PHENOXYMETHYL 2-CHLOROETHYL ETHERS[1]

BY MARSHALL KULKA

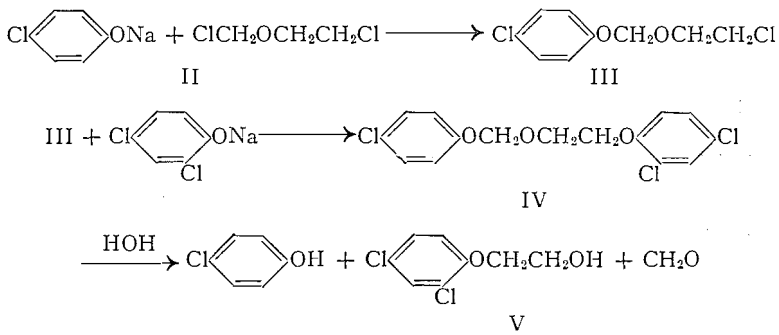
ABSTRACT

A series of phenoxymethyl 2-chloroethyl ethers has been prepared for testing as possible insecticides.

In this investigation a series of phenoxymethyl 2-chloroethyl ethers, $ArOCH_2OCHXCH_2Cl$ (I, X = H or CH_3), was prepared for testing as possible insecticides by alkylating various phenols with 2-chloroethyl (1, 2) and 1-chloro-2-propyl (5) chloromethyl ether. The toxic effects of these ethers (I) on insects is described by Musgrave and Kukovica (3).

It is well known that the halogen atom linked α to the oxygen atom of chloroethers is more reactive than the β-halogen (2). This considerable difference in the halogen reactivities was also noted in the reactions between chloromethyl chloroethyl ether (II) and sodium phenoxides.

When chloromethyl 2-chloroethyl ether (II) was treated with aqueous or alcoholic solutions of a sodium phenoxide at room temperature, only a monophenoxy derivative was formed and a higher reaction temperature was necessary in order to form the diphenoxy derivative, $ArOCH_2OCH_2CH_2OAr$. In order to establish that the α-chlorine and not the β-chlorine reacted under the milder conditions, the reaction product (III) of sodium *p*-chlorophenoxide and II was heated with sodium 2,4-dichlorophenoxide. The resulting product (IV) on mild acid hydrolysis yielded *p*-chlorophenol and 2,4-dichlorophen-



[1]*Manuscript received August 13, 1954.*
Contribution from the Dominion Rubber Company Limited Research Laboratories, Guelph, Ont.

oxyethanol (V) (4) and not 2,4-dichlorophenol and *p*-chlorophenoxyethanol, the products expected had the β-chlorine of II reacted before the α-chlorine. The wide difference in the degree of reactivity between the two chlorine atoms of II is further emphasized by the fact that III remains unaltered after boiling with diethylamine in benzene solution for several hours and requires prolonged boiling with alcoholic potassium thiocyanate in order to form 2-thiocyanatoethyl *p*-chlorophenoxymethyl ether. Phenoxymethyl 2-chloroethyl ether (I, Ar = C_6H_5, X = H) is stable in aqueous alkali but resinifies explosively when warmed with a drop of concentrated hydrochloric acid.

EXPERIMENTAL

Preparation of 2-Chloroethyl Phenoxymethyl Ethers

Method A

To a stirred solution of sodium (1 mole) in absolute ethanol (1 liter) was added the phenol (1 mole) and then dropwise chloromethyl 2-chloroethyl ether (1 mole) (1, 2) over about one-half hour, the temperature being kept at 20–25° by cooling. The reaction mixture was stirred for an additional two hours, the ethanol was distilled off *in vacuo*, and the residue treated with water. The product was extracted with benzene, washed with sodium hydroxide and with water. The solvent was then removed and the residue distilled.

Method B

To a stirred solution (or suspension) of sodium phenoxide (1 mole) in water (200 ml.) was added dropwise chloromethyl 2-chloroethyl ether (1 mole) in benzene (400 ml.) over about one-half hour, the temperature being kept at 10° by cooling. After the solution had been stirred for an additional two hours the benzene layer was separated from the reaction mixture, washed with sodium hydroxide and with water. The solvent was removed and the residue distilled.

Method C

A reaction mixture of chloromethyl 2-chloroethyl ether (1 mole), dry benzene (350 ml.), and the dry sodium phenoxide (1 mole) was heated under reflux for four hours. Water was added to the cooled reaction mixture, the benzene layer was separated, washed with sodium hydroxide and with water. The solvent was removed and the residue distilled.

p-Chlorophenoxymethyl 2-(2,4-Dichlorophenoxy)ethyl Ether (IV)

To a solution of sodium (5 gm.) in absolute ethanol (250 ml.) was added 2,4-dichlorophenol (34 gm.) and 2-chloroethyl *p*-chlorophenoxymethyl ether (45 gm.) and the resulting solution heated under reflux for 40 hr. About half of the ethanol was distilled off from the reaction mixture and the residue was treated with water and extracted with benzene.

The benzene extract was washed with water and the solvent was removed. Fractional distillation of the residue yielded unchanged *p*-chlorophenoxymethyl 2-chloroethyl ether (21 gm.) and a higher-boiling fraction, b.p. (0.2 mm.) = 170–172° (27 gm.). The latter was a viscous colorless liquid, n_D^{20} = 1.5752. Anal. calc. for $C_{15}H_{13}O_3Cl_3$: C, 51.81; H, 3.74. Found: C, 52.11; H, 3.60.

p-t-Butylphenoxymethyl 2-p-t-Butylphenoxyethyl Ether

This was prepared in 70% yield as above from *p-t*-butylphenoxymethyl 2-chloroethyl ether. It is a colorless viscous liquid, b.p. (12 mm.) = 245–250°, n_D^{20} = 1.5270. Anal. calc. for $C_{23}H_{32}O_3$: C, 77.54; H, 8.98. Found: C, 77.43; H, 9.06.

Hydrolysis of p-Chlorophenoxymethyl 2-(2,4-Dichlorophenoxy)ethyl Ether (IV)

A solution of *p*-chlorophenoxymethyl 2-(2,4-dichlorophenoxy)ethyl ether (15 gm.), water (150 ml.), ethanol (150 ml.), and concentrated hydrochloric acid (25 ml.) was heated under reflux for eight hours. Most of the ethanol was distilled and the cooled residue was extracted with ether. The ether was removed from the extract and the residue was fractionally distilled. Two main fractions were collected, fraction 1 boiling at 98–105° (12 mm.) (4 gm.) and fraction 2 boiling at 160–165° (12 mm.) (7 gm.). Fraction 1 solidified on cooling and melted at 35° alone or in admixture with *p*-chlorophenol. It depressed the melting point of 2,4-dichlorophenol. Fraction 2 after crystallization from benzene melted at 58–59° alone or in admixture with authentic 2,4-dichlorophenoxyethanol (4).

1,3-bis(2-Chloroethoxymethoxy)benzene

This was prepared in 20% yield by method A using two moles of sodium and two moles of chloromethyl 2-chloroethyl ether (II) per mole of resorcinol. It is a colorless liquid boiling at 150–154° (0.3 mm.), n_D^{20} = 1.5212. Anal. calc. for $C_{12}H_{16}O_4Cl_2$: C, 48.83; H, 5.41. Found: C, 48.80; H, 5.39.

1,4-bis(2-Chloroethoxymethoxy)benzene

This was prepared in 52% yield by method A as above from II and hydroquinone, b.p. (0.3 mm.) = 149–150°, n_D^{20} = 1.5197. Anal. calc. for $C_{12}H_{16}O_4Cl_2$: C, 48.83; H, 5.41. Found: C, 48.67; H, 5.31.

1,4-bis(2-Chloroethoxymethoxy)-2,3,5,6-tetrachlorobenzene

This was prepared in 12% yield by method A from tetrachlorohydroquinone and II. The white needles melted at 117–118° after crystallization from ethanol. Anal. calc. for $C_{12}H_{12}O_4Cl_6$: C, 33.26; H, 2.77. Found: C, 33.24; H, 2.82.

1,2-bis(2-Chloroethoxymethoxy)benzene

This was prepared in 41% yield by method A from II and catechol, b.p. (0.2 mm.) = 146–148°, n_D^{20} = 1.5222. Anal. calc. for $C_{12}H_{16}O_4Cl_2$: C, 48.83; H, 5.41. Found: C, 48.72; H, 5.18.

