ML_n = Re_2(CO)_9$
12c, $ML_n = Cr(CO)_5$
12e, $ML_n = W(CO)_5$

The structures of **12a—e** were determined on the basis of spectral data. The ^{13}C NMR resonances due to acyl carbons were observed around 294 ppm (Table 4) which are comparable with those of η^1-acyltitanium complexes $Cp^*_2\overline{TiOCH(R)CH_2CH_2CO}$ (**13**).[14a] The IR spectrum of **12b** exhibited an absorption at 1600 cm^{-1} which is consistent with acyltitanium structure. When ^{13}C enriched CO was allowed to react with complexes **3b** and **3e**, the products exhibited signals with ^{13}C–^{13}C coupling constants of 9.2 and 7.3 Hz for $J_{CO\text{-}C(4)}$, respectively. These values contrast with those of acyl complexes such as **14** and **15** which showed coupling constants of 19 Hz[23] and 28 Hz,[24] respectively, and comparable with the values 4.9 Hz and 11.9 Hz for **13**[14a] and titanacyclopentanone, $Cp_2\overline{TiCMe=CMeCH_2C(=O)}$,[25] respectively.

Table 4. NMR Spectral Data of Carbonylated Complexes

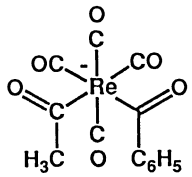
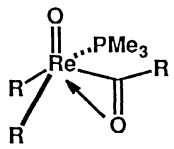
13



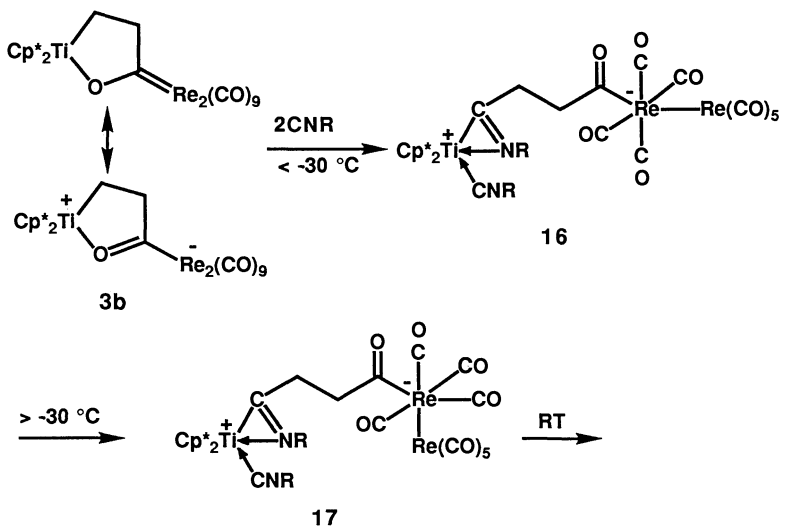
14



15 R = $CH_2Si(CH_3)_3$

Reaction of 3b and 3e with *t*-Butyl Isocyanide. Reaction of titanoxycarbene–dirhenium carbonyl complex **3b** with excess *t*-butyl isocyanide completed in 1 h at −15 °C in toluene to give a 1:1 mixture of **16** and **17** in 81% yield. Complex **17** crystallized as yellow plates at −20 °C. When the solution of **17** in toluene-d_8 was allowed to warm to 20 °C, the complex gradually decomposed and formations of ethylene, free *t*-butyl isocyanide, and unidentified species with titanocene moiety were detected by NMR spectroscopy. The first order disappearance of **17** was observed by ^{1}H NMR spectroscopy to give $\Delta G^{\neq}$ value at 30 °C of 25 kcal mol^{-1}.

The spectroscopic data of **17** are consistent with the structure assigned. ^{1}H NMR spectrum of **17** consists of two singlets at δ=1.50 and 1.80, indicating the presence of



$CH_2{=}CH_2$ + $Re_2(CO)_9L$

R = $C(CH_3)_3$
L = CO or $CNC(CH_3)_3$

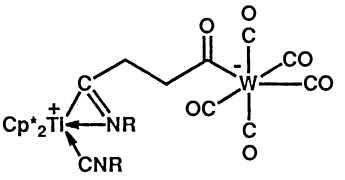
Scheme 2.

two magnetically nonequivalent *t*-butyl groups. Four kinds of carbon monoxide coordinated to rhenium were displayed by $^{13}C\{^1H\}$ NMR spectrum which supported the *cis* geometry between acyl group and dirhenium moiety. The low $\nu_{C=N}$ of 1586 cm^{-1} suggested the presence of iminoacyl moiety and the other $\nu_{C\equiv N}$ of 2162 cm^{-1} is due to an isocyanide coordinated to titanium. A weak absorption at 1650 cm^{-1} was tentatively assigned to acyl-rhenium moiety. The molecular geometry of **17** has been determined by a single-crystal X-ray analysis (vide infra).

When the above reaction was carried out at −55 °C for 4 h and then the liquid phase was decanted below −30 °C, another 1:2 complex **16** could be obtained as yellow crystals in 77% yield. ^1H NMR spectrum of the complex resembles with that of **17** which indicates that the complex is stereoisomer of **17**. $^{13}C\{^1H\}$ NMR spectrum is consistent with the structure **16** in which acyl ligand is trans to the Re–Re bond.

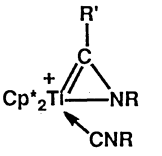
The compound **16** in THF-d_8 gradually isomerized to **17** even at −10 °C, as monitored by ^1H NMR spectroscopy. The half life of **17** in THF at 0 °C is 41 min. This indicates that the formation of *cis*-product **17** proceeds sequentially by way of the *trans*-isomer **16**. Although the driving force of the isomerization from **16** to **17** is not clear at present, *cis* structures are common to anionic acyl-$M(CO)_4M(CO)_5$ species (M=Mn and Re).[16]

Reaction of **3e** with *t*-butyl isocyanide gave the analogous tungsten derivative **18**, whose structural determination is based on spectroscopic data. Therefore, these reactions can be regarded as general for the cyclic titanoxycarbene–metal carbonyl complexes of type **3**. In spite of the strong oxophilic nature of the central titanium atom, dissociation of oxygen ligand from titanium occurred. This may be attributed to the important contribution from the dipolar resonance structure **7** in the starting complex **3**.



18 R = $C(CH_3)_3$

Molecular Structure of Zwitterionic Complex 17. In order to get more insights into the molecular structure of **17**, an X-ray crystal structure determination was performed. Figure 4 shows an ORTEP drawing of the molecule with the atom numbering scheme. Selected bond distances and angles are listed in Table 5. No unusually short intermolecular contacts are observed. The Ti–C(6) and Ti–N(2) bond distances are 2.14(3) and 2.17(2) Å, respectively. The bond distances 2.17(2) Å for Ti–C(1) and 1.14(3) Å for C(1)–N(1) in complex **17** are comparable with those of η^2-iminoacyl complexes of Y,[26] U,[27] Ti,[28-30] Zr,[30,31] and Mo.[32] Contribution from the carbene resonance form **19** can be considered to



19 R = $C(CH_3)_3$

be little, if any. Titanium atom has only three anionic ligands, but the coordination of an isocyanide on titanium brings about a closed 18-electron valence shell, and this might be the reason for the observed stability of **17**. Thus, intramolecular charge separation occurred upon reaction with isocyanides to afford a zwitterionic complex, where positive charge is on the titanium moiety, while negative charge is on the rhenium carbonyl residue. Such charge separation within a molecule has been reported recently.[13]

The acyl ligand in **17** is *cis* to Re–Re bond, which contrasts with the fact that in the starting complex **3b** the carbenic carbon is *trans* to Re–Re bond. The Re(1)–C(9)–O(1) bond angle of 127(2)° shows that the acyl ligand has η^1 coordination mode. To our knowledge, the present study provides the first structural data for anionic acyldirhenium carbonyl complex determined by a single-crystal X-ray analysis.

Conclusion

A direct synthesis of new Fischer-type carbene complexes has been developed by the reaction of titanocene–ethylene complex with various group 6 and 7 metal carbonyls and their molecular structures have been determined by spectroscopic techniques and X-ray crystallography. The structural characteristics of cyclic titanoxycarbene–metal carbonyl complexes **3** thus obtained have been shown to be reflected in their chemical properties. The modes of thermal reaction of **3** and of the reactions of **3** with CO are closely related to those of 1-oxa-5-titanacyclopentanes, though the carbonylation products **12** are much less stable than those derived from the latter complexes. Reactions of **3** with *t*-butyl isocyanide give rise to novel zwitterionic 1:2 adducts. These characteristic features of **3** could be attributed to an important contribution from the dipolar resonance structure **7**.

Experimental

General: All manipulations involving air- and moisture-sensitive organometallic compounds were carried out by the use of standard Schlenk techniques under argon atmosphere purified by passing through a hot column packed with BASF-Catalyst R3-11. All solvents were purified by distillation under argon after drying over calcium hydride or sodium benzophenone ketyl. All NMR spectra were recorded in toluene-d_8 at −30 °C using a Varian EM-390 (90 MHz) spectrometer or a JEOL GX400 (^{1}H, 400 MHz; ^{13}C, 100 MHz) spectrometer. Chemical shifts were determined using solvent absorption at δ=2.31 (^{1}H) and δ=137.70 (^{13}C) as internal standards. Other spectra were recorded by the use of the following instruments: IR, Hitachi 295; low and high resolution mass spectra, JEOL D300 (70 eV). Gas chromatographic (GLC) analyses were conducted on a Hitachi 263-30 equipped with a flame ionization detector. Elemental analyses were performed by the Wako Pure Chemical Ind. Ltd. All melting points were measured in sealed tubes and uncorrected. $Cp^*_2Ti(C_2H_4)$ was prepared according to the published procedure.[9a] The metal carbonyls **2a**—**e** were obtained from Strem Chem. Inc. *t*-Butyl isocyanide was obtained from Aldrich Chem. Co. 2-Butyne and diphenylacetylene were obtained from Tokyo Kasei Kogyo Co., Ltd. Carbon monoxide was obtained from Takachiho Chem. Ind. Co. ^{13}CO (99.3 atom %) was used as obtained from MDS Isotopes.

Titanoxycarbene-Dimanganese Complex 3a. To decacarbonyldimanganese (**2a**) (0.31 g, 0.80 mmol) and titanocene–ethylene complex **1** (0.28 g, 0.81 mmol) placed in a Schlenk tube at −50 °C was added toluene (25 mL) via a syringe. The mixture was stirred at −20 °C for a period of 120 h and the deep red solution was obtained. The liquid phase was separated from the residual manganese carbonyl, concentrated to 10 mL under reduced pressure at −30 °C, and to this hexane (15 mL) was layered. The solution was kept at −80 °C overnight to afford **3a** as orange red crystalline solid (0.18 g, 30% yield), mp 115—118 °C (decomp). ^{1}H and ^{13}C NMR data are listed in Table 1. IR (KBr) 2085 (vw), 2001 (sh), 1950 (vs), 1923 (vs) cm^{-1}. Mass spectrum (^{100}Mn^{48}Ti) *m*/*z* 391 (M^+ −345, base peak), 337 (M^+ −399), 318 (Cp^*_2Ti), 251 [$Mn_2(CO)_5$], 223 [$Mn_2(CO)_4$], 196 (M^+ −540), 167 [$Mn(CO)_4$]. Anal.Found: C, 52.06; H, 4.89%. Calcd for $C_{32}H_{34}O_{10}Mn_2Ti$: C, 52.20; H, 4.65%.

Titanoxycarbene-Dirhenium Complex 3b. To a solution of dirhenium decacarbonyl (**2b**) (0.52 g, 1.5 mmol) in toluene (10 mL) at −40 °C was added a solution of **1** (0.25 g, 0.38 mmol) in toluene (5 mL) via a syringe. The solution was stirred for 48 h at −20 °C until the color became deep red. The residual **2b** was separated by decantation, the solution was concentrated to 5 mL under reduced pressure in the temperature range of −30—−20 °C, and then hexane (15 mL) was layered. After

12 h at −80 °C, orange red crystals were isolated (0.41 g, 57% yield), mp 95—99 °C (decomp). IR (KBr) 2089 (w), 2011 (s), 1969 (vs), 1951 (vs), 1914 (vs) cm^{-1}. IR (toluene) 2091 (w), 2016 (m), 1985 (vs), 1951 (m), 1919 (m) cm^{-1}. Mass spectrum ($^{187}Re^{48}Ti$) m/z 654 [$Re_2(CO)_{10}$], 626 (M^+ −374), 596 [$Re_2(CO)_8$], 570 [$Re_2(CO)_7$, base peak], 542 [$Re_2(CO)_6$], 514 [$Re_2(CO)_5$], 337 (M^+ −663), 318 (Cp^*_2Ti), 299 [$Re(CO)_4$]. Anal. Found: C, 40.39; H, 3.74%. Calcd for $C_{32}H_{34}O_{10}Re_2Ti \cdot 1/2(C_7H_8)$: C, 40.80; H, 3.67%.

Titanoxycarbene–Chromium Complex 3c. To a solution of chromium hexacarbonyl (**2c**) (0.14 g, 0.64 mmol) in toluene (8 mL) cooled at −50 °C was added a solution of **1** (0.21 g, 0.61 mmol) in toluene (8 mL) via a syringe. After the mixture was stirred at −20 °C for a period of 120 h, the deep red solution was separated from the white solid of unreacted **2c**. Hexane (8 mL) was layered on the solution and the mixture was kept at −80 °C overnight to afford **3c** as deep red crystalline solid (0.09 g, 26% yield), mp 98—103 °C (decomp). IR (KBr) 2041 (vw), 1966 (sh), 1876 (vs) cm^{-1}. Mass spectrum ($^{52}Cr^{48}Ti$) m/z 337 (M^+ −229), 318 (Cp^*_2Ti), 220 [$Cr(CO)_6$, base peak]. Anal. Found: C, 59.76; H, 6.25%. Calcd for $C_{28}H_{34}O_3CrTi$: C, 59.37; H, 6.05%.

Titanoxycarbene–Molybdenum Complex 3d. To molybdenum hexacarbonyl (**2d**) (6.9 mg, 2.6×10^{-5} mol) and **1** (6.6 mg, 1.9×10^{-5} mol) placed in NMR tube (5ϕ) was added toluene-d_8 (0.5 mL) by trap-to-trap distillation and then the tube was sealed. ^1H and ^{13}C NMR data are summarized in Table 1, which showed the formation of titanoxycarbene–molybdenum complex **3d**. Attempted isolation of **3d** failed due to the thermal instability of the product even below −20 °C.

Titanoxycarbene–Tungsten Complex 3e. To a mixture of tungsten hexacarbonyl (**2e**) (0.31 g, 0.64 mmol) and complex **1** (0.22 g, 0.88 mmol) placed in a Schlenk tube was added toluene (15 mL) at −50 °C. The mixture was stirred at −20 °C for 90 h. To the deep red solution separated from the remaining white solid of tungsten hexacarbonyl was layered hexane (10 mL). The mixture was kept at −80 °C overnight and the product **3e** was obtained as deep orange crystalline solid (0.15 g, 34% yield), mp 106—110 °C (decomp). IR (KBr) 2051 (w), 1974 (m), 1904 (vs), 1887 (vs) cm^{-1}. IR (toluene) 2051 (vw), 1984 (vs), 1919 (s) cm^{-1}. Mass spectrum ($^{184}W^{48}Ti$) m/z 352 [$W(CO)_6$], 318 (Cp^*_2Ti), 296 [$W(CO)_4$], 268 [$W(CO)_3$, base peak], 240 [$W(CO)_2$], 212 [W(CO)]. Anal. Found: C, 47.84; H, 5.09%. Calcd for $C_{28}H_{34}O_6TiW$: C, 48.16; H, 4.91%.

Thermal Decomposition of Titanoxycarbene–Metal Complexes 3a—e. A solution of complex **3b** (10 mg) in toluene-d_8 (0.5 mL) was sealed in an NMR tube under argon. The disappearance of complex **3b** was measured at specified constant temperatures. The half lives (min) of **3a**, **3b**, **3c**, and **6e** in toluene-d_8 are 116 (30 °C), 223 (30 °C), 73 (0 °C), and 64 (30 °C), respectively. The thermodynamic parameters thus obtained are listed in Table 2.

Reaction of 3b or 3e with Diphenylacetylene. A solution of complex **3b** (15 mg, 1.5×10^{-2} mmol) and diphenylacetylene (2 equiv) in toluene-d_8 (0.5 mL) was placed in an NMR tube at room temperature. Color of the solution darkened. The formation of **10** was confirmed by the comparison of ^1H and ^{13}C NMR spectral data with those reported.[9b] Reaction of **3e** with diphenylacetylene in a similar manner gave the same complex **10** in quantitative yield.

Reaction of 3b or 3e with 2-Butyne. A solution of complex **3b** (10 mg, 1.0×10^{-5} mol) and 2-butyne (excess) in toluene-d_8 (0.5 mL) was placed in an NMR tube. Color of the solution gradually darkened. The formation of **11** was confirmed by the comparison of ^1H and ^{13}C NMR spectral data with the reported ones.[9b] Similar treatment of **3e** with excess 2-butyne did not give **11**, but afforded ethylene, tungsten hexacarbonyl (**2e**), and unidentified species containing titanocene residue.

Reaction of 3a—e with Carbon Monoxide. To complex **3b** (0.06 g, 0.06 mmol) placed in an NMR tube (10ϕ) was added toluene-d_8 (2.5 mL) by the trap-to-trap distillation technique. Atmospheric pressure of carbon monoxide was introduced into the tube and the tube was sealed. A yellow-green solution was obtained after a few min at −50 °C. ^1H and ^{13}C NMR data were taken which are listed in Table 4.

Reactions of **3a**, **3c**, and **3e** with carbon monoxide were carried out in similar manners as described above and the ^1H and ^{13}C NMR spectral data obtained are summarized in Table 4.

Reaction of 3b with *t*-Butyl Isocyanide. To a solution of **3b** (47 mg, 0.047 mmol) in toluene (12 mL) at −35 °C was added *t*-butyl isocyanide (0.05 μL, 0.44 mmol). The reaction mixture was slowly warmed up to −15 °C and then stirred at this temperature for 1 h in which pale yellow crystalline solid (43 mg, 81% yield) deposited. The product is a 1:1 mixture of **16** and **17**, from which **17** was separated by recrystallization of the product from toluene at −20 °C, mp 119—122 °C (decomp). ^1H NMR (22 °C, THF-d_8) δ=1.50 (s, CMe_3), 1.80 (s, CMe_3), 1.87 (s, $2C_5Me_5$), 3.29—3.33 (m) and 3.44—3.48 (m) [C(7)H_2 and C(8)H_2]. ^{13}C NMR (−30 °C, THF-d_8) δ=13.34 (J_{C-H} 125 Hz, C_5Me_5), 30.42 (129 Hz, CMe_3), 31.15 [127 Hz, C(7) or C(8)], 31.97 (127 Hz, CMe_3), 60.29 (CMe_3), 63.84 (CMe_3), 118.36 (C_5Me_5), 189.81, 195.76, 197.49, 200.22 (rel intensities 1.0:2.4:2.7:4.9, CO), 205.45 ($CNCMe_3$), 226.91 (C=N), 250.70 (C=O). When ^{13}C NMR was measured in CD_2Cl_2 (the absorption at δ=53.60 due to the solvent was used as internal standard), signals due to C(7) and C(8) were observed at δ=29.59 (J_{C-H} 127 Hz) and 66.16 (127 Hz). IR (KBr) 2162 (m, CN), 2084 (m), 2008 (s), 1973 (vs), 1955 (sh), 1932 (s), 1918 (s), 1876 (s) (CO), 1650 (m, acyl), 1586 (m, C=N) cm^{-1}. Anal. Found: C, 43.41; H, 4.78; N, 2.50%. Calcd for $C_{42}H_{52}N_2O_{10}Re_2Ti$: C, 43.29; H, 4.50; N, 2.40%.

Reaction of 3b with *t*-Butyl Isocyanide at Low Temperature. To a solution of **3b** (40 mg, 0.040 mmol) in toluene (8 mL) at −55 °C was added *t*-butyl isocyanide (0.05 μL, 0.44 mmol). The reaction mixture was stirred at this temperature for a period of 4 h. The pale yellow crystalline solid was isolated by decantation to give complex **16** (36 mg, 77% yield), mp 124—126 °C (decomp). NMR measurement at −50 °C showed that **16** was the only product. ^1H NMR (−50 °C, THF-d_8) δ=1.54 (s, CMe_3), 1.81 (s, CMe_3), 1.89 (s, $2C_5Me_5$), 3.45—3.49 (m) and 3.58—3.60 (m) [C(7)H_2 and C(8)H_2]. ^{13}C NMR (−50 °C, THF-d_8) δ=13.34 (J_{C-H} 127 Hz, C_5Me_5), 30.34 (129 Hz, CMe_3), 31.84 (129 Hz, CMe_3), 31.24 (127 Hz) and 72.49 (129 Hz) [C(7) and C(8)], 60.30 (CMe_3), 63.80 (CMe_3), 118.29 (C_5Me_5), 191.43, 203.21, 203.65 (rel intensity 1.0:7.8:5.6, CO), 205.52 ($CNCMe_3$), 226.89 (C=N), 235.60 (C=O). IR (KBr) 2162 (w) (CN), 2085 (m), 1960 (vs), 1935 (sh), 1883 (s) (CO), 1648 (w) (tentatively assigned to acyl), 1565 (vw) (C=N) cm^{-1}. Mass spectrum ($^{187}Re^{48}Ti$) m/z 1165 (M^+ −1), 1138 (M^+ −CO), 895 (M^+ −271), 707, 652, 624, 596, 570 (base peak), 135 (Cp*). Anal. Found: C, 43.28; H, 4.52; N, 2.23%. Calcd for $C_{42}H_{52}N_2O_{10}Re_2Ti$: C, 43.29; H, 4.50; N, 2.40%.

Reaction of Titanoxycarbene–Tungsten Complex with *t*-

Butyl Isocyanide. To a solution of **3e** (78.5 mg, 0.11 mmol) in toluene (10 mL) at −60 °C was added *t*-butyl isocyanide (0.05 mL, 0.44 mmol). The mixture was stirred at −50 °C for 1.5 h, and to this was added hexane (10 mL). The yellow precipitates formed were separated by filtration to give **18** (66.7 mg, 70% yield), mp 66—70 °C (decomp). ^{1}H NMR (−50 °C, THF-d_8) δ=1.52 (s, CMe_3), 1.81 (s, CMe_3), 1.87 (s, $2C_5Me_5$), 3.35—3.39 (m) and 3.45—3.48 (m) [C(7)H_2 and C(8)H_2]. ^{13}C NMR (−50 °C, THF-d_8) δ=12.00 ($J_{C\text{-}H}$=127 Hz, C_5Me_5), 12.05 (J=127 Hz, C_5Me_5), 28.05 [J=126 Hz, C(7) or C(8)], 29.46 (J=129 Hz, CMe_3), 30.53 (J=126 Hz, CMe_3), 58.21 (CMe_3), 62.00 (CMe_3), 68.41 [J=127 Hz, C(7) or C(8)], 116.30 ($2C_5Me_5$), 191.34 (CO, $J_{C\text{-}W}$=122 Hz), 202.95 (CO, $J_{C\text{-}W}$= 129 Hz), 207.90 ($CNCM_3$), 224.78 (C=N), 274.58 (C(9), $J_{C\text{-}W}$= 88 Hz). IR (KBr) 2162 (m) (NC), 2041 (m), 1986 (w), 1947 (w), 1894 (s), 1874 (sh) (CO), 1642 (w) (tentatively assigned to acyl), 1553 (w) (C=N) cm^{-1}. Anal. Found: C, 51.26; H, 5.69; N, 2.98%. Calcd for $C_{38}H_{52}N_2O_6TiW$: C, 52.79; H, 6.06; N, 3.24%.

X-Ray Structure Determination of 3b. Deep red crystals were grown from a saturated toluene–hexane solution of **3b** at −20 °C overnight. Crystals were placed in thin-walled glass capillaries under argon at −20 °C and then sealed. Preliminary measurements of several crystals yielded rough cell dimensions and peak profiles. A suitable crystal with dimensions 0.21×0.32×0.53 mm was finally mounted on Rigaku AFC-5 diffractometer at −40 °C and centered in the beam. Below this temperature the crystal cracked. Automatic peak search and indexing procedure yielded the primitive cell. The pertinent datails of data collection and the final cell dimensions, which were obtained from a least-squares refinement of 2θ values of 50 independent reflections in the range of $20°<2\theta<30°$, are given in Table 6.

The 6715 unique raw intensity data with $|F_o|>3\sigma(F_o)$ were corrected for absorption, Lorentz and polarization effects. Three standard reflections measured after every 50 reflections showed no systematic variation in intensity. In unit cell, two independent molecules of titanoxycarbene–dirhenium complex are involved and make an enantiomorphic pair. The location of four rhenium and two titanium atoms were determined by the direct method (MULTAN 78 program). A series of standard least-squares refinement and Fourier synthesis revealed the remaining carbon and oxygen atoms as anisotropic temperature factors. Aromatic carbons of the solvated toluene were located also by the following difference Fourier synthesis, but the methyl carbon of toluene was not located, which might be attributed to the disorder. Final difference Fourier synthesis did not locate all hydrogen atoms. Molecular and crystal structures of **3b** are shown in Figs. 2 and 3. Atomic coordinates have been deposited.[6a)]

X-Ray Structure Determination of 17. Pale yellow crystals were grown from the saturated toluene–hexane solution of **17** at 4 °C overnight. Selected crystals were mounted in thin-walled glass capillaries under argon at −40 °C, and a suitable crystal (0.10×0.15×0.45 mm) was selected as for **17**. Data were collected at −120 °C by using Rigaku AFC-5 diffractometer. The data collection procedure and the cell parameters, obtained from a least-squares refinement of 2θ values of 50 independent

reflections in the range of $20° < 2\theta < 30°$, are listed in Table 6.

The 4852 intensity data with $|F_o| > 3\sigma(F_o)$ were converted to the structure factor amplitudes by correction for absorption, Lorentz and polarization effects. No correction for systematic variation in intensity is necessary. The structure of **17** was solved by Patterson method to locate two rhenium atoms in unit cell. A series of standard least-squares refinement and Fourier synthesis revealed the remaining titanium, oxygen, nitrogen, and carbon atoms as anisotropic temperature factors. Aromatic carbons of the solvated toluene were also located by the following difference Fourier synthesis. Final difference Fourier synthesis did not locate any hydrogen atoms. Molecular structure of **17** is shown in Fig. 4. Atomic coordinates have been deposited.[6b]

Stability Constants of Imidazole- and Alkylimidazole-Copper(II) Complexes

Hiromu IMAI* and Hiroshi TAMURA
Faculty of Engineering, Kansai University, Yamate-cho, Suita 564
(Received February 28, 1991)

The stability constants of imidazole (HIm)- and alkylimidazoles-copper(II) acetate complexes were calculated from the potentiometric titration data with the aid of the SUPERQUAD computer program. The stability constants of ionic species of $[CuAL_r]^+$ type (A: CH_3COO, L: HIm **a**, 1-CH_3·Im **b**, 2-CH_3·HIm **c**, 4-CH_3·HIm **d**, 2-C_2H_5·HIm **e**, 2-$(CH_3)_2CH$·HIm **f**, r=1, 2, 3, and 4) detected from the complexes were ascertained to be decreased in the order of **b**(1-substituted)≥**d**(4-substituted)>**c**(2-substituted) relating to the position of methyl group bonded to the imidazole ring, and **c**(2-CH_3)>**e**(2-C_2H_5)>**f**(2-$(CH_3)_2CH$) relating to the kinds of alkyl group substituted on 2-position, respectively. The stability of these ionic species was discussed from the neutralization effect of the charge and the steric effect of alkyl group or acetate ion. The stability constants of the hydroxo species of $[CuL_2(OH)_2]$ type indicated the extremely small values, and its order did not indicate a similar tendency with those of ionic species of $[CuAL_r]^+$ types. The distribution of these complex species was investigated as a function of pH.

It has been well-known that the metalloproteins, such as plastocyanin,[1] azurin,[2] and hemocyanin[3] formed the active center by the coordination of Cu(II) to imidazole N of histidine residue, play an important roles, biologically. Since we were interested in the situation of coordination of such active center, imidazole-copper(II) acetate complex $[Cu(CH_3COO)_2(HIm)_2]$ (HIm; imidazole), which is similar to the structure of the active center in metalloprotains, was synthesized by the reaction of imidazole and copper(II) acetate monohydrate. It has been already reported by us that this compound is decomposed slowly by refluxing in ethanol.[4] On the other hand, the stability constants of the ionic species detected from imidazole- and alkylimidazoles-copper(II) acetate complexes ($[Cu(CH_3COO)_2L_r]$, L: HIm **a**, 1-CH_3·Im **b**, 2-CH_3·HIm **c**, 4-CH_3·HIm **d**, 2-C_2H_5·HIm **e**, 2-$(CH_3)_2CH$·HIm **f**, r=1 and 2) were determined by the potentiometric titration method.[5] The order of stability constants for the ionic species of $[Cu(CH_3COO)L]^+$ was favorably explicable from the relation of the steric hindrance between alkyl groups and acetate ion. However, that for the ionic species of $[Cu(CH_3COO)L_2]^+$ type could not be explained from the influence of steric hindrance. This cause is considered to be due to the calculation which neglected the presence of ionic species other than $[Cu(CH_3COO)L_r]^+$ (r=1 and 2) types.

To solve this question, the acetic acid solutions of imidazole- and alkylimidazoles-copper(II) acetate systems were potentiometrically titrated with sodium hydroxide, and the stability constants from the obtained data were calculated with the aid of the SUPERQUAD computer program.[6] The stability of ionic species detected was discussed from the influence of the kinds and the substituted position of alkyl group bonded to imidazole ring. Further, the distribution of these ionic species was investigated as the function of pH.

Experimental

Reagents. Imidazole (HIm) **a**, 2-methylimidazole (2-CH_3·HIm) **c**, 4-methylimidazole (4-CH_3·HIm) **d**, 2-ethylimidazole (2-C_2H_5·HIm) **e**, and 2-isopropylimidazole (2-$(CH_3)_2CH$·HIm) **f** of reagent grade were purchased from Kanto Chemical Co., Inc. and Tokyo Kasei, Co., Ltd., and used after recrystallization from benzene, respectively. 1-methylimidazole(1-CH_3·Im) **b** of reagent grade was purchased from Tokyo Kasei Kogyo Co., Ltd., and used after distillation under reduced pressure (51.5 °C/3 mmHg, 1 mmHg=133.322 Pa).

Copper(II) acetate monohydrate of special grade was purchased from Wako Pure Chemical Industries Ltd., and used without further purification. The stock solution of Cu(II) was standardized by the chelatometric titration with 0.01 M solution of EDTA (1 M=1 mol dm^{-3}).

The other reagents of special grade employed were purchased from Wako Pure Chemical Industries Ltd., and used without further recrystallization.

Preparation of Sample Solution. All the sample solution were prepared with distilled water decarbonated.

The sample solutions of 5.017×10^{-3} M acetic acid were prepared to measure the apparent activity coefficient of hydrogen ion (γ_H) and the ionic product of water (k_w).

The sample solution dissolved about 1×10^{-3} M of copper(II) acetate and $(4—12)\times10^{-3}$ M of imidazoles in about 5×10^{-3} M acetic acid were prepared to measure the stability constants of the complex species.

Potentiometric Titration. The sample solution of 50 ml was pipetted in the vessel of 100 ml, and titrated with sodium hydroxide standardized at about 0.1 M under a nitrogen atmosphere. The temperature was maintained at 25±0.1 °C, and the ionic strength was adjusted to 0.1 M with potassium nitrate. The combination glass electrode of Orion 81-20 was calibrated with pH 4.008 and 6.865 buffer solution at 25± 0.1 °C. All pH values were estimated with an Orion Research ion Analyser EA-920.

Calculation

The calculation of stability constants were performed by the use of a FACOM M-780/10 computer at Kansai University Information Processing Center.

(1) Apparent Activity Coefficient of Hydrogen Ion and Ionic Product of Water. On the bases of the procedure described in previous paper,[5,7] γ_H and K_w were calculated from pH value (α_H) obtained by the potentiometric acid-base titration. In this case, the 2.95×10^{-5} was used as the acid dissociation constant of acetic acid at 25 °C.[8]

$$\gamma_H = \alpha_H/[H] \qquad K_w = \alpha_H[OH] \tag{1}$$

(2) Stability Constants. The overall stability constants (β_{pqrs}) of complex species are represented as follows.

$$pCu + qA + rL + sH \rightleftharpoons Cu_pA_qL_rH_s$$

$$\beta_{pqrs} = \frac{[Cu_pA_qL_rH_s]}{[Cu]^p[A]^q[L]^r[H]^s} \tag{2}$$

Where, A and H denote acetate ion and hydrogen ion, and p, q, r, and s denote the numbers of Cu, A, L, and H, respectively. The coordinated water and the charge numbers of each ionic species were omitted to simplify the expression.

Hypothesizing the best model which is close to the equilibrum system in aqueous solution, the successive stability constants were calculated by the use of the SUPERQUAD computer program[6] inputted the titration data together with the values of γ_H, K_w, and K_L. (The acid dissociation constants of the protonated imidazoles cation, K_L, used the values reported in the previous paper.[5])

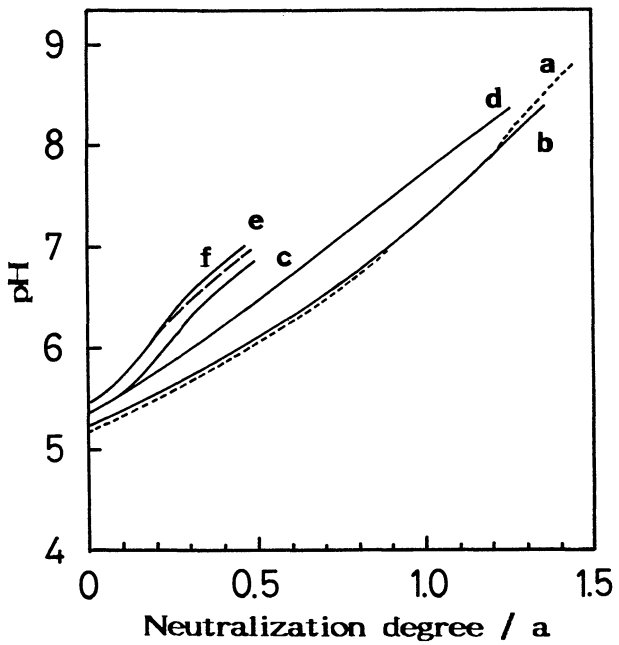

Fig. 1. Potentiometric titration curves of the $Cu(CH_3COO)_2$: L=1:4 system. L: HIm **a**, 1-CH_3·Im **b**, 2-CH_3·HIm **c**, 4-CH_3·HIm **d**, 2-C_2H_5·HIm **e**, 2-$(CH_3)_2CH$·HIm **f**. Concn of $Cu(CH_3COO)_2$: 9.546×10^{-4} M. Concn of L: $(3.820—4.004)\times10^{-3}$ M. Concn of CH_3COOH: 4.396×10^{-3} M. Concn of NaOH: 9.676×10^{-2} M.

Results

(1) Activity Coefficient of Hydrogen Ion and Ionic Product of Water. The average values of γ_H and K_w were 0.8073 (in the pH 3 to 5 region) and 1.334×10^{-14} (in the pH 10 to 12 region) in acetic acid solution, respectively. Hereinafter, the values of $[H^+]$ and $[OH^-]$ for some pH reading were calculated from Eq. 1 by the use of γ_H and K_w measured from the acetic acid solutions.

(2) Stability Constants. The representative titration curves shown in Fig. 1 were obtained from the solution of the 1:4 mole ratio of copper(II) acetate and imidazoles.

The titration was impossible to run because of the formation of copper(II) hydroxide at higher pH more than 8.5 for **a**, **b**, and **d**, and 6.5 for **c**, **e**, and **f**.

To calculate the stability constant of the complexes, the titration data obtained from the 1:4 mole ratio was inputted into the program together with those data obtained from the 1:8 and 1:12 mole ratios. In this case, the 2.10 was used as the stability constant (log K_{CuA}) of CuA^+.[5]

The stability constants shown in Table 1 are the average value obtained from the range of pH 5.0 to 8.5.

As the ionic species of $[CuAL_r]^+$ type, the four kinds corresponding to r=1, 2, 3, and 4 were detected from the complexes of **a**, **b**, and **d**, and the three kinds corresponding to r=1, 2, and 3, from the complexes of **c**, **e**, and **f**, respectively. From the results as mentioned above, the ionic species is conveniently classified into two groups such as Group(I) consisted of **a**, **b**, and **d**, and Group(2) consisted of **c**, **e**, and **f**.

The stability constants of the ionic species for r=1 were in good agreement with the values reported in the previous paper.[5] The stability constants of the other ionic species except for $[CuAL_4]^+$ of Group(1) indicated a slightly large value compared with those of the analogous species for Group(2).

On the other hand, the species of $[CuL_2H_s]^{(2+s)+}$ type

Table 1. Stability Constants of the Ionic Species Detected from $[Cu_pA_qL_rH_s]^{(2-q+s)+}$

L		Stability constant log β_{pqrs}				
		1110	1120	1130	1140[a)]	102—2
HIm	**a**	6.75 (0.06)	10.35 (0.07)	13.32 (0.06)	16.00 (0.08)	−7.83 (0.08)
1-CH_3·Im	**b**	6.48 (0.07)	10.03 (0.06)	12.92 (0.07)	15.65 (0.08)	−8.17 (0.09)
2-CH_3·HIm	**c**	6.31 (0.06)	9.71 (0.04)	12.83 (0.08)		−6.91 (0.12)
4-CH_3·HIm	**d**	6.44 (0.02)	9.91 (0.05)	12.89 (0.05)	15.27 (0.05)	−8.00 (0.06)
2-C_2H_5·HIm	**e**	6.15 (0.03)	9.30 (0.05)	12.18 (0.07)		−7.12 (0.10)
2-$(CH_3)_2CH$·HIm	**f**	5.73 (0.06)	8.62 (0.04)	11.35 (0.07)		−7.58 (0.11)

a) This ionic species seems to be the $[CuL_4]A^+$ type. The values in parenthesis are the standard deviations.

which indicated the value of s=−2, that is, hydroxo species which can be expressed by $[CuL_2(OH)_2]$ is considered to be formed by the hydrolysis of ionic species consisted of **a**—**f**. The stability constants were in the range of −6.9 to −8.2 as log β_{102-2}.

Discussion

(1) Stability of Ionic Species. 1) Influence of Acetate Ion. The stability constants for the ionic species of $[CuAL_r]^+$ type indicated the higher values in the range of 2—3 as log β_{11r0} than those of $[CuL_r]^{2+}$ (r=1, 2, 3, and 4) type reported by Nozaki et al.[9] and Sjöberg.[10] Therefore, the stability of ionic species for $[CuAL_r]^+$ type was found to be increased than those of $[CuL_r]^{2+}$ type because of the neutralization effect of charge by the coordination of acetate ion to copper(II).

2) Influence of Alkyl Groups. According to the X-ray crystal analysis of $[Cu(HIm)_4]^{2+}$, it has been reported that the imidazole ring is inclined at angle of 72.4° from the CuN_4 plane.[11] Then, the imidazole ring of ionic species consisted of the alkylimidazoles is presumed to be inclined at more than 72.4° because of the steric hindrance between alkyl group and acetate ion or between each alkyl group. Therefore, the stability constants of ionic species for the alkylimidazoles–copper(II) complexes shown in Table 1 indicated a slightly small value than those of ionic species for a imidazole–copper(II) complex.

The stability constants of these ionic species decreased in the order of **b**(1-substituted)≧**d**(4-substituted)>**c**(2-substituted) relating to the position of methyl group, and **c**(2-CH_3)>**e**(2-C_2H_5)>**f**(2-$(CH_3)_2CH$) relating to the kinds of alkyl group substituted at 2-position, respectively. The former is considered to be agreed with the order of the increase of steric hindrance. The latter is in agreement with the order of the polar substituent constant for the aliphatic series,[12] and is also considered to be agreed with the order of bulkiness for the alkyl groups.

The order of stability constants for the hydroxo species could not to be found the similar tendency with that for the ionic species. This reason is considered to be due to the different of the steric hindrance on hydroxide ion and acetate ion.

To investigate the stability of ionic species, we were discussed from the term of $\Delta\log K_r$ shown in Eq. 3.

$$\begin{aligned} \Delta\log K_r &= \Delta\log \beta_{11r0} - \log K_{CuA} \quad (r=1) \\ \Delta\log K_r &= \Delta\log \beta_{11r0} - \log K_{11(r-1)0} \quad (r=2, 3, \text{and } 4) \end{aligned} \tag{3}$$

These values are given in Table 2.

The $\Delta\log K_r$ of these ionic species for Group(1) indicated a slightly large value as compared with those of ionic species of the same type for Group(2). The magnitude of $\Delta\log K_r$ suggests the difficulty or facility of introduction of the rth ligand into the $[CuAL_{(r-1)}]^+$ species. The $\Delta\log K_r$ of each ionic species tend to decrease in the order of the r=1, 2, 3, and 4. Such result suggests that the introduction of ligand of rth into $[CuAL_{(r-1)}]^+$ species is made gradually difficult with the increase of numbers of r.

From the stability constants and the $\Delta\log K_r$, the stability of ionic species is summarized as follows.

(1) The ionic species consisted of **a** no having the substituent on the imidazole ring indicate the slightly high stability than those of **b**—**f**.

(2) As the ionic species consisted of **b**, **c**, and **d** do not suffer excessively the influence of steric hindrance on the position of methyl group bonded to the imidazole ring, the stability of these ionic species is similar to each other.

(3) The stability of the ionic species consisted of **c**, **e**, and **f** having the alkyl group on the 2-position of imidazole ring tends to decrease with the increase of bulkiness of the alkyl group.

(4) The ionic species consisted of **f** having the bulky alkyl group indicate the low stability than those consisted of **a**—**e**.

As mentioned above, the stability of imidazoles–copper(II) complexes is explained from the steric effect caused by the alkyl group.

(2) Distribution Curves of Complex Species. The distribution state of the ionic species and hydroxo species were investigated from the stability constants as a function of pH. These results are shown in Fig. 2.

The ionic species of $[CuAL_r]^+$ types were found to form in the order of r=1, 2, 3, and 4 with the increase of pH. The hydroxo species of $[CuL_2(OH)_2]$ type, which formed by the hydrolysis of these ionic species, was detected at pH more than 6.5, and its amounts increased rapidly with pH.

The distribution curves of these ionic species are classified into the two patterns of Group(1) and Group(2) as described already. On the basis of this classification,

Table 2. Values of $\Delta\log K_r$ for Each Ionic Species

r	Group (1)			Group (2)		
	HIm **a**	1-CH_3·Im **b**	4-CH_3·HIm **d**	2-CH_3·HIm **c**	2-C_2H_5·HIm **e**	2-$(CH_3)_2CH$·HIm **f**
1	4.65	4.38	4.34	4.21	4.05	3.63
2	3.60	3.55	3.74	3.40	3.15	2.89
3	2.97	2.89	2.98	3.12	2.88	2.73
4	2.68	2.73	2.38			

Table 3. The pH and the Percentage of Ionic Species at the Maximum Point of Distribution Curves

Ionic species	Group		Maximum point			
			r			
			1	2	3	4
$[CuAL_r]^+$	(1) **a**, **b**, **d**	pH	5.6—6.3	6.4—7.1	7.3—7.7	7.6—7.9
		%	42—50	42—47	32—36	8—22
	(2) **c**, **e**, **f**	pH	6.7—6.9	7.1—7.2	7.3—7.4	
		%	25—38	7—25	4—12	

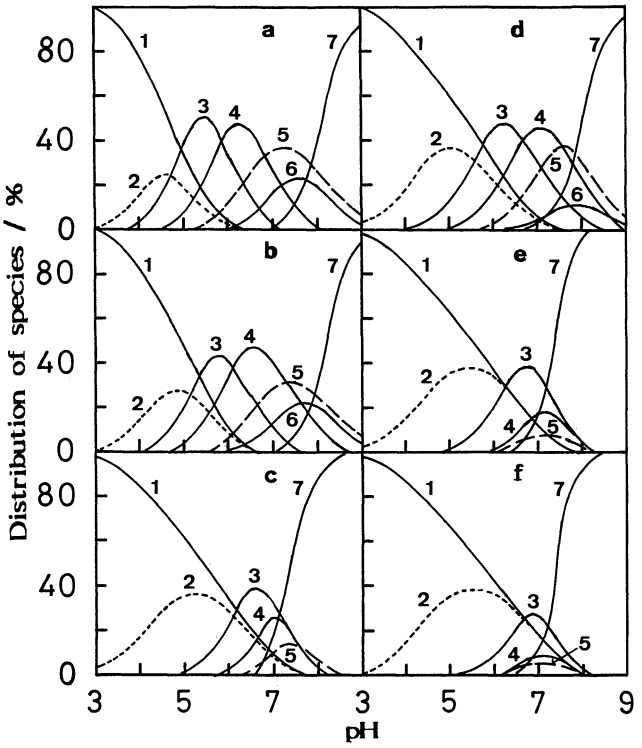

Fig. 2. Distribution curves of the $[CuA_qL_rH_s]^{(2-q+s)+}$ species obtained from the $Cu(CH_3COO)_2$:L=1:4 system. L: Same as Fig. 1. Concn of $Cu(CH_3COO)_2$, L and CH_3COOH: Same as Fig. 1. 1: $q=r=s=0$, 2: $q=1$ $r=s=0$, 3: $q=r=1$, $s=0$, 4: $q=1$ $r=2$ $s=0$, 5: $q=1$ $r=3$ $s=0$, 6: $q=1$ $r=4$ $s=0$, 7: $q=0$ $r=2$ $s=-2$.

the relationship between the pH and the percentage at the maximum point of each ionic species were summarized in Table 3.

The ionic species of $r=1$ and 2 detected from the complexes belong to Group(1), and $r=1$ detected from the complexes belong to Group(2) were ascertained to be preferentially formed in the acidic regions. Additionally, the ionic species of $[CuA]^+$ was present over a wide range of pH, and its maximum point of distribution was 24—35% at pH 4.7—5.6. On the other hand, the ionic species of $r=3$ and 4 detected from the complexes belong to Group(1), and $r=2$ and 3 detected from the complexes belong to Group(2) were ascertained mainly to be formed in the basic regions, respectively.

These ionic species were hydrolyzed with increase of pH, and were found to be changed to the hydroxo species of $[CuL_2(OH)_2]$ type.

Synthesis of Benzo[1,2:4,5]dicycloheptene-1,9-dione via 6,7,12,13-Tetrahydro-7,12-methano-3*H*-cycloheptacyclodecene-3,14-dione and Its Protonation Behavior

Masahiko KATO,* Masaru MITSUDA, Takuji SHIBUYA, and Kimiaki FURUICHI
Faculy of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received January 18, 1991)

6,7,12,13-Tetrahydro-7,12-methano-3*H*-cycloheptacyclodecene-3,14-dione has been synthesized starting from the [4+6]-cycloaddition product of the reaction of 3,4-bis(methylene)-7,7-dibromobicyclo-[4.1.0]heptane with tropone. The adducts were transformed to their epoxides, which were treated with trifluoroacetic acid to give the 3,14-dione. This was transformed to benzo[1,2:4,5]dicycloheptene-1,9-dione, bis(tropono)benzene, by two different methods: (1) by heating it with trichloroacetic acid and DDQ in toluene or (2) through bromination followed by heating in DMF. The 1,9-dione is protonated in concd sulfuric acid to give bis(hydroxytropylium) dication, while it is protonated mainly (>80%) on the C-9 carbonyl oxygen and less (<40%) on the C-1 carbonyl oxygen in deuteriochloroform containing trifluoroacetic acid.

In a previous paper,[1] we reported the scope and limitations for one pot synthesis of substituted tropones starting from 7,7-dihalo-2,3- (or 3,4-) epoxybicyclo-[4.1.0]heptane derivatives.

Using this procedure with the epoxides obtained from cycloaddition products of 3,4-bis(methylene)-7,7-dibromobicyclo[4.1.0]heptane (**1**)[1] with tropone, we obtained 6,7,12,13-tetrahydro-7,12-methano-3*H*-cycloheptacyclodecene-3,14-dione (**2**).

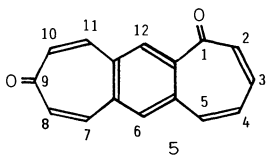
4

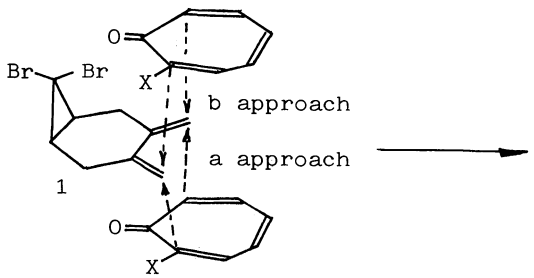


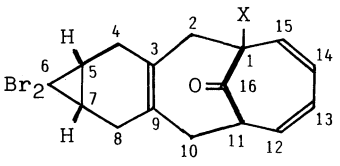
5

Fujise et al. observed the oxidative rearrangement of 5,6,12,13-tetrahydro-6,11-methanobenzocyclodecen-13-one (**3**) to 6*H*-cyclohepta[*b*]naphthalen-6-one (**4**) by heating with DDQ in DMF or with trityl tetrafluoroborate.[2] If this rearrangement is accomplished in dione **2**, we may obtain a new bis(tropono)benzene (**5**).

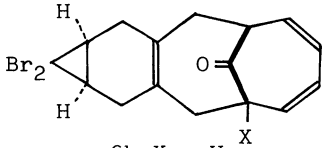
Results and Discussion

Synthesis of Benzo[1,2:4,5]dicycloheptene-1,9-dione (5). 6,7,12,13-Tetrahydro-7,12-methano-3*H*-cycloheptacyclodecene-3,14-dione (2). When 3,4-bis(methylene)-7,7-dibromobicyclo[4.1.0]heptane (**1**) was used as a diene in the [6+4] cycloaddition reaction with tropone in refluxing toluene, tetracyclic compounds **6a** and **6b** were obtained in a ratio of 3.8:1. This reaction proceeded more regioselectively in benzene solution in a sealed tube at 100 °C (yield, 90%; **6a**:**6b**=9:1). Because it is known that tropone adds anti to cyclopentadiene or furan in a sense of $[_6\pi_s+_4\pi_s]$cycloaddition preventing secondary orbital repulsion,[3,4] it seems reasonable to assume that the main product of the cycloaddition to **1** might be **6a**,





6a X = H
6c X = Cl

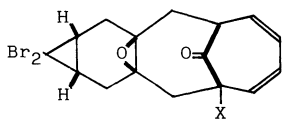


6b X = H

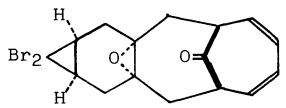
Scheme 1.

formed by the approach from the less hindered side (a) of **1**, and the minor product might be **6b**, formed by the attack from the more hindered side (b) of **1** (Scheme 1).

Though compound **1** did not react with 2-chlorotropone in refluxing toluene, they produced the [6+4] adduct **6c** in benzene solution in a sealed tube at 100 °C (yield 52%; solely *anti*).



7a X = H
7c X = Cl



7b

Epoxidation of a mixture of **6a** and **6b** with *m*-chloroperbenzoic acid (mCPBA) resulted in a mixture of **7a** and **7b** in the same ratio as that of the starting material. We have already seen that the epoxidation is usually prohibited or only proceeds with difficulty from the *syn*-face of the dibromomethylene bridge in the 3,4-annelated 7,7-dibromobicyclo[4.1.0]hept-3-ene moiety,[1,5] therefore, the major product is expected to be *anti*-7 (**7a**) and the minor one to be *syn*-7 (**7b**). Compound **6c** was also converted to an epoxide (**7c**) as a single product.

Treatment of the epoxides, **7a** or a mixture of **7a** and **7b**, with 20 equimolar amounts of trifluoroacetic acid (TFA) either in refluxing chloroform or preferably in toluene at 100 °C, gave tropone **2** in 41—55% yields.[6] On the other hand, when **7a** was treated with 4 equimolar amounts of trichloroacetic acid (TCA) in refluxing toluene for 4 h, it gave benzo[1,2:4,5]dicycloheptene-1,9-dione (**5**) in a 27% yield. As it is reasonable to assume that compound **5** might be formed via tropone **2**, this was treated with TCA in toluene at 100 °C in the presence or absence of 2,3-dichloro-4,5-dicyano-*p*-benzoquinone (DDQ) (Table 1). From Table 1, it is clear that the presence of DDQ did not much improve the yield of bistropone **5** and, on the other hand, in the presence of 1 or 2 equimolar amounts of TCA and DDQ, a new rearranged product, benzoheptalene derivative **8**, was isolated in a 10% yield in addition to **5**.

Structures of Tropones 2, 5, and 8. 6,7,12,13-Tetrahydro-7,12-methano-3*H*-cycloheptacyclodecene-3,14-dione (2). From ^{1}H and ^{13}C NMR spectra, it is clear that compound **2** has a plane of symmetry. Thus, it shows seven kinds of proton signals and nine kinds of carbon signals. The IR spectrum shows two strong absorptions at 1631 and 1595 cm^{-1} characteristic of tropone[7] in addition to a normal carbonyl absorption at 1703 cm^{-1}. These spectral data are compatible with structure **2** resulting from the normal ring opening of **7a** and **7b**.

Benzo[1,2:4,5]dicycloheptene-1,9-dione (5). In the ^{13}C NMR spectrum, two carbonyl carbon signals are seen at 187.9 and 187.2 ppm attributed to the tropone carbonyl,[8] in addition to twelve olefinic carbon signals in which four are assigned to quaternary carbons. Signals attributed to C_8/C_{10} or C_7/C_{11} are unresolved. In ^{1}H NMR spectra, all ten kinds of protons are detected, in which two singlets (8.75 and 7.94 ppm) are assigned to the aromatic protons on the benzene ring, and one in the lowest field is assigned to a proton on C_{12} as it is expected to be deshielded by the ortho carbonyl group. A series of signals, 6.99(bd), 7.13(ddd), 6.82(ddd), and 7.38 (bd) ppm are assigned to H_2, H_3, H_4, and H_5, respectively, and are coupled vicinally to each other with bond order alteration as shown by the coupling constants: $J_{2,3}$=12.2, $J_{3,4}$=7.8, $J_{4,5}$=11.6 Hz. Two pairs of signals coupled to each other (6.83(d), 7.63(d) and 6.86(dd), 7.52(d)) are assigned to H_8, H_7 and H_{10}, H_{11}. In the IR spectrum, two sets of characteristic tropone absorption are seen at 1634, 1610, 1594, and 1584 cm^{-1}.[7] In the mass spectrum, in addition to the molecular ion peak (m/z=234), peaks due to M^+—CO and M^+—2CO were observed, in which the latter constitutes the base peak. These spectral data support a structure in which the benzene ring is fused at its 1,2 and 4,5 positions with two tropone rings, one symmetrically (at the 4,5 position of the tropone ring) and the other unsymmetrically (at the 2,3 position) as in **5**.

6,12-Dihydrobenzo[*b*]heptalene-5,9-dione (8). In the ^{13}C NMR spectrum, in addition to two carbonyl carbon signals (204.0(ketone) and 186.2 ppm (tropone)), twelve aromatic and two aliphatic carbon signals were observed. In the ^{1}H NMR spectrum, characteristic AA'BB' proton signals for 4,5-annelated tropones were seen at δ=7.02 (1H, dd, J=12.7, 2.7 Hz), 7.05 (1H, dd, J=12.7, 2.7 Hz), and 7.21 (2H, bd, J=12.7 Hz). The

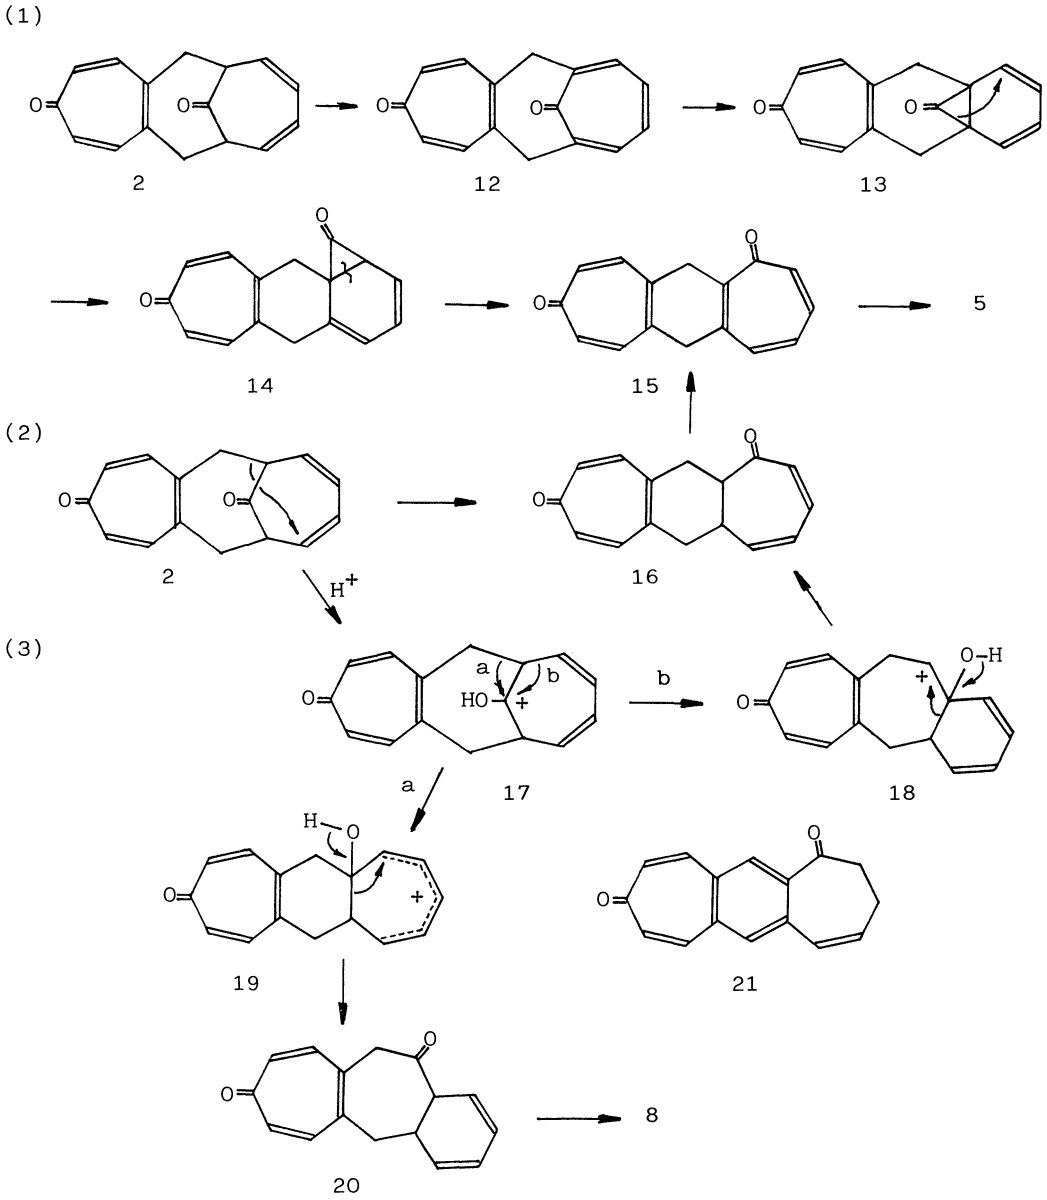
11

aromatic signals at 7.39, 7.65, 7.51, and 7.60 ppm in this order showed similar vicinal coupling constants, $J_{1,2}=J_{2,3}=J_{3,4}=7.8$ Hz, and meta coupling, $J_{1,3}=J_{2,4}=1.0—1.5$ Hz, which predicted a complete double bond delocalization. This supports the presence of an *o*-annelated benzene ring. Aliphatic proton signals were also seen as a broad singlet at 2.90—3.10 ppm (4H). Among four possible structures, (**8**)—(**11**), structure **8** may well predict the identical chemical shifts of H_7 and H_{11} (both are not adjacent to a carbonyl group or an aromatic ring), and the relatively low chemical shift of H_4.

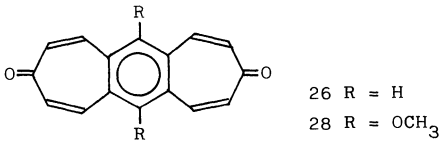
The Reaction Mechanism for Formation of 5. Formation of **5** (and **8**) from **2** may be explained by the three mechanisms shown in Scheme 2: (1) Initial dehydrogenation of **2** to bistropone (**12**), followed by a 6π-electrocyclic reaction to **13**, then a [1,5]sigmatropic

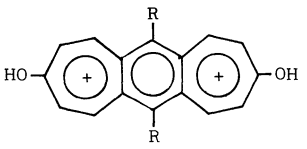


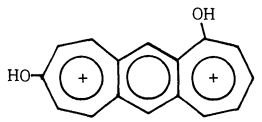
Scheme 2.

shift of the carbonyl carbon[2] results in a norcaradienone derivative (**14**), which undergoes 6π-retrocyclization to a 6,12-dihydro compound of **5** (**15**). (2) A thermal [1,5]-sigmatropic shift of **2** controlled by orbital symmetry gives a tetrahydro compound of **5** (**16**). Dehydrogenation of **16** may give **5** via **15**. (3) The protonated form (**17**) of **2** may undergo two successive 1,2-cationic rearrangements[9,10] to **16** via **18**. The last mechanism can only explain the formation of **8** through **19**. The NMR spectra of **2** in DMSO-d_6 revealed that compound **5** and its dihydro derivative (**21**) were formed at elevated temperatures (>155 °C), but these products were not detected below 145 °C.

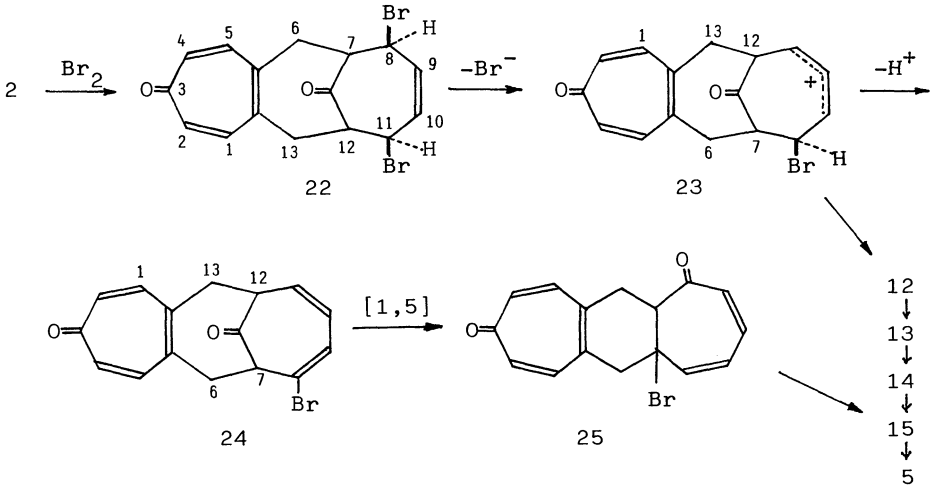
Another Route to 5 Starting from 2. Next, the bromination/dehydrobromination procedure of **2** was studied. We found that this procedure gave an improved yield (56%) of **5**. Thus, tropone **2** was treated with 1 equimolar amount of bromine to give a dibromide (**22**), which was transformed to **5** by heating at 100 °C in *N*,*N*-dimethylformamide (DMF). This reaction can be predicted by the following two mechanisms as shown in Scheme 3: (1) two successive dehydrobrominations of **22** may give bis(tropono)phane **12**, which follows the sequence (1) in Scheme 2 leading to **5**. (2) If deprotonation occurs on the brominated carbon of allylic cation **23** formed from **22** by Br^-- elimination in DMF, diene **24** may be formed. This can then undergo a [1,5]sigmatropic shift assisted by bromine to give **25**, which may be transformed to **5** via **15**. At present, it is left to be discovered which mechanism is involved.







Protonation of Benzo[1,2:4,5]dicycloheptene-1,9-dione (5). In 1969, Föhlisch et al. synthesized benzo-[1,2:4,5]dicycloheptene-3,9-dione (**26**) and suggested the formation of the corresponding bis(hydroxytropylium) dication (**27**) in concentrated sulfuric acid on the basis of a bathochromic shift (Δ+30 nm) of the absorption maximum compared with that in methanol (λ_{max} 296 nm).[11] We also compared the spectrum of the 6,12-dimethoxy derivative (**28**)[12] in ethanol (λ_{max} 313 nm) with the one in concd sulfuric acid (λ_{max} 347 nm) and found a similar bathochromic shift (Δ+34 nm), suggesting the formation of dication **29**. The same tendency (Δ+36 nm) was observed in the electronic spectra for **5** in ethanol (λ_{max} 284 nm) and in concd sulfuric acid (λ_{max} 320 nm). This fact supports the existence of dication (**30**) in concd



Scheme 3.

Table 2. ^{1}H NMR Chemical Shifts (δ in ppm) of Compounds **5** and **28** in the Presence or Absence of TFA[a]

Solvent	Compound **28**		Compound **5**							
	H_2, H_4, H_8, H_{10}	H_1, H_5, H_7, H_{11}	H_8 and H_{10}		H_7 and H_{11}		H_2	H_3	H_4	H_5
$CDCl_3$	6.92	8.08	6.83	6.86	7.52	7.63	6.99	7.13	6.82	7.38
$CDCl_3$ (TFA)	8.12	9.60	7.80	7.95	8.75	8.83	7.54	7.34	7.39	7.98
	−1.29	−1.52	−0.97	−1.09	−1.23	−1.20	−0.55	−0.21	−0.57	−0.60

a) 5 Drops of TFA and 1 drop of trifluoroacetic anhydride were added to a 5% solution of the sample in $CDCl_3$.

sulfuric acid.

Additionally, the ^{1}H NMR spectra of **5** and **28** in $CDCl_3$ in the presence of a large excess of TFA containing one drop of trifluoroacetic anhydride were examined. From Table 2, though the deshielding shifts of the signals due to protons H_7, H_8, H_{10}, and H_{11} of **5** are 80% of those due to the respective protons in **28**, signals due to protons H_2, H_3, H_4, and H_5 in **5** showed only a moderate deshielding shift, which means protonation occured mostly (>80%) on the C_9 carbonyl oxygen and less on the C_1 carbonyl oxygen (<40%) in **5** under the same conditions.

The reduction potential of **5** was examined by a cyclic voltammograph. An irreversible reduction curve was obtained. The reduction started at −1.03 V and the first peak was observed at −1.2 V, but the second peak varied considerably in the second and the later cycles. We have observed the corresponding peaks of the reduction wave for benzo- or naphtho-annelated tropones to range from −1.6 to −1.8 V.[13] Enhancement of the electron affinity of compound **5** is clearly recognized. The systematic study of the electron affinities of various troponobenzenes and bis(tropono)benzenes is now under investigation and will be reported in a separate paper.

Experimental

General Procedure. The NMR spectra were taken on JEOL Models GX400 (^{1}H; 400 MHz, ^{13}C; 100 MHz) and FX100 (1H; 100 MHz, ^{13}C; 25 MHz), or a Hitachi Model R90H (1H; 90 MHz) FT-NMR spectrometer. Deuteriochloroform was used as solvent in every case unless otherwise specified. The existence of spin–spin coupling was confirmed by double irradiation experiments. The IR spectra were recorded on a JASCO Model A-102 spectrometer and the UV spectra on a Hitachi Recording spectrometer Model 323. The reduction potential of **5** was recorded on a BAS voltammetry control unit Model CV-1B in acetonitrile containing tetrabutylammonium perchlorate (10^{-1} mol dm^{-3}) as the supporting electrolyte. Ferrocene was used as an internal standard (+0.40 V).

[4+6]Cycloaddition of Diene 1 to Tropone. Method A. A solution of diene **1** (550 mg, 2.0 mmol) and tropone (284 mg, 2.7 mmol) dissolved in toluene was refluxed for 17 h. The residue, obtained after evaporation of the solvent under reduced pressure, was purified by chromatography on silica gel to give products **6a** and **6b** (591 mg, 77%; 3.8:1). The main product **6a**; mp 166—168 °C. ^{1}H NMR (400 MHz): See Table 3. ^{13}C NMR (100 MHz) δ=26.2 (C5, C7), 28.7 and 34.7 (C2, C10 and C4, C8), 38.3 (C6), 55.1 (C1, C11), 127.4 (C3, C9), 125.2 and 127.6 (C12, C15 and C13, C14), 207.4 (C16). IR (nujol mull) ν_{max} 1695, 1680 cm^{-1}. Found: C, 50.01; H, 4.24%. Calcd for $C_{16}H_{16}OBr_2$: C, 50.03; H, 4.20%. Compound **6b** was not obtained in a pure state. The content of **6b** in a mixture was estimated by ^{1}H NMR spectra. **6b**: ^{1}H NMR (400 MHz): See Table 3. ^{13}C NMR (100 MHz) δ=26.1 (C_5, C_7), 29.1 and 34.4 (C_2, C_{10} and C_4, C_8), 36.7 (C_6), 55.7 (C_1, C_{11}), 127.4 (C_3, C_9), 124.9 and 126.7 (C_{12}, C_{15} and C_{13}, C_{14}), 207.4 (C_{16}).

Method B. A mixture of diene **1** (0.90 g, 3.24 mmol) and tropone (519 mg, 4.89 mmol) dissolved in benzene (2.7 mL) was sealed in a glass tube and heated at 100 °C for 16 h. The mixture was then concentrated in vacuo and chromatographed on silica gel to give a mixture of **6a** and **6b** (9:1)(1.13 g, 90%).

[6+4]Cycloaddition of 1 to 2-Chlorotropone. A mixture of diene **1** (992 mg, 3.57 mmol) and 2-chlorotropone (600 mg, 4.27 mmol) dissolved in benzene (6 mL) was heated in a sealed tube at 100 °C for 37 h. The usual workup as above gave

colorless crystals of **6c** (755 mg, 52%), mp 176—177.5 °C. ^{1}H NMR (400 MHz): See Table 4. ^{13}C NMR (100 MHz) δ=197.4 (s), 132.4 (d), 131.1 (s), 128.2 (d), 126.1 (s), 124.8 (d), 123.4 (d), 81.4 (s), 53.0 (d), 41.7 (t), 37.7 (s), 36.4 (t), 29.7 (t), 28.6 (t), 26.2 (d), 26.1 (d). IR (nujol mull) ν_{max} 1716, 1420, 1320, 1200, 1125, 1155 cm^{-1}. Found: C, 45.95; H, 3.59%. Calcd for $C_{16}H_{15}OBr_2Cl$: C, 45.91; H, 3.61%.

Epoxidation of Adduct 6. A solution of *m*-CPBA (779 mg, 4.51 mmol) in dichloromethane (11 mL) was added dropwise at −10 °C to a mixture (3:1) of adducts **6a** and **6b** (1.17 g, 3.05 mmol) dissolved in dichloromethane (10 mL) and stirred for 4 h below 0 °C. More dichloromethane was added in order to dissolve precipitated *m*-chlorobenzoic acid and the solution was washed successively with 10% aq sodium hydrogensulfite (twice), 5% aq sodium hydrogencarbonate (twice), and saturated brine, and then dried. After concentration, the residue was chromatographed on silica gel to give epoxides **7a** (715 mg, 59%) and **7b** (202 mg, 17%). **7a**: Mp 97.5—101 °C (CH_2Cl_2–hexane). ^{1}H NMR (400 MHz): See Table 3. ^{13}C NMR (100 MHz) δ=191.1 (s), 129.1 (d), 126.0 (d), 61.6 (s), 51.9 (d), 38.5 (s), 34.1 (t), 28.7 (t), 24.6 (d). IR ($CHCl_3$) ν_{max} 3000, 2910, 1700, 995, 840 cm^{-1}. Found: C, 48.03; H, 4.05%. Calcd for $C_{16}H_{16}O_2Br_2$: C, 48.03; H, 4.03%. **7b**: Mp 101—104 °C. ^{1}H NMR (400 MHz): See Table 3. IR ($CHCl_3$) ν_{max} 3000, 2930, 1700, 1080, 860 cm^{-1}. Found: C, 48.06; H, 4.05%. Calcd for $C_{16}H_{16}O_2Br_2$: C, 48.03; H, 4.03%.

Tropone 2 from Epoxide 7a. TFA (1.67 mL, 5 molar equiv) was added to a solution of **7a** (1.74 g, 4.34 mmol) in toluene (17 mL) and heated at 80 °C for 1.5 h. At this point, an additional TFA (6.69 mL, 20 molar equiv) was introduced and the mixture was refluxed for an additional 27 h. After cooling, it was diluted with chloroform and washed successively with water, 5% aq sodium hydrogencarbonate, and saturated brine, and then dried. After concentration to dryness, the residue was triturated with ethyl acetate to give pale yellow crystals (509 mg) of **2**. The filtrate of the crystals gave a 2nd crop (58 mg) of **2** after chromatographic separation (total yield, 55%). **2**: Mp 226—231 °C (CH_2Cl_2–AcOEt). ^{1}H NMR (400 MHz) δ=3.00 (2H, dd, J=14.4, 7.2 Hz; H_6, H_{13}), 3.14 (2H, dd, J=14.4, 4.2 Hz; $H_{6'}$, $H_{13'}$), 3.68 (2H, m; H_7, H_{12}), 5.57 (2H, m; H_8, H_{11}), 5.78 (2H, m; H_9, H_{10}), 6.89 (2H, dm, J=12.5 Hz; H_2, H_4), 6.98 (2H, dm, J=12.5 Hz; H_5, H_1). ^{13}C NMR (100 MHz) δ=205.8 (s), 186.3 (s), 145.1 (s), 141.3 (d), 139.6 (d), 126.6 (d), 125.5 (d), 56.0 (d), 39.7 (t). IR ($CHCl_3$) ν_{max} 1703, 1631, 1595 cm^{-1}. Found: C, 80.48; H, 5.90%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%.

Direct Formation of Bis(tropono)benzene 5 from Tropone 2 (Table 1; Entry 3). DDQ (294 mg, 1.27 mmol) in toluene (7.5 mL) was added to a solution of tropone **2** (150 mg, 0.630 mmol) and TCA (208 mg, 1.27 mmol) in toluene (2.5 mL) and the resulting solution was stirred for 30 h at 100 °C. After cooling, the mixture was diluted with chloroform and then washed successively with water, 5% aq sodium hydrogencarbonate, and saturated brine, and then dried. After concentration, the residue was separated by chromatography to give **5** (27.5 mg, 19%) and **8** (15.5 mg, 10%). The procedures for other entries in Table 1 are similar to this one. **5**: Mp 206.5—209.0 °C. ^{1}H NMR (400 MHz) δ=6.82 (1H, ddd, J=11.6, 7.8, 1.0 Hz; H_4), 6.83 (1H, d, J=12.7 Hz) and 6.86 (1H, dd, J=12.9, 2.6 Hz)(H_8, H_{10}), 6.99 (1H, d, J=12.2 Hz; H_2), 7.13 (1H, ddd, J=12.2, 7.8 Hz; H_3), 7.38 (1H, bd, J=11.6 Hz; H_5), 7.52 (1H, d, J=12.9 Hz) and 7.63 (1H, d, J=12.7 Hz)(H_7, H_{11}), 7.94 (1H, s; H_6), 8.75 (1H, s; H_{12}). ^{13}C NMR (100 MHz) δ=187.9 (s), 187.2 (s), 140.7 (d), 139.6 (d), 139.5 (d), 138.8 (s), 138.2 (d), 138.0 (s), 137.6 (s), 136.8 (d), 136.7 (d), 136.5 (s), 135.8 (d), 135.7 (d), 128.6 (d, 2C). IR ($CHCl_3$) ν_{max} 3040, 1634, 1610, 1594, 1584, 1338 cm^{-1}. MS m/z (%) 234 (47, M^+), 206 (15, M^+−CO), 178 (100, M^+−2CO), 152 (10). UV λ_{max} (log ε) 237 (4.31), 284 (4.68), 351 (4.07). **8**: ^{1}H NMR (400 MHz); see in the text. ^{13}C NMR (100 MHz) δ=204.1, 186.2, 145.6, 143.5, 141.6, 140.5, 140.1, 139.8, 139.4, 138.6, 132.2, 129.4, 129.2, 127.9, 47.2, 33.9. IR ($CHCl_3$) ν_{max} 1680, 1624, 1594, 1570, 900 cm^{-1}.

Bis(tropono)benzene 5 from Epoxide 7a. A solution of **7a** (143 mg, 0.356 mmol) and TCA (140 mg, 0.51 mmol) in toluene (5.0 mL) was refluxed for 28 h. After cooling, the mixture was diluted with chloroform and washed successively with water, 5% aq sodium hydrogencarbonate, and saturated brine, and then dried. After concentration, the residue was chromatographed on silica gel to give **5** (27.4 mg, 27%).

Bis(tropono)benzene 5 from 2 via Bromination and Dehydrobromination. Bromination of 2. A solution of bromine (0.77 molar solution, 8.6 mL) in chloroform was added dropwise to a solution of **2** (158 mg, 0.66 mmol) in chloroform (6.0 mL) on ice in a period of 20 min. Stirring was continued for 30 min at the same temperature and the precipitates formed (**22**; 134 mg, 77%) were collected by filtration. This compound was used directly without further purification. The symmetrical nature of the ^{1}H NMR spectrum suggests that two bromine atoms add to **2** symmetrically from less-hindered *exo*-directions. **22**: ^{1}H NMR (90 MHz, DMSO-d_6 δ=2.8—3.1 (4H, m; $2H_6$, $2H_{13}$), 3.21—3.5 (2H, m; H_7, H_{12}), 5.0 (2H, bs; H_8, H_{11}), 6.1 (2H, bs; H_9, H_{10}), 6.7 (2H, d, J=12.0 Hz; H_2, H_4), 7.13 (2H, d, J=12.0 Hz; H_1, H_5). IR (nujol mull) ν_{max} 1710, 1600 cm^{-1}.

Bis(tropono)benzene 5 from Dibromide 22. A solution of dibromide **22** (151 mg, 0.38 mmol) in DMF (7.5 mL) was heated at 100 °C for 3 h with stirring. After cooling, the

solvent was evaporated under aspirator vacuum and the residue was purified with silica-gel chromatography to give **5** (65 mg, 73%).

Thermal Rearrangement of Epoxide 2 to Bis(tropono)benzene 5 via 6,12-Dihydro Compound of 5 (15). A 10% solution of **2** in DMSO-d_6 was heated to the appropriate temperature and the reaction was monitored by ^{1}H NMR measurement (90 MHz). Below 145 °C for 2 h, no change in the ^{1}H NMR spectrum of the starting material was observed. However, after 2 h at 155 °C, compound **2** was transformed to a product believed to be **21** in a 40% yield. This was isolated using chromatography and its NMR spectrum was taken. ^{1}H NMR (400 MHz) of the product, δ=2.56—2.64 ($2H_3$, m), 2.99—3.31 ($2H_2$, m), 6.35 (H_4, dt, J=11.8, 5.5 Hz), 6.58 (H_5, d, J=11.8 Hz), 6.78 (H_8 or H_{10}, dd, J=12.3, 2.6 Hz), 6.83 (H_{10} or H_8, dd, J=12.3, 2.6 Hz), 7.36 (H_{11} or H_7, d, J=12.3 Hz), 7.49 (H_7 or H_{11}, d, J=12.3 Hz), 7.54 (H_6, s), 8.18 (H_{12}, s). This compound does not seem to be the primary product resulting from a simple [1,5]shift but the product formed by dehydrogenation and migration of double bonds. It was observed that compound **2** was partially transformed to **5** concomitant with some decomposition by heating at 170 °C for 2 h.

This work was supported by the Grant-in-Aid for Scientific Reserch on Priority Areas No. 02230225 from the Ministry of Education, Science and Culture.

The authors wish to thank Mr. Jun-ichi Goda and Mr. Tetsuya Shimada of our University for the elementary analyses and measurements of mass spectra.

(Received February 15, 1991)

1,1′-(1,32-Dotriacontanediyl)bis[2-[(3*RS*,7*R*,11*R*)-3,7,11,15-tetramethylhexadecyl]-*sn*-glycero-3-phosphocholine] (the tetramethylhexadecyl group=phytanyl) was synthesized conveniently by reactions involving etherification of 1,1′-(1,32-dotriacontanediyl)bis(3-benzyl-*sn*-glycerol) (**1**) with (7*R*,11*R*)-3,7,11,15-tetramethyl-2-hexadecenyl bromide and hydrogenation of the resulting unsaturated ether with *p*-tolylsulfonylhydrazine; a total yield from **1**, 7—10%. Unlike usual monopolar double-chain-amphiphiles, the bipolar lipid bent into a U-form in a water–air interface to produce the Langmuir membrane, exhibiting peculiar surface pressure–surface area isotherms.

Previously we mentioned the highly thermostable liposomes made of 1,1′-(1,32-dotriacontanediyl)bis[2-[(3*RS*,7*R*,11*R*)-3,7,11,15-tetramethylhexadecyl]-*sn*-glycero-3-phosphocholine] (the tetramethylhexadecyl group=phytanyl) (**L-32-Phy**).[1] The membrane, despite its low gel-to-liquid crystalline phase temperature (T_m; 8 °C), could retain well not only small molecules such as 5-(and 6-)-carboxyfluorescein (MW 376) but also large phospholipase A_2 (MW 14000) at high temperature as 80 °C. The bipolar lipid, however, was obtained via a multistage synthetic pathway in a total yield of 3—8%. In this paper we wish to describe an improved preparation of **L-32-Phy** and surface pressure–surface area isotherms of the amphiphile in an interface between water and air.

Experimental

1,2-Distearyl-*sn*-glycero-3-phosphocholine (DSPC) was prepared previously[2]; cf., the "stearyl" means "octadecyl". Thin-layer, column and gel permeation chromatographies were performed using the supports mentioned previously.[1] Compound spots in TLC were visualized by spraying with 0.0012% Rhodamine 6G and the Dittmer–Lester reagent.[3] IR spectra were measured by the use of a JASCO A-100 spectrometer. ^{1}H NMR spectra were recorded on JEOL PS-100 and GX-400 spectrometers using a dilute solution in $CDCl_3$ and tetramethylsilane as an internal standard. Fast atom bombardment mass spectra (FABMS) were obtained using a JEOL HX-100, whereby a sample in a matrix was subjected to a beam of xenon atoms produced at 8 kV and 2 mA. Optical rotation was determined by means of a JASCO DIP-360 digital polarimeter. A microprocessor-controlled film balance, Sun-etsu FDS-20, was utilized for the monolayer study.

(7*R*,11*R*)-3,7,11,15-Tetramethyl-2-hexadecenyl bromide (2). Phosphorus tribromide (1.35 g) in anhydrous hexane (2 ml) was added dropwise to the solution of isophytol (2.97 g, 0.01 mol), pyridine (0.4 ml) and hexane (6 ml), which was stirred and cooled to −7—−10 °C. After addition, the mixture was stirred at the temperature for 3 h, then poured into ice-water and extracted with diethyl ether. The organic extract was washed with 1 M hydrochloric acid (1 M=1 mol dm^{-3}), then with aqueous sodium hydrogencarbonate and dried by anhydrous magnesium sulfate. Upon removal of the solvent, the bromide (**2**) was obtained as oil, 3.56 g (99%); mobility (R_f) in TLC (hexane) 0.6; IR (neat) 2960 (s), 1655 (w), 1465 (s), 1380 (m), and 1200 (m) cm^{-1}; ^{1}H NMR (100 MHz) δ=0.87 (d, 12H, *J*= 7 Hz, 4CH_3), 1.25 (m, 19H, CH and CH_2), 1.70 (d, 3H, *J*= 1 Hz, *trans*-CH_3), 2.00 [t, 2H, *J*= 7 Hz, $C\underline{H}_2(CH_3)CH{=}CH$], 4.05 (d, 2H, *J*= 8 Hz, CH_2Br), and 5.56 (t, 1H, *J*= 8 Hz, $C{=}C\underline{H}CH_2Br$). Although the ^{1}H NMR spectrum showed also the minor signals attributable to impurities, the bromide was used for the next reaction without further purification since it changed to unknown(s) when distillation was attempted under reduced pressure (bp about 145—155 °C/3 mmHg, 1 mmHg= 133.322 Pa).

1,1′-(1,32-Dotriacontanediyl)bis[2-[(7*R*,11*R*)-3,7,11,15-tetramethyl-2-hexadecenyl]-3-benzyl-*sn*-glycerol] (3). 1,1′-(1,32-Dotriacontanediyl)bis(3-benzyl-*sn*-glycerol)[4] (**1**; 1.78 g, 2.07 mmol) and sodium hydride (60% in oil, 0.34 g, 8.1 mmol) in anhydrous tetrahydrofuran (25 ml) were stirred at room temperature for 1 h. Compound (**2**, 3.0 g, 8.2 mmol) was added to the resulting alkoxide solution. After heating to reflux for 20 h, the reaction mixture was concentrated, fractionated between water and chloroform. The organic extract was subjected to a silica-gel column chromatography using hexane–ethyl acetate (25/1 v/v). The fraction, which showed a homogeneous spot in TLC under the UV-light and with the Rhodamine 6G spraying, gave **3** as colorless viscous liquid, 2.0 g (71%); R_f (hexane–ethyl acetate, 10/1 v/v) 0.40; 100 MHz ^{1}H NMR δ=0.83—0.87 (a mixture of s and d, 30H, 10CH_3), 4.15 (d with a complex line pattern, 4H, $=CHC\underline{H}_2$), 4.5 (s, 4H, $C\underline{H}_2C_6H_5$), 5.35 (s with a complex line pattern, 2H, $C\underline{H}{=}CH_2O$) and 7.32 (s, 10H, 2C_6H_5); positive FABMS (matrix: 3-nitrobenzyl alcohol and NaCl) *m*/*z* (rel intensity) 1389 ($M+Na$, 3%), 1366 (M^+, 1%).

1,1′-(1,32-Dotriacontanediyl)bis[2-[(3*RS*,7*R*,11*R*)-3,7,11,15-tetramethylhexadecyl]-3-benzyl-*sn*-glycerol] (4). A diglyme solution (15—20 ml) of **3** (1.79 g, 1.3 mmol) and *p*-tolylsulfonylhydrazine (2.5 g, 13 mmol) was heated to reflux under nitrogen for 3 h. The reaction mixture was concentrated to about 10 ml, diluted with hexane and, after removal of the resulting precipitates, was subjected into silica-gel column chromatography. Elution with hexane–ethyl acetate (15/1

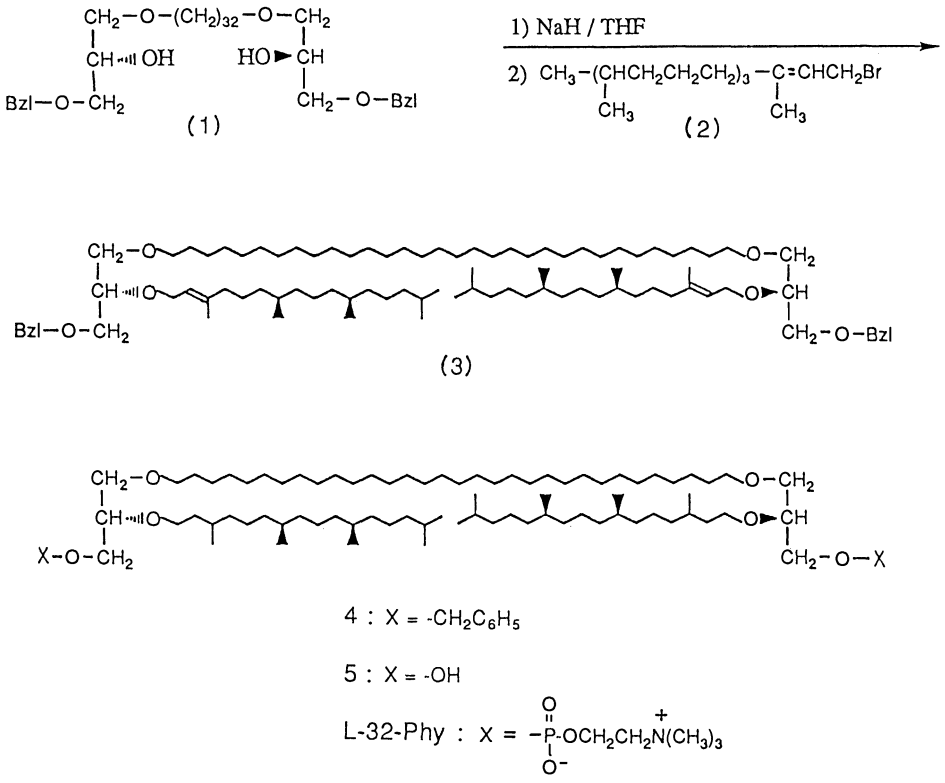

Fig 1.

v/v) gave the diglycerol (**4**) which was further purified by means of a Sephadex LH-20 column using chloroform–methanol (2/1 v/v) as an analytically pure compound, 1.3 g (73%); colorless oil; R_f (hexane–ethyl acetate, 10/1 v/v) 0.56; $[\alpha]_D^{25}$ +1.1° (*c* 1.0, chloroform); 100 MHz ^{1}H NMR and IR spectra were identical with that of the authentic sample;[1] FABMS (matrix: glycerol/3-mercapto-1,2-propanediol, 1/1 v/v) *m/z* (rel intensity) 1371 (M+H, 10%).

L-32-Phy. The dipolar lipid was obtained from **4** via the debenzylation and phosphocholination reactions which were described previously;[1] an overall yield from **4**, 13—18%; mp 152—158 °C (lit,[1] 152—160 °C); a mobility in TLC as well as ^{1}H NMR and IR spectra were identical with those of an authentic sample.

Surface Pressure-Surface Area Isotherms. The film balance system consisted of a Teflon-coated trough of 506 mm (length)×150 mm (width) and a microprocessor (NEC, PC-9801). Temperature of the subphase (water) was thermostated with circulating water within the aluminum trough. A benzene–ethanol solution of **L-32-Phy** (45 µl; 2.66 mg ml^{-1} of the solution) was placed gently on the surface of the subphase, then, a Teflon barrier was swept to compress the film at speed (1 point s^{-1} or 60 mm^2 s^{-1}). The pressure (π) was calibrated by the π–area curve of stearic acid monolayer. The typical results are shown in Fig. 1.

Results and Discussion

In the previous preparation of **L-32-Phy**, phytanyletherification of **1** at the *sn*-2- and -3-O atoms was the most inefficient step; viz., **3** was obtained in a yield of only 15—20% after refluxing a THF-suspension of the sodium salt of **1** and phytanyl bromide for 84 h. The present procedure utilized, instead of the saturated bromide, (7*R*,11*R*)-3,7,11,15-tetramethyl-2-hexadecenyl bromide (**2**). The allylic bromde was reactive to the alkoxide of **1** to produce **3** in a yield of as much as 72%. The reaction time was also shortened considerably. ^{1}H NMR as well as EIMS and FABMS spectra were in accordance with the assigned structure displaying the signals for the C(CH$_3$)=CH–CH$_2$O moiety.

Conversion of **3** into **4** was attempted using various reducing reactions. Palladium-catalyzed hydrogenation of **3** was not fruitful. Heating of **3** with *p*-tolylsulfonylhydrazine[5] in diglyme was efficient to afford **4** in a yield of 73%. Conversion of **4** into **L-32-Phy** was performed according to the previous procedure;[1] namely, (i) debenzylation of **4** by the use of BF_3·$O(C_2H_5)_2$/ethanethiol, (ii) phosphocholination of the resulting diglycerol (**5**) with 2-bromoethyl phosphorodichloridate and trimethylamine. A total yield from **1**: 7—10% in the present method.

Now, the bipolar **L-32-Phy** was different in surface pressure (π)–surface area isotherm from DSPC, one of typical monopolar amphiphiles (Fig. 2). Namely, DSPC gave a stable Langmuir membrane with a limiting area of about 50 Å^2/molecule (curves 1—3). The surface pressure raised sharply upon compressing the spreading area and collapsed at a high lateral pressure as 63 mN m^{-1}. The breakdown occurred instantaneously at an apparent surface area about 36 Å^2/molecule. By

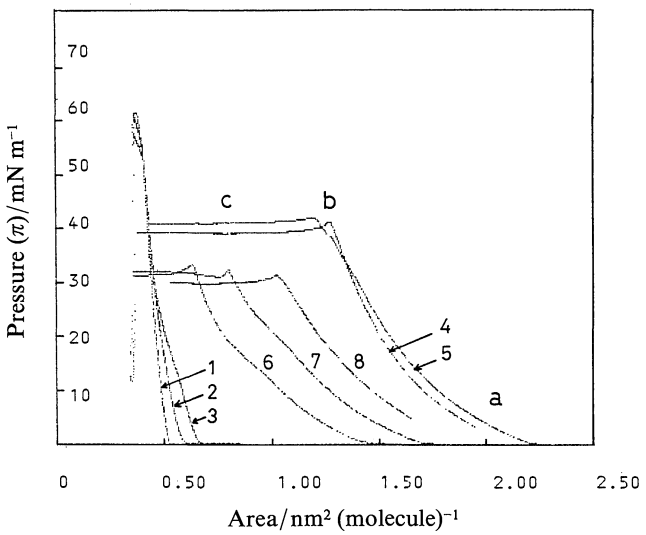

Fig. 2. Surface pressure (π)-surface area isotherms; subphase=water. **DSPC**: curve 1 (5 and 10°C), 2 (15°C), and 3 (20°C); **L-32-Phy**: curve 4 (5°C), and 5 (15°C) (the isotherm curve of 10°C was omitted); **L-32-16**: curve 6 (5°C), 7 (10°C), and 8 (20°C).

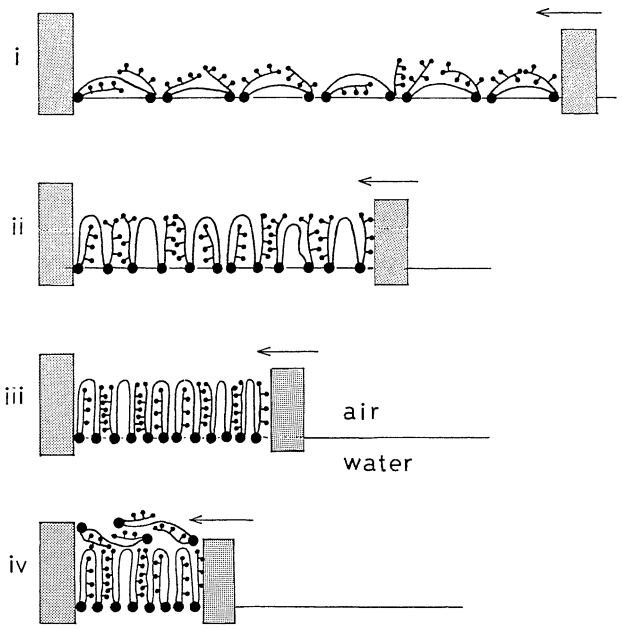

Fig. 3. Schematic representations of formation and collapse of **L-32-Phy** in an interface between water and air.

contrast, **L-32-Phy** did not exhibit a highly cooperative compression; viz., the surface pressure increased gradually upon compressing the spreading area (curves 4 and 5). The limiting area was as large as 160 Å^2/molecule. It appeared also that the monolayer did not collapse, holding constant pressure as inferred by the parallel lines with the abscissa (from point b through c). The peculiar isotherms of **L-32-Phy** may be rationalized as follows. At the low pressure, the bipolar lipids lie sporadically on a water/air interface with the polar heads in water and the hydrophobic residues in air (Fig. 2, point a; Fig. 3-i). With a continuing sweep of the barrier of a film balance, the bipolar lipids are bent gradually to a U-form interacting with neighboring bipolar lipids until the limiting area is closed to the value calculated for two phosphocholine heads (Fig. 2, point b; Fig. 3-ii and iii); cf. DSPC, and DOPC; 50 (this study) and 72 Å^2/molecule,[6] respectively. Upon further compression, the U-shaped **L-32-Phy** may be extruded from the monolayer to pile up on the membrane; the process may permit the constant surface pressure (Fig. 3-iv).

On the other hand, we dealt previously with a Langmuir membrane of 1,1′-(1,32-dotriacontanediyl)-bis(1,2-hexadecyl-*sn*-glycero-3-phosphocholine) (**L-32-16**).[4] The bipolar lipid bearing slim hexadecyl groups gave the π–area isotherms (Fig. 2, curves 6—8) which were characterized by (*a*) significant temperature-dependency as seen in the varying limiting area (90, 120, and 160 Å^2/molecule at 5, 10, and 20 °C, respectively; cf., T_m=61.5 °C; ΔS=0.8 eu/methylene unit) and (*b*) low maximum collapsing pressure (about 30 mN m^{-1}). By contrast, **L-32-Phy**, despite of the low T_m (8 °C),[1] showed that (*a′*) the π–area isotherm or the limiting area was relatively insensitive to temperature (5—15 °C), and (*b′*) the Langmuir membrane was more stable mechanically than the **L-32-16** membrane as judged from the relatively large collapsing pressure (about 40 mN m^{-1} in Fig. 2). Though the above aspects (*a′* and *b′*) have not been fully explained, the temperature-insensitivity might be explained by the ΔS in the phase transition which was as small as 0.4—0.6 eu/methylene unit or high fluidity of the phytanyl groups,[7] and the mechanical stability might be ascribed to the branched structure which would offer high frictional resistance between hydrophobic chains in the membrane. It, however, was apparent from the maximum collapsing pressure that a double-chain-monopolar amphiphile such as DSPC produce a more stable Langmuir membrane than **L-32-Phy**.

Syntheses and Properties of Dimethyl and Tetramethyl Anthra[1,9-*cd*:4,10-*c'd'*]-bis[1,2]dichalcogenoles and Their Charge-Transfer Complexes

Kazuo TAKIMIYA, Yoshio ASO, Tetsuo OTSUBO, and Fumio OGURA*
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Kagamiyama, Higashi-Hiroshima 724
(Received February 18, 1991)

The dimethyl and tetramethyl derivatives of a series of anthra[1,9-*cd*:4,10-*c'd'*]bis[1,2]dithiole, diselenole, and ditellurole have been prepared as a new type of electron donor. The introduced methyl groups serve to enhance not only the donor strength, but also the solubility, enabling a ready formation of their charge-transfer complexes with various electron acceptors such as 7,7,8,8-tetracyanoquinodimethane (TCNQ), its 2,3,5,6-tetrafluoro derivative, 2,5-dimethyl derivative (DMTCNQ), 2,5-dimethoxy derivative (DMOTCNQ), 2,6-bis(dicyanomethylene)-2,6-dihydronaphthalene (TNAP), 3,3'-dichloro-5,5'-bis(dicyanomethylene)-$\Delta^{2,2'}$-bi(3-thiolene) (DCBT), and 3,3'-dibromo-5,5'-bis(dicyanomethylene)-$\Delta^{2,2'}$-bi(3-selenolene) (DBBS). Although the resulting complexes are mostly 1:1 stoichiometrical, the TCNQ complexes tend to favor a composition rich in acceptors; on the contrary, the DMTCNQ and DMOTCNQ complexes tend to favor a composition rich in donors. Their electrical conductivities range widely from 8 to 10^{-9} S cm^{-1}, being apparently dependent on appropriate combinations of the donors and the acceptors. In general, the present donors have a tendency to form highly conductive complexes with TCNQ, TNAP, DCBT, and DBBS. These highly conductive complexes mostly show a broad electron absorption in the infrared region, being characteristic of a segregated stacked structure in a mixed valence state. On the other hand, the X-ray analyses of DMTCNQ complexes of 3,4-dimethyl, 8,9-dimethyl, and 3,4,8,9-tetramethylanthra[1,9-*cd*:4,10-*c'd'*]diselenoles and 3,4,8,9-tetramethylanthra[1,9-*cd*:4,10-*c'd'*]dithiole have revealed that all of the crystal structures have mixed stack columns of donor–donor–acceptor type. Of them, the 3,4-dimethyl derivative complex shows an unusually high conductivity (0.53 S cm^{-1}) for a mixed stacked structure, which is considered to be due to strong heteroatomic interactions of the intra- and inter-columns.

Polyacenes bearing peri-dichalcogen bridges are known as prototypes of superior electron donors. A representative is naphthaceno[5,6-*cd*:11,12-*c'd'*]bis-[1,2]dithiole, abbreviated as tetrathiotetracene or TTT; it has a stronger donating ability than does tetrathiafulvalene (TTF).[1] However, it has a very low solubility in common solvents, limiting any wide study concerning its molecular complexes. Although the selenium isologue (TST)[1] and the tellurium isologue (TTeT)[2] have also aroused interest concerning the introduction of interactive heavy chalcogens, they are intractable because of their poorer solubilities. The lower polyacene homologues, anthra[1,9-*cd*:4,10-*c'd'*]bis[1,2]dithiole (tetrathioanthracene or TTA),[3] naphtho[1,8-*cd*:4,5-*c'd'*]bis-[1,2]dithiole (tetrathionaphthalene or TTN),[4] and their selenium isologues (TSA[5] and TSN[6]), have thus been studied as more tractable materials. However, their donor characters considerably decrease, and their solubilities are not so much improved as expected. In addition, their tellurium isologues still remain unknown. We previously investigated the 2,3,6,7-tetramethyl derivatives of tetrachalcogenonaphthalenes.[7] This structural modification allowed the formation of all of the chalcogen derivatives (TMTTN, TMTSN, and TMTTeN) involving the tellurium isologue. In addition, the introduced methyl groups served to enhance not only the donor strength, but also the solubility, enabling a detailed study of their complexes. We have further designed the same modification in other peri-dichalogenide polyacenes. We here report on the syntheses and properties of 2,3-dimethyl, 6,7-dimethyl, and 2,3,6,7-tetramethyl derivatives of tetrachalcogenoanthracenes and their charge-transfer complexes.[8]

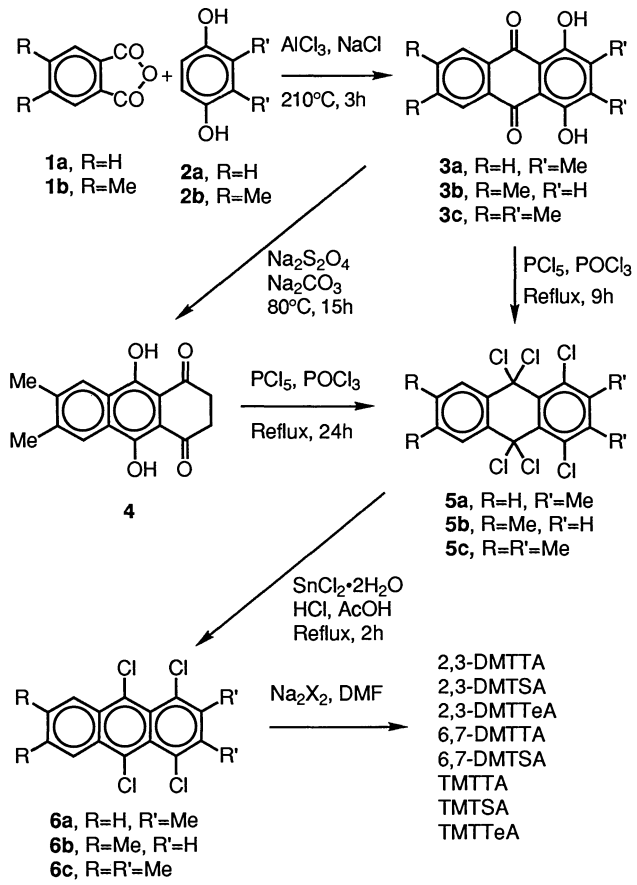
Results and Discussion

Syntheses. Syntheses of dimethyl and tetramethyl tetrachalcogenoanthracenes were carried out according



Scheme 1.

to Scheme 1. Thus 1,4-dihydroxy-2,3-dimethylanthraquinone (**3a**), prepared from a one-step condensation of phthalic anhydride (**1a**) with 2,3-dimethylhydroquinone (**2b**),[9] was allowed to react with phosphorus pentachloride to give 1,4,9,9,10,10-hexachloro-2,3-dimethyl-9,10-dihydroanthracene (**5a**) in 59% yield which, upon subsequent dechlorination with tin(II) chloride dihydrate, afforded 1,4,9,10-tetrachloro-2,3-dimethylanthracene (**6a**) in 75% yield. The treatment of **6a** with sodium disulfide, freshly prepared from sodium and sulfur, in refluxing *N*,*N*-dimethylformamide gave 2,3-dimethyltetrathioanthracene (2,3-DMTTA) in 43% yield. A similar reaction of **6a** with sodium diselenide gave the selenium isologue (2,3-DMTSA) in 31% yield. In contrast to an unsuccessful synthesis of the parent tetratelluroanthracene (TTeA), the tellurium isologue (2,3-DMTTeA) was obtained in 15% yield from a reaction of **6a** with sodium ditelluride at a lower temperature of 100 °C. The same approach to 6,7-dimethyl isomers from a combination of 4,5-dimethylphthalic anhydride (**1b**) and hydroquinone (**2a**) were unexpectedly troublesome regarding the following two steps. The first problem was that the treatment of 1,4-dihydroxy-6,7-dimethylanthraquinone (**3b**) with phosphorus pentachloride did not afford any amount of 1,4,9,9,10,10-hexachloro-6,7-dimethyl-9,10-dihydroanthracene (**5b**). Then, **3b** was reduced with sodium dithionite to 6,7-dimethylanthracene-1,4,9,10-tetrol, which mainly exists as the keto form, 2,3-dihydro-9,10-dihydroxy-6,7-dimethyl-1,4-anthracenedione (**4**) (88% yield). An alternative reaction of **4** with phosphorus pentachloride gave the desired hexachloro compound (**5b**) in 30% yield. The other problem arose in the last substitution reaction of the tetrachloro compound (**6b**) with sodium dichalcogenide. Although 6,7-dimethyltetraselenoanthracene (6,7-DMTSA) was obtained in 38% yield by the reaction, in spite of much effort 6,7-dimethyltetrathioanthracene (6,7-DMTTA) was obtained in only a trace yield and was hardly reproducible. Furthermore, no 6,7-dimethyltetratelluroanthracene was formed. On the other hand, a set of 2,3,6,7-tetramethyl derivatives (TMTTA, TMTSA, and TMTTeA) were smoothly completed by the same reaction sequence starting with a combination of **1b** and **2b**, as described for the 2,3-dimethyl derivatives.

Table 1. Half-Wave Oxidation Potentials of Peri-Dichalcogenide Donors[a]

Compound	$E_{1/2}(1)$/V	$E_{1/2}(2)$/V	ΔE/V
TTA	0.36	0.75	0.39
TSA	0.35	0.71	0.36
2,3-DMTTA	0.32	0.73	0.41
2,3-DMTSA	0.31	0.72	0.41
2,3-DMTTeA	0.20	0.63	0.43
6,7-DMTTA	0.31	0.72	0.41
6,7-DMTSA	0.30	0.68	0.38
TMTTA	0.26	0.69	0.43
TMTSA	0.26	0.68	0.42
TMTTeA	0.16	0.55	0.39
TTT	0.19	0.56	0.37
TTF	0.34	0.72	0.38

a) Cyclic voltammetry was measured at 100 mV s^{-1} scan rate with Pt working and counter electrodes and Ag/AgCl reference electorde in 10^{-3} mol dm^{-3} benzonitrile solution containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate as supporting electrolyte.

Oxidation Potentials. Cyclic voltammograms of all of the tetrachalcogenoanthracenes show two reversible one-electron redox waves; their half-wave oxidation potentials are summarized in Table 1. The first and second oxidation potentials of the parent TTA are almost comparable to the corresponding ones of TTF. The introduction of methyl groups actually lowers these values in the order of dimethylation and tetramethylation. The effect is more eminent in the first oxidation than in the second one. There is no essential difference between the enhanced effects due to dimethylation at the 2,3-positions and at the 6,7-positions. Substitution of selenium for sulfur in any series of the parent, dimethyl, and tetramethyl derivatives has little influence on the oxidation potentials. However, substitution of tellurium results in a considerable lowering of both the first and second potentials. As a result, 2,3-DMTTeA and TMTTeA have very strong donating abilities which are either comparable or superior to that of TTT.

a) Obtained from chlorobenzene. b) Calculated as stoichiometry indicated for the complex. c) Measured with a KBr disk method. d) $\Delta E_{redox}=E_{1/2}(D)-E_{1/2}(A)$. e) Measured on compressed pellets at RT with a two-probe or four-probe method.

Molecular Complexes. The methyl group of the present tetrachalcogenoanthracenes actually contributes to enhance their solubilities. This effect, however, is more remarkable in dimethylation than in tetramethylation. For example, the molar solubilities of a series of tetraselenoanthracenes in chloroform are as follows: TSA 2.1×10^{-4} mol dm^{-3}, 2,3-DMTSA 3.1×10^{-3} mol dm^{-3}, 6,7-DMTSA 8.5×10^{-4} mol dm^{-3}, and TMTSA 3.2×10^{-4} mol dm^{-3}. The stronger donating abilities and better solubilities of the dimethyl and tetramethyl derivatives than parent tetrachalcogenoanthracenes facilitated a study of their complexation. They thus gave a number of charge-transfer complexes, as summarized in Table 2. The acceptors used in this experiment involve not only those of well-known classes such as 7,7,8,8-tetracyanoquinodimethane (TCNQ), its 2,3,5,6-tetrafluoro derivative ($TCNQF_4$), 2,5-dimethyl derivative (DMTCNQ), 2,5-dimethoxy derivative (DMOTCNQ), and 2,6-bis(dicyanomethylene)-2,6-dihydronaphthalene (a common name: 9,9,10,10-tetracyano-2,6-naphthoquinodimethane or TNAP) but also of new types such as 3,3'-dichloro-5,5'-bis(dicyanomethylene)-$\Delta^{2,2'}$-bi(3-thiolene) (DCBT)[10] and 3,3'-dibromo-5,5'-bis(dicyanomethylene)-$\Delta^{2,2'}$-bi(3-selenolene) (DBBS).[11] The half-

wave reduction potentials and infrared nitrile frequencies of these acceptors are given in Table 3. The reduction potentials, except for that of $TCNQF_4$, are just appropriate to form conductive complexes with the present donors; the differences ΔE_{redox} between the oxidation potentials of the donors and the reduction potentials of the acceptors are in the range from −0.05 V to 0.32 V, which has a high probability of being organic metals.[12] The resulting complexes are mostly 1 : 1 stoichiometrical, but some complexes favor a composition rich in either donors or acceptors, even when both components are mixed in equimolar amounts. In addition, their electrical conductivities widely range from 8 to 10^{-9} S cm^{-1}, being independent of the stoichiometry. The stoichiometry and conductivities are apparently dependent on appropriate combinations of the donors

a) Cyclic voltammetry was measured at 100 mV s^{-1} scan rate with Pt working and counter electrodes and Ag/AgCl reference electorde in 10^{-3} mol dm^{-3} benzonitrile solution containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate as supporting electrolyte.

and acceptors, but can be somewhat systematized according to the used acceptors rather than the donors, as follows. The TCNQ complexes of the TTA and TSA derivatives tend to favor a composition rich in acceptor species, and the electrical conductivities measured on compressed pellets at room temperature are in the high range of 0.05—2.0 S cm^{-1}. These complexes, except for the TMTSA complex, show a broad electron absorption in the infrared region, being characteristic of a segregated stacked structure in a mixed valence state.[13] The incomplete charge transfer was also supported by nitrile vibrational frequencies, which are intermediate between those of neutral TCNQ (2232 cm^{-1}) and Na^+TCNQ^- (2174 cm^{-1}).[14] In contrast, the TCNQ complexes of stronger tellurium-containing donors, DMTTeA and TMTTeA, have the 1 : 1 composition and low conductivities. All of the complexes with a stronger acceptor, $TCNQF_4$, are also 1 : 1 stoichiometrical and exhibit a low conductivity. These low conductivity complexes must correspond to Mott insulators, since the increasing donor or acceptor character causes a complete charge transfer, as indicated by the low frequencies of the infrared nitrile vibrations. On the other hand, a weaker acceptor DMTCNQ takes complexes of a 2 : 1 composition rich in donor, reflecting increasing bulkiness of the acceptors. These complexes mostly exhibit a low conductivity, and the electronic spectra indicate segregated stacking only for a complex with 2,3-DMTTA. A similar result was observed for the DMOTCNQ complexes. Some of the DMTCNQ complexes were actually confirmed by X-ray crystallographic analyses to take mixed stacking, which is further discussed later in connection with their conductivities. The other acceptors (TNAP, DCBT, and DBBS) are strong electron acceptors comparable to TCNQ and have additional advantages of high polarization and reduced Coulomb repulsion due to their extensive conjugation. Their complexes are all 1 : 1 stoichiometrical and mostly high-conductive, indicating mutual fitness of the donors and the acceptors. The enhanced intermolecular interactions of the individual components due to the

extended π-systems as well as interactive heteroactoms are considered to lead to a ready formation of segregated columns. In particular, it is worth noting that the tellurium-containing donors can form highly conductive complexes with these acceptors.

Crystal Structures of DMTCNQ Complexes. The four DMTCNQ complexes with 2,3-DMTSA, 6,7-DMTSA, TMTSA, and TMTTA offered good single crystals for X-ray analysis. Table 4 shows their crystal data, in which all crystals belong to the monoclinic space group. Of these complexes, only the 2,3-DMTSA complex has a high conductivity (0.53 S cm^{-1}) and an electronic absorption band at 4.6×10^3 cm^{-1}. Although it is expected to have a different crystal structure, all of the DMTCNQ complexes are isostructural with mixed stacked columns of a donor–donor–acceptor sequence along the *c*-axis (Fig. 1). In addition, overlapping modes for donor–donor and donor–acceptor are quite similar (Fig. 2). Their infrared nitrile vibrations as compared with that (2230 cm^{-1}) of neutral DMTCNQ indicate a complete charge-transfer for the 2,3-DMTSA complex (2172 cm^{-1}) but some charge-transfer for the 6,7-DMTSA complex (2190 cm^{-1}), the TMTTA complex (2214 cm^{-1}), and the TMTSA complex (2210 cm^{-1}). The actual charge-transfer of the 2,3-DMTSA complex is also supported by a detailed consideration of the molecular structures of the components (Fig. 3, Table 5).

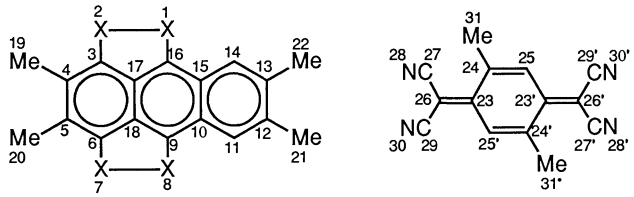

Fig. 3. Atomic numbering scheme for X-ray crystal structure analysis.

Because the strong donating character of the peri-dichalcogenide polyacenes is based on aromatization of the heterocyclic ring in the resulting cationic species, a charge-transfer in their complexes might bring about a change in the ring dimensions: that is, a shortening of the Se–Se and Se–C bond lengths.[15] For a comparison the molecular structures of neutral 2,3-DMTSA, 6,7-DMTSA, and 2,3-DMTTA were determined. 2,3-DMTSA was analyzed for a single crystal including one benzene per two molecules. The crystal data and the molecular structures are given in Tables 6 and 7, respectively. Since TMTTA and TMTSA did not offer good crystals for X-ray analyses, neutral 2,3-DMTTA and 2,3-DMTSA were used as substitutes for examining any dimensional change. Both the Se–Se and C–Se bond lengths of the 2,3-DMTSA complex are shorter

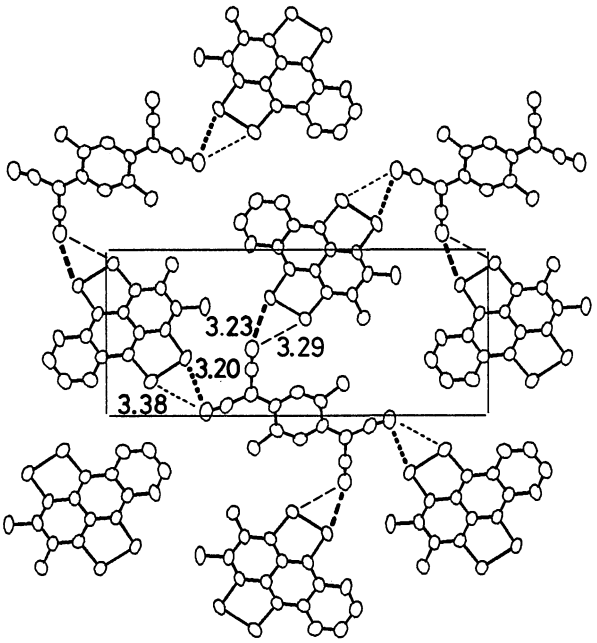

Fig. 4. Crystal structure of 2,3-DMTSA·DMTCNQ projected along the c axis.

than the corresponding ones of neutral 2,3-DMTSA, while the other complexes do not show such appreciable variations. In addition, the molecular geometry of DMTCNQ becomes more benzenoid in character for the 2,3-DMTSA·DMTCNQ complex (Table 5), supporting a complete charge transfer.[16] A question is why only the 2,3-DMTSA·DMTCNQ complex shows so large charge-transfer and high conductivity. As already pointed out, although its crystal structure is very similar to those of the other complexes, there is a small difference in overlapping distances. Thus the 2,3-DMTSA·DMTCNQ complex has a rather longer interplanar distance between the donor and acceptor than do the other omplexes, being in conflict with the actual degree of charge transfer. On the other hand, the interplanar distance between paired donors is shorter, and a short Se–Se contact (3.62 Å) is observed. In addition, there are observed some intercolumnar Se–N contacts between 2,3-DMTSA and the neighboring DMTCNQ, constituting a net-work sheet (Fig. 4). It is thus concluded that the large charge transfer and high conductivity of the 2,3-DMTSA·DMTCNQ complex are induced by strong heteroatomic interactions of Se–Se and Se–N.

Experimental

General. Melting points are uncorrected. All chemicals and solvent are of reagent grade. Elemental analyses were measured by Mr. Hideaki Iwatani, Microanalytical Laboratory in Department of Applied Chemistry, Faculty of Engineering, Hiroshima University. NMR spectra were recorded on a JEOL PMX-60 spectrometer (60 MHz) using deuteriochloroform as a solvent and tetramethylsilane as an internal standard. IR spectra were taken on a Hitachi 260-30 spectrometer with a KBr disk method. MS spectra were measured at 70 eV on a Shimadzu QP-1000A spectrometer using a direct insertion technique. Electronic spectra were recorded on a Shimadzu UV-160 spectrometer or on a Hitachi 330 spectrophotometer. Cyclic voltammetry was carried out on a Hokuto Denko HA-301 potentiostat and a Hokuto Denko HB-104 function generator.

1,4-Dihydroxy-2,3-dimethylanthraquinone (3a). Compound (**3**) was prepared by modifying the synthetic method of Kerdersky et al.[9] A mixture of anhydrous aluminium chloride (50 g) and sodium chloride (10 g) was well ground together in a mortor, and heated at 210 °C to melt. Into a stirred solution was added a mixture of phthalic anhydride (**1a**) (7.4 g, 50 mmol) and 2,3-dimethylhydroquinone (**2b**) (6.9 g, 50 mmol); heating at the temperature was continued for further 4 h. Concd hydrochloric acid (50 cm^3) and water (200 cm^3) were successively added into a mixture cooled to ca. 100 °C, which was then gently boiled for 2 h. The resulting solid, while still hot, was collected by filtration and dissolved in chloroform (2 dm^3). After the solution was filtered, the filtrate was concen-

trated to ca. 200 cm³ and purified by column chromatography on silica gel using chloroform as an eluent to give a reddish-orange solid of **3a** (11.3 g, 84.6%). An analytical sample was obtained as reddish-orange needles upon recrystallization from benzene–hexane: Mp 259—260 °C (lit,[9] mp 252—253 °C); ^{1}H NMR δ=2.40 (s, 6H, CH_3), 7.73 (AA'BB' m, 2H, ArH), 8.24 (AA'BB' m, 2H, ArH), and 13.48 (s, 2H, OH); IR 1590 cm^{-1} (C=O); MS *m/z* 268 (M^+); Anal. Calcd for $C_{16}H_{12}O_4$: C, 71.64; H, 4.51%. Found: C, 71.63; H, 4.51%.

1,4-Dihydroxy-6,7-dimethylanthraquinone (3b): 74% yield; reddish orange needles from chloroform; mp 228 °C; ^{1}H NMR δ=2.30 (s, 6H, CH_3), 7.20 (s, 2H, ArH), 7.95 (s, 2H, ArH), and 12.75 (s, 2H, OH); IR 1630 and 1590 cm^{-1} (C=O); MS *m/z* 268 (M^+); Anal. Calcd for $C_{16}H_{12}O_4$: C, 71.64; H, 4.51%. Found: C, 71.60; H, 4.49%.

1,4-Dihydroxy-2,3,6,7-tetramethylanthraquinone (3c): 69% yield; reddish orange needles from chloroform; mp 276 °C; ^{1}H NMR δ=2.25 (s, 6H, CH_3), 2.40 (s, 6H, CH_3), 7.96 (s, 2H, ArH), and 13.40 (s, 2H, OH); IR 1580 cm^{-1} (C=O); MS *m/z* 296 (M^+); Anal. Calcd for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%. Found: C, 72.84; H, 5.40%.

2,3-Dihydro-9,10-dihydroxy-6,7-dimethyl-1,4-anthracenedione (4). Into a suspension of **3b** (5.3 g, 19.8 mmol) and anhyd. sodium carbonate (5 g) in water (100 cm³) was added sodium dithionite (10 g); the mixture was heated at 80 °C for 15 h. After cooling, the resulting yellow solid was collected by filtration and dried. Chromatography on silica gel using dichloromethane as an eluent followed by recrystallization from benzene–hexane gave yellow needles of **4** (4.8 g, 88%): Mp 182 °C; ^{1}H NMR δ=2.45 (s, 6H, CH_3), 2.96 (s, 4H, CH_2), 8.00 (s, 2H, ArH), and 13.60 (s, 2H, OH); IR 1610 cm^{-1} (C=O); MS *m/z* 270 (M^+); Anal. Calcd for $C_{16}H_{14}O_4$: C, 71.11; H, 5.22%. Found: C, 71.40; H, 5.05%.

1,4,9,9,10,10-Hexachloro-2,3-dimethyl-9,10-dihydroanthracene (5a). A mixture of **3a** (4.2 g, 15.7 mmol), phosphorus pentachloride (23 g, 110 mmol), and phosphoryl oxychloride (40 cm³) was refluxed for 9 h. Concentration in a reduced pressure followed by thorough washing of the residue with hexane and then with methanol left a white solid of **5a** (3.8 g, 59%); mp 140 °C (decomp); ^{1}H NMR δ=2.55 (s, 6H, CH_3), 7.42 (AA'BB' m, 2H, ArH), and 7.95 (AA'BB' m, ArH); IR 710 cm^{-1} (C–Cl); MS *m/z* 414 (M^+) with an isotopic pattern hexachlorine. Anal. Calcd for $C_{16}H_{10}Cl_6$: C, 46.31; H, 2.43%. Found: C, 45.71; H, 2.36%.

1,4,9,9,10,10-Hexachloro-6,7-dimethyl-9,10-dihydroanthracene (5b): 30% yield from **4**; a white solid; mp 232 °C (decomp); ^{1}H NMR δ=2.45 (s, 6H, CH_3), 7.52 (s, 2H, ArH), and 7.73 (s, 2H, ArH); IR 740 cm^{-1} (C–Cl); MS *m/z* 414 (M^+) with an isotopic pattern of hexachlorine. Anal. Calcd for $C_{16}H_{10}Cl_6$: C, 46.31; H, 2.43%. Found: C, 45.72; H, 2.24%.

1,4,9,9,10,10-Hexachloro-2,3,6,7-tetramethyl-9,10-dihydroanthracene (5c): 44% yield from **3c**; a white solid; mp 139 °C (decomp); ^{1}H NMR δ=2.37 (s, 6H, CH_3), 2.58 (s, 6H, CH_3), and 7.73 (s, 2H, ArH); IR 750 cm^{-1} (C–Cl); MS *m/z* 440 (M^+) with an isotopic pattern of hexachlorine. Anal. Calcd for $C_{18}H_{14}Cl_6$: C, 48.80; H, 3.19%. Found: C, 48.37; H, 3.00%.

1,4,9,10-Tetrachloro-2,3-dimethylanthracene (6a). A mixture of **5a** (3.8 g, 9.2 mmol), tin(II) chloride dihydrate (29.2 g), acetic acid (40 cm³), and concd hydrochloric acid (36 cm³) was refluxed for 1.5 h. After cooling, the resulting yellow solid of **6a** was collected by filtration, washed, and purified by column chromatography on active alumina using

benzene as eluent (2.4 g, 75%). An analytical sample was obtained as yellow needles by recrystallization from chloroform–hexane; mp 119—120 °C (decomp); ^{1}H NMR δ=2.56 (s, 6H, CH_3), 7.52 (AA'BB' m, 2H, ArH), and 8.45 (AA'BB' m, 2H, ArH); IR 660 cm^{-1} (C–Cl); MS m/z 344 (M^+) with an isotopic pattern of tetrachlorine. Anal. Calcd for $C_{16}H_{10}Cl_4$: C, 55.85; H, 2.93%. Found: C, 55.84; H, 2.89%.

1,4,9,10-Tetrachloro-6,7-dimethylanthracene (6b): 80% yield; yellow needles from chloroform–hexane; mp 172 °C; ^{1}H NMR δ=2.48 (s, 6H, CH_3), 7.32 (s, 2H, ArH), and 8.45 (s, 2H, ArH); IR 810 and 605 cm^{-1}; MS m/z 344 (M^+) with an isotopic pattern of tetrachlorine. Anal. Calcd for $C_{16}H_{10}Cl_4$: C, 55.85; H, 2.93%. Found: C, 55.82; H, 3.06%.

1,4,9,10-Tetrachloro-2,3,6,7-tetramethylanthracene (6c): 75% yield; yellow needles from benzene; mp 187—188.5 °C; ^{1}H NMR δ=2.47 (s, 6H, CH_3), 2.53 (s, 6H, CH_3), and 8.23 (s, 2H, ArH); IR 670 cm^{-1} (C–Cl); MS m/z 370 (M^+) with an isotopic pattern of tetrachlorine. Anal. Calcd for $C_{18}H_{14}Cl_4$: C, 58.10; H, 3.79%. Found: C, 58.07; H, 3.58%.

3,4-Dimethylanthra[1,9-*cd*:4,10-*c'd'*]dithiole (2,3-DMTTA). In a nitrogen atmosphere, sodium metal (165 mg, 7.2 mmol) was allowed to react with sulfur (236 mg, 7.2 mmol) in dry DMF (30 cm^3) at 100 °C for 2 h, forming fresh sodium disulfide. Into the mixture was added a solution of **6a** (516 mg, 1.5 mmol) in dry DMF (30 cm^3). It was refluxed for 8 h, stirred overnight at room temperature with exposure to air, and then poured into brine (200 cm^3). The resulting brown solid was collected by filtration, dried, and extracted with hexane and then with carbon disulfide by use of a Soxhlet apparatus. The carbon disulfide extract was recrystallized from benzene to give black purple needles of 2,3-DMTTA (211 mg, 43%); mp 271 °C; IR 1610, 1300, and 740 cm^{-1}; MS m/z 330 (M^+); UV (CS_2) 450.5 (log ε 3.79), 531 (3.87), and 566.5 nm (3.90). Anal. Calcd for $C_{16}H_{10}S_4$: C, 58.15; H, 3.05%. Found: C, 58.41; H, 2.87%.

3,4-Dimethylanthra[1,9-*cd*:4,10-*c'd'*]diselenole (2,3-DMTSA). 2,3-DMTSA was prepared from a similar reaction of **6a** with sodium diselenide at 150 °C and recrystallized from benzene to give black crystals. The elemental analysis and X-ray crystallographic analysis showed that it consists of 2,3-DMTSA and benzene of 2:1 ratio. Its heating at 150 °C under a reduced pressure left the free 2,3-DMTSA: 31% yield; mp 289 °C; IR 1270 and 740 cm^{-1}; MS m/z 520 (M^+); UV (CS_2) 439.5 (log ε 3.75) and 568.5 nm (4.09). Anal. Calcd for $C_{16}H_{10}Se_4$: C, 37.09; H, 1.95%. Found: C, 37.21; H, 1.93%.

3,4-Dimethylanthra[1,9-*cd*:4,10-*c'd'*]ditellurole (2,3-DMTTeA). 2,3-DMTTeA was prepared from a similar reaction of **6a** with sodium ditelluride at 100 °C. Recrystallization from chlorobenzene gave black needles; 15% yield; mp >300 °C; IR 1250 cm^{-1}; MS m/z 714 (M^+); UV (CS_2) 598.5 nm (log ε 4.05). Anal. Calcd for $C_{16}H_{10}Te_4$; C, 26.97; H, 1.41%. Found: C, 26.96; H, 1.40%.

8,9-Dimethylanthra[1,9-*cd*:4,10-*c'd'*]dithiole (6,7-DMTTA): 2% yield; black purple powder from benzen mp >300 °C; IR 1340, 1290, 1165, and 790 cm^{-1}; MS m/z 330 (M^+); UV (CS_2) 451 (log ε 3.66), 529 (3.92), and 562 nm (3.98). Anal. Calcd for $C_{16}H_{10}S_4$: C, 58.14; H, 3.05%. Found: C, 58.08; H, 3.04%.

8,9-Dimethylanthra[1,9-*cd*:4,10-*c'd'*]diselenole (6,7-DMTSA): 38% yield; black plates from chlorobenzene; mp >300 °C; IR 1320, 1280, 1150, and 795 cm^{-1}; MS m/z 520 (M^+); UV (CS_2) 446.5 (log ε 3.66) and 568.5 nm (4.10). Anal. Calcd for $C_{16}H_{10}Se_4$: C, 37.09; H, 1.95%. Found: C, 37.19; H, 1.95%.

3,4,8,9-Tetramethylanthra[1,9-*cd*:4,10-*c'd'*]dithiole (TMTTA): 41% yield; black needles from chlorobenzene; mp >300 °C; IR 2990, 2850, and 1310 cm^{-1}; MS m/z 358 (M^+); UV (CS_2) 447.5 (log ε 3.82), 525.5 (3.89), and 557 nm (3.94). Anal. Calcd for $C_{18}H_{14}S_4$: C, 60.29; H, 3.94%. Found: C, 60.23; H, 3.85%.

3,4,8,9-Tetramethylanthra[1,9-*cd*:4,10-*c'd'*]diselenole (TMTSA): 29% yield; black powder from gradient sublimation; mp >300 °C; IR 3000, 2930, and 1290 cm^{-1}; MS m/z 548 (M^+); UV (CS_2) 559 nm (log ε 4.11). Anal. Calcd for $C_{18}H_{14}Se_4$: C, 39.59; H, 2.58%. Found: C, 39.55; H, 2.51%.

3,4,8,9-Tetramethylanthra[1,9-*cd*:4,10-*c'd'*]ditellurole (TMTTeA): 14% yield; black powder from carbon disulfide; mp >300 °C; MS m/z 740 (M^+); UV (CS_2) 586.5 nm (log ε 4.07). Anal. Calcd for $C_{18}H_{14}Te_4$: C, 29.19; H, 1.91%. Found: C, 29.48; H, 1.82%.

Charge-Transfer Complexes. All of the complexes described in this report were prepared by mixing two hot saturated solutions of the donor and acceptor in chlorobenzene. The resulting complexes precipitated out upon cooling, which were collected by filtration, washed with cold dichloromethane, and dried.

Crystal Structures. The X-ray diffraction data were collected with a Rigaku automated diffractometer using Cu $K\alpha$ radiation monochromatized with a graphite plate. Independent reflections within 2θ=126° ($|F_o| \geqslant 3.0\sigma(F_o)$) were used for analyses. The structures were solved by a direct method combined with the Monte-Carlo method for the selection of the initial set of phase,[17] and refined by a full-matrix least squares method.[18] Atomic scattering factors were taken from International Tables for X-ray Crystallography.[19] The anisotropic temperature factors were used for the refinement; hydrogen atoms were not included in the refinement. Tables of final atomic parameters, structure factors, and anisotropic thermal parameters are deposited as Document No. 9116 at the Office of the Editor of Bull. Chem. Soc. Jpn.

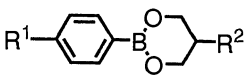
(Received February 21, 1991)

The crystal and molecular structure of the title nematogen (**1**), has been determined by an X-ray analysis. Compound **1** belongs to the triclinic system with space group $P\bar{1}$, a=9.798(2), b=11.579(2), c=9.716(2) Å, α=74.081(13), β=117.766(14), γ=108.179(13)°, and with two molecules in the unit cell. The geometry around the boron atom is planar, and the plane defined by O2BC is parallel to the phenyl ring bonded to the boron atom. The angle between two phenyl rings is 74.3°. The molecules are in their most extended conformation, with nearest neighbors oriented antiparallel to each other. The ^{1}H NMR studies have indicated that the half-chair conformation of the dioxaborinane is kept in a solution even at 125 °C where **1** forms a nematic phase, and the rigidity is essential for the formation of mesophases.

Relation between molecular structure and property of liquid crystalline materials are of current interest. In order to understand molecular arrangements in mesophases on the basis of the molecular structure, direct analyses of nematic or smectic phases by spectroscopic and X-ray methods have been made,[1] but only a little information has been obtained to date. Thus at present in many cases it may be obliged to infer the molecular structure and arrangement in a liquid crystalline state from those in a crystalline one.[2]

Previously we have shown[3] that 2-aryl-1,3,2-dioxaborinane derivatives (I) provide a new series of liquid crystalline materials and form nematic, smectic A and C, and chiral smectic C phases depending on their structures. Since they contain a metalloid atom, boron, in the



(I)

six-membered ring, it is supposed that they have a unique structural feature. In order to discuss the characteristics of the dioxaborinane compounds, especially in terms of the influence of the boron atom on the molecular structure and liquid crystalline property, we have performed structural analyses of a representative nematogen among them both in a solution and in a crystalline state. Here we report the NMR and X-ray analyses of 2-(4-cyanophenyl)-5-(4-butylphenyl)-1,3,2-dioxaborinane (**1**)[4] which forms a stable nematic phase in the temperature range of 120—128 °C as shown in Fig. 1.

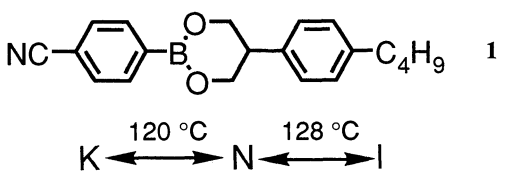


Fig. 1. Structure and phase sequence of **1**.

Experimental

Materials. 2-(4-Cyanophenyl)-5-(4-butylphenyl)-1,3,2-dioxaborinane (**1**) and 2-(4-butoxyphenyl)-5-octyl-1,3,2-dioxaborinane (**6a**) were prepared by the method[4] reported previously and the single crystals of **1** were obtained by slow evaporation from a solution of **1** in hexane.

2-(4-Butoxyphenyl)-5-octyl-4,4,6,6-tetradeuterio-1,3,2-dioxaborinane (**6b**) was similarly prepared by dehydrocondensation in toluene between 4-butoxyphenylboronic acid and 2-octyl-1,1,3,3-tetradeuterio-1,3-propanediol which was obtained by the reduction of diethyl octylmalonate with lithium alminum deuteride. Recrystallization from hexane gave colorless crystals of **6b** in 40% yield. IR (KBr) 2920 (ν_{CH}), 2220 and 2110 (ν_{CD}), 1340 cm^{-1} (ν_{BO}); MS m/z 350 (M^+).

Collection of X-ray Diffraction Data and Structure Determination. Crystal data and experimental conditions are summarized in Table 1. Three dimensional intensity data were collected on a Rigaku AFC-5FOS automated four circle diffractometer at room temperature. Mo K_α (λ=0.71069 Å) radiation with a graphite crystal monochrometor in the incident beam was used. Unit cell constants were determined by a least-squares fit of 25 reflections in the range of $21°<2\theta<27°$. Three standard reflections were checked every 55 reflections during the course of the intensity-collection and no intensity-decrease was observed. Intensity data were reduced to structure factors without any absorption corrections.

Structure was solved by direct methods (MULTAN84), refined by block-diagonal least-squares methods and RASA software was employed for the entire structure analyses. Non-hydrogen atoms were assigned with anisotropic temperature factors. Hydrogen atoms were found by difference Fourier calculations and refined with isotropic thermal parameters. The structure has been refined to R=0.070 (R_w=0.056) for 2121 observed reflections.

Computations were carried out on a FACOM S3500 superminicomputer at Material Analysis Center, ISIR, Osaka University.

were recorded on a Bruker WM360 spectrometer. Deuteriochloroform and 1,2-dideuterio-1,1,2,2-tetrachloroethane were used as solvents on the measurements at a room temperature and at a higher temperature, respectively.

Results and Discussion

Description of Structure. The crystal and molecular structures of **1** have been determined by a single-crystal X-ray analysis. This is the first X-ray structural analysis of the 1,3,2-dioxaborinane derivatives. The molecular structure of **1** is illustrated in Fig. 2. The final positional and thermal parameters of all the non-hydrogen atoms are listed in Table 2, and Tables 3 and 4 list the bond length and the angles, respectively.

It can be seen from the projection that the geometry around the boron atom is planar and the plane defined by O2BC is coplanar with the phenyl ring bonded to the boron atom. The conformation of the dioxaborinane ring is characterized to be in a half-chair form.

The bond length between boron and carbon is 1.562 Å, shorter than those of borates, compounds **2** (1.590 Å)[5] and **3** (1.628, 1.630 Å).[6] The length is somewhat shorter than that of triphenylborane **4** (1.571, 1.589 Å),[7] because

Table 2. Final Atomic Coordinates and Isotropic Thermal Parameters with esd's in Parentheses for the Non-Hydrogen Atoms of **1**

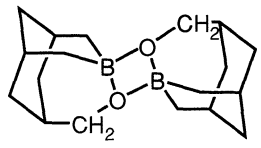
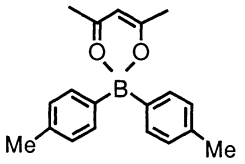
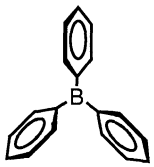
the boron atom in **4** is not in conjugation with the phenyl rings. The bond length between boron and oxygen are also shorter than those of compounds **2** and **3**. The amine adduct of boronic acid trimer **5** has rather longer B–O (1.400 Å) and B–C (1.574 Å) bonds,[8] which may be due to a borate character.



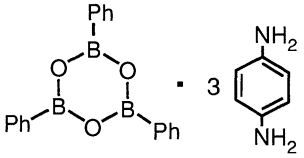
2



3



4



5

The two phenyl rings in compound **1** lie nearly perpendicular, i.e. the torsion angle between them is 74.3°, which compares well with the angles of 81.5° in the molecule of 4-(4-propylcyclohexyl)benzonitrile[9] and 64.5° of 4-(4-octylcyclohexyl)benzonitrile[10] which are well-known to form mesophases. The butyl chain is extended in a trans conformation and the molecule adopts a widely stretched and nearly linear form.

Molecular Packing. In Fig. 3 a projection along the *b*-axis is depicted, which shows the molecules of **1** are arranged in a head-to-tail manner parallel to each other. Such antiparallel arrangement is usually observed in the cases of cyano-substituted mesomorphic molecules (e.g. cyanobiphenyl and cyclohexylbenzonitrile[10,11]) and it is believed that the antiparallel imbricated molecular arrangement in the crystalline state would be kept in the nematic phase. As reported previously for dioxaborinane derivatives[4] the cyano terminal is actually effective for the formation of a nematic phase. The antiparallel dimer structure due to the cyano group effectively contributes to the thermal stability of nematic phases formed by the cyano derivatives of dioxaborinane compounds.

The distance between the cyano groups of neighboring molecules is 3.65 Å, which is within the distance (3.5—4.3 Å) reported on the nematogens having a cyano group by Haase et al.[10-12] The nearest atoms of the neighboring molecules are H3–H81: 2.447 Å, H14–H52:

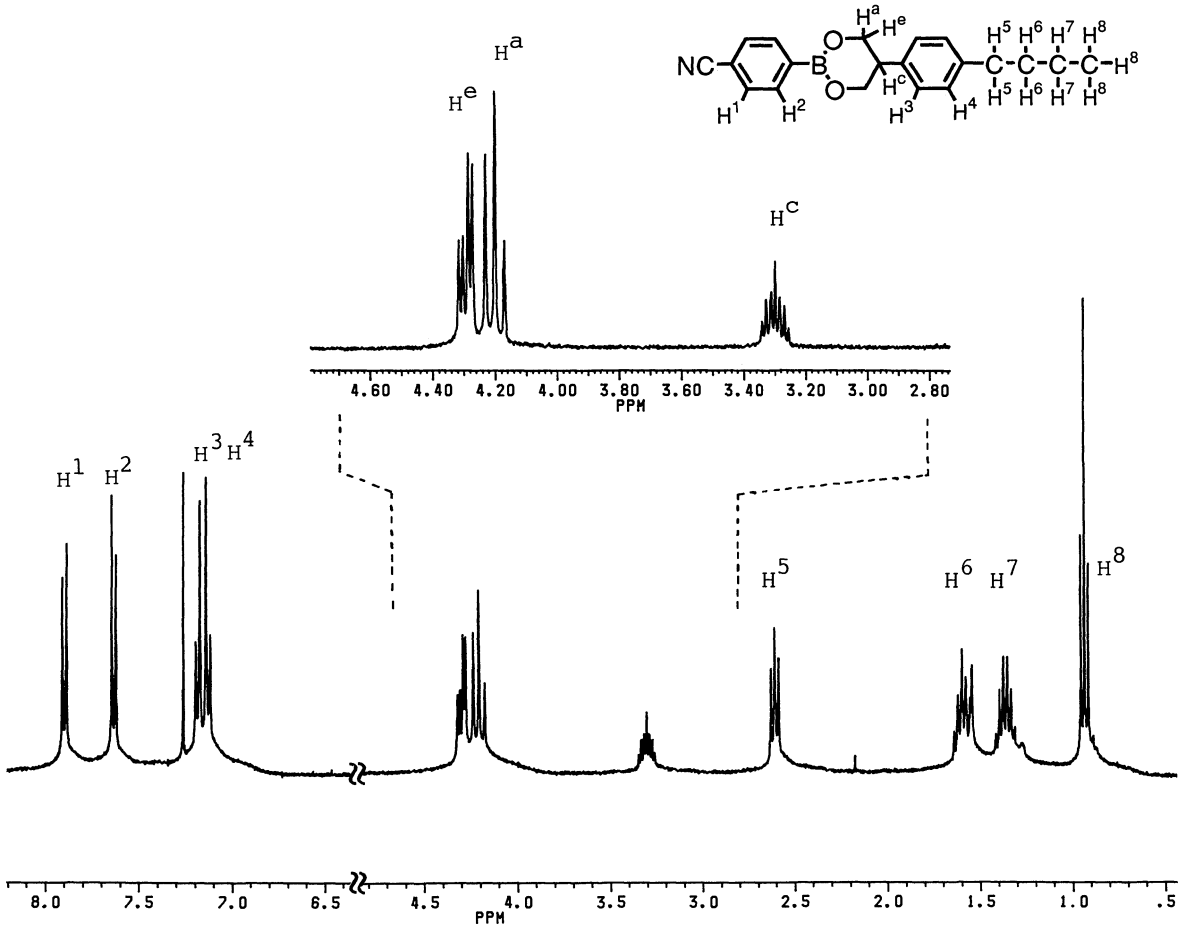


Fig. 4. ^{1}H NMR spectrum of **1** in deuterochloroform at 360 MHz and 25°.

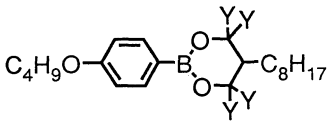
2.448 Å, the dioxaborinane ring is relatively close to a benzene ring, suggesting an interaction between these two rings.

Structure in a Solution. In order to obtain information on the molecular structure, in particular on the dioxaborinane ring of compound **1** in a solution, we have performed detailed investigations by an NMR method. In the $^{11}B\{^1H\}$ NMR spectrum of **1** in acetone-d_6 at ambient temperature showed a relatively broad singlet at 8.3 ppm down field from triethoxyborane as an internal standard. The chemical shift is comparable with that (10.4 ppm) of diethyl phenylboronate.[13] The ^1H NMR spectrum at room temperature is shown in Fig. 4 along with the expanded spectrum in the region of δ=5—3 ppm. Assignment of the signals observed at 4.20 and 4.29 ppm have been made by comparison between ^1H NMR spectra of 2-(4-butoxyphenyl)-5-octyl-1,3,2-dioxaborinane (**6a**) and its 4,4,6,6-tetradeuterio derivative (**6b**). The spetrum of **6a** exhibited three signals at



6a: Y=H
6b: Y=D

3.73, 3.97, and 4.14 ppm in the region of δ=3—5 ppm, whereas in the spectrum of deuterio derivative **6b** two of them completely disappeared and only the signal at 3.97 ppm remained, clearly indicating that the signals at 3.73 and 4.14 ppm can be assigned to the methylene protons attached to 4- and 6-carbons of the dioxaborinane ring and the signal at 3.97 ppm to the methylene protons (-O-CH_2-) of the butoxyl group. Thus we can assign the signals observed for compound **1** at 4.20 and 4.29 ppm to the methylene protons of the dioxaborinane ring which were shifted, as compared with **6a**, to a down field due to the phenyl substituent. The signals at 4.29 ppm appeared as a double doublet and at 4.20 ppm apparently as a triplet. The latter is expected to appear as a triplet by accidental superposition of a double doublet.

On the basis of the chemical shifts and the coupling constants observed for them the signal at 4.29 ppm is assigned to the equatorial hydrogens (H^e, $J_{H^e\text{-}H^a}$=11, $J_{H^e\text{-}H^c}$=5 Hz), and at 4.20 ppm to the axial ones (H^a, $J_{H^a\text{-}H^e}$=11, $J_{H^a\text{-}H^c}$=11 Hz) attached to the C4 and C6 of the dioxaborinane ring as shown in Fig. 4 and Table 5. Consequently observation of such the fine structure in the NMR spectra indicates that the half-chair conformation of the dioxaborinane ring is tightly fixed even in a solution. Moreover the spectra measured in 1,1,2,2-tetrachloroethane-d_2 at 125 °C showed the essentially same fine structure in which the geminal-geminal and geminal-axial proton couplings were observed, that is the rigidity of the ring is still kept at the

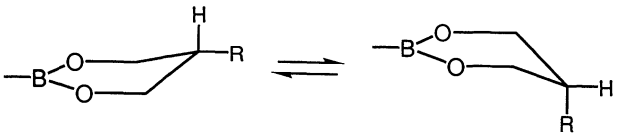

Scheme 1.

temperature where compound **1** forms a nematic phase.

On the other hand, compound **7**, which bears an alkoxyl group on 5-carbon of the dioxaborinane ring, showed a signal attributable to the methylene protons at 4.18 ppm as a doublet (J=4 Hz) and a siganal due to the methyne at 3.74 ppm as a triplet (J=4 Hz) in the NMR spectrum recorded at room temperature, and no geminal-geminal proton couplings were observed, indicating a rapid interconversion between two conformers within the NMR time scale for **7** in solution (Scheme 1). The similar phenomenon has recently been observed for a dioxane derivative.[14] When the alkoxyl group is replaced by an alkyl group, the dioxaborinane derivative **8**

clearly showed a geminal-geminal coupling (11 Hz). Though compound **8** exhibited smectic and nematic phases, **7** did no mesophases, strongly suggesting that the rigidity of the dioxaborinane ring is essential for the formation of mesophases.

In conclusion the rigid half-chair form of the dioxaborinane ring in crystalline state is kept in solution, thus suggesting a similar conformation in liquid crystalline state as well. Loss of the rididity does not lead to the formation of mesophases. The rigid dioxaborinane ring may constitute, in connection with phenyl nuclei, a suitable principal structure required for liquid crystalline compounds.

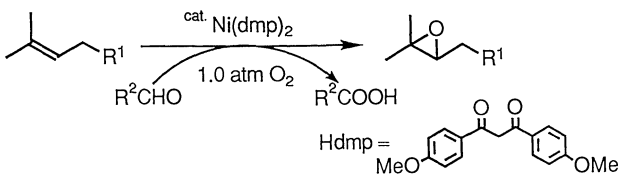
Direct Epoxidation of Olefins Catalyzed by Nickel(II) Complexes with Molecular Oxygen and Aldehydes

Tohru YAMADA,* Toshihiro TAKAI, Oliver RHODE, and Teruaki MUKAIYAMA†
Basic Research Laboratories for Organic Synthesis, Mitsui Petrochemical Industries, Ltd., Nagaura, Sodegaura-shi, Chiba 299-02
† Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received February 27, 1991)

In the presence of a bis(1,3-diketonato)nickel(II) complex, various olefins are directly monooxygenated into the corresponding epoxides on treatment with atmospheric pressure of oxygen or air and aldehydes. Especially, it is noted that bis[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato]nickel(II) behaves as an excellent catalyst in the present epoxidation.

Epoxides are one of the most useful synthetic intermediates for the preparation of oxygen-containing natural products or the production of epoxy resins, etc. Much effort has been made to develop the direct and selective epoxidation of olefins by use of molecular oxygen. However, it is difficult to control the reaction because of over-oxidations or side reactions under conventional severe reaction conditions, such as high pressure of oxygen or high reaction temperature. Then, it is desired to search milder reaction conditions to suppress these reactions for development of an efficient epoxidation method. Only several effective catalysts have been reported for the epoxidation with molecular oxygen under milder reaction conditions, for example, (tetramesitylporphinato)ruthenium(II),[1] or oxoethoxo(tetra-*p*-tolylporphinato)molybdenum(V).[2] We also reported that oxovanadium(IV) complexes[3] and nickel(II) complexes[4] coordinated with 1,3-diketone type ligands behave as fairly good catalysts when treated together with molecular oxygen (Oxidant) and primary or secondary alcohols (Reductant), and it was shown there that reductants are essential for the above catalytic epoxidation. Through our continued studies on the aerobic epoxidation of olefins catalyzed by nickel(II) complexes, it was found that an aldehyde acts as an excellent reductant when used with molecular oxygen at room temperature.[5]

Similar reactions have been reported in the literature. Propylene was monooxygenated into propylene oxide with molecular oxygen in the coexistence of metal complexes and aldehyde, such as acetaldehyde[6] or crotonaldehyde,[7] but the conversion of olefin and the selectivity of epoxide were never reached to satisfactory levels.



Scheme 1.

Recently, praseodymium(III) acetate was also shown to be an effective catalyst for the aerobic epoxidation of olefins in the presence of aldehyde.[8] In our previous communication, it was reported that both trisubstituted and *exo*-terminal olefins were smoothly monooxygenated into the corresponding epoxides in high to quantitative yields by combined use of atmospheric pressure of oxygen and aldehydes in the presence of catalytic amount of nickel(II) complexes.[5] However, the epoxidation of 1,2-disubstituted or terminal olefins stopped halfway, and conversions and yields were not reached satisfactory levels, because a part of aldehyde, being employed as a reductant, seemed to be consumed independently of the epoxidation.

Herein, we would like to discuss in detail the highly efficient method for epoxidation of various olefins catalyzed by nickel(II) complexes with molecular oxygen (Oxidant) and aldehydes (Reductant).

Results and Discussion

Epoxidation of Trisubstituted and *exo*-Terminal Olefins. First, several aldehydes, reductants, were screened by taking the epoxidation of 2-methyl-2-decene

(**1**) catalyzed by bis[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato]nickel(II) (Ni(dmp)$_2$, **3a**) as a model reaction. In the case of employing butyraldehyde, both conversion of olefin and yield of the epoxide were low (Entry 1 in Table 1), while the corresponding epoxide **2** was obtained in quantitative yields, respectively (Entries 2—4) when aldehydes having secondary or tertiary carbon next to the carbonyl carbon, such as isobutyraldehyde, cyclohexanecarbaldehyde or pivalaldehyde were employed. The reaction afforded the corresponding carboxylic acids, co-products as confirmed by GC analysis. Therefore, it is reasonable to assume that an aldehyde behaves as an effective reductant to accept one oxygen atom from molecular oxygen in the present epoxidation.

Next, several 1,3-diketone type ligands were examined for the epoxidation of 2-methyl-2-decene (**1**) using isobutyraldehyde under an atmospheric pressure of oxygen (see Table 2). It was found that nickel(II) complexes having 1,3-diketone type ligands behave as excellent catalysts for the present epoxidation of trisubstituted olefins (Entries 1—6, (**A**) **Standard Method**), while Ni(II)(salen) (**9b**)[9] or Ni(II)(dmg)$_2$ (**10b**)[10] is not effectively employed at all (Entries 7 and 8).

Epoxidation of 1,2-Disubstituted Olefins. According to the above procedure (**Method (A)**), the epoxidation of 1,2-disubstituted or terminal olefins was interrupted halfway, and the conversions and the yields were not reached satisfactory levels. Taking the epoxidation of *cis*-2-octene (**11**) as a model reaction, nickel(II) complexes having several 1,3-diketone type ligands were examined. As shown in Table 3, Ni(dmp)$_2$ (**3a**), Ni(mac)$_2$ (**4a**), and Ni(dpm)$_2$ (**7a**) behaved as efficient catalysts for the epoxidation of *cis*-2-octene (**11**) (Entries 2—4). On the contrary, Ni(acac)$_2$ (**8a**), which was an excellent catalyst for the epoxidation of trisubstituted olefin (Entry 6 in Table 2) or Ni(tfa)$_2$ (**13a**) was not effective for the epoxidation of 1,2-disubstituted olefin at all (Entries 1 and 2). Based on the measurements of the oxidation potentials of nickel(II) complexes,[4] it was suggested that Ni(dmp)$_2$ (**3a**, E_{ox} 1.14 V), Ni(mac)$_2$ (**4a**, E_{ox} 0.97 V), and Ni(dpm)$_2$ (**7a**, E_{ox} 1.05 V) would be more readily oxidized with molecular oxygen to form active species of the present epoxidation compared with Ni(acac)$_2$ (**8a**, E_{ox} 1.24 V) or Ni(tfa)$_2$ (**13a**, E_{ox} 1.89 V). Subsequently, the concentration of aldehyde or nickel(II) catalyst in the above reaction was examined in detail to improve yield of the epoxide **12** (see Table 4). In our previous letter,[11] it was reported that Ni(II) complexes, such as Ni(dmp)$_2$ (**3a**), are also employed as excellent

catalysts for the oxidation of aldehydes into the corresponding carboxylic acids in the absence of olefins. Therefore, it is reasonable to assume that a part of aldehyde was consumed to form carboxylic acid independent of epoxidation.

When 3.0 equivalent of isobutyraldehyde against olefin **11** was employed, both conversion and yield increased up to 89% and 77%, respectively, as expected (Entry 2 in Table 4). It was also found that the use of smaller amount of nickel(II) complex was effective to improve yield of the epoxide **12** (86%, Entry 3). Further, under highly diluted conditions, the corresponding epoxide **12** was obtained in 89% yield as a mixture of *cis*- and *trans*-epoxides. It is reasonable to assume that under highly diluted conditions, oxidation of aldehyde itself into the corresponding acid could be suppressed and then aldehyde would be effectively consumed for the epoxidation to improve both conversion of olefin and

yield of epoxide (**(B) Dilution Method**).

Epoxidation of Terminal Olefin. Next, when the present procedure (**Method B**) was applied to the epoxidation of terminal olefin, such as 1-decene (**13**), the corresponding epoxide **14** was obtained only in 42% yield (Entry 1 in Table 5). And then, several aldehydes were examined taking the above reaction as a model.

As shown in Table 5, it is interesting to note that normal aliphatic aldehydes were quite effective for the epoxidation of 1-decene (**13**) (Entries 3—6), whereas these aldehydes were less effective for the epoxidation of trisubstituted olefins (Entry 1 in Table 1). Especially, isovaleraldehyde was found to be remarkably effective for the epoxidation of 1-decene (**13**), and 1,2-epoxydecane (**14**) was obtained in 75% yield and 95% conversion (Entry 6, **(C) Isovaleraldehyde Method**).

Epoxidation of Various Olefins. The above procedures were successfully applied to the nickel(II)-catalyzed epoxidation of various trisubstituted or *exo*-terminal olefins, norbornene analogues, 1,2-disubstituted and terminal olefins.

According to the above procedure (**Method (A) Standard Method**), various trisubstituted or *exo*-terminal olefins and norbornene analogues were smoothly monooxygenated into the corresponding epoxides in high to quantitative yields under an atmospheric pressure of oxygen at room temperature as shown in Table 6. It was observed that epoxidation of isolated carbon–carbon double bonds was faster than that of allyl esters (Entries 4 and 5). It should be pointed out here that, in every case, no over-oxidation at allylic position nor cleavage reaction of carbon–carbon double bonds took place to any extent. *exo*-Terminal olefin **39** and styrene derivative **41** were also monooxidized into corresponding epoxides **40** and **42** in high yields, respectively (Entries 14 and 15). In the case of the epoxidation of trisubstituted olefin **1**, the corresponding epoxide **2** was obtained in quantitative yield even under air (Entry 2).

Various 1,2-disubstituted olefins were monooxygenated into the corresponding epoxides in high yields by **Method (B) (Dilution Method)**, and also in the case of terminal olefin by **Method (C) (Isovaleraldehyde Method)**, respectively (see Table 7).

As shown in Table 7, when **Method (B)** was applied to *cis*-olefin (*cis*-2-octene (**11**)) and *trans*-olefin (*trans*-2-octene (**43**)), the corresponding epoxides **12** and **44** were obtained in 97% and 92% yields, respectively, as mixture of *cis*- and *trans*-epoxides (Entries 1 and 2). It is noted

a) Reaction conditions; 2-Methyl-2-decene (**1**) 10.0 mmol, isobutyraldehyde 20.0 mmol, Ni(dmp)$_2$ **3a** 0.6 mg in 6.0 ml of 1,2-dichloroethane 1.0 atm of oxygen for 12 h. b) Determined by GC.

that cyclohexene (**47**) was also smoothly monooxygenated into 1,2-epoxycyclohexane (**48**) in high yield (Entry 4) accompanied by less than 5% yields of by-product, such as allylic oxidation product, 2-cyclohexen-1-ol or 2-cyclohexen-1-one. With regard to the epoxidation of terminal olefins, isovaleraldehyde was quite effective (**Method C**), and 1-decene (**13**) and 1-tetradecene (**49**) were converted into the corresponding 1,2-epoxyalkanes **14** and **50** in 75% and 89% yields, respectively (Entries 5 and 6).

Table 9. Stereochemistry in Epoxidation of *cis*-2-Octene (**11**)

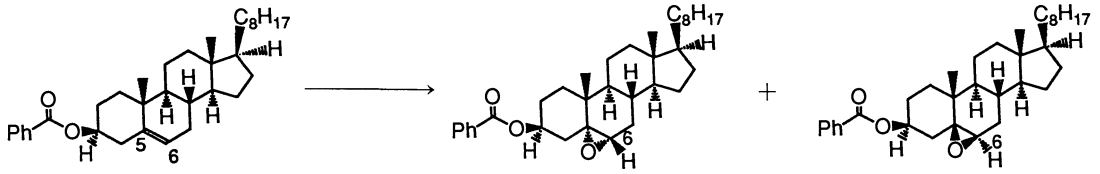
a) Determined by GC analysis. b) During the reaction, isomerization of *cis*-olefin into *trans*-olefin was not observed by GC analysis.

Efficiency of Nickel(II) Complex Catalyst. The efficiency of nickel(II) complexes in the present epoxidation was demonstrated by taking epoxidation of 2-methyl-2-decene (**1**) as a model reaction. Through three experiments carried out in the presence of 4.0 mol%, 0.256 mol%, and 0.0096 mol% of Ni(dmp)$_2$ (**3a**) against olefin **1**, respectively (see Table 8), it was found that, even in the case of employing only 0.0096 mol% of Ni(dmp)$_2$, the epoxidation proceeded smoothly and the corresponding epoxide **2** was obtained in 1020000% yield based on Ni(dmp)$_2$ (**3a**) (Entry 3).

Stereochemistry of the Present Epoxidation.

a) Epoxidation of *cis*-Olefin. According to the

Table 10. Stereoselective Epoxidation of Cholesteryl Benzoate(**55**) Catalyzed by Ni(dmp)$_2$ **3a**



55 — **56** α-Epoxide — **57** β-Epoxide

Entry	Epoxidation reagent	α-Epoxide **56**:β-Epoxide **57**[c]
1[a]	cat. Ni(dmp)$_2$ **3a**, O_2,	31:69
2[b]	 (*m*CPBA)	71:29
3[b]	 (MMPP)	85:15

Reaction Conditions: a) Cholesteryl Benzoate (**55**) 245 mg (0.5 mmol), isobutyraldehyde (2.0 mmol), catalyst (0.0047 mmol, 0.94 mol%) in 1,2-dichloroethane (5.0 ml), RT, 1.0 atm O_2, 2.0 h. b) Ref. 10. c) Determined by HPLC analysis.

present procedure, *cis*-olefin **11** was converted into a mixture of *cis*- and *trans*-epoxides (**12** and **44**), whereas *cis*-epoxide was formed predominantly when generally known peroxy acid such as *m*-chloroperbenzoic acid (*m*CPBA) was employed (see Table 9).

b) Epoxidation of Cholesterol Derivatives. Stereochemistry of the epoxidation of double bond on 5,6-position in cholesteryl benzoate (**55**) was examined by using $Ni(dmp)_2$ (**3a**) as a catalyst together with molecular oxygen and isobutyraldehyde (see Table 10). It was found that epoxidation catalyzed by nickel(II) complex afforded the *hindered* 5,6β-epoxide **57** as major product (Entry 1). On the contrary, it was reported that by using peroxy acids, such as *m*CPBA or magnesium monoperoxyphthalate hexahydrate (MMPP), cholesteryl benzoate was converted into the corresponding mixture of 5,6α- and 5,6β-epoxides in the ratio of 71:29 or 85:15 indicating that 5,6α-epoxide **56** is formed as a major product, respectively (Entries 2 and 3).[12] It is interesting to point out that the *less hindered* 5,6α-epoxide **56** was obtained as major product in above mentioned peracid epoxidation.[13]

Remarkably opposing stereoselection shown in the above two epoxidations clearly indicates that the active oxidant of the present nickel(II) complex-catalyzed epoxidation is not a simple peroxy carboxylic acid generated from aldehydes by autoxidation manner.

Conclusion

It is concluded that bis(1,3-diketonato)nickel(II) complexes effectively catalyzes the epoxidation of various olefins with an atmospheric pressure of oxygen (Oxidant) and an aldehyde (Reductant) at room temperature to afford the corresponding epoxides in high to quantitative yields. It was shown that $Ni(dmp)_2$ (**3a**) is an effective catalyst, and when $Ni(dmp)_2$ (**3a**) as employed as a catalyst, the epoxide was obtained in more than 1000000% yield based on the catalyst. Further, it is suggested that the active species in the present epoxidation reaction is not a simple carboxylic peracid generated from aldehyde by autoxidation manner. The present procedure thus provides a highly efficient and useful method for the preparation of a variety of epoxides from trisubstituted, 1,2-disubstituted and terminal olefins under mild conditions.

Experimental

General: Melting points were measured on a Mettler FP62 apparatus and uncorrected.

(a) Spectrometers: IR spectra were obtained by using a JASCO Model IR-700 infrared spectrometer on KBr pellets or liquid film on KBr. ^1H NMR spectra were recorded with a JEOL Model FX270 spectrometer using $CDCl_3$ as solvent and with tetramethylsilane as internal standard.

(b) Chromatography: Column chromatography was conducted under silica gel (Daiso gel IR-60). Preparative TLC was carried out on silica gel (E. Merck, 5714). HPLC analysis were performed on a Shimadzu LC-6A chromatograph using a Shimadzu Shimpack-Sil, and the peak area were calculated on a Shimadzu chromatopack CR-4A. GC-analyses were performed on a Shimadzu GC-15A or GC-14A chromatograph using a glass capirally column (Shimadzu CBP-10, 25 m), and the peak areas were obtained with a Shimadzu chromatopack CR-5A.

(c) Cyclic Voltammetry: All cyclic voltammograms were recorded with a BAS Model CV1B-120 in acetonitrile solution containing 0.1 M (M=mol dm^{-3}) tetrabutylammonium perchlorate (TBAP) and 0.001 M nickel(II) complex. The working and auxiliary electrodes were platinum and the reference electrode was Ag/AgCl (Model RE-1B). Tetrabutylammonium perchlorate and acetonitrile (HPLC-grade) were purchased from TCI (Tokyo Kasei Kogyo, Inc) and Kanto Chemical Co. Ltd., respectively.

Preparation of 1,3-Diketones and Bis(1,3-diketonato)nickel-(II) Complexes. Bis(acetylacetonato)nickel(II) (**8a**, $Ni(acac)_2$) and bis(1,1,1-trifluoro-2,4-pentanedinonato)nickel(II) (**13a**, $Ni(tfa)_2$) were purchased from TCI Co., Ltd. Bis(3-methyl-2,4-pentanedionato)nickel(II) (**4a**, $Ni(mac)_2$),[16] bis-(2,2,6,6-tetramethyl-3,5-heptanedionato)nickel(II) (bis(dipivaloylmethanato)nickel(II), **7a**, $Ni(dpm)_2$),[16] bis(2-acetylcyclopentanonato)nickel(II) (**5a**, $Ni(acp)_2$),[16] and bis(3-phenyl-2,4-pentanedionato)nickel(II) (**6a**, $Ni(pac)_2$)[16] were prepared according to the reported methods, respectively, and the ligands were purchased from TCI Co., Ltd. (**5b** and **7b**), Dojindo laboratories (**6b**), and Aldrich Chemical Company, Inc. (**4b**), respectively.

1,3-Bis(*p*-methoxyphenyl)-1,3-propanedione (3b, Hdmp):[15,17] A refluxing suspension of sodium hydride (0.39 mol) in cyclohexane (400 ml), a solution of *p*-methoxyacetophenone (0.33 mol) and ethyl *p*-methoxybenzoate (0.33 mol) in cyclohexane (200 ml) was added over 1 h, and reflux was continued for another 2 h. After cooling, reaction was quenched with 1.0 mol dm^{-3} aqueous HCl, then crude product was extracted with THF–Et_2O. The organic extract was washed with brine, and dried over anhydrous sodium sulfate, then solvent was removed in vacuo. Recrystallization from hexane–ethyl acetate gave slightly colored needle (58% yield). Mp 131—138 °C; ^1H NMR ($CDCl_3$) δ=3.90 (6H, s), 6.80 (1H, s), 7.00 (4H, m), 7.95 (4H, m); IR(KBr) 2938, 2840, 1687, 1605, 1507, 1429, 1305, 1263, 1230, 1170 cm^{-1}.

Bis[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato] nickel-(II) (3a):[15] A vigorously stirred mixture of Hdmp (0.1 mol) in ether (300 ml), a solution of nickel(II) acetate (0.05 mol) in 10% aqueous ammonia (800 ml) was added in one portion. Precipitated pale green solid was filtered and washed with water. After dried in vacuo for 6 h (110 °C/0.1 mmHg, 1 mmHg= 133.322 Pa), $Ni(dmp)_2$ was yielded as yellow solid. Found: C, 65.45; H, 4.87%. Calcd for $C_{34}H_{30}O_8Ni$: C, 65.31; H, 4.84%.

Bis(3-methyl-2,4-pentanedionato)nickel(II) (4a):[14,16] To the stirred mixture of nickel(II) acetate (0.1 mol) in water (150 ml), 3-methyl-2,4-pentanedione (Hmac, 0.2 mol) in methanol (5 ml) was added. After stirring for 5 min, aqueous sodium acetate (0.2 mol) in water (10 ml) was added over 10 min. Precipitated yellowish green solid was filtered and washed with water. After drying in vacuo for 6 h (90 °C/ 0.1 mmHg), $Ni(mac)_2$ was yielded as purple solid.

Melting Points and IR Spectra of Nickel(II) Complexes. Bis[1,3-bis(*p*-dimethoxyphenyl)-1,3-propanedionato]nickel-(II) (3a, $Ni(dmp)_2$): Yellow solid; mp 279—284 °C; IR (KBr)

2932, 2834, 1604, 1529, 1492, 1431, 1391, 1304, 1256, 1227, 1174 cm^{-1}.

Bis(3-methyl-2,4-pentanedionato)nickel(II) (4a, Ni(mac)$_2$): Purple solid; mp 180 °C (decomp); IR (KBr) 2920, 1599. 1570, 1424, 1388 cm^{-1}.

Bis(2,2,6,6-tetramethyl-3,5-heptanedionato)nickel(II) (bis-(dipivaloylmethanato)nickel(II), 7a, Ni(dpm)$_2$): Purple solid; mp 221—223 °C; IR (KBr) 2956, 1570, 1542, 1502, 1401, 1360 cm^{-1}.

Bis(2-acetylcyclopentanonato)nickel(II) (5a, Ni(acp)$_2$): Light green solid; mp >250 °C (decomp); IR (KBr) 2950, 1602, 1478, 1401, 1272 cm^{-1}.

Bis(3-phenyl-2,4-pentanedionato)nickel(II) (6a, Ni(pac)$_2$): Purple solid; mp 204—207 °C; IR (KBr) 2922, 1583, 1420, 1377, 1301 cm^{-1}.

Epoxidation of 1,5-Dimethyl-4-hexenyl Benzoate (27) (Method (A), Standard Method, see Entry 8 in Table 6). A mixture of olefin (3.0 mmol), Ni(dmp)$_2$ (40.0 mg, 0.064 mmol, 2.1 mol%) an isobutyraldehyde (6.25 mmol) in 1,2-dichloroethane(2.0 ml)[3,4] was stirred at room temperature under an atmospheric pressure of oxygen overnight. The crude product was purified by column chromatography on silica gel (hexane–ethyl acetate) to afford the corresponding epoxide[7] (713.0 mg, 95% yield).

Epoxidation of *trans*-4-Phenyl-2-butene (45) (Method (B), Dilution Method, see Entry 3 in Table 7). A mixture of olefin (2.0 mmol), Ni(dmp)$_2$ (4.0 mg, 0.006 mmol, 0.3 mol%) and isobutyraldehyde (6.0 mmol) in 1,2-dichloroethane (10.0 ml)[3,4] was stirred at room temperature under an atmospheric pressure of oxygen overnight. After the reaction, organic layer was washed with sat. $NaHCO_3$ and brine. Purification with TLC on silica gel to afford the corresponding epoxide (223 mg, 75% yield).

Epoxidation of 1-Tetradecene (49) (Method (C), Isovaleraldehyde Method, see Entry 6 in Table 7). A mixture of olefin (10.0 mmol), Ni(dmp)$_2$ (12.0 mg, 0.019 mmol, 0.19 mol%) and isovaleraldehyde (60.0 mmol) in 1,2-dichloroethane (30 ml)[3,4] was stirred at room temperature under an atmospheric pressure of oxygen for 47 h. After the reaction, organic layer was washed with sat.$NaHCO_3$ (4 times) and brine. Purification with silica-gel column chromatography afforded the corresponding epoxide (1.89 g, 89.2% yield).

^{1}H NMR and IR Spectra of the Epoxides (in Table 6 and Table 7). **1,2-Epoxydecane (14), *exo*-2,3-Epoxybicyclo[2.2.1]-heptane (34), 1,2-Epoxycyclohexane (48).** ^{1}H NMR spectra, IR spectra, and retention time in GC analysis agreed with those of the authentic sample.

Synthesis of Optically Active Substituted Cyclohexenones from Carbohydrates by Catalytic Ferrier Rearrangement

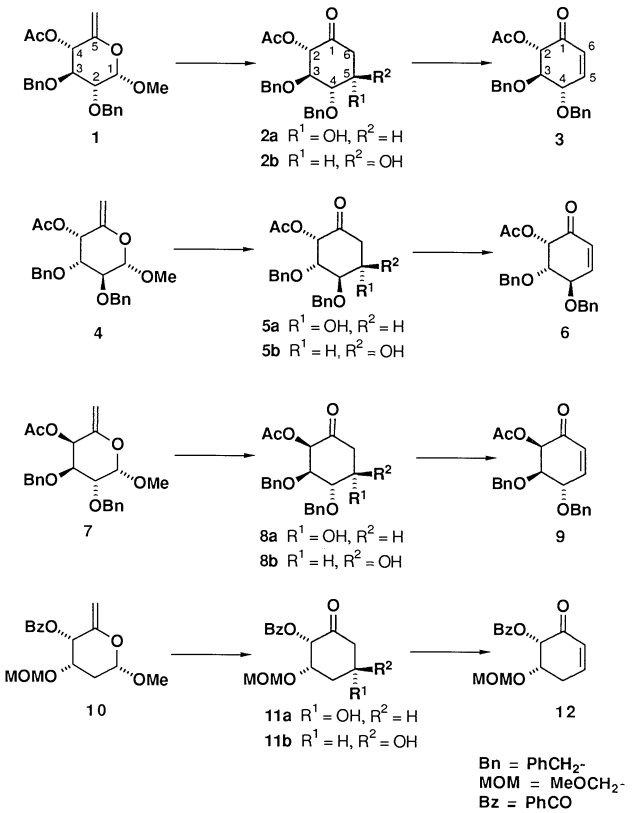
Noritaka CHIDA, Masami OHTSUKA, Katsuyuki OGURA, and Seiichiro OGAWA*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received March 6, 1991)

Conversion of hex-5-enopyranosides into substituted cyclohexanones (Ferrier rearrangement) was found to proceed efficiently with a catalytic amount of various mercury(II) salts at room temperature in a neutral solvent system. Among the mercury(II) salts tested, mercury(II) trifluoroacetate showed the highest activity. Four optically active cyclohexenones were prepared from hex-5-enopyranosides utilizing this method.