1,2,3-tris(2-Chloroethoxymethoxy)benzene

This was prepared in 15% yield by method A from II and pyrogallol, b.p. (0.2 mm.) = 212–215°. Anal. calc. for $C_{15}H_{21}O_6Cl_3$: C, 44.62; H, 5.25. Found: C, 44.91; H, 5.24.

p-Chlorophenoxymethyl 2,N-Morpholinoethyl Ether

A solution of *p*-chlorophenoxymethyl 2-chloroethyl ether (III) (16 gm.), morpholine (16 gm.), and toluene (100 ml.) was heated under reflux for 24 hr. The morpholine hydrochloride was filtered and the filtrate was extracted with dilute hydrochloric acid. The acid solution was basified with sodium hydroxide and extracted with benzene. Removal of the benzene and distillation of the residue yielded 14 gm. (or 68%) of a colorless liquid b.p. (12 mm.) = 196–198°, n_D^{20} = 1.5278. Anal. calc. for $C_{13}H_{18}NO_3Cl$: C, 57.45; H, 6.63. Found: C, 57.27; H, 6.54.

p-Chlorophenoxymethyl 2-Dimethylaminoethyl Ether

This was prepared as above from dimethylamine and *p*-chlorophenoxymethyl 2-chloroethyl ether (III), the reaction being carried out in a sealed bomb at 120–130°. It distilled as a colorless liquid boiling at 149–150° (12 mm.), n_D^{20} = 1.5100. Anal. calc. for $C_{11}H_{16}NO_2Cl$: C, 57.51; H, 6.97. Found: C, 57.24; H, 6.93. The *ethiodide* melted at 106–107° after crystallization from ethyl acetate. Anal. calc. for $C_{13}H_{21}NO_2ClI$: C, 40.46; H, 5.45. Found: C, 40.41; H, 5.59. The *butiodide* melted at 86–87° after crystallization from methanol. Anal. calc. for $C_{15}H_{25}NO_2ClI$: C, 43.53; H, 6.04. Found: C, 43.55; H, 6.13.

p-Chlorophenoxymethyl 2-Diethylaminoethyl Ether

This was prepared as above from diethylamine and III. It distilled as a colorless liquid boiling at 165–167° (12 mm.), n_D^{20} = 1.5032. Anal. calc. for $C_{13}H_{20}NO_2Cl$: C, 60.57; H, 7.77. Found: C, 60.68; H, 7.82.

p-Chlorophenoxymethyl 1-Chloro-2-propyl Ether

This was prepared in 63% yield by method A from chloromethyl 1-chloro-2-propyl ether (5) ($ClCH_2OCH(CH_3)CH_2Cl$) and *p*-chlorophenol. It distilled as a colorless liquid boiling at 155–157° (13 mm.), n_D^{20} = 1.5210. Anal. calc. for $C_{10}H_{12}O_2Cl_2$: Cl, 30.2. Found: Cl, 30.5.

p-Nitrophenoxymethyl 1-Chloro-2-propyl Ether

This was prepared in 63% yield by method C from chloromethyl 1-chloro-2-propyl ether and *p*-nitrophenol. It crystallized from methanol as white

prisms melting at 43–44°. Anal. calc. for $C_{10}H_{12}NO_4Cl$: C, 48.88; H, 4.89. Found: C, 49.00; H, 4.84.

p-Nitrophenoxymethyl 2-Thiocyanatoethyl Ether

A solution of *p*-nitrophenoxymethyl 2-chloroethyl ether (12 gm.) and potassium thiocyanate (6 gm.) in 95% ethanol (100 ml.) was heated under reflux for 24 hr. Most of the ethanol was distilled off and the residue treated with cold water. The white solid was filtered, washed, dried, and crystallized from benzene – petroleum ether. The white prisms melted at 58–59°. Anal. calc. for $C_{10}H_{10}N_2O_4S$: C, 47.26; H, 3.94. Found: C, 46.88; H, 4.05.

p-Nitrophenoxymethyl 1-Thiocyanato-2-propyl Ether

This was prepared as above from *p*-nitrophenoxymethyl 1-chloro-2-propyl ether. The white prisms melted at 42–43°. Anal. calc. for $C_{11}H_{12}O_4N_2S$: C, 49.25; H, 4.48. Found: C, 49.30; H, 4.78.

ACKNOWLEDGMENT

The author is indebted to Miss Gisela Rotermann for the microanalyses.

SOME CHLORINATION PRODUCTS OF BUTYNE-1, BUTYNE-2, AND PENTYNE-1[1]

By A. T. Morse and L. C. Leitch

ABSTRACT

The following new compounds were isolated from the vapor phase chlorination of butyne-1, butyne-2, and pentyne-1: 1,1,2,2-tetrachlorobutane, 2,2,3,3-tetrachlorobutane, 1,1,2,2-tetrachloropentane, *trans*-1,2-dichloro-1-butene, *trans*-2,3-dichloro-2-butene, and *trans*-1,2-dichloro-1-pentene. Dehydrochlorination of 1,1,2,2-tetrachlorobutane and 1,1,2,2-tetrachloropentane gave 1,1,2-trichloro-1-butene and 1,1,2-trichloro-1-pentene respectively. Partial dechlorination of 1,1,2,2-tetrachlorobutane and 1,1,2,2-tetrachloropentane gave *cis* and *trans* isomers of 1,2-dichloro-1-butene and 1,2-dichloro-1-pentene respectively. 2,2,3,3-Tetrachlorobutane gave chiefly *trans*-2,3-dichloro-2-butene. 1,1,1,2,2-Pentachlorobutane and 1,1,1,2,2-pentachloropentane were prepared by chlorination of 1-chloro-1-butyne and 1-chloro-1-pentyne respectively.

In a previous communication (2) one of us reported the preparation of 1,1,2,2-tetrachloropropane and *trans*-1,2-dichloro-1-propene in 65 and 20% yields respectively by the vapor phase chlorination of propyne at 50° to 60°C. These compounds were in turn later used to synthesize others of the C_3 series (3). The successful outcome of this investigation led us to attempt the chlorination of other acetylenic hydrocarbons by the same method in the hope of obtaining some hitherto unknown polychlorinated hydrocarbons. Such studies might also enable us to correlate chemical behavior with structure. This paper deals with the chlorination products of butyne-1, butyne-2, and pentyne-1 and some of their reactions.

Chlorination of butyne-1 in the vapor phase at 40°C. gave a 36.5% yield of 1,1,2,2-tetrachlorobutane and 11% of *trans*-1,2-dichloro-1-butene. Between these compounds an intermediate fraction was collected over a wide range of temperature. A second careful fractionation of this mixture gave a product, b.p. 64–65°C. at 25 mm., which was first thought to be a trichlorobutane. However, dehalogenation in ethanol with zinc dust gave a mixture of compounds. The original material therefore appears to be a mixture of trichlorobutanes and/or trichlorobutenes. In addition to these fractions a considerable amount of distillate was obtained boiling above the tetrachlorobutane from which no pure compound could be separated. The presence of penta- and hexachlorobutanes was indicated by the index of refraction of the distillate.

Dehalogenation of 1,1,2,2-tetrachlorobutane with zinc dust in ethanol gave *trans*- and *cis*-1,2-dichloro-1-butene, b.p. 99.5° to 100°C. and 118° to 119°C. respectively. The yield of *cis* isomer was nearly twice that of the *trans*. Dehydrohalogenation of the tetrachlorobutane gave 1,1,2-trichloro-1-butene, b.p. 137°C. The latter compound was also obtained from butyne-1 by the sequence of reactions:

[1]*Manuscript received August 20, 1954.*
Contribution from the Division of Pure Chemistry, National Research Laboratories, Ottawa, Canada. Issued as N.R.C. No. 3439.
Presented at the 37th Canadian Chemical Conference, Toronto, Ontario, June, 1954.

$$C_2H_5C{\equiv}CH \xrightarrow{NaOCl} C_2H_5C{\equiv}CCl \xrightarrow{2Cl_2} C_2H_5CCl_2CCl_3 \xrightarrow{-Cl_2} C_2H_5CCl{=}CCl_2.$$

The physical constants of the two compounds were identical.

The chlorination of butyne-2 proceeded smoothly at room temperature. From the first fraction of chlorinated product *trans*-2,3-dichloro-2-butene, b.p. 99.5° to 100°C., was recovered in 23.6% yield. At this point the distillation had to be discontinued on account of the separation of solid from the residue which was removed by filtration. This product analyzed correctly for a tetrachlorobutane and was in fact 2,2,3,3-tetrachlorobutane, m.p. 174°C. The filtrate from the solid boiled over a wide range of temperature; its index of refraction indicated that it was a mixture of penta- and hexachlorobutanes.

2,2,3,3-Tetrachlorobutane was dehalogenated with zinc dust in ethanol. The chief product isolated was a substance b.p. 100°C., apparently *trans*-2,3-dichloro-2-butene. Very little of the *cis*-isomer was present. These compounds had been previously prepared by Tishchenko and Churbakov (4) by removal of hydrogen chloride from 2,2,3-trichlorobutane.

The chlorination of pentyne-1 gave a 19.3% yield of *trans*-1,2-dichloro-1-pentene and 15% of 1,1,2,2-tetrachloropentane. A large amount of by-products was obtained from which no pure compounds could be isolated.

Dechlorination of 1,1,2,2-tetrachloropentane gave *cis*- and *trans*-1,2-dichloro-1-pentene, b.p. 62° to 62.5°C. at 47 mm. and 49 to 50°C. at 47 mm. respectively. The proportion of *cis*- to *trans*- isomer was in the ratio 2:1. Removal of hydrogen chloride from the tetrachloro compound gave 1,1,2-trichloro-1-pentene, b.p. 74–75°C. at 45 mm. The same compound was prepared by the following sequence of reactions from pentyne-1:

$$C_3H_7C{\equiv}CH \xrightarrow{NaOCl} C_3H_7C{\equiv}CCl \xrightarrow{2Cl_2} C_3H_7CCl_2CCl_3 \xrightarrow{-Cl_2} C_3H_7CCl{=}CCl_2.$$

DISCUSSION

The chlorination of the acetylenic hydrocarbons described in the present work was much less specific than that of propyne. In all three instances chlorination by substitution took place to a certain extent as well as by addition. The formation of substitution products in the case of butyne-1 and pentyne-1 is consistent with Haas' rule (1) relating to the ease of substitution of chlorine for hydrogen in hydrocarbons, viz., that hydrogen is more readily replaced by chlorine in a methylene than in a methyl group. However, this does not account for the presence of appreciable amounts of products formed by substitutive chlorination in butyne-2, and none in propyne. It may well be that electron mobility in butynes and pentyne is greater than in propyne, and chlorination by substitution is thus facilitated.

Another curious observation made in the present work is the predominance of *cis*-isomer formed in the dechlorination of 1,1,2,2-tetrachlorobutane and pentane and the almost exclusive formation of *trans*-isomer in the dechlorination of 2,2,3,3-tetrachlorobutane. No obvious explanation can be offered for these results at this time.

EXPERIMENTAL

Chlorination of Butyne-1

This chlorination was carried out in an apparatus similar to that described in an earlier paper (2).

Dry chlorine gas and butyne-1 were introduced into the evacuated reaction flask in the ratio 2: 1. After they were heated to 40°C. with an infrared lamp, reaction began and proceeded smoothly at 55° to 60°C. without further external heating provided that the correct ratio of the gases was maintained. The liquid product collected in the trap at the bottom of the reactor. Under these conditions, 32.5 liters of butyne-1 were chlorinated in 12 hr. The crude product was shaken twice with 100 ml. of dilute sodium bicarbonate solution and finally washed with water. After drying over potassium carbonate, the dry product, weighing 227 gm., was fractionally distilled under reduced pressure.

Fraction I was collected over the range 23° to 28°C. at 27 mm. When refractionated through a Stedman column (12 in. × 3/8 in.) at atmospheric pressure, 15.8 gm. of *trans*-1,2-dichloro-1-butene were obtained. Yield 11.3%, b.p. 99.5° to 100.5°C., n_D^{20} 1.4522. Fraction II (35.0 ml.) distilled over the range 31° to 85°C. at 25 mm. When carefully refractionated, a sample of 12.0 ml. with constant boiling point (64 to 64.5°C. at 25 mm.) was collected. This material is probably a mixture of trichlorobutanes and/or trichlorobutenes.

Fraction III consisted of 80.0 gm. of 1,1,2,2-tetrachlorobutane. Yield 36.5%, b.p. 85° to 85.5°C. at 25 mm., n_D^{20} 1.4908; calc. for Cl, 72.39%, found, 72.17%. Fraction IV consisting of 8.0 ml. distilled over the range 88° to 105°C. at 25 mm., n_D^{20} 1.5000. Fraction V (13.5 ml.) was collected at 105° to 106.5°C. at 23 mm., n_D^{20} 1.5074. Fraction VI (4.0 ml.) distilled at 108° to 117°C. at 25 mm., n_D^{20} 1.5102. Fraction VII (10.0 ml.) distilled at 119° to 121°C. at 24 mm., n_D^{20} 1.5162.

cis- and trans-1,2-Dichloro-1-butene

1,1,2,2-Tetrachlorobutane (69.0 gm.) in 25 ml. of ethanol was added dropwise to a refluxing mixture of 30.0 gm. of zinc dust in 200 ml. of ethanol. After refluxing for 30 min. the reaction products were distilled off as azeotropes through a Stedman column. The distillate was washed with water and dried by distilling on the vacuum line through a U-tube filled with P_2O_5. The isomers were separated by fractional distillation through a Stedman column. The total yield was 80.0%. The *trans*-isomer weighed 12.6 gm. (37% of the total), distilled at 100° to 101.0°C., n_D^{20} 1.4526; calc. for Cl, 56.73%, found, 55.80%. The *cis*-isomer weighed 21.5 gm. (63% of the total) and distilled at 118.5° to 119.0°C., n_D^{20} 1.4598.

1,1,2-Trichloro-1-butene

1,1,2,2-Tetrachlorobutane (20.0 gm.) and calcium oxide (6.0 gm.) in 100 ml. of water were refluxed for eight hours. The yield of 1,1,2-trichloro-1-butene which distilled off as an azeotrope was nearly quantitative. After drying over calcium chloride, the halide was distilled through a Stedman column. It boiled at 137.0°C. at atmospheric pressure (58° to 58.5°C. at 46.0 mm.), n_D^{20} 1.4816; calc. for Cl, 66.71%, found, 66.06%.

1,1,1,2,2-Pentachlorobutane

1-Chlorobutyne-1 (15 gm.; prepared as in Ref. 3) was dissolved in 25 ml. of methylene chloride in a 100 ml. flask. The latter was fitted with a cold finger condenser filled with dry ice. Chlorine gas (28.4 gm.) was slowly distilled into this solution which was allowed to stand in the dark for four hours. The colorless solution was fractionally distilled at reduced pressure through a Stedman column. 1,1,1,2,2-Pentachlorobutane distilled at 102–103.5°C. at 25 mm. Yield 25.6%, n_D^{20} 1.5096; calc. for Cl, 76.95%, found, 71.03%. A sample of this compound added to zinc dust in ethanol gave a product identical with 1,1,2-trichloro-1-butene reported above.

Chlorination of Pentyne-1

Pentyne-1 (122 gm.) was placed in a 200 ml. flask, which was connected to the same apparatus as was used in the chlorination of butyne-1. The pentyne and vacuum line leading to the reaction flask were heated to 45°C. in order to keep the vapor pressure of the compound slightly above one atmosphere. By this means it was possible to feed it into the reaction flask as a vapor, in which form it reacted with the chlorine. As soon as the gases mixed chlorination began without external heating. Reaction temperature fluctuated between 45° and 50°C. On several occasions flashes occurred during the chlorination but these were neither dangerous nor did they retard reaction; they merely deposited carbon on the walls of the flask. After eight hours the pentyne was all reacted. The crude product (236 gm.) was treated in the same manner as described for the lower homologue. After drying it was fractionally distilled through a Stedman column.

Fraction I consisted of 51 gm. of unreacted pentyne-1.

Fraction II was collected over the range 31° to 51°C. at 24 mm. When refractionated at atmospheric pressure, 28.0 gm. of *trans*-1,2-dichloro-1-pentene were collected. Yield 19.3%, b.p. 124.5–125°C. (48° to 49°C. at 47 mm.), n_D^{20}1.4556.

Fraction III was a mixture of chloro compounds from which no single compound was isolated.

Fraction IV was 1,1,2,2-tetrachloropentane. It distilled at 95–97°C. at 23 mm. Yield 33.0 gm. (15.3%), n_D^{20} 1.4887; calc. for Cl, 67.61%, found, 66.61%.