In 1979, Ferrier disclosed the efficient synthesis of chiral substituted cyclohexanones (2-deoxyinsoses) from hex-5-enopyranosides by the action of stoichiometric amount of mercury(II) chloride in hot aqueous acetone.[1] After this discovery, many reports concerning the mechanistic study,[2] application for syntheses of natural products,[3-8] and improved reaction conditions[5,9,10] have appeared so far. Lukacs and co-workers have reported that the Ferrier rearrangement proceeds with a catalytic amount (2 mol%) of mercury(II) sulfate in aqueous 1,4-dioxane containing sulfuric acid.[11] Recently, Adam has reported $PdCl_2$ or $Pd(OAc)_2$ also catalyzes conversion of hex-5-enopyranoside with an amino function at C-2 into 4-amino-2,4-dideoxyinososе in the solvent containing sulfuric acid.[12] Although this reaction is very useful and convenient for preparations of optically active cyclohexanones and/or cyclohexenones, sometimes difficulty is encountered in isolating the pure products due to the presence of excess Hg salts,[10] or in suppressing side reactions which might be caused by the acidic reaction conditions.[11,13]

During our study for the synthesis of natural products containing cyclohexane rings utilizing the Ferrier rearrangement,[14] we have investigated milder and simpler reaction conditions to avoid undesired side reactions such as β-elimination and aromatization. We report here our findings that the Ferrier rearrangement proceeds in high yields with a catalytic amount of various Hg(II) salts at room temperature in the neutral solvent system (acetone–water, without sulfuric acid), and the preparation of optically active cyclohexanones and cyclohexenones using this methodology.

The results of the catalytic Ferrier rearrangement of several hex-5-enopyranosides are shown in Table 1.

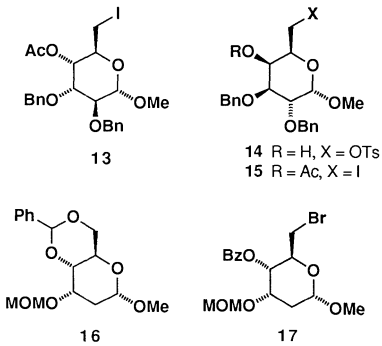


Scheme 1.

Table 1. Catalytic Ferrier Rearrangement of Some Hex-5-enopyranosides[a]

Run	Enopyranoside	Catalyst mol%	Time h	Products	Yield %	a/b[b]
1	**1**	$HgCl_2$ (10)	72	**2a, 2b**	97	6/1
2	**1**	HgO (10)	180	**2a, 2b**	94	6/1
3	**1**	$Hg(OAc)_2$ (10)	72	**2a, 2b**	96	8/1
4	**1**	$Hg(OCOCF_3)_2$ (10)	6	**2a, 2b**	96	8/1
5	**1**	$Hg(OCOCF_3)_2$ (5)	15	**2a, 2b**	96	8/1
6	**4**	$Hg(OCOCF_3)_2$ (10)	1	**5a, 5b**	79	1/4
7	**7**	$Hg(OCOCF_3)_2$ (10)	5	**8a, 8b**	91	4/1
8	**10**	$Hg(OCOCF_3)_2$ (10)	1.5	**11a, 11b**	86	1/19

a) All reactions were carried out at room temperature. b) Determined with 270 MHz ^{1}H NMR spectra.



Scheme 2.

Although reactions of methyl 4-*O*-acetyl-2,3-di-*O*-benzyl-α-D-*xylo*-5-enopyranoside (**1**)[7] with 10 mol% of $HgCl_2$, HgO, and $Hg(OAc)_2$ in acetone–water (2 : 1) at room temperature were sluggish, they afforded the cyclized products (**2a**) and (**2b**)[7] in high yields (Runs 1—3). On the other hand, use of $(CF_3CO_2)_2Hg$[15] as the catalyst (5 or 10 mol%) accelerated the reaction and gave (**2a**) and (**2b**) in high yield as well as in much shorter time (Runs 4 and 5). Reaction of hex-5-enopyranosides having D-*arabino* configuration (**4**, Run 6), prepared from compound **13** in one step, with 10 mol% of $(CF_3CO_2)_2Hg$ at room temperature also provided the corresponding cyclohexanones (**5a** and **5b**) in 79% yield. Similar reaction of compounds **7** possessing L-*arabino* configuration (Run 7), synthesized from compound **14** in 3 steps, afforded the products (**8a** and **8b**) which were enantiomers of **5b** and **5a**, in 91% yield. Treatment of 2-deoxy-D-*erythro*-hex-5-enopyranoside derivative (**10**, Run 8), obtained from compound **16** in 2 steps via compound **17**, under the same reaction condition gave the desired products (**11a** and **11b**).

These β-hydroxycylohexanones, (**2a**, **2b**), (**5a**, **5b**), (**8a**, **8b**), and (**11a**, **11b**) were effectively converted into the corresponding cyclohexenones (**3**,[16] **6**, **9**, and **12**) by the action of methanesulfonyl chloride and triethylamine in moderate-to-good yields, respectively. The compounds thus obtained would be useful precursors for syntheses of optically active cyclitols, aminocyclitols, and other natural products.

Therefore, use of $(CF_3CO_2)_2Hg$ as the catalyst is found to be very effective for the Ferrier rearrangement. The mild reaction conditions as well as the short reaction time using a small amount (5—10 mol%) of $(CF_3CO_2)_2Hg$ should allow us to apply this reaction to the synthesis of complex natural products having acid labile functions. Use of the catalytic amount of mercury(II) salt also makes the work-up procedure of this reaction quite easy.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. ^1H NMR spectra were taken on JEOL GX 270 (270 MHz) or JEOL EX 90 (90 MHz) spectrometers in chloroform-*d* with tetramethylsilane as an internal standard. Specific rotations were measured in a 0.1 dm tube with a JASCO DIP-370 Digital Polarimeter. Mass spectra were taken on a JEOL JMS-DX 302 spectrometer with EI (70 eV) mode. IR spectra were recorded with a JASCO IR-810 spectrometer.

Organic solutions were dried over anhydrous sodium sulfate and concentrated below 40 °C under reduced pressure.

General Procedure for Catalytic Ferrier Rearrangement: To a stirred mixture of hex-5-enopyranoside (**1**, **4**, **7**, and **10**; 1 mmol) in acetone–water (2:1, 10 ml) at room temperature was added Hg(II) salt (0.05 or 0.1 mmol) and the mixture was stirred at room temperature for the period indicated in Table 1. The mixture was partially evaporated to remove acetone and extracted with ethyl acetate, and the extract was dried. Removal of the solvent left a residue, which was purified on a column of silica gel (ethyl acetate–toluene) to afford the products.

2L-(2,4,5/3)- and 2L-(2,4/3,5)-2-*O*-Acetyl-3,4-di-*O*-benzyl-2,3,4,5-tetrahydroxycyclohexanone (2a) and (2b). Treatment of methyl 4-*O*-acetyl-2,3-di-*O*-benzyl-α-D-*xylo*-5-enopyranoside (**1**)[7] (398 mg) with mercury(II) trifluoroacetate (43 mg) in acetone–water afforded 370 mg (96%) of a mixture of **2a** and **2b** (8:1): $[\alpha]_D^{27}$ −24° (*c* 2.2, $CHCl_3$). The ^1H NMR data for the major isomer (**2a**) were identical with those reported in the literature.[7]

2L-(2,4/3)-2-*O*-Acetyl-3,4-di-*O*-benzyl-2,3,4-trihydroxy-5-cyclohexen-1-one (3). A mixture of **2a** and **2b** (8:1, 161 mg) was converted into compound **3** by the same procedure reported in the reference[14] to give 140 mg (91%) of **3** as a colorless syrup. The physical and spectral properties were all identical with those of the authentic sample.[14]

Methyl 4-*O*-Acetyl-2,3-di-*O*-benzyl-α-D-*arabino*-5-enopyranoside (4). A mixture of **13** (530 mg) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU, 0.30 ml) in toluene (6 ml) was heated at 80 °C for 3 h. The mixture was diluted with ethyl acetate and washed successively with diluted hydrochloric acid solution, saturated aqueous sodium hydrogencarbonate solution and brine, and dried. Evaporation of the solvent left a residue, which was purified on a column of silica gel (10 g) with acetone–hexane (1:6) to give 364 mg (91%) of compound **4** as a colorless syrup. $[\alpha]_D^{27}$+21° (*c* 0.25, $CHCl_3$); IR (neat) 1740 and 1660 cm^{-1}; ^1H NMR (270 MHz) δ=2.12 (3H, s, OAc), 3.60 (3H, s, OMe), 3.64 (1H, dd, $J_{2,3}$=9.2 Hz, $J_{3,4}$=3.3 Hz, H-3), 3.78 (1H, dd, $J_{1,2}$=6.2 Hz, H-2), 4.45 (1H, d, H-1), 4.58 (1H, d, *J*=11.7 Hz, benzyl), 4.67 (1H, bs, H-6), 4.70 (1H, d, *J*=11.7 Hz, benzyl), 4.73 (1H, d, *J*=11.0 Hz, benzyl), 4.80 (1H, bs, H-6′), 4.82 (1H, d, *J*=11.0 Hz, benzyl), 5.73 (1H, d, H-4), and 7.26—7.36 (10H, m, phenyl). Found: *m*/*z* 399.1808 ($M+H^+$). Calcd for $C_{23}H_{27}O_6$: 399.1808 (M+H).

2L-(2,3,5/4)- and 2L-(2,3/4,5)-2-*O*-Acetyl-3,4-di-*O*-benzyl-2,3,4,5-tetrahydroxycyclohexanone (5a) and (5b). Treatment of compound **4** (398 mg) with mercury(II) trifluoroacetate (43 mg) in acetone–water gave 303 mg (79%) of a mixture of **5a** and **5b** (1:4) as a colorless syrup. $[\alpha]_D^{27}$ −37° (*c* 0.95, $CHCl_3$); IR (neat) 3450 and 1750 cm^{-1}; ^1H NMR (270 MHz) for the major isomer (**5b**) δ=2.19 (3H, s, OAc), 2.20—2.30 (1H, m, H-6), 2.71—2.75 (2H, m, H-6′ and OH), 3.90 (1H, dd, $J_{3,4}$=4.0 Hz, $J_{4,5}$=3.7 Hz, H-4), 4.09 (1H, dd, $J_{2,3}$=3.3 Hz, H-3), 4.20—4.40 (1H, m, H-5), 4.51 and 4.60 (each 1H, 2d, *J*=12 Hz, benzyl), 4.70 (2H, d, *J*=12 Hz, benzyl), 5.60 (1H, d, H-2), and 7.30—7.35

(10H, m, phenyl). Found: m/z 384.1585 (M^+). Calcd for $C_{22}H_{24}O_6$: M, 384.1573.

2L-(2,3/4)-2-*O*-Acetyl-3,4-di-*O*-benzyl-2,3,4-trihydroxy-5-cyclohexen-1-one (6). To a solution of a mixture of **5a** and **5b** (1:4, 39 mg) in dichloromethane (1.5 ml) were added triethylamine (0.15 ml) and methanesulfonyl chloride (0.023 ml). After stirring at room temperature for 15 min, the mixture was diluted with dichloromethane and washed successively with 0.25 mol dm^{-3} aqueous sulfuric acid and water, and dried. Evaporation of the solvent left a syrup, which was purified on a column of silica gel (1 g) with ethyl acetate–toluene (1:15) to afford **6** (29 mg, 79%) as a colorless syrup. $[\alpha]_D^{27}$ −92° (c 1.36, $CHCl_3$); IR (neat) 1750 and 1700 cm^{-1}; ^{1}H NMR (270 MHz) δ=2.19 (3H, s, OAc), 4.12—4.18 (2H, m, H-3 and 4), 4.55, 4.57, 4.64, and 4.70 (each 1H, 4d, J=12.1 Hz, benzyl), 5.84 (1H, d, $J_{5,6}$=2.6 Hz, H-6), 6.10 (1H, d, $J_{2,3}$=10.3 Hz, H-2), 6.74 (1H, ddd, $J_{3,4}$=4.6 Hz, $J_{3,5}$=1.8 Hz H-5), and 7.29—7.33 (10H, m, phenyl). Found: C, 72.07; H, 6.11%. Calcd for $C_{22}H_{22}O_5$: C, 72.12; H, 6.05%.

Methyl 4-*O*-Acetyl-2,3-di-*O*-benzyl-6-deoxy-β-L-*arabino*-hex-5-enopyranoside (7). A mixture of **15** (31 mg) and DBU (0.035 ml) in toluene (1 ml) was heated at 80 °C for 2 d. The mixture was worked up similarly as described for a preparation of compound **4** to give **7** (13 mg, 57%) as a colorless syrup. $[\alpha]_D^{27}$ +28° (c 0.79, $CHCl_3$); IR (neat) 1740 and 1660 cm^{-1}; ^{1}H NMR (270 MHz) δ=2.10 (3H, s, OAc), 3.42 (3H, s, OMe), 3.94 (1H, dd, $J_{1,2}$=3.3 Hz, $J_{2,3}$=9.9 Hz, H-2), 4.06 (1H, dd, $J_{3,4}$=3.7 Hz, H-3), 4.61 (1H, d, J=11.7 Hz, benzyl), 4.68 and 4.71 (each 1H, 2d, J=9.2 Hz, benzyl), 4.72 (2H, bs, H-6 and 6′), 4.75 (1H, d, H-1), 4.87 (1H, d, J=11.7 Hz, benzyl), 5.80 (1H, d, H-4), and 7.33 (10H, m, phenyl). Found: C, 69.17; H, 6.61%. Calcd for $C_{23}H_{26}O_6$: C, 69.33; H, 6.58%.

2D-(2,3/4,5)- and 2D-(2,3,5/4)-2-*O*-Acetyl-3,4-di-*O*-benzyl-2,3,4,5-tetrahydroxycyclohexanone (8a) and (8b). Treatment of compound **7** (398 mg) with mercury(II) trifluoroacetate (43 mg) in acetone–water gave 349 mg (91%) of a mixture of **8a** and **8b** (4:1) as a colorless syrup: $[\alpha]_D^{28}$ +45° (c 0.48, $CHCl_3$). The IR and ^{1}H NMR spectra were identical with those of compound **5b** and **5a**. Found: C, 69.02; H, 6.49%. Calcd for $C_{22}H_{24}O_6$: C, 68.74; H, 6.29%.

2D-(2,3/4)-2-*O*-Acetyl-3,4-di-*O*-benzyl-2,3,4-trihydroxy-5-cyclohexen-1-one (9). A mixture of **8a** and **8b** (4:1, 14 mg) was treated similarly as described for a preparation of compound **6** to afford **9** (9.6 mg, 71%) as a colorless syrup. $[\alpha]_D^{27}$ +91° (c 0.48, $CHCl_3$). The IR and ^{1}H NMR spectra of **9** were all identical with those of compound **6**. Found: C, 71.79; H, 6.07%. Calcd for $C_{22}H_{22}O_5$: C, 72.12; H, 6.05%.

Methyl 4-*O*-Benzoyl-2,6-dideoxy-3-*O*-methoxymethyl-α-D-*erythro*-hex-5-enopyranoside (10). A mixture of **17** (522 mg) and DBU (0.50 ml) in toluene (15 ml) was heated at 90 °C for 8 h. The mixture was worked up similarly as described for a preparation of compound **4** to afford **10** (378 mg, 91%) as a colorless syrup. $[\alpha]_D^{29}$ +79° (c 0.73, $CHCl_3$); IR (neat) 1740 and 1670 cm^{-1}; ^{1}H NMR (270 MHz) δ=2.14—2.56 (2H, m, H-2 and 2′), 3.33 and 3.58 (each 3H, 2s, OMe), 4.06 (1H, ddd, $J_{2,3}$=4.8 Hz, $J_{2',3}$=9.5 Hz, $J_{3,4}$=3.5 Hz, H-3), 4.66 and 4.75 (each 1H, 2d, J=7.0 Hz, methylene), 4.68 (1H, dd, $J_{1,2}$=3.7 Hz, $J_{1,2'}$=10.6 Hz, H-1), 4.79 (1H, s, H-6), 4.83 (1H, bs, H-6′), 5.75 (1H, d, H-4), and 7.44—8.11 (5H, m, phenyl). Found: C, 62.46; H, 6.35%. Calcd for $C_{16}H_{20}O_6$: C, 62.33; H, 6.54%.

2L-(2,3,5/0)- and 2L-(2,3/5)-2-*O*-Benzoyl-3-*O*-methoxymethyl-2,3,5-trihydroxycyclohexanone (11a) and (11b). Treatment of compound **10** (308 mg) with mercury(II) trifluoroacetate (43 mg) in acetone–water gave 253 mg (86%) of a mixture of **11a** and **11b** (1:19) as a colorless syrup. $[\alpha]_D^{27}$ −37° (c 1.1, $CHCl_3$); IR (neat) 3450, 1750, and 1730 cm^{-1}; ^{1}H NMR (270 MHz) for the major isomer (**11b**) δ=2.02 (1H, ddd, $J_{3,4}$=2.2 Hz, $J_{4,5}$=11.2 Hz, $J_{4,4'}$=13.4 Hz, H-4), 2.14 (1H, b, OH), 2.54 (1H, m, H-4′), 2.60 (1H, dd, $J_{5,6}$=10.7 Hz, $J_{6,6'}$=13.7 Hz, H-6), 2.95 (1H, ddd, $J_{5,6'}$=4.9 Hz, $J_{4',6'}$=2.4 Hz, H-6′), 3.39 (3H, s, OMe), 4.36—4.47 (2H, m, H-3 and 5), 4.74 and 4.79 (each 1H, 2d, J=6.5 Hz, methylene), 5.52 (1H, d, $J_{2,3}$=2.9 Hz, H-2), and 7.43—8.08 (5H, m, phenyl). Found: m/z 294.1104 (M^+). Calcd for $C_{15}H_{18}O_6$: M, 294.1104.

2L-(2,3/0)-2-*O*-Benzoyl-3-*O*-methoxymethyl-2,3-dihydroxy-5-cyclohexen-1-one (12). To a mixture of **11a** and **11b** (1:19, 48 mg) in dichloromethane (2 ml) at 0 °C were added methanesulfonyl chloride (33 μl) and triethylamine (0.158 ml). After stirring at room temperature for 90 min, the reaction mixture was treated similarly as described for a preparation of compound **6** to afford **12** (43 mg, 95%) as a crystalline residue. Mp 118—119 °C (from ethanol); $[\alpha]_D^{25}$ −12° (c 0.97, $CHCl_3$); IR (KBr) 1730 and 1695 cm^{-1}; ^{1}H NMR (270 MHz) δ=2.86 (2H, m, H-4 and 4′), 3.35 (3H, s, OMe), 4.53 (1H, dddd, $J_{3,4}$=4.4 Hz, $J_{3,4'}$= 2.9 Hz $J_{2,3}$=2.6 Hz, $J_{3,5}$=1.8 Hz, H-3), 4.73 and 4.78 (each 1H, 2d, J=7.0 Hz, methylene), 5.76 (1H, d, H-2), 6.19 (1H, ddd, $J_{4,6}$=$J_{4',6}$=1.8 Hz, $J_{5,6}$=9.9 Hz, H-6), 6.86 (1H, dddd, $J_{4,5}$=$J_{4',5}$=4.3 Hz, H-5), and 7.46—8.12 (5H, m, phenyl). Found: C, 64.92; H, 5.87%. Calcd for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%.

Methyl 4-*O*-Acetyl-2,3-di-*O*-benzyl-6-deoxy-6-iodo-α-D-altropyranoside (13). To a solution of methyl 2,3-di-*O*-benzyl-6-deoxy-6-iodo-α-D-altropyranoside[14] (200 mg) in pyridine (1.5 ml) was added acetic anhydride (1.5 ml), and the mixture was stirred at room temperature overnight. The reaction mixture was concentrated and co-distilled with toluene several times to give a residue, which was purified on a column of silica gel (10 g) with acetone–toluene (1:40) to afford **13** (210 mg, 97%) as a colorless syrup. $[\alpha]_D^{27}$ +21° (c 0.25, $CHCl_3$); IR (neat) 1740 cm^{-1}; ^{1}H NMR (90 MHz) δ=2.02 (3H, s, OAc), 3.17 (1H, dd, $J_{5,6}$=9.8 Hz, $J_{6,6}$=13.0 Hz, H-6), 3.36 (1H, dd, $J_{5,6}$=4.0 Hz, H-6′), 3.49 (3H, s, OMe), 3.65 (1H, dd, $J_{1,2}$=2.5 Hz, $J_{2,3}$=5.2 Hz, H-2), 3.88 (1H, dd, $J_{3,4}$=4.0 Hz, H-3), 4.10 (1H, ddd, $J_{4,5}$=8.6 Hz, H-5), 4.42 and 4.59 (each 1H, 2d, J=12.0 Hz, benzyl), 4.57 (2H, s, benzyl), 4.68 (1H, d, H-1), 5.00 (1H, dd, H-4), and 7.20—7.43 (10H, m, phenyl). Found: m/z 527.0925 ($M+H^+$). Calcd for $C_{23}H_{28}O_6I$: 527.0931 (M+H).

Methyl 2,3-Di-*O*-benzyl-6-*O*-tosyl-α-D-galactopyranoside (14). A mixture of methyl 2,3-di-*O*-benzyl-α-D-galactopyranoside[17] (255 mg), *p*-toluenesulfonyl chloride (470 mg) and 4-dimethylaminopyridine (8 mg) in pyridine (4.5 ml) was stirred at room temperature for 16 h. The mixture was diluted with ethyl acetate and then washed successively with diluted hydrochloric acid and brine, and dried. Removal of the solvent gave a residue, which was purified on a column of silica gel (10 g) with ethyl acetate–toluene (1:5) to afford **14** (365 mg, 100%) as a colorless syrup. $[\alpha]_D^{24}$ +37° (c 1.9, $CHCl_3$); IR (neat) 3500 and 1360 cm^{-1}; ^{1}H NMR (90 MHz) δ=2.42 (3H, s, $PhC\underline{H}_3$), 3.32 (3H, s, OMe), 3.72—4.24 (6H, m, H-2,3,4,5,6 and 6′), 4.59 (1H, d, $J_{1,2}$=3.0 Hz, H-1), 4.60 and 4.63 (each 1H, 2d, J=12.0 Hz, benzyl), 4.80 (2H, d, J=12 Hz, benzyl), and 7.33—7.38 (14H, m, phenyl). Found: C, 63.39; H, 5.86%. Calcd for $C_{28}H_{32}O_8S$: C, 63.62; H, 6.10%.

Methyl 4-*O*-Acetyl-2,3-Di-*O*-benzyl-6-deoxy-6-iodo-α-D-

galactopyranoside (15). A mixture of **14** (202 mg) and sodium iodide (172 mg) in *N,N*-dimethylformamide (1 ml) was heated at 80 °C for 4 d. The mixture was diluted with ethyl acetate and washed with water, and dried. Evaporation of the solvent left a residue, which was then treated with acetic anhydride (1.8 ml) and pyridine (3.6 ml) at room temperature overnight. The mixture was concentrated and diluted with ethyl acetate, and washed successively with diluted hydrochloric acid, saturated aqueous sodium hydrogencarbonate solution and brine, and dried. Evaporation of the solvent gave a syrup, which was purified on a column of silica gel (4.2 g) with ethyl acetate–hexane (1:9) to afford **15** (139 mg, 70%) as a colorless syrup. $[\alpha]_D^{25}$ +65° (*c* 0.54, $CHCl_3$); IR (neat) 1740 cm^{-1}; ^1H NMR (270 MHz) δ=2.13 (3H, s, OAc), 3.11 (2H, m, H-6 and 6′), 3.46 (3H, s, OMe), 3.75 (1H, dd, $J_{1,2}$=3.7 Hz, $J_{2,3}$=9.9 Hz, H-2), 3.96 (1H, dd, $J_{3,4}$=4.0 Hz, H-3), 4.00 (1H, ddd, $J_{5,6}$=2.9 Hz, $J_{5,6'}$=8.1 Hz, $J_{4,5}$=1.8 Hz, H-5), 4.57 (1H, d, *J*=11.4 Hz, benzyl), 4.64 (1H, d, *J*=12.1 Hz, benzyl), 4.67 (1H, d, H-1), 4.73 (1H, d, *J*=11.4 Hz, benzyl), 4.84 (1H, d, *J*=12.1 Hz, benzyl), 5.59 (1H, dd, H-4), and 7.26—7.35 (10H, m, phenyl). Found: 526.0857 (M^+). Calcd for $C_{23}H_{27}O_6I$: M, 526.0853.

Methyl 4,6-*O*-Benzylidene-2-deoxy-3-*O*-methoxymethyl-α-D-ribopyranoside (16). A mixture of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-ribopyranoside[18] (1.00 g), chloromethyl methyl ether (0.57 ml) and *N,N*-diisopropylethylamine (2.62 ml) in dichloromethane (20 ml) was heated under reflux overnight. The mixture was diluted with dichloromethane and washed successively with diluted hydrochloric acid, saturated aqueous sodium hydrogencarbonate solution and brine, and dried. Concentration of the mixture afforded a residue, which was purified on a column of silica gel (30 g) with ethyl acetate–toluene (1:8) to give **16** (1.15 g, 86%) as needles. Mp 53—53.5 °C (from ether–petroleum ether); $[\alpha]_D^{27}$ +95° (*c* 1.0, $CHCl_3$); ^1H NMR (270 MHz) δ=2.00 (1H, ddd, $J_{1,2}$=4.4 Hz, $J_{2,3}$=4.0 Hz, $J_{2,2'}$=15.0 Hz, H-2), 2.19 (1H, ddd, $J_{1,2'}$=0.7 Hz, $J_{2',3}$=2.6 Hz, H-2′), 3.39 (6H, s, OMe), 3.65 (1H, dd, $J_{3,4}$=2.9 Hz, $J_{4,5}$=8.4 Hz, H-4), 3.70 (1H, dd, $J_{5,6}$=$J_{6,6'}$=12.1 Hz, H-6), 4.19 (1H, ddd, H-3), 4.26—4.37 (2H, m, H-5 and 6′), 4.71 (1H, dd, H-1), 4.76 and 4.85 (each 1H, 2d, *J*=7.0 Hz, methylene), 5.55 (1H, s, PhCH), and 7.31—7.56 (5H, m, phenyl). Found: C, 62.07; H, 6.96%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

Methyl 6-Bromo-4-*O*-benzoyl-2,6-dideoxy-3-*O*-methoxymethyl-α-D-ribopyranoside (17). A mixture of **16** (1.0 g), *N*-bromosuccinimide (599 mg), 1,1,2,2-tetrachloroethane (1.6 ml), and barium carbonate (332 mg) in carbon tetrachloride (20 ml) was heated at 90 °C for 4 h. After cooling, the insoluble matter was removed by filtration and washed with chloroform. The filtrate was concentrated to give a residue, which was dissolved in ethyl acetate and washed with water, and dried. Evaporation of the solvent left a residue, which was purified on a column of silica gel (80 g) with acetone–hexane (1:16) to afford **17** (1.13 g, 90%) as a colorless syrup. $[\alpha]_D^{27}$ +129° (*c* 1.5, $CHCl_3$); IR (neat) 1720 cm^{-1}; ^1H NMR (90 MHz) δ=1.87—2.40 (2H, m, H-2 and 2′), 3.24 and 3.46 (each 3H, 2s, OMe), 3.36—3.73 (2H, m, H-6 and 6′), 4.22—4.58 (2H, m, H-3 and 5), 4.57 and 4.73 (each 1H, 2d, *J*=7.0 Hz, methylene), 4.84 (1H, m, H-1), 5.02 (1H, dd, $J_{3,4}$=3.4 Hz, $J_{4,5}$=10.0 Hz, H-4), and 7.39—8.12 (5H, m, phenyl). Found: C, 49.60; H, 5.28%. Calcd for $C_{16}H_{21}O_6Br$: C, 49.37; H, 5.44%.

Asymmetric Reactions of Enamines with Methyl (*E*)-4-Oxo-4-(2-oxo-1,3-oxazolidin-3-yl)-2-butenoate by the Use of a Chiral Titanium Reagent

Yujiro HAYASHI, Ken OTAKA, Nobuo SAITO, and Koichi NARASAKA*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 6, 1991)

Asymmetric Michael and [2+2] cycloaddition reactions between enamines and methyl (*E*)-4-oxo-4-(2-oxo-1,3-oxazolidin-3-yl)-2-butenoate proceed with a chiral titanium reagent generated in situ from dichlorodiisopropoxytitanium and a tartrate-derived chiral 1,4-diol. In the presence of excess amounts of the chiral titanium reagent, good to moderate enantioselectivity is attained. The reactions are also well catalyzed even with a catalytic amount of the titanium reagent.

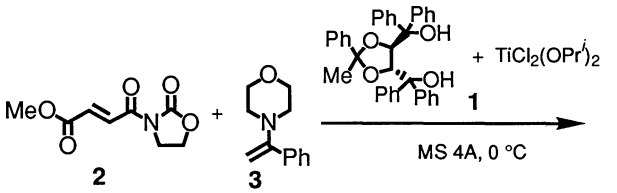
Michael reaction, one of the most versatile carbon–carbon bond forming reactions, is an indispensable tool in organic synthesis and the asymmetric version of this reaction has been intensively examined.[1] A variety of asymmetric Michael reactions have been devised by the use of chiral Michael acceptors or donors such as chiral enamines[2] or chiral vinyl sulfoxides.[3] Furthermore, in this decade, several good results have been reported on the enantioselective Michael reaction of prochiral substrates,[4] but only a few examples are known for the asymmetric Michael reactions by the use of a catalytic amount of chiral auxiliaries.[5]

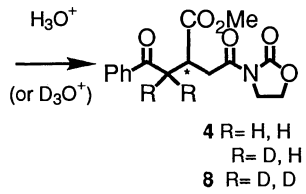
We have reported the preparation and properties of a chiral titanium reagent which is prepared in situ from dichlorodiisopropoxytitanium and optically active 1,1,4,4-tetraphenyl-2,3-(1-phenylethylidene)dioxy-1,4-butanediol (**1**) derived from dimethyl tartrate.[6] This reagent promotes the inter- and intra-molecular Diels–Alder reactions,[7] the [2+2] cycloaddition reaction,[8] the intramolecular ene reaction[9] and the hydrocyanation,[10] in which very high enantioselectivities are attained. For another application of this chiral titanium reagent, the Michael reaction of enamines[11] was investigated by employing the chiral titanium reagent as a reaction promoter.

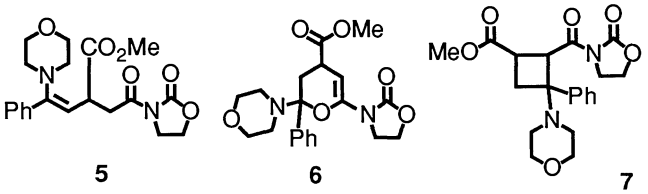
Results and Discussion

Methyl (*E*)-4-oxo-4-(2-oxo-1,3-oxazolidin-3-yl)-2-butenoate (**2**) which was a suitable dienophile in the above asymmetric Diels–Alder reaction[7a] was chosen as a Michael acceptor, and the reaction with enamines was examined in the presence of the chiral titanium reagent prepared by mixing dichlorodiisopropoxytitanium and the chiral (2*R*, 3*R*)-1,4-diol **1**. When **2** and 4-(1-phenylethenyl)morpholine (**3**) was treated with an equimolar amount of the chiral titanium reagent at 0 °C for 24 h in the presence of Molecular Sieves 4A (MS 4A) in CH_2Cl_2, the Michael adduct **4** was obtained in 61% yield in 22% ee after hydrolysis of the reaction mixture. The reference reaction of **2** and **3** without the Lewis acid proceeded very slowly under the same reaction conditions to give the product **4** in only 6% yield.

After screening the amino moiety of acetophenone enamines and the reaction solvents, **4** was found to be obtained in 51% yield with 58% ee when the morpholino enamine **3** reacted with **2** in ether in the presence of an equimolar amount of the titanium reagent. The enantioselectivity was further improved to 73% ee by the use of excess amounts (2 molar amounts) of the chiral titanium reagent (54% yield). Moreover, even by a catalytic use (20% molar amount) of the chiral titanium reagent, the reaction proceeded with slight loss of the optical purity (68% yield, 55% ee), which indicates that the catalyst is regenerated during the course of the reaction. The product before hydrolysis[12] is considered to be the enamine **5**,[12b] the dihydropyran **6**,[12c,d] or the cyclobutane derivative **7**.[12e,f]

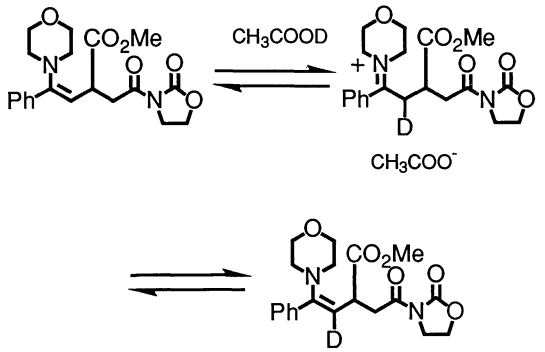




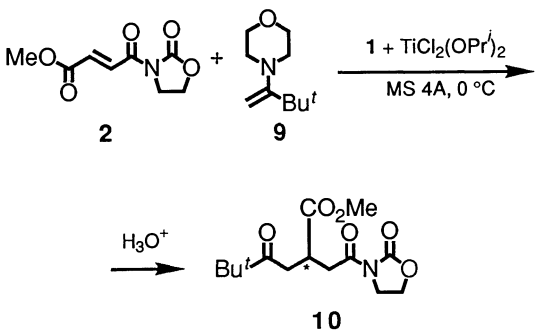


To determine which is the real intermediate, the reaction was quenched with D_2O–CH_3COOD. The Michael product was obtained in 30% yield, which consisted of d_0(**4**, 4%), d_1(24%), and d_2(**8**, 72%) deriva-

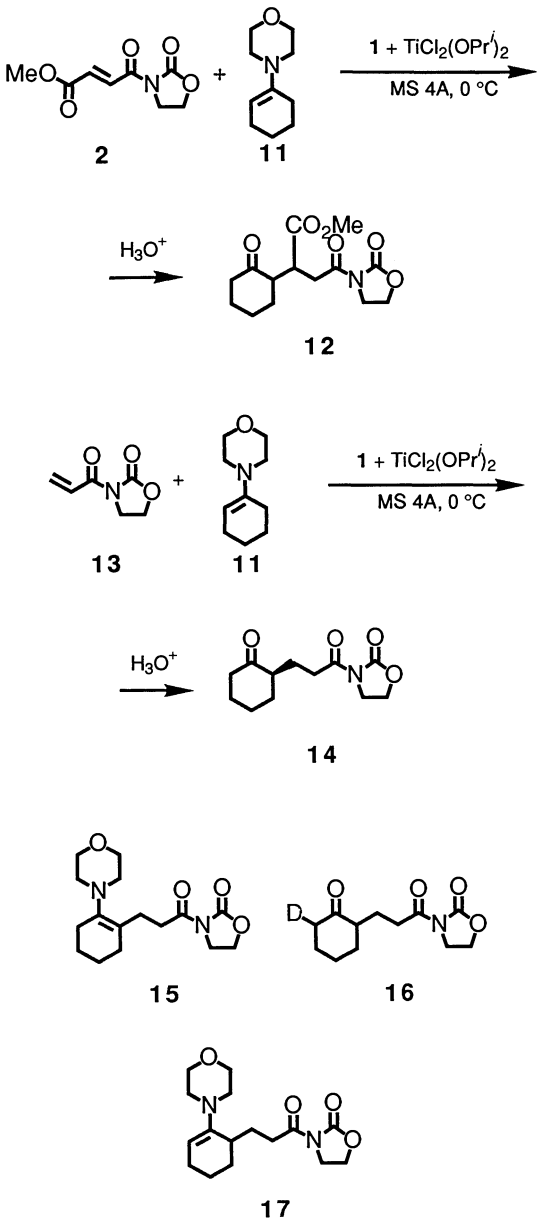
tives. The major d_2-product **8** is considered to be generated by the rapid equilibrium between the enamine and the iminium salt during the hydrolysis.[13] The selective deuteration at the α-position of the phenacyl group clearly indicates that the enamine **5** is the intermediate before hydrolysis.



The reaction of **2** and 4-(1-*t*-butylethenyl)morpholine (**9**) was also examined by varying the amount of the chiral titanium reagent. By the use of excess amount of the chiral Lewis acid, good enantioselectivity was attained (78% ee). And, in the cases of a catalytic and an equimolar use of the chiral titanium reagent, the adduct **10** was obtained with moderate optical purity (53 and 57% ee, respectively).

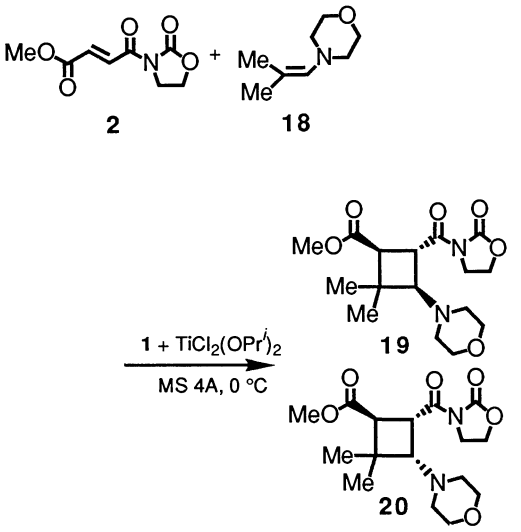


Morpholino enamine of cyclohexanone **11** also reacted in the presence of an equimolar amount of the chiral titanium reagent to afford the addition product **12** in 78% yield as a mixture of two diastereomers in a ratio of 2 : 1. Although the mixture exhibited optical rotation ($[\alpha]_D$ +17.8 (*c* 1.6, CH_2Cl_2)), the optical purity of each isomer could not be determined because of the difficulty of the separation. Accordingly, 3-acryloyl-1,3-oxazolidin-2-one (**13**), the product of which has a single chiral center, was employed as a Michael acceptor. When an ether solution of **11** and **13** was treated with an equimolar amount of the chiral reagent, the Michael product **14** was obtained in 38% yield as an optically active form (28% ee). The asymmetric induction at the chiral center is the clear evidence of the generation of a different type of intermediate from the former one **5** which should give the racemic product after hydrolysis. D_2O–CH_3COOD quenching of the reaction mixture afforded the 6-deuterated and nondeuterated cyclohexanone derivatives **16** and **14** in the ratio of 70 : 30, indicating the formation of the alternative enamine intermediate **17**. The present reaction using an enamine **11** with an α-substituent having a hydrogen is considered to proceed via the ene reaction or/and the Michael reaction followed by the successive proton transfer.[12b]

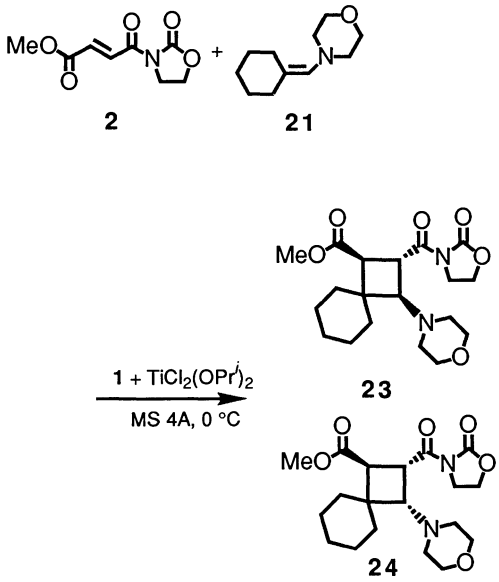


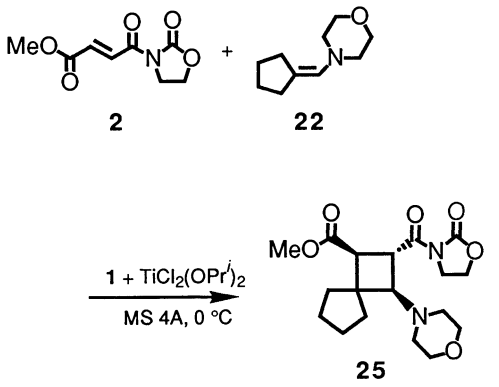
Contrary to the Michael reaction of the above enamines, the reactions of 2,2-disubstituted enamines with **2** were found to afford cyclobutanes. That is, 4-(2-methyl-1-propenyl)morpholine (**18**) reacted with **2** at 0 °C in ether by the use of an equimolar or a catalytic amount of the chiral titanium reagent to give the cyclobutane derivative **19** as a single stereoisomer in 86% and 78% yield with 53% ee and 56% ee, respectively, in which morpholino and oxazolidinylcarbonyl groups are

trans. By the usage of the excess amount of the catalyst, the *trans* isomer **19** was obtained in higher optical purity (48%, 77% ee), but a small amount (22%) of the *cis* isomer **20** was also isolated.



Since the reaction of the 2,2-disubstituted enamine **18** afforded the optically active cyclobutane, the preparation of optically active spiro compounds was next examined by employing enamines **21** and **22** prepared from cyclohexanecarbaldehyde and cyclopentanecarbaldehyde. The reactions were carried out with a catalytic amount (20% mol) of the chiral titanium reagent and the results are shown in the following equations. Two diastereomers **23** and **24** were obtained in the reaction of **21**. The optical purity of the *trans* and *cis* isomers **23**, **24** were found to be 69 and 64% ee, respectively. In the case of **22**, the *trans* isomer **25** was obtained exclusively in 71% yield with 38% ee.





Thus, in the chiral titanium catalyzed reaction, enamines react with unsaturated carboxylic acid derivatives **2** in various courses depending on their structures, which is almost the same tendency observed in the noncatalyzed reactions.[12b] As for the enantioselectivity, good asymmetric induction is attained by the use of excess amount of the chiral titanium reagent, and moderate enantioselectivity is observed in the reaction with a catalytic and an equimolar amount of the reagent. The absolute configurations of the adducts have not been determined except for **14**. In the Diels–Alder reaction[7] and the [2+2] cycloaddition reaction[8] using **2** and the chiral titanium reagent prepared from the (2*R*, 3*R*)-diol **1**, the *re*-face of the β-carbon of α,β-unsaturated acyl moiety is attacked without exception. The same sence of the enantioselection would be anticipated in these reactions with enamines.

Experimental

General. (a) NMR spectra were recorded on Hitachi R24B, and Bruker AM500 spectrometers using tetramethylsilane as the internal standard and $CDCl_3$ as a solvent. IR spectra were recorded on Hitachi 260-30 or Horiba FT-300S spectrometers. Optical rotations were measured with JASCO DIP-180 or DIP-370 digital polarimeters. Mass spectra were obtained with JEOL JMS-D300 mass spectrometer operating at 70 eV. Melting points were uncorrected.

(b) Chromatography: Flash column chromatography was conducted on silica gel (E. Merck, 7734, 70—230 mesh) and the medium pressure column chromatography was performed with the YFLC-254 system of Yamazen Corp. Preparative thin-layer chromatography (TLC) was carried out on silica gel (Wakogel B-5F).

(c) Solvents and Reagents: Toluene and petroleum ether were distilled and stored over Molecular Sieves 4A (MS 4A). Ether was freshly distilled from sodium diphenylketyl. Dichlorodiisopropoxytitanium was prepared from titanium(IV) chloride and titanium(IV) isopropoxide according to the literature method.[14] (2*R*, 3*R*)-1,1,4,4-Tetraphenyl-2,3-(1-phenylethylidene)dioxy-1,4-butanediol (**1**) was prepared according to the method in our previous paper.[7a] Methyl (*E*)-4-oxo-4-(2-oxo-1,3-oxazolidin-3-yl)-2-butenoate (**2**) and 3-acryloyl-1,3-oxazolidin-2-one (**13**) were prepared according to the procedure of Evans.[15] Enamines **3**,[16] **9**,[16] **11**,[17] **18**,[18] **21**,[19] and **22**[19] were prepared according to the methods in the

literatures. All the operations were performed under an argon atmosphere.

Typical Procedure for the Reaction of 2 and Enamines Using a Catalytic Amount of the Chiral Titanium Catalyst. To an ether solution (3 ml) of dichlorodiisopropoxytitanium (30.9 mg, 0.13 mmol) was added the chiral diol **1** (74.5 mg, 0.14 mmol) at room temperature. After stirring for 20 min, MS 4A (powder, 100 mg) was added and the mixture was cooled to 0 °C. Then **2** (129.6 mg, 0.65 mmol) and an ether solution (1.5 ml) of 4-(1-phenylethenyl)morpholine (**3**) (135.0 mg, 0.71 mmol) was added, and the reaction mixture was stirred for 24 h at 0 °C. The reaction was quenched with pH 7 phosphate buffer and inorganic materials were removed by filtration. The organic materials were extracted three times with ethyl acetate and the combined extracts were washed with brine and dried over anhydrous Na_2SO_4. After evaporation of the solvent, the crude product was purified by preparative TLC (hexane : ethyl acetate, 1 : 1) to afford the Michael product **4** (140.9 mg, 0.44 mmol, 68% yield).

The procedure of the reactions using one or two equimolar amounts of the chiral titanium catalyst was identical with that described above, excepting the amount of the catalyst. Reaction conditions, chemical and optical yields are summarized in Table 1.

Spectral data and physical properties of the adducts and the determination of the optical purities were as follws.

Methyl (*R*)-2-Phenacyl-4-oxo-4-(2-oxo-1,3-oxazolidin-3-yl)butyrate (4). IR (neat) 1775, 1725, 1680 cm^{-1}; ^1H NMR (500 MHz) δ=3.20—3.27 (m, 2H), 3.42 (dd, J=7.4, 18.2 Hz, 1H), 3.48—3.55 (m, 1H), 3.57—3.62 (m, 1H), 3.69 (s, 3H), 3.98 (t, J=8.1 Hz, 2H), 4.41 (t, J=8.1 Hz, 2H), 7.44 (t, J=7.4 Hz, 2H), 7.55 (t, J=7.4 Hz, 1H), 7.93 (d, J=7.4 Hz, 2H); ^{13}C NMR (125 MHz) δ=35.72, 36.52, 39.50, 42.31, 52.10, 62.18, 127.94, 128.54, 133.28, 136.30, 153.43, 171.22, 174.47, 197.15; $[\alpha]_D^{21}$ +2.07° (*c* 1.4, CH_2Cl_2), $[\alpha]_{435}^{21}$ +5.68° (*c* 1.4, CH_2Cl_2):55% ee; HRMS Found: m/z 319.1003. Calcd for $C_{16}H_{17}NO_6$: M, 319.1056.

The Michael product **4** was converted to the bis-(+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionic acid (MTPA) ester[20] **26** by the following procedure shown in Scheme 1, and the opitical purity was determined by the intergration of the signals at 30.09 (major) and 29.91 (minor) ppm of the ^{13}C NMR (125 MHz) spectrum.

Methyl (*R*)-5,5-Dimethyl-4-oxo-2-[(2-oxo-1,3-oxazolidin-3-yl)carbonylmethyl]hexanoate (10). Mp 87 °C; IR (neat) 1790, 1740, 1710 cm^{-1}; ^1H NMR (60 MHz) δ=1.1 (s, 9H), 2.7—3.0 (m, 5H), 3.6 (s, 3H), 3.8—4.6 (m, 4H); $[\alpha]_D^{24.5}$ +4.07° (*c* 1.17, CH_2Cl_2): 57% ee; Found: C, 56.06; H, 7.08; N, 4.61%. Calcd for $C_{14}H_{21}NO_6$: C, 56.18; H, 7.07; N, 4.68%.

The enantiomeric excess of the Michael adduct **10** was determined by the ^1H NMR analysis of the compound **10** with the existence of a chiral reagent, Eu(hfc)$_3$,[21] in which *t*-Bu group was sufficiently separated.

(*R*)-3-[(3-(2-Oxocyclohexyl)propanoyl]-1,3-oxazolidin-2-one (14). IR (neat) 1775, 1705 cm^{-1}; ^1H NMR (500 MHz) δ=1.32—1.41 (m, 1H), 1.47—1.54 (m, 1H), 1.58—1.67 (m, 2H), 1.78—1.84 (m, 1H), 1.97—2.11 (m, 3H), 2.21—2.28 (m, 1H), 2.30—2.37 (m, 2H), 2.82—2.92 (m, 2H), 3.94 (t, J=8.2 Hz, 2H), 4.35 (t, J=8.2 Hz, 2H); ^{13}C NMR (125 MHz) δ=24.08, 25.01, 27.95, 32.92, 34.15, 42.10, 42.47, 49.70, 62.00, 153.50, 173.22,

Table 1. Asymmetric Reaction between **2** and Enamines

Enamine	Product	Amount of the catalyst/mol%	Time/h	Yield/%	Optical purity/%ee
3	**4**	200[a]	23	54	73
		110[a]	29	51	58
		20[a]	24	68	55
9	**10**	200[a]	41	16	78
		110[a]	30	37	57
		20[a]	108	36	53

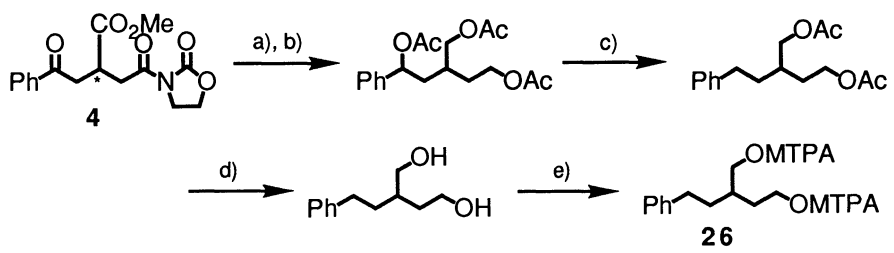
		110[a]	15	86[d]	53[e]
		20[a]	72	78[d]	56[e]
21	**23, 24**	20[b]	70[c]	41, 23	69, 64
22	**25**	20[b]	70[c]	71	38

a) Ether was used as solvent. b) Toluene-petroleum ether (1:1) was used as solvent. c) The reaction time is 70 h at 0 °C, then 24 h at r.t. d) **20** was not obtained. e) The optical purity is that of **19**.



Scheme 1. a) $LiAlH_4$, b) Ac_2O, Pyridine, c) H_2, Pd/C, d) LiOH/H_2O-MeOH, e) (+)-MTPACl, Pyridine.

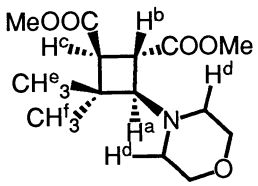
212.60; $[\alpha]_D^{26}$ +1.38° (*c* 0.755, CH_2Cl_2); HRMS Found: *m/z* 239.1178. Calcd for $C_{12}H_{17}NO_4$: M, 239.1158. The optical yield and the absolute configuration was determined by the comparison of the optical rotation of methyl 3-(2-oxocyclohexy)propionate derived from **14** with that of the literature; $[\alpha]_{435}^{27}$ +4.65° (*c* 1.55, MeOH), 27% ee (lit, $[\alpha]_{436}^{20}$ +17.13° (*c* 5.1, MeOH), 97% ee).[22]

Methyl (1*S*, 3*R*, 4*S*)-2,2-Dimethyl-3-morpholino-4-(2-oxo-1,3-oxazolidin-3-ylcarbonyl)cyclobutanecarboxylate (19). IR (neat) 1775, 1735, 1690 cm^{-1}; ^1H NMR (500 MHz) δ=1.08 (s, 3H), 1.33 (s, 3H), 2.22—2.28 (m, 2H), 2.29—2.35 (m, 2H), 2.75 (d, *J*=9.7 Hz, 1H), 2.76 (d, *J*=8.8 Hz, 1H), 3.67 (s, 3H), 3.63—3.70 (m, 4H), 4.03 (t, *J*=8.2 Hz, 2H), 4.35—4.44 (m, 2H), 4.75 (dd, *J*=8.8, 9.7 Hz, 1H); $[\alpha]_D^{23}$ −8.71° (*c* 0.81, CH_2Cl_2): 56% ee; Found: C, 58.70; H, 8.07; N, 4.81%. Calcd for $C_{14}H_{23}NO_5$: C, 58.93; H, 8.13; N, 4.91%.

The relative stereochemistry of morpholino and oxazolidinylcarbonyl groups was determined after conversion of the latter to the methoxycarbonyl group. The procedure is as follows; dry methanol (2 ml) and a drop of carbon tetrachloride was added to metal magnesium (15.75 mg, 0.648 mmol) at 0 °C to generate magnesium methoxide. After the magnesium dissolved completely, a THF solution (1.5 ml) of **19** (52.45 mg, 0.154 mmol) was added and stirred for 1 h. The reaction was quenched with saturated aqueous ammonium chloride solution and the organic materials were extracted with ethyl acetate. The combined organic layers were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by TLC (hexane:ethyl acetate, 1 : 1) to afford dimethyl (1*S*, 2*S*, 3*R*)-4,4-dimethyl-3-morpholino-1,2-cyclobutanedicarboxylate 24.25 mg (55%).

IR (neat) 1735 cm^{-1}; ^1H NMR (500 MHz) δ=0.99 (s, $3H^e$), 1.30 (s, $3H^f$), 2.23—2.36 (m, 2H), 2.36—2.43 (m, $2H^d$), 2.61 (d, *J*=9.4 Hz, H^a), 2.74 (d, *J*=9.6 Hz, H^c), 3.17 (dd, *J*=9.4, 9.6 Hz, H^b), 3.65—3.68 (m, 4H), 3.69 (s, 3H), 3.70 (s, 3H).

The relative stereochemistry was determined as shown below by the NOESY spectrum, because NOEs were observed between H^a and H^d, H^b and H^d, H^b and H^e, H^a and H^c, H^a and H^f, H^c and H^f.



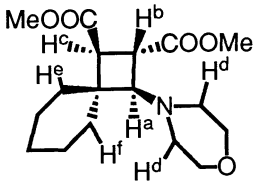
The determination of the optical purity is as follows; the cyclobutane derivative **19** was converted to the bis-(+)-MTPA esters[20] by the following sequence; 1) $Mg(OMe)_2$, 2) $LiAlH_4$, 3) (+)-MTPA-Cl, pyridine, cat. DMAP. The two sets of two singlet signals due to the methyl group appeared at 0.953, 0.934 (major) and 0.940, 0.910 (minor) ppm by 500 MHz ^1H NMR, and the optical yield was determined by the integration of these signals.

Methyl (1*S*, 2*S*, 3*R*)-3-Morpholino-2-(2-oxo-1,3-oxazolidin-3-ylcarbonyl)spiro[3.5]nonane-1-carboxylate (23) and Methyl (1*S*, 2*S*, 3*S*)-3-Morpholino-2-(2-oxo-1,3-oxazolidin-3-ylcarbonyl)spiro[3.5]nonane-1-carboxylate (24). **23** and **24** were obtained as a mixture. IR (neat) 1785, 1730, 1695 cm^{-1}; Found: C, 59.71; H, 7.50; N, 7.16%. Calcd for $C_{19}H_{28}N_2O_6$: C, 59.99; H, 7.42; N, 7.36%. ^1H NMR of the major isomer **23**; (500 MHz) δ=0.98—1.86 (m, 9H), 1.96—2.02 (m, 1H), 2.28—2.51 (m, 4H), 2.70 (d, *J*=9.5 Hz, 1H), 2.75 (d, *J*=9.2 Hz, 1H), 3.63—3.69 (m, 4H), 3.67 (s, 3H), 3.99 (t, *J*=8.1 Hz, 2H), 4.24—4.46 (m, 2H), 4.87 (dd, *J*=9.2, 9.5 Hz, 1H). The distinguishable peaks of the minor isomer **24** were as follows; δ=3.19 (d, *J*=9.7 Hz, 1H), 3.48 (d, *J*=9.7 Hz, 1H), 3.66 (s, 3H).

The mixture of spirononanes **23** and **24** was treated with $Mg(OMe)_2$ in THF to afford the corresponding dimethyl esters, which were separated by TLC (hexane:ethyl acetate, 3:2). The physical data of these dimethyl esters are as follows.

Dimethyl (1*S*, 2*S*, 3*R*)-3-morpholinospiro[3.5]nonane-1,2-dicarboxylate; IR (neat) 1729 cm^{-1}; ^1H NMR (500 MHz) δ=0.91—1.02 (m, 1H), 1.08—1.18 (m, 1H), 1.37 (dt, *J*=4.0, 13.6 Hz, 1H), 1.48—1.63 (m, 5H), 1.74—1.81 (m, H^e), 1.88-1.94 (m, H^f), 2.33—2.46 (m, $4H^d$), 2.58 (d, *J*=9.4 Hz, H^a), 2.69 (d, *J*=10.0 Hz, H^c), 3.32 (dd, *J*=9.4, 10.0 Hz, H^b), 3.65—3.71 (m, 4H), 3.67 (s, 3H), 3.71 (s, 3H); ^{13}C NMR (125 MHz) δ=22.06, 22.44, 25.84, 26.25, 40.18, 41.51, 45.93, 46.42, 51.88, 52.00, 66.69, 68.96, 172.46, 173.70; $[\alpha]_D^{27}$ −6.58° (*c* 1.02, CH_2Cl_2).

The relative stereochemistry was determined as shown below by the NOESY spectrum, because NOEs were observed between H^b and H^e, H^b and H^d, H^a and H^f, H^a and H^d, H^c and H^f, and H^a and H^c.



Dimethyl (1*S*, 2*S*, 3*S*)-3-morpholinospiro[3.5]nonane-1,2-dicarboxylate; IR (neat) 1733 cm^{-1}; ^1H NMR (500 MHz) δ=1.07—1.76 (m, 10H), 2.33—2.50 (m, 4H), 3.05 (dd, *J*=9.6, 9.8 Hz, 1H), 3.13 (d, *J*=9.6 Hz, 1H), 3.17 (d, *J*=9.8 Hz, 1H), 3.64—3.73 (m, 4H), 3.64 (s, 3H) 3.68 (s, 3H); $[\alpha]_D^{27}$ −1.18° (*c* 1.18, CH_2Cl_2).

The dimethyl ester derived from cycloadduct **23** was converted to the corresponding bis-(+)-MTPA ester[20] and the optical purity was determined by the integration of the signals (CH_2OMTPA) at 3.98 (dd, *J*=3.4, 11.7 Hz, major) and 4.13 (dd, *J*=3.8, 11.6 Hz, minor) ppm by the 500 MHz ^1H NMR.

The dimethyl ester derived from cycloadduct **24** was converted to the corresponding (+)-MTPA ester[20] and the optical purity was determined by the integration of the signals at 2.47 (m, 1H, major) and 2.58 (m, 1H, minor) ppm by the 500 MHz ^1H NMR.

Methyl (1*S*, 2*S*, 3*R*)-3-Morpholino-2-(2-oxo-1,3-oxazolidin-3-ylcarbonyl)spiro[3.4]octane-1-carboxylate (25). IR (neat) 1780, 1725, 1690 cm^{-1}; ^1H NMR (500 MHz) δ=1.43—1.97 (m, 8H), 2.22—2.35 (m, 4H), 2.87 (d, *J*=9.9 Hz, 1H), 2.98 (d, *J*=8.9 Hz, 1H), 3.66 (s, 3H), 3.62—3.71 (m, 4H), 3.97—4.07 (m, 2H), 4.35—4.46 (m, 2H), 4.63 (dd, *J*=8.9, 9.9 Hz, 1H); $[\alpha]_D^{24}$ −1.53° (*c* 0.806, CH_2Cl_2). 38% ee. The elemental analysis was performed after conversion to the corresponding dimethyl ester. Found: C, 61.58; H, 8.06; N, 4.47%. Calcd for $C_{16}H_{25}NO_5$: C, 61.72; H; 8.09, N; 4.50%.

The cycloadduct **25** was converted to the corresponding (+)-MTPA ester.[20] By the 500 MHz ^1H NMR, one of the four ester methylene protons (CH_2OMTPA) of the major distereomer appeared at 4.07 (dd, *J*=3.6, 11.7 Hz) ppm with the integration of 0.69 proton, which indicated the optical purity to

be 38% ee.

The D_2O Quenching of the Reactions 2 with 3, and 13 with 11. The reactions between **2** and **3**, and **13** and **11** were performed by the use of a catalytic amount of the chiral titanium reagent as described previously and were quenched by adding a mixture of D_2O (1 ml) and CH_3COOD (0.5 ml) at 0 °C. After stirring for 30 min at 0 °C, pH 7 phosphate buffer was added and the inorganic materials were filtered off. The organic materials were extracted with ethyl acetate and the purification was carried out by the same procedure as described before. Methyl 4-oxo-4-(2-oxo-1,3-oxazolidin-3-yl)-2-[α,α-$^2H_2$]phenacylbutanoate (**8**) was obtained by the reaction between **2** and **3** as a mixture with the mono- and nondeuterated adduct (d_2:d_1:d_0=72:24:4). The products ratio was determined by the mass spectrum of the mixture.

Spectral data of **8** is as follows; ^1H NMR (500 MHz) δ=3.24 (dd, J=5.5, 18.1 Hz, 1H), 3.44 (dd, J=7.3, 18.1 Hz, 1H), 3.60 (dd, J=5.5, 7.3 Hz, 1H), 3.69 (s, 3H), 3.98 (t, J=8.1 Hz, 2H), 4.41 (t, J=8.1 Hz, 2H), 7.44 (t, J=7.7 Hz, 2H), 7.55 (t, J=7.4 Hz, 1H), 7.93 (d, J=7.2 Hz, 2H); ^{13}C NMR (125 MHz) δ=35.62, 36.50, 39.20 (quintet), 42.32, 52.13, 62.18, 127.94, 128.57, 133.30, 136.35, 153.43, 171.25, 174.49, 197.24; HRMS Found: m/z 321.1151. Calcd for $C_{16}H_{15}D_2NO_6$: M, 321.1181.

The quintet of the carbon at 39.2 ppm indicates that the two deuteriums were attached at the same carbon, which was a secondary carbon by the DEPT measurement and it was also assigned as an α position of the phenacyl group because deuterium effect was observed at the carbonyl carbon of the benzoyl group.

(*R*)-3-[(2-Oxo[3-^{2}H]cyclohexyl)propanoyl]-1,3-oxazolidin-2-one (**16**) was obtained by the reaction of **13** and **11** as a mixture with the nondeuterated product **14** (**16**:**14**=70:30). Spectral data of **16** is as follows; ^1H NMR (500 MHz) δ=1.32—1.41 (m, 1H), 1.47—1.54 (m, 1H), 1.58—1.67 (m, 2H), 1.78—1.84 (m, 1H), 1.97—2.11 (m, 3H), 2.21—2.28 (m, 1H), 2.30—2.37 (m, 1H), 2.82—2.92 (m, 2H), 3.94 (t, J=8.2 Hz, 2H), 4.35 (t, J=8.2 Hz, 2H); ^{13}C NMR (125 MHz) δ=24.07, 25.01, 27.86, 32.90, 34.15, 41.77 (t, J=10.3 Hz), 42.45, 49.70, 62.00, 153.50, 173.21, 212.64.

The position of deuterium was assigned as follows; the carbon at 41.77 ppm, which was connected with deuterium, was assigned as a secondary carbon and α to the carbonyl group of cyclohexanone by the chemical shift of ^{13}C NMR, DEPT measurement, and the deuterium effect observed at the carbonyl carbon of cyclohexanone.

One-Step Hydroamidation of a Schiff Base with Trichlorosilane

Hidenori OKAMOTO* and Shozo KATO
Tsukuba Research Lab., Tokuyama Soda Co., Ltd., 40 Wadai, Tsukuba, Ibaraki 300-42
(Received January 5, 1991)

We have found that the treatment of a Schiff base (**2**) with trichlorosilane and chloroacetyl chloride results in a highly active chloroacetamide herbicide (**1**) in an excellent yield. This one-step hydroamidation reaction of a Schiff base is a useful synthetic method.

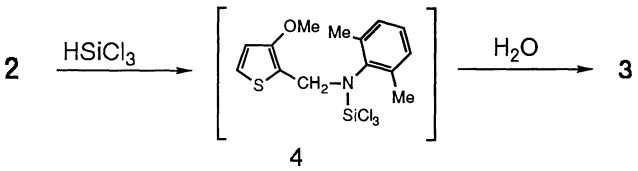
Recently, we have reported on a highly active chloroacetamide herbicide (**1**) for paddy field rice.[1] The compound (**1**) has previously been synthesized in two steps (a reducing step and a chloroacetylating step) from a Schiff base (**2**) as shown in Scheme 1.

During the course of our studies, we found that treatment of a Schiff base (**2**) with trichlorosilane and chloroacetyl chloride produces the chloroacetamide (**1**) in one step with an excellent yield. Further studies have revealed this method to be quite general and versatile for the synthesis of amides from Schiff bases.

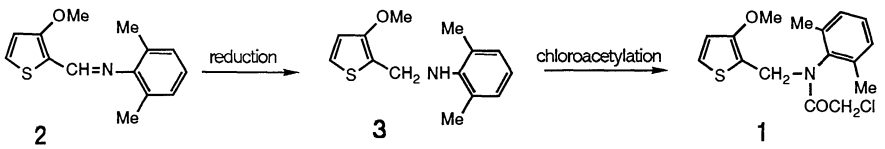
Results and Discussion

One-Step Hydroamidation of a Schiff Base (2). The reduction of a Schiff base (**2**) has previously been accomplished by two steps as shown in Scheme 2. The *N*-trichlorosilyl adduct (**4**) can be converted to the amide without hydrolysis by treatment with chloroacetyl chloride. These results are summarized in Table 1. As we expected, the trichlorosilylation of **2** in the presence of BF_3·Et_2O, followed by the chloroacetylation of the intermediary silyl adduct, resulted in the chroloacetamide (**1**) (Entry 2). Further work established that the amide could be obtained without the BF_3·Et_2O catalyst (Entry 3).

We have examined the chloroacetamidation of **2** in the presence of trichlorosilane. Chloroacetyl chloride (1.1 equiv) and trichlorosilane (1.6 equiv) in benzene were added to **2** in benzene at room temperature and the mixture was heated at 40 °C for 3 h to give **1** in 97% yield. Consequently, by reacting **2** with chloroacetyl chloride in the presence of trichlorosilane in benzene, we could prepare **1** easily in an almost quantitative yield (Scheme 3).

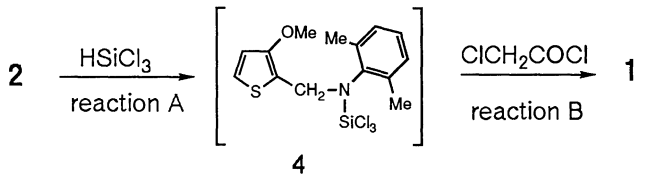


Scheme 2.



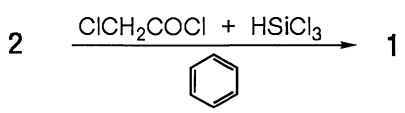
Scheme 1.

Table 1. Hydroamidation of a Schiff Base (2)



Entry	Reaction A[a]			Reaction B[b]		Yield of **1**[c]
	$HSiCl_3$/**2**	Cat.	Time/h	Temp/°C	Time/h	%
1	1.5	BF_3·Et_2O	6	50	1	23
2	3.0	BF_3·Et_2O	6	r.t.	12	69
3[d]	1.5	None	10	50	1	74

a) Reaction was carried out at 70°C. b) The ratio of chloroacetyl chloride to **2** was 1.1:1. c) The yield was determined by ^{1}H NMR. d) Reaction was carried out in an autoclave.



Scheme 3.

Reaction Mechanism. In order to study the mechanism of this reaction, we have measured the ^{1}H NMR spectra of the reactants in C_6D_6. When the Schiff base (**2**) was treated with trichlorosilane in C_6D_6 at room temperature, the spectral pattern of the Schiff base did not change; it showed only an additional signal originating from trichlorosilane (at 5.59 ppm). No interaction between **2** and trichlorosilane could be observed in the benzene solution. When **2** was treated with chloroacetyl chloride in C_6D_6 at room temperature, the signal at 8.40 ppm (CH=N) disappeared and a signal at 3.49 ppm, attributable to the $NCOCH_2Cl$ group (δ=3.72 in **1**), was observed. This indicates that chloroacetyl chloride reacts or interacts with **2**. When trichlorosilane was added to this mixture, a new signal at 4.89 ppm (CH_2–N) appeared. The spectrum of this product was the same as that of **1**. From these observations, it has been concluded that **2** and chloroacetyl chloride react to form an iminium salt-type compound (**5**) or its chlorine adduct (**6**) as an intermediate which further reacts with trichlorosilane to form the desired amide compound **1** as shown in Scheme 4.

Generalization of the One-Step Hydroamidation of Schiff Bases. We have extensively studied a new preparative method of an amide from a Schiff base. The results are summarized in Table 2. A Schiff base prepared by the reaction of an aldehyde or a ketone with an amine was treated with an acyl chloride and trichlorosilane in benzene. The amide was obtained in a good yield. According to the ^{1}H NMR spectra, the products formed were highly pure before purification. When an acyl chloride was treated with a Schiff base at room temperature, a slight exothermic reaction occured with the formation of either an iminium salt or its chlorine adduct. This was demonstrated by ^{1}H NMR studies of compound **8a.** The signal from the methine proton (CH=N) at 8.33 ppm disappeared and a new signal at 7.88 ppm appeared after the addition of chloroacetyl chloride in $CDCl_3$. In the case of **8i**, no exothermic reaction took place. When the reaction was carried out in acetonitrile instead of benzene, **8a** was obtained in 53% yield accompanied by some decomposed products, such as chloroacetanilide. When trifluoroacetic anhydride was employed as an acid derivative, trifluoroacetamide (**8j**) was produced in 76% yield.

Previously, several reports have been published on the

preparation of amides from Schiff bases using hydrosilanes.[2,3] However, these reactions required a catalyst, such as a rhodium compound, and required several steps.

This one-step reaction is applicable to the reaction of a wide range of Schiff bases with a variety of carboxylic acid derivatives.

Experimental

The IR spectra were measured with a Hitachi I-2000 spectrometer. The ^{1}H NMR spectra were measured in a $CDCl_3$ solution with a Hitachi R-1500 spectrometer using tetramethylsilane as an internal standard. The mass spectra were obtained on a Hitachi M-80 spectrometer.

Synthesis of the Schiff Base (2). 3-Methoxy-2-thiophenecarbaldehyde (18.4 g, 0.13 mol), 2,6-dimethylaniline (15.6 g, 0.13 mol), benzene (30 ml), and a catalytic amount of BF_3·Et_2O were added to a flask equipped with a Dean–Stark trap. The mixture was refluxed in an oil bath until the water had distilled out. The resulting yellow liquid (31.1 g, 99% yield) was composed of *N*-[(3-methoxy-2-thienyl)methylene]-2,6-dimethylaniline which boiled at 144 °C/0.1 mmHg (1 mmHg= 133.322 Pa). ^{1}H NMR ($CDCl_3$) δ=2.13 (6H, s, CH_3), 3.78 (3H, s, OCH_3), 6.77—7.31 (5H, aromatic H), and 8.29 (1H, s, CH=N); IR (KBr) 1640 cm^{-1} (CH=N); MS m/z 245 (M^+). Other Schiff bases were prepared from aldehydes or ketones by reaction with amines according to an established method similar to that described above.

Reduction of 2 with Trichlosilane Followed by Chloroacetamidation. To a flask were added **2** (2.48 g, 10 mmol), trichlorosilane (4.00 g, 30 mmol), benzene (20 ml), and a catalytic amount of BF_3·Et_2O. The mixture was stirred for 1 h at room temperature and then heated in an oil bath (70 °C) for 6 h. A solution of chloroacetyl chloride (1.19 g, 11 mmol) in benzene (10 ml) was then gradually added dropwise with stirring at room temperature. This mixture was stirred overnight at room temperature. The low-boiling components were evaporated, and the resulting viscous liquid was dissolved in benzene, cooled to 5 °C, and neutralized with aqueous potassium carbonate. The organic layer was extracted with benzene and dried over sodium sulfate. The benzene was then distilled out and the resulting viscous liquid was dried under reduced pressure to give a brown solid (2.29 g, 69% yield) composed of **1**.

One-Step Hydroamidation of 2. Compound **2** (3.80 g, 15 mmol) and benzene (25 ml) were combined in a flask. A solution of trichlorosilane (3.58 g, 26 mmol) and chloroacetyl chloride (1.90 g, 17 mmol) in benzene (10 ml) was gradually added dropwise while stirring at 5 °C. The mixture was heated in an oil bath (40 °C) for 3 h, then stirred for 1 h at room temperature. The low-boiling components were evaporated and the resulting liquid was dried under reduced pressure to give a brown solid (5.03 g, 97% yield) composed of **1**. ^{1}H NMR ($CDCl_3$) δ=1.95 (6H, s, CH_3), 3.50 (3H, s, OCH_3), 3.72 (2H, s, $COCH_2Cl$), 4.75 (2H, s, CH_2N), 6.55 (2H, q, thienyl H), and 7.00—7.45 (3H, m, aromatic H); IR (KBr) 1670 cm^{-1} (C=O); MS m/z 323 (M^+), 288 (M^+—Cl), and 246 (M^+—$COCH_2Cl$).

One-Step Hydroamidation of a Schiff Base. The general procedure is as follows. A Schiff base (10 mmol) and benzene (15 ml) were combined in a flask. A solution of trichlorosilane (15—20 mmol) in benzene and a carboxylic acid derivative (11—12 mmol) in benzene were gradually added dropwise while stirring at 5—10 °C. The mixture was heated in an oil bath for several hours, and then stirred for 1 h at room temperature. The low-boiling components were evaporated, and the resulting viscous liquid was dissolved in benzene, cooled to 5 °C, and neutralized with aqueous potassium carbonate. The organic layer was extracted with benzene and dried over sodium sulfate. The benzene was then distilled out and the resulting viscous liquid was dried under reduced pressure to give the desired amide. The ^{1}H NMR data of the amides obtained by this procedure are summarized in Table 3.

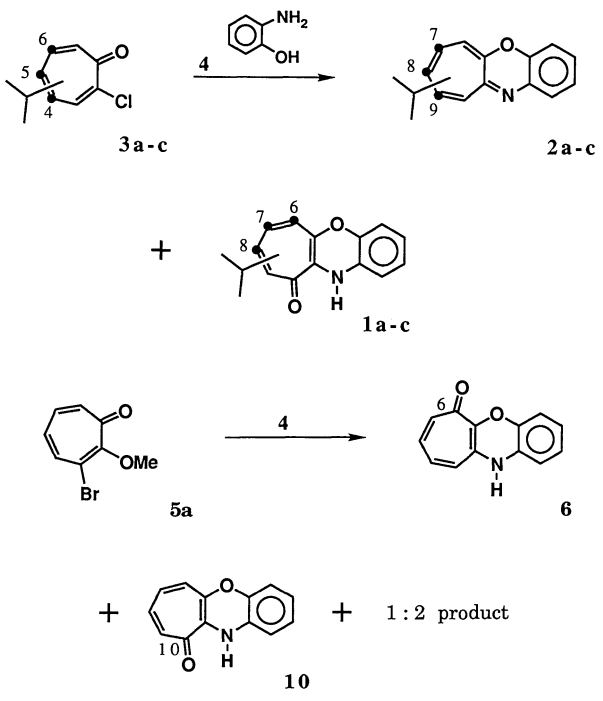
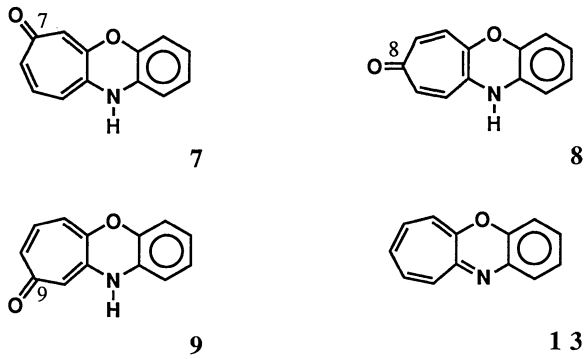
(Received January 24, 1991)

Five isomeric benzo[*b*]cyclohept[*e*][1,4]oxazin-6~10-ones (hereafter refered to as benzoxazinotropones) and bromobenzoxazinotropones were prepared almost quantitatively by the hydrolysis of the corresponding mono-, di-, and tribromobenzo[*b*]cyclohept[*e*][1,4]oxazines with refluxing acetic acid. On the basis of spectral data and theoretical calculations, benzo[*b*]cyclohept[*e*][1,4]oxazin-6~9(11*H*)-ones are believed to exist in the keto form. These compounds gave respective methoxy- and acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazines when reacted with diazomethane and acetic anhydride. On the other hand, benzo[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-one was found to exist in a stable, intermolecularly hydrogen-bonded form and did not form acetoxylated or methylated compounds. Possible reaction pathways for the formation of these products are discussed.

One of the authors (T.N.) and his co-worker reported[3] that a small amount (less than 1%) of isomeric isopropylbenzo[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-ones (**1a—c**) were produced along with the main products 7-, 8-, and 9-isopropylbenzo[*b*]cyclohept[*e*][1,4]oxazines (**2a—c**), when isomeric 2-chloro-4-, 5-, and 6-isopropyltropones (**3a—c**) were refluxed in acetic acid with *o*-aminophenol (**4**). We later reported[4] that the condensation of 3-bromo-2-methoxytropone (**5a**) with an excess of **4** in refluxing acetic acid gave a small amount of benzo[*b*] cyclohept[*e*][1,4]oxazin-6(11*H*)-one (**6**), and its 10(11*H*)-one isomer (**10**) as 1:1-condensation products, along with various interesting 1:2-condensation products. Although some possible reaction pathways for the formation of **6** and **10** (and for **1**) were presented, we did not have enough experimental evidence to distinguish between them.[1] In this paper we wish to describe the details of the synthesis, structures, and keto-enol tautomerism of all possible isomers of the benzo[*b*]cyclohept[*e*][1,4]oxazin-6~10(11*H*)-ones (hereafter refered to as benzoxazinotropones, **6—10**), as well as a possible mechanism for the formation of these compounds.





Results and Discussion

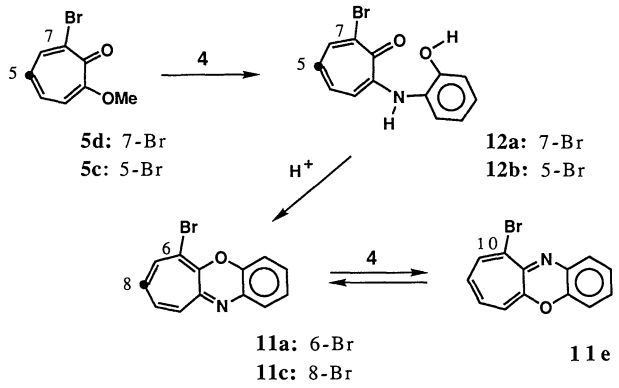
Synthesis of Various Bromobenzo[*b*]cyclohept[*e*]-[1,4]oxazines (11a—e). 6-Bromo- (**11a**)[5] and 8-bromobenzo[*b*]cyclohept[*e*][1,4]oxazine (**11c**)[6] were respectively prepared by the condensation of 7-bromo- (**5d**) and 5-bromo-2-methoxytropone (**5c**) with **4**, via the respective bromo-2-(2-hydroxyanilino)tropones (**12a, b**). The 10-bromo compound (**11e**) was obtained from **11a** by an intermolecular heterocycle exchange reaction[7] with **4** in

§ Benzo[*b*]cyclohept[*e*][1,4]oxazine was refered to as cyclohepta[*b*][1,4]benzoxazine in the preceding paper.

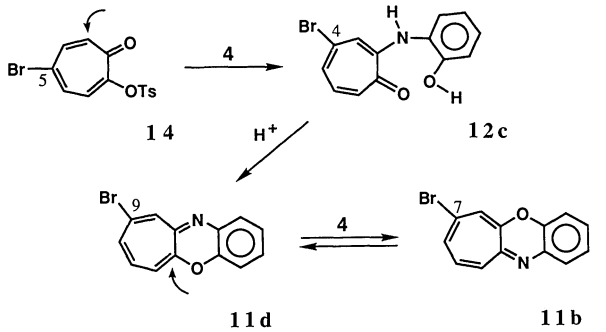
methanol (Scheme 1).

The reaction of 5-bromotropolone *p*-toluenesulfonate (**14**) with **4** in pyridine gave anilinotropone **12c** (84% yield) through cine substitution.[8] Compound **12c** underwent cyclization in hot acetic acid containing a trace amount of concd sulfuric acid to give **11d** (82% yield, Scheme 2). The structures of **12c** and **11d** were determined to be 4-bromo-2-(2-hydroxyanilino)tropone and 9-bromobenzo[*b*]cyclohept[*e*][1,4]oxazine, respectively, on the basis of the spectral data (see the Experimental section).

The reaction of **11d** with 2 equiv of **4** in MeOH at room temperature was studied by time-dependent HPLC. It was determined that **11d** and **11b** attained an approximately 1:1 equilibrium within 1 h by an intermolecular heterocycle exchange reaction (Scheme 2).[7] The reaction mixture was separated by silica-gel chromatography and **11b** (45% yield) was identified as 7-bromobenzo[*b*]cyclohept[*e*][1,4]oxazine on the basis of NMR spectra and comparison of its UV spectra with **11d**.



Scheme 1.

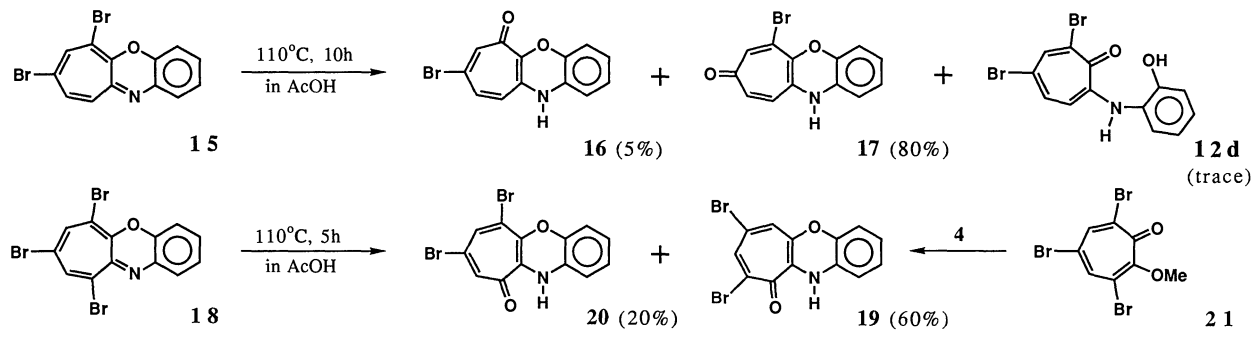


Scheme 2.

Synthesis of Benzoxazinotropones. Heating of bromo compounds **11a—e** in acetic acid at 110 °C for 20 min to 2 h (depending on the position of the Br atom) gave the corresponding benzoxazinotropones (**6—10**) in nearly quantitative yields. Compounds **6** and **10** were identified as benzo[*b*]cyclohept[*e*][1,4]oxazin-6(11*H*)-one and -10(11*H*)-one, respectively, by direct comparison with the authentic samples.[4] The structure of **7** was shown spectroscopically to be benzo[*b*]cyclohept[*e*]-[1,4]oxazin-7(11*H*)-one. Compounds **8** and **9** were also shown to be benzo[*b*]cyclohept[*e*][1,4]oxazin-8(11*H*)-one and -9(11*H*)-one, respectively, on the basis of the spectral data (see the Experimental section).

Similarly, 6,8-dibromobenzo[*b*]cyclohept[*e*][1,4]-oxazine (**15**)[6] produced two bromobenzoxazinotropones (**16** (5% yield) and **17** (80% yield)) as well as a small amount of **12d**. The structures of **16** and **17** were determined to be 8-bromobenzo[*b*]cyclohept[*e*][1,4]-oxazin-6-(11*H*)-one and 6-bromobenzo[*b*]cyclohept[*e*]-[1,4]oxazin-8(11*H*)-one, respectively, on the basis of high resolution mass spectral data and comparison of their UV spectra with those of **6** and **8**, as well as the results of acylation (see below). On the other hand, 6,8,10-tribromobenzo[*b*]cyclohept[*e*][1,4]oxazine (**18**)[9] gave, under similar conditions, isomeric dibromobenzoxazinotropones **19** (60% yield) and **20** (20% yield). Zinc dust reduction of compounds **19** and **20** resulted in the same benzoxazinotropone **10**. Compound **19** was also prepared by the reaction of 2,4,6-tribromo-7-methoxytropone (**21**) with **4**. This evidence along with the spectral data mentioned above showed the structures of **19** and **20** to be 7,9-dibromo- and 6,8-dibromobenzo-[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-one, respectively (Scheme 3).

Hydrolysis of **18** with AcOH gave only the dibromo derivatives of benzo[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-one (**10**), but neither 6(11*H*)-one nor 8(11*H*)-one deriva-

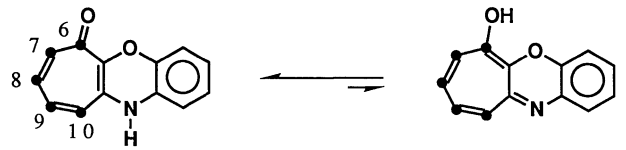


Scheme 3.

tives were produced, whereas the same treatment of **15** gave a mixture of 6(11*H*)-one derivative **16** and 8(11*H*)-one derivative **17** in a 1:16 ratio. These results suggest that the facility of the hydrolytic cleavage is in order C-10>C-8>C-6.

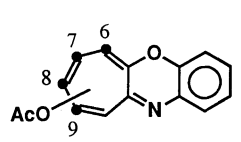
The bonding energies between the Br-attached carbon and Br of **11a—e** were calculated by the MINDO/3 method to be −11.38, −11.27, −11.32, −11.31, and −11.34 eV, respectively. In the case of **15**, the binding energy between C-6 and Br was calculated to be −11.45 eV, while that between C-8 and Br was −11.35 eV. Therefore, the bond between C-8 and its Br atom is hydrolyzed more readily than the bond between C-6 and its Br atom. In the case of **18**, the binding energies between a Br-attached carbon and its Br atom are in order C-6 (−11.47 eV) < C-8 (−11.42 eV) < C-10 (−11.40 eV). These results agree with the order of the facility of the hydrolytic cleavage.

Keto-Enol Tautomerism of Benzoxazinotropones. Keto-enol tautomerism is believed to exist in compounds **6—10**. In order to clarify the tautomerism, the acetylation and methylation of benzoxazinotropones **6—10** were studied. Moreover, HMO[10] and MINDO/3[11] molecular orbital theoretical calculations were performed and the theoretical results were compared with the experimental results.

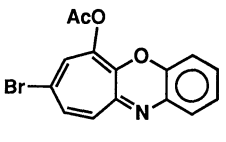


6-10 **6a-10a**

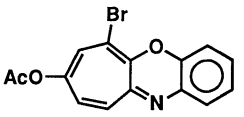
a) Acylation and Methylation. No products were obtained when **6—10** were combined with acetic anhydride in pyridine at 80 °C. However, acetates **22a—d** were produced in ca. 80% yields when **6—9** were mixed with acetic anhydride in acetic acid containing a trace amount of concd sulfuric acid at room temperature. Compound **22a** was determined to be 6-acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazine from the high resolution mass spectral determination of molecular weight (*m/z* M^+, 253.0769) and other spectral data. The IR spectrum showed an *O*-acetyl carbonyl absorption peak near 1770 cm^{-1}. The electronic spectrum is very similar to that of the parent compound **13**. The structures of **22b—d** were also identified as 7-, 8-, and 9-acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazine, respectively, on the basis of their NMR and other spectral data (see the Experimental section). Similarly, **16** and **17** were reacted as above to form acetoxyl derivatives **23** and **24**, respectively. Acetylated compounds **22a—d**, **23**, and **24** reverted to the corresponding benzoxazinotropones **6—9**, **16**, and **17** when treated with refluxing acetic acid for about 5 min.



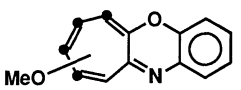
22a-d



23



24



25a-d

Compounds **6—9** reacted slowly with diazomethane to give the corresponding methylated products **25a—d** as brown needles. However, **10** did not result in acetylated and methylated compounds under similar conditions. The structures of **25a—d** were assigned to 6-, 7-, 8-, and 9-methoxybenzo[*b*]cyclohept[*e*][1,4]oxazines, respectively, on the basis of their NMR and other spectral data (see the Experimental section). Methylated compounds **25a—d** gradually reverted to the corresponding benzoxazinotropones **6—9** on standing in methanol at room temperature.

b) Theoretical Calculations. The resonance energies and bond currents of the keto forms **6—10** and the enol forms **6a—10a** have been calculated by means of Aihara's graph theory of aromaticity.[12] The HMO theory is assumed to be in its simplest form. Streitwieser[10] evaluated the heteroatom parameters for the amine nitrogen, the

RE: Resonance energy (in β units). CRE: Circuit resonance energy (in β units). ΔH_f: Heats of formation calculated by the MINDO/3 method.

imine nitrogen, the ether oxygen, and the ketone oxygen. We have used these values in this paper.

MINDO/3[11] is a reasonably reliable method for the prediction of heats of formation. The molecular geometries of **6**—**10** and its enol forms **6a**—**10a** were calculated by MINDO/3 optimizations. In all cases, the MINDO/3 optimized geometries were planar and exhibited appreciable bond alternation. As shown in Table 1, the heats of formation of the keto forms are more stable than those of the enol forms by 0.7—4.3 kcal mol^{-1}.

All the keto and enol compounds are predicted to be aromatic with positive resonance energies.[12a] The keto form species have larger resonance energies than those of the enol forms. With a view to clarifying the origin of the aromaticity, we calculated the circuit resonance energies[12c] of the keto forms by means of Aihara's graph theory of aromaticity. The π-electron ring system in the keto forms consists of six π-ring components, from r_1 to r_6, as shown in Fig. 1. Geometrically unidentical π-electron circuits are shown and numbered in Fig. 1. The results are listed in Table 1. The circuit resonance energies of r_1 and r_3 are positive, while those of r_2, r_4, r_5, and r_6 are near zero or negative. Consequently, the keto form compounds are stabilized as the 6-π-tropylium-6-π-benzenoid form.

Since **6**—**10** are only slightly soluble in less polar solvents, the NMR spectra were measured in DMSO-d_6. In all cases, the ^{13}C NMR spectra exhibited a peak at about δ=180 resulting from a carbonyl group. These results match the keto form but not the enol form in a polar solvent such as DMSO. In the ^1H NMR spectra, the chemical shifts of the seven-membered ring protons for **6**—**10** differ from those of parent compound **13**. This can also be explained by assuming the compounds are in the keto form. This causes the signals of the β proton of the carbonyl groups to appear at a lower field compared with those of compounds **13**, **22**, and **25**. The observed values of the average chemical shifts of the seven-membered ring protons and benzene ring protons of **6**—**10** are at δ=6.61 and 6.70, respectively. In contrast, the chemical shifts of the seven-membered ring protons of the enol forms and **13** are expected to be much higher than those of the benzene ring protons.[13] Furthermore, ring currents of the keto forms of **6**—**10** and their enol forms **6a**—**10a** have been calculated by Aihara's method,[12b] and the results are shown in Fig. 1. The average ring currents of the seven-membered rings (r_1) and benzene rings (r_3) of **6**—**10** are 0.930 I_0 and 1.000 I_0, respectively, whereas those of **6a**—**10a** are 0.710 I_0 and 1.040 I_0 respectively. We therefore conclude that benzoxazinotropones **6**—**10** exist mainly in the keto form on the basis of the experimental facts, NMR spectral data, and theoretical calculations.

Though compounds **6**—**9** were almost the same yellow-brown color and had very similar electronic absorption bands, **10** had a red color. The electronic spectra of **10**, in methanol solution, showed the longest

wavelength band centered at 480 nm. We have also calculated the electronic transitions for **6**—**10** by the CNDO/S-CI method. For example, the spectra of **7** showed an absorption band, deriving from the HOMO–LUMO transition, lying in the UV region at 3.13 eV (395 nm). The electronic transitions calculated by adopting the MINDO/3 geometries of **10** are predicted to have $\pi\pi^*$ λ_{max} of 2.73 eV (454 nm, f=0.000), 2.75 eV (450 nm, f=0.000), 2.98 eV (416 nm, f=0.094), and 3.05 eV (406 nm, f=0.072) in the long wavelength region. The calculated results, however, do not conform to the electronic spectra of **10**.

To elucidate the molecular structure of **10**, an X-ray diffraction analysis was carried out.[14] The molecular framework is illustrated in Fig. 2. The definitive structure determination of **10** was particularly interesting, because this compound was shown to exist in an intermolecularly hydrogen-bonded form in the solid state.

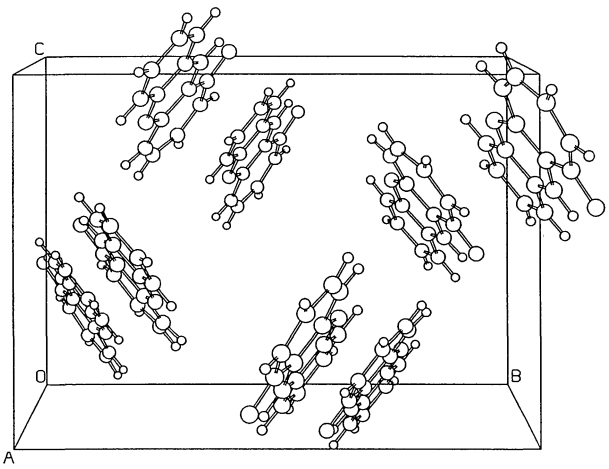

Fig. 2. A perspective view of **10**.

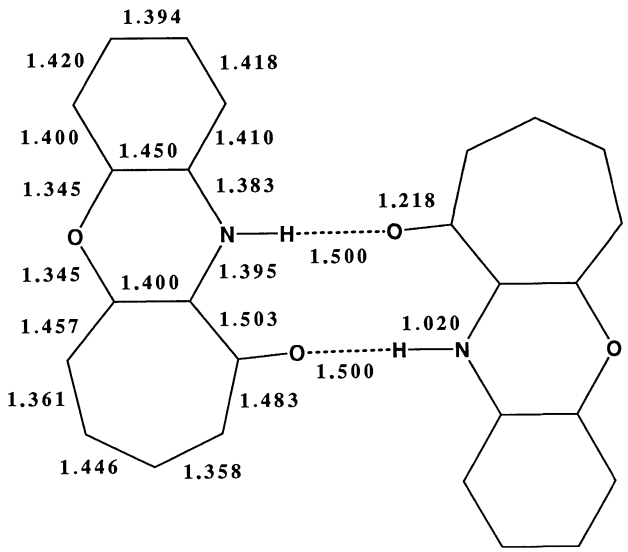

Fig. 3. Assumed structure of Model A. Bond lengths are expressed in Angstroms (Å).

The *H*-bond is between the ketone oxygen in one molecule and the imine hydrogen in another molecule. We therefore propose two dimeric model structures on the basis of the above X-ray experimental geometry and MINDO/3 optimized values. Model A is a planar molecule with an assumed N···O bond length of 2.718 Å (Fig. 3), whereas Model B is a nonplanar molecule. The geometries of Model B are the same as those of Model A, except that the separation of two molecular planes is assumed to be 1.9 Å and the N···O bond length is 2.2 Å. The calculated electronic transitions of Model A are predicted to have $\pi\pi^*$ λ_{max} of 2.57 eV (481 nm, f=0.000), 2.80 eV (442 nm, f=0.000), 2.85 eV (435 nm, f=0.166), and 2.96 eV (418 nm, f=0.238) in the long wavelength region and are very close to the calculated transitions of monomeric compound **10**. The calculated electronic transitions of Model B are predicted to have $\pi\pi^*$ λ_{max} of 2.48 eV (500 nm, f=0.002), 2.53 eV (490 nm, f=0.215), 2.84 eV (436 nm, f=0.012), 2.92 eV (424 nm, f=0.151), 2.93 eV (423 nm, f=0.180), and 3.06 eV (405 nm, f=0.051) in the same region. In the calculated results of Model B, its next longest absorption band can be attributed to an intermolecular charge-transfer transition from one molecule to another molecule because this absorption band was assigned to a HOMO–LUMO transition, and π charges in HOMO or LUMO orbitals were distributed on each molecule of the assumed dimer. The electronic transitions calculated for Model B agree with the expeprimental electronic spectra of **10**. The agreement between calculated and experimental data is satisfactory, especially if we bear in mind that theoretical values refer to the gas phase and experimental values to the solution state.

Possible Reaction Pathways for the Formation of Benzoxazinotropones. As mentioned above, bromo compounds **11a**—**e** gave an almost quantitative yield of benzoxazinotropones **6**—**10**, respectively, upon heating in 97% acetic acid. However, upon heating in ethanol, **11a**—**d** did not result in benzoxazinotropones **6**—**9**, while **11e** gave **10** almost quantitatively. Additionally, by periodically checking the reaction with reversed-phase HPLC we observed the formation of **22d** when **11d** was heated in anhydrous acetic acid at 110 °C. As shown in Fig. 4, a peak corresponding to acetoxyl compound **22d** appears first, then the peak corresponding to **9** increases as the peaks corresponding to **22d** and **11d** decrease in the chromatogram. In this transformation, as shown in Scheme 4, intermediate **a** may be produced first by the attack of an acetoxyl anion (not by moisture in the acetic acid) at the bromine-substituted C-9 position of **11d**. Compound **a** may then give **9** via acetoxyl derivative **22d**. Similarly, **11a**—**c** are likely to produce **6**—**8** via acetoxyl compounds **22a**—**c**, respectively, and **15** is likely to produce **16** and **17** via acetoxyl compounds **23** and **24**, respectively.

As we reported earlier,[7] position C-5a in the benzo[*b*]cyclohept[*e*][1,4]oxazine nucleus is most easily

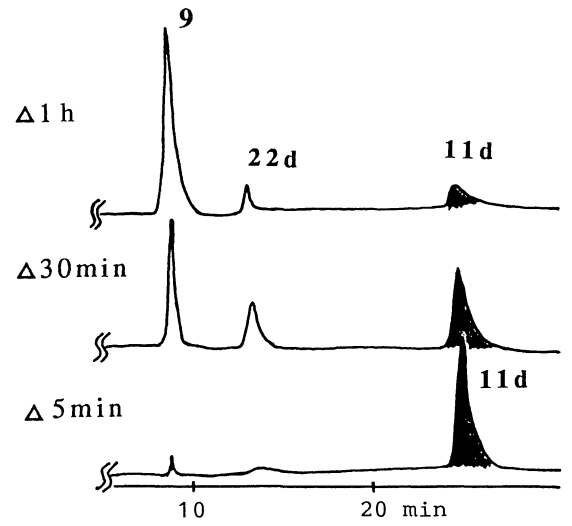

Fig. 4. Time-dependent HPLC chromatograms of the hydrolysis of **11d** in dry AcOH at 110°C.

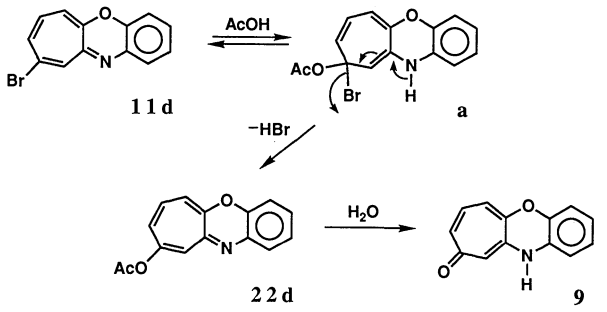
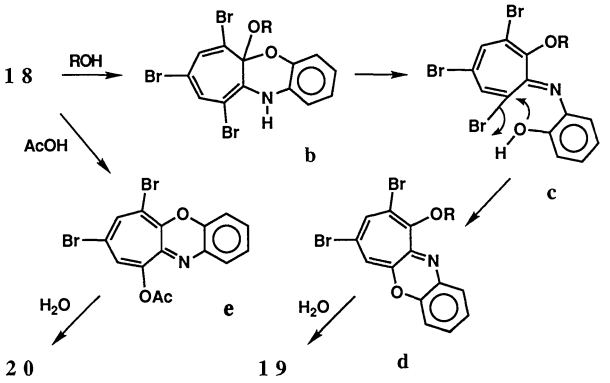


Scheme 4.



Scheme 5.

attacked by nucleophiles, and when the C-10 position is substituted with a group such as a bromine atom, that group acts as a good leaving group. Therefore, it is quite understandable that the 10-bromo compound **11e** is readily transformed to **10** even in MeOH (containing a small amount of water), and the tribromo compound **18** gives 7,9-dibromobenzoxazinotropone **19** as the main product along with the 6,8-dibromo compound **20**, as illustrated in Scheme 5.

Experimental

Melting points were determined with a Yanagimoto MP-3S melting point apparatus and were uncorrected. The IR and electronic spectra were measured by using a Shimadzu IR-450 and a Shimadzu UV-265FS spectrometer, respepctively; the UV spectra in acid and alkali solutions were taken after adding a few drops of 6 M HCl or 6 M NaOH (1 M=1 mol dm^{-3}) to the sample solution. The NMR spectra were measured in $CDCl_3$ (unless otherwise specified) with a JEOL JNM-PS/PET (100 MHz) or a JEOL JNM-GX270 (270 MHz for 1H and 67.8 MHz for ^{13}C) spectrometer using TMS as the internal standard. The assignments of all signals were made by employing a first-order analysis with the aid of a decoupling technique. The mass spectra were taken on a JEOL JMS-DX300 mass spectrometer and a Shimadzu LKB 9000 GC-mass spectrometer at 70 eV. The HPLC was carried out on Hitachi gel #3011 with MeOH–hexane (9:1) as the solvent. The centrifugal chromatography was performed with a Hitachi CLC-5 instrument in a Fuji silica-gel layer (KT-2151, 3 mm thickness) using benzene as an eluent. The TLC analyses were carried out with Merck Kieselgel 60F-254 plates.

4-Bromo-2-(2-hydroxyanilino)tropone (12c). A mixture of 5-bromotropolone *p*-toluenesulfonate[15] (**14**, 506 mg, 1.42 mmol) and *o*-aminophenol (**4**, 310 mg, 2.82 mmol) in pyridine (5 cm^3) was heated at 60 °C for 5 h. The solvent was evaporated in vacuo and the residue was chromatographed on a column of silica gel with benzene–MeOH (50:1), giving **12c** (345 mg, 84% yield):Orange needles (from MeOH); mp 170—172 °C (decomp); UV_{max} (MeOH) 240 (log ε 4.20), 262 (4.31), 347 (4.04), and 407 nm (4.18), (MeOH+ 6 M NaOH) 244 (log ε 4.29), 272 (4.17), 346 (3.89), and 413 nm (4.11); IR (KBr) 3430 (OH) and 3250 cm^{-1} (NH); ^1H NMR (270 MHz, CD_3OD) δ=6.96 (1H, td, *J*=8.0 and 2.0 Hz, H-5′), 7.00 (1H, dd, *J*=8.0 and 2.0 Hz, H-3′), 7.05—7.10 (4H, m, H-3,5,6,7), 7.20 (1H, td, *J*=8.0 and 2.0 Hz, H-4′), and 7.28 (1H, dd, *J*=8.0 and 2.0 Hz, H-6′). Found: C, 53.26; H, 3.57; N, 4.60%; M^+, 292. Calcd for $C_{13}H_{10}NO_2Br$: C, 53.45; H, 3.45; N, 4.79%; M, 292.

9-Bromobenzo[*b*]cyclohept[*e*][1,4]oxazine (11d). A solution of **12c** (210 mg) in acetic acid (5 cm^3) containing a trace amount of concd sulfuric acid was heated at 120 °C for 2 h under nitrogen. The solvent was then evaporated in vacuo. The residue was neutralized with aq $NaHCO_3$ and extracted twice with benzene. The extracts were combined, dried (Na_2SO_4) and evaporated in vacuo. The residue was chromatographed centrifugally on a layer of silica gel with benzene as the eluent, giving **11d** (161 mg, 82% yield): Brown needles; mp 145—147 °C (from benzene); UV_{max} (MeOH) 263 (log ε 4.47), 270 (4.47), 305 (4.03), and 414 nm (4.10), (MeOH +6M HCl) 267 (log ε 4.37), 287 (4.27), 320 (4.15), and 449 nm (3.99); ^1H-NMR (270 MHz) δ=5.29 (1H, d, *J*=9.8 Hz, H-6), 5.70 (1H, dd, *J*=11.5 and 9.8 Hz, H-7), 5.90 (1H, dd, *J*=11.5 and 2.0 Hz, H-8), 6.40 (1H, m, H-4), 6.54 (1H, d, *J*=2.0 Hz, H-10), and 6.78 (3H, m, H-1,2,3). Found: C, 57.00; H, 3.08; N, 4.99%; M^+, 274. Calcd for $C_{13}H_8NOBr$: C, 56.96; H, 2.94; N, 5.11%; M, 274.

7-Bromobenzo[*b*]cyclohept[*e*][1,4]oxazine (11b). A mixture of **11d** (30 mg, 0.11 mmol) and **4** (24 mg, 0.22 mmol) in methanol (5 cm^3) was allowed to stand for 1 h at room

temperature. The reaction contents were checked by means of time-dependent HPLC. The solvent was evaporated in vacuo. The residue was chromatographed on silica-gel thin-layer plates with benzene as the eluent. The product was recrystallized from benzene, giving **11b** (13 mg, 45% yield)(along with 50% recovered **11d**): Brown needles; mp 130—132 °C; UV_{max} (MeOH) 222 (log ε 4.31), 262 (4.39), 272 (4.36), 309 (4.15 sh), 322 (3.76 sh), and 415 nm (4.05), (MeOH+6 M HCl) 230 (log ε 4.35), 267 (4.30), 285 (4.17 sh), 317 (4.01), 439 (3.98), and 427 nm (3.87 sh); ^{1}H NMR (270 MHz) δ=5.69 (1H, d, *J*=1.5 Hz, H-6), 5.82 (1H, dd, *J*=12.4 and 8.8 Hz, H-9), 6.00 (1H, d, *J*=12.4 Hz, H-10), 6.12 (1H, dd, *J*=8.8 and 1.5 Hz, H-8), 6.43 (1H, m, H-4), and 6.73—6.85 (3H, m, H-1,2,3). Found: C, 56.74; H, 3.05; N, 4.89%; M$^+$, 274. Calcd for $C_{13}H_8NOBr$: C, 56.96; H, 2.94; N, 5.11%; M, 274.

Similarly, when a methanolic solution of **11b** and **4** was allowed to stand at room temperature, an additional peak due to compound **11d** began to appear in the HPLC chromatogram and an equilibrium was reached within a few hours. The isomerized **11d** was isolated in pure crystalline form.

Hydrolysis of 11a—e. A solution of **11c** (55 mg) in acetic acid (10 cm^3) was heated at 110 °C for 1 h, followed by the same procedures as those described above for **12c**. The residual solid was recrystallized from MeOH to give **8** (40 mg, 95% yield). Similarly, **6**[4] (95% yield), **7** (95% yield), **9** (90% yield), and **10**[4] (95% yield) were obtained from **11a, 11b, 11d,** and **11e**, respectively.

Benzo[*b*]cyclohept[*e*][1,4]oxazin-6(11*H*)-one (6): Mp 270—271 °C (lit,[4] mp 270 °C); UV_{max} (DMSO) 264, 305, 315, 330 (sh), and 393 nm, ($CHCl_3$) 259, 300, 310, 326 (sh), and 388 nm; ^{1}H NMR (270 MHz, DMSO-d_6) δ=6.42 (1H, dd, *J*=8.0 and 1.8 Hz, H-4), 6.49 (1H, dd, *J*=12.2 and 2.6 Hz, H-7), 6.56 (1H, dd, *J*=8.0 and 1.8 Hz, H-1), 6.64 (1H, td, *J*=8.0 and 1.8 Hz, H-2), 6.72 (1H, td, *J*=8.0 and 1.8 Hz, H-3), 6.81 (3H, m, H-8,9,10), and 8.57 (1H, br, NH); ^{13}C NMR (67.8 MHz, DMSO-d_6) δ=113.4 (d), 114.9 (d), 123.1 (d), 124.6 (d), 126.9 (d), 130.9 (s), 131.0 (d), 131.6 (d), 139.9 (s), 140.9 (d), 143.2 (s), 145.2 (s), and 173.3 (s).

Benzo[*b*]cyclohept[*e*][1,4]oxazin-8(11*H*)-one (8): Brown needles; mp>300 °C (from MeOH); UV_{max} (MeOH) 222 (log ε 4.12), 266 (4.34), 275 (4.32), 318 (3.39 sh), and 420 nm (4.02), (MeOH+6 M HCl) 227 (log ε 4.25), 266 (4.29), 275 (4.31), 330 (3.60), 443 (3.81), and 466 nm (3.79 sh), (DMSO) 268, 277, 315, and 408 nm, ($CHCl_3$) 264, 274, 320 (sh), and 402 nm; IR (KBr) 3250—2800 and 1644 cm^{-1}; ^{1}H NMR (270 MHz, DMSO-d_6) δ=6.36 (1H, dd, *J*=12.7 and 2.0 Hz, H-7), 6.43 (1H, dd, *J*=8.0 and 2.0 Hz, H-4), 6.52 (1H, dd, *J*=8.0 and 2.0 Hz, H-1), 6.64 (1H, td, *J*=8.0 and 2.0 Hz, H-3), 6.69 (2H, m, H-9,10), 6.73 (1H, td, *J*=8.0 and 2.0 Hz, H-2), 6.75 (1H, d, *J*=12.7 Hz, H-6), and 8.70 (1H, br, NH); ^{1}H NMR (270 MHz, CD_3OD) δ=6.57 (1H, dd, *J*=13.1 and 2.5 Hz, H-7), 6.77 (1H, d, *J*=13.1 Hz, H-10), 6.84 (1H, dd, *J*=13.1 and 2.5 Hz, H-9), and 6.89 (1H, d, *J*=13.1 Hz, H-6); ^{13}C NMR (67.8 MHz, DMSO-d_6) δ=114.3 (d), 114.9 (d), 123.7 (d), 124.9 (d), 129.5 (d), 129.6 (d), 130.0 (s), 131.1 (d), 138.8 (d), 139.7 (s), 143.2 (s), 143.4 (s), and 179.5 (s). Found: C, 73.76; H, 3.99; N, 6.28%; M$^+$, 211. Calcd for $C_{13}H_9NO_2$: C, 73.92; H, 4.29; N, 6.63%; M, 211.

Benzo[*b*]cyclohept[*e*][1,4]oxazin-9(11*H*)-one (9): Yellow needles; mp 243—245 °C (from MeOH); UV_{max} (MeOH) 239 (log ε 4.19), 294 (4.48 sh), 307 (4.55), 338 (4.00 sh), 373 (3.77), and 394 nm (3.77), (MeOH+6 M HCl) 226 (log ε 4.14), 251 (4.22), 257 (4.24), 289 (4.36), 308 (4.54), and 426 nm (3.94), (MeOH+6 M NaOH) 240 (log ε 3.99), 305 (4.54), 324 (4.27 sh), 340 (4.07 sh), 423 (4.09), and 453 nm (3.91 sh), (DMSO) 298, 308, 340 (sh), and 380 nm (sh), ($CHCl_3$) 296, 307, 340 (sh), and 394 nm (sh); IR (KBr) 3250 and 1614 cm^{-1}; ^{1}H NMR (270 MHz, DMSO-d_6) δ=6.05 (1H, d, *J*=2.5 Hz, H-10), 6.32 (1H, dd, *J*=12.4 and 2.5 Hz, H-8), 6.39 (1H, d, *J*=10.3 Hz, H-6), 6.70 (1H, dd, *J*=12.4 and 10.3 Hz, H-7), 6.71 (1H, dd, *J*=8.0 and 1.5 Hz, H-4), 6.78 (1H, td, *J*=7.5 and 1.5 Hz, H-2), 6.83 (1H, dd, *J*=8.0 and 1.5 Hz, H-1), 6.88 (1H, td, *J*=7.5 and 1.5 Hz, H-3), and 9.80 (1H, br, NH); ^{13}C NMR (67.8 MHz, DMSO-d_6) δ=114.0 (d), 114.2 (d), 114.8 (d), 115.2 (d), 121.8 (d), 124.2 (d), 127.1 (s), 132.2 (d), 136.3 (d), 140.8 (s), 141.5 (s), 151.0 (s), and 183.1 (s). Found: C, 73.61; H, 4.38; N, 6.30%; M$^+$, 211. Calcd for $C_{13}H_9NO_2$: C, 73.92; H, 4.29; N, 6.63%; M, 211.

Benzo[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-one (10): Mp 171—172 °C (lit,[4] mp 170 °C); UV_{max} (DMSO) 265, 273, 312, 330, 406, and 487 nm, ($CHCl_3$) 261, 271, 305, 324, 404, and 483 nm; ^{1}H NMR (270 MHz, DMSO-d_6) δ=6.57 (1H, dd, *J*=8.0 and 2.0 Hz, H-4), 6.68 (2H, m, H-3,7), 6.73 (1H, td, *J*=8.0 and 2.0 Hz, H-2), 6.78 (1H, dd, *J*=11.1 and 1.2 Hz, H-6), 6.93 (1H, dd, *J*=8.0 and 2.0 Hz, H-1), 6.94 (1H, dd, *J*=11.4 and 1.5 Hz, H-9), 7.03 (1H, ddd, *J*=11.4, 8.3, and 1.5 Hz, H-8), and 8.85 (1H, br, NH); ^{13}C NMR (67.8 MHz, DMSO-d_6) δ=114.4 (d), 115.5 (d), 123.8 (d), 124.6 (d), 125.2 (d), 128.2 (d), 129.3 (s), 133.9 (d), 134.2 (d), 141.4 (s), 143.7 (s), 146.5 (s), and 171.9 (s).

Acetylation of 6—10. A mixture of **9** (10 mg, 0.05 mmol) and acetic anhydride (0.6 cm^3) in acetic acid (1 cm^3) containing a trace amount of concd sulfuric acid was stirred for 2 h at room temperature, followed by the same procedures as those described above for **11b**. The residual solid was recrystallized from MeOH to give **22d** (10 mg, 83% yield). Similarly, **22a** (80% yield), **22b** (80% yield), and **22c** (80% yield) were obtained from **6**, **7**, and **8**, respectively. Compound **10** was recovered unchanged under similar conditions.

6-Acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (22a): Brown needles; mp 120—122 °C (from MeOH); UV_{max} (MeOH) 259 (log ε 4.33), 267 (4.30), 300 (3.80), 316 (3.70 sh), 330 (3.54 sh), and 405 nm (3.99), (MeOH+6 M HCl) 225 (log ε 4.35), 263 (4.29), 271 (4.33), 319 (3.84), 431 (3.91), and 453 nm (3.88 sh); IR (KBr) 1770 cm^{-1} (C=O); ^{1}H NMR (270 MHz, CD_3CN) δ=2.19 (3H, s, Me), 5.89 (1H, ddd, *J*=12.4, 6.4, and 2.5 Hz, H-8), 5.98 (1H, dd, *J*=12.4 and 2.0 Hz, H-7), 6.19 (1H, dd, *J*=12.5 and 2.5 Hz, H-10), 6.23 (1H, ddd, *J*=12.5, 6.4, and 2.0 Hz, H-9), 6.50 (1H, m, H-4), and 6.82 (3H, m, H-1,2,3). Found: C, 70.92; H, 4.65; N, 5.34%; M$^+$, 253. Calcd for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.38; N, 5.53%; M, 253.

7-Acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (22b); Brown

needles; mp 95—97 °C (from MeOH); UV_{max} (MeOH) 259 (log ε 4.17), 268 (4.12), 294 (3.95), and 410 nm (3.94), (MeOH+6 M HCl) 225 (log ε 4.27), 261 (4.17), 272 (4.12), 311 (3.82), 429 (3.77), and 457 nm (3.75 sh); IR (KBr) 1755 cm^{-1} (C=O); ^1H NMR (270 MHz, CD_3CN) δ=2.14 (3H, s, Me), 5.60 (1H, d, *J*=2.0 Hz, H-6), 5.84 (1H, dd, *J*=10.0 and 2.0 Hz, H-8), 6.37 (1H, dd, *J*=12.0 and 10.0 Hz, H-9), 6.47 (2H, m, H-4,10), and 6.80 (3H, m, H-1,2,3). Found: *m/z* 253.0737. Calcd for $C_{15}H_{11}NO_3$: M, 253.0737.

8-Acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (22c): Brown needles; mp 139—141 °C (from MeOH); UV_{max} (MeOH) 260 (log ε 4.36), 269 (4.32), 300 (3.82), 320 (3.70 sh), 334 (3.66 sh), and 415 nm (4.05), (MeOH+6 M HCl) 225 (log ε 4.35), 263 (4.38), 272 (4.41), 323 (3.87), 441 (3.97), and 467 nm (3.93 sh); IR (KBr) 1750 cm^{-1} (C=O); ^1H NMR (270 MHz, CD_3CN) δ=2.10 (3H, s, Me), 5.40 (1H, d, *J*=10.1 Hz, H-6), 5.77 (1H, dd, *J*=10.1 and 2.7 Hz, H-7), 6.00 (1H, dd, *J*=12.7 and 2.7 Hz, H-9), 6.10 (1H, d, *J*=12.7 Hz, H-10), 6.42 (1H, m, *J*=8.0 and 2.0 Hz, H-4), and 6.77 (3H, m, H-1,2,3). Found: *m/z* 253.0721. Calcd for $C_{15}H_{11}NO_3$: M, 253.0737.

9-Acetoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (22d): Brown needles; mp 149—151 °C (from MeOH); UV_{max} (MeOH) 260 (log ε 4.49), 268 (4.39), 295 (3.94), and 410 nm (4.07), (MeOH+6 M HCl) 226 (log ε 4.29), 262 (4.32), 272 (4.37), 315 (4.00), 432 (3.95), and 457 nm (3.91 sh); IR (KBr) 1743 cm^{-1} (C=O); ^1H NMR (270 MHz, CD_3CN) δ=2.12 (3H, s, Me), 5.40 (1H, d, *J*=9.6 Hz, H-6), 5.57 (1H, dd, *J*=11.6 and 2.6 Hz, H-8), 5.79 (1H, d, *J*=2.6 Hz, H-10), 6.02 (1H, dd, *J*=11.6 and 9.6 Hz, H-7), 6.44 (1H, dd, *J*=8.0 and 2.0 Hz, H-4), and 6.66—6.88 (3H, m, H-1,2,3). Found: C, 70.85; H, 4.55; N, 5.29%; M^+, 253. Calcd for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.38; N, 5.53; M, 253.

Methylation of 6—10. Ethereal diazomethane (0.5 mmol) was added to a solution of **9** (10 mg, 0.05 mmol) in ether (2 cm^3) and the mixture was stirred for 24 h at room temperature. After removal of the ether, the residue was recrystallized from benzene to give **25d** (10 mg, 80% yield). Similarly, **25a** (70% yield), **25b** (70% yield), and **25c** (80% yield) were obtained from **6**, **7**, and **8**, respectively. Compound **10** was recovered unchanged under similar conditions.

6-Methoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (25a): Brown needles; mp 94—96 °C (from benzene); UV_{max} (MeOH) 263, 269, 312, and 415 nm, (MeOH+6 M HCl) 230, 275, 310, and 436 nm; ^1H NMR (270 MHz, CD_3CN) δ=3.68 (3H, s, OMe), 6.08 (1H, ddd, *J*=12.0, 6.5, and 3.0 Hz, H-8), 6.34 (2H, m, H-7,9), 6.39 (1H, d, *J*=12.0 Hz, H-10), 6.49 (1H, m, H-4), and 6.74—6.85 (3H, m, H-1,2,3). Found: *m/z* 225.0771. Calcd for $C_{14}H_{11}NO_2$: M, 225.0790.

7-Methoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (25b): Brown needles; mp 87—89 °C (from benzene); UV_{max} (MeOH) 222, 260, 268, 325, and 414 nm, (MeOH+6 M HCl) 226, 261, 271, 310, 430, and 467 nm (sh); ^1H NMR (270 MHz) δ=3.66 (3H, s, OMe), 5.65 (1H, d, *J*=1.5 Hz, H-6), 5.92 (1H, dd, *J*=12.5 and 9.7 Hz, H-9), 6.10 (1H, d, *J*=12.5 Hz, H-10), 6.25 (1H, dd, *J*=9.7 and 1.5 Hz, H-8), 6.49 (1H, m, H-4), and 6.74—6.86 (3H, m, H-1,2,3); MS (70 °C) *m/z* 225 (M^+, 64%), 210 (M^+—Me, 24%), and 182 (M^+—Me—CO, 100%). Found: *m/z* 225.0763. Calcd for $C_{14}H_{11}NO_2$: M, 225.0790.

8-Methoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (25c): Brown needles; mp 105—107 °C (from benzene); UV_{max} (MeOH) 220, 263, 272, 320, and 427 nm, (MeOH+6 M HCl) 228, 265, 271, 300, 325, 440, and 510 nm (sh); ^1H NMR (270 MHz) δ=3.58 (3H, s, OMe), 5.35 (1H, dd, *J*=10.3 and 2.0 Hz, H-7), 5.51 (1H, d, *J*=10.3 Hz, H-6), 6.12 (1H, dd, *J*=13.0 and 2.0 Hz, H-9), 6.28 (1H, d, *J*=13.0 Hz, H-10), 6.34 (1H, dd, *J*=7.5 and 1.5 Hz, H-4), and 6.64—6.81 (3H, m, H-1,2,3). Found: *m/z* 225.0793. Calcd for $C_{14}H_{11}NO_2$: M, 225.0790.

9-Methoxybenzo[*b*]cyclohept[*e*][1,4]oxazine (25d): Brown needles; mp 89—91 °C (from benzene); UV_{max} (MeOH) 224 (log ε 4.09), 258 (4.39), 267 (4.44), 350 (3.99 sh), 412 (4.08), and 448 nm (3.72 sh), (MeOH+6 M HCl) 225 (log ε 4.13), 252 (4.25), 259 (4.30), 287 (4.32), 305 (4.21), and 432 nm (3.94); ^1H NMR (270 MHz) δ=3.64 (3H, s, OMe), 5.44 (1H, d, *J*=9.7 Hz, H-6), 5.69 (2H, m, H-8,10), 5.99 (1H, dd, *J*=12.3 and 9.7 Hz, H-7), 6.47 (1H, m, H-4), and 6.72—6.86 (3H, m, H-1,2,3). Found: C, 74.35; H, 5.06; N, 5.93%; M^+, 225. Calcd for $C_{14}H_{11}NO_2$: C, 74.65; H, 4.92; N, 6.22%; M, 225

Hydrolysis of 22a—d. Similar procedures as those described above for compounds **11a—e** were followed. Thus, the treatment of **22a—d** (ca. 5 mg) with AcOH (2 cm^3) at 100 °C for 5—15 min gave **6—9**, respectively, in an almost quantitative yield.

Hydrolysis of 25a—d. Solutions of **25a—d** (ca. 2 mg) in methanol (5 cm^3) were allowed to stand for 48 h at room temperature. After removal of the solvent in vacuo, the residue was recrystallized from methanol, giving **6—9** in an almost quantitative yield.

Hydrolysis of 15. A solution of **15**[6] (50 mg) in acetic acid (10 cm^3) was heated at 110 °C for 10 h. The reaction mixture was chromatographed over thin-layer plates with benzene–MeOH (10:1) as the eluent, giving **16** (2 mg, 5% yield), **17** (34 mg, 80% yield), and **12d**[6] (trace).

8-Bromobenzo[*b*]cyclohept[*e*][1,4]oxazin-6(11*H*)-one (16): Brown solid; UV_{max} (MeOH) 230, 260, 300, 320 (sh), and 400 nm; MS (70 °C): *m/z* 291 (M^+, 15%), 289 (M^+, 17%), 263 (M^+—CO, 71%), 261 (M^+—CO, 65%), 182 (67%), and 154 (100%). Found: *m/z* 290.9741 and 288.9739 (1:1). Calcd for $C_{13}H_8NO_2Br$: M, 290.9718 and 288.9738.

6-Bromobenzo[*b*]cyclohept[*e*][1,4]oxazin-8(11*H*)-one (17): Brown solid; UV_{max} (MeOH) 250, 275, 315, and 410 nm, (MeOH+6 M HCl) 236, 264, 270, 320, and 435 nm, (MeOH+6 M NaOH) 238, 265, 275, 320, 463, and 495 nm (sh). Found: *m/z* 290.9759 and 288.9741 (1:1). Calcd for $C_{13}H_8NO_2Br$: M, 290.9718 and 288.9738.

Acetylation of 16 and 17. Acetylation of **16** and **17** was conducted in a manner similar to that described above for **6—10**, and gave **23** and **24**, respectively, in an almost quantitative yield.

6-Acetyloxy-8-bromobenzo[*b*]cyclohept[*e*][1,4]oxazine (23): Brown needles; mp 139—140 °C (from benzene); UV_{max} (MeOH) 220 (log ε 4.33), 258 (4.40), 269 (4.32), 294 (3.94), 305 (3.94), 319 (3.89 sh), and 409 nm (4.08), (MeOH+6 M HCl) 232 (log ε 4.29), 263 (4.40), 270 (4.42), 325 (3.95), 445 (4.03), and 472 nm (3.98 sh); IR (KBr) 1770 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=2.22 (3H, s, Me), 6.05 (1H, d, *J*=13.0 Hz, H-10), 6.27 (1H, d, *J*=2.0 Hz, H-7), 6.28 (1H, dd, *J*=13.0 and 2.0 Hz, H-9), 6.41 (1H, m, H-4), and 6.76—6.90 (3H, m, H-1,2,3). Found: *m/z* 330.9792 and 332.9832 (1:1). Calcd for $C_{15}H_{10}NO_3Br$: M, 330.9844 and 332.9824.

8-Acetyloxy-6-bromobenzo[*b*]cyclohept[*e*][1,4]oxazine (24): Brown needles; mp 110—111 °C (from benzene); UV_{max} (MeOH) 259 (log ε 4.25), 268 (4.23), 307 (3.76), 320 (3.71 sh), and 410 nm (3.90), (MeOH+6 M HCl) 227 (log ε 4.27), 263 (4.42), 270 (4.24), 321 (3.81), 441 (3.82), and 471 nm (3.77 sh); IR (KBr) 1750 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=2.17 (3H, s,

Me), 5.89 (1H, dd, J=13.0 and 2.2 Hz, H-9), 6.18 (1H, d, J=13.0 Hz, H-10), 6.22 (1H, d, J=2.2 Hz, H-7), 6.60 (1H, dd, J=8.0 and 2.0 Hz, H-4), 6.78—6.94 (3H, m, H-1,2,3). Found: C, 54.50; H, 3.27; N, 3.95%; M^+, 332. Calcd for $C_{15}H_{10}NO_3Br$: C, 54.24; H, 3.03; N, 4.22%; M, 332.

Hydrolysis of 18. A solution of **18**[9] (25 mg) in acetic acid (5 cm^3) was heated at 110 °C for 5 h, followed by the same procedures as those described above for **15**, and produced **19** (13 mg, 60% yield) and **20** (4 mg, 20% yield).

7,9-Dibromobenzo[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-one (19): Reddish-violet needles; mp 256—257 °C (from benzene); UV_{max} (MeOH) 256 (log ε 4.42), 272 (4.26 sh), 302 (4.20), 339 (3.79 sh), 418 (3.51 sh), and 520 nm (4.08), (MeOH+6 M NaOH) 260 (log ε 4.31), 274 (4.25), 304 (4.16), and 503 nm (4.16); IR (KBr) 3270 and 1557 cm^{-1}; ^{1}H NMR (100 MHz) δ=6.43—6.82 (4H, m, H-1,2,3,4), 7.62 (1H, d, J=2.0 Hz, H-6), and 8.08 (1H, d, J=2.0 Hz, H-8); MS (140 °C): m/z 370 (M^+, 50%), 368 (M^+, 100%), and 366 (M^+, 51%). Found: C, 42.41; H, 2.12; N, 3.59%. Calcd for $C_{13}H_7NO_2Br_2$: C, 42.31; H, 1.91; N, 3.80%. Compound **19** was also obtained (90 mg, 90% yield) by heating **21**[16] (100 mg, 0.27 mmol) with **4** (50 mg, 0.46 mmol) in ethanol (3 cm^3) at 60 °C for 2 h, followed by the same procedures as those described above for **12c**.

6,8-Dibromobenzo[*b*]cyclohept[*e*][1,4]oxazin-10(11*H*)-one (20): Reddish-violet solid; UV_{max} (MeOH) 225, 260, 270 (sh), 320, 420, and 510 nm; ^{1}H NMR (270 MHz) δ=6.54 (2H, m, H-2,4), 6.77 (2H, m, H-1,3), 7.12 (1H, d, J=1.8 Hz, H-9), 7.84 (1H, br, NH), and 8.08 (1H, d, J=1.8 Hz, H-7). Found: m/z 370.8789, 368.8847, and 366.8838 (1:2:1). Calcd for $C_{13}H_7NO_2Br_2$: M, 370.8804, 368.8824, and 366.8844.

Reduction of 19 and 20 Zinc dust (20 mg) was added to a solution of **19** (30 mg, 0.08 mmol) in acetic acid (5 cm^3), and the mixture was stirred at room temperature for 2 h. The reaction mixture was filtered and evaporated to dryness in vacuo. The residue was then chromatographed on silica-gel thin layer plates with benzene–MeOH (50:1) as the eluent, giving compound **10**[4] (40% yield). Compound **10** was also obtained from **20** by following an identical procedure.

We thank professor Hiroshi Yamamoto (Okayama Univ.) for helpful discussions. We also thank Professor Jun-ichi Aihara (Shizuoka Univ.) for helpful discussions on the resonance energy and ring currents. We are grateful to Dr. Chizuko Kabuto, Instrumental Analysis Center for Chemistry, Faculty of Science, Tohoku University, for helpful discussions concerning the X-ray crystallograph analysis. We also thank Mr. Hiroshi Isa and Miss Rie Taguchi for their assistance with some of the experiments.

Benzophenone-Sensitized Photolysis of *N*,*N*-Dibenzyl-*O*-acylhydroxylamines. Mechanism of the Imine-Forming Radical Elimination Reaction

Tadamitsu SAKURAI,* Hisashi MIZUNO, Tsuneari KUBOTA, and Hiroyasu INOUE
Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221
(Received January 28, 1991)

Title hydroxylamines (**1**) undergo benzophenone-sensitized photolysis to give *N*-benzylidenebenzylamine (**2**), *p*-substituted benzoic acids (**3**), and monosubstituted benzenes (**4**) derived from decarboxylation of *p*-substituted benzoyloxyl radicals. Analysis of the linear Stern–Volmer plots, both for the sensitized photolysis of **1** and for the phosphorescence quenching of benzophenone by **1**, demonstrates the participation of triplet **1** in this photolysis. The logarithm of the ratio (k_r/k_d), where k_r is the rate constant for homolytic cleavage of the N–O bond in triplet **1** and k_d is that for its deactivation, used as a measure of the triplet-state reactivities of **1**, exhibited a good Hammett-type relationship against the substituent constant (σ) with a slope (ρ) of −0.75. This indicates the exclusive occurrence of homolysis of the N–O bond in the first excited triplet state of **1**. Thus the decomposition of **1** activated by triplet benzophenone is classified as an imine-forming radical elimination. The results of deuterium isotope and micellar effects on the sensitized photolysis suggest that the "out-of-cage" products **4** are obtained by decarboxylation and subsequent hydrogen abstraction of *p*-substituted benzoyloxyl radicals which escaped from the triplet cage in competition with spin inversion to the singlet cage. In this singlet cage, hydrogen abstraction giving **2** and **3** and recombination affording the starting **1** were found to take place exclusively.

Much effort has been devoted to synthetic, mechanistic, and theoretical studies on olefin-forming eliminations and has contributed to the establishment of one of the chemical paradises.[1] A detailed mechanistic investigation of these unimolecular and bimolecular eliminations has unraveled the delicate transition-state structure for the reactions.[2] Base-promoted imine-forming eliminations have recently been found[3] and a detailed comparison has been made between mechanisms of olefin- and imine-forming eliminations, with attention focusing primarily upon the effects of the nitrogen atom in a molecule on the transition-state structure.[4] On the other hand, there are some interesting reports describing the stereochemistry of olefin-forming radical eliminations.[5]

In contrast with ionic imine-forming eliminations there has been no study on imine-forming radical eliminations as far as we know. As an extension of our systematic study of the direct and sensitized photolyses of hydroxamic acid derivatives,[6a-e] we prepared *N*,*N*-dibenzyl-*O*-acylhydroxylamines (**1a**—**c**) and investigated benzophenone (BP)-sensitized photolysis of these compounds, hoping to find an imine-forming radical elimination and to gain an insight into its mechanism. In this paper we present the first observation of imine-forming radical eliminations of **1a**—**c** and discuss their mechanism.

Results

Products Derived from the Sensitized Photolysis. An oxygen-free acetonitrile solution of **1a** (0.020 M, 1 M=1 mol dm^{-3}) containing BP (0.020 M) was irradiated for a given period of time with light of wavelengths longer than 320 nm on a merry-go-round irradiation apparatus. The products were identified by comparing their HPLC or GLC behavior with that of commercially available authentic samples. As shown in Fig. 1, *N*-benzylidenebenzylamine (**2**), *p*-anisic acid (**3a**), and anisole (**4a**, data

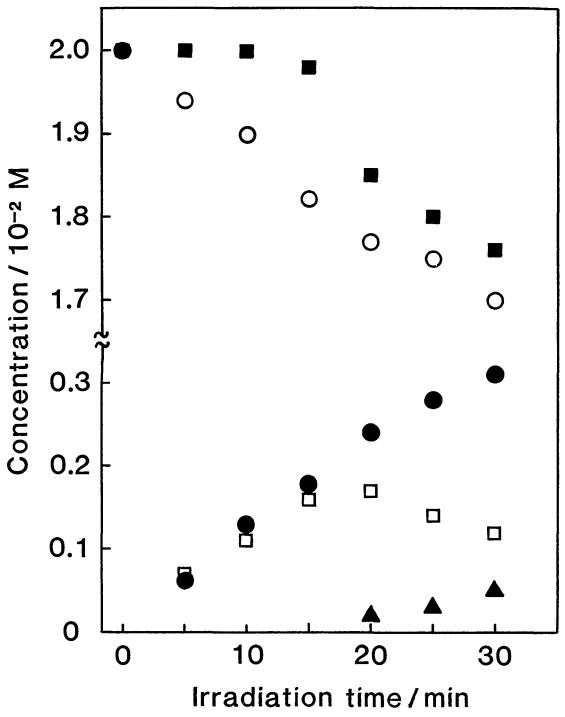

Fig. 1. Plots of reactant and product concentrations against irradiation time for the BP (0.020 M)-sensitized photolysis of **1a** (0.020 M) with light of wavelengths longer than 320 nm in oxygen-free acetonitrile. ○: **1a**, ●: **3a**, □: **2**, ■: BP, ▲: benzopinacol.

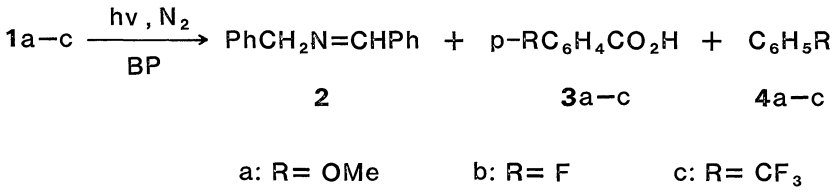
not presented) were obtained as the only detectable products at conversions lower than 9%, while BP remained unchanged during the irradiation. On the other hand, a secondary photoreaction between **2** and BP in excited states occurred to give benzopinacol as one of the products at conversions higher than 12%. This secondary photoreaction is reflected in a decrease in both **2** and BP concentrations (Fig. 1) and was confirmed by independent irradiation of **2** in the presence of BP under identical conditions. Control experiments revealed that there was no decomposition of **1a** without BP under the same irradiation conditions. The detectable formation of **4a**, derived from decarboxylation of *p*-anisoyloxyl radical, suggests the involvement of homolytic cleavage of the N–O bond in **1a**. Similar results were obtained by BP-sensitized photolysis of **1b** and **1c** (Scheme 1).

Quenching of the BP Phosphorescence by 1a—c. The room-temperature phosphorescence of BP (the first triplet excitation energy, E_{T_1}=69 kcal mol^{-1}; 1 kcal=4.184 kJ)[7] was quenched by **1a—c** according to the Stern–Volmer equation (Fig. 2). The E_{T_1} values of **1a—c** (69, 67, and 67 kcal mol^{-1} for **1a**, **1b**, and **1c**, respectively) were estimated from the 0–0 peaks of their phosphorescence spectra in methanol–ethanol (1:1 v/v) at 77 K. Although the fluorescence of **1a—c** is too weak to be detected, it is evident from a comparison of the UV spectra of **1a—c** with that of BP that the first singlet excitation energy of **1a—c** is much higher than that of BP. Thus the BP-phosphorescence quenching is due to triplet-triplet energy transfer from BP to **1a—c** but not due to singlet–singlet energy transfer. The quenching constants ($k_t\tau_T$, where k_t and τ_T refer to the rate constant for triplet–triplet energy transfer and the lifetime of triplet BP without **1a—c**, respectively) were determined from the slopes of linear Stern–Volmer plots (Fig. 2) to be 62, 48, and 56 M^{-1} for **1a**, **1b**, and **1c**, respectively. A comparison of these constants demonstrates that the triplet energy transfer efficiency undergoes substituent effects, if any, to only a small extent.

Quantum Yields for the Sensitized Photolysis. The results of BP-phosphorescence quenching as well as product analysis suggest that the BP-sensitized photolyses of **1a—c** proceed according to Scheme 2 which allows us to derive Eqs. 1 and 2 under the steady-state approximation:

$$1/\Phi_{-1}=1/\Phi_2=(1+k_d/k_r)(1+1/k_t\tau_T[\mathbf{1a—c}]) \quad (1)$$



Scheme 1.

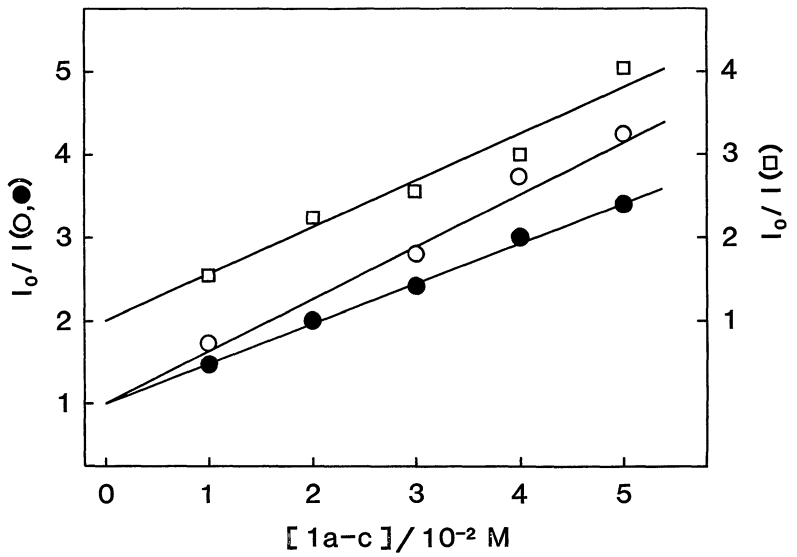


Fig. 2. Stern–Volmer plots for the quenching of BP (0.050 M) phosphorescence by **1a** (○), **1b** (●), and **1c** (□) under nitrogen in acetonitrile at room temperature (26±1°C). I and I_0 are the phosphorescence intensity of BP with and without **1a—c**, respectively.

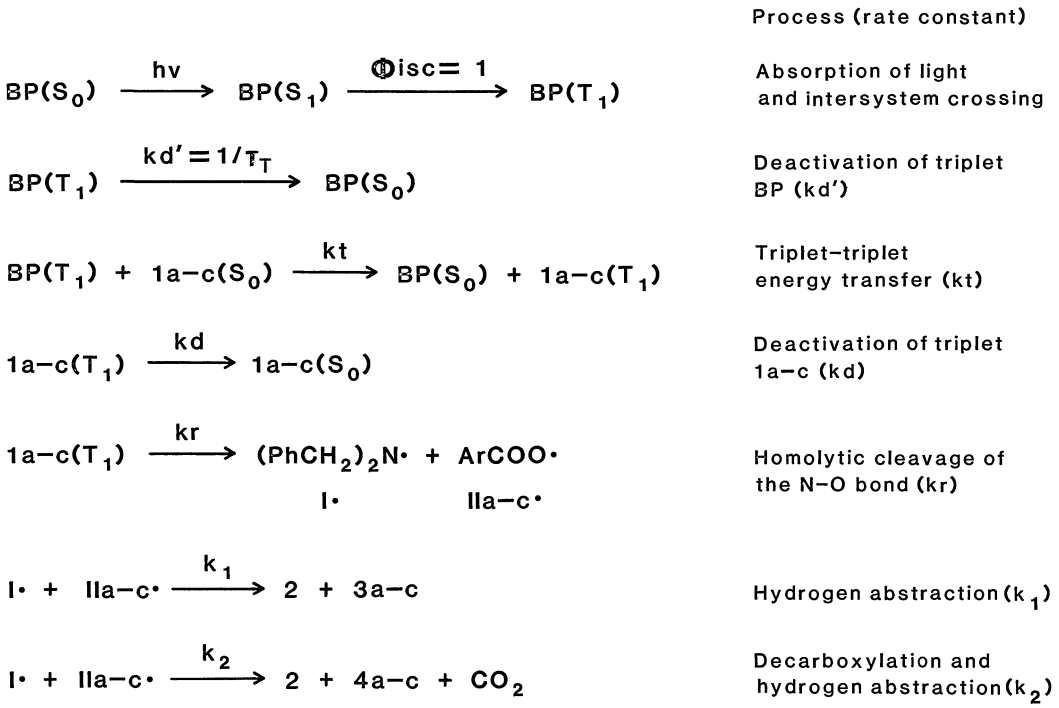

Scheme 2.

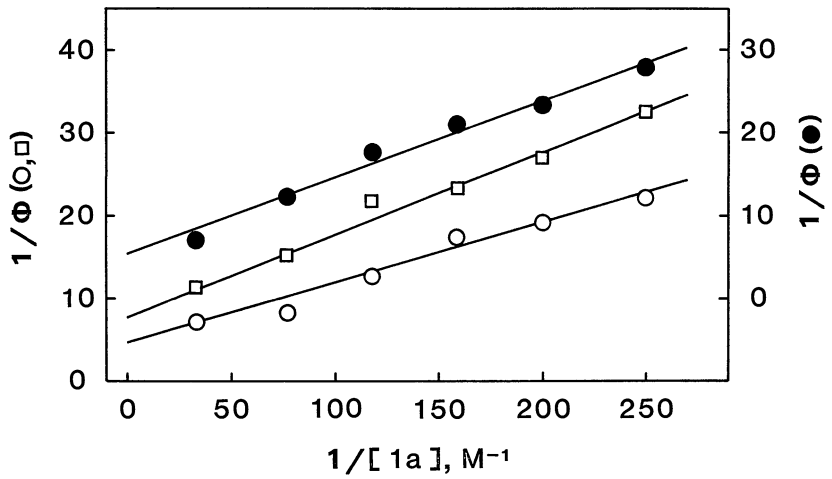

Fig. 3. Stern-Volmer plots of $1/\Phi_{-1a}$ (○), $1/\Phi_2$ (●), and $1/\Phi_{3a}$ (□) versus 1/[**1a**] for the BP (0.050 M)-sensitized photolysis of **1a** with 366-nm light in oxygen-free acetonitrile.

$$1/\Phi_3=(1+k_d/k_r)(1+k_2/k_1)(1+1/k_t\tau_T[\mathbf{1a}—\mathbf{c}]) \quad (2)$$

where Φ_{-1}, Φ_2, and Φ_3 are the quantum yields for the disappearance of **1a**—**c** and for the appearance of **2** and **3**, respectively. These quantum yields were determined by using a potassium trioxalatoferrate (III) actinometer at low conversions (3—4%) of the starting **1a**—**c**. If our Scheme for the sensitized photolysis is valid, then we expect a linear relationship between $1/\Phi$ and the reciprocal of **1a**—**c** concentrations (1/[**1a**—**c**]). In Fig. 3 are shown typical double reciprocal plots for the BP-sensitized photolysis of **1a** in acetonitrile. Similar plots were obtained also for **1b** and **1c**.

The good linear correlation between $1/\Phi$ and 1/[**1a**—**c**], therefore, justifies the validity of Scheme 2. These linear Stern-Volmer plots of $1/\Phi_{-1}$, $1/\Phi_2$, and $1/\Phi_3$ vs. 1/[**1a**—**c**] allow us to estimate the limiting quantum yields for the disappearance of **1a**—**c** ($\Phi_{-1,\mathrm{lim}}$) and for the appearance of **2** ($\Phi_{2,\mathrm{lim}}$) and **3a**—**c** ($\Phi_{3,\mathrm{lim}}$). In addition, the intercept/slope ratios of these linear plots provide the $k_t\tau_T$ values, while the k_r/k_d values can be evaluated based on Eq. 1. All of these values (Φ_{lim}, $k_t\tau_T$, and k_r/k_d) are

Table 1. Limiting Quantum Yields and Related Parameters for the BP (0.050 M)-Sensitized Photolysis of **1a—c** (0.0040—0.030 M) with 366-nm Light under Nitrogen at 28±2°C

a) Calculated by assuming $\Phi_{4,\lim}=1/2(\Phi_{-1,\lim}+\Phi_{2,\lim})-\Phi_{3,\lim}$. b) Determined from the BP-phosphorescence quenching experiments. c) Average of the $k_t\tau_T$ values determined from the quantum yield (Φ_{-1}, Φ_2, and Φ_3) measurements. d) Determined for **[1a]**=0.030 M (GLC analysis). e) Could not be determined. f) Not determined.

collected in Table 1 which also includes the results of solvent and deuterium isotope effects on the quantum yields for the BP-sensitized photolysis of **1a**. The latter effects were examined in acetonitrile by use of *N,N*-di(benzyl-α-d_2)-*O*-(*p*-anisoyl)hydroxylamine (**1a-d_4**). An additional supporting evidence for Scheme 2 comes from the finding that the $k_t\tau_T$ value determined from the BP-phosphorescence quenching corresponds well to that obtained from the linear plot of $1/\Phi$ against $1/[\mathbf{1}]$ for any starting **1** as well as in any solvent studied.

Discussion

Substituent and Deuterium Isotope Effects. Because the $k_t\tau_T$ values obtained for **1a**, **1b**, and **1c** in acetonitrile may be taken as consistent with each other within the experimental error, we can discuss a difference in the reactivity among these compounds from the standpoint of substituent effects on the triplet-state reactivities (k_r/k_d). One expects that an increased electron-withdrawing ability of the substituent R should accelerate heterolytic cleavage of the N–O bond in **1**[3] whereas it may suppress homolytic cleavage of this bond because of an electrophilic character of the aroyloxyl radical formed by this type of N–O bond cleavage.[8] A comparison of the k_r/k_d values obtained for **1a—c** in acetonitrile establishes that the triplet-state reactivity decreases with increasing electron-withdrawing ability of the substituent R; this strongly evidences that homolytic cleavage of the N–O bond occurs in triplet **1a—c**. An important problem is whether the substituent R affects the triplet-state deactivation (k_d) or the N–O bond cleavage (k_r) process. Figure 4 shows that there is a nice Hammett-type linear relationship with a slope (ρ) of −0.75 between $\log(k_r/k_d)$ and the substituent constant σ values. This ρ value suggests a relatively large contribution of the ionic structure to the transition-state structure **III** for homolytic N–O bond cleavage in triplet **1a—c**.

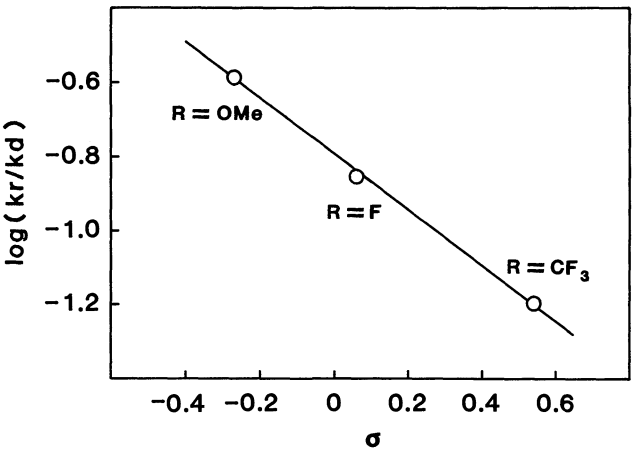

Fig. 4. Correlation of $\log(k_r/k_d)$ and σ values for the BP-sensitized photolysis of **1a—c** with 366-nm light in acetonitrile.

On the other hand, the Hammett ρ–σ correlation has been applied in order to scrutinize the transition-state structure for the homolysis of the benzylic C–H bond. The ρ values in a range of −0.4 to −1.0 have been obtained from this correlation depending on the structures of both substrates and attacking radicals, and explained in terms of a similar transition-state structure.[9] Thus the fact that our ρ value is comparable to these ρ values suggests that the N–O bond cleavage process rather than the triplet-state deactivation is mainly subject to polar substituent effects.

Inspection of Scheme 2 provides us another important problem: Is the benzylic hydrogen atom of dibenzylaminyl radical (**I**·) abstracted by aroyloxyl radical (**II**·)? To solve this problem we prepared **1a-d_4** and examined

$^3[\ BzI_2N\text{----}OC(=O)Ar \longleftrightarrow BzI_2N\text{----}OC(=O)Ar\ ]^{\neq}$ (δ• δ• ↔ δ− δ+)

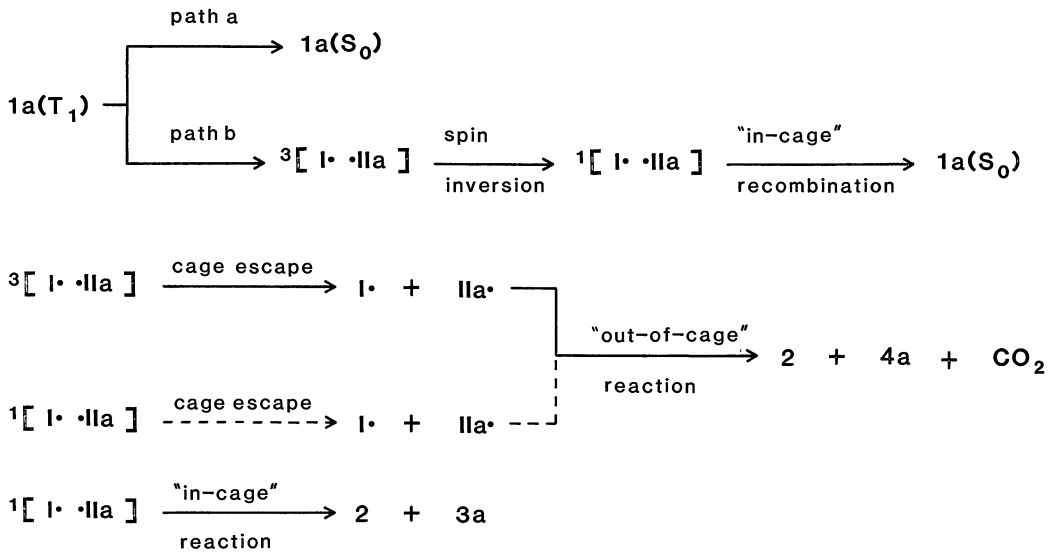

Scheme 3.

deuterium isotope effects on the reaction of **1a** with triplet BP. The deuterium substitution decreases both the Φ_{lim} and k_r/k_d values by a factor of about 2, whereas the $k_t\tau_T$ value is not affected by deuteration (Table 1). In order to discuss the mechanism of our imine-forming radical eliminations in more detail, we present Scheme 3 which takes into account the spin-correlated (singlet or triplet) radical pair in a solvent cage as already successfully applied to the BP-sensitized photolysis of *N*-(1-naphthoyl)-*O*-(*p*-toluoyl)-*N*-phenylhydroxylamine (NT).[6b] A comparison of Schemes 2 and 3 shows that the rate constants k_r and k_d in Scheme 2 correspond to the rate of the N–O bond cleavage in triplet **1a**—**c** giving the triplet radical pair and to the total rate of physical (path a) and chemical (path b) deactivations of triplet **1a**—**c** affording eventually the starting **1a**—**c**, respectively. In addition, the rate constants k_1 and k_2 in Scheme 2 conform to the total rate of triplet→singlet cage spin inversion and subsequent "in-cage" hydrogen abstraction yielding **2** and **3a**—**c** and to the total rate of diffusive escape from the triplet cage, decarboxylation of "out-of-cage" aroyloxyl radicals, and subsequent hydrogen abstraction forming eventually **2**, **4a**—**c**, and CO_2, respectively.

The observation that the relative phosphorescence quantum yield $[\Phi_p(\mathbf{1a})/\Phi_p(\mathbf{1a}\text{-}d_4)]$ of **1a** and **1a**-d_4 (E_{T_1}= 69 kcal mol^{-1}) at 77 K is nearly equal to unity makes it reasonable to assume that in addition to the N–O bond cleavage process of triplet **1a**, its physical deactivation process (path a in Scheme 3) also undergoes deuterium isotope effects to a negligible extent. Thus a decrease in Φ_{lim} as well as k_r/k_d observed by deuteration implies that hydrogen abstraction from **I**· by **IIa**· takes place in competition with recombination of these two radicals to generate the starting **1a**. The latter process (path b in Scheme 3) contributes to accelerating the deactivation process of triplet **1a** and, hence, the deuteration of **1a** should enhance the chemical deactivation process of this triplet to reduce k_r/k_d as observed. In view of the fact that hydrogen abstraction to give **2** and **3a**—**c** (k_1 in Scheme 2) competes with decarboxylation to form eventually **2** and **4a**—**c** (k_2 in Scheme 2), the retardation of hydrogen abstraction by the deuterium incorporation is expected to be reflected in an increase in the relative rate of this decarboxylation and, thus, in the enhanced k_2/k_1 value. From Eqs. 1 and 2 we can estimate the k_2/k_1 values using the Φ_{lim} values listed in Table 1: k_2/k_1 =0.57 (**1a**), 0.49 (**1a**-d_4), 0.25 (**1b**), and 1.0 (**1c**) in acetonitrile. A comparison of these values for **1a** and **1a**-d_4 clearly indicates that decarboxylation of **IIa**· cannot compete with hydrogen abstraction from **I**· by this radical. This means that diffusive separation of **I**· and **IIa**· from the caged singlet radical pair must be slow enough to allow the exclusive hydrogen abstraction and recombination in this cage (Scheme 3). It is thus very likely that anisole (**4a**), one of the "out-of-cage" products, originates from decarboxylation of **IIa**· which escaped from the triplet cage in competition with spin inversion from the triplet to the singlet pair. Because diffusive separation of the caged radical pair is thought to undergo negligible deuterium isotope and polar substituent effects, our k_2/k_1 value may reflect the relative ease of this spin inversion, which is in the following order: R=F (k_2/k_1=0.25)>R=OMe (0.57)>R=CF_3 (1.0). Although this order seems to be consistent with that of the magnitude of heavy-atom effects of these substituents on the rate of spin inversion, we cannot discuss it in detail at the present stage.

Solvent and Micellar Effects. Our previous study on the BP-sensitized photolysis of NT indicated that the triplet-state reactivity (k_r/k_d) of this diacylhydroxylamine increases with decreasing solvent polarity.[6a,b] On

the other hand, a study of the micellar effects on the photolysis of NT provided us an interesting result that the "out-of-cage" reaction of the resulting radicals is almost completely suppressed in the micelle cage.[6b] In order to discuss further the reaction course of imine-forming radical eliminations, we examined solvent and micellar effects on the BP-sensitized photolysis of **1a** chosen for this purpose.

The $k_t\tau_T$ values obtained by the above-mentioned two methods are in good agreement with each other also for 1,2-dichloroethane and benzene (Table 1), indicating that the reaction proceeds according to Scheme 2 in any solvent employed. In addition the triplet-state reactivity tends to increase with decreasing solvent polarity, although this reactivity is little affected by a change in solvent polarity. Interestingly the sensitized photolysis of **1a** in benzene does not give any **4a** derived from decarboxylation of **IIa·**. Because benzene is not so viscous (viscosity at 30 °C=0.5621 cP),[10] it is very unlikely that only the "in-cage" reaction occurs in this nonpolar solvent. Ingold and co-workers have recently reported that in a nonpolar solvent, carbon tetrachloride, the rates of unimolecular decarboxylation and bimolecular hydrogen abstraction of **IIa·** increase by a factor of about 20 and 2—3, respectively, compared with those in a polar solvent, acetonitrile.[11] Their results suggest that the reactivities of **IIa·** should increase to more extent in the nonpolar solvent, benzene, than in acetonitrile, and thus allow us to expect that we obtain a larger $\Phi_{4,\mathrm{lim}}$ value in benzene than in acetonitrile since solvent changes can have a dramatic effect on the rate of decarboxylation of **IIa·**. However, the result (Table 1) is not in line with this expectation. Aromatic solvents including benzene are known to form a charge-transfer-type π-complex with an electrophilic chlorine atom.[12] The fact that aroyloxyl radicals add easily to alkenes suggests that these radicals also have an electrophilic character.[8] Thus it is reasonable to assume that the radical **IIa·** forms a similar type of π-complex with benzene to stabilize this radical and, hence, to reduce the relative rate of decarboxylation of the "out-of-cage" radical **IIa·** to hydrogen abstraction from **I·** by **IIa·**. If benzene can enhance the reactivity of **I·** toward hydrogen abstraction to an extent similar to or more than that of **IIa·**, then the existence of such a π-complex provides a good explanation for the negligible formation of **4a** in benzene.

It is well established that micelles offer a large energy barrier to diffusive separation of a radical pair generated within the micellar phases, so that the efficiency of "in-cage" reaction of the triplet-derived radical pair is enhanced in a micellar solution to a larger extent than that in a homogeneous solution.[13] Based on this characteristic of micelles we expect in the sensitized photolysis of **1a** in micelles that the quantum yield for the formation of **4a**, one of the "out-of-cage" products, becomes negligibly small.

The sensitized photolysis of **1a** (1.3×10^{-2} M) by BP (2.0×10^{-2} M) in hexadecyltrimethylammonium chloride (HTAC) micelles (1.8×10^{-3} M) under nitrogen at 28±1 °C gave the following results: Φ_{-1a}=0.03, Φ_2=0.03, Φ_{3a}=0.03, and $\Phi_{4a}\approx0$. For comparison these quantum yields were determined in acetonitrile under identical conditions except for the omission of HTAC micelles: Φ_{-1a}=0.10, Φ_2=0.09, Φ_{3a}=0.08, and Φ_{4a}=0.01. The finding that the ratio (I_0/I=1.9) of BP-phosphorescence intensity with (I) and without (I_0) **1a** in micelles is consistent with that (I_0/I=1.8) obtained in acetonitrile under the same conditions allows us to discuss the differences in the quantum yields on the basis of micellar effects not on the triplet–triplet energy transfer efficiency but solely on the "in-cage" reaction efficiency. As we would expect, the formation of **4a** in HTAC micelles is negligible, whereas the quantum yields Φ_{-1a}, Φ_2, and Φ_{3a} for the reaction in this micelle decreased by a factor of about 3 compared with those in acetonitrile. Owing to the relatively large intramicellar viscosity of HTAC (18 cP at 30 °C),[14] translational movement of the paired radicals **I·** and **IIa·** in this micelle should be restricted to a large extent to result in a more efficient recombination of **I·** and **IIa·** giving the starting **1a** than hydrogen abstraction from **I·** by **IIa·** forming **2** and **3a**, as observed. These observations, therefore, constitute further evidence for the occurrence of recombination in competition with hydrogen abstraction within the singlet solvent cage.

Experimental

General Methods. HPLC analysis of the photoproducts was performed on a Shimadzu Model LC-6A high-performance liquid chromatograph equipped with a 4.6×250-mm ODS (Zorbax) column and a Shimadzu Model SPD-2A UV detector (240 nm). IR spectra were taken with a Hitachi Model 270-30 infrared spectrometer. ^{1}H NMR spectra were recorded on a JEOL Model FX-200 spectrometer. GLC analysis was carried out on a Shimadzu Model GC-8AP gas chromatograph using a 3.0×3000-mm glass column packed with 10% Silicone SE-30 on Uniport B (60/80 mesh, Gasukuro Kogyo). Room-temperature phosphorescence of benzophenone with and without quencher was measured under nitrogen with a Shimadzu Model RF-5000 spectrofluorimeter. UV spectra at room temperature and phosphorescence spectra at 77 K were taken on a Shimadzu Model UV-210A spectrophotometer and a Shimadzu Model RF-500 spectrofluorimeter equipped with a cylindrical rotating sector, respectively.

Materials and Solvents. *N*,*N*-Dibenzylhydroxylamine was prepared according to the method of Jones and Sneed, mp 123—124 °C (lit,[15] 124 °C). *O*-Aroylation of this hydroxylamine with *p*-substituted benzoyl chlorides in the presence of pyridine in dichloromethane gave *N*,*N*-dibenzyl-*O*-(*p*-substituted benzoyl)hydroxylamines in good yields. The crude products were purified by column chromatography over silica gel (70—230 mesh, Merck) using chloroform as eluent followed by repeated recrystallization from hexane to give colorless needles with the following physical properties.

N,*N*-Dibenzyl-*O*-(*p*-anisoyl)hydroxylamine (**1a**), mp 84.5—85.5 °C (lit,[3] 83—84 °C); IR (KBr) 1730 cm^{-1} (ester C=O); ^{1}H NMR ($CDCl_3$) δ=3.83 (3H, s), 4.20 (4H, s), 6.87 (2H, d,

J=8 Hz), 7.24—7.48 (10H, m), and 7.82 (2H, d, J=8 Hz).

N,N-Dibenzyl-*O*-(*p*-fluorobenzoyl)hydroxylamine (**1b**), mp 99—100 °C; IR (KBr) 1740 cm^{-1} (ester C=O); ^1H NMR ($CDCl_3$) δ=4.20 (4H, s), 7.04 (2H, dd, J=8 and 8 Hz), 7.22—7.48 (10H, m), and 7.86 (2H, dd, J=8 and 5 Hz). Found: C, 75.32; H, 5.47; N, 4.16%. Calcd for $C_{21}H_{18}NO_2F$: C, 75.20; H, 5.41; N, 4.18%.

N,N-Dibenzyl-*O*-(*p*-trifluoromethylbenzoyl)hydroxylamine (**1c**), mp 98—99 °C; IR (KBr) 1745 cm^{-1} (ester C=O); ^1H NMR ($CDCl_3$) δ=4.22 (4H, s), 7.22—7.48 (10H, m), 7.59 (2H, d, J=8 Hz), and 7.91 (2H, d, J=8 Hz). Found: C, 68.59; H, 4.61; N, 3.69%. Calcd for $C_{22}H_{18}NO_3F_3$: C, 68.56; H, 4.71; N, 3.64%.

N,N-Di(benzyl-α-d_2)-*O*-(*p*-anisoyl)hydroxylamine (**1a**-d_4), mp 85—86 °C, was obtained from the reaction of *p*-anisoyl chloride with *N,N*-di(benzyl-α-d_2)hydroxylamine, which was prepared according to the previous method,[3] under the same conditions as those used for syntheses of **1a**—**c**. The content of deuterium in **1a**-d_4 was determined to be 98 atom% by ^1H NMR spectroscopy. Benzophenone was purified by repeated recrystallization from ethanol. Fractional distillation of *N*-benzylidenebenzylamine (**2**), anisole (**4a**), fluorobenzene (**4b**), and trifluoromethylbenzene (**4c**) gave analytically pure samples. *p*-Methoxy (**3a**)-, *p*-fluoro (**3b**)-, and *p*-trifluoromethyl (**3c**)-benzoic acids were recrystallized twice from aqueous ethanol. Benzene and 1,2-dichloroethane were of spectroscopic grade and were used without further purification. Purification of acetonitrile was done by standard methods. Hexadecyltrimethylammonium chloride (HTAC) was recrystallized twice from acetone–methanol and dried in vacuo.

Quantum Yields. A potassium trioxalatoferrate(III) actinometer[16] was employed to determine quantum yields for the benzophenone-sensitized photolysis at low conversions (3—4%) of the starting **1a**—**c**. A 450 W high-pressure Hg lamp was used as the light source from which 366-nm light for the photolysis was selected with Corning 0-52, Corning 7-37, and Toshiba IRA-25S glass filters. Linear calibration curves for each compound, made under the same analytical conditions, were utilized to quantify both the disappearance of **1a**—**c** and the appearance of **2** and **3a**—**c**. Quantum yields for the photolysis in HTAC micelles were determined similarly. All the quantum yields are average of more than six determinations. Quantitative GLC analysis of **4a** was done by using its calibration curve. Any attempt to separate the GLC peak of **4b** or **4c** from that of the solvent was unsuccessful so that quantum yields for these products could not be estimated.

The micelle concentration was evaluated on the basis of the equation [micelle]=([HTAC surfactant]−cmc)/N, where [HTAC surfactant]=0.20 M, critical micelle concentration, cmc=1.3×10^{-3} M, and aggregation number, N=113.[17] Both benzophenone and **1a** were stable in micellar solutions for a long period of time so that undesired dark reactions including hydrolysis of **1a** can be ignored during quantum yield determinations.

Parallel Irradiations. Ten milliliters of an acetonitrile solution of **1a**—**c** (0.020 M) and benzophenone (0.020 M) was placed in a Pyrex tube, degassed by bubbling oxygen-free nitrogen through it for 10 min, and sealed. The sealed tubes were irradiated in parallel for a given period of time on a merry-go-round apparatus (Riko Model RH400-10W) with a 400 W high-pressure Hg lamp through a Pyrex-cylindrical solution filter, which was an aqueous solution of Copper(II) sulfate pentahydrate (250 g dm^{-3}) and isolated light of wavelengths longer than 320 nm. All the irradiations were carried out in a water bath thermostated by circulating water.

Amidoselenation of Olefins Using *p*-Toluenesulfonamide as a Nitrogen Nucleophile

Akio Toshimitsu,* Takehiro Kusumoto, Tatsuo Oida, and Shigeo Tanimoto
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received March 4, 1991)

The reaction of olefins, benzeneselenenyl chloride, and *p*-toluenesulfonamide in the presence of zinc(II) chloride affords *N*-[2-(phenylseleno)alkyl]-*p*-toluenesulfonamides in good to excellent yields. When combined with alkylation on the carbon atom bearing the phenylseleno group thus introduced and subsequent oxidative or reductive removal of the selenium moiety, this reaction can be utilized in the preparation of a wide range of allylic or saturated amides.

We have already reported the organoselenium-induced Ritter-type amide syntheses which resulted in the introduction of arylseleno and acylamino groups into the olefins.[1] These reactions were utilized in the preparation of allylic and saturated amides by oxidative and reductive removal of the arylseleno group thus introduced.[1b,2] For the application of selenium chemistry to organic syntheses, introduction of various nitrogen functional groups would be desirable. We now found that *p*-toluenesulfonamide, usually considered as poor nucleophile, reacts cleanly with episelenonium ion to afford *N*-[2-(phenylseleno)alkyl]-*p*-toluenesulfonamides in good to excellent yields. We also tried and succeeded in the lithiation and subsequent alkylation of the carbon atom bearing the phenylseleninyl group generated by the in situ oxidation of the phenylseleno group. In the combination of these procedures, suitable choice of an olefin and an alkylating reagent would allow the preparation of any kind of β-tosylamino-substituted selenide which is a good precursor of allylic or saturated amide by oxidative or reductive removal of phenylseleno group.

Results and Discussion

p-Toluenesulfonamide (1 equiv) was added to the adduct of benzeneselenenyl chloride to styrene (prepared in situ) and the resulting mixture was heated under reflux to afford *N*-[1-phenyl-2-(phenylseleno)ethyl]-*p*-toluenesulfonamide (**1**). The effect of solvent was examined briefly and summarized in Scheme 1 which showed that 1,2-dichloroethane was the suitable solvent for this reaction. By the increase of the amount of sulfonamide to 1.5 equivalent, the yield of **1** was improved up to 96%.

When applied to cyclohexene, the yield of β-tosylamino-substituted selenide (**2**) was 66% under the analogous conditions (Scheme 2). We tried to improve the yield by the addition of a catalyst. Typical results are summarized in Scheme 2. Among various acids ex-

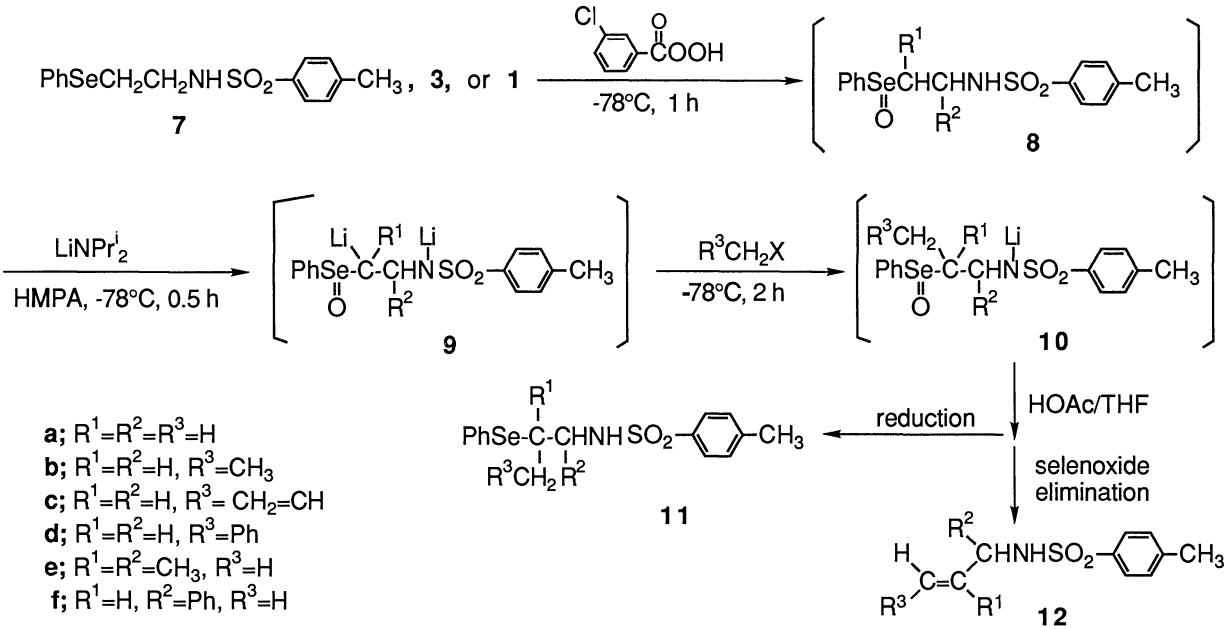
amined, zinc(II) chloride and cation-exchange resin Dow X showed the remarkable effect to produce **2** in satisfactory yields. It is interesting that trifluoromethanesulfonic acid, which was a good catalyst in the amidoselenation using nitriles as the nitrogen source (Ritter-type reaction),[1] did not facilitate the present reaction. The role of the catalyst may be ascribed to the interaction with chlorine atom in 2-chlorocyclohexyl phenyl selenide to form an episelenonium ion intermediate, but the detail is not yet clear.

To confirm the stereospecificity of this reaction, *cis*- and *trans*-2-butene were employed as substrates. In the case of *trans*-2-butene, the yield of **3** (18%) was much worse than that of **2** in the absence of catalyst. The addition of Dow X improved the yield of **3** to moderate (53%), and a satisfactory result was obtained by the use of zinc(II) chloride as catalyst (92%). In all cases, the *erythro*-isomer was found to be the sole product. On the other hand, the *threo*-isomer (**4**) was produced selectively from *cis*-2-butene in quantitative yield ($ZnCl_2$ as catalyst). This stereospecificity can be explained by trans addition of benzeneselenenyl chloride to olefins[3] and subsequent substitution of chlorine atom by *p*-toluenesulfonamide with an anchimeric assistance of phenylseleno group.

When applied to 1-hexene under the same conditions, a mixture of regioisomers (**5** and **6**) was produced in 76% total yield. The Markovnikov-type adduct (**5**) was the major product and the ratio (78:22) was similar to those in the previously reported selenium-induced Ritter-type reactions.[1] This result suggests that the nature of episelenonium ion is similar in both reactions despite the difference of the catalysts and solvents.

It is interesting that **1** was produced in an excellent yield without catalyst while the addition of catalyst was required for the formation of **2**, **3**, **4**, and **5** and **6** in good yields. This difference seems to reflect the activation energy for the formation of episelenonium ion from β-chloroalkyl phenyl selenide. It is reasonable to assume that the episelenonium ion stabilized by phenyl group can be generated more easily than those stabilized by one or two alkyl group(s).

As we succeeded in the introduction of tosylamino and phenylseleno groups into various types of olefins, our interest was focused on the lithiation and subsequent alkylation of the carbon atom bearing the phenylseleno group thus introduced. We adopted the one-pot procedure reported by Reich.[4] As summarized in Scheme 3, this procedure consists of four steps; 1) the oxidation of selenide to selenoxide (**8**) at −78 °C; 2) hydrogen abstraction by lithium diisopropyl amide (LDA) on the carbon atom bearing the seleninyl group in **8**; 3) replacement of the lithium by carbon electrophile (**9**→**10**); 4) reduction of the alkylated selenoxide to selenide (**11**) or to allow the selenoxide to eliminate to afford olefinic compounds (**12**) by raising the reaction temperature. Reaction conditions were examined using unsubstituted selenide **7**. Typical results are summarized in Table 1 using various carbon electrophiles. When the lithiation (**8**→**9**) was carried out in the absence of hexamethylphosphoric triamide (HMPA)(Run 1), the yield of **11a** was a little lower than that in Run 2. Although sodium iodide reduced the selenoxides to selenides effectively in the cases of R^3=H and CH_3 (Runs 2 and 3), it could not reduce the selenoxides **10c** and **10d** efficiently and considerable amounts of elimination products (**12c** and **12d**) were obtained in the cases of R = CH_2=CH and Ph (Runs 4 and 7). This difference seems to be due to the



Scheme 3.