A high boiling residue of 30 ml. remained but no pure compound was isolated from it.

cis- and trans-Dichloro-1-pentene

1,1,2,2-Tetrachloropentane (20.6 gm.) in 10 ml. of ethanol was added to a suspension of 10 gm. of zinc dust in 60 ml. of ethanol. The reaction products were distilled off as azeotropes and dried over calcium chloride. The yield of dry product was 13.0 gm. (95%). The two isomers were separated by careful distillation. *trans*-1,2-Dichloro-1-pentene distilled at 49–50°C. at 47 mm. Yield 4.0 gm. (34.8% of total), n_D^{20} 1.4552; calc. for Cl, 51.00%, found, 50.98%. The *cis*-isomer, 7.5 gm. (65.2% of total), distilled at 62–62.5°C. at 47 mm., n_D^{20} 1.4614; calc. for Cl, 51.00%, found, 51.04%.

1,1,2-Trichloro-1-pentene

This compound was prepared by adding 7.2 gm. of 1,1,2,2-tetrachloropentane to a mixture of 3.0 gm. of calcium oxide in 50 ml. of water. The dry 1,1,2-trichloro-1-pentene distilled at 74–75°C. at 45 mm. Yield 4.1 gm. (70%), n_D^{20} 1.4798; calc. for Cl, 61.31%, found 61.23%.

1,1,1,2,2-Pentachloropentane

Dry chlorine gas (0.80 mole) was slowly distilled into a solution of 40.0 gm. (0.39 mole) of 1-chloro-1-pentyne in 40 ml. of methylene chloride in the dark. The 1,1,1,2,2-pentachloropentane, fractionated through a Stedman column, distilled at 83–84°C. at 7.00 mm. Yield 44.8 gm. (47.2%), n_D^{20} 1.5062; calc. for Cl, 72.53%, found, 70.53%.

A sample of this compound treated with zinc dust in ethanol gave a product identical with 1,1,2-dichloro-1-pentene described above.

Chlorination of Butyne-2

Butyne-2 (45 gm.) was placed in a 100 ml. flask, and the flask connected to the chlorination apparatus. The hydrocarbon was heated to 32°C. at which it had a vapor pressure slightly above one atmosphere. Chlorine and butyne-2 were fed into the evacuated reaction flask in the ratio 2: 1. Reaction began at once and proceeded smoothly at 36–38°C. The liquid product collected in the receiver at the bottom of the apparatus. There was also evidence of solid product forming on the walls of the reaction flask.

After 10 hr. all the butyne-2 had been added and the product was fractionated without further treatment through a glass helices packed column.

Fraction I consisted of 4.0 gm. of unreacted butyne-2.

Fraction II was composed of 21 gm. of *trans*-2,3-dichloro-2-butene. Yield 22.0%, b.p. 98° to 100°C., n_D^{20} 1.4570.

A solid began to separate in the fractionating column and distilling flask shortly after the apparatus had been evacuated. The flask was cooled to −20°C. and the solid filtered off. A sample recrystallized from pentane gave pure 2,2,3,3-tetrachlorobutane. Yield 25 gm. (16.8%), m.p. 171.5–174°C.; calc. for Cl, 72.38%, found, 71.94%.

A high boiling residue of 34 gm. remained from which no pure compound could be isolated. It appeared to be a mixture of penta- and hexachlorobutanes.

cis- and trans-2,3-Dichloro-2-butene

2,2,3,3-Tetrachlorobutane (28 gm.) in 200 ml. of ethanol was added to a refluxing mixture of 15 gm. of zinc dust in ethanol. After reaction was complete the products were distilled as azeotropes with ethanol. About 200 ml. had to be distilled before all the halide had distilled. The distillate was worked up in the usual manner. The total yield was 60%. The *trans*-isomer weighing 9.1 gm. (90% of the total) distilled at 99–101°C., n_D^{20} 1.4582. The *cis*-isomer weighed 1.2 gm. (10% of the total), distilled at 124–126°C., n_D^{20} 1.4672.

ANTITUBERCULOUS ISONICOTINYLHYDRAZONES OF LOW TOXICITY[1]

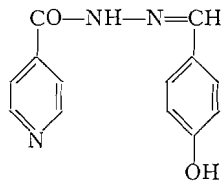
By A. Zubrys and C. O. Siebenmann

ABSTRACT

In a search for antituberculous compounds of low toxicity, the isonicotinylhydrazones of monohydroxybenzaldehydes and of the corresponding aldehydophenoxyacetic acids were prepared. When tested *in vivo*, the isonicotinylhydrazones of 2-formyl-phenoxyacetic acid and of 6-methoxy-2-formyl-phenoxyacetic acid showed the most marked antituberculous activity combined with low toxicity. The preparation of 6-methoxy-2-formyl-phenoxyacetic acid and of the isonicotinylhydrazone of 2-formyl-phenoxyacetic acid are described as representative examples. The results of microanalysis include data which define the antituberculous isonicotinylhydrazones of 2-hydroxybenzaldehyde, 4-hydroxybenzaldehyde, and 2-hydroxy-3-methoxybenzaldehyde (*o*-vanillin).

INTRODUCTION

Following the discovery of the antituberculous activity of isonicotinic acid hydrazide (isoniazid) by Grunberg and Schnitzer (5) and by Bernstein *et al.* (1) we recorded the marked therapeutic action in the experimental tuberculous infection in mice of isonicotinylhydrazones of hydroxy substituted benzaldehydes (8). As a representative example of this group of compounds the isonicotinylhydrazone of 4-hydroxybenzaldehyde (I) was studied more closely (7).



I

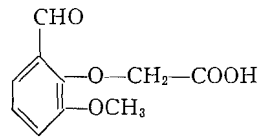
The low toxicity in mice shown by (I), as well as by isonicotinylhydrazones of other monohydroxybenzaldehydes, encouraged us to extend our research in this field.

As the *in vitro* antituberculous activity of (I) approaches that of isoniazid, it was considered likely that the limited *in vivo* activity of this compound, as compared to that of isoniazid, may in part be due to its low solubility. It appeared desirable, therefore, to introduce suitable modifications in the molecular structure to render this type of compound more soluble. On the basis of this idea we have prepared, as starting materials for isonicotinylhydrazones, a series of aldehydo-phenoxyacetic acids, namely:
4-formyl-phenoxyacetic acid (3) from 4-hydroxybenzaldehyde,
2-formyl-phenoxyacetic acid (2, 6) from salicylaldehyde,
6-methoxy-2-formyl-phenoxyacetic acid from *o*-vanillin (2-hydroxy-3-methoxybenzaldehyde), and

[1]*Manuscript received August 16, 1954.*
Contribution from the Connaught Medical Research Laboratories, University of Toronto, Toronto, Ont.

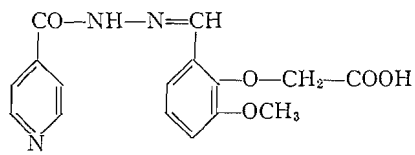
2-methoxy-4-formyl-phenoxyacetic acid (4) from vanillin (4-hydroxy-3-methoxybenzaldehyde).

One of these acids, namely, 6-methoxy-2-formyl-phenoxyacetic acid (II) was unknown.

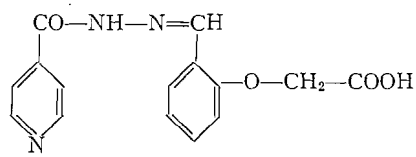


II

The isonicotinylhydrazones of all four above-mentioned aldehydophenoxyacetic acids, when tested in mice, showed a consistently higher antituberculous activity than the isonicotinylhydrazones of the corresponding unsubstituted hydroxybenzaldehydes. The best results were obtained with the isonicotinylhydrazones of 6-methoxy-2-formyl-phenoxyacetic acid (III) and of 2-formyl-phenoxyacetic acid (IV).



III



IV

The marked antituberculous activity of these two compounds, mentioned in an earlier communication (9), is of the order of 35–50% of that of isoniazid,

and deserves special attention on account of the low toxicity which both compounds exhibit in laboratory animals. The acute oral toxicity of (III), when tested in mice, is less than $\frac{1}{40}$, and that of (IV) less than $\frac{1}{25}$, of that of isoniazid.

In the experimental part the synthesis of 6-methoxy-2-formyl-phenoxyacetic acid, 2-formyl-phenoxyacetic acid and its isonicotinylhydrazone are described as representative examples. The results of microanalysis (Table I) include data defining the antituberculous isonicotinylhydrazones, prepared by us in 1952, from 4-hydroxybenzaldehyde, 2-hydroxybenzaldehyde, 2-hydroxy-3-methoxybenzaldehyde, and vanillin. These hydrazones were prepared using essentially the same procedure as for the isonicotinylhydrazone of 2-formyl-phenoxyacetic acid. The biological properties of all above-mentioned compounds are the subject of a separate communication (10).