Table 1. Yields of **11** and/or **12** Using Various Electrophiles and Reducers[a]

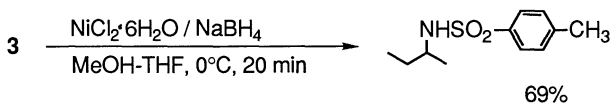
a) Carried out using selenide (1 mmol), *m*-CPBA (1.1 mmol), LDA (3.6 mmol), HMPA (5 mmol) in THF (5 ml) and AcOH/THF (1/10; 3.5 ml). b) Isolated yield by column chromatography. c) Carried out without HMPA. d) LDA (4.8 mmol) was used.

conjugation of the forming double bond with the vinyl or phenyl group, which would facilitate the selenoxide elimination reaction. We searched for more powerful reducers and found that selenides **11c** and **11d** were obtained as the major products by the use of trimethyl phosphite (Runs 5,6, and 8). We also studied the methylation of substituted selenides (**3** and **1**) under the analogous conditions. To our surprise, reduced selenide (**11e**) was not obtained even by the use of trimethyl phosphite as reducer in the dimethyl-substituted case (**3**) (Run 10). This seems to reflect the rate enhancement of the elimination reaction by the presence of methyl group (R^1) on the carbon atom bearing the seleninyl group.[7] The yield of **12e** was a little better when the reaction mixture was allowed to warm up to room temperature without the addition of any reducer (Run 9). The structure of the elimination product was allylic amide (**12e**) and we could not detect the regioisomer (vinylic amide) which would result from the selenoxide elimination with the hydrogen atom attached to the carbon bearing the nitrogen functional group. Similar to the acetamide case,[1b,2] selenoxide elimination "away from" the nitrogen functional group was confirmed in this sulfonamide case. Even in the phenyl-substituted case (**1**), allylic amide (**12f**) was the product of the selenoxide elimination reaction and vinylic amide, double bond in which would conjugate with phenyl ring, was not detected in the producuts.[5] In good agreement with the fact that R^1=H in **10f**, selenide (**11f**) was the major product accompanied with the elimination product (**12f**) when trimethyl phosphite was employed as reducer (Run 12).

Finally, we confirmed that reductive removal of phenylseleno group by nickel boride[6] to afford saturated compounds is applicable to our β-tosylamino-substituted selenides. Thus, the reaction of **3** with nickel chloride and sodium borohydride afforded *N*-(1-methylpropyl)-*p*-toluenesulfonamide in a satisfactory yield (Scheme 4).

As a conclusion, our methodology would allow the introduction of phenylseleno and tosylamino groups into various types of olefins with predicted regioselectivity and also allow the further introduction of various carbon electrophiles into the carbon atom bearing the phenylseleno group. Subsequent reductive or oxidative removal of the phenylseleno group will afford saturated or allylic amide selectively. Thus, the preparation of a wide range of saturated or allylic amides is now possible by the present methodology by a suitable choice of olefins and carbon electrophiles.



Scheme 4.

Experimental

The IR spectra were taken with a JASCO IR-810 spectrometer. ^{1}H and ^{13}C NMR spectra were recorded with JEOLCO JNM-FX-100 (100 MHz), JNM-GX-400 (400 MHz), and Varian VXR-200 (200 MHz) instruments in $CDCl_3$ using TMS as internal standard. Melting points were determined with a Shimadzu MM-2 micro melting point determination apparatus and were uncorrected. Liquid chromatographic analyses were carried out with a Waters HPLC system equipped with a 6000A solvent delivery system, a Model 440 absorbance detector (at 254 nm), and a Cosmosil packed column (4.6 mm×10 mm). GLC analyses were carried out on a Shimadzu 4CMPF apparatus using EGSS-X (15%)–Chromosorb W (3 m) column. Mass spectra were measured on a JEOL JMS-DX-300 mass spectrometer.

Materials. Tetrahydrofuran (THF) and diethyl ether were dried over benzophenone ketyl and were distilled just before use. All other organic solvents were purified before use by distillation. Zinc(II) chloride was purified by sublimation and was stored and used as saturated solution in diethyl ether (0.69 mol dm^{-3}). LDA was prepared by the addition of a solution of butyllithium in hexane (1.5 mol dm^{-3}) to a solution of diisopropylamine in THF at −78 °C and subsequent stirring at 0 °C for 30 min. Dow X (50 w×8, Na type, 20—50 mesh, Dow

Chemical Company) were treated with aqueous HCl before use. All other organic and inorganic materials were commercial products and were used without further purification.

Preparation of *N*-[2-(Phenylseleno)cyclohexyl]-*p*-toluenesulfonamide (2). Typical Procedure. Cyclohexene (0.12 ml; 1.1 mmol) was added to a solution of benzeneselenenyl chloride (97%, 0.20 g; 1.0 mmol) in 1,2-dichloroethane (3.0 ml) and the resulting colorless solution was stirred at ambient temperature for 15 min. After the addition of *p*-toluenesulfonamide (0.26 g, 1.5 mmol) and stirring for 0.5 h, a saturated solution of zinc(II) chloride in diethyl ether (0.29 ml; 0.20 mmol) was added and the resulting mixture was stirred at ambient temperature for 24 h. The reaction mixture was added to saturated aqueous $NaHCO_3$ (60 ml) and the products were extracted with dichloromethane (20 ml×3). The organic layer was washed with brine (30 ml), dried over $MgSO_4$, and evaporated in vacuo to leave a pale yellow oil. Column chromatography [silica gel (200 mesh), hexane–ethyl acetate (2:1) as eluant] of this oil afforded **2** (0.35 g, 0.85 mmol; 85%) as white crystals; mp 133—134 °C [from hexane–ethyl acetate (5:1)]. IR (KBr disc) 3270 cm^{-1}. ^1H NMR (400 MHz) δ=1.2—1.7 (m. 8H), 2.44 (s. 3H), 2.9—3.1 (m. 2H), 5.10 (br. d. 1H, J=3.4 Hz), 7.2—7.4 (m. 7H), and 7.75 (d. 2H, J=8.3 Hz). ^{13}C NMR (25 MHz) δ=21.5 (q), 23.3 (t), 25.2 (t), 32.2 (t), 32.5 (t), 47.6 (d), 55.8 (d), and phenyl signals. Found: C, 56.07; H, 5.65; N, 3.40%. Calcd for $C_{19}H_{23}NO_2SSe$: C, 55.87; H, 5.69; N, 3.43%.

Spectral and analytical data other β-tosylamino-substituted selenides are as follows.

***N*-[1-Phenyl-2-(phenylseleno)ethyl]-*p*-toluenesulfonamide (1):** White crystals, mp 92—93 °C [from hexane–ethyl acetate (5:1)]. IR (KBr disc) 3270 cm^{-1}. ^1H NMR (100 MHz) δ=2.34 (s. 3H), 3.09 (dd. 1H, J=12.7 and 6.8 Hz), 3.27 (dd, 1H, J=12.7 and 6.8 Hz), 4.36 (q. 1H, J=6.7 Hz), 5.65 (d. 1H, J=6.3 Hz), and 6.8—7.7(m. 14 H). ^{13}C NMR (25 MHz) δ=21.5 (q), 35.1 (t), 57.3 (d), and phenyl signals. Found: C, 58.64; H, 4.73; N, 3.18%. Calcd for $C_{21}H_{21}NO_2SSe$: C, 58.60; H, 4.93; N, 3.26%.

***N*-[*erythro*-1-Methyl-2-(phenylseleno)propyl]-*p*-toluenesulfonamide (3):** White crystals, mp 117—118 °C (from hexane). IR(KBr disc) 3275 cm^{-1}. ^1H NMR (400 MHz) δ=1.08 (d. 3H, J=6.8 Hz), 1.37 (d. 3H, J=7.3 Hz), 2.36 (s. 3H), 3.20 (dq. 1H, J=3.6 and 7.3 Hz), 3.4—3.5 (m. 1H), 5.33 (d. 1H, J=8.8 Hz), 7.2—7.4 (m. 7H), and 7.72 (d. 2H, J=8.3 Hz). ^{13}C NMR (25 MHz) δ=18.3 (q), 19.5 (q), 21.4 (q), 47.7 (d), 53.8 (d), and phenyl signals. Found: C, 53.16; H, 5.43; N, 3.57%. Calcd for $C_{17}H_{21}NO_2SSe$: C, 53.39; H, 5.55; N, 3.66%.

***N*-[*threo*-1-Methyl-2-(phenylseleno)propyl]-*p*-toluenesulfonamide (4):** White crystals, mp 123—124 °C (from hexane). Methylation of β-Position on *N*-Ethyl Group of 7. General Procedure. To a solution of **7** (0.35 g, 1.0 mmol) in THF (2.0 ml) was added a solution of *m*-chloroperbenzoic acid (*m*-CPBA) (80%; 0.24 g, 1.1 mmol) in THF (1.0 ml) under nitrogen atmosphere at −78 °C and the resulting mixture was stirred at the same temperature for 1 h. A solution of LDA (3.6 mmol) in THF (2.0 ml) and then HMPA (0.87 ml, 5.0 mmol) were added slowly to the mixture and the resulting mixture was stirred at −78 °C for 0.5 h. Methyl iodide (98%; 0.13 ml, 2.0 mmol) was added and the reaction mixture was further stirred at −78 °C for 2 h. Afterward it was not necessary to keep the reaction under nitrogen atmosphere. A mixture of acetic acid and THF (1:10, 3.5 ml) and then sodium iodide (0.30 g, 2.0 mmol) in water (1.0 ml) were added and the resulting mixture was stirred vigorously at ambient temperature for 0.25 h. Saturated aqueous $Na_2S_2O_3$ was added in small portions until pale yellow and the reaction mixture was further stirred at the same temperature for 0.25 h. The reaction mixture was added to saturated aqueous $Na_2S_2O_3$ (10 ml) and the products were extracted with chloroform (15 ml×3). The organic layer was washed with saturated aqueous $NaHCO_3$ and brine, dried ($MgSO_4$), and evaporated in vacuo to leave a brown oil. Column chromatography [silica gel (200 mesh), hexane–ethyl acetate (3:1) as eluant] afforded *N*-[2-(phenylseleno)propyl]-*p*-toluenesulfonamide (**11a**)(0.275 g, 0.75 mmol; 75%) as a brown oil. IR (liq. film) 3280 cm^{-1}. ^1H NMR (400 MHz) δ=1.33 (d. 3H, J=6.8 Hz), 2.40 (s. 3H), 2.96 (dt. 1H, J=19.0 and 6.3 Hz), 2.99 (dt. 1H, J=19.0 and 6.3 Hz), 3.23 (sextet, 1H, J=6.7 Hz), 5.37 (t. 1H, J=6.4 Hz), 7.1—7.4(m. 7H), and 7.69(d. 2H, J=8.3 Hz). ^{13}C NMR(25 MHz) δ=19.1 (q), 21.5 (q), 38.3 (d), 48.2 (t), and phenyl signals. Found: C, 52.13; H, 5.24; N, 4.10%. Calcd for $C_{16}H_{19}NO_2SSe$: C, 52.16; H, 5.21; N, 3.80%.

Spectral and analytical data of other alkylated products are as follows.

***N*-[2-(Phenylseleno)butyl]-*p*-toluenesulfonamide (11b):** Brown oil. 1-Chloroalkyl *p*-Tolyl Sulfoxides as Acetylide Anion Equivalent: A Novel Synthesis Including Asymmetric Synthesis of Propargylic Alcohols from Carbonyl Compounds

Tsuyoshi SATOH, Yasumasa HAYASHI, and Koji YAMAKAWA*
Faculty of Pharmaceutical Sciences, Science University of Tokyo,

(Received March 7, 1991)

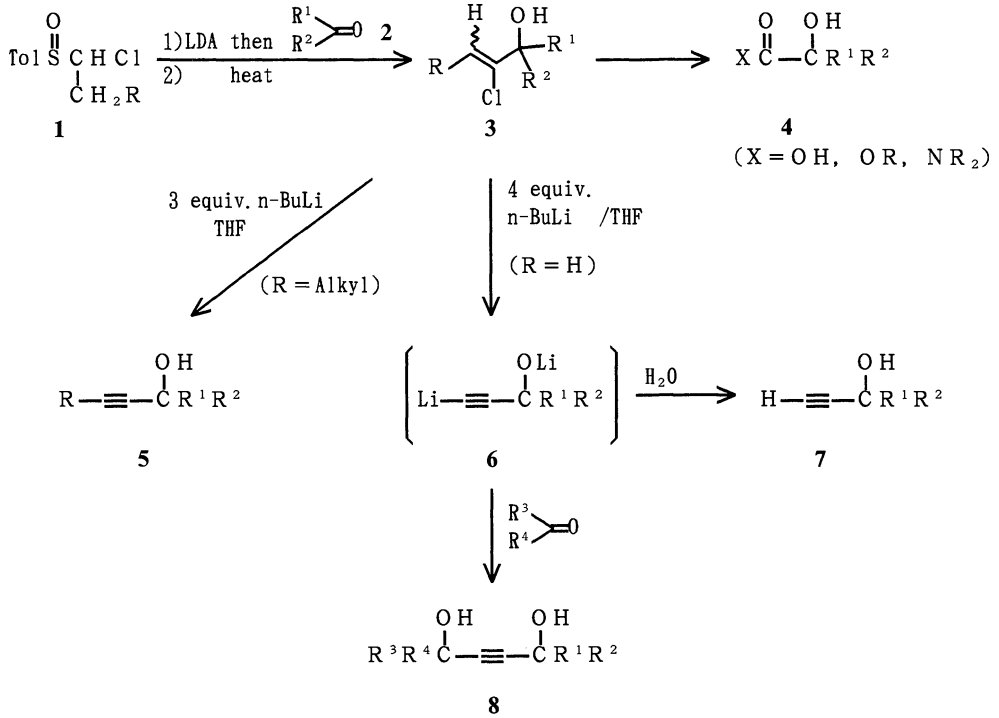
Addition of the carbanion of 1-chloroalkyl *p*-tolyl sulfoxide to carbonyl compounds gave the adducts, which were heated in refluxing toluene or xylene to give vinyl chlorides in high overall yield. Dehydrochlorination of the vinyl chlorides with excess *n*-BuLi afforded propargylic alcohols in high yields. Asymmetric synthesis of both enantiomers of the propargylic alcohols was realized using optically active 1-chloroalkyl *p*-tolyl sulfoxide and aldehyde.

Acetylenes are very important compounds in synthetic organic chemistry.[1] In the acetylenes, propargylic alcohols, including optically active ones, are now recognized to be quite useful building blocks in natural product synthesis.[2] Many methods for synthesizing propargylic alcohols have been reported; however, in view of the usefulness of propargylic alcohols in organic synthesis, new methods are eagerly sought.

We recently reported some new synthetic methods using 1-chloroalkyl *p*-tolyl sulfoxides **1**.[3] For example, ozonolysis of vinyl chlorides **3**, which were synthesized from **1** and carbonyl compounds **2** through chloro alcohols, gave α-hydroxy carboxylic acids and their derivatives **4** in high yields.[4] In this method **1** acted as a hydroxycarbonyl-, alkoxycarbonyl-, and formamide anion equivalent (Scheme 1). In continuation of our study concerning the use of 1-chloroalkyl aryl sulfoxides in organic synthesis, we report here a novel synthesis of propargylic alcohols (**5**, **7**, and **8**) form **1** and carbonyl compounds through vinyl chloride **3**. In this method **1** acts as an acetylide anion and acetylide dianion equivalent.

Results and Discussion

A Synthesis of Propargylic Alcohols from Carbonyl Compounds and 1-Chloroalkyl *p*-Tolyl Sulfoxides. The synthesis of 1-(1-butynyl)-1-cycloheptanol **5a** from cycloheptanone and 1-chlorobutyl *p*-tolyl sulfoxide (**1**: R=Et) as acetylide anion equivalent is reported as a representative example. 1-Chlorobutyl *p*-tolyl sulfoxide, easily prepared from butyl *p*-tolyl sulfide,[5] was treated with lithium diisopropylamide (LDA) in THF at



Scheme 1.

Table 1. Synthesis of Propargylic Alcohols **5** and **7** from **1** and Carbonyl Compound **2** through Vinyl Chlorides **3**

	1 R	**2** R^1	**2** R^2	**3** (Yield/%)[a]	*n*-BuLi (equiv)	Conditions[b]	**5** or **7** (Yield/%)	
a	Et	$-(CH_2)_6-$		**3a** (77)	(3)	A	 **5a**	(92)
b	Et	$CH_3(CH_2)_8$	H	**3b-L** (34)[c]	(3)	A	$CH_3CH_2C{\equiv}C-CH(CH_2)_8CH_3$ (OH) **5b**	(99)
				3b-P (46)[c]	(3)	B		(51)
c	H	$-(CH_2)_2CH(CH_2)_2-$		**3c** (80)	(4)	A	 **7c**	(85)
d	H			**3d** (92)	(4)	C	 **7d**	(95)
e	H			**3e** (90)	(4)	D	 **7e**	(92)
f	H	$CH_3(CH_2)_8$	H	**3f** (91)	(4)	E	$HC{\equiv}CCH(CH_2)_8CH_3$ (OH) **7f**	(93)

a) Two-step overall yield from **1** and carbonyl compound **2** through chloro alcohol. Isolated yield. b) Conditions: A, −35 to 0 °C (2 h) then 0 °C (0.5 h); B, −35 °C to room temperature (4 h) then at room temperature (0.75 h); C, −45 to −35 °C (0.7 h); D, −50 to −40 °C (0.7 h); E, −40 to −10 °C (2 h). c) L: less polar isomer, P: more polar isomer.

−60 °C followed by addition of cycloheptanone to give the adduct, which was then heated in refluxing toluene for 5 min to afford cleanly the vinyl chloride **3a** (R=Et, R^1=R^2=$-(CH_2)_6-$) in 77% overall yield.

As vinylic hydrogen is relatively more acidic than that of saturated carbon, it might be expected that on treatment of vinyl chloride **3** with a strong base elimination of hydrogen chloride takes place to afford propargylic alcohol **5**.[6] The vinyl chloride **3a** was treated with a variety of bases (such as LDA, *t*-BuOK, *n*-BuLi etc.) under various conditions, and three-equivalents of *n*-BuLi in THF at low temperature (below 0 °C) was found to be the best conditions to give **5a** (Table 1) in 92% yield. Interestingly, treatment of **3a** with *n*-BuLi in hexane gave a quite sluggish and incomplete reaction even at room temperature.

Representative examples of the synthesis of propargylic alcohols **5** and **7** from carbonyl compounds are summarized in Table 1. As shown in the Table 1, various kinds of propargylic alcohols are synthesized in good overall yield. In the step of the elimination of hydrogen chloride, some difference in the reaction was found between the stereoisomers (Entry b). Generally speaking, the elimination giving monosubstituted acetylenes (**7c**–**7f**) is more reactive than that giving disubstituted acetylenes (**5a**, **5b**).

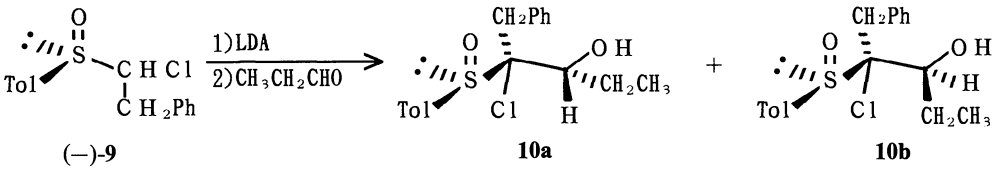
The elimination of hydrogen chloride from vinyl chloride (**3**: R=H) derived from 1-chloroethyl *p*-tolyl sulfoxide (**1**: R=H) gave propargylic alcohol dianion **6**. This dianion **6** was trapped with carbonyl compounds at −15 °C to afford acetylenic diol **8** in good yields. As shown in Table 2, this reaction gave almost quantitative yields with aldehydes; however, the yields was 72% with cyclohexanone because of its high enolizability. It is worth noting that 1-chloroethyl *p*-tolyl sulfoxide (**1**: R=H) acts as dianion of acetylene.

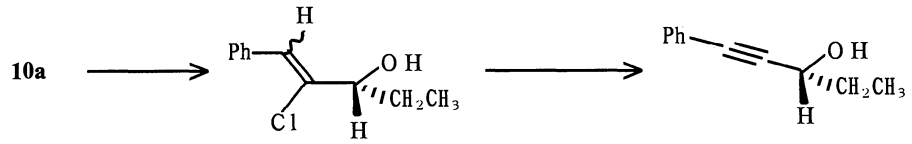
Asymmetric Synthesis of Both Enantiomers of Propargylic Alcohols. Asymmetric synthesis is one of the most important subjects in modern organic synthesis. We recently reported some new methods for synthesis of optically active 1-chloroalkyl *p*-tolyl sulfoxide.[3a,3b,4] Here we describe an asymmetric synthesis of both enantiomers of propargylic alcohols (**12a** and **12b**) using the above-mentioned method from (−)-**9** (Scheme 2).[7]

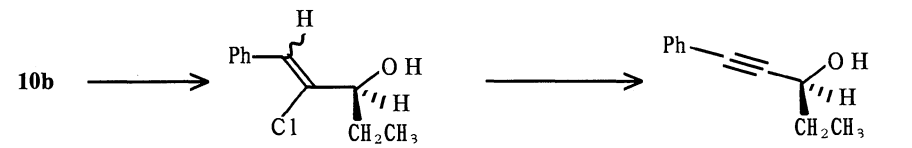
Treatment of (−)-1-chloro-2-phenylethyl *p*-tolyl sulfoxide **9** (over 98% ee) with LDA in THF at −60 °C followed by addition of propanal afforded two adducts, which were easily separated by silica-gel column chromatography to give the less polar adduct **10a** (41%) and the more polar adduct **10b** (53%). The absolute stereo-

Table 2. Synthesis of Acetylenic Diol **8** from Vinyl Chloride **3**

Entry	Vinyl chloride **3**	Carbonyl compound	**8** (Yield/%)
1	**3c**		 **8a** (72)
2		$CH_3(CH_2)_8CHO$	 **8b** (88)
3			 **8c** (98)
4	**3f**		 **8d** (91)
5			 **8e** (96)







Scheme 2.

chemistry of **10a** and **10b** were presumed as depicted in Scheme 2 based on the experiences gained from the study with α,β-epoxy sulfoxides.[3a] Thermal elimination of the sulfinyl group in **10a** and **10b** in refluxing toluene under N_2 for 20 min afforded cleanly the desired vinyl chlorides **11a** (single isomer) and **11b** (*E*/*Z*-mixture), both in 99% yield. Elimination of hydrogen chloride from **11b** was carried out with three equivalents of *n*-

BuLi at −35 to 0 °C for 2 h to afford (*S*)-(−)-1-phenyl-1-pentyn-3-ol **12b** in 92% yield. The specific rotation of (−)-**12b** ($[\alpha]_D^{24}$ −20.0° (*c* 2.6, Et_2O) was consistent with that of the reported value ($[\alpha]_D^{25}$ −13.7° (*c* 2.0, Et_2O); 70% ee).[7g] Similar treatment of **11a** with *n*-BuLi gave (*R*)-(+)-**12a** ($[\alpha]_D^{26}$ +19.3° (*c* 2.3, Et_2O)) in 96% yield.

Unfortunately, as the addition of the carbanion of 1-chloroethyl *p*-tolyl sulfoxide with aldehyde gave an inseparable diastereomeric mixture of the adducts, this method could not be used for the asymmetric synthesis of the propargylic alcohols of type **7**. However, because of its overall simplicity and high overall yields, we believe that the presented method will prove valuable in the synthesis of propargylic alcohols in racemic and optically active form.

Experimental

All melting points are uncorrected. ^1H NMR spectra were measured in a $CDCl_3$ solution with a JEOL FX-100 spectrometer. Electron-impact mass spectra (MS) were obtained at 70 eV by direct insertion. Silica gel BW-127 ZH (Fuji-Devison) containing 2% fluorescence reagent 254 and quartz column were used for column chromatography, and products having UV absorption were detected by UV irradiation. In experiments requiring dry solvents, THF was distilled from diphenylketyl; toluene, xylene, and diisopropylamine were dried over CaH_2 and distilled.

1-(1-Chloro-1-butenyl)-1-cycloheptanol (3a). A solution of 1-chlorobutyl *p*-tolyl sulfoxide **1** (R=CH_2CH_3; 1.15 g; 5 mmol) in 2 ml of THF was added dropwise to a solution of LDA (6 mmol) in 6 ml of THF under N_2 at −60 °C with strring. The reaction mixture was stirred at −60 °C for 10 min, then cycloheptanone (6 mmol) was added to the mixture. The reaction mixture was stirred for 10 min, then the reaction was quenched with sat. aqueous NH_4Cl. The whole was extracted with ether–benzene and the organic layer was washed once with sat. aqueous NH_4Cl. The solution was dried over $MgSO_4$ and then the solvent was evaporated under vacuum to give the residue, which was purified by silica-gel column chromatography to afford 1.51 g (88%) of chloro alcohol.

A solution of the chloro alcohol (1.46 g; 4.26 mmol) in 15 ml of toluene was refluxed under N_2 for 5 min. The toluene was evaporated under vacuum to leave a residue, which was purified by flash chromatography (hexane:AcOEt=10:1) to give 0.75 g (87%) of **3a** (single isomer; *E*/*Z* not determined) as a colorless oil. Ir (neat) 3380 (OH), 1645 (C=C) cm^{-1}; ^1H NMR δ=1.01 (3H, t, *J*=7 Hz), 1.2–2.2 (13H, m), 2.17 (2H, quintet, *J*=7 Hz), 5.79 (1H, t, *J*=7 Hz); MS *m*/*z* (%) 202 (M^+, 26), 173 ($[M-C_2H_5]^+$, 84), 145 (100). Found: *m*/*z* 202.1131. Calcd for $C_{11}H_{19}ClO$: M, 202.1124.

4-Chloro-3-tetradecen-5-ol (3b). Addition of the carbanion of 1-chlorobutyl *p*-tolyl sulfoxide to decanal gave less polar adduct and more polar adduct; these were easily separated by silica-gel column chromatography. The less polar adduct: 42% yield; mp 66–67 °C (AcOEt–Hexane); IR (KBr) 3470 cm^{-1}; ^1H NMR δ=3.80 (1H, t, *J*=5 Hz); Found: C, 65.14; H, 9.42; Cl, 9.19; S, 8.08%. Calcd for $C_{21}H_{35}ClO_2S$: C, 65.12; H, 9.12; Cl, 9.16; S, 8.28%. The more polar adduct: 51% yield; colorless oil; IR (neat) 3400 cm^{-1}; ^1H NMR δ=3.76 (1H, dd, *J*=8, 2 Hz). Thermal elimination of the sulfinyl group of the less polar adduct in refluxing xylene for 15 min gave **3b-L** as a colorless oil in 80% yield (*E*/*Z*-mixture; ratio about 10:1). IR (neat) 3350 (OH), 1655 (C=C) cm^{-1}; ^1H NMR δ=0.87 (3H, t, *J*=7 Hz), 1.01 (3H, t, *J*=7 Hz), 1.1–1.9 (16H, m), 2.21 (2H, quintet, *J*=7 Hz), 4.11 (0.9H, t, *J*=7 Hz), 4.54 (0.1H, t, *J*=7 Hz), 5.71 (1H, t, *J*=7 Hz); MS *m*/*z* (%) 246 (M^+, 2), 211 ($[M-Cl]^+$, 8), 119 (100). Found: *m*/*z* 246.1751. Calcd for $C_{14}H_{27}ClO$: M, 246.1749. In a similar way, the more polar adduct gave **3b-P** as a colorless oil in 96% yield (*E*/*Z*-mixture; ratio about 2:1). IR (neat) 3350 (OH), 1655 (C=C) cm^{-1}; ^1H NMR δ=4.11 (2/3H, t, *J*=7 Hz), 4.54 (1/3H, t, *J*=7 Hz), 5.70 (1/3H, t, *J*=7 Hz), 5.72 (2/3H, t, *J*=7 Hz); MS and high resolution mass spectral data are quite similar to those of **3b-L**.

1-(1-Chlorovinyl)-4-*t*-butyl-1-cyclohexanol (3c). Addition of the carbanion of 1-chloroethyl *p*-tolyl sulfoxide to 4-*t*-butylcyclohexanone gave the adduct in 83% yield as colorless crystals; mp 215–216 °C (AcOEt–hexane). IR (KBr) 3360 (OH) cm^{-1}; ^1H NMR δ=0.89 (9H, s), 1.44, 2.43 (each 3H, s). Found: C, 63.56; H, 8.47; Cl, 10.13, S, 8.87%. Calcd for $C_{19}H_{29}ClO_2S$: C, 63.93; H, 8.19; Cl, 9.93; S, 8.98%. Thermal elimination of the sulfinyl group of this adduct in refluxing xylene for 20 min gave **3c** as a colorless crystals, mp 51–52 °C (AcOEt–hexane). IR (KBr) 3375 (OH), 1630 (C=C) cm^{-1}; ^1H NMR δ=0.89 (9H, s), 1.0–1.9 (10H, m), 5.24, 5.46 (each 1H, d, *J*=2 Hz); MS *m*/*z* (%) 216 (M^+, 1), 181 (5), 142 (12), 107 (20), 57 (100). Found: *m*/*z* 216.1288. Calcd for $C_{12}H_{21}ClO$: M, 216.1279.

Vinyl Chloride (3d, 3e, 3f). These vinyl chlorides were reported in the Ref. 8.

1-(1-Butynyl)-1-cycloheptanol (5a). To a solution of vinyl chloride **3a** (61 mg; 0.3 mmol) in 3 ml of dry THF under N_2 was added *n*-BuLi (0.9 mmol) dropwise with stirring at −35 °C. The reaction mixture was stirred and allowed to warm to 0 °C in 2 h, and finally stirred at 0 °C for 30 min. The reaction was quenched with sat. aqueous NH_4Cl. The whole was extracted with ether–benzene and the organic layer was dried over $MgSO_4$. The product was purified by silica-gel column chromatography to afford 46 mg (92%) of **5a** as a colorless oil. IR (neat) 3370 (OH), 2230 (C≡C) cm^{-1}; ^1H NMR δ=1.13 (3H, t, *J*=7 Hz), 1.3–2.1 (13H, m), 2.21 (2H, q, *J*=7 Hz); MS *m*/*z* (%) 166 (M^+, 3), 151 ($[M-CH_3]^+$, 4), 137 ($[M-C_2H_5]^+$, 42), 109 (100). Found: *m*/*z* 166.1357. Calcd for $C_{11}H_{18}O$: M, 166.1357.

Propargylic Alcohol (5b, 7c—7f). These propargylic alcohols were synthesized from corresponding vinyl chlorides with three or four equivalents of *n*-BuLi in a similar way as described above for the synthesis of **5a**. The conditions and the yields are summarized in Table 1.

3-Tetradecyn-5-ol (5b). Colorless oil; IR (neat) 3340 (OH), 2225 (C≡C) cm^{-1}; ^1H NMR δ=0.88 (3H, t, *J*=7 Hz), 1.13 (3H, t, *J*=7 Hz), 1.2–1.8 (13H, m), 2.22 (2H, dq, *J*=7, 2 Hz), 4.31 (1H, m); MS *m*/*z* (%) 210 (M^+, trace), 181 ($[M-C_2H_5]^+$, 7), 83 (100). Found: *m*/*z* 210.1972. Calcd for $C_{14}H_{26}O$: M, 210.1981.

1-Ethynyl-4-*t*-butyl-1-cyclohexanol (7c). Low melting solid; IR (KBr) 3530, 3420, 3320, 3260 (OH), 2100 (C≡C) cm^{-1}; ^1H NMR δ=0.86 (9H, s), 1.0–2.2 (10H, m), 2.41 (1H, s); MS *m*/*z* (%) 180 (M^+, trace), 165 (1.5), 106 (44), 57 (100). Found: *m*/*z* 180.1515. Calcd for $C_{12}H_{20}O$: M, 180.1513.

4-Ethynyl-4-hydroxyl-1-cyclohexanone Ethylene Acetal (7d). Colorless oil; IR (neat) 3450, 3320, (OH), 2125 (C≡C) cm^{-1}; ^1H NMR δ=1.6–2.1 (8H, m), 2.48 (1H, s), 3.94 (4H, s); MS *m*/*z* (%) 182 (M^+, 0.4), 154 (2), 125 (2), 99 (100). Found:

m/z 182.0942. Calcd for $C_{10}H_{14}O_3$: M, 182.0942.

2-Ethynyl-2-indanol (7e). Colorless crystals; mp 91–92.5 °C (AcOEt–hexane); IR (KBr) 3450, 3290 (OH), 2125 (C≡C) cm^{-1}; ^1H NMR δ=2.52 (1H, s), 3.26, 3.40 (each 2H, d, J=17 Hz), 7.17 (4H, s); MS m/z (%) 158 (M^+, 51), 129 (18), 105 (100). Found: C, 83.35; H, 6.27%. Calcd for $C_{11}H_{10}O$: C, 83.51; H, 6.37%.

1-Dodecyn-3-ol (7f). Colorless oil; IR (neat) 3330 (OH), 2130 (C≡C) cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=7 Hz), 1.0–2.0 (17H, m), 2.45 (1H, d, J=2 Hz), 4.35 (1H, dq, J=7, 2 Hz); MS m/z (%) 182 (M^+, trace), 181 (0.3), 121 (14), 43 (100). Found: m/z 182.1660. Calcd for $C_{12}H_{22}O$: 182.1669.

1-[2-(1-Hydroxycyclohexyl)ethyl]-4-*t*-butyl-1-cyclohexanol (8a). To a solution of the vinyl chloride **3c** (54 mg; 0.25 mmol) in 3 ml of dry THF at −25 °C under N_2 was added *n*-BuLi (1 mmol) with stirring. The reaction mixture was stirred and allowed to warm to −15 °C in 1 h. To this reaction mixture was added cyclohexanone (0.3 mmol) and the mixture was stirred at −15 °C for 10 min. The reaction was quenched with sat. aqueous NH_4Cl and the whole was extracted with ether–benzene. The product was purified by silica-gel column chromatography to give 50 mg (72%) of **8a** as colorless crystals; mp 164.5–165 °C (AcOEt–hexane). IR (KBr) 3390 (OH) cm^{-1}, the signal due to C≡C stretching vibrations could not be observed; ^1H NMR δ=0.85 (9H, s), 1.0–2.3 (20H, m); MS m/z (%) 278 (M^+, 14), 260 (14), 232 (19), 203 (45), 162 (63), 57 (100). Found: C, 77.66; H, 10.97%. Calcd for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86%.

1-(3-Hydroxy-1-dodecynyl)-4-*t*-butyl-1-cyclohexanol (8b). Colorless crystals; mp 73–74 °C (hexane); IR (KBr) 3370 (OH) cm^{-1}; ^1H NMR δ=0.85 (9H, s), 0.88 (3H, t, J=7 Hz), 1.0–2.2 (27H, m), 4.35 (1H, t, J=7 Hz); MS m/z (%) 336 (M^+, 0.8), 318 ([$M-H_2O$]$^+$, 3), 303 (5), 57 (100). Found: C, 78.70; H, 12.24%. Calcd for $C_{22}H_{40}O_2$: C, 78.51; H, 11.98%.

1-[3-Hydroxy-3-(3-methoxyphenyl)-1-propynyl]-4-*t*-butyl-1-cyclohexanol (8c). Colorless crystals; mp 104–105 °C (AcOEt–hexane) IR (KBr) 3360 (OH) cm^{-1}; ^1H NMR δ=0.85 (9H, s), 0.9–2.2 (10H, m), 3.79 (3H, s), 5.41 (1H, d (+D_2O singlet), J=6 Hz), 6.7–7.4 (4H, m); MS m/z (%) 316 (M^+, 100), 298 ([$M-H_2O$]$^+$, 5), 283 (4), 241 (15), 200 (48). Found: C, 75.97; H, 8.87%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

1-Cyclohexyl-2-tridecyne-1,4-diol (8d). Colorless oil; IR (neat) 3310 (OH) cm^{-1}; ^1H NMR δ=0.88 (3H, t, J=7 Hz), 1.0–2.0 (27H, m), 4.16 (1H, d, J=4 Hz), 4.38 (1H, t, J=5 Hz); MS m/z (%) 294 (M^+, 0.3), 276 ([$M-H_2O$]$^+$, 1.5), 233 (1.5), 194 (60), 83 (100). Found: m/z 294.2553. Calcd for $C_{19}H_{34}O_2$: M, 294.2556.

1-(3-Methoxyphenyl)-2-tridecyne-1,4-diol (8e). Colorless oil; IR (neat) 3340 (OH) cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=7 Hz), 1.1–1.9 (16H, m), 3.79 (3H, s), 4.40 (1H, dt, J=6, 1 Hz), 5.44 (1H, s), 6.7–7.4 (4H, m); MS m/z (%) 318 (M^+, 15), 138 (100). Found: m/z 318.2199. Calcd for $C_{20}H_{30}O_3$: M, 318.2193.

(2*R*, 3*R*, R_s)-2-Chloro-1-phenyl-2-(*p*-tolylsulfinyl)-3-pentanol (10a) and (2*R*, 3*S*, R_s)-Isomer (10b). The carbanion of (−)-1-chloro-2-phenylethyl *p*-tolyl sulfoxide (**9**; 98% ee) was reacted with propanal in a similar way as described above to give two adducts **10a** (41%) and **10b** (53%). These products were easily separated by silica-gel column chromatography.

10a: Colorless oil; IR (neat) 3400 (OH), 1080, 1040, 1015 (SO) cm^{-1}; ^1H NMR δ=0.93 (3H, t, J=7 Hz), 1.4–1.8 (4H, m), 2.44 (3H, s), 3.36 (1H, d, J=15 Hz), 3.82 (1H, dd, J=8, 4 Hz), 4.13 (1H, d, J=15 Hz), 7.2–7.7 (5H, m); $[\alpha]_D^{27}$ −128.1° (*c* 0.2, acetone).

10b: Colorless crystals; mp 156–157 °C (AcOEt–hexane); IR (KBr) 3430 (OH), 1080, 1050, 1030 (SO) cm^{-1}; ^1H NMR δ=0.90 (3H, t, J=7 Hz), 1.3–1.8 (2H, m), 1.8–2.3 (2H, m), 2.41 (3H, s), 3.34 (1H, d, J=15 Hz), 3.38 (1H, dd, J=8, 2 Hz), 3.41 (1H, d, J=15 Hz), 7.1–7.7 (5H, m). Found: C, 64.03; H, 6.03; Cl, 10.59; S, 9.25%. Calcd for $C_{18}H_{21}ClO_2S$: C, 64.18; H, 6.28; Cl, 10.52; S, 9.52%. $[\alpha]_D^{25}$−68.0° (*c* 1.0, acetone).

(3*R*)-2-Chloro-1-phenyl-1-penten-3-ol (11a) and (3*S*)-Isomer (11b). Thermal elimination of **10a** in refluxing toluene for 20 min gave **11a** in 99% yield as a colorless oil (single isomer; *E*/*Z* not determined). IR (neat) 3380 (OH), 1645 (C=C) cm^{-1}; ^1H NMR δ=0.96 (3H, t, J=7 Hz), 1.79 (2H, m), 4.21 (1H, t, J=7 Hz), 6.70 (1H, s), 7.2–7.7 (5H, m); MS m/z (%) 196 (M^+, 29), 167 (100), 31 (85). Found: m/z 196.0652. Calcd for $C_{11}H_{13}ClO$: M, 196.0654. $[\alpha]_D^{23}$+10.4° (*c* 0.7, acetone). Similar treatment of **10b** in refluxing toluene for 10 min gave **11b** in 99% yield as a colorless oil (a mixture of geometrical isomers; ratio about 2:1; *E*/*Z* not determined). IR (neat) 3380 (OH), 1650 (C=C) cm^{-1}; ^1H NMR δ=0.89 (1H, t, J=7 Hz), 0.96 (2H, t, J=7 Hz), 1.79 (2H, m), 4.21 (2/3H, t, J=7 Hz), 4.59 (1/3H, t, J=7 Hz), 6.71 (2/3H, s), 6.85 (1/3H, s), 7.1-7.7 (5H, m); MS m/z (%) 196 (M^+, 31), 167 (100), 131 (80). Found: m/z 196.0646. Calcd for $C_{11}H_{13}ClO$: M, 196.0654. $[\alpha]_D^{25}$ +15.3° (*c* 0.9, acetone).

(3*R*)-1-Phenyl-1-pentyn-3-ol (12a) and (3*S*)-Isomer (12b). To a solution of **11a** (60 mg; 0.3 mmol) in 3 ml of dry THF at −50 °C under N_2 was added *n*-BuLi (0.9 mmol) dropwise with stirring. The reaction mixture was then stirred at −35 °C and allowed to warm to 0 °C in 2 h, and finally at 0 °C for 30 min. The reaction was quenched with sat. aqueous NH_4Cl, and the usual workup gave **12a** (46 mg; 96%) as a colorless oil. IR (neat) 2350 (OH), 2240 (C≡C) cm^{-1}; ^1H NMR δ=1.07 (3H, t, J=7 Hz), 1.82 (2H, m), 4.53 (1H, t, J=6 Hz), 7.1–7.5 (4H, m); MS m/z (%) 160 (M^+, 15), 131 (100), 103 (26). Found: m/z 180.0893. Calcd for $C_{11}H_{12}O$: M, 180.0888. $[\alpha]_D^{26}$+19.3° (*c* 2.3, Et_2O).

Vinyl chloride **11b** gave (−)-(3*S*)-isomer **12b** in 92% yield. $[\alpha]_D^{24}$−20.0° (*c* 2.6, Et_2O). The IR and NMR spectra were superimposable on those of **12a**.

We are grateful to Dr. Mikio Takeda, Tanabe Seiyaku Co., Ltd., for elemental analysis, and to Noriko Sawabe and Fukiko Hasegawa of this laboratory for NMR and MS measurements. This work was supported by a Grant-in-Aid for Scientific Research No. 01571168 from the Ministry of Education, Science and Culture, which is gratefully acknowledged.

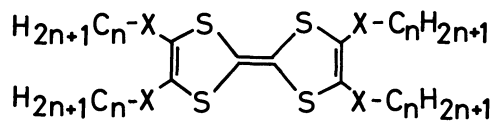
(Received October 25, 1990)

The crystal structures and the electrical conductivities have been studied for tetrakis(alkylchalcogeno)tetrathiafulvalene (TXC_n-TTF (X=sulfur, selenium, tellurium; n=2,3)) complexes with tetracyanoquinodimethane (TCNQ). All the complexes with a composition of 1 : 1 had the same crystal system (triclinic) and the same space group ($P\bar{1}$). The donor and acceptor molecules were alternately stacked in their crystals. (TSeC$_2$-TTF)TCNQ was obtained as plate and needle crystals. The molecular structure of TSeC$_2$-TTF and the overlapping mode between TSeC$_2$-TTF and TCNQ molecules of the two complexes were subtly different. All the complexes were semiconductors because of their mixed-stack structures. (TTeC$_2$-TTF)TCNQ showed the lowest resistivity (5 Ω cm at room temperature). Its good conductivity was brought about by the effective degree of charge-transfer and the favorable overlap between TTeC$_2$-TTF and TCNQ molecules. An overall discussion on the structural and physical properties of a series of TCNQ complexes with TXC_n-TTF (X=sulfur, selenium, tellurium; n=1,2,3) is presented.

Tetrakis(alkylchalcogeno)tetrathiafulvalene (TXC_n-TTF) has exhibited novel electronic properties as a consequence of the intermolecular interactions between the tetrachalcogeno-TTF conjugated π systems and the alkyl side chains. TTC_n-TTF compounds with long alkyl chains had relatively low resistivities because of a reduction of the interplanar distances between the TTF skeletons through the van der Waals interactions of the alkyl side chains between molecules. This was termed "a molecular fastener effect".[1-4] This finding was significant since high conductivities in single-component organic solids are produced not by an external pressure but by an internal pressure derived from attractive forces between attached organic functional groups. TTeC$_1$-TTF is a new organic semiconductor with high electrical conductivity and high carrier mobility, which does not belong to the category of molecular fasteners. The unusual properties of TTeC$_1$-TTF are caused by a formation of regular Te chains through quasi-covalent Te–Te interatomic contacts between neighboring TTeC$_1$-TTF stacks.[5]



X=S : TTC_n-TTF
Se : $TSeC_n$-TTF
Te : $TTeC_n$-TTF

Scheme 1.

TXC_n-TTF compounds are also attractive donors used in the formation of charge-transfer (CT) complexes.[6-9] TXC_1-TTF complexes with various acceptors have been actively investigated and a metallic conductivity has been found in $(TTC_1\text{-TTF})(I_3)_{0.823}$.[10-13] TXC_n-TTF compounds with long alkyl side chains may form highly conductive CT complexes since they are expected to generate charge carriers in addition to their fastener effect. The present system allows us to systematically study how the chain length of alkyl groups and the variation of chalcogen atoms affect the physical properties of the complexes.

Various (TXC_1-TTF)–TCNQ complexes have been previously studied: the crystal structures and the physical properties of (TTC_1-TTF)TCNQ and (TTC_1-TTF)$_2$TCNQ were reported by Mori et al.[14] and those of ($TSeC_1$-TTF)TCNQ and ($TTeC_1$-TTF)TCNQ were reported by Iwasawa et al.[9,15,16] In this work, we prepared single crystals of TXC_n-TTF (X=S, Se, Te; n=2,3) complexes with TCNQ. We present the experimental results of their crystal structure determinations and electrical conductivity measurements. The correlation between the structure and the conductivity is discussed on the basis of the degree of charge-transfer (ionicity) and the molecular overlap between the donor and the acceptor.

Experimental

Black single crystals of TXC_n-TTF (X=S, Se, Te; n=2,3)·TCNQ were prepared by mixing hot CH_3CN solutions of each component and then keeping the solutions cool in a refrigerator (5 °C) or a freezer (−20 °C) for several days. (TTC_2-TTF)-TCNQ, ($TSeC_3$-TTF)TCNQ, ($TTeC_2$-TTF)TCNQ, and ($TTeC_3$-TTF)TCNQ crystallized in needles, while (TTC_3-TTF)TCNQ crystallized in plates. In the case of ($TSeC_2$-TTF)TCNQ, two kinds of crystals were obtained depending on

the temperature; plates formed at 5 °C and needles formed at −20 °C.

X-Ray diffraction data were collected at room temperature with a Rigaku AFC-5 automated four circle diffractometer with monochromatized Mo $K\alpha$ (λ=0.71069 Å) radiation in the range of $2\theta<60°$ using a θ–2θ scan technique. The unit cell parameters were determined by a least-squares fit of 50 reflections with $20°<2\theta<30°$. The crystallographic data are summarized in Table 1. The independent reflections ($|F_o|>3\sigma(|F_o|)$) were used for structure analyses. The crystal structures were solved by the Patterson method for (TTeC$_3$-TTF)TCNQ and the direct method using the MULTAN 78 program system[17] for the other complexes, and were refined by the block diagonal least-square method after an absorption correction. Anisotropic thermal parameters were adopted for non-hydrogen atoms and the hydrogen atoms were refined isotropically. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[18] All the calculations were carried out on a HITAC M-680H computer with the UNICS III program system.[19] The atomic parameters are listed in Table 2.[20]

The electrical conductivity along the long axis of the crystals, which corresponds to the a-axis, was measured between room temperature and 200 K with a four-probe method for (TTeC$_2$-TTF)TCNQ and a two-probe method for the other complexes using a gold paste as electrical contacts.

Results and Discussion

Crystal Structure. The TXC_n-TTF (X=S, Se, Te; n=2,3) complexes with TCNQ crystallized in the triclinic system and the $P\bar{1}$ space group, as listed in Table 1. (TTC$_2$-TTF)TCNQ and (TSeC$_3$-TTF)TCNQ crystals were isomorphous to the (TSeC$_2$-TTF)TCNQ needle-shaped crystal (abbreviated as n-(TSeC$_2$-TTF)TCNQ). (TTC$_3$-TTF)TCNQ and (TTeC$_2$-TTF)TCNQ crystals were isomorphous to the (TSeC$_2$-TTF)TCNQ plate-shaped crystal (abbreviated as p-(TSeC$_2$-TTF)TCNQ). The crystal structure of (TTeC$_2$-TTF)TCNQ was identical to that reported by Ahalon-Shalom et al.[21] Therefore, we have described the crystal structures of p-(TSeC$_2$-TTF)TCNQ and n-(TSeC$_2$-TTF)TCNQ only.

The molecular structures with atomic numbering schemes for p-(TSeC$_2$-TTF)TCNQ and n-(TSeC$_2$-TTF)TCNQ are illustrated in Figs. 1 and 2, respectively. The tetraseleno-TTF ($C_6S_4Se_4$) moieties in both complexes are nearly planar, in contrast to the nonplanar structure in the crystal of uncomplexed TSeC$_2$-TTF.[22] The ethyl groups attached to Se(2) of p-(TSeC$_2$-TTF)TCNQ lie almost coplanar to the $C_6S_4Se_4$ plane. The other ethyl groups attached to Se(1) are perpendicular to the $C_6S_4Se_4$ plane. This configuration of the molecule is denoted as the p-form. In constrast, the four ethyl groups of n-(TSeC$_2$-TTF)TCNQ are perpendicular to the $C_6S_4Se_4$ plane. This configuration of the molecule is denoted as the n-form. The comparatively large temperature factors of the terminal carbon atoms of the ethyl groups in both complexes may be caused by large thermal vibrations. The molecular structure of TCNQ in these complexes is planar with a

a) Positional parameters ($\times 10^5$).

maximum deviation of only 0.033 Å for CC(1). The planar structure is commonly observed in many TCNQ complexes.

Figures 3(a) and 3(b) show the intermolecular overlap between the donor and the acceptor of p-(TSeC$_2$-TTF)TCNQ and n-(TSeC$_2$-TTF)TCNQ, respectively. In the case of p-(TSeC$_2$-TTF)TCNQ, a six-membered ring of TCNQ overlaps one of the two five-membered rings of TSeC$_2$-TTF. This overlapping manner is denoted as the p-mode. On the other hand, n-(TSeC$_2$-TTF)TCNQ has a disadvantageous donor–acceptor overlap with a smaller overlap between a six-membered ring of TCNQ and a five-membered ring of TSeC$_2$-TTF. This overlapping manner is denoted as the n-mode.

Figures 4(a) and 4(b) show the crystal structures of p-(TSeC$_2$-TTF)TCNQ and n-(TSeC$_2$-TTF)TCNQ, respectively. In both complexes, the donor and acceptor molecules alternately stack along the a-axis. The molecular short axis of the C$_6$S$_4$Se$_4$ molecular plane is nearly parallel to the c-axis.

The molecular structure of TTeC$_3$-TTF in the (TTeC$_3$-TTF)TCNQ complex is analogous to that of TSeC$_2$-TTF in n-(TSeC$_2$-TTF)TCNQ and the donor-acceptor overlapping mode is analogous to that of p-(TSeC$_2$-TTF)TCNQ. The characteristic difference between (TTeC$_3$-TTF)TCNQ and the other complexes is that in the (TTeC$_3$-TTF)TCNQ complex the stacking axis is [101] which is different from the growing axis [100] of the crystal.

We have observed interchain atomic contacts in the (TXC$_2$-TTF)TCNQ complexes which are shorter than the sum of the van der Waals radii. n-(TSeC$_2$-TTF)-TCNQ possesses a contact between the outer chalcogen atoms, while (TTeC$_2$-TTF)TCNQ possesses a contact between the outer chalcogen atom and the nitrogen atom. The shortest distances are 3.58 Å (Se(2)–Se(2) in n-(TSeC$_2$-TTF)TCNQ) and 3.28 Å (Te(2)–N(2) in (TTeC$_2$-TTF)TCNQ). In contrast, (TXC$_3$-TTF)TCNQ complexes do not possess any interchain atomic contacts due to a disturbance of the longer propyl groups elongated in the interchain direction.

Degree of Charge-Transfer. The degree of CT (γ) for the TCNQ complexes was estimated from the bond lengths of TCNQ by the procedure developed by Kistenmacher et al.[23] Table 3 presents the calculated values of γ for the present TCNQ complexes.

a) The average value of the two equivalent bond lengths.

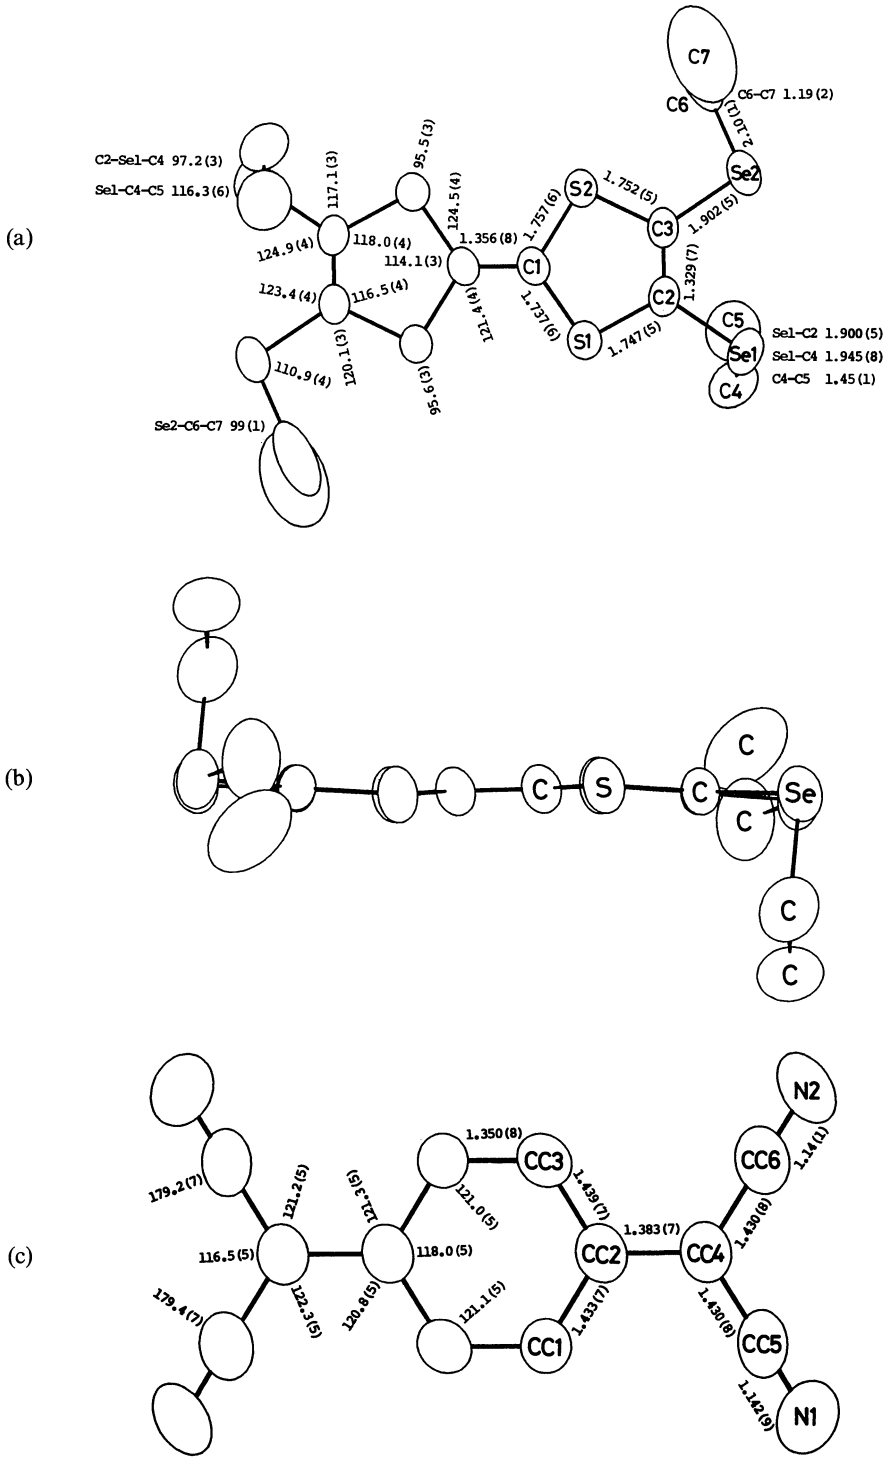

Fig. 1. Molecular structures and atomic numbering schemes of the donor (top view (a) and side view (b)) and the acceptor (c) of p-(TSeC$_2$-TTF)TCNQ.

Furthermore, γ was also estimated by the IR procedure established by Chappell et al.[24] The calculated γ from the CN stretching vibration frequencies in the nujol samples are listed in Table 4.

The electronic spectra in the KBr pellets showed the charge-transfer bands. These CT absorption energies are also listed in Table 4. The charge-transfer transition energy (E_{CT}) in a neutral complex with a mixed-stack can be expressed by the following equation:[25]

$$E_{CT} = I_p - E_A - E_M,$$

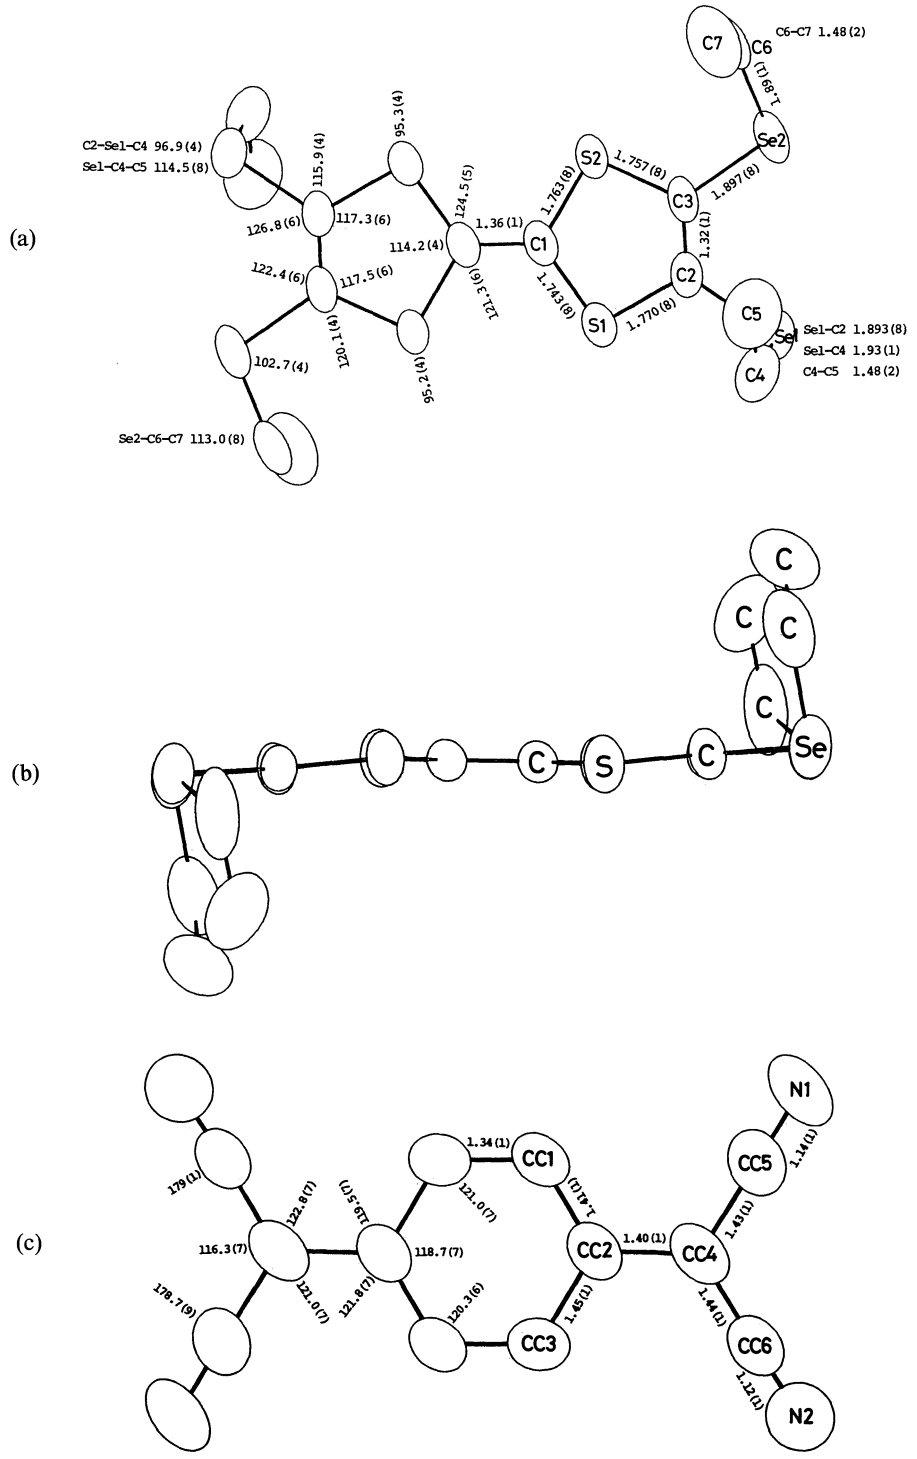

Fig. 2. Molecular structures and atomic numbering schemes of the donor (top view (a) and side view (b)) and the acceptor (c) of n-($TSeC_2$–TTF)TCNQ.

where I_p is the ionization potential of a donor, E_A is the electron affinity of an acceptor, and E_M is a crystal Madelung energy value. A large E_{CT} gives a small γ, while a small E_{CT} gives a large γ.

The X-ray and IR methods gave somewhat different estimated values of γ. However, TTC_n-TTF(n=2,3)·TCNQ, $TSeC_n$-TTF(n=2,3)·TCNQ, and $TTeC_n$-TTF(n=2,3)·TCNQ had about the same CT absorption energies (6100—5200 cm^{-1}, 4700—4600 cm^{-1}, and 4200—3900 cm^{-1}, respectively). This fact suggested that γ of

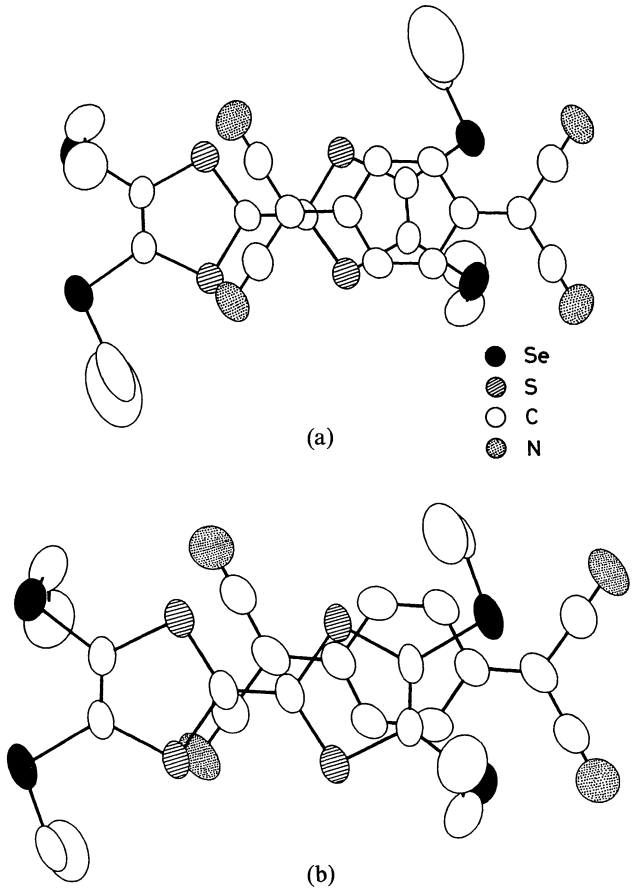

Fig. 3. Overlapping modes between the donor and acceptor molecules; (a) p-($TSeC_2$-TTF)TCNQ, (b) n-($TSeC_2$-TTF)TCNQ.

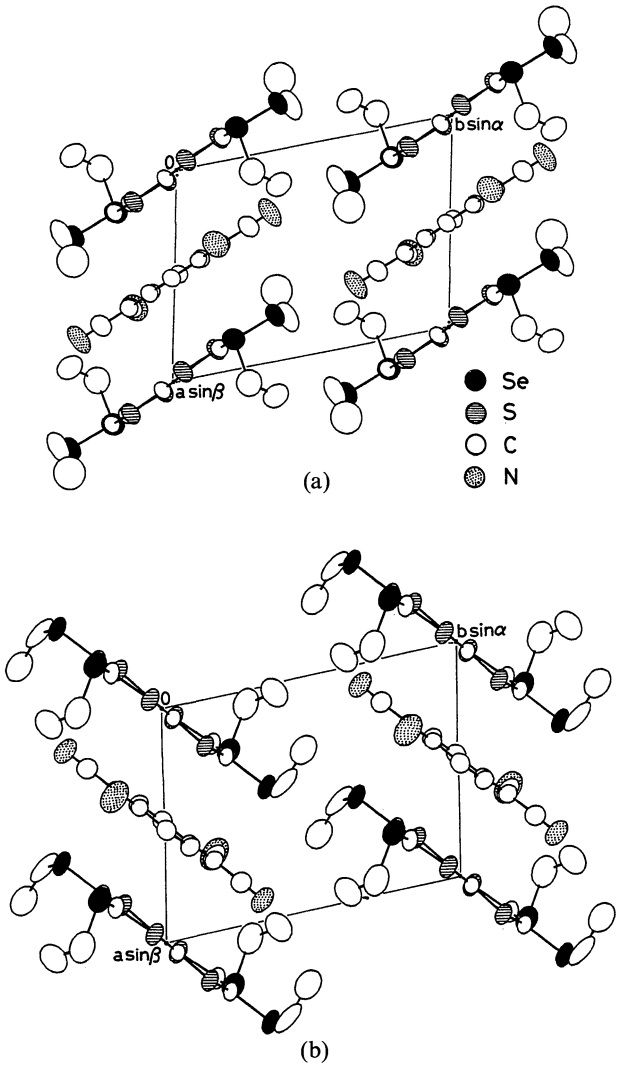

Fig. 4. Crystal structures projected along the c-axis; (a) p-($TSeC_2$-TTF)TCNQ, (b) n-($TSeC_2$-TTF)TCNQ.

TTC_n-TTF(n=2,3)·TCNQ, $TSeC_n$-TTF(n=2,3)·TCNQ, and $TTeC_n$-TTF(n=2,3)·TCNQ were in the ranges of 0.04—0.30, 0.25—0.50, and 0.33—0.71, respectively.

In the present system, γ increased in the order TTC_n-TTF(n=2,3)·TCNQ<$TSeC_n$-TTF(n=2,3)·TCNQ<$TTeC_n$-TTF(n=2,3)·TCNQ. According to the cyclic voltammetry studies of TXC_n-TTF (X=S, Se, Te; n=1—18),[9] the first redox potentials of TXC_n-TTF compounds were independent of n and decreased in the order TTC_n-TTF>$TSeC_n$-TTF>$TTeC_n$-TTF. Thus, the tendency of the ionicity observed in the present system could be explained by the decrease of (I_p-E_A).

Electrical Conductivity. The electrical resistivity at room temperature (ρ_{RT}) and the activation energy (E_a) are given in Table 4. ($TTeC_2$-TTF)TCNQ showed a markedly low resistivity of 5 Ω cm, which was smaller than the value (ca. 10^2 Ω cm) reported by Aharon-Shalom et al.[21] The measurement by Aharon-Shalom et al. may have included a contact resistance. p-($TSeC_2$-TTF)TCNQ and ($TTeC_3$-TTF)TCNQ also showed

relatively low resistivities of 3.5×10^3 and 7.5×10^3 Ω cm, respectively. The other complexes showed comparatively high resistivities of 10^5—10^7 Ω cm. The temperature dependence of the resistivities for all the complexes was simply semiconductive, which resulted from the alternate stacks of the donor and acceptor molecules in their crystal structures. (TTeC$_2$-TTF)-TCNQ, which had the lowest resistivity, had the lowest E_a (0.06 eV).

The electrical conductivity is universally expressed by a simple relation: $\sigma=ne\mu$. The carrier number n and the carrier mobility μ are believed to depend on γ and the magnitude of the molecular orbital overlap of the donor and the acceptor in the crystal, respectively. According to the band calculation by the extended Hückel method,[26] the intermolecular overlap integrals between the highest occupied molecular orbital (HOMO) of TSeC$_2$-TTF and the lowest unoccupied molecular orbital (LUMO) of TCNQ along the stacking direction were -8.78×10^{-3} and 7.36×10^{-3} for p-(TSeC$_2$-TTF)TCNQ and n-(TSeC$_2$-TTF)TCNQ, respectively. The p-mode had an overlap integral larger than of the n-mode.

The high resistivities of (TTC$_2$-TTF)TCNQ and (TTC$_3$-TTF)TCNQ are easily understood in terms of the smaller γ values. n-(TSeC$_2$-TTF)TCNQ and (TSeC$_3$-TTF)TCNQ also showed high resistivities due to the n-mode overlap with a smaller overlap integral (as shown in Fig. 3(b)) in spite of having a larger γ than the S analogues.

The best planes for the C$_6$S$_4$X$_4$(X=S, Se, Te) moieties of the donor and TCNQ were parallel to each other. The interplanar distances were 3.45, 3.44, 3.51, 3.49, 3.43, 3.57, and 3.47 Å for (TTC$_2$-TTF)TCNQ, (TTC$_3$-TTF)-TCNQ, p-(TSeC$_2$-TTF)TCNQ, n-(TSeC$_2$-TTF)TCNQ, (TSeC$_3$-TTF)TCNQ, (TTeC$_2$-TTF)TCNQ, and (TTeC$_3$-TTF)TCNQ, respectively. These complexes had nearly the same interplanar spacings, which meant that the complexes including Se and Te atoms with larger van der Waals radii had stronger intermolecular interactions than the S analogues. The lower resistivities of p-(TSeC$_2$-TTF)TCNQ, (TTeC$_2$-TTF)TCNQ, and (TTeC$_3$-TTF)TCNQ compared with the S analogues are qualitatively explained in terms of the difference of the van der Waals radii of the chalcogen atoms. (TTeC$_2$-TTF)TCNQ had the lowest resistivity among the present complexes, owing to the p-mode overlap with a larger overlap integral (as shown in Fig. 3(a)) and the effective γ.

(TTeC$_3$-TTF)TCNQ possessed the p-mode overlap shown in Fig. 3(a) and the highest γ. However, (TTeC$_3$-TTF)TCNQ showed a higher resistivity than (TTeC$_2$-TTF)TCNQ, because of a mismatch between the measuring direction of the conductivity and the stacking direction of the donor and acceptor molecules. If we can measure along the stacking axis, a lower resistivity of (TTeC$_3$-TTF)TCNQ is expected to be observed.

Finally, we compared the crystal structures and the electrical properties of the TXC$_1$-TTF(X=S, Se, Te)-TCNQ complexes,[9,14-16] The structural and physical properties of TXC$_n$-TTF(X=S, Se, Te; n=1,2,3)-TCNQ complexes are presented in Table 5. The molecular structure of the donor and the donor(D)-acceptor(A) overlapping mode in TXC$_1$-TTF(X=S, Se, Te)·TCNQ were analogous to those of p-(TSeC$_2$-TTF)TCNQ. (TTeC$_1$-TTF)TCNQ made simple DA type stacks, similar to TXC$_n$-TTF (X=S, Se, Te; n=2,3)·TCNQ. In contrast, (TTC$_1$-TTF)TCNQ and (TSeC$_1$-TTF)TCNQ formed DDAA mixed-stacks, and (TTC$_1$-TTF)$_2$TCNQ formed a DDA mixed-stack.

(TTC$_1$-TTF)TCNQ and (TSeC$_1$-TTF)TCNQ had interchain atomic contacts between the outer chalcogen atom and the nitrogen atom, similar to (TTeC$_2$-TTF)TCNQ. In particular, (TTeC$_1$-TTF)TCNQ had a unique crystal structure with three-dimensional intermolecular interactions through two kinds of DA stacks along the [110] and [1$\bar{1}$0] direction and strong interchain Te-N contacts. These chalcogen-N interactions modulated the CN stretching vibration frequency and caused an overestimation of γ by the IR method for (TXC$_1$-TTF)TCNQ.

Judging from the value of γ calculated by the X-ray method and E_{CT}, (TTC$_1$-TTF)TCNQ, (TTC$_1$-TTF)$_2$-TCNQ, and (TSeC$_1$-TTF)TCNQ were in the neutral CT state, similar to TTC$_n$-TTF(n=2,3)·TCNQ. It was difficult to determine the ionicity of (TTeC$_1$-TTF)TCNQ by the IR and X-ray methods.

Summary

TXC$_n$-TTF (X=S, Se, Te; n=2,3) formed semiconductive 1 : 1 CT complexes with TCNQ, in which donor and acceptor molecules alternately stacked with a uniform spacing. This situation was in contrast to (TXC$_1$-TTF)-TCNQ complexes with a variety of stoichiometries and donor-acceptor stacks. It was of interst that (TSeC$_2$-TTF)TCNQ crystallized in plates and needles. These two phases had different crystal structures and showed different electrical properties. The crystal structures of the other complexes were isomorphous to either p-(TSeC$_2$-TTF)TCNQ or n-(TSeC$_2$-TTF)TCNQ.

The ionicity of TXC$_n$-TTF (X=Se, Te; n=2,3)·TCNQ was at the boundary between the neutral (N) and ionic (I) states. These complexes may exhibit an N-I phase transition induced by temperature and/or pressure.

(TXC$_1$-TTF)TCNQ and (TXC$_2$-TTF)TCNQ had two- or three-dimensional networks in the crystals through intrachain and interchain atomic contacts less than the van der Waals distance. On the other hand, (TXC$_3$-TTF)TCNQ was one-dimensional. TXC$_n$-TTF($n\geq4$) did not form CT complexes with TCNQ. The reason was speculated to be a decrease of lattice energy by further weakened interchain interactions, in addition to a size mismatch between the donor and TCNQ molecules.

(Received December 25, 1990)

The mechanism and active species of drug-induced photosensitive reactions were investigated by measuring the absorption spectra of the transient species on photoexcitation as well as by determining the efficiency of singlet oxygen production on quenching by oxygen of the excited state of drugs. The quantum yields of singlet oxygen production were determined for chlorpromazine hydrochloride, mequitazine, and afloqualone as 0.27, 0.28, and 0.14, respectively. These rather high yields of singlet oxygen suggest its important role in photosensitivity of the drugs. On the basis of the transient-spectroscopic investigations the quenching mechanism of excited-state drugs by oxygen was discussed.

Much attention has been focused on the real active species in photosensitive reactions of drugs. Among drugs benoxaprofen[1] and chlorpromazine[2-6] are reported to undergo photodecarboxylation and photodechlorination, respectively, yielding radical species which can add to DNA or cause disruption of cell membrane. Furthermore, it was reported that benoxaprofen[1b] and chlorpromazine[7] produce singlet oxygen while piroxicam[8,9] produces no detectable amount of singlet oxygen on photoexcitation. In this respect, we investigated the mechanism and active species of drug-induced photosensitive reactions by measuring the absorption spectra of the transient species on photoexcitation and by determining the efficiency of singlet oxygen production on quenching by oxygen of the excited state of drugs which are shown in Chart 1. Among these drugs chlorpromazine hydrochloride (CPZ), mequitazine (MQZ), afloqualone (AQ), and piroxicam (PRX) are known to induce skin photosensitivity, and 5- (5-MOP) and 8-methoxypsoralen (8-MOP) are phototoxic.

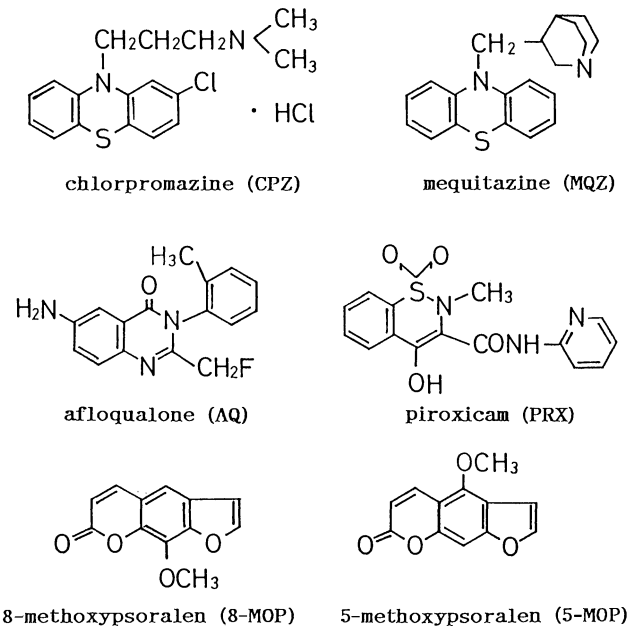

Chart 1.

Experimental

Materials. CPZ was supplied by Sionogi & Co., MQZ by Nippon Shoji Co., AQ by Tanabe Seiyaku Co., PRX by Pfizer Taito Co., 8-MOP by Tokyo Chemical Industry Co. 5-MOP was a gift from Kanebo Cosmetic Laboratory. These drugs were used as received. Solvent benzene (Luminazol) was obtained from Dojin Chem Co.

Laser Flash Photolyses. Laser flash photolyses and singlet oxygen detections were performed as described previously[10,11] by using 308-nm laser pulses of 10-ns fwhm from an excimer laser (Lambda Physik EMG 101, XeCl) as an exciting light source.

The efficiency of the singlet oxygen production was determined as follows. The decay curves of singlet oxygen ($^1\Delta_g$) emission at 1.27 μm were measured for the solutions optically matched at 308 nm for drugs and benzophenone using a germanium diode as a detector.[10-12] The initial intensities of the singlet oxygen emission were obtained from the decay curves, and the quantum yields for singlet oxygen production (Φ_{SO}) were obtained by comparing the initial intensities with that of benzophenone (BP, Φ_{SO}=0.29) as a standard.[13] The detection limit of the present instrument is 0.02 as the quantum yield of singlet oxygen production.

Results

Determination of the Singlet Oxygen Yields. Figure 1a shows a decay profile of the near-infrared emission of singlet oxygen on excitation of benzophenone in benzene at ambient temperature by a 308-nm laser pulse. Excitation of either CPZ, MQZ, or AQ afforded a similar decay curve. The decay curve observed for MQZ is shown in Figure 1b as an example. The singlet oxygen lifetime (28—32 μs) thus obtained is in good agreement with the value reported.[13] The quantum yields of singlet oxygen production (Φ_{SO}) from the drugs are

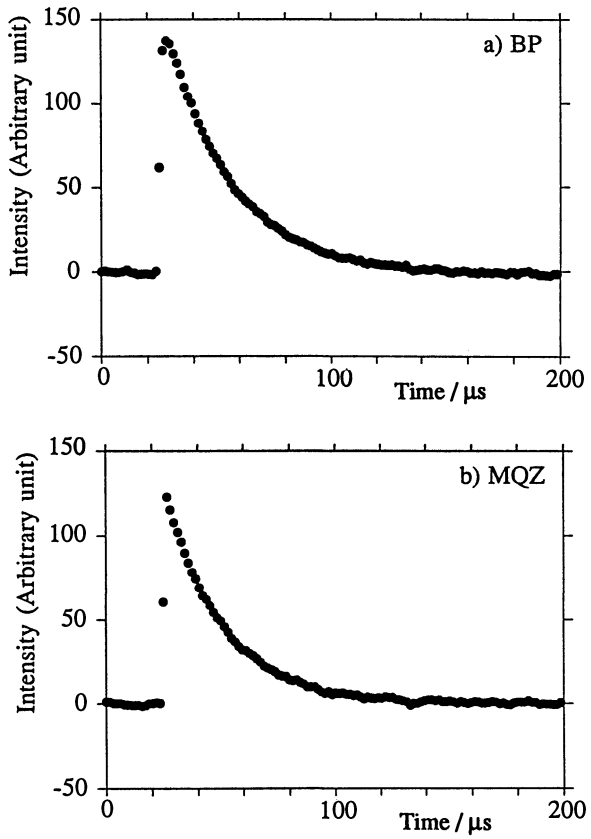

Fig. 1. Decay profiles of singlet oxygen luminescence at 1.27μm in the presence of BP (a) or MQZ (b) in aerated benzene.

obtained using the initial intensities of the emission compared with that of BP (0.29).[13] The quantum yields for CPZ, MQZ, and AQ are 0.27, 0.28, and 0.14, respectively. However, the emission could not be detected for PRX,[9] 5-MOP, and 8-MOP under our experimental conditions, indicating that Φ_{SO} for these compounds must be lower than 0.02. These low values for 5-MOP and 8-MOP are in accordance with the values reported.[14]

T_1-T_n Absorption Spectra and Their Quenching Rate Constants by Oxygen. Figure 2 shows the transient absorption spectra of CPZ, MQZ, and AQ in benzene. CPZ exhibited its transient spectrum at 360—700 nm (λ_{max}: 480 nm) which decayed by first-order kinetics (τ_T=5.8 μs) under argon atmosphere and was efficiently quenched by oxygen (k_q=1.4×10^{10} M^{-1} s^{-1}, M=mol dm^{-3}). The maximum wavelength in the present observation in benzene is shifted to the longer wavelength compared with that reported[15,16] in mixed solvents of alcohols and water (λ_{max}: 460—465 nm). The observed lifetime and the oxygen quenching rate constant suggest that this spectrum is attributed to the T_1–T_n absorption. MQZ also exhibited the T_1–T_n absorption spectrum at 360—700 nm (λ_{max}: 480 nm, τ_T=4.2 μs) and was quenched by oxygen (k_q=1.6×10^{10} M^{-1} s^{-1}). AQ exhibited an intense

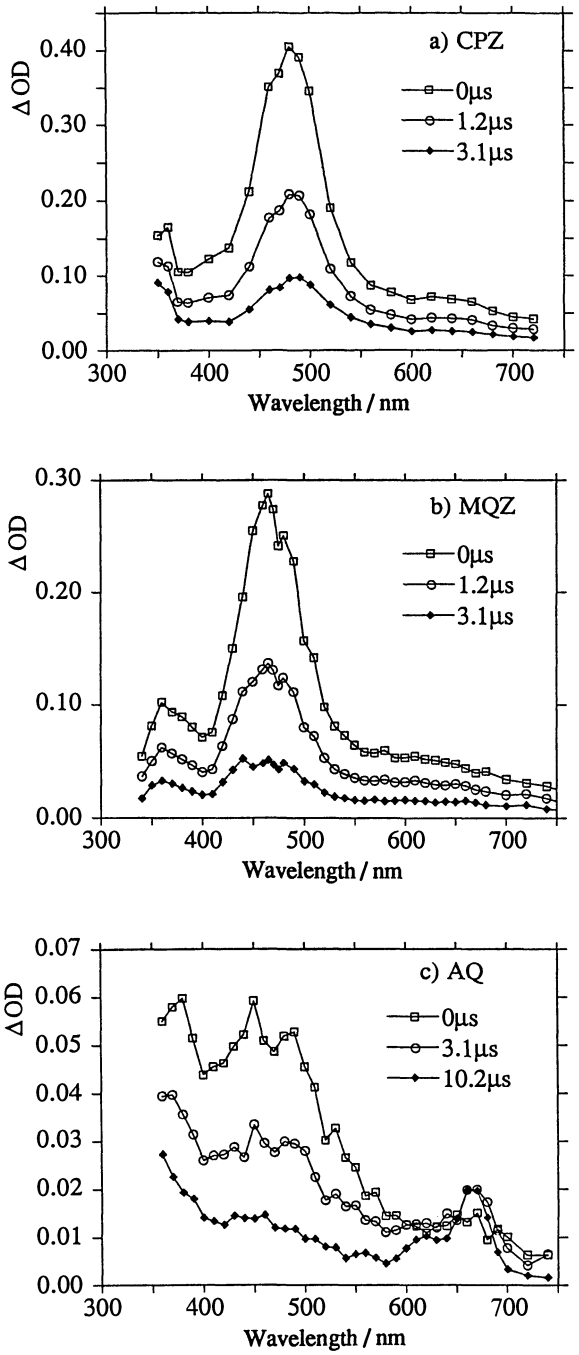

Fig. 2. Transient absorption spectra observed on 308 nm excitation of CPZ (a), MQZ (b), and AQ (c) in benzene.

absorption band at 360—600 nm (λ_{max}: 450 nm) accompanied by a weak band at 600—720 nm; the former band decayed with a lifetime of 6.7 μs (Fig. 3a and b) under argon and was quenched by oxygen at a nearly diffusion-controlled rate (k_q=6.4×10^9 M^{-1} s^{-1}), and the latter band around 670 nm increased in intensity with the μs time scale (Fig. 3c). This behavior indicates occurrence of chemical reactions at the excited state of AQ.

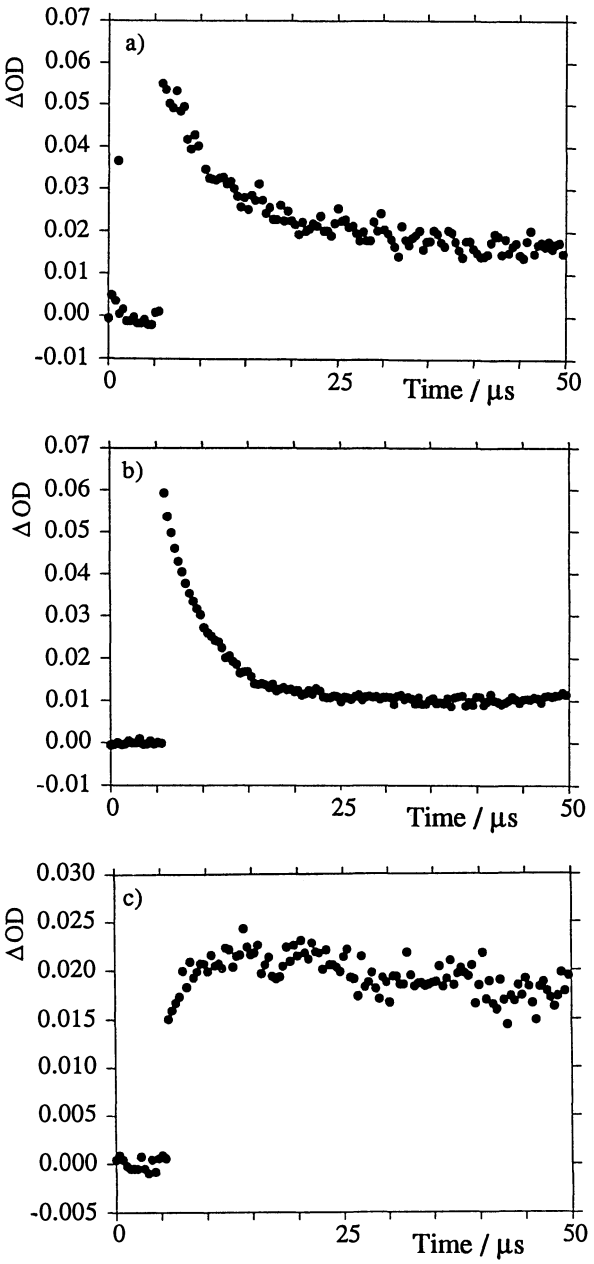

Fig. 3. Time profiles of transient absorptions monitored at 360 nm (a), 450 nm (b), and 670 nm (c) following 308 nm laser photolysis of AQ in benzene.

Discussion

Possible Quenching Mechanism by Oxygen. The quenching of excited triplet states by oxygen proceeds as shown by Eqs. 1—3, where spin statistical factors in triplet-triplet annihilation play an important role. If the triplet state of a substrate has an energy higher than that of singlet oxygen, 95 kJ mol^{-1}, the quenching proceeds through energy transfer (Eq. 1). The probability for this process is only 1/9 for every collisional encounter, and thus, the rate constant for this process must be 1/9 of the diffusion-controlled rate constant (3×10^9 M^{-1} s^{-1}).[17] On the other hand, quenching by acceleration of intersystem crossing to the ground state (Eq. 2) becomes more important as the energy difference between the ground S_0 and triplet T_1 states becomes smaller than 95 kJ mol^{-1}. The triplet energies of CPZ, MQZ, AQ, 5-MOP, and 8-MOP were determined as 246, 247, 238, 252, and 259 kJ mol^{-1}, respectively, by phosphorescence measurements.[18] From these values the oxygen quenching is presumed to proceed through energy transfer (Eq. 1).

$$^3S^*+{}^3O_2 \underset{}{\overset{k_d/9}{\rightleftarrows}} {}^1[S\cdots O_2]^* \longrightarrow {}^1S+{}^1O_2^* \quad (1)$$

$$\overset{3k_d/9}{\rightleftarrows} {}^3[S\cdots O_2]^* \longrightarrow {}^1S+{}^3O_2 \quad (2)$$

$$\overset{5k_d/9}{\rightleftarrows} {}^5[S\cdots O_2]^* \quad (3)$$

Mechanism of Singlet Oxygen Production.

$$S \xrightarrow{h\nu} {}^1S^* \quad (4)$$

$$^1S^* \xrightarrow{k_5} S \quad (5)$$

$$^1S^* \xrightarrow{k_6} S+h\nu \quad (6)$$

$$^1S^* \xrightarrow{k_7} {}^3S^* \quad (7)$$

$$^1S^*+O_2 \xrightarrow{k_8} {}^3S^*+{}^1O_2^* \quad (8)$$

$$^1S^*+O_2 \xrightarrow{k_9} {}^3S^*+O_2 \quad (9)$$

$$^3S^*+O_2 \xrightarrow{k_{10}} S+{}^1O_2^* \quad (10)$$

$$^3S^*+O_2 \xrightarrow{k_{11}} S+O_2 \quad (11)$$

$$^3S^* \xrightarrow{k_{12}} S \quad (12)$$

$$\Phi_{SO}=\frac{\{k_8[O_2]+\dfrac{k_{10}[O_2]\{k_7+(k_8+k_9)[O_2]\}}{\{(k_{10}+k_{11})[O_2]+k_{12}\}}\}}{\{k_5+k_6+k_7+(k_8+k_9)[O_2]\}} \quad (13)$$

$$\Phi_{SO}=k_7k_{10}/(k_5+k_6+k_7)(k_{10}+k_{11})=\Phi_{isc}\Phi_\Delta \quad (14)$$

The quenching of excited drugs by oxygen should take place as shown in Eqs. 4—12, where S denotes a drug. The quantum yield of singlet oxygen production (Φ_{SO}) is described as Eq. 13. If the quenching of excited singlet drugs by oxygen is not important ($(k_5+k_6+k_7)\gg$

$(k_8+k_9)[O_2])$, Φ_{SO} can be reduced to Eq. 14, where Φ_{isc} $(=k_7/(k_5+k_6+k_7))$ and Φ_Δ $(=k_{10}/(k_{10}+k_{11}))$ mean the quantum yields of intersystem crossing from the singlet excited states to the triplet excited states and the efficiency of singlet oxygen production in the quenching of the triplet molecules by oxygen, respectively.

Therefore, the efficiency of singlet oxygen production is related to the quantum yield of intersystem crossing of the excited singlet state of drugs. The quantum yields of intersystem crossing were reported to be as low as 0.067 and 0.011[19] for 5-MOP and 8-MOP, respectively. Thus, these low Φ_{ISC} values might be the reason why no singlet oxygen emission was detected from 5-MOP and 8-MOP. Actually, Φ_{SO}'s are reported as 0.021 and 0.0044 for 5- and 8-MOP,[14] respectively, which are below our detection limit.

Quenching of a singlet excited state by oxygen can give directly singlet oxygen together with the triplet excited state, if the energy difference between the singlet and triplet excited states is higher than the excitation energy of singlet oxygen (95 kJ mol^{-1}). However, this is not the case since the energies of the singlet excited state of CPZ and AQ are measured as 271 and 276 kJ mol^{-1},[18] respectively, and accordingly, they cannot produce singlet oxygen on their quenching by oxygen (E_T: 246 and 238 kJ mol^{-1} for CPZ and AQ, respectively).[18]

Therefore, the efficiency of singlet oxygen production observed for the drugs examined mainly reflects those of intersystem crossing and singlet oxygen production in the quenching of their triplet state. The quenching of the triplet molecules having enough energies to produce singlet oxygen is usually assumed to produce singlet oxygen with a nearly unit efficiency, and thus, we can tentatively assume the efficiency of singlet oxygen production as a lower limit of the intersystem crossing efficiency for these drugs.

The observed quenching rate constants for ^{3}CPZ*, ^{3}MQZ*, and ^{3}AQ* by oxygen are 2—5 times larger than the assumed value (3×10^9 M^{-1} s^{-1}) from Eq. 1. Therefore, there must be some other interactions resulting in the efficient production of singlet oxygen.

For some molecules, participation of the electron transfer mechanism[20] is proposed in the quenching of their triplet states by oxygen. For example, the observed rate constats of oxygen quenching for substituted benzophenone triplets exceed a limit imposed by the spin-statistical restriction (3×10^9 M^{-1} s^{-1}); the quenching rate constant for 4,4′-bis(dimethylamino)benzophenone (DAB, $k_q=12.3\times10^9$ M^{-1} s^{-1}) is more than 5 times higher than that for benzophenone (2.3×10^9 M^{-1} s^{-1}). However, the singlet oxygen is produced with the same efficiency in the quenching of triplet DAB as from triplet benzophenone. The aforementioned large rate constants determined for the present drugs might suggest an intervention of the electron transfer interaction in addition to the usual energy transfer mechanism in the quenching process to produce singlet oxygen.

It should be noted that singlet oxygen ($^1\Delta_g$) is often claimed as an acting species of photosensitivity of drugs based only on the observation of their triplet states and their quenching by oxygen. However, as has been revealed recently, the efficiency of singlet oxygen production is very much dependent on the properties of the triplet excited state. For example, aromatic ketones such as benzophenone produce singlet oxygen not with a unit efficiency but with a rather low value, 0.29.[13] In this case the quenching is supposed to proceed not only by energy transfer but also by addition of oxygen on the carbonyl moiety producing biradical species.[21] Measurements of intersystem crossing yields of durgs will be useful to elucidate the quenching mechanism and the relation between quenching rates and singlet oxygen yields. However, the present determination of the singlet oxygen yields by the direct observation of emission gives an important information for the elucidation of real active species in the photosensitive reactions of drugs.

Conclusion

Quenching of the triplet state of CPZ, MQZ, and AQ by oxygen efficiently produces singlet oxygen, which seems to be responsible for the photosensitive reactions induced by these drugs. Furthermore, AQ also undergoes photoreactions even without oxygen, and can cause additional photosensitive reactions.

Structural Transition Behavior of Potassium Salts of Saturated Fatty Acids, $CH_3(CH_2)_nCO_2K$ (n=14, 16, 18, 20)

Tsutomu ISHIOKA
Department of Material Systems Engineering, Faculty of Technology,
Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received January 16, 1991)

The structural transition behavior of potassium soaps (99% purity), $CH_3(CH_2)_nCO_2K$ (n=14, 16, 18, 20), having low water contents of less than 10 wt% was investigated by both DSC and vibrational spectroscopies. Nine phases from crystal (I<80 °C) to liquid crystal (260 °C<IX) were observed for n=14 and 16 by thermal measurements. An additional phase I′ (I<I′<II) was found for n=18 and 20. The structural changes of the alkyl chains accompanied by these transitions were investigated by using IR and Raman methods. With increase in temperature, the itensities of the IR methylene progressive bands which were characteristic of all-trans conformation decreased and conformational defect bands ascribed to *gt*-, *gg*-, and *gtg′* conformations, were observed in phases I′, II, and III for n=14—20. These indicate the onset of a partial melting of the chains in these phases. At the transition from phase III to IV, the chains entered liquid-like conformations. The result was also confirmed by the Raman spectra.

Even-numbered anhydrous potassium soaps, $CH_3(CH_2)_nCO_2K$ (where n is the number of the methylene groups), take successive phase transitions from the crystalline phase to the liquid crystalline phase with an increase in temperature.[1] The lowest temperature crystalline phase of n=10—16 is ascribed to the triclinic B-form (space group $P\bar{1}$). The unit cell contains two molecules having an all-trans conformation. The molecules are parallel to each other and are packed with a triclinic $T_{//}$ subcell. With an elevation in temperature, the B-form is transformed to the monoclinic C-form ($P2_1/a$) at 50—80 °C. The molecule in the C-form is supposed to have a partially conformational disorder at the methyl end. A further increase in the temperature causes the transition from the crystalline phase to the two-dimensional rectangular or oblique lattice at 170—195 °C for n=12—16. The lattice is changed into the lamellar liquid crystalline phase at 270—280 °C.

Several experimental techniques, such as x-ray diffraction or NMR methods, have been applied in order to characterize the molecular structure in these phases, while the detailed molecular transition behavior, especially the melting process of the alkyl chains during these successive transitions, has not yet been clearly shown. In this study, we tried to clarify the melting behavior of the alkyl chains in soaps with n=14, 16, 18, and 20 using differential scanning calorimetry (DSC), infrared, and Raman methods.

Experimental

Potassium soaps of n=14—20 were synthesized from even-numbered saturated fatty acids (Σ company, 99%) by the titration of potassium carbonate in ethanol solution kept at 70 °C. The products were purified by reprecipitation with diethyl ether from the solutions and dried at 100 °C in vacuo for 24 h. Neutralization was confirmed by the IR spectrum. The contents of water were evaluated as a few wt% by a elementary analysis.

DSC measurements were carried out with a Rigaku DSC using sealed pans at a heating rate 10 K min^{-1}. The transition temperatures and enthalpy changes were calibrated using seven standards: carbon tetrachloride, benzene, naphthalene, benzoic acid, indium, tin, and lead. Infrared measurement was made with a JASCO IR-810 spectrophotometer. The wavenumbers were calibrated with an indene standard. The sample for IR measurements was pressed into a KBr disk. Raman measurements were made with a JASCO R-800 double monochromator using a 514.5 nm exciting beam from an Ar^+ laser. A powder sample sealed in a glass capillary was subjected to a Raman measurement. The heating rate for the IR and Raman measurements was 10 K min^{-1}. In order to achieve thermal equilibrium, the measurements were carried out after 1 h of temperature setting.

Results and Discussion

The results of DSC measurements for n=14, 16, 18, and 20 are shown in Fig. 1. With increasing temperature from room temperature to 280 °C, eight endothermic peaks were observed for n=14 and 16 and nine peaks for n=18 and 20. According to Cingolani et al.,[2] these transitions are described with symbols from b′ to F, as shown in Fig. 1. Their temperatures, enthalpy, and entropy changes were the same as those obtained by Cingolani et al.[2] for n=14, 16, and 18 within the experimental error. Those for n=20 are listed in Table 1. Nine phases were designated as from phase I

(crystalline phase) to phase IX (lamellar liquid crystalline phase) for n=14 and 16. An additional phase I′ was observed for n=18 and 20. The crystal structure of phase I of n=14—20 was ascribed to the triclinic B-form by analysis of the X-ray powder pattern, while that of phase I′ of n=18 and 20 is uncertain at the present stage. Transition A was attributed to that from the crystalline phase to the two-dimensional lattice and F from the lattice to the lamellar liquid-crystalline phase.

In order to reveal any structural changes in the alkyl chains accompanied by these transitions, the temperature dependence of the IR and Raman spectra was measured. First, the spectra of n=14—20 at room temperature (phase I) were measured (Fig. 2) and their assignments were made with a normal coordinate calculation. The calculation was carried out by the Wilson GF matrix method using an NEC computer (ACOS 1000) at this university. The molecules were assumed to have an all-trans conformation and to belong to the C_s point group. A tetrahedral geometry was assumed for C–C–C, C–C–H, and H–C–H angles with C–C and C–H bond lengths equal to 1.54 and 1.093 Å, respectively. The C–C–O and O–C–O angles were assumed to be 120° with a C–O length equal to 1.27 Å.[3] The force constants regarding $CH_3(CH_2)_n$ group were transformed from the valence force constants derived by Snyder for normal paraffins (calculation V).[4] For the constants of the $C_\alpha H_2$ group and the torsional constants around all of the C–C bonds, those derived by Umemura were used.[5] For the COO^- group, the Urey-Bradley force constants derived by Nakamura[3] were transformed into the valence force constants[6] as initial values, and then adjusted to fit both

the observed and calculated frequencies by a trial-and-error method. The calculated frequencies in the methylene progressive region from 700 to 1400 cm^{-1}, which were sensitive to the conformational change of the chain, are listed in Table 2—5 for n=14—20, respectively. The frequencies of the observed progressive bands were satisfactorily assigned according to the all-trans conformation, although the above-mentioned force constants gave slightly higher calculated frequencies for the CH_2 wagging modes.[7] The assignment was almost the same as that derived by Gotoh and Takenaka[8] for n=14 and 16, except for that of the CH_3 rocking band.

Second, the conformational change with an increase in the temperature was considered. With increasing temperature, the intensities of the progressive bands ascribed to the all-trans conformation decreased at the transition from phase I to II for n=16, as shown in Fig. 3. New bands appeared at 1348, 1077, 932, 867, 855, 772, and 752 cm^{-1} (marked with asterisks in Fig. 3). At the transition from phase II to III, the intensities of the progressive bands further decreased and those of the new bands observed in phase II decreased and became slightly detectable. At temperatures above phase IV, all of these bands were smeared out. Similar spectral changes were also observed for n=14, 18, and 20. The new bands observed in phases I′, II, and III for n=14—20 are summarized in Table 6.

Comparing the new bands observed in phases I′, II, and III with the conformationally disordered bands of normal alkanes, we considered the structural transition behavior. Because of the localized character of the defect modes in normal alkanes, they may be well transferable among the molecules of the same class, as in the present cases. The frequencies of the defect modes have been evaluated for the end gauche (*gt-* where *g* and *t* represented trans and gauche conformations, respectively, and the dash meant the remainder of the chain was in all-trans or nearly all-trans conformation), double gauche (*gg-*), and kink (*gtg′*) conformations by normal-mode analysis for normal alkanes.[9-11] According to the analysis, the new bands observed in phases I′, II, and III were assigned as listed in Table 6, indicating that there was a conformational defect at the methyl-end. With an increase in the chain length, there appeared *gtg′* conformation for n=20. There remained several bands which could not be assigned at the present stage. Based

( ): uncertain. *: not assigned at the present stage.

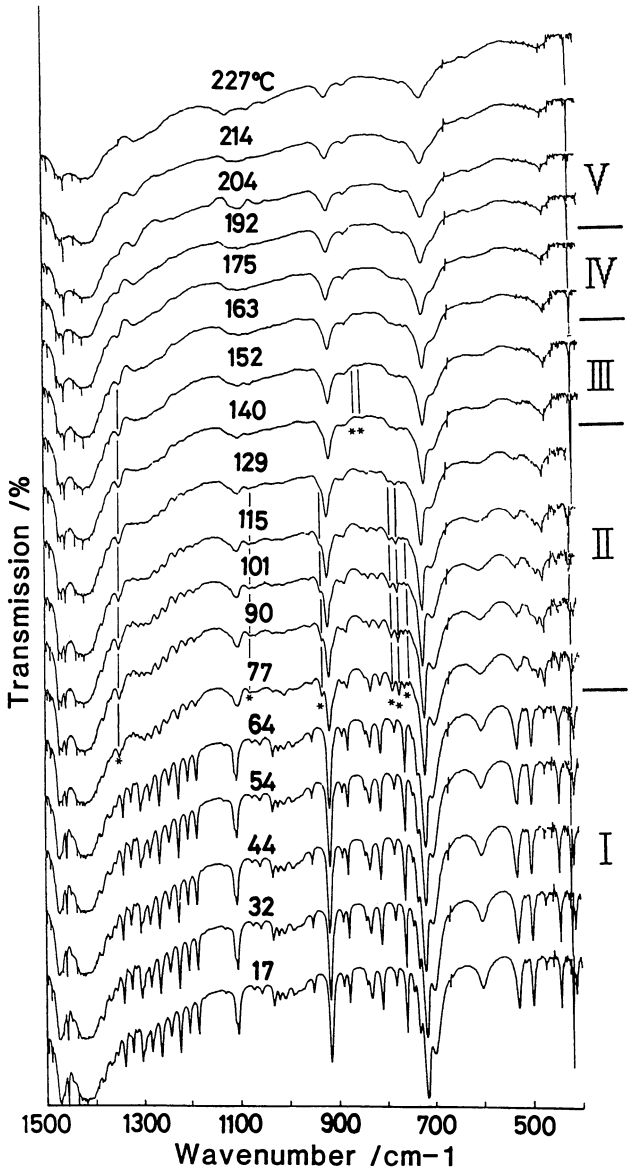

Fig. 3. Temperature dependence of IR spectrum for n=16 in the 400—1500 cm^{-1} region.

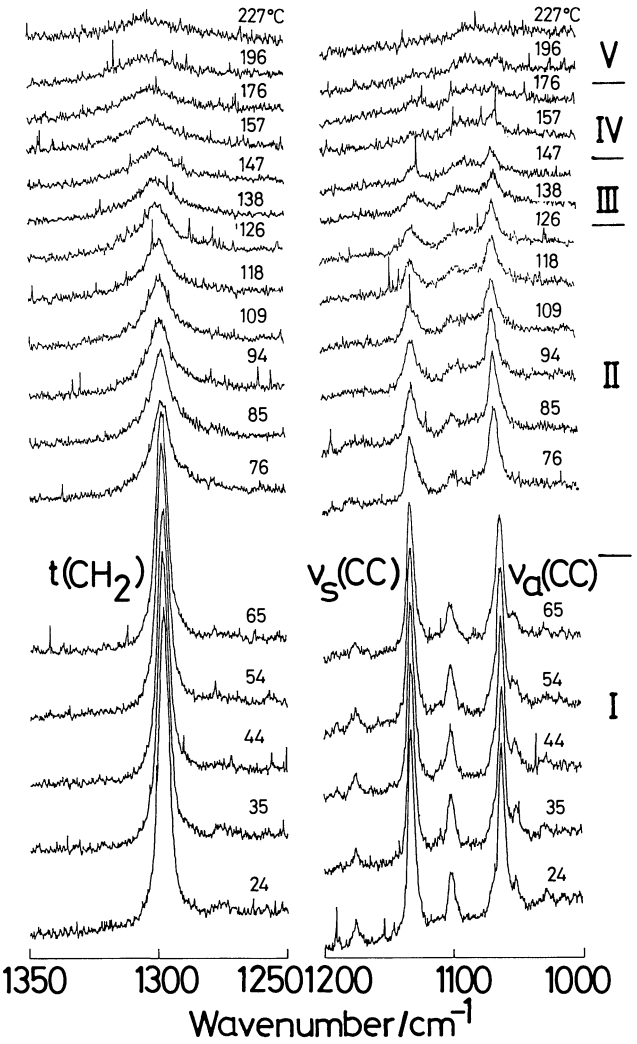

Fig. 4. Temperature dependence of Raman spectra for n=14.

on the result of a decrease in the intensities of the progressive bands and the appearance of defect bands, it was concluded that the conformational disordering proceeded in phases I′, II, and III, and the disappearance of these bands indicated that the chains went into a liquid state above phase IV for n=14—20.

In order to confirm the structural transition, the temperature dependence of the Raman spectra was observed, as shown in Fig. 4. The Raman spectra of the alkyl chains in the 1000—1500 cm^{-1} region are sensitive to the conformational order of the chains. The intensities of the bands at 1295 cm^{-1} [the CH_2 twisting $t(CH_2)$], and 1170 cm^{-1} [the CH_2 rocking $r(CH_2)$], as well as 1130, 1062 cm^{-1} [the symmetric and antisymmetric C–C stretchings ν_s(CC) and ν_a(CC)] are proportional to the amount of all-trans segments longer than a certain length characteristic of each vibrational mode. For example, the 1295 cm^{-1} band is due to all-trans sequences of 6 or more methylene units, the 1130 cm^{-1} band to those of 16—20 or more units, and the 1062 cm^{-1} band to those of 8 or more units.[12] The temperature dependence of the peak intensities of the Raman $t(CH_2)$, ν_s(CC), and ν_a(CC) modes relative to the peak intensity of the $t(CH_2)$ mode[13] at room temperature for n=14—20 is plotted in Fig, 5. With an increase in the temperature, at the transition from phase I to I′ or II, the intensity of the 1130 cm^{-1} band (which is characteristic of the long methylene sequences) decreased selectively. At the temperatures in phase II and III, the intensities of all of bands (including those characteristic of short trans sequences) decreased. At temperatures above phase IV, these bands were smeared out. Therefore, the result of the IR measurements was confirmed by the Raman measurements.

In conclusion, from the IR and Raman methods it was revealed for n=14—20 that the conformational disordering of the alkyl chains proceeded in phases I′, II,

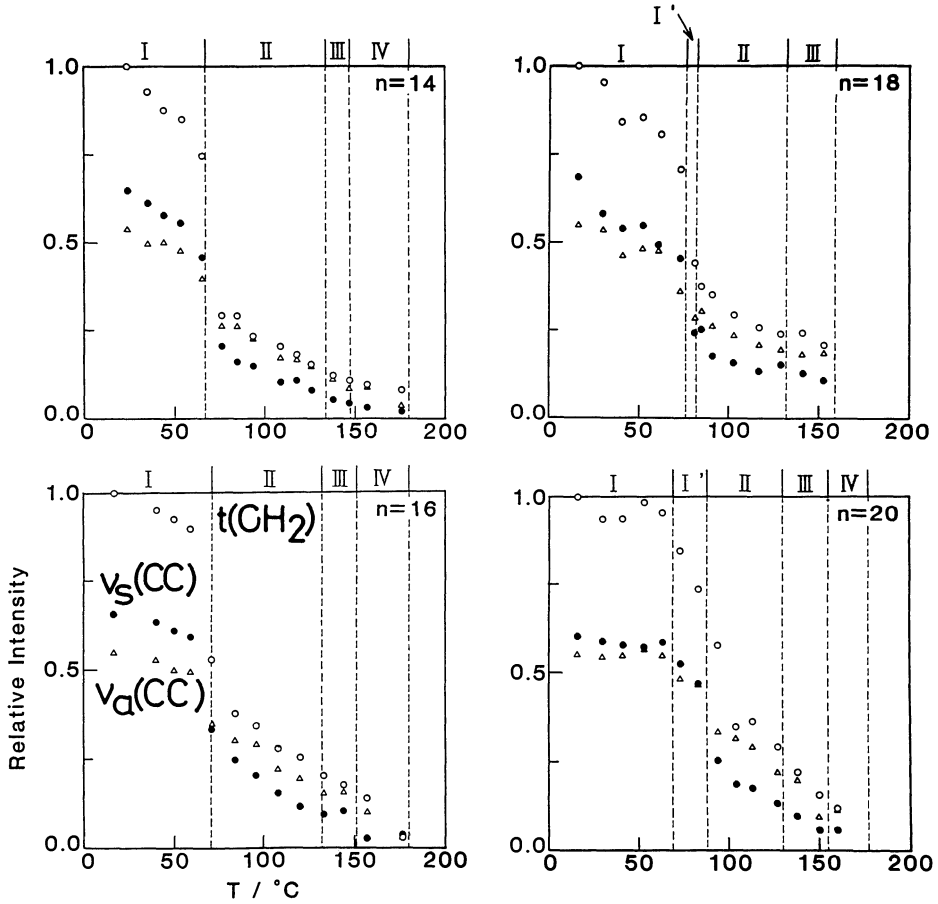

Fig. 5. Temperature dependence of relative peak intensities of Raman spectra for n=14—20.

and III. At temperatures above phase IV, the chains entered a liquid-like conformation.

β-α Photoisomerization of Cobaloxime Complexes in the Solid State. III. Accelerated Reaction Rate by Hydrogen Bond

Akiko SEKINE* and Yuji OHASHI
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo 152
(Received January 18, 1991)

The crystal structures of two cobaloxime complexes with different axial base ligands have been determined by X-ray analysis at room temperature. I: (3-Aminopyridine)(2-cyanoethyl)bis(dimethylglyoximato)cobalt(III); the cystal is monoclinic, the space group being $C2/c$, $Z=8$ with $a=28.849(8)$, $b=7.746(2)$, $c=18.429(5)$ Å, and $\beta=105.71(3)°$. II: (Aniline)(2-cyanoethyl)bis(dimethylglyoximato)cobalt(III) aniline solvate; the crystal is monoclinic, the space group being $P2_1/c$, $Z=4$ with $a=14.228(7)$, $b=11.426(4)$, $c=14.178(3)$ Å, and $\beta=91.92(3)°$. Both structures were refined by a full-matrix least-squares method to final R values of 0.070 and 0.074 for 3886 and 3311 observed reflections, respectively. Their photoisomerization rates in the solid state obtained from changes in the IR spectra, 3.2 and 4.2×10^{-4} s^{-1}, respectively, are significantly greater than those of the related compounds. The hydrogen bonds between the reactive 2-cyanoethyl groups and the atoms of the neighboring molecules in the two crystals should be responsible for the greater reaction rates. Taking into account the role of the hydrogen bonds, a probable isomerization mechanism is proposed.

The 2-cyanoethyl group bonded to the cobalt atom in the bis(dimethylglyoximato)cobalt(III), cobaloxime, complex was found to be isomerized to the 1-cyanoethyl group upon exposure to visible light.[1] The photoreaction, β–α isomerization, proceeds only in the solid state, and the reverse reaction has not yet been observed.

Since the reactive group is very similar to that in crystalline-state racemization, we expected that the reaction rate would be well explained by the reaction cavity for the reactive group, as observed in the crystalline-state reaction.[2] A series of cobaloxime complexes with different axial base ligands has been prepared and the relation between the reaction rate and the reaction cavity examined.

For a complex with 3-methylpyridine as an axial base ligand (3mp), two crystal forms (I and II) were obtained under the same conditions. The powdered sample of form II revealed a significantly greater rate than that of form I. The reaction cavity around the 2-cyanoethyl group of form II is greater than that of the form I, indicating that the cavity size is one factor controlling the reaction rate.[3] For a complex with pyridine used as an axial base ligand (py), two forms were also crystallized under the same conditions. Although the reaction cavity of form II was significantly smaller than that of form I, form II revealed a significantly greater reaction rate than did form I. The 2-cyanoethyl group in form II takes a nearly parallel conformation to the cobaloxime plane, whereas that of form I takes a perpendicular conformation. The 2-cyanoethyl group with a parallel conformation would be more easily transformed to the α-cyanoethyl group than that with a perpendicular conformation, since the former has a closer resemblance in shape to the 1-cyanoethyl group than does the latter. Therefore, such a topochemical factor should be the second factor controlling the reaction rate in the case of the complex (py).[4]

It was recently reported that for four complexes with 3-ethylpyridine (3ep),[5] 4-ethylpyridine (4ep),[5] 3-cyanopyridine (3cp),[6] and 4-aminopyridine (4ap)[6] the reaction rates could be well-explained in terms of the above two factors. However, the two complexes with 3-aminopyridine (3ap) and aniline (1ab) as axial base ligands revealed significantly greater reaction rates than those expected from the above two factors.

The present paper deals with the two complexes, 3ap and 1ab, and proposes a third factor.

Experimental

Crystal Structures. The complexes were synthesized by a previously reported method.[7] The crystals were obtained from hot methanol solutions. The approximate dimensions of the crystals used were 0.3×0.3×0.1 (3ap) and 0.3×0.3×0.1 mm (1ab). X-Ray measurements were performed with a Rigaku four-circle diffractometor (AFC-4). Mo $K\alpha$ radiation monochromated by graphite ($\lambda=0.71069$ Å) was used. The cell parameters were refined by least-squares on the basis of 16 and 15 independent 2θ values ($20°<2\theta<30°$) for 3ap and 1ab, respectively. Three-dimensional intensity data were collected up to $2\theta=55°$ (3ap) and 50° (1ab); the ranges of hkl were −36 to 36, 0, to 10, and 0 to 22 (3ap), and −16 to 16, 0 to 13, and 0 to 16 (1ab). The intensities were measured using an ω–2θ scan technique and a scan speed $4°(2\theta)$ min^{-1}. The background counts were accumulated for 5 s both before and after each scan. Three standard reflections were monitored for every 50 reflections, and no significant variations in the intensities were observed. The reflections for $|F_o|>3\sigma(|F_o|)$ were considered as being observed and used for structural determinations. Although corrections for the Lorentz and polarization factors were made, no correction for the absorption was applied.

The structure of 3ap was solved by the direct method with a program called MULTAN 78,[8] refined by full-matrix least-squares with the program called SHELX 76.[9] All of the hydrogen atoms were found on the difference map. The final refinement was made with the anisotropic temperature factors for non-hydrogen atoms and the isotropic ones for hydrogen atoms. The quantities minimized were $\sum w(|F_o|-|F_c|)^2$ and $w=[\sigma^2(|F_o|+0.004|F_o|^2]^{-1}$. The final R and R_w values became 0.070 and 0.084 for 3886 observed reflections. No peaks higher than 0.3 $eÅ^{-3}$ were found on the final difference map.

The procedure of a structure determination for the lab was similar to that for 3ap. An aniline molecule appeared in the difference map, which occupies an inversion center with disordered orientations. Some of the hydrogen atoms were found on the difference map. The others were calculated geometrically and refined with C–H distances constrained to 1.00 Å. The final refinement was made with the anisotropic temperature factors for non-hydrogens atoms and isotropic ones for hydrogen atoms. The weighting scheme was $w=[\sigma^2(|F_o|)+0.004|F_o|^2]^{-1}$. The final R and R_w values became 0.074 and 0.074 for 3311 reflections. No peaks higher than 0.5 e Å^{-3} were found on the final difference map. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[10] The final atomic coordinates and equivalent isotropic temperature factors for non-hydrogen atoms are given in Tables 1 and 2. Lists of the anisotropic temperature factors for non-hydrogen atoms, atomic coordinates and temperature factors for hydrogen atoms, all the bond distances and angles, as well as the observed and calculated structure factors are kept in the office of Chemical Society of Japan. Computations were carried out on M-280H and M-680H computers at the Computer Centre of the University of Tokyo.

β–α Isomerization. KBr disks which contained 1% of the 2-cyanoethyl complex were exposed to a 500 W Xe lamp. The IR spectra of the KBr disk were measured at intervals of 5 min and 10 min for 3ap and 1ab, respectively. The absorption assigned to the stretching vibration mode of the cyano group, ν_{CN} in 2-cyanoethyl complex, was at 2250 cm^{-1}. The peak decreased with the irradiation time and ν_{CN} of the 1-cyanoethyl complex appeared at 2200 cm^{-1}, and increased. Since the change during the early stages, within 40 min, was represented by first-order kinetics, the rate constant was obtained by least-squares fitting.

Results

The crystal structures of 3ap and 1ab are shown in Figs. 1 and 2, respectively. For 3ap, N(5) in the cyanoethyl group is hydrogen-bonded to N(7) of the amino group in the neighboring molecule at (x,$-y$, $0.5+z$)[N(5)···N(7) 3.135(10) Å]. The molecules are connected along the c axis as a ribbon by hydrogen bonds. For 1ab, a unit cell contains two free aniline molecules, which occupy the inversion centers. The N(5) atom in the cyanoethyl group is hydrogen-bonded to N(6) of the amino group of the neighboring molecule at (x, $0.5-y$, $0.5+z$) [N(5)···N(6) 3.076(10) Å], and O(3) is hydrogen-bonded to N(6) of the adjacent molecule at ($1-x$, $-y$, $-z$). The molecules form a ribbon comprising two rows along the c axis. Free aniline mole-

cules are hydrogen-bonded to the O(1) of the neighboring cobaloxime molecule, forming walls between the ribbons.

The molecular structures of 3ap and 1ab are shown in Figs. 3 and 4, respectively. The selected bond distances and angles of 3ap and 1ab are shown in Tables 3. Torsional angles of Co(1)–C(9)–C(10)–C(11) in 3ap and 1ab are +84.7(6)° and +96.9(4)°, respectively. This means the 2-cyanoethyl groups in both complexes are approximately parallel to their cobaloxime planes. The

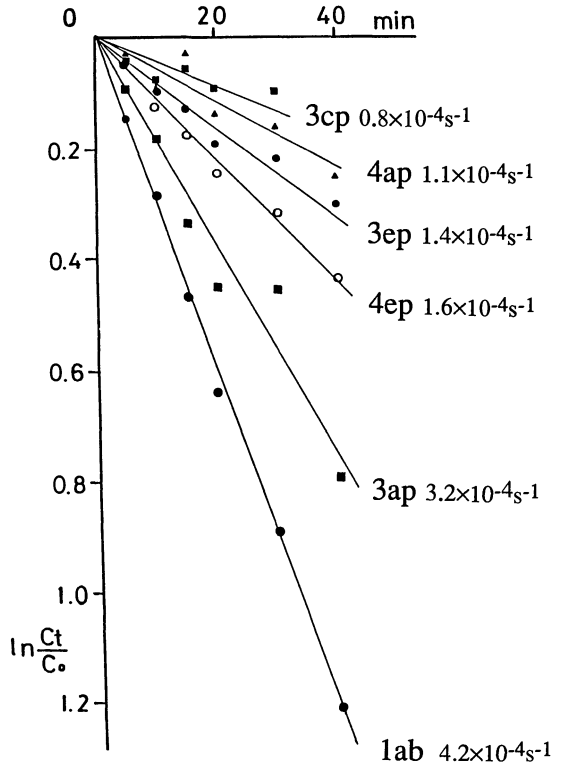

Fig. 5. Reaction rate for β–α isomerization for 3ep, 4ep, 3cp, 4ap, 3ap, and 1ab. Solid lines are obtained by least-squares fitting, assuming the first-order kinetics.

molecular structure of 3ap is similar to those of the other cobaloxime complexes with pyridine derivatives; pyridine,[4] 3-methylpyridine,[3] 3-ethylpyridine, and 4-ethylpyridine.[5] For 1ab, the Co(1)–N(6)–C(12) angle is 119.3(4)°. Approximately the same angle was observed in bis(aniline)bis(dimethylglyoximato)cobalt(III)chloride,[11] 119.5(7)°. Such expanded angles would be caused by short contacts between the aniline and cobaloxime moieties. The shortest distances between the nitrogen atom of the cobaloxime moieties and the benzene ring of aniline ligand are 3.016(7) Å and 2.920(8) Å for 1ab and the bis(aniline) complex.

Table 4. Cavity Size (V/Å^3) and Rate Constant (k/s^{-1}, $\times 10^4$)

	V	k	Conformation
3cp	12.24	0.8	Perpendicular
4ap	14.99	1.1	Perpendicular
3ep	13.12	1.4	Parallel
4ep	14.00	1.6	Parallel
3ap	10.06	3.2	Parallel
1ab	14.97	4.2	Parallel

The rate of isomerization during the early stages follows first-order kinetics (Fig. 5), in which the rates of 3-cyanopyridine (3cp), 4-aminopyridine (4ap), 3-ethylpyridine (3ep), 4-ethylpyridine (4ep), 3-aminopyridine (3ap), aniline (1ab) are given. The 3ap and 1ab crystals have significantly greater values than do the other four crystals.

Discussion

Table 4 gives the cavity size,[12] the rate constant during the early stages and the conformation of the 2-cyanoethyl group for six complex crystals: 3ep, 4ep, 3cp, 4ap, 3ap, and 1ab. The crystals with a parallel conformation have greater rate constants than do those with the perpendicular type. The second topochemical factor observed in the two crystal forms of the pyridine complex[4] plays an important role, even if the crystals have different base ligands. Moreover, in the two crystals with a perpendicular conformation, 3cp and 4ap, the crystal with a greater cavity has a greater rate constant. The first cavity factor observed in the two crystal forms of 3mp[3] controls the reaction rate when the reactive group takes the perpendicular conformation. For crystals with a parallel conformation, however, the first factor has no effect on the reaction rate. Although the cavity of 3ap is smaller than those of 3ep and 4ep, the rate constant of 3ap is greater than those of 3ep and 4ep. This fact indicates that the third factor should be taken into account.

It appears that solvent molecules may cause the greater reaction rate, since the 1ab crystal has another aniline as a crystalline solvent. However, the 3ap crystal, which has a greater reaction rate too, has no solvent and the 3cp has a water molecule used as a solvent in spite of the smallest reaction rate. This suggests that the solvation may have no significant effect on the reaction rate.

Only in the 3ap and 1ab crystals, the nitrogen atoms of the 2-cyanoethyl groups have hydrogen bonds with the

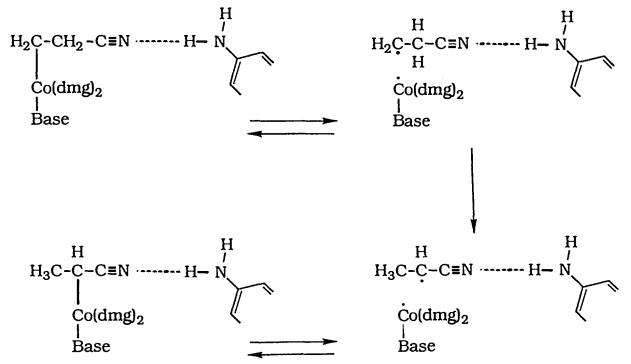

Fig. 6. Mechanism of β–α isomerization. The hydrogen bonds are indicated by broken lines.

amino groups of the neighboring molecules. Although hydrogen bonds are also observed in the 3cp crystal, they connect the solvent water molecules with the neighboring cobaloxime moieties; the nitrogen atom of the 2-cyanoethyl group does not take part in the hydrogen bonding.

A probable mechanism of the β–α photoisomerization associated with the hydrogen bond is shown in Fig. 6. When the Co–C bond is cleaved by visible light, the 2-cyanoethyl radical is produced. Such a homolyitic Co–C bond cleavage of the cobaloxime complexes has been extensively reported.[13,14] Since the produced radicals may be unstable, and cannot move so easily in the crystalline lattice, most part of the radicals would return to the original 2-cyanoethyl group. However, a small parts of the radicals may be transformed to the 1-cyanoethyl radicals by virtue of lattice vibration; the rate-determining step is probably the 2→1 radical transformation in this photoisomerization.

If the nitrogen atom of the 2-cyanoethyl group is hydrogen bonded to the amino group in a neighboring molecule, the produced 2-cyanoethyl radical may be stabilized and the prolonged lifetime of the 2-cyanoethyl radical would cause an increased extent of the 2→1 radical transformation. The four crystals with a parallel-type conformation, therefore, can be divided into two classes depending on whether or not the reactive group has a hydrogen bond with the neighboring molecule. The first factor, the cavity factor, controls the reaction rate in both classes.

In conclusion, the reaction rate is well explained by three factors in the solid state β–α photoisomerization of cobaloxime complexes; the size of the cavity, the conformation of the reactive group and the hydrogen bond with the reactive group. Although the structure in which the 2-cyanoethyl group with a perpendicular conformation is hydrogen-bonded to the neighboring molecule has not yet been observed, the third factor seems to be most important among the three factors, considering the significantly greater reaction rate of 3ap and 1ab crystals. As a matter of course, the second factor is more important than the first. Table 4 indicates that the reaction rate is affected by the first factor only if the second and third factors are equivalent.

ESR Studies at High Pressures. III.[1] Spin-Exchange Reactions of Some Nitroxide Radicals in Acetone and Hexane

Yoshimi Sueishi,* Masahiro Kuzukawa, Shunzo Yamamoto, and Norio Nishimura
Department of Chemistry, Faculty of Science, Okayama University,
Tsushima Naka 3-1-1, Okayama 700
(Received February 7, 1991)

Pressure effects on the rate of spin–spin exchange of some nitroxide radicals in acetone and hexane at 298.2 K have been studied by means of a high-pressure ESR technique. It was found that this exchange reaction is diffusion-controlled. The rate of the spin exchange is related to that of diffusion, the probability of the spin exchange, $P = f(J, \tau_1)$, and steric factor f_s. The values of P and hence τ_1 were estimated as a function of pressure. A method for evaluating the steric factor and the exchange integral is proposed.

It has been recognized over the past half a century that kinetic studies at high pressures are informative for characterizing reaction processes in condensed systems. When investigations at high pressures are undertaken, we often face some difficulties that should be surpassed. For high-pressure NMR and ESR experiments in particular, sophisticated techniques are required. At present, high pressure/high temperature NMR probse have been designed, and this has enabled us to know detailed information about the dynamic structure of liquids.[2] On the contrary, only a few high-pressure ESR studies have been done; among them, papers concerning the effects of pressure on spectral linewidth[3,4] and hyperfine splittings[5] besides chemical equilibria[6,7] and reaction rates[8] have been put forward.

In previous papers,[1,9] we have reported the pressure effects on the rate of spin–spin exchange of 2,2,6,6-tetramethyl-4-oxo-1-piperidinyloxyl (TANONE) in various solvents. The rate constant for the spin-exchange process was found to be strongly correlated to solvent viscosity η, indicating that a diffusion-controlled process is involved. Since viscosity variation with temperature inevitably involves unfavorable energetic problems, the viscosity was changed by applying pressure p. It was found that in aprotic solvents except acetone, the activation volumes for the spin-exchange process ($\Delta V_{ex}^{\neq}$) coincided well with the apparent activation volumes for diffusive processes ($\Delta V_{diff}^{\neq}$).

In the present work, we used acetone and hexane as low viscosity solvents to utilize available η–p data together with compressibility data. In order to obtain further information about the effect of pressure on the rate of the spin–spin exchange, we investigated the spin-exchange reaction of three kinds of nitroxides: 2,2,6,6-tetramethyl-4-oxo-1-piperidinyloxyl (TANONE), 2,2,6,6-tetramethyl-1-piperidinyloxyl (TEMPO), and di-*t*-butyl nitroxide (DTBN) in acetone and hexane.

Experimental

TANONE, TEMPO, and DTBN were purchased from Wako Pure Chemicals Co., Ltd., and used without further purification. Reagent grade acetone and hexane were used after distillation. The instrumentation of a high-pressure ESR cell has already been described elsewhere.[9] A sample solution was deaerated by bubbling nitrogen and was transferred into the cell under nitrogen atmosphere. After a required pressure had been attained, the stop valve on the cell was closed and then cell was separated from the pump system. By doing that, troublesome instrumentations[6–8] have been overcome.

ESR signals were monitored by using a JEOL JES-FE3XG ESR spectrometer with a 100 kHz field modulator. The peak-to-peak width of the central signal was measured at 298.2 K within a precision of ±1.5%.

Theoretical Background

The rate constant of spin-exchange reaction k_{ex} is related to the line broadening of an ESR signal by Eq. 1.[10]

$$\Delta H = (k_{ex}/A)C + \Delta H_0, \quad (1)$$

where ΔH and ΔH_0 are the linewidth in the presence and absence of spin exchange, respectively; A is a constant characteristic of each radical, and is equal to 2.28×10^8 mT^{-1} s^{-1} for the Lorentzian type of ESR signals of nitroxides.[10] Since no activation energy will be needed for the exchange process, the exchange rate constant can be given by the rate constant for a diffusive process k_{diff} multiplied by P:

$$k_{ex} = Pk_{diff}, \quad (2)$$

where P is the probability of spin exchange upon "collision". The probability (P) is related to the exchange integral J and collision time τ_1 by Eq. 3,[10]

$$P = J^2\tau_1^2/(1 + J^2\tau_1^2). \quad (3)$$

The term collision is used here in the sense that a pair of reacting molecules are encountering in a solvent cage. According to the Stokes–Einstein–Smoluchowski equation, k_{diff} for spherical molecules in a medium-incontinuum of bulk viscosity η is given by:

$$k_{diff} = 8000RT/3\eta. \quad (4)$$

In real solution, the shape, mutual orientation and solvation of reacting molecules would affect k_{ex}. Hereafter such composite effects will be called comprehensive-

ly the steric factor f_s. Then, Eq. 2 can be modified as:

$$k_{ex} = Pf_s k_{diff}. \quad (5)$$

According to Plachy and Kivelson,[11] the collision time τ_1 can be given by Eq. 6

$$\tau_1 = \pi b\lambda^2\eta/kT, \quad (6)$$

where b is the effective hydrodynamic radius of a molecule moving in a liquid, and $\lambda=\lambda(p, T)$ is the jump length which may be, according to the hole theory, inversely proportional to the cube root of the liquid density.[11] Thus, the following relationship will approximately hold.

$$\lambda_p^3 = \lambda_0^3\rho_0/\rho_p, \quad (7)$$

where λ_0 and ρ_0 denotes the jump length and the (liquid) density at the freezing point under atmospheric pressure, respectively and λ_p and ρ_p represent them at pressure p and 298.2 K. By combining Eqs. 3, 5, 6, and 7, and eliminating P and λ_p, we finally obtain Eq. 8 which enables us to estimate the steric factor f_s and exchange integral J:

$$k_{diff}/k_{ex} = 1/f_s + (k^2T^2/J^2\pi^2\lambda_0^4\rho_0^{4/3}b^2f_s)(\rho_p^{4/3}/\eta^2). \quad (8)$$

Another equation that will be useful for our discussion is obtained by the combination of Eqs 4 and 5:

$$k_{ex}\eta \propto P. \quad (9)$$

Results

Figure 1 shows that ΔH increases linearly with the radical concentration at each pressure (correlation coefficient $r\geqslant 0.9985$) in accordance with Eq. 1. From the linewidth of the central peak of the triplet signals, the spin-exchange rate constants k_{ex} at various pressures were estimated by means of Eq. 1, and are given in Table 1. From the pressure dependence of k_{ex}, the activation volumes $\Delta V_{ex}^{\neq}$ at 1 bar for the spin exchange have been estimated. These are given in Table 2. Using available

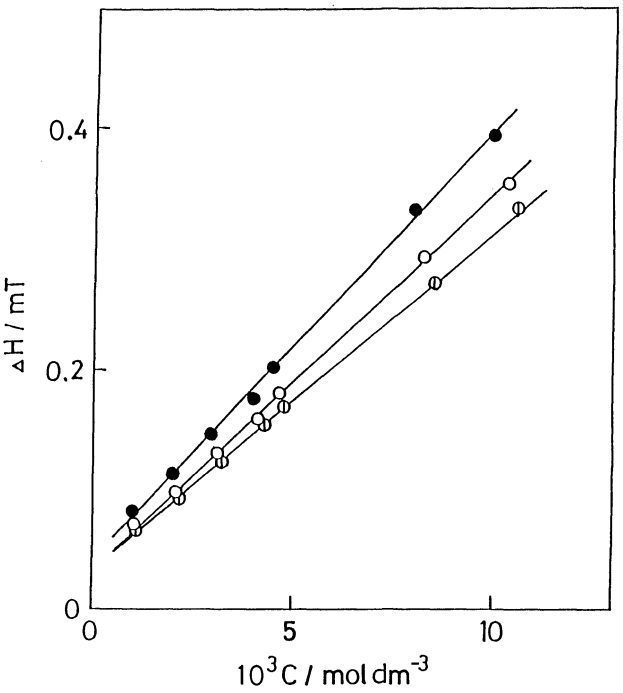

Fig. 1. Concentration dependence of ESR linewidth for TANONE radical in acetone at 1 (●), 343 (○), and 637 (◫) bar.

η–p data[12] the apparent activation volumes for diffusion $\Delta V_{diff}^{\neq}$ extrapolated to 1 bar have been calculated to be 15.8 cm^3 mol^{-1} in acetone and 23.2 cm^3 mol^{-1} in hexane. The differences between $\Delta V_{ex}^{\neq}$ and $\Delta V_{diff}^{\neq}$ are about -5 and -11 cm^3 mol^{-1} in acetone and hexane, solvents of low viscosity, but are near zero in toluene, benzene, and *o*-xylene. The physical meaning of the activation volume for a diffusive process has already been discussed.[9]

Discussion

Pressure Dependence of the Probability *P*. It is seen in Table 1 that k_{ex}-values clearly decrease inversely to the applied pressure and that they are smaller in toluene than in acetone and hexane. The above findings may simply

be interpreted in terms of viscosity dependence of k_{ex}. As stated in the introductory section, acetone behaves differently from other aprotic solvents of comparatively high viscosity. The reason is as follows. In Fig. 2, $k_{ex}\eta$ is plotted against η. It could safely be said that $k_{ex}\eta$ and hence P is independent of η in toluene, benzene, and *o*-xylene. Judging from Eq. 3, the condition $J^2\tau_1^2\gg1$ and hence $P\approx1$ must hold in this case. In acetone and hexane, $k_{ex}\eta$ increases with viscosity, suggesting that P is susceptible to η. By means of Eqs. 4 and 5, the P-values for spin exchange of some nitroxide radicals in acetone and hexane were calculated as a function of pressure assuming the steric factor (vide infra) is independent of pressure and they are given in Table 3. No significant difference among P-values of the some nitroxide radicals listed in Table 3 was observed. In acetone and hexane, the P-values become progressively larger and approach unity, as the external pressure increases. The pressure dependence of P-value in acetone and hexane is ascribed to that of the collision time τ_1 in agreement with the prediction of Eqs. 3 and 6. The discussion on τ_1 will be made below. In any case, it is obvious that the difference $\Delta V_{ex}^{\neq}-\Delta V_{diff}^{\neq}$ in acetone and hexane is a result of the pressure dependence of the probability in accordance with Eq. 5.

Estimation of the Steric Factor and the Exchange Integral. According to Eq. 8, a plot of k_{diff}/k_{ex} against $\rho_p^{4/3}/\eta^2$ will give a straight line with the slope $(k^2T^2/J^2\pi^2\lambda_0^4\rho_0^{4/3}b^2f_s)$ and the intercept $1/f_s$. The plots are shown in Fig. 3. It follows that each plot constitutes a straight line, and this strongly suggests that the f_s- and J-values are independent of pressure or viscosity. It is difficult to estimate the numerical value of b and λ_0 exactly. Plachy and Kivelson[11] measured the diffusion coefficient of DTBN in pentane and estimated the radius b as 0.32 nm. Here, this value was used as the standard of estimating the b-values (TANONE and TEMPO) and λ_0 (acetone and hexane) referring the size of their CPK models. The estimated b-values are 0.39 nm for TANONE and 0.37 nm for TEMPO, and λ_0=0.50 nm for acetone and λ_0=0.59 nm for hexane. The liquid density extrapolated to its freezing point ρ_0 was estimated as 0.920 g cm^{-3} for acetone[12] and 0.757 g cm^{-3} for hexane.[13] After these numerical values were substituted in Eq. 8, f_s-

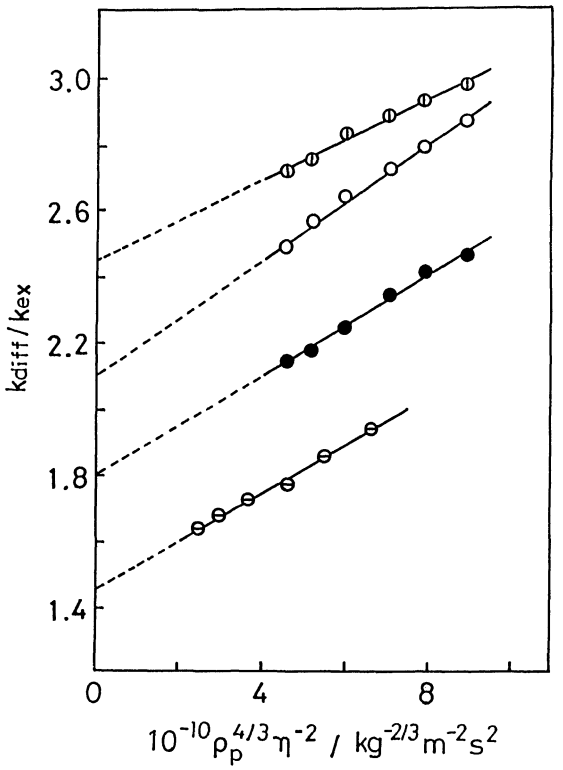

Fig. 3. Plots of k_{diff}/k_{ex} against $\rho_p^{4/3}\eta^{-2}$ for spin exchange: TANONE (○) in acetone, TEMPO (◫) in acetone, DTBN (●) in acetone, TANONE (⊖) in hexane.

and J-values for the spin exchange of the nitroxide radicals were calculated from the slope of the linear plot of Eq. 8, and they are given in Table 2. The f_s-values of some nitroxide radicals listed in Table 2 are about 0.5 and the J-values are of the order of 10^{10} s^{-1}.

According to Kivelson,[14] J should be a rapidly varying function of the radical-radical separation r, but approximately be regarded as constant if $r \leqslant r_c$, and zero if $r > r_c$, where r_c is a critical distance. The straight line of the above plot indicates the constancy of J. This means that the radicals are remaining within a distance r_c to each other during the collision time.

The J- and f_s-values seem to depend somewhat on the nature of radical species (Table 2). Studies are under way using various types of nitroxides. As the numerical values agree fairly well with the reported J-value for DTBN in pentane ($J=6\times10^{10}$ s^{-1}),[11] these values could be regarded as reasonable. It is notable that the exchange integral which is a very important quantity for radical-radical reactions can be simply estimated.

Estimation of Collision Time. The jump length at pressure p and at 298.2 K can be estimated by means of Eq. 7, using available ρ-p data.[12] If the numerical values of b, ρ_p, and ρ_0 are substituted into Eqs. 6 and 7, one obtains the collision time τ_1. They are listed in Table 3. The viscosity η raises while the jump length λ decreases with increasing pressure. We can see that the product $\lambda^2\eta$ increases proportionately with pressure resulting in the net increase in τ_1. The collision times τ_1 for the spin exchange of the nitroxide radicals in acetone and hexane are of the order of 10^{-11} s (Table 3). These values are nearly equal to the rotational correlation time ($\tau_{rot}=1.7\times10^{-11}$ s TANONE in acetone) estimated from the following equation:[15]

$$\tau_{rot} = 4\pi\eta b^3/3kT. \quad (10)$$

This suggests that the collision time in acetone and hexane is deeply correlated to the rotational correlation time, which is responsible for $P<1$. Meanwhile for toluene, if the numerical values of b, λ, and η (b=0.39 nm TANONE, λ=0.86 nm, η=0.556 mPa s at 1 bar and λ_p= 0.84 nm, η_p=0.853 mPa s at 637 bar) are substituted in Eq. 6, we have $\tau_1=1.22\times10^{-10}$ and 1.79×10^{-10} s at 1 and 637 bar, respectively. With these values and $J=6.9\times10^{10}$ s^{-1}, $J^2\tau_1^2$ becomes 71 and 153 at 1 and 637 bar, respectively, in agreement with our foregoing prediction from Fig. 2.

Mesomorphic Properties of 4-[3,4-Bis(4-alkoxybenzoyloxy)benzylideneamino]azobenzenes and Related Compounds

Tatsuya MASUDA and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 16, 1991)

The mesomorphic properties of a homologous series of 4-[3,4-bis(4-alkoxybenzoyloxy)benzylideneamino]azobenzenes have been studied by differential scanning calorimetry and microscopy. While the nematic phases exhibited by the ethoxy and propoxy homologues are metastable, those exhibited by all of the butoxy-to-hexadecyloxy homologues exhibit the temperature range of stable existence. A metastable smectic A-phase is observed for the tetradecyloxy and hexadecyloxy homologues. Among the examined 4-[2,4-bis(4-alkoxybenzoyloxy)benzylideneamino]azobenzenes, only the dodecyloxy and tetradecyloxy members are nematogenic. Their clearing points are located at more than 30 °C below the melting points. 4-(Benzylideneamino)azobenzene and its 3-(4-dodecyloxybenzoyloxy) derivative are nonmesogenic; however, the phase diagrams of binary systems with 4-(4-nonyloxybenzylideneamino)azobenzene revealed that the addition of a 3-(4-dodecyloxybenzoyloxy) group to the former molecule depresses the virtual nematic behavior, but promotes the smectic A behavior. A further addition of the same group at the 4-position drastically raises the nematic-isotropic transition temperature.

Systematic studies on the influence of lateral substitutents on the mesomorphic properties of rod-like molecules indicated that only relatively small ones allow the persistence of the liquid crystalline state.[1-3] However, Weissflog and Demus discovered that some molecules with a long alkyl group, and even with an aromatic branch bound to the middle moiety of a rod-like molecule, can form mesophases.[4-7] The compounds of the latter type include 4-nitrophenyl 2,5-bis(4-octyloxybenzoyloxy)benzoate and 4′-ethoxy-3-[*N*-(4-ethoxyphenyl)iminomethyl]-4-(4-methoxybenzoyloxy)azobenzene. The former compound exhibits a stable smectic A-phase covering the temperature range from 96 to 164 °C, whereas the latter exhibits a metastable nematic phase, the transition into an isotropic liquid of which is located far below the melting point (73 °C vs. 160 °C). A single-crystal X-ray analysis performed on the azobenzene derivative disclosed that the molecule is in a bifurcated shape. The phenyliminomethyl branch is markedly bent from the nearly linear three-ring basic fragment, but is almost coplanar with the azobenzene moiety.

More extensive synthetic studies concerning closely-related compounds were carried out by Takenaka et al.[8-10] Tris(4-alkoxyphenyl) 1,2,4-benzenetricarboxylates were shown to exhibit a metastable nematic phase when the alkyl group is heptyl or octyl and a smectic A-phase as well as a nematic phase when the alkyl group is nonyl or decyl.[8] 4-Cyanophenyl 3,4-bis(4-alkoxybenzoyloxy)benzoates, in which the alkyl group is from pentyl to octyl, are nematogenic. Among these members only the hexyl compound gives a nematic phase with a temperature range of stable existence. A metastable smectic A-phase was observed for the heptyl-to-decyl homologues.[9] The 4-alkoxylphenyl esters of the same acid are also nematogenic when the alkyl group is butyl-to-nonyl. The nematic–isotropic transitions in the hexyl compound and the higher homologous members are enantiotropic. The nonyl compound shows a metastable smectic-A phase in addition to a nematic phase. Thus, many 1,2,4-benzene derivatives comprising four-rings are mesogenic; however, the mesophase–isotropic transitions are known to be mostly monotropic. Consequently, we prepared a series of 4-[3,4-bis(4-alkoxybenzoyloxy)benzylideneamino]azobenzene (**1**) and the related compounds (**2**), both of which have a linear four-ring basic fragment, and studied their liquid-crystalline behavior. In order to clarify the effects of an aromatic branch on the mesomorphic properties, the thermal behavior of 4-[3-(4-alkoxybenzoyloxy)benzylideneamino]azobenzenes (**3**) were also examined.

Experimental

Materials. Equimolar amounts of 4-aminoazobenzene and

3-hydroxybenzaldehyde or 2,4- or 3,4-dihydroxybenzaldehyde were dissolved in ethanol, and then a few drops of acetic acid were added. The precipitated orange-colored 4-(benzylideneamino)azobenzene derivative was collected by filtration and washed first with ethanol and then with hexane. Compounds **1** were obtained by the reaction of 4-(3,4-dihydroxybenzylideneamino)azobenzene with 4-alkoxybenzoic acids in chloroform, following a procedure of Hassner and Alexanian.[11] Found: C, 76.61; H, 8.10; N, 4.79%. Calcd for $(C_{12}H_{25}OC_6H_4CO_2)_2C_6H_3$–CH=N–$C_6H_4$–N=N–$C_6H_5$: C, 76.56; H, 8.00; N, 4.70%. Compounds **3** were similarly prepared. In order to synthesize compounds **2**, the esterification of 4-(2,4-dihydroxybenzylideneamino)azobenzene had to be carried out by the reaction with 4-alkoxybenzoyl chloride in boiling benzene by the addition of pyridine.

Measurements. The transition temperatures and associated enthalpy changes were measured by means of a Rigaku Denki Thermoflex differential scanning calorimeter. Phase diagrams were determined by the calorimetric curves of mixtures.

Results and Discussion

The mesomorphic transition temperatures and associated enthalpy changes of compounds **1** are summarized in Table 1. Here, K, S_A, N, and I stand for crystalline, smectic A, nematic, and isotropic liquid phases, respectively. In spite of the presence of an aromatic lateral branch, all of the ethoxy-to-hexadecyloxy homologues were found to be mesogenic. The N–I transition temperature gradually decreases with increasing the alkyl chain length throughout this series. The mesophases given by the ethoxy and propoxy compounds are metastable, whereas those given by the butoxy-to-hexadecyloxy compounds have a temperature range of stable existence. Thus, the presence of the 4-(phenylazo)phenyliminomethyl group in the molecule greatly enhances the thermal stability of the mesophases, compared with those reported by other workers.[5-10] They show a marble texture characteristic of nematic phases formed by rod-like molecules. The temperature ranges of stable existence given by the octyloxy homologue and the later members of the series are about 30 °C. In addition, a metastable smectic phase exhibiting a fan texture is observable with the tetradecyloxy and hexadecyloxy homologues.

As is shown in Fig. 1, the nematic phase of the dodecyloxy compound is completely miscible with the nematic phase of 4-(4-nonyloxybenzylideneamino)azobenzene, indicating that the mesophase is classical nematic, in spite of the molecular shape being far from rod-like. The latter compound has been reported to give the following transitions: K 109.5 S_B 126 S_A 156 N 162 I.[12] The present conclusion is in a sharp contrast with our previous finding that *N*,*N*′-dialkanoyl-2,5,6-trimethyl-4-alkanoyloxy-1,3-benzenediamines (the molecular shape of which is supposed to resemble, to some degree, that of the present series) is discotic nematic.[13] The smectic A- and B-phases of the reference mesogen are considerably destabilized upon mixing. The S_A–N transition point curve intersects with the melting point curve of the reference compound at 108 °C and 68 mol% and the S_B–S_A transition point curve at 111 °C and 92 mol%. Fitting Van Hecke's equation, $T=\Delta H_{AV}/\Delta S_{AV}$, to the diagram using the entropy ratio as a parameter suggests that the virtual S_A–

N transition of the dodecyloxy compound is located at about 35 °C.[14] It may be noted that the destabilization of the ordered smectic phase is more drastic than that of the non-ordered one.

Table 2 presents the thermal properties of series **2** and **3**. For the former series, only the decyloxy, undecyloxy, dodecyloxy, tetradecyloxy, and hexadecyloxy members were studied. The melting point tends to be higher than that of the corresponding member of series **1**. A metastable mesophase is detectable only with dodecyloxy and tetradecyloxy compounds. Judging from the magnitude of the enthalpy change at the clearing point, the mesophase is undoubtedly nematic. The transition is located more than 30 °C below the melting point. In other words, the N–I transition temperature is depressed by 41 or 48 °C by the shift of the 4-alkoxybenzoyloxy branch from the 3-position to the 2-position of the benzylideneamino moiety. This mesomorphic behavior of compound **2** may be ascribed to the difference in the rigidity between the specific moieties of the linear four-ring basic fragment located close to the 4-alkoxybenzoyloxy branch. While the more-or-less planar 4-(phenylazo)phenyliminomethyl group is favorable for an enhancement of the thermal stability of the mesophase (as seen earlier), the 4-alkoxybenzoyloxy branch at the 2-position in compound **2** is not allowed to adopt configurations relaxed well from the Y-shape because of the rigidity of the afore-mentioned group. On the other hand, the two 4-alkoxybenzoyloxy groups at the 3- and 4-positions may easily take configurations less deviated from the rod-like shape by rotating rather freely around the C–O and C–C single bonds.

All of the three examined members of compounds **3**, the molecule of which has a bent, is not mesogenic at all. In order to explore the potential mesogenic properties, we studied the phase diagrams of binary systems comprising the dodecyloxy homologue and the corresponding member of series **1**, as well as the afore-mentioned reference compound, 4-(4-nonyloxybenzylideneamino)-azobenzene. In the former system, which shows a eutectic point at 75 °C and 37 mol% of compound **3**, the thermal stability of the mesophases given by the reference compound is so diminished that the N–I transition point curve meets the melting point curve of compound **1** at 78 °C and 27 mol%.

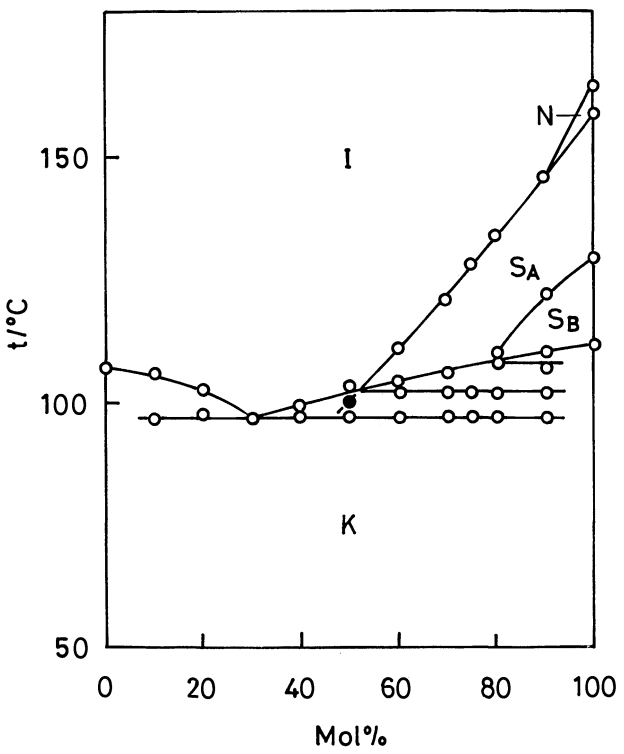

Fig. 2. Phase diagram of the binary system consisting of 4-[3-(4-dodecyloxybenzoyloxy)benzylideneamino]azobenzene and 4-(4-nonyloxybenzylideneamino)azobenzene. The latter compound is located on the right-hand side. As to the open and shaded circles, see the caption of Fig. 1.

The phase diagram given by the latter system is presented in Fig. 2. The nematic phase disappears upon the addition of 10 mol% of compound **3**; therefore, the N–I transition point curve is only our eye guide drawn so as to be consistent with the curve in the former system. The S_A–I transition point curve intersects with the melting point curve of the reference compound at 102 °C and 52 mol% and the S_B–S_A transition point curve at 108 °C and 79 mol%. The virtual S_A–I transition of compound **3** may be located at about 60 °C by the extrapolation of the transition point curve, which is slightly concave upwards, observable down to 50 mol% of the reference compound to 0 mol%.[14] This temperature is undoubtedly higher than the S_A–N transition temperature estimated for the corresponding member of series **1**. In contrast to the S_A–I transitions, the S_A–S_B transitions seem to form a curve that is slightly convex upwards. Thus, the introduction of a 4-(4-dodecyloxybenzoyloxy) group to the molecule of compound **3** leads to very significant stabilization of the

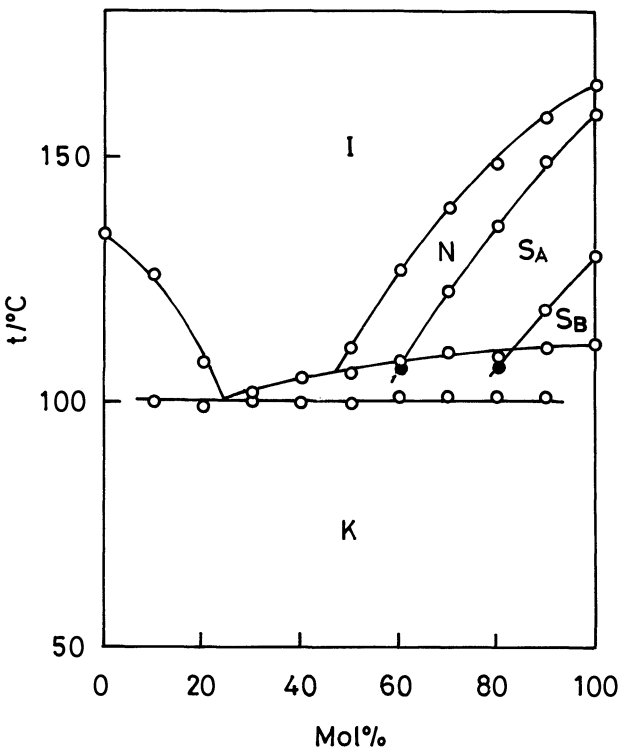

Fig. 3. Phase diagram of the binary system consisting of 4-(benzylideneamino)azobenzene and 4-(4-nonyloxybenzylideneamino)azobenzene. The latter compound is located on the right-hand side. As to the open and shaded circles, see the caption of Fig. 1.

nematic phase and a relatively small destabilization of the smectic A-phase. If we consider that the dodecyloxy homologue of series **1** is formed by the introduction of a (4-dodecyloxybenzoyloxy) group to the 3-position of 4-[4-(4-dodecyloxybenzoyloxy)benzylideneamino]-azobenzene, the depression of the N–I transition by the branching is as much as 157 °C, since this linear four-ring compound exhibits transitions, K 142 N 277 I.

Fig. 3 presents a phase diagram of a binary system comprising nonmesogenic 4-(benzylideneamino)azobenzene, the common moiety of all the compounds studied here, and 4-(4-nonyloxybenzylideneamino)azobenzene. The N–I transition is enantiotropic above 47 mol%, the S_A–N transition above 61 mol%, and the S_B–S_A transition above 83 mol%. The maximum temperatures of both the virtual nematic and smectic phases of 4-(benzylideneamino)azobenzene may be located near or below 0 °C.[14] A comparison of the present diagram with the one in Fig. 2 strongly suggests a depression of the N–I transition temperature, as well as a promotion of the S_A–N or S_A–I transition temperature by the introduction of a 3-(4-dodecyloxybenzoyloxy) group to this common moiety. Therefore, if a mesogenic compound could be obtained employing molecules with an obtuse-angled configuration one would speculate that it tends to be smectogenic rather than nematogenic. The mesomorphic properties of 1,3-phenylene bis[4-(4-alkoxybenzylideneamino)benzoates] and their related compounds will be the subject of a forthcoming paper.[15]

The Number of Organic Radicals on a Decationated Y-Type Zeolite before, during, and after Irradiating with Ultraviolet Light or Heating

Hiroshi KASHIWAGI
Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani, Toyama 930-01
(Received March 18, 1991)

A decationated Y-type zeolite (HY) was adsorbed by a single organic compound from a heptane solution, and dried in vacuo. The numbers of the radicals in these binary systems before, during, and after irradiating with ultraviolet (UV) light or heating were followed by electron paramagnetic resonance spectroscopy and then compared. During UV irradiation, the number of radicals increased from the constant number of spins before illumination (C_1) to the second constant number of spins (C_2). After stopping the illumination, the C_2 decreased up to the third constant number of spins (C_3). The C_3 value was smaller than C_2, but was significantly greater than C_1. The enhancement of radicals induced by UV light, expressed quantitatively in terms of the C_3/C_1 ratio, was pronounced when either a weak donor or a weak acceptor was adsorbed on HY calcined at a low temperature. C_1 was proportional to the amount of adsorption up to the maximal amount of adsorption, whereas C_2 and C_3 were proportional only at a considerably decreased amount of adsorption. A similar tendency was observed when the binary systems were heated at 40 or 80 °C. A quantitative determination of the mechanically induced enhancement of radicals would prompt either an improvement in the reproducibility of physicochemical data or an elucidation of the solid acidity or basicity.

Organic radical formation on the surface of an aluminosilicate due to a charge-transfer interaction has frequently been studied.[1] In order to find some new factors available for improving the reproducibility of the physicochemical data concerning relatively complicated systems, or for correlatively and comprehensively elucidating the solid acidity or basicity, we followed in a preceding paper the time course of the number of spins (NOS) in either a binary system comprising a decationated Y-type zeolite (HY) and a single organic compound or a ternary system comprising HY and two organic compounds after removing a solvent (heptane).[2] The NOS values and their time courses were dependent on the calcination temperature of HY (T_{ca}) as well as the electron-donating or -accepting characteristics of the organic molecules. The NOS values of the binary system were reversible and linear up to the amount of adsorption,[2,3] whereas those of the solvent-free ternary (HY–two organic) systems, which were irreversible and nonlinear to the amount of adsorption, were dependent on the order of adsorption.[2]

The NOS values of the solvent-free ternary systems were suitable for quantitative consideration of this kind of irreversibility. However, vigorous stirring of the HY–organic binary system in heptane caused another qualitative irreversible dependence of NOS on the amount of adsorption. Furthermore, this kind of irreversibility was also induced in solvent-free binary systems either by ultraviolet (UV) irradiation or by heating.

The radical species produced at solid (Lewis) acid sites induced by photoillumination were identified based on analyses of the hyperfine structures of the electron paramagnetic resonance (EPR) spectra.[4] In addition, the stoichiometric formation of complexes between the Lewis acids and the radicals induced by photoirradiation was confirmed.[4]

In the present study, we followed by EPR spectroscopy the NOS values of the solvent-free HY–organic binary systems before, during, and after UV irradiation or before, during, and after the application of heat. The results obtained with binary systems comprising both HY calcined at 400 or 650 °C and perylene (PE, a strong donor), naphthalene (NA, a weak donor), tetracyanoethylene (TCNE, a strong acceptor), or 1,3-dinitrobenzene (DNB, a weak acceptor) were compared with one another. The NOS values obtained after illumination or heating were significantly greater than those obtained before the treatment. The enhancement of radicals was related to the T_{ca} and electron-donating or -accepting characteristics of the organic molecules. Furthermore, nonlinear dependence of the NOS values on the amount of adsorption was determined quantitatively. We thought that a quantitative consideration of the mechanically induced enhancement of radicals would prompt the finding of some new factors necessary either for improving the reproducibility of physicochemical data of relatively complicated systems or for elucidating the mechanically induced solid acidity or basicity.

Experimental

Materials. An HY was obtained by calcining an NH_4^+-exchanged Y-type zeolite (Si/Al=1.90) at 400 or 650 °C. The purification of PE, NA, TCNE, and DNB has been previously described.[2]

Procedure. HY was brought into contact with a heptane solution (0.01—0.1 mol dm^{-3}) of PE, NA, TCNE, or DNB, dried under reduced pressure (ca. 3 Pa), and stored in an EPR cell in dry nitrogen at 25 °C until the first constant number of spins (C_1) was attained. This binary system, being stored in

the EPR cell, was then irradiated with UV light or heated at 40 or 80 °C with occasional shaking until the second constant number of spins (C_2) was reached. After stopping either the illumination or heating, the sample was permitted to stand at 25 °C until the third constant number of spins (C_3) was attained. The EPR spectra were followed throughout all of these processes.

The heating temperature was adjusted by using a thermostat. A JEOL ES-05 H-type UV irradiation unit fitted with a 500-W mercury lamp was used for illumination.

Spectral Measurement. The EPR spectrometer, experimental conditions, and method for determinating both NOS and amount of adsorption have been described previously.[2] The experimental errors in NOS and the amount of organic molecules adsorbed on HY were less than 10%.[2]

Results and Discussion

Time Courses of NOS before, during, and after UV Irradiation or Heating. As described previously, a fairly well-resolved hyperfine structure was obtained in the EPR spectrum of the PE or NA cation radicals on solid acid sites or of the DNB anion radicals on solid base sites; the spectrum of the TCNE anion radicals, however, was unresolved.[3,5]

The time courses of the NOS before, during, and after UV irradiating or before, during, and after heating were examined using a solvent-free binary system comprising a maximal amount of adsorption (A_{max}) of PE, NA, TCNE, or DNB and HY calcined at 400 or 650 °C. As descrived previously,[2] the NOS for the binary system before illumination was initially small, gradually increased with the passage of time, and finally reached C_1.

The time courses of NOS during or after UV irradiation are demonstrated in Figs. 1 and 2, respectively.[6] As shown from Fig. 1, the NOS increases with the passage of time from C_1 to C_2 after the start of UV irradiation. As illustrated in Fig. 2, NOS is the greatest (C_2) immediately after stopping the illumination; it gradually decreases with the passage of time, finally reaching C_3. As described below, the NOS values and their time courses are dependent on T_{ca} and the electron-donating or -accepting characteristics of the organic molecules.

The time courses of the values of NOS obtained before, during, or after heating at 40 or 80 °C were analogous to

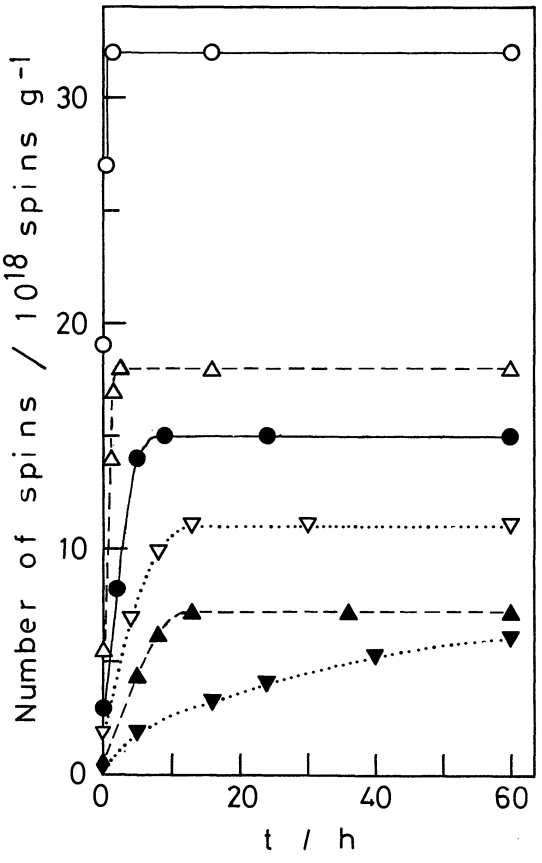

Fig. 1. Time course of the number of PE cation radicals on HY calcined at 650 (○) or 400 (●)°C, TCNE anion radicals on HY calcined at 650 (△) or 400 (▲)°C, or DNB anion radicals on HY calcined at 650 (▽) or 400 (▼)°C during UV irradiation. The amount of the organic molecules adsorbed on HY was A_{max}.

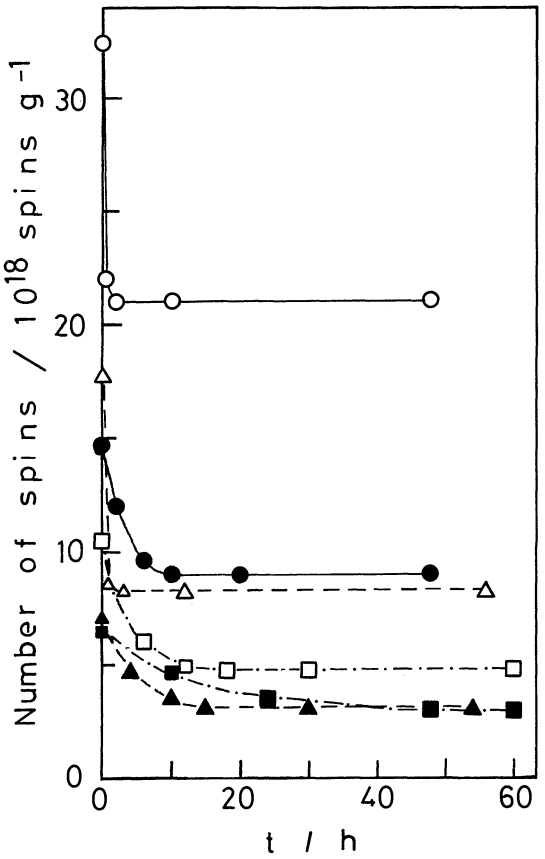

Fig. 2. Time course of the number of PE cation radicals on HY calcined at 650 (○) or 400 (●)°C, NA cation radicals on HY calcined at 650 (□) or 400 (■)°C, or TCNE anion radicals on HY calcined at 650 (△) or 400 (▲)°C after stopping illuminating. The amount of adsorption was A_{max}.

a) The amount of adsorption on HY was A_{max}.

those obtained upon UV irradiation.

Enhancement of Radicals by Illuminating or by Heating. Table 1 summarizes the values of C_1, C_2, C_3, the time required for attaining the C_1 (t_{C1}), the time required for attaining C_2 (t_{C2}), and the time required for attaining C_3 (t_{C3}), as well as the ratio C_3 to C_1 (C_3/C_1) obtained upon UV irradiation of the HY–organic system at a given amount of adsorption (A_{max}). Tables 2 and 3 list the corresponding values obtained upon heating at 80 or 40 °C, respectively. Although not shown in Table 3, the values of t_{C1}, t_{C2}, and t_{C3} obtained by heating at 40 °C were close to those obtained by heating at 80 °C (Table 2).

In general, C_3 is significantly greater than C_1, indicating that an enhancement of the radicals is induced by either heating or photoillumination applied after HY is adsorbed by the organic molecules. The C_1, C_2, and C_3 are small, while the t_{C1}, t_{C2}, t_{C3}, and C_3/C_1 are large when either a weak donor (NA) or a weak acceptor (DNB) is adsorbed on HY calcined at a low temperature (400 °C).

Dependence of the C_2 and C_3 Values on the Amount of Adsorption. As described previously,[2)] the C_1 value of the solvent-free HY–organic binary system before photoillumination increased linearly with an increase in the amount of adsorption, finally reaching a maximum number of spins at the amount of adsorption of A_{max}. Independent of T_{ca}, the A_{max} value for PE, NA, TCNE, or DNB was determined to be 3.1, 6.2, 3.6, or 2.2×10^{20} molecules/g-HY, respectively.[2)] The maximum numbers of spins/g–HY, shown as the C_1 in Table 1, however, were significantly dependent on T_{ca}.

Table 3. Constant Number of Spins upon Heating at 40°C[a)]

Organic compound	T_{ca}	C_1	C_2	C_3	C_3/C_1
	°C	10^{18} spins g^{-1}			
PE	650	19	21	19	1.0
	400	2.9	5.3	3.7	1.3
NA	650	4.4	5.9	4.5	1.0
	400	0.92	1.8	1.2	1.3
TCNE	650	5.5	7.0	5.7	1.0
	400	0.61	1.6	0.94	1.5
DNB	650	1.8	2.8	2.0	1.1
	400	0.22	0.75	0.40	1.8

a) The amount of adsorption was A_{max}.

The dependence of the C_2/C_1 or C_3/C_1 obatined upon photoillumination on the amount of adsorption/A_{max} (A) from 0.1 to 1.0 is demonstrated in Table 4 or 5, respectively. The C_2 and C_3 values at A=0 were, of course, nil. On the surface of HY calcined at 650 °C, as can be seen from Table 5, the C_3 value for PE, NA, TCNE, or DNB is identical with the corresponding C_1 value at an A value of less than 0.6, 0.3, 0.5, or 0.1, respectively. With a further increase in the A value, C_3 gradually becomes greater than the corresponding C_1. On the surface of HY calcined at 400 °C, C_3 becomes greater than C_1, even at a decreased A value (less than 0.1); it further increases with an increase in the A value.

Table 4. Dependence of the C_2/C_1 Ratio on the Amount of Adsorption upon UV Irradiation

Organic compound	T_{ca}	C_2/C_1 at $A^{a)}$=

	400	2.8	3.2	3.8	4.6	5.4	6.8	8.1	9.9	11	12

a) The amount of adsorption/A_{max}.

In the vicinity of A=1.0, however, the slope of the increase curve of C_3 decreases. Therefore, different from the C_1, C_3 is proportional to the amount of adsorption only at a decreased amount of adsorption.

The C_2/C_1 depends on the amount of adsorption, similarly to C_3/C_1. It can be seen from Table 4 that the C_2 values are much greater than C_1 and C_3. However, C_2/C_1 is constant at a decreased A value. It increases with a further increase in the A value. Therefore, C_2 is linear with respect to the amount of adsorption for a small amount of adsorption. The range of the A values providing a linear dependence of C_2 on the amount of adsorption is somewhat wider than that of C_3. Moreover, the ratio of C_2/C_1 at A=0.1 to that at A=1.0 is much smaller than the corresponding ratio for C_3/C_1.

Both C_3/C_1 and the C_2/C_1 are great, while the range of A values providing the linear dependence of C_2 and C_3 on the amount of adsorption is small when a weak donor (NA) or a weak acceptor (DNB) is adsorbed on HY calcined at 400 °C. At an identical A value, the C_2/C_1 or C_3/C_1 obtained at T_{ca}=650 °C is remarkably smaller than that obtained at T_{ca}=400 °C. Although not shown in Tables 4 and 5, the t_{C2} and t_{C3} values increased very slightly with an increase in the amount of adsorption.

The values of C_2/C_1 or C_3/C_1 obtained upon heating (40 or 80 °C) depended on the amount of adsorption in a manner similar to those shown in Table 4 or 5, respectively.

The C_2 and C_3 Values Obtained upon Heating Twice at Different Temperatures. The solvent-free HY–organic binary system was at first heated at a low temperature (40 °C) until attaining C_2; heating was then stopped and left at 25 °C until attaining C_3. This binary system was again heated at a sufficiently high temperature (80 °C) until attaining another C_2; heating was then stopped and left at 25 °C until attaining another C_3. In this case, the C_2 and C_3 values obtained upon the second heating at 80 °C was little influenced by the first heating at 40 °C. On the contrary, when the binary system was treated at first at 80 °C and subsequently at 40 °C, the final C_3 was identical with that obtained without the second heating at 40 °C.

Heating with a Slow Raise in Temperature. The C_2 and C_3 values shown in Tables 2 and 3 were obtained by placing the HY–organic system, having been stored at 25 °C, directly into a thermostat of 40 or 80 °C. On the other hand, when the temperature of the binary system was slowly raised from 25 to 40 or 80 °C (less than 0.3 °C h^{-1}), the C_2 and C_3 values at an increased amount of adsorption became smaller than those shown in Tables 2 and 3. By way of heating with a slow temperature rise, the C_2 and C_3 obtained at a heating temperature of 40 °C became proportional to the amount of adsorption up to A=1.0. Although the range of the A values providing the linear dependence on the amount of adsorption increased, the C_2 and C_3 obtained by heating at 80 °C were still nonlinear to the amount of adsorption.

Comparison of the Results Obtained by Continuous and Discontinuous Photoirradiation. Although not shown in Table 1, the C_3 obtained at a decreased

irradiation duration ($<t_{C2}$) was smaller than that shown in Table 1. The C_3 obtained by continuous irradiation was smaller than that obtained by discontinuous irradiation of the same total duration. For example, the C_3 for NA or DNB (A_{max}) on HY calcined at 400 °C induced by continuous irradiation for 20 h was 2.9 or 0.75×10^{18} spins/g-HY, respectively, while the corresponding value induced by 20-times irradiation for 1 h was 3.0 or 0.91×10^{18} spins/g-HY, respectively. This difference in the C_3 value was pronounced when NA or DNB was adsorbed on HY calcined at 400 °C. In general, the C_3 values and their nonlinear dependence on the amount of adsorption became pronounced in the case of discontinuous photoirradiation. Similarly, the C_3 induced by continuous heating was somewhat smaller than that induced by discontinuous heating of the same total duration.

As shown from Tables 1 and 2, t_{C1} is the smallest, while t_{C3} is greatest among the t_{C1}, t_{C2}, and t_{C3} values. Generally, the time required for attaining a constant number of spins increased with an increase in the number of operations (discontinuous heating or illumination).

Enhancement of Radicals Induced by General Mechanical Energy. General mechanical energy (e.g., shaking or compressing) applied after the adsorption of the organic molecules on HY qualitatively increased the C_2/C_1 and C_3/C_1 ratios and decreased the range of A values providing the linear dependence of the C_2 and C_3 values on the amount of adsorption.