EXPERIMENTAL PART

6-Methoxy-2-formyl-phenoxyacetic Acid (II)

To a solution of 45.6 gm. (0.3 M.) of 2-hydroxy-3-methoxybenzaldehyde in 100 ml. of ether, 25 gm. of sodium hydroxide dissolved in 50 ml. of water were added slowly while the solution was cooled and stirred. To this mixture a solution of 28.35 gm. (0.3 M.) of chloracetic acid in 30 ml. of water was added in the same way. The ether was removed and the mixture heated under reflux for two hours at 120–125° C. (oil bath temp.). The resulting solution was cooled, diluted with water, acidified with hydrochloric acid to Congo red, and allowed to stand for three hours at room temperature. The precipitate which formed was filtered, dissolved in sodium bicarbonate solution, and extracted with ether. The aqueous layer was acidified to Congo red and left in the cold-room for two hours. The precipitated impure 6-methoxy-2-formyl-phenoxyacetic acid was crystallized from boiling water. Yield: 20 gm., m.p. 111–114.5° C. After two recrystallizations from benzene the m.p. rose to 118–121° C.

The 6-methoxy-2-formyl-phenoxyacetic acid crystallizes from benzene in white needles and has the characteristic properties of an aldehydo-carbonic acid. It reduces ammoniacal silver nitrate solution, gives a violet coloration with Schiff's reagent, forms a hydrazone with isonicotinic acid hydrazide, and a thiosemicarbazone with thiosemicarbazide. It dissolves slowly in sodium bicarbonate solution with elimination of carbon dioxide. The acid is easily soluble in ethanol, methanol, acetone, ethylacetate, amylacetate, ether, acetic acid, dimethylformamide, hot benzene, and hot water.

2-Formyl-phenoxyacetic Acid

This acid was prepared in a similar way as 6-methoxy-2-formyl-phenoxyacetic acid. The final product was crystallized from water. From 36.6 gm. of salicylaldehyde the yield was 25 gm., m.p. 130–132° C.

Isonicotinylhydrazone of 2-formyl-phenoxyacetic Acid (IV)

A hot solution of 13.7 gm. (0.1 M.) of isonicotinic acid hydrazide* in 100 ml.

**For the synthesis of isonicotinic acid hydrazide a generous initial supply of isonicotinic acid was obtained through the courtesy of Fine Chemicals of Canada, Ltd.*

of water was mixed with a hot solution of 18 gm. (0.1 M.) of 2-formyl-phenoxy-acetic acid in 120 ml. of ethanol, heated for 15 min. under reflux, and allowed to stand in the cold-room over night. The slightly yellowish precipitate which formed was filtered, washed with water, ethanol, acetone, and dried. Yield: 29 gm., m.p. 246–248° C. An analytical sample, recrystallized from 75% ethanol, had m.p. 247–248° C.

The hydrazone is soluble in dilute sodium bicarbonate solution; it reduces ammoniacal silver nitrate solution.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council for financial assistance which made this investigation possible. We are indebted to Dr. R. D. Defries, Director of the Connaught Medical Research Laboratories, for his encouragement and valuable support. Grateful acknowledgment is made to Prof. G. F Wright, University of Toronto, for the X-ray diffraction pattern and to Dr. R. N. Jones, Division of Pure Chemistry, National Research Council, for the infrared spectra taken of some of the compounds recorded in this report.

A NEW MATERIAL AND TECHNIQUES FOR THE FABRICATION AND MEASUREMENT OF VERY THIN FILMS FOR USE IN 4π-COUNTING[1]

By B. D. Pate[2] and L. Yaffe

ABSTRACT

A new method for preparing thin films for use in beta-spectrometry and 4π-counting is described. These films, made of polyvinylchloride-acetate copolymer are readily prepared with superficial densities as low as 1 μgm. per cm.^{2} The films have good tensile strength and show excellent resistance to acids, alkalies, and many organic reagents. The thickness of the films may be determined (*a*) gravimetrically, (*b*) radiometrically, and (*c*) optically either by transmission or reflection. The films can be made conducting by distilling a thin gold layer on to them. The thickness of the gold layer can be determined spectrophotometrically.

INTRODUCTION

In the course of work in this laboratory (to be published shortly) on the improvement of the accuracy of disintegration-rate determinations by 4π gas-ion counting, it became necessary to develop methods for producing films of synthetic resin of superficial density much lower than hitherto reported. This paper reports the successful fabrication of films of good chemical and mechanical stability, of superficial densities down to below 1 μgm./cm.^{2} (thickness < 7 mμ) and of area up to 100 cm.^{2}

Materials used for the production of source-mounts for the purposes of 4π-counting or beta-spectrometry must satisfy a number of criteria. They must be of:

(*a*) minimal superficial density and low average atomic number, in order to reduce absorption and scattering of radiation;

(*b*) adequate mechanical strength to withstand shocks received during normal, careful handling and the pipetting out of radioactive solutions;

(*c*) adequate chemical resistance to reagents present during the rapid evaporation of these solutions, e.g. under infrared irradiation;

(*d*) adequate thermal resistance to withstand infrared irradiation during this evaporation procedure and during metallizing procedures if these are required (see later).

The use of a number of materials has been reported in the literature. Aluminum foil has been used (3, 4, 5, 6, 20, 21) in superficial densities as low as 260 μgm./cm.^{2} (19). Such foils will however be very weak mechanically, and in addition aluminum does not exhibit very good chemical resistance to acids or alkalies. Certain synthetic resins have been found to lend themselves to the fabrication of thin films suitable for source mounts and have been used extensively with conventional low-geometry counters and in beta-spectrometry where back-scattering effects were to be minimized (7, 15). Formvar (7, 9, 22),

[1]*Manuscript received August 13, 1954.*
Contribution from the Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec, with financial assistance from the National Research Council of Canada.
[2]*Holder of a National Research Council Studentship.*

a polyvinylformal, has excellent mechanical properties, being strong and resistant to abrasion (8, 16, 17). A method (2) to produce films of less than 10 μgm./cm.^{2} superficial density by means of very specialized handling techniques has recently been described. Unfortunately Formvar is readily attacked by acids, concentrated alkalies, and organic solvents. It has however found application in laminates with films of polystyrene or Zapon (8, 10, 13) which possess better chemical properties, but are alone too fragile.

Cellulose nitrate (1, 11, 14) and acetate (19) are probably the most successful of the materials used up to this time. They are resistant to hydrochloric acid in all concentrations, oxidizing acids in concentrations up to 12 N, and dilute alkalies. They are attacked however by concentrated alkalies, and other substances, e.g. an aqueous slurry of a metallic sulphide. Films of these materials with a superficial density of as low as 3 μgm./cm.^{2} have been reported. However these are of small area, and it is found that films of less than 40 μgm./cm.^{2} do not make satisfactory mounts owing to increasing fragility which impedes their manufacture, handling, and use during pipetting operations.

When it is desired to work with source-mounting films of 5–10 μgm./cm.^{2}, therefore, it is clear that a material with much better characteristics is required. We propose the use of VYNS resin* (a polyvinylchloride-acetate copolymer). Films of this material can be made with superficial densities below 1 μgm./cm.^{2} These show remarkable tensile strength, and excellent chemical resistance to acids and alkalies in all concentrations and to most organic solvents. The only common chemicals found to attack the films are ketonic compounds and esters which act as solvents for the resin. These properties, together with resistance to all but the severest of shocks, make VYNS resin an ideal material for source mounts.

PROCEDURES

(1) *Film Production*

VYNS resin as supplied by the manufacturers is a finely ground white powder. The most convenient solvent is found to be cyclohexanone, one volume of resin requiring about two volumes of solvent for complete dissolution. First addition of solvent to the resin produces a gel, which dissolves in further solvent only slowly in the course of several days. The process can however be accelerated somewhat by maintaining the mixture at 50–60°C. for several hours. The saturated solution thus obtained forms a convenient stock solution. This is diluted with further cyclohexanone before use to give a one-third saturated solution.

VYNS in cyclohexanone does not spread satisfactorily on a water surface, and dilution with a second solvent produces on evaporation very weak and uneven films. The conventional techniques for film formation are therefore not applicable, and a new method has had to be developed. This is found to

**This material is a product of the Bakelite Co. N.Y., available in Canada through Canadian Resins and Chemicals Ltd., Montreal. We are indebted to Mr. I. Maclaine of Dominion Oilcloth and Linoleum Ltd. for introduction to this material, and to Mr. F. M. King of Canadian Resins and Chemicals Ltd. for a supply of the resin for experimental purposes.*

produce films whose constancy of thickness is better than previously obtainable, and possesses the additional merit of improving the tensile strength of the thinner films, possibly by orientation of polymer molecules.