Strong and Weak Acid or Base Sites. According to the preceding paper,[2] there coexist two kinds of active sites on the surface of HY: A strong active site is related to an induction of PE cations or TCNE anion radicals on HY calcined at 650 °C, whereas a weak active site is related to the formation of radicals from a weak donor (NA) or a weak acceptor (DNB) on HY calcined at a low temperature (400 °C). Since weak active sites may be related to a slow increase in the NOS values,[2] they may play some important roles in the mechanically induced enhancement of radicals, especially in a binary system comprising NA or DNB and HY calcined at 400 °C.

Improvement of the Reproducibility of Physicochemical Data of Relatively Complicated Systems. By using the physicochemical properties of complicated systems it is quite difficult to reproduce the same phenomena constantly. In the case of HY–organic systems, the NOS values of the binary systems were proportional,[2,3] while those of the ternary systems were not proportional to the amount of adsorption.[2] As described above, a similar nonlinearity (irreversibility) was induced by either heating or irradiating the HY–organic systems. A quantitative determination of the mechanically induced enhancement of radicals, and of the nonlinear dependence of NOS on both the amount of adsorption and the method of applying the mechanical energy, may be available for finding some new factors necessary for improving the reproducibility of physicochemical data of relatively complicated systems.

Radical Formation Induced by Mechanical Energy Applied after the Adsorption of Organic Molecules on HY. The results described above may also provide some new factors necessary for constructing a model of solid acid or base sites. The spin-generating sites on the surface of an aluminosilicate have been attributed to Lewis acid sites,[1,3] which are known to be produced from Brönsted acid sites at an elevated T_{ca} (over 500 °C).[1,3] However, radicals were induced by mechanical energy, such as UV light or heat, and applied after the adsorption of organic molecules on HY calcined at 400 °C. Extremely, the PE cations or TCNE anion radicals were induced by either heating or illuminating an NH_4^+-exchanged zeolite without any calcination which had been adsorbed by the organic molecules. A pronounced increase in the NOS obtained with a binary system comprising either a weak donor (NA) or a weak acceptor (DNB) and HY calcined at a low temperature (400 °C) as well as great t_{C1}, t_{C2}, and t_{C3} values might indicate some important roles of weak acid sites on the surface of HY.[2]

Conclusion

The NOS values of the HY–organic binary systems were proportional,[2,3] while those of the HY–two organic systems were only partly proportional to the amount of adsorption.[2] The nonlinearity of the NOS to the amount of adsorption was also induced by heating or irradiating the solvent-free binary systems. These findings may provide some new factors necessary for improving the reproducibility of physicochemical data.

Although the charge-transfer interaction, mechanochemistry, and properties of polymers appear in large and relatively complicated systems, they may disappear when a large, complicated system is divided into subsystems possessing appropriately equal sizes. In the present study we dealt quantitatively with the mechanically (UV light or heat) induced enhancement of radicals and the nonlinear dependence of NOS on the amount of adsorption, regarding not only the surface of HY, but also adsorbate molecules, the experimental conditions (e.g., temperatures and UV light), and the methods and processes of heating or illuminating as constituents of a large system. Such a correlative, comprehensive approach would prompt an elucidation of solid acidity or basicity. The other factors necessary for constructing a model of solid acidity or basicity will be described in a subsequent publication.

6) Even during irradiating with UV light or during heating at 80 °C, the shape and intensity of an EPR spectrum of the HY–organic system after attaining the C_2 was unchanged. After stopping illuminating or heating, the organic molecules adsorbed on HY were recovered unchanged by desorbing them with a large excess of the solvent. Since HY (Si/Al=1.9) was composed of relatively weak acid sites (Refs. 1 and 2), no further reaction of the ion radicals produced on HY occurred even during irradiating or heating.

Discrimination of Rotational Isomers of Jet-Cooled Acetophenone Derivatives as Studied by Sensitized Phosphorescence Excitation Spectroscopy

Seiji YAMAMOTO, Nobuhisa HASHIMOTO, and Mitsuo ITO*
Department of Chemistry, Faculty of Science, Tohoku University,
Sendai 980
(Received March 20, 1991)

The $S_1(n,\pi^*)\leftarrow S_0$ and $T(n,\pi^*)\leftarrow S_0$ sensitized phosphorescence excitation spectra of jet-cooled *o*- and *m*-substituted (fluoro- and methyl-) acetophenones have been measured. The two rotational isomers (*O-cis* and *O-trans* isomers) of each molecule arising from the orientation of the acetyl group with respect to *o*- or *m*-substituent have been discriminated. The energy difference in the 0–0 transition between the two isomers is less than 100 cm^{-1} for *m*-substituted acetophenone but more than 300 cm^{-1} for *o*-substituted acetophenone. The characteristic energy difference can be explained from the fact that the electronic excitation is localized on the C=O group.

In a series of papers, we have reported the studies on discrimination of the rotational isomers of *o*- and *m*-substituted phenols, anisoles, and benzaldehydes using the electronic transition in a supersonic free jet.[1-6] In molecules such as phenols and anisoles, the $S_1(\pi,\pi^*)\leftarrow S_0$ excitation energy difference between the rotational isomers amounts to 100—300 cm^{-1} for both *m*- and *o*-substituted compounds. On the other hand, it was found that the $S_1(n,\pi^*)\leftarrow S_0$ and $T(n,\pi^*)\leftarrow S_0$ transition energy differences between the rotational isomers are quite different for *m*- and *o*-substituted benzaldehydes (several tens cm^{-1} for the former and 400—500 cm^{-1} for the latter). The characteristic difference in the transition energy between phenol derivatives and benzaldehyde derivatives is caused by their difference in the nature of the electronic excited state.

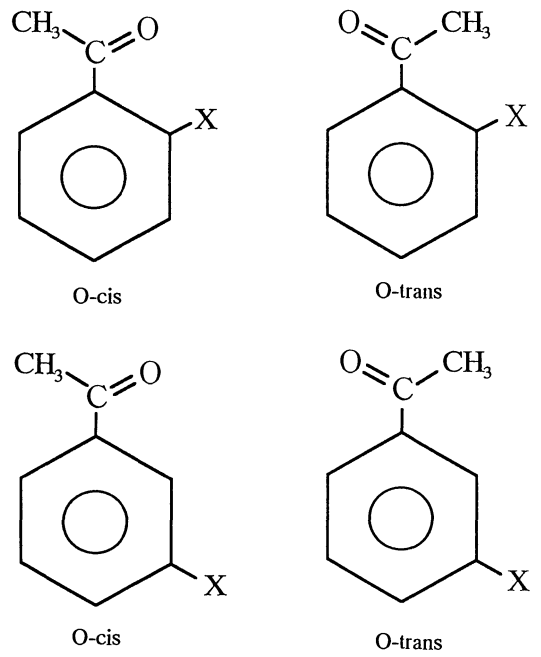

Fig. 1. The molecular structures of *O-cis* (*sp*) and *O-trans* (*ap*) rotational isomers of *o*- and *m*-substituted acetophenones. X indicates substituent.

In the present work, we extended the study to the rotational isomers of *o*- and *m*-substituted acetophenones. There exist two rotational isomers for each molecule. They are *O-cis(sp)* and *O-trans (ap)* isomers arising from orientation of the oxygen atom of the acetyl group with respect to the *o*- or *m*-substituent (Fig. 1). Similar to the case of substituted benzaldehydes, it is expected that the rotational isomers of subsitituted acetophenone are easily discriminated by the electronic spectrum of the jet-cooled molecule. In general, acetophenone derivatives are nonfluorescent and have a low efficiency of ionization. It is difficult therefore to apply the technique such as laser induced fluorescence (LIF) and multiphoton ionization (MPI) to these molecules. However, they are usually highly phosphorescent, and we can measure the electronic spectrum by phosphorescence excitation spectroscopy. However, the application of this technique to jet-cooled molecules is not easy because of a very weak phosphorescence signal gained by a space fixed photomultiplier from the molecules having a long phosphorescence lifetime and moving with a high speed in the jet. The difficulty had been solved by the development of a new spectroscopy called sensitized phosphorescence excitation spectroscopy, which uses sensitized phosphorescence emitted by a solid phosphor to which the triplet-state molecules in the jet collide.[7,8] We used this spectroscopy for the measurements of the electronic spectra of the substituted acetophenones.

By using this spectroscopy, we observed the $S_1(n,\pi^*)\leftarrow S_0$ transitions of *o*-, *m*-, and *p*-fluoroacetophenones, and *o*-, *m*-, and *p*-methylacetophenones. For each molecule except for *p*-derivatives, the existence of the two rotational isomers was confirmed. The difference in the electronic excitation energy between the two isomers is large for *o*-substituted acetophenone, but very small for *m*-substituted acetophenone, indicating the electronic excitation localized on the C=O group in the $S_1(n,\pi^*)$ state. Similar results were also obtained for the $T_1(n,\pi^*)\leftarrow S_0$ transitions. These results are consistent with those of benzaldehyde derivatives.

In our recent work, a remarkable difference was found

for photochemical behaviors of the rotational isomers of *o*-methylbenzaldehyde in their $S_1(n,\pi^*)$ and $T(n,\pi^*)$ states.[6] The *O-cis* isomer was found to undergo a photochemical reaction involving intramolecular hydrogen abstraction (photoenolization). A similar reaction was also suggested for *o*-methylacetophenone.

Experimental

The sensitized phosphorescence excitation spectra of jet-cooled molecules were measured with the same apparatus as that reported elsewhere.[7] The sample was heated up to about 320 K to obtain sufficient vapor pressure and was seeded in 3 atm He gas. The gas mixture was expanded into a vacuum chamber through a pulsed nozzle with an orifice of 800 μm diameter. The UV output of a dye laser (Lambda Physik FL 3002) pumped by a XeCl excimer laser (Lambda Physik LPX100) was used as an exciting light source. The laser light crossed the jet 15 mm down stream of the nozzle. The triplet state molecules produced by the intersystem crossing from the S_1 state or by the direct laser excitation travel for about 40 μs further down stream from the excitation position and collides with a liquid-nitrogen-cooled copper surface which is covered with the solid sample serving as a sensitized phosphor. When the triplet state molecules collide with the phosphor surface, the energy transfer occurs and the sensitized phosphorescence is emitted. The sensitized phosphorescence was detected by a photomultiplier (HTV R585) and the signal was processed by a gated photon counting system (Ortec 9302, 9315, 9325 and a home made gate generator).

The samples, *o*-, *m*-, and *p*-fluoroacetophenones and *o*-, *m*-, and *p*-methylacetophenones (Tokyo Kasei) were used without further purification.

Results

A. *p*-Substituted Acetophenones. First of all, the results of *p*-substituted acetophenones having no rotational isomer are shown. Figure 2(a) shows the $S_1(n,\pi^*)\leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *p*-fluoroacetophenone. The longest wavelength, prominent band at 27591 cm^{-1} is assigned to the band origin. On the higher frequency side of the 0–0 band, several low frequency bands appear with displacements of 34, 64, and 88 cm^{-1} from the origin. These bands can be assigned to the levels of the internal rotation of the methyl group in the S_1 state similar to the case of acetophenone.[8] The frequencies of 34, 64, and 88 cm^{-1} represent the 2e, $3a_1$, and 4e levels in the conventional notation of the internal rotation levels. It is suggested from the observed intensity pattern that the most stable conformation of the methyl group with respect to the molecular framework is quite different between the S_0 and S_1 states.

Figure 2(b) shows the $S_1(n,\pi^*)\leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *p*-methylacetophenone. The 0–0 band is located at 27445 cm^{-1}. The spectral feature is almost the same as that of *p*-fluoroacetophenone. The frequencies of 43, 75, and 96 cm^{-1} represent the internal rotation levels.

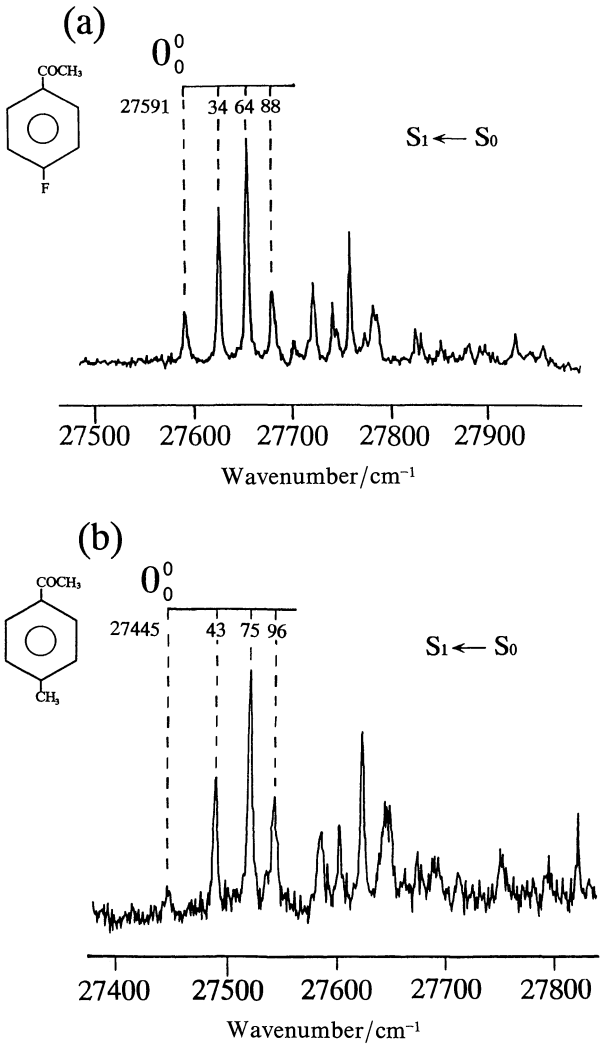

Fig. 2. (a) The $S_1(n,\pi^*)\leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *p*-fluoroacetophenone. (b) The $S_1(n,\pi^*)\leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *p*-methylacetophenone.

The $T(n,\pi^*)\leftarrow S_0$ transition was also observed. The energy of the 0–0 transition of *p*-fluoroacetophenone is 26104 cm^{-1}. The 0–0 band is exclusively strong in the spectrum but its absolute intensity is about 1/20 of that of the $S_1\leftarrow S_0$ transition. For *p*-methylacetophenone, the transition could not be observed because of the very low signal intensity.

From these results, the $S_1(n,\pi^*)$—$T(n,\pi^*)$ energy gap is 1341 cm^{-1} for *p*-fluoroacetophenone.

B. *m*-Substituted Acetophenones. Figure 3(a) shows the $S_1(n,\pi^*)\leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *m*-fluoroacetophenone. As seen from the figure, it has a complex structure. The structure can be decomposed to two progressions due to methyl torsion. The two band origins are located at 27047 and 27111 cm^{-1}, the energy difference being 64 cm^{-1}. The frequencies of 31, 60, and 85 cm^{-1} for the former, and 31, 60, and 82 cm^{-1} for the latter represent 2e,

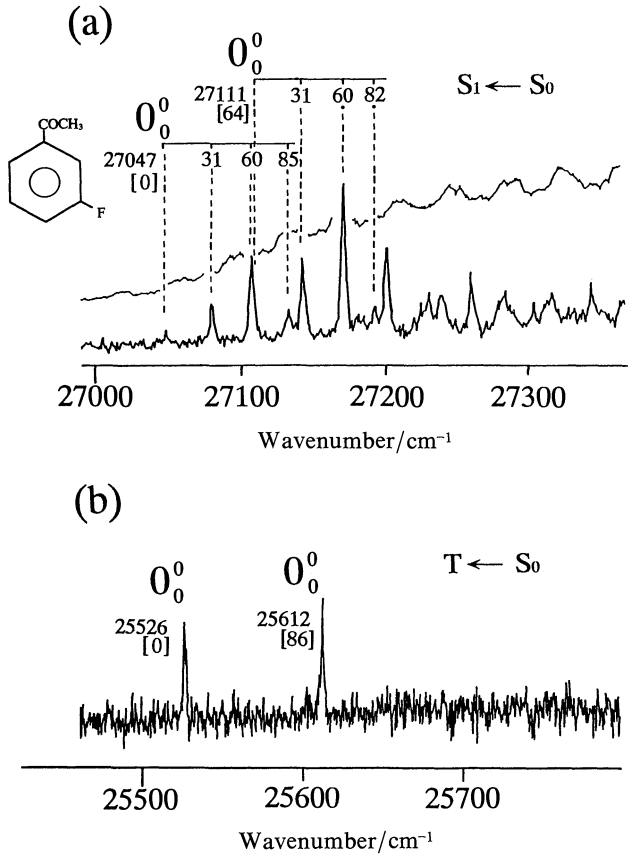

Fig. 3. (a) The $S_1(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *m*-fluoroacetophenone. (b) The $T(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *m*-fluoroacetophenone. The upper trace in (a) represents the laser power.

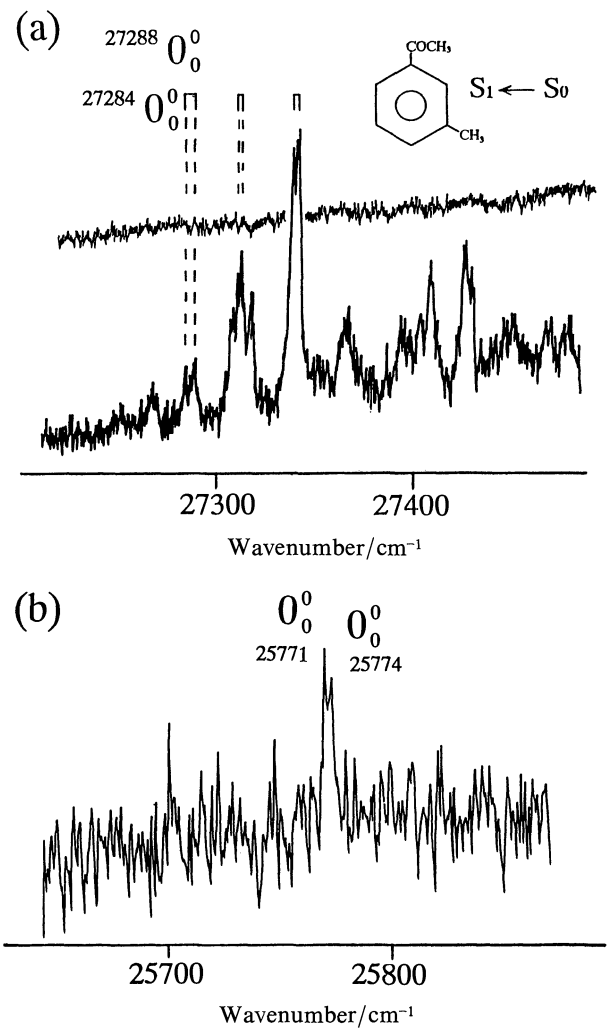

Fig. 4. (a) The $S_1(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *m*-methylacetophenone. (b) The $T(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *m*-methylacetophenone. The upper trace in (a) represents the laser power.

$3a_1$, and 4e levels, respectively. The $3a_1$ band of the former accidentally overlaps with the 0–0 band of the latter. The two band origins are ascribed to the two rotational isomers, namely *O-cis* and *O-trans* isomers of *m*-fluoroacetophenone. If this assignment is right, we also expect the appearance of two origin bands in the spectrum due to $T(n,\pi^*) \leftarrow S_0$ transition.

Figure 3(b) shows the $T(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *m*-fluoroacetophenone. As expected, two 0–0 bands are observed at 25526 cm^{-1} and 25612 cm^{-1}, which are assigned to the two rotational isomers. The energy difference between the two rotational isomers is 86 cm^{-1}. The intensities of the two bands are comparable, indicating that the two isomers have almost equal stabilities.

Figures 4(a) and 4(b) show the $S_1(n,\pi^*) \leftarrow S_0$ and $T(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectra of jet-cooled *m*-methylacetophenone. All the bands appear in pair of a small frequency separation. The pair bands can be ascribed to two rotational isomers. For the $S_1(n,\pi^*) \leftarrow S_0$ transition, the band origins of the two isomers are located at 27284 and 27288 cm^{-1}, the energy difference being 4 cm^{-1}. The situation is similar for the $T(n,\pi^*) \leftarrow S_0$ transition. The 0–0 bands are located at 25771 and 25774 cm^{-1}, the energy difference being only 3 cm^{-1}. Such a small energy difference was seen also in the case of *m*-methylbenzaldehyde.[6]

C. *o*-Substituted Acetophenones. Figures 5(a) and 5(b) show the $S_1(n,\pi^*) \leftarrow S_0$ and $T(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectra of jet-cooled *o*-fluoroacetophenone, respectively. It is seen in Fig. 5(b) that two 0–0 bands appear at 25746 and 26074 cm^{-1}, the frequency difference being 328 cm^{-1}. These bands are attributed to the 0–0 bands of the $T(n,\pi^*) \leftarrow S_0$ transitions of the two rotational isomers. The $S_1 \leftarrow S_0$ spectrum also consists of two components. One origin is located at 27188 cm^{-1} and the other origin at 27522 cm^{-1}. The energy difference amounts to 334 cm^{-1}, which is nearly equal to the difference in the $T \leftarrow S_0$ transition energy. The progression developing from the origin is assigned to the internal rotation of the methyl

group. The frequencies of the internal rotation shown in the figure are slightly different from those of *m*- and *p*-substituted acetophenones. This suggests that the internal rotation of the methyl group is considerably affected by the *o*-substituent. In the case of *o*-methylacetophenone, the signal of sensitized phosphorescence could not be detected. But a spectrum having a complicated structure could be observed by multiphoton ionization spectroscopy. The complicated MPI spectrum and the absence of the sensitized phosphorescence suggest the existence of a fast nonradiative relaxation process (probably, intramolecular reaction) in the triplet state.

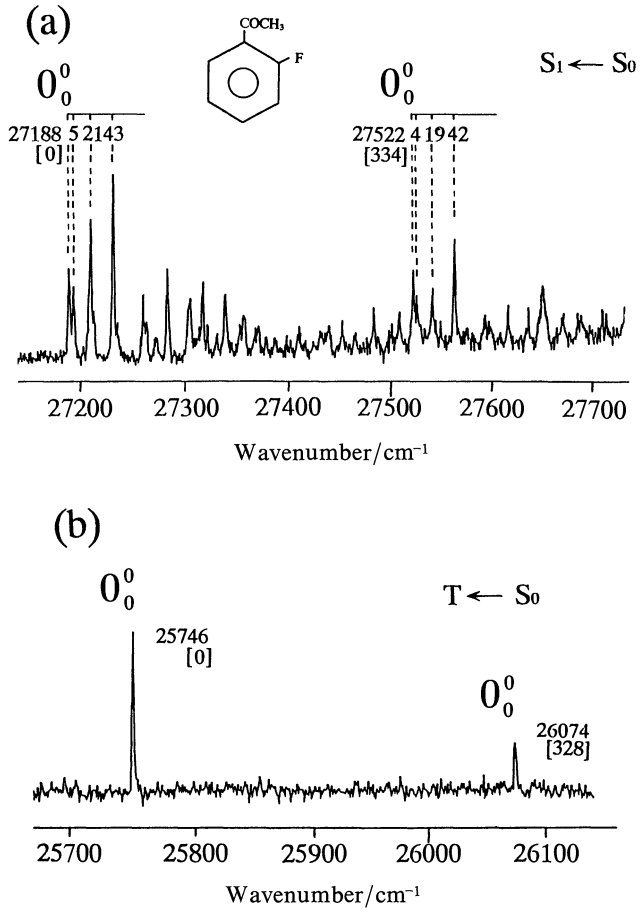

Fig. 5. (a) The $S_1(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *o*-fluoroacetophenone. (b) The $T(n,\pi^*) \leftarrow S_0$ sensitized phosphorescence excitation spectrum of jet-cooled *o*-fluoroacetophenone.

Discussion

The spectroscopic data obtained in the present work are summarized in Tables 1 and 2. It is seen from the tables that both the $S_1(n,\pi^*) \leftarrow S_0$ and $T(n,\pi^*) \leftarrow S_0$ transitions are shifted to blue in *p*-substituted acetophenone relative to those of acetophenone. On the other hand, red shift is seen for all the isomers of *m*-substituted acetophenones except for the $S_1 \leftarrow S_0$ transition of the isomers of *m*-methylacetophenone. In *o*-fluoroacetophenone, the band origin of one isomer is red-shifted but the other blue-shifted. It is interesting to compare the direction of the shift with that of the $S_1(n,\pi^*) \rightarrow S_0$ transition of substituted benzaldehyde. For example, in *p*-fluorobenzaldehyde, the $S_1(n,\pi^*) \leftarrow S_0$ transition exhibits a large blue shift relative to benzaldehyde, and all the rotational isomers of *o*- and *m*-fluorobenzaldehydes except for the $T_1 \leftarrow S_0$ transition of the isomers of *m*-fluorobenzaldehyde show red shift.[6] So the direction of shift is parallel between substituted benzaldehyde and substituted acetophenone. It is noted that the direction of the shift is entirely different between substituted phenol and substituted benzaldehyde or acetophenone. In phenols, *o*- and *p*-substituted phenol exhibits red shift while *m*-substituted phenol shows blue shift. The difference reflects the difference in the nature of the S_1 state, that is, the (π,π^*) states for substituted phenol and the (n,π^*) state for substituted benzaldehyde or acetophenone.

The characteristic nature of the $S_1(n,\pi^*)$ or $T(n,\pi^*)$ state of substituted acetophenone is also reflected in the difference in the excitation energy between the two rotational isomers, that is, the difference is very small for *m*-substituted acetophenone but very large for *o*-substituted acetophenone. This can be explained from the fact that the electronic excitation is essentially localized on C=O of the acetyl group in the $S_1(n,\pi^*)$ or $T(n,\pi^*)$ state. In *m*-substituted acetophenone, the

distance between the C=O group and the substituent at *m*-position is far for both rotational isomers. Therefore, the electronic excitation energy is not greatly affected by the orientation of the C=O group. Contrary, in *o*-substituted acetophenone, the excitation energy changes greatly by the orientation because of a close distance between the C=O group and the substituent. In the case of the $S_1(\pi,\pi^*)$ of substituted phenol, the difference in the excitation energy between the rotational isomers is comparable between the *o*- and *m*-substituted phenols, showing the spread of the π-electronic excitation over the whole molecule.

The $S_1(n,\pi^*)$—$T(n,\pi^*)$ energy gap is almost constant at ca. 1490 cm^{-1} for all the molecules and isomers, although a slightly smaller value is found for *m*-fluoroacetophenone. The constant energy gap implies that the electronic structures of the $S_1(n,\pi^*)$ and $T(n,\pi^*)$ states of each molecule are very similar except for spin, and the energies of the both states are perturbed by almost equal amounts irrespective of the nature of the perturbation.

The remaining problem is the assignment of the two 0–0 bands to individual rotational isomers. In the case of *o*-fluoroacetophenone, the intensity ratio of the two origin bands is about 3:1, the lower energy 0–0 band being more intense. The reported population ratio is 1:9 for *O-cis* isomer to *O-trans* isomer.[9] Therefore, we tentatively assigned the 0–0 band of 27188 cm^{-1} to *O-trans* isomer and that of 27522 cm^{-1} to *O-cis*. In the case of *m*-substituted acetophenone, the intensities of two 0–0 bands are almost the same, suggesting nearly equal population. Therefore, the assignment is difficult only from the intensity ratio.

Finally, we have to mention the case of *o*-methylacetophenone for which the measurement of the phosphorescence excitation spectrum failed. *o*-Methylacetophenone is known to be a typical molecule undergoing the intramolecular photoenolization reaction like *o*-methylbenzadehyde or *o*-methylbenzophenone.[10-16] The oxygen atom of the acetyl group abstracts the hydrogen atom of the methyl group at *o*-position after photoexcitation. The reaction will selectively occur in the *O-cis* isomer. This explains the nonphosphorescence of the *O-cis* isomer. It was reported that the ratio of *O-cis* to *O-trans* is 7:3[17] or 84:16[18] in the solution and 93:7[19] from calculation. The intramolecular enolization reaction for the abundant *O-cis* isomer and a small amount of the *O-trans* isomer explain the failure of the measurement of the phosphorescence excitation spectrum for this molecule.

VUV Photoionization Efficiency Curves and Appearance Energies of *N*, *N*-Dimethylformamide Ion and Its Fragment Ions

Masana ARIMURA* and Yozaburo YOSHIKAWA
Institute of Chemistry, College of General Education, Osaka University,
1-1 Machikaneyama, Toyonaka, Osaka 560
(Received December 28, 1990)

Ionization efficiency curves of *N*,*N*-dimethylformamide (DMF) ion and of its fragment ions, $C_3H_6NO^+$, $C_2H_4NO^+$, and $C_2H_6N^+$ were obtained by use of vacuum ultraviolet photoionization method. The appearance energy of the parent ion was 9.12±0.06 eV. The appearance energies of $C_3H_6NO^+$, $C_2H_4NO^+$, and $C_2H_6N^+$ were very close (10.77±0.08 eV for $C_3H_6NO^+$ and $C_2H_4NO^+$, 10.59±0.08 eV for $C_2H_6N^+$). The relative intensity curve of $C_2H_6N^+$ normalized by the sum of fragment ions vs. photon energy has the second rise at 12.2±0.3 eV, which implies that another fragmentation process appears at the photon energy above 12.2 eV. The second fragmentation process is ascribed to a channel through DMF cation in an excited electronic state.

Determination of the ionization energy of a parent molecule and appearance energies of its fragment ions is most important to elucidate the fragmentation mechanism and their reactions with other molecules. Several methods have been carried out to determine the ionization energy of a molecule and appearance energies of its fragment ions.[1] By using a photoionization technique, ionization energies of molecules are determined from the photon energy at which the ion current vanishes. This method is also useful for the estimation of appearance energies of the fragment ions which are produced through processes faster than ca. 10^4 sec^{-1} in the vicinity of critical energies.

Most of unimolecular reactions of the parent and fragment ions have been examined mainly in term of statistical partitioning of the whole energy to the vibration and rotation modes. Fragmentation rates are successfully understood by means of the statistical RRKM theory.[2] It has been reported that the statistical theory, however, can not be applied to the fragmentations of small molecular ions and fragmentations via the stable isomers of parent ion.[3] On the high energy excitation, another kind of unimolecular reactions, which the statistical theory failed to explain, occurs from electronic excited states before converting the electronic energy to the vibrational energy of ground state.[4]

Participation of another process is expected to emerge as another rise in the relative intensity curve normalized by the sum of the fragment ions (RI curve) which is derived from the ionization efficiency curves. We have found by using vacuum ultraviolet (VUV) photoionization technique that the CHO· elimination reaction of DMF cation exhibits plural thresholds at 10.59 eV and 12.2 eV of photon energy and that the fragmentations eliminating $C_3H_6NO^+$, $C_2H_4NO^+$, and $C_2H_6N^+$ appear at nearly the same energy. Ionization efficiency curves of DMF and the RI curves of the fragment ions were utilized to elucidate the fragmentation mechanisms.

Experimental

Photoionization efficiency curves were obtained by using a quadrupole mass spectrometer (QMS; Extranucler Co.). The mass resolution (ΔM) of QMS was ca. 1 (about 10 channels per mass unit for measurement).[5] An H_2 discharge lamp was used as the VUV light source for the ionization. The H_2 discharge lamp was operated at about 1 kW with 20—25 A cm^{-2} of current. The wavelength resolution of a monochrometor (McPherson model 234) is 8 Å full width at half maximum (FWHM), or ca. 0.07 eV in the energy range covered when the width and length of both entrance and exit slits are 100 μm and 3 mm respectively. The wavelength of light beam was calibrated by Lyman α line (1216 Å). The light beam strikes a thin layer of sodium salicylate as phosphor after traversing the ionization chamber. The fluorescence was led through an optical fiber to a photonmultiplier to obtain the photon intensity. The ions were counted by using a secondary electron multiplier (Ceratoron, Murata Seisakusyo). Values of ion-counting were given as the sum of the counted number of ions at three points (the peak top, before and behind the peak top of the resolved mass peak). The measurements of the ionization efficiency curves were fully operated by using a microcomputer. The light wavelength was scanned by 3 Å step for the measurements. The sample gas was introduced into the ion source without temperature control through a variable leak valve (the sample stagnation pressure was its vapor pressure at 0 °C).

The pressure of the vaccum chamber was measured intermittently by an ionization gauge just above the QMS and was held lower than 8×10^{-6} Torr (1 Torr=133.322 Pa).

The ionization energy 9.24±0.06 eV of benzene obtained here (Fig. 1) agrees very closely with the data obtained by others.[6]

The fragment ions were assigned by using a high resolution electron impact mass spectrometer (JMS-01SG-2, JEOL Co) at ca. 15 eV electron energy.

Results

Photoionization efficiency curves of DMF ion, m/z 73, and of its fragment ions, m/z 72, 58, and 44, were obtained in the photon energy range of 8.85—13.0 eV (Fig. 2). The other fragment ion in this energy region is mainly m/z 30.

The RI curves for the four fragment ions were obtained from the ionization efficiency curves, as are shown in Fig. 3. The RI curves give the relative fragmentation rates which are the convoluted rate from the critical photon

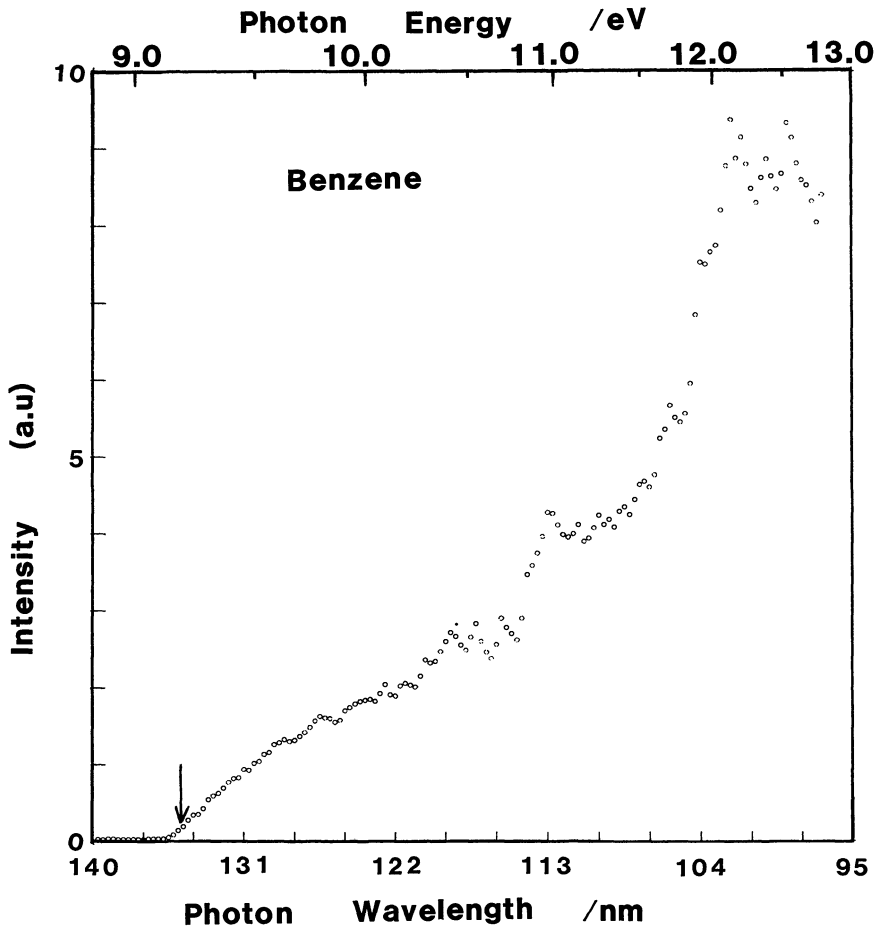

Fig. 1. The photoionization efficiency curve of benzene. The arrow shows the vertical ionization energy, 9.24±0.06 eV.

Table 1. Ionization and Appearance Energy of *N,N*-Dimethylformamide and Its Fragments (eV)

energy up to the marked photon energy.

The ionization energy of the parent ion and the appearance energies of the four fragment ions were determined from the ionization efficiency curves (Fig. 2) and are listed in Table 1 with the reference data.

Metastable peak at m/z ca. 26.5 due to slow fragmentation of m/z 73→44[16] was observed in the 30 eV electron impact ionization. The other metastable peak implying a successive reaction, m/z 73→58→30, is also observed at m/z ca. 15.5 due to m/z 58→30.

Discussion

The appearance energy (9.12±0.06 eV) of the parent ion, m/z 73, is agreed well with the value of an adiabatic ionization energy determined by PES.[7] Mass numbers of the fragment ions, m/z 72, 58, and 44, are assigned to $C_2H_6NO^+$, $C_2H_4NO^+$, and $C_2H_6N^+$, respectively (see Fig. 4). All of three fragment ions except for m/z 30 are produced in the unimolecular decompositions of the parent ion m/z 73, Eqs. 1—3.

$$C_3H_7NO^{+\cdot} \rightarrow C_2H_6N^+(44) + {\cdot}CHO \quad (1)$$

$$\rightarrow C_2H_4NO^+(58) + {\cdot}CH_3 \quad (2)$$

$$\rightarrow C_2H_6NO^+(72) + H \quad (3)$$

***m/z*=44.** The m/z 44 appears at 10.59±0.07 eV of photon energy and grows rapidly from ca. 1.5 eV above the appearance energy. The intensity ratios of m/z 44 against m/z 72 and 58 did not change so much up to ca. 12 eV of photon energy. The appearance of $C_2H_6N^+$ at 10.59 eV was not detected previously by mean of electron impact ionization. Meanwhile, the second rise at

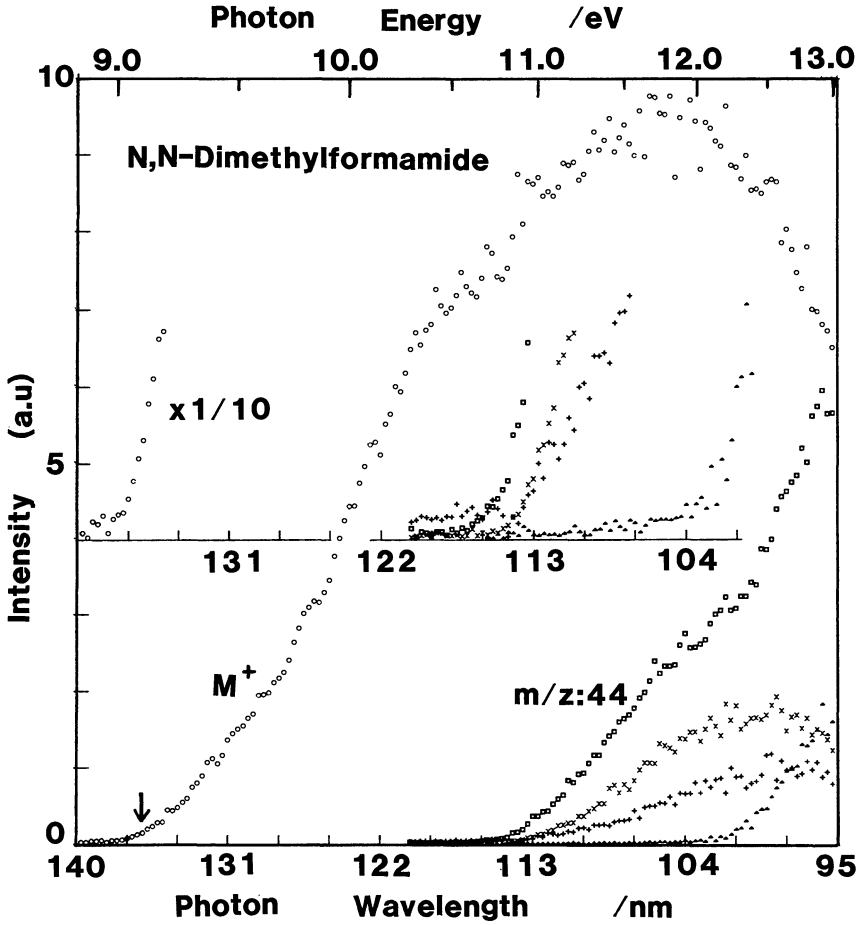

Fig. 2. The photo-ionization efficiency curves of *N,N*-dimethylformamide ion and three fragment ions. Each ions are denoted by ○: the parent ion m/z 73$^+$, +: m/z 72 ($C_3H_6NO^+$), ×: m/z 58 ($C_2H_4NO^+$), □: m/z 44 ($C_2H_6N^+$), ▲: m/z 30 (CH_4N^+).

12.2±0.3 eV is rather close to the previously reported appearance energy of $C_2H_6N^+$ by electron impact.[8] The second rise for m/z 44 in the RI curve (Fig. 3) indicates the appearance of another process at the photon energy above 12.2 eV. Four kinds of process are candidates or another fragmentation to m/z 44; (i) the fragments in Eq. 1 have high KER, (ii) the fragment ion is in an electronically excited state as given in Eq. 4, (iii) the fragment neutral is in an electronically excited state as is given in Eq. 5, (iv) the total enthalpy of the products by the successive reaction is so large as is given in Eq. 6.

$$C_3H_7NO^{+\cdot}* \rightarrow C_2H_6N^+(m/z\ 44)+CHO\cdot \quad (4)$$

$$\rightarrow C_2H_6N^+ + CHO\cdot* \quad (5)$$

$$\rightarrow C_2H_6N^+ + H + CO \quad (6)$$

Here, the asterisk denotes the species in an excited state. The processes Eqs. 4—6 are not clear from the energetic point of view. Alternative assignment of m/z 44 as $C_2H_4^+$ having the same mass number as $C_2H_6N^+$ is not coincided with the high resolution mass spectrum (electron impact) obtained. The fragments produced by electron impact are assumed not to be so different from those produced by photoionization. The sum of enthalpy ($\Sigma\Delta H_f$) of the products is not estimated for Eq. 4, because the excitation energies of $C_2H_6N^{+}*$ are unknown. The product CHO·* in Eq. 5 has excited electronic states at 1.15 eV and 3.0 eV[9] above the ground state. The first excitation energy of CHO·, 1.15 eV, is lower than ca. 1.5 eV which is the energy difference between the appearance energy and the second rise of m/z 44. The sum of enthalpy for CO and H[17] (1.11 eV), which are the products in Eq. 3, is larger than the ΔH_f of CHO· by 0.94 eV. This difference in energy is smaller than the difference of ca. 1.5 eV obtained.

Formations of high energetic products such as CHO·* in the excited electronic state or a pair of CO and H substantially reduce their kinetic energy released (KER) of $C_2H_6N^+$ compared with the formation of $C_2H_6N^+$ via the first decomposition channel. Effects of the ion repeller voltage on the intensity of $C_2H_6N^+$ and of the parent ion were measured as are shown in Figs. 5 (a) and (b) in place for direct measurement of KER. For the

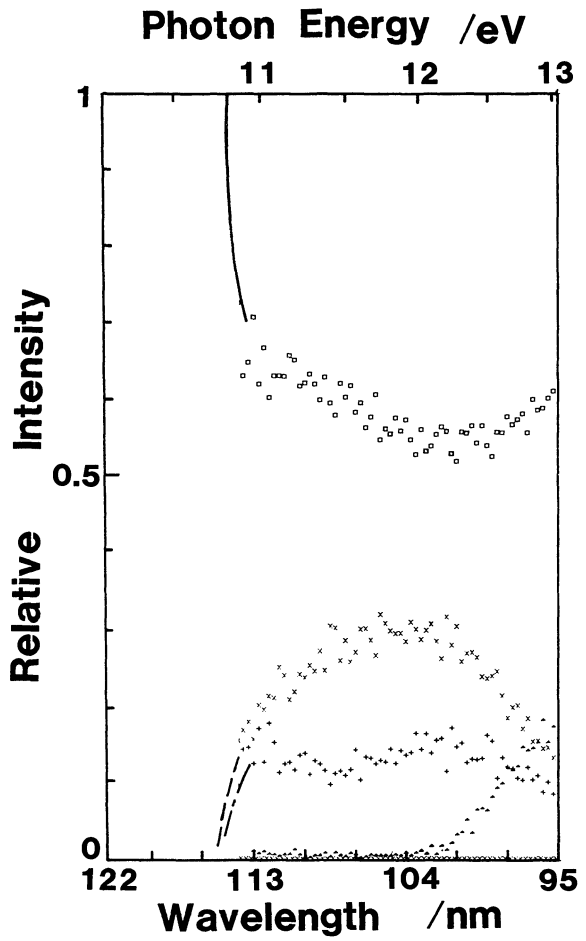

Fig. 3. The relative intensity curve normalized by the sum of four fragment ions (breakdown curves). Each ions are denoted by +: m/z 72 ($C_3H_6NO^+$), ×: m/z 58 ($C_2H_6NO^+$), □: m/z 44 ($C_2H_6N^+$), ▲: m/z 30 (CH_4N^+).

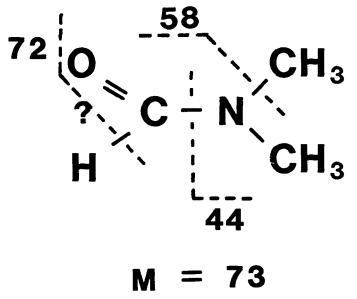

Fig. 4. The molecular structure of *N,N*-dimethylformamide. The dotted lines show the scheme of bonds rupture to produce the fragment ions.

sake of comparison, the dependence of ion repeller voltage on the intensities of $C_2H_5Br^{+\cdot}$ and of $C_2H_5^+$ are shown in Figs. 5 (c) and (d) for a fragmentation, $C_2H_5Br^{+\cdot} \rightarrow C_2H_5^+ + \cdot Br$, where $C_2H_5^+$ is known to have a higher KER than that partitioned statistically above 12.0 eV excitation.[10] At lower repeller voltages, the higher relative intensity of $C_2H_6N^+$ than the parent ion obtained on the 13.0 eV excitation implies a higher KER of $C_2H_6N^+$ as in the case of $C_2H_5^+$. The high KER of $C_2H_6N^+$ is inconsistent with Eqs. 4—6. Therefore, m/z 73 on the excitation above 12.2 eV decomposes along a repulsive potential to give $C_2H_6N^+$ with a high KER.

High energy electron impact ionization (30 eV) produces a metastable peak at m/z 26.5 due to fragmentation, M^+ (73)→44^+ as is shown in Fig. 6. The slow fragmentation giving the metastable peak at m/z 26.5 can not be ascribed to DMF^+ formed on the lower excitation energy than 12.2 eV, because the rate of the fragmentation to m/z 44 is the greatest among those to m/z 44, 58, and 72 assuming from the greatest intensity. Most probably, the slow fragmentation rises from an electronically excited DMF^+ formed on the high excitation energy. The metastable peak at m/z 26.5 suggests that the DMF^+ in the excited electronic state having a high vibrational energy takes the long way round before crossing the potential to dissociate. The second process producing $C_2H_6N^+$ presumably takes place along a repulsive potential after the slow crossing.

Fig. 7 shows a schematic energy diagram of $C_3H_7NO^{+\cdot}$ with its PES and the ionization efficiency curve of $C_2H_6N^+$. The point D indicates the lowest energy level of $C_3H_7NO^{+\cdot}$ dissociating to $C_2H_6N^+$ and CHO·. The parent ion excited above the threshold energy B stretches the N–C bond to dissociate. The transition probability to a hatched part above level B is very small, which is in agreement with the efficiencies of photoelectron and the photoionization efficiency curves. The transition probability to a repulsive energy level is also very small. The parent ion is efficiently excited to an energy level C by a vertical transition shown by a big arrow in PES. The formation of $C_2H_6N^+$ and CHO· in the ground state occurs at an intersystem-crossing point (C) between a bonding and an antibonding potential curve. After some vibrational relaxation the parent ion in the excited electronic state decomposes along the repulsive potential. The major part of the energy difference between the intersystem-crossing point and the dissociation limit D is converted to the kinetic energies of the dissociation products.

***m/z*=30.** The RI curve for m/z 30 arises in place of m/z 58 coming down. The m/z 30 is assigned to CH_4N^+ over NO^+ (m/z 30 produced from CH_3NO_2 by help of high resolution mass spectrum.)

$$C_3H_7NO^{+\cdot *} \rightarrow (C_2H_4NO^+) \rightarrow CH_4N^{+\cdot} + CO + \cdot CH_3 \quad (7)$$

This CH_4N^+ produced from DMF^+ is also discriminated from both CH_2O^+ and $C_2H_6^+$ having the same m/z 30. This assignment is supported by the $\Sigma\Delta H_f$ of the decomposition products in the following alternative reactions.

The formation of $CH_4N^{+\cdot}$ together with CO (Eq. 7) is supported by the $\Sigma\Delta H_f$ of the decomposition products. The sum of enthalpy is calculated to be 8.0 eV, which is

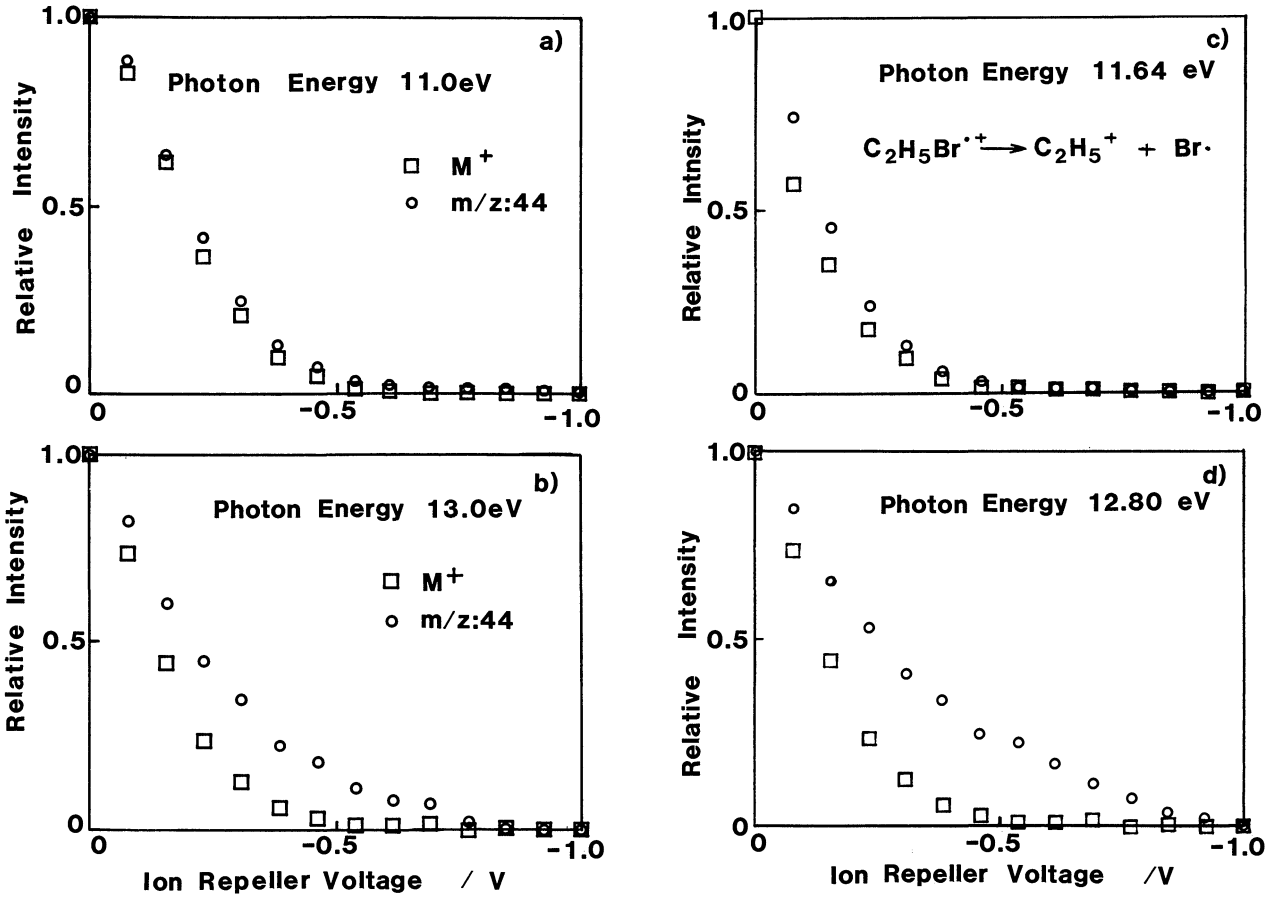

Fig. 5. The dependence of m/z 44 (○) and parent ion (□) on the reverse ion repeller voltages at the photon energy 11.0 eV (a) and 13.0 eV (b). The dependence of $C_2H_5^+$ (○) eliminated from ethyl bromide ion (□) at the photon energy 12.8 eV (c) and 11.64 eV (d) on the reverse ion repeller voltages. Since the ionization still occurs via the first channel in the higher photon energy region than ca. 12.2 eV, even if the new channel occurs through one of the processes such as Eqs. 1—3, the average KER of $C_2H_6NO^+$ will not drop significantly.

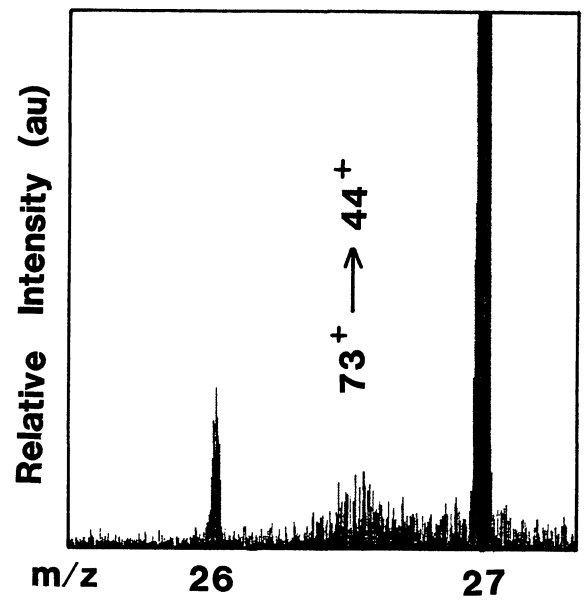

Fig. 6. A metastable peak at m/z ca. 26.5 corresponds to the fragmentation, $73^+ \rightarrow 44^+$, by 30 eV electron impact.

lower than the activation potential (9.9 eV[18]) estimated from the appearance energy (11.9 eV) for m/z 30. For alternative fragmentation processes, Eqs. 8—10 are followings.

$$C_3H_7NO^{+\cdot *} \rightarrow (C_2H_4NO^+) \rightarrow NO^{+\cdot} + C_2H_4 + \cdot CH_3 \quad (8)$$

$$\rightarrow CH_2O^{+\cdot} + CH_2N + \cdot CH_3 \quad (9)$$

$$\cdots\cdots\cdots \rightarrow C_2H_6^{+\cdot} + CHNO \quad (10)$$

The $\Sigma\Delta H$ are estimated to be 12.2,>11.2, and >10.8 eV, respectively, which are larger than the activation potential of the process giving m/z 30.

The appearance of fragment ions, $C_3H_6NO^+$, $C_2H_4NO^+$, and $C_2H_6N^+$, at the similar energies (Table 1) may be realized by ionization mechanism (kinetics and/or energetics). The small transition probability at the appearance energies makes the onsets of the ionization efficiency curves ambiguous. A tentative explanation is as follows. DMF is ionized above 9.12 eV via the

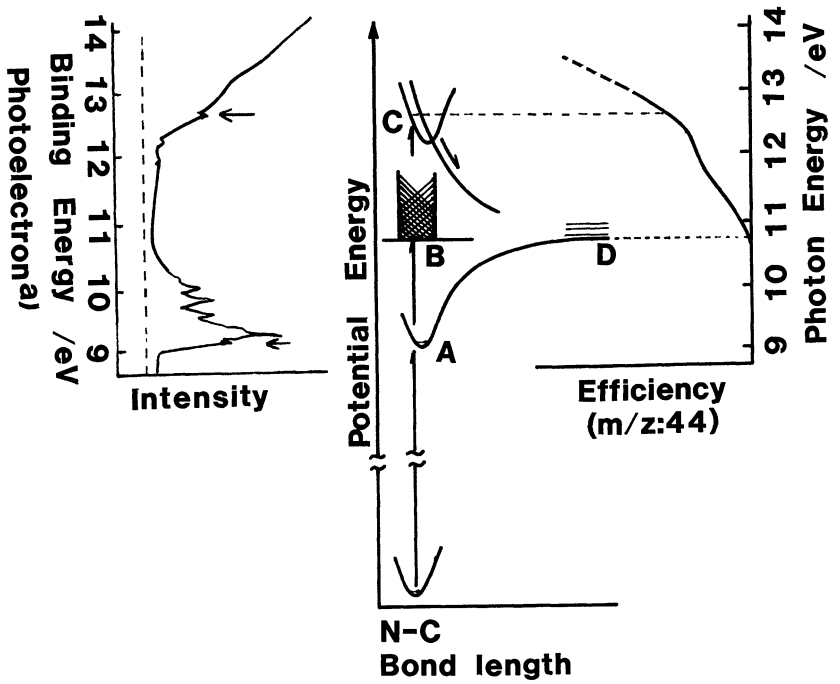

Fig. 7. The schematic energy diagram of fragmentation of *N,N*-dimethylformamide ion with the PES and the breakdown curve of m/z 44. The arrow in the PES points the vertical ionization energy A. *N,N*-dimethylformamide is excited vertically in the higher energy region than 10.7 eV of its continuum energy level B in producing CHO· and $C_2H_6N^+$ at D. A predissociative ionization producing CHO· occurs at C (ca. 12.2 eV) corresponding to a peak in the PES which is pointed by the big arrow.

removal of nonbonding electron of the nitrogen and/or the oxygen atom.[11] The ionization mechanism suggests that the removal of a nonbonding electron causes a change in the molecular orbital hybridization from sp^3 to sp^2 on the nitrogen atom of $C_3H_7NO^{+\cdot}$[12] accompanied by reduction of the length of C–N and the bond angle of C–N–C and C–N–O. This brings about a conversion of the electronic energy to the internal vibrational and rotational energy for the parent ion. The increased internal energy of $C_3H_7NO^{+\cdot}$ exceeds the activation energy of the decompositions to $C_3H_6NO^+$, $C_2H_4NO^+$, or $C_2H_6N^+$. This seems to be one of the reasons why the appearance energies of three fragment ions are nearly the same, though the bond energies may be different from each other.

We thank Professor Takesi Ohno of Osaka University for his discussions on the kinetics.

16) The mass number of metastable peak m due to the reaction $m_1 \rightarrow m_2^+ + n$ before the magnetic sector of mass spectrometer is given as follows.[a]

$m^*=m_2^2/m_1$

[a] Ref. 13.

17) The ΔH_f of respective species[a] are the followings in kcal mol^{-1}.

Species	$C_3H_7NO^{+\cdot}$	$NO^{+\cdot}$	CH_4N^+	$CH_2O^{+\cdot}$	$C_2H_6^{+\cdot}$
ΔH_{f298}	165	235	178	224	249
Species	C_2H_4	CO	$\cdot CH_3$	H	HCO
ΔH_{f298}	12.5	−26.4	34.0	52.1	8

The ΔH_f of $C_2H_4NO^+$, which is unknown, can be estimated from the appearance energy of $C_2H_4NO^+$ by using the following relation.

$$\Delta H_f(C_2H_4NO^+)+\Delta H_f(\cdot CH_3)\leqslant AE(C_2H_4NO^+) - IE(C_3H_7NO^{+\cdot})+\Delta H_f(C_3H_7NO^{+\cdot})$$

Where AE and IE are an appearance energy and an ionization energy, respectively. The enthalpy of $C_2H_4NO^+$ is estimated to $\leqslant$169 kcal mol^{-1}.

[a] Ref. 1, Ref. 14, Ref. 11.

18) Under the conservation of energy and momentum, the released energy from the parent ion is partitioned into the fragmentation products in a decomposition. The fragment ions, $C_2H_6N^+$ and $C_2H_5^+$, get about 40 and 73% of the respective whole released kinetic energy.

Additional Formation of Brønsted Acid Sites on Silica-Alumina Catalyst Surfaces by Depositing Silica Component

Satoshi SATO,* Masahiro HIRATSUKA, Toshiaki SODESAWA, and Fumio NOZAKI
Department of Applied Chemistry, Faculty of Engineering, Chiba University,
Yayoi-cho, Chiba 260
(Received January 21, 1991)

The chemical vapor deposition (CVD) of silica onto an amorphous silica–alumina was investigated using tetraethoxysilane in order to create Brønsted acid sites on the surface of original silica–alumina. Silica loading could be readily controlled by the CVD time at 160 °C; the silica covered an internal wall of mesopore of the support of silica–alumina. The resulting CVD silica–alumina was catalytically more active than the original silica–alumina support for such test reactions as the cracking of cumene and the isomerization of 1-butene. The characteristic changes in the amount of Brønsted acid sites were clarified by means of the temperature-programmed desorption of adsorbed 2,6-dimethylpyridine. Strong Lewis acid sites of the original silica–alumina were converted into strong Brønsted acid sites upon depositing the silica component.

Chemical vapor deposition (CVD) techniques are effective for attaining the high dispersion of a deposit on the surface of a catalyst support, and have recently been investigated regarding both the modification and preparation of solid acid catalysts.[1-9] We previously reported a supported type of silica–alumina catalyst prepared by depositing silica on an alumina surface.[5,9] Silica was effectively deposited onto the alumina by using tetraethoxysilane at 240 °C in the presence of oxygen; silica loading was readily controlled by the deposition time. The obtained alumina-supported silica catalyst was found to have predominantly Brønsted acid sites which are transformed from the Lewis acid sites of an alumina surface. The silica–alumina catalyst exhibited catalytic activities for several reactions such as cracking, isomerization, and dehydration.

Silica–alumina is an important catalyst for manufacturing various petrochemical products, and is commercially prepared by wet methods, such as co-precipitation and co-gelation. Although the conventional preparation methods are suitable for obtaining a "bulk" level dispersion of the binary oxide component, the respective oxide species do not disperse atomically. Thus, amorphous silica–alumina usually has both Brønsted and Lewis acid sites. In contrast to the wet methods, CVD techniques are attractive for surface modifications used to attain atomical dispersions of other oxide species on the surface of a catalyst support.

If the Lewis acid sites of amorphous silica–alumina are able to be converted into Brønsted acid sites by the deposition of silica, the catalytic properties must be improved. In this paper we describe various experimental results concerning the CVD of silica onto an amorphous silica–alumina support commercially produced by the co-gelation preparation method. In addition, we describe the acidic character of the CVD silica–alumina catalyst, which has been clarified by means of temperature-programmed desorption (TPD) using 2,6-dimethylpyridine as an adsorbate, together with the pore characteristics.

Experimental

Commercial silica–alumina (N631-L) with a specific surface area of 420 $m^2 g^{-1}$, an alumina content of 13 wt%, and a granule size of 24—60 mesh was supplied by Nikki Chemical Co., Ltd. A CVD silica–alumina catalyst was prepared at the prescribed temperatures by bringing tetraethoxysilane vapor together with a carrier gas into contact with the silica–alumina support in a CVD reactor made up of a Pyrex glass tube rotating in an electrical furnace inclined at 45°;[9] the flow rates of tetraethoxysilane and the carrier gas were 2.7 and 400 mmol h^{-1}, respectively. After CVD operation, the sample was calcined at 550 °C for 3 h in an air atmosphere. The silica loading was calculated by measuring the weight increase of the CVD samples after calcination.

The cracking of cumene was tested at 350 °C using a fixed-bed continuous-flow apparatus under atmospheric pressure at a W/F of 28 g h mol^{-1}, where W is the weight of the catalyst and F is the molar flow rate of cumene, together with a nitrogen carrier gas (15 ml min^{-1}). The reactor effluent was analyzed by on-line GLC using a column of Bentone 34 and dinonyl phthalate (1 m).

The isomerization of 1-butene was performed in a closed circulation reactor comprising a circulation volume of 200 ml. After a catalyst (55 mg) had been evacuated at 200 °C for 1 h, the reaction was carried out at 50 °C at an initial pressure of 22 kPa. The products were analyzed by on-line GLC with a VZ-7 column (4.5 m). The isomerization activity was evaluated by the first-order rate constant during the initial reaction period.

A BET surface area and pore characteristics were obtained by nitrogen physisorption at −196 °C. The pore volume distribution was calculated using the method of Cranston and Inkley[10] and the desorption isotherm of nitrogen. A T-plot, giving an information about micropores with radii less than 0.35 nm, was also obtained from the desorption isotherm according to the articles by Boer and co-workers.[11-13]

A TPD measurement of the adsorbed pyridine or 2,6-dimethylpyridine was performed in order to evaluate the acidic property. After a sample (10 mg) had been evacuated at 500 °C for 1 h, pyridine was injected at 200 °C; the sample was then evacuated at 200 °C for 1 h. The TPD measurement was run from 200 to 700 °C at a heating rate of 5 °C min^{-1}. The

desorbed pyridine was bubbled into a conductivity cell containing 0.5 mmol dm^{-3} of a sulfuric acid solution (30.0 g) together with nitrogen flow (70 ml min^{-1}); the amount of desorbed pyridine was monitored by the change in the solution conductivity.[14] The obtained cumulative curve differentiates to give an acid strength distribution as a function of desorption temperature.

Results and Discussion

Catalyst Preparation. Figure 1 shows the influence of the CVD temperature and time upon silica loading. In a stream of air, silica loading was increased with the CVD temperature at temperatures below 200 °C, and maximized at nearly 200 °C. Above this temperature, the silica loading decreased with the CVD temperature; above 280 °C the obtained catalyst had a color which varied from brown to black, due to coking. Thus, the optimum CVD temperature was found to be below 200 °C. At CVD temperature of 160 °C, the silica loading increased monotonously with the CVD time up to 2 h, and then leveled off. The silica loadings were 0.20 and 0.39 g/g-support for 2 and 8 h, respectively. In a stream of nitrogen, the silica loading also changed with the CVD time at 160 °C in the same manner as in the presence of oxygen. It can consequently be said that silica loading is readily controlled by the CVD time at 160 °C. No oxygen was needed for to accelerate the deposition rate at 160 °C, although oxygen was effective for the acceleration of silica deposition onto an alumina support at 240 °C.[9] Silica deposition onto silica–alumina occurred at lower temperatures (about 80 degree) compared to that for silica deposition onto an alumina support. In a stream of nitrogen above 200 °C, silica loading was almost unchanged with the CVD temperature, whereas it varied with the CVD temperature below 200 °C in a similar way as in air. This observation is presumed to be related to the deposition rate, as will be discussed later.

Physical Properties. Changes in the surface area of CVD catalysts with silica loading are shown in Fig. 2. For CVD catalysts prepared at 160 °C, the surface area (based on the unit weight of the original silica–alumina support) slightly decreased with an increase in silica loading up to a loading of 0.2 g/g-support; it then decreased steeply. For an alumina support which has relatively large mesopores (ranging from 4 to 20 nm in diameter[9]), the deposited silica is uniformly dispersed on the support, since the surface area (based on the unit weight of the support) is almost unchanged, irrespective of the silica loading. For the present silica-alumina, the deposition of silica is considered to be affected by the pore structure of the support. Figure 3 shows the pore volume distribution of CVD catalysts together with the original silica–alumina support. The silica–alumina support had 0.47 ml g^{-1} of total pore volume and a maximum pore volume at a diameter of about 3.8 nm, which was smaller than that of the alumina support mentioned above. The CVD catalysts had the maximum pore volume at a diameter close to 3.8 nm, although the total pore volume was significantly decreased with silica loading. Furthermore, for CVD catalysts prepared at

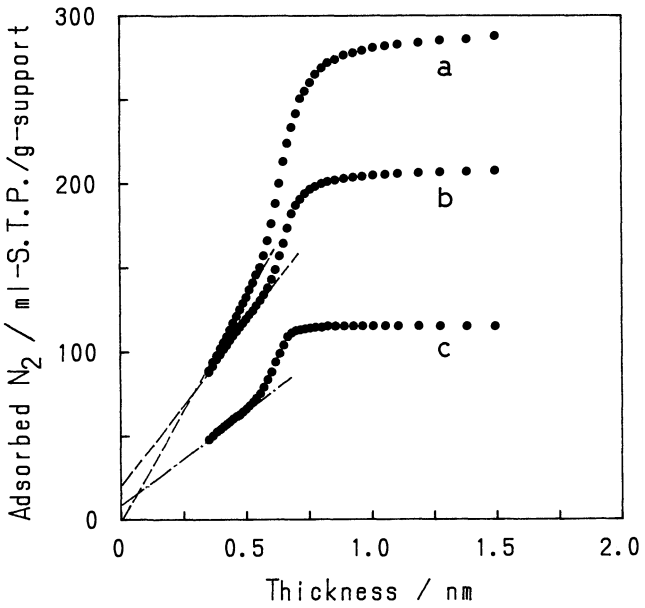

Fig. 4. T-plot for CVD catalysts. Symbols as those in Fig. 3.

temperatures higher than 200 °C in air, the surface area was much smaller than those prepared at 160 °C (Fig. 2). This indicates that aggregated deposition occurred in the neighborhood of the entrance of the micropores of the support; it then followed by the closure of the micropores at higher temperatures in air owing to a too-fast deposition. For a catalyst prepared at 300 °C in nitrogen, however, the surface area was not so small as those prepared in air. Since oxygen results in an aggregated deposition of silica at high temperatures (above 200 °C), the surface area steeply decreased.

In order to elucidate the existence of micropores under a diameter of 0.7 nm, a T-plot was examined according to the procedure proposed by Boer et al.[11-13] T-plots for CVD catalysts are shown in Fig. 4. A T-plot passes through the origin for a sample having no micropores, whereas it has an intercept which expresses the micropore volume for a sample having micropores.[13] Thus, an original silica–alumina support has no micropores because of the passing through the origin in the T-plot. For a CVD catalyst with a silica loading of 0.20 g/g-support, micropores (21 ml-STP) were generated with a small decrease in the BET surface area (Fig. 4b). Further silica deposition (0.39 g/g-support) led to a decrease in the micropore volume (10 ml-STP) together with a large decrease in the surface area (Figs. 2 and 4c). The deposition of silica resulted in the formation of micropores in the silica–alumina support. These results indicate that silica deposition develops on the interior wall of mesopore in such a characteristic way that the pore size decreases with silica deposition.

Acidic Properties. It has been known that 2,6-dimethylpyridine (2,6-DMP) selectively adsorbs on Brønsted acid sites, but not on Lewis acid sites because of a steric hindrance of two methyl groups, whereas sterically nonhindered pyridine adsorbs on both Brønsted and Lewis acid sites.[15,16] 2,6-DMP has been used for the characterization of acid surfaces with pulse adsorption,[15] IR spectroscopy,[16] and gravimetric titration.[17] We recently applied the TPD measurement of adsorbed 2,6-DMP to the elucidation of the acidic nature of an alumina-supported silica catalyst.[14] This investigation has elucidated that silica deposition creates Brønsted acid sites on the surface of alumina together with the disappearance of Lewis acid sites.

The TPD spectra of adsorbed pyridine and 2,6-DMP are illustrated in Fig. 5. The original silica–alumina support had a large desorption peak of pyridine and a somewhat smaller peak of 2,6-DMP than that of pyridine at peak tops of about 300 °C. Since curve b shows the acid strength distribution of Brønsted acid sites, the difference between curves a and b is a measure of Lewis acid sites. The silica–alumina support dominates Brønsted acid sites with a small amount of Lewis acid sites. This fact is also supported by the ^{31}P NMR of trimethylphosphine adsorbed on it.[9] In contrast, for a CVD catalyst loaded 0.20 g/g-support of silica, it had no significant difference between two distribution curves of pyridine and 2,6-DMP. This indicates that the CVD catalyst has dominantly Brønsted acid sites. In addition, the total numbers of acid sites, represented by the amount of desorbed pyridine, were reduced, as can be seen from a comparison of curves c and a. Moreover, the amount of desorbed 2,6-DMP decreased in the low-

(0.39)	2,6-DMP	58	17	10

a) Silica loading (g/g-support). b) Desorption temperature (°C).

temperature region, but increased in the high-temperature region, as can be understood from a comparison of curves d and b. This indicates that strong Brønsted acid sites, represented by the desorption of 2,6-DMP at temperatures above 500 °C, were increased together with a decrease in the total number of Brønsted acid sites.

Figure 6 illustrates the changes in the Brønsted acidity, measured by the desorption of 2,6-DMP, with a variation of silica loading; Table 1 summarizes the amounts of disorbed pyridine and 2,6-DMP. A small silica loading of 0.11 g/g-support decreased the total amounts of desorbed pyridine and 2,6-DMP. Interestingly, a further silica loading increased the total amounts, and enhanced the Brønsted acid strength. Especially, the number of strong Brønsted acid sites (expressed by the desorption of 2,6-DMP at temperatures above 400 °C) was maximized at silica loadings near 0.20 g/g-support. Above this loading, the total numbers of desorbed pyridine and 2,6-DMP monotonically decreased with increasing the silica loading. Another catalyst, such as a K^+ ion-exchanged silica–alumina, which gave no desorption of 2,6-DMP in the temperature region above 400 °C, exhibited no catalytic activity for 1-butene isomerization.[14] The effective Brønsted acid sites for 1-butene isomerization held 2,6-DMP, even at high temperatures above 400 °C. The present TPD results indicate that strong Brønsted acid sites were generated upon depositing silica onto strong Lewis acid sites.

Catalytic Activities. The catalytic activities were examined for CVD catalysts prepared at 160 °C. Figure 7 shows the change in the cumene-cracking activity with process time at 350 °C. Cumene conversion was significantly improved by depositing silica on the

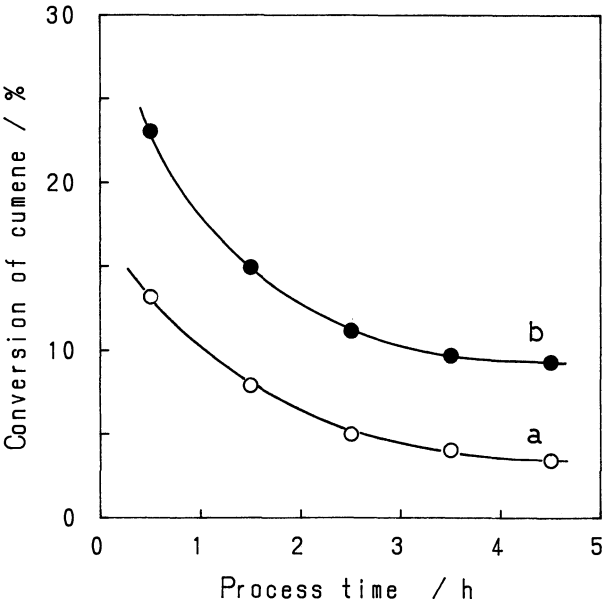

Fig. 7. Cumene conversion with process time. a, Original silica–alumina support; b, CVD catalyst (silica loading, 0.20 g/g-support).

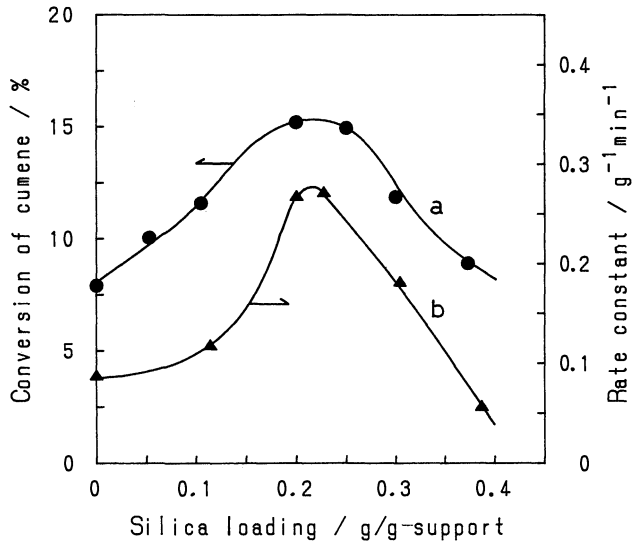

Fig. 8. Changes in the catalytic activities with silica loading. a, Cumene cracking at 350 °C; b, 1-butene isomerization at 50 °C.

original silica–alumina support. Figure 8 depicts the change in the catalytic activity for the cracking of cumene with silica loading, together with the results concerning the isomerization of 1-butene at 50 °C. Since the conversion of cumene decreased with the process time, the cracking activity was evaluated in terms of the average conversion during process times of 1—2 h. Cumene conversion increased with increasing silica loading, and attained a maximum at a silica loading of about 0.2 g/g-support. Above this loading, the cracking activity decreased with silica loading. For 1-butene isomerization, the initial first-order rate constant exhibited a maximum at a silica loading of about 0.2 g/g-support. This activity-pattern was similar to that for cumene conversion. Although the original silica–alumina support has essential activities for the reactions, the deposition of silica made it possible to increase the catalytic activities to twice the value for cumene cracking, and three times that for 1-butene isomerization, compared with the activity levels of the original silica–alumina support. In addition, with regard to the product distribution of 1-butene isomerization, the ratio of *cis*-/*trans*-2-butene was slightly decreased (from 0.95 to 0.83) with an increase in the silica loading, compared to the values at 1-butene conversion of 50%.

It is worth noting that the silica loading of a 0.2 g/g-support, at which catalytic activities were maximized, is equal to the loading at which the rate of silica deposition decelerated (Fig. 1), the loading at which the strong Brønsted acid sites were maximized (Fig. 6 and Table 1), and the loading at which the surface area steeply decreased (Fig. 2). Below this critical loading, the catalytic activity for 1-butene isomerization was apparently unchanged (Fig. 8b). For the cracking of cumene, however, the cumene conversion increased with increasing silica loading (Fig. 8a). Since the pretreatment conditions for the cracking of cumene were different from those for the isomerization of 1-butene, the surface acidities are presumed to be different from each other. On the other hand, above the critical loading, the decreasing features in both the deposition rate and the catalytic activities are in fair agreement with the decreasing pattern in strong Brønsted acidity of the CVD silica–alumina catalyst.

In view of practical usage, the present CVD catalyst was compared with an alumina-supported silica catalyst that has been previously reported.[9,14] For the isomerization of 1-butene, the alumina-supported silica catalyst was active, even at a low temperature of 0 °C,[14] and superior to the present CVD catalyst. This shows no discrepancy with the fact reported by Imizu and Tada.[8] In contrast, for the cracking of cumene, the present CVD silica–alumina catalyst was much preferable because even the original support was superior to the alumina-supported silica catalyst.[9] It is interesting that the enhanced activities vary regarding reaction type.

Formation of Active Site on Silica–Alumina Surface. Although the original silica–alumina support, itself, has Brønsted acidity, an optimal silica deposit results in an increase in the number of strong Brønsted acid sites as well as enhancements in catalytic activity. The superiority of CVD catalysts for catalytic reactions is presumably caused by an increase in the number of Brønsted acid sites for CVD catalysts. When alumina is used as a support, these features are much clearer.[5,9,14] Since an alumina surface almost comprises Lewis acid sites, Brønsted acid sites are effectively generated by the deposition of silica. The resulting alumina-supported silica shows significant catalytic activities for various reactions, whereas the alumina support showed few activities by itself. An excess of the silica deposit, however, weakened strong Brønsted acid sites.[14]

The present silica–alumina support originally had not only strong Brønsted acid sites, but also Lewis acid sites.[9] A small amount of silica loading decreased the number of strong Brønsted acid sites (Fig. 6b). Prior to CVD operation, a support was heated at a low temperature of 160 °C in a stream of carrier gas, so that strong Lewis acid sites could be hydrated to form hydroxyl groups. Silica deposits proceed via an ester exchange of tetraethoxysilane with the surface hydroxyl groups. During the initial stage of deposition, a silica deposit is mainly initiated on strong Brønsted acid sites, and contributes to a weakening of the acid strength. After the original Brønsted acid sites are weakened, further silica deposition induces a transformation of Lewis acid sites into Brønsted acid sites. Furthermore, an excess of silica deposits weaken Brønsted acid sites. Consequently, strong Brønsted acid sites were maximized at silica loadings close to 0.2 g/g-support, as shown in Table 1. Such Lewis acid sites are probably localized

not on isolated alumina in the original silica–alumina, but on the boundary between silica and alumina. If Lewis acid sites exist on isolated alumina, the *cis*/*trans* ratio of produced 2-butene for 1-butene isomerization should be increased from 1 to close to about 3, which has been reported for silica overlayers deposited on alumina.[8] The ratio actually decreased to less than 1 for the present CVD silica–alumina. The difference in Lewis acidity of support materials results in variations of the catalytic properties for the above-mentioned reactions.

In conclusion, an enhancement of catalytic efficiency was achieved by depositing silica onto amorphous silica–alumina. This favorable nature should be attributed to an additional formaton of Brønsted acid sites which are ascribable to the transformation of Lewis acid sites through the CVD process.

(Received February 8, 1991)

Molecular sieving carbon (MSC) has been characterized for CO_2-adsorbers in a controlled atmosphere storage (CA storage) system by a gas-adsorption method. Experimental data were analyzed by means of the Dubinin–Astakhov equation, the *t*-method, and the micropore analysis method. The BET surface area of MSC was 592 $m^2 g^{-1}$. In the pore size distribution curve of MSC, the most common pore diameter was 0.68 nm. The temperature and the space velocity dependence of adsorbers with MSC have been investigated. The CO_2 adsorption capacity of adsorbers was determined by the gas-flow method. The capacity of the adsorbers at 60 °C decreased to 55%, compared with that at 20 °C; it decreased with increasing space velocity.

It has been known that the decay of fruits and vegetables can be reduced under atmospheres of highly concentrated CO_2 (2—15%) and low concentrations of O_2 (2—10%) during storage at low temperatures of 0—10 °C.[1,2]

The controlled atmosphere storage (CA-storage) system has been used practically for reducing the decay of fruits and vegetables. Several types of CA-storage have been proposed.[3] They mainly comprise of three parts; a storeroom, a CO_2-generator, and a CO_2-adsorber. In a previous paper we reported that the reliability of CO_2-adsorbers with molecular sieving carbon (MSC) is better than that of an adsorber with an X-type zeolite.[4] The difference in reliability of the two types of adsorbers was probably attributed to a difference in the micropore structure between MSC and X-type zeolite. The temperature and space velocity (flow rate/volume of the adsorbent) dependence of CO_2-adsorbers with MSC are also influenced by the micropore structure. However, the characterization of MSC by the gas-adsorption method using different analysis approaches has not yet been carried out.

Adsorption methods are frequently used and several adsorbates have been proposed to analyze the micropores of activated carbons.[5-7] Micropores are defined as pores that do not exceed 2 nm, according to the IUPAC classification of pore size. Recent experimental measurements have revealed that micropores influence the adsorption properties of adsorbents.[8,9]

In this report, experimental data concerning adsorption isotherms are analyzed using three different approaches. The first one is the Dubinin–Astakhov (DA) equation (1),[10] which is a general expression of the Dubinin–Radushkevich (DR) equation,[11]

$$W=W_0\{\exp-(A/E)^n\}. \quad (1)$$

Here, W is the volume of the gas adsorbed at a relative pressure, P/P_0, considered to be a characteristic similar to a bulk liquid at the experimental temperature, W_0 the micropore volume, n an additional parameter, and E the characteristic free energy of adsorption for the given system. At the relative pressure, P/P_0, the adsorption potential, or the differential free energy of adsorption, A, is given by

$$A=RT\ln(P_0/P). \quad (2)$$

The second approach is the so-called "*t*-method",[12-14] which is an empirical procedure used for the analysis of adsorption isotherms. This method is based on a comparison between the isotherm on a specimen (porous carbon) and the standard isotherm on a nonporous reference carbon. The amount of adsorbed gas on a porous carbon is plotted against the statistical film thickness, t, for a nonporous reference carbon.

The third approach is the so-called "MP-method" (micropore analysis method).[15] The MP-method is based on the de Boer V–t plot obtained from an adsorption isotherm on nonporous carbons.[15] In the de Boer plot, V is the volume of adsorbed gas. The pore-size distribution and the specific surface area of porous carbon are obtained from this method. Details of the analytical procedure were reported in Ref. 15.

In the present study, MSC was characterized by the gas adsorption method and analyzed by the above-mentioned three methods. The temperature and space velocity dependences of the CO_2-adsorber with MSC were also investigated.

Experimental

1. Materials. The molecular sieving carbon (MSC) used is a product of Takeda Chemical Industries Co., Ltd., (X_2M), the size being about 3 mm in diameter and 3 to 8 mm in length. The nonporous carbon black of Spheron 6 was supplied by Cabot Carbon Co., Ltd. The isotherm of the carbon black was used as the standard adsorption isotherm in the "*t*-method".

2. Apparatus and Procedure. Adsorption experiments for

characterizing MSC were carried out in a conventional volumetric apparatus of BEL Japan, Inc. (BELSORP28) equipped with a high-precision Baratron capacitance manometer. Before the experiments, the samples were out-gassed at 423 K for 2 h. N_2 and CO_2 adsorption isotherms were measured at 77 and 195 K, respectively.

The CO_2 adsorption capacity of the adsorber was measured by the flow method using the same apparatus reported in a previous paper.[4] The apparatus comprises three parts: an adsorber, gas-mixing equipment, and gas-analyzing equipment. The adsorber was 55 mm in diameter and 700 mm in height. To carry out the adsorption experiment, gas of 3.4—14.0% CO_2 was introduced from the bottom of the adsorber at a space velocity of 140—700 h^{-1}. The adsorption temperature was controlled by heating the adsorber with a tape-heater. During adsorption, small portions of the leaked gas were withdrawn from the adsorber, and the concentration of CO_2 was measured by a combustion gas analyzer (Shimadzu, CGT-10-1A).

Results and Discussion

1. Properties of MSC. Figure 1 shows the adsorption (a) and desorption (b), N_2 isotherms of MSC at 77 K and CO_2 adsorption (c) at 195 K. The hysterisis of the N_2 isotherm is small. Brunauer et al. proposed to classify the adsorption isotherms into five different groups.[16] According to their classification, the isotherms of N_2 and O_2 belong to type I. From the N_2 isotherm, the BET surface area (S_{BET}) was calculated to be 592 $m^2 g^{-1}$ by using the well-known BET equation. The S_{BET} of MSC is not so large as that of conventional activated carbons.[7]

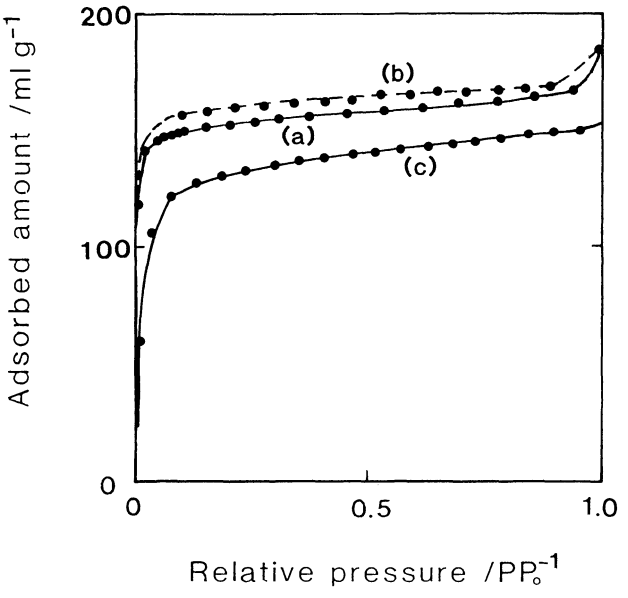

Fig. 1. Adsorption-desorption isotherm of MSC for N_2 at 77 K and for CO_2 at 195 K. (a): adsorption of N_2, (b): desorption of N_2, and (c): adsorption of CO_2.

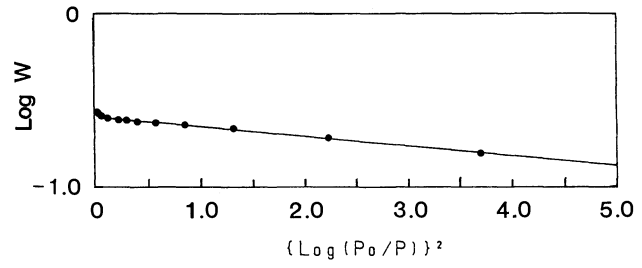

Fig. 2. DA-plots of MSC.

The CO_2 adsorption data were fitted to the DA equation (1). In Fig. 2, $\log W$ is plotted against $\log^2 (P_0 / P)$. The DA plot of MSC lies on a straight line in the case of n=2. According to Eq. 1, the intercept of the linear DA plot should equal to $\log W_0$; from the slope, the value E is obtained. It is known that decreases in the characteristic free energy of the DA equation, E, are correlated with increases in the micropore sizes.[9] The value of n was determined by the relative size between adsorbate and adsorbent. In fact, the value of n on MSC was 3 due to the adsorption of benzene.[17] In this experiment, the value seemed to be 2. This is because the volume of CO_2 was smaller than that of benzene. The E and W_0 values of MSC were 10.43 kJ mol^{-1} and 0.254 ml g^{-1}, respectively. The E value of MSC was larger than that of carbon black and activated carbon.[10] The larger E value suggested that the size of the micropore is smaller than that of carbon black and activated carbon.

Figure 3 shows a t-plot of MSC obtained from the N_2 adsorption isotherm shown in Fig. 1. Carrott et al.[8] has proposed that back extrapolation of the linear portion of the plot to the ordinate yields the total micropore volume, V; the slope of the linear section provides the external area, S_{EXT}, of the adsorbent; and extrapolation to the origin of the initial part of the plot provides the total surface area, S_t. From the figure, S_t and S_{EXT} were calculated to be 711 and 16.4 $m^2 g^{-1}$, respectively. The

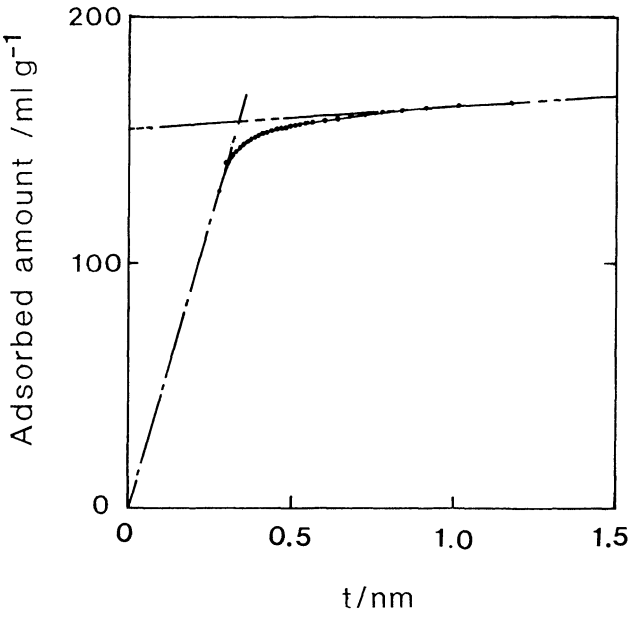

Fig. 3. t-plots of MSC.

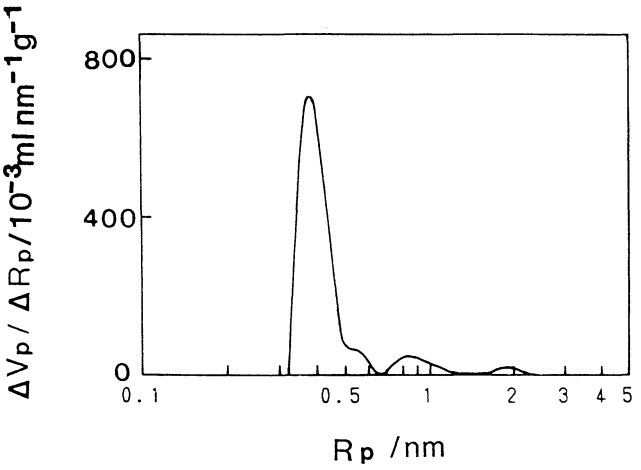

Fig. 4. Pore size distribution of MSC.

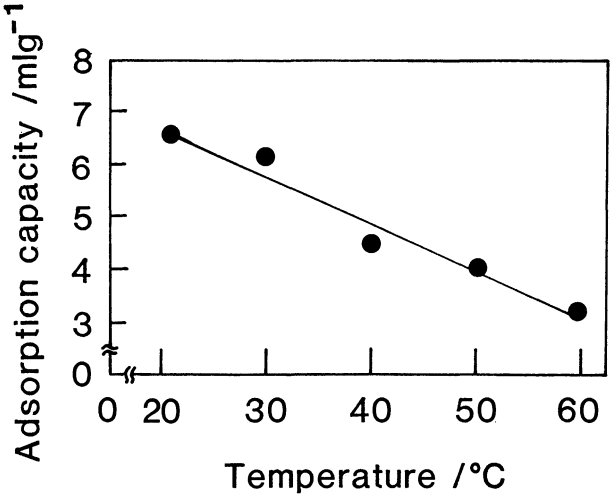

Fig. 5. Temperature dependence of CO_2-adsorber with MSC.

S_{BET} was smaller than S_t. The difference seems to be due to the fact that the t-method is based on a standard adsorption isotherm of nonporous carbon.

The pore-size distribution of MSC obtained from N_2 adsorption isotherms by using the MP-method is shown in Fig. 4. In the figure, R_p shows the micropore radius, and V_p the pore volume. The maximum of $\Delta V_p/\Delta R_p$ (differential value of V_p/R_p) is located at R_p=0.34 nm. Assuming that the walls of the pores are parallel plates, the most common pore diameter is 0.68 nm. The MSC is, thus, concluded to contain only micropores.

2. Characteristics of Adsorber. In a CA storage system, the adsorption of CO_2 was usually carried out in a temperature range of 5 to 60 °C. The concentration and the space velocity of adsorbed CO_2 varied with the concentration of CO_2 in the storeroom. It is therefore important to study both the temperature and the space velocity dependence of adsorbers with MSC.

The CO_2 adsorption capacity was estimated as follows: The concentration of leaked CO_2 was plotted against the time of adsorption and the amount of adsorbed CO_2 was accumulated until the time when CO_2 began to leak (break point).

Figure 5 shows the temperature dependence of the CO_2 adsorption capacity of adsorbers with MSC. The gas used in this experiment was a mixture of 9% CO_2 and 91% N_2. The adsorption capacity of adsorbers at 20 °C is 6.5 ml g^{-1}. In this experiment, the adsorption pressure of CO_2 was not clear; therefore, the estimated amount of adsorbed CO_2 by the flow method could not be compared with that by the conventional volumetric method. The CO_2 adsorption capacity decreases with increasing the temperature of adsorption. This result indicates that the physical adsorption of CO_2 onto MSC occurred. The adsorption capacity of CO_2 at 60 °C decreased to 55% in comparison with that at 20 °C. Almost all of the adsorbed CO_2 was desorbed from MSC by blowing air into the adsorber over a temperature range of 20 to 60 °C. It is known that the pore shape of MSC was a parallel

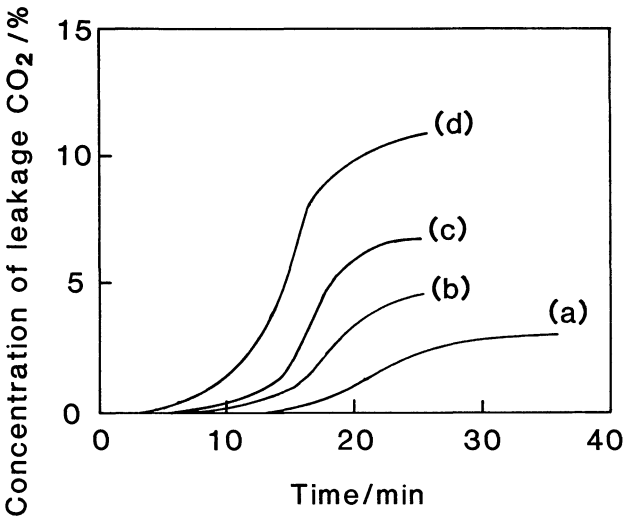

Fig. 6. Leaked CO_2 concentration vs. adsorption time for various concentration of introduced CO_2. (a): 3.4; (b): 5.7, (c): 8.0, and (d): 12.4%.

plate slit;[17] the desorption of gases from MSC was therefore easy. In accordance with this fact, the hysterisis of the adsorption isotherm for MSC was small, as is shown in Fig. 1.

The CO_2 breakthrough curves for CO_2 adsorbers with MSC at various concentrations of introduced CO_2 are shown in Fig. 6. The concentrations of introduced CO_2 were 3.4% (curve a), 5.7% (curve b), 8.0% (curve c), and 12.4% (curve d). In this experiment, the space velocity was 270 h^{-1} and the adsorption was carried out at 17 °C. In the figure, the break points are inversely proportional to the concentration of introduced CO_2. In the CO_2 adsorption isotherm of MSC shown in Fig. 1, the adsorbed amount of CO_2 increases rapidly within the low relative pressure region. It is reported[17] that gas adsorption on MSC within the low relative pressure

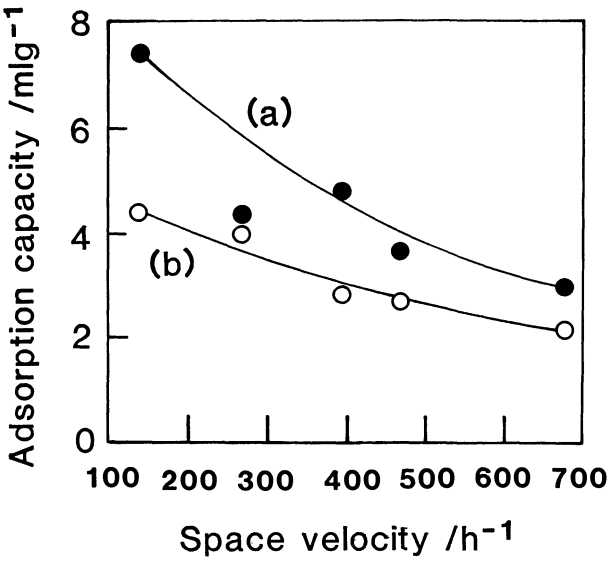

Fig. 7. Space velocity dependence of CO_2-adsorber with MSC for different concentration of introduced CO_2. (a): 12.4 and (b): 3.4%.

region can be attributed to adsorption by micropores. Therefore, MSC was a suitable adsorbent for CO_2 adsorbers in a CA storage system.

Figure 7 shows the space-velocity dependence of CO_2 adsorbers with MSC for different concentrations of introduced CO_2. The experiment was carried out at 17 °C. The concentration of introduced CO_2 was 12.4% (curve a) and 3.4% (curve b). In the case of (b), the CO_2 adsorption capacity gradually decreases with increasing space velocity. In the cass of (a), the capacity decreses largely with increasing space velocity. Thus, the CO_2 adsorption capacity in this experiment seems to be smaller than that of the volumetric method (saturated adsorption amount of CO_2). In order to operate the adsorber effectively, it was important to study the dependence on both the temperature and space velocity of the adsorbers.

Only MSC with micropores showed a large CO_2 adsorption capacity over a wide range of temperature, concentration, and space velocity. It is, thus, a suitable adsorbent for CO_2-adsorbers in a CA storage system.

Conclusion

1) The BET surface area of MSC was 592 $m^2 g^{-1}$. In the pore size distribution curve of MSC, the most common pore diameter was 0.68 nm. From the *t*-plot of MSC obtained from the N_2 adsorption isotherm, the specific surface area (S_t) and external surface area (S_{EXT}) of the MSC were calculated to be 711 and 16.4 $m^2 g^{-1}$, respectively. The S_{BET} was smaller than S_t.

2) The adsorption capacity of CO_2-adsorber with MSC was determined by the gas-flow method. The capacity of the adsorbers at 60 °C decreased to 55% in comparison with that at 20 °C; it decreased with increasing the space velocity.

The authors would like to acknowledge Professor T. Minami of the University of Osaka Prefecture for his helpful discussion and critical reading of the manuscript.

(Received February 27, 1991)

The solvent polarity parameters of supercritical carbon dioxide were determined as a function of the temperature and pressure within the ranges 318—353 K and 5.85—28.5 MPa. An infrared (IR) spectroscopic technique has been employed to determine the values of π^* dipolarity/polarizability and the Lewis basicity parameter B_{MeOD} by measuring the transitions in the IR absorption wavelength of functional groups (such as C=O and O–H···BA, where BA is a hydrogen-bond acceptor), in supercritical carbon dioxide. Ultraviolet/visible (UV/vis) spectroscopy was used to determine the value of the Kamlet–Taft's solvatochromic acidity partameter, α. The B_{MeOD}-value was enhanced with density, but was very small at the temperatures and pressures examined, almost the same as that for hexane. The α-value tended to be dependent on density at lower pressures, but was remarkably smaller compared with those for alcohols. The π^*-value significantly increased with an increase in the density, becoming more negative at higher temperatures above 10 MPa. Furthermore, the $E_T(30)$-value was estimated by using the determined π^*-value. A reliable $E_T(30)$-value for supercritical carbon dioxide has been obtained.

Supercritical carbon dioxide and some other supercritical fluids have recently been attracting much attention concerning their interesting properties for extraction solvents and reaction media.[1-5] When we use cabon dioxide at supercritical conditions, the desired extractions and chemical reactions are expected to be attained at around the ambient temperatures by adjusting the pressures and/or using proper entrainers.[6] In particular, in the near-critical region, the solvent stength varies widely with both the pressure and temperature; this sensitivity in solvent strength could be applied to controling the chemical reaction processes, as well as that of extraction. It is, therefore, be very important to know the solvent strength of supercritical fluids as a function of the pressure, temperature, and/or other variables of state.

For the above-mentioned use of supercritical carbon dioxide to be well effected, its solvent strength should be quantitatively evaluated. The solvent strength has so far been represented by the dipole monent, dielectric constant, refractive index, and solubility parameter.[7-9] When one is interested in the solvent strength at molecular levels, however, these are not adequate, since in these evaluations solvents are regarded as being nonstructured types; solute/solvent interactions, such as hydrogen-bond donor (HBD)/acceptor (HBA) interactions, are not considered, even though they often play dominant roles in many chemical processes.

The variation of the absorption wavelength of a chromophore in IR, NMR, ESR, or UV/vis spectroscopy represents the intermolecular solute–solvent interaction forces,[10-14] and can be used as a good measure of the solvent strength. A few spectroscopic studies have been applied to fluids under supercritical conditions. For example, Johnston et al. measured the solvent strength with the transition energy of a phenol blue indicator in a given solvent by the UV/vis method.[15] Leffler et al. estimated the π^* dipolarity/polarizability of supercritical carbon dioxide using several indicators by the UV/vis method as well.[16] For supercritical carbon dioxide, as well as others, however, the spectroscopic solvent strength is not widely available, since either no convenient polarity parameters could be determined or the precision in measurements and evaluations of its solvent strength was low; the spectroscopic approach is therefore still very much limited at present.

The present work has been aimed at determining the HBD acidity parameter, α; the HBA basicity parameter, B_{MeOD}; and the dipolarity/polarizability parameter, π^*, of carbon dioxide within the range 5.85—28.5 MPa and 318—353 K. In order to consider two or more aspects of solvation, the following multiparameter approach has been presented and shown to be useful:[17]

$$A = A_o + s\pi^* + a\alpha + bB_{MeOD}, \quad (1)$$

where A is a solvent-dependent physicochemical property in a given solvent; A_o is a quantity corresponding to this property in an inert solvent; and the coefficients s, a, b describe the sensitivity to property A. The present study has used FTIR spectroscopy methods to determine the values of B_{MeOD} and π^* as well as UV/vis spectroscopy for the α-value. According to the literature the FTIR method has been only slightly used so far,[18] while many studies have used UV/vis methods.[19-23] In addition, we have attempted to estimate the $E_T(30)$ parameter by using the determined π^*-values. The $E_T(30)$ parameter is one of the polarity parameters

used most widely and possesses great advantages.[24–28] Little is presently known about the $E_T(30)$-values for supercritical fluids.

Experimental

The solvatochromic indicator molecules chosen for the measurements of the π^*-values were methyl acetate (Tokyo Kasei Co., Inc.), cyclohexanone (Merck), acetone (Merck), and *N*,*N*-dimethylformamide (Tokyo Kasei Co., Inc.). As indicators, methanol-*d* CH_3OD (Merck) for Lewis basicity B_{MeOD} and 1-ethyl-4-methoxycarbonylpyridinium iodide (Tokyo Kasei Co., Inc.) and 4-nitroanisole (Tokyo Kasei Co., Inc.) for Lewis acidity α measurements were used. Commercial-grade carbon dioxide (above 99.999%) was used. All chemicals were used without further purification.

Details concerning the experimental apparatus used have been described elsewhere.[6-c] Liquid carbon dioxide was charged into a JASCO Model 880-PU syringe pump through a 1/16-in. tube (1 in.=2.54 cm) and a check valve, and then compressed to the desired pressures. Pressure control was achieved by a back-pressure regulator (Model 880-81, JASCO), which can perform a high-speed flow switching and also control the outlet pressure, irrespective of the mass flow rate of SCF. Then, a 0.2-μL of an indicator was injected using an injection valve (Pheodyne Inc.) which contained a 10-μL sample loop; this made it easy to introduce an indicator into the cell.

The infrared spectrometer used in this study was a JASCO Model FTIR-7300 instrument (Japan Spectroscopic Co., Ltd.) equipped with a narrow-bandwidth mercury cadmium telluride (MCT) detector cooled by liquid nitrogen. The low-frequency cut-off was approximately 800 cm^{-1}. Spectra were acquired at 1 cm^{-1} nominal resolution and interferrograms were accumulated at a rate of 1 scan per 1.2 s. Details concerning the high-pressure IR flow cell used (nominal volume of 16-μL, optical path length of 5 mm, and cross section area of 3 mm^2 were described previously.[6-c] The IR flow cell which was placed in a JASCO Model HC-12 cell heating unit was maintained at temperatures of 318—353±0.5 K. The UV/vis absorption spectra were measured by a Model JASCO MULTI-340 recording spectrometer. The high-pressure cell used for UV/Vis was constructed from stainless steel with quartz windows 1 mm i.d., having a 1-cm path length and a 8 μL nominal total volume. The flow cell was wrapped with heating tape and maintained at a temperature of 318±1 K.

An indicator was passed into the high-pressure flow cell, trapped there by stopping the flow, and the absorption spectrum of the indicator in supercritical carbon dioxide was recorded. Only the spectrum of supercritical carbon dioxide was measured in advance in order to provide a background spectrum. No data manipulation, such as spectral subtraction or base line corrections, was used.

Results and Discussion

Density-Dependence of the HBD Acidity, α. We examined Kamlet–Taft α-value[29] for supercritical carbon dioxide by using the wavenumber (ν_{max}) of the maximum absorbance of 4-nitroanisole in the UV/vis spectrum through the following relationship:

$$Z = 79.6(1 + S) \tag{2}$$

and

$$Z = 2.859 \times 10^{-3}\nu, \tag{3}$$

where S is Brownstein's polarity parameter,[30] Z is Kosower's Z-value,[31] and ν is the charge-transfer band in the UV/vis spectrum of 1-ethyl-4-methoxycarbonylpyridinium iodide. These relations were obtained for a number of solvents and will be applied to supercritical carbon dioxide. This S-value from Eq. 2 is here defined as S_{obs}.

Plots of the S-values for non-hydrogen-bonding solvents against the corresponding ν_{max}-values yielded linear relationship, as expressed by[17]

$$S = -0.0846\nu_{max} + 2.569,$$
$$r = 0.9925,\ \mathrm{SD} = 0.0052,\ \text{and}\ n = 8. \tag{4}$$

Here, r is the correlation coefficient, SD the standard deviation, and n the number of solvents examined. The S-value determined using Eq. 4 is here expressed as S_{cal}, and is evaluated to be

$$\Delta\Delta S = S_{obs} - S_{cal}. \tag{5}$$

The $\Delta\Delta S$-values represent the deviations of the HBD solvents from the correlation line for non-hydrogen-bonding solvents. Furthermore, the solvatochromic displacement ($\Delta\Delta\nu$) attributable to enhanced hydrogen bonding by HBD solvents to the strong HBA Dimroth' betaine dye[32] is related to $\Delta\Delta S$ as follows:

$$\Delta\Delta S = 0.0403\cdot\Delta\Delta\nu + 0.002,$$
$$r = 0.9962,\ \mathrm{SD} = 0.0036,\ \text{and}\ n = 8. \tag{6}$$

Using $\Delta\Delta S$, Kamlet and Taft determined the α-value using the following equation:

$$\alpha = (\Delta\Delta S - 0.002)/(0.0403\cdot 6.24). \tag{7}$$

Figure 1 shows the dependence of the α-value for supercritical carbon dioxide on the density at 318 K. The α-value ranges from the negative values at densities above 0.44 g cm^{-3} to 0.195 at 0.25 g cm^{-3}. The negative α-values at higher densities are assumed to be zero by taking into account errors in the present calculations. The α-value of 0.19 for supercritical carbon dioxide at 0.25 g cm^{-3} is larger than that for acetone (α=0.08),[29] and is comparable to that for acetonitrile (α=0.23).[17] Although the α-values at lower densities show a certain strength of acidity, the α-values are remarkably smaller than those of formamide and alcohols.

Temperature- and Pressure-Dependence of the HBA Basicity, B_{MeOD}. The large solvent-induced shifts of the IR stretching vibrations, $\nu_{X=H}$, do not occur in HBD solvents, but do in the HBA solvents of the Lewis-base type, as shown in Eq. 8:[33,34]

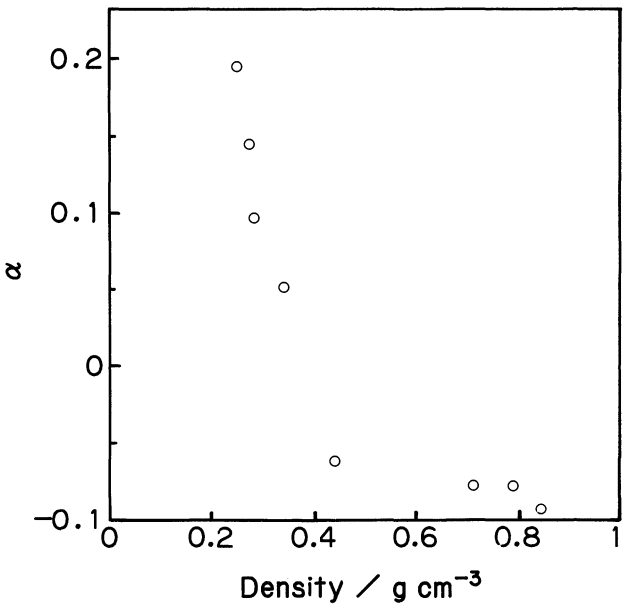

Fig. 1. Plot of α versus density of supercritical carbon dioxide at 318 K.

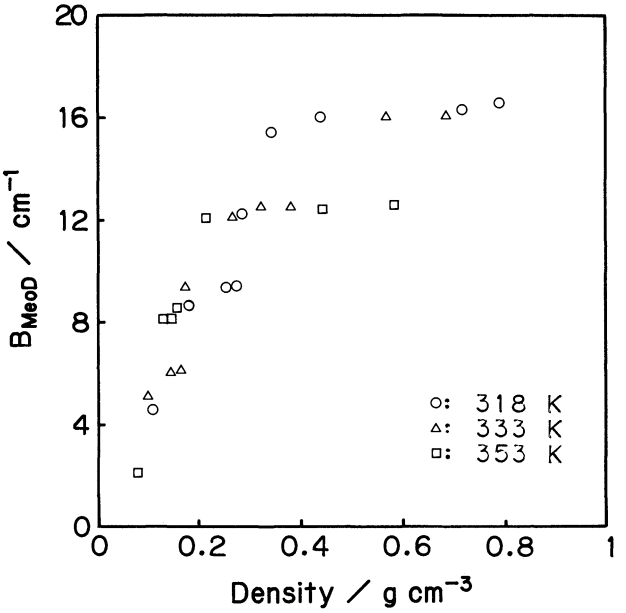

Fig. 2. Plots of B_{MeOD} versus density of supercritical carbon dioxide at (○) 318, (△) 333, and (□) 353 K.

$$R\text{-}O^{\delta\ominus}\text{-}H^{\delta\oplus} + |X\text{-}H \rightleftarrows R\text{-}O^{\delta\ominus}\text{-}H^{\delta\oplus}\cdots X\text{-}H. \quad (8)$$

Here, X=B, C, N, S, etc. In accordance with Eq. 8, the $\nu_{O\text{-}D}$ IR stretching absorption band of methanol-*d* (CH_3OD) undergoes larger bathochromic shifts in less dipolar HBA solvents, compared with those observed in dipolar non-HBA solvents.[35] Thus, a Lewis basicity parameter, B_{MeOD}, has been introduced based on measurements of the O-D IR stretching frequency of CH_3OD, as follows:[36,37]

$$B_{MeOD} = \nu^{\circ}{}_{MeOD} - \nu_{MeOD\cdots B}, \quad (9)$$

where $\nu^{\circ}{}_{MeOD}$ and $\nu_{MeOD\cdots B}$ are the O-D IR stretching frequencies of CH_3OD in the gas phase ($\nu^{\circ}{}_{MeOD}$[36]=2720 cm^{-1}) and in a given solvent, B, respectively. This Lewis basicity parameter, B_{MeOD}, can be linearly correlated well with the Kamlet-Taft parameter, β,[38] with $r>0.98$.[16,29,34] The β- and B_{MeOD}-values for supercritical carbon dioxide can bear the same linear relationship together with a number of organic solvents. Figure 2 indicates the values of B_{MeOD} for supercritical carbon dixide at 318, 333, and 353 K as a function of the density. The B_{MeOD}-value is gradually enhanced as the density increases and reaches 16 cm^{-1} in the range of higher densities above 0.4 g cm^{-3} at 318 and 333 K; the Lewis basicity of supercritical carbon dioxide is found to increase with density. In addition, the B_{MeOD}-value does not seem to show a distinct temperature dependence, except that the values at 353 K are somewhat lower than those at 318 and 333 K at higher densities. The B_{MeOD}-value of hexane is 24 cm^{-1}, the lowest among the organic solvents examined.[35] The B_{MeOD}-value of supercritical carbon dioxide is maximally 16 cm^{-1} under the above-mentioned conditions and is comparable to that of hexane; supercritical carbon dioxide can be regarded as being a non-HBA solvent. The values of β of supercritical carbon dioxide at various densities under constant temperatures of 309—315 K were determined by Leffler et al.[16] based on solvent shifts of the absorption of 4-nitroaniline and *N*,*N*-diethyl-4-nitroaniline. It was reported that since all of the values are either zero or near to zero, the Lewis basicity of supercritical carbon dioxide is negligibly small. However, the density-dependence of the Lewis basicity (as described above) could not be confirmed by the UV/vis method.

Temperature- and Pressure-Dependence of the Dipolarity/Polarizability Parameter, π^*. As shown above, the α-value of supercritical carbon dioxide is very small at densities larger than 0.3 g cm^{-3}. The B_{MeOD}-value is also small at densities lower than 0.2 g cm^{-3} and, even at higher densities, is smaller compared to that of hexane, a low HBA basic solvent.[34] In the following treatment, therefore, the contribution of the HBD acidity and HBA basicity to the solvent properties of supercritical carbon dioxide will not be taken into consideration. Strict treatment is now in progress, including those two parameters, evaluating coefficients *a* and *b* for them in Eq. 1. Eq. 1 can be thus be approximated by Eq. 10 (with $A=\nu$), reducing to

$$\nu = \nu_o + s\pi^*. \quad (10)$$

Here, ν is the frequency of a chromophore in supercritical carbon dioxide. The *s*-values for several indicators have previously been determined.[39-43] The *s*-values for

the C=O stretching frequencies of cyclohexanone, acetone, *N*,*N*-dimethylformamide, and methyl acetate chosen as indicators in the present work are −18.90±0.50, −12.15±0.38, −22.80±0.75, and −15.36±0.73, respectively. The values of ν_0 can also be quoted from the literature.[40-43] One can determine the change in the π^*-value of supercritical carbon dioxide as a function of the temperature and pressure by using Eq. 10 along with the *s*- and ν_0-values.

Figure 3 shows the dependence of the π^*-values on the density of supercritical carbon dioxide at temperatures of 318, 333, and 353 K. The mean values of the π^*-values measured for the four indicators are plotted in those figures. Figure 3 includes the value obtained by Essfar et al.[44] for a vacuum at temperatures between 278 and 345 K. The π^* vs. density plot at each temperature is extrapolated to the intercept with the vacuum system. The intercept at 318, 333, and 353 K calculated by a first-order least-squares method give values of −1.03, −0.95, and −1.17, respectively; the mean is −1.05 and agrees closely with a π^*-value of −1.06±0.10 for a vacuum, obtained by Essfar et al.[44] Furthermore, the extrapolated π^*-values determined at different temperatures are the same within the experimental errors, indicating the insensitivity of π^* to the temperature. The π^*-values for supercritical carbon dioxide from shifts of the absorption maxima of several kinds of indicators in the UV/vis spectra have been reported in the literature; the π^*-values for carbon dioxide at 6.89 MPa and 315 K estimated by Hyatt[45] using dyes as indicators are −0.52 to −0.60, and are close to our π^*-value of −0.40 at 6.86 MPa and 318 K. With regard to the effect of the temperature on π^*, the values at 317 and 335 K and 10 MPa measured by Yonker and Smith[46] using 2-nitroanisole are −0.18 and −0.42, respectively; our values at 318 and 333 K and at 9.81 MPa are −0.15 and −0.38, respectively, in good agreement with their results within experimental errors. These show a high reliability in the measurements of the π^*-values for supercritical carbon dioxide by our IR method. The average π^*-values for carbon dioxide at different pressures, and around 313 K using ten indicators, were reported by Leffler;[16] these are also plotted with error ranges in Fig. 3. It has been found that the discrepancy in π^* due to the indicators in this UV/vis method is remarkably larger compared with that in our IR method. This might be because, in this work, the shifts for the C=O stretching vibrations of indicators are used for determining the π^*-values, and the diffence in the degree of C=O dipolarity among the indicators (which reflects the relative contribution of the two mesomeric forms) is less than that in the UV/vis method using entirely different types of indicator molecules.

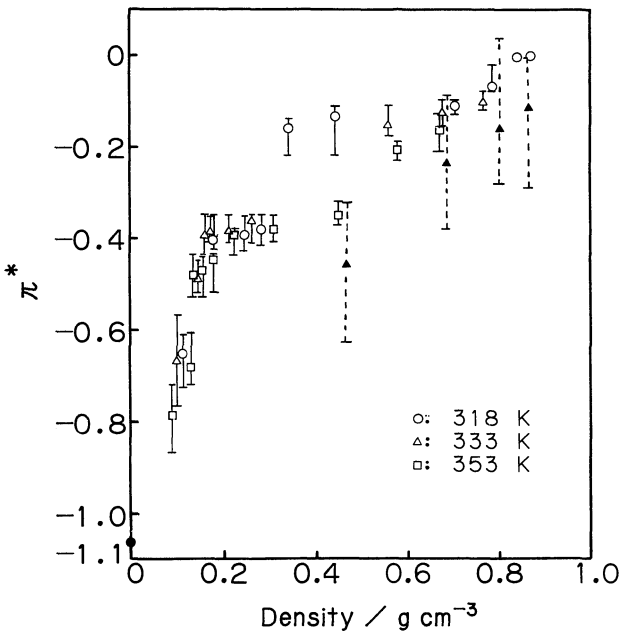

Fig. 3. Plots of π^* versus density for supercritical carbon dioxide at (○) 318, (△) 333, and (□) 353 K. The mean values of the data are plotted by the symbols ○, △, □ and the bars given are the data ranges: ●, π^* for vacuum at temperatures between 298 and 345 K determined by Essfar.[44] ⊢−▲−⊣, the mean π^*-values with error ranges measured at 309—315 K by Leffler.[16]

As shown in Fig. 3, the π^*-value decreases from a value near to zero (or zero) to a more negative value as the density decreases; it becomes more negative at higher temperatures in the range above about 10 MPa. From Fig. 3, irrespective of the temperature, the π^*-value decreases with a decrease in the density. The π^*-values of supercritical fulids have previously been reported to be dependent on the density, but not on temperature;[47] this agrees with the present result given in Fig. 3.

Estimation of the $E_T(30)$-Value. The $E_T(30)$ parameter has been shown to be related to the polarization of solvent molecules through linear relationships using the Kirkwood function and the Onsager reaction field function,[48] while the transition energy for the dissolved betaine dye has been demonstrated to have a linear dependence on the Kamlet-Taft's parameters.[29] According to Bekárek,[48] the $E_T(30)$-values for a set of 24 solvents including nonpolar liquids can be correlated with the π^* parameter, the Kirkwood function $[f(\varepsilon)=(\varepsilon-1)/(2\varepsilon+1)]$, and the Onsager reaction field function $[f(n^2)=(n^2-1)/(2n^2+1)]$ by Eq. 11:

$$E_T(30) = 31.84 + 10.61\pi^* f(\varepsilon)/f(n^2) - 10.85\pi^*,$$
$$r = 0.984, \text{ and } SD = 0.86. \quad (11)$$

Using the π^*-values determined in the present work in the above relationship, one can calculate the value of $E_T(30)$ of supercritical carbon dioxide as a function of the temperature and pressure. The refractive index and the dielectric constant for supercritical carbon dioxide as a function of the temperature and pressure can be determined from the Lorents-Lorenz equation and a virial expansion of the Clausius-Mossotti function with

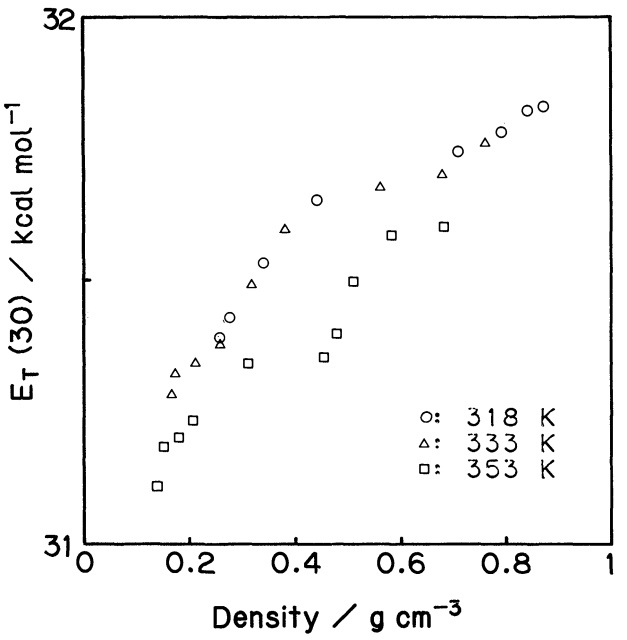

Fig. 4. Relationship between $E_T(30)$-values estimated by Eq. 11 and density of supercritical carbon dioxide at (○) 318, (△) 333, and (□) 353 K.

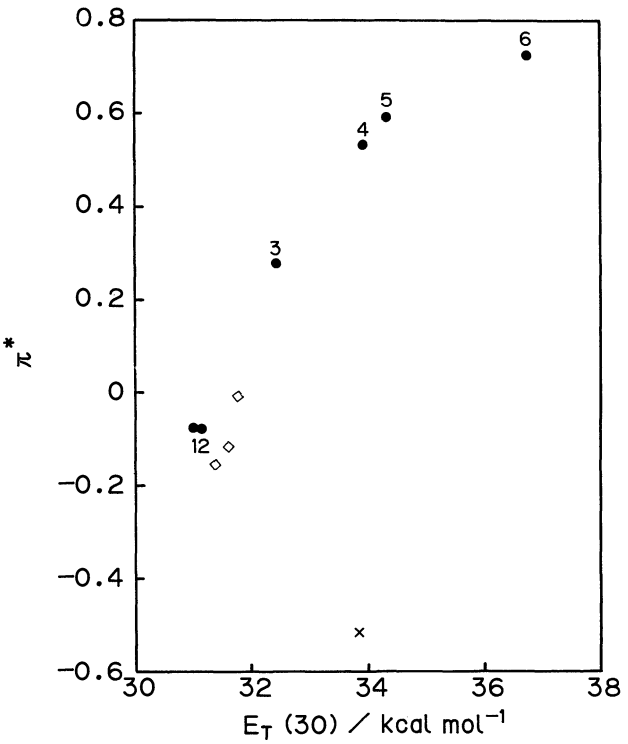

Fig. 5. Relationship between $E_T(30)$- and π^*-values[29] for 1, hexane; 2, heptane; 3, tetrachloromethane; 4, toluene; 5, benzene; 6, chlorobenzene; ◇, supercritical carbon dioxide at 318 K estimated in this work; ×, supercritical carbon dioxide at 297 K and 6.9 MPa reported by Hyatt.[45]

respect to density, respectively:

$$(n^2 - 1)/(n^2 + 2) = A_R\rho_m + B_R\rho_m^2 + \cdots \quad (12)$$

and

$$(\varepsilon - 1)/(\varepsilon + 2) = A_E\rho_m + B_E\rho_m^2 + \cdots, \quad (13)$$

where ρ_m is the molar density; A_R and B_R the first and second refractivity virial coefficients, respectively; and A_E and B_E the first and second dielectric virial coefficients, respectively.[49,50] The refractivity (A_R, B_R) and dielectric virial coefficients (A_E, B_E) for carbon dioxide have been reported by Bose and St-Arnaud[49] and Johnston and Cole.[50] The refractive index and the dielectric constant determined by substituting the corresponding virial coefficients into Eqs. 12 and 13 are used for calculating $f(n^2)$ and $f(\varepsilon)$ for supercritical carbon dioxide.

Figure 4 shows the $E_T(30)$-values for supercritical carbon dioxide at 313, 333, and 353 K as a function of the density. The $E_T(30)$-value increases with an increase in the density, and seems to be not much dependent on the temperature, although in the range of about 0.4—0.6 g cm^{-3} the $E_T(30)$-values at 353 K are only slightly lower, compared with those at 318 and 333 K.

Figure 5 shows the relationship between the π^*- and $E_T(30)$-values for solvents that have very low HBD acidities and HBA basicities (α, $\beta<0.1$), including supercritical carbon dioxide. The $E_T(30)$-values for supercritical carbon dioxide are linked to the relationship for the other solvents, as shown in Fig. 5; the $E_T(30)$-values for supercritical carbon dioxide estimated by the present method are believed to be both reasonable and reliable results. Although the $E_T(30)$-value for supercritical carbon dioxide at 6.9 MPa and 297 K (estimated by Hyatt[45]) is 33.8 kcal mol^{-1}, supercritical carbon dioxide scarcely contains a hydrogen-bonding contribution; in Figure 5 the $E_T(30)$-value (given as symbol (×)) seems to be only slightly greater than that expected from the π^*-values of −0.07[46]—−0.20[16] of supercritical carbon dioxide determined at around 6.9 MPa and 297 K. The reason for this discrepancy is unknown.

Conclusions

Although the B_{MeOD}-value increases with density, the value is very small and almost the same as that for hexane. The α-value is also relatively small, although it tends to increase with a decrease in the density in the range below 0.44 g cm^{-3}. The π^*-values of supercritical carbon dioxide at 5.85—28.5 MPa and 318—353 K are determined using the displacements of the IR stretching frequencies of the same chromophore of the four indicators based on the assumption that the B_{MeOD}- and α^*-values are negligibly small. The π^*-value become more negative as the pressure decreases. The π^*-value decreases with temperature above 10 MPa, but is scarcely dependent on the temperature at lower pressures. The

π^*-value deterrmined by the IR method is found to be highly reliable and the discrepancy in the π^*-values due to the indicators in this IR method have the advantage of being smaller than that in the UV/vis method. The $E_T(30)$-values for supercritical carbon dioxide have been estimated by using the π^*-values determined in this study as well as the $f(\varepsilon)$ and the $f(n^2)$ functions. The $E_T(30)$-value increases with an increase in density. The $E_T(30)$-value can be well-correlated with the π^*-value together with other nonpolar organic solvents, and the estimated $E_T(30)$-values are believed to be reliable.

Computational Studies of the Isomerization Pathways of Isocyanic Acid HNCO

Keiichi YOKOYAMA, Shin-ya TAKANE, and Takayuki FUENO*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received April 18, 1991)

Paths of isomerizations of isocyanic acid HNCO into various chain isomers via ring intermediates have been investigated by ab initio MO calculations with the MRD-CI procedure employing the 6-31G** basis sets. Geometry optimizations were accomplished at the RHF, UHF, or CASSCF level of theory. It is found that the isomerization from HNCO to cyanic acid HOCN is energetically the most favorable and that it should proceed via successive 1,2-hydrogen migrations rather than by a single 1,3-hydrogen migration. The overall barrier height is calculated to be 423 kJ mol^{-1}, which is ca. 60 kJ mol^{-1} higher than the critical energy for the main decomposition channel, HNCO→NH($^3\Sigma$)+CO. Implications of the results to the kinetics of the thermal decompostion of HNCO at high temperatures are discussed.

Isocyanic acid HNCO decomposes mainly into NH ($^3\Sigma$)+CO in the temperature region above 2000 K.[1-3] Another bond dissociation channel to produce H+NCO has been reported to contribute by less than 5% to the total HNCO consumption.[3] In addition to these two dissociation channels, we observed an indication of the occurrence of an apparent "direct" decomposition leading to CN+OH at higher temperatures.[4]

	$\Delta H°_0$/kJ mol^{-1}	
HNCO + M → NH($^3\Sigma^-$) + CO + M	361	(1a)
→ H + NCO + M	474	(1b)
→ CN + OH + M	574	(1c)

This last process must involve an initial isomerization of HNCO into HOCN or HONC. Characteristics of the saddle points for the isomerizations are of particular interest in this connection.

Potential energy surfaces for various isomers of the four-atomic HCNO entity were first studied by Poppinger, Radom, and Pople[5] using ab initio MO calculations at the RHF/4-31G level of theory. Their study has revealed that the surfaces are complicated with many potential wells corresponding to various chain isomers and ring isomers. Thus, a number of isomerization pathways would have to be considered in order to clarify the dynamical mechanism of reaction (1c).

The isomerizations we will consider in the present work include the following:

HNCO → $\overline{\text{HCON}}$ → HOCN	(2a)
→ HONC	(2b)
→ HCNO	(2c)
HNCO → $\overline{\text{HNCO}}$ → HOCN	(2d)

where both $\overline{\text{HCON}}$ and $\overline{\text{HNCO}}$ denote ring structures while the remaining species are chain isomers. Theoretical assessments of the relative eases of the various isomerization processes at the split-valence+polarization+correlation level are the principal concern of this work.

Method

Geometry optimizations for the minimum energy structures and the saddle points were carried out by the SCF procedure with the energy gradient technique. For a ring intermediate and the relevant transition states(TS), the complete-active-space (CAS) SCF procedure was utilized.

At all the stationary points located, the multi-reference single- and double-excitation (MRD) configuration-interaction (CI) calculations were carried out to obtain the electronic correlation energy. For singlet state the configurations whose contributions $|c_i|^2$ to a state exceed 0.25% were all regarded as the main (reference) configurations. In the case of triplet states, however, we were obliged to loosen the weight limit to $|c_i|^2$=1.0% because of otherwise too many configurations selected for handling properly. Triplet state energies might thus be somewhat inaccurate. At any rate, the lowest configuration-selection threshold T was deliberately assigned a value between 1 and 30 μhartree, so that the maximal dimension of the configurational space fell in the region 7000—9000. Four successive threshold values increasing stepwise by 5 μhartree each were used to obtain the CI energy extrapolated to T=0 hartree. Further, the generalized Langhoff-Davidson approximation[6,7] was used to correct for possible errors which might arise from the use of a limited number of reference configurations. The CI energies thus corrected are regarded as estimates of full CI values,[7,8] which will be denoted as E_{CI}. The iterative natural-orbital CI method was applied occasionally with two or three cycles at each state.

All calculations were done by using the 6-31G** basis set. The Gaussian 86[9] and HONDO7[10] programs were used for SCF optimization calculations, and the TABLE

MRD-CI program furnished by Buenker[11,12] was used for CI calculations.

Results

(A) Chain Isomers. For molecular entities constituted of one each of the H, C, N, and O atoms, several isomeric structures are conceivable. Under the constraint that the H atom is attached to the terminal heavy atom (C, N, or O), one can anticipate six chain structures as follows:

HNCO	HOCN	HCNO
1	**2**	**3**
HNOC	HONC	HCON
6	**4**	**5**

Preliminary STO-3G calculations have shown that the entities **1**—**4** indeed possess the restricted Hartree–Fock (RHF) SCF minima at their respective chain structures. By contrast, the entity **6** is liable to dissociate into NH+CO, and the entity **5** tends to cyclize into the form HCON upon geometry optimizations. Although the four chain isomers have already been the matter of thorough investigations by Teles et al.,[14] we also treat these molecules here for the sake of quantitative considerations of the potential energy profiles for isomerizations.

Geometries of the four chain isomers **1**—**4** optimized by the restricted Hartree–Fock (RHF) SCF procedure employing the 6-31G** functions are shown in Fig. 1. Their energies at the RHF and MRD-CI levels are listed in Table 1. HNCO (**1**, isocyanic acid) is a well-known stable entity, and HCNO (**3**, fulminic acid) has been recognized as an isomer that can exist in the gas phase. However, HOCN (**2**, cyanic acid) and HONC (**4**, isofulminic acid) have been observed only in the rare gas matrices.[14,15] The relatively low total energy calculated for **2** suggests the possibility that it could be detected in the gas phase. The quasi-degeneracy noted between **3** and **4** at the RHF SCF level is released at the CI level. The relative energies deduced by the present CI calculations agree reasonably well with the coupled-

cluster double-excitation (CCD) energies reported by Teles et al.[14]

The dissociation energies D_0 calculated for HNCO (**1**) in particular are listed in Table 2, together with the experimental enthalpy change, ΔH°_0.[16] Zero-point energy corrections were made by use of the experimental vibrational frequencies.[16] Theoretical dissociation energies D_0 are in fairly good agreement with the experimental ΔH°_0 values.

(B) Ring and Branched Isomers. For the entities **5** and **6**, we took a step further to carry out the perfect-pairing multi-configuration (PPMC) SCF calculations[13] with the STO-3G basis set. The active space included eight orbitals accommodating six electrons (8,6) with only double excitations permitted.

In the PPMC/STO-3G optimization for the entity HCON (**5**), use of the initial RHF MO's gave an apparent ring structure, whereas use of the initial guess molecular orbital (MO) coefficients prepared from a UHF solution (diradical type MO's) resulted in a curious ring-like structure in which the OCN angle exceeded 90°. The latter form may be visualized as a "branched" structure. The discrepancy is probably because of an unavoidable incompleteness in the configuration space utilized rather than due to the presence of two hardly distinguishable electronic states.

In the RHF/6-31G** optimization of **5**, no ring isomer has been found. All initial guess geometries we tried led to the potential well of HNCO (**1**). The tendency is similar to that reported by Poppinger et al. using the 4-31G basis set.[5] On the other hand, the UHF/6-31G** optimization has given a branched structure with the OCN angle being 123.5°. The branched isomer is strongly spin-polarized and its eigenvalue of the $\hat{S}^2$ operator is $S^2=1.16$, indicative of a strong diradical character. The two odd electrons are localized mainly on the in-plane orbitals of the O and N atoms.

In order to settle this problem, we performed CASSCF/6-31G** optimization in which four frontier orbitals were invoked for four electrons (4,4) to be accommodated. Both the diradical and the closed-shell type MO coefficients were used as initial guess. As a result, the optimized geometries have proved to be identical, showing a structure intermediate between the ring the the branched forms. The electronic structure found is such as described with two major configurations, one being of the diradical type while the other, the closed-shell type:

$$\cdots(1a'')^2(8a')^2(2a'')^2(9a')^1(10a')^1,$$

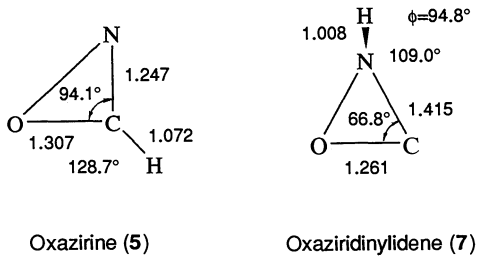
$$\cdots(1a'')^2(8a')^2(2a'')^2(9a')^2.$$

Their CI coefficients are 0.84 and −0.46, respectively.

Figure 2 shows the structure for HCON (**5**) in its electronic ground state optimized by the CASSCF(4,4) procedure assuming Cs symmetry. The remarkable feature is that its OCN angle is 94.1°, with the O–N bond index of ca. 0.5. These values indicate that **5** in its ground state takes a "half-ring structure". The normal ring species called oxazirine, which was proposed as a reaction intermediate in matrix experiments,[17,18] has still been unknown. We will here refer to the half-ring isomer as "oxazirine" and simply regard it as a ring isomer.

Table 3 lists the geometric parameters and the CI energies for the ground-state oxazirine (**5**) and its three excited states. All these excited states are low-lying and have branched structures with the OCN angle of ca. 120°. Both the $^3A''$ and $^1A''$ states to be regarded as formylnitrene have their odd electrons in the nearly degenerate in-plane and out-of-plane p orbitals of the N atom.

The ring isomer in which the H atom is attached to the N atom, HNCO (**7**, oxaziridinylidene), was suggested by



Oxazirine (**5**) Oxaziridinylidene (**7**)

Fig. 2. Optimized geometries of the isomers. The bond lengths are given in units of Å. ϕ indicates the dihedral angle ϕ_{HNCO}.

Table 3. Geometries and Energies of the Cyclic HNCO Isomers

State	Geometry					Energies

Poppinger et al.[5] We have confirmed that it lies in a potential well on the RHF/6-31G** surface as well. It has a nonplanar structure with the HNCO dihedral angle ϕ=94.8°, as can be seen in Fig. 2. Its CI energy is listed in Table 3. The high energy value (504 kJ mol^{-1} relative to HNCO) makes us suspect that the potential well will be shallow. The situation will be clarifed with the results of MRD-CI calculation for the transition state of its ring opening reaction to form HNCO (**1**).

(C) Isomerizations. We examined four isomerization pathways (2a)—(2d). All these pathways from HNCO (**1**) consist of two steps involving a cyclic intermediate **5** or **7**. We denote the transition state of the cyclization of **1** to **5** as TS1. The transition states from **5** to **2**, **3**, and **4** will be denoted as TS2, TS3, and TS4, respectively. TS5 stands for the transition state for the ring-closure of **1** giving **7**, and TS6 for that of the path from **7** to **2**. All these elementary steps involved are diagrammatically illustrated in Fig. 3.

Since neither UHF nor RHF calculation can describe the electronic state of **5** properly, we have carried out CASSCF(6,10) optimizations to determine the geometries of TS1 and TS2. The geometries obtained are shown in Fig. 4. TS2 on the UHF surface was also examined for the sake of comparison with the CASSCF geometry. It can be seen that the goemetry of TS2 is sensitive to the extent of assessment of correlation energy. Either way, TS2 is structurally more HOCN(**2**)-like than is TS1. TS1 is more HNCO(**1**)-like, as it should be.

Strictly speaking, TS2 was found to be slightly nonplanar at the CASSCF level, the dihedral angle ϕ (HNCO) being 0.5°. Since vibrational analysis at the CASSCF level is a formidable task, we carried out the analysis by the UHF procedure at the planar TS2 (UHF) geometry, to confirm a single imaginary frequency being 2362i cm^{-1}. Assumption of the Cs symmetry for TS2 will cause no serious error.

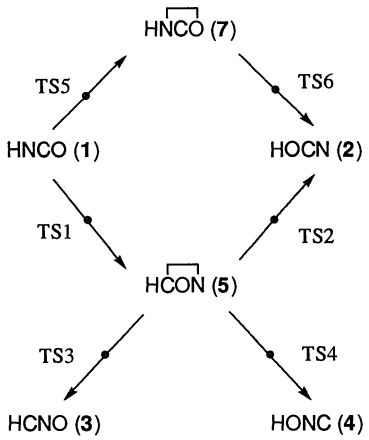

Fig. 3. Isomerization pathways of HNCO (**1**). TS 1—6 denote the SCF saddle points on the isomerization pathways indicated with arrows.

TS3 and TS4 are responsible for the formations of **3** and **4**, respectively, from the cyclic intermediate **5**. Their geometries obtained by the RHF SCF procedure are shown in Fig. 4.

The remaining transition states, TS5 and TS6, are related to the isomerization of **1** to **2** via the cyclic intermediate **7**. The first saddle point, TS5, was found only on the UHF surface and its geometry (Fig. 4) proved to closely resemble that of **7**. On the contrary, TS6 was found on the RHF surface. Its geometry is also shown in Fig. 4. Both TS5 and TS6 were confirmed to have a single imaginary frequency of vibration.

All the transition state structures, TS1 through TS6, were then subjected to the MRD-CI calculations. The CI energies obtained are summarized in Table 4. The relative energies ΔE_{CI} are the values expressed by taking HNCO (**1**) as the common standard.

Figure 5 diagrammatically illustrates the calculated potential energy profiles for all the isomerization pathways considered here. It is apparent that the most favorable isomerization pathway of HNCO (**1**) is reaction (2a), which proceeds through the cyclic intermediate HCON (**5**) to give HOCN (**2**). In a sense, it is a suc-

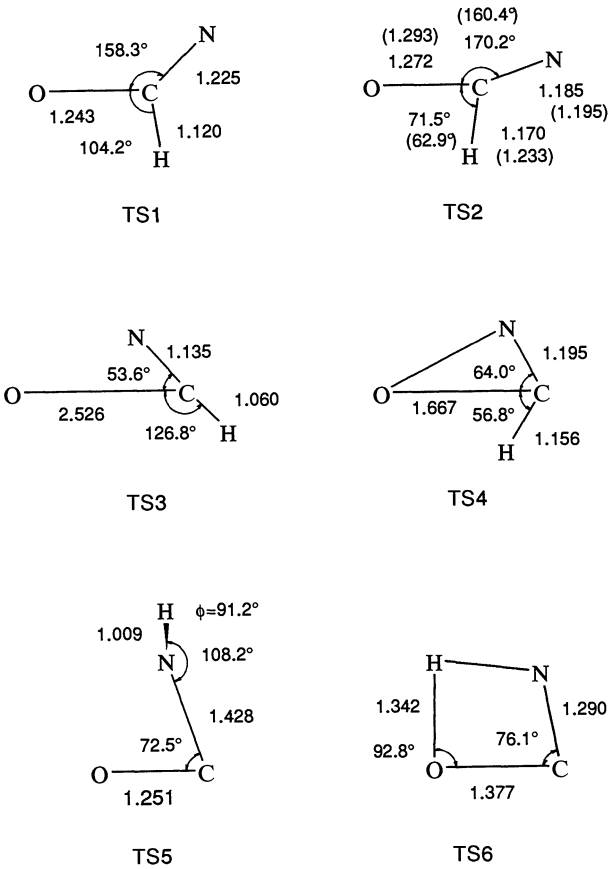

Fig. 4. Optimized geometries of the transition states for isomerizations. The bond lengths are given in units of Å. The figures given in parentheses for TS2 are the bond lengths and angles obtained by the UHF SCF procedure.

Table 4. MRD-CI Energies for the Transition States of Various Isomerizations

TS	Reaction	Method	E_{SCF}+167 / hartree	E_{CI}+167 / hartree	ΔE_{CI}[a] / kJ mol^{-1}
TS1	**1**→**5**	CAS (6,10)	−0.63668	−1.11305	354
TS2	**5**→**2**	CAS (6,10)	−0.62758	−1.08653	423
TS3	**5**→**3**	RHF	−0.54022	−0.98838	681
TS4	**5**→**4**	RHF	−0.50022	−1.00423	639
TS5	**1**→**7**	UHF	−0.58488	−1.05843	497
TS6	**7**→**2**	RHF	−0.51115	−1.00929	626

a) Relative to HNCO (**1**).

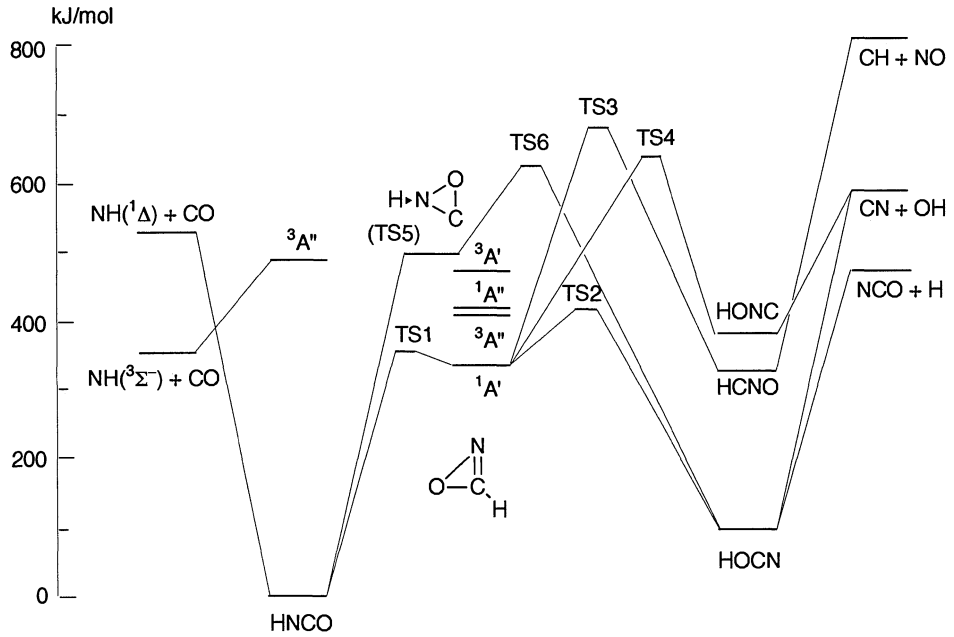

Fig. 5. Potential energy profiles of the HNCO systems calculated by the MRD-CI/6-31G** computations.

cession of two 1,2-hydrogen migrations. Its overall TS is TS2, the net barrier height being 423 kJ mol^{-1}.

Another pathway of isomerization of **1** to **2** is reaction (2d), which involves the cyclic intermediate HNCO (**7**). According to the present CI calculations, however, the TS for the initial cyclization, i.e., TS5, is more stable than **7**. Hence, the existence of **7** as an intermediate is dubious, in contradiction to the conclusion reached by Poppinger et al.[5] on the basis of the SCF/4-31G calculations. The overall reaction should thus be regarded as a one-step 1,3-hydrogen migration passing over TS6. Because TS6 lies much higher (626 kJ mol^{-1}) than does TS2, the 1,3-hydrogen migration (2d) will be far less important than reaction (2a).

In both reactions (2b) and (2c), the second steps seem to be rate-controlling. Since the net barriers TS3 and TS4 lie at much higher energy levels (681 and 639 kJ mol^{-1}, respectively) as compared to TS2, reactions (2b) and (2c) will both be much less favorable than reaction (2a).

Discussion

All the isomerization reactions considered in this work have been presumed to proceed through a cyclic intermediate, **5** or **7**. Oxazirine (**5**) is calculated to lie in energy minimum even though the barrier (TS1) preventing its transfomation into HNCO (**1**) is low (only 12 kJ mol^{-1}). On the other hand, oxaziridinylidene (**7**) does not seem to be a stable entity; it is liable to be led to the HNCO (**1**) minimum with no activation barrier at all. It should be noted that both these conclusions based on CI calculations are just opposite to the views presented by Poppinger et al.[5] at the SCF level.

Direct isomerizations may deserve attention as well. Among others, the HONC (**4**)–HOCN (**2**) isomerization is likely to be an elementary reaction of the well-documented isonitrile-nitrile rearrangement type.[19,20] Practically, however, formation of **4** from **1** requires a high activation energy, so that the direct isomerization in question will have little significance in the present context.

The most important point to be noted in this work is the demonstration that the two-step isomerization reaction of HNCO (**1**) to HOCN (**2**), i.e., reaction (2a), is energetically the most favorable process. The net activation barrier (TS2) lies 423 kJ mol^{-1} above HNCO (**1**). Corrected for the vibrational zero-point energy, the barrier height is slightly lowered to 411 kJ mol^{-1}, which is only modestly higher than the experimental activation energy (355±4 kJ mol^{-1}) reported recently by Wu et al.[3] for the main decomposition reaction (1a) of HNCO. Thus, reaction (2a) could well be an unignorable side reaction of reaction (1a) particularly at high temperatures. HOCN (**2**) thus formed will be liable to decompose into H+NCO, just as HNCO (**1**) is partly led to the same fragments beside the principal decomposition products NH($^3\Sigma^-$)+CO.[3] At still higher temperatures, formation of CN from **2** may be feasible. Our observation of a sizable amount of CN radicals in the shock-heated decomposition of HNCO in the high temperature region (2500—3500 K) could only be rationalized from this view. The anomalously low heat of formation of the CN radical at high temperatures (ΔH°_f at 3000 K being 221.3 kJ mol^{-1} as compared to 436.8 kJ mol^{-1} at 0 K)[16] may assist this formation of CN in the high temperature region.

Conclusion

Ab initio MO calculations based on the MRD-CI method reveal that the isomerization reaction HNCO→HOCN can compete with the primary decomposition channel HNCO→NH($^3\Sigma$)+CO. The isomerization consists of two 1,2-hydrogen migrations with an intermediacy of oxazirine, a half-ring isomer HC(O)N. The transition state of the second step HC(O)N→HOCN constitutes the overall barrier top. Both the intermediate and the transition state are sensitive to the degree of assessment of the correlation energy involved.

This work was supported by the Grants-in-Aid Nos. 62303002 and 02303002 from the Ministry of Education, Science and Culture. The authors are grateful to Professor R. J. Buenker for supplying his Table MRD-CI program to them. All calculations were carried out on a HITAC M-680 at the Computer Center of the Institute for Molecular Science. The authors thank the Center for an allocation of CPU time.

Selective Isomerization of 1,5-Cyclooctadiene to 1,4-Cyclooctadiene Catalyzed by Bis(acetylacetonato)nickel–Triethyldialuminum Trichloride–Phosphorus Ligand

Yasumasa SAKAKIBARA,* Isao YAMAMOTO, Ken SASAKI, Mutsuji SAKAI, and Norito UCHINO
Department of Polymer Science and Engineering, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received January 29, 1991)

The isomerization of 1,5-cyclooctadiene (1,5-COD) with Ni(acac)$_2$–$Et_3Al_2Cl_3$–phosphorus ligand (Ni : Al_2 : P= 1 : 10 : 3) was first examined with varying P ligands in toluene in order to find suitable conditions for the formation of 1,4-COD. The product distribution depended largely on the P ligands. For several phosphites possessing very strong π-acceptor properties, the main product was 1,4-COD. In particular, the less-bulky bicyclic phosphite, 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane (L-**3**) was very effective and gave 1,4-COD in a high selectivity of 93% at 66% conversion (1,5-COD/Ni=500, molar ratio) by employing a low temperature of −30 °C. However, the reaction stopped before reaching completion because the catalyst was deactivated by the accumulation of 1,4-COD product. The conversion, depending on the 1,5-COD/toluene ratio (volume) rather than the 1,5-COD/Ni ratio, increased with a decrease in the 1,5-COD/toluene ratio and was 66—69% at a ratio of 0.19. On the other hand, the catalyst (P: L-**3**) was much less active for 1,4-COD than for 1,5-COD and was deactivated quickly under the same reaction conditions. This appeared to result in a high selectivity of 1,4-COD in the isomerization of 1,5-COD. The mechanistic implications of the experimental results are discussed.

The ordinary methods of preparation of 1,4-cyclooctadiene (1,4-COD) are either tedious[1] or use rather expensive starting materials.[2] Recently, selective isomerization of 1,5-COD to 1,4-COD with homogeneous transition-metal catalysts has been noted and investigated as a method of large-scale synthesis of 1,4-COD.[3] In the isomerization, from the standpoints of the selectivity of 1,4-COD and its separation by fractional distillation, it is desirable to suppress the formation of the 1,3-isomer, which has a boiling point near that of 1,4-COD.

The isomerization of 1,5-COD to 1,4-COD and 1,3-COD has previously been attempted with homogeneous transition-metal catalysts, such as $PtCl_2(PPh_3)_2$–$SnCl_2 \cdot 2H_2O$,[4,5] $PtCl_2(PPh_3)_2$–Ph_3SnCl,[6] $Ru_2(1,5\text{-COD})_2(O_2CCF_3)_2(\mu\text{-}O_2CCF_3)_2(\mu\text{-}OH_2)$,[7] $(\eta^5\text{-}C_5H_5)_2TiCl_2$–*i*-PrMgBr,[8] $Ti(OBu)_4$–Et_3Al,[3] or $Ru_3(CO)_{12}$[9] (vide infra). A satisfactory yield of 1,4-COD, however, has not been obtained because of a subsequent rapid isomerization of 1,4-COD to 1,3-COD under the reaction conditions used. We have observed previously that Ni(acac)$_2$–$Et_3Al_2Cl_3$–phosphorus ligand, which forms an active nickel species, catalyzed the isomerization of 1,5-COD to bicyclo[3.3.0]oct-2-ene (BCO, transannular product), 1,4-COD, and 1,3-COD (double-bond isomerization product) and that the latter two products, especially 1,4-COD, increased with a decrease in the electron-donating ability of the phosphorus ligands.[10] This observation prompted us to study the selective isomerization of 1,5-COD to 1,4-COD with this catalyst system. This paper details the results of our investigation.

Experimental

Materials. Toluene was purified by the ordinary method. 1,5-COD was distilled after drying over metallic natrium. Bis(acetylacetonato)nickel (anh.) and triethyldialuminum trichloride were obtained commercially.

Several phosphorus ligands, tris(*p*-chlorophenyl) phosphite,[11] 2-phenoxy-1,3,2-dioxaphospholane,[12] tri-*o*-tolyl phosphite,[11] and diphenyl phenylphosphonite,[13] were prepared according to the literature methods. Other phosphorus ligands were obtained commercially.

Reaction Procedure. A typical example is detailed below. In a 100 cm^3 flask fitted with a three-way stopcock and a thermometer were placed bis(acetylacetonato)nickel (25.7 mg, 0.10 mmol) and 4-ethyl-2,6,7-trioxa-1-phosphabicyclo-[2.2.2]octane (48.6 mg, 0.30 mmol). Liquid phosphorus ligands were added with 1,5-COD as a toluene solution. After replacing the air with nitrogen, a solution of 1,5-COD (5.41 g, 50 mmol) and propylbenzene (GLC internal standard) in toluene (30 cm^3) was added by syringe while stirring. The reaction was started by adding triethyldialuminum trichloride (1.0 mmol: 2.0 cm^3 of a 0.5 M (1 M=1 mol dm^{-3}) toluene solution) by syringe at −30 °C. The reaction mixture was kept at this temperature for 6 h. Small aliquots of the mixture were withdrawn, if necessary, during the course of the reaction and treated with a methanol–aqueous hydrochloric acid mixture. The organic layer was then separated and subjected to GLC analysis.

Analysis. The gas chromatographic analysis was made by a Shimadzu-GC-4AIT with a TC detector and He carrier gas using a 9-m PEG-20M column at 80 °C.

Results and Discussion

Effect of the Phosphorus Ligands. The isomerization of 1,5-COD with Ni(acac)$_2$–$Et_3Al_2Cl_3$–P ligand (Ni: Al_2 : P=1 : 10 : 3 molar ratio) was carried out at −30 °C and 10 °C in toluene. Various phosphites having π-acceptor properties were used as phosphorus ligands in view of the results of our previous work.[10] The results

are shown, together with $\nu_{CO}(A_1)$ of $Ni(CO)_3L$ and the cone angle (θ) of the P ligands,[14] in Table 1. The effect of the P ligands on the product distribution was remarkable at both temperatures of −30 and 10 °C. Of the various P ligands used, a bicyclic phosphite, 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane (L-**3**), which has the smallest cone angle (θ=101°) and comparatively weak electron-donating ability (ν_{CO}=2086.8 cm^{-1}), gave the best result. At −30 °C, the selectivities of 1,4-COD, 1,3-COD, and BCO were 93, 6, and 1%, respectively, with 66% conversion. It was particularly noteworthy that the subsequent isomerization of 1,4-COD to 1,3-COD was suppressed satisfactorily.

Judging from the ν_{CO} values, strong π-acceptor ligands L-**1**—**6**, which have ν_{CO} values higher than 2084 cm^{-1}, gave 1,4-COD at the major product, while weaker π-acceptor ligands L-**7**—**9** and no ligand gave BCO as the major product.[15] On the other hand, the small cone angle of the ligand favors the formation of 1,4-COD, as indicated by the results with ligands L-**3** (ν_{CO}=2086.8 cm^{-1}, θ=101°) and L-**4** (ν_{CO}=2086.5 cm^{-1}, θ=114°) which have almost the same ν_{CO} values. In conclusion, P ligands such as L-**1** and L-**3**, which are less bulky and have strong π-acceptor abilities, appear to facilitate the formation of 1,4-COD.

With ligands L-**1**—**6**, however, the reaction stopped before reaching completion, e.g., only 66% conversion with ligand L-**3** at −30 °C. Although the rate of the isomerization to 1,4-COD was generally fast at the initial stage, as seen by the values of the conversion at 5 min (Table 1, Footnote c), it dropped rapidly and the reaction stopped prematurely. This termination was found to occur at especially low conversions in the cases of triaryl phosphite-type ligands L-**2**, **5**, and **6** which have relatively large cone angles.

Effect of Temperature and Time. The isomerization was carried out at temperatures ranging from 10 °C to −50 °C in toluene using L-**3** as the P ligand. These results are shown in Table 2. The reaction proceeded more rapidly in the early stages at higher temperatures, as indicated by the variations of conversion with time, but stopped before reaching completion in all runs. For example, the conversion at −30 °C (Run 3) stopped at about 65% for the times ranging from 4 to 6 h, though reaching 62% in just 2 h. In the temperature range of 10 to −30 °C, the conversion of 1,5-COD increased with a decrease in the temperature from 52% at 10 °C to 66% at −30 °C. At the lower temperature of −50 °C, however, the conversion was less than 50% (Run 4). Additionally, the selectivity of 1,4-COD at about 50% conversion increased with a decrease in the temperature from 90% at 10 °C to 96% at −50 °C. This was due largely to the decrease in the formation of BCO. With respect to the values of both the conversion and the selectivity, −30 °C appeared to be the most suitable temperature. The variation of the conversion of 1,5-COD and the selectivity of 1,4-COD with time at −30 °C showed that the isomerization of 1,4-COD to 1,3-COD proceeded much more slowly compared with that of 1,5-COD to 1,4-COD, and that both the isomerizations stopped at almost the same time. It was noteworthy that the Ni–Al_2–L-**3** catalyst favorably suppressed the isomerization of 1,4-COD to 1,3-COD even at a fairly high conversion of 66%, in contrast to several transition-metal complex catalysts previously reported[3-9] (See Table 4). Allinger et al.,[16] who investigated the isomer-

ization equilibrium of the cyclooctadienes, reported that the equilibrium composition in dimethyl sulfoxide at 70 °C is <0.01% 1,5-COD, 0.5% 1,4-COD, and 99.5% 1,3-COD. We have found that the nickel catalyst is not very active in the isomerization of 1,4-COD to 1,3-COD and , in addition, is probably deactivated by the accumulation of 1,4-COD to result in a practical stop of the isomerization of 1,5-COD to 1,4-COD. As an apparent phenomenon concerning the deactivation, it was observed that the color of the reaction mixture changed from its initial reddish-brown to pale yellow as the reaction approached termination.

The use of other solvents was also investigated. With dichloromethane as solvent, the conversion of 1,5-COD increased to 75%, but the selectivity of 1,4-COD decreased to 73%, the selectivities of 1,3-COD and BCO being 20 and 7%, respectively (Table 2, Run 5). With THF as solvent, the isomerization did not occur.

Effect of the Amounts of 1,5-COD and Catalyst. The P ligand L-**3** gave a high selectivity of 1,4-COD, but the reaction stopped at a certain degree of conversion, as described above. In an attempt to increase the degree of conversion, the isomerization was performed at various 1,5-COD/Ni molar ratios and 1,5-COD/toluene volume ratios at −30 °C (Table 3). In all cases, the reaction stopped after several hours without reaching completion, though 1,4-COD was formed in selectivities higher than 92% (except for Run 11 which was carried out in a very dilute solution). When the reaction was performed using 50 mmol of 1,5-COD in 32 cm^3 of toluene (1,5-COD/toluene=0.19), the conversions and catalyst turnovers were 66% and 307 with 0.1 mmol Ni (Run 3), and 69% and 159 with 0.2 mmol of Ni (Run 6), respectively. It is noteworthy that irrespective of the catalyst amount, the conversions are almost the same and the catalyst turnover in the former reaction was about twice that in the latter. A similar result was also observed in the case in which the amount of 1,5-COD was increased from 50 to 100 mmol (1,5-COD/toluene ratio=0.38). The conversions and catalyst turnovers were 52% and 484 with 0.1 mmol of Ni (Run 7), and 54% and 257 with 0.2 mmol of Ni (Run 8), respectively. Thus, it was concluded that the conversion of 1,5-COD did not greatly increase with an increase in the catalyst amount.

On the other hand, the conversion appears to be influenced largely by the dilution of 1,5-COD with toluene, namely, the 1,5-COD/toluene ratio. In fact,

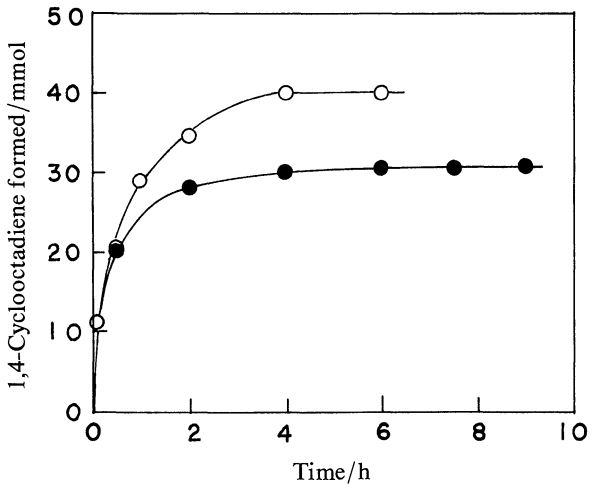

Fig. 1. Addition of 1,5-cyclooctadiene during the course of reaction. Reaction conditions: 1,5-COD, 50 mmol; $Ni(acac)_2$, 0.1 mmol ($Ni:Al_2:L\text{-}3=1:10:3$); Toluene, 32 cm^3; Temp, −30°C. ○: After 0.5 h 50 mmol of additional 1,5-COD was added. ●: After 6 h 50 mmol of additional 1,5-COD was added.

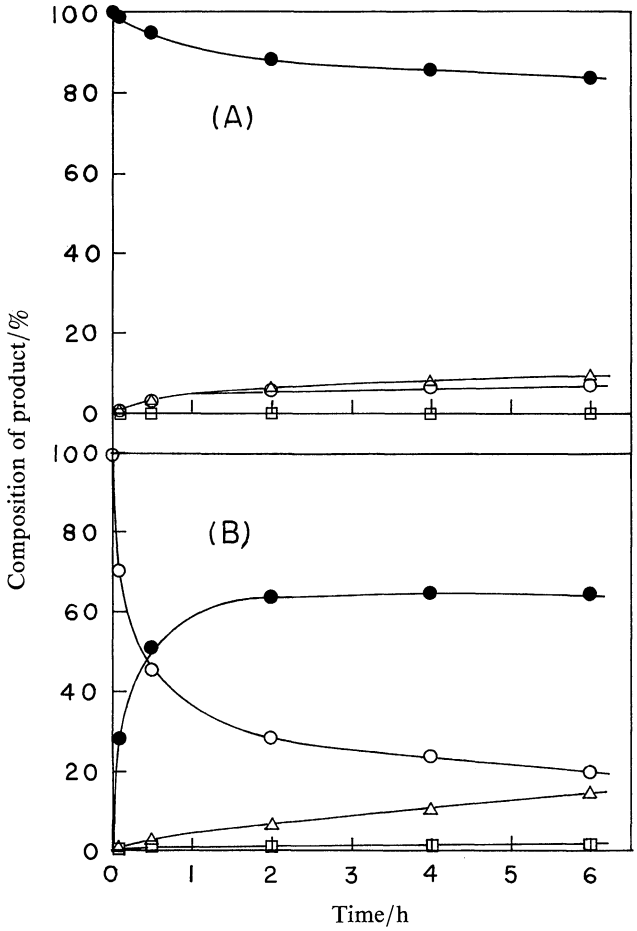

Fig. 2. Isomerization of 1,4- and 1,5-cyclooctadienes. (A): From 1,4-COD; (B): From 1,5-COD. Reaction conditions: COD, 6 mmol; $Ni(acac)_2$, 0.1 mmol ($Ni:Al_2:L\text{-}3=1:10:3$); Toluene, 32 cm^3; Temp, −30°C. ●: 1,4-COD; ○: 1,5-COD; △: 1,3-COD; □: BCO.

the conversion decreased with an increase in the 1,5-COD-toluene ratio, being 66, 54, and 37% at ratios of 0.19, 0.38, and 0.88, respectively, in the case of 1,5-COD/Ni=500 (Runs 3, 8, and 9). Furthermore, when the ratio was 3.5 (no additional toluene was added, only the 0.5 M toluene solution of $Et_3Al_2Cl_3$ was used), the conversion remained at only 16% (Run 10). Conversely, a very dilute solution with a ratio of 0.023 gave a high conversion of 80% (Run 11). From the above results, we have concluded that toluene as solvent contributes to the stabilization of the catalytically active nickel species (vide infra) to result in a higher conversion at a lower 1,5-COD/toluene ratio and that the accumulation of 1,4-COD product deactivates the catalyst. In order to confirm the deactivation of the catalyst, an attempt was made to add additional 1,5-COD to the reaction. The reaction was started under the same conditions as those for Run 3 (Fig. 1). When additional 1,5-COD was introduced after 6 h, at which time the reaction had practically stopped, no further isomerization was observed. On the other hand, when additional 1,5-COD was added after 30 min of reaction, 1,4-COD was obtained in a larger amount than that obtained in the former additional reaction. We interpret this to mean that after 6 h, the catalytically active species are no longer present. Thus, the termination of the reaction is not due to an equilibrium between 1,5-COD and 1,4-COD,[17] but to the deactivation of the catalyst.

The Characteristics of the Catalyst. The isomerization of 1,4-COD with the Ni–Al_2–L-**3** catalyst was investigated in comparison with the isomerization of 1,5-COD (Fig. 2). In both cases, the reaction had stopped practically after 6 h. The conversion of 1,4-COD at that time was only 16% in contrast to 80% cnversion for 1,5-COD. The ratio of the relative initial rates of 1,4-COD to 1,5-COD, calculated based on the conversions at 5 min, was about 0.04. These data, together with the results of the isomerization of 1,5-COD, indicated that the catalytically active species was much less active for 1,4-COD than for 1,5-COD and was rapidly destroyed by the accumulation of the 1,4-COD product.[18] In addition, it was noteworthy that 1,4-COD isomerized to the better-chelating 1,5-COD at almost the same initial rate as that of its isomerization to 1,3-COD (Fig. 2-(A)). As a result, the catalyst suppressed the isomerization of 1,4-COD to 1,3-COD to result in a highly selective isomerization of 1,5-COD to 1,4-COD. Several investigations on the isomerization of 1,5-COD to 1,4-COD are summarized in Table 4. Since the 1,4-COD product isomerizes rapidly to 1,3-COD with catalysts other than ours, the selectivities of 1,4-COD at 45—66% conversions are shown for comparison. With our catalyst, the selectivity was especially high compared with the selectivities of the others. Furthermore, good suppres-

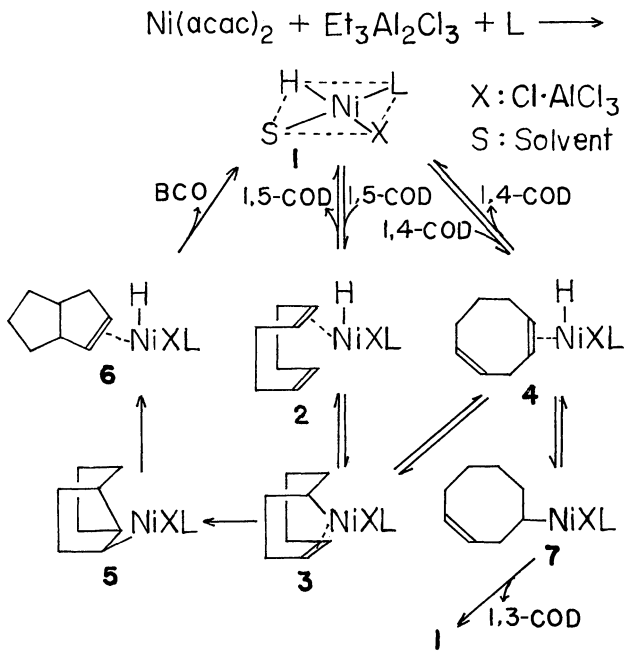
sion of the formation of 1,3-COD is favorable for the isolation of 1,4-COD by distillation,[3,19] because the boiling points of 1,5-COD (150.8 °C/755 mmHg (1 mmHg=133.322 Pa)), 1,4-COD (145.1 °C/758 mmHg), and 1,3-COD (142.7 °C/754 mmHg),[20] (and especially of the latter two), are close to each other.

Mechanistic Implications. In general, the catalyst $Ni(acac)_2$–$Et_3Al_2Cl_3$–P ligand, which in situ generates a specific square planar nickel hydride complex **1**, operates by the addition and elimination of a Ni–H function in double-bond migration.[21] A reaction mechanism, being essentially the same as that described in our previous paper,[10] is proposed to account for the experimental results (Scheme 1). The Ni–H species **1** may coordinates 1,5-COD[22] which then undergoes insertion into the Ni–H bond and subsequent coordination of the second double bond to give a σ, π-cyclooctenyl nickel complex **3**. In complex **3**, a β-H elimination reaction and an intramolecular insertion reaction take place competitively to result in double-bond isomerization (complex **4**) and cyclization (complex **5**) of 1,5-COD, respectively. The isomerization/cyclization ratio depends primarily on the P ligands.[10] The η^2-1,4-COD complex **4** gives 1,4-COD and **1**, and the catalytic cycle recurs.

The Ni–H species **1** with weak σ-donor P ligands may be normally unstable and ineffective for the isomerization of common olefins. In practice, 1,4-COD was only slightly isomerized with the Ni–Al_2–L-**3** catalyst, as shown in Fig. 2-(A), but 4-methyl-1-pentene was not isomerized at all.[18] With 1,5-COD, however, complex **3** would be stabilized by coordination of the second



Scheme 1. Reaction mechanism.

double bond to act as an intermediate in the isomerization of 1,5-COD. In view of the high selectivity of 1,4-COD, it seems likely that the coordinate double bond in **3** is not adequately activated with strong π-acceptor P ligands and therfore **3** undergoes Ni–H elimination in preference to intramolecular insertion. In addition, the less bulky phosphite L-**3** appears to favor the formation of complex **4**, which has a more crowded environment

around the nickel than does complex **5**, compared with bulky phosphites such as L-**4** and L-**5** having almost the same ν_{CO} values. Then, complex **4** would give complex **2** rapidly via the dissociation of 1,4-COD if 1,5-COD exists in large amounts and the double bond in **4** coordinates weakly to the nickel. Thus, the use of strong π-accepting and less bulky phosphites may lead to the highly selective isomerization of 1,5-COD to 1,4-COD.

Next, the deactivation of the catalyst caused by the accumulation of 1,4-COD will be discussed in some detail. In the isomerization of 1,5-COD, while the 1,5-COD/1,4-COD ratio is large, complex **4** may transfer to the stabilized complex **3**, via complex **2** rather than complex **7**. As 1,4-COD is produced with subsequent 1,5-COD depletion, however, the ratios of complexes **4** and **7** to total active nickel species would increase. This seems to relate to the deactivation of the catalytic species in view of the fact that the isomerization of 1,4-COD with the Ni–Al_2–L-**3** catalyst stops at a very low conversion, as described above. However, the deactivation process is not clear at the present time. As a possible process, it may be proposed that, besides undergoing normal β-elimination, complex **7** is converted to the inactive nickel species Ni[L-**3**]$_n$, 1,3-COD, and HX by the action of L-**3**.[23] Consequently, this conversion could result in the termination of the reaction and the suppression of 1,3-COD formation.

Concerning solvents, suitable ones such as toluene and dichloromethane may participate in stabilizing the catalytically active species, in contrast to THF in which the isomerization does not proceed. Therefore, high dilution of 1,5-COD with toluene along with low reaction temperature would bring about its high conversion to 1,4-COD.

15) In this connection, it has been reported that the isomerization of 1,5-COD can be directed to almost complete formation of 1,3- and 1,4-COD by employing trimethylphosphine (ν_{CO}=2064 cm^{-1}, θ=118°) as P ligand and that it is possible, by terminating the reaction before completion, to isolate 1,4-COD in up to 40% yield (B. Bogdanović, "Selectivity Control in Nickel-Catalyzed Olefin Oligomerization," in "Advances in Organometallic Chemistry," ed by F. G. A. Stone and R. West, Academic Press, New York (1979), Vol. 17, p. 105). Therefore, the use of PMe_3 was attempted under our conditions. The result was considerably different from that reported by Bogdanović, but it was observed that PMe_3 gave 1,4-COD in a moderate selectivity of 49%, together with BCO in 45% selectivity, at 48% conversion at 10 °C, in contrast with other trialkylphosphines such as PEt_3 and PBu_3.[10]

17) It has been reported that the isomerization of 1,5-COD to 1,4-COD catalyzed by $Ir_2H_2Cl_2$(1,5-COD) is reversible (M. Gargano, P. Giannoccaro, and M. Rossi, *J. Organomet. Chem.*, **84**, 389 (1975)).

18) Furthermore, the isomerization of an alkene, 4-methyl-1-pentene, with the catalyst Ni–Al_2–L-**3**, was attempted for reference. We found that the catalyst did not have the ability to isomerize the olefin, in contrast with the Ni–Al_2–PPh_3 (L-**9**) catalyst (Y. Sakakibara, M. Mukai, M. Sakai, and N. Uchino, *Nippon Kagaku Kaishi*, **1972**, 1457).

19) In many cases, 1,4-COD is separated from the mixture of 1,3- and 1,4-COD by the method of $AgNO_3$ adduct formation, because the boiling points are close to each other (Ref. 1).

Jolly, "Nickel Catalyzed Oligomerization of Alkenes and Related Reactions," in "Comprehensive Organometallic Chemistry," ed by G. Wilkinson, F. G. A. Stone, and E. W. Abel, Pergamon Press, Oxford (1982), Vol. 8, p. 615.

22) In the 1,5-COD complex **2**, the nickel may also be able to coordinate the second double bond of 1,5-COD (C. A. Tolman and W. C. Seidel, *J. Am. Chem. Soc.*, **96**, 2780 (1974)). In this connection, the relative stability of the various conformations of 1,5-COD was reported to be the following order: twist-boat>chair>boat>twist (N. L. Allinger and J. T. Sprague, *Tetrahedron*, **31**, 21 (1975)).

23) The reaction of acetylacetonato(4-cyclooctenyl)nickel with triphenyl phosphite forms Ni[$P(OPh)_3$]$_4$, 1,3-COD, and Hacac (B. Bogdanović, M. Kröner, and G. Wilke, *Justus Liebigs Ann. Chem.*, **699**, 1 (1966)). In view of the formation of 1,3-COD, it can be assumed that the above reaction proceeds via the isomerization of the 4-cyclooctenylnickel complex to the 3-cyclooctenylnickel complex.

Selenation of 1,5-Naphthoquinones: Novel Synthesis of Naphthopyridoselenazines

Makoto SAKAKIBARA, Tetsuya ISHIDA, Yoshihiko WATANABE, Takeshi TORU, and Yoshio UENO*
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso, Showa-ku, Nagoya 466
(Received February 15, 1991)

Selenation of 2-chloro- and 2,6-dichloro-1,5-naphthoquinones with benzeneselenolate ion, generated from diphenyl diselenide and tributylphosphine in an alkaline medium, afforded 2-phenylseleno- and 2,6-bis(phenylseleno)-1,5-naphthoquinones in excellent yields. Reaction of halo-1,4-naphthoquinones with 3-amino-2-pyridineselenolate ion generated from bis(3-amino-2-pyridyl) diselenide gave naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]-selenazines and pyrido[2,3-*b*]pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*][1,4]selenazines in high yields.

Phenothiazinones[1] and phenoselenazinones[2] are known as potent dyes for semiconductor lasers used for optical information recording media. We previously synthesized 4*H*-benzo[*a*]phenothiazin-4-ones[3] and 4*H*-benzo[*a*]phenoselenazin-4-ones[4] and found that they show absorptions in the near infrared. In a previous report[5] we described a new efficient selenation method for conversion of 2-halo-1,4-naphthoquinones into 2-phenylseleno-1,4-naphthoquinones. We herein describe the application of this new selenation to the synthesis of naphthopyridoselenazines using bis(3-amino-2-pyridyl) diselenide as a selenating reagent. We also report the selenation of 2-chloro- and 2,6-dichloro-4,8-bis(alkylamino)-1,5-naphthoquinones.

Results and Discussion

Preparation of Seleno-Substituted 1,5-Naphthoquinones. We were interested in the reaction site of benzeneselenolate ion to 2-chloro-1,5-naphthoquinones and examined the selenation of 2,6-dichloro- and 2-chloro-4,8-bis(2-propylamino)-1,5-naphthoquinones (**3** and **5**), and 2-chloro-4,8-bis(methylamino)-1,5-naphthoquinone (**6**). We found that 2,6-dichloro- and 2-chloronaphthoquinones **3** and **5** were obtainable by the reaction of 4,8-bis(2-propylamino)-1,5-naphthoquinone[6] (**1**) with bromine in hydrochloric acid in 45 and 26% yield, respectively. Chlorination of 4,8-bis(methylamino)-1,5-naphthoquinone[6] (**2**) in the same manner affored chloronaphthoquinone **6** in 36% yield, together with 2,6-dichloronaphthoquinone **4** (yield 22%) (Scheme 1).

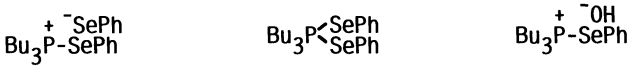
Scheme 1.

With chloronaphthoquinones **3**, **5**, and **6** in hand, we then attempted the selenation. A solution of benzeneselenolate ion was prepared as follows. To a vigorously stirred tetrahydrofuran (THF) solution of 1.10 molar equiv of diphenyl diselenide and 1.20 molar equiv of tributylphosphine, was added 2.20 molar equiv of an aqueous NaOH solution. The mixture was vigorously stirred for 15 min during which time the yellow two-phase solution became colorless and homogeneous, a mixture containing benzeneselenolate ion being formed. The mechanism for the generation of selenolate ion can be postulated as we described earlier:[5] A selenophosphonium ion **I** and/or a pentavalent phosphorus species **II** are initially formed in the reaction of diphenyl diselenide and a phosphine, and addition of NaOH liberates benzenselenolate ion and the phosphonium ion **III**, from which is



I **II** **III**

further generated selenolate ion together with phosphine oxide by the action of NaOH. In line with this mechanism, tributylphosphine oxide was be isolated quantitatively. Treatment of dichloronaphthoquinone **3** with a solution of benzeneselenolate ion thus obtained at room temperature yields bisphenylselenated naphthoquinone in 88% yield. The regioselectivity of the phenylseleno group, however, could not be determined directly on the basis of the spectral data. The structure was eventually assigned as 4,8-bis(2-propylamino)-2,6-bis(phenylseleno)-1,5-naphthoquinone (**7**) by X-ray analysis (see Fig. 1 and Tables 2 and 3). Consequently, the selenation presumably starts with the attack of benzeneselenolate ions on both carbons α to the carbonyl groups, i.e., on each carbon attached to the chloro group, of 2,6-dichloro-1,5-naphthoquinone **3**, followed by β-elimination of chloride ions to form 2,6-bis(phenylseleno)-1,5-naphthoquinone **7**.

The selenation of **5** and **6** using diphenyl diselenide

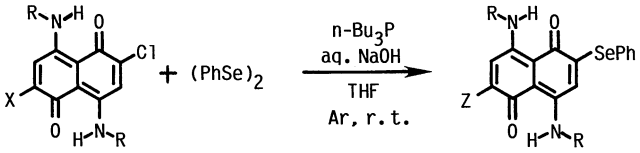
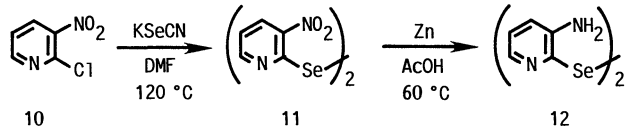


Scheme 2.



Scheme 3.

(0.55 molar equiv), tributylphosphine (0.60 molar equiv), and an aqueous NaOH (1.10 molar equiv) solution afforded phenylselenated 4,8-bis(2-propylamino)- and 4,8-bis(methylamino)-1,5-naphthoquinones **8** and **9** in 94 and 89% yield, respectively. In the ^{1}H NMR spectrum, the protons on C-3 and C-7 of **7** appeared at δ=6.39. The protons on C-3 of **8** and **9** appeared at δ=6.46 and 6.51, respectively. From the mechanistic point of view, as shown above in the selenation of **3** as well as the ^{1}H NMR data, **8** and **9** were tentatively assigned as 4,8-bis(2-propylamino)- and 4,8-bis(methylamino)-2-phenylseleno-1,5-naphthoquinones, respectively (Scheme 2).

Preparation of Naphthopyridoselenazines. Recently we found that the reaction of naphthoquinones with zinc 2-aminobenzeneselenenate, prepared from bis(2-nitrophenyl) diselenide and zinc in acetic acid, gave phenoselenazinones in high yield.[4] In order to prepare naphthopyridoselenazine derivatives in a similar manner as above, we first attempted to prepare zinc 3-amino-2-pyridineselenenate by the reaction of bis(3-nitro-2-pyridyl) diselenide (**11**) with zinc. The reaction, however, did not give zinc 3-amino-2-pyridineselenenate but instead gave bis(3-amino-2-pyridyl) diselenide (**12**) in good yield. Thus, dipyridyl diselenide **12** was obtained in 53% yield by the reaction of 2-chloro-3-nitropyridine (**10**) with potassium selenocyanate in DMF at 120 °C followed by reduction with zinc and acetic acid (Scheme 3). Fortunately, the 3-amino-2-pyridineselenolate ion was found to be generated from the dipyridyl diselenide **12** on treatment with triphenyl- or tributylphosphine in an alkaline medium. An acetonitrile solution of dipyridyl diselenide **12** (0.58 molar equiv) and triphenylphosphine (1.25 molar equiv) was vigirously stirred under argon at room temperature. To this was added an aqueous NaOH (1.08 molar equiv) solution, and the mixture was vigorously stirred for 15 min to give a mixture containing 3-amino-2-pyridineselenolate ion. Treatment of 2-bromo-3-methyl-1,4-naphthoquinone (**13**) with a solution of 3-amino-2-pyridineselenolate ion at room temperature gave 6-methyl-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]selenazin-5-one (**14**) in 91% yield, which would have been formed via selenation and subsequent condensation between the quinone carbonyl and aromatic amino group (or vice versa). 3-Amino-2-pyridineselenolate ion formed from diselenide **12** (0.58 molar equiv) and tributylphosphine (1.25 molar equiv) in place of triphenylphosphine in an alkaline medium (1.08 molar equiv) was also effective, giving **14** in 93% yield. The reaction of 2,3-dichloro-1,4-naphthoquinone (**15**) with 3-amino-2-pyridineselenolate ion generated from diselenide **12** (0.69 molar equiv) and triphenylphosphine (1.46 molar equiv) afforded 6-chloro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]selenazin-5-one (**16**) and pyrido[2,3-

b]pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*][1,4]selenazine (**17**) in 61 and 18% yield, respectively. When tributylphosphine was used instead of triphenylphosphine, **16** and **17** was formed in 20 and 54% yield, respectively. The bisselenated product **17** was formed predominantly when tributylphosphine was used. This is presumably because of higher reducing ability of Bu_3P compared to Ph_3P, which caused a rapid formation and thus higher concentration of selenolate ion in the reaction mixture (reaction time: 20 min for Bu_3P vs. 1 h for Ph_3P), resulting in the formation of a larger amount of the bisselenated product **17**. A similar result was obtained in the following reaction. Treatment of 2,3-dichloro-5-nitro-1,4-naphthoquinone[7] (**18**) with 3-amino-2-pyridineselenolate ion gave two regioisomeric nitro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]-selenazin-5-ones (**19** and **20**), and a bisselenated product, 6-nitropyrido[2,3-*b*]pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*][1,4]selenazine (**21**), in 47, 19, and 17% yield, respectively, when triphenylphosphine was used, and in 30, 18, and 40% yield, respectively, when tributylphosphine used (Scheme 4).

Though two regioisomeric products **19** and **20** could not be distinguished from each other by examining their spectral data, they were unambiguously assigned to be a 6-chloro-1-nitro compound **19** and a 6-chloro-4-nitro compound **20**, respectively, by the correlation with known compounds 6-chloro-4-nitro-5*H*-benzo[*a*]phenothiazin-5-one[8] (**24**) and the corresponding 6-chloro-1-nitro isomer[8] **26**. Two reference compounds **24** and **26** were respectively subjected to selenation with dipyridyl diselenide **12** and tributylphosphine in a mixture of acetonitrile, dimethyl sulfoxide and an aqueous NaOH solution (160 °C), giving 6-nitrobenzo[*b*]pyrido-[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*]-[1,4]thiazine (**23**) and the 9-nitro isomer **25** in 32% and 52% yield. The reaction of the above-mentioned product **19** with 2-aminobenzenethiol (**22**) and Na_2CO_3 in DMF–toluene at 120 °C gave naphthothiazine, which was readily identified as the 6-nitro compound **23** in terms of the spectral data. On the other hand, the naphthothiazine obtained from the reaction of **20** with **22** was shown to be identical to the 9-nitro isomer **25** (Scheme 5). Thus, two isomeric products **19** and **20**

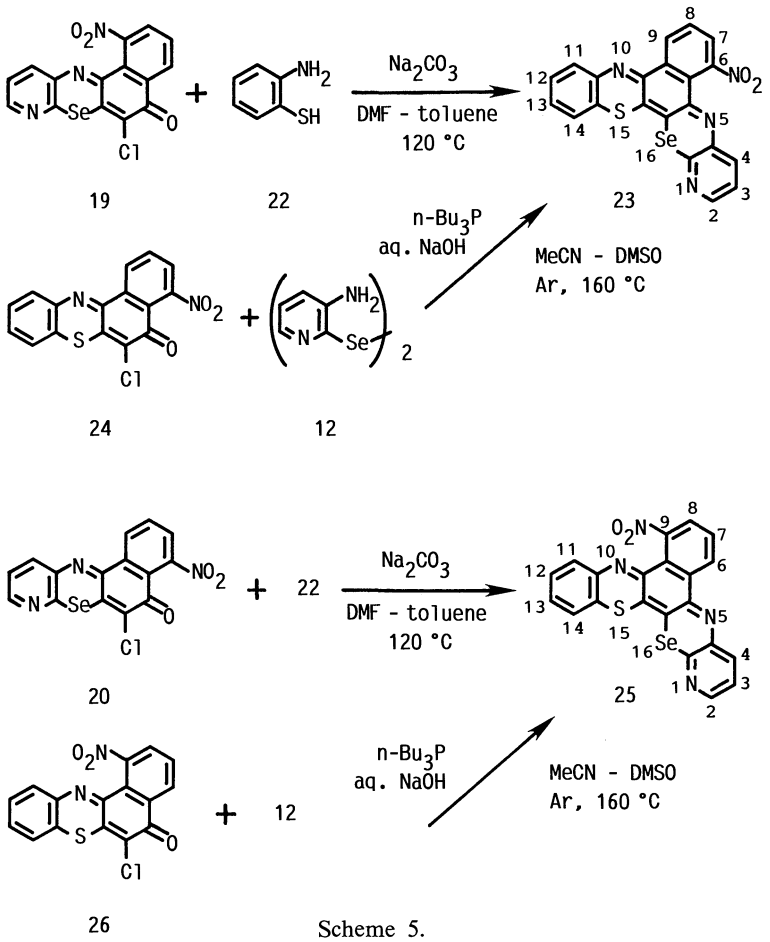

Scheme 5.

were identified to have 6-chloro-1-nitro and 6-chloro-4-nitro structures, respectively.

Since gallium arsenide, a semiconductor for optical recording media, emits a laser light at 800—830 nm, optical absorption in the near infrared region is required for dyes used in optical recording. In previous reports we described that 4*H*-benzo[*a*]phenothiazin-4-ones[3] and 4*H*-benzo[*a*]phenoselenazin-4-ones[4] absorbed at 750—770 nm. The naphthopyridoselenazines and phenylselenated 1,5-naphthoquinones prepared in the present work unfortunately do not show satisfactory absorptions compatible with semiconductor lasers: The naphthopyridoselenazines and naphthopyridoselenazine derivatives absorb at wavelengths in a region of 470—573 nm, whereas phenylseleno- and bis(phenylseleno)-1,5-naphthoquinones absorb at 664—666 nm. The λ_{max} values of these compounds are given in Table 1.

a) In chloroform.

Experimental

General. Mps were recorded on a Yanaco micro-melting point apparatus and are uncorrected. IR spectra were measured on KBr discs on a JASCO A-102 spectrometer. ^{1}H NMR spectra were taken with a JEOL JNM-PMX 60SI NMR spectrometer for solutions in deuteriochloroform with TMS as internal standard. Mass spectra were obtained with a Hitachi M-2000 spectrometer. Elemental analyses were

performed by the Microanalytical Laboratory of Kyoto University.

Preparation of 2,6-Dichloro- and 2-Chloro-4,8-bis(2-propylamino)-1,5-naphthoquinone (3 and 5). To a solution of 4,8-bis(2-propylamino)-1,5-naphthoquinone[6] (**1**) (400 mg, 1.47 mmol) in 27% hydrochloric acid (30 ml) was added bromine (0.30 ml, 5.82 mmol) in 27% hydrochloric acid (10 ml) at 0 °C slowly over 2 h. After stirring for 30 min, the mixture was neutralized with a 5% aqueous $NaHCO_3$ solution, thereby the dark-brown color of the solution turned to blue. The solution was extracted with chloroform (3×15 ml). The combined extracts were washed successively with water (2×5 ml) and brine (2×5 ml). The solution was dried over $MgSO_4$ and evaporated. Column chromatography on silica gel with chloroform–ethyl acetate (9:1) as eluent yielded dichloronaphthoquinone **3** (226 mg, 45%) and chloronaphthoquinone **5** (117 mg, 26%).

3: Mp 200—210 °C (decomp) (from hexane–CH_2Cl_2); IR (KBr) 1593 and 1558 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (12H, d, J=6.0 Hz), 3.71—4.40 (2H, m), 7.46 (2H, s), and 12.78—13.14 (2H, m); MS m/z 342 (M^+; 47), 340 (M^+; 63), 338 (M^+; 11), 327 (61), 325 (100), and 323 (33). Found: C, 56.12; H, 5.08%. Calcd for $C_{16}H_{18}Cl_2N_2O_2$: C, 56.32; H, 5.32%.

5: Mp 145—150 °C (decomp) (from hexane–CH_2Cl_2); IR (KBr) 1598 and 1542 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (12H, d, J=6.0 Hz), 3.88—4.42 (2H, m), 7.00 (1H, d, J=10.0 Hz), 7.24 (1H, d, J=10.0 Hz), 7.45 (1H, s), and 12.45—13.46 (2H, m); MS m/z 307 (M^+; 28), 305 (M^+; 62), 291 (42), and 289 (100). Found: C, 62.65; H, 6.32%. Calcd for $C_{16}H_{19}ClN_2O_2$: C, 62.64; H, 6.24%.

Preparation of 2,6-Dichloro- and 2-Chloro-4,8-bis(methylamino)-1,5-naphthoquinone (4 and 6). Chlorination of 4,8-bis(methylamino)-1,5-naphthoquinone[6] (**2**) (300 mg, 1.39 mmol) with bromine (0.20 ml, 3.88 mmol) in 27% hydrochloric acid (10 ml) afforded **4** (87 mg, 22%) and **6** (125 mg, 36%).

4: Mp 220—230 °C (decomp) (from hexane–CH_2Cl_2); IR (KBr) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.24 (6H, d, J=6.0 Hz), 7.51 (2H, s), and 12.63—12.86 (2H, m); MS m/z 286 (M^+; 41), 284 (M^+; 87), 282 (M^+; 58), and 207 (100). Found: C, 50.14; H, 3.47%. Calcd for $C_{12}H_{10}Cl_2N_2O_2$: C, 50.55; H, 3.54%.

6: Mp 190—200 °C (decomp) (from hexane–CH_2Cl_2); IR (KBr) 1595 and 1532 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.17 (3H, d, J=6.0 Hz), 3.24 (3H, d, J=6.0 Hz), 6.92 (1H, d, J=10.0 Hz), 7.18 (1H, d, J=10.0 Hz), 7.37 (1H, s), and 12.07—13.30 (2H, m); MS m/z 252 (M^+; 37), 250 (M^+; 100), 235 (17), and 233 (42). Found: C, 57.39; H, 4.28%. Calcd for $C_{12}H_{11}ClN_2O_2$: C, 57.50; H, 4.42%.

Selenation of 2,6-Dichloro-4,8-bis(2-propylamino)-1,5-naphthoquinone (3). A solution of diphenyl diselenide (68 mg, 0.22 mmol) and tributylphosphine (60 µl, 0.24 mmol) in THF (0.5 ml) was vigorously stirred ultrasonically under argon atmosphere at room temperature for 5 min. To this was added a 10% aqueous NaOH solution (160 µl, 0.44 mmol), and the mixture was ultrasonically stirred further for 15 min, during which time the two-phase mixture became homogeneous and the starting yellow solution turned to colorless. Then, the mixture was added dropwise to a solution of **3** (68 mg, 0.20 mmol) in THF (0.5 ml) at room temperature under argon atmosphere and stirred for 15 min. The mixture was then poured into a mixture of brine (10 ml) and dichloromethane (10 ml), and the aqueous layer was extracted with dichloromethane (2×5 ml). The combined extracts were washed with brine (5 ml), dried over $MgSO_4$, and evaporated. Column chromatography on silica gel with hexane–ethyl acetate (7:3) as eluent yielded 4,8-bis(2-propylamino)-2,6-bis(phenylseleno)-1,5-naphthoquinone (**7**) (102 mg, 88%). Mp 220—223 °C (from hexane–CH_2Cl_2); IR (KBr) 1585 and 1532 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12 (12H, d, J=6.0 Hz), 3.09—3.74 (2H, m), 6.39 (2H, s), 7.21—7.83 (10H, m), and 12.33—12.60 (2H, m); MS m/z 584 (M^+; 35), 582 (M^+; 33), 580 (M^+; 15), 427 (94), 425 (45), 411 (100), and 409 (53). Found: C, 58.02; H, 4.76%. Calcd for $C_{28}H_{28}N_2O_2Se_2$: C, 57.74; H, 4.85%.

Selenation of 2-Chloro-4,8-bis(2-propylamino)-1,5-naphthoquinone (5). Selenation of **5** (61 mg 0.20 mmol) using diphenyl diselenide (34 mg, 0.11 mmol), tributyphosphine (30 µl, 0.12 mmol), and a 10% aqueous NaOH solution (80 µl, 0.22 mmol) gave 4,8-bis(2-propylamino)-2-phenylseleno-1,5-naphthoquinone (**8**) (80 mg, 94%). Mp 141—143 °C (from hexane–CH_2Cl_2); IR (KBr) 1588 and 1540 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12 (6H, d, J=6.0 Hz), 1.38 (6H, d, J=6.0 Hz), 3.05—3.77 (1H, m), 3.77—4.30 (1H, m), 6.46 (1H, s), 6.98—7.33 (2H, m), 7.33—7.78 (5H, m), and 12.37—12.98 (2H, m); MS m/z 428 (M^+; 100), 426 (M^+; 56), 411 (43), 409 (20), 272 (34), and 270 (15). Found: C, 61.80; H, 5.71%. Calcd for $C_{22}H_{24}H_2O_2Se$: C, 61.82; H, 5.67%.

Selenation of 2-Chloro-4,8-bis(methylamino)-1,5-naphthoquinone (6). Selenation of **6** (50 mg 0.20 mmol) using diphenyl diselenide (34 mg, 0.11 mmol), tributylphosphine (30 µl, 0.12 mmol), and a 10% aqueous NaOH solution (80 µl, 0.22 mmol) gave 4,8-bis(methylamino)-2-phenylseleno-1,5-naphthoquinone (**9**) (66 mg, 89%). Mp 185—187 °C (from hexane–CH_2Cl_2); IR (KBr) 1583 and 1544 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.63 (3H, d, J=5.4 Hz), 3.30 (3H, d, J=5.4 Hz), 6.51 (1H, s), 7.01—7.35 (2H, m), 7.35—7.82 (5H, m), and 12.27—12.93 (2H, m); MS m/z 372 (M^+; 100) and 370 (M^+; 56). Found: C, 57.98; H, 4.20%. Calcd for $C_{18}H_{16}N_2O_2Se$: C, 58.23; H, 4.34%.

Preparation of Bis(3-amino-2-pyridyl) diselenide (12). A solution of 2-chloro-3-nitropyridine (**10**) (5.0 g, 31.5 mmol) and potassium selenocyanate (7.5 g, 52.1 mmol) in DMF (40 ml) were heated at 120 °C for 8 h. To this was added a 10% aqueous NaOH solution (100 ml, 277.5 mmol). After stirring for 2 h at room temperature, the mixture was poured into water to form precipitates, which were filtered. The precipitates were dissolved in acetic acid (250 ml), and to this solution was added powder zinc (10.0 g, 153.0 mmol) at 60 °C. The mixture was stirred for 40 min at the same temperature. A 20% hydrochloric acid (80 ml) was then and stirred for 10 min. The mixture was filtered and the filtrate was neutralized with a 5% aqueous $NaHCO_3$ solution to form precipitates, which were filtered, washed with water, and dried under reduced pressure. Recrystallization from EtOH gave **12** (2.88 g, 53%). Mp 193—195 °C (from $CHCl_3$); IR (KBr) 3420 and 3260 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.60—5.85 (4H, m), 6.83—7.20 (4H, m), and 7.60—7.83 (2H, m); MS m/z 346 (M^+; 100) and 344 (M^+; 91). Found: C, 34.81; H, 2.74; N, 16.46%. Calcd for $C_{10}H_{10}N_4Se_2$: C, 34.90; H, 2.93; N, 16.28%.

Preparation of 6-Methyl-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*]-[1,4]selenazin-5-one (14). Method A: solution of **12** (25 mg, 0.07 mmol) and triphenylphosphine (40 mg, 0.15 mmol) in acetonitrile (3 ml) was ultrasonically stirred under argon atmosphere at room temperature for 5 min. To this was added a 5% aqueous NaOH solution (100 µl, 0.13 mmol) and stirred for 15 min. Then, 2-bromo-3-methyl-1,4-naphthoquinone

(**13**) (30 mg, 0.12 mmol) was added and stirred for 40 min. The mixture was poured into a water (20 ml) to form precipitates, which were filtered washed with water (10 ml), dried under reduced pressure. Column chromatography on silica gel with toluene–ethyl acetate (8:2) as eluent yielded **14** (36 mg, 91%).

Method B: The reaction of **13** (30 mg, 0.12 mmol) with 3-amino-2-pyridineselenolate ion generated from **12** using tributylphosphite (38 μl, 0.15 mmol) gave **14** (37 mg, 93%). Mp 237—238 °C (from benzene); IR (KBr) 1620 cm^{-1}; ^1H NMR (DMSO-d_6, 90 °C) δ=2.10 (3H, s), 7.54—7.66 (1H, m), 7.76—7.92 (2H, m), 8.14—8.30 (2H, m), 8.51—8.60 (1H, m), and 8.72—8.82 (1H, m); MS *m/z* 326 (M^+; 100) and 324 (M^+; 56). Found: C, 59.34; H, 3.10; N, 8.51%. Calcd for $C_{16}H_{10}N_2OSe$: C, 59.09; H, 3.10; N, 8.61%.

Reaction of 2,3-Dichloro-1,4-naphthoquinone (15) with 3-Amino-2-pyridineselenolate Ion Generated from 12. Method A: The reaction of **15** (30 mg, 0.13 mmol) with selenolate ion generated from **12** (30 mg, 0.09 mmol), triphenylphosphine (50 mg, 0.19 mmol), and a 5% aqueous NaOH solution (112 μl, 0.15 mmol), gave 6-chloro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*]-[1,4]selenazin-5-one (**16**) (28 mg, 61%) and pyrido[2,3-*b*]-pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*][1,4]selenazine (**17**) (11 mg, 18%).

Method B: The reaction of **15** (30 mg, 0.13 mmol) with 3-amino-2-pyridineselenolate ion generated from **12** using tributylphosphine (48 μl, 0.19 mmol) gave **16** (9 mg, 20%) and **17** (33 mg, 54%).

16: Mp 282—285 °C (from benzene); IR (KBr) 1628 cm^{-1}; ^1H NMR (DMSO-d_6, 90 °C) δ=7.64—7.72 (1H, m), 7.87—7.99 (2H, m), 8.22—8.33 (1H, m), 8.36—8.45 (1H, m), 8.62—8.68 (1H, m), and 8.84—8.91 (1H, m); MS *m/z* 348 (M^+; 42), 346 (M^+; 100), and 344 (M^+; 50). Found: C, 52.40; H, 1.99; N, 8.18%. Calcd for $C_{15}H_7ClN_2OSe$: C, 52.12; H, 2.04; N, 8.10%.

17: Mp 280—281 °C (from EtOH); IR (KBr) 1562 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.36—7.46 (2H, m), 7.74—7.82 (2H, m), 8.04—8.14 (2H, m), 8.43—8.50 (2H, m), and 8.88—8.99 (2H, m); MS *m/z* 466 (M^+; 100) and 464 (M^+; 96). Found: C, 51.80; H, 2.08; N 11,85%. Calcd for $C_{20}H_{10}N_4Se_2$: C, 51.74%; H, 2.17; N, 12.07%.

Reaction of 2,3-Dichloro-5-nitro-1,4-naphthoqionone[7] (18) with 3-Amino-2-pyridineselenolate Ion Generated from 12. Method A: The reaction of **18** (60 mg, 0.22 mmol) with selenolate ion generated from **12** (50 mg, 0.15 mmol), triphenylposphine (84 mg, 0.32 mmol), and a 5% aqueous NaOH solution (190 μl, 0.25 mmol), gave 6-chloro-1-nitro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]selenazin-5-one (**19**) (40 mg, 47%), 6-chloro-4-nitro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]-selenazin-5-one (20) (16 mg, 19%), and 6-nitropyrido[2,3-*b*]-pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*]-[1,4]selenazine (**21**) (19 mg, 17%).

Method B: The reaction of **18** (60 mg, 0.22 mmol) with 3-amino-2-pyridineselenolate ion generated from **12** using tributylphosphine (80 μl, 0.32 mmol) gave **19** (26 mg, 30%), **20** (15 mg, 18%), and **21** (45 mg, 40%).

19: Mp 277 °C (from EtOH); IR (KBr) 1635, 1523, and 1372 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.56—7.68 (1H, m), 7.84—8.11 (3H, m), 8.36—8.44 (1H, m), and 8.50—8.66 (1H, m); MS *m/z* 393 (M^+; 40), 391 (M^+; 100), nad 389 (M^+; 47). Found: C, 46.28; H, 1.51; N, 10.82%. Calcd for $C_{15}H_6ClN_3O_3Se$: C, 46.12; H, 1.55; N, 10.76%.

20: Mp 313 °C (from EtOH); IR (KBr) 1620, 1522, and 1362 cm^{-1}; ^1H NMR (DMSO-d_6, 90 °C) δ=7.70—7.80 (1H, m), 8.09—8.16 (2H, m), 8.44—8.52 (1H, m), 8.68—8.74 (1H, m), and 9.08—9.16 (1H, m); MS *m/z* 393 (M^+; 45), 391 (M^+; 100), and 389 (M^+; 47). Found: C, 46.09; H, 1.48; N, 10.71%. Calcd for $C_{15}H_6ClN_3O_3Se$: C, 46.12; H, 1.55; N, 10.76%.

21: Mp 332 °C (from benzene); IR (KBr) 1514 and 1352 cm^{-1}; ^1H NMR (DMSO-d_6, 90 °C) δ=7.39—7.53 (1H, m), 7.74—7.82 (1H, m), 7.86—8.00 (2H, m), 8.08—8.18 (1H, m), 8.42—8.52 (2H, m), and 9.02—9.10 (1H, m); MS *m/z* 511 (M^+; 100) and 509 (M^+; 89). Found: C, 47.18; H, 1.70; N, 13.50%. Calcd for $C_{20}H_9N_5O_2Se_2$: C, 47.17; H, 1.78; N, 13.75%.

Condensation of 6-Chloro-1-nitro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]selenazin-5-one (19) with 2-Aminobenzenethiol (22). A mixture of **22** (16 mg, 0.13 mmol), Na_2CO_3 (28 mg, 0.26 mmol), and **19** (40 mg, 0.10 mmol) in DMF (1 ml) and toluene (1 ml) was heated at 120 °C for 6 h. The mixture was poured into water (20 ml) to form precipitates, which were filtered, washed with water (10 ml), and dried under reduced pressure. Column chromatography on silica gel with toluene–ethyl acetate (8:2) as eluent yielded 6-nitrobenzo[*b*]pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]naphtho[1,2-*e*][1,4]thiazine (**23**) (26 mg, 57%). Mp 308—309 °C (from benzene); IR (KBr) 1530 and 1377 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.40—7.54 (3H, m), 7.68—7.90 (5H, m), 8.33—8.44 (1H, m), and 9.10—9.19 (1H, m); MS *m/z* 462 (M^+; 79), 460 (M^+; 43), 430 (100), and 428 (55). Found: C, 54.84; H, 2.11; N, 11.91%. Calcd for $C_{21}H_{10}N_4O_2SSe$: C, 54.67; H, 2.18; N, 12.14%.

Condensation of 6-Chloro-4-nitro-5*H*-naphtho[2,1-*b*]pyrido[3,2-*e*][1,4]selenazin-5-one (20) with 22. The condensation of **20** (15 mg, 0.04 mmol) carried out as above using **22** (6 mg, 0.05 mmol), Na_2CO_3 (11 mg, 0.10 mmol) yielded 9-nitrobenzo[*b*]pyrido[3″,2″:5′,6′][1,4]selenazino[2′,3′:3,4]-naphtho[1,2-*e*][1,4]thiazine (**25**) (15 mg, 81%). Mp 337—339 °C (from benzene); IR (KBr) 1532 and 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.37—7.47 (2H, m), 7.52—7.60 (2H, m), 7.69—7.79 (3H, m), 7.96—8.03 (1H, m), 8.39—8.43 (1H, m), and 9.09—9.16 (1H, m); MS *m/z* 462 (M^+; 100), 460 (M^+; 52), 430 (53), and 428 (25). Found: C, 54.41; H, 2.58; N, 11.71%. Calcd for $C_{21}H_{10}N_4O_2SSe$: C, 54.67; H, 2.18; N, 12.14%.

Reaction of 6-Chloro-4-nitro-5*H*-benzo[*a*]phenothiazin-5-one (24) with 3-Amino-2-pyridineselenolate Ion Generated from 12. To a mixture containing 3-amino-2-pyridineselenolate ion generated from **12** (20 mg, 0.06 mmol), tributylphosphine (30 μl, 0.12 mmol), and a 5% aqueous NaOH solution (76 μl, 0.10 mmol) as described in the preparation of **14** was added a solution of **24** (30 mg, 0.09 mmol) in DMSO (1 ml). The mixture was heated at 160 °C for 4 h. The mixture was poured into a water (20 ml) to form precipitates, which were filtered, washed with water (10 ml), and dried under pressure. Column chromatography on silica gel with toluene as eluent yielded **23** (13 mg, 32%).

Reaction of 6-Chloro-1-nitro-5*H*-benzo[*a*]phenothiazin-5-one (26) with 3-Amino-2-pyridineselenolate Ion Generated from 12. The reaction of **26** (30 mg, 0.09 mmol) with 3-amino-2-pyridineselenolate ion generated from **12** (20 mg, 0.06 mmol), tributylphosphine (30 μl, 0.12 mmol), and a 5% aqueous NaOH solution (76 μl. 0.10 mmol) gave **25** (22 mg, 52%).

Crystallographic Study. A crystal was obtained by slow crystallization from CH_2Cl_2–hexane. A Rigaku automated four-circle diffractometer AFC-5R was used with graphite monochromated Cu radiation (CuK=1.5418 Å).

Table 2. Final Position Parameters and B_{eq} in Crystal Structure of 7[a)]

Atom	x/a	y/b	z/c	B_{eq}/Å^2

a) Labeling corresponds to that indicated in Fig. 1. Estimated standard deviations in parentheses.

$C_{28}H_{28}N_2O_2Se_2$, M_r=582.46; triclinic, $P\bar{1}$, a=9.273 (1) Å, b=9.849 (1) Å, c=8.468 (1) Å, α=93.90 (1)°, β=119.83°, γ=100.64 (1)°, V=647.7 (1) Å^3, D_C=1.493 g cm^{-3}; Crystal size, 0.10×0.20×0.30 mm; 2081Intensities were collected, $2\theta_{max}$=126°.

Structures were solved with the aids of Texsan program system, and refined by the full-matrix least squares program using 1816 greater than $3\sigma(F)$. Non-H atoms were assigned anisotropic temperature factors. Hydrogen atoms were located from a difference Fourier map and refined with the equivalent isotropic temperature factor to that for the bonded carbon atoms.

$$R=0.057,\ R_W=[\sum_W(|F_o|^2-|F_c|^2)^2/\sum_W|F_o|^2]^{1/2}$$

$$W=1/\sigma^2(F^2),\ \Delta\rho_{max}=2.8/\text{eÅ}^3.$$

Atomic scattering factors were employed from "International Table for X-Ray Crystallography". ORTEP was employed for drawing the molecular structures (Fig. 1). All calculations were made on a microVax 3500. Listing of atomic parameters, thermal parameters, selected bond lengths and bond angles are included in the supplementary material Tables 2 and 3.[9)]

We thank Mr. Shigeru Takaoka and Mr. Takuya Seko, Ono Pharmaceutical Co., Ltd., for performing the X-ray structural analysis.

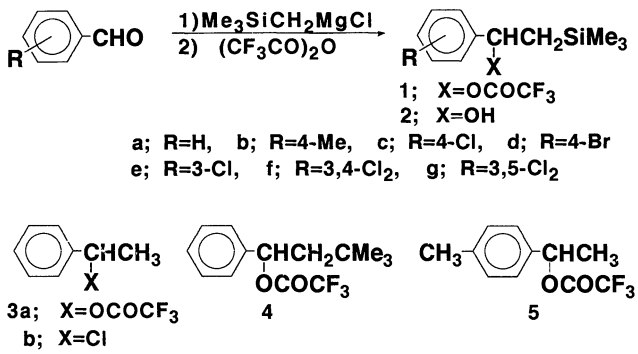
(Received March 2, 1991)

Solvolysis rates have been measured in various solvents at 25 °C for 1-(substituted phenyl)-2-(trimethylsilyl)ethyl trifluoroacetates (**1a**—**1g**; R=H, 4-Me, 4-Cl, 4-Br, 3-Cl, 3,4-Cl_2, and 3,5-Cl_2, respectively) and structurally related compounds, 1-phenylethyl-, 3,3-dimethyl-1-phenylbutyl-, and 1-(4-methylphenyl)ethyl trifluoroacetates (**3a**, **4**, and **5**). In dioxane/water mixtures **1g** solvolyzes with the same sensitivity to the change in solvent ionizing power as that for a k_c substrate **5**. The solvolyses of **1e** and **5** exhibit almost identical α-deuterium kinetic isotope effects (k_H/k_D) of 1.18—1.19 in aq dioxane. Substituent effect on the solvolysis of **1** in 90% aq dioxane is expressed by an LArSR equation: $\log k^X/k^H=-3.05$ ($\sigma^\circ+1.05\Delta\bar{\sigma}_R^+$) ($R$=0.9997). These findings are consistent with k_c mechanism for the solvolysis of **1**. Relative rates for the solvolysis of **1a**, **3a**, and **4** in 30% aq dioxane are 2.99×10^5 : 2.84 : 1.0 indicating solvolytic generation of α-(trimethylsilylmethyl)benzyl cation to be about 7 kcal mol^{-1} energetically more favorable than that of the corresponding α-alkylbenzyl cations.

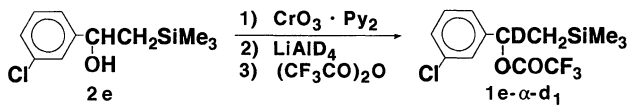
Previously[2] we have shown in a preliminary report that α-(pentamethyldisilanyl)benzyl bromide solvolyzes 2×10^5 times more rapidly than does α-trimethysilybenzyl bromide indicative of a marked β-silicon effect of the disilanyl group. It is of interest to compare the effect of the Si–Si bonds on stability of adjacent carbocations with the effect of the corresponding carbon–silicon bonds. Lambert and co-workers have shown that an anti β-$SiMe_3$ group exerts a rate-acceleration effect of 2.4×10^{12} relative to hydrogen in the solvolysis of cyclohexyl derivatives suggesting a β-$SiMe_3$ group to stabilize cyclohexyl cation by about 17 kcal mol^{-1} (1 cal=4.184 J) relative to hydrogen.[3] Seemingly, the β-silicon effect appears much less effective in a $R^1R^2C^+$–Si–$SiMe_3$ system than in a $R^1R^2C^+$–C–$SiMe_3$ system, although the Si–Si single bonds possess low ionization potentials as compared to the C–Si bonds.[4] However, a direct comparison of the β-silicon effects in the benzylic and cyclohexyl solvolyses is not justified. There is a marked difference in the electronic demands at the carbenium carbon in the two systems. Theoretical study[5] indicates marked dependence of the β-silicon effect on the electronic demands of the carbocations as well as on the stereoelectronic restraint for the β-silicon group. In order to discuss the effect of the disilanyl group, it is therefore desirable to estimate the β-silicon effect of the corresponding silylmethyl group in the same benzylic system. This paper describes kinetic details on the solvolysis of 1-aryl-2-(trimethylsilyl)ethyl trifluoroacetates (**1a**—**1g**) and related α-alkylbenzyl trifluoroacetates **3**—**5**, and discusses mechanistic implications on the β-silicon effect in the benzylic solvolysis.

Results

The trifluoroacetates **1a**—**1g** were prepared by treatment of the corresponding alcohols **2** with trifluoroacetic anhydride in the presence of pyridine.[3] The trifluoroacetates **1** were labile at room temperature and a crude



product was directly used for kinetic measurements. We used three α-alkylbenzyl trifluoroacetates as alkyl reference standards. They were 1-phenylethyl trifluoroacetate (**3a**), 3,3-dimethyl-1-phenylbutyl trifluoroacetate (**4**), and 1-(4-methylphenyl)ethyl trifluoroacetate (**5**). Oxidation of **2e** followed by reduction with $LiAlD_4$ gave corresponding α-deuterated alcohol, which was converted into its trifluoroacetate **1e**-α-d_1.



Solvolysis reactions were followed spectrometrically at 25.0±0.05 °C by measuring either increase in produced trifluoroacetic acid as its acridinium salt[1] or increase in styrene derivatives which were formed practically as a single product under solvolytic conditions. All the solvolyses followed good first-order kinetics over 3 to 4 half-lives (correlation coefficient R>0.9999) and both methods gave identical rate constants within experimental error (±3%). We also compared spectrometric rates with conductimetric rates in several cases; for example, a spectrometric rate for the solvolysis of **1e** in

a) A: acetone/water (v/v), D: dioxane/water (v/v), E: ethanol/water (v/v), and 97T: 97/3 (w/w) trifluoroethanol/water mixtures. b) Single run except otherwise noted. c) Average of four runs. d) Calculated from the following rates: 10^5 k/s^{-1} (temp/°C) 113 (7.6), 189 (11.7), 296 (16.0), 494 (20.5), and 752 (25.0). e) Extrapolated value from other temperatures. f) Calculated from the following rates: 10^5 k/s^{-1} (temp/°C) 4680 (20.5), 2890 (16.0), 1920 (11.7), 1130 (7.6), and 687 (2.9). g) Average of two runs. h) Average of six runs. i) Calculated from the following rates: 10^5 k/s^{-1} (temp/°C) 5.45 (25.0), 60.3 (46.2), and 451 (67.4). j) Average of three runs. k) Calculated from the following rates: 10^5 k/s^{-1} (temp/°C) 696 (11.7), 1071 (16.0), 1733 (20.5), and 2570 (25.1). l) Calculated from the following rates: 10^5 k/s^{-1} (temp/°C) 19.1 (25.0), 47.5 (33.8), and 127 (43.2). m) Calculated from the following rates: 10^5 k/s^{-1} (temp/°C) 14.4 (11.7), 23.8 (16.0), 59.8 (25.0), 161 (34.3), and 418 (43.2).

90% aq acetone at 25.0°C measured by the acridine method, k=(2.765±0.003)×10^{-3} s^{-1}, was identical to a conductimetric rate, k=(2.772±0.001)×10^{-3} s^{-1}. The conductimetric method could not be successfully applied to the solvolyses in 90% aq dioxane because of a poor conductimetrical response of trifluoroacetic acid. Table 1 summarizes solvolysis rates for **1a**—**1g**, **3a**, **4**, and **5** in various solvents including 20/80 to 95/5 (v/v) dioxane/water (D series), 20/80 to 90/10 (v/v) acetone/water (A series), 30/70 to 100/0 (v/v) ethanol/water (E series), 97/3 (w/w) 2,2,2-trifluoroethanol (TFE)/water (T series) binary mixtures and methanol. Table 2 shows the β-silicon effect in the α-alkylbenzyl solvolysis.

α-Deuterium kinetic isotope effects (KIE) were measured for the solvolysis of **1e** in 80D and in 90D. We also measured KIE for the solvolysis of the reference compound **5** in 40D for comparison. The results are given in Table 3.

Solvent effects were examined for **1g**. Unfortunately, a solvent ionizing power scale for the trifluoroacetoxy

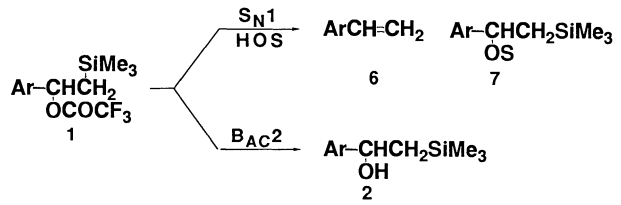
leaving group is not available; so we chose 1-phenylethyl chloride (**3b**) as a standard benzylic substrate undergoing k_c solvolysis.[6,7] Figure 1 represents a plot of the rates (log k) for **1g** against log k for **3b**[6] in various solvents. Aq dioxane and alcoholic solvents show a single linear response with a slope (m') of 0.78, while acetone/water mixtures exhibit a separate line (m'=0.61). Figure 1 includes a log k–log k plot for **5** for comparison. Judging from a comparable nucleofugality of the trifluoroacetoxy leaving group to that of Cl,[8] we can

Table 4. Comparison of Solvent Effect

Substrate	m'[a]	
	For aq dioxane	For all solvents
1g	0.80 (n=4, R=0.999)[b]	0.78 (n=7, R=0.999)[c]
5	0.79 (n=4, R=0.999)	0.80 (n=12, R=0.999)

a) Slope for a plot of log k vs. log k (1-phenylethyl chloride) (Ref. 6). b) Except for 90D. c) Except for aq acetone and 90D.

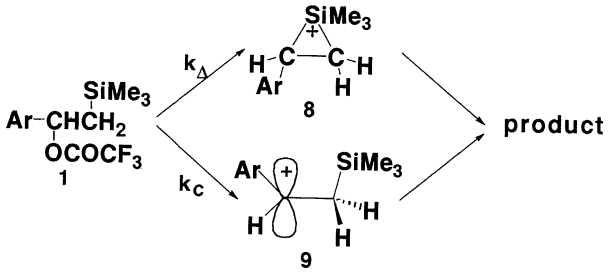
assume k_c mechanism for the solvolysis of **5**. This is consistent with the fact that the solvolysis rates for **5** exhibit a linear response to those for **3b** for a range of solvents of varying solvent nucleophilicity and ionizing power including aq dioxane, aq acetone, aq ethanol, and aq trifluoroethanol. A significantly reduced slope for **5**, m'=0.80 relative to the chloride **3b**, should be ascribed to the leaving group effect. Since trifluoroacetate ion is a highly delocalized species, it must be less strongly solvated hence less sensitive to the change in solvent ionizing power than chloride ion. Table 4 shows a comparison of the solvent effect between the solvolyses of **1g** and **5**.



Solvolytic reactions of **1** in aq dioxane and ethanol gave the corresponding styrenes (**6**) exclusively. In the case of the reaction of **1e** in methanol, a significant amount (14%) of a methanolysis product **7** was also formed. Under basic conditions, however, was produced the alcohol **2** as the major product instead. For example, a reaction of **1e** in methanol containing sodium methoxide (0.09 M; 1 M=1 mol dm^{-3}) gave **2e** in 93% yield. The formation of **2** undoubtedly arises from a $B_{AC}2$ reaction of the trifluoroacetates. Amines promoted this process and hence accelerated the rate of reaction; the presence of 0.01 M triethylamine accelerated the reaction rate of **1g** in 70D by a factor of 4.85. Thus, the amine-induced $B_{AC}2$ reaction may become a serious problem in the rate measurement for the solvolysis of the trifluoroacetates **1** when acridine is used as a monitoring base. Fortunately, however, we found that acridine did not affect significantly the rate of the solvolysis under solvolytic conditions at acridine concentrations around 10^{-4} M; for instance, the solvolyses of **1g** in 70D in the presence of 1.0×10^{-3} M acridine showed an identical rate constant to that measured in the absence of acridine within experimental error: k=1.58×10^{-3} and 1.54×10^{-3} s^{-1} at 25°C, respectively.

Discussion

Table 2 indicates that a β-$SiMe_3$ group exerts a rate-acceleration effect of (1—3)$\times 10^5$ relative to hydrogen or *t*-Bu in the α-alkylbenzyl solvolysis. Although the solvolysis of α-alkylbenzyl derivatives is subjected to the steric effect of the α-alkyl groups,[2,9,10] a rate ratio of **1a** and a structurally related compound **4** provides a reasonable estimate for the β-silicon effect in the benzylic solvolysis. The rate acceleration by the β-silicon can be interpreted either by a σ-participation mechanism (k_Δ) via a bridged siliconium ion intermediate **8** or by a simple ionization mechanism (k_c) via an open 1-aryl-2-(trimethylsilyl)ethyl cation **9**.[3,11-15]



The following kinetic features are informative on the structure of the transition state. First, the KIE for **1g**, i.e., k_H/k_D=1.18—1.19 in aq dioxane, is comparable to the KIE, k_H/k_D=1.18, for the reference compound **5** which can be assumed to be a k_c substrate (Table 3). These isotope effects can be compared with KIE values for the typical k_c solvolysis of α-alkylbenzyl derivatives e.g., k_H/k_D=1.157 for the solvolysis of 1-(4-methoxyphenyl)ethyl chloride in aq ethanol.[16] Apparently, the isotope effect indicates a striking resemblance in the structures of the transition state for the solvolysis of **1g** and **5**.

Second, solvolytic reactivities of a series of 1-aryl-2-(trimethylsilyl)ethyl trifluoroacetates **1a**—**1g** were well linearly correlated with σ^+ [17] affording a ρ^+ value of -3.07 (R=0.9997). The application of the LArSR equation (Eq. 1)[18] gave an almost identical expression with a resonance parameter close to unity, r=1.05, and a reaction constant ρ=-3.05 (R=0.9997, SD=0.029).[19]

$$\log k^X/k^H = \rho(\sigma^\circ + r\Delta\bar{\sigma}_R^+) \quad (1)$$

The limited number of π-donor substituents may not give us a precise r value; nevertheless, a rather high r value around 1.0 is apparently inconsistent with the bridged siliconium ion intermediate **8**. The result is interestingly compared with the substituent effect for the α-alkylbenzyl solvolysis which has been characterized by r close to 1.15 and ρ around -5.[20] A reduced r value for **1** is quite reasonable judging from the anticipated high stability of the cation **9a** as compared to 1-phenylethyl cation. It has been shown that r decreases with increasing stability of the benzylic cations $ArC^+R^1R^2$.[20] The rate ratio, k(**1a**)/k(**3a**)=1.1$\times 10^5$, would suggest the electronic demand of the carbenium carbon in the cation **9a** to be comparable to that in the α,α-dimethylbenzyl cation which is characterized by r=1.0 by definition.[18]

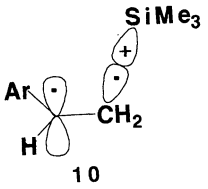
It is also instructive to note that **1g** and **5** showed very similar activation entropies in their solvolyses in a common solvent. For example, it is clear from Table 1 that a rate ratio of **1g** to **5** observed in 50D at 25 °C of a factor of 135 is entirely attributable to a 2.8 kcal mol^{-1} low enthalpy of activaion for **1g** relative to **5**. Again the result is more in accord with thr k_c mechanism than with the k_Δ mechanism which must involve substantial restraint of rotational motions at the transition state.

Finally it should be noted that in a log k–log k (**3b**) plot (Fig. 1), **1g** showed an identical slope to that for **5** (Table 4). This means that **1g** solvolyzes with the same susceptibility to the change in solvent ionizing power as that for **5** indicative of a marked resemblance in mechanism for ionization of the two substrates. Obviously, the solvent effect support the k_c solvolysis for **1**, although we do not understand quite well the origin for deviations of aq acetone at present.

Thus, the combined results lead us to conclude that **1** solvolyzes via rate-determining formation of a classical 1-aryl-2-(trimethylsilyl)ethyl cation **9**. The cation must be effectively stabilized by the β-$SiMe_3$ group through hyperconjugation.[5,21] It is worth stating that the k_c mechanism has been proposed also for the solvolysis of α-(pentamethyldisilanyl)benzyl halides which cleanly give 1,2-$SiMe_3$ rearranged products seemingly suggestive of σ-participation.[2] Extensive hyperconjugative interactions between the β-C–$SiMe_3$ σ-bond and the carbenium carbon would naturally involve changes in bond angles and bond lengths associated with the β-silicon atom.[5] However, the absence of compelling evidence suggesting bond-forming interactions between the β-silicon and the benzylic carbon leads us at present to prefer a simple k_c mechanism to a σ-participated ionization. The k_c mechanism for **1** is compatible with the recent theoretical[5] and experimental results in the gas phase[22] that an open structure of β-silyl-substituted alkyl cations is energetically more favorable than a bridged form except for the primary cation which preferably takes a bridged form. It can thus be said that the solvolytic generation of 1-phenyl-2-(trimethylsilyl)ethyl cation is about 7 kcal mol^{-1} energetically more favorable than that of the corresponding α-alkylbenzyl cations.

Noteworthy is a marked reduction in ρ value for the k_c solvolysis of **1** indicative of substantial dispersion of the positive charge on the benzylic carbon to the β-C–$SiMe_3$ σ-bond in the transition state without significant bridging of the β-silicon. This would undoubtedly result from the electronic interaction between the empty 2p orbital and the β-C–Si bond, although it is not clear at present whether such the interaction is purely hyperconjugative or includes intramolecular charge or elec-

tron transfer interaction as illustrated by the structure **10**.



10

The β-silicon effects in the present α-alkylbenzyl system as well as in the α-silylbenzyl system[2] are obviously much smaller than would be expected from a reported rate-acceleration of 2.4×10^{12} in the cyclohexyl solvolysis corresponding to a reduction of activation energy by 17 kcal mol^{-1} by a β-$SiMe_3$ group relative to hydrogen.[3] The reduced β-silicon effect would undoubtedly arise from the low electronic demands at the carbenium carbon for benzylic cations as compared to cyclohexyl cation. Li and Stone[22] have shown from the gas-phase experiments that the stabilization of the carbocations afforded by a β-$SiMe_3$ group relative to hydrogen markedly decreases with increasing stability of the parent carbocations from 38 kcal mol^{-1} for isopropyl cation to 22 kcal mol^{-1} for 1-phenylethyl cation. The difference in the β-silicon effect between the secondary alkyl and 1-phenylethyl cations by 16 kcal mol^{-1} in the gas phase reasonably accounts for the observed ca. 10 kcal mol^{-1} difference in the β-silicon effect between the α-alkylbenzyl and cyclohexyl solvolyses.

Experimental

IR spectra were recorded on a Hitachi R-215 spectrophotometer. NMR spectra were taken on a Hitachi R-20B spectrometer in carbon tetrachloride using TMS as internal standard. GLC were performed with a Hitachi 163 gas chromatograph using a 4 mm×2 m column packed with 5% Silicone GE SE-30 on Chamelite CS. UV spectra were recorded on a Hitachi 220A spectrophotometer equipped with a programmed data printer.

Dioxane was refluxed first with potassium hydroxide for 3 days, then with sodium for 3 days, and distilled. Acetone was refluxed with potassium permanganate and the distillate was dried over potassium carbonate and fractionated. Ethanol was distilled twice over sufficient amounts of magnesium ethoxide.

1-Aryl-2-(trimethylsilyl)ethyl Trifluoroacetates (1a—1g). These trifluoroacetates were prepared from the corresponding alcohols **2** according to the literature method.[3] The alcohols **2** were prepared by the Grignard reaction between the corresponding benzaldehyde and (trimethylsilyl)methylmagnesium chloride. A typical example is shown below:

To a stirred solution of (trimethylsilyl)methylmagnesium chloride prepared from trimethylsilylmethyl chloride (4.88 g, 40 mmol) and Mg (1.07 g) in ether (50 cm^3) was added a solution of 3-chlorobenzaldehyde (5.07 g, 36 mmol) in ether (25 cm^3) at room temperature. The mixture was stirred for 3 h at ambient temperature. A crude oil obtained after workup was distilled to give 4.75 g (93%) of 1-(3-chlorophenyl)-2-(trimethylsilyl)-ethanol (**2e**) as a colorless oil: Bp 121—121.5 °C (1.5 Torr; 1 Torr=133.3 Pa); IR (neat) 3350, 1250, 860, 840, 785 cm^{-1}; ^{1}H NMR δ=0.0 (9H, s), 1.03—1.17 (2H, m), 2.32 (1H, broad s, OH), 4.72 (1H, t, J=7.2 Hz), 7.20—7.29 (4H, m). Found: C, 57.66; H, 7.46%. Calcd for $C_{11}H_{17}ClOSi$: C, 57.75; H, 7.49%. To a stirred solution of **2e** (286 mg, 1.3 mmol) and pyridine (2.5 mmol) in ether (4 cm^3) precooled in an ice-salt bath was added slowly trifluoroacetic anhydride (525 mg, 2.5 mmol) in ether (2 cm^3) and the mixture was stirred for 30 min at that temperature. Pentane (15 cm^3) was added. Organic layer was decanted, washed first with 10% hydrochloric acid, then with aq $NaHCO_3$, and dried. Solvent was removed under reduced pressure affording a crude oil which was shown to be a practically pure 1-(3-chlorophenyl)-2-(trimethylsilyl)ethyl trifluoroacetate (**1e**; 353 mg, 87%) by ^{1}H NMR analysis: IR 1780, 1255, 1220, 1150, 860, 840, 780 cm^{-1};^{1}H NMR δ=—0.06 (9H, s), 1.33—1.47 (2H, m), 5.89 (1H, t, J=7.8 Hz), 7.27 (4H, broad s). Found: C, 48.33; H, 4.97%. Calcd for $C_{13}H_{16}ClF_3O_2Si$: C, 48.07; H, 4.97%.

In a similar procedure, the following alcohols and their trifluoroacetates were prepared.

1-Phenyl-2-(trimethylsilyl)ethanol (**2a** in 98% yield): IR 3350, 1250 cm^{-1}; ^{1}H NMR δ=—0.09 (9H, s), 1.00—1.13 (2H, m), 1.74 (1H, s, OH), 4.68 (1H, t, J=7.8 Hz), 7.18 (5H, broad s). Found: C, 67.81; H, 9.19%. Calcd for $C_{11}H_{18}Si$: C, 67.98; H, 9.38%. **1a**: ^{1}H NMR δ=—0.11 (9H, s), 1.45 (2H, d, J=7.8 Hz), 5.93 (1H, t, J=7.8 Hz), 7.33 (5H, broad s).

1-(4-Methylphenyl)-2-(trimethylsilyl)ethanol (**2b**; 98%): IR 3350, 1250, 860, 820 cm^{-1}; ^{1}H NMR δ=—0.06 (9H, s), 1.08 (2H, d, J=6.6 Hz), 1.50 (1H, s, OH), 4.70 (1H, t, J=6.6 Hz), 7.08 (4H, broad s). Found: C, 43.49; H, 4.23%. Calcd for $C_{13}H_{15}Cl_2F_3O_2Si$: C, 43.46; H, 4.21%.

1-Phenylethyl Trifluoroacetate (3a): Bp 33-33.5 °C (1 Torr) [lit,[8] bp 32 °C (0.5 Torr)]; IR 1785, 1230, 1160 cm^{-1}; ^1H NMR δ=1.68 (3H, d, J=6.6 Hz), 5.99 (1H, q, J=6.6 Hz), 7.33 (5H, broad s).

3,3-Dimethyl-1-phenylbutyl Trifluoroacetate (4): Bp 50—55 °C (1 Torr); IR 1780, 1225, 1170, 1150 cm^{-1}; ^1H NMR δ= 0.97 (9H, s), 1.76—2.07 (2H, m), 5.84—6.05 (1H, m), 7.29 (5H, broad s). Found: C, 61.44, H, 6.28%. Calcd for $C_{14}H_{17}F_3O_2$: C, 61.31; H, 6.25%.

1-(4-Methylphenyl)ethyl Trifluoroacetate (5): Bp 30—31 °C (0.5 Torr); IR 1780, 1220, 1160, 810 cm^{-1}; ^1H NMR δ=1.64 (3H, d, J=6.6 Hz), 2.34 (3H, s), 5.95 (1H, q, J=6.6 Hz), 7.16 (4H, broad s). Found: C, 56.94; H, 4.78%. Calcd for $C_{11}H_{11}F_3O_2$: C, 56.90; H, 4.78%.

Kinetic Procedure. Solvolyses were followed spectrophotometrically by measuring increase in trifluoroacetic acid as its acridinium ion at 402.5 nm[1] or increase in producing styrenes at 252 nm by using (0.5—2)$\times 10^{-4}$ M solutions. In the former case, the solvolysis was carried out in the presence of (1—3)$\times 10^{-4}$ M acridine and 1.0×10^{-4} M of acridinium trifluoroacetate. The initial addition of the acridinium salt was necessary for linear response of absorbance to concentration of acridinium ion under solvolysis conditions.[1]

Product Studies. Solvolysis reactions were performed with 0.02—0.04 M solutions of a substrate in a given solvent at 25 °C and a crude product obtained after workup was directly analyzed by GLC using an appropriate internal standard. A reaction of **1d** in ethanol qunatitatively gave *p*-bromostyrene (**6d**). A reaction of **1e** in 90% aq dioxane gave *m*-chlorostyrene (**6e**) in 95% yield. A reaction of **1e** in methanol gave **6e** and *m*-chloro-α-ethoxy-α-(trimethylsilylmethyl)toluene (**7e**) in 86 and 14% yield, respectively. **7e**: IR 1250, 1100, 860 cm^{-1}; ^1H NMR δ=−0.04 (9H, s), 0.94—1.15 (2H, m), 3.10 (3H, s), 4.10 (1H, dd, J=8.5 and 6.6 Hz), 7.17 (4H, broad s). A reaction of **1e** in methanol containing sodium methoxide (0.087 M) gave a mixure of **2e**, **6e**, and **7e** in the ratio 1.0 : 0.04 : 0.03. A reaction of **1e** in methanol in the presence of equimolar amounts of lutidine gave a mixture of **6e**, **7e**, and **2e** in the ratio 1.0 : 0.37 : 0.02.

The present work was supported by a Grant-in-Aid for Scientific Research No. 01470025 from the Ministry of Education, Science and Culture.

(Received March 27, 1991)

The title reaction was achieved by UV (254 nm) irradiation with CF_3I. The methylthio group was introduced to increase electron density and to limit available reactive sites in the rings. Following trifluoromethylation, the methylthio groups were readily removed by hydrogenolysis (Raney Ni) to give the desired trifluoromethyl heterocycles.

Heterocyclic compounds containing the trifluoromethyl group are of considerable interest because of their utility as drugs and agricultural chemicals. Trifluoromethyl groups on imidazoles and pyrroles possess the additional property of undergoing facile transformations to other functional groups.[1)]

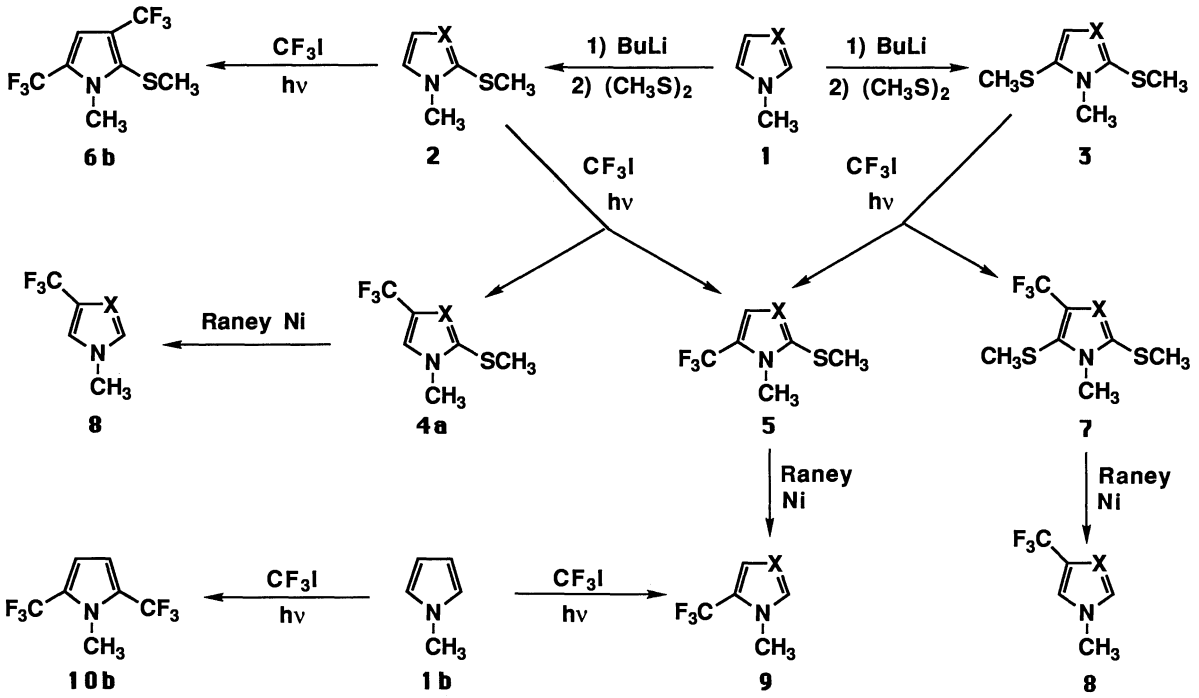
Regiospecific introduction of this group has been achieved by reaction of the carboxyl group with SF_4,[2a)] by reaction of hetaryl halides with trifluoromethyl organometallics,[2b)] by ring closure of 1,2-bis(acylamino)-ethylenes with trifluoroacetic anhydride[3)] and by ring closure involving various ketones.[4)] Of these methods, only the latter two can be performed under reaction conditions mild enough for use in polyfunctional or biologically significant systems. Comparably mild are methods involving photochemical[1d,5)] or electrochemical[6)] generation of trifluoromethyl radicals, or generation from trifluoroacetyl peroxide.[7)] These methods often yield isomer mixtures or, when regioselective, may give mainly undesired isomers. In order to provide better routes to specific isomers, we considered the introduction of reversible blocking groups on ring carbons prior to photochemical trifluoromethylation, and demonstrate here the utility of methylthio groups for this purpose. Such groups are introduced and removed with relative ease. In addition, the mildly electron-donating methylthio group would be expected to help reverse the deactivation of heteroaromatic rings by electronegative substituents,[5a)] and offers the further possibility of conversion to potentially bioactive sulfoxides and sulfones. In views of our particular interest in (perfluoroalkyl)imidazoles and pyrroles, these heteroaromatic systems received our first attention. In this study, the ring NH functions are blocked as *N*-methyl but other photostable protective groups, which are readily removed by acid hydrolysis or by hydrogenolysis, should be equally applicable. Furthermore, our previous results[5a)] have shown that trifluoromethylation is representative of perfluoroalkylation in general.

Results and Discussion

The methylthio group was introduced by selective deprotonations of **1a**[8)] and **1b**[9)] (Scheme 1) with butyllithium and reaction of the resulting carbanions with dimethyl disulfide. The use of an equivalent of butyllithium provided mono(methylthio) derivatives **2** in high yield. Two equivalents of butyllithium led to the bis(methylthio) derivatives **3** but, even in the presence of excess base or with **2** as the starting material, formation of **3** was never complete. Fortunately, **2** and **3** are readily separated by fractional vacuum distillation. In contrast to our results, **2a** (containing *N*-methoxymethyl in place of methyl) has been reported to undergo deprotonation at $S-CH_3$ rather than at a ring position.[10)] The preferential formation of the carbanion at C-2 in *N*-methylimidazole (**1a**)[11)] and in *N*-methylpyrrole (**1b**)[9,12)] is governed by the inductive effects of the ring nitrogen atoms. The generation of the second carbanion in **1a** occurs exclusively at C-5 and leads to the single bis(methylthio) product **3a**.[8)] This selectivity is determined by the strong repulsion that would exist between adjacent sp^2 lone pairs at N-3 and a C-4 carbanion (the ALP effect).[13)]

Photochemical trifluoromethylation was performed according to our published procedure,[5a)] samples being irradiated in quartz ampules for 7 d at ambient temperature. According to the solubility of the starting compound, either methanol or acetonitrile was used as solvent and triethylamine was added to neutralize the hydrogen iodide evolved. As seen from the results in Table 1, the choice of solvent has relatively little effect on yield or isomer distribution.

The photochemical trifluoromethylation of 1-methyl-2-(methylthio)imidazole (**2a**) gave mixtures of **4a** and **5a**, the latter being the major isomer (Table 1).[14)] A bis(trifluoromethyl) product was not observed. Several criteria were used to assign isomer structure: (a) coupling patterns of the ^{13}C NMR signal for C-4 and C-5 with CF_3 group;[15)] (b) the ^{19}F NMR signal for 4-CF_3 appears at higher field than for 5-CF_3;[5b)] (c) the ring proton in **5a** (meta-like) is found at higher field than that in **4a** (para-like);[16)] (d) weak coupling is observed between the $N-CH_3$ and the adjacent CF_3 group; (e) products were compared with authentic samples following reductive



Scheme 1.

Table 1. Yields and Conversions in Trifluoromethylation by UV Irradiation of 1-Methyl-2-methylthioimidazole (**2a**)

CF_3I (equiv)	Solvent	Yields[a]/%		
		4a	**5a**	**2a**
0.5	CH_3CN	0.8	11.9	31.2
0.5	CH_3OH	2.7	14.1	30.3

removal of the methylthio group. The direct trifluoromethylation of 1-methylimidazole had given three isomeric products (2-CF_3 : 4-CF_3 : 5-CF_3) in the ratio 43 : 8 : 50, separation requiring the use of both preparative gas and column chromatography.[5a] On the other hand, isomers **4a** and **5a** were formed in the ratio 10 : 90, the increased degree of substitution at C-5 probably being due to the electron-releasing effect of the methylthio group.

The 4-CF_3 isomer is the most difficult to obtain by photochemical trifluoromethylation of either **1a** or **2a**. Although C-4 is the only vacant ring position in **3a**, yields of **7a** never exceeded 6—8% (Table 2), even with 2.5 equiv of CF_3I. Interestingly, **7a** was accompanied by smaller amounts of **5a**, which may have arisen due to a slow photochemical conversion of **3a** to **2a**.

Photochemical trifluoromethylation of 1-methylpyrrole (**1b**) has been reported to yield the 2-trifluoromethyl derivative (**9b**) in 35% yield.[1d] We have confirmed this result, but found that excess CF_3I also provides a small yield (Table 3) of the 2,5-bis(trifluoromethyl) derivative (**10b**). Unfortunately, the boiling points of **9b** and **10b** are too close to permit clean separation and yields given in Table 3 are based on GC analysis. Although *N*-methylpyrrole undergoes efficient α-perfluoroalkylation with higher bis(perfluoroalkanoyl) peroxides, introduction of the CF_3 group could not be achieved.[7] The results of trifluoromethylation of **2b** are given in Table 4. Significant yields of **5b** require the use of at least 2.5 equiv of CF_3I, but small amounts of a bis(trifluoromethyl) derivative, presumably **6b**, are also formed. Fortunate-

ly, the methylthio group facilitates the separation of mixtures by increasing boiling points and R_f differences in silica-gel chromatography.

Introduction of the trifluoromethyl group at the β-position of the pyrrole ring has not been achieved by direct or indirect methods. The reaction of 5-methyl-2-pyrrolecarbaldehyde with bis(heptafluorobutyryl) peroxide provided the 3-heptafluoropropyl derivative,[7] but this method failed to provide the trifluoromethyl derivative. Photochemical trifluoromethylation of **3b** provided the desired product **7b**. Even at a level of 2.5 equiv of CF_3I, the yield of **7b** was only 7% and was accompanied by 17% of **5b** (Table 5). Detection of a trace of **2b** suggested that the apparent replacement of the methylthio group by trifluoromethyl, both in the conversion of **3a** to **5a** and **3b** to **5b**, may actually be due to a prior loss of the methylthio group by irradiation. On the other hand, products devoid of the methylthio group were not detected in the photochemical trifluoromethylation of **2a** or **2b**.

Methylthio groups were removed by hydrogenolysis with Raney nickel in refluxing ethanol.[17] The imidazole derivatives provided the expected products in yields of 50—90%, and these products were readily isolated and purified by vacuum distillation in a microtube oven. In each case, properties of the sulfur-free imidazole coincided with those of authentic samples.[5a] On the other hand, the lower boiling points of (trifluoromethyl)pyrroles (and their closeness to that of ethanol) rendered isolation and purification difficult. Even the use of higher boiling alcohols as reaction solvents did not eliminate this problem. Thus, spectral properties were determined in mixtures containing some solvent. Yields were determined by GC analysis and were found comparable to those of the imidazoles. Reduction at 90—100 °C gave somewhat higher yields than at the temperature of refluxing ethanol. For certain (trifluoromethyl)pyrroles, therefore, it may be necessary to use the materials for further synthetic procedures without recovery of the pure product.

In these test cases, the overall yields of trifluoromethylated products were found to be comparable (or even inferior) to those obtained by direct photochemical trifluoromethylation. On the other hand, laborious isomer separations have been eliminated. Finally, this method provides a route to β-(trifluoromethyl)pyrroles, isomers which have not yet been obtained by direct trifluoromethylation.

Experimental

Analytical Methods and Instrumentation. All boiling and melting points are uncorrected. ^1H NMR spectra were measured on a Hitachi R-90H (90 MHz) instrument with tetramethylsilane as internal reference. ^{19}F NMR spectra were measured on a Hitachi R-90F (84.67 MHz) instrument with trifluoroacetic acid as external reference. Gas chromatographic analyses were performed on a Shimadzu GC-4A instrument (column KF-96, 3m). Mass spectra were obtained on a Hitachi M-80 instrument with 20 eV electron impact ionization.

Materials. Trifluoromethyl iodide was prepared by reaction of silver trifluoroacetate and iodine.[18] The following methylthio compounds were prepared according to literature methods: 1-methyl-2-(methylthio)imidazole, **2a**, 55% yield, bp 124—125 °C/30 Torr (1 Torr=133.322 Pa) (lit,[8] 65—70 °C/0.5 Torr); 1-methyl-2,5-bis(methylthio)imidazole, **3a**, 34% yield, bp 104—105 °C/5 Torr (lit,[8] 100—110 °C/0.5 Torr); 1-methyl-2-(methylthio)pyrrole, **2b**, 73% yield, bp 90—91 °C/30 Torr (lit,[9] 144—145 °C/12 Torr). Raney nickel (Aldrich) was used as a suspension in ethanol after thorough washing of the commercial material with water and ethanol.

2,5-Bis(methylthio)pyrrole (3b). To a solution of 2-(methylthio)pyrrole (**2b**, 2.77 g, 21.8 mmol) and *N,N,N',N'*-tetramethylethylenediamine (3.33 g, 28.7 mmol) in hexane (20 mL), was added dropwise a hexane solution of butyllithium (1.6 M, 18 mL, 1.2 equiv) at 30 °C under nitrogen. The reaction mixture became dark red instantly, and the suspension was stirred for 1 h. To the reaction mixture, cooled in an ice bath, was added dimethyl disulfide (2.70 g, 28.7 mmol) in hexane (5 mL). The reaction mixture was stirred at 0 °C for 1 h, and was then poured into water (50 mL). The organic layer was separated, washed with water and dried ($MgSO_4$). The water

layer was extracted with ethyl acetate (2×100 mL) and the organic layer was treated in a similar manner. Vacuum distillation of the combined organic layers afforded 2,5-bis(methylthio)pyrrole (**3b**, 1.58 g, 31.8% yield) as a colorless oil, bp 94—95 °C/7 Torr; ^{1}H NMR ($CDCl_3$) δ=2.26 (s, 6H, SCH_3), 3.72 (s, 3H, NCH_3), 6.30 (s, 2H, ring); MS *m/z* 173 (M^+ 100%), 158 (84), 117 (70). Found: C, 48.78; H, 6.23; N, 8.35%. Calcd for $C_7H_{11}NS_2$: C, 48.52; H, 6.40; N, 8.08%.

UV-Induced Trifluoromethylation of 1-Methyl-2-(methylthio)imidazole (2a). Into a solution of **2a** (2.56 g, 20.0 mmol) and triethylamine (2.43 g, 24.0 mmol) in acetonitrile (10 mL), was bubbled gaseous trifluoromethyl iodide until the weight had increased by 4.70 g (24.0 mmol). The solution was placed in a quartz tube and the remaining upper space was filled with argon. The tube was sealed with a glass stopper and then the solution was irradiated for 7 d at ambient temperature, using a 60 W low-pressure mercury lamp equipped with a Vycor filter.

The dark orange reaction mixture was poured into water and the products were extracted with ethyl acetate (3×100 mL). The combined organic layers were washed with water, dried (Na_2SO_4) and evaporated under reduced pressure. The residual oil was subjected to silica-gel chromatography with CH_2Cl_2 and ether as successive eluents to provide, in order, **4a** (1.5%), **5a** (25.0%), and **2a** (12.7%). The eluting solvent was removed and the product purified by vacuum distillation using a glass tube oven. Additional runs are summarized in Table 1.[19]

1-Methyl-2-methylthio-4-(trifluoromethyl)imidazole (4a): White needles, mp 44—46 °C; ^{1}H NMR (acetone-d_6) δ=26.0 (s, 3H, SCH_3), 3.66 (br s, 3H, NCH_3), 7.63 (q, 1H, *J*=1.1 Hz, H-5); ^{13}C NMR ($CDCl_3$) δ_C=15.8 (s, SCH_3), 33.3 (s, NCH_3), 121.7 (q, *J*=267 Hz, CF_3), 121.8 (q, *J*=4.1 Hz, C-5), 131.9 (q, *J*=39 Hz, C-4), 145.8 (s, C-2); ^{19}F NMR (acetone-d_6) δ_F=14.8 (s); MS *m/z* 196 (M^+ 100%), 163 (54) Found: C, 36.65; H, 3.57; N, 14.40%. Calcd for $C_6H_7N_2F_3S$: C, 36.73; H, 3.60; N, 14.28%.

1-Methyl-2-methylthio-5-(trifluoromethyl)imidazole (5a): Colorless oil, bp 98—99 °C/30 Torr; ^{1}H NMR (acetone-d_6) δ=2.64 (s, 3H, SCH_3) 3.65 (br s, 3H, NCH_3), 7.42 (q, *J*=1.5 Hz, H-4); ^{13}C NMR ($CDCl_3$) δ_C=15.3 (s, SCH_3), 31.6 (d, *J*=1.4 Hz, NCH_3), 121.0 (q, *J*=266 Hz, CF_3), 123.2 (q, *J*=39 Hz, C-5), 130.9 (q, *J*=4.2 Hz, C-4), 149.1 (br s, C-2); ^{19}F NMR (acetone-d_6) δ_F=17.3 (s); MS *m/z* 196 (M^+ 100%), 163 (59). Found: C, 36.30; H, 3.68; N, 14.77%. Calcd for $C_6H_7N_2F_3S$: C, 36.73; H, 3.60; N, 14.28%.

UV-Induced Trifluoromethylation of 1-Methyl-2,5-bis(methylthio)imidazole (3a). Trifluoromethylation of **3a**, by the procedure described above, gave **7a** (7.8%), **5a** (2.9%), and unreacted **3a** (32.0%). The mixture of imidazoles was separated by silica-gel chromatography with 50% hexane/50% CH_2Cl_2 and 100% CH_2Cl_2 as successive eluents and products were eluted in the order given. Additional runs are summarized in Table 2.

1-Methyl-2,5-bis(methylthio)-4-(trifluoromethyl)imidazole (7a): White needles, mp 39—40 °C; ^{1}H NMR (acetone-d_6) δ=2.33 (s, 3H, SCH_3), 2.63 (s, 3H, SCH_3), 3.65 (br s, 3H, NCH_3); ^{19}F NMR (acetone-d_6) δ_F=16.6 (s); MS *m/z* 242 (M^+ 100%), 227 (46), 209 (45), 186 (37). Found: C,34.38; H, 3.77; N, 11.52%. Calcd for $C_7H_9N_2F_3S_2$: C, 34.70; H, 3.74; N, 11.56%.

UV-Induced Trifluoromethylation of 1-Methylpyrrole (1b). Following the procedure used with **2a**, **1b** gave **9b** and **10b** or **9b** and recovered **1b**. The results are given in Table 3. It was difficult to separate **9b**, **10b**, and **1b** because the boiling points are very close to one another, therefore, these materials were identified in a mixture and the yields are based on GC analysis.

1-Methyl-2-(trifluoromethyl)pyrrole (9b): ^{1}H NMR (acetone-d_6) δ=3.73 (s, 3H, SCH_3), 6.07 (m, 1H, ring), 6.53 (m, 1H, ring), 6.88 (m, 1H, ring); ^{19}F NMR (acetone-d_6) δ_F=18.6 (s); MS *m/z* 149 (M^+ 100%), 130 (36).

1-Methyl-2,5-bis(trifluoromethyl)pyrrole (10b): ^{1}H NMR (acetone-d_6) δ=3.83 (s, 3H, SCH_3), 6.66 (s, 2H, ring); ^{19}F NMR (acetone-d_6) δ_F=17.6 (s); MS *m/z* 217 (M^+ 100%), 198 (40), 156 (21).

UV-Induced Trifluoromethylation of 1-Methyl-2-(methylthio)pyrrole (2b). Following the procedure used with **2a**, **2b** gave **5b** (17.7%) and **2b** (4.7%). The mixture of pyrroles was separated by silica-gel chromatography with 90% hexane/10% CH_2Cl_2 and 100% CH_2Cl_2 as successive eluents. The results of additional runs are given in Table 4. At higher ratios of CF_3I, small amounts of a bis(trifluoromethyl)derivative, probably **6a**, were also obtained. The material was identified by mass spectrum (M^+ 263) and yields are based on GC analysis; however, no effort was made to isolate **6b**.

1-Methyl-2-methylthio-5-(trifluoromethyl)pyrrole (5b): Colorless oil, bp 80—81 °C/30 Torr; ^{1}H NMR (acetone-d_6) δ=2.32 (s, 3H, SCH_3), 3.77 (q, 3H, *J*=0.7 Hz, NCH_3), 6.31 (AB, 1H, *J*=4.0 Hz, H-3), 6.57 (AB-q, 1H, *J*=4.0 Hz and 0.9 Hz, H-4); ^{19}F NMR δ_F=17.9 (s); MS *m/z* 195 (M^+ 100%), 180 (61). Found: C, 43.02; H, 4.17; N, 7.09; S, 16.36%. Calcd for $C_7H_9NF_3S$: C, 43.07; H, 4.13; N, 7.18; S, 16.42%.

UV-Induced Trifluoromethylation of 1-Methyl-2,5-bis(methylthio)pyrrole (3b). Following the procedure used with **2a**, **3b** gave **7b** (3.9%), **5b** (10.2%), and unreacted **3b** (38.1%). The mixture of pyrroles was separated by silica-gel chromatography with 100% hexane; the pure products were obtained following removal of solvent in a glass tube oven. The results of additional runs are given in Table 5.

1-Methyl-2,5-bis(methylthio)-3-trifluoromethylpyrrole (7b): Colorless oil, bp 164—168 °C; ^{1}H NMR (acetone-d_6) δ=2.29 (s, 3H, SCH_3), 2.36 (s, 3H, SCH_3), 3.83 (br s, 3H, NCH_3), 6.56 (br s, 1H, H-4); ^{19}F NMR (acetone-d_6) δ_F=20.9 (s); MS *m/z* 241 (M^+ 100%), 226 (73) 185 (74). Found: C, 39.88; H, 4.21; N, 5.72%. Calcd for $C_7H_9N_2F_3S_2$: C, 39.82; H, 4.18; N, 5.80%.

Hydrogenolysis of Methylthio Groups of Imidazoles. To an ethanol solution (30 mL) of 1-methyl-2-methylthio-5-(trifluoromethyl)imidazole (**5a**) (1.34 g, 6.81 mmol) was added Raney nickel dampened with ethanol (ca. 10 g), and the reaction mixture was vigorously stirred under reflux for 5 h. The nickel was removed by filtration, the filtrate was poured into water (100 mL) and the mixture was extracted with dichloromethane (3×100 mL). The combined organic layers were washed with water and dried (Na_2SO_4). The solvent was evaporated and the residue was vacuum distilled in a glass tube oven to give **9a** in 57.3% yield.

1-Methyl-5-(trifluoromethyl)imidazole (7a): White needles, mp 38—41 °C; ^{1}H NMR (acetone-d_6) δ=3.83 (s, 3H, NCH_3), 7.41 (br s, 1H, H-4), 7.76 (br s, 1H, H-2) (lit,[5a] δ=3.83, 7.40, 7.75); ^{19}F NMR δ_F=17.8 (s); MS *m/z* 150 (M^+).

Hydrogenolysis of methylthio groups in other imidazoles was carried out by a similar procedure.

1-Methyl-4-(trifluoromethyl)imidazole (8a): 54.5% yield from **4a**, 86.6% yield from **7a**; colorless oil, bp 222—225 °C; ^{1}H NMR (acetone-d_6) δ=3.82 (br s, 3H, NCH_3), 7.58 (br s, 1H, H-2), 7.66 (br s, 1H, H-5) (lit,[5a] δ=3.88, 7.58, 7.64); ^{19}F NMR

δ_F=15.3 (s); MS *m*/*z* 150 (M^+).

Hydrogenolysis of Methylthio Groups in Pyrroles. To an ethanol solution (25 mL) of 1-methyl-2-methylthio-5-(trifluoromethyl)pyrrole (**5b**) (1.68 g, 8.60 mmol), was added Raney nickel dampened with ethanol (ca. 15 g), and the reaction mixture was vigorously stirred under reflux for 1 h. The nickel was removed by filtration, the filtrate was poured into water (100 mL), and the mixture was extrated with dichloromethane (2×100 mL). The organic layers were combined, washed with water and dried (Na_2SO_4). The solvent was removed and the estimated yield of **9b** was 60%, determined by GC analysis. Properties of **9b** were determined using a sample (90% purity) obtained in a microdistillation apparatus.

1-Methyl-2-(trifluoromethyl)pyrrole (9b): Colorless oil, bp. 114 °C; ^{1}H NMR (acetone-d_6) δ=3.75 (br s, 3H, NCH_3), 6.08 (m, 1H, ring) 6.55 (m, 1H, ring), 6.91 (m, 1H, ring) (lit,[1d] ($CDCl_3$) δ=3.60, 5.90, 6.36, 6.48); ^{19}F NMR δ_F=18.8 (s); MS *m*/*z* 149 (M^+).

Hydrogenolysis of the methylthio groups of **7b** was carried out by a similar procedure, and the estimated yield of **8b** was 41% determined by GC analysis. A sample of **8b** could not be obtained by preparative GC and microdistillation led to a dark tarry product; properties of **8b** were determined using a dichloromethane solution.

1-Methyl-3-(trifluoromethyl)pyrrole (8b): ^{19}F NMR (acetone-d_6) δ_F=21.0 (s); *m*/*z* 149 (M^+).

Synthesis of Optically Active Polyamides Having Axially Dissymmetric 1,1′-Binaphthalene-2,2′-dicarboxylic Acid Component and Their Optical Resolution Ability as Chiral Adsorbent for HPLC

Yasufumi TAMAI, Yutaka MATSUZAKA, Shuichi ÔI, and Sotaro MIYANO*
Department of Biochemistry and Engineering, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Aoba-ku, Sendai 980

(Received April 4, 1991)

Optically active polyamides **4a**—**4c** were synthesized from the polycondensation of axially dissymmetric 1,1′-binaphthalene-2,2′-dicarbonyl dichloride (**2**) with 1,4-benzenediamine, 1,6-hexanediamine, and 1,10-decanediamine, respectively. CD spectra of the polyamides **4a**—**4c** are essentially the same as those of the corresponding model diamides **6a**—**6c** prepared from **2** and benzenamine, 1-hexanamine, and 1-decanamine, respectively. This similarity indicates that the conformation of the 1,1′-binaphthalene-2,2′-dicarboxamide moieties of the polyamides **4a**—**4c** in solution state are rather similar to those of the corresponding model diamides **6a**—**6c**. Several axially chiral biaryl compounds and 3,5-dinitrophenylcarbamates (3,5-DNPCs) derived from 1-aryl-1-alkanols were resolved by HPLC equipped with the columns packed the chiral stationary phases (CSPs) prepared from **4a**—**4c** adsorbed on spherical silica gel. A main control factor for the chiral discrimination seems to be the hydrogen bonding between the amide groups of the CSPs and the hydrogen-bonding sites of the atropisomeric biaryls. The donor–acceptor interaction between the binaphthalene moiety of the CSPs and the 3,5-dinitrobenzene moiety of the 3,5-DNPCs may also be important for the chiral discrimination of the 3,5-DNPCs.

A wide variety of polymeric chiral stationary phases (CSPs) have recently been developed for the separation of enantiomers by means of high-performance liquid chromatography (HPLC).[1] Some kinds of optically active polyamides have been reported to show the chiral recognition ability as the chiral adsorbents for the CSPs.[2] It is well-known that axially dissymmetric 1,1′-binaphthalene derivatives serve as highly efficient chiral inducers for a wide range of asymmetric reactions.[3] Therefore, the optically active polyamide having axially dissymmetric 1,1′-binaphthalene component in the main chain is expected to serve as the efficient chiral adsorbent of the CSP for HPLC. Although the chiroptical properties of some axially chiral polyamides have been investigated,[4] no report has dealt with the chiral recognition ability of the axially chiral polyamide. Previously, we reported a practical method for the synthesis of optically pure 1,1′-binaphthalene-2,2′-dicarboxylic acid (**1**) derivatives and their usefulness as the chiral modifiers of the packing material for HPLC.[5] In this paper, we wish to report the synthesis of polyamides **4a**—**4c** from optically pure **1** and 1,4-benzenediamine (**3a**), 1,6-hexanediamine (**3b**), and 1,10-decanediamine (**3c**). Further reported are the chiroptical properties of these polyamides and their optical resolution ability as the chiral adsorbents for the CSPs.

Results and Discussion

Synthesis of Polyamides 4a—4c and Model Diamides 6a—6c. The syntheses of the polyamides **4a**—**4c** were carried out by the method of solution polycondensation at ambient temperature in *N*,*N*-dimethylacetamide (DMAc) as shown in Scheme 1. Diamines **3a**—**3c** were reacted with the dicarbonyl dichloride **2** derived from optically pure (*S*)-**1** to yield the optically active polyamides **4a**—**4c**, respectively (Table 1). For the synthesis of **4b** and **4c**, concomitant formation of linear and/or cyclic oligomers was observed.

All the polyamides were soluble in 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) and aprotic polar solvents such as *N*,*N*-dimethylformamide (DMF), DMAc, and dimethyl sulfoxide (DMSO), but insoluble in chloroform, tetrahydrofuran (THF), and usual nonpolar solvents.

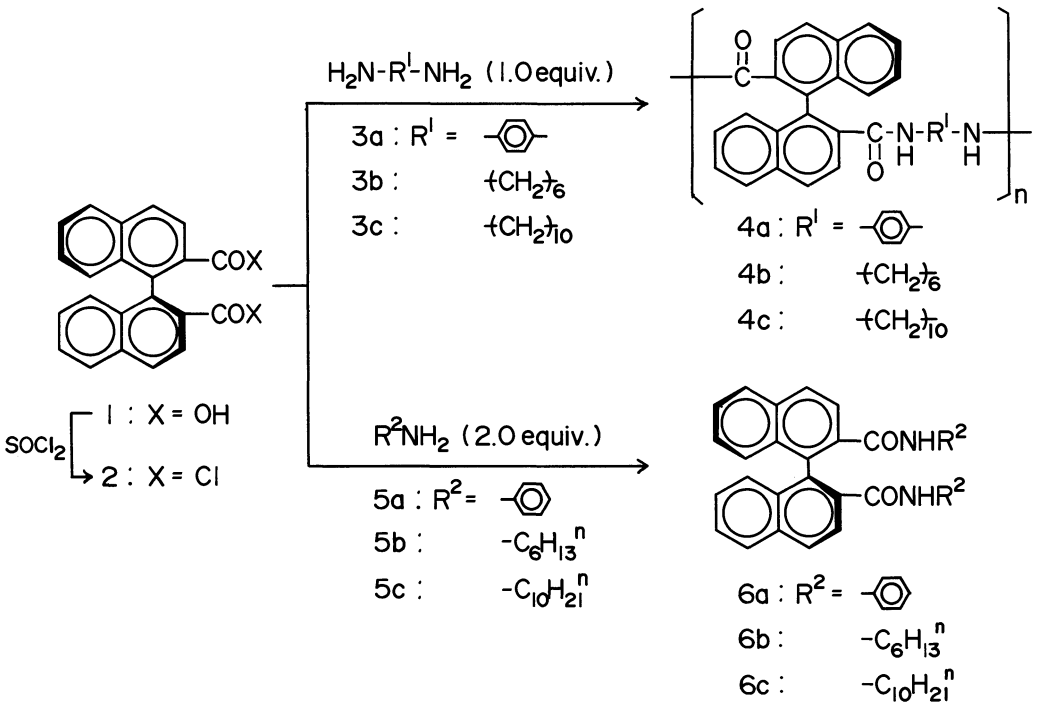
Model diamides **6a**—**6c** were prepared by condensation of **2** with benzenamine (**5a**), 1-hexanamine (**5b**), and 1-decanamine (**5c**) in benzene at reflux temperature, respectively (Table 1).

Comparison of the Chiroptical Properties of the Polyamides 4a—4c to the Corresponding Diamides 6a—6c. As shown in Table 1, the mean residue rotations ($[m]_D$) of **4b** and **4c** were comparable to the molar rotations ($[\phi]_D$) of the corresponding model diamides **6b** and **6c** in DMAc solution. CD spectra of **4b** and **4c** in both DMAc and HFIP were almost comparable to those of **6b** and **6c**, respectively, as shown in Figs. 2 and 3. In contrast, the mean residue rotation of **4a** was rather

Table 1. Synthesis of Polyamides (**4a**—**4c**) and Diamides (**6a**—**6c**)

	Yield / %	$\bar{M}_n$ [a]	$\bar{M}_w/\bar{M}_n$ [a]	$[m]_D$ [b] for **4a**—**4c** ($[\phi]_D$ [c] for **6a**—**6c**)
4a	84	20000	1.92	−2.1°
6a	95			−70.5°
4b	59	27000	1.49	−48.9°
6b	83			−71.7°
4c	27	26000	1.48	−59.4°
6c	94			−64.0°

a) Determined by GPC calibrated with polystylene standards. b) Mean residue rotation. Measured at ca. 0.024 (repeating unit mol) dm^{-3} in DMAc at ambient temperature. c) Molar rotation. Measured at ca. 0.024 mol dm^{-3} in DMAc at ambient temperature.



Scheme 1.

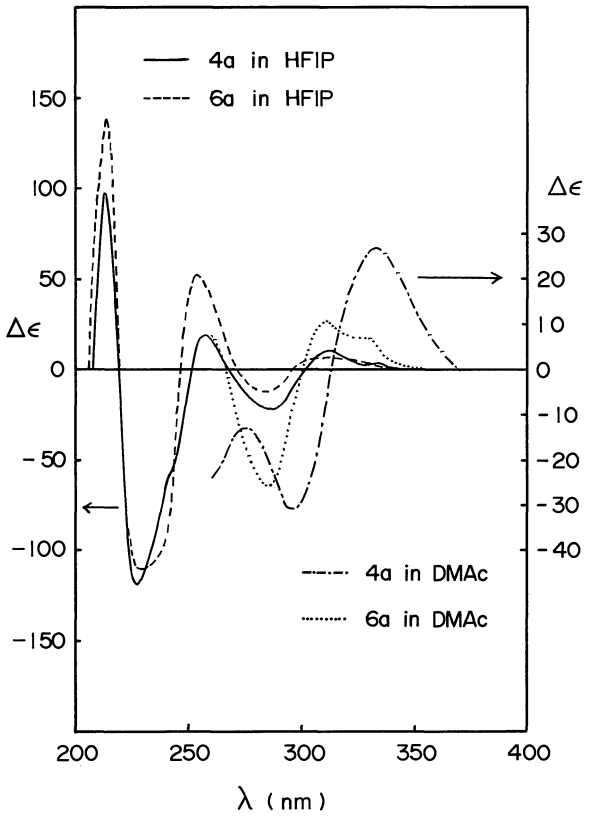


Fig. 1. CD spectra of polyamide **4a** and model diamide **6a**.

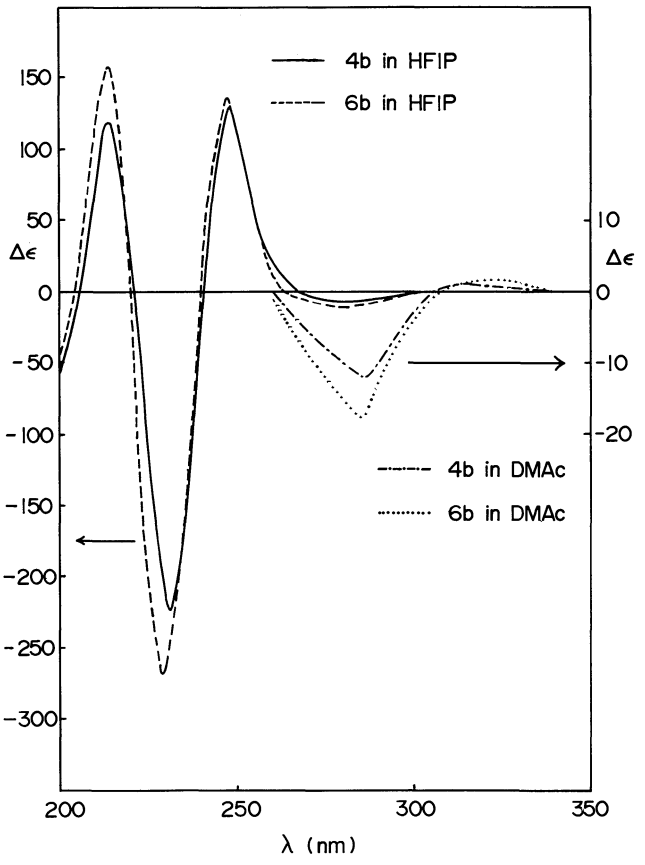

Fig. 2. CD spectra of polyamide **4b** and model diamide **6b**.

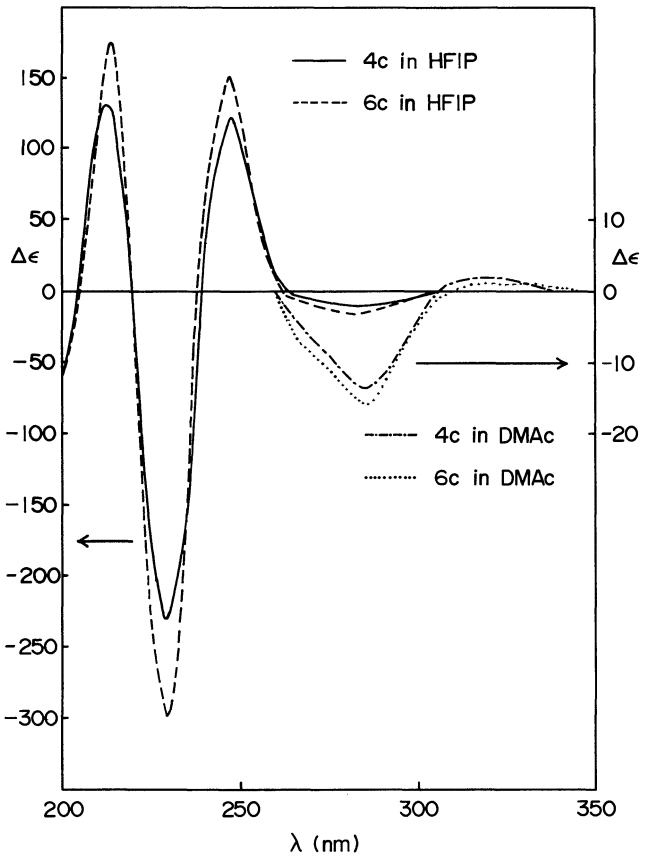

Fig. 3. CD spectra of polyamide **4c** and model diamide **6c**.

smaller than the molar rotation of **6a**. CD spectrum of **4a** at wavelength longer than 260 nm in DMAc was somewhat different from that of **6a**, while the spectrum at wavelength shorter than 260 nm in HFIP was almost comparable to that of **6a** (Fig. 1).

It is known that the Cotton effects derived from the ^1B_b transition of the naphthalene chromophores in 1,1′-binaphthalene derivatives appear at wavelength shorter than 260 nm; the Cotton effects are supposed to reflect the conformation of the binaphthalene skeletons more closely than those derived from other transitions of the naphthalene chromophores.[6] Thus, the similarity of the CD spectra of **4a**—**4c** at wavelength shorter than 260 nm to those of the corresponding model diamides **6a**—**6c** suggests that the conformations of the 1,1′-binaphthalene-2,2′-dicarboxamide moieties of the polyamides in the solution state are similar to those of the model diamides. It seems that the differences of the chiroptical properties between **4a** and **6a** at wavelength longer than 260 nm are attributed to the differences of transition properties between the 1,4-bis(acylamino)benzene chromophore of the polyamide **4a** and the (acylamino)benzene chromophore of the model diamide **6a**.

Chiral Recognition Ability of Polyamides 4a—4c as the Chiral Adsorbents for the CSPs. To investigate the chiral recognition ability of the polyamides **4a**—**4c**, CSP-4a—CSP-4c were prepared by coating spherical, macroporous silica gel with DMAc solutions of **4a**—**4c** using a conventional technique.[7] Polyamides **4a**—**4c** are constituted of amide linkages which can function as hydrogen-bonding site and bulky binaphthalene moieties which can serve as π-electron-donor group. Thus, dia-

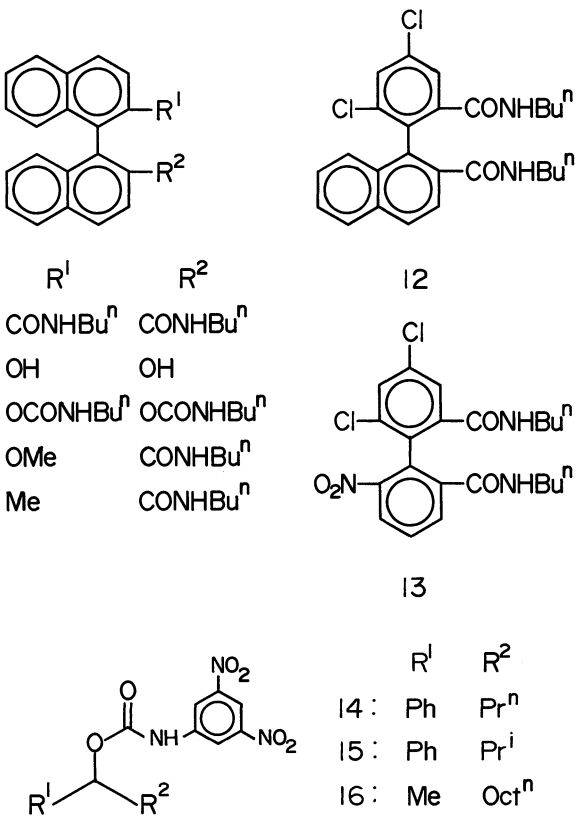
a) A, 2-propanol/hexane=10/90, Flow rate=1.0 ml min^{-1}; B, 2-propanol/hexane=1/99, Flow rate=1.0 ml min^{-1}. b) Capacity factor of the enantiomer eluting first=(retention volume of enantiomer—void volume of column)/(void volume of column). c) Separation factor=(k' of more retained enantiomer)/(k' of less retained enantiomer). d) Resolution factor=2×(distance between the peaks of more and less retained enantiomers)/(sum of band width of two peaks). e) Absolute configuration of the enantiomer eluting first. f) The capacity factor of the racemate was so large that no clear peak of the racemate was observed. g) This racemate couldn't be resolved even by use of eluent B. h) Flow rate=0.5 ml min^{-1}.

stereomeric interactions via π–π interaction and hydrogen bonding are expected between the CSPs and racemates which have an electron-accepting aromatic group and a hydrogen-bonding site. Table 2 shows the results of the HPLC analyses of such racemates **7**—**16**. Figure 4



Structure of racemates.

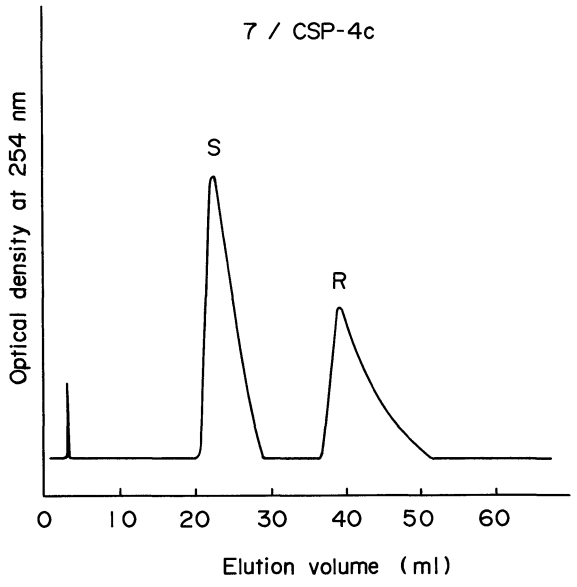


Fig. 4. Chromatographic resolution of racemate **7** on CSP-**4c** column. Column: 25×0.46 (i.d.) cm, eluent: 1% 2-propanol in hexane, flow rate: 1.0 ml min^{-1} at room temperature.

shows the chromatogram of the resolution of **7** on a CSP-4c column using 1% 2-propanol in hexane as the eluent. CSP-4b and CSP-4c could resolve the axially chiral 1,1'-biaryl compounds **7**, **9**, **12**, and **13**, which possessed two amide or carbamate groups, respectively. Racemate **10** which had an amide group and a methoxyl group could be resolved by CSP-4b and CSP-4c. CSP-4a could also resolve the racemates **7**, **9**, and **12**, but couldn't resolve **10** and **13**. On the other hand, none of the CSPs could resolve racemate **11** which had only an amide group as the hydrogen-bonding site. These results indicate that the presence of two hydrogen-bonding sites in a racemate is necessary for efficient chiral discrimination of these biaryl compounds. Thus, a main control factor for the chiral discrimination of biaryl atropisomers seems to be the hydrogen bonding between the amide groups of the polyamides and the hydrogen-bonding sites of the racemates. The capacity factor (k_1') and the separation factor (α) of all of the racemates decreased with a increase in the content of 2-propanol in the eluent. This result also supports the importance of the hydrogen bonding for the chiral discrimination; hydrogen bonding between the polyamides and 2-propanol in competition with the racemates should decrease the interaction between the polyamide CSPs and the racemates.

Racemate **8** couldn't be resolved by all of the CSPs despite bearing two phenolic hydroxyl groups as the hydrogen-bonding sites. This result indicates that a suitable alignment of the two hydrogen-bonding sites of a racemate is also important for efficient chiral discrimination.

Although having only one hydrogen-bonding site, 3,5-dinitrophenylcarbamates (3,5-DNPCs) **14** and **15** derived from the corresponding 1-aryl-1-alkanols were also resolved efficiently (α>1.3) by CSP-4b and CSP-4c. An important control factor of the chiral discrimination should be donor–acceptor interaction between the binaphthalene moiety of the polyamides and the 3,5-dinitrobenzene moiety of the 3,5-DNPCs.

In conclusion, we have shown here that optically active polyamides **4a**—**4c**, obtained by solution polycondensation of 1,1'-binaphthalene-2,2'-dicarbonyl dichloride (**2**) with diamines **3a**—**3c**, have chiral discriminating ability for atropisomeric biaryls **7**,**9**—**13**, and 3,5-DNPCs **14** and **15**.

Experimental

Measurements. Melting points were measured on a Yamato MP-21 and uncorrected. Microanalyses were carried out in the Microanalytical Laboratory of the Chemical Research Institute of Non-aqueous Solutions, Tohoku University. Optical rotations were obtained at room temperature (23—25 °C) using a Union Giken PM-101 polarimeter. CD spectra were measured in an 0.10 cm cell at room temperature on a JASCO J-400X spectropolarimeter. HPLC measurements were carried out on a Shimadzu LC-6A, with UV detection at 254 nm. IR spectra were measured on a Shimadzu IR-460

infrared spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL JNM-FX60 instrument. GPC measurements were carried out at 40 °C on a Tosoh HLC-8020 instrument equipped with TSK gel GMH$_{XL}$ (×2) and G2000H$_{XL}$ columns using a 5 mM LiBr solution of DMF as an eluent.

Materials. Homochiral (*S*)-1,1′-binaphthalene-2,2′-dicarboxylic acid (**1**) was prepared by a previously reported procedure[5] and converted to the bis(acid chloride) **2** by the usual method using thionyl chloride. Diamines **3a**—**3c** and amines **5a**—**5c** were purchased from Tokyo Kasei Kogyo Co., Ltd. and purified by distillation under reduced pressure (**3b**, **3c**, and **5a**—**5c**) or by recrystallization from benzene (**3a**) before use. DMAc was purified by distillation under reduced pressure over calcium hydride before use. Triethylamine was purified by distillation over calcium hydride before use. Other solvents were purified by distillation.

Preparation of Polyamides. The synthetic procedure for **4a** is representative. To a stirred solution of diamine **3a** (181 mg, 1.68 mmol) and triethylamine (343 mg, 3.39 mmol) in DMAc (14 ml) was added finely powdered dicarbonyl dichloride **2** (636 mg, 1.68 mmol) portionwise at room temperature under a nitrogen atmosphere. After stirring for 30 min, the reaction mixture was dropped into 200 ml of methanol with stirring. The resultant precipitate was collected by filtration and washed with methanol and then with acetone. Polyamide **4a** thus obtained was purified by reprecipitation from methanol and dried at 90 °C for 20 h. The polyamide weighed 580 mg (83%). **4b** and **4c** were similarly prepared (Table 1).

4a: IR (KBr) 1636, 1303, 827, and 757 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=7.0—8.1 (16H, m, Ar–H) and 10.8 (2H, br, N–H). Found: C, 79.02; H, 4.49; N, 6.86%. Calcd for $(C_{28}H_{18}N_2O_2)_n$: C, 81.14; H, 4.38; N, 6.76%.

4b: IR (KBr) 1619, 1541, 1280, 819, and 749 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=−0.1—0.9 (8H, br, CH_2), 2.4—3.2 (4H, br, CH_2–N), 6.8—8.3 (12H, m, Ar–H), and 8.6—9.2 (2H, br, N–H). Found: C, 78.40; H, 6.20; N, 6.39%. Calcd for $(C_{28}H_{26}N_2O_2)_n$: C, 79.59; H, 6.20; N, 6.63%.

4c: IR (KBr) 1643, 1538, 824, and 756 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=0.3—1.5 (16H, br, CH_2), 2.4—3.2 (4H, br, CH_2–N), 6.9—8.1 (12H, m, Ar–H), and 8.7—9.2 (2H, br, N–H). Found: C, 77.83; H, 7.17; N, 6.18%. Calcd for $(C_{32}H_{34}N_2O_2)_n$: C, 80.30; H, 7.16; N, 5.85%.

The discrepancies in these carbon analyses may be attributed to the carbonization of the binaphthalene moieties of the polyamides.[8]

Synthesis of Model Diamides. The synthetic procedure for **6a** is representative. To a stirred solution of the dicarbonyl dichloride **2** (212 mg, 0.558 mmol) in dry benzene (10 ml) were added benzenamine (**5a**) (125 mg, 1.34 mmol) and triethylamine (136 mg, 1.34 mmol) at room temperature under a nitrogen atmosphere. The solution was refluxed with stirring for 1 h and then cooled to room temperature. The reaction mixture was washed (2 M HCl (1 M=1 mol dm^{-3}), 10% Na_2CO_3, and distilled water) and dried over Na_2SO_4. Solvents were removed under reduced pressure, and the residue was purified by silica-gel column chromatography (eluent: 50% ethyl acetate in hexane) to afford the diamide **6a** in 95% yield (260 mg) as amorphous powder. Diamides **6b** and **6c** were similarly prepared as colorless glass (Table 1).

6a: IR (KBr) 1643, 1545, 1332, 755, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.80—8.10 (22H, m, Ar–H) and 8.90—9.30 (2H, br, N–H). Found: C, 82.90; H, 5.00; N, 5.70%. Calcd for $C_{34}H_{24}N_2O_2$: C, 82.90; H, 4.91; N, 5.69%.

6b: IR (neat) 1624, 1543, 1326, 1299, 824, and 756 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.85—1.00 (22H, m, CH_2 and CH_3), 2.82—3.14 (4H, m, CH_2–N), and 7.05—8.08 (14H, m, Ar–H and N–H). Found: C, 80.63; H, 8.06; N, 5.47%. Calcd for $C_{34}H_{40}N_2O_2$: C, 80.27; H, 7.93; N, 5.51%.

6c: IR (neat) 1631, 1563, 1331, 1301, 825, and 756 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.80—1.24 (38H, m, CH_2 and CH_3), 2.82—3.14 (4H, m, CH_2–N), and 6.96—8.04 (14H, m, Ar–H and N–H). Found: C, 81.04; H, 9.30; N, 4.41%. Calcd for $C_{42}H_{56}N_2O_2$: C, 81.24; H, 9.09; N, 4.51%.

Preparation of Packing Material and Column Packing. Macroporous silica gel (Merck, LiChrospher SI 1000: mean particle size, 10 μm; pore size, 100 nm) was silanized with dichlorodiphenylsilane according to the literature method.[7] A polyamide (ca. 0.15 g) was dissolved in 7 ml of DMAc and the silanized silica gel (3.0 g) was wetted with the polymer solution. The resultant mixture was irradiated with ultrasound for 1 min. Then the solvent was evaporated in vacuo. Obtained polymer-coated silica gel was dried in vacuo at 80 °C for 5 h and then dispersed in 30 ml of methanol with sonication during 5 min. After filtration and washing with methanol, the silica gel was dried in vacuo at 80 °C for 5 h. The chiral packing material thus obtained was packed in a stainless steel HPLC column (i. d.: 0.46 cm, length: 25 cm) by a slurry method. The plate number of the columns packed CSP-4a—CSP-4c were about 4500, 2900, and 2500, respectively, for benzene using 10% 2-propanol in hexane as the eluent at ambient temperature.

We thank Professor Hisashi Uda and Professor Nobuyuki Harada of the Chemical Research Institute of Non-aqueous Solutions of our university for CD measurement. We also thank Mr. Katsuo Komiya and Dr. Ryuichi Kitayama of Tosoh Co., Ltd. for GPC measurements and analyses. A part of this work was supported by a Grant-in-Aid for Scientific Research No. 02555177 from the Ministry of Education, Science and Culture.

A Synthesis of 5′-*O*-Acryloyl-5-fluorouridine by Use of *p*-Methoxybenzyl Group as an N^3-Imide Protecting Group of 5-Fluorouridine[1)]

(Received February 18, 1991)

5′-*O*-Acryloyl-5-fluorouridine was prepared by use of *p*-methoxybenzyl (PMB) group as an N^3-imide protecting group of 5-fluorouridine. PMB group was introduced chemoselectively by use of *N*,*N*-diisopropylethylamine or DBU as a base. A new deprotection method was developed by means of $AlCl_3$–anisole system at room temperature.

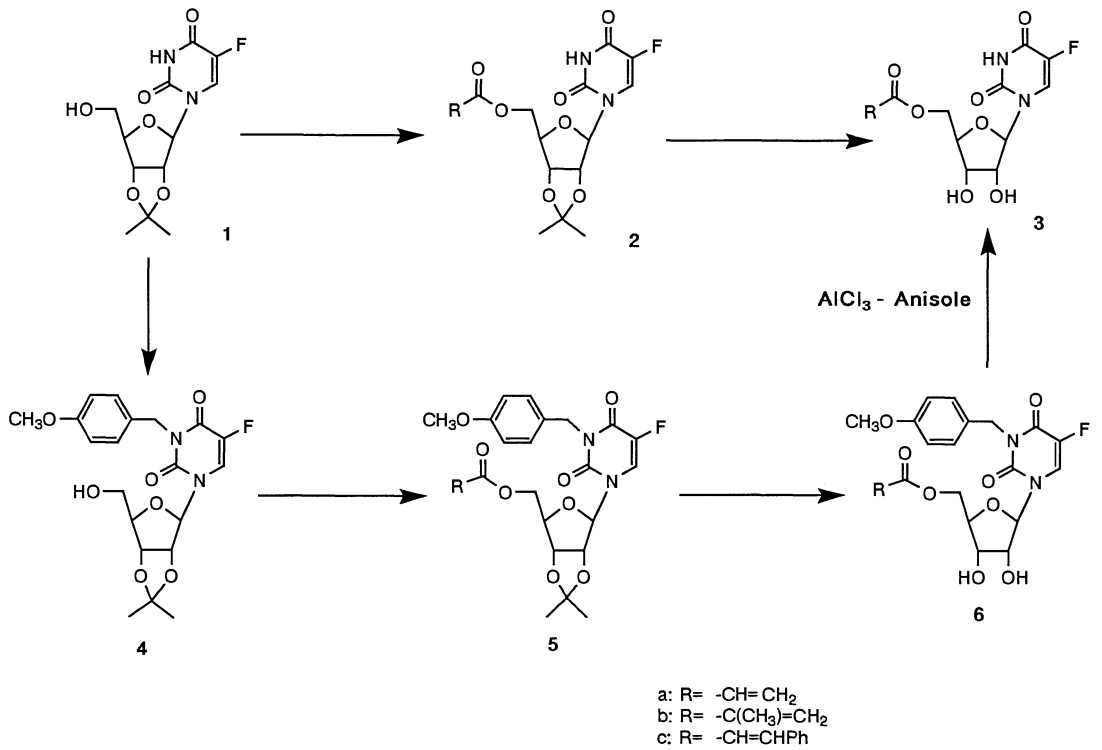
In our laboratory, as part of a continuing synthetic program designed to develop antitumor agents with high antitumor activity and low toxicity, we have synthesized various kinds of 5-fluorouracil (5-FU) derivatives such as 1-carbamoyl-,[2)] 1-acyloxyalkyl-,[3)] 1-alkylthiocarbamoyl-,[4)] 1-alkoxyalkyl-5-fluorouracils,[5)] and also functional polymers bearing 5-FU as a side chain.[6)] Recently, functional polymers containing 5-FU have attracted considerable attention from the standpoint of polymeric drugs. Polymeric drugs bearing 5-fluorouridine (FUR) as a side chain, however, have not been developed so far. In previous papers,[1,7)] we reported syntheses and antitumor activity of 5′-*O*-acyl-5-fluorouridines, which showed high antitumor activity against L-1210 leukemia in mice. These results prompted us to synthesize functional polymers containing FUR as a side chain. We focused on 5′-*O*-acryloyl-5-fluorouridine (**3a**) as a promising ester monomer containing FUR and attempted to synthesize it. Unexpectedly, **3a** was not obtained by the usual method (5′-*O*-acylation of 2′,3′-*O*-isopropylidene-5-fluorouridine (**1**) followed by acidic hydrolysis). In order to synthesize it efficiently, protection of the N^3-imide function was necessary. Protection of N^3-imide function in uridine moiety has attracted considerable attention in nucleotide chemistry and various kinds of protecting groups such as benzoyl,[8)] 2-(4-nitrophenyl)ethyl,[9)] 2-(4-nitrophenylsulfonyl)-ethyl,[10)] phenyl,[11)] and 2-(methoxy)ethoxymethyl[12)] groups have been developed. Because N–glycosidic bonds are acid labile and *O*-acryloyl moiety is unstable in basic conditions, an N^3-imide protecting group removable under mild conditions is desirable. We have found that *p*-methoxybenzyl (PMB) group meets above requirements. The PMB group has following features; 1) selective introduction is possible in the presence of free OH group with DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) as a base, 2) deprotection was effected smoothly by the action of $AlCl_3$ in anisole at room temperature under mild conditions.[13)] In this paper we wish to describe a synthesis of **3a** by use of PMB group as a N^3-imide protecting group removable under weakly acidic conditions by means of $AlCl_3$–anisole system.[14)]

Results and Discussion

A variety of 5′-*O*-acyl-5-fluorouridines were synthesized by 5′-*O*-acylation of **1** followed by acidic hydrolysis of the isopropylidene moiety.[1)] However, when **1** was treated with acryloyl chloride in the presence of tertiary amine, corresponding 5′-*O*-acylated compound **2a** was obtained in a very low yield and was too labile to purify by column chromatography. All our attempts to synthesize **2a** in a pure form failed. We therefore speculated that **2a** could be obtained by protecting N^3-imide function in advance and sought a protecting group for the N^3-imide function. We have found that a PMB group meets above requirements.

Introduction of a PMB group was carried out as follows. Treatment of **1** with *p*-methoxybenzyl bromide (1.5 equiv) in the presence of *N*,*N*-diisopropylethylamine (2.0 equiv) as a base in CH_3CN at room temperature for 3 h gave 2′,3′-*O*-isopropylidene-3-(4-methoxybenzyl)-5-fluorouridine (**4**) quantitatively. The PMB group was introduced more conveniently by use of commercially available *p*-methoxybenzyl chloride in the presence of DBU as a base in CH_3CN without protecting 5′-OH group to afford **4** in a good yield. No formation of 5′-*O*-alkylated compound was observed under these conditions. Next, acylation of N^3-protected derivative **4** with acryloyl chloride proceeded smoothly to obtain 5′-*O*-acryloyl-2′,3′-*O*-isopropylidene-3-(4-methoxybenzyl)-5-fluorouridine (**5a**) in a good yield. Acidic hydrolysis of the isopropylidene moiety afforded 5′-*O*-acryloyl-3-(4-methoxybenzyl)-5-fluorouridine (**6a**).

An $AlCl_3$–anisole system has been utilized in the deprotection of benzyl esters.[15)] We employed the $AlCl_3$–anisole system for the deprotection of N^3-benzyl moieties of FUR. Deprotection of the PMB group was achieved by treatment of **6a** with $AlCl_3$ (10 equiv) in anisole at room temperature overnight to obtain 5′-*O*-acryloyl-5-fluorouridine (**3a**) in 96% yield. When ammonium cerium(IV) nitrate was used for the deprotection of PMB moiety,[13)] **3a** was not obtained at all presumably due to the decomposition of **3a** or **6a** under the reaction conditions. This result demonstrates mild conditions of our deprotection methods.



Scheme 1.

Table 1. Deprotection of the *p*-Methoxybenzyl Group[a)]

Run	R_1	R_2	R_3	Product	Yield/%
1	**6a** $-COCH=CH_2$	H	H	**3a**	96
2	**6b** $-COC(CH_3)=CH_2$	H	H	**3b**	81
3	**6c** $-COCH=CHPh$	H	H	**3c**	93
4	**5c** $-COCH=CHPh$	$C(CH_3)_2$		**2c**	81

a) 10 equiv of $AlCl_3$ was used in anisole at room temperature.

The present method was successfully applied to other PMB-protected 5-fluorouridine derivatives as shown in Table 1. In the case of cinnamoyl (**6c**), methacryloyl (**6b**) derivatives, PMB groups were also cleaved without harming N-glycosidic bond to afford the NH free compounds in good yields. It is noted that PMB group was cleaved in preference to the 2′,3′-*O*-isopropylidene moiety (Run 4).

Finally, we tested an unsubstituted benzyl group. When 5′-*O*-cinnamoyl-3-benzyl-5-fluorouridine (**9**) was treated with $AlCl_3$ (10 equiv) in anisole at room temperature, no reaction took place. Deprotection of the benzyl group proceeded at a higher temperature (80 °C, 4 h) with concurrent cleavage of the N-glycosidic bond to afford **3c** in a low yield (<10%). Thus, presence of the *p*-methoxy substituent is essential for the smooth cleavage of N^3-benzyl moiety in the present method.

Experimental

Melting points were determined on a Yamato melting point apparatus and are uncorrected. ^1H NMR spectra were recorded on a JEOL GSX-270 spectrometer with tetramethylsilane as an internal standad. IR spectra were recorded on a Hitachi EPI G-3 spectrometer. $AlCl_3$ was ground into fine powder and stored under N_2 atmosphere. Anisole was distilled over CaH_2 and stored over Molecular Sieves 4A. *p*-Methoxybenzyl bromide[17)] was prepared by NBS-mediated bromination[18)] of *p*-methoxytoluene and used immediately. Purification of products was performed by column chromatography on silica gel (Wako gel C-300) or preparative TLC on silica gel (Wako gel B-5F).

2′,3′-*O*-Isopropylidene-3-(4-methoxybenzyl)-5-fluorouridine (4). To a solution of 2′,3′-*O*-isopropylidene-5-fluorouridine[19)] (**1**) (1.35 g, 4.47 mmol) in CH_3CN (15 ml) was added *p*-methoxybenzyl chloride (1.12 ml, 8.94 mmol) and DBU (1.34 ml, 8.94 mmol). The mixture was allowed to reflux at 50—60 °C for 3 h. After the mixture was cooled to room temperature, H_2O was added. The mixture was extracted with ethyl acetate. The combined organic layers were successively washed with 1 M HCl (1 M=1 mol dm^{-3}) and brine, and then concentrated to dryness to give an oil, which was purified by column chromatography on silica gel (CH_2Cl_2 : ethyl acetate=5.5 : 1, v/v) to afford an oil. Recrystallization of it from a mixture of hexane and ethyl acetate (v/v=1 : 1) gave **4** as crystals (1.85 g, 98%): Mp 118—119 °C; ^1H NMR ($CDCl_3$) δ=1.36 (3H, s, CH_3), 1.58 (3H, s, CH_3), 2.46—2.51 (1H, m, OH), 3.78 (3H, s, OCH_3), 3.81 (1H, ddd, $J_{5',5''}$=11.9 Hz, $J_{4',5'}$=2.7 Hz, $J_{5',OH}$=6.1 Hz, H-5′), 3.94 (1H, dt, $J_{4',5''}$=2.7 Hz, H-5″), 4.33 (1H, q, $J_{3'4'}$=2.7 Hz, H-4′), 4.88—4.95 (2H, m, H-2′,3′), 5.02, 5.08 (2H, ABq, J=13.6 Hz, CH_2), 5.68 (1H, d, $J_{1',2'}$= 2.4 Hz, H-1′), 6.80—6.86 (2H, m, aromatic), 7.42—7.48 (2H, m, aromatic), and 7.59 (1H, d, J=5.8 Hz, H-6); IR (nujol) 3420, 1690, 1660, and 1640 cm^{-1}. Found: C, 56.81; H, 5.51; N,

6.41%. Calcd for $C_{20}H_{23}N_2O_7F$: C, 56.87; H, 5.49; N, 6.63%.

General Procedure for the 5′-*O*-Acylation of 4. A typical procedure is described for 5′-*O*-acryloyl-2′,3′-*O*-isopropylidene-3-(4-methoxybenzyl)-5-fluorouridine (**5a**). To a solution of **4** (1.53 g, 3.63 mmol) in CH_3CN (2 ml) was added successively *N*,*N*-diisopropylethylamine (1.26 ml, 7.25 mmol) and acryloyl chloride (0.884 ml, 10.9 mmol) at room temperature. The mixture was stirred at that temperature for 4 h, and 5% $KHSO_4$ solution was added. Organic phase was separated and aqueous layers were extracted with ethyl acetate. The combined orgaic layers were successively washed with brine, 2.5% $NaHCO_3$ solution, and brine, dried over anhydrous Na_2SO_4, and concentrated to leave an oil, which was purified by column chromatography on silica gel (CH_2Cl_2 : ethyl acetate=2 : 1, v/v) to give **5a** (1.66 g, 96%): ^{1}H NMR ($CDCl_3$) δ=1.36 (3H, s, CH_3), 1.58 (3H, s, CH_3), 3.77 (3H, s, OCH_3), 4.32—4.51 (3H, m, H-4′,5′), 4.79 (1H, dd, $J_{3',4'}$=2.1 Hz, $J_{2',3'}$=6.4 Hz, H-3′), 4.89 (1H, dd, $J_{1',2'}$=2.1 Hz, H-2′), 4.99, 5.10 (2H, ABq, J=13.6 Hz, CH_2), 5.74 (1H, d, H-1′), 5.84 (1H, dd, J=10.4 Hz, 1.4 Hz, vinyl-H), 6.08 (1H, dd, J=10.4 Hz, 17.3 Hz, =CHCO), 6.41 (1H, dd, J=1.4 Hz, 17.3 Hz, vinyl-H), 6.87 (2H, d, J=8.9 Hz, aromatic), 7.39 (2H, d, J=5.5 Hz, H-6), and 7.47 (2H, d, J=8.9 Hz, aromatic); IR (nujol) 3000, 1700, 1680, and 1650 cm^{-1}. Found: C, 57.75; H, 5.31; N, 5.77%. Calcd for $C_{23}H_{25}N_2O_8F$: C, 57.98; H, 5.29; N, 5.88%.

2′,3′-*O*-Isopropylidene-5′-methacryloyl-3-(4-methoxybenzyl)-5-fluorouridine (5b): ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s, CH_3), 1.58 (3H, s, CH_3), 1.91 (3H, s, =CCH_3), 3.78 (3H, s, OCH_3), 4.28—4.50 (3H, m, H-4′,5′), 4.79 (1H, dd, $J_{3',4'}$=3.4 Hz, $J_{2',3'}$=6.4 Hz, H-3′), 4.86 (1H, dd, $J_{1',2'}$=2.1 Hz, H-2′), 5.01, 5.09 (2H, ABq, J=13.4 Hz, CH_2), 5.51—5.55 (1H, m, vinyl-H), 5.72 (1H, d, H-1′), 6.03 (1H, brs, vinyl-H), 6.80—6.85 (2H, m, aromatic), 7.36 (1H, d, J=5.8 Hz, H-6), 7.42—7.49 (2H, m, aromatic; IR ($CHCl_3$) 2990, 1700, 1645, 1490, and 1400 cm^{-1}. Found: C, 58.98; H, 5.78; N, 5.63%. Calcd for $C_{24}H_{27}N_2O_8F$: C, 58.77; H, 5.55; N, 5.71%.

5′-*O*-Cinnamoyl-2′,3′-*O*-isopropylidene-3-(4-methoxybenzyl)-5-fluorouridene (5c): ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s, CH_3), 1.59 (3H, s, CH_3), 3.75 (3H, s, OCH_3), 4.42—4.51 (3H, m, H-4′,5′), 4.82—4.85 (1H, m, H-3′), 4.89 (1H, dd, $J_{1',2'}$=1.8 Hz, $J_{2',3'}$=6.4 Hz, H-2′), 4.99, 5.05 (2H, ABq, J=13.4 Hz, CH_2), 5.79 (1H, d, H-1′), 6.42 (1H, d, J=15.8 Hz, PhCH=), 6.79—6.84 (2H, m, aromatic), 7.37—7.52 (7H, m, aromatic), and 7.72 (1H, d, =CHCO); IR ($CHCl_3$) 2950, 1700, 1650, 1500, 1440, 1360, 1260, and 1240 cm^{-1}. Found: C, 62.79; H, 5.34; N, 5.00%. Calcd for $C_{29}H_{29}N_2O_8F$: C, 63.04, H, 5.29; N, 5.07%.

General Procedure for the Cleavage of Isopropylidene Moiety. A typical procedure is described for 5′-*O*-acryloyl-3-(4-methoxybenzyl)-5-fluorouridine (**6a**). A solution of **5a** (1.65 g, 3.45 mmol) in an 80% methanolic solution of trifluoroacetic acid (4.0 ml) was stirred at room temperature for 10 min. The reaction mixture was concentrated in vacuo to leave an oil, which was purified by column chromatography on silica gel (hexane : ethyl acetate=1 : 2, v/v) to give **6a** (1.32 g, 88%) as an amorphous solid: ^{1}H NMR ($CDCl_3$: CD_3OD=95 :5, v/v) δ=2.70 (2H, brs, OH), 3.79 (3H, s, OCH_3), 4.00—4.10 (2H, m, H-2′,3′), 4.22—4.30 (1H, m, H-4′), 4.50 (1H, brs, H-5′), 4.51 (2H, brs, H-5″), 5.03, 5.09 (2H, ABq, J=13.7 Hz, CH_2), 5.79 (1H, brs, H-1′), 5.93 (1H, dd, J=1.2 Hz, J=10.4 Hz, vinyl-H), 6.14 (1H, dd, J=10.4 Hz, 17.2 Hz, =CHCO), 6.46 (1H, dd, J=1.2 Hz, J=17.2 Hz, vinyl-H), 6.78—6.88 (2H, m, aromatic), 7.35—7.48 (2H, m, aromatic), and 7.73 (1H, d, J=6.1 Hz, H-6); IR (nujol) 3400, 3000, 1690, 1660, and 1630 cm^{-1}. Found: C, 54.93; H, 4.91; N, 6.08%. Calcd for $C_{20}H_{21}N_2O_8F$: C, 55.05, H, 4.85; N, 6.42%.

5′-*O*-Methacryloyl-3-(4-methoxybenzyl)-5-fluorouridine (6b): ^{1}H NMR ($CDCl_3$: CD_3OD=95 : 5, v/v) δ=1.95 (3H, brs, CH_3), 2.46 (2H, brs, OH), 3.79 (3H, s, OCH_3), 4.02—4.15 (2H, m, H-2′,3′), 4.23—4.52 (1H, m, H-4′), 4.46 (1H, dd, $J_{4',5'}$=3.4 Hz, $J_{5',5''}$=12.5 Hz, H-5′), 4.51 (1H, dd, $J_{4',5''}$=2.7 Hz, H-5″), 5.03, 5.08 (2H, ABq, J=13.7 Hz, CH_2), 5.63—5.67 (1H, m, vinyl-H), 5.75—5.81 (1H, m, H-1′), 6.09 (1H, brs, vinyl-H), 6.77—6.88 (2H, m, aromatic), 7.39—7.49 (2H, m, aromatic), and 7.62 (1H, d, J=5.8 Hz, H-6); IR (nujol) 3350, 1700, 1630, and 1260 cm^{-1}. Found: C, 56.13; H, 5.15; N, 5.92%. Calcd for $C_{21}H_{23}N_2O_8F$: C, 56.00; H, 5.15; N, 6.22%.

5′-*O*-Cinnamoyl-3-(4-methoxybenzyl)-5-fluorouridine (6c): ^{1}H NMR ($CDCl_3$: CD_3OD=95 : 5, v/v) δ=3.76 (3H, s, OCH_3), 4.10—4.16 (2H, m, H-2′,3′), 4.32 (1H, m, H-4′), 4.48—4.51 (2H, m, H-5′, 5″), 5.01, 5.06 (2H, ABq, J=13.7 Hz, CH_2), 5.85 (1H, brs, H-1′), 6.46 (1H, d, J=15.9 Hz, =CHCO), 6.81 (2H, d, J=8.5 Hz, aromatic), 7.39—7.42 (5H, m, aromatic), 7.50—7.54 (2H, m, aromatic), 7.75 (1H, d, PhCH=), and 7.89 (1H, d, J=6.1 Hz, H-6); IR (nujol) 3450, 1700, 1620, 1290, 1230, 1160, and 1090 cm^{-1}. Found: C, 60.10; H, 5.31; N, 5.15%. Calcd for $C_{26}H_{25}N_2O_8F \cdot 0.5H_2O$: C, 59.88, H, 5.03, N, 5.37%.

General Procedure for the Cleavage of PMB Group. A typical procedure is described for 5′-*O*-acryloyl-5-fluorouridine (**3a**). To a solution of **6a** (208 mg, 0.477 mmol) in anisole (1 ml) and $AlCl_3$ (636 mg, 4.77 mmol) in anisole (1 ml). After stirring at that temperature overnight, methanol (1.0 ml) was added to the reaction mixture at 0 °C, the mixture was evaporated by rotary evaporator at a bath temperature below 40 °C. The resultant anisole solution was subjected to short column chromatography on silica gel (methanol: CH_2Cl_2=1 : 10 (v/v)) to afford an oil, which was further purified by TLC on silica gel (methanol : CH_2Cl_2=1 : 10 (v/v)) to give **3a** (144 mg, 96%): ^{1}H NMR ($CDCl_3$: DMSO-d_6=95 : 5, v/v) δ=3.33 (2H, s, H-2′,3′), 4.09—4.17 (1H, m, H-5′), 4.17—4.28 (1H, m, H-4′), 4.39—4.53 (2H, m, H-2′,3′), 5.93 (1H, dd, J=1.5 Hz, 10.4 Hz, vinyl-H), 6.21 (1H, dd, J=17.0 Hz, 10.4 Hz, =CHCO), 6.46 (1H, dd, J=1.5 Hz, 17.0 Hz, vinyl-H), 7.65 (1H, d, J=6.4 Hz, H-6), and 11.51 (1H, brs, H-3); IR (nujol) 3450, 3370, 3330, 1700, 1680, and 1660 cm^{-1}. Found: C, 45.52; H, 4.44; N, 8.51%. Calcd for $C_{12}H_{13}N_2O_7F$: C, 45.58; H, 4.14; N, 8.86%.

3-Benzyl-2′,3′-*O*-isopropylidene-5-fluorouridine (7). This was obtained by the similar procedure as described for the preparation of **4** in a quantitative yield: Mp 124—125 °C; ^{1}H NMR ($CDCl_3$) δ=1.36 (3H, s, CH_3), 1.58 (3H, s, CH_3), 2.45—2.49 (1H, m, OH), 3.81 (1H, ddd, $J_{5',5''}$=12.0 Hz, $J_{4',5'}$=2.6 Hz, $J_{5',OH}$=5.8 Hz, H-5′), 3.94, (1H, dt, $J_{4',5''}$=2.6 Hz, H-5″), 4.33 (1H, q, $J_{3',4'}$=2.6 Hz, H-4′), 4.87—4.95 (2H, m, H-2′3′), 5.08, 5.15 (2H, ABq, J=13.9 Hz, CH_2), 5.69 (1H, d, $J_{1',2'}$=2.5 Hz, H-1′), 7.23—7.35 (3H, m, aromatic), 7.45—7.55 (2H, m, aromatic), and 7.62 (1H, d, J=5.8 Hz, H-6); IR (nujol) 3400, 1700, 1675, and 1640 cm^{-1}. Found: C, 58.18; H, 5.33; N, 6.95%. Calcd for $C_{19}H_{21}N_2O_6F$: C, 58.16; H, 5.39; N, 7.14%.

3-Benzyl-5′-*O*-cinnamoyl-2′,3′-*O*-isopropylidene-5-fluorouridine (8). This was obtained by the similar procedure as described for the preparation of **5a** in 75% yield: ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s, CH_3), 1.56 (3H, s, CH_3), 4.42—4.55 (3H, m, H-4′,5′), 4.80—4.86 (1H, m, H-3′), 4.88 (1H, dd, $J_{1',2'}$=1.8 Hz, $J_{2',3'}$=6.4 Hz, H-2′), 5.05, 5.12 (2H, ABq,

J=13.7 Hz, CH_2), 5.79 (1H, d, H-1′), 6.42 (1H, d, J=15.9 Hz, PhCH=), 7.20—7.75 (10H, m, aromatic), and 7.72 (1H, d, =CHCO); IR ($CHCl_3$) 1700, 1650, 1250, 1150, and 1040 cm^{-1}. Found: C, 63.75; H, 5.06; N, 5.47%. Calcd for $C_{24}H_{27}N_2O_7F$: C, 63.52; H, 5.33; N, 5.49%.

3-Benzyl-5′-*O*-cinnamoyl-5-fluorouridine (9). This was obtained by the similar procedure as described for the preparation of **6a** in 93% yield: ^1H NMR ($CDCl_3$: CD_3OD (v/v=95/5)) δ=2.62 (2H, s, OH), 4.03—4.17 (2H, m, H-2′,3′), 4.23—4.33 (1H, m, H-4′), 4.51 (1H, dd, $J_{4',5'}$=2.4 Hz, $J_{5',5''}$=12.8 Hz, H-5′), 4.60 (1H, dd, $J_{4',5''}$=3.1 Hz, H-5″), 5.09, 5.14 (2H, ABq, J=13.7 Hz, CH_2), 5.81 (1H, brs, H-1′), 6.47 (1H, d, J=15.9 Hz, PhCH=), 7.20—7.60 (10H, m, aromatic), 7.76 (1H, d, =CHCO), and 7.93 (1H, d, J=6.1 Hz, H-6); IR ($CHCl_3$) 3600, 1720, 1650, and 1200 cm^{-1}. Found: C, 61.24; H, 4.81; N, 5.68%. Calcd for $C_{24}H_{23}N_2O_7F$: C, 61.27; H, 4.93; N, 5.95%.

The authors wish to thank the Advanced Center for Chemical Analysis, Ehime University, for elemental analyses.

CO Hydrogenation over TiO_2-Supported Ultrafine Fe_3O_4 Particle Catalysts Prepared by a Colloid Chemical Method

Byong-tae CHANG* and Sung-jin KIM
Department of Chemistry, Faculty of Science, Korea University, Kodaira, Tokyo 187
(Received January 16, 1991)

The properties of TiO_2 supports and the H_2 reduction temperature of Fe_3O_4/TiO_2 catalysts were found to play imortant roles in determining their activity and light olefin selectivity. For each catalyst, a good linear relationship was observed between the CO conversion and the light olefin selectivity. The sequence of the latter under identical conditions was JRC-TIO-5>TIO-3>TIO-4.

In recent years, much attention has been focused on the interactions between metal and support in various supported catalysts.[1-3] Previously we found that the catalytic activity of ultrafine particles of metallic Fe (10—20 nm), prepared by a gas evaporation method, depends largely on the nature of support (TiO_2, SiO_2, Al_2O_3, NaZSM-5 and HZSM-5), and that the physical and chemical properties of TiO_2 supports exert considerable influence on the activity, particularly the light olefin selectivity.[4,5]

According to Ito,[6] ultrafine particles (smaller than 10 nm) of several metal oxides can be prepared by a colloid chemical method. The purpose of this work was to study the catalytic properties of TiO_2-supported Fe_3O_4 prepared by this method; effects of TiO_2 support, H_2 reduction temperature and potassium-promoter on the CO hydrogenation activity and the product distribution.

Experimental

Ultrafine Particle Fe_3O_4 (UFP-Fe_3O_4) were supplied from

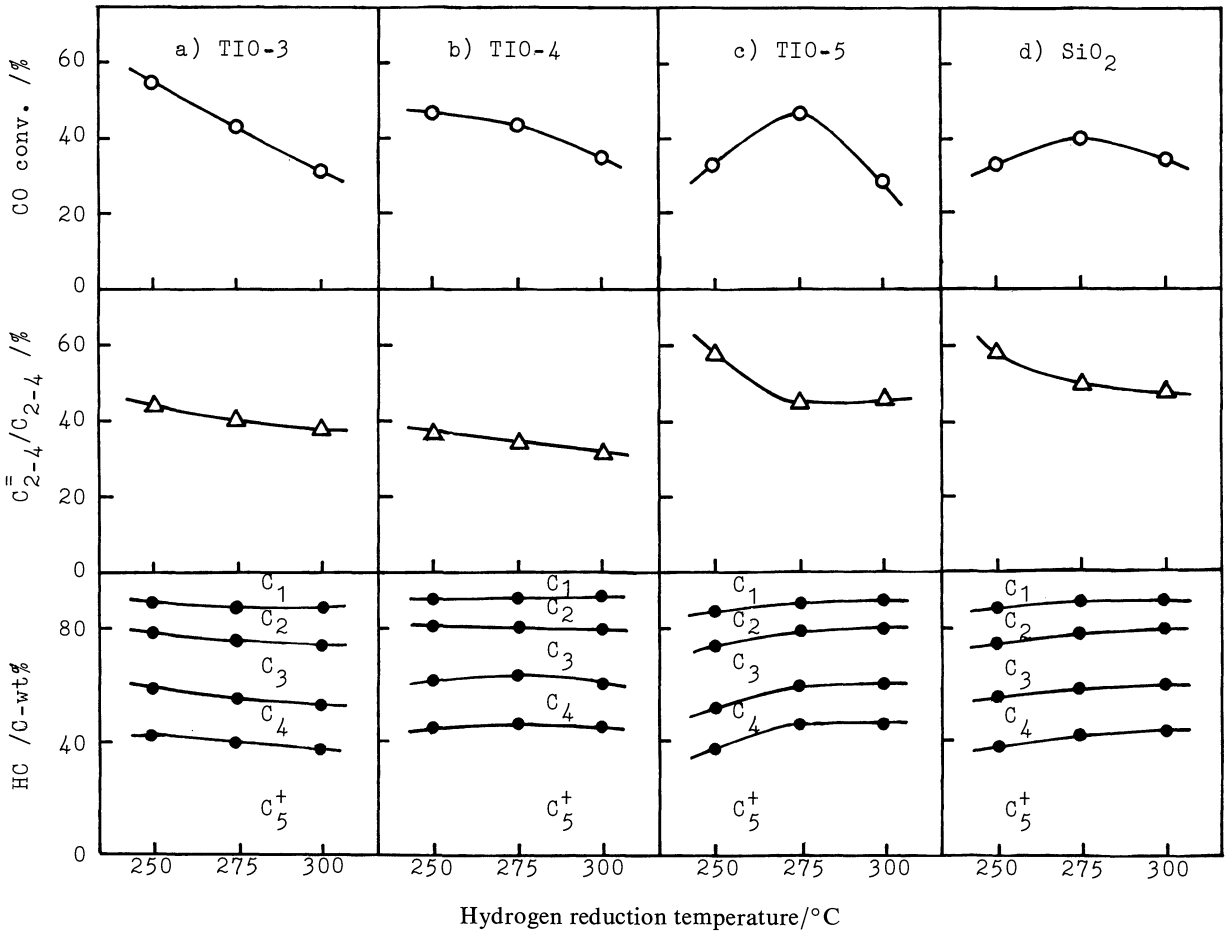

Fig. 1. Effects of hydrogen reduction temperature on the CO conversion, the light olefin selectivity, and the distribution of hydrocarbons produced over UFP-Fe_3O_4/support catalysts. CO hydrogenation conditions; t=250°C, P=5 kg cm^{-2}, and W/F=24±3 g h mol^{-1}.

Okamura Oil Co. By chemical analysis UFP-Fe_3O_4 was found to contain Fe at 55.2 wt% together with several organics. The X-ray diffraction pattern was in good agreement with that of Fe_3O_4, and the particle size determined by X-ray broadening analysis was 9.6±0.2 nm.

Three kinds of TiO_2 (JRC-TIO-3, 4, and 5) and, for comparison, SiO_2 (Aerosil 300) were used as supports. Catalysts were prepared by mechanically mixing UFP-Fe_3O_4 (20 wt%) with one of the supports in an agate mortar, then adding a K_2CO_3 solution (K_2CO_3/Fe=6 wt%) to the Fe_3O_4/support and subsequent drying at 60 °C. Prior to the CO hydrogenation, each catalyst was reduced in situ by hydrogen at a temperature of 225—300 °C, a pressure of 2 kg cm^{-2} and a flow rate of 60 ml min^{-1} for 13 h.

The CO hydrogenation was conducted with a flow type fixed-bed stainless steel reactor, using a feed gas of CO : H_2 : Ar=47.5 : 47.5 : 5 (vol%) under the common condition of t=250 °C, P=5 kg cm^{-2}, and W/F (contact time)=19—33 g h mol^{-1} (W=weight of catalyst, F=molar flow rate of CO and H_2). The products were analyzed by gas chromatography as detailed elsewhere.[5] The conversion of CO (η_{CO}) was calculated on the basis of Ar as an internal standard.

Results and Discussion

UFP-Fe_3O_4/Support Catalysts. Figure 1 shows the effects of hydrogen reduction temperature on the CO conversion (stationary values at time on stream of 5—6 h), the distribution of hydrocarbons produced (HC, carbon-wt%) and the light olefin selectivity ($C^{=}_{2-4}$/total C_{2-4}). As seen in Figs. 1-(a) and (b), in the cases of TIO-3 (rutile type, 40 m^2 g^{-1}) and TIO-4 (anatase type, 50 m^2 g^{-1}), the CO conversion decreases as the reduction temperature increases. On the other hand, the TIO-5 (rutile type, 2.6 m^2 g^{-1})-supported catalyst exhibits a maximum value of η_{CO} at 275 °C (Fig. 1-(c)). A similar temperature dependence of η_{CO} was observed for the SiO_2-supported catalyst, as shown in Fig. 1-(d).

The carbon number distribution of the products, except for CO_2 with yields of 40±5% in η_{CO}, does not depend so much on the nature of support used. The probability of carbon chain growth (α) was in a range of 0.66±0.3. On the other hand, the value of $C^{=}_{2-4}/C_{2-4}$ slightly decreases with a rise of the reduction temperature regardless of the nature of support. The sequence of $C^{=}_{2-4}/C_{2-4}$ under identical conditions was TIO-5> SiO_2>TIO-3>TIO-4. The rutile type and small surface area of TiO_2 seem advantageous for the formation of light olefins, as observed for TiO_2-supported ultrafine Fe

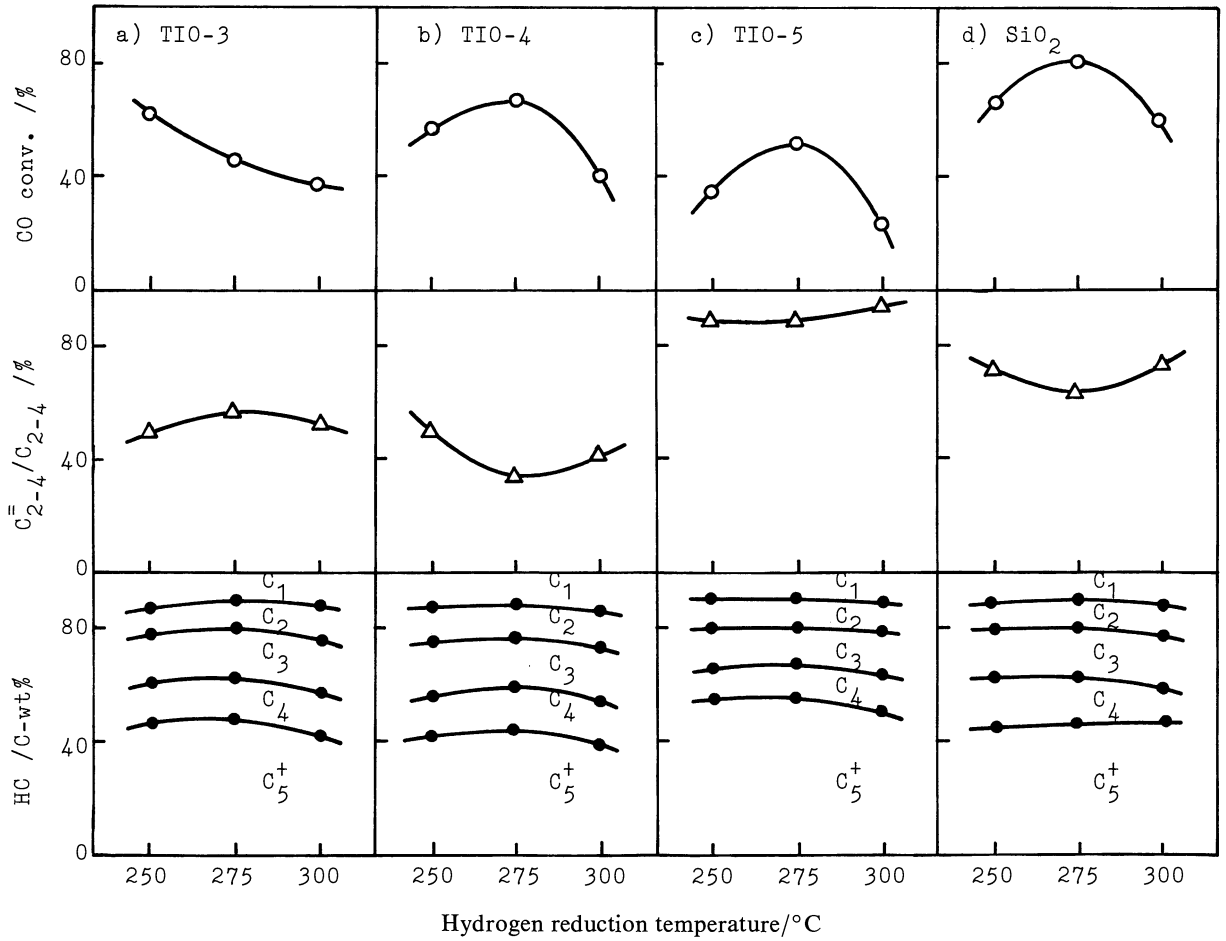

Fig. 2. Effects of hydrogen reduction temperature on the CO conversion, the light olefin selectivity, and the distribution of hydrocarbons produced over the K-promoted UFP-Fe_3O_4/support catalysts. CO hydrogenation conditions; t=250 °C, P=5 kg cm^{-2}, and W/F=23±4 g h mol^{-1}.

metal particles prepared by the gas evaporation method.[5] This tendency becomes more conspicuous when the potassium promoter is added to Fe_3O_4, as will be described below.

K-Promoted UFP-Fe_3O_4/Support Catalysts. Potassium is well known as one of the most effective promoters for CO hydrogenation on iron catalysts.[7,8] Figure 2 shows the effects of K-promoter on η_{CO}, $C_{2-4}^{=}/C_{2-4}$, and the carbon number distribution. In general, the addition of K-promoter to Fe results in an increase in the electron density on Fe through electron donation from potassium. This in turn leads to electron donation to the bonding orbital of Fe–C and to the antibonding orbital of C–O in the adsorbed CO molecules, thereby weakening the C–O bond and suppressing the H_2 adsorption. Thus the catalytic activity, the olefin selectivity, and the average molecular weight of the products are enhanced. Also the water shift reaction is accelerated by a similar mechanism.[7,8] As is obvious from Fig. 2, such discussions are in principle valid for the effects of K-promoter on the catalytic properties of UFP-Fe_3O_4, although the increase in the average molecular weight of the products cannot be clearly depicted except for the case of TIO-5.

The light olefin selectivity depends clearly on the support. TIO-5 gave the highest value (ca. 90%) of $C_{2-4}^{=}/C_{2-4}$ and larger amounts of C_5^+ (carbon number $\geqslant 5$) than TIO-3 or TIO-4. The α values (0.73—0.74) of TIO-5 are neatly higher than those for TIO-3 or TIO-4. These results are consistent with a view that, in the CO hydrogenation process, chemisorbed hydrogen is involved in both chain termination and addition to olefin to form paraffin.

Changes in Fe Particle Size. To clarify the effect of H_2 reduction temperature, changes in the phase of Fe_3O_4 and the particle size of metallic Fe formed during the reduction process have been examined by X-ray diffraction analysis (XRD). As given in Table 1, the reduction at 225 °C does not result in the formation of metallic Fe thick enough to be detectable by XRD. Practically no change was noted in the particle size. An extremely low value of η_{CO} indicated that catalyst has not been sufficiently activated. On the other hand, reduction at 250 °C leads to a neat increase in η_{CO}, accompanied by partial reduction of Fe_3O_4 to Fe, and a slight increase in the particle size.

On an assumption that the Fe particles are uniform and spherical, the specific activity (a_{CO}) of the catalysts can be evaluated from the particle size, the space velocity of CO, and η_{CO}. For each catalyst (except TIO-3), the a_{CO} value is maximal at 275 °C. The specific activity seems to depend on the degree of the reduction to metallic Fe and its particle size; probably the smaller the particle size, the higher the a_{CO} value.

Correlation between η_{CO} and $C_{2-4}^{=}/C_{2-4}$. In Fig. 3 are plotted the light olefin selectivity against the CO con-

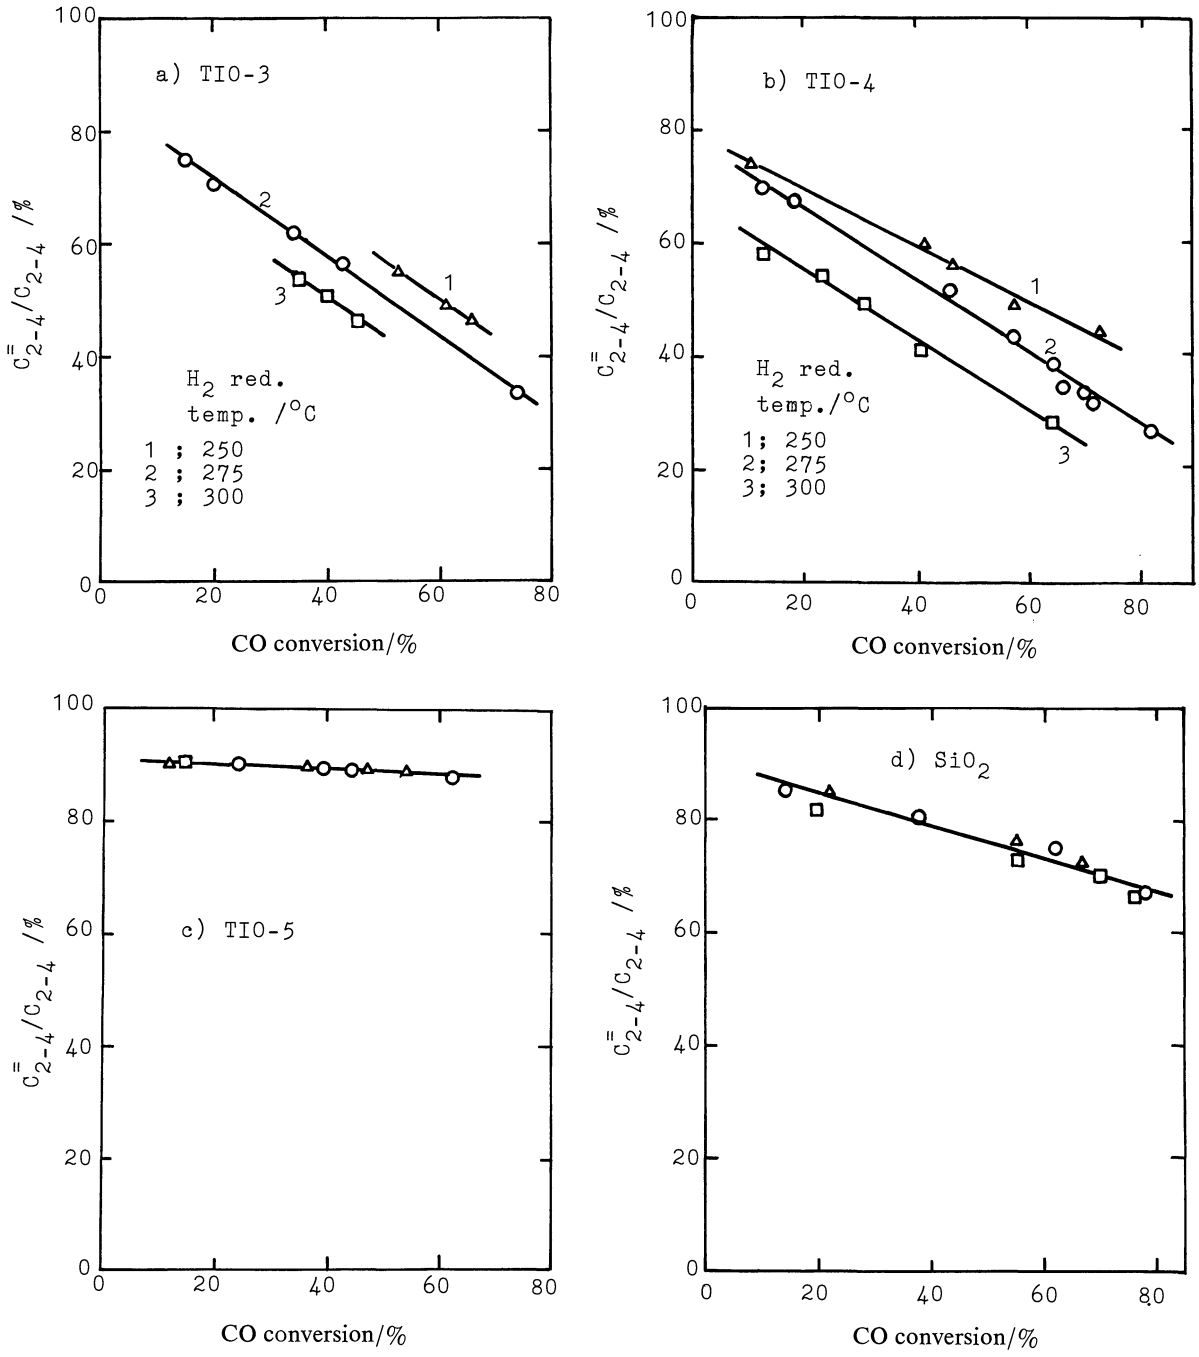

Fig. 3. Correlations between the CO conversion and the light olefin selectivity for the K-promoted UFP-Fe_3O_4/support catalysts under various reduction and CO hydrogenation conditions.

version over the K-promoted catalysts, observed under the reaction conditions in a range of t=225—275 °C, P=5—10 kg cm^{-2}, and W/F=10—33 g h mol^{-1}. For each catalyst a good linear relationship is seen, with a slope characterstic of the support used. In the cases of TIO-3 and TIO-4, the light olefin selectivity abruptly decreases with an increase in η_{CO}, so that it is impossible to carry out the reaction with high activity and high light olefin selectivity at the same time. The clear shift of the correlation line by a change in the H_2 reduction temperature could be attributed mainly to a change in the Fe particle size and consequently in the magnitude of a_{CO}.

In contrast, TIO-5 always exhibits very high values of $C_{2-4}^{=}/C_{2-4}$ almost independently of η_{CO}. Under the same conditions, the sequence of $C_{2-4}^{=}/C_{2-4}$ is TIO-5>SiO_2>TIO-3>TIO-4, as is the case for the unpromoted catalysts. In comparison with SiO_2, which is expected to

interact weekly with metallic Fe, TIO-3 and TIO-4 render the Fe active sites more hydrogenating, while TIO-5 does so to a lesser extent. These findings strongly suggest that TiO_2 supports exert significant influence on the CO hydrogenation process on Fe metal. According to Vannice,[9] the rate-determining step of CO hydrogenation on Fe catalysts is the adsorption and dissociation of H_2 on Fe surface. Also the properties (amount, activity etc.) of adsorped hydrogen play an important role in controlling the formation ratio of olefin to paraffin.[10] In view of this, the support effects observed in this work could be ascribed to promotion (TIO-3 and TIO-4) or suppression (TIO-5) of the H_2 adsorption and dissociation by the TiO_2 support.

On the Role of Gallium for the Aromatization of Lower Paraffins with Ga-Promoted ZSM-5 Catalysts

Kaoru FUJIMOTO,* Ikusei NAKAMURA,† Kohshiroh YOKOTA, and Kohjiroh AIMOTO

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo 113
(Received January 30, 1991)

H-ZSM-5 showed a high selectivity of propane and low selectivity of aromatic hydrocarbons in butane conversion at 450 °C, whereas Ga-supportd ZSM-5 (Ga-ZSM-5) showed higher selectivities of aromatic hydrocarbons and hydrogen. A small amount of oxygen in the feed promoted butane conversion to aromatic hydrocarbons on H-ZSM-5. Hybrid catalysts composed of the physical mixture of Ga/Al_2O_3 and H-ZSM-5 showed comparable activities and aromatic selectivities to those of the Ga-supported ZSM-5 zeolite (Ga-ZSM-5). Hydrogen was adsorbed quickly on the Ga-ZSM-5 and on the hybrid catalyst at 400 °C and the adsorbed hydrogen was desorbed at around 450 °C during the temperature programmed desorption experiment from both catalysts. However, little hydrogen was adsorbed on H-ZSM-5 and was desorbed from it. It was pointed out that the supported Ga promoted the zeolite-catalyzed aromatization of lower paraffins by promoting hydrogen desorption via the "reverse spillover" effecct.

Conversion of lower paraffins into aromatic hydrocarbons is of great interest because of its potential application for producing transportation fuel or chemicals from natural gas. Cattanach has claimed that H-ZSM-5 type or Zn-supported ZSM-5 zeolites are effective catalysts for this reaction.[1] Recently, it has been found that a Ga-supported ZSM-5 type zeolite is an exceptionally effective catalyst for this type of reaction.[2] Ga and Zn are effective in promoting the reaction in the impregnated form,[3,4] in the ion exchanged form,[5,6] in the physically mixed form[7] or even when they are incorporated in the zeolite framework.[8]

There are many interpretations postulated as to why Ga or Zn are so effecctive in promoting the formation of aromatic hydrocarbons. Anderson and Mole suggested that the dehydrogenation of propane was promoted by Zn on H-ZSM-5.[9] Ono et al. has concluded from the study of pentane conversion that the Ga-loading does not affect the cracking ability of the zeolite, but enhances the activity of aromatization of olefins.[10] They also observed that Ga-loading promotes propane conversion and suggested that the Ga-promoted aromatization suppresses the formation of propane from intermediate products.[10] Inui et al. showed that Pt-ion-exchanged Ga-silicate exhibited excellent performance for the conversion of C_2—C_5 paraffins and claimed that Pt promotes the paraffin dehydrogenation to olefins and Ga promotes aromatization of olefins.[8] On the other hand, Yashima et al. claimed that Ga on ZSM-5 promotes the dehydrogenation of cycloparaffins or cycloolefins which are formed on zeolite.[3] Recently, Gnep et al. pointed out that Ga_2O_3 showed a catalytic activity for propane dehydrogenation and claimed that Ga on ZSM-5 exists as Ga_2O_3 and promotes the naphthene dehydrogenation.[11] The present authors have found that added oxygen gas in the propane or butane conversion on H-ZSM-5 selectively oxidizes hydrogen on the zeolite to promote the conversion of the feed and especially the formation of aromatic hydrocarbons. We claimed that H-ZSM-5 exhibits an excellent ability for paraffin conversion and aromatics formation if the hydrogen atom on the zeolite surface is effectively removed. Also, the authors have found that the hybrid catalyst composed of the compressed physical mixture of finely powdered H-ZSM-5 and alumina-supported Ga_2O_3 exhibits the activity of butane conversion and the selectivity of aromatics which are comparable to those of Ga-supported H-ZSM-5 and have postulated a concept that hydrogen atoms on the zeolite surface come out through the Ga-site (to result in the promoted aromatics formation[12-14]. Recently, Mao et al. found that an H-ZSM-5 to which a small quantity of zinc oxide/aluminum oxide co-precipitate was admixed mechanically could convert selectively light olefins and/or paraffins to aromatic hydrocarbons and claimed that the high aromatic selectivity should be attributed to hydrogen "back-spillover" from the zeolite to ZnO/Al_2O_3.[16]

The present work tries to clarify the role of gallium on ZSM-5 in the conversion of lower paraffins from the stand point of hydrogen spillover and reverse spillover.

Experimental

The ZSM-5 zeolite was supplied by Tosoh Chem. Ind. Ltd. (Si/Al atom ratio: 50, 850 NAA). X-ray diffraction confirmed that the material was Na-ZSM-5. A protonic ZSM-5 (H-ZSM-5) was prepared by repeated ion exchange of the Na-ZSM-5 with aqueous ammonium nitrate solution (5 times) followed by calcination in air at 500 °C. Ga was supported on the H-ZSM-5 (Ga-ZSM-5) or a commercially available γ-alumina (Ga/Al_2O_3) by impregnating them with gallium nitrate from its aqueous solution and then calcining the precursors in air at 500 °C for 3 h. Ga contents were 1.5 wt%, and 5 wt% for Ga-ZSM-5 and Ga/Al_2O_3, respectively. Hybrid catalysts were prepared by co-grinding the two type of catalysts into a

† Present address: Central Research Laboratories, Idemitsu Kosan Co., Ltd., 1280, Kamiizumi, Sodegaura, Kimitsu, Chiba 299-02.

fine powder and then pressure-molding the mixture to granules (20—40 mesh).

Conversion of butane was conducted with a flow type fixed bed reaction apparatus operated under atmospheric pressure. Catalysts were packed in a stainless steel tube with an inner diameter of 4 mm. Products were analyzed by gas chromatography. Adsorption of hydrogen and its desorption were measured using a flow through cell connected to a conventional glass vacuum system. The adsorption measurement was crried out at 400 °C and the temperature programmed desorption (TPD) was carried out from room temperature to 800 °C with a heating rate of 400 °C h^{-1}. The desorbed hydrogen was determined by mass spectrometry.

Results and Discussion

Effect of Oxygen. In Table 1 are shown some of the results of butane conversion over H-ZSM-5 and Ga-ZSM-5 in the presence and absence of oxygen. The product was propane with a small amount of isomerized butane, C_2—C_4 olefins and aromatic hydrocarbons. The composition of the aromatics was scarcely affected by the oxygen and was quite similar to those reported in other papers.[4,8,9] As it has been already pointed out, the protonic ZSM-5 (H-ZSM-5) producted propane and C_2—C_4 olefins as the main products, with only a small amount of aromatic hydrocarbons.[13] However, when the feed gas contained 5% oxygen, the butane conversion on the H-ZSM-5 catalyst increased considerably and the selectivity of the aromatic hydrocarbons increased drastically from 4.1 to 16.4%. Since the yield of dehydrogenated products or oxygenated products was less than 1% in the non-catalyzed reaction, the higher conversion for the reaction in the presence of oxygen should never be attributed to the oxidation of butane. Also, since the non-catalyzed oxidation of hydrogen under the same reaction condition was less than 10%, the low hydrogen production should be attributed to the direct oxidation of hydrogen on the zeolite surface.[13] Results shown in Table 1 suggest that if hydrogen atoms on the zeolite surface are removed effectively, H-ZSM-5 exhibits a high selectivity for aromatic hydrocarbons.

Effect of Additives. Figure 1 shows the results of butane conversion on H-ZSM-5, Ga-ZSM-5 and Pt-ZSM-5 as a function of reaction temperature. The catalytic activity of Pt-ZSM-5 was much higher than those of the other two catalysts. Also, the selectivity of aromatics over Pt-ZSM-5 was higher than those of the other catalysts. However, the aromatic selectivity on Ga-ZSM-5 increased markedly with increasing reaction temperature and reached a level comparable to that of Pt-ZSM-5 at around 500 °C, whereas the selectivity of the aromatics on H-ZSM-5 stayed at a much lower level than the other two catalysts. Also, the mole ratio of hydrogen to reacted butane on Ga-ZSM-5 catalyzed reaction increased with increasing temperature finally reaching that on Pt-ZSM-5.

It has been well known that supported platinum on H-ZSM-5 promotes the dehydrogenation of lower paraffins to olefins,[8] which are much more reactive in dehydroaromatization.[14] The slight increase in the conversion activity and the drasic increace in the aromatics selectivity caused by adding Ga on H-ZSM-5 has been also reported in other papers,[2-8] which will be discussed in a later chapter.

Catalytic Performances of Ga-containing Hybrid Catalysts. Table 2 shows some of the results of the butane conversion on a variety of Ga-containing catalysts. The first point which should be noted is that the hybrid catalyst containing Ga/Al_2O_3, which was finely powdered and pressed in to granules with H-ZSM-5,

a) Reaction temperature 450 °C, $P_{C_4H_{10}}$ =20 kPa, P_{N_2}=80 kPa, W/F=10 g h mol^{-1}. b) Powdery mixture, Content of Ga/γ-Al_2O_3 was 20 wt%. c) Granular mixture, Content of Ga/γ-Al_2O_3 was 20 wt%. d) Propene was reacted instead of butane.

exhibited high aromatic selectivity which was comparable to those of the Ga–ZSM-5 catalyst, whereas the Ga/Al_2O_3 itself exhibited little catalytic activity for the butane conversion and olefin aromatization. It should be also noted that the content of the ZSM-5 zeolite in the hybrid was only 80% and thus the catalytic activity of the H–ZSM-5 hybrid catalyst is estimated to be 1.4 times higher than that of only H–ZSM-5. The second important point is that the physical mixture of granular Ga/Al_2O_3 and granular H–ZSM-5 showed catalytic performances much inferior to the powdery mixed hybrid catalyst with the same composition.

The former studies indicated that the higher aromatic selectivity of the Ga–ZSM-5 catalyst than that of H–ZSM-5 should be attributed to the dehydrogenation or dehydroaromatization of olefins[4,7,15] or the dehydrogenation of naphthenic hydrocarbons.[3,11] However, the data in Table 2 show that Ga/Al_2O_3 showed little catalytic activity for both olefin aromatization and paraffin dehydrogenation, whereas it exhibited an excellent promotional effect for the aromatics formation when it was intimately contacted with H–ZSM-5. Thus, the promotional effect of gallium should be attributed to functions other than its dehydrogenation activity. If the promotional effect of the gallium is attributed to its dehydrogenation activity, Ga/Al_2O_3 should exhibit catalytic activity for the dehydrogenation of butane or the dehydroaromatization of propene and also the granular mixture of Ga/Al_2O_3 and H–ZSM-5 should exhibit comparable performances to that of the hybrid catalyst.

Hydrogen Effect. In Fig. 2 are shown the results of the Temperature Programmed Reaction (TPRE) of C_2H_4 in a hydrogen atmosphere on H–ZSM-5, Ga–ZSM-5, and Pt–ZSM-5. On Pt–ZSM-5, C_2H_4 was converted completely at any temperature producing mostly ethane. On H–ZSM-5, on the other hand, the conversion of C_2H_4 started at 150 °C and reached 100% at around 300 °C. Neither the ethane formation nor the hydrogen consumption occurred below 450 °C, which means that H–ZSM-5 exhibits little catalytic activity for the olefin hydrogenation under the reaction conditions previously

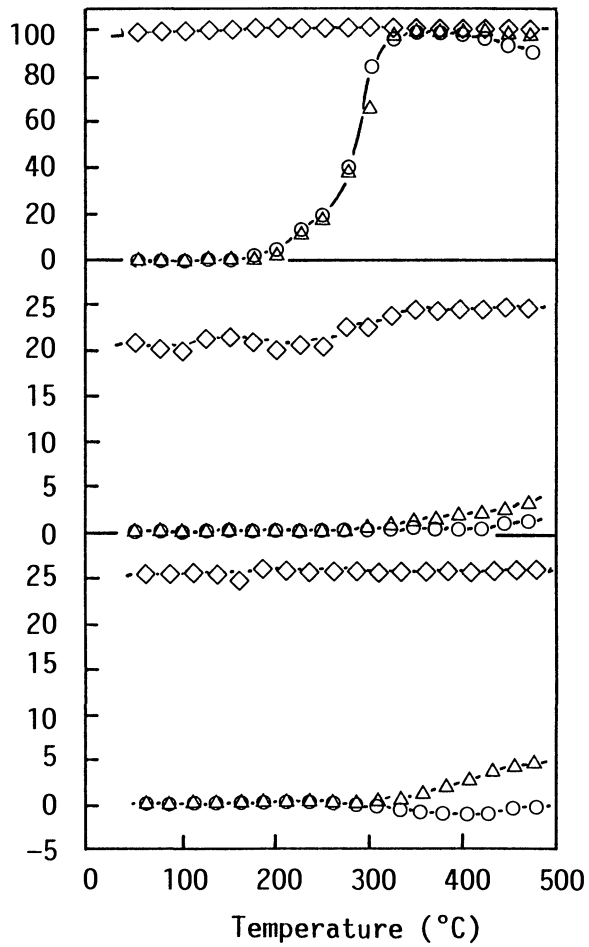

Fig. 2. TRPE of C_2H_4 with hydrogen. C_2H_4 25%, H_2 75%, 5 °C min^{-1}, W/F; 10 g h mol^{-1}. ◇ Pt–ZSM-5, △ Ga–ZSM-5, ○ H–ZSM-5.

mentioned. Ga–ZSM-5 showed similar catalytic character to those of H–ZSM-5 except that a slight hydrogenation of ethylene proceeded above 350 °C, pointing out that the hydrogenation activity of Ga–ZSM-5 was quite low, while its activity for olefin conversion is similar to that of H–ZSM-5. Thus, ethylene was mostly polymerized to higher hydrocarbons. The low hydrogenation activity of Ga–ZSM-5 should contribute

Table 3. Effects of Hydrogen on the Conversion of Butane[a)]

to the high aromatic selectivity during the paraffin conversion.