The procedure used is as follows. A trough or sink is filled with water at room temperature and a floating wooden barrier placed in contact with one end. One to two milliliters of resin solution are pipetted between the barrier and the trough, so as to wet both the side of the trough and the barrier; the latter is released and the resin solution allowed to expand into a band about 2–3 cm. wide, the outer edge (nearest the barrier) of which immediately begins to solidify. The barrier is lifted from the water, lowered lightly on to the solidified film, and then moved away along the water surface at a speed of about 30–40 cm. per second. During this process a film of resin is observed to feed out of the solution band, and continues to do so covering the water surface, until either the barrier reaches the far end of the trough, or the band of solution is exhausted. The thickness of film produced is governed by the speed at which the barrier is pulled out, the thinnest films being obtained with the highest speeds. The evenness of the film in one direction is conditioned by the evenness of the original pipetting operation, and in the other by the constancy of barrier velocity. Success in operation of this procedure is largely a matter of manual dexterity, which can easily be obtained.

The film produced is quite dry and may be lifted from the water surface for use immediately. The lifting may be accomplished by the use of wire frames (coated with VYNS to give better film adhesion) which allow larger areas of film to be obtained, e.g. up to 40 cm. × 20 cm. of 10–20 μgm./cm.^{2} film. The film may then be transferred to other supports which have previously been wetted with water. Alternatively the supports, in our apparatus aluminum annuli of area 40 cm.^{2}, may be used to pick up the film directly, 30 or 40 rings being covered in one operation. In either case the support or frame is lowered to contact the upper surface of the film, the latter torn away at the edges, and the film lifted with a rolling motion, one edge separating first. This procedure often gives a film completely free of water droplets. Any that may be left can be cautiously pulled to the edge of the film with a wisp of absorbent material. An alternative procedure useful for the thinnest films is to sink the film and support carefully and to bring them out through the water surface at right angles, reducing the effect of surface tension forces. Marks remaining after evaporation of water droplets left by this procedure may be avoided by dipping the film on edge below the surface of some distilled water. VYNS is hydrophobic, and films produced by this method, once any adhering water is removed, are quite dry and ready for use. No appreciable change in weight is observed over long periods of time, either with plain films or after metallizing (see later).

This simple technique as described is suitable for the production of uniform films of up to 20 μgm./cm.^{2} superficial density. Films of greater thicknesses are conveniently produced by lamination, two films placed in contact adhering readily; laminates of greater than 100 μgm./cm.^{2} and quite even in thickness have been made in this way. Alternatively one can use a mechanical means of

ensuring constant barrier speed to produce the thicker films. The manual method does not operate too satisfactorily in this region.

It is standard procedure in this laboratory to store films on edge. This arrangement renders the stock of films less liable to damage by vibration, and further allows a large number of films to be stored in a small space.

(2) *Measurement of Film Superficial Density*

For the purposes of 4π-counting and beta-spectroscopy it is desirable to know the superficial density of the material used as a source mount. Four methods have been found useful in this connection.

(*a*) *Optical Reflection Method*

As is well known, thin films are often observed to be brilliantly colored by reflected light, owing to the occurrence of interference and reinforcement between the light reflected from the top and bottom surfaces of the film. The conditions for reinforcement and destructive interference for light of wave length λ are given by:

$$\text{reinforcement:} (n+\tfrac{1}{2})\lambda = 2\mu d \cos\theta,$$
$$\text{destruction:} \quad n\lambda = 2\mu d \cos\theta$$

where μ is the film refractive index (for VYNS = 1.5), d is the film thickness, θ is the angle of reflection, and n is an integer. The wave lengths for which interference is expected for various VYNS film thicknesses with normally incident light, together with the color actually observed, are listed in Table I. The effects observed below 10 μgm./cm.^{2} are due to a falling off in reflectivity of the film.

TABLE I

Superficial density of film (μgm./cm.^{2})	Film thickness (mμ)	Wave length for reinforcement calculated (mμ)	Wave length for destructive interference calculated (mμ)	Color observed
1	7	(14)	(21)	Dark gray
5	36	(72)	(108)	Light gray
10	70	(140)	(210)	White
20	140	280	420	Light yellow
25	180	360	540	Yellow-brown
30	210	420	630	Purple (First
35	250	500	750	Blue order
40	290	580	870	Yellow spectrum
45	320	640	960	Red ($n = 1$)
50 and above	360 and above	—	—	Second order and above ($n \geq 2$). Colors of diminishing intensity

We have used these color differences, as observed visually, for the rough sorting of films of differing thicknesses, and especially for the selection of areas of film of the desired thickness and evenness for lifting from the water surface. It is clear that this could be made into a precision method, if desired, by use of a spectrophotometer with a reflection attachment.

(*b*) *Gravimetric Method*

A five decimal place analytical balance is capable of measuring the superficial density of 40 cm.^{2} (for our apparatus) of 5 μgm./cm.^{2} film with an accuracy of 5%. This gives a very useful, absolute means of superficial density standardization. We have used films specially selected for their uniformity and calibrated gravimetrically to standardize other methods of determination. As a routine method, however, weighing has certain disadvantages:

(i) Measurements to the required accuracy are very tedious and time-consuming.

(ii) The superficial density measured is an average for the whole film, not for the region of interest (the center). This method is not therefore applicable to films with peripheral irregularities which are nevertheless quite suitable for source mounts.

(iii) Finally the mounting of a film on a weighed support is not easily accomplished without a concomitant change in support weight, and measurements are subject to random errors far in excess of those imposed by the sensitivity limit of the balance used.

(*c*) *Beta Radiation Absorption Method*

Figs. 1 and 2 show as a function of their superficial density the transmission of VYNS films for the beta radiation of Ni^{63} (which has a maximum energy of

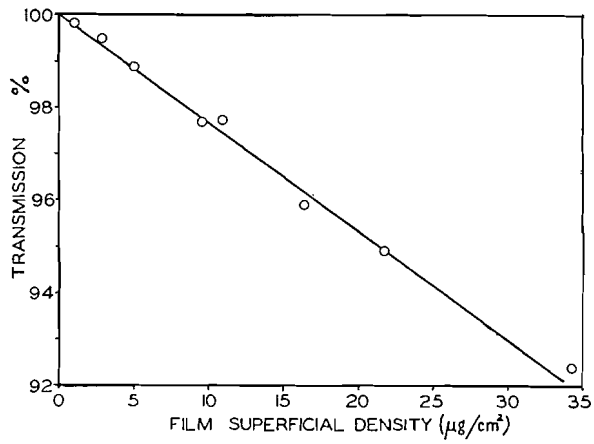

FIG. 1. Transmission of VYNS film to Ni^{63} beta radiation. Film superficial density range 0–35 μgm./cm.^{2}

67 kev.). Providing the radiation measurements can be made to the necessary precision, the method is limited by the accuracy of the superficial density values of the films used for calibration. We estimate that measurements can be made to 2 μgm./cm.^{2} in the range 0–30 μgm./cm.^{2}, and with a somewhat larger error at greater thicknesses. The actual form of the curves obtained depends a great deal on the radiation scattering and other characteristics of the apparatus used, but the details of procedure as used by us are as follows.

A Ni^{63} source of about 2×10^3 dis./sec. is deposited in a depression at the

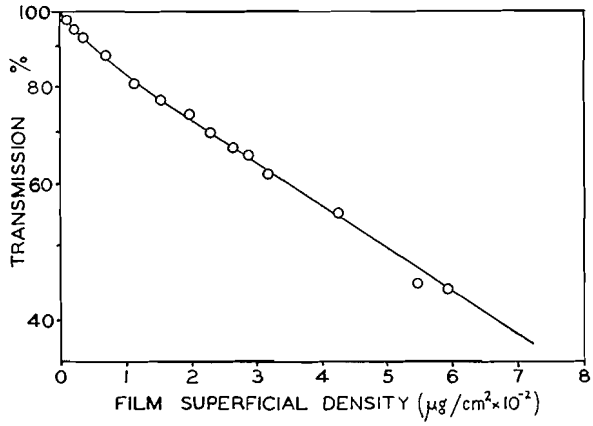

FIG. 2. Transmission of VYNS film to Ni^{63} beta radiation. Film superficial density range 0–600 μgm./cm.²

center of an aluminum plate, and the whole is covered with a VYNS film of about 50 μgm./cm.² to give a completely planar surface. This is then mounted in a conventional hemispherical 2π-proportional counter, and the counting rate measured to the required accuracy. Curves of transmission versus superficial density are then obtained, using specially selected gravimetrically calibrated films which are placed in contact with the plate. Advantages of the method include insensitivity to peripheral film irregularities—the superficial density measured is that observed by a source centrally located on the film used for a source mount—and a rapidity of operation much greater than for the gravimetric method. Disadvantages include the tendency for films of less than 10 μgm./cm.² to adhere to the plate and subsequently to rupture (which can to some extent be ameliorated by a light dusting of talc away from the central part of the film), the need for ensuring close contact between the film and plate (since a layer of methane counting-gas entrapped between them can cause considerable error in the apparent film thickness), and the need for electronic counting apparatus, etc.

(d) Optical Absorption Method

This method is now in routine use in this laboratory, and proves quite satisfactory for the measurement of superficial densities in the range 0–30 μgm./cm.² We employ a Beckman Model DU Spectrophotometer, which is first balanced against air, and then used to measure the optical transmission at a wave length of 360, 600, or 1300 mμ according to the thickness range and accuracy required. Calibration with selected weighed films produces curves as shown in Fig. 3, the features of which will be further discussed in a forthcoming publication. The potential precision of the method is about 0.05 μgm./cm.², but calibration difficulties impose at the moment a limit of ±0.5 μgm./cm.², which is nevertheless adequate for the present purposes. The method is found to be very rapid and facile in operation, and is applicable to the thinnest films since they need not be placed in contact with anything. It also meas-

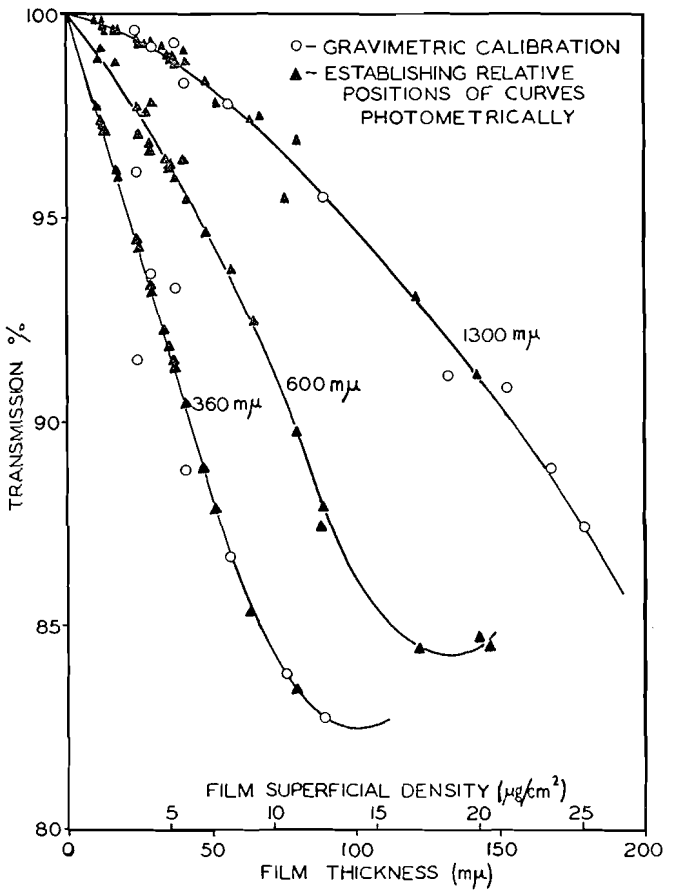

FIG. 3. Optical transmission of VYNS film.

ures the thickness of the center of the film, and is useful in measuring small irregularities of superficial density in this area.

(3) *Gold Coating*

The plastic film used for mounting a source within a counting chamber (or for beta-spectrometry) must be essentially at cathode potential in order that the counter shall function correctly. It has been reported (18) that a small area of plastic film can be satisfactorily used as a source mount, but most authors agree that films must be rendered conducting by a suitable coating, either of Aqua-dag (12, 15) or of metal applied by sputtering or distillation *in vacuo*. The use of aluminum (19), copper (11, 14), silver (1), and gold (7, 10) has been reported. We find gold coating of one side of the film by distillation from a tungsten ribbon filament at about 1200°C. and under <1 μ Hg to be satisfactory.

Low distillation rates of gold give approximately isotropic distribution of metal, and several films may be coated simultaneously if arranged spherically around the filament.

The progress of distillation may be followed by observing the color of the film by reflected light from the reverse face to that being coated. With an initially uncolored film of 5–10 μgm./cm.^{2} for example, a faint purple coloration is first noticed at a superficial density of 0.4 μgm./cm.^{2} gold, and this progressively deepens in shade until at 5 μgm./cm.^{2} a rich red-purple coloration is obtained. By transmitted light gold layers appear as increasing intensity of blue, and this color, due to absorption or reflection of light at about 600 mμ, has been made the basis of a satisfactory precision method of measuring the thickness of a gold layer applied. The Beckman Spectrophotometer is again used, balanced against air, and the transmission at 600 mμ of a series of films of known gold superficial density is measured, the film being arranged so that the light beam is incident on it from the uncoated side. A satisfactory method of preparing the calibration films is to employ increasing distillation times from a filament of constant distillation rate, which is known from gravimetric measurements. The optical transmission of the film plus gold as measured is the product of the transmission of the film and that of the gold. The former may be read from the 600 mμ curve in Fig. 3, and the curve of the gold transmission thus calculated versus gold superficial density is given in Fig. 4. The

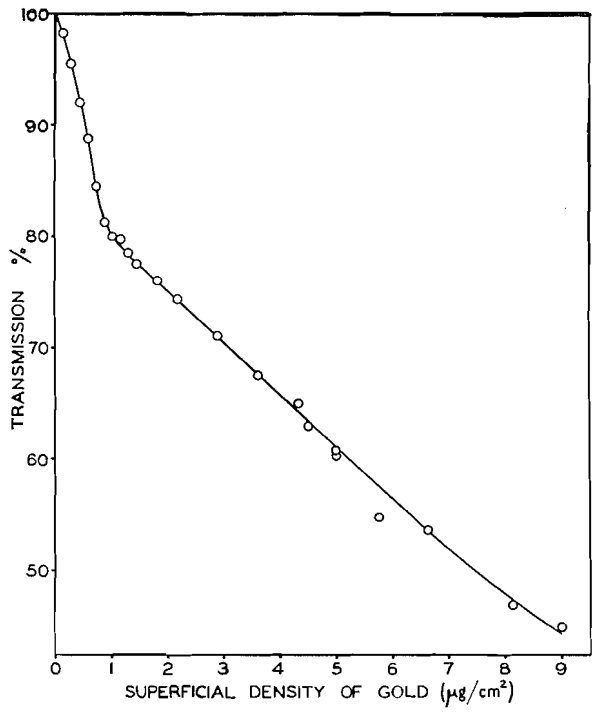

FIG. 4. Optical transmission of gold on VYNS film at 600 mμ wave length.

form of the curve, which has several unusual features, will be discussed in the forthcoming publication mentioned earlier. Spectrophotometer readings can be taken with an accuracy which gives a precision for the method of 0.05

μgm./cm.^{2} of gold, and in this case the calibration is probably of comparable accuracy.

ACKNOWLEDGMENTS

We wish to thank Mr. W. L. Elsdon of Dr. C. A. Winkler's laboratory for discussions on the spectrophotometric measurement of thin films. We would like to express our appreciation to the National Research Council for a grant-in-aid and to Atomic Energy of Canada Ltd. for loan of equipment. One of us (B. D. P.) wishes to thank the National Research Council for assistance received in the form of a studentship.

THE ALKALINE NITROBENZENE OXIDATION OF ASPEN WOOD AND LIGNIN MODEL SUBSTANCES[1]

By K. R. Kavanagh and J. M. Pepper

ABSTRACT

The yields of vanillin and syringaldehyde obtained by the alkaline nitrobenzene oxidation of aspen wood meal have been determined at various temperatures for various times. The maximum yield of each of these aldehydes, *ca.* 15 and 36% respectively, was obtained under the same conditions. Similar maximum yields result at 130±5°C. as at 170±5°C. if the reaction time is markedly increased. Treatment of the wood meal with sodium hydroxide at 160°C. for two and one half hours prior to the addition of nitrobenzene and subsequent heating under the same conditions decreases, by over 30%, the yields of aldehydes. Samples of 3,4,5-trimethoxybenzaldehyde, β-D-glucovanillin, and β-D-glucosyringaldehyde were oxidized by alkaline nitrobenzene at 160°C. for two and one half hours and yields of the corresponding phenolic aldehydes of 10.7, 69.6, and 71.9% respectively were obtained. These results are discussed with respect to the chemistry of aspen lignin.