Table 3 shows the effects of hydrogen on the conversion of butane over the 3 types of catalysts previously mentioned. In the case of the H-ZSM-5, hydrogen in the gas phase affected neither the butane conversion nor product selectivity. This phenomenon is consistent with the fact the H-ZSM-5 has no hydrogenation activity. The catalytic activity of the Pt-ZSM-5 was promoted slightly by hydrogen while the selectivities of aromatic hydrocarbon and C_2—C_4 olefins were markedly suppressed. The phenomena should be attributed to its excellent hydrogenation activity. In the case of the Ga-ZSM-5, the selectivity of aromatic hydrocarbons and C_2—C_4 olefins were much lower in the presence of hydrogen than that in the presence of nitrogen. This should not be attributed to the hydrogenation of olefins, because the Ga-ZSM-5 exhibits little hydrogenation activity but should be explained in terms of the spillover of hydrogen. This inconsistency will be discussed later in this report.

Adsorption and Desorption of Hydrogen. Figure 3 shows the adsorptions of H_2 at 400 °C on H-ZSM-5, Ga-ZSM-5, and hybrid samples composed of H-ZSM-5 and Ga/Al_2O_3. Apparently from the figure, a fairly large amount of hydrogen was adsorbed quickly on Ga-ZSM-5, while little hydrogen was adsorbed on H-ZSM-5. The difference between H-ZSM-5 and Ga-ZSM-5 is explained as follows. In the case of Ga-ZSM-5, Ga has the function to adsorb hydrogen molecule and to dissociate hydrogen molecule to hydrogen atom and then the hydrogen atom on Ga particle moves to ZSM-5 zeolite by spillover effect. On the other hand, H-ZSM-5 has no entrance of hydrogen such as Ga, so only little hydrogen was adsorbed to H-ZSM-5. The data in Fig. 3 shows that on the physical mixture of H-ZSM-5 and Ga/Al_2O_3 more hydrogen was adsorbed than on Ga/Al_2O_3 only.

Figure 4 shows the spectra of temperature programmed desorption (TPD) of adsorbed hydrogen from Ga-ZSM-5 and H-ZSM-5. The desorption of hydrogen was prominent at two temperature ranges around 400 °C and at higher than 700 °C, while H-ZSM-5 showed only one prominent desorption temperature at higher than 700 °C.

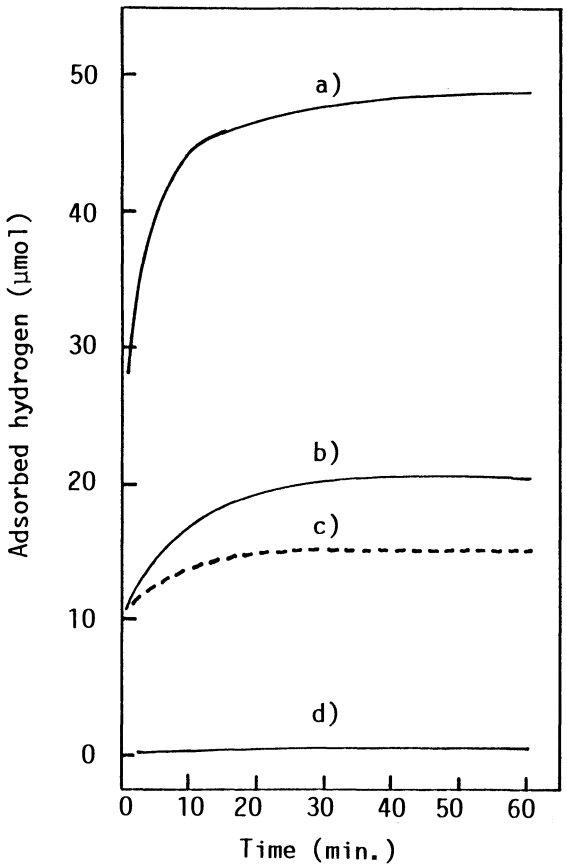

Fig. 3 Hydrogen spillover on ZSM-5 catalysts. Pretreatment; 600 °C 1 h evacuated, adsorption temperature; 400 °C. a) Ga-ZSM-5 1.0 g, b) (Ga/Al_2O_3 0.2 g+H-ZSM-5 0.8 g) hybrid catalyst, c) (Ga/Al_2O_3 0.2 g)+(H-ZSM-5 0.8 g) calculated value, d) H-ZSM-5 1.0 g.

The desorption of hydrogen at lower temperature range was in the molecular state whereas that at higher temperature range was in the atomic state. This suggests that desorption in the lower temperature range is of the "reverse spillover" type. The process is composed of (1) the transfer of hydrogen atoms on the solid surface to the gallium site, (2) the combination of two hydrogen atoms to form one hydrogen molecule, and (3) the desorption of the hydrogen molecule into gas phase. This is just the reverse process of hydrogen spillover. On the other hand, the desorption of hydrogen in the atomic state at higher temperature range may be attributed to the direct dissociation of zeolite-hydrogen bonds by thermal energy. Although the hydrogen atoms in the gas phase usually recombine quickly to molecules, the ultra high vacuum ($<10^{-8}$ Torr, 1 Torr=133.322 Pa) may prevent the collision between hydrogen atoms of the removal of excess energy from hot hydrogen molecules produced by the collision of two hydrogen atoms. Also this desorption of atomic hydrogen at high temperature was observed in the case of

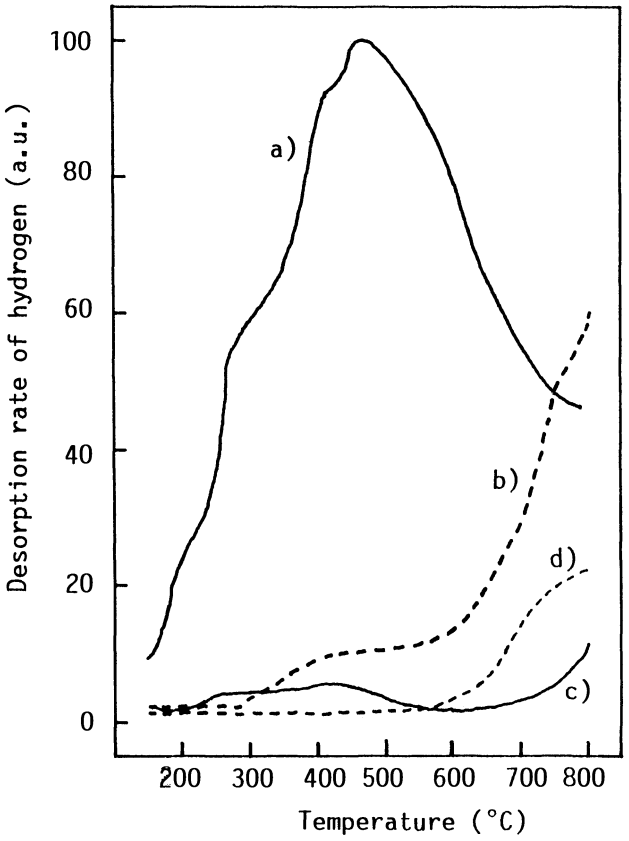

Fig. 4. Temperature programmed desorption spectra of hydrogen on ZSM-5 catalysts. Heating rate; 400°C h^{-1}, a) Ga–ZSM-5 1.0 g mass number 2, b) Ga–ZSM-5 1.0 g mass number 1, c) H–ZSM-5 1.0 g mass number 2, d) H–ZSM-5 1.0 g mass number 1.

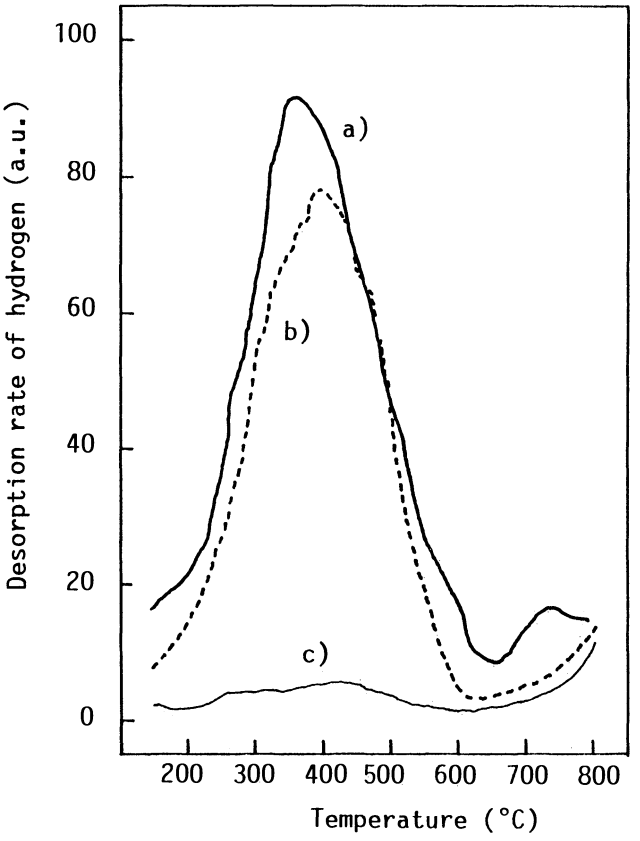

Fig. 5. Temperature programmed desorption spectra of hydrogen on ZSM-5 hybrid catalyst. Heating rate; 400°C h^{-1}, mass number 2, a) (Ga/Al_2O_3 0.2 g+H–ZSM-5 0.8 g) hybrid catalyst, b) (Ga/Al_2O_3 0.2 g)+(H–ZSM-5 0.8 g) calculated value, c) H–ZSM-5 1.0 g.

hybrid catalyst. The more important process of hydrogen desorption for catalytic dehydrogenation is convinced to be the reverse spillover process.

Figure 5 shows the TPD spectra of molecular hydrogen. From H–ZSM-5 hydrogen molecule desorbed mostly at higher than 700 °C. The TPD spectra of H_2 desorption from Ga–ZSM-5 is characterized by its much larger peak between 300 and 600 °C and the peak at 700 °C. The TPD spectrum from Ga/Al_2O_3 is rather close to that from Ga–ZSM-5 but the peak top is shifted to lower temperature (by about 100 °C). The character of H_2 desorption from the Ga/Al_2O_3/H–ZSM-5 hybrid is quite close to that from Ga/Al_2O_3 but its amount is considerably larger than the former. These phenomena clearly suggest that hydrogen molecules are desorbed much more easily from Ga on Al_2O_3 than on zeolite, and that even the hydrogen on H–ZSM-5 is desorbed at much lower temperature when the zeolite is hybridized with Ga/Al_2O_3. The desorption of H_2 below 600 °C from the hybrid catalyst should be attributed to the reverse spillover of hydrogen including inter-particle hydrogen transfer (Fig. 7).

Reaction Model. The most probable explanation of the promotional effect of gallium should be attributed to the "reverse spillover" effect whose model is shown in Fig. 6.[21] In the model, gallium acts as the exit of hydrogen on the zeolite surface. It has been reported in many studies that the conversion of lower paraffins on H–ZSM-5 gives a small amount of aromatic hydrocarbons or hydrogen but a large amount of lower paraffins such as propane and ethane.[4,9] It means that hydrogen atoms generated upon aromatization reaction do not come out of the zeolite surface into the gas phase but hydrogenate ethylene or propene which are intermediates in paraffin-to-aromatic conversion.

On the gallium-supported ZSM-5 zeolite, on the other hand, hydrogen atoms on the zeolite surface migrate to Ga site where they recombine to form hydrogen molecules and then desorb into the gas phase.

When hydrogen atoms on a zeolite surface are effectively removed, their concentration in the zeolite surface should be reduced. As is the case of the reaction in the presence of oxygen, H–ZSM-5 itself exhibits a high conversion activity and aromatic selectivity, if the surface hydrogen is effectively removed. The desorbed hydrogen is rather inactive for a hydrogenation reaction in the

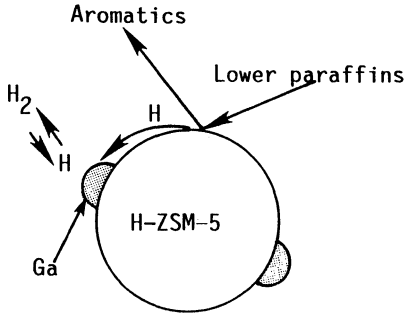

Fig. 6. Model of hydrogen reverse spillover.

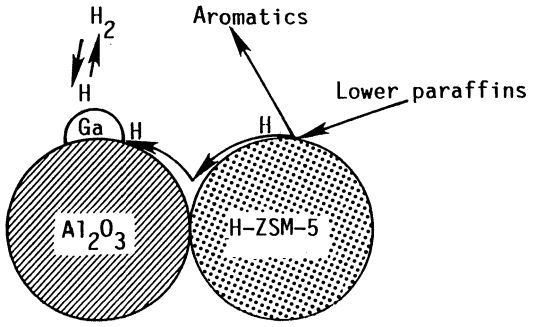

Fig. 7. Model of interparticle hydrogen reverse spillover.

Ga–ZSM-5 catalyzed system as shown in Fig. 2. In the case of hybrid catalysts, their high catalytic performances should be attributed to inter-particle hydrogen transfer and reverse spillover as demonstrated in Fig. 7. The hydrogen atom on H–ZSM-5 moves to the alumina surface and then goes into the gas phase through the Ga sites (reverse spillover). It is reasonable that the granular mixture of Ga/Al_2O_3 and H–ZSM-5 exhibited a significantly inferior ability for butane conversion as compared to the hybrid catalyst. In the granular system the poor contact between the two components impede hydrogen transfer from the H–ZSM-5 to the Ga/Al_2O_3.

The concept of spillover also reasonably explain the fact that the selectivity of aromatic hydrocarbons on the Ga–ZSM-5 was suppressed by hydrogen in the gas phase in spite of its low hydrogenation activity. When hydrogen exists in the gas phase, the desorption of hydrogen atoms from the zeolite is suppressed by the spillover effect. If the hydrogen desorption is slow, it will react with olefins or carbonium ions to form paraffins, suppressing the formation of aromatic hydrocabons.

Conclusion

1) Gallium on ZSM-5 promotes the formation of aromatic hydrocarbons in the conversion of lower paraffins through the reverse spillover of hydrogen atoms on the zeolite surface.

2) H–ZSM-5 is sufficiently active and selective for the conversion of butane to aromatic hydrocarbons if the hydrogen atoms on its surface are effectively removed during the reaction.

Optical Properties of CdS Microcrystallite-Doped Al_2O_3 Thin Films Prepared by Rf-Sputtering

Ichiro TANAHASHI,* Masaru YOSHIDA, and Tsuneo MITSUYU
Central Research Laboratories, Matsushita Electric Industrial Co., Ltd.,
Yagumo-Nakamachi, Moriguchi, Osaka 570
(Received February 6, 1991)

Synopsis. Al_2O_3 thin films containing CdS microcrystallites were successfully prepared by an rf-magnetron sputtering technique. Photoluminescence spectra of films exhibited blue band-edge emission at a higher energy than that of bulk CdS. The spectral change seems to arise from a zero-dimensional confinement of electrons and holes in CdS microcrystallites.

Semiconductor microcrystallites doped in solid matrices, such as glasses and polymers, exhibit a large optical nonlinearity due to the quantum size effect.[1-3] In fact, the diameter of semiconductor microcrystallites in bulk glasses was less than 100 Å, where the microcrystallites could be considered as "quantum dots".

In order to improve the uniformity of the crystallite size, the doping of semiconductors to glasses is carried out by alternative preparation processes such as melt-quenching,[1,2] sol-gel,[4-5] and sputtering methods.[6-8] Sputtering is one of the promising technique for the preparation of various types of semiconductor-doped glass thin-films. Most of the matrices investigated for the films were SiO_2. However, the effects of the matrices on the chemical bond of a doped semiconductor and on the optical properties of the films have not yet been investigated. To clarify the nature of the quantum size effect, it is important to study the relation between the chemical bond of doped semiconductors and the matrices.

In this paper, we report on the preparation of Al_2O_3 thin films containing CdS microcrystallites by the rf-magnetron sputtering technique. The optical properties of the films have also been investigated.

Experimental

Al_2O_3 thin films containing CdS microcrystallites were prepared by a conventional rf-magnetron sputtering systems. The targent used was an Al_2O_3 plate (100 mm in diameter with 5 mm in thickness) with a number of CdS tablets (10 mm in diameter with 1.5 mm in thickness). The concentration of CdS was controlled by changing the number of tablets. The substrates used were SiO_2 glass or GaAs. Sputtering was carried out for 5 h in Ar gas of 5.32 Pa while applying an rf power of 200 W. The substrate was not intentionally heated.

X-Ray photoelectron spectra (XPS) analyses were performed using a Mg$K\alpha$ X-ray source. Details of the measurements were described previously.[8] For calculating the binding energies of each peak, the peak position of the main component in the 1s core level spectrum of carbon was assumed to be 284.6 eV.

The composition of the films was determined by electro-probe microanalysis (EPMA) using the films on GaAs substrates. X-Ray diffraction measurements (XRD) were carried out in order to examine the crystallinity of the films.

The optical absorption spectra were measured in the range from 200 to 700 nm by a spectrometer. The photoluminescence spectra were measured at room temperature by using a spectrofluorophotometer with filters to eliminate the excitation light.

Results and Discussion

Figure 1 shows the Al2p electron spectra of a film with 25.4 cadmium wt%. In this figure, the arrows indicate the standard peak position for Al2p of Al metal[9] and Al_2O_3.[10] The peak of the film coincides with that of Al_2O_3. The Ols electron spectra of the film also coincided with that of Al_2O_3.[10] Thus, Al_2O_3 was

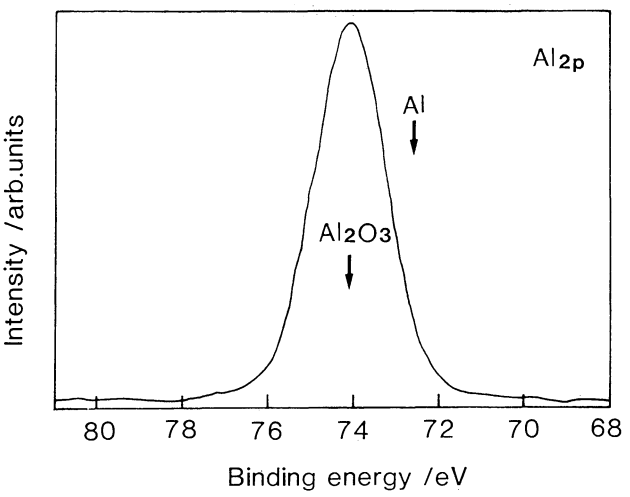

Fig. 1. A12p electron spectra of the film containing 25.4 cadmium wt%. Al indicates the standard peak position of A12p electron spectra of Al metal, Al_2O_3; A12p of Al_2O_3.

successufully formed by rf-magnetron sputtering.

Figure 2 shows the Cd3d electron spectra of the film. The film examined was the same as that shown in Fig. 1. The spin-doublet of $Cd3d_{3/2}$ and $Cd3d_{5/2}$ is given in Fig. 2. In this figure, the arrows indicate the peak position of the Cd3d electron spectra for CdS, Cd metal, and CdO.[11] These experimental peak positions are close to those of the standard CdS. The Cd and S atoms were reasonably doped in the Al_2O_3 matrix as CdS. In conclusion, CdS was successfully doped into Al_2O_3.

The XRD patterns of the films showed no reflection lines, suggesting that the Al_2O_3 thin film was amorphous. The crystal system of the doped CdS could not be identified in this expepriment. The doped CdS was too small to identify its crystal system by the XRD patterns.

By means of the EPMA measurements, the ratio of S to Cd atoms (S/Cd) of a film containing 25.4 cadmium wt% was estimated to be 0.83. This is because the reevaporation of S atoms from the substrates was larger than that of Cd atoms under the experimental condition. Although the Cd and S atoms were reasonably doped as CdS by XPS analyses, it seemed that part of the Cd atoms were doped as Cd metal and CdO.

Figure 3 shows the transmission spectra measured at room temperature for Al_2O_3 thin films containing CdS: (a) film with 10.9 cadmium wt%, (b) 20.0 wt%, and (c) 25.4 wt%. The thickness of the films was 0.4—0.6 μm. The films, thus, show interference oscillations (the waves in the spectra) in the transparent region. The three spectra are different in the region below 500 nm. From the figure, the power of the absorption coefficient, α, was plotted against the photon energy, $h\nu$. The α^2 varied linearly with $h\nu$, indicating that the direct interband transition took place. The optical band-gap energy, E_g, of the film (a) was estimated to be 2.66 eV from the α^2 vs. $h\nu$ plot. The E_g of the film (a) is clearly blue-shifted by about 0.25 eV, compared with that of the bulk CdS (2.41 eV). With increasing the concentration of CdS, E_g decreased. This is because the diameter of CdS microcrystallites became large.

In spherical semiconductor quantum dots enclosed by the insulating matrix, the blue shift, ΔE_g, is expressed by

$$\Delta E_g = h^2/8a^2\mu \quad (2)$$

where a and μ are the radius of the spherical dots and the reduced effective mass of an electron-hole pair, respectively; h is Planck's constant. This equation is valid when the radius, a, is smaller than the Bohr radius of the bulk exciton.[12] The diameter of the CdS-microcrystallites in the film (a) was 57 Å, as calculated by Eq. 2. The blue shift of an Al_2O_3 thin film with 25.4 cadmium wt% was 0.04 eV larger than that of SiO_2 thin films with 35.9 cadmium wt%.[8] The reasons for the larger blue shift of the films have not been clarified. However, the larger shift seems to represent the difference in the size between the CdS in an Al_2O_3 thin film and that in a SiO_2 thin film. Direct observations of CdS in Al_2O_3 thin films is the next problem.

The effect of the dielectric constant of the matrix on the blue shift has also been reported by Brus et al.[13] They calculated the blue shift for CdS microcrystallite in vacuum using an equation with three energy terms; kinetic, coulomb, and polarization. The polarization term was influenced by the dielectric constant of the matrices. According to the calculation: 1) the blue shift became small with increasing the value of the dielectric constant of matrices and 2) the contribution of the polarization term to the blue shift was rather small in comparison with the other two terms. The dielectric

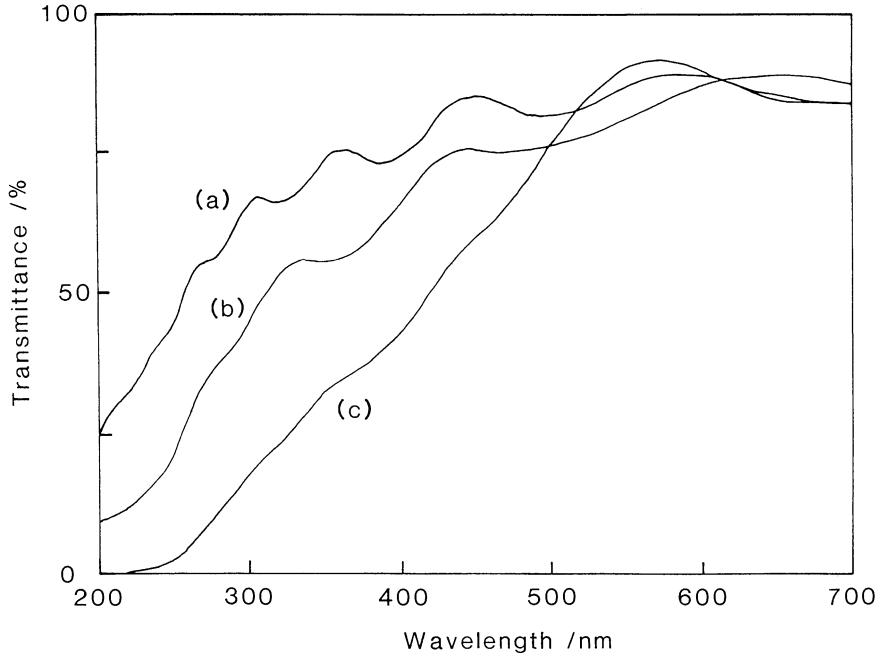

Fig. 3 Optical transmission spectra of the films at room temperature. (a) the films with 10.9 cadmium wt%, (b) 20.0wt%, and (c) 25.4 wt%.

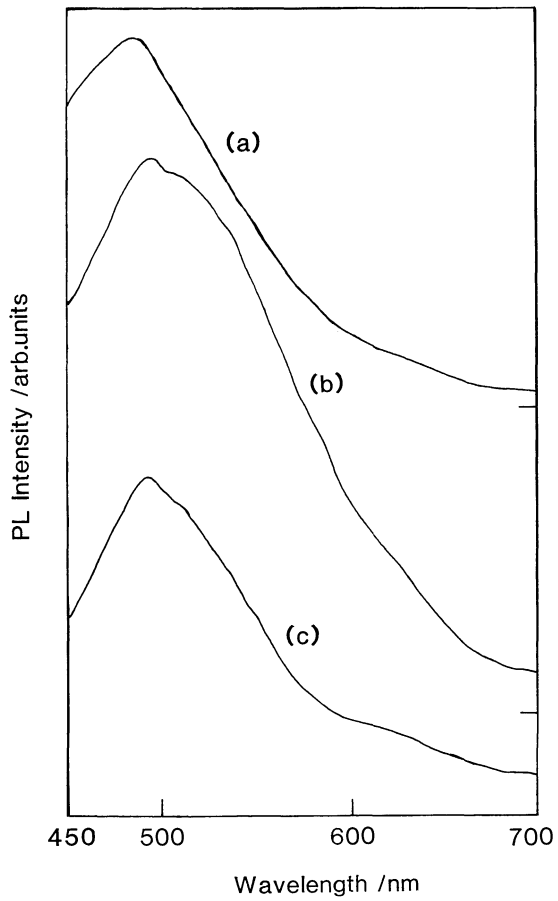

Fig. 4. Photoluminescence spectra of the films at room temperature. (a) the film with 10.9 cadmium wt%, (b) 20.0 wt%, and (c) 25.4 wt%.

constants of Al_2O_3 and SiO_2 were 8.6 and 4.5, respectively. Therefore, the larger blue shift of the Al_2O_3 thin films with CdS seems to be due to the smaller size of CdS.

Figure 4 shows the photoluminescence (PL) spectra at room temperature measured for films (a), (b), and (c). The emission of the films appears below 500 nm. It is reported that CdS deposited in porous vycor glass showed emission associated with a sulfur vacancy at 680 nm and band-edge emission at 520 nm.[14] The PL spectrum of CdS deposited in porous vycor glass was close to that of bulk CdS. The band-edge emission of the films examined were clearly blue-shifted in comparison with that of bulk CdS. The emission of the films is broad, suggesting that the size distribution of doped CdS was rather large. With increasing concentration of CdS, the PL peak position of the films shift to lower energy. In accordance with the results of the optical transmission spectra, the energy of the band-edge emission of the films is higher than that of bulk CdS. The shift to higher energy is attributed to a low-dimensional quantum size effect due to the confinement of electrons and holes in CdS microcrystallites.

The authors would like to thank Drs. T.Nitta and A.Nishino for their continuous encouragement. A part of this work was performed under the management of Japan High Polymer Center as a part of the R&D of Nonlinear photonics materials supported by NEDO (New Energy and Industrial Technology Development Organization).

A Theorem on *p*-Densities in the Hückel Model of Linear Chains

Makoto ISIHARA
Department of General Education, Shotoku-Gakuen Women's Junior College,
Nakauzura 1-38, Gifu 500
(Received February 18, 1991)

Synopsis. The hyperivial condition upon *p*-densities is applied to the simple Hückel model of linear chains. The invariance of the modified *p*-density is derived in fully generalized form. Any bond order between nonadjacent sites is shown expressible in terms of two electron densities or two bond orders between adjacent sites.

The author has manifested the significance and the usefulness of the hypervirial condition upon *p*-densities[1] in the Hückel model in the previous paper,[2] where he has mentioned a few consequences of the condition in the simple Hückel model[3] of linear chains as an illustrative example. In this note, the invariance of the modified electron density and that of the modified bond order between adjacent sites are fully generalized in a systematic way. The resulting theorem enables us to express any bond order between nonadjacent sites in terms of two electron densities or two bond orders between adjacent sites. In particular, for the neutral ground state, this means that an analytic expression is given to the bond order between nonadjacent sites. A few remarks are added last on the treatment of linear chain parts.

The following mathematical notation is used throughout. The symbol $[z_s,z_l]$ stands for the set of integers that contains z_s and z_l as the smallest and the largest elements, respectively; understand the set to be empty if $z_l<z_s$. The symbol $[z]$ means the largest integer not more than z.

Suppose the linear chain of m sites in the simple Hückel model. Number the sites consecutively from 1 to m and denote $[1,m]$ by M. Each stationary state has its *p*-densities $\{p_{rs}\}$ $(r,s\in M)$, which fulfil the hypervirial relationships[2]

$$p_{r+1,s}+p_{r-1,s}-p_{r,s-1}-p_{r,s+1}=0 \qquad (r<s\in M). \tag{1}$$

Here, understand the term having an improper subscript as being absent. Although the inherent symmetry

$$p_{sr}=p_{rs} \qquad (r,s\in M) \tag{2}$$

is assumed, we need not consider the symmetry of the system for the present purpose.

Introduce the index b taking the two values 0 and 1, and define p_{bvi} by

$$p_{bvi}=p_{v-i,v+b+i} \tag{3}$$

for vi of the range expressed as follows. Let M_b be $[1,m-b]$ and d_{bv} be the largest i for each $v\in M_b$;

$$d_{bv}=\begin{cases} v-1 & (v\in[1,c_b]) \\ m-b-v & (v\in[c_b+1,\,m-b]) \end{cases} \tag{4}$$

with

$$c_b=[(m-b+1)/2]. \tag{5}$$

Denoting $[0,d_{bv}]$ by D_{bv}, we have $i\in D_{bv}$ with $v\in M_b$. The other expression of the range is often useful. Let d_b be the largest of d_{bv}'s $(v\in M_b)$ given by

$$d_b=[(m-b-1)/2] \tag{6}$$

and denote $[0,d_b]$ by D_b and $[1+i,m-b-i]$ by M_{bi}. Then, we have $v\in M_{bi}$ with $i\in D_b$. Any site pair index rs $(r\leqq s\in M)$ can be transformed by

$$b=\begin{cases} 0 & (s-r \text{ even}) \\ 1 & (s-r \text{ odd}), \end{cases} \tag{7}$$

$$v=(r+s-b)/2, \tag{8}$$

and

$$i=(s-r-b)/2 \tag{9}$$

into the present triple index bvi uniquely.

Now, let us define the modified *p*-density ξ_{bvi} for each $i\in D_b$ as

$$\xi_{bvi}=\begin{cases} p_{bvi}-p_{bv,i+1} & (v\in M_{b,i+1}) \\ p_{bvi} & (v=1+i,\,m-b-i). \end{cases} \tag{10}$$

Then, the hypervirial relationships can be rewritten as

$$\xi_{bvi}=\xi_{b,v+1,i} \qquad (v,\,v+1\in M_{bi})\ (i\in D_b). \tag{11}$$

Successive applications of these lead immediately to[4]

$$\xi_{bvi}=\xi_{bwi} \qquad (v,\,w\in M_{bi})\ (i\in D_b), \tag{12}$$

which can be further generalized as shown below.

Let $D_b(f)$ be $[0,d_b-f]$ for each $f\in D_b$ and redefine the modified *p*-density $\xi_{bvi}(f)$ for each $i\in D_b(f)$ as

$$\xi_{bvi}(f)=\begin{cases} p_{bvi}-p_{bv,i+f+1} & (v\in M_{b,i+f+1}) \\ p_{bvi} & (v=1+f+i,\,m-b-f-i), \end{cases} \tag{13}$$

which contains the preceding modified p-density as the particular case of f=0. Because $\xi_{bvi}(f)$ can be written as

$$\xi_{bvi}(f) = \sum_{k=i}^{i+f} \xi_{bvk}, \tag{14}$$

we attain the theorem

$$\xi_{bvi}(f) = \xi_{bwi}(f) \quad (v, w \in M_{b,i+f}) \ (i \in D_b(f)) \ (f \in D_b), \tag{15}$$

namely, "The modified p-density is an invariant every fi." The theorem is ready to yield readable relationships:

(1) Let both of v and w belong to $M_{b,i+f+1}$ and rewrite $i+f+1$ as j. Then, for $i<j$, we have

$$p_{bvj} - p_{bwj} = p_{bvi} - p_{bwi} \qquad (v, w \in M_{bj}). \tag{16}$$

(2) Let v be $1+f+i$ and d_{bw} be larger than d_{bv}. Then, we have

$$p_{bwv} = p_{bwi} - p_{bvi} \qquad (i \in D_{bv}). \tag{17}$$

(3) Let v be $1+f+i$ and w be $m-b-f-i$. Then, the symmetry condition

$$p_{bvi} = p_{b,m-b+1-v,i} \qquad (v \in [1,c_b]) \tag{18}$$

follows.

Important is the i=0 case of the second. Arranging the letters relevantly, we find that

$$p_{bvi} = p_{bv0} - p_{bi0} \qquad (0 < i \in D_{bv}) \ (v \in M_b), \tag{19}$$

which connects bond orders between nonadjacent sites with two electron densities (b=0) or with two bond orders between adjacent sites (b=1).[5] In particular, for the m-electron ground state, using an analytic expression of the bond order between adjacent sites,[6] we obtain

$$p_{1vi} = (A_m(v) - A_m(i))/(m+1) \tag{20}$$

with

$$A_m(t) = \begin{cases} (-1)^{t-1}\mathrm{cosec}((2t+1)\pi/(2m+2)) & (m \text{ even}) \\ (-1)^{t-1}\cot((2t+1)\pi/(2m+2)) & (m \text{ odd}) \end{cases} \tag{21}$$

from the b=1 case. The b=0 case connects the two well-known consequences[7] of the alternant symmetry with each other.

The above theorem is essentially valid for any linear chain part aside from bifurcation sites. For the linear chain part having an end site, number the sites from 1 to m with the end site as 1 and the bifurcation site as m. Considering the hypervirial relationships for $r<s\in[1,m-1]$, we find that the theorem holds with the range for v and w restricted to $M_{b,i+f+1}$ plus $1+f+i$. On the other hand, for the linear chain part between bifurcation sites, number the sites from 1 to m with the bifurcation sites as 1 and m. The hypervirial relationships for $r,s\in[2,m-1]$ leave p_{1m} extraneous, so that we have

$$d_{bc_b} = c_b - 2 \qquad (c_b \text{ odd}), \tag{22}$$

which affects d_b. The range for v and w is further restricted to $M_{b,i+f}$. The expressions obtained by utilizing the property at the terminal $1+f+i$ of $M_{b,i+f}$ remain valid only if the linear chain part has an end site.

(Received November 2, 1990)

Synopsis. The dicopper(I) complex with 2-(diphenylphosphino)pyridine (Ph_2Ppy), $[Cu_2(\mu\text{-}Ph_2Ppy)_2(CH_3CN)_2](PF_6)_2$ has been prepared. The crystal structure has been determined crystallographically: Space group $P\bar{1}$, a=10.807(6), b=11.756(8), c=8.606(7) Å, α=90.36(6), β=95.98(5), γ=92.90(5)°, Z=1, R=0.067. The two copper atoms are bridged by two Ph_2Ppy molecules in a head-to-tail arrangement, resulting in a rare staggered conformation of the eight-membered ring $Cu_2P_2N_2C_2$, whose factor is concerned with the coordination numbers of the central metal atoms. ^1H NMR studies show that the ligand of a CH_3CN in the titled compound undergoes dissociation in acetone solution.

2-(diphenylphosphino)pyridine (Ph_2Ppy) can form dimetal complexes[1-4] having an eight-membered ring $M_2P_2N_2C_2$, because of its ability to act as a bidentate bridging ligand. The two sort donor atoms in Ph_2Ppy stabilize metals in the lower oxidation state. However, there is sparse literature on its copper(I) and silver(I) complexes. Recently the dicopper(I) complex containing three Ph_2Ppy molecules as bridging ligands was reported.[5] The framework of the eight-membered ring gives an eclipsed[1-4,6-11] and a staggered conformation.[12] The latter seldom occurs in metal complxes, whereas the former often occurs in various metal complexes.

We have synthesized the dicopper(I) complex bridged by two Ph_2Ppy molecules which form a eight-membered ring and have determined the crystal structure in order to clarify the factors governing the eclipsed and staggered conformations.

$B_{eq}=(4/3)\{\Sigma_i\Sigma_{ij}B_{ij}\boldsymbol{a}_i\boldsymbol{a}_j\}$.

two days at 0 °C. A small colorless crystal, $[Cu_2(\mu\text{-}Ph_2Ppy)_2(CH_3CN)_2](PF_6)_2$ (**1a**) was obtained together with many pale yellow-green crystals (**1b**).[15] The structure of **1a** was determined by X-ray crystallography, but that of **1b** could not determined because of the decay of the reflection intensities during data collection of the X-ray diffraction. ^{1}H NMR ($(CD_3)_2CO$) **1a** δ=9.45 (d, 6-H), 8.16 (t, 4-H), 7.93 (t, 5-H), 7.00 (d, 3-H), 7.34—7.49 (m, ph), and 2.03(s, CH_3CN); ^{31}P NMR ($(CH_3)_2CO$) **1a** 4.02. Yield **1a** 5 mg (3%).

X-Ray Data Analysis for $[Cu_2(\mu\text{-}Ph_2Ppy)_2(CH_3CN)_2](PF_6)_2$. The colorless crystal suitable for X-ray diffraction study was mounted on a Rigaku AFC-6B diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The conditions of data collection and the crystal data are listed in Table 1. A total of 3753 independent reflections having $F_o > 3\sigma(F_o)$ were used. The structure was solved by a direct method (MULTAN 78)[16] and refined by Block diagonal least-squares calculations with anisotropic thermal parameters including isotropic H atoms located on a difference Fourier synthesis, using the program system KPPXRAY.[17] Reliability factors are defined as $R=\sum(|F_o|-|F_c|)/\sum|F_o|$ and $R_w=\{\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2\}^{1/2}$, where $w=1/\sigma^2(F_o)$. Atomic scattering factors and anomalous dispersion terms were taken from the International Tables for X-ray Crystallography, Vol. IV. The final R and R_w values were 0.067. Atomic coordinates of nonhydrogen atoms are given in Table 2.[18]

Results and Discussion

This section describes only the structure of **1a** because that of **1b** could not be determined by X-ray crystal analysis. The X-ray crystal structure of the complex **1a** is shown in Fig. 1. The complex consists of a centrosymmetric cation and noninteracting PF_6^- anions. Each copper atom is coordinated to one nitrogen atom of one Ph_2Ppy molecule and the nitrogen of CH_3CN, and one phosphorus atom of the other Ph_2Ppy molecule, resulting in a distorted trigonal geometry. The two copper atoms are bridged by two Ph_2Ppy molecules to form an eight-membered ring $Cu_2P_2N_2C_2$. The bridging mode of each Ph_2Ppy molecule is head-to-tail.[1-3,5,9] The most striking feature of the complex is that the eight-membered ring has a staggered conformation. To our knowledge, there is only one report of the conformation for $[Au_2(\mu\text{-dppm})_2Cl_2]$[12] in which the gold(I) atoms are three-coordinate. On the other hand, the dimetal complexes having a four-coordinate copper(I) atom[6,7,9] and silver(I) atom[8] give an eclipsed conformation. The complex **1a** and the Au(I) complex $[Au_2(\mu\text{-dppm})_2Cl_2]$ in which the central ions are three-coordinate give staggered conformations as described above. It was reported that the conformation of an eight-membered ring depends on the size and mode of binding of the other ligands which don't form part of the eight-membered ring.[8] In addition, the coordination numbers of the central metal ions are considered to be one of the most important factors governing the eight-membered ring conformation.

The Cu–N(1′)(pyridyl) distance of 2.038(4) Å is slightly shorter than those (2.048(4)—2.114(4) Å) reported for three-coordinate copper(I) complexes.[5,9,19] It is interesting to note that the Cu–N(2)(CH_3CN) distance of 1.933(5) Å is between those (1.843(8)—1.846(10) Å) of three-coordinate copper(I) complexes[19] with CH_3CN and those (1.999(9)—2.161(3) Å) of four-coordinate copper(I) complexes[5,6] with CH_3CN. The Cu–P(1) distance of 2.204(2) Å is close to those (2.231(3)—2.296(8) Å) of copper(I) complexes with 1,1′-bis(diphenylphosphino)methane[6,20-22] and Ph_2Ppy.[5] The Cu···Cu′ distance of 3.584(3) Å is much longer than that (2.721(3) Å) of the analogous dicopper(I) complex[5] $[Cu_2(\mu\text{-}Ph_2Ppy)_3(CH_3CN)]^{2+}$.

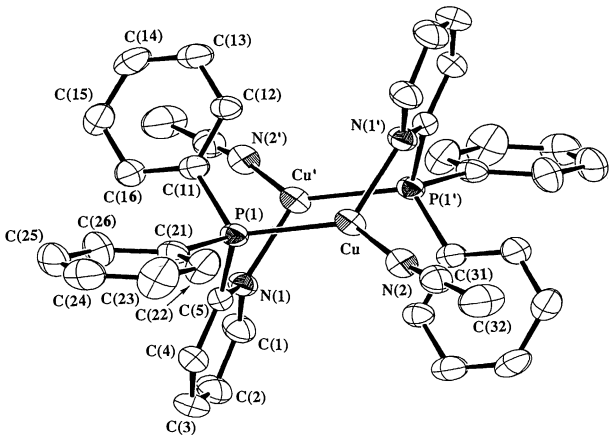

Fig. 1. ORTEP drawing of $[Cu_2(\mu\text{-}Ph_2Ppy)_2(CH_3CN)_2]^{2+}$ cations with 30% probability plots for thermal ellipsoids and atomic numbering. Half the atoms are labeled: the others are related by a center of inversion at the midpoint of the Cu···Cu′ vector. Only Cu′, P(1′), N(1′) and N(2′) in the coordination sphere are labeled. Selected bond distances (Å) and bond angles (°); Cu···Cu′=3.584(3), Cu–P(1)=2.204(2), Cu–N(2)=1.933(5), Cu–N(1′)=2.038(4), C(18)–N(2)=1.123(8), P(1)–Cu–N(2)=128.3(2), P(1)–Cu–N(1′)=120.0(1), N(2)–Cu–N(1′)=106.7(2), Cu–P(1)–C(5)=113.9(2), Cu–P(1)–C(11)=115.4(2), Cu–P(1)–C(21)=113.7(2), Cu–N(2)–C(31)=171.1(5).

The angles around copper(I) are P(1)–Cu–N(1′)=120.0(1), P(1)–Cu–N(2)=128.3(2), and N(2)–Cu–N(1′)=106.7(2)°, summing to 355.0°, since the copper atom lies 0.2661 Å from the plane defined by one phosphorus and two nitrogen atoms. The P(1)–Cu–N(1′) angle of 120.0(1)° is much smaller than the corresponding P–Au–P angle (155.9(1)°) of $[Au_2(\mu\text{-dppm})_2Cl_2]$[12] (the only complex reported to have a staggered conformation), while it is similar to those of eclipsed copper(I) complexes.[6,7]

^{1}H and ^{31}P NMR chemical shifts[23] of complex **1a** are shown in the experimental section. The ^{1}H NMR coordination shifts ($\Delta\delta=\delta_{complex}-\delta_{free}$) of the pyridine ring protons are 0.09—0.78 ppm, indicating the coordination of the nitrogen atom of Ph_2Ppy to Cu(I). On the other hand, the coordination shift of the CH_3 signal of CH_3CN was not observed within experimental error. This fact reveals the dissociation of a CH_3CN in acetone solution in contrast to the crystal structure. The ^{31}P NMR coordination shift of 7.70 ppm indicates the coordination of the phosphorus atom of the Ph_2P group to Cu(I). This value is significantly large when compared with other dinuclear complexes[2-4] with Ph_2Ppy and slightly larger than those of dinuclear complexes[6,12] with dppm.

We thank Mr. Hisao Shimono and Mr. Shinji Matsuyama for their assistance with the X-ray measurements. This work was partially supported by a Grant-in-Aid for Scientific Research No. 63540465 from the Ministry of Education, Science and Culture.

Demetalation of (5,10,15,20-Tetraphenylporphyrinato)iron Complexes: Effect of Substituents at the *o*-Positions of Phenyl Groups

Etsuo HASEGAWA, Eriko MATSUBUCHI, and Eishun TSUCHIDA*
Department of Applied Chemistry, Waseda University, Tokyo 169
(Received November 26, 1990)

Synopsis. The demetalation of a series of (5,10,15,20-tetraphenylporphyrinato)iron(III) complexes having bulky substituents at the *o*-positions of phenyl rings was studied in acetic acid in the presence of iron(II) chloride and HCl. The reaction occurred simultaneously with the reduction of Fe(III) porphyrin to Fe(II) porphyrin, since no demetalation was observed without iron(II) chloride. The pseudo-first-order rate constants, which were determined spectrophotometrically, decreased with an increase in the bulkiness of the *o*-substituents on the phenyl rings. The atropisomeric structures of the products were determined by high-resolution NMR measurements.

The metal insertion reaction was studied kinetically and thermodynamically in order to understand the mechanism of how porhyrins form the metalloporphyrin complexes in nature.[1,2] An intermediate complex (sitting-atop model) was proposed.[3] Still, less attention has been pain to the demetalation process, although the reaction is closely related to metalation.[4] It is expected that the introduction of bulky substituents to a porphyrin induces not only a decrease in intermolecular metal-metal interaction (dimerization), but also affects the reactivities of the porphyrin group. A preliminary report appeared concerning the effect of such bulky substituents on copper incorporation into tetraphenylporphyrins.[5]

In this paper we describe the demetalation of a series of (5,10,15,20-tetraphenylporphyrinato)iron(III) complexes with bulky ortho-substituents at the phenyl groups in a $FeCl_2$–HCl–acetic acid system at 20 °C and the rate of demetalation in order to discuss the effect of the ortho-substituents on the intramolecular reaction. In addition, a method to determine the atropisomeric structure was established by the use of high-resolution ^1H NMR measurements on the demetalated products prepared by the present method.

Experimental

Materials. Reagent-grade iron(II) chloride, concd HCl and acetic acid were purchased from Wako Chem. Co. and used without further purification. (5,10,15,20-Tetrapheylporphyrinato)iron(II) chloride (**1**) was purchased from Aldrich Chemical Co. and purified by silicagel column chromatography. [5,10,15,20-*Tetrakis*(α,α,α,α-*o*-pivalamidophenyl)-porphyrinato] iron(III) chloride (**3**) was prepared according to methods described in the literature.[6,7] Fe(III) porphyrin chloride (**4**) and Fe(III) porphyrin chloride (**5**) were prepared according to previous papers.[8,9][5,10,15,20-*Tetrakis*(*p*-pivalamidophenyl)porphyrinato]iron(III) chloride (**2**) was propared by the reaction of pivaloyl chloride with 5,10,15,20-tetrakis (*p*-aminophenyl)porphyrin.[10]

Kinetic Measurements. The rate constants of demetalation were determined spectrophotometrically by measuring the UV and VIS adsorption spectra of a porphyrin. A double-beam UV and VIS absorption spectrophotometer (Shimadzu MPS-2000) was used. The kinetic runs were conducted under pseudo-first-order conditions, i.e. in the presence of a large excess of HCl and $FeCl_2$ over porphyrinatoiron(III). The reaction temperature was 20 °C. A solution of a Fe(III) porphyrin (20 μmol dm^{-3}) in acetic acid (5 cm^3) was mixed under argon with 0.02 ml of concd HCl. The reaction was started by adding a $FeCl_2$-saturated aqueous solution under an argon atmosphere in a sealed quartz cell (path length: 10 mm). The final concentrations of HCl, $FeCl_2$, and water were 0.33 mol dm^{-3}, 3.9 mmol dm^{-3}, and 1.8 mol dm^{-3}, respectively.

Preparative Demetalation for ^1H NMR Spectral Measurements. Measurements of the ^1H NMR spectra of demetalated products were carried out with derivatives **3** and **5**. Sample preparations were as follows. Fe(III) porphyrin **3** (30 mg, 26 μmol) was dissolved in a mixed solution of acetic acid (150 ml) and concd HCl (30 ml). To the porphyrin solution was added solid $FeCl_2$ (30 mg, 0.42 mmol) under an argon atmosphere at 20 °C. After 1 h of stirring, the solvent was removed under reduced pressure. The residue dissolved in chloroform was washed with 5% $NaHCO_3$, dried over Na_2SO_4 and then evaporated to dryness. The residue was chromatographed on silica gel eluted with benzene–diethyl ether (4/3 by volume) to give the metal-free porphyrin **3′**. The yield was 23 mg (87%). Anal. Found: C, 74.27; H, 7.28; N, 9.23%. Calcd for $C_{64}H_{66}N_8O_4 \cdot 1H_2O$: C, 74.68; H, 6.54; N, 9.89%. IR (KBr) 1690 and 1580 cm^{-1}. VIS ($CHCl_3$) λ_{max} 643, 587, 545, 511, 480(sh), and 418 nm.

Fe(III) porphyrin **5** (100 mg, 35 μmol) was demetalated by the same procedure described for **3**. The product, however, was purified by column chromatography on Toyopearl HW-40F (Tosoh Co.) eluted with methanol. During column

purifivation, porphyrin dication was spontaneously converted to the correponding porphyrin. The yield was 76 mg (80%). Anal. Found: C, 61.76; H, 9.35; N, 5.23; P, 3.97%. Calcd for $C_{152}H_{248}N_{12}O_{20}P_4 \cdot 15H_2O$: C, 61.69; H, 9.53; N, 5.68; P, 4.19%. IR (KBr) 1690, 1580, 1240, 1080, and 960 cm^{-1}. VIS (MeOH) λ_{max} 644, 589, 547, 513, 480(sh), and 418 nm.

The ^1H NMR spectra of the products were obtained by JEOL GSX-400 FTNMR spectrometer in $CDCl_3$ or CD_3OD with Me_4Si used as an internal standard.

Results and Discussion

It is well-known that the metalloporphyrins can be divided into five 'stability classes' which indicate their resitance towards protic acids.[11] A porphyrinatoiron(III) complex belongs to class-III in demetalation,[12] and the reduced one (porphyrinatoiron(II)) is much more susceptible to demetalation. From this view a demetalation reaction of an iron(III) porphyrin was studied with the concomitant reduction to iron(II) by various reductants.[13] The mechanism of iron(III) demetalation in the presence of iron(II) chloride and HCl as a 'catalytic' reductant has been studied kinetically and the following mechanism was postulated:[13]

$$ClFe(III)P + Fe(II) + HCl \rightleftarrows HFe(III)Cl_4 + Fe(II)P \quad (1)$$

and

$$Fe(II)P + n\ HCl \rightarrow Fe(II) + H_4P^{2+}, \quad (2)$$

where P indicates a porphyrinato ligand. The reaction follows pseudo-first-order kinetics:

$$-d[ClFe(III)P]/dt = k_{obsd}\,[ClFe(III)P], \quad (3)$$

where k_{obsd} indicates a pseudo-first-order rate constant for demetalation.

In the present paper, the demetalation of a series of iron(III) porphyrins was conducted in acetic acid containing concd HCl in the presence of an excess amount of iron(II) chloride, as described in the Experimental section. For example, the original spectrum of **5** (absorption maxima at 506, 589, and 645 nm) disappeared and changed to that of the metal-free porphyrin dication (absorption maxima at 585 and 636 nm). The isosbestic points (472, 560, and 661 nm) were maintained during the reaction. This indicates that the reaction is apparently from Fe(III)P to H_4P^{2+}. No demetalation reaction occurred in the absence of iron(II) chloride under the HCl concentration employed in the present study; in the absence of HCl no reaction could be induced by iron(II) chloride. This fact indicates that the demetalation is caused by a concurrent reaction accompanying both a reduction process and a removal process of an iron ion, shown by the ternary reaction (1). Other iron(III) porphyrins also showed the same reaction behavior.

The pseudo-first-order rate constants (k_{obsd}) were determined by pseudo-first order plots. The linearity of the plots revealed the first-order kinetics, and the determined rate constants were independent of employed wavelength (480—680 nm). Table 1 summarizes the rate constants, under the same experimental conditions, for the demetalation reactions of a series of (5,10,15,20-tetraphenylporphyrinato)iron(III) having different substituents at the ortho positions of phenyl rings (complexes **1**—**5**). Table 1 clearly shows that the rate constants are remarkably dependent on the substituents at ortho-positions.

Table 1. Values of Pseudo-First-Order Rate Constants (k_{obsd}) of Demetalation Reactions

Compound	k_{obsd}/s^{-1} [a]
1	1.5×10^{-2}
2	1.0×10^{-2}
3 (α_4) [b]	1.4×10^{-3}
3 ($\alpha_n\beta_{4-n}$) [b]	1.3×10^{-3}
4	3.1×10^{-4}
5 (α_4) [b]	1.8×10^{-4}
5 ($\alpha_n\beta_{4-n}$) [b]	4.3×10^{-4}

a) Pseudo-first-order rate constants at 20°C, in acetic acid–H_2O. [Fe(III)porphyrin]=20 μmol dm^{-3}, [HCl]= 0.33 mol dm^{-3}, [$FeCl_2$]=3.9 mmol dm^{-3}. b) α_4 and $\alpha_n\beta_{4-n}$ (n=4, 3, 2) mean a $\alpha,\alpha,\alpha,\alpha$-atropisomer and a mixture of four atropisomers, respectively.

The rate of a demetalation reaction is considered to be affected largely by the following three factors: (1) the basicity of a porphyrinato ligand, (2) the deformability of a porphyrin ring plane, and (3) the solvation on a porphyrin ring plane.

The basicity of these tetraphenylporphyrin ligands having various ortho-substituents is considered to be almost the same, since the Hammet sigma coefficient of the alkanamido groups is practically zero.[14]

An X-ray diffraction analysis revealed that the porphyrin dications (diacids), that is, products of demetalation, form a domed structure by a van der Waals repulsion of the inner hydrogen atoms of the porphyrin ring.[15] During a demetalation reaction, it can be postulated that an intermediate complex having a domed structure of a porphyrin ring, like a sitting-atop model,[3] is formed. It has been reported concerning a kinetic study of the thermal atropisomerization and photomerization study of [5,10,15,20-*tetrakis*($\alpha,\alpha,\alpha,\alpha$-*o*-substituted phenyl)porphyrinato]metal complexes that the planality of a porphyrin ring is closely related to the steric repulsion of the bulky groups and regulates the rotation of the phenyl rings.[16] That is, the bulky substituents restrict the tilting of pyrrole rings, resulting in less deformability of a porphyrin ring. The fact that the bulky groups (pivalamido groups) at the para positions, as in the case of the complex **2**, showed a rate constant similar to that of **1** also suggests that a steric interation of the bulky groups at the ortho positions is important. Our results are consistant with the conclusion that the ruffling of the porphyrin may results in an enhancement of the reactivity on the electrophilic meso-substitution in metalloporphyrins.[17]

The porphyrin ring is considered to be less solvated on the side of bulky ortho-substituents and desolvated irons are expected to be more easily removed. However, this is inconsistent with the experimental results.

The demetalation of **3** and **5** was carried out in preparative scales in order to give the corresponding

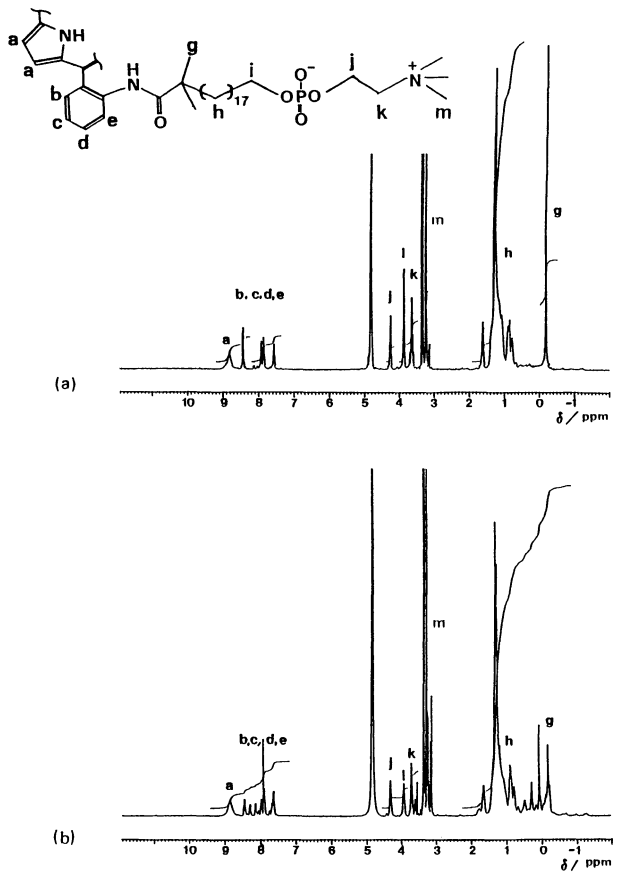

Fig. 1. 400 MHz ^{1}H NMR spectra of the demetalated products of **5**(α_4) (a) and a mixture of four atropisomers (**5**($\alpha_n\beta_{4-n}$)) (b) in CD_3OD.

demetalated products in high yields (>80%). The structures of the products were confimed by various analyses, as described in the experimental section. Figure 1 shows the 400 MHz ^{1}H NMR spectra of the demetalated products of **5**(α_4) and a mixture of four atropisomers **5**($\alpha_n\beta_{4-n}$). The structure of the α_4 atropisomer of **5** was supported by the single peak at δ=−0.2 ppm due to the methyl protons of the 2,2-position of the acyl chains of the same chemical environment (Fig. 1(a)), while the Fe(III) porphyrin comprising of a mixture of four atropisomers,**5**($\alpha_n\beta_{4-n}$), gave a product having multiple signals near δ=0.0 ppm due to the multiple methyl protons of chemically different environments (Fig. 1(b)). It is therefore obvious that no atropisomerization was induced during the demetalation reaction under the conditions used in the present study.

(Received February 16, 1991)

Synopsis. The intercalation of enzymes with molecular weights of 23000—240000 was examined for layered inorganic compounds. The intercalation of papain and catalase into γ-type titanium(IV) phosphate was achieved by coexisting propylamine in an aqueous medium. The intercalation compound of papain was enzyme active for *N*-benzoyl-L-arginine ethyl ester and a catalase intercalation compound for H_2O_2 decomposition.

A great variety of methods for the preparation of immobilized enzymes have been reported and practically applied in many quarters. Inorganic materials, such as clay minerals, have been used as supports of immobilized enzymes.[1] However, such immobilized enzymes are prepared by simple adsorption or ion-exchange reaction of enzymes on the surface of clay minerals. Intercalation occurs in layered inorganic compounds in which each lamella is combined by weakly interacting forces, such as van der Waals force. Enzymes which are intercalated between such weakly interacting lamellae are expected to be utilized as immobilized enzymes. Such an approach may develop different conceptions regarding the immobilization of enzymes.

This paper deals with the intercalation of some common enzymes in layered γ-type titanium(IV) phosphate ($Ti(HPO_4)_2 \cdot 2H_2O$: γ-TiP). The enzyme activity of the intercalation compounds was also examined.

Experimental

Layered Materials. The H^+ form γ-TiP was prepared according to the procedure reported by Kobayashi and Yamazaki[2] as follows. Amorphous titanium(IV) phosphate was heated hydrothermally in 10 M (M=mol dm^{-3}) phosphoric acid for 24 h at 280 °C. Well crystallized γ-TiP with an average diameter of 10—20 μm was prepared.[3] The crystal thus prepared was carefully washed with deionized water and air-dried.

Procedure. The direct intercalation of enzymes into inorganic layered compounds seemed to be improbable because of the tremendously large size of the enzymes. The following procedures were employed according to the intercalation reaction of α-zirconium(IV) phoshate with propylamine reported previously.[4] It was found that delamination occurred in the reaction of α-zirconium(IV) phosphate with an aqueous propylamine solution, and gave a colloidal solution of α-zirconium phosphate. Relamination, which gave a transparent film, was found to occur when the solvent was removed from the colloidal soluion. If delamination and the following relamination occurred in the presence of enzymes, the intercalation of enzymes with large moleculr weights could be achieved by coexisting enzymes in such a colloidal solution.

We have found that γ-TiP gave similar colloidal (delaminated) materials in an aqueous propylamine solution.[5] Two procedures for the intercalation were examined in this study according to the above-mentioned findings.

Table 1. Enzymes and Their Molecular Weight

Enzymes	Mol. weight
Papain (Protein decomposition)	23000
Lipase (Triglyceride decomposition)	38000
Peroxidase (H_2O_2 decomposition)	40000
α-Amylase (Starch hydrolysis)	51000
Gluco-Amylase (Starch-Glucose)	70000
Glucose-Oxidase (Glucose oxidation)	153000
Catalase (H_2O_2 decomposition)	240000

Procedure (1): Enzymes were reacted with a colloidal solution of γ-TiP which was prepared in an aqueous propylamine solution.

Procedure (2): γ-TiP was reacted with an enzyme–propylamine mixed solution (cointercalation).

Enzymes. Seven commonly available enzymes were selected for the intercalation, and are listed in Table 1. They were used without any pretreatment. Intercalation was carried out at 30 °C for 1 week unless otherwise stated. The reaction product was developed on a glass plate and the X-ray diffraction spectrum was measured using Mn-filtered Fe-$K\alpha$ radiation. The X-ray diffractometer used could measure down to $2\theta=0.9°$ which corresponds to the *d*-value of about 12 nm.

Assay. An enzme assay for the intercalation compounds was examined by contacting the substrate solutins (*N*-benzoyl-L-arginine ethyl ester (BAEE) for papain and H_2O_2 for catalase) with those corresponding intercalation compounds which were developed on glass plates and were fixed by air-drying.

Results and Discussion

Procedure (1): Few systematic results were obtained although a variety of reaction products were observed in the reaction of enzymes with colloidal solution of γ-TiP. The only result that implied the success of enzyme intercalation was observed in a reaction with papain. Figure 1a shows the X-ray diffraction pattern of the reaction products with respect to the added amount of papain. The peak for the propylamine intercalation compound[6] ($2\theta=5.9°$; *d*-value=1.9 nm,) which was observed in a dilute papain solution, completely disappeared at a papain content of 30 mg, suggesting the perfect conversion of γ-TiP into the papain intercalation compound. The first two sequences of the baseal plane reflection ($n\lambda$: n=1,2,3...) were observed. Such sequential reflections generally imply the formation of an intercalation compound. The average interlayer spacing of the product calculated from the peak angle was 5.6 nm, which was compared with 1.2 nm for the host γ-TiP or 1.9 nm for propylamine intercalated γ-TiP. The line width of the peak was 1.7°—2.3°, corresponding to the interlayer spacing of 6.5—4.8 nm. The large line

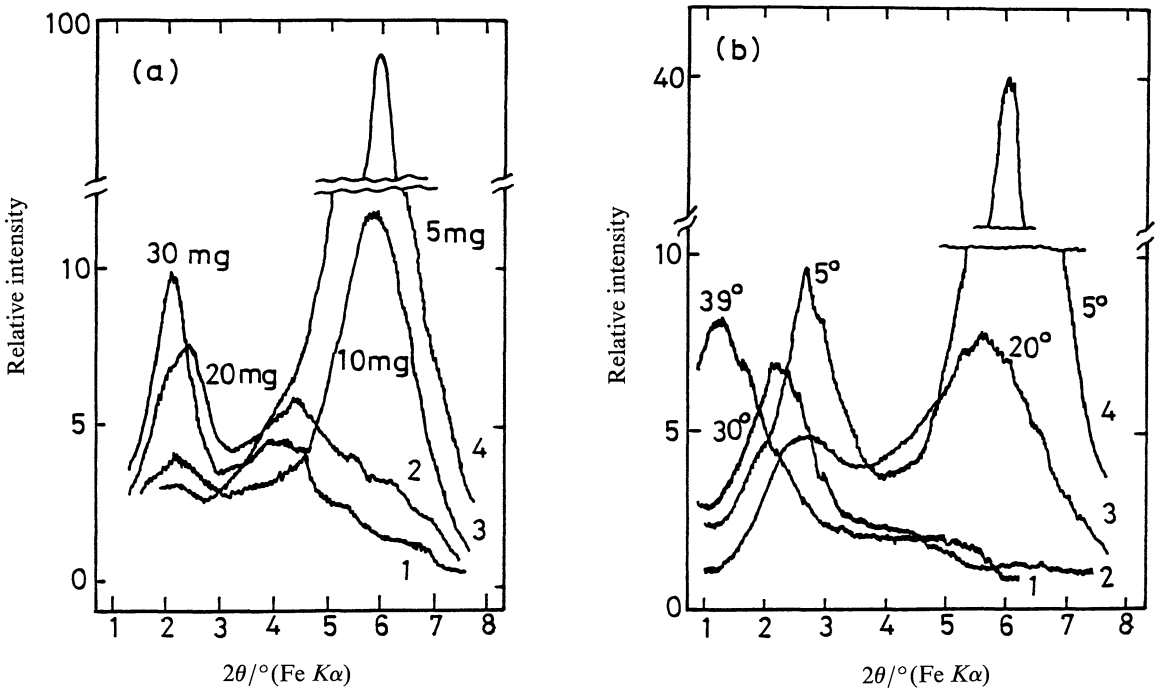

Fig. 1a. X-Ray diffraction patterns of papain intercalation compound of γ-TiP. Solution: 10 ml-aq, propylamine: 25 μL (0.04 mol dm^{-3}), γ-TiP: 0.1 g, Temp 30°C. Papain: (1): 30 mg, (2): 20 mg, (3): 10 mg, (4): 5 mg.

Fig. 1b. X-Ray diffraction patterns of catalase intercalation compound of γ-TiP. Solution: 10 ml-aq, γ-TiP: 0.1 mg, propylamine: 25 μl. Intercalation was carried out at (1): 39°C, (2): 30°C, (3): 20°C, (4): 5°C.

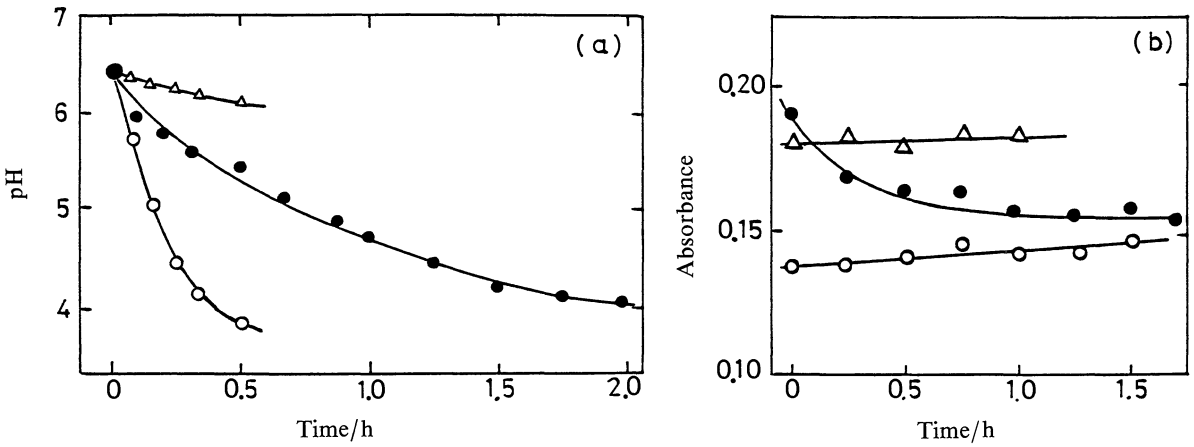

Fig. 2a Activity measurement for papain intercalation compound of γ-TiP (on decomposition of BAEE). Absorbance at 270 nm for buffer solutions containing; (○): aqueous papain solution, (●): papain intercalated γ-TiP, (△): supernatant solution of Fig. 1a-1.

Fig. 2b. Activity measurement for catalase intercalation compound of γ-TiP (on decomposition of H_2O_2). Absorbance at 240 nm for buffer solutions containing, (○): H_2O_2, (△): Catalase intercalated γ-TiP, (●): H_2O_2+catalase intercalated γ-TiP.

width might reflect the irregular arrangement of enzymes in the layered material.

An enzyme assay for the intercalation compound was carried out through the time dependence of the absorbance at 270 nm for BAEE according to the standard procedure.[7] The results are shown in Fig. 2b. A decay in absorbance was observed (closed circles), and indicating that the intercalated papain retained enzyme activity against BAEE. The decay was slow in comparison with that observed in a papain solution. Such slowness may be ascribable to the difficulty in contacting BAEE with papain in layered lattices. In addition, the

reaction was heterogeneous while the reaction of papain solution was homogeneous. The activity of papain in the supernatant solution was rather low since the intercalation reaction was carried out in a basic medium (propylamine solution). The activity of papain decreased rapidly in such a basic solution. (Papain must be kept in a buffer solution at pH=6.2.)

Procedure (2) Cointercalation of enzymes with propylamine was examined according to the success concerning the intercalation of phosphatidyl-ethanolamine.[8] No systematic results was obtained similar to that for Procedure (1). However, intercalation was found to occur in a catalase solution. The X-ray diffraction pattern strongly depended on the temperature in this reaction. At 5 °C, little evidence for the intercalation was observed, and most of the products were propylamine intercalation compound.[6] A product with a large interlayer spacing appeared at higher temperatures. The peak for the propylamine intercalation compound completely disappeared at around 39 °C (Fig. 1b) and a single-phase product with an average interlayer spaing of 8.5 nm (2θ=1.3°) was obtained. The line width was estimated to be 12 nm (0.9°)—5.5 nm (2.0°). The sequence of the basal plane reflection was not observed because of the large width of the spectrum.

It seems improbable that the γ-TiP formed a colloidal solution of single lamellae, which was cleaved from γ-TiP crystals in a propylamine solution. Thus the catalase intercalation compound with an interlayer spacing of around 8.5 nm must be formed through the delamination-relamination reaction of colloidal thin lamellae[4] of γ-TiP. A similar mechanism has been proposed in the intercalation of *t*-alkylamines into clay minerals.[9]

An enzyme assay of the catalase intercalation compound was carried out according to the standard procedure[10] (oxidation of H_2O_2). The enzyme activity was examine through the decrease in the absorbance at 240 nm due to H_2O_2 decomposition. Figure 2b shows the result. Catalase as well as its decomposition products show a strong absorbance at this wavelength, which often disturbs the measurements. A blank solution in the absence of H_2O_2 containing a catalase intercalation compound showed a certain residual absorbance due to catalase which might be released from the glass plates on which intercalation product was fixed. The solution of (H_2O_2+catalase intercalation compound) showed a rapid decay at this wavelength (closed circles). The infinite value did not reach zero because of the absorbance due to either catalase or its decomposition products which were released from the glass plate.

The supernatant solution which was used for the intercalation changed its original color (from brown to yellow) and did not show any enzyme activity against H_2O_2. On the other hand, the catalase intercalation compound kept its original color, suggesting that catalase was still alive. It can be concluded from the present results that the catalase intercalated in γ-TiP retained activity against H_2O_2 decomposition.

The intercalation of large-size enzymes was achieved in this study; the intercalation products exhibited enzyme activity even in an alkaline medium. Althogh the intercalation procedures adopted here seem to be somewhat tricky and no systematic results were obtained, the success of our methods offer some guiding priniciples regarding the intercalation of enzymes or new immobilizing methods for enzymes.

The authors wish to thank Professor M. Aizawa and Dr. H. Shinohara, Tokyo Institute of Technology, for their helpful suggestions and discussion concerning enzymes.

Ortho Lithiation of 2-Hydroxymethyl-1,4,5,6,8-pentamethoxynaphthalene, a Supplement[1)]

Yasuhiro TANOUE* and Akira TERADA*,†
Department of Food Science and Technology, Shimonoseki University of Fisheries, Nagatahonmachi, Shimonoseki, Yamaguchi 759-65

(Received August 9, 1990)

Synopsis. The structures of the products in our previous report "One-Pot Ortho Hydroxylations of 2-(1-Hydroxyalkyl)-naphthalenes and (1-Hydroxyalkyl)benzenes"[2)] were reexamined by ^{13}C NMR spectra and part of our previous interpretation will be corrected here. The lithiations of 2-(1-hydroxyalkyl)-1,4,5,6,8-pentamethoxynaphthalenes occurred at the 7-position, and not at the 3-position as we reported.

During our synthetic study of fusarubin (**1**)[3)] (see Scheme 1), we found an error in our previous report titled "One-Pot Ortho Hydroxylations of 2-(1-Hydroxyalkyl)-naphthalenes and (1-Hydroxyalkyl)benzenes" published in this Journal.[2)] We therefore used ^{13}C NMR spectroscopy to reexamin the hydroxylation products in further detail.

In this paper, we wish to correct part of our previous explanation.

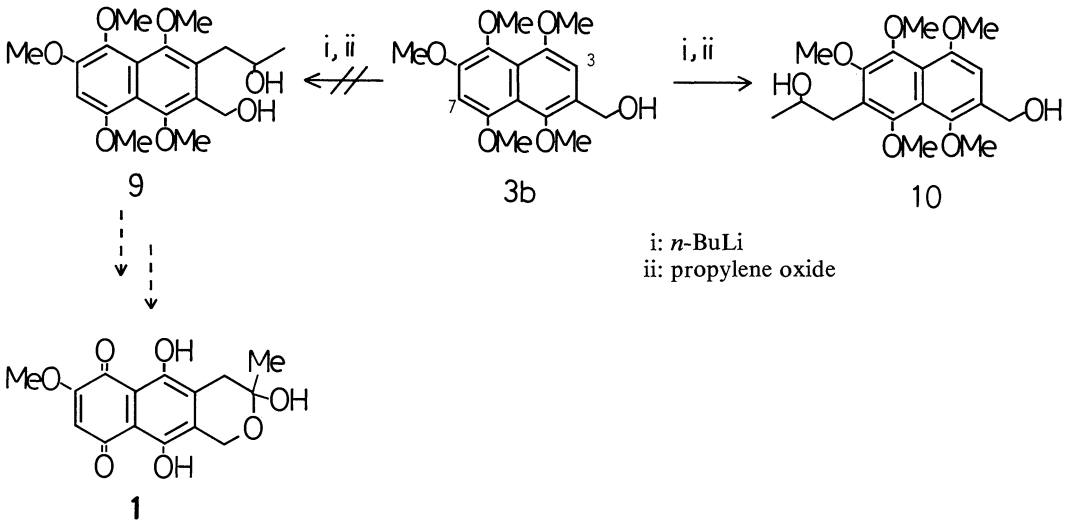
Results and Discussion

We have already reported that the lithiation of 2-hydroxymethyl-1,4,5,6,8-pentamethoxynaphthalene (**3b**) with butyllithium and subsequent oxidation by oxygen gave 3-hydroxymethyl-1,4,5,7,8-pentamethoxy-2-naphthol (**2b**).[2)] However, a question during our synthetic study of fusarubin led us to reexamine the structure of the product. The ^{13}C NMR spectrum of **3b** showed the C-2,3, and 7-signals at δ=128.30, 108.20, and 98.91, respectively. If the structure of our product was **2b**, the 6-position carbon would be slightly affected by the hydroxyl group and the C-6 signal would have been found near δ=96 (i.e., shifted upfield by 2—3 ppm relative to that (δ=98.91) of **3b**). However, the aromatic carbon signal bearing no substituent in our product was found at δ=104.38, not near δ=96. If we presume the formation of 7-hydroxymethyl-1,3,4,5,8-pentamethoxy-2-naphthol (**2B**) instead of **2b**, these ^{13}C NMR results could be reasonably interpreted. That is to say, the C-6 signal (δ=104.38) in **2B** was shifted upfield by 3.8 ppm relative to that (δ=108.20) of **3b** by the introduction of a hydroxyl group (see Chart 1).

This explanation was also supported by the following reaction result. The lithiation of **3b** with butyllithium and subsequent treatment with propylene oxide gave 2-hydroxymethyl-7-(2-hydroxypropyl)-1,4,5,6,8-pentamethoxynaphthalene (**10**) in 62% yield, and no 2-hydroxymethyl-3-(2-hydroxypropyl)-1,4,5,6,8-pentamethoxynaphthalene (**9**) (Scheme 1). The ^{13}C NMR spectrum of **10** is shown in Chart 1.

In the cases of **3d** and **3f**, the hydroxyl group was also introduced at the 7-position between two methoxyl groups. We have concluded, therefore, that the lithiation of **3b**, **3d**, and **3f** with butyllithium occurred at the 7-position.

A similar hydroxylation of 3-methoxybenzylalcohol (**6c**) gave a mixture of 2-hydroxy-3-methoxybenzylalcohol (**7c**) and 4-hydroxy-3-methoxybenzylalcohol (**8C**). The product mixture could be separated by silica gel column chromatography. The ^{13}C NMR spectra of these products are shown in Chart 1. The IR and ^{1}H NMR spectra of **7c** and **8C** agreed with those of the authentic samples obtained by reduction of *o*-vanillin and vanillin, respectively.



Scheme 1.

a) Conversion yield.

Correcting Tables 1 and 3 in our previous report,[2] we present our new results in Table 1 of this text. The C-4 chemical shift of δ=128.83 in the ^{13}C NMR spectrum of 2-hydroxymethylnaphthalene (**4a**) noted in the previous report should be corrected to δ=128.98.

Experimental

Melting points were determined with a Yanagimoto micro-melting point apparatus and were uncorrected. ^1H and ^{13}C NMR spectra were taken on a JEOL JNM-60 in $CDCl_3$ solutions, using Me_4Si and $CDCl_3$ as internal standards, respectively. Mass spectra and IR spectra were obtained with a JEOL DX-300 spectrometer and a Hitachi 260-30 spectrometer, respectively. Column chromatography was carried out on silica gel (Wakogel C-200) eluting with chloroform. The procedure for the hydroxylation of **3b**, **3d**, **3f**, and **6c**—**6f** is described in Ref. 2. The spectra (IR, ^1H NMR, MS, and HRMS) of **2B**, **2D**, and **2F** were the same as those of **2b**, **2d**, and **2f** in the previous report.[2]

2-Hydroxymethyl-7-(2-hydroxypropyl)-1,4,5,6,8-pentamethoxynaphthalene (10). A solution of 2-hydroxymethyl-1,4,5,6,8-pentamethoxynaphthalene **3b**[5] (1.62 g, 5.26 mmol) in

THF (70 ml) was cooled to −10 °C and allowed to react with *n*-BuLi (16.8 ml, 26.3 mmol, 10% (w/v) in hexane) for 1.5 h. Propylene oxide (2.02 ml, 28.9 mmol) in THF (10 ml) was then added to this solution at −10 °C and stirred for 5 h. The reaction mixture was stored in a refrigerator overnight, then quenched with aqueous ammonium chloride, and extracted with chloroform. The chloroform solution was washed with brine, dried over Na_2SO_4, and concentrated. The residue was chromatographed on silica gel to give **10** (1.06 g, 62% yield) and **3b** (0.59 g, 36% yield) was recovered.

10: Viscous oil: IR (neat) 3370 (broad, OH), 1610, 1595, 1355, 1045 cm^{-1}; ^1H NMR δ=1.29 (d, J=6.2 Hz, 3H, CH_3), 2.35 (broad, 2H, 2×OH), 3.0 (m, 2H, CH_2), 3.75 (s, 6H, 2×OCH_3), 3.84, 3.98 (each s, 3H, OCH_3), 3.90 (m, 1H, CH), 4.00 (s, 3H, OCH_3), 4.85 (s, 2H, CH_2OH), and 6.85 (s, 1H, ArH); ^{13}C NMR δ=23.71 (CH_3), 33.88 (CH_2), 56.42 (CH_2OH), 60.72, 61.12, 61.56, 62.29, and 62.53 (OCH_3), 69.13 (CH), 106.24 (C-3), 121.11, 121.94, 126.14 (C-7), 129.86 (C-2), 145.26, 145.90, 149.66 (2C), and 152.55 (C–OCH_3); MS, m/z 366 (M^+), 319, and 289. HRMS, Found: m/z 366. 1690. Calcd for $C_{19}H_{26}O_7$: M, 366.1689.

Synopsis. The reaction of tris(*t*-butylthio)cyclopropenylium perchlorate with phenyl-, *o*-tolyl-, or 1-naphthylmagnesium bromide in tetrahydrofuran at room temperature gave *t*-butylthio-substituted allenes and indenes. The reaction with 2,6-xylylmagnesium bromide gave only the corresponding allene derivative.

The cyclopropenyl cations are interesting from the viewpoint of their applications to synthetic reactions. Recently, we reported that tris(isopropylthio)cyclopropenyl cation reacts with pyrrole and indoles in the presence of sodium hydride in dimethyl sulfoxide to give pyrrolizine and fluorazene derivatives, respectively, in good yields.[1] On the other hand, recent studies have shown that the 1-(methylthio)- and 1-(diphenylamino)-2,3-diphenylcyclopropenyl cations react with phenylmagnesium bromide in tetrahydrofuran (THF) at room temperature to give 1-(methylthio)- and 1-(diphenylamino)-2,3,3-triphenylcyclopropenes, and the resulting cyclopropenes are converted into the 1-(methylthio)- and 1-(diphenylamino)-2,3-diphenylindenes, respectively, on heating at 50-70 °C.[2,3] In the course of our studies on the reactivity of the tris(alkylthio)cyclopropenyl cations, we examined the reactions of tris(*t*-butylthio)cyclopropenylium perchlorate (**1**) with phenyl-, *o*-tolyl-, 1-naphthyl-, and 2,6-xylylmagnesium bromides (**2a—d**). The reaction was carried out under argon in dry THF at room temperature for 4 h. In the cases of **2a—c**, *t*-butylthio-substitutd allenes (**3a—c**) and indenes (**4a—c**) were obtained (reaction 1 and Table 1). The reaction with **2d** gave only the allene **3d**. Thus, we found that the cyclopropenyl cation **1** reacts with arylmagnesium bromides to bring about the formation of *t*-butylthio-substituted allenes. The reactions proceeded more readily than those using 1-(methylthio)- and 1-(diphenylamino)-2,3-diphenylcyclopropenyl cations,[2,3] indicating that the cyclopropene ring with three *t*-butylthio groups undergoes ring opening much more readily than the ring with two phenyl groups. It has been reported that the conversion of 1-(methylthio)-2,3,3-triphenylcyclopropene into the corresponding indene derivative proceeds through the formation of a vinylcarbene intermediate, followed by the C-H insertion of the carbene into the benzene ring.[2] From these results, it is reasonable to believe that the reaction proceeds through the formation of a vinylcarbene intermediate (**5a—d**) to give allenes (**3a—d**) by rearrangement of the *t*-butylthio group and indenes (**4a—c**) by intramolecular cyclization, as shown in Scheme 1.

Experimental

IR spectra were measured on a Hitachi 215 spectrophotometer. All ^{1}H NMR spectra (270 MHz) and ^{13}C NMR spectra (68 MHz) were determined on a JEOL JNM-GX 270 FT NMR spectrometer in $CDCl_3$ using TMS as an internal standard. Mass spectra were recorded on a Shimadzu LKB-9000 spectrometer operating at an ionization potential of 70 eV. Elemental analysis data (C and H) agreed within ±0.3% with the calculated values.

General Procedure for the Reaction of Tris(*t*-butylthio)cyclopropenylium Perchlorate (1) with Arylmagnesium Bromides. To a solution of arylmagnesium bromides (**2a**—**d**) (1.5 mmol) in dry THF (5 ml) was added the compound **1** (0.5 mmol) in one portion. The mixture was stirred under argon at room temperature for 4 h. A saturated aqueous ammonium chloride solution was then added, and the mixture was extracted with dichloromethane (100 ml). The organic layer was washed with water (100 ml) and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and the residual oil was chromatographed over silica gel using hexane-dichloromethane (5:1) as the eluent to give the products (**3a**—**d** and **4a**—**c**). The structures of all products described above were determined by ^{1}H and ^{13}C NMR, IR, mass spectra, and elemental analyses.

Vinyl Polymers Bearing a Pyrrole Ring. II. 5,10,15,20-Tetraphenylporphyrins with a Substituent-Bearing Vinyl Group at the Pyrrole Residue and Their Zinc Complexes

Hiroyoshi KAMOGAWA,* Takuharu NAKATA, and Sei KOMATSU
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received February 2, 1991)

Synopsis. 5, 10, 15, 20-Tetraphenylporphyrins (**Por**) with a styrenic double bond-bearing substituent attached at the pyrrole residue with an amide or ester spacer were synthesized starting with 3-substituted pyrroles. Free radical copolymerization of **ZnPor**, prepared from **Por**, with 1-vinyl-2-pyrrolidone gave more favorable results than did **Por**.

Numerous studies on the preparation of polymers bearing porphyrin or metalloporphyrin units have been reported.[1-5] The present note discusses the preparation of novel water-soluble vinyl polymers with pendant porphyrin and zinc porphyrin units. 5, 10, 15, 20-tetraphenylporphyrins with a substituent-bearing vinyl group (**Por**) attached at the pyrrole residue and their zinc complexes (**ZnPor**) were synthesized. Subsequent copolymerizations of these vinyl monomers with 1-vinyl-2-pyrrolidone (VP) produced copolymers soluble in aqueous solvents. For the **Por** monomer synthesis, 3-substituted pyrroles, synthesized as in a previous study,[6] were employed as starting materials, as shown in **Methods A** and **B**.

Results and Discussion

Method A consisted of the application of a conventional procedure[7] for the preparation of 5, 10, 15, 20-tetraphenylporphyrins from **1a—f**, and easily produced the desired products, **Por-1a—f** (Eq. 1), which were purified by silica-gel column chromatography.

In **Method B**, carboxyl group-bearing **Por-2a—f** were first synthesized using **2a—c** (Eq. 2) and then converted to **Por-1a—c**, **Por-1a′—c′**, and **Por-1d—f** with p- and m-anilines and p-vinylbenzyl chloride, respectively, also without any difficulty (Eqs. 3 and 4).

An advantage of **Method B**, compared to **Method A**, was that **Por-2a—f** could be separated easily from the by-product porphyrins bearing no COOH group. Addition of triethylamine (TEA) to the benzene solutions of the crude products neutralized the COOH group and precipitated the resulting salts, thereby facilitaing the purification of the final products **Por-1a—f**. The analytical data for the **Por-1a—f** synthesized according to **Method B** are given in Table 1. The absorption spectra of **Por-1a—f** in chloroform indicated the Soret

a) **Por** or **ZnPor**, 0.1 mmol; VP, 5.0 mmol; AIBN, 2%/total monomers; 20% total monomers concentration in DMF; at 80°C for 4 h under N_2. b) Determined spectrophotometrically employing the Soret band. c) Intrinsic viscosity (dLg^{-1}) in DMF at 25°C.

band at 418.5—421 nm and had several longer λ_{max} with decreasing, ε_{max}, which was characteristic of a porphyrin structure. The introduction of a Zn atom caused the reversal of the order of λ_{max} around 515 and 550 nm together with slight red λ_{max}-shifts [e. g. λ_{max} (ε_{max}): 515.0 (2.50×10^4 mol^{-1} dm^3 cm^{-1})) and 549.5 (1.09) for **Por-1c**; 517.5 (1.71) and 552.5 (2.13) for **ZnPor-1c**].

The results obtained by subjecting **Por-1a—c′** and **ZnPor-1c,c′** to conventional free-radical copolymerization with VP are summarized in Table 2. As Table 2 shows, copolymerization of **Por-1a—c′** without Zn gave poor results; both the conversions and the values of the intrinsic viscosity of the polymer were low and **Por**-contents in the polymer were also much lower than those (>10%) in the initial monomer mixture.

IR-spectra indicated, however, that the vinyl absorptions around 990—980 and 910—900 cm^{-1} (Table 1) no longer existed and a strong C=O absorption around 1650 cm^{-1} (attributable to the VP portion) appeared, indicating that water-soluble polymers of low molecular weights were obtained by this procedure.

ZnPor-1c and **-1c′** gave, on the other hand, larger values of conversion, **ZnPor**-content, and intrinsic viscosity, indicating a satisfactory process of copolymerization. Particularly, the values of the **ZnPor**-content in the copolymer were close to that (13.5%) in the initial monomer mixture. Visible absorption spectra for polymers made from **Por-1a—c′** were somewhat deformed, whereas those for polymers made from **ZnPor-1c** and **-1c′** indicated no signs of deformity. From these observations, especially as regards **Por-1a—c′**, we suppose that the porphyin ring may participate in free-radical polymerization. The applications of these polymers, e. g. as redox catalysts, will be the subject of another study.

Experimental

N-[*p*- and *m*-Vinylphenyl)-1*H*-pyrrole-3-carboxamides (**1a,a'**), -3-acetamides (**1b,b'**), and -3-butyramides (**1c,c'**), and *p*-vinylbenzyl 1*H*-pyrrole-3-carboxylate (**1d**), -3-acetate (**1e**), and -3-butyrate (**1f**) were synthesized via the respective carboxylic acids (**2a**—**c**) according to the methods described in a previous study.[6]

5,10,15,20-Tetraphenylporphyrins (Por-1a—f). Method A: Pyrroles bearing the vinylphenyl group [**1a**—**f** (2 mmol)], pyrrole (0.40 g, 6 mmol), and benzaldehyde or *p*-tolualdehyde (8 mmol) were dissolved in propionic acid (5 mL). The resulting solution was added to refluxing propionic acid (50 mL), followed by further refluxing for 30 min, with hydroquinone (0.1 g) added. Upon standing at room temperature overnight, the resulting crystals were washed thoroughly with hot water and subjected to silica-gel column chromatography.

Method B: Pyrroles bearing a carboxyl group [**2a**—**c** (5 mmol)], pyrrole (1.0 g, 15 mmol), and benzaldehyde or *p*-tolualdehyde (20 mmol) were refluxed in propionic acid (50 mL) for 30 min, as in **Method A**. Upon cooling, the resulting crystals were dissolved in benzene (50 mL). TEA (10 mL) was added to the benzene solution to precipitate out the TEA-salts of **Por-2a**—**f**, which were washed thoroughly with benzene. Methyl chloroformate (0.2 g, 2 mmol) was added with vigorous shaking to a solution of the salt (2 mmol) in tetrahydrofuran (THF; 15 mL) at −15—15 °C. After stirring for 20 min, the mixture was cooled to below 0 °C and a solution of *p*- or *m*-vinylaniline (0.24 g, 2 mmol) and TEA (0.3 mL) in $CHCl_3$ (15 mL) was added dropwise. Stirring was continued for one hour at this temperature and then overnight at 20 °C. The reaction mixture was extracted with H_2O (200 mL) and $CHCl_3$ (500 mL). The organic layer was washed successively with aq $NaHCO_3$ and H_2O and worked up. Silica-gel column chromatography ($CHCl_3$–acetone; 5:1 v/v) gave purified products (**Por-1a**—**c'**). To prepare **Por-1d**—f, *p*-vinylbenzyl chloride (0.6 g, 4 mmol) was added to solutions of the TEA-salts of **Por-2d**—**f** (2 mmol) and TEA (0.3 g, 3 mmol) in DMF (10 mL) and the mixtures were stirred at 20 °C for 24 h and kept moisture-free. The reaction mixtures were poured into water and extracted with ether (150 mL). The organic layers were worked up and silica-gel column chromatography gave purified products. The analytical data for **Por-1a**—f prepared by **Method A** were almost identical to the data for **Por-1a**—**f** prepared by **Method B**.

Introduction of a Zn-Atom into Por-1a—**f.** The application of the conventional procedure[8] provided crude products, which were purified by SiO_2 column chromatography.

Copolymerization of Por or ZnPor with 1-Vinyl-2-pyrrolidone (VP). In a typical example, a solution of **Por** or **ZnPor** (0.1 mmol), VP (0.5 g, 5.0 mmol), and α,α-azobisisobutyronitrile (AIBN; 1 mg) in DMF (2.5 mL) was put into a glass ampule, which was sealed under N_2 in a conventional manner and kept at 80 °C for 4 h. The contents of the ampule were then poured into ether to precipitate the polymerization product. All polymers produced by this method were soluble in aqueous solvents. IR (KBr) 1650, [1700 (for polymers of **Por**- and **ZnPor-1d**—**f**)] $cm.^{-1}$

(Received February 15, 1991)

Synopsis. The X-ray analysis of the title compound has been carried out to give unambiguous assignment of the absolute configurations of the liverwort sesquiterpenoids (−)-chiloscyphone and (+)-chiloscypholone, each for which the enantiomerically opposite configurations had been assigned in the previous report.

Determination of the absolute structure of the terpenoids isolated from the liverworts is a matter of interest, since it is closely related to their biological activities. In the previous work,[1] the absolute structures of **1** and **6** were elucidated on the basis of the analysis of the CD spectra of the synthetic intermediates in the total synthesis of **1**. In the present work, the absolute configuration of the title compound (**2**), one of the intermediates in the total synthesis of **1**,[1] was determined by X-ray analysis. The results gave the revision of our previous assignment of the absolute configurations of **1** and **6**.

Among the four ω-camphanic esters prepared,[1] **2**, $[\alpha]_D$ −1.4° (*c* 4.9 $CHCl_3$); mp 159—160 °C, was nicely recrystallized from chloroform–methanol, whose X-ray analysis has been carried out. The final atomic coordinates are listed in the Table 1.[2] Perspective view of the molecule is given in Fig. 1. This clearly shows that **2** has 1*S*, 2*R*, 5*R*, 6*S*, 7*R* configurations, since the absolute configurations of the camphanic ester part are known. That is, the absolute configuration of **2** is expressed as in the structure formula. This figure also shows that the conformation of the six-membered ring of the hydrindan system is chair and that the hydrindan system adopts nonsteroidal conformation.

In the total synthesis of **1**, we used the diastereomeric ω-camphanic ester **3** ($[\alpha]_D$ −7.8°), whose absolute configurations were clear, because both **2** and **3** were prepared from the corresponding alcohol (±)-**4** by camphanoylation and HPLC separation. The alcohol

a) $U_{eq}=\frac{1}{3}\sum_i\sum_j U_{ij}a_i^*a_j^*\boldsymbol{a}_i\boldsymbol{a}_j$.

(+)-**4** was derived from **3** by alkaline treatment.[1] The sign of the specific rotation of the corresponding ketone **5** was (−) and the sign of the Cotton effect was (−). The back octant of (−)-**5** shown in Fig. 2 suggests that the expected sign of the Cotton effect should be (−), which was erroneously assigned previously.[1] Since the results of the X-ray analysis of **2** are unambiguous and natural (−)-chiloscyphone (**1**) had been synthesized from the diastereomeric isomer **3**,[1] the absolute configuration of (−)-**1** as well as (+)-chiloscypholone (**6**), which was converted to (−)-**1**,[1] should be formulated as depicted in the scheme.

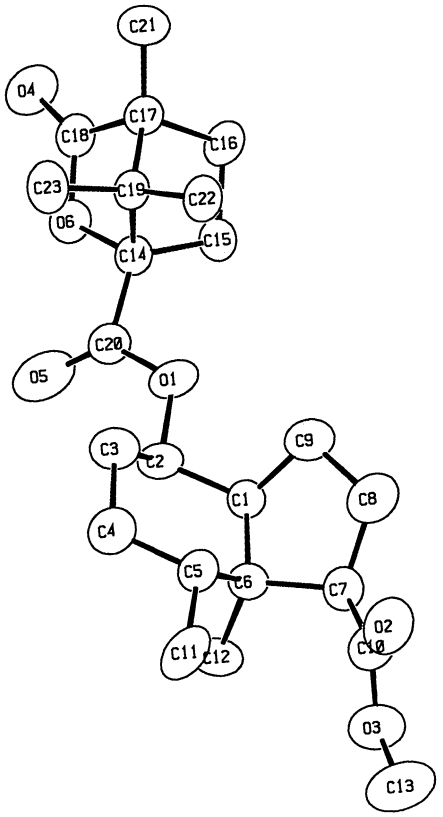

Fig. 1. Computer generated perspective view of **2**.

Experimental

General. See Ref. 1.

Single-Crystal X-Ray Structure Analysis. Crystals of **2** were recrystallized from chloroform–methanol. A truncated rectangular prism of approximately 0.5×0.5×0.5 mm was chosen for X-ray measurements. The crystals are monoclinic, space group $P2_1$ (No. 4), with a=13.516 (1), b=7.1924 (7), c=11.398 (1) Å, β=93.94 (1)°, V=1105.4 (2) Å^3, and d_{calcd}=1.221 g cm^{-3} for Z=2 ($C_{23}H_{34}O_6$, M=406.52). Intensity data were measured at 298 K on a Rigaku AFC-5 diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The cell dimensions were obtained from the least-squares refinement of 50θ values in the range of $25<2\theta<40°$. The data were collected using the ω–2θ scan technique at an ω rate of 3.0° min^{-1} with a 2θ range from 3.0—60.0°. Data having $-19\leqq h\leqq 19$, $-10\leqq k\leqq 0$, $0\leqq l\leqq 16$ were measured. Three reflections (200, 040, 004) were remeasured every 100 reflections to monitor instrument and crystal stability, and the intensity monotonically decreased 17% during the measurement. All the intensity data were empirically corrected on the basis of the intensity variation of the three standard reflections using UNICS3.[3] Of 2928 reflections with $F_o\geqq 3\sigma(F_o)$, 2491 were unique, with R_{int}=0.0071 from averaging symmetry-equivalent reflections. The data were corrected for Lp effects, but not for absorption.

The structure was solved by direct methods with SHELXS86[4] and refined by full-matrix least squares with SHELX76.[5] The number of the parameters refined was 397. The non-H atoms were refined with anisotropic displacement parameters. All of the H-atoms were initially calculated in idealized positions but were refined under the C–H bond length constraint during the final refinement cycles. The function $\Sigma(|F_o|-|F_c|)^2$ was optimized, where $w=[\sigma^2(F_o)+0.0004(F_o)^2]^{-1}$. In the final least-squares refinement, R=0.045, R_w=0.051, S=1.544, and $(\Delta/\sigma)_{max}$=0.396. The maximum and the minimum height in the final difference Fourier synthesis were 0.15 and −0.26 eÅ^{-3}, respectively. Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[6] Calculations of the geometrical parameters and drawing of the ORTEP diagrams were performed using XTAL3.0 software.[7]

Synthesis of Pyrazole Nucleosides Using Acylketene Dithioacetal Derivatives

Masataka YOKOYAMA,* Toshihiro IKUMA, Sadataka SUGASAWA, and Hideo TOGO
Department of Chemistry, Faculty of Science, Chiba University,
Yayoi-cho, Chiba 260
(Received March 1, 1991)

Synopsis. Several nucleosides bearing pyazole ring as the base moiety were synthesized by the reaction of D-ribofuranosylhydrazine or 2-deoxy-D-ribosuranosylhydrazine with easily available acylketene ditioacetal derivatives.

In a part of our study directed toward the synthesis of pharmaceutically important compounds,[1] we found that several kinds of pyrazole nucleosides could be easily synthesized by the reaction of ketene dithioacetals de rived from cyanoacetamide or malononitrile with pro tected D-ribofuranosylhydrazine.[2] In this paper the work was extended to acylketene dithioacetal derivatives as ketene dithioacetals and to protected 2-deoxy-D-ribofuranosylhydrazine as a sugar moiety. The acylketene dithioacetal derivatives could be easily synthesized by the reaction of the corresponding ketones and carbon disulfide followed by methylation. The protected 2-deoxy-D-ribofuranosylhydrazine could be synthesized by the reaction of protected 2-deoxy-D-ribose with hydrazine.

This report presents a simple synthetic method for 5-substituted or 4,5-disubstituted 3-(methylthio)pyrazole nucleosides. The nucleosides obtained by this method are β-anomer or a mixture of α- and β-anomers, which can be separated by usual preparative TLC on silica gel.

Results and Discussion

The reaction of 3,3-bis(methylthio)-1-phenyl-2-propen-1-one (**1a**) with 2,3-*O*-isopropylidene-D-ribofuranosylhydrazine **2a′(H)** gave an expected nucleoside **3a″(H)** as only β-form. However **1a** reacted with 2,3-*O*-isopropylidene-5-*O*-trityl-D-ribofuranosylhydrazine **2a′(T)** to afford the corresponding nucleoside **3a″(T)** in 77% yield (α/β=51/26). The steric hindrance of bulky trityl group seems to have effect on the increase of the α-anomer. In the reaction of 4,4-bis(methylthio)-3-buten-2-one (**1b**) with **2a′(H)**, 1-(2,3-*O*-isopropylidene-β-D-ribofuranosyl)-5-methyl-3-(methylthio)pyrazole **3b″** and its regioisomer **4b″** were isolated in 13% and 22% yields, respectively. The reaction of 2-[bis(methylthio)methylene]-cyclohexanone (**1c**) with **2a′(H)** gave 1-(2,3-*O*-isopropylidene-D-ribofuranosyl)-3-methylthio-4,5,6,7-tetrahydro-1*H*-indazole **3c″** as β-form.

Further, the present reaction was extended to the synthesis of 2-deoxy-D-ribonucleosides. 3,5-Di-*O*-benzyl-2-deoxy-D-ribofuranosylhydrazine (**5**) was prepared by the reaction of 3,5-di-*O*-benzyl-2-deoxy-D-ribofuranose with hydrazine. Its ^{1}H NMR observation shows that **5** comprises an equilibrium mixture of the hydrazone form **5a** and the hydrazino form **5b**, in which the former predominates (ca. 90%). This result is the same as in the

a) The value in the parenthesis shows the yield of α-anomer.

case of 2,3-*O*-isopropylidene-D-ribofuranosylhydrazine.[3]

The reaction of **1a** with **5** in the presence of boron trifluoride etherate gave 1-(3,5-di-*O*-benzyl-2-deoxy-D-ribofuranosyl)-3-methylthio-5-phenylpyrazole **6a** in 30% yield. Thus obtained **6a** was a mixture of α- and β-anomers, which could be separated easily by low-pressure chromatography (α-anomer 12%; β-anomer 18%). Several nucleosides prepared by this procedure are summarized in Table 1.

The structures of α- and β-anomers of **3** were determined on the basis of a difference of chemical shift values for the two methyl protons of the isopropylidene moiety in the ^{1}H NMR.[4] Regioisomers, **3b″** and **4b″** could be differentiated by the splitting pattern of $^3J_{C-H}$ of the ^{13}C NMR[5] [**3b″**: quartet splitting (C-3 and C-4), doublet splitting (C-5); **4b″**: singlet splitting (C-3), quartet splitting (C-4), multiplet splitting (C-5)]. The structures of α- and β-anomers for **6** were tentatively assigned by the characteristic splitting pattern of **1′-H**[6] (dd, $J_{1',2'A}$=8.0 Hz, $J_{1',2'B}$=4.0 Hz for the α-anomer; t, $J_{1',2'A}=J_{1',2'B}$=5.5 Hz for the β-anomer).

The deblocking of **3** and **6** could be easily carried out in the usual way (stir at r.t. with AcOH for **3**; Ac_2O/BF_3, followed by NH_3–MeOH for **6**).

Experimental

Microanalysis was performed with a Perkin–Elmer elemental 240 analyser at the Chemical Analysis Center of Chiba University. IR, MS, UV, and ^{1}H NMR spectra were measured with Hitachi 215, RMU 6MC, EPS-3T, JOEL MH-100, and JMN-GX-270 spectrometers, respectively. Optical rotation was measured on a JASCO-DIP-370 polarimeter. Wakogel C-200 was used for low-pressure liquid chromatography and Wakogel B-5F was used for TLC. 3,3-Bis(methylthio)-1-phenyl-2-propen-1-one (**1a**),[7] 4,4-bis(methylthio)-3-buten-2-one (**1b**),[8] and 2-[bis(methylthio)methylene]cyclohexanone (**1c**),[9] were prepared according to the literature. 2,3-*O*-Isopropylidene-D-ribofuranosylhydrazine **2a′(H)** was prepared by our previous method.[2]

2,3-*O*-Isopropylidene-5-*O*-trityl-D-ribofuranosylhydrazine 2a′(T). 2,3-*O*-Isopropylidene-5-*O*-trityl-D-ribofuranose was prepared according to the literature,[10] and then allowed to react with anhydrous hydrazine by the same method for the preparation of **2a′(H)** (R^3=H). The colorless crystals thus obtained (mp. 59—60 °C in sealed tube) were used without purification in the next step.

1-(2,3-*O*-Isopropylidene-β-D-ribofuranosyl)-3-methylthio-5-phenylpyrazole 3a″(H). A mixture of **2a′(H)** (0.57 g, 3 mmol), dry ethanol (5 ml), Zeolite A-3 (400 mg), and **1a** (224 mg, 1 mmol) was refluxed under stirring for 3 d. The reaction mixture was filtered through Celite and then the filtrate was evaporated to give an oil, which was purified by TLC on silica gel (eluent: $CHCl_3$–MeOH, 9:1) to form colorless crystals **3a″(H)** (91 mg, 25%), mp 84—85 °C; IR (KBr) 3220 (OH), 3020 (Ph), and 2980, 2920 cm^{-1} (CH); ^{1}H NMR ($CDCl_3$) δ=1.36 (s, 3H, Me), 1.49 (s, 3H, Me), 2.55 (s, 3H, SMe), 3.77, 3.98 (AB pattern, J_{gem}=14 Hz, $J_{4',5'}$=7 Hz, 2H, CH_2OH), 4.49 (s, 1H, OH), 5.06 (dd, $J_{4',5}$=7 Hz, $J_{3',4'}$=2 Hz, 1H, 4′-H), 5.26 (dd, $J_{2',3'}$=3 Hz, $J_{1',2'}$=2 Hz, 1H, 2′-H), 5.70 (dd, $J_{2',3'}$=3 Hz, $J_{3',4'}$=2 Hz, 1H, 3′-H), 5.90 (d, $J_{1',2'}$=2 Hz, 1H, 1′-H), 6.22 (s, 1H, 4-H), and 7.26—7.50 (m, 5H, Ph); MS *m/z* 362 (M$^+$); UV (99% EtOH) 208 (ε 27000) and 242 nm (21000); $[\alpha]_D$ −126° (*c* 0.55, EtOH); Found: C, 59.6; H, 6.14; N, 7.66%. Calcd for $C_{18}H_{22}N_2O_4S$: C, 59.6; H, 6.12; N, 7.73%.

Compounds **3b″** and **3c″** were prepared from **1b** and **1c** by the same method as above.

1-(2,3-*O*-Isopropylidene-β-D-ribofuranosyl)-5-methyl-3-(methylthio)pyrazole 3b″. Syrup; IR (neat) 3280 (OH) and 2990, 2860 cm^{-1} (CH); ^{1}H NMR ($CDCl_3$) δ=1.37 (s, 3H, Me), 1.60 (s, 3H, Me), 2.31 (s, 3H, Me), 2.48 (s, 3H, SMe), 3.66, 3.88 (AB pattern, J_{gem}=13 Hz, $J_{4',5'}$=7 Hz, 2H, CH_2OH), 4.52 (s, 1H, OH), 5.10 (m, 2H, 2′-H and 4′-H), 5.82 (m, 2H, 1′-H and 3′-H), and 5.94 (s, 1H, 4-H); MS *m/z* 300 (M$^+$); UV (99% EtOH) 210 (ε 7000), 230 (6460), and 250 nm (sh, 3420); $[\alpha]_D$ −52 ° (*c* 0.07, EtOH); Found: C, 51.6; H, 6.72; N, 9.30%. Calcd for $C_{13}H_{20}N_2O_4S$: C, 51.9; H, 6.71; N, 9.32%.

1-(2,3-*O*-Isopropylidene-β-D-ribofuranosyl)-3-(methylthio)-4,5,6,7-tetrahydro-1*H*-indazole 3c″. Syrup; IR (neat) 3250 (OH) and 2960, 2920, 2840 cm^{-1} (CH); ^{1}H NMR ($CDCl_3$) δ=1.36 (s, 3H, Me), 1.59 (s, 3H, Me), 1.78 (m, 4H, CH_2×2), 2.33 (s, 3H, SMe), 2.50 (m, 4H, CH_2×2), 3.73, 3.94 (AB pattern, J_{gem}=12 Hz, $J_{4',5'}$=8 Hz, 2H, CH_2OH), 4.52 (s, 1H, OH), 5.10 (m, 2H, 2′-H and 4′-H), 5.75 (d, $J_{1',2'}$=2 Hz, 1H, 1′-H), and 6.16 (m, 1H, 3′-H); MS *m/z* 340 (M$^+$); UV (99% EtOH) 242 (3900), and 309 nm (7200); $[\alpha]_D$ −21 ° (*c* 0.12, EtOH); Found: C, 56.0; H, 7.10; N, 8.17%. Calcd for $C_{16}H_{24}N_2O_4S$: C, 56.4; H, 7.11; N, 8.23%.

1-(2,3-*O*-Isopropylidene-β-D-ribofuranosyl)-3-methyl-5-(methylthio)pyrazole 4b″. Syrup; IR (neat) 3280 (OH) and 2980, 2840, 2710 cm^{-1} (CH); ^{1}H NMR ($CDCl_3$) δ=1.36 (s, 3H, Me), 1.62 (s, 3H, Me), 2.24 (s, 3H, Me), 2.40 (s, 3H, SMe), 3.69, 3.92 (AB pattern, J_{gem}=13 Hz, $J_{4',5'}$=7 Hz, 2H, CH_2OH), 4.53 (s, 1H, OH), 5.05 (m, 2H, 2′-H and 4′-H), 6.15 (m, 2H, 1′-H and 3′-H), and 6.25 (s, 1H, 4-H); MS *m/z* 300 (M$^+$); UV (99% EtOH) 207 (ε 5620), 238 (sh, 5420), and 260 nm (6250); $[\alpha]_D$ −85° (*c* 1.24, EtOH); Found: C, 51.6; H, 6.72; N, 9.30%. Calcd for $C_{13}H_{20}N_2O_4S$: C, 51.9; H, 6.71; N, 9.32%.

3,5-Di-*O*-benzyl-2-deoxy-D-ribofuranosylhydrazine 5. A mixture of methyl 3,5-di-*O*-benzyl-2-deoxy-D-ribofuranoside[11] (5.1 g, 16 mmol) and 80% aqueous acetic acid (50 ml) was refluxed for 15 min. The reaction mixture was evaporated to give an oil, which was purified by column chromatography on silica gel (eluent: AcOEt–hexane, 1:2) to afford colorless crystals (3.19 g, 66%). 3,5-Di-*O*-benzyl-2-deoxy-D-ribofuranose obtained thus (0.63 g, 2 mmol), dry methanol (3 ml), and anhydrous hydrazine (0.64 ml, 20 mmol) was stirred for 17 h at room temperature. The solvent was removed under reduced

pressure. The residue was evaporated with dry methanol (4 ml×4) and then under vacuum pump (133.3 Pa) below 50 °C to remove excess hydrazine. A pale yellow syrup was used without purification for next step.

1-(3,5-Di-*O*-benzyl-2-deoxy-D-ribofuranosyl)-3-methylthio-5-phenylpyrazole 6a. A mixture of **5** (2 mmol), dry ethanol (5 ml), Zeolite A-3 (400 mg), **1a** (449 mg, 2 mmol), and boron trifluoride etherate (0.3 ml, 2 mmol) was refluxed for 18 h. The reaction mixture was filtered through Celite and the filtrate was evaporated to give a light brown oil, which was purified by TLC on silica gel (eluent: AcOH–hexane, 1:4): A lower band gave α-anomer (113 mg, 12%) and an upper band gave β-anomer (170 mg, 18%); MS *m/z* 487 $(M+1)^+$; Found: C, 71.8; H, 6.10; N, 5.70%. Calcd for $C_{29}H_{30}N_2O_3S$: C, 71.6; H, 6.17; N, 5.76%.

α-Anomer: IR (neat) 3050, 3020 (Ph) and 2900, 2850 cm^{-1} (CH); ^1H NMR ($CDCl_3$) δ=2.4 (s, 3H, SMe), 3.1 (m, 2H, 2′-H), 3.6 (m, 2H, 5′-H), 4.3—4.4 (m, 2H, 3′-H and 4′-H), 4.6 (bs, 4H, CH_2Ph×2), 6.0 (dd, $J_{1',2'A}$=8.0, $J_{1',2'B}$=4.0 Hz, 1H, 1′-H), 6.2 (s, 1H, 4-H), 7.2 (bs, 10H, CH_2Ph×2), and 7.3—7.4 (m, 5H, 5-Ph); UV (99% EtOH) 208 (ε 36000) and 248 nm (16000); $[\alpha]_D$ +81° (*c* 0.93, EtOH).

β-Anomer: IR (neat) 3050, 3020 (Ph) and 2920, 2850 cm^{-1} (CH); ^1H NMR ($CDCl_3$) δ=2.3, 3.1 (m, 2H, 2′-H), 2.4 (s, 3H, SMe), 3.6 (m, 2H, 5′-H), 4.3 (m, 1H, 3′-H), 4.4 (m, 1H, 4′-H), 4.5—4.6 (m, 4H, CH_2Ph×2), 6.0 (t, $J_{1',2'A}$=$J_{1',2'B}$=5.5 Hz, 1H, 1′-H), 6.2 (s, 1H, 4-H), 7.2—7.3 (m, 10H, CH_2Ph×2), and 7.4—7.5 (m, 5H, 5-Ph); UV (99% EtOH) 211 (ε 22600) and 245 nm (12500); $[\alpha]_D$−70° (*c* 0.06, EtOH).

Compound **6b** was prepared from **1b** by the same method as above.

1-(3,5-Di-*O*-benzyl-2-deoxy-D-ribofuranosyl)-5-methyl-3-(methylthio)pyrazole 6b. Purification by TLC on silica gel (eluent: AcOEt–hexane, 1:4); α-anomer (66 mg, 14%) in a lower band; β-anomer (114 mg, 24%) in an upper band. Found: C, 67.8; H, 6.53; N, 6.70%. Calcd for $C_{24}H_{28}N_2O_3S$: C, 67.9; H, 6.60; N, 6.60%.

α-Anomer: IR (neat) 3050, 3020, (Ph) and 2900, 2850 cm^{-1} (CH); ^1H NMR ($CDCl_3$) δ=2.3 (s, 3H, 5-Me), 2.4 (s, 3H, SMe), 2.4, 3.1 (m, 2H, 2′-H), 3.6 (m, 2H, 5′-H), 4.3 (m, 1H, 3′-H), 4.4 (m, 1H, 4′-H), 4.5—4.6 (m, 4H, CH_2Ph×2), 5.9 (s, 1H, 4-H), 6.0 (dd, $J_{1',2'A}$=8.0, $J_{1',2'B}$=4.0 Hz, 1H, 1′-H), and 7.3—7.4 (bs, 10H, CH_2Ph×2); UV (99% EtOH) 211 (ε 8100), 235 (2300), and 248 nm (sh, 2100); MS 424 (M^+); $[\alpha]_D$+54° (*c* 0.08, EtOH).

β-Anomer: IR (neat) 3050, 3020, (Ph) and 2920, 2850 cm^{-1} (CH); ^1H NMR ($CDCl_3$) δ=2.2 (s, 3H, 5-Me), 2.4 (s, 3H, SMe), 2.4, 3.0 (m, 2H, 2′-H), 3.6 (m, 2H, 5′-H), 4.3 (m, 1H, 3′-H), 4.4 (m, 1H, 4′-H), 4.5—4.6 (m, 4H, CH_2Ph×2), 6.1 (s, 1H, 4-H), 6.3 (t, $J_{1',2'A}$=$J_{1',2'B}$=6.3 Hz, 1H, 1′-H), and 7.3—7.4 (bs, 10H, CH_2Ph×2); UV (99% EtOH) 211 (ε 18400), 229 (4500), and 247 nm (2100); MS 424 (M^+); $[\alpha]_D$−3.7° (*c* 0.10, EtOH).

1-(β-D-Ribofuranosyl)-3-methylthio-5-phenylpyrazole. A mixture of **3a″(H)** (26.5 mg, 0.07 mmol) and 10% acetic acid (1 ml) was stirred under refluxing for 4 h. The reaction mixture was evaporated under reduced pressure and then purified by TLC on silica gel using AcOEt as eluent to give a colorless oil (21 mg, 93%); IR (neat) 3500—3200 (OH) 3020 (Ph), and 2840 cm^{-1} (CH); ^1H NMR ($CDCl_3$–CCl_4) δ=2.3 (s, 3H, SMe), 3.2—4.2 (br, 3H, OH×3), 3.68 (m, 2H, CH_2OH), 4.2 (m, 1H, 4′-H), 4.4 (m, 1H, 2′-H), 4.8 (m, 1H, 3′-H), 5.6 (d, $J_{1',2'}$=4 Hz, 1H, 1′-H), 6.0 (s, 1H, 4-H), and 7.2 (s, 5H, Ph); MS 332 (M^+); UV(99% EtOH) 209 (ε 18600) and 243 nm (16600); $[\alpha]_D$−97.4° (*c* 0.09, EtOH); Found: C, 55.8; H, 5.56; N, 8.72%. Calcd for $C_{15}H_{18}N_2O_4S$: C, 55.9; H, 5.63; N, 8.69%.

1-(2-Deoxy-β-D-ribofuranosyl)-3-methylthio-5-phenylpyrazole. The reported procedure[12] was modified as follows: Boron trifluoride etherate (0.05 ml, 0.4 mmol) was added to a stirred solution of **6a** (β-isomer, 94.4 mg, 0.2 mmol) in acetic anhydride (3 ml). The resulting solution was kept at room temperature for 16 h and then evaporated in vacuo. The residue was subjected to TLC on silica gel (eluent: AcOEt–hexane, 1:1) to give 1-(3,5-di-*O*-acetyl-2-deoxy-β-D-ribofuranosyl)-3-methylthio-5-phenylpyrazole as a colorless syrup, which was then stirred with methanolic ammonia (saturated at 0 °C, 10 ml) in a closed flask at room temperature for 16 h and then evaporated. The usual work-up by TLC on silica gel gave a colorless oil (32 mg, 53%); IR (neat) 3300—3400 (OH), 3020 (Ph), and 2900—2850 cm^{-1} (CH); ^1H NMR ($CDCl_3$) δ=2.0 (m, 2H, 2′-H), 2.4 (s, 3H, SMe), 3.6—6.0 (m, 5H, 1′,3′,5′-H), 6,2 (s, 1H, 4-H), and 7.1 (m, 5H, Ph); MS 306 (M^+); Found: C, 58.8; H, 5.90; N, 9.04%. Calcd for $C_{15}H_{18}N_2O_3S$: C, 58.8; H, 5.91; N, 9.14%.

Synthesis of D-Altrose via D-Altrosan from Levoglucosenone

Katsuya MATSUMOTO,* Takashi EBATA,* Koshi KOSEKI, Hiroshi KAWAKAMI, and Hajime MATSUSHITA
Life Science Research Laboratory, Japan Tobacco Inc., 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227
(Received March 16, 1991)

Synopsis. The stereoselective reduction and *cis*-dihydroxylation of levoglucosenone (1,6-anhydro-3,4-dideoxy-β-D-*glycero*-hex-3-enopyranos-2-ulose), gave D-altrosan (1,6-anhydro-β-D-altropyranose), which could be converted to D-altrose in high yield.

Levoglucosenone (1,6-anhydro-3,4-dideoxy-β-D-*glycero*-hex-3-enopyranos-2-ulose, **1**)[1] is a pyrolytic product of cellulose.[2] The structure of **1** is attractive as a starting material for a variety of organic syntheses, since it includes convertible functional groups and one chiral center. We have synthesized various useful compounds from **1** to date and have demonstrated its great utility as a chiral building block.[3] In this paper, we describe a novel synthesis of D-altrose (**4**) via D-altrosan (1,6-anhydro-β-D-altropyranose, **3**)[4] from **1**. D-Altrose (**4**) is a rare sugar which cannot be obtained from natural products. Besides, the conventional syntheses of **4** are complicated due to the many steps required, or low selectivity.[5] Thus, a synthesis of **4** using fewer reaction steps with a high overall yield is required.

1,6-Anhydro-3,4-dideoxy-β-D-*threo*-hex-3-enopyranose (**2**) was synthesized by the reduction of **1**, according to the method of previous papers.[2,6,7] The *cis*-dihydroxylation of the carbon–carbon double bond of **2** stereoselectively gave D-altrosan (**3**) with catalytic osmium tetroxide in 86.0% yield, and with stoichiometric potassium permanganate in 32.7% yield. These facts arise due to an attack of osmium tetroxide and potassium permanganate on the carbon–carbon double bond from the less-hindered side, thus avoiding any steric hindrance by the 1,6-anhydro bond of the acetal ring. This observation is similar to that in the reduction of **1**. D-Altrose (**4**) was obtained by an acid hydrolysis of **3**.

In conclusion, we have developed a simple method for the preparation of D-altrose (**4**) in 3 steps in 29.1% overall yield, via D-altrosan (**3**) from levoglucosenone (**1**).

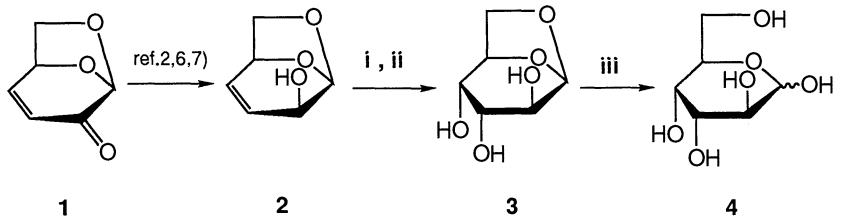
Experimental

Spectral Measurements. The IR spectra were measured with a JASCO FT/IR-5000 Spectrometer. The ^{1}H NMR spectra (300 MHz) and ^{13}C NMR spectra (75 MHz) were measured with a Bruker AM-300.

D-Altrosan (1,6-Anhydro-β-D-altropyranose, 3). *cis*-Dihydroxylation of the double bond between C-3 and C-4 of **2** was carried out by osmium tetroxide or potassium permanganate.

***cis*-Dihydroxylation by Osmium Tetroxide:** A solution (23 cm^3) of osmium tetroxide in *t*-butyl alcohol (osmium tetroxide/*t*-butyl alcohol=1/30; w/v) was added to a mixture of **2** (3.84 g, 30.0 mmol) and *N*-methylmorpholine *N*-oxide (7.03 g, 60.0 mmol) in acetone–water (150 cm^3, 8/1; v/v), and stirred for 13 h at room temperature. Na_2SO_3 (81.0 g, 643 mmol) was added to the reaction mixture with ice-cooling, and was then vigorously stirred for 10 min at room temperature. The reaction mixture was evaporated under reduced pressure. Purification of the residue by column chromatography on silica gel (eluent: dichloromethane/acetone=1/2—4; v/v) and recrystallization from 2-propanol afforded 4.19 g (86.0%) of **3** as white powder: Mp 129—130 °C; $[\alpha]_D^{25}$ −219° (*c* 1.00, H_2O) [lit,[4a,8] mp 134—135 °C; $[\alpha]_D^{20}$ −215° (*c* 1, H_2O)]; IR (KBr) 3400 (br), 1450 (br), 1137 (s), and 1073 cm^{-1} (s); ^{1}H NMR (CD_3OD, ppm from CD_3OD, 3.40 ppm) δ=3.75—3.83 (2H, m, H-6), 3.61 (1H, dd, *J*=1.7 and 8.6 Hz, H-2), 3.69 (1H, dd, *J*=4.4 and 8.6 Hz, H-3), 3.89 (1H, dd, *J*=2.5 and 4.4 Hz, H-4), 4.61 (1H, ddd, *J*=2.1, 2.5 and 4.6 Hz, H-5), 5.30 (1H, d, *J*=1.7 Hz, H-1); ^{13}C NMR (D_2O, ppm from 1,4-dioxane; 67.4 ppm) δ=102.0, 77.8, 72.9, 70.4, 70.0, 66.1. Found: C, 44.46; H, 6.26%. Calcd for $C_6H_{10}O_5$: C, 44.45; H, 6.22%.

***cis*-Dihydroxylation by Potassium Permanganate:** A 0.6% aqueous sodium hydroxide (16 cm^3) was added to a solution of **2** (128 mg, 1.00 mmol) in 2 cm^3 of water. Potassium permanganate (190 mg, 1.20 mmol) was then gradually added to the ice-cooled reaction mixture. After stirring for 20 min at room temperature, the reaction mixture was neutralized by 1 mol dm^{-3} hydrochloric acid, and filtered through a Celite pad. The residue was washed with water. The filtrate was evaporated under reduced pressure. Purification of the residue by



1 2 3 4

Scheme 1. i) OsO_4, *N*-methylmorpholine *N*-oxide, acetone, H_2O, ii) Na_2SO_3, iii) 1 mol dm^{-3} HCl, 1,4-dioxane.

column chromatography on silica gel (eluent: dichloromethane/acetone=1/2—4; v/v) afforded 53 mg (32.7%) of **3** as a white powder, which was identified with the **3** obtained above by a ^{1}H NMR spectral comparison.

D-Altrose (4). A solution of **3** (1.62 g, 10.0 mmol) in 1 mol dm^{-3} hydrochloric acid (100 cm^3) and 1,4-dioxane (50 cm^3) was heated at 100 °C for 5 h. The reaction mixture was neutralized by passing it through Amberlite IRA-410 (OH^- form); the aqueous eluent was evaporated under reduced pressure. The residue was purified by column chromatography on silica gel (eluent: chloroform/methanol=5—1; v/v). The first fraction, having R_f=0.4 (eluent: chloroform/methanol=4/1; v/v), was evaporated and dried under reduced pressure, and 1.09 g (6.7 mmol) of the starting material **3** was recovered. The second fraction, having R_f=0.2 (eluent: chloroform/methanol=4/1; v/v), was evaporated and dried under reduced pressure. 0.40 g of **4** was obtained.[9] The recovered **3** was hydrolyzed by the procedure described above. As a result, 0.70 g of **4** was obtained and 0.32 g of **3** was recovered (the procedures were rapeated three times). The obtained compound **4** was identified by comparing its IR spectra data and ^{13}C NMR spectra data with those of an authentic sample.[10] IR (nujol) 3300 (br) and 1065 cm^{-1} (br); ^{13}C NMR (D_2O, ppm from 1,4-dioxane; 67.4 ppm): α-Pyranose form;[11] δ=61.4 (C-6), 66.0 (C-4), 71.0 (C-3), 71.1 (C-5), 72.1 (C-2), 94.5 (C-1), β-pyranose form;[11] δ=62.4 (C-6), 65.1 (C-4), 71.4 (C-3), 71.6 (C-2), 74.9 (C-5), 92.6 (C-1), α-furanose form;[11] δ=63.2 (C-6), 72.5 (C-5), 76.7 (C-3), 82.2 (C-2), 84.1 (C-4), 102.0 (C-1), β-furanose form;[11] δ=63.2 (C-6), 73.5 (C-5), 75.9 (C-3), 77.4 (C-2), 81.9 (C-4), 96.1 (C-1).

Reductive Deacetoxylation of Allylic Acetates Using Hexacarbonylmolybdenum(0)

(Received March 22, 1991)

Synopsis. Aliphatic allylic acetates were reduced to alkenes with hexacarbonylmolybdenum(0) in refluxing dioxane under nitrogen atmosphere. These reactions were accelerated by the addition of H_2O. 1-Aryl- or 3-arylallyl acetates caused deacetoxylative allylic homocoupling under the same conditions.

Hexacarbonylmolybdenum [$Mo(CO)_6$] seems to have both oxidizing and reducing ability, since molybdenum has a variety of oxidation states between −2 and +6. In particular, the reducing ability can be presumably applied to organic synthesis. We have recently reported that hexacarbonylmolybdenum is a useful reducing agent for reductive chalcogenization of allylic sulfides, sulfones, and selenides.[1-3] The reductive desulfonylation of allylic sulfones with $Mo(CO)_6$ should proceed via the formation of π-allylmolybdenum complexes.[2-4] Allylic acetates have also reacted with $Mo(CO)_6$ to form π-allylmolybdenum complexes, which have been utilized to nucleophilic substitution by carbon nucleophiles.[5] If carbon nucleophiles were absence in the reaction system, allylic acetates would be reduced to alkenes by electron transfer from molybdenum atom to η^3-allyl ligand π-allylmolybdenum intermediates,[6] similarly to reductive desulfonylation of allylic sulfones.[2,3]Here we report a reductive deacetoxylation of various allylic acetates with $Mo(CO)_6$ under the same conditions as π-allylmolybdenum complex has been formed.

The reaction of methyl 9-acetoxy-10-undecenoate with $Mo(CO)_6$ was investigated under various conditions. Reductive deacetoxylation proceeded in refluxing THF or dioxane (Entries 1—4 in Table 1). Addition of H_2O accelerated the reductive deacetoxylation similarly to reductive dechalcogenization of allylic sulfides, sulfones, and selenides with $Mo(CO)_6$ (Entries 2 and 3). In refluxing THF (Entry 3), an elimination of acetic acid occurred to give a diene, in contrast with the reaction in refluxing dioxane (Entry 2). The reaction of various allylic acetates with $Mo(CO)_6$ was carried out in the presence of H_2O (5 equiv) in refluxing dioxane (Table 1). Aliphatic allylic acetates caused only the reductive deacetoxylation to produce the corresponding alkene isomers (Entries 1—11, and 16, Scheme 1). Allylic acetates bearing an aryl substituent on an allylic position of the π-allylmolybdenum intermediates, caused reductive allylic homocoupling with the reductive deacetoxylation without adding a reducing agent such as zinc powder (Entries 13, 14, and 17, Scheme 1).[7] In the case having a proton on an α-position of 1-aryl-π-allylmolybdenum intermediate, a diene was obtained as a single product without base, as shown in Scheme 2 (Entries 18 and 19).[8] The reductive deacetoxylation smoothly proceeded with even a half equimolar amount of $Mo(CO)_6$ (Entries 15 and 16).[9] Hexacarbonylmolybdenum(0) proved to have such a reducing ability that more than two electrons apparently transfered from molybdenum(0) to allylic acetates. Addition of D_2O instead of H_2O produced a quantitatively deuterated product, and use of dioxane-d_8 as a solvent did not cause the deuteration (Entries 7 and 8). Hence, a proton or radical hydrogen source is presumably H_2O.[10]

Experimental

General Procedure of Reductive Deacetoxylation of Allylic Acetates with $Mo(CO)_6$. To a solution of allylic acetate (1 mmol) and H_2O (5 mmol) in dioxane (3—5 ml) was added hexacarbonylmolybdenum(0) (0.5—1 mmol). The mixture was refluxed for 14—25 h under nitrogen atmosphere. The reaction mixture was diluted with ether (50 ml), washed with water (20×3 ml), and dried over $MgSO_4$. Evaporation of ether followed by purification of a residue by column chromatography on silica gel (Merck 60) using hexane or hexane/ethyl acetate as an eluent gave reductively deacetoxylated products and/or allylic homocoupling products. The structures were determined by IR (Hitachi 260-50), ^1H NMR (JEOLCO GX-270), and mass spectra (JEOLCO JMS-D300). The isomer ratios were determined by ^1H NMR.

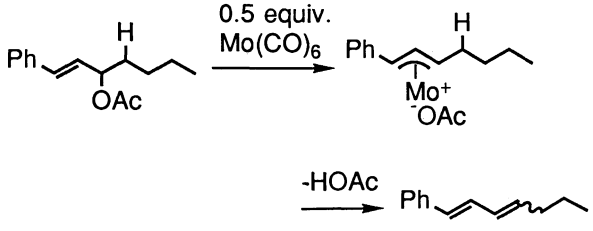

Scheme 2.

Table 1. Reductive Deacetoxylation of Allylic Acetates with $Mo(CO)_6$

Entry	Allylic acetate	H^+ (or H·) source	Time/h	Product	Yield[a]/%
1		—	20	 13 : 70 : 17	40
2	R^1: $(CH_2)_6COOMe$	H_2O	15	15 : 54 : 31	58
3		H_2O	19	16 : 39 : 18 : 27	31[b]
4		CH_3COOH	18	15 : 63 : 15 : 7	64[b]
5		—	15	 H	47
6		H_2O	15	H	55
7		D_2O	15	D	49[c]
8		—	19	H	49[c,d]
9		—	24		39
10		H_2O	20	20 : 80	50
11		H_2O	22		60
12		H_2O	17		35
13		H_2O	23	 31% 19%(56:44)	50[e]
14		H_2O	21	 19% 37%	56[e]
15		H_2O	25	 67 : 20 : 13	70[e]
16		H_2O	19		82[e]
17		—	14	 71 : 29	48
18		H_2O	20		50[e]
19		—	22	cis:trans=50:50	50[e]

a) Yields of mixtures of regio- and/or stereoisomers. The ratio was determined by ^1H NMR (JEOLCO GX-270). b) THF as a solvent was used. c) The deuteration was confirmed by ^1H NMR and GC-MS (JEOLCO JMS-D300). d) Dioxane-d_8 as a solvent was used. e) A half equimolar amount of $Mo(CO)_6$ was used.

A Mixture of Methyl 8-Undecenoate, Methyl 9-Undecenoate, and Methyl 10-Undecenoate (Entry 1 in Table 1): IR (neat) 3000, 2920, 2845, 1735, 1430, 1160 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.95, 0.96 (2t, J=7.33 Hz, 0.5H), 1.22—1.42 (br, 8H), 1.54—1.70 (m, 4.1H), 1.90 (m, 2.3H), 2.30 (t, J=7.36 Hz, 2H), 3.66 (s, 3H), 4.89—5.03 (m, 0.25H), 5.30—5.50 (m, 1.7H), 5.80 (ddt, J=17.1, 10.3, 6.65 Hz, 0.13H). MS (70 eV) m/z (rel intensity) 198 (M^+, 6), 166 (21), 124 (28), 97 (21), 96 (27), 87 (46), 84 (34), 83 (37), 82 (25), 81 (23), 74 (83), 69 (55), 68 (24), 67 (25), 59 (23), 55 (100). Found: m/z 198.1622. Calcd for $C_{12}H_{22}O_2$: M, 198.1619.

2,6,10-Trimethyl-2,6,10-dodecatriene (Entry 5 in Table 1): IR (neat) 2950, 2900, 2850, 1435, 1370 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.56 (d, J=6.72 Hz, 3H), 1.59 (br.s, 6H), 1.62 (br.s, 2H), 1.67 (br.s, 4H), 1.93—2.13 (m, 8H), 5.05—5.16 (m, 2H), 5.20 (q, J=6.68 Hz, 1H). MS (70 eV) m/z (rel intensity) 206 (M^+, 3.7), 137 (12), 136 (11), 123 (12), 95 (27), 82 (11), 81 (40), 69 (100), 67 (13), 55 (14). Found: m/z 206.2027. Calcd for $C_{15}H_{26}$: M, 206.2033.

11-Acetoxy-2-undecene (Entry 9 in Table 1): IR (neat) 2920, 2860, 1730, 1440, 1365, 1235, 1035, 960 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.20—1.45 (br, 10H), 1.56—1.67 (m, 5H), 1.91—

2.01 (m, 2H), 2.04 (s, 3H), 4.06 (t, J=6.60 Hz, 2H), 5.37—5.44 (m, 2H). MS (70 eV) m/z (rel intensity) 212 (M^+, 1.2), 109 (20), 97 (28), 96 (31), 95 (34), 84 (32), 83 (22), 82 (51), 81 (66), 69 (63), 68 (90), 67 (66), 61 (21), 55 (100), 54 (40). Found: m/z 212.1773. Calcd for $C_{13}H_{24}O_2$: M, 212.1775.

Ethylidenecyclododecane (Entry 11 in Table 1): IR (neat) 2920, 2840, 1455 cm^{-1}. ^1H NMR (CCl_4) δ=1.00—1.70 (br, 18H), 1.57 (d, J=7.0 Hz, 3H), 1.80—2.23 (m, 4H), 4.93—5.37 (m, 1H). MS (70 eV) m/z (rel intensity) 194 (M^+, 44), 165 (24), 110 (23), 109 (46), 96 (62), 95 (61), 83 (56), 82 (70), 81 (69), 71 (32), 70 (88), 69 (55), 68 (50), 67 (81), 55 (100), 54 (32). Found: m/z 194.2034. Calcd for $C_{14}H_{26}$: M, 194.2033.

1-(3,4-Methylenedioxyphenyl)propene (Entry 12 in Table 1): IR (neat) 2900, 2850, 1485, 1440, 1245, 1120, 1035 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.84 (dd, J=6.52, 1.49 Hz, 3H). 5.93 (s, 2H), 6.06 (dq, J=15.6, 6.44 Hz, 1H), 6.31 (dq, J=15.6, 1.45 Hz, 1H), 6.73 (s, 2H), 6.87 (s, 1H). MS (70 eV) m/z (rel intensity) 162 (M^+, 100), 161 (31), 135 (46), 131 (40), 104 (42), 103 (33), 97 (36), 85 (30), 83 (37), 81 (32), 77 (34), 71 (46), 69 (46), 57 (77), 55 (59). Found: m/z 162.0678. Calcd for $C_{10}H_{10}O_2$: M, 162.0680.

1,3-Diphenylpropene (Entry 14 in Table 1): IR (neat) 3010, 2910, 2850, 1595, 1485, 1445, 960, 735, 690 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.54 (d, J=6.30 Hz, 2H), 6.34 (dt, J=15.7, 6.30 Hz, 1H), 6.45 (d, J=15.7 Hz, 1H), 7.14—7.37 (m, 10H). MS (70 eV) m/z (rel intensity) 194 (M^+, 100), 193 (54), 179 (37), 116 (36), 115 (58), 91 (35). Found: m/z 194.1096. Calcd for $C_{15}H_{14}$: M, 194.1095.

1,3,4,6-Tetraphenyl-1,5-hexadiene (Entry 14 in Table 1): IR (neat) 3030, 2930, 1600, 1490, 1450, 965, 745, 705 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.84—3.93 (m, 2H), 6.16—6.58 (m, 4H), 7.03—7.33 (m, 20H). MS (70 eV) m/z (rel intensity) 194 (21), 193 (100), 178 (12), 115 (51), 91 (17). Found: C, 92.93; H, 6.64%. Calcd for $C_{30}H_{26}$: C, 93.21; H, 6.78%.

A Mixture of 1-Ethylidenetetralin, 1-Ethyl-3,4-dihydronaphthalene, and 1-Vinyltetralin (Entry 15 in Table 1): IR (neat) 3010, 2920, 2850, 1475, 1445, 745 cm^{-1}. ^1H NMR (CCl_4) δ=1.14 (t, J=7.36 Hz, 0.60H), 1.76 (d, J=6.92 Hz, 2.0H), 1.64—1.97 (m, 1.9H), 2.17—2.54 (m, 2.1H), 2.64—2.82 (m, 2.1), 4.96—5.09 (m, 0.3H), 5.78—5.96 (m, 0.30H), 5.99—6.16 (m, 0.70H), 7.00—7.15 (m, 4H). MS (70 eV) m/z (rel, intensity) 158 (M^+, 48), 141 (23), 131 (49), 130 (69), 129 (100), 128 (49), 127 (20), 118 (20), 115 (41), 91 (25). Found: m/z 158.1095. Calcd for $C_{12}H_{14}$: M, 158.1095.

3-Ethylidenecholestane (Entry 16 in Table 1): IR (neat) 2930, 2860, 1455, 1380, 910 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.65 (s, 3H), 0.87 (d, J=6.89 Hz, 9H), 0.92 (s, 3H), 0.95—2.20 (m, 31H), 1.55 (d, J=6.61 Hz, 3H), 4.96—5.15 (m, 1H). MS (70 eV) m/z (rel intensity) 398 (M^+, 30), 396 (33), 243 (30), 161 (38), 149 (34), 147 (41), 135 (52), 134 (45), 133 (41), 123 (43), 122 (55), 121 (62), 120 (31), 119 (44), 109 (66), 108 (36), 107 (71), 105 (51), 97 (31), 95 (96), 93 (65), 91 (36), 83 (42), 81 (100), 79 (46), 71 (38), 69 (66), 67 (53), 57 (80), 55 (94). Found: m/z 398.3898. Calcd for $C_{29}H_{50}$: M, 398.3910.

A Mixture of 3,4-Dibutyl-1,6-diphenyl-1,5-hexadiene and 7,8-Diphenyl-5,9-tetradecadiene (Entry 17 in Table 1): IR (neat) 3020, 2940, 2920, 2850, 1485, 1445, 960, 735, 690 cm^{-1}. ^1H NMR (CCl_4) δ=0.93 (br, 6H), 1.10—2.80 (m, 13.4H), 3.17—3.43 (0.60H), 5.17—5.57 (m, 1.2H), 5.96(dd, J=15.0, 5.6 Hz, 1.4H), 6.36 (d, J=15.0 Hz, 1.4H), 6.93—7.33 (m, 10H). MS (70 eV) m/z (rel intensity) 174 (35), 131 (15), 118 (15), 117 (100), 116 (10), 115 (29), 105 (28), 104 (89), 92 (13), 91 (63), 81 (13), 77 (19), 69 (26), 57 (11), 55 (23). Found: C, 89.75; H, 10.12%. Calcd for $C_{26}H_{34}$: C, 90.10; H, 9.90%.

1-Phenyl-1,3-heptadiene (Entry 18 and 19 in Table 1): IR (neat) 3020, 2960, 2870, 1490, 1460, 990, 745, 690 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.92 (t, J=7.04 Hz, 1.5H), 0.95 (t, J=7.04 Hz, 1.5H), 1.36—1.53 (m, 2H), 2.11 (br.q, J=7.23 Hz, 1H), 2.26 (br.q J=7.42 Hz, 1H), 5.52 (dt, J=9.89, 7.42 Hz, 0.5H), 5.80 (dt, J=15.0, 7.04 Hz, 0.5H), 6.10 (m, 1H), 6.42 (d, J=15.6 Hz, 0.5H), 6.50 (d, J=15.6 Hz, 0.5H), 6.74 (dd, J=15.6, 10.3 Hz, 0.5H), 7.06 (ddd, J=15.6, 10.8, 1.33 Hz, 0.5H), 7.12—7.42 (m, 5H). MS (70 eV) m/z (rel intensity) 172 (M^+, 42), 143 (63), 131 (22), 130 (24), 129 (100), 128 (69), 117 (42), 115 (56), 91 (60), 77 (23), 71 (27). Found: m/z 172.1252. Calcd for $C_{13}H_{16}$: M, 172.1251.

9) The reductive deacetoxylation scarcely occurred in the use of a 0.1—0.2 equimolar amount of $Mo(CO)_6$ to allylic acetate.

10) The reductive deacetoxylation of allylic acetates may occur via the reductive elimination of hydrido(π-allyl)molybdenum intermediates derived from initially prepared π-allylmolybdenum complexes with H_2O. In order to detect the hydrido(π-allyl)molybdenum intermediate, ^1H NMR spectroscopic investigation was carried out in the reaction of allyl acetate with $Mo(CO)_6$ and H_2O in dioxane-d_8. The formation of the hydrido(π-allyl)molybdenum complex was not confirmed, since the reductive deacetoxylation probably occurred rapidly at high reaction temperature (100 °C), which needed in the formation of initial π-allylmolybdenum complex. For reductive elimination of hydrido(η^1-allyl)molybdenum complexes, see: T. Ito, T. Matsubara, and Y. Yamashita, *J. Chem. Soc., Dalton Trans.*, **1990**, 2407.

(Received March 14, 1991)

Photoreduction of Fe(OEP) (OEP: octaethylporphyrin) in organic solvents by visible light was demonstrated to be a ligand-aided process in which simultaneous coordinations of a base such as 2-methylimidazole (2MeIm) and of an aliphatic alcohol to two axial positions of the iron ion were required. Coordination of an alcohol was evidenced from the observation of the Fe–alcohol stretching ($\nu_{Fe\text{-}alcohol}$) resonance Raman (RR) band. Since this band exhibited an appreciable frequency shift between ROH and ROD, coordination of the alcohol in a protonated form was suggested. When a primary or secondary alcohol was added to the CH_2Cl_2 solution of Fe^{III} (OEP)Cl in the presence of 2MeIm, a new absorption band appeared around 560—590 nm and the $\nu_{Fe\text{-}alcohol}$ RR band was most intense for excitation at the maximum of the new absorption band. The new absorption was therefore assigned to the alcohol to Fe^{III} charge transfer (CT) band. A tertiary alcohol gave neither the CT band nor the $\nu_{Fe\text{-}alcohol}$ RR band, although some spectral changes were noticed after long laser illumination at 441.6 nm, and the photoreduction as seen for other alcohol solutions did not take place. This photoreduction was not apparently recognized in the presence of oxygen. However, flash photolysis experiments demonstrated that the photoreduction occurs irrespective of the presence or absence of oxygen but rapid reoxidation results in apparent no effect.

Photoreduction of iron-porphyrins has been attracting chemists' interest since the initial finding of photoreduction on cytochrome oxidase by visible light.[1–3] Afterwards the photoreduction has been extensively observed for various heme proteins[4–8] and metalloporphyrins.[9–16] While a mechanism of photoreduction of Pd-, Zn-, and a few water soluble porphyrins has been studied in detail,[9,16] little is known about the photoreduction mechanism of iron porphyrins as well as heme proteins. Ozaki et al.[17] recognized occurrence of photoreduction of an iron porphyrin during resonance Raman (RR) measurements of 2-methylimidazole (2MeIm) complex of Fe^{III}(OEP)Br in CH_2Cl_2 (OEP: octaethylporphyrin). It was shown that any ring reduction to a porphyrin anion radical or chlorin did not take place and that the photoreduction was a ligand-aided process.

Recently, we noticed that the photoreduction observed by Ozaki et al.[17] was catalyzed by a trace amount of alcohol contained as a stabilizer of solvent.[18,19] In this paper we report detailed results on isotope substitution experiments which show that the catalytic alcohol binds to the sixth coordination position of Fe^{III}(OEP)(2MeIm) in the ROH form and gives rise to a charge transfer (CT) band around 560—590 nm. Although apparently the photoreduction does not seem to occur in the presence of oxygen, the flash photolysis experiments revealed that the photoreduction occurred but it was promptly reoxidized. It is most surprising that the laser illumination within the CT band induces no photoreduction.

†† Present address: Department of Physical Chemistry, Faculty of Science, Charles University, 128-40 Praha 2, Czechoslovakia.

Experimental

Fe^{III}(OEP)X (X=Cl, Br, and I) were synthesized by the procedure described elsewhere.[20,21] Since no difference was observed by using X=Cl, Br or I for Fe^{III}(OEP)X, Fe^{III}(OEP)Cl was used unless otherwise stated. 2MeIm was recrystallized from benzene and its ^1H NMR spectrum did not show any detectable impurity. CH_2Cl_2 of spectroscopic grade from different suppliers were found to contain different stabilizers. We analyzed CH_2Cl_2 from Wako, Kanto-kagaku, Cica-MERCK, Aldrich, and Dojin companies with gas chromatography and their influence on photoreduction of Fe^{III}(OEP)(2MeIm). Since the Cica-MERCK product contained the smallest amount of stabilizer and/or impurities (less than 0.1%) and had no side-effect on photoreduction, it was used without further purification. The standard concentration of the sample was 2 mM of Fe^{III}(OEP)X, 50—100 mM of 2MeIm, and a few % (v/v) of added alcohol. Fresh solution was prepared for each experiment.

Raman spectra were measured with a JEOL-400D Raman spectrometer equipped with a cooled RCA-31034a photomultiplier and a home-made computer-controlled data aquisition system based on NEC 9801 computer. As an excitation source of Raman scattering were used Kr^+ laser (Spectra Physics, 164), He/Cd laser (Kinmon Electrics, CDR80MGE), Ar^+ laser (NEC, GLG3200), and Ar^+ laser-pumped dye laser (Spectra Physics, 164/175) with rhodamine 6G. Laser power was measured at the sample point with a hand power-meter (Advantest TA-8210). Raman shifts were calibrated with indene for individual excitation lines. Uncertainties in wavenumbers of well-defined band are less than ± 1 cm^{-1}. During the Raman measurements the sample was kept at 10 °C by circulating temperature-controlled water through the cell holder. For the measurements under anaerobic conditions, the sample solution in the air-tight cell was degassed through three freeze/thaw cycles and stopped by a cock.

Conventional absorption spectra were recorded with a Hitachi 220S spectrophotometer. For the test of photoreduc-

tion the sample in the anaerobic cell was illuminated by a projector lamp through the short cut filter (L-38, Hoya Corp.) for 5 min. During illumination the sample cell was placed in a water bath at 20 °C. Time profiles of absorption changes of the sample after pulse illumination were measured by a home-made apparatus described elsewhere.[22]

Results

At the beginning of this study we encountered some problems regarding reproducibility of the previous results.[17] The RR spectrum of Fe^{III}(OEP)(2MeIm) (Fig. 1A) was the same as that reported previously[17] but Fe^{III}(OEP)(2MeIm) in pure CH_2Cl_2 did not exhibit any photoreduction even after careful degassing and long-lasting illumination by white light or laser. Figure 1(B) shows the spectrum obtained for Fe^{III}(OEP)Cl in a CH_2Cl_2–CH_3OH mixed solvent (1 : 1 in v/v). This is again the same as that of Fe^{III}(OEP)Cl. Following systematic tests of all components of the system revealed that photoreduction of Fe^{III}(OEP)(2MeIm) went on only when the solvent CH_2Cl_2 contained alcohol as a stabilizer. Figure 1(C) shows the RR spectrum observed for Fe^{III}(OEP)(2MeIm) in CH_2Cl_2 in the presence of MeOH. The resultant spectrum remained unaltered by the concentration change of MeOH from 0.5 to 20% (v/v) and is the same as that of Fe^{II}(OEP)(2MeIm) as noted previously.[17] In the presence of oxygen, however, the spectrum was the same as Fig. 1(A). It became evident, therefore, that both 2MeIm and MeOH are required for photoreduction to occur and apparently the photoreduction seems not to occur in the presence of oxygen. A similar phenomenon was seen for Fe^{III}(OEP)(1,2-Me_2Im) but not at all for Fe^{III}(OEP)$(Im)_2$ and Fe^{III}(OEP)$(1MeIm)_2$.

Figure 2 shows the effect of alcohol on absorption spectra. The spectra in the upper panel were obtained in the presence of oxygen. Although Soret band is little affected by the presence of alcohol except its slight weakening, Q band of Fe^{III}(OEP)(2MeIm) at 535 nm disappears and a new band appears at 584 nm in the presence of MeOH (B). The 584 nm band did not appear when MeOH was added to Fe^{III}(OEP)Cl in CH_2Cl_2. A similar spectral change was observed when ethanol (EtOH), or 1-propanol (*n*-PrOH) was used for

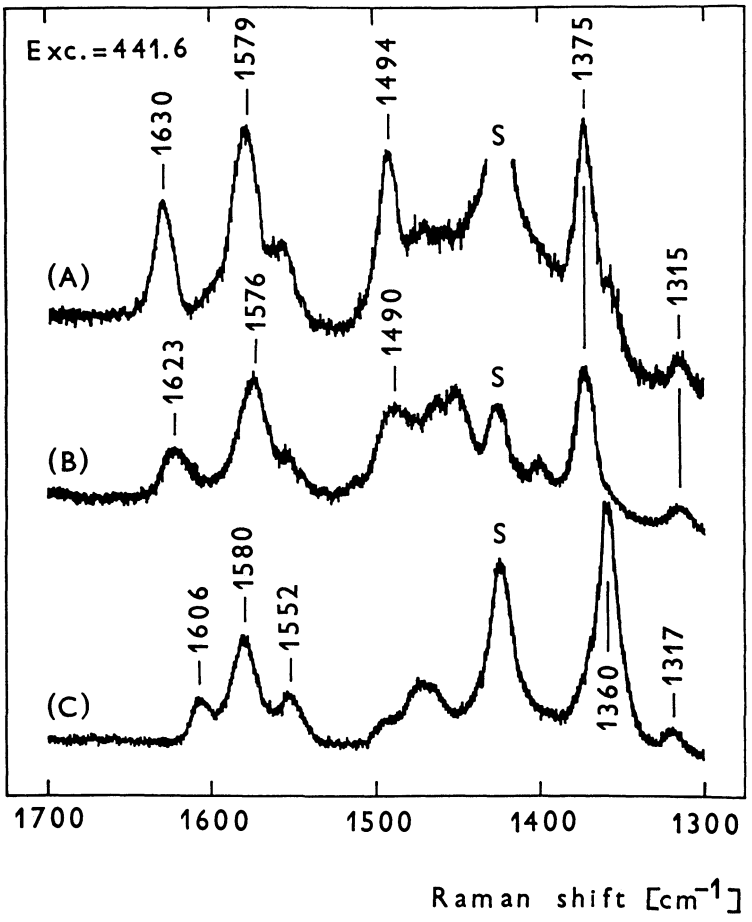

Fig. 1. Typical RR spectra of Fe(OEP) complexes under different solvent conditions. A) Fe^{III}(OEP) (2MeIm) in CH_2Cl_2, B) Fe^{III}(OEP)Cl in MeOH: CH_2Cl_2=1 : 1 (v/v), C) Fe^{III}(OEP)-(2MeIm)(MeOH) in CH_2Cl_2. Excitation: 441.6 nm. All spectra were observed under anaerobic conditions.

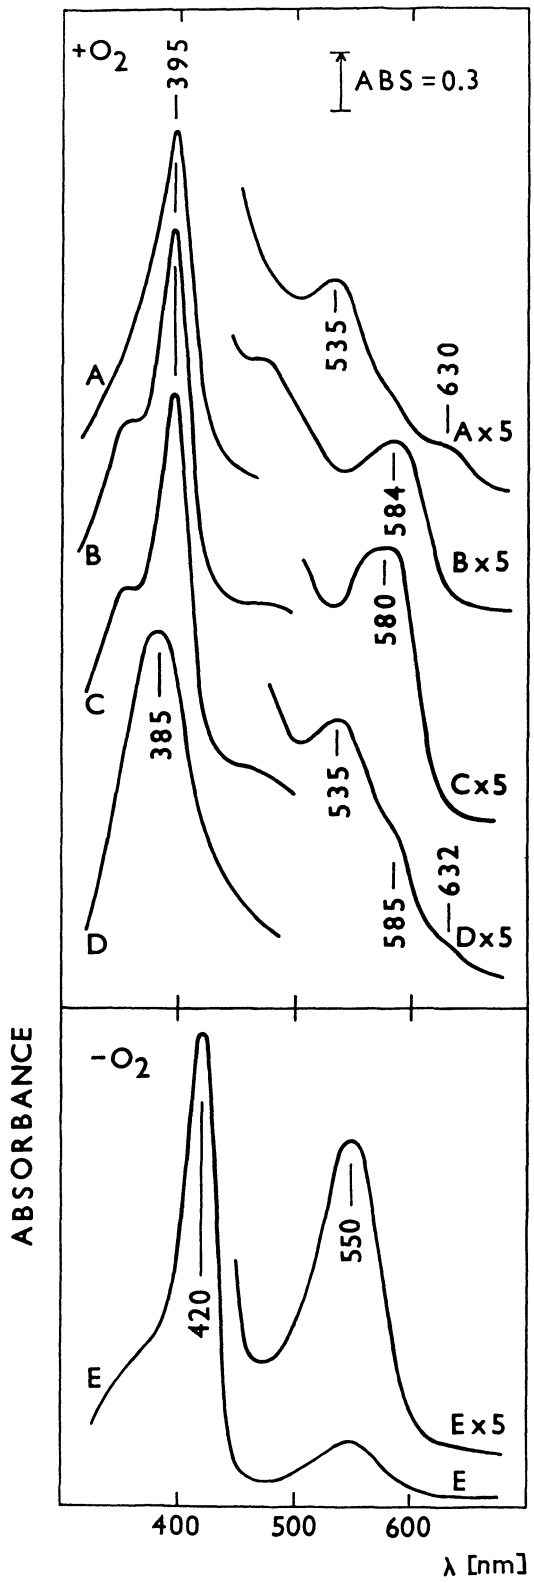

Fig. 2. Visible absorption spectra of Fe^{III}(OEP)(2MeIm) in various alcohol-containing CH_2Cl_2 solutions. A) without alcohol, B) MeOH (EtOH and *n*-PrOH are the same as this), C) *i*-PrOH, D) *t*-BuOH, E) MeOH (EtOH, *n*-PrOH, and *i*-PrOH are the same as this). Spectra A through D (upper panel) were obtained in the presence of oxygen but spectrum E (lower panel) was obtained under anaerobic conditions.

Fe^{III}(OEP)(2MeIm) (Fig. 2B). In the case of 2-propanol (*i*-PrOH) the new band was appreciably broader at 580 nm (Fig. 2C). A spectral change recognized for *t*-butyl alcohol (*t*-BuOH) was quite small in the 500—600 nm region as shown by Fig. 2D, but the shape of the Soret band was altered. When these solutions were brought to anaerobic conditions and subjected to light illumination at 380—450 nm, the spectrum shown in the lower panel (Fig. 2E) was obtained. It gave strong Soret band at 420 nm and weak Q band at 550 nm and the whole spectrum was almost the same as that of Fe^{II}(OEP)(2MeIm) prepared separately. Note that MeOH, EtOH, *n*-PrOH, or *i*-PrOH did not yield any difference in the resultant absorption spectra but *t*-BuOH did not induce the light-illumination effect. With this it changed only after long illumination of laser light at 441.6 nm; bands at 635 and 535 nm became pronounced and the Soret band shifted to red by a few nm. Consequently, it became evident that alcohols active to photoreduction cause a distinctive spectral change in the oxidized state, implying their coordination to the iron ion, but different alcohols bring no difference after photoreduction.

Since the active alcohols yield a new absorption band around 584—590 nm, RR spectra were excited at 590 nm. In contrast with the excitation at 441.6 nm, the RR spectra excited at 590 nm obtained in the absence of oxygen were the same as those obtained when it was present. The polarized RR spectra of Fe^{III}(OEP)(2MeIm)(MeOH) and its *meso*-(5, 10, 15, 20-) deuterated and ^{15}N-substituted derivatives are shown in Fig. 3 (1700—1300 cm^{-1}) and Fig. 4 (1300—900 cm^{-1}). The ν_4 band, which exhibits a downward shift by 6 cm^{-1} upon ^{15}N-substitution, appears at a typical frequency of iron(III) porphyrins (1376 cm^{-1}). Two anomalously polarized (ap) bands are seen at 1564 and 1315 cm^{-1} which are little shifted upon ^{15}N-substitution but greatly upon *meso*-deuteration; they are assigned to ν_{19} and ν_{21}, respectively.[23-25] The strong enhancement of the two ap bands is general characteristic of the Q-band excited RR spectra of metalloporphyrins.[26,27]

The highest frequency depolarized (dp) band, which exhibits a downshift by 16 cm^{-1} upon *meso*-deuteration and 5 cm^{-1} upon ^{15}N-substitution, is assigned to ν_{10}.[23-25] This band is sensitive to the coordination number;[28,29] in typical cases the five coordinate iron(III) high-spin complexes give it around 1629—1631 cm^{-1} while the six-coordinate iron(III) high-spin complexes do it around 1615—1625 cm^{-1}. Since Fe^{III}(OEP)$(CH_3OH)_2$ and Fe^{III}(OEP)$(Im)_2$ give ν_{10} at 1624 and 1640 cm^{-1}, respectively,[30] the present compounds are clearly different. For six-coordinate complexes with an oxygen of ClO_4^- and a nitrogen of pyridine derivative, which have the intermediate spin state,[28] this band is observed around 1634—1636 cm^{-1}. Therefore, the ν_{10} frequency is not unreasonable if the present compound is a six-coordinate intermediate spin complex. Its difference from the five-coordinate high-spin state is seen in the

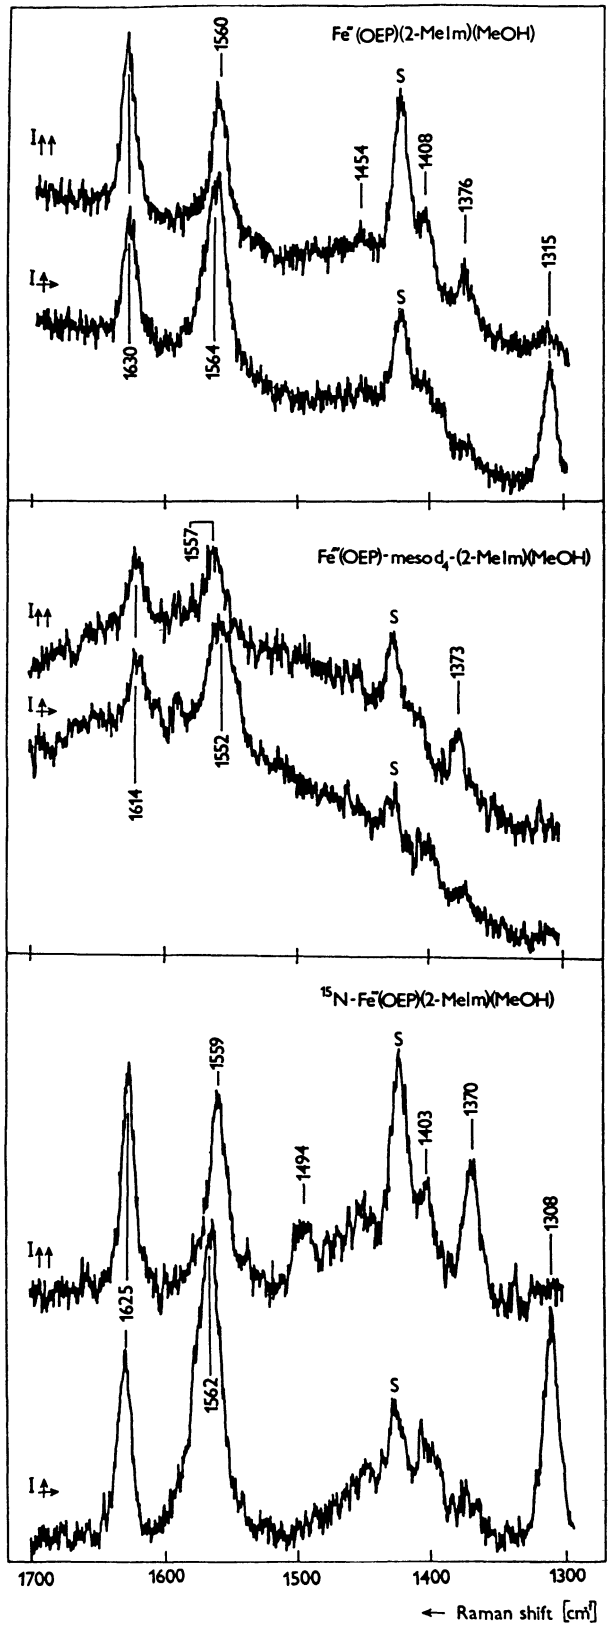

Fig. 3. Polarized RR spectra of Fe^{III}(OEP)(2MeIm)(MeOH) and its isotopic substitutes in the 1700—1300 cm^{-1} region; Fe^{III}(OEP-d_4) (2MeIm)(MeOH) (middle) and Fe^{III}(OEP-$^{15}N_4$)(2MeIm)(MeOH) (bottom). All spectra were excited at 590 nm (100 mW) under aerobic conditions. $I_{\parallel}$ and $I_{\perp}$ mean the parallel and perpendicular components, respectively.

size of deuteration shift; ^{15}N-isotope shift is much smaller (1 cm^{-1}) for five-coordinate complex[31] than for the present complex (5 cm^{-1}).

In Figure 4 an ap band is observed at 1132 cm^{-1} and is

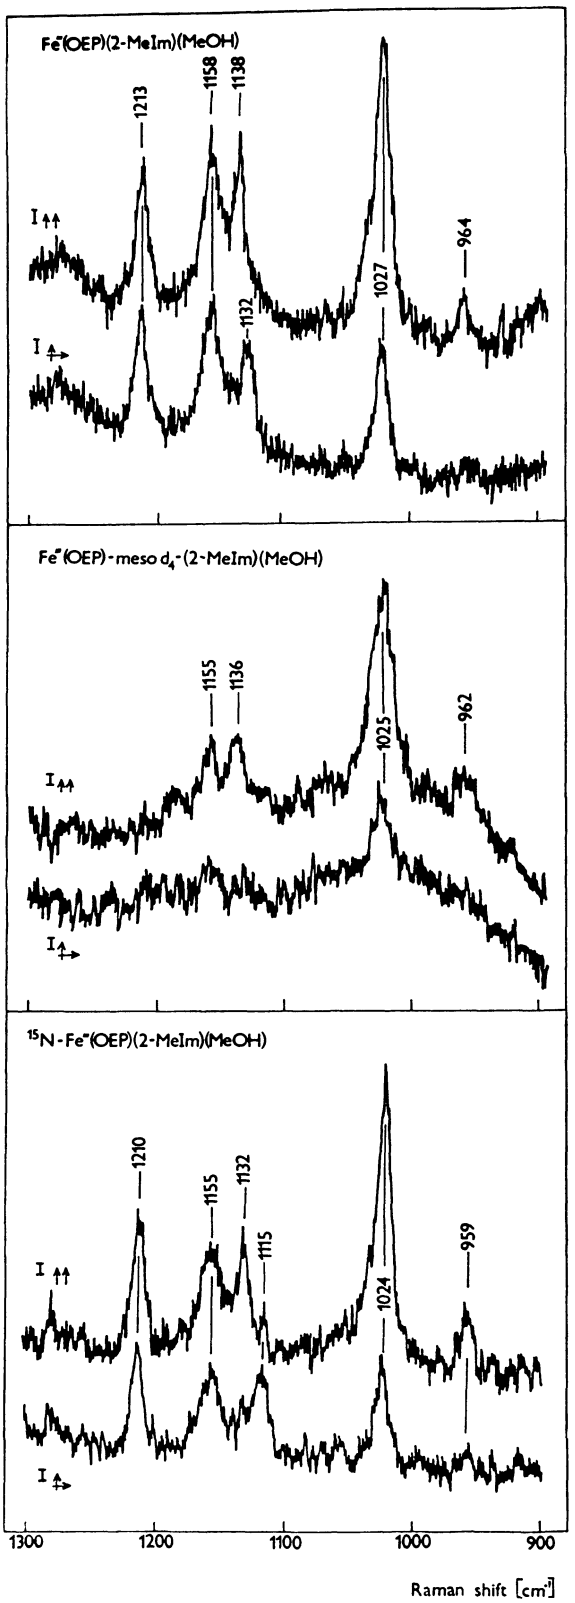

Fig. 4. The same set of spectra as in Fig. 3 but in the 1300—900 cm^{-1} region.

assigned to ν_{22}. This band is downshifted by 17 cm^{-1} upon ^{15}N-substitution for expectation of 13 cm^{-1},[24] and is thought to largely upshift to ca. 1200 cm^{-1} upon *meso*-deuteration. Two p bands at 1138 and 1027 cm^{-1} were originally assigned to a combination and ν_5 modes, respectively,[24] but recently Li et al.[25] reassigned them to ν_5 and the ethyl C–C stretching vibrations. Two dp bands at 1213 and 1158 cm^{-1} are assigned to ν_{13} and ν_{30}; ν_{13} is expected to show little shift upon ^{15}N-substitution but a large down-shift (to ca. 950 cm^{-1}) upon *meso*-deuteration, while ν_{30} is expected to show little shift upon *meso*-deuteration and appreciable down-shift (9—10 cm^{-1}) upon ^{15}N-substitution.[24,25]

The observed frequencies and isotope shifts of the alcohol complex are compared with those of Fe^{III}(OEP)(2MeIm) and Fe^{III}(OEP)Cl[31,32] in Table 1. The ν_2, ν_{21}, and ν_{22} frequencies are lower and the size of *meso*-deuteration shift of ν_{19} is distinctly larger for Fe^{III}(OEP)Cl. Therefore, even within the five coordinate ferric high-spin complexes, Fe^{III}(OEP)(2MeIm) is slightly different from Fe^{III}(OEP)Cl. The magnitude of the isotopic frequency shifts reflects the vibrational displacement of the isotope-replaced atoms in the vibration in question and accordingly it is sensitive to the vibrational mode. On the basis of the observed isotopic shifts, the vibrational modes of Fe^{III}(OEP)(2MeIm)(MeOH) are closer to those of Fe^{III}(OEP)(2MeIm) than to those of Fe^{III}(OEP)Cl. It may imply the similarity of their geometrical structure and raise a question about the coordination of MeOH to the sixth coordination position.

The evidence for alcohol coordination was obtained from the 590 nm-excited RR spectra in the lower frequency region shown in Figure 5. In the absence of MeOH, there are no prominent RR bands in the 600—400 cm^{-1} region as shown by spectrum E. When CH_3OH was added to the CH_2Cl_2 solution of Fe^{III}(OEP)(2MeIm), a new band appeared at 524 cm^{-1} as shown by spectrum B and it is shifted to a higher frequency by 4 cm^{-1} upon replacement of ^{56}Fe with ^{54}Fe as shown by spectrum A. Isotope replacement of CH_3OH with CH_3OD and CD_3OD gave rise to spectra C and D, respectively. The peak frequencies for CH_3OH and CH_3OD derivatives are definitely different, indicating that MeOH is bound in the protonated form but not in the alkoxide form. When we assume that MeOH is a single dynamic unit, a simple harmonic approximation for the Fe–MeOH stretching vibration provides the isotopic frequency shifts as follows; +3.5 cm^{-1} for ^{54}Fe, −5.0 cm^{-1} for CH_3OD, and −18.7 cm^{-1} for CD_3OD. The observed value for ^{54}Fe agrees with the expected one but those for MeOH are smaller than expected values, implying the vibrational coupling of the Fe–alcohol stretching mode with internal vibrations of MeOH. Anyway, the 524 cm^{-1} band is assigned to the Fe–MeOH stretching vibration. This band did not appear in the MeOH–CH_2Cl_2 (1 : 1 in v/v) mixed solution of Fe^{III}(OEP)Cl. It means that the 524 cm^{-1} band appears from the six-coordinated complex with MeOH and 2MeIm as axial ligands.

The excitation profile of the 524 cm^{-1} band is illustrated in Fig. 6, where relative intensities of the 524 cm^{-1} band to the solvent band at 1158 cm^{-1} are plotted against the excitation wavelengths. The relative intensities were corrected for different transmittances at 524 and 1158 cm^{-1} for each excitation wavelength on the basis of the observed transmission spectrum. The broken line in Fig. 6 indicates the background subtracted absorption spectrum for the 585-nm band which is normalized at the maximum absorption to the Raman excitation profile. The peak of Raman excitation profile is noticeably coincident with the absorption curve, suggesting strongly that the 585 nm absorption has a charge transfer character from MeOH to the Fe^{III} ion.

The Raman excitation at 585 nm within the CT band did not exhibit a trace of Raman spectrum of the reduced species; this was unexpected. This is not due to poor resonance but to nonphotoreduction. Indeed,

the anaerobic sample illuminated by laser light around 570—610 nm did not yield a change of visible absorption spectrum. Therefore, the mechanism of the photoreduction of $Fe^{III}(OEP)(2MeIm)(MeOH)$ is distinct from a trivial photoreduction in which the electron transfer takes place via a CT excited state.

Since no photoreduction was observed by a Raman spectrum in the presence of oxygen, we pursued the time course of the phenomenon by using transient absorption spectroscopy. The results are shown in Fig. 7(A), where a change of absorption at 420 nm is drawn against time; (a) and (b) were obtained in the absence and presence of oxygen, respectively, for the MeOH containing solution while (c–e) were obtained in the presence of oxygen for various alcohol-containing solutions; EtOH (c), *i*-PrOH (d) and *n*-PrOH (e). Since the reduced species has the absorption maximum at 420 nm, the increase of absorption at $t=0$, when the laser pulse at 355 nm with 10 ns duration was fired, indicates that photoreduction has occurred. It is apparent that the photoreduction takes place irrespective of the presence or absence of oxygen. In the presence of oxygen (b–e), however, it is reoxidized in 50 ms, while the reduced state lasts in its absence (a). The rate of oxidation depends on the O_2 concentration. The individual curves shown in Fig. 7A(b–e) are well reproduced by a single exponential decay curve with an arbitrary time constant (the determined values are cited in the figure captions) as illustrated by thin solid lines in Fig. 7A. The curve displayed in Fig. 7(B) was observed for the

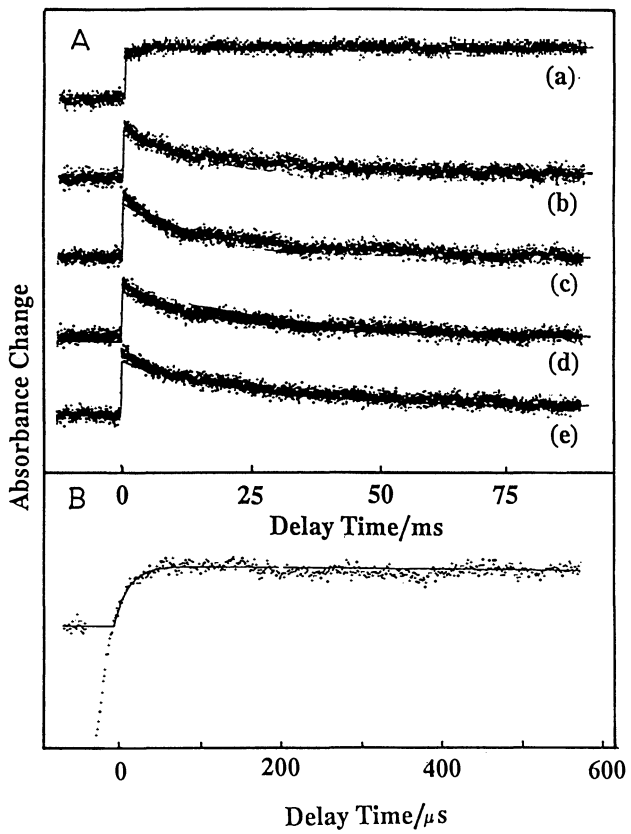

Fig. 7. Time profile of the absorbance at 420 nm after photolysis by the 355 nm pulse (10 ns width). A) (a) Fe^{III}(OEP)(2MeIm)(MeOH) under anaerobic conditions. (b) Fe^{III}(OEP)(2MeIm)(MeOH), (c) Fe^{III}(OEP)(2MeIm)(EtOH), (d) Fe^{III}(OEP)(2MeIm)-(*n*-PrOH), (e) Fe^{III}(OEP)(2MeIm)(*i*-PrOH). All spectra for (b—e) were obtained under the same aerobic conditions. The thin solid lines were calculated by assuming the single exponential decay; the decay constants are 17.9 ms for MeOH, 16.5 ms for EtOH, 20.7 ms for *n*-PrOH, and 25.0 ms for *i*-PrOH under an atmospheric pressure. B) Time profile in the shorter delay time region of (A-a). The solid line indicates the calculated curve obtained by assuming that both the rise and decay are single exponential; τ_{rise}=14.1 μs and τ_{decay}=15.8 ms.

MeOH containing solution on shorter time scale. The thin solid line was obtained by assuming that both the rise and decay are single exponential. This suggests that the photoreduction occurs with a time constant of 17 μs. The apparently slow photoreaction implicates that it involves ligand replacement besides simple electron transfer.

Discussion

The photoreduction described here has two characteristics; cooperative action of axial ligands and no photoreducibility under the CT excitation. When Im or 1-MeIm are present besides alcohol, it forms a biscoordinate complex and alcohol cannot bind to the axial position due to its weak ligand field. Accordingly, photoreduction does not occur. On the other hand, when Fe^{III}(OEP)Cl is dissolved in CH_2Cl_2–MeOH mixed solvent, MeOH is considered to bind to the iron ion but photoreduction was not seen. Therefore, simultaneous coordinations of a N base and an alcohol are required for photoreduction to occur. The next question is what is an electron donor?

The primary and secondary alcohols were effective but a tertiary alcohol was not. One interpretation assumes a role of C_α-hydrogen of alcohol, which occasionally serves as a reductant.[10,33] This would be likely if *t*-BuOH were bound to the sixth coordination position but photoreduction did not occur. Actually, however, *t*-BuOH gave neither the CT absorption band nor the Fe–alcohol stretching RR band, and therefore it is more reasonable to deduce that *t*-BuOH was not bound to the iron ion. The coordination of *t*-BuOH to the iron ion is probably inhibited by steric hindrance between CH_3 hydrogen and pyrrole nitrogen. An alternative interpretation is to regard an N base as an electron donor as postulated in the previous study.[17] In order to determine the alternative we carried out gas chromatographic analysis of the photoreduced solution. The product was not a simple compound like formaldehyde and acetone. Unfortunately, however, we failed to identify the product by this analysis. The requirement is to prepare an enough of the product to determine its NMR spectrum.

Upon excitation of Raman scattering within the new absorption band around 590 nm, both the Fe–alcohol stretching RR band and the ordinary porphyrin bands characteristic for the Q band excitation[26,27] were observed. Therefore, the 585 nm absorption band should have a CT character besides the porphyrin $\pi\pi^*$ character. The fact that the laser illumination in the 550—600 nm region did not induce photoreduction may imply alcohol is not an electron donor.

The Fe–2MeIm stretching RR band for Fe^{II}(OEP)(2MeIm) was observed at 206 cm^{-1} upon excitation at 441.6 nm[17] but not upon red excitations. We failed to observe the Fe^{III}-2MeIm stretching RR band and therefore it is not clear where a CT band from 2MeIm to Fe^{III} is located. If it were present below 450 nm, the occurrence of photoreduction would be reasonably explained in terms of the CT excited state from 2MeIm to the Fe^{III} ion. Anyway, elucidation of photoreduction mechanism of iron porphyrin as well as heme proteins requires further study and the pump/probe time-resolved RR experiments for determining the structure of photoreduction intermediates are currently under investigation in this laboratory.

The authors thank Professor Y. Ozaki of Kwansei Gakuin Univ. for stimulating discussion and Dr. T. Ohta of chemical material center of this institute for the gas chromatographic analysis of solvents and products. V. F. is indebted to IMS for financial support during his stay in IMS at Okazaki.

Emission Spectra of Fluorobenzenes by Controlled Electron Impact

Takahiro FUKUZUMI, Keiji NAKASHIMA, and Teiichiro OGAWA*
Department of Molecular Science and Technology, Kyushu University, Kasuga-shi, Fukuoka 816
(Received May 15, 1991)

The fluorescence emission spectra of fluorobenzene, *p*-difluorobenzene and hexafluorobenzene excited in collisions with electrons were measured for the study of the dynamics of the exciting aromatic system. These spectra showed a band assignable to the $S_1 \rightarrow S_0$ transition of the parent molecule. The bands of fluorobenzene and *p*-difluorobenzene were intense and showed a pronounced vibrational structure and the intense vibrational transitions were optically allowed. Whereas, that of hexafluorobenzene was broad and weak and did not show any clear vibrational structure.

An electron impact method has a distinctive advantage over a photoexcitation method in the excitation to highly-excited states, to optically-forbidden states and to triplet states. An interaction between an electron and a molecule is the simplest case of a chemical reaction and the elementary process in the plasma. Many organic compounds have been investigated by means of the electron impact method. Aromatic compounds have shown an intense optical emission of the S_1–S_0 transition of the parent molecule as well as bands of the fragment species such as H*, CH*, and C_2*.[1,2] Their exciting processes have been investigated and differences between the spectra excited by electrons and those by photons were revealed.[1]

Electrons can induce both optically allowed and forbidden transitions when the energy of the incident electron is close to the threshold energy of an excitation process.[3] The emission spectrum of benzene by controlled electron impact was different from the one by the photoexcitation;[4] the vibrational structure due to the $6^0 1^n$ series, which was symmetry forbidden for optical excitation, was clearly observed in the former at the electron energy of 25 eV.[5] However, comparisons of the spectra of other aromatic compounds by electron impact with those by photoexcitation remain as a subject of research.

Fluorobenzene (C_6H_5F) and *p*-difluorobenzene (*p*-$C_6H_4F_2$) have both a large optical absorption cross section and fluorescence quantum yield, and the vibrational structure of their absorption[6,7] and the fluorescence[8,9] spectra has been discussed in detail. Hexafluorobenzene (C_6F_6) showed no vibrational structure in both the absorption[10] and the fluorescence[11] spectra, although the excitation process of C_6F_6 would be expected to be identical with benzene since C_6F_6 has the same symmetry (D_{6h}). Though the emission spectrum of C_6H_5F by controlled electron impact has already been measured at 200 eV,[12] no detailed investigation on the excitation process has been reported.

In the present paper the optical emission spectra of C_6H_5F, *p*-$C_6H_4F_2$ and C_6F_6 were measured in the 250—450 nm region under the electron impact excitation as an extension of our investigation[2,12] on aromatic compounds. The electron energy dependence of the emission spectrum was also measured since the optically forbidden bands will become intense as the electron energy is decreased.[3] The vibrational structure of the S_1–S_0 transition of the parent molecule was also measured at 24 eV in order to compare it with that obtained by photoexcitation.

Experimental

The apparatus is almost identical with that described previously.[2,13] In brief, the collision chamber (20 cm) was evacuated with a 10 cm oil-diffusion pump (650 $dm^3 s^{-1}$) having a liquid nitrogen trap. The sample gas was introduced into a gas cell, and was collided with an electron beam from a tungsten filament. The base pressure was of the order of 10^{-6} Torr (1 Torr=133 Pa) and the operating pressure in the gas cell was kept at about 3×10^{-3} Torr for a single collision condition to be valid.

The optical emission was observed through a quartz window at an angle of 90° with respect to the electron beam. The overall spectrum was obtained with a SPEX MINIMATE 1670 monochromator and the high-resolution spectrum with a SPEX 1269 monochromator equipped with a 1200 grooves/mm grating blazed at 300 nm and a Hamamatsu R585 photomultiplier. Photons were counted with a Hamamatsu C1230 photon counter. When the optical emission was very weak, the electron beam was pulsed so that stray radiation from the tungsten filament could be subtracted (a digital boxcar technique). A JASCO CT-50 monochromator equipped with a 1200 grooves/mm grating blazed at 300 nm and an NF PC545 photon counter were used in such cases so as to obtain a medium-resolution spectrum with a high detection efficiency.

The instrumental response of the optical system was calibrated with a Hamamatsu L591 standard deuterium lamp. The electron energy was calibrated with the peak of N_2* (337.1 nm) at 14.02 eV and its energy resolution was about ±1—2 eV at 11eV.

C_6H_5F was obtained from the Nakarai Chemicals, Ltd. and *p*-$C_6H_4F_2$ and C_6F_6 were obtained from the Wako Pure Chemical Industries, Ltd. Each sample was frozen and pumped repeatedly to remove any dissolved gases.

Results and Discussion

Mono and Difluorobenzene. Typical emission spectra of C_6H_5F and *p*-$C_6H_4F_2$ in the 250—450 nm region with an optical resolution of 1.0 nm are shown in Fig. 1

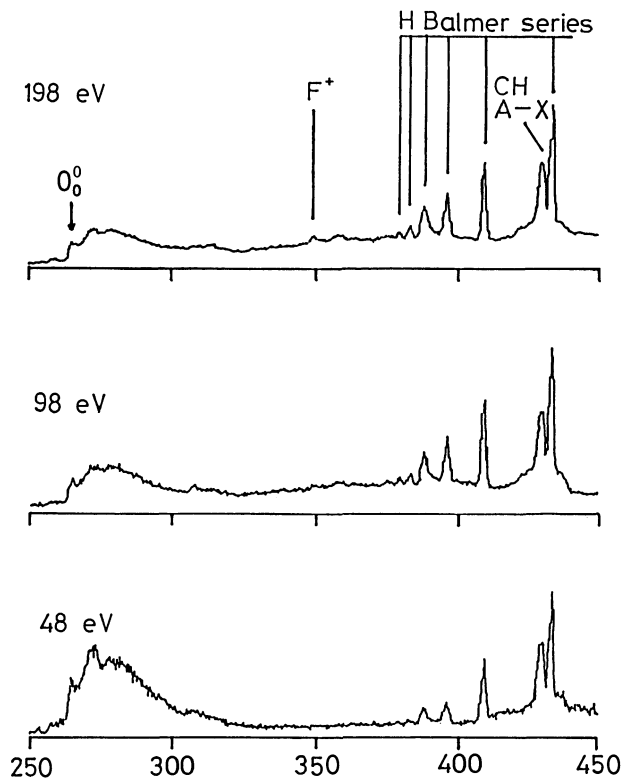

Fig. 1. Emission spectra of fluorobenzene by controlled electron impact measured by a SPEX MINIMATE 1670 monochromator. Optical resolution: 1.0 nm, electron beam current: 2—10 μA.

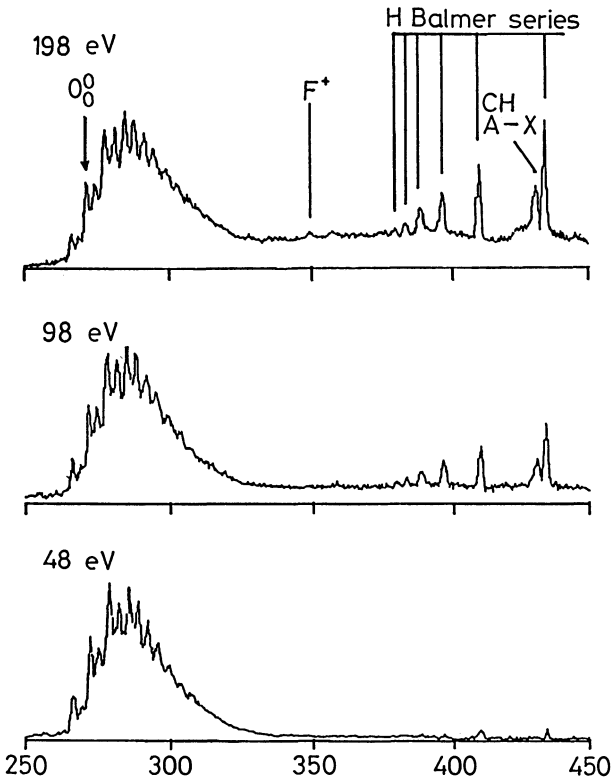

Fig. 2. Emission spectra of *p*-difluorobenzene by controlled electron impact measured by a SPEX MINIMATE 1670 monochromator. Optical resolution: 1.0 nm, electron beam current: 2—10 μA.

and Fig. 2, respectively. An intense band at 260—320 nm was assigned to the transition from the lowest-excited singlet state (S_1) to the ground state (S_0), since an optical fluorescence spectrum was located in the same region.[8,9] The excitation functions of these bands were also measured and the threshold energies were found at 4.4 eV and 4.1 eV, respectively; they agree well with the absorption edge[6,7] of the two molecules within experimental errors.

In the wavelength region longer than 350 nm, there are several lines and bands of excited fragment species as in the case of other aromatic molecules.[2] They have been assigned to H (the Balmer lines), F^+ ($3p^5\,P$–$3d^5\,D$), and CH (the A–X transition), as shown in the figures. No CF* (A–X) emission at 220—280 nm was observed; whereas, it was intense in the spectra of CF_4 excited by $He(2^3S)$, He^+, and He_2^+.[14] At higher incident electron energy, a continuous emission becomes clear in the region longer than 320 nm. This may be due to the excited fragment species made of 3—4 atoms such as C_2H^* and C_2F^*; C_6F_6 shows this continuous emission as will be mentioned later.

As the electron energy increases, the dipole Born approximation becomes valid, the optically allowed transition becomes dominant, and finally the process would be equivalent to the photoexcitation process.[3] For example, the $S_0(^1A_{1g})$–$S_1(^1B_{2u})$ excitation of benzene is the symmetry-forbidden transition; this band almost disappears at 100 eV.[2,15] On the other hand, the corresponding transitions of toluene and *p*-xylene are no longer optically forbidden because of their descending symmetry (C_{2v} or D_{2h}), and they are intense even at higher energy.[16] The spectra of C_6H_5F and *p*-$C_6H_4F_2$ would be similar to those of toluene and *p*-xylene. Indeed, the S_1–S_0 emission of these molecules is intense at higher energy as shown in Figs. 1 and 2. A rough estimate of the S_1–S_0 emission intensity can be done in comparison with the intensity of the Balmer line.[17] At the electron beam energy of 50 eV, the relative S_1–S_0 emission intensity of C_6H_5F and *p*-$C_6H_4F_2$ is about 2 times and 40 times as large as that of benzene, respectively.

Hexafluorobenzene. Typical emission spectra of C_6F_6 in the 250—470 nm region are shown in Fig. 3. At an excitation energy of 9 eV, the emission spectrum of C_6F_6 shows a broad band in the 290—470 nm region; this spectrum is noisy in the region longer than 450 nm owing to an intense stray radiation from the tungsten filament. This broad band was assigned to the S_1–S_0 transition since its fluorescence spectrum was located in the same region.[11] The threshold energy could not be measured owing to its small intensity. The fluores-

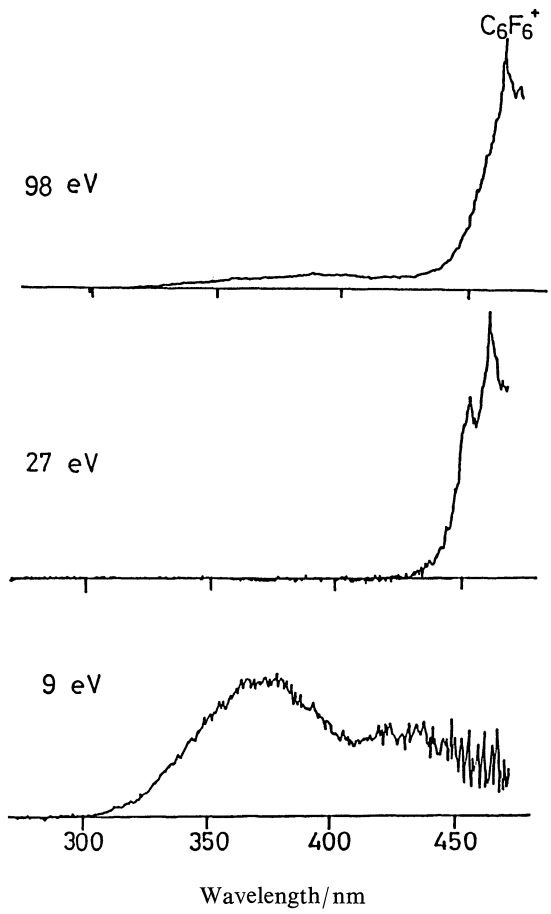

Fig. 3. Emission spectrum of hexafluorobenzene by controlled electron impact. 9 eV: The electron beam was pulsed to subtract the stray radiation. Optical resolution: 3.0 nm, monochromator used: JASCO CT-50, electron beam current: 8—10 μA. 27 eV and 98 eV: The electron beam was direct. Optical resolution: 1.0 nm, monochromator used: SPEX MINIMATE 1670, electron beam current: 2—5 μA.

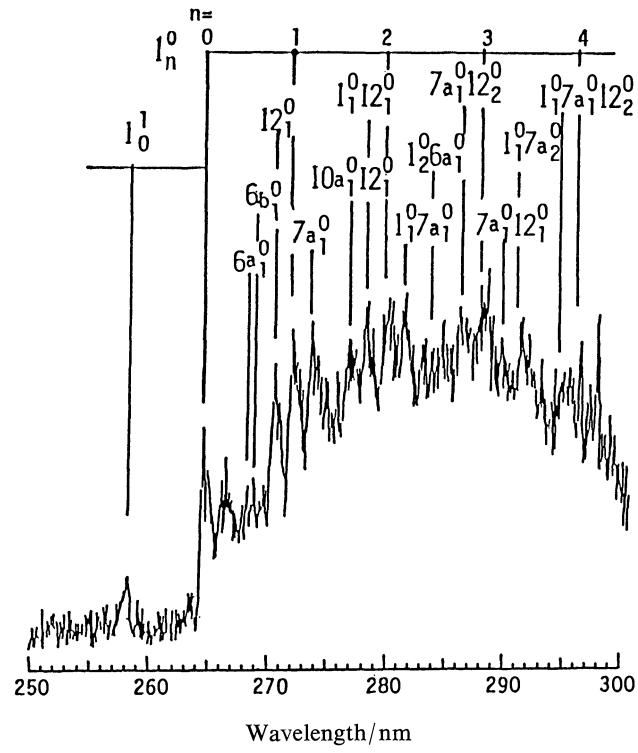

Fig. 4. High-resolution emission spectrum of fluorobenzene by controlled electron impact measured by a SPEX 1269 monochromator. Optical resolution: 0.20 nm, electron energy: 24 eV, electron beam current: 3 μA.

cence quantum yield of C_6F_6 is 1.4×10^{-3} (excited by a medium-pressure mercury arc at 235 nm).[11] Such a small value is consistent with the observed weakness of the emission of the parent molecule. The observation of this band of C_6F_6 was made possible by lowering the electron beam energy to 9 eV so as to remove all bands of the fragment species and of the parent ion which has a threshold energy of 12.56 eV.[18] There are, however, some contributions of the parent ion in the spectrum due to a low energy resolution of the electron beam at 9 eV.

At excitation energies of 27 and 98 eV, in contrast with C_6H_5F and *p*-$C_6H_4F_2$, C_6F_6 shows no detectable optical emission of the S_1–S_0 transition but shows intense bands of the parent molecule ion ($C_6F_6^+$).[18] A continuous band, which has a peak at about 400 nm, is also shown in the region longer than 320 nm at the electron energy of 98 eV. This band can be assigned to the emission of the excited fragment species made of 3—4 atoms as in the case of the other two molecules, since a fluorescence spectrum by photoexcitation was located nearly in the same region (ca. 290—470 nm) with a peak at 365 nm[11] and the threshold energy of this band is considerably higher. No CF* emission was also observed as in the case of the other two molecules.

Vibrational Structure. The high-resolution emission spectra of the S_1–S_0 transition of these molecules were also measured and are compared with those obtained by photoexcitation. A typical spectrum of C_6H_5F and that of *p*-$C_6H_4F_2$ with an optical resolution of 0.20 nm are shown in Figs. 4 and 5. The vibrational structure was well resolved and assigned by referring to the fluorescence spectra by the photoexcitation[8,9] as partly described in the figures with the Wilson notation.[19] However, no vibrational structure was resolved for C_6F_6 in the spectrum taken at a resolution of 0.60 nm.

C_6H_5F shows the following bands:[20] 6a (517 cm^{-1} at S_0), 6b (612), 16a (411), 12 (808), 1 (1012), 18a (1030), 9a (1153), 7a (1220), and C–F stretching (824), and combinations of these bands such as 1_n^0, $12_1^0 1_n^0$, $6a_1^0 1_n^0$, $6b_1^0 1_n^0$, $6b_1^0 12_1^0 1_n^0$, $7a_1^0 1_n^0$, $6b_1^1 1_n^0$, $6b_2^1 12_1^0 1_n^0$, $6b_1^1 7a_0^1 1_n^0$, and $6b_2^1 1_n^0$. *p*-$C_6H_4F_2$ shows the following bands:[21] 6a (451), 6b (507), 16a (370), 1 (859), and 7a (1245), and combinations of these bands such as 1_n^0, $7a_1^0 1_n^0$, $7a_1^0 16a_1^1 1_n^0$, $16a_1^1 7a_n^0$, $16a_1^1 1_n^0$, and $1_1^0 7a_n^0$. Since *p*-$C_6H_4F_2$ has higher symmetry than C_6H_5F, its vibrational structure is simpler than that of C_6H_5F. The bands due to the skeletal vibration are

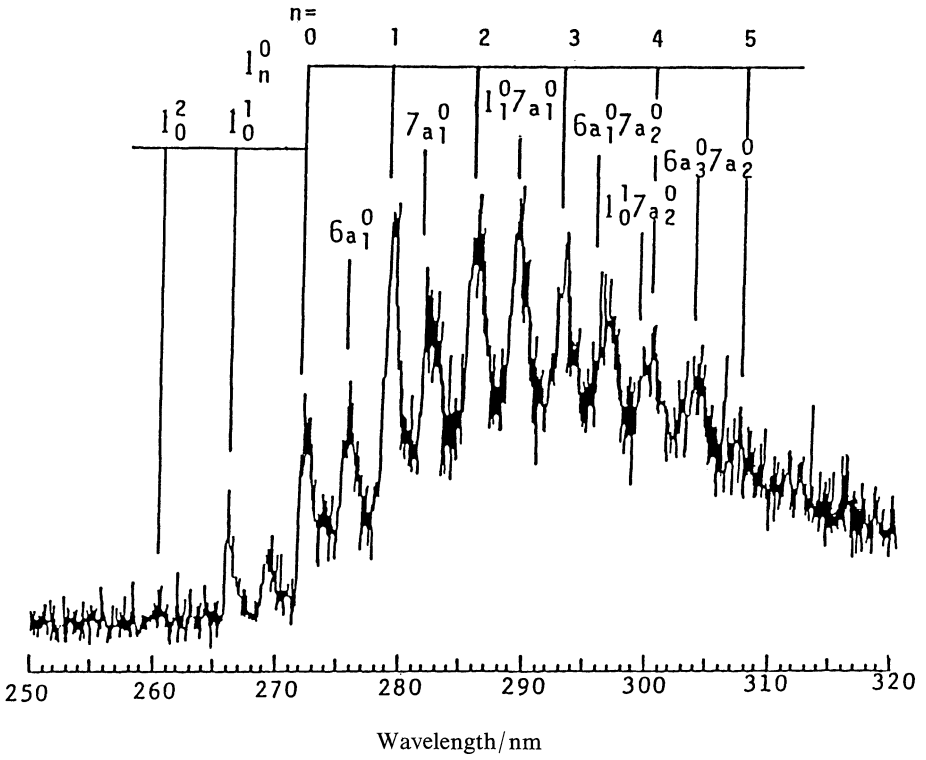

Fig. 5. High-resolution emission spectrum of *p*-difluorobenzene by controlled electron impact measured by a SPEX 1269 monochromator. Optical resolution: 0.20 nm, electron energy: 24 eV, electron beam current: 3 μA.

intense in both molecules. Furthermore, the bands from the vibrationally excited states of the S_1 state (1^n_0 series and combinations with them) are also shown although these hot bands did not appear in the spectra excited by monochromatic light even at a low operating pressure.[8,9] This finding is characteristic of the excitation process by electron impact.

Although benzene showed the optically forbidden ($6^0 1^n$ series) vibrational bands,[5] major bands observed for C_6H_5F and *p*-$C_6H_4F_2$ are due to optically allowed transitions; they were also found in the fluorescence spectra[8,9] and/or the SVL spectra[19] by photoexcitation. The optically-forbidden transitions of C_6H_5F and *p*-$C_6H_4F_2$ are the out-of-plane vibrations, and their Franck–Condon factors are small, thus, the transitions from the S_0 state to these modes in the S_1 state would be very weak. Indeed, benzene also showed no band assignable to an out-of-plane mode.[5]

On the other hand, C_6F_6 does not show any vibrational bands though it has the same symmetry with benzene. None of the optical absorption,[10] the fluorescence[11] and the electron energy loss[22] spectra of C_6F_6 shows vibrational structure. It has been suggested that upon fluorination $\pi \rightarrow \pi^*$ transitions will not show any substantial shift and $\pi \rightarrow \sigma^*$ transitions will be red shifted.[10] As a result of this shift, the $^1A_{1g} \rightarrow {}^1B_{2u}$ transition and the $\pi \rightarrow \sigma^*$ transition (the C band[22]) would overlap[10,22] and the band becomes broad and structureless.

The authors thank Professor Yukio Nishimura for the use of his standard deuterium lamp and Dr. Masaaki Fujii of Tohoku University for his useful discussion on the excited states of C_6F_6. The present work was partially supported by a Grant-in-Aid for Scientific Research on Priority Area Nos. 62606519, and 63606512 from the Ministry of Education, Science and Culture.

Combustion Reactions in Silane-Air Flames I. Flat Premixed Flames

Seishiro FUKUTANI,* Yasuhiro UODOME, Nílson KUNIOSHI, and Hiroshi JINNO†
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida-honmachi, Sakyo-ku, Kyoto 606
†Department of Chemistry, Faculty of Science and Engineering, Sophia University, Kioicho 7-1, Chiyoda-ku, Tokyo 102
(Received April 1, 1991)

In this work the combustion mechanism of silane–air flames is elucidated through a simulation employing a detailed chemical scheme. Two different pathways for the consumption of silane were found: $SiH_4 \rightarrow SiH_3 \rightarrow SiH_2O \rightarrow HSiO$, which proceeds in low-temperature regions, and $SiH_4 \rightarrow SiH_2 \rightarrow HSiO$, occurring at high temperatures; this supports results previously reported in the literature. It was also found that some reactions occur over wide ranges of temperature and that the governing step for the whole silane combustion is the reaction of silane with hydroxyl radicals. A least square fitting to the burning velocities and adiabatic flame temperatures obtained for the four investigated mixtures, with equivalence ratios of 2.0, 1.43, 1.0, and 0.5, indicated that a mixture with equivalence ratio of about 1.2 would have the largest burning velocity and the highest flame temperature.

The oxidation of silicon tetrachloride or silane yields silicon dioxide in condensed states. The production of solid or liquid phases from gases is a complicated phenomenon comprising chemical reactions and physical processes such as nucleation and crystal growth; it is interesting and, at the same time, important to investigate these processes from standpoints of both fundamental and applied researches on production of clusters and fine particles or on the CVD methods.

Silane is widely used as a silicon-containing material in semiconductor industries, for instance. This species is, however, spontaneously explosive in the air or sometimes causes production of undesirable products because of its high reactivity. The reaction between silane and oxygen should be investigated in detail to treat them safely and to maintain their efficient reactions. This work aims to simulate flat premixed silane–air flames using a model which neglects the physical processes to avoid complexities, and to elucidate the mechanisms of silane–oxygen combustion reactions under various conditions.

Recently some experimental and theoretical works have been done on the chemistry of silane. McLain et al.[1,2] have proposed the most reliable reaction schemes at present for the combustion of silane, which has been derived on the basis of the similarity to that of methane, and compared the predicted ignition delay times with the corresponding experimental values. Koda et al.[3–7] have studied experimentally silane combustion reactions by use of counterflow diffusion flames, and Tokuhashi et al.[8] have experimentally and theoretically investigated premixed silane flames. The explosion behavior of silane–oxygen mixtures has been investigated by Hartman et al.[9] in thermochemical discussion on the reaction mechanism. In spite of these pioneering works, the mechanism of silane combustion is still left unknown in many points. At present it is inevitable to accumulate the information in this field by both experimental and theoretical approaches.

Simulation Model

We used the same assumptions as those made in a previous work[10] in constructing the simulation model. Additional assumptions applicable only for this investigation are that (1) silicon dioxide exists in condensed phases over the temperature range considered here: high-temperature cristobalite phase below 1996 K and liquid phase above it; (2) only chemical processes are considered in the formation of silicon dioxide and hence the processes of condensation or crystallization such as nucleation and crystal growth are neglected. According to these two assumptions the produced silicon dioxide is removed from the gaseous reaction system but its amount is evaluated in terms of molar concentration and not of the size or number of silica particles. As thermochemical data for silicon dioxide, the data for high-temperature cristobalite were used below 1996 K and those corresponding to the liquid state were employed above the melting point.

The governing equations are expressed as follows:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho v) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(c_p \rho T) + \frac{\partial}{\partial x}(c_p \rho T v) = \frac{\partial}{\partial x}\left(\lambda \frac{\partial T}{\partial x}\right) + \sum_i D_i \rho \frac{\partial h_i}{\partial x}\frac{\partial \omega_i}{\partial x} - \sum_i h_i \varphi_i \tag{2}$$

$$\frac{\partial}{\partial t}(\rho \omega_i) + \frac{\partial}{\partial x}(\rho \omega_i v) = \frac{\partial}{\partial x}\left(D_i \rho \frac{\partial \omega_i}{\partial x}\right) + \varphi_i \tag{3}$$

$$p = \rho R T \sum_i \frac{\omega_i}{m_i} \tag{4}$$

where ω_i and φ_i are the mass fraction and chemical production rate of the i-th species. The other symbols have their usual meanings.

The partial differential terms were discretized into the corresponding finite difference terms according to the

a) The rate constants are expressed in m, mol, s units.

control-volume method;[11] the meshes have unequal sizes being roughly proportional to the product of the temperature and its gradient so that even fast reactions occurring there can be simulated with accuracy.

The boundary conditions at the unburned side are that the gas mixture is at 298 K and has given composition and velocity, and those at the burned side are that all the gradients of the dependent variables are zero.

A reaction scheme composed of forty-five pairs of elementary reactions was used for silane combustion; the first twenty-one pairs of reactions belong to hydrogen combustion, and the rest are reactions of silicon-containing species, which are SiH_4, SiH_3, SiH_2, SiH_2O, HSiO, SiO, and SiO_2, and were selected from the most reliable scheme at present (Table 1).

Since produced silicon dioxide is extinguished from the system the reverse reactions of (R43), (R44), and (R45) are neglected; in the actual system, however, the chemical equilibrium is reached between the gaseous and the condensed phases of silicon dioxide at high temperatures, and these reactions have their reverse partners.

Results and Discussion

Stoichiometric Flame. Figure 1 shows the profiles

of the temperature and the stable species mole fractions in a stoichiometric silane-air premixed flame and Figs. 2 and 3 show those of active species. The abscissas of these figures are, strictly speaking, the distance from an arbitrary origin. As described above, silicon dioxide is not a gaseous component, but, for convenience' sake, it is referred to with the mole fraction defined as the quotient of its concentration over the total concentration of the gaseous phase.

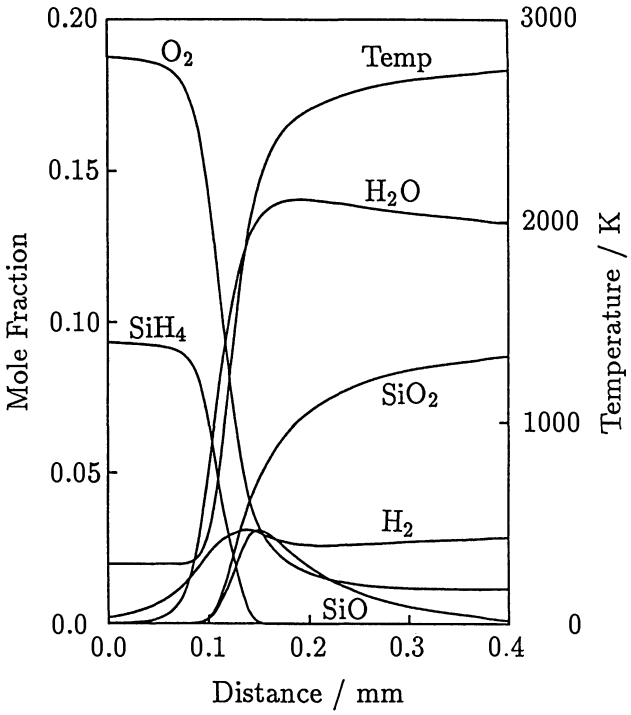

Fig. 1. Profiles of the temperature and the concentrations of stable species in the stoichiometric silane flame.

The reaction zone is about 0.05 mm thick and very thin in comparison with those of hydrogen and methane premixed flames; the combustion reaction is confined within this thin area. The second last and the last oxidation products of silane, that is, SiO and SiO_2, appear at fairly high temperatures, but hydrogen and water are present even at room temperature; their presence at low temperatures suggests that these species are produced at an early stage of silane combustion though hydrogen, in particular, has a large diffusion coefficient and diffuses from the high-temperature region to extremely upstream zones.

The intermediate species of silane combustion reactions, SiH_3, SiH_2, SiH_2O, and HSiO, are not distributed in a common region; SiH_3 appears in a low-temperature region, both SiH_2 and HSiO in a high-temperature region, and SiH_2O over a wide temperature range.

The three active species of the hydrogen–oxygen system, OH radicals and H and O atoms, increase above 1000 K. Hydroxyl radicals are particularly present in a large amount even in the low-temperature region comparing with that in hydrogen premixed flames.[10] Hydroperoxyl radicals are scattered widely and clearly have a shoulder in their profile suggesting that different reaction mechanisms contribute to their production depending on temperature.

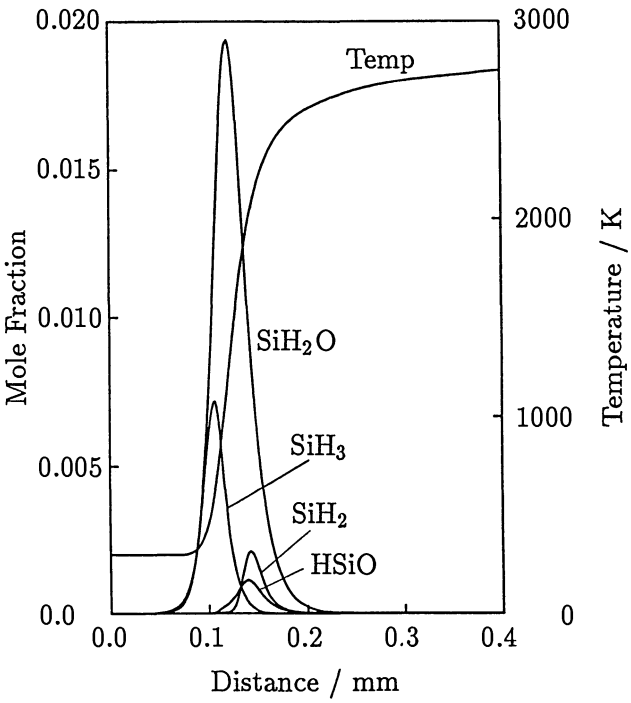

Fig. 2. Profiles of the temperature and the concentrations of intermediate silicon-containing species in the stoichiometric silane flame.

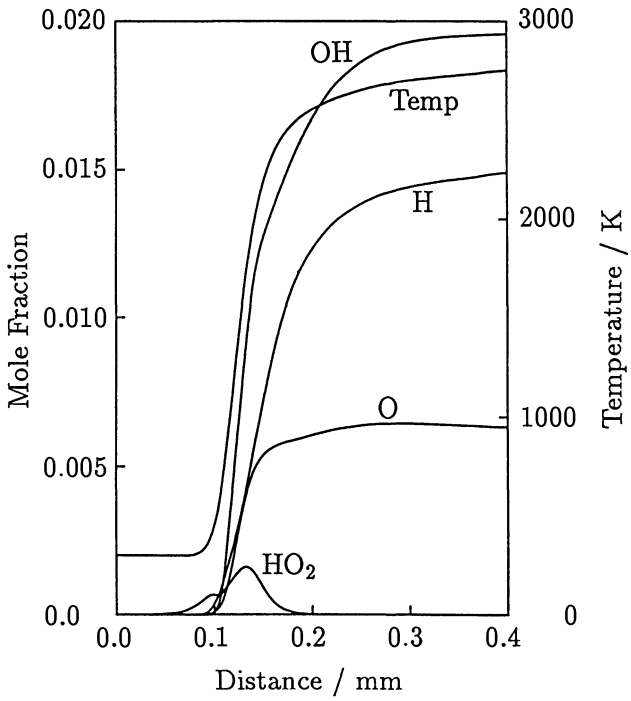

Fig. 3. Profiles of the temperature and the concentrations of intermediate hydrogen–oxygen-containing species in the stoichiometric silane flame.

Koda et al.[7] has already pointed out that the reaction scheme proposed by McLain gives two alternative pathways in the silane reaction from SiH_4 to HSiO: one via SiH_3 and the other via SiH_2. Our simulation also supports their result.

Figures 4 and 5 show, respectively, the reaction rates and the heat release rates for the predominant silicon-containing species reactions as functions of temperature. The profiles indicate that those reactions can be classified into three different groups based on the temperature range of their activation: low-temperature reactions, high-temperature reactions and wide-temperature-range reactions.

Reactions

$$SiH_4 + OH \rightarrow SiH_3 + H_2O, \quad \text{(R27)}$$

$$SiH_4 + H \rightarrow SiH_3 + H_2, \quad \text{(R25)}$$

$$SiH_3 + O_2 \rightarrow SiH_2O + OH, \quad \text{(R31)}$$

$$SiH_3 + O \rightarrow SiH_2O + H, \quad \text{(R29)}$$

and

$$SiH_2O + OH \rightarrow HSiO + H_2O \quad \text{(R36)}$$

are low-temperature reactions. They oxidize silane following the sequence $SiH_4 \rightarrow SiH_3 \rightarrow SiH_2O \rightarrow HSiO$. Hydroxyl radicals hold a particularly important role at the first step of this series of reactions due to their cyclic consumption and production by reactions (R27) and (R31). Since reaction (R27) is already activated and also begins to release considerable amounts of heat at temperatures as low as 500 K, it can be considered the most important of the governing elementary steps for the low-temperature combustion mechanism. At temperatures higher than 700 K, SiH_3 is oxidized by oxygen to SiH_2O through reaction (R31) with formation of hydroxyl radicals, and the SiH_2O is dehydrogenated with hydroxyl radicals by reaction (R36); reactions (R31) and (R36) are also exothermic, leading to a steep temperature increase and allowing the activation of reactions with higher activation energies, like the silane decomposition.

The activation of the silane decomposition reaction is the origin of an alternative reaction pathway, that is, $SiH_4 \rightarrow SiH_2 \rightarrow HSiO$, which predominates at temperatures higher than 1500 K. The overall silane consumption rate has then two peaks, one being located at about 1000 K and other at about 2000 K, and the fuel remaining from the low-temperature region is completely exhausted at the second pathway. The initiation reaction of the high-temperature route,

$$SiH_4 \rightarrow SiH_2 + H_2, \quad \text{(R22)}$$

is a spontaneous unimolecular dissociation which, however, cannot occur at low temperatures because of its large activation temperature (see Table 1) and endothermic character, as shown by Fig. 5. This is actually the only route for the production of SiH_2 though the assumed reaction scheme gives another possible step for the production of SiH_2 (R28). The formed SiH_2 is

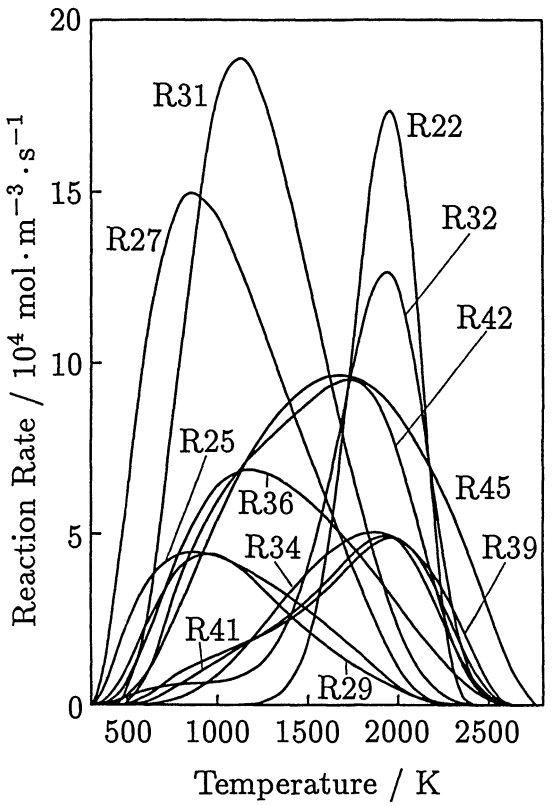

Fig. 4. Reaction rates in the stoichiometric silane flame as functions of temperature. The numbers in the figure correspond to those in Table 1.

immediately oxidized by reaction

$$SiH_2 + O_2 \rightarrow HSiO + OH \quad (R32)$$

so that this species is not considerably accumulated in the system.

The final product SiO_2 is produced by two reactions:

$$HSiO + O_2 \rightarrow SiO + HO_2 \quad (R42)$$

and

$$SiO + O_2 \rightarrow SiO_2 + O. \quad (R45)$$

Both reactions, corresponding to the last steps of the oxidation, are activated through a wide range of temperature and constitute direct oxidation with oxygen; therefore an insufficient amount of oxygen would hinder the progression of these steps. Above 1000 K, two additional reactions,

$$HSiO + H \rightarrow SiO + H_2 \quad (R39)$$

and

$$HSiO + OH \rightarrow SiO + H_2O, \quad (R41)$$

contribute to the consumption of HSiO so that HSiO does not remain in appreciable amounts, as shown in Fig. 2.

Although the reaction scheme gives many possible ways for the silane dehydrogenation, only the reactions (R27) and (R22) are promoted around 1000 K and 2000 K, respectively. Thus, the silane consumption clearly occurs by two alternative routes, each one being well identified by the temperature activation and the intermediate species. Figure 6 illustrates the obtained reaction pathways at three temperatures in the stoichiometric silane–air flame.

Since hydroxyl radicals contribute to a great extent to the initial step of the low-temperature mechanism of silane combustion, the chemical behavior of the species which contain hydrogen and/or oxygen will be discussed. Change in a species concentration is deter-

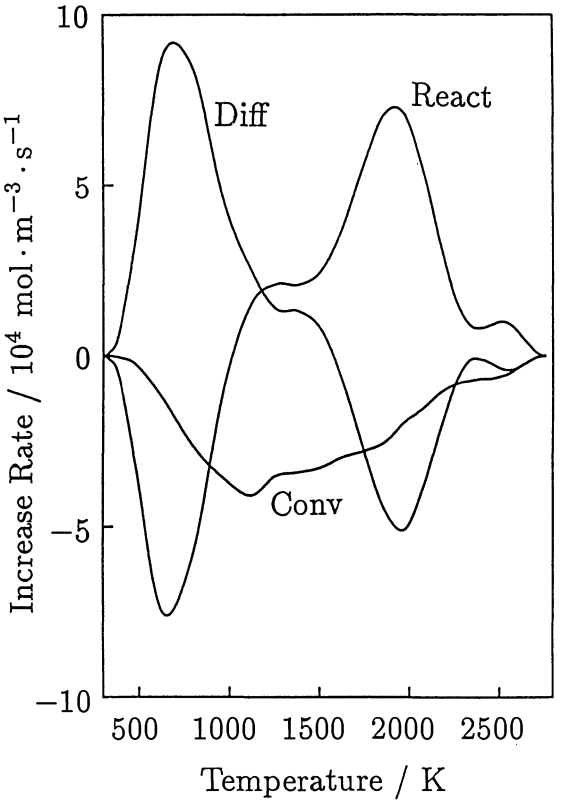

Fig. 7. Increase rates of hydroxyl radicals due to reactions (React), diffusion (Diff), and convection (Conv).

mined according to the governing equation for each species, Eq. 3. Figure 7 shows the rates of the individual terms constituting Eq. 3 for hydroxyl radicals. The reaction term expresses the net rate for the elementary reactions in which that species participates. According to the figure, hydroxyl radicals are supplied by diffusion to the low-temperature region and decrease mostly by reactions; reaction (R27) keeps the largest contribution to their consumption.

On the other hand, the reactions

$$H + O_2 + M \rightarrow HO_2 + M \qquad (R10)$$

and

$$H + HO_2 \rightarrow OH + OH \qquad (R12)$$

proceed with fairly large rates among hydrogen–oxygen reactions, particularly at low temperatures, though their rates are only about 1/5 of that of reaction (R27), for instance. Hydroxyl radicals are thus produced via hydroperoxyl radicals by this pair of reactions, which start from diffused hydrogen atoms supplied with a rate similar to the diffusion rate of hydroxyl radicals. Hydroperoxyl radicals, which have an interesting profile at low temperatures as shown in Fig. 3, are produced by reaction (R10) and then consumed by reaction (R12), and above 800 K are also produced by reaction (R42).

The starting point of the hydrogen–oxygen reactions in this flame is the liberation of hydrogen by reaction (R22) at high temperatures. The hydrogen is transformed into hydroxyl radicals and hydrogen atoms by the chain-branching reaction (R3) at temperatures around 2000 K, and then is oxidized by reaction (R5) also producing hydrogen atoms. The hydrogen atoms are oxidized into hydroxyl radicals by reaction (R12) reacting with the hydroperoxyl radicals. These hydroxyl radicals and hydrogen atoms are carried toward the low-temperature region by diffusion and used as the reactant of the initiation reaction (R27). Water, on the other hand, is produced in a large amount by reaction (R5) and also by the dehydrogenation reactions of the silicon-containing species with hydroxyl radicals over a wide range of temperature so that it exists widely in the flame, as shown in Fig. 1.

Rich and Lean Flames. We simulated also rich and lean silane premixed flames with equivalence ratios (ϕ) equal to 2.0, 1.43, and 0.5 to discuss the reaction mechanisms under various conditions. The calculated burning velocities are 1.8 m s^{-1} for the flame with ϕ=2.0, 2.2 m s^{-1} for ϕ=1.43, 2.2 m s^{-1} for ϕ=1.0, and 0.9 m s^{-1} for ϕ=0.5. The least square method approximating them with a cubic function of the silane content gives the maximum burning velocity of 2.6 m s^{-1} at 11%, which corresponds to an equivalence ratio of 1.2. The adiabatic flame temperature changes similarly to the burning velocity.

The oxidation of Si and H takes place in parallel in silane flames; therefore it is important to determine which oxidation takes precedence particularly under the conditions of insufficient oxygen.

Concentration profiles of silicon-containing species indicated clearly that SiH_2 remains in rich flames, and at the richest investigated condition SiH_2 increases monotonically up to 2.8% in mole fraction showing no overshoot; this species holds 19% of the silicon atoms at the final state. The rest of them are shared by SiO (59%) and SiO_2 (22%). Hydrogen atoms, on the contrary, are shared by H_2O (50%), H_2 (41%), and SiH_2 (9%). At the final state of the flame with ϕ=1.43, unburned SiH_2 still remains in a small amount, and 62% and 60% of the silicon and hydrogen atoms are kept in SiO_2 and H_2O, respectively. In the stoichiometric flame, all the silicon atoms are contained in silicon dioxide and water shares 82% of the hydrogen atoms at the final state.

Water is produced already at very early stages of combustion by reactions such as (R27) and (R31) throughout the four flames so that the oxidation of H proceeds fast at first. In the highest temperature region of the rich and stoichiometric flames, however, the produced water is reduced by the reverse reactions of (R5) and

$$OH + OH \rightarrow O + H_2O, \qquad (R4)$$

and the formed hydroxyl radicals are used by the final oxidation toward SiO_2

$$SiO + OH \rightarrow SiO_2 + H. \qquad (R44)$$

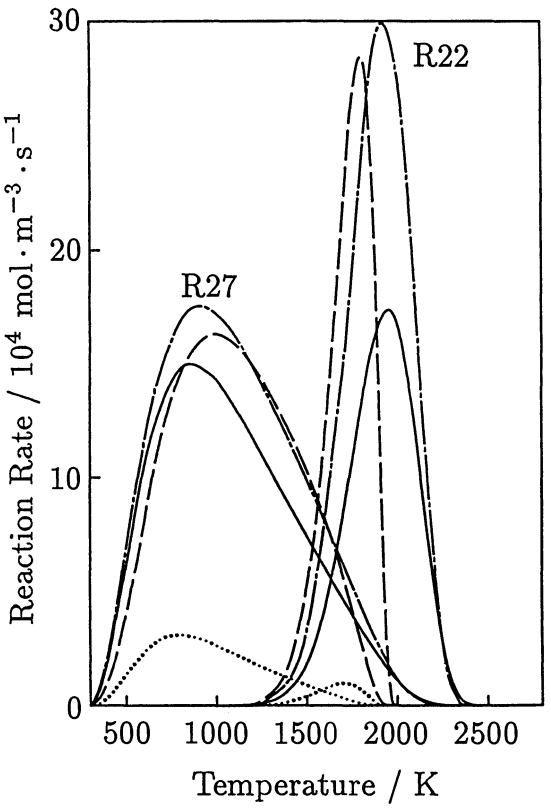

Fig. 8. Rates of reactions (R27) and (R22) in four silane premixed flames with equivalence ratio of 2.0 (dashed lines), 1.43 (dashed-dotted lines), 1.0 (solid lines), and 0.5 (dotted lines).

Formation of SiO_2 through free oxygen (reaction (R45)) is also promoted in this stage.

The rich and stoichiometric flames possess a similar low-temperature reaction mechanism, indicating that the product between the concentrations of silane and hydroxyl radicals, which determine the rate of the initiation reaction of this mechanism (R27), are almost equal one another: the maximum rates of reaction (R27) are 1.63×10^5 mol m^{-3} s^{-1} in the flame with $\phi=2.0$ (at 1000 K), 1.77×10^5 mol m^{-3} s^{-1} at $\phi=1.43$ (at 930 K) and 1.51×10^5 mol m^{-3} s^{-1} at $\phi=1.0$ (at 870 K); and those of reaction (R31) are 1.89×10^5 mol m^{-3} s^{-1} at $\phi=2.0$ (at 1210 K), 2.15×10^5 mol m^{-3} s^{-1} at $\phi=1.43$ (at 1190 K) and 1.89×10^5 mol m^{-3} s^{-1} at $\phi=1.0$ (at 1130 K). In the leanest flame, both rates are only about 1/5 of those in the above flame because of insufficient amounts of silane and hydroxyl radicals.

As for the high-temperature mechanism, on the contrary, the rates of reaction (R22) are remarkably different since this is a unimolecular reaction and its rate is simply proportional to the concentration of silane. Its maximum rate, however, becomes the largest at $\phi=1.43$ but not at $\phi=2.0$. The reason is that the flame temperature of the latter flame is much lower than that of the former one.

The rates of reactions (R27) and (R22) are consequently a good index for the reaction mechanisms in silane flames as shown in Fig. 8.

Conclusions

The simulation of silane–air flat premixed flames using a detailed reaction scheme and the analyses of the obtained results led to the following conclusions:

(I) In the flames with equivalence ratio around 1.0 the combustion reactions take place very intensely, and consequently are confined within thin areas of about 0.05 mm thick. The burning velocity of the stoichiometric flame is 2.2 m s^{-1}, Which is a little smaller than that of the hydrogen flame.

(2) Two mechanisms are provided for the reaction from SiH_4 to HSiO: one proceeds along $SiH_4\rightarrow SiH_3\rightarrow SiH_2O\rightarrow HSiO$ and the other along $SiH_4\rightarrow SiH_2\rightarrow HSiO$. These pathways are activated in different temperature ranges. The former starts even at low temperatures because it progresses as chain reactions having hydroxyl radicals as chain carriers, which are produced in a large amount even at low temperatures. The latter is activated at high temperatures because the initiation reaction of this route has a large activation temperature. The second mechanism is also accelerated under rich conditions since it starts with dissociation of silane.

Combustion Reactions in Silane-Air Flames II. Counterflow Diffusion Flame

Seishiro FUKUTANI,* Nílson KUNIOSHI, Yasuhiro UODOME, and Hiroshi JINNO†
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida-honmachi, Sakyo-ku, Kyoto 606
†Department of Chemistry, Faculty of Science and Engineering, Sophia University, Kioicho 7-1, Chiyoda-ku, Tokyo 102
(Received April 1, 1991)

A detailed chemical reaction scheme and a full set of governing equations for fluid dynamics were used to elucidate the chemical and physical phenomena involved in a silane–air counterflow diffusion flame, where the fuel and air issue from the lower and upper nozzles, respectively. It was found that a stagnation surface, where the axial velocities fall down to zero, is kept in a position slightly shifted to the upper side, dividing the system into two zones: the upper air side and the lower fuel side; after leaving the nozzle silane begins to dissociate itself into SiH_2 and H_2 when it reaches the region of rising temperature; oxygen penetrates into the fuel side by diffusion and reacts with H_2 forming OH radicals and H atoms. The produced SiH_2 is further dehydrogenated to SiO via HSiO; comparing with premixed flames, the diffusion flames have large local equivalence ratios, so that the combustion reactions in the latter flames occur through a different mechanism.

Opposite flow of gaseous fuel and air originates a stagnation point at an intermediate position between the two nozzles on the center line. The fuel and air are mixed each other within a narrow region near the stagnation point mainly due to diffusion and can hold stably a diffusion flame as shown in Fig. 1 if the flow velocities of the fuel and air do not exceed certain critical values. The flame maintained in the stagnation area is called a counterflow diffusion flame and has the simplest structure among the various types of diffusion flames.

Silane–air mixtures are very reactive and hence the gas mixtures should be treated carefully to avoid eventual explosions. In diffusion flames, on the contrary, the characteristic time of the diffusion process which mixes the fuel and air is usually longer than that of the chemical reactions, so that the former process controls the rate of the whole combustion phenomenon. Diffusion flames of silane are, therefore, preferred to premixed flames in both academic and industrial fields.

The mechanisms of chemical reactions occurring in diffusion flames, however, are not necessarily the same as those in the corresponding premixed flames. This investigation aims to elucidate the mechanism of combustion reaction of a silane–air counterflow diffusion flame and also its structure by means of computer simulation.

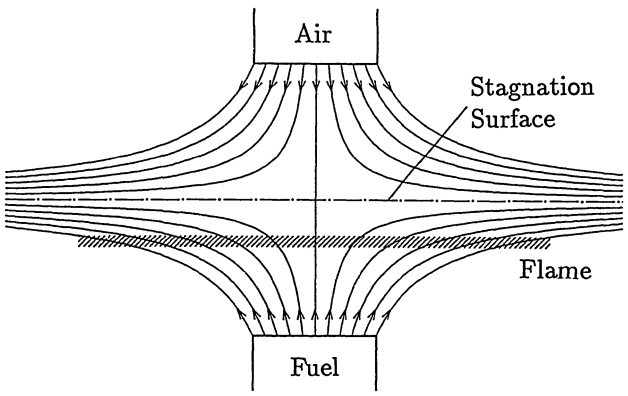

Fig. 1. Schematic figure of a counterflow diffusion flame.

Since diffusion flames have more complicated structures than premixed flames, their theoretical investigations have been predominantly based on the simple model called Burke–Schumann flame sheet model.[1] This model is constructed upon the following assumptions; (1) fuel and air react with a rate much larger than their diffusion rates so that the reaction zone is thin enough to be considered as a geometrical plane; (2) the ratio between the diffusion rates of fuel and air into the reaction zone equals the stoichiometry of the combustion reaction of both components or, in other words, the reaction zone is located at a position so that the above condition is satisfied. The Burke–Schumann model has been applied to various kinds of diffusion flames and derived many useful results.[2–6] However, most of those researches have necessarily represented their combustion reactions with overall reactions or replaced them with correspondent exothermic processes to simplify the analyzing algorithms.

The application of one-step reaction approximations is not appropriate, in particular, for diffusion flames where combustion reactions take place step by step such as methane[7] and silane flames.[8] A model containing a full reaction scheme can describe precisely the reaction mechanism and details of the flame structure such as the distributions of temperature, reaction rates and chemical species.

Theoretical studies have been done on counterflow diffusion flames by various workers;[9,10] in most of their studies the flames are treated as hypothetical one-dimensional flames by simulating only along the center line. The one-dimensional treatment of such diffusion

flames, however, is not satisfactory because the flames do not strictly possess homogeneous structures along any radial axis. Both full reaction scheme and detailed fluid mechanics are included in the model used in this investigation.

Simulation Model

The simulation model for the silane–air counterflow diffusion flame treated here was formulated under the same assumptions made in the previous work of this series[8] plus the additional condition of axial symmetry of the flame. The governing equations can be written as:

$$\frac{\partial \rho}{\partial t}+\frac{1}{r}\frac{\partial}{\partial r}(\rho u r)+\frac{\partial}{\partial z}(\rho v)=0 \tag{1}$$

$$\frac{\partial \rho u}{\partial t}+\frac{\partial \rho u^2}{\partial r}+\frac{\partial \rho uv}{\partial z}=\frac{\partial}{\partial r}\left[\mu\left\{2\frac{\partial u}{\partial r}-\frac{2}{3}\left(\frac{1}{r}\frac{\partial}{\partial r}(ur)+\frac{\partial v}{\partial z}\right)\right\}\right]+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial u}{\partial z}+\frac{\partial v}{\partial r}\right)\right]+\frac{2\mu}{r}\left(\frac{\partial u}{\partial r}-\frac{u}{r}\right)-\frac{\partial p}{\partial r} \tag{2}$$

$$\frac{\partial \rho v}{\partial t}+\frac{\partial \rho uv}{\partial r}+\frac{\partial \rho v^2}{\partial z}=\frac{\partial}{\partial z}\left[\mu\left\{2\frac{\partial v}{\partial z}-\frac{2}{3}\left(\frac{1}{r}\frac{\partial}{\partial r}(ur)+\frac{\partial v}{\partial z}\right)\right\}\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[\mu r\left(\frac{\partial u}{\partial z}+\frac{\partial v}{\partial r}\right)\right]-\frac{\partial p}{\partial z}-\rho g \tag{3}$$

$$\frac{\partial c_p \rho T}{\partial t}+\frac{\partial c_p \rho Tu}{\partial r}+\frac{\partial c_p \rho Tv}{\partial z}=\frac{1}{r}\frac{\partial}{\partial r}\left(\lambda r\frac{\partial T}{\partial r}\right)+\frac{\partial}{\partial z}\left(\lambda\frac{\partial T}{\partial z}\right)+\sum_i D_i\rho\frac{\partial h_i}{\partial r}\frac{\partial \omega_i}{\partial r}+\sum_i D_i\rho\frac{\partial h_i}{\partial z}\frac{\partial \omega_i}{\partial z}-\sum_i h_i\varphi_i \tag{4}$$

$$\frac{\partial \rho\omega_i}{\partial t}+\frac{\partial \rho\omega_i u}{\partial r}+\frac{\partial \rho\omega_i v}{\partial z}=\frac{1}{r}\frac{\partial}{\partial r}\left(D_i\rho r\frac{\partial \omega_i}{\partial r}\right)+\frac{\partial}{\partial z}\left(D_i\rho\frac{\partial \omega_i}{\partial z}\right)+\varphi_i \tag{5}$$

$$p=\rho RT\sum_i\frac{\omega_i}{m_i} \tag{6}$$

where t is the time, r and z the radial and axial distances, u and v the radial and axial flow velocities; and h_i, ω_i, and φ_i are the enthalpy, the mass fraction and the production rate due to chemical reactions of the i-th species. The viscosity μ, the thermal conductivity λ and the diffusion coefficient D of the components were estimated, respectively, using Hirschfelder's, Eucken's, and Hirschfelder's approximated equations.[11] The other thermodynamic data, including the equilibrium constants were obtained from JANAF data.[12]

The partial differential equations were transformed into the corresponding finite difference equations based on the control-volume method.[13] The resulting finite difference equations were solved iteratively until time-independent solutions were obtained.

The reaction scheme used in this investigation is the same as that in the previous work, and composed of forty-five pairs of elementary reactions among SiH_4, SiH_3, SiH_2, SiH_2O, HSiO, SiO, SiO_2, OH, H, O, HO_2, H_2O_2, H_2O, H_2, O_2, and N_2. Silicon dioxide is present in the solid or liquid phase and hence the produced SiO_2 is assumed to disappear from the gaseous reaction system; therefore the steps producing SiO_2 from SiO do not have their reverse reactions. Nitrogen is assumed to be inert and any NO_x production reactions are not included in the reaction scheme.

The following conditions were imposed on the system as the boundary conditions:

1. A mixture of 5% of silane and 95% of nitrogen and air issue in the opposite directions from lower and upper nozzles, respectively, with uniform flow velocity of 0.3 $m\,s^{-1}$ at 298 K. The two nozzles are 8 mm in diameter, and located oppositely with a displacement of 10 mm.
2. Nitrogen flows with constant velocity of 0.3 $m\,s^{-1}$ outside both nozzles in order to stabilize the flow of the fuel and air.
3. The gradients of all dependent variables are zero at the lateral boundaries.

Results and Discussion

Flame Structure. The combustion conditions given above can provide a stable diffusion flame without any turbulence nor vortexes.

Figure 2 shows the flow velocity and temperature distributions over the whole calculation area. The points where the axial flow velocity becomes zero define the stagnation surface; on the center line, the stagnation point is located at 5.4 mm above the fuel nozzle. The axial velocity temporarily increases by about 0.05 $m\,s^{-1}$ at the lower edge of the high-temperature region because of the sharp temperature rise; the momentary increase in the axial velocity observed at the edges of the high-temperature region is characteristic of this type of diffusion flames.[10] The radial component of the flow velocity increases as the gas flows away from the nozzles and becomes 0.61 $m\,s^{-1}$ at the lateral boundary.

The high-temperature region is confined into a fairly narrow zone of about 2 mm wide and is unevenly distributed to the side lower than the stagnation surface.

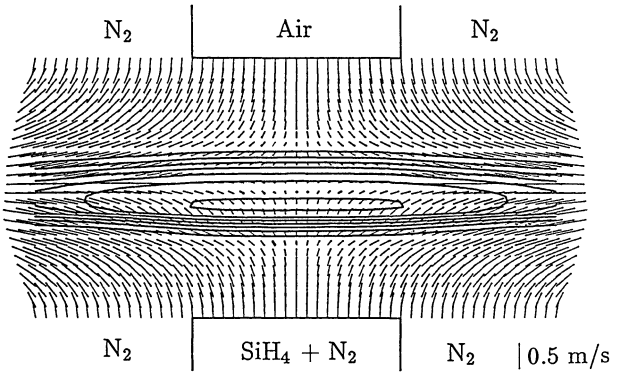

Fig. 2. Distributions of the flow velocity and temperature. The two nozzles are 8 mm in diameter and separated by a distance of 10 mm. The contour lines of the temperature are drawn for every 250 K from 500 K to 2000 K.

The temperature reaches about 2000 K, which is the highest temperature in this flame, at 4.0 mm in height on the center line; the maximum value is much lower than that found in premixed flames[8] due to the excess dilution of the combustion gas with nitrogen. The averaged temperature gradient in the axial direction is about 1420 K mm^{-1} at the lower side and larger than that at the upper side suggesting that exothermic reactions occur intensely at the lower side. The radial gradients of the temperature are almost zero within the cylindrical region between the nozzles.

The concentrations of the reactants and products are shown with contour lines in Fig. 3. As described above silicon dioxide is assumed to exist in the condensed states and is removed out from the gaseous reaction system. Its amount should be expressed with the number and the size of deposited silicon dioxide particles but it is expressed here, for convenience' sake, with the mole fraction defined as the molar concentration over the total molar concentration of the gaseous components.

The fuel and oxygen are both exhausted at about 4 mm in height. The following two points should be noted on their profiles; (1) oxygen penetrates deeply into the lower side across the stagnation surface; (2) a gap of about 0.2 mm wide is observed between the disappearing positions of the fuel and oxygen even on the center line and such a displacement is much wider than the reaction zone of silane–air premixed flames.[8]

The location and thickness of the fuel-and-air mixing region depend on the chemical and transport properties of the gases such as reactivity and diffusivity. The binary diffusion coefficient between oxygen and nitrogen is about 1.6×10^{-4} $m^2 s^{-1}$ at 1000 K, for instance, and about 1.6 times as large as that between silane and nitrogen. The diffusional flux of oxygen overwhelms that of silane and this species penetrates into the lower side transgressing the stagnation surface. In a hydrogen–air counterflow diffusion flame, on the contrary, hydrogen enters deeply into the air side over the stagnation surface.[10] Hereafter the regions below and above the stagnation surface will be called fuel side and air side, respectively.

As for the second point, the empty region of both fuel and air indicates that the Burke–Schumann assumption of the diffusion-rate ratio equal to the stoichiometry of reaction between the two components is not valid in this flame and that the fuel and oxygen do not directly react each other.

Silicon dioxide is present in a narrow region lying between the stagnation surface and the fuel-and-oxidizer exhaustion layer; the confinement suggests that the SiO_2 formation occurs just below the stagnation surface and, in addition, the species is carried by the upstream flow toward the stagnation surface. The other final product, water, however, extends widely due to its movability.

Figure 4 shows the distributions of silicon-containing intermediate species having important roles. The rest three species are present in small amounts. The maximum mole fractions are 2.9×10^{-3} for SiH_3, 6.9×10^{-4} for SiH_2O, and 2.1×10^{-5} for HSiO; the amounts of the last two species, in particular, are more than 100 times as small as those in the premixed flame. The presence of this group of species is concentrated in the fuel side, while SiH_2O and HSiO are distributed in regions with radius larger than 6 mm.

The hydrogen–oxygen-containing species, however, extend over fairly wide regions even in the air side crossing over the stagnation surface as shown in Fig. 5. Hydroperoxyl radicals distribute mainly in the region above the stagnation surface though the amount is much smaller than the three active species OH, H, and O.

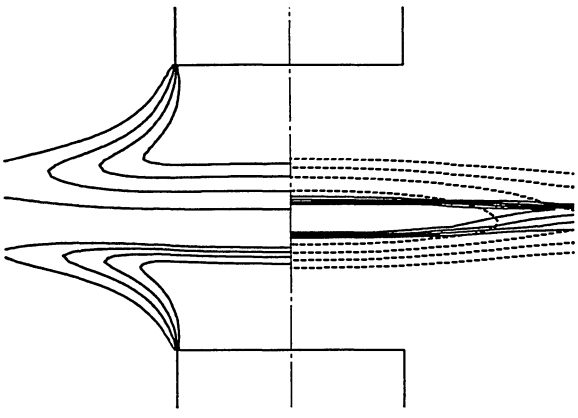

Fig. 3. Distributions of the stable species mole fractions. The contour lines for each species correspond to four values of equal intervals from the minimum to the maximum mole fraction (x_{max}). The mole fractions of SiH_4 ($x_{max}=5.0\times10^{-2}$) and O_2 ($x_{max}=2.1\times10^{-1}$) are shown in the left half of the figure, and those of SiO_2 ($x_{max}=1.3\times10^{-1}$) and H_2O ($x_{max}=4.5\times10^{-2}$) are shown in the right half with the solid and the dashed lines, respectively.

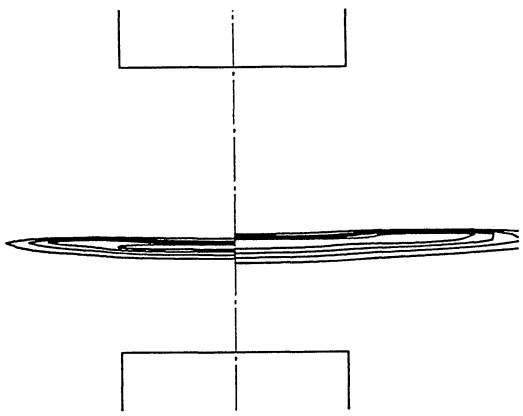

Fig. 4. Distributions of the mole fractions of silicon-containing intermediate species. The four contour lines are defined as those in Fig. 3. The mole fraction of SiH_2 ($x_{max}=8.9\times10^{-3}$) is shown in the left half and that of SiO ($x_{max}=4.1\times10^{-3}$) in the right half.

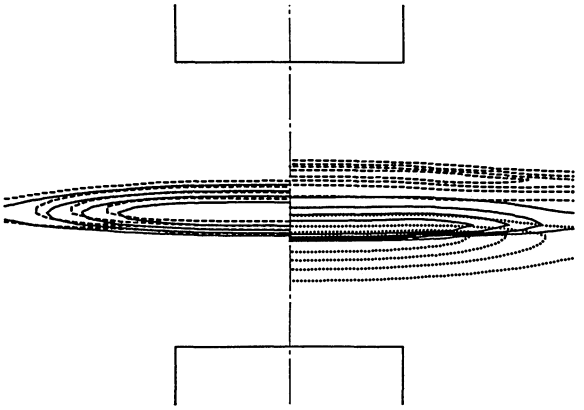

Fig. 5. Distributions of the mole fractions of hydrogen–oxygen-containing intermediate species. The four contour lines are defined as those in Fig. 3. The mole fractions of OH ($x_{max}=3.4\times10^{-3}$) and O ($x_{max}=1.9\times10^{-3}$) are shown with the solid and dashed lines, respectively, in the left half and those of H_2 ($x_{max}=8.3\times10^{-3}$), H ($x_{max}=1.9\times10^{-3}$), and HO_2 ($x_{max}=2.0\times10^{-5}$) are shown with the dotted, solid and dashed lines, respectively, in the right half of the figure.

According to Figs. 4 and 5 the silicon-containing and hydrogen–oxygen-containing species are present in two regions clearly divided at about 4 mm in height, which just coincides with the exhaustion zone of the fuel and air suggesting that the reactions of silicon-containing species and those of hydrogen–oxygen-containing species take place separately in the fuel and the air sides, respectively.

Combustion Reaction. Figure 6 shows the distributions of the predominant reactions occurring at the early silane combustion and the species participating in that step. Silane is dehydrogenated by hydrogen atoms at a height as low as 3.5 mm through reaction

$$SiH_4 + H \longrightarrow SiH_3 + H_2, \qquad (R25)$$

and the produced SiH_3 further reacts also with hydrogen atoms through reaction

$$SiH_3 + H \longrightarrow SiH_2 + H_2. \qquad (R28)$$

About 35% of SiH_4 is transformed into SiH_2 by the above pair of reactions even at very low positions of the fuel side, where the temperature is about 1400 K. The rest of the fuel is directly decomposed to SiH_2 by reaction

$$SiH_4 \rightarrow SiH_2 + H_2 \qquad (R22)$$

in a region located 0.2 mm above that for reactions (R25) and (R28). It is noticeable that the reactions converting SiH_4 to SiH_2 do not require O_2 or any oxygen-containing species.

Figure 7 shows the distributions of the other silicon-containing species and the reactions yielding the products up to SiO_2. The SiH_2 formed by either of the above reaction pathways is oxidized through

$$SiH_2 + O_2 \longrightarrow HSiO + OH. \qquad (R32)$$

Then, the produced HSiO is immediately dehydrogenated by reactions

$$HSiO + H \longrightarrow SiO + H_2 \qquad (R39)$$

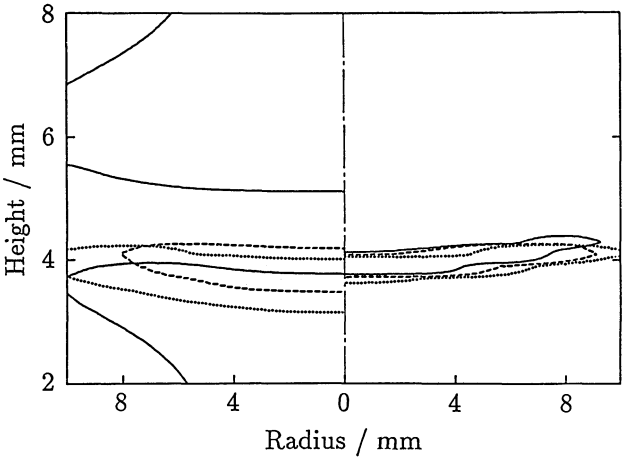

Fig. 6. In the left-hand side: distributions of SiH_4 (lower solid contour line for the mole fraction of $x=9.0\times10^{-3}$), SiH_3 (dotted line, $x=5.9\times10^{-4}$), SiH_2 (dashed line, $x=1.8\times10^{-3}$), and O_2 (upper solid line, $x=3.9\times10^{-2}$); in the right-hand side: distributions of reactions (R22) (solid contour line for the reaction rate of $\varphi=57$ mol m^{-3} s^{-1}), (R25) (dotted line, $\varphi=43$ mol m^{-3} s^{-1}), and (R28) (dashed line, $\varphi=33$ mol m^{-3} s^{-1}). The reaction numbers correspond to those in the text. The mole fractions and the reaction rates designated by the contour lines are 80% of the corresponding maximum values.

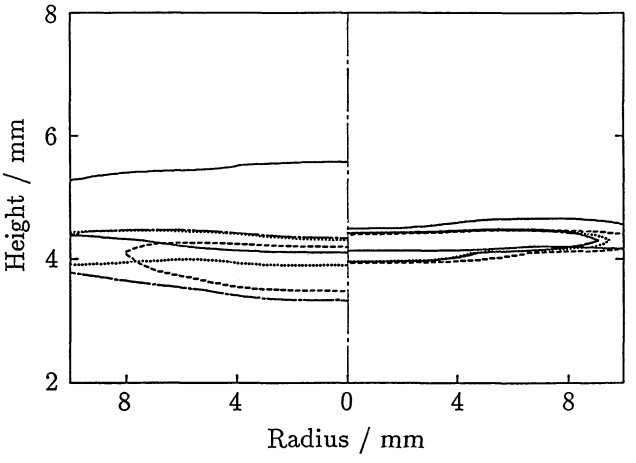

Fig. 7. In the left-hand side: distributions of SiH_2 (dashed line, $x=1.8\times10^{-3}$), HSiO (dotted line, $x=4.3\times10^{-6}$), SiO (dotted-dashed line, $x=8.2\times10^{-4}$), and SiO_2 (solid line, $x=2.7\times10^{-2}$); in the right-hand side: distributions of reactions (R32) (dotted line, $\varphi=66$ mol m^{-3} s^{-1}), (R38) and (R44) (the two dotted-dashed lines, for $\varphi=23$ mol m^{-3} s^{-1} and $\varphi=29$ mol m^{-3} s^{-1}, respectively, lie upon each other), (R39) (dashed line, $\varphi=34$ mol m^{-3} s^{-1}), and (R45) (solid line, $\varphi=39$ mol m^{-3} s^{-1}).

or

$$HSiO + M \longrightarrow SiO + H + M. \quad (R38)$$

According to Fig .7 the SiO-producing reactions are intensely activated from about 4 mm in height but the produced SiO appears even at 3 mm on the center line. The conservation equation of chemical species requires, in the steady state, that each species must keep the balance among the five terms of Eq. 5, that is, axial and radial convection and diffusion, and reaction terms; only one steady state should be realized due to given boundary conditions but independently of initial conditions. Silicon monoxide in the mesh located at 3 mm in height and on the center line, for instance, increases with a rate of 1.9×10^{-1} mol m^{-3} s^{-1} by diffusion in the axial direction, decreases with a rate of 1.6×10^{-1} mol m^{-3} s^{-1} by axial convection and is compensated with the other three terms. The reaction term is negligible as described above, and the two radial terms, particularly radial diffusion, are also small.

The final oxidation predominantly consists of reactions

$$SiO + OH \longrightarrow SiO_2 + H \quad (R44)$$

and

$$SiO + O_2 \longrightarrow SiO_2 + O. \quad (R45)$$

The former reaction occurs in lower positions.

Consequently SiH_4 is oxidized step by step according to the sequence $SiH_4 \rightarrow SiH_2 \rightarrow HSiO \rightarrow SiO \rightarrow SiO_2$; the first step is composed of two routes, the direct dehydrogenation and the route via SiH_3.

The hydrogen–oxygen-containing species required by the above reactions as reactants are hydrogen atoms at the early stages, hydroxyl radicals at the final stage and oxygen at the middle and final stages. Those species and the main reactions related to them are shown in Fig. 8. The comparison of Figs. 7 and 8 indicates that the reactions among the hydrogen–oxygen-containing species take place at higher positions than those occurring among the silicon-containing species.

Hydrogen liberated by reaction (R22) reacts with oxygen at positions higher than 4 mm by reactions

$$O + H_2 \longrightarrow OH + H \quad (R3)$$

and

$$H + O_2 \longrightarrow OH + O. \quad (R2)$$

These are the predominant chain-branching reactions which are of great importance in almost all flames of hydrogen-containing fuel, and produce hydroxyl radicals with exponentially increasing rate. The hydroxyl radicals oxidize hydrogen to water and further produce hydrogen atoms by reaction

$$OH + H_2 \longrightarrow H + H_2O. \quad (R5)$$

Reactions (R2) and

$$OH + OH \longrightarrow O + H_2O \quad (R4)$$

proceed backward between 4 and 4.5 mm in height.

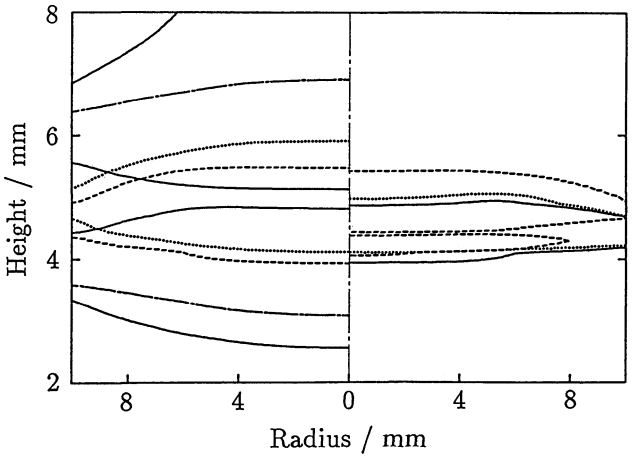

Fig. 8. In the left-hand side: distributions of H_2 (lower solid line, $x=1.7\times10^{-3}$), H (dashed line, $x=3.8\times10^{-4}$), OH (dotted line, $x=6.2\times10^{-4}$), H_2O (dotted-dashed line, $x=8.9\times10^{-3}$), and O_2 (upper solid line, $x=3.9\times10^{-2}$); in the right-hand side: distributions of reactions (R2) (upper dashed line, $\varphi=66$ mol m^{-3} s^{-1} for forward reaction and lower dashed line, $\varphi=18$ mol m^{-3} s^{-1} for backward reaction), (R3) (dotted line, $\varphi=18$ mol m^{-3} s^{-1}), and (R5) (solid line, $\varphi=39$ mol m^{-3} s^{-1}).

Oxygen and hydroxyl radicals are produced so that their insufficient supply to the lower region is compensated by those reactions. Hydrogen atoms are produced at heights above 4 mm and diffuse toward lower positions because of their large diffusion coefficient and are consumed by reactions (R25) and (R28).

In the previous paper on the combustion mechanism of silane–air premixed flames[8] two different pathways between SiH_4 and HSiO have been reported under a wide range of equivalence ratios: $SiH_4 \rightarrow SiH_3 \rightarrow SiH_2O \rightarrow HSiO$, which proceeds in low-temperature regions, and $SiH_4 \rightarrow SiH_2 \rightarrow HSiO$, occurring at high temperatures. These two routes can be clearly distinguished by the parameters of temperature and equivalence ratio. Hydroxyl radicals are the most important oxidizer in those pathways and in the former mechanism, in particular, they promote the dehydrogenation

$$SiH_4 + OH \longrightarrow SiH_3 + H_2O \quad (R27)$$

and

$$SiH_3 + O_2 \longrightarrow SiH_2O + OH \quad (R31)$$

with the cooperation of oxygen. The direct dehydrogenation of SiH_4 to SiH_2 by reaction (R22) is not accelerated until about 2000 K.

The two dehydrogenation pathways of SiH_4 are also observed in the counterflow diffusion flame; however, the one via SiH_3 does not proceed toward SiH_2O and, in addition, the reaction partners of SiH_4 and SiH_3 are hydrogen atoms instead of hydroxyl radicals. The main reason for those differences is that the local equivalence ratio in the region where the silicon-containing

species reactions occur is remarkably small in the diffusion flame so that SiH_3 is not oxidized into SiH_2O.

Conclusions

A silane–air counterflow diffusion flame was simulated using a detailed reaction scheme and complete fluid-dynamic governing equations, and the following conclusions were obtained:

(1) Oxygen which issues from the upper nozzle transgresses the stagnation surface, and hence reaction zone is formed in the fuel side. The temperature becomes maximum near the fuel-side edge of the reaction zone. Silane is preferentially oxidized in the fuel side of the reaction zone, and then the liberated hydrogen is oxidized producing active species necessary for silane combustion such as hydroxyl radicals and hydrogen atoms.

(2) Silane reacts through the sequence: $SiH_4 \rightarrow SiH_2 \rightarrow HSiO \rightarrow SiO \rightarrow SiO_2$. The first step is composed of two alternative routes: the direct dehydrogenation of SiH_4 to SiH_2 and the route $SiH_4 \rightarrow SiH_3 \rightarrow SiH_2$; the direct hydrogenation is predominant though the activation energy of unimolecular dissociation (R22) is much larger than the initiation reaction of the indirect dehydrogenation. In the premixed flames a large variety of species are present even at early stages of the reactions, but in the diffusion flame the initiation reaction, in particular, inevitably proceed in the state of insufficient oxygen-containing species relatively to premixed flames. The fuel oxidation up to silicon dioxide, therefore, occurs only in small amounts in the fuel side.

Luminescence and Circularly Polarized Luminescence of Mononuclear and Binuclear Chromium(III) L-Alaninato Complexes

Taro TSUBOMURA,* Iwao OHKOUCHI, and Makoto MORITA*
Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180
(Received December 28, 1990)

Luminescence and circularly polarized luminescence (CPL) spectra were investigated at low temperatures in order to clarify the chiroptical and electronic structures of monomeric and dimeric chromium(III) alaninato complexes. In the monomeric complexes, [Cr(L-(or D-)ala)$_3$]·H_2O, R_1 and R_2 lines of opposite spectral signs were found in the CPL spectra. The signs and relative intensities of the peaks were found to be comparable with circular dichroism (CD) spectra by employing theoretical arguments based on a strong crystal field theory. In the case of hydroxo-bridged dimeric complexes, [$Cr_2(OH)_2$(L-(or D-)ala)$_4$]·$3H_2O$, although the luminescence spectra of exchange-coupled pair states were clearly observed with a deduction of reasonable exchange interaction parameters, the CPL spectral components were not discernible because of the *meso*-type structure.

The luminescence properties of a large number of chromium(III) complexes have been thoroughly investigated over several decades.[1] A series of chromium complexes having amino acid ligands was carefully synthesized and the crystallographical as well as electronic structural data of the complexes were accumulated.[2] We have synthesized various series of monomeric and dimeric chromium amino acid complexes, and have found that they show a wide variety of luminescence spectra, although the energy and the intensity of the spin-allowed transitions are quite similar.[3]

We have been studying the chiroptical properties of chromium(III) complexes by using circularly polarized luminescence (CPL) spectroscopy.[4] Recently, we have reported that complexes with L-(or D-)alaninato (ala) ligands showed very sharp and split-line spectra, from which much interesting chiroptical information can be obtained. In this paper we precisely describe the luminescence properties of some chromium alaninato complexes: namely, monomeric *Λ-fac*-[Cr(L-ala)$_3$],[5] and dimeric [$Cr_2(OH)_2$(L-ala)$_4$],[6] whose structures are shown in Fig. 1. The complexes of the enantiomer containing D-ala ligands were also used to confirm the results. Powdery samples of the chromium(III) complexes showed reproducible luminescence and CPL spectra at low temperatures. We would represent clearly resolved R_1 and R_2 lines of opposite signs for the circularly polarized luminescence (CPL) of the [Cr(L- (and D-) ala)$_3$]·H_2O complex. A conventional crystal field theory regarding chirality is employed in order to explain some experimental foundations in the CPL spectra of the monomeric chromium(III) complexes. Then, fine structures due to exchange-coupled chromium pair are examined in the luminescence spectra of the binuclear complex.

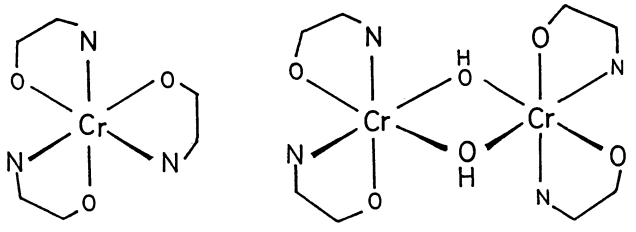

Fig. 1. Schematic drawings of the chromium complexes. (left) [Cr(L-ala)$_3$]·H_2O (right) [$Cr_2(OH)_2$(L-ala)$_4$]·$3H_2O$.

Experimental

Preparation of Mononuclear and Binuclear Chromium Complexes. The complexes were prepared by the reaction of [$Cr(NH_3)_6$](NO_3)$_3$ and L-alanine, according to Oki's method,[7] but with a slight modification. The molar ratio of the hexaammine complex to the L-alanine ligand was intentionally varied in greater amounts in order to obtain good yields of mononuclear or binuclear chromium alaninato complexes separately.

[Cr(L-(or D-)ala)$_3$]·H_2O. To a solution of [$Cr(NH_3)_6$](NO_3)$_3$ (6 mmol) in 70 mL of water was added 60 mmol of L- (or D-) alanine. This solution was heated to 70 °C for 90 min. Fine red needles of *fac-Λ*-[Cr(L-ala)$_3$]·H_2O or *fac-Δ*-[Cr(D-ala)$_3$]·H_2O were deposited and then separated and washed thoroughly with cold water. Anal. Calcd for $CrC_9H_{20}N_3O_7$: C, 33.51; H, 6.02; N, 12.66%. Found for L-ala complex: C, 33.84; H, 5.84; N, 13.06%. Found for D-ala complex: C, 33.48; H, 5.68; N, 13.09%.

[$Cr_2(OH)_2$(L-(or D-)ala)$_4$]·$3H_2O$. To obtain the binuclear metal complex, 50 mL of an aqueous solution containing 6 mmol of [$Cr(NH_3)_6$](NO_3)$_3$ and 6 mmol of L- (or D-) alanine was heated to 70 °C for 90 min. The solution was kept for several days at room temperature. [$Cr_2(OH)_2$(L-(or D-)ala)$_4$]·$3H_2O$ was obtained as violet crystals. Anal. Calcd for $Cr_2C_4H_{32}N_4O_{13}$: C, 26.47; H, 5.92; N, 10.29%. Found for L-ala complex: C, 26.49; H, 6.05; N, 9.99%. Found for D-ala complex: C, 25.97, H, 5.56; N, 10.44%.

Spectroscopic Measurements. Since the obtained samples were almost insoluble in water, the absorption spectra were obtained using the complex (2—2.5 mg) in KBr (150 mg) pellets on a Hitachi U-3200 spectrophotometer. The magnitudes of the molar absorption coefficients ε in KBr pellets were estimated on the basis of Lambert–Beer's law. The CD spectra of the same sample were recorded on a JASCO J-40 spectropolarimeter.

The luminescence spectra were measured on an instrumental system constructed in this laboratory.[8] Finely ground

powder samples were excited by the 514.5 nm line of an argon-ion laser (Spectra Physics, model 2025-05). The luminescent light was analyzed by a Spex 1401 double monochrometer set at 0.5 nm spectral resolution, and detected by a cooled Hamamatsu R943-02 photomultiplier tube. The luminescence signal was monitored by a Keithley model 614 electrometer. These instruments were totally controlled by an Apple II GS microcomputer. The emission spectra were corrected for monochrometer and photomultiplier photoefficiency by using a standard tungsten lamp.

Several optical devices were inserted into this system in order to detect CPL signals. The excitation light was chopped by an optical chopper at 30 Hz, and the luminescent light was passed through a photoelastic modulator (Morvue PEM-1) operated at 50 kHz with a polarizer sheet. The output signal of the photomultiplier tube was fed to a PAR 181 current-sensitive preamplifier; the AC signals were processed simultaneously by a NF Circuit Design LI-573 lock-in amplifier for the total luminescent (TL) current at 30 Hz, and by a EG&G PAR 5206 lock-in amplifier for the CPL current at 50 kHz. The two output signals were digitized and sent to an Apple II GS computer.

Optical glass cryostats for liquid-nitrogen and liquid-helium temperatures were used for the low-temperature luminescence measurements. An Air Products "Displex" model 202 helium closed cycle refrigerator was used for the experiments between 12 and 77 K.

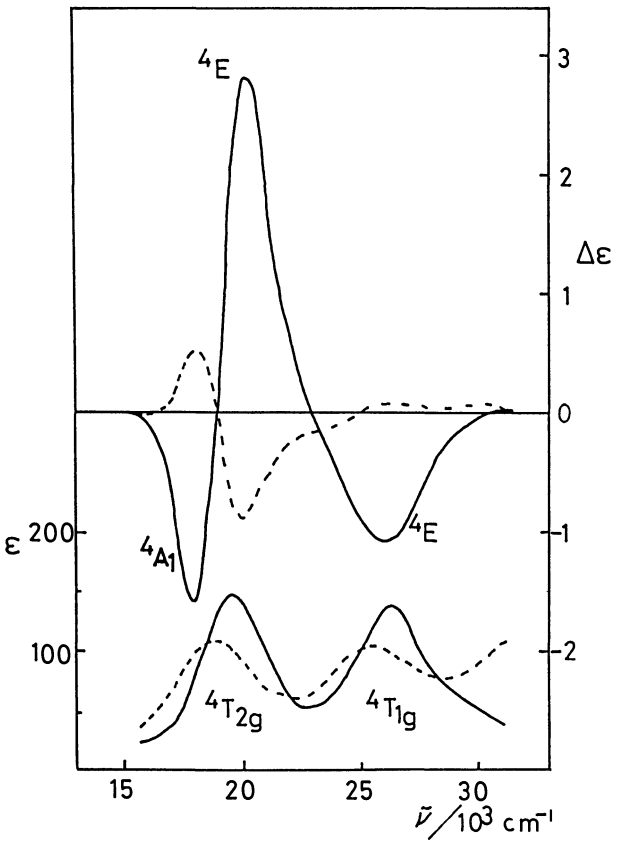

Fig. 2. Circular dichroism (upper part) and absorption spectra (lower part) of (——) [Cr(L-ala)$_3$]·H_2O and (– – –) [$Cr_2(OH)_2$(L-ala)$_4$]·$3H_2O$ in KBr pellets at room temperature.

Results

Absorption and Luminescence Spectra of [Cr(L-ala)$_3$]·H_2O. The room-temperature absorption spectra are displayed in Fig. 2 to give the spin-allowed transitions of the monomeric and dimeric chromium L-alaninato complexes in KBr pellets. The two broad bands are indicated as corresponding to the $^4A_{2g}\rightarrow{}^4T_{2g}$, $^4T_{1g}$ transition, respectively.

The 77 K absorption spectrum in the 14400 cm^{-1} energy region in a KBr pellet is shown in Fig. 3. The two peaks separated by 40 cm^{-1} correspond to the R lines; these have been assigned to the transition from the $^4A_{2g}$ state to the trigonal components of the $^2E_g(O_h)$ level. Two other peaks were observed at 15108 cm^{-1} and 15051 cm^{-1} at 77 K (not shown in the figure) and assigned to the $^4A_{2g}\rightarrow{}^2T_{1g}$ transition.

The low-temperature luminescence spectrum of a powdered sample is shown in Fig. 4. At 77 K, two prominent peaks were observed at 14386 cm^{-1} (R_1) and 14424 cm^{-1} (R_2), separated by 38 cm^{-1} in energy. A strong peak was further observed at 14185 cm^{-1}. The luminescence spectrum of the enantiomer, [Cr(D-ala)$_3$]·H_2O, was confirmed to be identical in both shape and position with that of L-ala complex. The integrated relative R_2/R_1 intensity ratio of these peaks is 0.42 at 77 K. The highest-energy peak was found to lose its intensity at 4 K, though the spectral resolution at 4 K was not significantly improved at 4 K, as compared to 77 K.

Therefore, the two distinct peaks, R_1 and R_2, should be assigned to transitions which occur from the split states of $^2E_g(O_h)$ in a trigonal field.

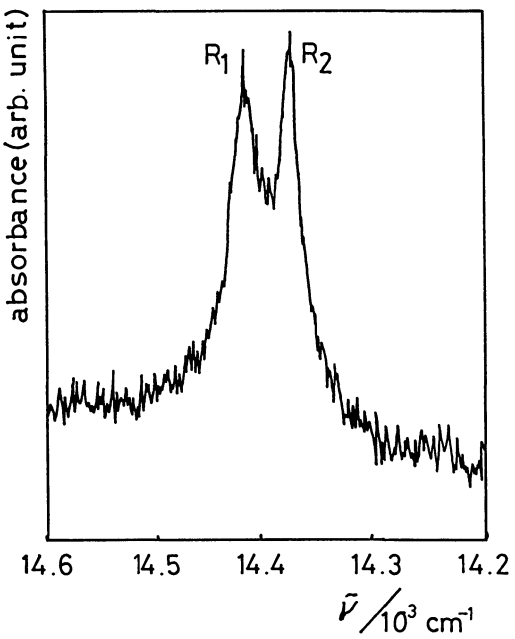

Fig. 3. Absorption spectrum of [Cr(L-ala)$_3$]·H_2O in KBr pellets at 77 K in the R line spectral region.

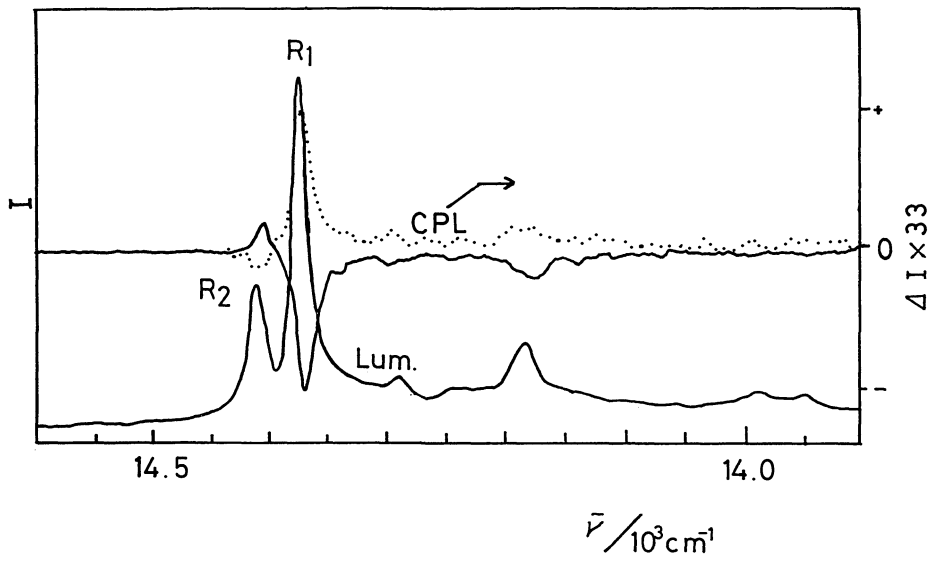

Fig. 4. Luminescence (I) and CPL (ΔI) spectra of tris alaninato chromium(III) complexes at 77 K. (——) $[Cr(L\text{-ala})_3]\cdot H_2O$, (– – –) $[Cr(D\text{-ala})_3]\cdot H_2O$. The intensity of ΔI is multipied by 33 compared to that of I.

CD and CPL Spectrum of $[Cr(D\text{-ala})_3]\cdot H_2O$. The room-temperature CD spectrum is also shown for the spin-allowed transition of $[Cr(L\text{-ala})_3]\cdot H_2O$ in KBr pellets in Fig. 2. A similar spectrum pattern (but of opposite CD sign) was obtained for $[Cr(D\text{-ala})_3]\cdot H_2O$ (but not displayed for clarity). The absolute values of $\Delta\varepsilon_{max}$ of a pair of enantiomers coincide with each others within 15% experimental discrepancies. In the CD spectrum of $[Cr(L\text{-ala})_3]\cdot H_2O$, a pair of bands of (+) and (−) signs was observed at 20,000 cm^{-1} in the $^4A_{2g}\rightarrow{}^4T_{2g}$ transition, and a single (−) band at 26,000 cm^{-1} in the $^4A_{2g}\rightarrow{}^4T_{1g}$ transition region.

Circularly polarized luminescence spectra of the powdered samples were recorded at 77 K. Figure 4 clearly shows two prominent R_1 and R_2 peaks of opposite CPL sign as well as some vibronic bands associated with the R_1 peak. The ordinate in the CPL spectrum indicates the (I_L—I_R) component of luminescence, where I_L and I_R refer to left-handed and right-handed circularly polarized luminescence, respectively. It is well-known that artificial CPL signals are often observed if the emitted light is partially linearly polarized under some conditions.[9] To reduce artifacts in the CPL measurement of a powdered sample, the following precautions were carefully taken. The exciting beam was aligned at 90° angle with respect to the emission direction, and the exciting Argon laser light was aligned so that its linearly polarized **E** vector was aligned in directions parallel to the detective direction of emission.[9] Furthermore, in order to examine the genuiness of the observed CPL spectra, both of the enantiomeric samples (i.e., $[Cr(L\text{-ala})_3]\cdot H_2O$ and $[Cr(D\text{-ala})_3]\cdot H_2O$) were measured, and the luminescent dissymmetry factor g_{em} ($g_{em}=2\times(I_L-I_R)/(I_L+I_R)$) was evaluated for comparisons. The absolute values of g_{em} of the two enantiomers should, in principle, be equal. For the L-ala complex, the g_{em} value of the R_1 line was estimated to be −0.024 and that of R_2 line to be +0.0040. For the D-ala complex, the g_{em} of R_1 was +0.025, while that of R_2 line was −0.0038. These g values agreed in repeated experiments within ca. 10% errors. From these results it was confirmed that these CPL spectra were not caused by any artificial factors but were genuine.

A negative CPL peak was observed at 14185 cm^{-1} in $[Cr(L\text{-ala})_3]\cdot H_2O$, with $g_{em}=-0.021$. This peak may be a vibronic sideband of the R_1 line, since R_1 was found to have a negative sign. The vibrational progression was calculated to be 201 cm^{-1}.

Luminescence and Absorption Spectral Results of $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$. The luminescence spectra of the powdered sample of the binuclear complex are shown at low temperature in Fig. 5. At 43 K (solid curve), there are six peaks at around 14200 cm^{-1}. The peak locations are as follows: 14290, 14258, 14248, 14230, 14200, and 14164 in units of cm^{-1}. The luminescence intensity of these peaks was found to be very weak in comparison with the monomeric L-alaninato complex. A series of similar structures was also found in the 14000 cm^{-1} energy region. They were assigned to the vibronic peaks of 200 cm^{-1} energy relative to a group of 14200 cm^{-1} peaks. As the temperatures were lowered, the luminescence intensities of peaks **1** and **2** became reduced in intensity; at 4 K they completely disappeared.

The absorption spectrum of $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$ is also shown in Fig. 2. Two spin-allowed bands, $^4A_{2g}\rightarrow{}^4T_{2g}$ and $^4T_{1g}$, are red-shifted in comparison with the monomeric complex. This corresponds to the fact that the dimeric complex (N_2O_4 coordination) has a weaker crystal field strength than the monomeric com-

plex (N_3O_3 coordination).

CD and CPL Spectra of $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$. The room-temperature CD spectrum of the dimeric complexes is also shown in Fig. 2. The CD intensity of the dimeric complex is considerably weak in contrast to the CD spectra of the monomeric complexes, and a higher energy CD band ($^4A_{2g}\rightarrow{}^4T_{1g}$) can scarcely be seen. This spectral result can be rationalized by the fact that the dimer has a "*meso*"-type structure, i.e. the absolute configuration around two chromium ions are opposite to each other. Some discussions are given later concerning these results.

Although we have attempted CPL measurements of this complex at 77 K several times, a reproducible CPL signal could not be obtained. The CPL intensity should be too small to be observed within our detection limits.

Discussion

I. Mononuclear Complex, *fac*-$[Cr(L\text{-ala})_3]\cdot H_2O$. The absolute configuration of this almost insoluble pink isomer was determined to be Λ by Gillard et al.[5] According to their report, this chromium complex was found to be isomorphous with *fac*-$[Co(L\text{-ala})_3]$ of the Λ structure.

Spin-Allowed Transitions. The broad bands (Fig. 2), assigned to the transitions $^4A_{2g}\rightarrow{}^4T_{2g}$ and $^4T_{1g}$ (in O_h notation) split in a trigonal crystal field, i.e., the $^4T_{2g}$ (O_h) electronic level must split into two components, ^4E and $^4A_1$. Actually, two CD bands of opposite signs are seen in the $^4T_{2g}$ absorption band in Fig. 2. According to a static crystal field model, Shinada[10] theoretically discussed the CD spectra of trigonally-distorted bidentate Cr(III) and Co(III) complexes in general. The Λ-$[Cr(ox)_3]^{3-}$ (ox=oxalato ion) complex is already known to show a positive CD band at higher energy, and a negative CD band at lower energy in the $^4A_{2g}\rightarrow{}^4T_{2g}$ transition regions. The CD data were reported to be as follows: ν ($\Delta\varepsilon$), 18.1×10^3 cm^{-1} (+2.83), 16.1×10^3 cm^{-1} (−0.12).[11] The higher- and lower-energy bands were assigned to transitions due to the ^4E and $^4A_1$ components. This analysis assumes, in turn, a positive trigonal splitting parameter, K. Considering the second-order rotatory strength, the net rotatory strength of the $^4A_{2g}\rightarrow{}^4T_{2g}$ band was estimated to have a positive value.[10] This theoretical result agrees with the observed spectrum.

A similar assignment can be made for the CD spectrum of $[Cr(L\text{-ala})_3]\cdot H_2O$. Although the actual point symmetry of this molecule is C_3, we analyzed the electronic levels of this complex by assuming a D_3 chromophore. Richardson has extended the static crystal field model[12] so that it can be applied to distorted octahedral complexes. As a result, he concluded theoretically that both the net rotatory strength of the $^4A_{2g}\rightarrow{}^4T_{2g}$ band and the trigonal splitting parameter K are positive for trigonally compressed and azimuthally contracted O_h chromium(III) complexes. This alaninato complex can be reasonably classified to have this type of structure. According to these considerations, it is concluded that the trigonal splitting parameter K of $[Cr(L\text{-ala})_3]\cdot H_2O$ is positive, i.e. the ^4E electronic level lies above the $^4A_1$ level. The observed fact that the net rotatory strength of the $^4A_{2g}\rightarrow{}^4T_{2g}$ transition is positive, i.e. (+) CD component is larger than the (−) CD component, is also consistent with his theory.

It is notable that a comparatively large CD band is observed in the $^4A_{2g}\rightarrow{}^4T_{1g}$ region (in O_h notation). This is attributed to the ^4E component of the $^4T_{1g}$ level, since the $^4A_{2g}\rightarrow{}^4E$ transition is magnetically allowed, but the other transition ($^4A_{2g}\rightarrow{}^4T_2$) is forbidden under D_3 symetry. According to another theory,[13] the $^4A_2\rightarrow{}^4E$ ($^4T_{1g}$) transition borrows CD intensity from $^4A_{2g}\rightarrow{}^4E$ ($^4T_{2g}$) by configuration interaction. The CD sign of this $^4A_{2g}\rightarrow{}^4E$ ($^4T_{1g}$) transition is opposite to that of $^4A_{2g}\rightarrow{}^4E$ ($^4T_{2g}$) if K is positive. The observation of a negative CD sign in the $^4T_{1g}$ band is in accordance with this prediction. However, the matrix element of the configuration interaction, which equals $3K/2$, is too small to interpret the CD intensity. Another mechanism[14] must contribute in addition to the configuration interaction with ^4E ($^4T_{2g}$).

Spin Forbidden Transitions. Two sharp peaks were detected in luminescence at 14424 and 14386 cm^{-1}. The peak locations and the energy separation (38 cm^{-1}) of these two luminescent peaks are in good agreement with the absorption peaks at 77 K. They have been assigned to the split components of the $^2E_g\rightarrow{}^4A_{2g}$ transition by a contribution of trigonal crystal field and spin-orbit coupling. According to Tanabe and Sugano's strong ligand field theory,[15] the splitting of Kramers doublet λ can be expressed as

$$\lambda = E(2\bar{A}) - E(\bar{E}) = 4K\zeta_{so}/(E(^2E_g) - E(^2T_{2g})), \qquad (1)$$

where ζ_{so} denotes the spin-orbit coupling constant. The denominator, $E(^2E_g)-E(^2T_{2g})$, must be negative, and the trigonal splitting parameter, K, being positive (as described in the previous section) is such that the splitting energy, λ, should be negative. The energy difference, $E(^2E_g)-E(^2T_{2g})$, in $[Cr(L\text{-ala})_3]$ was estimated to be −6900 cm^{-1} by considering the position of the $^4T_{2g}$ and $^4T_{1g}$ absorption bands using a conventional Tanabe and Sugano diagram with C/B=4.5. If the K parameter is assumed to be +300 cm^{-1}, we obtain a ζ_{so} parameter of 220 cm^{-1} in energy for λ=−38 cm^{-1}.

It is interesting to quote a large splitting of the ^2E_g state of other amino acid complexes, i.e., λ of *fac*-$[Cr(gly)_3]\cdot 3H_2O$ is 89 cm^{-1}, where gly=glycine.[16] The analysis of a large ^2E splitting is still controversial.[17] However, in the case of the L-alaninato complex, λ is comparable to 29 cm^{-1} in ruby. We conclude that λ should be negative in sign and that the 14424 (R_2) and 14386 (R_1) peaks should be assigned to the transition from the $\bar{E}$ and $2\bar{A}$ states, respectively.

CPL Spectrum of $[Cr(L\text{-ala})_3]\cdot H_2O$. Both positive

and negative CPL peaks were detected in the R line region. For the $[Cr(L\text{-ala})_3]\cdot H_2O$ complex, the R_1 and R_2 peaks show a strong negative peak and a weak positive peak, respectively. Kaizaki et al. have presented theoretical arguments[18] to deduce the rotatory strength of the R lines based on Tanabe and Sugano's perturbation theory. The spin-forbidden transitions acquire both electric and magnetic dipole strengths through spin-orbit coupling from the spin-allowed transitions. In their calculation, only an electronic coupling between the ^2E_g and $^4T_{2g}$ states were taken into consideration, because, in trigonal symmetry, the $^4A_{2g}\rightarrow{}^4T_{2g}$ transitions are allowed in CD absorption, whereas the $^4A_{2g}\rightarrow{}^4T_{1g}$ transitions are forbidden. According to their theory, the rotatory strength of the R lines in trigonal symmetry can be calculated from the rotatory strength of the $^4A_{2g}\rightarrow{}^4E(^4T_{2g})$, $^4A_1(^4T_{2g})$ transitions, as follows:

$$R(\bar{E}) = 8R(^4A_1) + 20R(^4E) \quad (2)$$

and

$$R(2\bar{A}) = 24R(^4A_1) + 12R(^4E), \quad (3)$$

where $R(2\bar{A})$ and $R(\bar{E})$ are the rotatory strength of the R_1 and R_2 lines.

The low-temperature CD or CPL spectra of the R lines of $[Cr(en)_3]^{3+}$ (en=ethylenediamine) doped in a single crystal have already been reported.[19] Since only the axial spectra were measured, the R-line transitions borrow their intensity only from the ^4E component of the $^4T_{2g}(O_h)$ state. According to Eqs. 2 and 3, the axial rotatory strength ratio, $R_{ax}(\bar{E})/R_{ax}(2\bar{A})$, is estimated to be 5/3. Geiser and Güdel observed[19a] an axial circular dichroism of $[Cr(en)_3]^{3+}$ doped in a $2[Ir(en)_3]Cl_3\cdot KCl\cdot 6H_2O$ single crystal. They reported that the CD intensity of the $^4A_2\rightarrow\bar{E}$ transition is slightly larger than that of $^4A_2\rightarrow 2\bar{A}$ transition. The optical activity of single crystals of the spin-forbidden transitions of $[Cr(en)_3]^{3+}$ complex seems to be interpreted by Kaizaki's treatment.

In our case, the complex molecules are randomly dispersed in KBr pellets. We therefore have to take into account the contribution of the $^4A_1(^4T_{2g})$ components. From Eqs. 2 and 3, one can deduce that the signs and magnitudes of $R(\bar{E})$ and $R(2\bar{A})$ are mainly determined by the values of $R(^4E)$ and $R(^4A_1)$, respectively. In the observed spectra, indeed, the signs of the R_1 and R_2 lines in the CPL spectrum coincide with the signs of the $^4A_1$ and ^4E CD bands.

The relative CPL intensity ratios of the two peaks of ^2E are given by

$$\Delta I(\bar{E})/\Delta I(2\bar{A}) = (2+5\alpha)/(6+3\alpha)\times\exp(-\Delta E/k_BT), \quad (4)$$

where $\Delta I(\bar{E})$ and $\Delta I(2\bar{A})$ are CPL intensities of the two peaks, and $\alpha=R(^4E)/R(^4A_1)$ is the rotatory strength ratio of the $^4T_{2g}$ transition, ΔE the splitting of the ^2E_g level, and the k_B the Boltzmann constant. The CPL intensity ratio, $I(\bar{E})/I(2\bar{A})$, was evaluated from the observed 77 K CPL spectra to be −0.15. By employing this value, the calculated α ratio is −0.63. The room-temperature CD spectrum (Fig. 2), however, gives an α ratio of −2.0. This quantity seems not to be agreeable with this treatment.

We now consider some reasons why the theoretical predictions differ from the observations. First of all, we must reconsider the validity of Eqs. 2 and 3, as follows. In the theoretical considerations described so far, only the spin-orbit coupling between the ^2E_g and $^4T_{2g}$ (O_h) levels were considered for calculations of the rotatory strength. Under strict octahedral symmetry, indeed, the ^2E_g level can only mix with the $^4T_{2g}$ level, not with the $^4T_{1g}$ level (theoretically) through a spin-orbit interaction. Furthermore, most chromium complexes have a very small rotatory strength in the $^4A_{2g}\rightarrow{}^4T_{1g}$ region, as compared with the $^4A_{2g}\rightarrow{}^4T_{2g}$ region, so that the contribution from the $^4A_{2g}\rightarrow{}^4T_{1g}$ transition to the CPL intensity in the R lines can be reasonably ignored for ordinary cases. However, for the $[Cr(L\text{-ala})_3]\cdot H_2O$ complex, a large negative CD band, the rotatory strength of which is comparable to that of $^4T_{2g}$, was observed at the $^4A_{2g}\rightarrow{}^4E(^4T_{1g})$ transition (as described before). It should therefore be quite reasonable that the CPL transition of the R lines in trigonal symmetry acquire an additional negative rotatory strength by an introduction of the ^4E component of the $^4T_{1g}$ state. However, in perturbation theory, mixing of the ^4E state with the ^2E state is in inverse proportion to the energy difference, $\Delta E(^4E—^2E)$, the contribution of $^4E(^4T_{1g})$ being about half that of $^4E(^4T_{2g})$. Such a comparatively small negative contribution of the $^4E(^4T_{1g})$ state to the CPL intensity reduces the α value substantially; the observed α value approaches the theoretical value, −0.64. This contribution, however, may not be sufficient to understand the entire CPL intensity.

Secondary, one more assumption concerning Eqs. 2 and 3 must be pointed out. Eqs. 2 and 3 were obtained on the assumption that the trigonal splitting of $^4T_{1g}$ is small. The apparent trigonal splitting of the state, however, is very large (about 20000 cm^{-1}) in the CD spectrum. The actual splitting parameter must be smaller than this (as described in the next paragraph) and the difference between $\Delta E(^2E—^4E(^4T_{2g}))$ and $\Delta E(^2E—^4A_1(^4T_{2g}))$ must be considered. For the alaninato complex, since the energy of the $^4A_1(^4T_{2g})$ state is lower than that of $^4E(^4T_{2g})$, the coefficients of $R(^4A_1)$ become larger and those of $R(^4E)$ become smaller for Eqs. 2 and 3. Consequently, the theoretical value approaches the experimental value.

Thirdly, we examine the experimental value of α obtained from CD data. Since the rotatory strength of the $^4A_1$ and ^4E components of the $^4T_2$ band should have different signs, it is very difficult to correctly resolve the $^4T_2$ band into two components. An apparent splitting of the $^4T_2$ band in Fig. 2 is estimated to be 2000 cm^{-1}; this gives a trigonal splitting parameter of K=1300 cm^{-1}. The obtained K value is too large in comparison

with that of ordinary chromium(III) complexes. Clearly, an overlapping of two components of the $^4T_2$ band must occur; it is therefore difficult to estimate the correct α value from the spectrum.

No further quantitative discussion can be presented because of theoretical and experimental ambiguities. We think that the quantitative disagreement of the theoretical and experimental values results from a combination of the above-mentioned causes. However, it should be mentioned here that the signs of the CPL peaks of the R lines correspond to those of the CD bands. Therefore, Eqs. 2 and 3 are very useful expressions to qualitatively explain the CPL spectra of trigonal chromium(III) complexes.

We consider the g_{em} value of a vibronic peak. A single vibronic peak was clearly observed in the CPL spectrum. In general, it is hard to predict the rotatory strength of a vibronically induced transition which strongly depends on the nature of the vibration modes. According to the Herzberg–Teller mechanism, it is shown that if the vibronic band is coupled with e-mode vibrations, the dissymmetry factor, g, is smaller in vibronics than in their electronic origin.[19a] Geiser and Güdel[19a] have considered the vibronic CD intensity of $[Cr(en)_3]^{3+}$ at low temperatures. They obtained very small g_{abs} values for almost all of the peaks which are coupled with e-mode vibrations. Still, they found some interesting vibronic levels, the g_{abs} values of which are 0.5—4 times larger in magnitude with respect to their electronic origins. These prominent vibronic peaks are assigned to correspond to totally symmetric vibration. Peacock and Stewart[19b] reported that the g_{em} values for the R lines are 0.19 in the CPL of $[Cr(en)_3]^{3+}$. The g_{em} values of the vibronic bands seemed not to be as large as those of the electronic origin.

In the CPL spectra of $[Cr(L\text{-ala})_3]\cdot H_2O$, the g_{em} value of a peak seen at 14185 cm^{-1} was found to be −0.021, which is almost equal in magnitudes to −0.024 at the electronic origin. Considering the above-mentioned arguments, this peak is assigned to be a vibronic peak of R_1 coupled with a symmetric vibrational mode.

II. Binuclear Complex, $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$. Electronic Eenergy Levels of Chromium Pair States. A series of peaks observed at low temperature (Fig. 5) can be interpreted as being due to the luminescence of a pair of chromium(III) ions. The ground state $|^4A_{2g}{}^4A_{2g}>$ are usually well described by the eigenvalues of the Hamiltonian,[20]

$$H = JS_1\cdot S_2 - j(S_1\cdot S_2)^2, \tag{5}$$

where J denotes an isotropic exchange parameter, j is the biquadratic contribution and S_1, S_2 are the spin quantum numbers of the Cr(1) and Cr(2) ions, respectively. The exchange interactions lead to a splitting of the ground state into four spin sub-levels, denoted by S_t=0, 1, 2, and 3, where S_t is total spin quantum number,

$$S_t = S_1 + S_2, \tag{6}$$

At 4.2 K, four peaks were detected in luminescence (peak number **3**, **4**, **5**, and **6** in Fig. 5). They have been assigned to a transition from the lowest excited electronic levels to the ground pair states. According to Eq. 5, the theoretical energy splitting between the neighboring pair levels are calculated to be $J+13j/2$, $2J+7j$, and $3J-9j/2$ for the S_t=0, 1, 2, and 3, respectively. From the observed peak separations (18, 30, and 36 cm^{-1}) the exchange parameters were calculated to be J=13.3 cm^{-1} and j=0.6 cm^{-1}. These energy levels are illustrated in Fig. 6. The J value of this complex is consistent with that of 17.1 cm^{-1}, which was deduced from magnetic susceptibility measurements while neglecting the j terms.[21] At higher temperatures, some

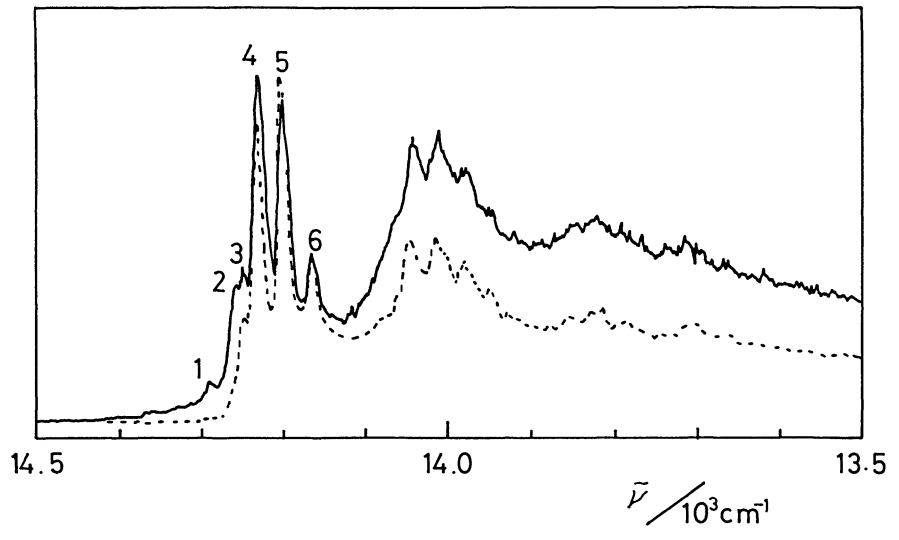

Fig. 5. Luminecsence spectra of $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$. (——) at 43 K and (– – –) at 16 K.

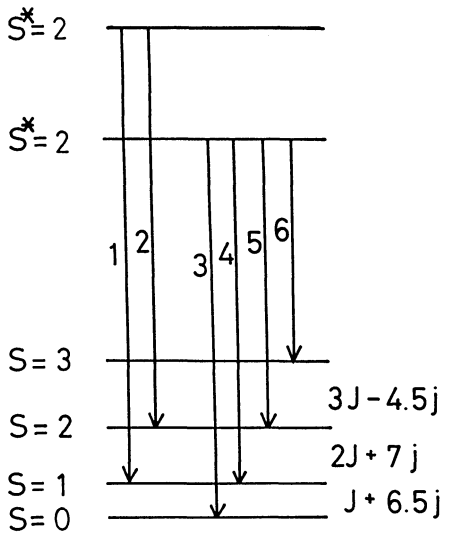

Fig. 6. Energy level diagram of exchange-coupled pair states in $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$.

high-energy peaks (peak number **1** and **2**) grow in intensity; these have been assigned to the transition from the next higher excited state. The interval between the lowest and the next-higher excited states was determined to be 42 cm^{-1}. The total spin numbers of the excited pair states were supposed from the peak intensity, as follows. The $|^4A_{2g}{}^2E_g>$ pair state comprises four triplet (S_t*=1) and four quintet (S_t*=2) states. The observed transitions occur from these excited states and ground pair states (S_t=0, 1, 2, and 3). Two mechanisms[22] are possible to obtain the optical intensity in the pair system. They are a single ion mechanism and an exchange mechanism. The ΔS=0 transition is allowed by both mechanisms; thus, this ΔS=0 transition generally gives the most intense luminescence. Since the luminescence spectrum at 4 K (Fig. 5) shows that peak **5**, which is assigned to the S_t=2 state, is the most intense, the total spin number of the lowest excited state is determined to be 2 (see Fig. 6). A small peak, **3**, is assigned to the transition from S_t*=2 to S_t=0. Although both mechanisms cannot explain a ΔS=2 transition, a weak ΔS=2 transition had already been reported for μ-$(OH)_2$-$[Cr_2(OH)_2(en)_2]^{2+}$.[23] Since, no distinct peak assigned to the transition from the next lower excited state to the S_t=0 ground state could be observed, the next excited state may also be assigned to S_t*=2.

Optical Activity of $[Cr_2(L\text{-ala})_4(OH)_2]\cdot 3H_2O$. We were not successful in detecting the CPL spectra for this binuclear complex. It has already been shown[6] that the structure of this complex is of the "*meso*" type, i.e., one chromium moiety has a *Λ* configuration and the other has *Δ* (Fig. 1). Accordingly, the entire optical activity was smaller than that of the monomeric complex, $[Cr(L\text{-ala})_3]\cdot H_2O$. The CD intensity of the dimeric complex is, indeed, one third of the monomer (see Fig. 4). Furthermore, the total luminescence intensity of this dimer was found to be considerably lower than that of the corresponding monomer. It is reasonable to think that no CPL spectrum could be obtained at the present stage.

Conclusion. We have obtained the following results from the luminescence and CPL spectra of chromium alaninato complexes:

(1) Sharp luminescence and CPL spectra were obtained at low temperatures in the R-line energy regions for $[Cr(L\text{-(or D-)ala})_3]\cdot H_2O$. The CPL spectral features are qualitatively well explained if we assume that the rotatory strength of the R lines are mainly determined by contributions from the trigonally split components of the allowed $^4A_{2g}\rightarrow{}^4T_{2g}$ transitions. However, both theoretical and experimental difficulties prevent us from obtaining any quantitative discussion regarding the limit of crystal-field theory.

(2) Highly structured luminescence spectra of $[Cr_2(OH)_2(L\text{-ala})_4]\cdot 3H_2O$ were observed and interpreted by a Heisenberg-type of an exchange-coupled system. The exchange parameters were determined as being J=13.3 cm^{-1} and j=0.6 cm^{-1}. The CPL spectrum, however, was not observed, since this complex is considered to be a *meso*-type dimer complex.

X-Ray Crystal Structures of Octahedral Diaquabis(*N,N*-dialkylethylenediamine)nickel(II) Complexes Possessing Elongated Nickel(II)-Nitrogen Bonds along Axial Direction

Yoshinori IHARA, Yasuhiro SATAKE,† Yumi FUJIMOTO, Hitoshi SENDA,††
Masatatsu SUZUKI,† and Akira UEHARA*,†
Laboratory of Chemistry, Faculty of Education, Kanazawa University, Kanazawa 920

(Received January 9, 1991)

The structures of two diaquabis(*N,N*-dialkylethylenediamine)nickel(II) chlorides ($[Ni(H_2O)_2(diamine)_2]Cl_2 \cdot nH_2O$) were determined by X-ray crystallographic studies, where diamine is *N,N*-dimethylethylenediamine(*NN*-dmen) or *N,N*-diethylethylenediamine (*NN*-deen). Both complexes are trans and crystallize in the monoclinic space group $P2_1/n$. The unit cell parameters of the *NN*-dmen complex, $NiCl_2C_8N_4O_4H_{32}$, are a=7.531(1), b=13.092(1), c=9.591(1) Å, β=107.76(1)°, and Z=2, and those of the *NN*-deen complex, $NiCl_2C_{12}N_4O_2H_{36}$, are a=9.154(1), b=8.692(1), c=12.395(2) Å, β=104.46(1)°, and Z=2. In *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$ and *trans*-$[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2$, the Ni–$NMe_2$ and Ni–NEt_2 bond distances (2.183 and 2.271 Å) are much longer than the Ni–NH_2 distances (2.078 and 2.064 Å), forming tetragonally distorted octahedrons with four close in-plane neighbors(N_2O_2) and two remote axial ones(N_2). It is apparent that this distortion originates from the steric requirement of N-substituted groups. Such a distortion significantly affects the electronic spectra of these complexes.

We have studied on the coordination structures of various octahedral diaquabis(N- or C-substituted ethylenediamine)nickel(II) complexes and the products of their thermal reactions, and also on the effects of N- or C-substituent group(s) upon their structural changes during thermal treatments.[1-5] In general, the diaqua complexes could readily be characterized to be trans from the feature of their electronic spectra in near IR region, and they changed to the corresponding dianiono species upon thermal deaquation-anation, retaining trans configuration as shown below.[1,2]

$$\textit{trans}\text{-}[Ni(H_2O)_2(diamine)_2]X_2 \xrightarrow{-2H_2O} \textit{trans}\text{-}[NiX_2(diamine)_2]$$

The diaqua complexes with *N,N*-dialkylated ethylenediamines, however, showed a somewhat obscure splitting or a red shift of the two bands in near IR region, compared with a typical trans spectrum. In addition, some of these complexes peculiarly produced cis dianiono complexes by thermal treatment.[6] Accordingly, to understand the unusual spectra and thermal behaviors of these asymmetric diamine complexes, the structures of the octahedral diaqua complexes with *NN*-dmen (*N,N*-dimethylethylenediamine) and *NN*-deen (*N,N*-diethylethylenediamine) were determined by X-ray crystallographic studies in the present study.

Experimental

The complexes, *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$ (**A**) and *trans*-$[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2$ (**B**) were prepared by the known methods.[7,8] The single crystals of the former grew as violet blocks upon slow evaporation from the ethanolic solution containing stoichiometric amounts of the diamine and nickel(II) chloride hexahydrate, and those of the latter were obtained as blue blocks by recrystallization from methanol.

The unit-cell parameters and intensities were measured on a Rigaku AFC-5R automated four-circle diffractometer using graphite-monochromatized Mo $K\alpha$ (λ=0.71073 Å) radiation at room temperature. The 2θ–ω scan mode at a rate of 6° min^{-1} was employed to record the intensities. The intensity data were corrected for Lorentz-polarization and absorption effects. Both structures were solved by the heavy atom method and refined by the block-diagonal least-squares method. Calculations were performed with the TEXSAN Structure Analysis software package on microVax II and with the UNICS III programs[9,10] on a FACOM 760/10 computer at the Kanazawa University Information Processing Center. a) Lattice water.

(A) (B)

Fig. 1. Crystal structures of the complex cations; (A) *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]^{2+}$, which involves disorder, and (B) *trans*-$[Ni(H_2O)_2(NN\text{-deen})_2]^{2+}$.

The nickel(II) ion lies at a center of symmetry. Two coordinated waters of the complexes occupy trans positions of the N_4O_2 octahedrons and the two alkylated nitrogen atoms (N(1)) occupy axial sites apart from each other to minimize their mutual steric hindrance. Complex **A** shows a disorder of gauche and eclipsed five-membered chelate rings: C(4) and C(5) methyl carbon atoms belong to C(1) methylene one of gauche form. The relative occupancy of the dislocated atoms C(1) (C(4), and C(5)) and C(3) (C(6) and C(7)) is 0.75 : 0.25:[11] namely gauche form is predominant in the crystal. All chloride ions (not shown) fall within a distance of hydrogen bonding with adjacent amino group and either coordinated water or lattice water.[12]

The selected bond distances and angles are listed in Tables 3 and 4 for the *NN*-dmen and *NN*-deen complexes, respectively. It can be seen that the common striking characteristic in these structures is the elongated nickel(II)-nitrogen(N(1)) bonds along axial direction: the Ni–N(1) bond distances (2.183(2) Å for the *NN*-dmen and 2.271(3) Å for the *NN*-deen complexes) are much longer than the Ni–N(2) ones (2.078(2) Å for the former and 2.064(3) Å for the latter), so that tetragonally distorted octahedrons with four in-plane neighbors (N(2)N(2′)OO′ or N(2)N(2′)O(1)O(1′)) and two remote axial ones (N(1)N(1′)) are formed rather than familiar N_4(plane)O_2(axial) octahedrons.[13,14] Such distortion is noticeable in the *NN*-deen complex. The relevant bond distances in analogous nickel(II) complexes are collected in Table 5 along with our results. Similar elongated Ni–NR_2 bonds are observed in complexes **1**—**3**, which also contain either *NN*-dmen or *NN*-deen. It is additionally found that the distances of Ni–N bonds increase in the order of Ni–NH_2<Ni–NHR<Ni–NR_2.

a) *NN*′-dmen=*N,N*′-dimethylethylenediamine; *NN*′-deen=*N,N*′-diethylethylenediamine; *m*-stien=*meso*-1,2-diphenyl-1,2-ethanediamine; *dl*-chxn=*dl*-1,2-cyclohexanediamine.

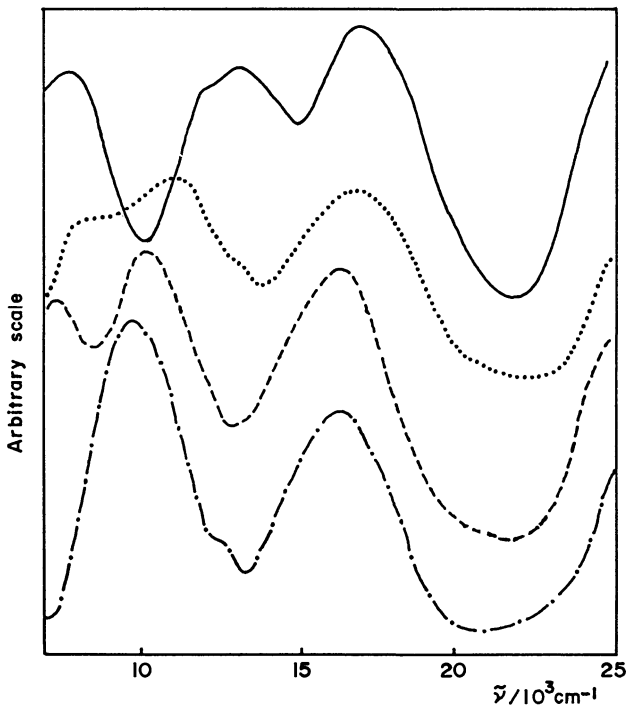

Fig. 2. Electronic spectra of *trans*-$[Ni(H_2O)_2(diamine)_2]Cl_2 \cdot nH_2O$, where diamine is *NN'*-dmen (——), *NN*-dmen (·····), or *NN*-deen (——), and of *cis*-$[Ni(H_2O)_2(NN\text{-dmen})_2]I_2$ (— - —). (*NN'*-dmen is *N,N'*-dimethylethylenediamine.)

It is thus apparent that these tetragonal distortions of complexes **A** and **B** originate from the steric requirement of N-substituted groups.

The electronic spectra of the two complexs are shown in Fig. 2, together with those of *trans*-$[Ni(H_2O)_2(NN'\text{-dmen})_2]Cl_2$ and *cis*-$[Ni(H_2O)_2(NN\text{-dmen})_2]I_2$ which are typical of trans and cis configurations, respectively.[15] Compared with the typical trans spectrum, it can be seen that complex **A** shows a somewhat obscure splitting of the two bands in near IR region, and complex **B** shows a red shift of all the bands in their spectra. These spectra can now be interpreted in terms of the above structural results: in comparison with the symmetric diamine complexes, it is anticipated that (1) the difference between ligand field strength along O–O axis and that in N_4 rhombus becomes small because of the elongation of the $Ni–NMe_2$ (or $–NEt_2$) bond length, and (2) the overall ligand field strength becomes weak (cf. the data of complexes **4** and **5** in Table 5). The effects of (1) and (2) should be responsible for the somewhat obscure splitting and the red shift of the bands in their spectra, respectively.

Both *trans*-diaqua complexes were transformed into the *cis*-dichloro complexes upon thermal deaquation-anation.[6] This is contrary to the complexes with the symmetric diamines which show simple deaquation-anation retaining a trans configuration. The differences in their reactivities seem to be related to the finding that the bonds between nickel(II) and the alkylated nitrogen atom are much weaker than the other coordination bonds in the asymmetric diamine complexes: it appears reasonable to assume that, in the case of the complexes with the asymmetric diamines, the rupture of a $Ni–NR_2$ bond precedes the liberation of the coordinated water, providing a driving force for these peculiar reactions.

Effect of Water Vapor on the Formation of Lithium *cyclo*-Hexaphosphate

Hiroyuki NARIAI,* Itaru MOTOOKA, and Mitsutomo TSUHAKO†
Department of Chemistry, Faculty of General Education, Kobe University, Tsurukabuto, Nada-ku, Kobe 657
†Kobe Women's College of Pharmacy, Kitamachi, Motoyama, Higashinada-ku, Kobe 658
(Received February 4, 1991)

The effect of water vapor on the formation of lithium *cyclo*-hexaphosphate $Li_6P_6O_{18}(P_{6m})$ from trilithium hydrogenpyrophosphate monohydrate $Li_3HP_2O_7 \cdot H_2O$ was investigated by means of DTA-TG, X-ray diffraction analysis, isothermal heating with electric furnace, and HPLC. $Li_3HP_2O_7 \cdot H_2O$ lost the water of crystallization at about 180 °C to give anhydrous $Li_3HP_2O_7$. At 300 °C the disproportionation of $Li_3HP_2O_7$ anhydride to $Li_4P_2O_7$ and $Li_4P_4O_{12}$ (P_{4m}) proceeded faster under humid conditions than under dry air, and subsequently P_{4m} increased with a decrease in P_2 and soluble polyphosphates (P_{poly}). At 400 °C, P_{4m} changed largely to P_{6m} under humid conditions. In these reaction processes, water plays an important role as catalyst in the cyclization by dehydration of the end group and in ring opening by attacking the P–O–P bond. At 450 °C, the amounts of P_2 and P_{6m} were almost equal under both humid and dry conditions, because all of P_{4m} thermally changed to P_{6m}.

It is well known that phosphates hydrolyze or condense on heating to form various kinds of phosphates.[1–4] Some types of them, linear and cyclic phosphates, have been investigated from the viewpoint of their thermal behavior.[5–21] These phosphates have been used for water treatment, as food additives, detergents, catalysts, and components of laser materials, and in phosphate glasses, and so forth.[22–26] The practical importance of these phosphates has been reviewed.[27]

In the syntheses of these phosphates, several factors including the nature of the metal, the temperature, the atmosphere, the time and rate of heating, and the state of the starting material, influence the structure and composition of the products. However, many works have been carried out on the thermal behavior of these phosphates without adequate consideration of the above-mentioned factors.

In a previous paper[28] we reported that, when lead *cyclo*-tetraphosphate decomposed to lead *cyclo*-octaphosphate, the cyclic phosphates were prepared optimally at a low water-vapor pressure, while linear phosphates were produced at a high water-vapor pressure.

The synthesis and thermal behavior of formation of lithium *cyclo*-hexaphosphate was investigated by Griffith and Buxton in 1965.[29] Schülke and Kayser reported a detailed formation mechanism in 1985.[30]

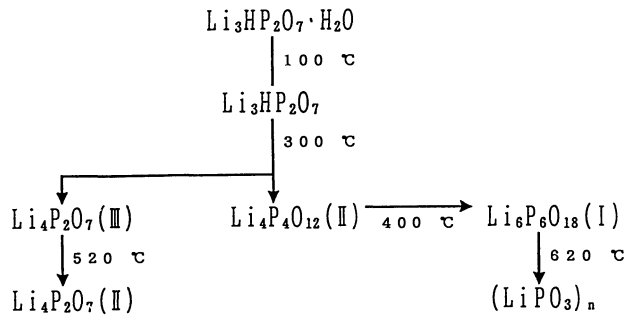

Fig. 1. Thermal dehydration processes of $Li_3HP_2O_7 \cdot H_2O$ as described by Schülke and Kayser.

Figure 1 shows the formation process of *cyclo*-hexaphosphate proposed by Schülke and Kayser.[30] $Li_3HP_2O_7$ changes to $Li_4P_2O_7$(III) and $Li_4P_4O_{12}$(II) by disproportionation at around 300 °C, followed by the transformation of $Li_4P_4O_{12}$(II) to $Li_6P_6O_{18}$(I) at around 400 °C. In spite of extensive works on the formation mechanism of *cyclo*-hexaphosphate, the yield of product exhibits a heavy scatter among the published results. A dominant cause for such a scatter appears to be a difference in the heating atmosphere from one experiment to another. In view of this, the effect of water vapor on the formation of lithium *cyclo*-hexaphosphate from trilithium hydrogenpyrophosphate monohydrate on heating was investigated in the present work.

Experimental

Chemicals. Trilithium hydrogenpyrophosphate monohydrate $Li_3HP_2O_7 \cdot H_2O$ was prepared by the method given in the literature.[30] Guaranteed reagent sodium pyrophosphate decahydrate ($Na_4P_2O_7 \cdot 10H_2O$) was used after double recrystallization. Other chemicals were of guaranteed reagent from Wako Chemical Industries, Ltd. and were used without further purification.

Determination of Lithium, Phosphorus, and the Water of Crystallization. Atomic absorption analysis was used for the determination of lithium ion in the sample solution with a Hitachi atomic absorption spectrophotometer Model 207. The total amount of phosphorus in phosphates was determined by absorptiometry after hydrolyzing the condensed phosphates with dilute hydrochloric acid. The condensed phosphates obtained by calcination were separated by HPLC, and then each phosphate was determined by the Molybdenum Blue Method.[18,20,21,28,31] The amount of the water of crystallization was calculated from the weight loss in TG curves. Other analytical procedures and apparatus were essentially the same as those used in previous works.[18,28]

Results and Discussion

Thermal Decomposition of the Phosphates Examined by DTA-TG. Figure 2 shows the DTA-TG curves for

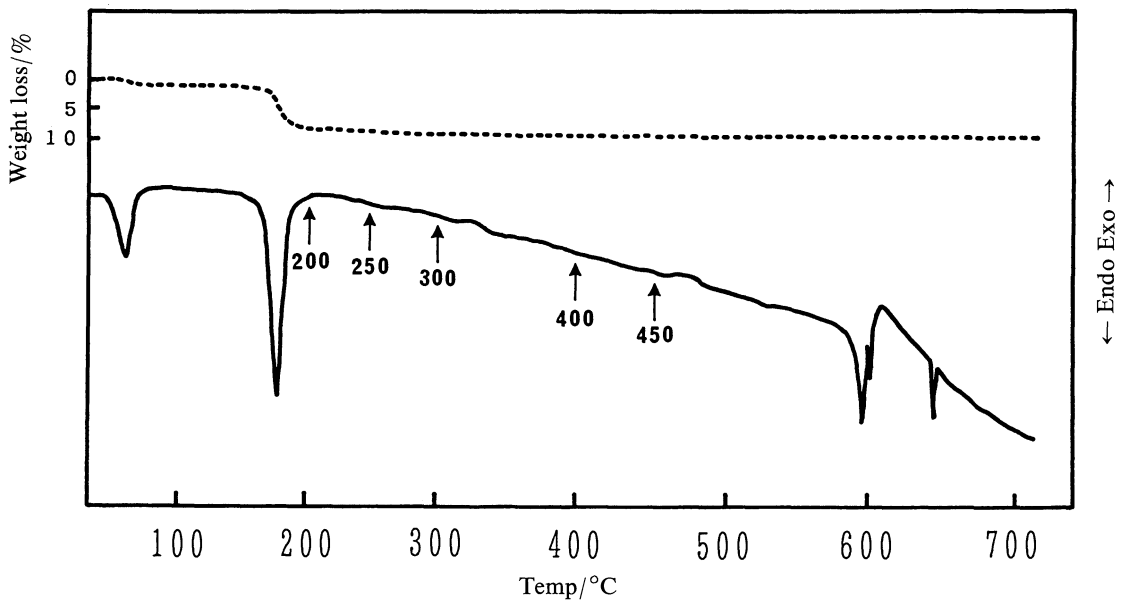

Fig. 2. DTA-TG curves for $Li_3HP_2O_7 \cdot H_2O$. Solid line: DTA, dotted line: TG.

$Li_3HP_2O_7 \cdot H_2O$ at atmospheric pressure. Endothermic peaks are noted at about 50, 180, 600, and 640 °C. From the HPLC analytical results, the first endothermic peak accompanying a small weight loss at 50 °C seemed to be due to liberation of absorbed acetone, and/or methanol, and/or water, since no change took place in the X-ray diffraction pattern of $Li_3HP_2O_7 \cdot H_2O$. The second endothermic peak with a large weight loss at 180 °C was attributed to elimination of the water of crystallization. HPLC analysis showed that anhydrous $Li_3HP_2O_7$ alone was present in the sample heated at 200 °C. No change in the TG curve occurred at temperatures above 300 °C. From the HPLC analysis, the products were found to be P_2, P_{4m}, and P_{poly} at 300 °C, P_2, P_{4m}, and P_{6m} at 400 °C, and P_2 and P_{6m} at 500 °C. The sample melted at around 600 °C. HPLC results indicated that P_{6m} and P_2, and P_{4m} and P_2 were present before and after the endothermic peak at 600 °C, respectively. Lithium metaphosphate (polymetaphosphate) was observed after the endothermic peak at 640 °C.

Isothermal Change. Although the DTA-TG curves do not exhibit definite peaks in the 200—500 °C region in Fig. 2, P_2 gradually changed to P_{4m} and/or P_{6m} and/or P_{poly}. Therefore, the influence of water vapor on the thermal decomposition was examined by heating $Li_3HP_2O_7 \cdot H_2O$ at 200, 250, 300, 400, or 450 °C for 1 h in air of 0 or 90% (at 25 °C) relative humidity. Figure 3 shows the X-ray diffraction patterns of the sample heated in dry air. In the 200—300 °C region, the diffraction lines of $Li_3HP_2O_7$ anhydride are dominant. At 400 °C, the characteristic diffraction lines of P_2(III) at 2θ=21.2°, and P_{4m}(II) at 2θ=17.5, 26.8, and 30.3° began to appear. At 450 °C, the diffraction lines of P_{4m}(II) disappeared, and those of P_{6m}(I) at 2θ=18.6, 19.2, 22.4, 23.7, and 33.6°, and P_2(II) at 21.2, 27.4, 28.5, 35.6, and

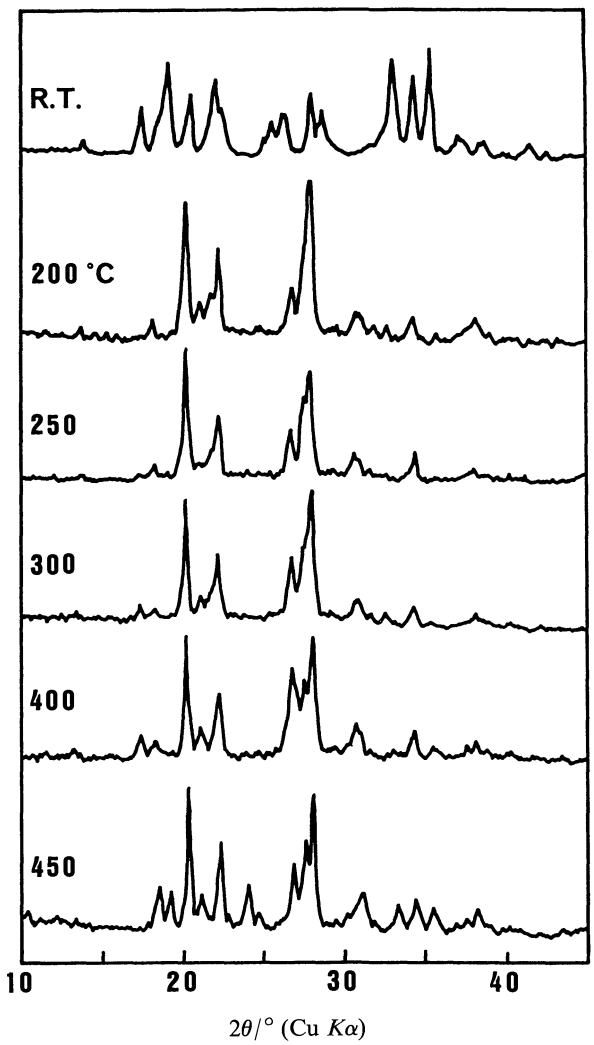

Fig. 3. X-Ray diffraction patterns of products in the course of heating. Sample: $Li_3HP_2O_7 \cdot H_2O$, relative humidity: 0%. R.T. is room temperature.

Table 1. Changes in the Amounts of Phosphates (Starting Material: $Li_3HP_2O_7 \cdot H_2O$)

Temp/°C	Compound[a] R.H.[b]/%	P_2 %	P_{4m} %	P_{6m} %	P_{poly} %
200	0%	93.5			6.5
	90%	96.5			3.5
250	0%	88.0	7.9		4.1
	90%	90.1	8.7		1.2
300	0%	79.4	15.9		4.7
	90%	69.7	28.4	1.9	
400	0%	66.3	30.8	2.9	
	90%	65.7	17.9	16.4	
450	0%	65.0		35.0	
	90%	65.1		34.9	

a) P_{4m}, P_{6m}, and P_{poly} represent *cyclo*-tetra-, *cyclo*-hexa-, and polyphosphates, respectively. P_2 represents the sum of diphosphates of $Li_3HP_2O_7$ and $Li_4P_2O_7$. P% denotes the percentage of phosphorus atoms present in these phosphate anions. b) Relative humidity at 25 °C.

38.0° began to appear. The persistence of the diffraction lines of $Li_3HP_2O_7$ anhydride at 450 °C in Fig. 3 indicates that the starting material remains even at this temperature.

Table 1 summarizes the changes in the amounts of phosphorus compounds in the samples. At 200—250 °C, a decrease in the amount of P_2 is accompanied by a 5-% level formation of P_{poly}. The condensation reaction was somewhat faster in dry air than in humid air. At 250 °C, P_{4m} was formed at about 8% in both dry air and humid air: the influence of atmosphere is hence negligible at this temperature. At 300 °C, P_{4m} increased with a decrease in P_2. In 90% relative humidity this trend was significant, and further P_{6m} was formed in a slight amount and P_{poly} was lost. At 400 °C, a fairly large amount of P_{4m} was convented into P_{6m}, particularly in 90% relative humidity. At 450 °C, the amounts of P_2 and P_{6m} were almost equal under both atmospheric conditions, since all the P_{4m} formed by the disproportionation changed to P_{6m}.

These results clearly show that a dry atmosphere is more favorable for the dehydration reaction at temperatures below about 300 °C, while a humid atmosphere is more favorable for the thermal process at above 300 °C where P_2 and P_{poly} change to P_{4m} and further to P_{6m}. In the processes at above 300 °C, water most probably plays a role of catalyst; the water molecule accelerates the ring opening by attacking the P–O–P bond, and promotes the difussion and recombination of the radicals formed by the ring opening.

Chromatographic Optical Resolution Based on the Chiral Discrimination between Ions of the Same Sign, Anionic Cobalt(III) Complex Racemates and Anionic Selector $[Sb_2(d\text{-tart})_2]^{2-}$

Norio KOINE

(Received December 10, 1990)

Column chromatographic optical resolutions of twenty-six typical univalent anionic cobalt(III) complexes, e.g., $[Co(edta)]^-$ and *fac*-$[Co(NO_2)_3(edma)]^-$, were carried out, using as a chiral eluent an aqueous solution of $[Sb_2(d\text{-tart})_2]^{2-}$ on a strongly basic anion exchanger, where edta=ethylenediamine-*N,N,N',N'*-tetraacetate(4-), edma=ethylenediamine-*N*-acetate(1-), and *d*-tart=*d*-tartrate(4-). The racemates were resolved with separation factors comparable to those obtained in conventional resolutions by use of cationic selectors. From a comparison of elution orders of enantiomers and separation factors obtained for the racemates, a chiral discrimination mechanism without direct contact between the racemate and selector was proposed.

Chromatographic complete resolution of anionic metal complexes is difficult to achieve compared with that of cationic ones, although many attempts have been made from of old.[1–3] The first complete resolution of anionic complexes was achieved for $[Co(ox)_2(gly)]^{2-}$[4] by use of Λ-$[Co(en)_3]^{3+}$ as a selector (resolving agent) by Tatehata et al.[5] in 1981. Since then complete resolutions of several anionic cobalt(III) complexes have been attained by Tatehata et al.[6] and Yoneda et al.,[3,7–9] but the selectors used have been limited to cations, cationic metal complexes and alkaloid cations. In such systems, the resolution is governed by the chiral discrimination between ions of opposite signs. We have recently reported of a complete resolution based on the chiral discrimination between ions of the same sign: anionic racemates, *cis*(*N*)-$[Co(ida)_2]^-$ and $[Co(edta)]^-$, were resolved by an anionic selector $[Sb_2(d\text{-tart})_2]^{2-}$ on a strongly basic anion exchanger.[10] This resolution technique was first adopted on a DEAE-Sephadex (DEAE=2-(diethylamino)ethyl) column by Yoshikawa and Yamasaki[2] but resulted in unseparated elution curves with partial resolution. The efficiency of our resolutions is comparable to that obtained by the chiral discrimination between ions of opposite signs.[3,5–9] Such an unexpectedly high ability of discrimination is of interest for the stereoselective interaction in general between charged species, particularly in connection with weak chemical interactions important in biological systems.[11]

Chiral discrimination phenomena dependent on diastereomeric interactions have been recognized between ions of the same sign, in spite of the occurrence of interference with the mutual approach of ions by the inevitable electrostatic repulsion. Discriminatory interactions in cation–cation systems have been recognized as phenomena such as the Pfeiffer effect (the displacement of enantiomer equilibrium of a labile racemic complex caused by an optically active "environment substance")[9,12–14] and optical resolution.[15] On the other hand, phenomena in anion-anion systems have rarely been reported[16] except for the above observation.[2,10] Although the mechanism of chiral discrimination for the phenomena observed has been widely examined, its nature has not yet been clearly elucidated.[12–19] Furthermore, the phenomena have strangely been manifested only for systems containing racemic complexes with N-heterocyclic unsaturated ligands, such as 1,10-phenanthroline and 2,2'-bipyridine. Under these circumstances, further investigation on the present phenomenon, which occurs between anions having no unsaturated ligands, can be expected to provide important information regarding the origin of chiral discrimination.

The present work deals with chromatographic optical resolutions of a series of typical anionic cobalt(III) complexes by our method.[10] The mechanism of chiral discrimination will be discussed on the basis of the relation between the resolution behavior of enantiomers and the structure of complexes.

Experimental

Materials. The twenty-six racemic cobalt(III) complex anions (**1a**—**11**) used in this work are listed in Table 1, where the complexes are numbered with the same numeral for the same type of complexes. All these anions have been isolated as their sodium or potassium salts and their structures have been well characterized. Optical resolution has been achieved except for *unsym*-$[Co(ox)(aeida)]^-$ (**5a**). Absolute configurations have been determined on the basis of X-ray crystallographic, circular dichroism (CD) spectral, or stereochemical analysis, except for the aeida (**5a**[20] and **5b**[21]) and edma (**7**)[22] complexes: **1a**, **1b**, **1d**—**4**, and **6a** in a review by Radanović,[23] **1c**,[8] **6b**—**6e**,[24] **8a**, **9a**, **10a**,[25] **8b**, **9b**, **10b**,[26] and **11**.[27] Three (**1a**, **1b**, and **11**) of these complexes were determined X-ray crytallographically.

The optical resolution of the racemic *unsym*-K[Co(ox)(aeida)]·H_2O (**5a**)[20] was achieved by an up-scaled present type chromatography and the resolved complex was isolated as a potassium salt, $(+)^{CD}_{567}$-*unsym*-K[Co(ox)(aeida)]·$3H_2O$, from an eluate containing the early eluted enantiomer. Found: C, 23.33; H, 3.97; N, 6.66%. Calcd for K[Co(ox)(aeida)]·

$3H_2O$=$KCoC_8H_{16}N_2O_{11}$: C, 23.20; H, 3.89; N, 6.76%. $[\alpha]_D$= +300°. $\Delta\varepsilon_{max}$=+1.82 (at 567 nm), −0.71 (497), and +0.23 (375).

The selector potassium bis(*d*-tartrato)diantimonate(III) trihydrate, $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$, was commercially available.

Chromatographic Resolution. The strongly basic anion-exchanger used was derived from Toyopearl (Fractogel TSK) HW50s gel (20—40 μm on swelling in water) in this laboratory.[10] The exchanger of form $[Sb_2(d\text{-tart})_2]^{2-}$ was packed in a glass column (1.0 cm×80 cm) and about 5 mg of a racemic cobalt(III) complex was loaded on the top of the column. The adsorbed band was eluted with 0.02 mol dm^{-3} aqueous solution of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$. The elution rate was regulated to 0.25—0.27 cm^3 min^{-1} by a Pharmasia LKB 2132 type peristaltic pump. The elution curve was recorded at the wavelength of the first absorption maximum of the complex on a Shimadzu SPD-6AV spectrophotometric detector. The elution order of the enantiomers was determined by measuring CD spectra of fractional eluates.

Measurements. Elemental analysis was carried out at the Advanced Instrumentation Center for Chemical Analysis, Ehime University. The CD spectra were recorded on a JASCO J-20 spectropolarimeter using a 1.0 cm cell at room temperature.

Results and Discussion

Absolute Configuration of the Cobalt(III) Complexes. As described in the Experimental section, the absolute configurations of the three complexes, *unsym*-$[Co(ox)(aeida)]^-$ (**5a**), *unsym*-$[Co(NO_2)_2(aeida)]^-$ (**5b**), and *fac*-$[Co(NO_2)_3(edma)]^-$ (**7**), are unknown. The ring-pairing method cannot be applied to the absolute configurations of these complexes, because the complexes lack the net ring-pairing chirality.[28,29] Fortunately, the absolute configuration of *fac*-$[Co(edma)(NH_3)_3]^{2+}$, which has the same chromophore (CoN_5O) as *fac*-$[Co(NO_2)_3(edma)]^-$, has been determined: $(+)^{CD}_{512}$-*fac*-$[Co(edma)(NH_3)_3]^{2+}$ has an (*S*)-configuration with respect to the secondary nitrogen atom of the coordinated edma.[30] The CD curve of the early eluted enantiomer of *fac*-$[Co(NO_2)_3(edma)]^-$ ($\Delta\varepsilon_{max}$=+1.095 (at 485 nm) and −0.822 (at 427 nm))[22] shows the same general shape and sign pattern in the first absorption region as that of the (*S*)-isomer of *fac*-$[Co(edma)(NH_3)_3]^{2+}$ ($\Delta\varepsilon_{max}$=+1.641 (at 512 nm) and −0. 811 (at 444 nm)).[30] By comparison of the CD curves, thus, the absolute configuration of the early eluted enantiomer, $(+)^{CD}_{485}$-*fac*-

a) The mean value for the enantiomers. b) The void volume is not considered for the estimation of factor. c) Racemic $[Co(pdta)]^-$ and $[Co(cydta)]^-$ are an equimolar mixture of the enantiomers *Λ*-$[Co\{(R)\text{-pdta}\}]^-$ ··· *Λ*-$[Co\{(S)\text{-pdta}\}]^-$ and *Λ*-$[Co\{(R,R)\text{-cydta}\}]^-$ ··· *Λ*-$[Co\{(S,S)\text{-cydta}\}]^-$, respectively. d) Single elution curve. e) Not characterized by the IUPAC nomenclature concerned with the octahedral complexes (Ref. 29). f) Tentative assignment; see text. g) Erroneously determined in Ref. 10 and thus corrected here. h) Absolute configuration of the secondary nitrogen atom of coordinated edma.

$[Co(NO_2)_3(edma)]^-$, can be assigned to (*S*).

Chromatographic Resolution and Chiral Discrimination Mechanism. The representative elution curves in the present optical resolutions are shown in Fig. 1. The mean retention volumes and separation factors (α) are summarized in Table 1. The α value greater than about 1.07 corresponds to the virtual complete resolution in the present resolutions. Single elution curves were obtained for the five complexes (**1e**, **8a**—**9b**), but in every case partial resolution was confirmed by measuring CD spectra of fractional eluates. The α value is regarded approximately as the difference in free energy of distribution between for the enantiomers which results from the diastereomeric interaction of enantiomers with a selector in the ion-exchange process: $\Delta(\Delta G^\circ)=-RT\ln\alpha$.[31] In the present estimation of α values, the void volume of column used is not contained in the retention volumes, so that the true α values are larger than those shown in Table 1; for example, the value for *cis*(*N*)-$[Co(ida)_2]^-$ (**6a**) has been found to be 1.23 in a preliminary experiment. It is noted that the α values in the present resolutions are, on the whole, comparable to those obtained by use of cationic selectors, which are smaller than 1.28 except for two special examples[9] in many resolutions.[3,5–9]

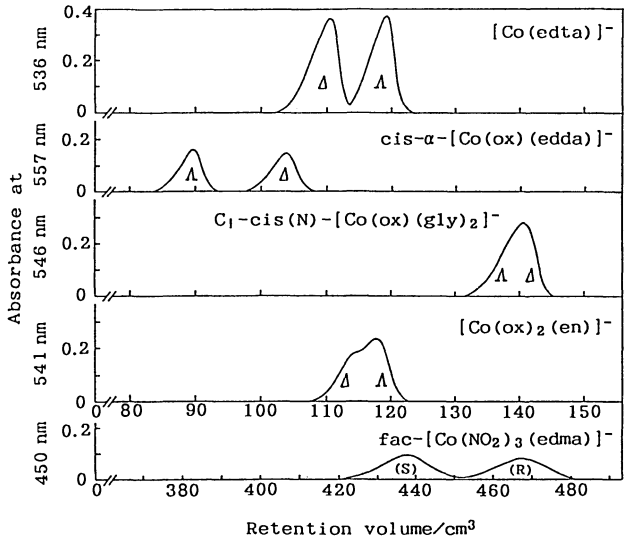

Fig. 1. Representative elution curves in the chromatographic resolution of the cobalt(III) complexes.

The signs of the CD extrema and absolute configurations of the early eluted enantiomers are shown in the forth and the fifth column, respectively, in Table 1. The absolute configurations of the ed3a type (**2a**—**2c**), aeida type (**5a** and **5b**), and edma (**7**) complexes cannot be characterized by the current IUPAC nomenclature concerned with octahedral complexes, because of the lack of net ring-pairing chirality.[29] The absolute configuration of the edma complex is designated with that of the secondary nitrogen atom. The structures of the enantiomers eluted early in each type are illustrated with chelate skeletons in Fig. 2. In each of the types with the plural complexes (**1**, **2**, **3**, **8**, **9**, and **10**), except for the bis(ida) type (**6**), the elution orders of the enantiomers are the same for all the complexes, as seen in Table 1. In the bis(ida) type, the elution order of *cis*(*N*)-$[Co(ida)_2]^-$ (**6a**) and that of the other complexes (**6b**—**6e**) are opposite; the structure in Fig. 2 is for the latter complexes. The absolute configurations of the aeida type complexes (**5a** and **5b**) are tentatively assigned in the present work (vide infra) and the structure for *unsym*-[Co(ox)(aeida)]$^-$ (**5a**) is illustrated in Fig. 2. As described above, the elution order of enantiomers can be correlated to the absolute configuration for the com-

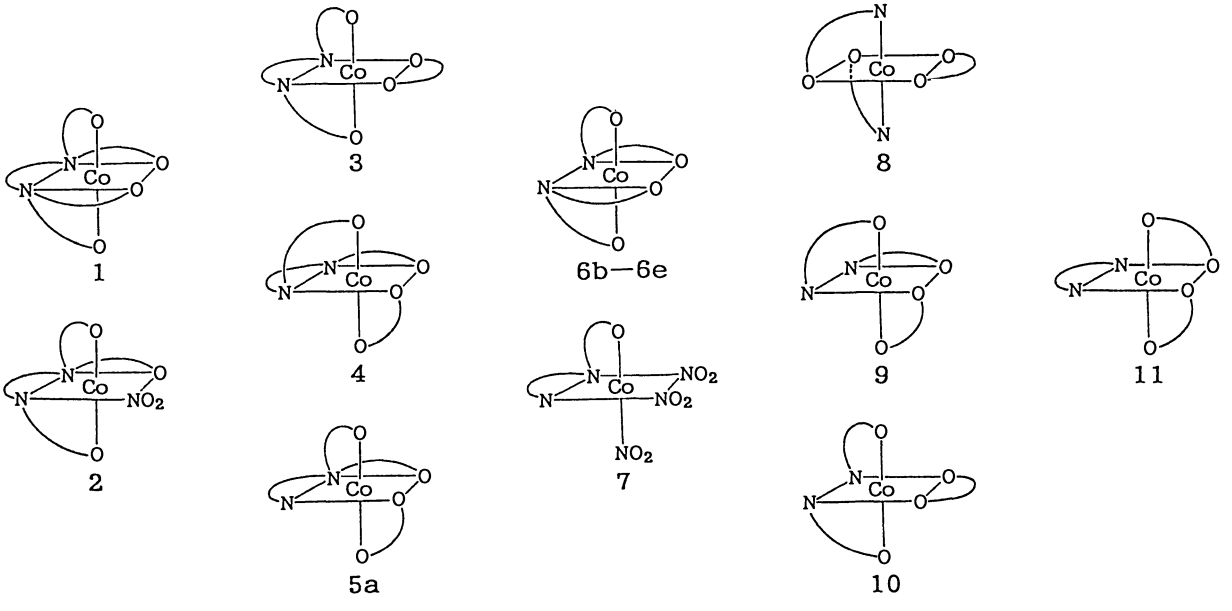

Fig. 2. Absolute configurations of the early eluted enantiomers.

plexes belonging to the same type, with the exception of *cis*(*N*)-[Co(ida)$_2$]$^-$ (**6a**). Such a correlation, however, is by no means recognized for the whole complexes used; namely, the *Δ*-isomers are early eluted for about half of the complexes and the *Λ*-isomers for the others. Accordingly, the chiral discrimination mechanism in the present systems is difficult to explain in relation with the absolute configuration, which is associated with the number of helical chelate pairs (*Δ* and *Λ*) in a complex.[29]

All the univalent anionic complexes used are coordinated by the two neutral nitrogen atoms of the amino carboxylato ligand(s) and the four anionic groups, carboxyl and/or nitro ones. It is reasonable to consider that the moiety near the two nitrogen atoms of the amino carboxylato ligand(s), where a relatively positive charge is produced owing to charge localization in a complex, favorably interacts with the anionic selector. The complexes have one or two triangular "NNO-facets" in a complex as a common structural unit, except for *trans*(*N*)-[Co(ox)(gly)$_2$]$^-$ (**8a**), *trans*(*N*)-[Co(ox)(*β*-ala)$_2$]$^-$ (**8b**), and [Co(ox)$_2$(en)]$^-$ (**11**). The NNO-facet consists of the two nitrogen atoms of the amino carboxylato ligand(s) and the glycinato or *β*-alaninato chelate ring (N–O) toward the apical position from either of the two nitrogen atoms. The enantiomeric forms are possible for the NNO-facet and illustrated in Fig. 3. The configurations of NNO-facets are defined here as L (left) and R (right) to indicate the direction of the nitrogen atom contained in the N–O chelate ring, when the NNO-facet is viewed as in Fig. 3.

The configurations of the NNO-facets in the early eluted enantiomers are shown in the last column in Table 1. In the complexes having two NNO-facets in a complex, the NNO-facets share the moiety of two nitrogen atoms. In the complexes having the NNO-facet, except for the aeida complexes (**5a** and **5b**), the early eluted enantiomers for the seventeen complexes contain the NNO-facet of L- or LL-configuration, while those for the four complexes, *cis*-*β*-[Co(ox)(edda)]$^-$ (**4**), *cis*(*N*)-[Co(ida)$_2$]$^-$ (**6a**), C_1-*cis*(*N*)-[Co(ox)(gly)$_2$]$^-$ (**9a**), and C_1-*cis*(*N*)-[Co(ox)(*β*-ala)$_2$]$^-$ (**9b**), contain the NNO-facet of R- or RR-configuration. Thus, it is reasonable to expect that the elution order of enantiomers can be correlated to the configuration of NNO-facet. On the other hand, all the complexes (**8a**, **8b**, and **11**) that have no NNO-facets give small *α* values (single—1.03). These facts suggest that the chirality of NNO-facet plays a dominant role in the chiral discrimination in the present resolution systems.

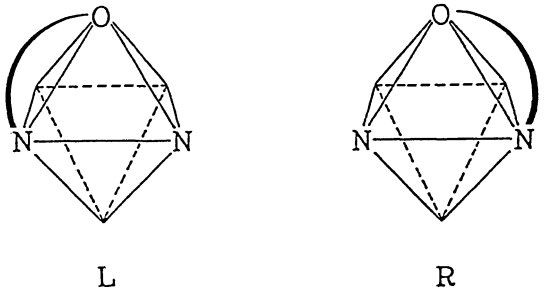

Fig. 3. L and R configurations of the NNO-facet.

It is to be noted as a simplified model for the chiral discrimination that *fac*-[Co(NO$_2$)$_3$(edma)]$^-$ (**7**) was completely resolved (Fig. 1), in spite of having no helical chelate arrangement (Fig. 2). This fact indicates that the helical chelate system is not essentially required for the chiral discrimination and that a significant unit in the discriminatory interactions exist in the facially coordinated edma moiety. The fact also is a strong support for the above suggestion concerning the role of NNO-facet for the discrimination, because the structure of edma is very close to that of the NNO-facet. It should also be noted for *cis*(*N*)-[Co(ida)$_2$]$^-$ (**6a**) that not only, the elution order is exceptional as described above but the *α* value is largest in the present resolutions (Table 1). This specific behavior in the bis(ida) type complexes (**6a**—**6e**) is particularly noteworthy, because it is caused only by the difference in *N*-substituent. This fact seems to hold a key to elucidate the chiral discrimination mechanism in the present resolutions. Although it cannot clearly be explained at present (vide infra), the fact at least adds support for the importance of NNO-facet for the chiral discrimination.

In most experimental studies on chiral discrimination phenomena between ions of the same sign, the direct contact mechanism has been proposed, where the racemic complex and environment substance (or selector) interact directly.[12–16] On the other hand, a non-contact mechanism has also been postulated experimentally[17] and theoretically.[18] In all systems for which the direct contact mechanism was proposed, one or both of the racemic (e.g., [Zn(phen)$_3$]$^{2+}$ (1,10-phenanthroline)) and environment (*d*-cinchoninium) ions contain groups with aromaticity (N-heterocyclic unsaturated groups in most cases). The mechanism has been explained in terms of a sequence that the hydrogen bonding or the hydrophobic interactions in a wide sense lead to direct contact between ions of the same sign against their mutual electrostatic repulsion inevitably expected, and that this contact provides a main driving force for the chiral discrimination.

In the present resolution systems, in contrast, both the racemate and selector are hydrophilic. The selector has acceptor oxygen atoms but no donor hydrogen atoms. Accordingly, a probable attractive force is brought about by the hydrogen bonding between the donor hydrogen atom of racemate and the acceptor oxygen atom of selector. Nine of the present racemates, edta type (**1a**—**1e**), med3a (**2b**), dmedda (**3b**), bis(mida) (**6c**), and bis(eida) (**6e**), have no donor hydrogen atoms, indicating the absence of attractive force. Nevertheless, the *α* values for these complexes are fairly large on the average, although they are somewhat smaller than those for the other complexes having N–H

bonds available for the hydrogen bonding (Table 1). By the way, it may be possible that direct contact is electrically allowed under special conditions at exchanging sites on the anion exchanger. Even if this is so, however, it appears to be difficult to explain the present results that the four edta type complexes (**1a**—**1d**) give α values (1.06—1.09) similar to one another; namely, it is difficult to construct such an interacting model as suggests the direct contact of the NNO-facet with the selector, because the N–N backbone chelates are distinctly different in their bulkiness.

The C_1- and C_2-cis(N) isomers of [Co(ox)(gly or β-ala)$_2$]$^-$ (**9a**—**10b**) have four N–H bonds in the NNO-facet. From X-ray structural studies, it has been found that the five-membered glycinato chelate is almost planar,[32] whereas the six-membered β-alaninato chelate exists in a puckered conformation with two kinds of N–H bonds, axial and equatorial.[33] In spite of such a clear difference of the N–H geometries in the NNO-facet, the glycinato and β-alaninato complexes show practically the same resolution behavior in the same geometrical isomer (Table 1). This fact is also difficult to explain in terms of direct and concrete interactions through hydrogen bonding to the selector, even if the N–H bonds participate in the chiral discrimination.

From these considerations, we conclude that the ability of the present discrimination has nothing to do with direct contact between the racemate and selector. Bosnich and Watts[17] have speculated such a noncontact mechanism, where the chiral discrimination is induced by the diastereomeric interaction between chiral solvent sheaths formed about enantiomers and selector. This mechanism can favorably explain the present discrimination phenomenon, because the presence of some waters intervening between ions of the same sign will effectively reduce the electrostatic repulsion between ions.

The alkyl substitution of the N–H proton of [Co(NO$_2$)(ed3a)]$^-$ (**2a**), forming [Co(NO$_2$)(med3a)]$^-$ (**2b**), significantly lowers the α value (from 1.10 to 1.06). Such is the case with the other pairs, *cis*-α-[Co(ox)(edda)]$^-$ (**3a**)···*cis*-α-[Co(ox)(dmedda)]$^-$ (**3b**) (1.16 to 1.04) and *cis*(N)-[Co(ida)(mida)]$^-$ (**6b**)···*cis*(N)-[Co(mida)$_2$]$^-$ (**6c**) (1.13 to 1.07), but the α values of *cis*(N)-[Co(ida)(eida)]$^-$ (**6d**) and *cis*(N)-[Co(eida)$_2$]$^-$ (**6e**) (1.04 to 1.05) are comparable to each other. This behavior is in contrast to the fact that the four edta type complexes (**1a**—**1d**) show similar α values (1.06—1.09) in spite of the variation in alkyl N–N backbone, as pointed out above. This fact, therefore, indicates a participation of the N–H proton in the chiral discrimination. According to our proposal, this may imply that the N–H proton(s) contribute to the formation of water sheaths about the racemate. It may first be considered that the number and direction of N–H bonds in an NNO-facet effectively affect the formation of water sheath. Molecular model considerations show that the two N–H bonds of cis(N)-[Co(ida)$_2$]$^-$ (**6a**) roughly face to each other. There are no complexes which have such a geometry of two N–H bonds in the present complexes, except for the four complexes (**9a**—**10b**), C_1- and C_2-*cis*(N)-[Co(ox)(gly or β-ala)$_2$]$^-$. The excluded complexes have two N–H bonds of a geometry similar to those of *cis*(N)-[Co(ida)$_2$]$^-$, but additionally two more N–H bonds. Thus, *cis*(N)-[co(ida)$_2$]$^-$ has the characteristic donor hydrogen atoms in the present complexes. This is a possible explanation for the exceptional behavior of *cis*(N)-[Co(ida)$_2$]$^-$ described above.

The α value for [Co(cydta)]$^-$ (**1e**) is markedly small compared with those for the other edta type complexes (**1a**—**1d**). This may be ascribed to the high hydrophobicity of the large-sized cyclohexane ring, by which the formation of water sheath about the complex is depressed. The *cis*-β-[Co(ox)(edda)]$^-$ (**4**), C_1-*cis*(N)-[Co(ox)(gly)$_2$]$^-$ (**9a**), and C_1-*cis*(N)-[Co(ox)(β-ala)$_2$]$^-$ (**9b**) complexes show the exceptional behavior in elution order, as mentioned above. In addition to this fact, these complexes give small α values (single—1.04), out of proportion to the structure that the complexes have both the NNO-facet and some N–H bonds. The complexes have the same chelate skeleton, except for the presence or absence of the ethylene bridge spanned between two nitrogen atoms. Although it is presumed that the reason for the behavior observed is concealed in the common chelate structure in these complexes, its detail is not clear.

Under the situation described above, the elution order of enantiomers cannot confidently be correlated to the configuration of NNO-facet. The aeida complexes, *unsym*-[Co(ox)(aeida)]$^-$ (**5a**) and *unsym*-[Co(NO$_2$)$_2$(aeida)]$^-$ (**5b**), of which the absolute configurations are unknown, do not have such a structure as brings about the exceptional relation as described above. Accordingly, the regular relation may be applicable to these complexes; namely, their early eluted enantiomers are tentatively considered to have the NNO-facet of L-configuration and the absolute configuration which is self-evidently derived from it (Table 1 and Fig. 2). The *unsym*-[Co(NO$_2$)$_2$(aeida)]$^-$ (**5b**) complex is another example which has been completely resolved in spite of the lack of helical chelate arrangement.

In the present chromatographic resolution systems, the [Sb$_2$(*d*-tart)$_2$]$^{2-}$ selector participates in the chiral discrimination in both the stationary phase and the mobile phase. If it is assumed that the mode of diastereomeric interaction between the selector and racemate is the same in both phases, the selector exerts an opposite effect upon the elution order of the enantiomers, and the elution order depends on the relative concentrations of the selector in the phases. The concentration of the selector in the stationary phase (0.24 mmol cm^{-3} on the basis of the ion-exchange capacity of the exchanger used)[10] is more than ten times as high as that in the mobile one (0.02 mol dm^{-3}). Thus, the elution order is governed by the selector in the stationary phase,

that is, one of the enantiomers which interacts more favorably with the selector is late eluted than the other. A further study is now in progress.

The author wishes to thank Professor Takaji Yasui and his co-workers of Kochi University for helpful supports in the preparation of cobalt(III) complexes. This work was supported by a Grant-in-Aid for Scientific Research No. 01540513 from the Ministry of Education, Science and Culture.

Spectrochemical Series for the Outersphere Coordination of Carboxylatocobaltate(III) Complexes with Solvent Molecules[1)]

Toshiaki TAURA
Department of Chemistry, University of Aichi Prefecture, Takadacho 3-28, Mizuho-ku, Nagoya 467
(Received March 2, 1991)

The d–d transition spectra of K[Co(edta)]·2H_2O, K[Co(mal)$_2$en]·H_2O, K[Co(ox)$_2$en]·1.5H_2O, K$_2$[Co(ox)$_2$gly]·3H_2O, and K$_3$[Co(ox)$_3$]·3H_2O (edta=ethylenediaminetetraacetate, mal=malonate, en=ethylenediamine, ox=oxalate, and gly=glycinate) were measured in a variety of solvents: H_2O, $HOCH_2CH_2OH$, CH_3OH, $HCONH_2$, C_2H_5OH, *i*-C_3H_7OH, $CHCl_3$, CH_3NO_2, CH_2Cl_2, $(CH_3)_2SO$, CH_3CN, $HCON(CH_3)_2$, C_6H_5CN, $C_6H_5NO_2$, $CH_3CON(CH_3)_2$, $(CH_3)_2CO$, and $[(CH_3)_2N]_3PO$. The ^{59}Co NMR spectra of K[Co(edta)]·H_2O and K$_3$[Co(ox)$_3$]·3H_2O were also recorded at 25 °C in these solvents. It was found that the peak positions (λ_{max}) of the first and second d–d transition bands were greatly influenced by solvent molecules; the peak positions (λ_{max}) of all the cobalt(III) complexes were linearly correlated to the electrophilic ability (Gutmann's acceptor number) of the solvent and those of K[Co(edta)]·2H_2O and K$_3$[Co(ox)$_3$]·3H_2O were linearly correlated to the ^{59}Co NMR chemical shifts in the corresponding solvents. This suggests that the d–d transition energy (ΔE) is influenced by solvent molecules as electron acceptors since ^{59}Co NMR chemical shifts are theoretically correlated linearly to the peak positions in the first d–d transition (A_{1g}–T_{1g}). The ^{13}C NMR measurements indicated that solvent molecules directly interact with the carboxyl groups of cobalt(III) complexes. Therefore, the influence of the solvent on the d–d transition energy of the carboxylatocobaltate(III) complex is due to the electron-withdrawing effect of solvent molecules on the carboxyl oxygens of the cobalt(III) complex. A spectrochemical series for the outersphere coordination of the cobalt(III) complex with solvent molecules is proposed.

It was reported that potassium ethylenediaminetetraacetatocobaltate(III) dihydrate, K[Co(edta)]·2H_2O, was solubilized by macrocyclic polyethers, crown ethers and cryptand 222, in a variety of organic solvents including low-polarity chloroform (dielectric constant=4.8).[2)] In the course of this work, it was discovered that the color of this cobalt(III) complex changed from reddish violet in water to bluish violet in acetone. This complex was quite stable and inert against ligand substitution or redox reaction in these solvents, and thus this color change has been due to the outersphere interaction of $[Co(edta)]^-$ with solvent molecules.

In a previous paper,[3)] it was suggested that the peak positions (λ_{max}) of the first d–d transition band (corresponding to the color of the complex) were linearly correlated with the acceptor numbers of solvents, which were proposed by Mayer, et al.[4)] as a measure of the electrophilic ability of solvents. The solvent influence on the peak position and the interaction between $[Co(edta)]^-$ and solvent molecules could then be quantitatively estimated by using the acceptor number of the solvent. Using this procedure, the solvent influence of some cobalt(III) or chromium(III) complexes has been studied.[1,5–7)]

The present work is an attempt to elucidate what kind of interaction between solvent molecules and $[Co(edta)]^-$ or some related carboxylatocobaltate(III) complexes plays an important role in the solvent influence on the d–d transition spectra. The solvent influence on the electronic and ^{59}Co NMR spectra of K[Co(edta)]·2H_2O, K[Co(mal)$_2$en]·H_2O, K[Co(ox)$_2$en]·1.5H_2O, K$_2$[Co(ox)$_2$gly]·3H_2O, and K$_3$[Co(ox)$_3$]·3H_2O, where edta=ethylenediaminetetraacetate, mal=malonate, en=ethylenediamine, ox=oxalate, and gly=glycine, was investigated, and was compared with the influence of the solvent on the ^{13}C NMR spectra which has already been reported.[5)]

Experimental

Materials. The cobalt(III) complexes used in this work (K[Co(edta)]·2H_2O,[8)] K[Co(mal)$_2$en]·H_2O,[9)] K[Co(ox)$_2$en]·1.5H_2O,[10)] K$_2$[Co(ox)$_2$gly]·3H_2O,[11)] K$_3$[Co(ox)$_3$]·3H_2O,[12)] [Co(en)$_3$](ClO$_4$)$_3$,[13)] and [Co(NH$_3$)$_6$](ClO$_4$)$_3$[14)]) were prepared by the usual methods. The anhydrous salt of K[Co(edta)]·2H_2O was prepared by heating the complex at 110 °C in an oven. The purities of these complexes were checked by elemental analysis and spectroscopic methods. The organic solvents and cryptand 222 (Merck: Kryptofix 222) were of the purest commercial grade available and were used without further purification. The solvents used in this study were; water (H_2O), ethylene glycol (EG), methanol (CH_3OH), formamide (FA), ethanol (C_2H_5OH), 2-propanol (*i*-C_3H_7OH), chloroform ($CHCl_3$), nitromethane (CH_3NO_2), dichloromethane (CH_2Cl_2), dimethyl sulfoxide (Me_2SO), acetonitrile (CH_3CN), *N,N*-dimethylformamide (DMF), benzonitrile (C_6H_5CN), nitrobenzene ($C_6H_5NO_2$), *N,N*-dimethylacetamide (DMA), acetone (Me_2CO), and hexamethylphosphoric triamide (HMPA).

Measurements. Electronic Spectra: The electronic absorption spectra of the cobalt(III) complexes in solutions of appropriate concentrations (0.001—0.005 mol dm^{-3}) were measured at room temperature. The complex salts were dissolved in organic solvents by the addition of an excess of cryptand 222 (amounts 1.5 times larger than the concentration of the K^+ ion). The spectra were recorded on a Shimadzu UV-240 recording spectrophotometer. The spectra were not influenced by the addition of various amounts of cryptand 222, by a change in the concentration of the cobalt(III) complex, or by a change in the temperature. Water of crystallization in the complexes was not found to change the peak positions of the absorption spectra.[15)]

The reflection spectra of the cobalt(III) complexes and the anhydrous salt of K[Co(edta)] were measured on a JASCO UVIDEC-410 spectrophotometer with a TIS-241 reflectance attachment.

^{59}Co NMR. The ^{59}Co NMR spectra of K[Co(edta)]·2H_2O and K_3[Co(ox)$_3$]·3H_2O were measured at 25 °C in solutions of the complex anion for water, and for organic solvents containing cryptand 222 (amounts 1.5 times larger than the concentration of the K^+ ion). The ^{59}Co chemical shift is influenced by the concentration of the complex. Therefore, measurements were carried out in solutions of various concentrations. A JEOL JNM-GX400 NMR spectrometer was operated in Fourier transform mode at 95.856 MHz for K[Co(edta)]·2H_2O and 96.095 MHz for K_3[Co(ox)$_3$]·3H_2O. The 10-mm NMR tube used here contained a sample solution of 2.5 ml; D_2O in a 2-mm tube was fixed inside a sample 10-mm tube during spectra accumulation. The reference was not used, but the signal of the complex appeared quite broad and the peak position in water was set at 0 ppm before the other ^{59}Co NMR measurements were taken. The position of the signal in water did not change after the measurements of the other samples. The spectra were recorded after 256—4096 accumulations of 0.1 s pulse intervals.

Results and Discussion

Electronic Spectra in a Variety of Solvents. The electronic spectra of K[Co(edta)]·2H_2O and K[Co(mal)$_2$en]·H_2O in water, methanol, ethanol, and chloroform are shown in Fig. 1. The spectral bands in the longer wavelength region correspond to the first d–d transition[16] of the cobalt(III) center. The second d–d transition bands appear in the shorter wavelength region. It is clear that the peak positions of the first and second d–d transition bands appear in the shorter wavelength regions in water, and shift to longer wavelengths in the other solvents.[17] As the [Co(edta)]$^-$ and [Co(mal)$_2$en]$^-$ anions are inert and stable in these solvents under the conditions of the measurements, the differences in the peak positions are due to the outersphere interaction between the complex anion and solvent molecules.

As for the other complex anions, the peak positions also appear in the shorter wavelength regions in water and shift to longer wavelengths in the other solvents. The data of the observed peak positions (λ_{max} : λ_1 and λ_2) of the first and second d–d transition bands are presented in Table 1 for the solvents listed in the Experimental section. This table also includes some solvent parameters: Gutmann's acceptor number (*AN*) and Kosower's parameter (*Z*).[18]

Correlation between the Peak Positions in the d-d Transition Spectrum and the Acceptor Numbers of Solvents. As the solvent influence should be generated by the outersphere interaction between the complex anion and solvent molecules, we have considered the solvent influence on the peak position (λ_{max}) on the basis of the acceptor numbers (*AN*) which were proposed by Mayer, Gutmann, and Gerger as a measure of estimating the electrophilic ability of solvents.[4] The *AN* values of the solvents were determined on the basis of ^{31}P NMR chemical shifts of triethylphosphine oxide ((C_2H_5)$_3$P=O) in the solvents. A large acceptor number indicates that a solvent is a good electron acceptor. Therefore, solvent molecules could interact strongly with an anion like [Co(edta)]$^-$ if the solvent has a large acceptor number.

In Fig. 2, the λ_{max} (λ_1) values of the first d–d transition bands of the complex anions are plotted versus the acceptor numbers of the solvents: H_2O, CH_3OH, FA,

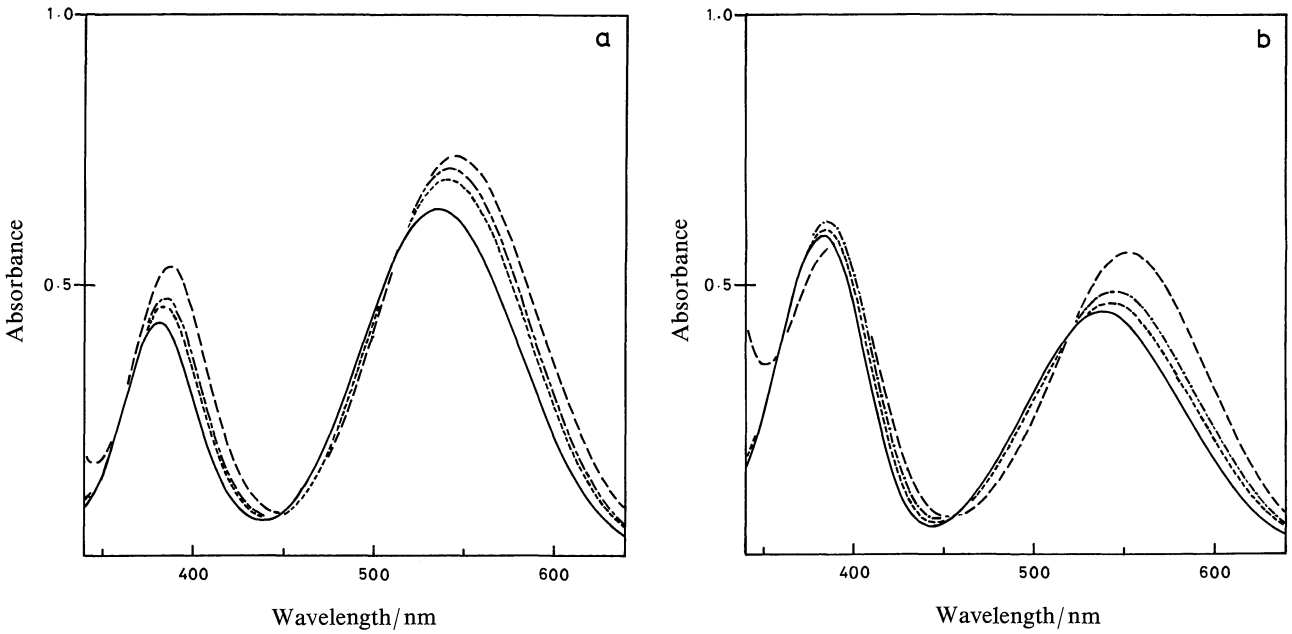

Fig. 1. The electronic absorption spectra of K[Co(edta)]·2H_2O (0.002 mol dm^{-3}) (a) and K[Co(mal)$_2$en]·H_2O (0.005 mol dm^{-3}) (b) in water (——), methanol (------), ethanol (— - —), and chloroform (——).

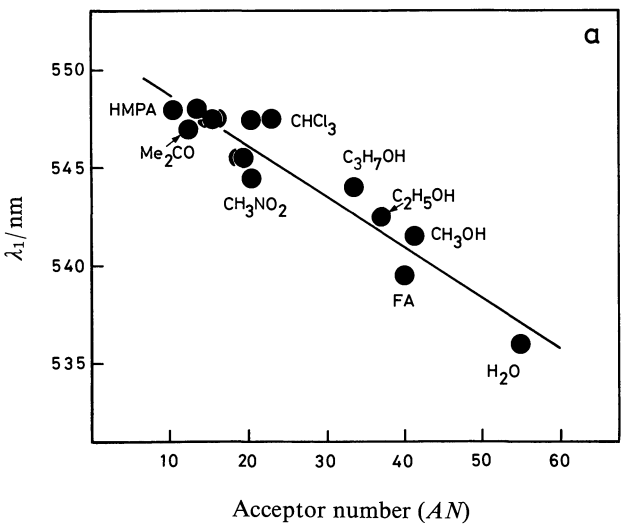
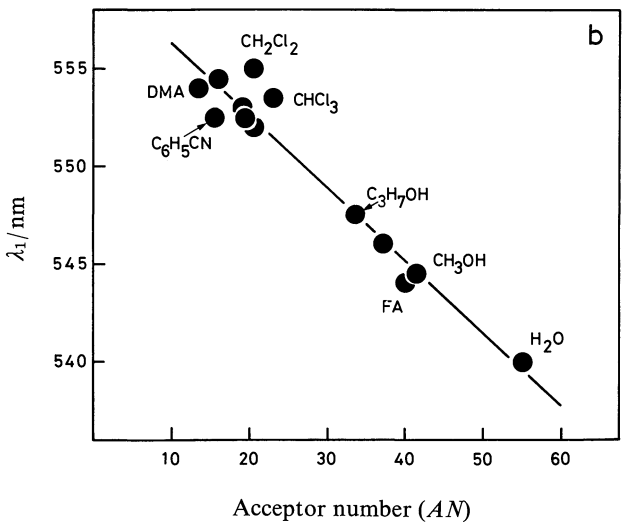
a) AN and Z refer to the acceptor number of the solvent and Kosower's solvent parameter, respectively. b) A, B, and r refer to the intercept, the slope, and the correlation coefficient in Eq. 2, respectively.

C_2H_5OH, *i*-C_3H_7OH, $CHCl_3$, CH_3NO_2, CH_2Cl_2, Me_2SO, CH_3CN, DMF, C_6H_5CN, $C_6H_5NO_2$ DMA, Me_2CO, and HMPA. The λ_1 value shifts to the longer wavelength regions as the acceptor number becomes smaller. For example, the λ_1 value (Fig. 2a, Table 1) for K[Co(edta)]·2H$_2$O is 536 nm in water (AN=54.8) and shifts to 547 nm in acetone (AN=12.5) (the color changes from reddish violet in water to bluish violet in acetone). According to the literature,[19] protic solvents such as ethanol, methanol, and water having large AN values can strongly solvate the anion through hydrogen bonding, while dipolar aprotic solvents such as acetone, dimethyl sulfoxide, and acetonitrile having small AN values solvate the anion weakly. Therefore, the λ_1 values in aprotic solvents correspond to those of weakly solvated $[Co(edta)]^-$ anions and the values in protic solvents seem to be greatly influenced by solvating molecules as outersphere ligands.

Therefore, the colors (corresponding to the λ_1 values) of the $[Co(edta)]^-$ anions are caused by the ligands (edta) and the solvating molecules. A plot of the λ_1 values in Table 1 versus the acceptor numbers of the





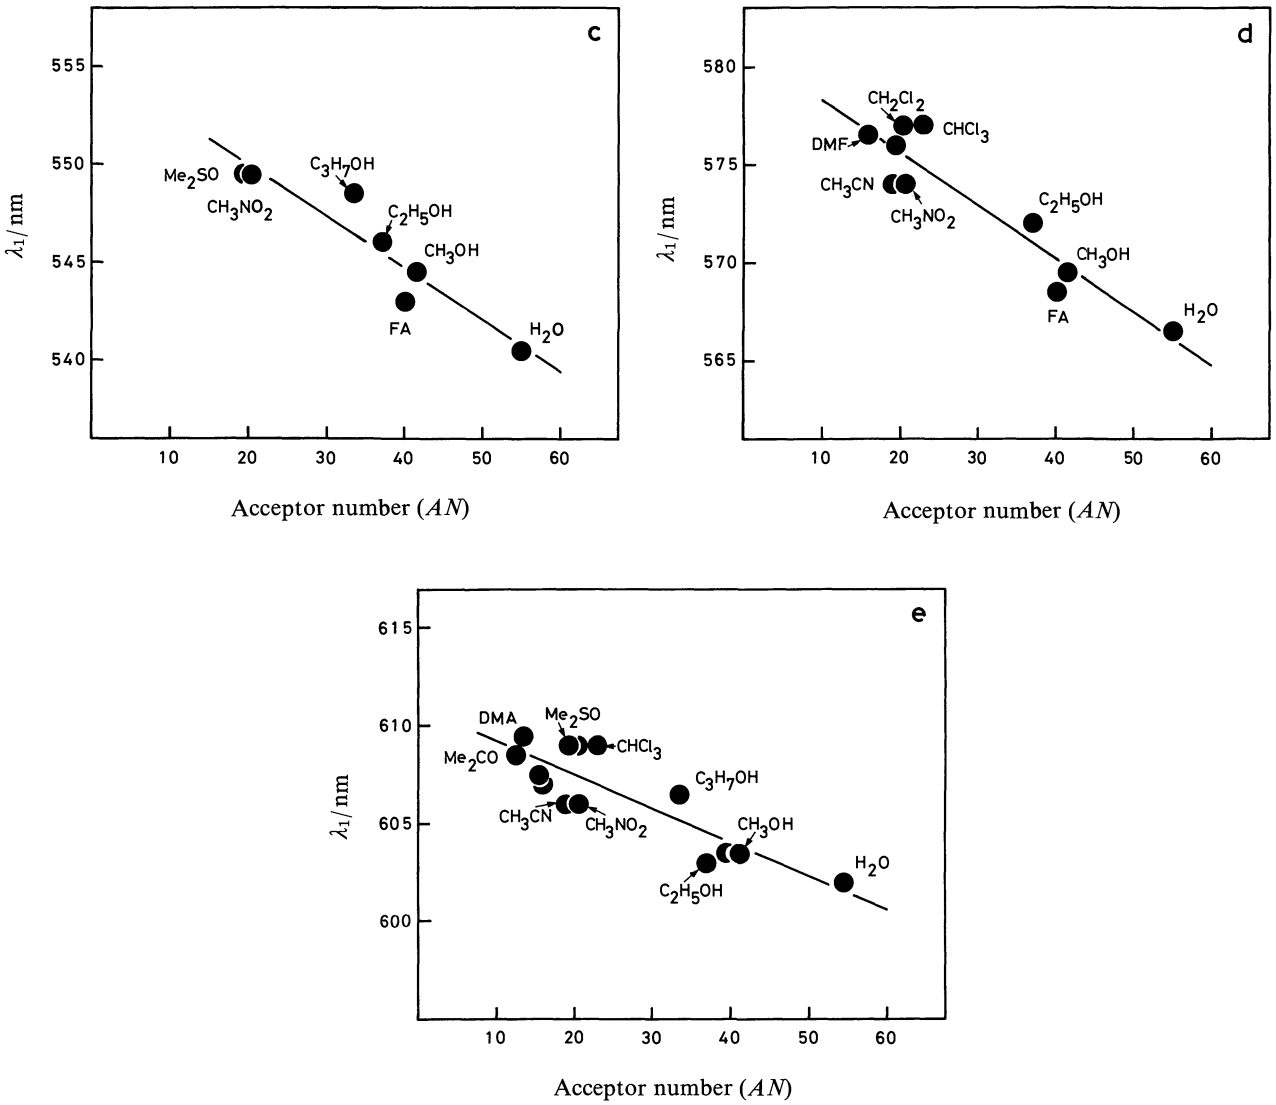


Fig. 2. The correlation between the peak positions (λ_1 in Table 1) of the first d–d transition bands of K[Co(edta)]·2H$_2$O (a), K[Co(mal)$_2$en]·H$_2$O (b), K[Co(ox)$_2$en]·1.5 H$_2$O (c), K$_2$[Co(ox)$_2$gly]·3H$_2$O (d), and K$_3$[Co(ox)$_3$]·3H$_2$O (e) and the acceptor numbers (*AN*) of the solvents.

solvents gives a straight line as shown in Fig. 2a.[20] The linearity of the line suggests that the contribution of the solvent molecules to the peak position is linearly correlated to the *AN* values of the solvents. The peak position in the solvent is calculated by the following equation (error bars are one standard deviation):

$$\lambda_1 = \lambda_1^\circ - (0.259 \pm 0.023) \times AN \quad (1)$$

where λ_1° refers to the peak position (λ_1°=551.3±0.6 nm determined by a least-squares analysis) in hexane as a standard solvent (*AN*=0), and *AN* is the acceptor number of the solvent. The first term in this equation corresponds to the inherent peak position of the [Co(edta)]$^-$ anion which is not solvated and the second term to the outersphere-ligand effect which is caused by solvating molecules.

We have concluded that the color (or λ_1) of the cobalt(III) complex is changed by the outersphere coordination of solvent molecules and that this color (or λ_1) change can be predicted by using the acceptor number of the solvent.

The linear correlation[20] between the peak positions and the acceptor numbers was observed for the other anionic cobalt(III) complexes: K[Co(mal)$_2$en]·H$_2$O (Fig. 2b), K[Co(ox)$_2$en]·1.5H$_2$O (Fig. 2c), K$_2$[Co(ox)$_2$gly]·3H$_2$O (Fig. 2d), and K$_3$[Co(ox)$_3$]·3H$_2$O (Fig. 2e). The correlation is generally represented by the following equation:

$$\lambda_1 = A - B \times AN \quad (2)$$

The intercepts (*A*) and slopes (*B*), which refer to the inherent peak positions and the contribution of the solvent molecules, respectively, were also obtained by least-squares calculations, and are listed in Table 1.

The slopes (B) were slightly different from each other, but were independent of the charge of the complex anion (−, 2−, or 3−). The highly-charged anion could generally be strongly solvated by the solvent molecules. Therefore, this slight difference in the slopes (B) is attributed to an other factor; for example, the probability of the d–d transition for the 1:1 solvation of the anion and solvent molecules. The magnitude of the slope is smaller for $K_3[Co(ox)_3]\cdot 3H_2O$ than for $K_3[Co(CN)_6]$, which has already been obtained.[6] Therefore, the magnitude of the solvent influence depends on the ligand which is coordinated with the cobalt(III) ion.

On the other hand, Fig. 3 presents the correlation between the peak positions of the first d–d transition of $K[Co(edta)]\cdot 2H_2O$ (λ_1) and Kosower's solvent parameters (Z).[18] This plot also gives a straight line. The linearity of the plot is higher than that of the plot versus the acceptor number (AN): the correlation coefficient (−0.980) is greater in the plot versus Z than in the plot versus AN (Table 1: −0.947). For other carboxylato complexes described here, the linearity is also higher in the plots versus Z than the plots versus AN, though the data are not presented in this paper. Kosower's parameters were determined on the basis of the peak positions in the UV absorption spectra (CT: charge transfer) of 1-ethylpyridium iodide in the solvents.[18] Therefore, the influence of the solvent on the d–d transition seems to be correlated more with the parameter from the CT transition than that from the NMR chemical shifts.[21]

In order to confirm that the blue shift of the peak position of $[Co(edta)]^-$ in H_2O was due to the interaction between the complex anion and solvent molecules, the reflection spectra of solid $K[Co(edta)]\cdot 2H_2O$ and $K[Co(edta)]$ were obtained. It was found that the peak positions of solid $K[Co(edta)]\cdot 2H_2O$ were 552 nm for the first d–d transition and 387 nm for the second d–d transition, and its anhydrous salt showed peaks at 556 nm and 387 nm for the first and second d–d transitions, respectively. If, in the solid state, the $[Co(edta)]^-$ anion does not interact with H_2O, these peak positions can be seen to be quite similar to the hypothetical positions (551 nm and 390 nm) in hexane in which the complex does not interact with solvent molecules. In contrast to the edta complexes, the λ_{max} values of other hydrates: $K[Co(mal)_2en]\cdot H_2O$, $K[Co(ox)_2en]\cdot 1.5H_2O$, $K_2[Co(ox)_2gly]\cdot 3H_2O$, and $K_3[Co(ox)_3]\cdot 3H_2O$ are 535, 541, 561, and 596 nm for the first d–d transition and 385, 384, 402, and 423 nm for the second d–d transition, respectively. These values are similar to those in water (540.5, 540.0, 566.5, and 602.0 nm for the first transition and 382.5, 384.0, 403.5, and 424.0 nm for the second transition). An interaction such as hydrogen bonding may exist in those complexes in the solid state, though it could not be confirmed by X-ray analysis.

Spectrochemical Parameter Δ and Interelectronic Repulsion Parameter B. The λ_{max} (λ_2) values of the second d–d transition are also correlated linearly to the AN values of the solvents, as shown in Fig. 4. Therefore, the spectrochemical parameter Δ and Racah parameter B can be evaluated by the λ_1 and λ_2 values of the first and second d–d transition bands. We have used these two parameters to clarify the mechanism of the change in the d–d transition spectra. The parameters Δ and B are approximately calculated by the equations of Schäffer.[22]

$$\Delta = 1/\lambda_1 + (1/\lambda_2 - 1/\lambda_1)[0.1824(\lambda_1/\lambda_2)^2 - 0.5531(\lambda_1/\lambda_2) + 0.6165], \quad (3)$$

$$B = (1/\lambda_2 - 1/\lambda_1)[4.077\times 10^{-2}(\lambda_1/\lambda_2)^2 - 7.090\times 10^{-2}(\lambda_1/\lambda_2) + 9.352\times 10^{-2}]. \quad (4)$$

a) The number of the solvent corresponds to the number assigned in Table 1.

bands shifted to shorter wavelengths as the acceptor number became larger. The spectrochemical parameter Δ, the energy splitting of d orbitals in the O_h field, also became larger as the acceptor number increased (Table 2). Therefore, we have concluded that the solvent influence on the electronic absorption spectra is attributed to an influence on the d–d transition energy (the energy splitting of the d orbital).

Table 2 indicates that the Racah parameter B of $K[Co(mal)_2en]\cdot H_2O$ in a variety of solvents becomes small as the electrophilic ability (AN value) of the solvents (outersphere ligand) becomes larger. It is well known that a decrease of the B value indicates a decrease in the interelectronic repulsion, and is generated by the expansion of the d electron cloud. This expansion of the d electron cloud is due to the electron-withdrawing effect of solvent molecules on the d electrons of $[Co(mal)_2en]^-$ through the ligand atoms (oxygen and carbon). This cloud expanding (nephelauxetic) effect roughly corresponds to the electrophilic ability of the solvents. The expansion of d electron clouds is known to be due to the increase of the covalency of the Co–L bond. We suggest that the solvent influence on the d–d transition energy of $[Co(mal)_2en]^-$ is based on the change of the covalency between the cobalt ion and the innersphere ligand, though the parameter B is similar in a variety of solvents for the other complexes. The spectrochemical series and the nephelauxetic series of outersphere coordination with solvent molecules could be proposed: for the spectrochemical series of $[Co(mal)_2en]^-$,

H_2O, EG, CH_3OH~FA, C_2H_5OH, i-C_3H_7OH, $CHCl_3$~Me_2SO~CH_3CN~C_6H_5CN, DMA, CH_2Cl_2~DMF,

and for the nephelauxetic series of $[Co(mal)_2en]^-$,

FA, H_2O, EG, Me_2SO, CH_3OH, DMF, C_2H_5OH, i-C_3H_7OH, DMA, CH_3CN, CH_2Cl_2, C_6H_5CN, $CHCl_3$.

Correlation between the Peak Positions in the Electronic Spectra and the Chemical Shifts in the ^{59}Co NMR Spectra. If the energy of the d–d electronic transition of the cobalt(III) ion could be changed by the interaction between the solvent molecules and this complex anion, the ^{59}Co NMR chemical shifts should also vary according to changes in the electronic spectrum. This is because the chemical shift of ^{59}Co NMR is correlated to the peak position in the electronic spectrum, as shown in the following equation (which is abbreviated):[23]

$$\delta(^{59}Co) \propto 1/\Delta E \quad (5)$$

where $\delta(^{59}Co)$ and ΔE are the ^{59}Co chemical shift and the energy difference for the first d–d transition band of the cobalt(III) complex, respectively.

Figure 5 shows the ^{59}Co NMR spectra of $K[Co(edta)]\cdot 2H_2O$ and $K_3[Co(ox)_3]\cdot 3H_2O$ in H_2O,

Table 3. The Chemical Shifts of the ^{59}Co NMR Spectra of $K[Co(edta)]\cdot 2H_2O$ and $K_3[Co(ox)_3]\cdot 3H_2O$ in a Variety of Solvents

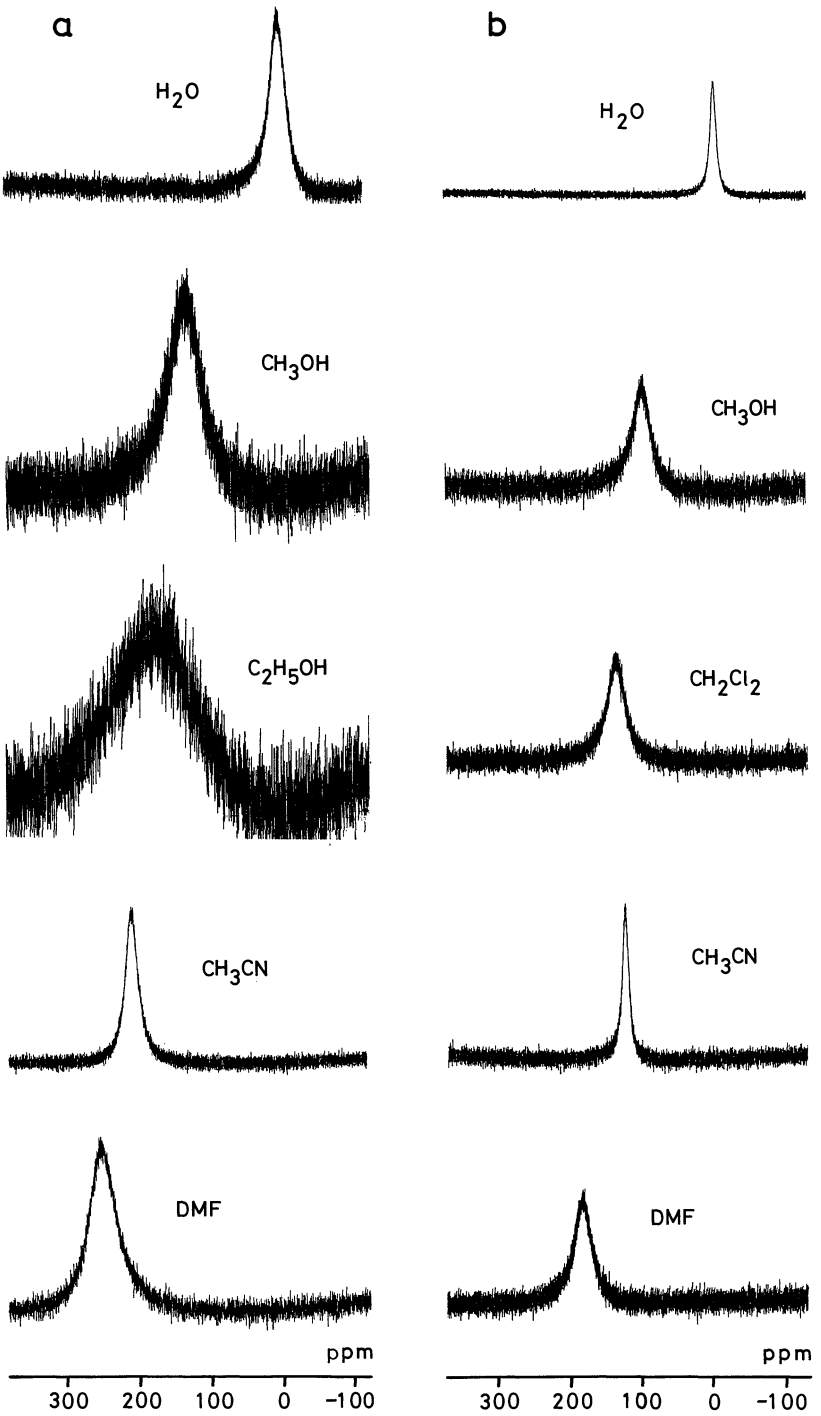

Fig. 5. ^{59}Co NMR spectra of K[Co(edta)]·2H$_2$O (a) and K$_3$[Co(ox)$_3$]·3H$_2$O (b) in a variety of solvents (0.1 mol dm^{-3}).

CH_3OH, C_2H_5OH, (or CH_2Cl_2), CH_3CN, and DMF. In all solvents, the signal appeared quite broad, but the chemical shifts of the ^{59}Co NMR were fairly solvent-dependent. The chemical shifts obtained are shown in Table 3; the solvents used were H_2O, CH_3OH, C_2H_5OH, CH_3NO_2, CH_2Cl_2, Me_2SO, CH_3CN, DMF, C_6H_5CN, and DMA. The chemical shifts also changed as the concentration of the complex decreased. This may have been due to the ion association between the complex anion and K^+ with cryptand 222. The chemical shifts, which were obtained by extrapolation to be the concentration zero, should be the value without any influence of the counter cation. Therefore, the extrapolated values are listed in Table 3 instead of the observed values.

It seemed that the ^{59}Co chemical shifts were linearly correlated to the λ_1 values listed in Table 1. In order to confirm this correlation, the chemical shifts ($\delta(^{59}Co)$)

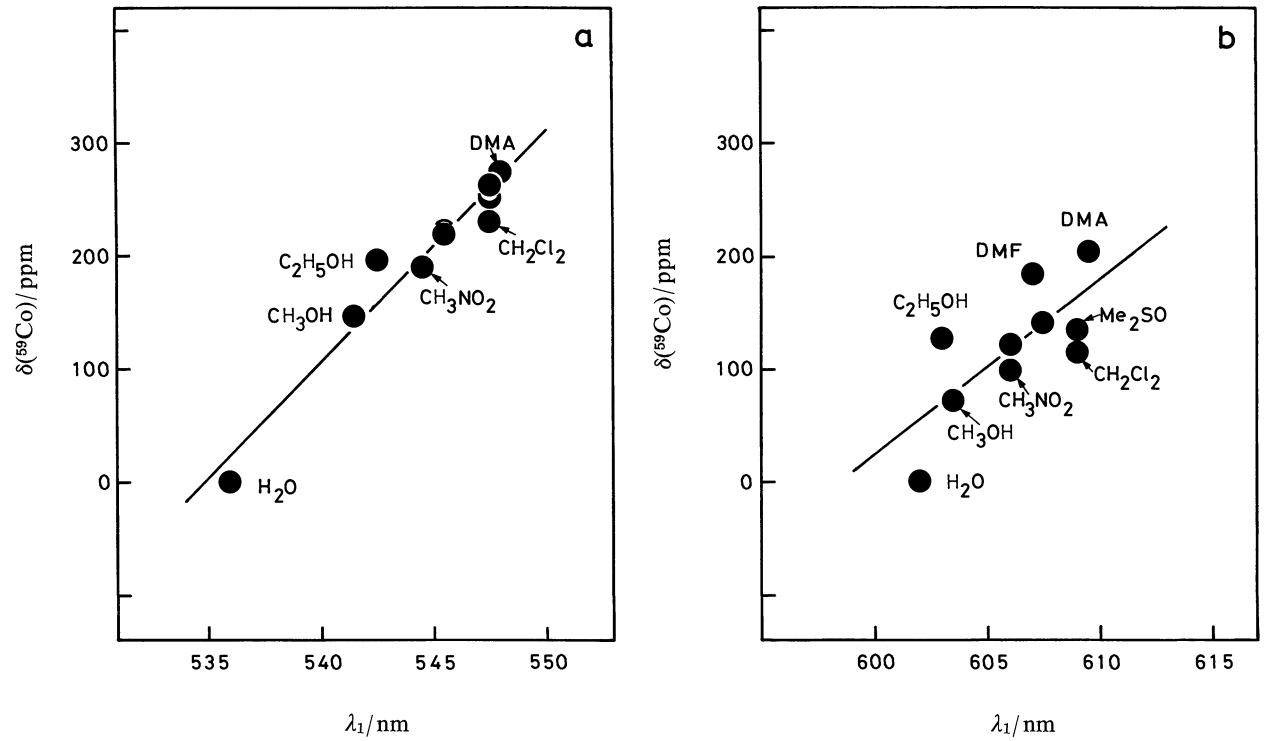

Fig. 6. The correlation between the ^{59}Co chemical shifts ($\delta(^{59}Co)$ in Table 3) and the peak positions (λ_1 in Table 1) of K[Co(edta)]·2H$_2$O (a) and K$_3$[Co(ox)$_3$]·3H$_2$O (b).

were plotted versus the λ_1 values of the first d–d transition band (A_{1g}—T_{1g}) in the corresponding solvents: H_2O, CH_3OH, C_2H_5OH, CH_3NO_2, CH_2Cl_2, Me_2SO, CH_3CN, DMF, C_6H_5CN, and DMA (Fig. 6a and 6b). It was clear that the $\delta(^{59}Co)$ values were linearly correlated to the λ_1 value (the intercepts were −11002.68 ppm for $[Co(edta)]^-$ and −9299.24 ppm for $[Co(ox)_3]^{3-}$, and the slopes were 20.57 for $[Co(edta)]^-$ and 15.54 for $[Co(ox)_3]^{3-}$).[24] This result indicated that the d–d transition energy (ΔE in Eq. 5) was influenced by the solvent molecules, and this influence changed the electronic spectrum and the ^{59}Co NMR of the cobalt(III) complex anion. The intercepts for $[Co(edta)]^-$, $[Co(ox)_3]^{3-}$, and $[Co(CN)_6]^{3-}$ (−9968.75 ppm: obtained in the previous study[6]) were similar to each other, but the slopes for $[Co(edta)]^-$, $[Co(ox)_3]^{3-}$, and $[Co(CN)_6]^{3-}$ (32.01[6]) were quite different. Thus, the solvent influence depended on the nature of the coordinated ligand atoms.

The influence of the solvent on the d–d transition energy (ΔE) has been speculatively interpreted as a change in the contribution of the empty π-orbital of the ligand oxygen to a complex that is composed of σ- and π-bonding between Co and the ligand.[6,25] If the contribution of the π-orbital in this case increases, the orbital split should become great, leading to blue shifts in hydrogen-bonding solvents. This model was preliminarily tested by EHMO calculation of the $[Co(ox)_2(NH_3)_2]^-$ and H_2O system. The result of the calculation showed that H_2O interacts with carboxyl oxygens along the direction of the angle ranging from about 40 °C to −40 ° for the σ-electron lobes, and not only with the π-electron lobes.[26]

Solvation Site. We now consider the correlation between the solvent influence on the d–d absorption spectrum and the solvation site. Prior to the work described here, we found that $[Co(en)_3]^{3+}$ and $[Co(NH_3)_6]^{3+}$, which have no carboxyl groups, did not show a solvent influence on the d–d transition spectra: for $[Co(en)_3]^{3+}$, λ_1=466.5, 466.5, 467.5, 467.0, 468.0, 468.0, 467.0, 467.0, and 468.0 nm and λ_2=338.0, 338.5, 339.0, 338.5, 339.0, 339.0, 339.0, 338.5, and no peak (in H_2O, EG, CH_3OH, FA, Me_2SO, CH_3CN, DMF, DMA, and Me_2CO, respectively); for $[Co(NH_3)_6]^{3+}$, λ_1=474.0, 474.0, 475.0, 475.0, and 475.5 nm and λ_2=339.0, 339.0, 340.0, 340.0, and 340.0 (in H_2O, FA, Me_2SO, DMF, and DMA, respectively). Therefore, the interaction between solvent molecules and carboxyl groups of complex anions could play an important role in the solvent influence on the d–d transition spectra. In a previous paper,[5] we reported that the ^{13}C NMR chemical shifts of the $[Co(edta)]^-$ anion were correlated to the electrophilic ability of the solvents (Gutmann's acceptor number). In order to elucidate the solvent influence on the d–d absorption, the peak positions (λ_1) in the first d–d transition were plotted versus the ^{13}C NMR chemical shifts of this complex anion in several solvents (Fig. 7). It is clear that the peak positions (λ_1) of the first d–d transition bands of the $[Co(edta)]^-$ anion were correlated linearly with the ^{13}C NMR chemical shifts (δ values) of the carboxyl carbon. The downfield shift of

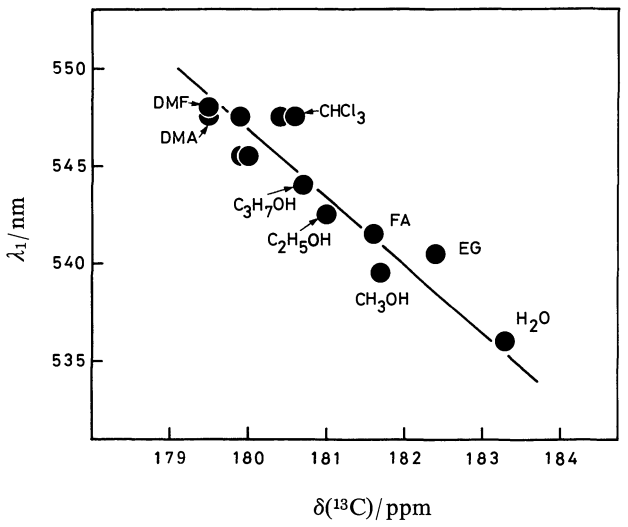

Fig. 7. The correlation between the peak positions (λ_1 in Table 1) and the ^{13}C chemical shifts (Ref. 5) of $K[Co(edta)]\cdot 2H_2O$.

carboxylate ^{13}C signals was due to the electron-withdrawing effect of solvent molecules on the carboxyl groups (specially, perhaps, the carboxyl oxygens) of the cobalt(III) complexes,[27] and thus this effect produced a change in the electronic state for the d–d transition band of the $[Co(edta)]^-$ anion.

We attempted to measure the ^{17}O NMR spectrum of $[Co(edta)]^-$ in the solvents, but no signals were detected. Therefore, we can not confirm the exact site of the interaction of solvation. However, the EHMO calculation of the solvation model, $[Co(ox)_2(NH_3)_2]^- \text{-} H_2O$, shows that H_2O interacts with carboxyl oxygens along the direction of the angle ranging from about 40° to −40° for the σ-electron lobes. A detailed examination of the correlation between the solvation mode and the change of the d–d transition state of the complex anion is now being carried out by ab initio calculations.

Conclusions

The color of the $[Co(edta)]^-$ anion was changed by the outersphere coordination of solvent molecules. This color change could be predicted by using the acceptor number of the solvent. The ^{59}Co NMR chemical shifts and the peak positions in the electronic spectra suggested that the color change was due to the change in the d–d transition energy of the cobalt(III) center. From a comparison with the solvent influence on the ^{13}C NMR, it was found that the $[Co(edta)]^-$ anion interacts with protic solvents through an interaction such as hydrogen bonding between solvent hydrogens and carboxyl oxygens of the cobalt(III) complex anion, and this interaction caused the color change of this complex anion in a variety of solvents. In this work, we have established the method by which the solvent influence on the UV, ^{59}Co NMR, and ^{13}C NMR spectra and the interaction between some carboxylatocobaltate(III) complex anions and solvent molecules can be quantitatively estimated by using the acceptor number of the solvent.

15) In order to check the influence of water of crystallization, we measured the absorption spectra of the sample solution of anhydrous K[Co(edta)]. The peak positions were the same as those of the dihydrate salt ($K[Co(edta)]\cdot 2H_2O$) within experimental error. For other complexes, the peak positions

did not change, though 1 vol% H_2O was added to the sample solution. As the volume of included water in the solution measured was less than that of the added water, there could be no influence of water of crystallization.

16) The first d–d transition band could contain some components since the complexes used here did not exhibit O_h symmetry. However, the band width was not influenced by the solvents. Therefore, the solvent influence on each component in the complex is similar.

17) The solvent influence on the extinction coefficient of the carboxylatocobaltate(III) anions were also checked in the solvents, and there was less than 20% change.

18) E. M. Kosower, *J. Am. Chem. Soc.*, **80**, 3253 (1958).

19) A. J. Parker, *Q. Rev., Chem. Soc.*, **16**, 163 (1962).

20) A plot of the wavenumbers (cm^{-1}) of the peak positions versus the acceptor number also gave a straight line. The intercepts and correlation coefficients were quite similar to those obtained from the plots of the wavelength (nm).

21) The CT bands which appeared in the UV region also shifted from solvent to solvent (226.5, 228.5, and 230.0 nm H_2O, CH_3OH, and C_2H_5OH, respectively, for $[Co(edta)]^-$).

22) R. Bramley, M. Brorson, A. M. Sargeson, and C. E. Schäffer, *J. Am. Chem. Soc.*, **107**, 2780 (1985).

23) J. S. Griffith and L. E. Orgel, *Trans. Faraday Soc.*, **53**, 601 (1957); J. S. Griffith, "The Theory of the Transition Metal Ion," Cambridge University Press, London (1961).

24) The ^{59}Co NMR chemical shift also correlated linearly to the electrophilic ability of the solvents. The chemical shift of the ^{59}Co NMR in the solvent was calculated by the following equations (error bars were one standard deviation):

$$\delta(^{59}Co) = \delta(^{59}Co)^\circ - (5.33\pm0.77) \times AN,$$

where $\delta(^{59}Co)^\circ$=336±22 ppm (the correlation coefficient was −0.924) for $K[Co(edta)] \cdot 2H_2O$, and

$$\delta(^{59}Co) = \delta(^{59}Co)^\circ - (3.51\pm0.77) \times AN,$$

where $\delta(^{59}Co)^\circ$=210±22 ppm (the correlation coefficient was −0.848) for $K_3[Co(ox)_3] \cdot 3H_2O$.

25) J. E. Huheey, "Inorganic Chemistry: Principle of Structure, and Reactivity," 2nd ed, Harper & Row, New York (1978).

26) T. Taura, *Inorg. Chim. Acta*, **163**, 133 (1989).

27) In the literature (O. W. Howarth, P. Moore, and N. Winterton, *J. Chem. Soc., Dalton Trans.*, **1974**, 2271) where the [Co(edta)X] (X: H_2O, Cl, Br, OH, and NO_2)-type complexes were studied, it was proposed that a lower-frequency absorption gave rise to a bigger paramagnetic contribution and to a downfield shift in the case of a positive slope of the line (λ_1 vs. $\delta(^{13}C)$). However, the slope was negative in this work. Therefore, the solvent influence on the ^{13}C chemical shift was not mainly related to the paramagnetic contribution which should be correlated with the mixing of the excited states of the cobalt(III) ion.

Preparation and Characterization of Cobalt(III) Complexes Containing 4,7-Diphenyl-4,7-diphosphadecane-1,10-diamine and 4,8-Diphenyl-4,8-diphosphaundecane-1, 11-diamine, $NH_2(CH_2)_3P(C_6H_5)$-$(CH_2)_nP(C_6H_5)(CH_2)_3NH_2$ (n=2,3)

Kazuo KASHIWABARA, Minho JUNG, and Junnosuke FUJITA*

(Received March 14, 1991)

Twelve new cobalt(III) complexes of the types, *cisα*-[Co(L)(*rac*(*P*)-323 or 333NPPN)]$^{p+}$ (L=2,4-pentanedionate (acac) and oxalate (ox) ions) (four complexes) and *cisβ*-[Co(L)(*rac*(*P*)- or *meso*(*P*)-323 or 333NPPN)]$^{p+}$ (eight complexes) were prepared and characterized by ^{1}H NMR and absorption spectra, where *rac*(*P*)- and *meso*(*P*)-323NPPN denote *rac*(*P*)- and *meso*(*P*)-$NH_2(CH_2)_mP(C_6H_5)(CH_2)_nP(C_6H_5)(CH_2)_mNH_2$ with m=3 and n=2, and 333NPPN the ligand with m=3 and n=3. Reactivities of the complexes towards hydrochloric acid were examined and compared with those of the corresponding 222NPPN (m=2, n=2) and 232NPPN (m=2, n=3) complexes. All the *cisα* isomers yield the *cisα*-dichloro complexes, the 333NPPN and 222NPPN complexes being more reactive than the 232NPPN and 323NPPN complexes in which five- and six-membered chelate rings of NPPN are involved. For the *cisβ* isomers, the acac complexes afford [Co(acac)(Cl)(mnmNPPNH$^+$)]$^{2+}$ except the *rac*(*P*)- and *meso*(*P*)-333NPPN complexes which give the *trans*-dichloro complexes, while all the ox complexes liberate the ox ion to yield the dichloro complex of the *cisα*, *cisβ*, or *trans* configuration. For both *cisβ*-acac and -ox isomers, the 222NPPN and 232NPPN complexes are more reactive than those of 323NPPN and 333NPPN, and the *meso*(*P*)-complexes are more reactive than the *rac*(*P*)-complexes.

In a previous paper,[1] we reported the preparation of stereoisomers of 2,4-pentanedionato (acac) and oxalato (ox) cobalt(III) complexes containing a linear quadridentate ligand with two chiral phosphorus donor atoms, $NH_2(CH_2)_2P(C_6H_5)(CH_2)_nP(C_6H_5)(CH_2)_2NH_2$ (n=2: 222NPPN, n=3: 232NPPN), and their novel reactivities towards hydrochloric acid. For example, the *cisβ* isomers of the acac complexes dissociate the amino group trans to the phosphorus donor atom of NPPN reversibly depending on the acidity of solution to form [Co(acac)-(H_2O)(NPPNH$^+$)]$^{2+}$, while the *cisα* isomers yield *cisα*-dichloro complexes in hydrochloric acid. These properties are quite different from those of analogous tetramine complexes[2] which are stable under the same conditions. In order to examine whether such chemical properties depend on the size of chelate rings of NPPN ligands, we have prepared 4,7-diphenyl-4,7-diphosphadecane-1,10-diamine (323NPPN) and 4,8-diphenyl-4,8-diphosphaundecane-1,11-diamine (333NPPN) complexes of cobalt(III) (Fig. 1).

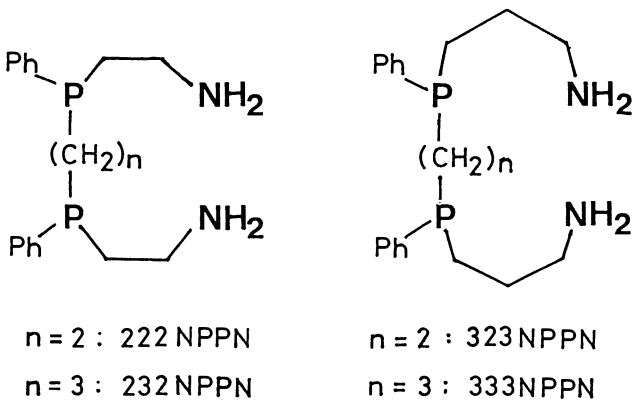

Fig. 1. Linear quadridentate phosphine ligands of the NPPN-type.

Experimental

The phosphine ligands were prepared and handled under an atmosphere of nitrogen until they formed cobalt(III) complexes. All solvents used for the preparation were made oxygen-free by bubbling nitrogen for 20 min immediately before use. Absorption spectra were recorded on a Hitachi U3400 spectrophotometer, and ^{1}H and ^{13}C NMR spectra on a Hitachi R-90H spectrometer.

Preparation of Ligands. 323NPPN and 333NPPN were prepared by a method similar to that for 333NPPN reported by Meek et al.,[3] except that (3-aminopropyl)phenylphosphine was obtained from (3-aminopropyl)diphenylphosphine and sodium.

(3-Aminopropyl)diphenylphosphine, $NH_2CH_2CH_2CH_2P(C_6H_5)_2$. The reported method for $NH_2CH_2CH_2CH_2P(C_6H_5)_2$ was reduction of $NCCH_2CH_2P(C_6H_5)_2$ with $LiAlH_4$.[4] In the present paper, it was prepared from $NH_2CH_2CH_2CH_2Cl$ and $NaP(C_6H_5)_2$. A liquid ammonia solution (300 cm^3) containing $P(C_6H_5)_3$ (65 g, 0.247 mol) and sodium metal (13 g, 0.565 mol) was stirred for 3 h at −78 °C. To the resulting red-orange solution were added $NH_2CH_2CH_2CH_2Cl \cdot HCl$ (Tokyo Kasei Kogyo Co., Ltd.) (32.5 g, 0.25 mol) and tetrahydrofuran (THF) (300 cm^3) by portions. After stirring for 2 h at −78 °C, liquid ammonia was allowed to evaporate slowly. The THF solution was refluxed for 8 h at 60—70 °C, and then the solvent was evaporated under reduced pressure. The residue was distilled at 150—160 °C/ca. 60 Pa to give a colorless viscous liquid. Yield: 48 g (80%).

(3-Aminopropyl)phenylphosphine, $NH_2CH_2CH_2CH_2PH(C_6H_5)$. To a liquid ammonia solution (300 cm^3) of sodium metal (8 g, 0.348 mol) was added (3-aminopropyl)diphenylphosphine (40 g, 0.164 mol) dropwise with stirring at −78 °C. The solution was stirred for 2 h to give an yellow-orange solution. Water (10 cm^3) was added by portions with care,

yielding a colorless solution. Liquid ammonia was evaporated, and the residue was stirred with a mixture of water (200 cm^3) and diethyl ether (200 cm^3). The ethereal layer was separated from water and dried over Na_2SO_4 (5 g) overnight. The solvent was evaporated and the residue was distilled at 95—100°/ca. 60 Pa to yield a colorless liquid. Yield: 22 g (80%).

4,7-Diphenyl-4,7-diphosphadecane-1,10-diamine (323NPPN), $NH_2(CH_2)_3P(C_6H_5)(CH_2)_2P(C_6H_5)(CH_2)_3NH_2$. A THF solution (50 cm^3) of (3-aminopropyl)phenylphosphine (10 g, 59.8 mmol) was added dropwise with stirring at 0 °C to sodium metal (1.5 g, 65.2 mmol) in THF (50 cm^3). After a while the orange solution was warmed at 20 °C, stirred for 6 h and cooled to 0 °C. To the solution was added a THF solution of 1,2-dichloroethane (2.9 g, 29.3 mmol) dropwise with stirring at 0 °C, and then the colorless solution was stirred at 25 °C for 5 h. The solvent THF was evaporated, and diethyl ether was added to precipitate NaCl, which was filtered off. The filtrate was evaporated under vacuum, yielding a colorless oily product. Yield: 15 g (70%). This was used for preparing Co(III) complexes without further purification.

4,8-Diphenyl-4,8-diphosphaundecane-1,11-diamine (333NPPN), $NH_2(CH_2)_3P(C_6H_5)(CH_2)_3P(C_6H_5)(CH_2)_3NH_2$. This ligand was prepared by the same method as that for 323NPPN using 1,3-dichloropropane instead of 1,2-dichloroethane. Yield: 16 g (73%).

Preparation of Cobalt(III) Complexes. *cis*α-[Co(acac)(*rac*(*P*)-323NPPN)]{$B(C_6H_5)_4$}$_2$·1/2$(CH_3)_2CO$ (A-I), *cis*β-[Co(acac)(*rac*(*P*)-323NPPN)]{$B(C_6H_5)_4$}$_2$·H_2O (A-II), and *cis*β-[Co(acac)(*meso*(*P*)-323NPPN)]{$B(C_6H_5)_4$}$_2$ (A-III). A methanol solution (100 cm^3) containing [$Co(acac)_3$] (590 mg, 1.66 mmol) and 323NPPN (600 mg, 1.67 mmol) was stirred at room temperature overnight. The dark orange solution was diluted with water (2 dm^3) and applied on a column (ϕ 4 cm×70 cm) of SP-Sephadex C-25. The adsorbed products were eluted with a 0.1 mol dm^{-3} NaCl aqueous solution. Three large orange bands (**A-I**, **A-II**, **A-III** in the order of elution) and two small red bands developed. Each eluate of **A-I** and **A-II** was evaporated to dryness under reduced pressure at 40 °C. The orange complex in the residue was extracted with ethanol, and the extract was evaporated again to dryness under reduced pressure. The residue was dissolved in water (10 cm^3). On addition of an aqueous solution of $NaB(C_6H_5)_4$, complexes **A-I** and **A-II** were precipitated and recrystallized from a mixture of acetone and water (2:1, 15 cm^3). Yield: **A-I**, 430 mg (33%); **A-II**, 150 mg (8%). The eluate of **A-III** was diluted ten times with water, and rechromatographed using a column (ϕ 3 cm×70 cm) of SP-Sephadex C-25 and a 0.1 mol dm^{-3} Na_2SO_4 aqueous solution. After elution of a small reddish orange band, the eluate of a large orange band (**A-III**) was collected and worked up by the same manner as for **A-I** and **A-II**. Yield: 350 mg (18%). Found for **A-I**: C, 75.54; H, 7.11; N, 2.28%. Calcd for [Co(acac)(323NPPN)]{$B(C_6H_5)_4$}$_2$·1/2$(CH_3)_2CO$=$C_{74.5}H_{80}N_2P_2O_{2.5}B_2Co$: C, 75.45; H, 6.80; N, 2.36%. Found for **A-II**: C, 74.40; H, 6.96; N, 2.27%. Calcd for [Co(acac)(323NPPN)]{$B(C_6H_5)_4$}$_2$·H_2O=$C_{73}H_{79}N_2P_2O_3B_2Co$: C, 74.63; H, 6.78; N, 2.38%. Found for **A-III**: C, 75.70; H, 6.81; N, 2.33%. Calcd for [Co(acac)(323NPPN)]{$B(C_6H_5)_4$}$_2$=$C_{73}H_{77}N_2P_2O_2B_2Co$: C, 75.79; H, 6.71; N, 2.42%. These three complexes are soluble in acetone and acetonitrile, but insoluble in water, methanol and ethanol.

***cis*α-[Co(acac)(*rac*(*P*)-333NPPN)]{$B(C_6H_5)_4$}$_2$·$2H_2O$ (B-I), *cis*β-[Co(acac)(*rac*(*P*)-333NPPN)]{$B(C_6H_5)_4$}$_2$·1/$2H_2O$ (B-II), and *cis*β-[Co(acac)(*meso*(*P*)-333NPPN)]{$B(C_6H_5)_4$}$_2$·1/$2H_2O$ (B-III).** A methanol solution (150 cm^3) containing [$Co(acac)_3$] (810 mg, 2.27 mmol) and 333NPPN (850 mg, 2.27 mmol) was stirred at 50 °C for 30 min, and then at room temperature for 6 h. The resulting brown solution was diluted with water (3 dm^3) and applied on a column (ϕ 4 cm×70 cm) of SP-Sephadex C-25. By elution with a 0.1 mol dm^{-3} NaCl aqueous solution, three large orange bands (**B-I**, **B-II**, **B-III** in the order of elution) and a small red one appeared. From eluates of the orange bands, complexes **B-I**, **B-II**, and **B-III** were isolated as tetraphenylborates by methods similar to those for complexes **A-I** and **A-II**. Yields: **B-I**, 370 mg (14%); **B-II**, 640 mg (24%); **B-III**, 620 mg (23%). Found for **B-I**: C, 73.95; H, 6.97; N, 2.31%. Calcd for [Co(acac)(333NPPN)]{$B(C_6H_5)_4$}$_2$·$2H_2O$=$C_{74}H_{83}N_2P_2O_4B_2Co$: C, 73.64; H, 6.93; N, 2.32%. Found for **B-II**: C, 75.63; H, 6.99; N, 2.19%. Found for **B-III**: C, 75.25; H, 6.96; N, 2.34%. Calcd for [Co(acac)(333NPPN)]{$B(C_6H_5)_4$}$_2$·1/$2H_2O$=$C_{74}H_{80}N_2P_2O_{2.5}B_2Co$: C, 75.33; H, 6.83; N, 2.34%. Solubilities of the complexes are quite similar to those of the 323NPPN analogues.

***cis*α-[Co(ox)(*rac*(*P*)-323NPPN)]$B(C_6H_5)_4$·H_2O·$(CH_3)_2CO$ (C-I), *cis*β-[Co(ox)(*rac*(*P*)-323NPPN)]$B(C_6H_5)_4$·$(CH_3)_2CO$ (C-II), and *cis*β-[Co(ox)(*meso*(*P*)-323NPPN)]$B(C_6H_5)_4$ (C-III).** A methanol solution (15 cm^3) of 323NPPN (695 mg, 1.93 mmol) was added to a solution of $K_3[Co(ox)_3]$·$3H_2O$ (953 mg, 1.93 mmol) in a mixture of water (20 cm^3) and methanol (120 cm^3). The resulting brown solution was stirred overnight and filtered. The filtrate was diluted with water (2 dm^3), and applied on a column (ϕ 3 cm×120 cm) of SP-Sephadex C-25. By elution with a 0.05 mol dm^{-3} NaCl aqueous solution, three large orange bands (**C-I**, **C-II**, **C-III** in the order of elution) and several slow-moving small reddish bands developed. Each eluate of the three orange bands was evaporated to dryness under reduced pressure at 40 °C. The orange complex in the residue was extracted with ethanol. The extract was evaporated again to dryness under reduced pressure, and the residue was dissolved in water (10 cm^3). On addition of an aqueous $NaB(C_6H_5)_4$ solution, the aqueous solution yielded a precipitate of the complex. Complexes **C-I** and **C-II** were recrystallized from a mixture of acetone and water (2:1, 10 cm^3), while complex **C-III** was not recrystallized because of its insolubility in solvents useful for recrystallization. Yields: **C-I**, 90 mg (6%); **C-II**, 400 mg (25%); **C-III**, 270 mg (17%). Found for C-I: C, 65.41; H, 6.43; N, 2.98%. Calcd for [Co(ox)(323NPPN)]$B(C_6H_5)_4$·H_2O·$(CH_3)_2CO$=$C_{49}H_{58}N_2P_2O_6BCo$: C, 65.20; H, 6.48; N, 3.10%. Found for **C-II**: C, 66.48; H, 6.55; N, 3.09%. Calcd for [Co(ox)(323NPPN)]$B(C_6H_5)_4$·$(CH_3)_2CO$=$C_{49}H_{56}N_2P_2O_5BCo$: C, 66.52; H, 6.38; N, 3.17%. Found for **C-III**: C, 66.70; H, 6.27; N, 3.36%. Calcd for [Co(ox)(323NPPN)]$B(C_4H_5)_4$=$C_{46}H_{50}N_2P_2O_4BCo$: C, 66.84; H, 6.10; N, 3.39%. Complexes **C-I** and **C-II** are soluble in acetone and acetonitrile, but insoluble in water and methanol. Complex **C-III** is soluble in dimethyl sulfoxide, slightly soluble in acetone and acetonitrile, and insoluble in water and methanol.

***cis*α-[Co(ox)(*rac*(*P*)-333NPPN)]$B(C_6H_5)_4$·$2(CH_3)_2CO$ (D-I), *cis*β-[Co(ox)(*rac*(*P*)-333NPPN)]$B(C_6H_5)_4$·$2(CH_3)_2CO$ (D-II), and *cis*β-[Co(ox)(*meso*(*P*)-333NPPN)]$B(C_6H_5)_4$ (D-III).** These complexes were prepared by the same method as that for the 323NPPN complexes. Yields: **D-I**, 7%; **D-II**, 36%; **D-III**, 30%. Found for **D-I**: C, 66.67; H, 6.52; N, 2.66%. Found for **D-II**: C, 66.93; H, 6.63; N, 2.85%. Calcd for

[Co(ox)(333NPPN)]$B(C_6H_5)_4 \cdot 2(CH_3)_2CO$=$C_{53}H_{64}N_2P_2O_6BCo$: C, 66.53; H, 6.74; N, 2.93%. Found for **D-III**: C, 67.07; H, 6.32; N, 3.35%. Calcd for [Co(ox)(333NPPN)]$B(C_6H_5)_4$=$C_{47}H_{52}N_2P_2O_4BCo$: C, 67.15; H, 6.24; N, 3.33%. The complexes show similar solubilities to those of the corresponding isomers of the 323NPPN complex.

Reactions of the Complexes with Hydrochloric Acid. All the complexes were converted to the chlorides, which were readily soluble in water, by treating with Dowex 1×8 (Cl^- form) in a mixture of acetone and water (2 : 1). The resin was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The residue was used for studying the reactivity of the complex in water or hydrochloric acid without further purification.

Results and Discussion

The [Co(acac or ox)(mnmNPPN)]$^{p+}$ (*m*, *n*=2, 3) complexes can have three possible geometrical isomers, *cisα-rac(P)*, *cisβ-rac(P)*, and *cisβ-meso(P)* (Fig. 2). The *meso(P)*-ligand can not form the *cisα* isomer, since the two terminal P–N chelate arms point to the same apical site with respect to the P–Co–P plane. These three isomers of [Co(acac or ox)(323NPPN or 333NPPN)]$^{p+}$ were obtained by reactions of [Co(acac)$_3$] or [Co(ox)$_3$]$^{3-}$ with 323NPPN or 333NPPN according to methods for the 232NPPN complexes described in a previous paper.[1] The structures of the acac complexes were assigned on the basis of ^{1}H NMR spectral data (Table 1). Complexes **A-I** and **B-I** show only one methyl signal of acac and are assigned to the *cisα-rac(P)* isomer, while other acac complexes **A-II**, **A-III**, **B-II**, and **B-III** are *cisβ* isomers, since they give two kinds of methyl signal. Of these complexes, **A-III** and **B-III** exhibit one of the two methyl signals at a remarkably high field, δ=0.93 and 1.04, respectively, compared with other methyl signals (δ=1.55—2.19). One methyl group in the *cisβ*-[Co(acac)(*meso(P)*-NPPN)]$^{2+}$-type complexes is located over the phenyl ring bonded to the phosphorus atom trans to the oxygen atom of acac (Fig. 2(c)), and is shielded by this phenyl group as reported for the corresponding 232NPPN complex.[1] Thus complexes **A-III** and **B-III** are assigned to the *cisβ-meso(P)* isomer, and the other **A-II** and **B-II** complexes to the *cisβ-rac(P)* isomer. Both *cisβ-rac(P)* and *cisβ-meso(P)* isomers have a phenyl group over the acac chelate ring, and show the methine proton signal of acac at a higher field than those of the *cisα* isomers (Table 1 and Fig. 2).

For the ox complexes, the *cisα* isomers (**C-I** and **D-I**) can be assigned from a similarity of the visible absorption spectra to those of the acac complexes. The *cisα* isomers show a nearly symmetrical first d–d band, while the *cisβ* isomers give a band with a shoulder in this region (Fig. 3). The spectra of the *cisβ-rac(P)* and *cisβ-*

a) δ, solvent $(CD_3)_2SO$. b) First absorption band $\tilde{\nu}/10^3$ cm^{-1} (log ε), solvent CH_3CN except for **C-III** and **D-III** (solvent $(CH_3)_2SO$). c) Shoulder.

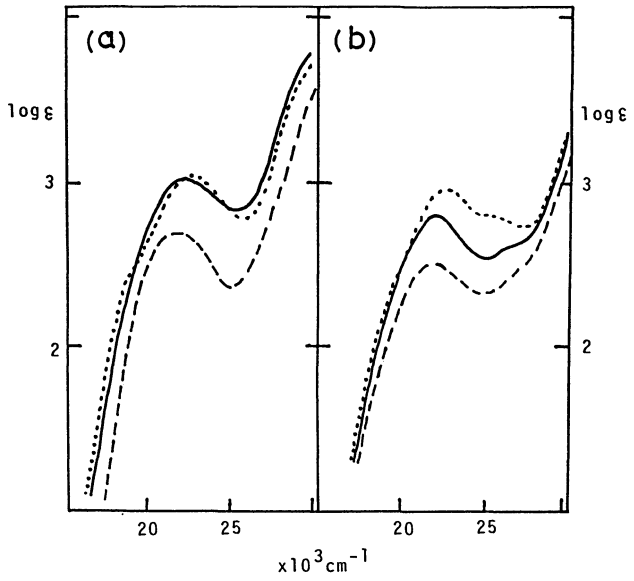

Fig. 3. Absorption spectra of (a) isomers **A-I** (——), **A-II** (——), **A-III** (·····), and (b) isomers **C-I** (——), **C-II** (——), **C-III** (·····).

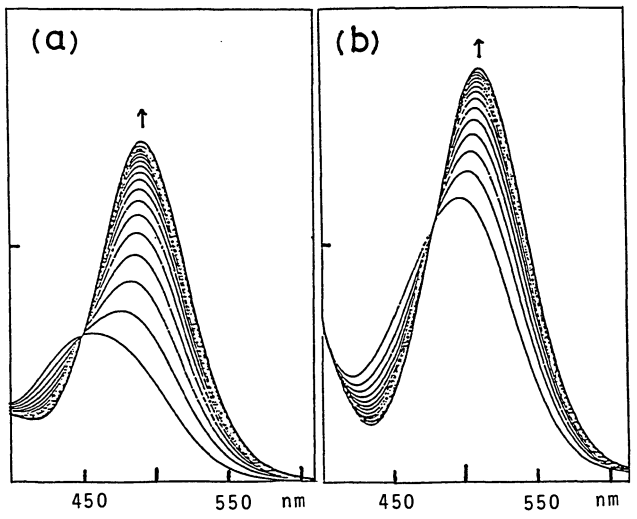

Fig. 4. Changes in absorption spectra of (a) isomer **A-I** in concd HCl recorded at 30 min intervals at 25 °C, and (b) isomer **B-I** in concd HCl recorded at 2 min intervals at 15 °C.

meso(*P*) isomers have a similar pattern, and no assignment can be made for the two *cisβ* isomers. Hence we derived the acac complexes from the ox complexes by treating with Li(acac), and assigned complexes **C-II** and **D-II** as the *cisβ-rac*(*P*) isomer and complexes **C-III** and **D-III** as the *cisβ-meso*(*P*) isomer.

The data of absorption spectra are given in Table 1. The spectra of the 333NPPN complexes are very similar to those of the corresponding 323NPPN and the previously reported 232NPPN[1] complexes. The first d–d bands of the *cisα* isomers shift to the higher energy side in the order of complexes, 333NPPN<232NPPN< 323NPPN<222NPPN. The complexes where the central P–Co–P chelate forms a five-membered ring show the band at higher energy than those containing a six-membered P–Co–P chelate ring. The *cisβ* isomers have all a broad d–d band, and their peak positions do not differ appreciably among the complexes.

The water-soluble chlorides of *cisα*-[Co(acac)(323 or 333NPPN)]$^{2+}$ are stable in water and dil HCl (ca. 1 mol dm^{-3}), but react gradually with concd HCl, changing the color of solutions from orange to red. Figure 4 shows the spectral changes with time. The spectra change with an isosbestic point, and the changes are very similar to those observed for the corresponding 232NPPN and 222NPPN complexes in concd HCl.[1] The products isolated by reactions of the 232NPPN and 222NPPN complexes with concd HCl were *cisα*-[$CoCl_2$(232 or 222NPPN)]$^+$.[1] The spectral changes of the 323NPPN and 333NPPN complexes in concd HCl indicate the formation of *cisα*-[$CoCl_2$(323 or 333NPPN)]$^+$, since their final spectra are very similar to those of the 232NPPN and 222NPPN complexes under the same conditions. The half-life times of the reactions are 390 min at 20 °C for the 323NPPN complex and 6 min at 15 °C for the 333NPPN complex, while those of the 222NPPN and 232NPPN complexes were 87 min and 364 min at 20 °C, respectively.[1] The reactivity of *cisα*-[Co(acac)(*mnm*NPPN)]$^{2+}$ towards concd HCl decreases in the order of the 333NPPN>222NPPN >232NPPN≈323NPPN complexes. The differences in reactivity of the complexes seem to result from steric factors as indicated by molecular models. The 333NPPN complex is the most crowded structure, and the 222NPPN complex involves strain arising from the NPPN skeleton formed by three small five-membered chelate rings. These crowded 333NPPN and strained 222NPPN complexes would be less stable than the 232NPPN and 323NPPN complexes in which such unfavorable conditions are reduced to some extent.

The *cisα*-[Co(ox)(323 or 333NPPN)]Cl complexes in HCl solutions show similar spectral changes, and the final spectra coincide with those of the corresponding acac complexes in concd HCl, indicating the formation of the same *cisα*-dichloro complexes. The ox complexes are more reactive towards HCl than the acac complexes. The half-life times of the reactions in 2 mol dm^{-3} HCl at 30 °C are 43 min for the 323NPPN complex and 3 min for the 333NPPN complex, while it was 220 min for the 232NPPN complex.[1] Thus the reactivity towards HCl decreases in the order of the 333NPPN>323NPPN>232NPPN complexes. The 333NPPN complex is also the most reactive towards HCl as well as the acac analog. For the ox complexes, there is a fairly large difference in reactivity between the 323NPPN and 232NPPN complexes, in contrast to their acac complexes with similar reactivity described above.

The chlorides of *cisβ*-[Co(acac)(*rac*(*P*)- or *meso*(*P*)-323NPPN)]$^{2+}$ are stable in water and fairly strong HCl (ca. 5 mol dm^{-3}) solutions, but react slowly with concd

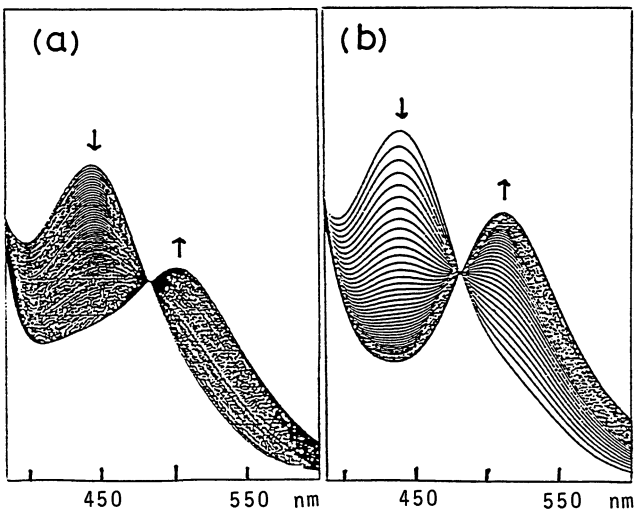

Fig. 5. Changes in absorption spectra of isomers **A-II** (a) and **A-III** (b) in concd HCl at 25 °C recorded at 60 min and 30 min intervals, respectively.

HCl. Figure 5 shows that the spectra of these *rac*(*P*) and *meso*(*P*) complexes change with an isosbestic point at 482 nm and 480 nm, respectively. The colors of solutions change from orange to red. The spectra of the red solutions show the first d–d band at 502 nm for the *rac*(*P*) and 509 nm for the *meso*(*P*) complexes. These values and spectral patterns are quite similar to those of [Co(acac)Cl(*rac*(*P*)- or *meso*(*P*)-232NPPNH$^+$)]$^{2+}$ (505 and 513 nm, respectively) reported in a previous paper.[1] The liberated amino group of the 232NPPN complexes in HCl solutions was found to be the one at the position trans to phosphorus, as shown in Fig. 6, from the ^{1}H NMR spectra of the complexes in DCl.[1] The red concd HCl solutions of the *rac*(*P*)- and *meso*(*P*)-323NPPN complexes turned orange by dilution with water. From the dilute solutions the original complexes were recovered by column chromatography, although some decomposition to Co(II) species occured for both complexes. These observations are also the same as those for the 232NPPN complexes. Therefore, the spectral changes of *cisβ*-[Co(acac)(*rac*(*P*)- or *meso*(*P*)-323NPPN)]$^{2+}$ in concd HCl are also attributable to the dissociation of the amino group trans to phosphorus to form [Co(acac)Cl(*rac*(*P*)- or *meso*(*P*)-323NPPNH$^+$)]$^{2+}$ shown in Fig. 6, although the ^{1}H NMR

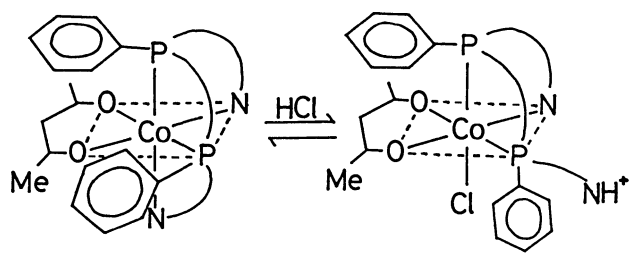

Fig. 6. Dissociation of one amino group of *cisβ*-[Co(acac)(323NPPN)]$^{2+}$ in concd HCl.

spectra in DCl did not show the liberated amino group because of the insufficient acidity of DCl for the 323NPPN complexes. The half-life times at 40 °C in concd HCl are 720 and 75 min for the *rac*(*P*)- and *meso*(*P*)-323NPPN complexes, respectively. The corresponding 232NPPN complexes are more reactive and dissociate the amino group fairly rapidly in 0.1 mol dm^{-3} HCl at room temperature.[1] The remarkable reactivity of the 232NPPN complexes may be attributed to the larger strain of the five-membered chelate ring of the leaving amino group linked meridionally with the P–Co–P chelate ring. The half-life time of 720 min for the reaction of *cisβ*-[Co(acac)(*rac*(*P*)-323NPPN)]$^{2+}$ in concd HCl at 40 °C is much longer than that of the reaction of the *cisα* isomer to *cisα*-[CoCl$_2$(*rac*(*P*)-323NPPN)]$^+$ (21 min at 40 °C in concd HCl), while the corresponding 232NPPN complexes are more stable in the *cisα* isomer than the *cisβ* isomer.

The *cisβ*-[Co(acac)(*rac*(*P*)- or *meso*(*P*)-333NPPN)]$^{2+}$ complexes show different reactivity from the other *cisβ*-acac complexes. The complexes, which are stable in water, react slowly with concd HCl to give a green-brown solution. These solutions exhibit a band around 630 nm, which can be assigned to the split component (Ia) of the first d–d band of the *trans*-[CoCl$_2$(NPPN)]$^+$-type complex.[5] The *trans*-dichloro complexes seem to decompose gradually in concd HCl, since the bands show weak structures characteristic of [CoCl$_4$]$^{2-}$ with passage of time. The reactivity of [Co(acac)(333NPPN)]$^{2+}$ towards HCl is *cisα*-*rac*(*P*) isomer$\gg$*cisβ*-*meso*(*P*) isomer$>$*cisβ*-*rac*(*P*) isomer. The 333NPPN complexes are also more stable in the *cisβ* form than the *cisα* form.

All the isomers of *cisβ*-[Co(ox)(323 or 333NPPN)]Cl are stable in water, but react with concd HCl. Both spectra of *rac*(*P*)- and *meso*(*P*)-323NPPN complexes in concd HCl change in a similar rate with isosbestic points. The final spectrum of the *rac*(*P*) isomer coincides with that of *cisα*-[CoCl$_2$(*rac*(*P*)-323NPPN)]$^+$ yielded from *cisα*-[Co(acac)(*rac*(*P*)-323NPPN)]$^{2+}$ in concd HCl, while that of the *meso*(*P*) isomer shows the first d–d band at 511 nm. The reaction product could not be isolated because of poor crystallization and a small amount. However, the product was tentatively assigned to *cisβ*-[CoCl$_2$(*meso*(*P*)-323NPPN)]$^+$ from the peak position of the d–d band. No starting oxalato complex was detected from the reaction product by column chromatography. The *cisβ* isomers of *rac*(*P*)- and *meso*(*P*)-333NPPN complexes are more reactive than those of the 323NPPN complexes. The orange solutions of the two 333NPPN complexes in 8 mol dm^{-3} HCl slowly turn dark green, and the spectra exhibit a band around 620 nm, which is characteristic of the *trans*-dichloro complex. The *meso*(*P*) isomer is more reactive than the *rac*(*P*) isomer, and its spectral change in a HCl solution has isosbestic points. For the *rac*(*P*) isomer, there is no isosbestic point in the spectra, indicating the presence of a rather stable intermediate

during the reaction of the *cisβ*-oxalato to *trans*-dichloro complexes. However, no further studies were made in this paper.

From the present and the previous papers,[1] the following features are pointed out for the [Co(acac or ox)(*mnm*NPPN)]$^{p+}$-type complexes. (1) The [Co(acac or ox)(*mnm*NPPN)]$^{p+}$ (*m*, *n*=2, 3) complexes yielded all of the three possible isomers (*cisα-rac*(*P*), *cisβ-rac*(*P*), and *cisβ-meso*(*P*)) except that the 222NPPN complex formed no *cisβ-rac*(*P*) isomer. On the other hand, the analogous tetramine (*mnm*NNNN) complexes of the type, [Co(bidentate)(*mnm*NNNN)]$^{p+}$ often afford particular isomers. For example, the 232NNNN complex yields only the *cisβ-rac*(*N*) isomer,[6] and the 323NNNN complex two isomers, *cisβ-rac*(*N*) and *cisβ-meso*(*N*), no *cisα-rac*(*N*) isomer being known.[7] Only known complex of 333NNNN is *cisβ*-[Co(sal)(333NNNN)]$^{+}$ (sal=salycilate ion),[8] and it is reported that [Co(ox)-(333NNNN)]$^{+}$ is too unstable to be isolated,[9] in contrast to the stable 333NPPN complex. The formation of all possible isomers in the *mnm*NPPN complexes may be related in part to the optical stability of a phosphorus donor atom. In the *mnm*NNNN complexes, inversion of the secondary amine group takes place rather easily, and the complexes tend to be stabilized in particular isomers. (2) All *cisα*-[Co(acac or ox)(*rac*(*P*)-NPPN)]$^{p+}$ react with hydrochloric acid to yield *cisα*-[$CoCl_2$(*rac*(*P*)-NPPN)]$^{+}$, and the 222NPPN and 333NPPN complexes are more reactive than the 232NPPN and 323NPPN complexes where the NPPN skeletal structures are formed by a combination of five- and six-membered chelate rings. The *cisα*-[Co(acac)(222NNNN)]$^{2+}$ complex is quite stable under the same conditions.[1] (3) Except the 333NPPN complexes, all *cisβ*-[Co(acac)-(NPPN)]$^{2+}$ in HCl solutions dissociate the amino group trans to phosphorus of NPPN reversibly depending on the acidity of solution, yielding [Co(acac)(Cl or H_2O)(NPPNH^{+})]$^{p+}$. Such a reversible dissociation of an amino end group of chelate has never been reported for cobalt(III) complexes. The *cisβ*-[Co(acac)(*rac*(*P*)- or *meso*(*P*)-333NPPN)]$^{2+}$ complexes yield the *trans*-dichloro complex by reaction with concd HCl. (4) All *cisβ*-[Co(ox)(NPPN)]$^{+}$ release the oxalate ion in hydrochloric acid to form the *cisα*-, *cisβ*-, or *trans*-dichloro complex. No dissociation of the amino group of NPPN was observed. (5) In hydrochloric acid solutions, the 222NPPN and 232NPPN complexes are more stable in the *cisα* isomer than the *cisβ* isomer, while the 323NPPN and 333NPPN complexes are more stable in the *cisβ* isomer than the *cisα* isomer. For each NPPN, the *cisβ-rac*(*P*) isomer is more stable than the *cisβ-meso*(*P*) isomer.

Kinetics and Mechanism of Reduction of Metmyoglobins by Dithionite. Role of the Heme Propionates

Keiichi TSUKAHARA* and Kazuyo ISHIDA
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received March 25, 1991)

The kinetics of the reduction by dithionite ions of metmyoglobins reconstituted with porphinatoiron(III) complexes containing the protoporphyrin IX dimethyl ester, the deuteroporphyrin IX dimethyl ester, and octaethylporphyrin were studied at 25 °C and pH 6.3—9.2 in aqueous solution. Esterification of the heme propionate groups accelerated the reduction rate by $SO_2^{\cdot-}$, as well as the case of octaethylporphyrin (which does not contain the propionate groups); it also affected the redox potential of metmyoglobin, but much less so the rate of the self-exchange reaction. The reaction mechanisms are discussed.

Myoglobin is an oxygen-storage heme protein found in the muscles of vertebrates. Although oxymyoglobin is quite stable under physiological conditions, it undergoes slow autoxidation to form iron(III) metmyoglobin (metMb), which is inactive to molecular oxygen. The reduction of metMb to deoxymyoglobin (deoxyMb) is therefore an important reaction used for recovering deoxyMb. The reduction kinetics of metMb have been extensively studied using both inorganic and organic reducing agents.[1] The modification of the heme environment is a useful technique for elucidating the mechanism of the electron-transfer reactions of hemoproteins. We have reported that modifying the heme distal histidine, heme propionates, and peripheral substituents of the heme affects the reduction rate of metMb and that the geometry change at the iron site upon reduction of metMb(H_2O) to deoxyMb is an especially important factor.[1,2]

The native metMb has protoporphinatoiron(III) ($Fe^{III}PP$) as a prosthetic group. The heme propionates in sperm whale metMb make a salt bridge with Arg 45 and a hydrogen bond to His 97, thereby stabilizing the structure of the heme pocket.[3] We previously suggested that the salt bridge as well as the hydrogen bond between these residues and the heme propionates are important regarding the reactivity differences in the redox reactions of sperm whale and horse heart metmyoglobins, the latter having a Lys residue in place of Arg 45 in the former.[4]

Dithionite ions are widely used as a reducing agent for the reductions of not only metal complexes, but also biological redox systems;[5] the reactive species is a $SO_2^{\cdot-}$ radical anion which is produced by a dissociation of the $S_2O_4^{2-}$ ion. In this work we report on a dithionite reduction of the reconstituted metmyoglobins with three artificial hemes containing methyl esters of propionate groups, or without propionic acid chains, which cannot make the salt bridge with Arg 45 and/or the hydrogen bond to His 97; it is therefore expected to clarify the role of the heme propionates on the reduction of metmyoglobin.

Experimental

Materials. Sperm whale skeletal muscle metmyoglobin (type II, Sigma) was purified as previously described.[4] The recombination of chloro(porphinato)iron(III) complexes containing protoporphyrin IX dimethyl ester (PPDME), deuteroporphyrin IX dimethyl ester (DPDME), and octaethylporphyrin (OEP) with apomyoglobin, as well as the purification, were carried out by a method which has already been published.[6,7] The purity of the reconstituted metmyoglobins was checked spectrophotometrically. Sodium dithionite (Fluka AG) was used without further purification. The concentration was determined spectrophotometrically by reactions with

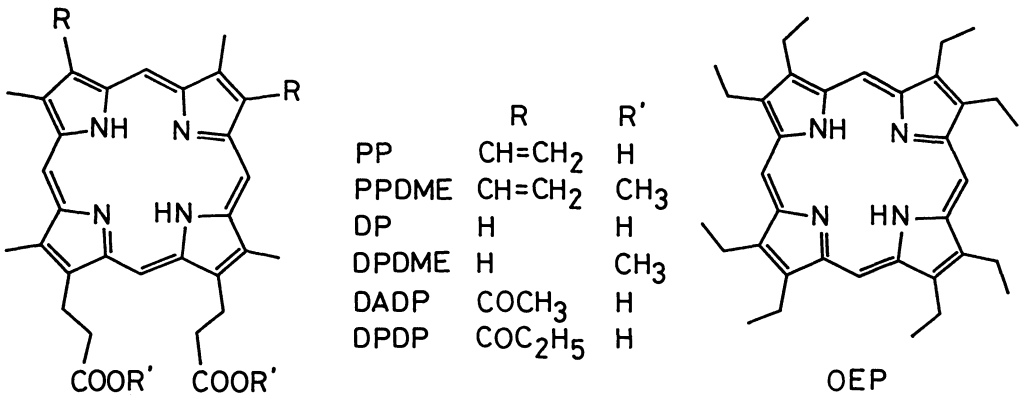

Fig. 1. Structures of porphyrins.

the hexacyanoferrate(III) ion (ε_{418}=1.01×10³ $M^{-1}cm^{-1}$; 1 M= 1 mol dm^{-3}).[8] Hexaammineruthenium(III) chloride ([Ru(NH_3)$_6$]Cl_3) was purchased from Aldrich Chemical Co. and purified by a method described in the literature.[9] The corresponding ruthenium(II) ion was prepared in situ by dithionite reduction. All other chemicals used were of guaranteed grade. All of the solutions used for measurements were prepared by using redistilled water.

Kinetic Measurements. All of the reactions were carried out in argon-saturated solutions at 25 °C. The solutions of the dithionite ion ((0.43—3.50)×10⁻³ M) and metmyoglobins ((2.0—4.0)×10⁻⁶ M) in a 0.1 M MES (2-morpholinoethanesulfonic acid) or a 0.1 M phosphate buffer at pH 6.3—9.2 and the ionic strength (I) of 0.1 M or 0.2 M (adjusted with NaCl) were mixed in Photal RA-401 stopped-flow and RA-415 rapid-scanning spectrophotometers. The reactions were followed by the decrease in absorbance at 407 nm (PPDMEmetMb(H_2O)), 393 nm (DPDMEmetMb(H_2O)), and 395 nm (OEPmetMb(H_2O)). The appearance of deoxyMb was also followed at 434 nm (PPDMEdeoxyMb), 422 nm (DPDMEdeoxyMb), and 420 nm (OEPdeoxyMb). The electron-transfer reaction between PPDMEmetMb(H_2O) and native deoxyMb produced by a dithionite ion was carried out at 25 °C, pH 6.3 (a 0.1 M MES buffer), and I=0.1 M. The reaction was followed at both 502 and 550 nm by the use of a Shimadzu UV-200S spectrophotometer. The concentrations of PPDMEmetMb(H_2O) and native deoxyMb were 3.00×10⁻⁵ M and (1.70—4.20)×10⁻⁴ M, respectively.

Equilibrium Measurements. The acid-dissociation constant for the heme-linked water molecule of DPDMEmetMb(H_2O) (1.00×10⁻⁵ M) was determined spectrophotometrically (380—395 nm) at 25 °C and I=0.1 M (a phosphate buffer). The redox potential of PPDMEmetMb(H_2O) was determined spectrophotometrically by using the [Ru(NH_3)$_6$]$^{2+}$ ion as a redox partner. Redox titration was carried out in an argon atmosphere at 25 °C, pH 6.3 (a 0.1 M MES buffer), I=0.1 M, [metMb]=4.40×10⁻⁵ M, [Ru(II)]=0—1.98×10⁻⁴ M, and [Ru(III)]=3.50×10⁻⁴ M. The spectral change was monitored in the 450—700 nm region by using a Shimadzu UV-200S spectrophotometer. The molar absorption coefficients used in this work were as follows: ε_{505}=8.80×10³ $M^{-1}cm^{-1}$ and ε_{555}=4.30×10³ $M^{-1}cm^{-1}$ for PPDMEmetMb(H_2O); ε_{505}= 6.00×10³ $M^{-1}cm^{-1}$ and ε_{555}=1.30×10⁴ $M^{-1}cm^{-1}$ for PPDMEdeoxyMb.

The pH's of the solutions were measured on a Hitachi-Horiba F-14RS pH meter.

Results and Discussion

Redox Potential of PPDMEmetMb(H_2O). The redox potential of PPDMEmetMb(H_2O) was determined spectrophotometrically in combination with the [Ru(NH_3)$_6$]$^{3+/2+}$ redox couple by a previously described method.[2] The [Ru(NH_3)$_6$]$^{2+}$ ion was prepared by a dithionite reduction of the [Ru(NH_3)$_6$]$^{3+}$ ion, since the Zn(Hg) reduction[2] of Ru(III) induced the denaturation of PPDMEmetMb(H_2O) in contrast to reconstituted metmyoglobins with hemins containing propionic acids. Four isosbestic points were observed in the 450—700 nm region during titration (Fig. 2). The equilibrium constant for the reaction

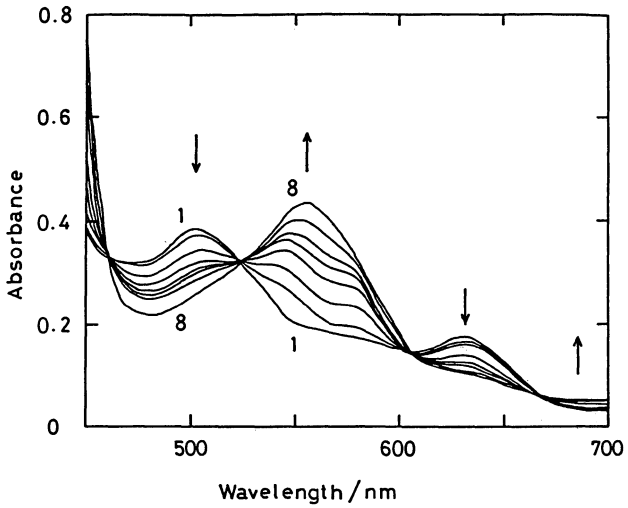

Fig. 2. Redox titration of PPDMEmetMb(H_2O) (4.40×10⁻⁵ M) in the presence of [Ru(NH_3)$_6$]$^{3+}$ ions (3.50×10⁻⁴ M) with various amounts of [Ru(NH_3)$_6$]$^{2+}$ ions at 25 °C, pH 6.3 (0.1 M MES buffer), and I=0.1 M. (1) 0, (2) 2.0×10⁻⁵, (3) 4.0×10⁻⁵, (4) 6.0×10⁻⁵, (5) 8.0×10⁻⁵, (6) 1.19×10⁻⁴, (7) 1.79×10⁻⁴, and (8) 1.98×10⁻⁴ M.

$$\text{PPDMEmetMb}(H_2O) + [Ru(NH_3)_6]^{2+} \rightleftarrows \text{PPDMEdeoxyMb} + [Ru(NH_3)_6]^{3+} \quad (1)$$

was determined from the slope of plots of [deoxyMb]/[metMb] against [Ru(II)]/[Ru(III)]. When the value of 0.05 V was used for the redox potential of the [Ru(NH_3)$_6$]$^{3+/2+}$ couple,[10] a value of 0.090±0.010 V was obtained for the redox potential of PPDMEmetMb(H_2O). The redox potential of PPDMEmetMb(H_2O) is higher than that of the native metMb(H_2O) by about 30 mV (E^0=0.059 V for the latter[11]). The shift of the E^0 value by esterification of the heme propionate groups is similar to that for cytochrome b_5.[12] The pK_a for the acid dissociation of the coordinated water molecule of PPDMEmetMb(H_2O) is 8.0, being smaller than that for native metMb(H_2O) (pK_a=9.16[1]). These results strongly suggest that the electron density of the Fe(III) center decreases upon esterification of the heme propionate groups.

Reduction of Reconstituted Metmyoglobins by Dithionite. Rapid scanning difference absorption spectra taken during the reduction of PPDMEmetMb(H_2O) by dithionite ions are shown in Fig. 3. Three isosbestic points were observed in the 380—540 nm region for each system. The plots of $-\ln(A_\infty - A_t)$ vs. time were linear for at least 90% completion of both the decay of metMb and the formation of deoxyMb, where A_∞ and A_t represent the absorbance at infinity and time t, respectively. The observed first-order rate constants (k_{obsd}) obtained from the slopes of the straight lines showed a half-order dependence on the initial concentrations of the dithionite ion ([$S_2O_4^{2-}$]$_0$), as is shown in Fig. 4. Therefore, the rate law for the dithionite reduction is given by

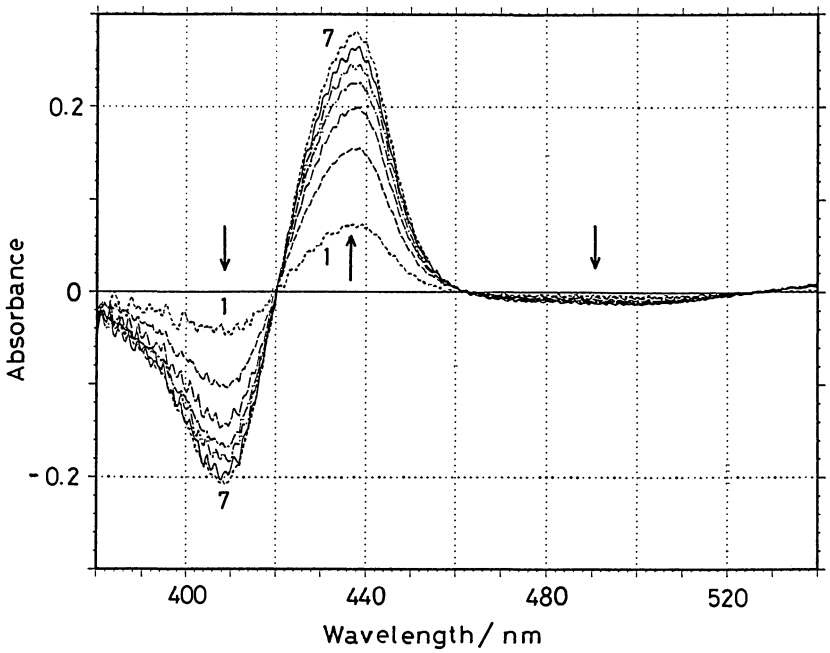

Fig. 3. Rapid-scanning spectra for the reduction of PPDME-metMb(H_2O) (3.9×10^{-6} M) by dithionite ions (1.10×10^{-3} M) at 25 °C and pH 6.7 (0.1 M phosphate buffer). (1) 18 ms, (2) 22 ms, (3) 26 ms, (4) 30 ms, (5) 34 ms, (6) 38 ms, and (7) 46 ms. The times given are for the start of scan at 380 nm.

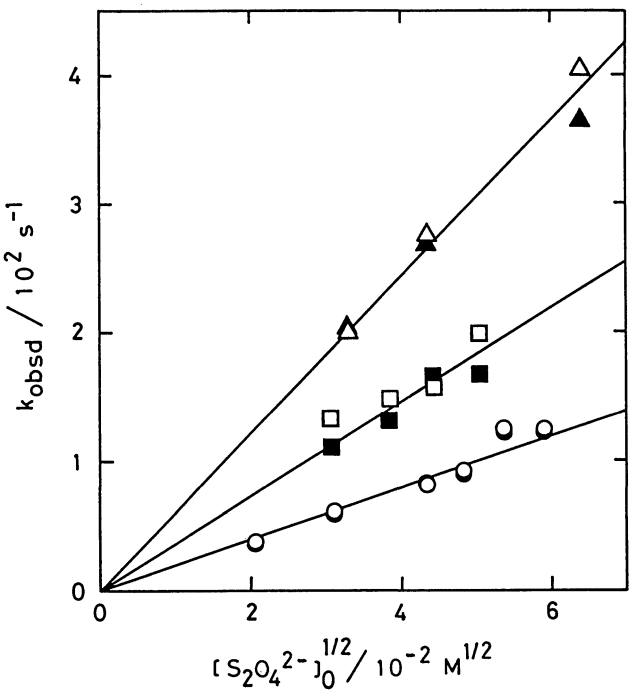

Fig. 4. Plots of k_{obsd} vs. $[S_2O_4^{2-}]_0^{1/2}$ for the dithionite reductions of reconstituted metmyoglobins at 25 °C, pH 6.3 (0.1 M MES buffer), and I=0.1 M. ○: PPDMEmetMb(H_2O) at 407 nm, ●: PPDME-metMb(H_2O) at 434 nm, □: DPDMEmetMb(H_2O) at 393 nm, ■: DPDMEmetMb(H_2O) at 422 nm, △: OEPmetMb(H_2O) at 395 nm, and ▲: OEP-metMb(H_2O) at 420 nm.

$$-d[Fe(III)]/dt = kK_D^{1/2}[S_2O_4^{2-}]_0^{1/2}[Fe(III)], \quad (2)$$

where K_D is the dissociation constant for the dithionite ion (K_D=1.4×10^{-9} M at 25 °C).[5a]

$$S_2O_4^{2-} \overset{K_D}{\rightleftarrows} 2SO_2^{\cdot-} \quad (3)$$

The second-order rate constant (k) obtained from the slopes of the straight lines in Fig. 4 decreased with an increase in pH (Fig. 5). The reduction of metMb can be accommodated by the following scheme:

$$metMb(H_2O) \overset{K_a}{\rightleftarrows} metMb(OH) + H^+ \quad (4)$$

$$metMb(H_2O) + SO_2^{\cdot-} \xrightarrow{k_{H_2O}} deoxyMb + SO_2 \quad (5)$$

$$metMb(OH) + SO_2^{\cdot-} \xrightarrow{k_{OH}} deoxyMb + SO_2 \quad (6)$$

Since the intercept in Fig. 4 is near zero, reduction by the $S_2O_4^{2-}$ species is negligible in the present systems. According to Reactions 4—6, the second-order rate constant (k) is represented as

$$k = \frac{k_{OH}K_a + k_{H_2O}[H^+]}{K_a + [H^+]}. \quad (7)$$

The k_{OH} path is at least 10-times slower than the k_{H_2O} path (k_{H_2O}=6.5×10^7 $M^{-1}s^{-1}$ and $k_{OH} \leqq 6.5\times10^6$ $M^{-1}s^{-1}$ for the PPDME system). This behavior is consistent with the results for the other dithionite reduction of metmyoglobins.[2,5] Since the electron density of the Fe(III) center increased upon the ligation of OH^-, more so than the water molecule, the rate of reduction by $SO_2^{\cdot-}$ is considered to decrease. The rate constants for Reaction 5 are listed in Table 1 along with the values of

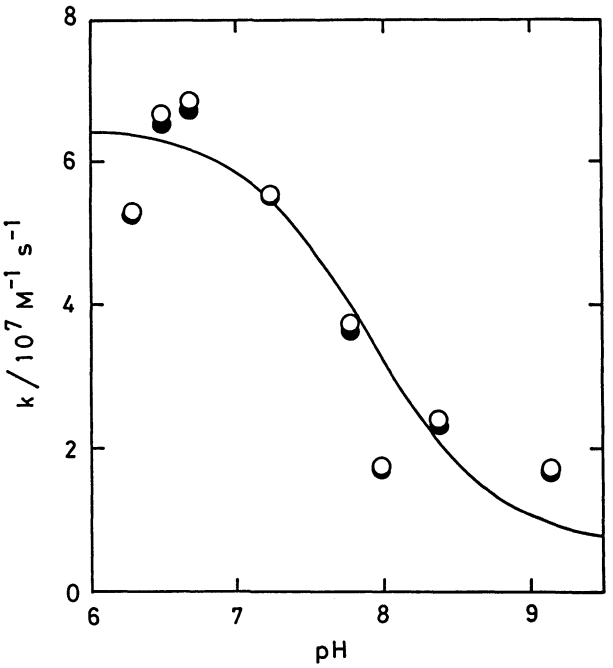

Fig. 5. pH Dependence of the second-order rate constants (k) for the reduction of PPDMEmetMb(H_2O) by $SO_2^{\cdot-}$ at 25 °C and I=0.2 M. The solid curve is on the basis of Eq. 7 by the use of pK_a=7.90, k_{H_2O}= 6.5×10^7 $M^{-1}s^{-1}$, and $k_{OH}=6.5\times10^6$ $M^{-1}s^{-1}$. ○: 407 nm and ●: 434 nm.

pK_a regarding the dissociation of the coordinated water molecule at the heme iron site of metMb(H_2O). Plots of log k_{H_2O} vs. pK_a of metMb(H_2O) are shown in Fig. 6. The values of log k_{H_2O} increase with a decrease in the pK_a values of metMb(H_2O). Since the decrease in pK_a corresponds to that in the electron density at the Fe(III) center, the electron of $SO_2^{\cdot-}$ may be easily transferred to the Fe(III) center. The slopes of the plots of log k_{H_2O} vs. pK_a for both the dimethyl esters and OEP are quite different from those of systems containing propionic acid side chains (−1.32 for the former and −0.51 for the latter). Although the redox potential of PPDMEmetMb(H_2O) is lower than that of either DADPmetMb(H_2O) or DPDPmetMb(H_2O), the reduction of the former by $SO_2^{\cdot-}$ is faster than that for the latter. It is known that the heme environmental structures of the DP-, DADP-, and DPDP-metmyoglobins are similar to that of the native metMb(H_2O).[1] Therefore, the acceleration in the reduction of the dimethyl esters cannot be explained by only electronic effects. A steric alteration in the heme environment due to esterification must be concerned. Esterification of the heme propionate groups breaks the salt bridge between Arg 45 and the heme propionic acids and the hydrogen bond with His 97. The heme pocket is thereafter expected to expand, allowing the $SO_2^{\cdot-}$ ion to easily attack the heme iron center and/or the heme edge. Neya et al.[7] have demonstrated by an NMR study of OEP-myoglobin that OEP iron(III) serves as a prosthetic group for myoglobin with normal function, despite the structural difference from native myoglobin, especially at the heme distal side.

Estimation of Self-Exchange Rate Constant for PPDMEmetMb(H_2O)/deoxyMb System. To estimate the self-exchange rate constants for the PPDME-

metMb(H_2O)/deoxyMb system, the reaction of PPDMEmetMb(H_2O) with native deoxyMb was examined at 25 °C, pH 6.3, and I=0.1 M. The differences in the molar absorption coefficients between metMb(H_2O) and deoxyMb are 3.1×10^3 M^{-1} cm^{-1} at 502 nm and -6.7×10^3 M^{-1} cm^{-1} at 505 nm for PPDME-myoglobins and 5.0×10^3 M^{-1} cm^{-1} at 502 nm and -9.3×10^3 M^{-1} cm^{-1} at 550 nm for native myoglobins, respectively. An increase in the absorbance at 502 nm and a decrease in the absorbance at 550 nm were observed during reactions under the condition [native deoxyMb]$_0$> [PPDMEmetMb(H_2O)]$_0$. Therefore, the following reaction occurs:

$$\text{PPDMEmetMb}(H_2O) + \text{native deoxyMb} \rightarrow \text{PPDMEdeoxyMb} + \text{native metMb}(H_2O). \quad (8)$$

This is also expected from the redox potentials for these myoglobins (0.090 V for PPDMEmetMb(H_2O) and 0.059 V for native metMb(H_2O)). The rate constants of Reaction 8 are given in Table 2. The rate constants of the electron-transfer reactions between myoglobins are about 1 M^{-1} s^{-1}, as is given in Table 3. This value is similar to the self-exchange rate constant estimated from the Marcus theory for the electron-transfer reactions of myoglobins containing heme propionic acids with inorganic and organic redox reagents.[2,13] The slowness of the self-exchange reaction of these myoglobins may be ascribable to a geometry change at the heme iron site from hexacoordinated metMb(H_2O) to pentacoordinated deoxyMb, where the release of the water molecule must occur upon reduction.[2] Contrary to the dithionite reduction of metmyoglobins, the electron-transfer reaction between PPDMEmetMb(H_2O) and native deoxyMb was not accelerated. This is probably due to a reaction between large molecules in the latter system.

Unique Condensation Reactions of Tropones with Bis(benzoylthio)trithiafulvene Leading to 10a*H*-Cyclohepta[*c*]-1,3-dithiolo[*e*][1,2]dithiin-2-thione

Katsuhiro SAITO,* Kazuaki ITO, Chizuko KABUTO,† and Kensuke TAKAHASHI

(Received December 5, 1990)

Reactions of tropone derivatives with 4,5-bis(benzoylthio)-1,3-dithiole-2-thione (2,3,6-trithiafulvene derivative) afforded 1,3,5-cycloheptatriene derivatives doubly substituted by trithiafulvene and S–S groups (10a*H*-cyclohepta[*c*]-1,3-dithiolo[*e*][1,2]dithiin-2-thione). The structure of the 1,3,5-cycloheptatriene derivative and its crystal structure were investigated by single crystal X-ray analysis to show the existence of a unique three-dimensional network of the molecules through S···S contacts.

Not only from the viewpoint of pharmacological utilities, but also from chemical and physical interests in their reactivities and electronic natures, the chemistry of sulfur-containing heterocyclic compounds have attracted much attention from chemists.[1] A trithiafulvene derivative, 4,5-bis(benzoylthio)-1,3-dithiole-2-thione (**2**)[2] has been used to prepare donor components of several types of organic superconductors such as bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF).[3] While many studies have been published on the reactivities of sulfur-containing heterocyclic compounds to show facile occurences of cleavages and recombinations of C–S and S–S bonds,[4] only a few have been researched the reaction of trithiafulvene derivatives. The trithiafulvene derivative (**2**) has two benzoylthio groups per molecule, forming a tetrathio-substituted ethylene moiety, which is expected to show characteristic reactivities.

Tropones are known to have dipolar components constructing 6π-electron aromatic structures.[5] Despite their aromaticities, tropones are fairly active in addition reactions. Tropones not only react easily with halogens or hydrogenes,[6] but they also behave as 4π- or 8π-electron units in [4+2]- or [8+2]-type cycloaddition reactions, respectively.[7] Although many types of addition reactions of tropones and olefins or heterocyclic compounds have been researched extensively, studies of reactions with sulfur-containing compounds seem to be relatively few in number. This is curious, considering that tropothione and 2-mercatotropone have been attracting the attention of chemists because of their unique and characteristic reactivities caused by the introduction of sulfur atoms.[8]

As part of our research on the addition reactions of troponoid compounds,[9] we have studied the reactions of **2** with various tropones (**1**) to obtain condensation products leaving benzoic anhydride. We present our results in this report.

Results and Discussion

A solution of **2** and an excess amount of tropone (**1a**) was allowed to react at room temperature for 3 d. Separation and purification of the reaction mixture with silica-gel chromatography gave a crystalline product **3a** in a 39% yield (Scheme 1).[10] The analogous reaction using 2-phenyltropone (**1b**) in benzene resulted in a quantitative recovery of the starting materials. At an elevated temperature of 60 °C for 3 d, however, **3b** was obtained in a 14% yield. The reactions with 2-(*p*-methoxyphenyl)- (**1c**) and 2-methyltropones (**1d**) at 60 °C gave **3c** (26% yield) and **3d** (26% yield), respectively.

The structures of the products were deduced on the basis of their spectral properties. The molecular ion peaks in the high-resolution MS spectra demonstrated

Scheme 1.

that the products were derived from the condensation reactions of **1** and **2** followed by the elimination of benzoic anhydride. ^{1}H NMR spectra and ^{13}C NMR spectra indicated the existence of a 1,3,5-cycloheptatriene moiety with a continued array of ring protons H_a, H_b, H_c, H_d, and H_e in that order, with H_a as a methine proton. The position of the substituents were determined by the use of NOE measurements.[11] The existence of thioxo groups was clearly demonstrated by characteristic absorptions at ca. 1060 cm^{-1} in the IR spectra.[2,3]

Finally, the structure of **3a** was determined unambiguously by X-ray analysis, indicating the existence of a disulfide bond (Fig. 1). The bond lengths and angles obtained were all normal (Table 1). The analysis of molecular planarity indicated that the trithiafulvene moiety had a planar conformation and that the S(5) atom deviated by 0.109 Å from this plane, while the cycloheptatriene moiety had a boat conformation.

In the crystal structure, a noticeable amount of overlapping was observed between two parallel-stacked trithiafulvenes as shown in Fig. 2. The interplanar distance of these rings was 3.57 Å. A three-dimensional network was also formed by intermolecular S ···· S interactions as shown in Fig. 3. The network was formed by four molecular linkages, which consisted of two types of S ···· S contacts, S(1) ···· S(4)=3.43 Å and S(2) ···· S(5)=3.57 Å, both shorter than the Van der Waals contact of 3.7 Å.

The formation of **3** is hypothesized to proceed as follows. The reaction is thought to be initiated by a nucleophilic attack of the oxygen atom of **1** on the carbonyl carbon of the benzoyl group of **2** to form the

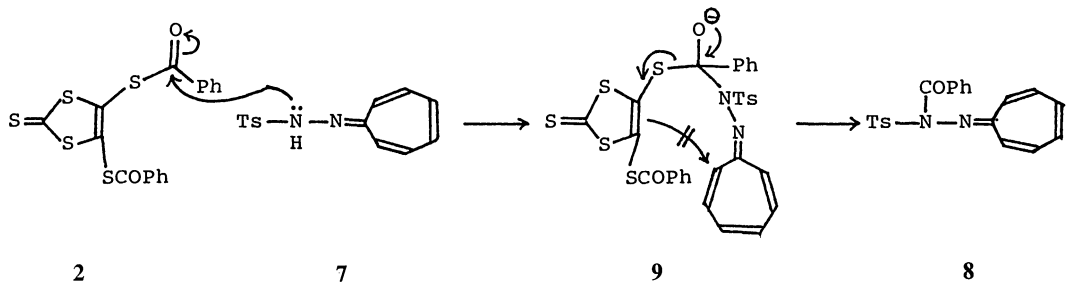
tropylium cation intermediate **4** (Scheme 2). The following observation seems to support this hypothesis.[7] Analogous reactions using tropones bearing electron-withdrawing groups such as a chloro (**1e**) or cyano (**1f**) group failed to give products of type **3**, but resulted in quantitative recoveries of the starting materials.

The MO calculations obtained by the MNDO method showed the existence of a relatively large charge separation between the carbon and the oxygen atoms of the carbonyl groups of **1a**—**1d**, supporting an initial nucleophilic attack by the carbonyl oxygen in the reaction as described above. The failure of the reactions of tropones bearing electron-attracting substituents such as chloro (**1e**) or cyano (**1f**) groups is thought to be attributable to the small degree of negative charge at the carbonyl oxygen atoms of these tropones (Table 2).[12]

The subsequent cleavage of a C–S bond and a nucleophilic attack of a C=C double bond of the trithiafulvene part on the tropylium cation moiety gives intermediate **5**. The substitution of four sulfur atoms is thought to contribute to the promotion of the nucleophilicity of the C=C bond. An attack by the carbonyl oxygen on the carbon atom of another carbonyl group yields intermediate **6**. A C–S bond cleavage and the elimination of benzoic anhydride produces the final product **3**.

The important role of the tropylium cation moiety in the reaction pathway was shown by the following experiment. Reaction of tropone tosylhydrazone (**7**)[13] with **2** in benzene at room temperature for 3 d gave no product corresponding to **3**, but yielded tropone *N*-benzoyltosylhydrazone (**8**) in a 74% yield (Scheme 3).

The reaction is thought to proceed through a pathway analogous to that of **1** initiated by an attack of the amino group of **7** on the carbonyl group of **2** to form an intermediate (**9**), which then undergoes a C–S bond cleavage.[14]



Scheme 3.

Experimental

Melting points were recorded on a Yanagimoto Micro Melting Point Apparatus and were uncorrected. The NMR spectra were measured with Hitachi R20B or Varian XL-200 spectrometers. IR, UV, and MS spectra were measured with JASCO FT/IR-5300, Hitachi 220A, and Hitachi M-2000S spectrometers, respectively. Wakogel C-200 and Wakogel B5-F were used for column and thin-layer chromatography, respectively.

Reaction of Tropone (1a) and 2. A mixture of **1a** (2.00 g, 20 mmol) and **2** (410 mg, 1 mmol) was stirred at room temperature for 3 d. Separation of the reaction mixture by column chromatography on silica gel gave crystals of **3a** (110 mg, 39% yield, with hexane), recovery of **2** (80 mg, with hexane–ethyl acetate 9 : 1), benzoic acid (78 mg, 32% yield, with hexane–ethyl acetate 4 : 1), and recovery of **1a** (1.67 g, with hexane–ethyl acetate 3 : 1). Recrystallization from benzene gave yellow plates of **3a**: Mp 147—149 °C. Found: C, 41.78; H, 2.00; S, 56.06%. Calcd for $C_{10}H_6S_5$: C, 41.93; H, 2.11; S, 55.96%. MS m/z (rel intensity) 286 (M^+, 46), 253 (41), 210 (46), 177 (82), and 146 (100). IR (KBr) 3030, 1360, 1050, 1030, 790, and 710 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.72 (dd, H_a), 5.43 (dd, H_b), 6.45 (m, H_c), and 6.62—6.84 (m, 3H, $H_{d,e,f}$). Coupling constants in Hz: J_{ab}=6.0, J_{ac}=1.0, J_{bc}=9.2, and J_{cd}=4.8. ^{13}C NMR ($CDCl_3$) δ=42.4, 122.7, 123.8, 126.7, 127.1, 130.2, and 131.7.

Reaction of 2-Phenyltropone (1b) and 2. A solution of **1b** (960 mg, 6 mmol) and **2** (410 mg, 1 mmol) in benzene (5 ml) was heated at 60 °C for 4 d. The reaction mixture was separated by column chromatography on silica gel to give crystals of **3b** (34 mg, 14% yield, with hexane–ethyl acetate 49 : 1), recovery of **2** (130 mg, with hexane–ethyl acetate 11 : 1), benzoic acid (60 mg, 25% yield, with hexane–ethyl acetate 11 : 1), and recovery of **1b** (830 mg, by hexane–ethyl acetate 9 : 1). Recrystallization from benzene gave yellow plates of **3b**: Mp 144—145 °C. High-resolution MS Found: m/z 361.9382. Calcd for $C_{16}H_{10}S_5$: m/z 361.9385. MS m/z (rel intensity) 362 (M^+, 14), 197 (50), and 165 (100). IR (KBr) 3030, 1480, 1070, 760, and 700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.38 (d, H_a), 5.47 (dd, H_b), 6.38 (dd, H_c), 6.81 (d, H_e), 6.90 (dd, H_d), and 7.26—7.52 (m, 5H, Ph). Coupling constants in Hz: J_{ab}=6.0, J_{bc}=8.0, J_{cd}=4.8, and J_{de}=10.4. ^{13}C NMR ($CDCl_3$) δ=48.0, 123.4, 123.9, 125.7, 128.6, 129.7, 132.2, 134.0, 135.3, and 137.7.

Reaction of 2-(*p*-Methoxyphenyl)tropone (1c) with 2. A solution of **1c** (760 mg, 4 mmol) and **2** (410 mg, 1 mmol) in benzene (5 ml) was reacted at 60 °C for 5 d. The reaction mixture was separated by column chromatography on silica gel to give recovery of **2** (200 mg, with hexane–ethyl acetate 1 : 9), recovery of **1c** (680 mg, with hexane–ethyl acetate 1 : 4), and **3c** as an oil (50 mg, 26% yield, with hexane–ethyl acetate 1 : 9).

3c: High-resolution MS Found: m/z 391.9501. Calcd for $C_{17}H_{12}OS_5$: m/z 391.9492. MS m/z (rel intensity) 392 (M^+, 40), 290 (14), and 239 (100). IR (oil) 3030, 1600, 1500, 1240, 1060, 760, and 700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.34 (d, H_a), 3.88 (s, 3H, Me), 5.48 (dd, H_b), 6.38 (dd, H_c), 6.82 (d, H_e), 6.91 (dd, H_d), and 6.96—7.40 (AA'BB', 4H, benzene ring protons). Coupling constants in Hz: J_{ab}=4.5, J_{bc}=6.6, J_{cd}=3.9, and J_{de}=8.4. ^{13}C NMR ($CDCl_3$) δ=47.7, 55.2, 113.8, 114.1, 123.0, 123.3, 125.5, 129.9, 130.0, 131.0, 132.1, and 134.1.

Reaction of 2-Methyltropone (1d) with 2. A solution of **1d** (390 mg, 3 mmol) and **2** (410 mg, 1 mmol) in benzene (5 ml) was heated at 60 °C for 6 d. The reaction mixture was separated by column chromatography on silica gel to give **3d** as an oil (41 mg, 26% yield, with hexane), recovery of **2** (190 mg, with hexane–ethyl acetate 4 : 1), and recovery of **1d** (290 mg, with hexane–ethyl acetate 7 : 3).

3d: High-resolution MS Found: m/z 299.9217. Calcd for $C_{11}H_8S_5$: m/z 299.9229. MS m/z (rel intensity) 300 (M^+, 17), 205 (39), and 110 (100). IR (oil) 3020, 2950, 1050, 760, and 700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.08 (s, 3H, Me), 3.30 (d, H_a), 5.41 (dd, H_b), 6.26 (dd, H_c), 6.73 (dd, H_d), and 6.87 (d, H_e). Coupling constants in Hz: J_{ab}=4.2, J_{bc}=6.8, J_{cd}=3.1, and J_{de}=8.3. ^{13}C NMR ($CDCl_3$) δ=29.7, 30.3, 123.2, 123.6, 125.4, 125.5, 130.9, and 135.5.

Reaction of Tropone Tosylhydrazone (7) with 2. A solution of **7** (280 mg, 1 mmol) and **2** (200 mg, 0.5 mmol) in benzene (5 ml) was stirred at room temperature for 4 d. The reaction mixture was separated by column chromatography on silica gel to give recovery of **2** (110 mg, with hexane–ethyl acetate 4 : 1) and an oil of a mixture of **7** and **8** (330 mg, with hexane–ethyl acetate 7 : 3). The mixture was subjected to preparative thin-layer chromatography on silica gel using chloroform–hexane 2 : 1 as a developing solvent to give **8** as an oil (63 mg, 74% yield, R_f=0.16).

8: High resolution MS Found: m/z 378.1045. Calcd for $C_{21}H_{18}N_2O_3S$: m/z 378.1039. MS m/z (rel intensity) 378 (M^+, 100), 278 (41), and 245 (38). IR (oil) 3030, 2980, 1670, 1530, 1350, 1250, and 1160 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.44 (s, 3H, Me), 6.60—7.00 (m, 6H, seven-membered ring protons), and 7.28—8.00 (m, 9H, benzene-ring protons). ^{13}C NMR ($CDCl_3$) δ=21.6, 127.7, 128.5, 128.9, 129.2, 129.6, 131.8, 133.0, 134.1, 134.9, 135.0, 135.1, 135.6, 136.6, 144.7, and 173.8.

Single Crystal X-Ray Analysis of 3a. The colorless crystals of $C_{10}H_6S_5$ belonged to the monoclinic space group $P2_1/c$. The cell constants were a=10.536(2), b=8.603(1), c=12.624(5) Å, β=102.62(2)°, and V=1116.6(6) Å^3. The unit cell contained four molecules giving a calculated density of 1.70 g cm^{-3}. A total of 4799 reflections within 2θ=65° were collected on a Rigaku-AFC-5PR defractometer with a rotating anode (200 mA, 45 kV) using graphite monochromated Mo-$K\alpha$ radiation (λ=0.71069 Å) with 2θ–ω mode. The structure was solved by the direct method and refined by the block-diagonal least-squares method anisotropically for non-hydrogen atoms and isotropically for hydrogen atoms which were located by a D-Fourier map. The final R-factor was 0.069 (R_w=0.054) for 4177 unique reflections with $F_o<3\sigma(F_o)$. All calculations were carried out on an ACOS2000 computer at Tohoku University using the applied library program UNICSIII.[15] A listing of positional and thermal parameters, bond lengths and angles, and structure factors are deposited as Document No. 8948 at the Office of the Editor of Bull. Chem. Soc. Jpn.

The Cycloaddition of *N*,α-Diarylnitrones and Substituted *p*-Benzoquinones

Shinsaku SHIRAISHI,* Yukihiko INOUE, and Kiyoshi IMAMURA
The Institute of Industrial Science, The University of Tokyo, Roppongi 7-22-1, Minatoku, Tokyo 106
(Received February 26, 1991)

N,α-Diarylnitrones reacted with 2,5- or 2,6-dialkyl-*p*-benzoquinones at their C=C bond regioselectively to give fused isoxazolidine cycloadducts. These cycloadducts were proved to undergo retrocycloaddition. *p*-Benzoquinones having electron-withdrawing substituents did not give any cycloadduct.

p-Benzoquinone derivatives play an important role in bioorganic redox reactions and the modification reactions of *p*-benzoquinones were paid much attention in the synthetic chemistry. 1,3-Dipolar cycloaddition reaction is known as a versatile synthetic reaction because of its regioselectivity and mild reaction conditions. 1,3-Dipolar cycloaddition reaction of *p*-benzoquinones was reported with many 1,3-dipoles; nitrile ylide,[1] phenyl azide,[2] diazoalkane[3] etc., but site selectivity or regioselectivity of the reactions is still uncertain. As dipolarophile, *p*-Benzoquinones have two kinds of potential reactive sites, i.e. C=C and C=O bonds, and were considered to be good probe compounds for such investigation. In the previous papers,[4] cycloaddition reactions of substituted *p*-benzoquinones with aromatic nitrile *N*-oxides were reported and discussed.

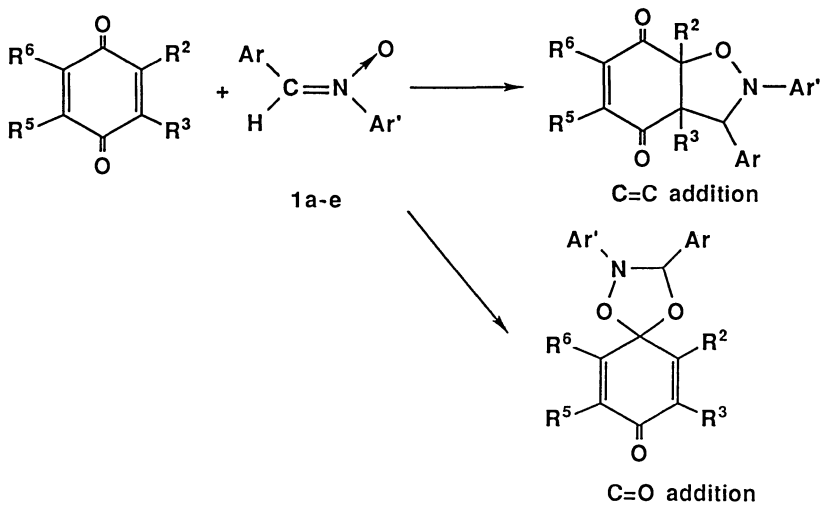
Nitrones compose a class of typical 1,3-dipoles and their cycloaddition reactions have been widely investigated. However, very few reports on the reactions with *p*-benzoquinones have been reported. Mourad and Nour-el-Din[5] described the formation of charge transfer complex between substituted *N*,α-diarylnitrones and *p*-benzoquinones having electron-withdrawing substituents. Schultz et al. reported successful intramolecular nitrone–quinone cycloaddition, attempted intermolecular cycloaddition being unsuccessful.[6]

In this paper, we report the reactions of substituted *p*-benzoquinones with *N*,α-diarylnitrones, some of which gave cycloaddition products. This is the first example of the successful intermolecular nitrone–quinone cycloaddition.

Results and Discussion

As nitrones, *N*,α-diphenylnitrone (**1a**) and *N*,α-bis(substituted phenyl)nitrones (**1b**—**e**) were employed. The nitrones were prepared from the corresponding arenecarbaldehydes and *N*-arylhydroxylamines by a known method.

Nitrones were allowed to react with quinones in refluxing benzene, unless otherwise noted. In the reaction of **1a** with 2,5-dimethyl-*p*-benzoquinone (25DMQ), practically no color change was observed at the initial stage of the reaction, but with the progress of the reaction the color changed gradually from yellow to light orange. The progress of the reaction was followed by TLC or HPLC analyses during the reaction period and it was confirmed that the reaction gave one product, except for the decomposition of **1a** (less than 5%), along with the decrease of **1a** and 25DMQ. After two days, the product was isolated from the reaction mixture by chromatographic technique followed by recrystallization from hexane, and the product was



Scheme 1. Possible reaction course of the nitrone–quinone cycloaddition.

obtained as light orange powder.

The structure of the product was determined by IR, ^1H and ^{13}C NMR, mass spectra and elemental analyses. Elemental analyses and mass spectra showed that the product was 1 : 1 adduct of the nitrone and the quinone.

To determine the structure of this adduct, the first problem is the site selectivity of this addition; the addition to the C=C double bond to give a fused isoxazolidine derivative, or to C=O double bond to give spirodioxazolidine derivative (Scheme 1). ^{13}C NMR spectrum has two signals around 195 ppm which are assignable to carbonyl carbons. The IR spectrum showed a strong absorption at 1680 cm^{-1}. These facts suggest that two carbonyls arising from 25DMQ remain in the product, suggesting that the addition reaction proceeded at the C=C double bond.

^1H NMR spectrum showed two doublets at δ=3.68 and 5.00 having coupling constants J=7 Hz and integrating each one proton. This is well-consistent with the structure **2a**, 3,6-dimethyl-8,9-diphenyl-7-oxa-8-azabicyclo[4.3.0]-3-nonen-2,5-dione, and not with the regio-isomer **2a'** (Scheme 2).

Two stereoisomers are possible for the structure **2a** (Scheme 3). The coupling constant of two protons at 3- and 4-position in isoxazolidine ring was 7 Hz, suggesting the protons being in *cis*-position. The coupling constants reported for *N,α*-diarylnitrones-*N*-phenylmaleimide cycloadducts[7] were 8 Hz when the two protons were in *cis*-position and 1 Hz in *trans*. However,

2a,f,g

various values were reported to the coupling constants of isoxazolidine ring protons,[8)] and these values are not always the same due to the changes in the conformation of isoxazolidine ring. Therefore, the structure determination by X-ray diffraction analysis was desirable, but attempts to obtain well-crystallized sample of **2a** were unsuccessful.

The reactions of 25DMQ with substituted *N*,α-diarylnitrones (**1b—e**) were summarized in Table 1. All of these reactions gave 1 : 1-C=C adducts (**2b—e**) as the sole product. The spectral pattern of the products was very similar to those of **2a**. There was no marked difference in the yield with the substitution on either benzene rings.

There are two possible reaction patterns for the formation of *cis*-adduct, *exo*-addition of the *trans*-nitrone and *endo*-addition of the *cis*-nitrone (Scheme 4). In all of these reactions, *cis*-adduct was the sole product. It is known that **1d** exists exclusively as a *trans*-form under the temperature conditions where the reactions are carried out.[9)] Therefore, the *endo*-addition of the *cis*-nitrone could be ruled out. Thus, diarylnitrones are proved to react with 2,5-dimethyl-*p*-benzoquinone at C=C site, in such an orientation as forming *cis*-adducts via *exo*-cycloaddition.

The reactions of **1a** with other *p*-benzoquinones were also examined (Table 2). The reactions of **1a** with 2,6-dimethyl-*p*-benzoquinone and with 2,5-di-*t*-butyl-*p*-benzoquinone gave corresponding adducts **2f** and **2g**, respectively. In each of these reactions, **2f** or **2g** was the only product which was recognized by chromatographic analyses. The reaction of **1a** with 2,6-di-*t*-butyl-*p*-benzoquinone gave an indication of the formation of a trace amount of an product from **1a** and quinone in HPLC analysis, but the isolation of the product was not successful.

The reaction of **1a** with unsubstituted *p*-benzoquinone gave a tarry material and attempts to isolate a definite product were unsuccessful. In the reaction of *p*-benzoquinone and benzonitrile *N*-oxide, it is known that the reaction gave isoxazoline cycloadduct and the adduct and starting materials undergo complex redox reactions.[10)] In this reaction, similar complex reactions were thought to be involved but nothing was clarified.

In the reactions of **1a** with *p*-benzoquinones having electron-withdrawing substituents, e.g. chloranil and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), instantaneous color changes were observed when the solution of the nitrone and the quinone was mixed (yellow to red in the reaction with chloranil, and yellow to blue with DDQ) presumably due to the formations of charge-transfer complexes.[5)] HPLC analyses of the reaction mixtures showed gradual degradation of **1a** and no adduct formation.

Temperature effect on the reaction of **1a** with 25DMQ was also examined (Table 3). No significant difference was observed in the reactions at room temperature, in refluxing benzene (80 °C), and in refluxing toluene (110 °C). However, in refluxing xylene (140 °C), the reaction mixture after the removal of the solvent left black tarry material, and no cycloadduct nor any definite product could be isolated. Thermal analyses of **2a** (TG and DTA) showed thermal degradation of the compound just above the melting point (>92 °C).

The retrocycloaddition reaction was observed when

Table 3. The Reaction of 2,5-Dimethyl-*p*-benzoquinone with **1a** at Various Temperature

Solvent	Temperature/°C	Reaction time/d	Yields/%
Benzene	Room temp.	7	18
Benzene	80(reflux)	2	20
Toluene	110(reflux)	2	18
Xylene	140(reflux)	2	0

2a was placed in the cycloaddition reaction conditions. The reaction was confirmed with NMR and HPLC analyses. (see experimental section). This retroaddition was thought to be responsible to the low yields of the cycloaddition reactions. The reason of the result of Schultz et al. that *C*-phenyl-*N*-methylnitrone and 2,6-dimethyl-*p*-benzoquinone did not give any adduct[6] may be ascribed to that the nitrone is less reactive than *N*,α-diarylnitrones[9] as well as that the lack of *N*-aryl group destabilize the isoxazolidine to be labile to undergo the retroaddition reaction.

In conclusion, *N*,α-diarylnitrones cycloadded to alkyl-substituted *p*-benzoquinones at quinone C=C double bond to give fused isoxazolidine derivatives but electron-deficient quinones did not give any adduct. The isoxazolidines were found to undergo retrocycloadditions.

Experimental

Melting points were measured with a micro melting point measuring apparatus (Yazawa BY-1) and are uncorrected. The IR spectra were recorded with a JASCO IRA-1 spectrometer. The ^{1}HNMR and ^{13}CNMR spectra were measured in $CDCl_3$, unless otherwise indicated, with JEOL JMN-MH100 and GX-270 spectrometers respectively, and chemical shifts were reported in ppm from internal tetramethylsilane. Mass spectra were recorded with a Hitachi RMU-7M spectrometer. Thermal analysis (DTA and TGA) was measured with Shimadzu DT-30 apparatus.

Materials. *p*-Benzoquinone, 2,5-di-*t*-butyl-*p*-benzoquinone, 2,6-di-*t*-butyl-*p*-benzoquinone, chloranil and 2,3-dicyano-5,6-dichloro-*p*-benzoquinone(DDQ) were commercially obtained. 2,5-dimethyl-*p*-benzoquinone and 2,6-dimethyl-*p*-benzoquinone were synthesized with Jones oxidation of 2,5-xylenol and 2,6-xylenol, respectively[11] and purified by column chromatography. All of the quinones except for DDQ were recrystallized from hexane. *N*,α-Diarylnitrones (**1a**—**e**) were prepared in dry ethanol from corresponding arenecarbaldehydes and *N*-arylhydroxylamines[12] which were synthesized by the zinc mediated reduction of the corresponding nitroaryl compounds.

Reactions of *N*,α-Diphenylnitrones(1a) with 2,5-Dimethyl-*p*-benzoquinone. Method A: To 50 ml of benzene, 592 mg of **1a** (3.00 mmol) and 408 mg of 2,5-dimethyl-*p*-benzoquinone (3.00 mmol) were dissolved. The mixture was heated to reflux for 2 d. The reaction was followed by TLC analysis (Merck, Kieselgel 60 F-254, benzene as an eluent). After the reaction, solvent was evaporated under reduced pressure and the residue was subjected to column chromatography on silica gel (Wakogel C-200, Wako Chemicals Co., Ltd.) using benzene as an eluent. 2,5-Dimethyl-*p*-benzoquinone and the product were eluted in this order. After the evaporation of the solvent, 207 mg (51%) of 2,5-dimethyl-*p*-benzoquinone was recovered. The fraction of the product was concentrated under reduced pressure, triturated with hexane and recrystallized from hexane and 198 mg (20%) of 1 : 1 cycloadduct (**2a**) was obtained. The reactions with other nitrones (**1b**—**e**) or with other benzoquinones were performed with the same procedures. In all of these reaction, the 1 : 1-C=C cycloadduct was a sole product (**3b**—**g**) and no other product formation was observed in TLC analyses in each of these reactions.

a) Assignment Alkyl moieties H^{7a} H^{8} Vinyl proton Aromatic moieties

b) Signal of Substituent Methyl Group at 9-*p*-Tolyl Moiety.

The yields and characterization data for these products were summarized in Tables 1 and 2, and in Tables 4 and 5, respectively.

Method B: The reaction was carried out in refluxing 1,2-dichloroethane (80 °C) with the same concentration as Method A. The reaction progress was followed by HPLC analysis (ODS column, 85% acetonitrile as an eluent, detector (UV) wavelength 254 m, 100 mg of biphenyl as an internal stan-

dard). After 2 d, the solution was worked up in the same manner as described in method A.

Temperature Effect on the Reaction of 2a with 25DMQ. The reaction was carried out in benzene (room temperature), refluxing benzene (80 °C), toluene (110 °C), or xylene (140 °C). The other reaction conditions and the treatments after the reaction were the same as method A. The results of the reactions were summarized in Table 3.

Retrocycloaddition Reaction of 2a. Compound **2a** (100 mg) was dissolved in 50 ml of 1,2-dichloroethane, and allowed to reflux overnight. After the reaction, the reaction mixture was subjected to HPLC analysis. The chromatogram indicated that **2a** was decomposed almost completely and **1a** and 25DMQ were produced. It was found that some amount of **1a** (less than 10%) was decomposed. But the identification of the degradation product was unsuccessful. ^{1}H NMR analysis was also performed. Compound **2a** (4 mg) was dissolved in 2 ml of benzene-d_6 and heated to 80 °C for 2 d. The reaction mixture was subjected to ^{1}H NMR analysis. The spectrum showed the overlap of **1a** (confirmed with the multiplet signal at 8.5 ppm), 25DMQ (confirmed with two singlet signals at 6.1 ppm and 2.6 ppm), and **2a**. The other signals were very weak and negligible (less than 5% from the integral intensity). The integral ratio of 25DMQ : **2a** was about 3 : 1.

Reactions of 2-Aminoazulenes with Electron-Deficient Acetylenes

Noritaka ABE
Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753
(Received February 27, 1991)

2-Aminoazulene (**1a**) reacted with dimethyl acetylenedicarboxylate (DMAD) to give dimethyl 1,2-azulenedicarboxylate, tetramethyl 2,2′-(2-amino-1,3-azulenediyl)bis[fumarate], and dimethyl 2-(4-methoxycarbonyl-2-oxo-1,2-dihydroazuleno[2,1-*b*]pyridin-10-yl)fumarate. The reaction of ethyl 2-amino-1-azulenecarboxylate (**1b**) with DMAD gave dimethyl 2-(2-amino-3-ethoxycarbonyl-1-azulenyl)fumarate and 10-ethyl 4-methyl 2-oxo-1,2-dihydroazuleno[2,1-*b*]pyridine-4,10-dicarboxylate (**8a**). The treatment of **8a** with phosphoryl chloride gave the 2-chloroazuleno[2,1-*b*]pyridine derivative. Reactions of **1a** and **1b** with methyl propiolate gave corresponding Michael adducts and the azuleno[2,1-*b*]pyridin-3(4*H*)-one derivatives. Reactions of **1a** and **1b** with dibenzoylacetylene gave 4-benzoyl-2-phenylazuleno[2,1-*b*]pyridine derivatives.

Cycloaddition of azaazulenes to acetylenic esters has received attention,[1–6] and it is known that the reactions are strongly influenced by the substituents and/or reaction conditions. In the study of carbocyclic azulene chemistry, it was discovered that azulene reacts with electron-deficient acetylenes or electron-deficient olefines to give Michael-type adducts.[7,8] Later, K. Hafner reported that azulene reacted with reactive acetylenes in aprotic solvent and gave cycloadducts via dipolar intermediates.[9,10] At present, the effects of substituents in these reactions have not been investigated. In order to determine how the substituents on the azulene ring influence the reactions, I investigated the reactions of 2-aminoazulenes with electron-deficient acetylenes. The reactions preferentially gave Michael adducts and azuleno[2,1-*b*]pyridin-2(1*H*)-ones; cycloaddition occurred only rarely.

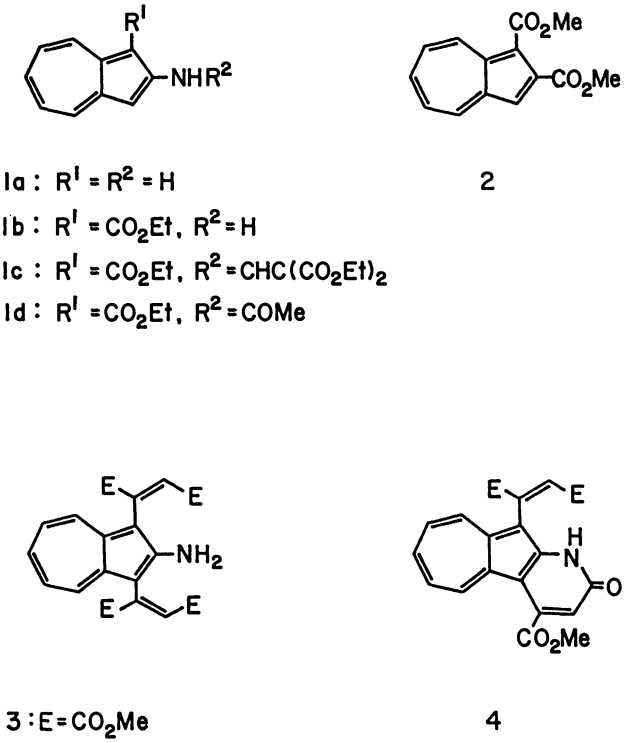

Fig. 1.

The treatment of 2-aminoazulene (**1a**) with dimethyl acetylenedicarboxylate (DMAD) in refluxing *t*-butylbenzene for 1 h gave a complex mixture. From the mixture, three compounds, dimethyl 1,2-azulenedicarboxylate[1,11,12] (**2**), tetramethyl 2,2′-(2-amino-1,3-azulendiyl)bis[fumarate] (**3**), and dimethyl 2-(4-methoxycarbonyl-2-oxo-1,2-dihydroazuleno[2,1-*b*]-pyridin-10-yl)fumarate (**4**) in 0.3, 3, and 15% yields, respectively, were isolated by column chromatography on silica gel. The structures of these compounds were determined on the basis of their spectra, especially ^{1}H NMR spectra, as well as elemental analyses. The yields of **3** and **4** were somewhat increased at room temperature by ultrasonic irradiation, but **2** was not produced. Therefore, I concluded that the formation of **2** required high temperature.

The treatment of ethyl 2-amino-1-azulenecarboxylate (**1b**) with DMAD in benzene at room temperature for 4 d gave dimethyl 2-[(1-ethoxycarbonyl-2-azulenyl)-amino]maleate (**5**) (13% yield), azulenylmaleate derivative **6a** (18% yield), azulenylfumarate derivative **7** (24% yield), and azuleno[2,1-*b*]pyridin-2(1*H*)-one derivative **8a** (35% yield). Ultrasonic irradiation facilitated the reaction which was complete within 6 h, though the yields were slightly low. When the reactions were carried out with heat, **5** was not produced. Refluxing in acetonitrile rather than benzene enhanced the yield of **6a** (61% yield).

To confirm the structure of **8a**, which had the 2-oxo, rather than 4-oxo, form, cyclizations of **6a** and **7** were attempted. Treatment of **6a** with triethylamine in refluxing acetonitrile for 1 h or the contact of **6a** with silica gel for 50 d gave **8a** in 73.5 and 81% yields, respectively. The fumarate **7** did not react under these conditions, but gave **8a** (47% yield) after treatment with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in refluxing xylene for 15 h.

Furthermore, for the purpose of comparison, azuleno[2,1-*b*]pyridin-4(1*H*)-one derivative **9** was synthesized. Treatment of **1b** with diethyl (ethoxy-

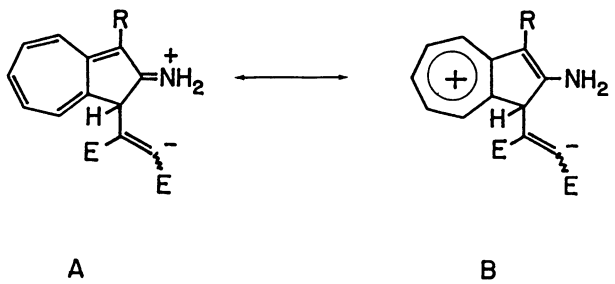
Fig. 3.

methylene)malonate (DEEM) gave diethyl [*N*-(1-ethoxycarbonyl-2-azulenyl)aminomethylene]malonate (**1c**) in a 74% yield. Heating of **1c** in refluxing *t*-butylbenzene for 5 h gave **9** in a 95% yield. In the ^{1}H NMR spectra, the H-5 proton of **8a** resonated at δ=8.88, whereas the H-5 proton of **9** resonated at δ=10.31. These results supported my conclusion that the structure of **8a** was in the 2-oxo form. The downfield shift of the H-5 proton in **9** may be due to a shielding effect by the carbonyl group at C-4.

Reactions of **1a** and **1b** with methyl propiolate (MP) gave results similar to the reactions with DMAD. Thus, the treatment of **1a** with MP in refluxing *t*-butylbenzene in the presence of Pd–C gave **10** (7% yield) and **11** (16% yield). The treatment of **1b** with MP in refluxing *t*-butylbenzene in the presence of Pd–C gave **6b** (16%) and **8b** (14.5%). The *trans*-configurations of the vinylic protons of **10** and **6b** were confirmed by their ^{1}H NMR spectra, in which pertinent vicinal coupling constants (both J=15.9 Hz) were observed. Compound **6b** produced **8b** (11% yield) when reacted with DBU in refluxing xylene for 4 d.

When **1a** was treated with dibenzoylacetylene (DBA) in benzene with ultrasonic irradiation in the presence of Pd–C, azuleno[2,1-*b*]pyridine derivatives[13] **12a** (28.5% yield) and **12b** (53% yield) were obtained. Reaction of **1b** with DBA under similar conditions gave **12c** in a 63% yield.

All the results showed that the Michael adducts were obtained in greater yields than the cycloadducts in the reactions of 2-aminoazulenes with electron-deficient acetylenes. The resonance form **A** of the intermediates may facilitate the prototropy of the dipolar intermediates leading to the preferential formation of the Michael adducts. I believe that the amino substituent may enhance the reactivity of the C-1 position of **1a** (and the C-3 position of **1b**) allowing the reaction of **1a** (or **1b**) to occur under milder conditions than those used for azulene.[9] The presence of an electron-withdrawing group on the amino group, such as an acetylamino group, should supress the reaction. Indeed, ethyl 2-acetylaminoazulene-1-carboxylate (**1d**) reacted very lit-



A B

Fig. 4.

tle with DMAD even under refluxing tetralin; over 95% of the starting material was recovered after 70 h.

Chlorination of **6a** with phosphoryl chloride gave the azuleno[2,1-*b*]pyridine derivative **12d** in a 54% yield. In its ^{1}H NMR spectrum, the H-10 proton resonated at δ=9.31, and this again supported the 2-oxo form of 8a. A large divergence of the vicinal spin–spin coupling constants in the seven-membered ring protons of **12d**, $\Delta J=J_{8,9}-J_{5,6}$=1.8 Hz, was observed. This indicated a bond alternation in the azulene ring, reflecting the large aromaticity of the pyridine ring.[14,15]

Experimental

Melting points were uncorrected. ^{1}H NMR spectra (250 MHz) were taken on a Hitachi R-250H spectrometer using $CDCl_3$ as a solvent (TMS as an internal standard) unless otherwise stated. IR spectra were recorded for Nujol mulls with a Hitachi 270-50 infrared spectrophotometer. Column chromatography was performed on Kieselgel 60.

Reaction of 1a with DMAD. a) A mixture of **1a**[16] (0.500 g) and DMAD (1.50 g) in dry *t*-butylbenzene (20 ml) was refluxed for 1 h. The solvent was then evaporated, and cromatography of the residue with benzene gave **2**[1,11,12] (0.003 g, 0.3% yield). Elution with benzene–chloroform (1 : 1) gave **3** (0.041 g, 23% yield) and **4** (0.249 g, 15% yield), successively.

3: Red prisms (from hexane–dichloromethane); mp 155—157 °C; ^{1}H NMR δ=3.82 (6H, s), 3.89 (6H, s), 5.91 (2H, brs), 6.11 (2H, s), 7.20—7.60 (3H, m), and 8.09 (2H, dm, J=9.8 Hz); IR 3452, 3340 (NH), 1730, and 1710 cm^{-1} (C=O). Found: C, 61.73; H, 4.94; N, 3.19%. Calcd for $C_{22}H_{21}NO_8$: C, 61.82; H, 4.95; N, 3.28%.

4: Red needles (from hexane–dichloromethane); mp 199—200 °C; ^{1}H NMR δ=3.86 (3H, s), 3.92 (3H, s), 4.09 (3H, s), 6.22 (1H, s), 6.77 (1H, s), 7.52 (2H, t, J=9.8 Hz), 7.73 (1H, t, J=9.8 Hz), 8.57 (1H, d, J=9.8 Hz), 8.77 (1H, d, J=9.8 Hz), and 10.28 (1H, brs); IR 3092 (NH), 1738, 1728, 1720, and 1648 cm^{-1} (C=O). Found: C, 63.47; H, 4.46; N, 3.26%. Calcd for $C_{21}H_{17}NO_7$: C, 63.79; H, 4.34; N, 3.54%.

b) A mixture of **1a** (0.500 g), DMAD (1.50 g), and 5% Pd–C (0.500 g) in *t*-butylbenzene (30 ml) was refluxed for 1 h. The solvent was then evaporated, and chromatography of the residue with benzene gave **2** (0.005 g, 0.6% yield). Elution with benzene–chloroform (1 : 1) gave **3** (0.103 g, 7% yield) and **4** (0.212 g, 15% yield), successively.

c) A mixture of **1a** (0.500 g), DMAD (1.50 g), and 5% Pd–C (0.500 g) in dry benzene (50 ml) was ultrasonically irradiated for 1 h. The solvent was then evaporated, and chromatography of the residue with benzene–chloroform (1 : 1) gave **3** (0.144 g, 9% yield) and **4** (0.356 g, 26% yield).

Reaction of 1b with DMAD. a) A mixture of **1b**[16] (0.215 g) and DMAD (0.430 g) in dry benzene (50 ml) was set for 4 d at room temperature. The solvent was then evaporated, and the residue was chromatographed. Elution with benzene gave **5** (0.045 g, 13% yield) and **6a** (0.064 g, 18% yield), successively. Elution with benzene–chloroform (1 : 1) gave **7** (0.085 g, 24% yield). Elution with chloroform gave **8a** (0.115 g, 35% yield).

5: Red needles (from hexane); mp 116—117; ^{1}H NMR δ=1.51 (3H, t, J=7.0 Hz), 3.80 (3H, s), 3.86 (3H, s), 5.62 (1H, s), 6.47 (1H, s), 7.36—7.60 (3H, m), 8.04 (1H, d, J=9.8 Hz), 9.22 (1H, d, J=10.4 Hz), and 11.78 (1H, s); IR 3248 (NH), 1735, 1696, and 1668 cm^{-1} (C=O). Found: C, 64.19; H, 5.38; N, 4.06%. Calcd for $C_{19}H_{19}NO_6$: C, 63.86; H, 5.36; N, 3.92%.

6a: Orange needles (from hexane); mp 96—97 °C; ^{1}H NMR δ=1.46 (3H, t, J=7.3 Hz), 3.82 (3H, s), 3.88 (3H, s), 4.44 (2H, q, J=7.3 Hz), 6.14 (1H, s), 6.90 (2H, brd), 7.28—7.46 (3H, m), 8.08—8.15 (1H, m), and 9.00 (1H, d, J=9.8 Hz); IR 3480, 3324 (NH), 1738, 1714, and 1662 cm^{-1} (C=O). Found: C, 63.45; H, 5.26; N, 3.86%. Calcd for $C_{19}H_{19}NO_6$: C, 63.86; H, 5.36; N, 3.92%.

7: Red needles (from hexane); mp 123—124 °C; ^{1}H NMR δ=1.47 (3H, t, J=7.3 Hz), 3.55 (3H, s) , 3.76 (3H, s), 4.45 (2H, q, J=7.3 Hz), 5.6—6.5 (2H, br), 7.23 (1H, t, J=9.2 Hz), 7.30 (1H, t, J=9.2 Hz), 7.39 (1H, t, J=9.2 Hz), 7.53 (1H, d, J=9.2 Hz), and 8.99 (1H, d, J=9.2 Hz); IR 3440, 3332 (NH), 1714, and 1668 cm^{-1} (C=O). Found: C, 63.71; H, 5.43; N, 3.91%. Calcd for $C_{19}H_{19}NO_6$: C, 63.86; H, 5.36; N, 3.92%.

8a: Red needles (from hexane–dichloromethane); mp 175—176 °C; ^{1}H NMR δ=1.53 (3H, t, J=7.0 Hz), 4.10 (3H, s), 4.56 (2H, q, J=7.0 Hz), 6.79 (1H, d, J=2.4 Hz), 7.68 (1H, dd, J=10.2 and 9.8 Hz), 7.76 (1H, dd, J=10.4 and 9.8 Hz), 7.87 (1H, dd, J=10.2 and 9.8 Hz), 8.88 (1H, d, J=9.8 Hz), 9.64 (1H, d, J=10.4 Hz), and 10.84 (1H, brd, J=2.4 Hz); IR 3388 (NH), 1734, 1696, and 1668 cm^{-1} (C=O). Found: C, 66.17; H, 4.84; N, 4.19%. Calcd for $C_{18}H_{15}NO_5$: C, 66.46; H, 4.65; N, 4.31%.

b) A mixture of **1b** (0.430 g), DMAD (0.860 g), and 5% Pd–C (0.500 g) in dry benzene (100 ml) was ultrasonically irradiated for 3 h at room temperature. The solvent was then evaporated, and chromatography of the residue as above gave **5** (0.067 g, 9% yield), **6a** (0.117 g, 16% yield), **7** (0.113 g, 16% yield), and **8a** (0.116 g, 18% yield).

c) A mixture of **1b** (0.430 g) and DMAD (0.86 g) in *t*-butylbenzene (30 ml) was refluxed for 3 h. The solvent was then evaporated, and chromatography of the residue as above gave **6a** (0.187 g, 26% yield), **7** (0.070 g, 9% yield), and **8a** (0.133 g, 20.5% yield).

d) A mixture of **1b** (0.500 g), DMAD (0.99 g), and 5% Pd–C (0.500 g) in *t*-butylbenzene (30 ml) was refluxed for 2 h. The residue was then evaporated, and chromatography of the residue as above gave **6a** (0.164 g, 20% yield), **7** (0.143 g, 17% yield), and **8a** (0.148 g, 20% yield).

e) A mixture of **1b** (0.580 g) and DMAD (1.15 g) in acetonitrile (50 ml) was refluxed for 6 h. The solvent was then evaporated, and chromatography of the residue as above gave **6a** (0.587 g, 61% yield), **7** (0.117 g, 12% yield), and **8a** (0.102 g, 12% yield).

Reaction of 7 with Triethylamine. A solution of **7** (0.13 g) and triethylamine (0.5 ml) in acetonitrile (10 ml) was refluxed for 1 h. The solvent was then evaporated, and the residue was chromatographed with benzene to give **8a** (0.087 g, 73.5% yield).

Cyclization of 7 on Silica Gel. A mixture of **7** (0.045 g) and silica gel (5.0 g) in chloroform (20 ml) was allowed to stand at room temperature for 50 d. The mixture was then filtered and residual silica gel was washed with chloroform. Evaporation of the combined filtrates gave **8a** (0.033 g, 81% yield).

Reaction of 6a with DBU. A mixture of **6a** (0.160 g) and DBU (0.3 ml) in dry xylene (50 ml) was refluxed for 15 h. The solvent was then evaporated, and chromatography of the residue with benzene gave **8a** (0.068 g, 47% yield).

Reaction of 1b with DEEM. A mixture of **1b** (0.250 g) and DEEM (0.750 g) in ethanol (50 ml) was refluxed for 64 h.

The solvent was then evaporated, and chromatography of the residue with benzene gave **1c** (0.424 g, 95% yield), which was recrystallized from hexane–dichloromethane to give red needles, mp 118—119 °C; ^{1}H NMR δ=1.37 (3H, t, J=7.3 Hz), 1.40 (3H, t, J=7.0 Hz), 1.52 (3H, t, J=7.0 Hz), 4.30 (2H, q, J=7.3 Hz), 4.40 (2H, q, J=7.0 Hz), 4.58 (2H, q, J=7.0 Hz), 7.12 (1H, s), 7.42 (1H, d, J=9.8 Hz), 7.52 (1H, dd, J=9.8 and 9.2 Hz), 7.60 (1H, t, J=9.8 Hz), 8.21 (1H, d, J=9.8 Hz), 8.65 (1H, d, J=14.0 Hz), 9.31 (1H, d, J=9.2 Hz), and 12.59 (1H, brd, J=14.0 Hz); IR 3260 (NH), 1698, 1680, and 1660 cm^{-1} (C=O). Found: C, 65.42; H, 6.06; N, 3.55%. Calcd for $C_{21}H_{23}NO_6$: C, 65.44; H, 6.01; N, 3.63%.

Cyclization of 1c. A solution of **1c** (0.210 g) in *t*-butylbenzene (15 ml) was refluxed for 5 d. The solvent was then evaporated, and chromatography of the residue with ethyl acetate gave **9** (0.176 g, 95% yield), which was recrystallized from hexane–dichloromethane to give orange needles, mp 185—187 °C; ^{1}H NMR δ=1.44 (3H, t, J=7.0 Hz), 1.52 (3H, t, J=7.0 Hz), 4.43 (2H, q, J=7.0 Hz), 4.55 (2H, q, J=7.0 Hz), 7.83 (1H, t, J=9.8 Hz), 7.88 (1H, dd, J=9.8 and 9.2 Hz), 7.96 (1H, t, J=9.8 Hz), 8.61 (1H, s), 9.50 (1H, d, J=9.8 Hz), 10.31 (1H, d, J=9.2 Hz), and 10.95 (1H, brs); IR 3320 (NH), 1724, 1690, and 1644 cm^{-1} (C=O). Found: C, 67.17; H, 4.99; N, 4.23%. Calcd for $C_{19}H_{17}NO_5$: C, 67.25; H, 5.05; N, 4.13%.

Reaction of 1a with MP. A mixture of **1a** (0.500 g), MP (0.880 g), and 5% Pd–C (0.500 g) in dry *t*-butylbenzene (30 ml) was refluxed for 1 h. The solvent was then evaporated, and the residue was purified by silica-gel column chromatography with benzene–chloroform (1 : 1) to give **10** (0.075 g, 7% yield). Elution with chloroform gave **11** (0.068 g, 16% yield).

10: Red-brown prisms (from hexane–dichloromethane); mp 188—190 °C; ^{1}H NMR δ=3.85 (6H, s), 5.38 (2H, brs), 6.25 (2H, d, J=15.9 Hz), 7.30—7.50 (3H, m), 8.19 (2H, d J=10.4 Hz), and 8.26 (2H, d, J=15.9 Hz); IR 3384, 3250 (NH), 1710, 1690, and 1652 cm^{-1} (C=O). Found: C, 69.16; H, 5.39; N, 4.64%. Calcd for $C_{18}H_{17}NO_4$: C, 69.44; H, 5.51; N, 4.50%.

11: Red needles (from hexane–dichloromethane); mp 280 °C (decomp); ^{1}H NMR δ (DMSO-d_6)=6.31 (1H, d, J=9.8 Hz), 7.06 (1H, s), 7.37 (1H, t, J=9.8 Hz), 7.45 (1H, dd, J=9.8 and 9.2 Hz), 7.64 (1H, t, J=9.8 Hz), 8.36 (1H, d J=9.8 Hz), 8.47 (1H, d, J=9.8 Hz), 8.62 (1H, d, J=9.2 Hz), and 12.12 (1H, brs); IR 3200 (NH) and 1642 cm^{-1} (C=O). Found: C, 79.65; H, 4.78; N, 7.18%. Calcd for $C_{13}H_9NO$: C, 79.98; H, 4.64; N, 7.17%.

Reaction of 1b with MP. A mixture of **1b** (0.500 g), MP (0.590 g), and 5% Pd–C (0.500 g) in dry *t*-butylbenzene (30 ml) was refluxed for 2 h. The solvent was then evaporated, and the residue was purified by silica-gel column chromatography with benzene to give **1b** (0.117 g, 23% yield) and **6b** (0.112 g, 16% yield), successively. Elution with chloroform gave **8b** (0.135 g, 14.5% yield).

6b: Red needles (from hexane); mp 107—108 °C; ^{1}H NMR δ=1.49 (3H, t, J=7.0 Hz), 3.84 (3H, s), 4.48 (2H, q, J=7.0 Hz), 6.22 (2H, d, J=15.9 Hz), 6.5—7.0 (2H, br), 7.35—7.58 (3H, m), 8.21 (1H, dm, J=10.4 Hz), 8.23 (1H, d, J=15.9 Hz), and 9.02 (1H, d, J=9.8 Hz); IR 3500, 3348 (NH), 1720, and 1672 cm^{-1} (C=O). Found: C, 68.50; H, 5.68; N, 4.80%. Calcd for $C_{17}H_{17}NO_4$: C, 68.21; H, 5.73; N, 4.68%.

8b: Red-violet needles (from hexane–dichloromethane); mp 209—210 °C; ^{1}H NMR δ=1.53 (3H, t, J=7.0 Hz), 4.56 (2H, q, J=7.0 Hz), 6.57 (1H, d, J=9.2 Hz), 7.65—7.90 (3H, m), 8.23 (1H, d, J=9.8 Hz), 8.59 (1H, d, J=9.2 Hz), 9.60 (1H, d, J=10.4 Hz), and 10.44 (1H, brs); IR 3392 (NH), 1682, and 1660 cm^{-1} (C=O). Found: C, 71.83; H, 4.97; N, 5.18%. Calcd for $C_{16}H_{13}NO_3$: C, 71.90; H, 4.90; N, 5.24%.

Reaction of 6b with DBU. A solution of **6b** (0.110 g) and DBU (0.1 ml) in dry xylene (20 ml) was refluxed for 4 d. The residue was then evaporated, and chromatography of the residue with chloroform gave **6b** (0.057 g, 52% yield) and **8b** (0.011 g, 11% yield), successively.

Reaction of 1a with DBA. A mixture of **1a** (0.500 g), DBA (2.454 g), and 5% Pd–C (0.500 g) in dry benzene (50 ml) was ultrasonically irradiated for 3 h. The solvent was then evaporated, and chromatography of the residue with benzene gave **12a** (0.358 g, 28.5% yield), and **12b** (1.092 g, 53% yield).

12a: Blue-green needles (from hexane–dichloromethane); mp 182—183 °C; ^{1}H NMR δ=6.92 (1H, dd, J=11.0 and 8.6 Hz), 7.01 (1H, dd, J=11.0 and 8.5 Hz), 7.25 (1H, dd, J=11.0 and 8.5 Hz), 7.42—7.68 (6H, m), 7.65 (1H, s), 7.70 (1H, s), 7.96 (2H, dd, J=7.9 and 1.8 Hz), 8.06 (1H, d, J=8.6 Hz), 8.14 (1H, d, J=11.0 Hz), and 8.19 (2H, dd, J=7.9 and 1.2 Hz); IR 1668 (C=O), 714, and 700 cm^{-1} (phenyl). Found: C, 87.21; H, 4.91; N, 3.96%. Calcd for $C_{26}H_{17}NO$: C, 86.88; H, 4.77; N, 3.90%.

12b: Yellow-brown prisms (from hexane–dichloromethane); mp 184—186 °C; ^{1}H NMR δ=7.06 (1H, dd, J=11.0 and 8.6 Hz), 7.19 (1H, dd, J=11.0 and 8.6 Hz), 7.30—7.55 (11H, m), 7.57 (1H, brd, J=6.7 Hz), 7.66 (1H, brd, J=6.7 Hz), 7.79 (1H, s), 7.95 (4H, dd, J=7.9 and 1.2 Hz), 8.07 (2H, dd, J=7.3 and 1.2 Hz), 8.18 (1H, d, J=8.6 Hz), 8.26 (2H, dd, J=7.9 and 1.2 Hz), 8.42 (1H, s), and 8.70 (1H, d, J=11.0 Hz); IR 1668, 1634 (C=O), 714, and 688 cm^{-1} (phenyl). Found: C, 85.01; H, 4.70; N, 2.42%. Calcd for $C_{42}H_{27}NO_3$: C, 84.97; H, 4.58; N, 2.36%.

Reaction of 1b with DBA. A mixture of **1b** (0.160 g), DBA (0.350 g), and 5% Pd–C (0.200 g) in dry benzene (50 ml) was urtrasonically irradiated for 4 h. The solvent was then evaporated, and chromatography of the residue with benzene–chloroform (1 : 1) gave **12c** (0.166 g, 63% yield).

12c: Brown-violet needles (from hexane); mp 176—177 °C; ^{1}H NMR δ=1.66 (3H, t, J=7.0 Hz), 4.65 (2H, q, J=7.0 Hz), 7.26 (1H, dd, J=9.8 and 8.5 Hz), 7.40—7.70 (8H, m), 7.80 (1H, s), 7.92 (2H, dd, J=7.3 and 1.2 Hz), 8.36 (2H, dd, J=7.9 and 1.5 Hz), 8.41 (1H, d, J=8.6 Hz), and 9.66 (1H, d, J=9.8 Hz); IR 1680, 1666 (C=O), 714, and 700 cm^{-1} (phenyl). Found: C, 80.70; H, 4.98; N, 3.11%. Calcd for $C_{29}H_{21}NO_3$: C, 80.71; H, 4.91; N, 3.26%.

Chlorination of 8a. A mixture of **8a** (0.100 g), phosphoryl chloride (10 ml), and a drop of pyridine was refluxed for 1 h. The mixture was poured into ice-water, neutralized with sodium hydrogen carbonate, and extracted with chloroform. The extract was dried (Na_2SO_4) and the solvent was evaporated. Chromatography of the residue with benzene gave **12d** (0.057 g, 54% yield), which was recrystallized from hexane–dichloromethane to give violet needles, mp 150—151 °C; ^{1}H NMR δ=1.55 (3H, t, J=7.0 Hz), 4.13 (3H, s), 4.59 (2H, q, J=7.0 Hz), 7.58 (1H, dd, J=10.4 and 9.2 Hz), 7.62 (1H, dd, J=11.0 and 7.9 Hz), 7.68 (1H, s), 7.80 (1H, dd, J=10.4 and 7.9 Hz), 9.31 (1H, d, J=9.2 Hz), and 9.64 (1H, d, J=11.0 Hz); IR 1728 and 1686 cm^{-1} (C=O). Found: C, 63.04; H, 4.26; N, 4.15%. Calcd for $C_{18}H_{14}ClNO_4$: C, 62.89; H, 4.10; N, 4.08%.

I am grateful to Dr. Akira Mori, Kyushu University, for the elemental analyses.

(Received March 29, 1991)

(5*R* and 5*S*)-3-*O*-Acetyl-5-deoxy-1,2-*O*-isopropylidene-5-[(methoxy)phenylphosphinyl]-6-*O*-(tetrahydro-2-pyranyl)-α-D-*xylo*-hexofuranoses (**7**) were prepared from 3-*O*-acetyl-5,6-dideoxy-6-nitro-α-D-*xylo*-hex-5-enofuranose in 4 steps. Reduction of **7** with sodium dihydridobis(2-methoxyethoxy)aluminate followed by acid hydrolysis provided the title compounds, among which the 5-deoxy-5-phenylphosphino-D-glucoses are the first example of hexopyranose analogs having a phosphinidene group in place of hemiacetal ring-oxygen. These compounds were converted into 1,2,3,4,6-penta-*O*-acetates, whose structures were established by spectroscopy.

In the chemical modification of sugar compounds, various sugar analogs containing phosphorus as the ring heteroatom have been prepared.[1] As for analogs of D-glucopyranose type, 5-deoxy-5-hydroxyphosphinyl- (**1**)[2] and 5-ethylphosphinyl-D-glucopyranoses (**2**)[3] have been reported. In this paper we wish to describe the synthesis of hitherto unreported 5-deoxy-5-arylphosphino- and 5-arylphosphinyl-D-glucopyranose analogs by taking phenyl as a model functional group. Besides, the former compound becomes the first hexopyranose analog having a phosphinidene group in the hemiacetal ring.[4]

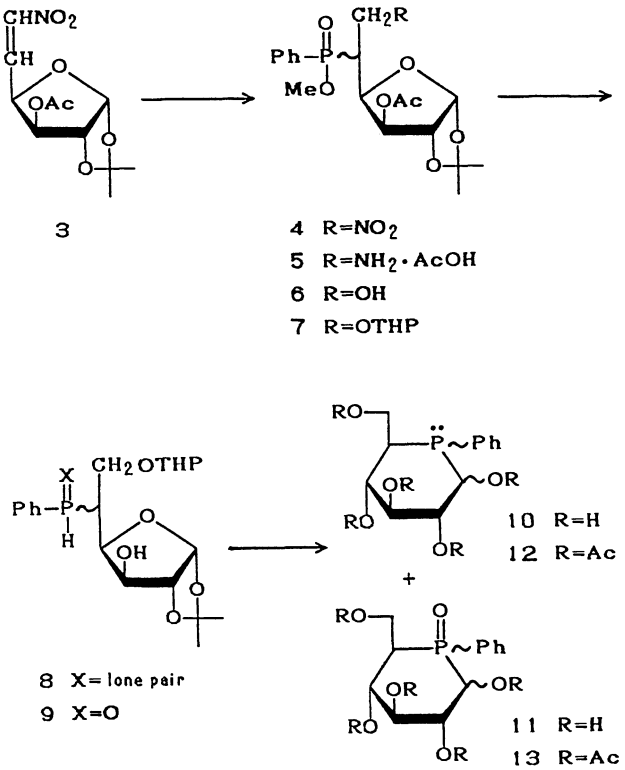
Results and Discusion

The addition reaction of methyl hydrogenphenylphosphinate to 3-*O*-acetyl-5,6-dideoxy-6-nitro-α-D-*xylo*-hex-5-enofuranose (**3**)[5] in the presence of triethylamine (TEA) at 25 °C gave an inseparable mixture (9:9:1:1) of two major D-"gluco" and two minor L-"ido" furanoses (**4**) in a 85% yield (Scheme 1). The assignments of the configuration of the products were made by comparison of their spectral data with those of other 5-phosphinyl compounds having similar structures;[2,6] see the Experimental section. Catalytic hydrogenation of **4** over palladium hydroxide on carbon [to convert it into 6-amino derivatives (**5**)], followed by diazotization and then hydrolysis, gave (5*R* and 5*S*)-3-*O*-acetyl-5-deoxy-1,2-*O*-isopropylidene-5-[(methoxy)-phenylphosphinyl]-α-D-*xylo*-hexofuranose (**6**). Compound **6** was converted into 6-*O*-(tetrahydro-2-pyranyl) derivatives (**7**) by treatment with dihydropyran in the presence of pyridinium *p*-toluenesulfonate (PPTS).



Scheme 1.

Compound **7** was then subjected to the reduction with sodium dihydridobis(2-methoxyethoxy)aluminate (SDMA), giving an unstable colorless syrup. This was found to consist exclusively of compounds having a 5-phenylphosphino structure (**8**) on the basis of the characteristic ^{31}P NMR data (δ=−53.4 and −51.5); judging from the presence of a very weak ^{31}P NMR signal (δ=30.1), only an extremely small proportion (<5%) of a 5-phenylphosphinyl compound (**9**) appeared to be present among the above reduction products. This presents a rather unexpected contrast to the fact that when the 5-[(ethyl)methoxyphosphinyl] congener of **7** was subjected to the SDMA reduction, its 5-

ethylphosphinyl derivative was exclusively obtained.[3] The reason for this difference has remained to be studied.

The phenylphosphino intermediate **8** was hydrolyzed in ethanolic 0.25 M hydrochloric acid (1 M=1 mol dm^{-3}) to effect the ring transposition, affording 5-deoxy-5-phenylphosphino-D-hexopyranose (**10**) and a minor proportion of their 5-phenylphosphinyl derivatives (**11**) as well (Scheme 1). Despite the attempted inert atmosphere during the procedure, **11** is presumably derived either from the oxidized intermediate **9** before the ring enlargement or from compound **10**; both **8** and **10** would become liable to suffer autoxidation upon prolonged heating at 90 °C.

Because of the difficulty in separation and purification, compounds **10** and **11** were converted into the corresponding per-*O*-acetyl derivatives (**12** and **13**, respectively) by the usual method for characterization. By purification in a column of silica gel, the following penta-*O*-acetyl compounds were isolated: 5-[(*R*)-phenylphosphino]-α-D-glucopyranose (**12a**, 2.0% overall yield from **7**), its β-anomer **12b** (9.9%), 5-[(*S*)-phenylphosphinyl]-α-D-glucopyranose (**13a**, 4.5%), and its β-anomer (**13b**, 5.3%). Besides these compounds, a small amount (ca. 2%) of three additional products were obtained as an inseparable mixture (ca. 1 : 1 : 1). The products were presumed to be the two remaining diastereomers of **13a,b** (namely, 5-[(*R*)-phenylphosphinyl]-α,β- isomers) and an L-idopyranose on the basis of ^{31}P NMR data, although the exact structures of these extremely minor products remained unestablished.

Structures of the final products **12a,b** and **13a,b** were established on the basis of high-resolution mass spectrometry and ^{1}H and ^{31}P NMR spectral data (see, Table 1). As large $J_{4,5}$ values (11.1—11.6 Hz) of **12a,b** and **13a,b** are characteristic coupling constants for an axial–axial conformation of H-4 and H-5, all of these compounds have D-glucopyranose configuration with $^{4}C_{1}$(D) conformation. With regard to the anomeric orientation of C-1, small $J_{1,2}$ values (2.2 and 2.8 Hz) of **12a** and **13a** indicate α-configuration, whereas large $J_{1,2}$ values (10.8 and 11.2 Hz) of **12b** and **13b** indicate β-configuration. The anti connection of H–C_1–P=O for **12b** and **13b** is confirmed by the smaller $J_{1,P}$ values (5.0 and 3.0 Hz) compared with the corresponding parameters (9.3 and 10.6 Hz) of **12a** and **13a** having this group in the gauche connections.[3] The H-2, H-4, and H-6′ signals of **13a,b** appear at a considerably downfield compared with those of **12a,b**. This can be explained by deshielding effect of the axial P=O bond at 1,3-diaxial positions, while the axial P-lone pair does not exert such an effect. The precise NMR parameters summarized in Table 1 are thought to be of value in determining the structures of other sugar analogs having similar constituents.

It should be noticed that while the precursor **7** was a ca. 9 : 1 mixture of D-gluco and L-idofuranose, the final, isolated products **12a,b** and **13a,b** all possessed D-glucopyranose configuration. This indicates that no epimerization apparently takes place at C-5 of **7** by the strongly basic reagent SDMA during the reduction to yield phosphine **8**.[7]

Although yields of some of the steps of the reaction scheme have to be improved, the present work thus demonstrates a possible way for preparation of 5-deoxy-5-arylphosphino- and 5-arylphosphinyl-D-glucopyranoses from an appropriate intermediate. Extension of this work including studies of reactivities of the phosphinidene functional group of **12a,b**, as well as biological evaluation of all products, is in progress.