Little has been reported regarding the establishment of the optimum conditions for obtaining the maximum yields for each of vanillin and syringaldehyde by the alkaline nitrobenzene oxidation of hardwood lignins. Brauns (2) has summarized the value of this technique in lignin chemistry. The major part of this work was concerned with softwood lignins and various reaction temperatures, ranging from that of boiling alkaline sulphite spent liquor to 200°C., and various reaction times from 10 min. to three hours. Since this book was published Leopold (9) has determined the vanillin yields obtainable from synthetic model lignin substances as a function of temperature and time and found that at 180°C. for two hours the best yields were obtained. Subsequently Leopold and co-workers (10, 11, 12) used these conditions to study the oxidation products of a wide variety of both hardwoods and softwoods. It is significant that almost all the conifers studied gave small amounts of *p*-hydroxybenzaldehyde while several (*Pinaceae* family) gave small amounts of syringaldehyde, this latter observation representing the first isolation of syringaldehyde from softwoods. Stone and Blundell (14) used a temperature of 160°C. for two and one half hours in their analytical micromethod for the alkaline nitrobenzene oxidation of plant materials.

A detailed study of these conditions of oxidation as applied to hardwoods was undertaken, therefore, with the belief that some useful information would be obtained with respect to the following problem. If vanillin and syringaldehyde arise by the hydrolysis and/or oxidative cleavage of different type linkages in the protolignin, then maximum yields of each might be obtained under different conditions. In this way a greater combined yield of aldehydes could result than that now obtained under conditions whereby both yields are deter-

Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Sask. This paper constitutes part of a thesis submitted by K. R. Kavanagh in partial fulfillment of the requirements for the degree of Master of Arts in Chemistry, November, 1953. Presented before the second Western Regional Conference, The Chemical Institute of Canada, Vancouver, September, 1954.

mined from the same reaction mixture. On the other hand, should the release of the two compounds be equally dependent on the conditions, some evidence would be presented for the existence of similar type linkages in the lignin. Other information, from such studies, such as the variance of the vanillin to syringaldehyde ratio with changing reaction conditions and the effect, on the aldehyde yield, of a prior treatment of the wood meal with alkali, could be interpreted with respect to the hardwood lignin structure. Little is known concerning the relative amount and the mode of linkage of the guaiacyl- and syringyl-containing nuclei in the protolignin of angiosperms.

For these experiments small (*ca.* 40 mgm.) samples of solvent extracted aspen wood meal were oxidized and the reaction mixture analyzed according to the procedure of Stone and Blundell (14). The results are given in Table I.

[c]*Bracketed results refer to duplicate chromatograms from the same oxidation product.*
[d]*Less significance should be given to these values; see text.*

It is significant that, at a temperature of 170–180°, the maximum yield of each of the individual aldehydes is obtained. This observation suggests that similar linkages are being cleaved to release each type of aldehyde. The decreasing ratio of syringaldehyde to vanillin with increasing temperature suggests that the 4-hydroxy grouping of the former is released more readily than that of the latter. Some support for this idea is found in the known ready selective demethylation of 3,4,5-trimethoxyphenyl compounds to the 3,5-dimethoxy-4-hydroxyphenyl derivatives. A similar decreasing ratio of syringaldehyde to vanillin was noted by Chisholm (5) in experiments wherein condi-

tions of progressively stronger severity of the alkaline nitrobenzene oxidation of aspen wood were made. These included experiments with no added nitrobenzene, with nitrobenzene at reflux temperatures, and with nitrobenzene at 160°C.

At the higher temperatures (200° and 215°) an increasing number of unknown interfering compounds began to appear on the developed chromatograms and therefore the absorption recorded may not have been due to the aldehydes only. Up to 195° however, this presented no problem since a comparison of the ultraviolet spectra of individual spots with those of authentic aldehyde samples showed excellent agreement.

On the basis that lignin may be represented as a polymer of phenylpropane units and that the major part of the wood methoxyl is associated with this lignin, then the total yield of aldehydes obtained represents only about a 60% recovery of the lignin both on a weight and on a methoxyl basis.* This consistent maximum total aldehyde yield was found even in experiments carried out at a lower temperature of 130°±5° but for an extended time and in those at 170° for periods longer than the normal two and one half hours. These data are given in Table II.

TABLE II

VARIATION OF ALDEHYDE YIELDS WITH TIME[a]

[a]*Time does not include that required to reach the reported temperature.*
[b]*Reported as percentages by weight of the Klason lignin.*
[c]*This chromatogram showed presence of additional products; see Table I*[d].

From these results it would appear that only part of the lignin has linkages amenable to cleavage to the simple aldehyde by this treatment. This may be interpreted to suggest that protolignin is a polymer of a repeating unit comprising a part from which the phenolic aldehydes arise and another part of

**It has been shown by A. J. McNamara in these laboratories that no change in total alkoxyl occurs during the alkaline nitrobenzene oxidation treatment of aspen wood at 160° for two hours.*

which little is known, rather than a simple polymer of a single phenylpropane structure.

The liberation of phenolic aldehydes by this oxidative process means that two processes at least are occurring, namely, that whereby the free phenolic group is released and that whereby the carbonyl group is established. It seems likely that these two reactions occur for the most part independently of each other. Therefore it would be of interest to arrive at the same final result but by means of two separate reaction stages. Experiments were conducted to determine the aldehyde yields as a result of an alkaline treatment alone at 160° and others to determine the effect of a similar alkaline treatment of the wood meal prior to the addition of nitrobenzene with subsequent heating under standard conditions. The results are compared in Table III.

TABLE III

VARIATION OF ALDEHYDE YIELDS WITH MODE OF ALKALINE TREATMENT

Ratio S/V	1.69	2.36	2.34	2.48	2.60

The small yields of aldehyde obtained using alkali without nitrobenzene suggest the existence of a small percentage of much more readily cleaved units, e.g. those that are terminal. Or such yields may be the result of an hydrolysis and/or an alkaline oxidation reaction aided by the fact that no attempt was made to exclude the air in sealing the microbombs or that dissolved in the reagents. Of greater interest is the marked decrease in the yields of aldehydes that result if a prior alkali treatment at 160° is given the wood meal. This may mean that, by this treatment, part of the linkages have been modified so that it is no longer possible for them to be cleaved to yield the phenolic aldehydes. Whether this interference is concerned with the liberation of the phenolic or

aldehydic groups or whether it involves secondary reactions (see below) remains to be shown. Experiments are in progress to determine, by analysis, the extent of the individual liberation of the phenolic and carbonyl functional groups under varying conditions. Such information would assist in determining the mechanism by which the aldehydes are released.

Such a secondary reaction as mentioned above is that pointed out recently by Brickman and Purves (3) and Hlava and Brauns (7). These authors showed that under conditions of alkaline nitrobenzene oxidation similar to those used in this work, namely, 160° for three hours and 180° for two hours respectively, veratraldehyde is converted to vanillin in approximately 30% yield. Since vanillin itself is essentially unchanged by such a procedure (14) a major portion of the veratraldehyde has undergone other reactions, likely the Cannizzaro oxidation–reduction change (6). If a similar reaction for both the guaiacyl and syringyl nuclei were occurring during the oxidation of wood lignin, it would account for the low total aldehyde yields and also suggest that the carbonyl-releasing reaction is more rapid than that whereby the phenol hydroxyl is liberated. If the reverse were true very little of the liberated vanillin would undergo further reaction and higher yields might be expected. In order to gain some experimental evidence for or against these ideas, other model substances were similarly oxidized at 160° for two and one half hours and the yields of the corresponding phenolic aldehydes determined. These results are given in Table IV.

TABLE IV

OXIDATION OF MODEL LIGNIN SUBSTANCES

Model substance	Molar recovery, %			Remarks
	Vanillin	Syringaldehyde	Mean	
Vanillin	99.3 96.4 97.8		97.8	According to Stone and Blundell (14) corrected for chromatographic losses
Veratraldehyde	31.3 30.6 31.9		31.3	No unchanged veratraldehyde Reported by Brickman and Purves, 29.7 and 34.2%
β-D-Glucovanillin*	68.4 72.7 67.8		69.6	
Syringaldehyde		93.0 86.0	89.5	Uncorrected for chromatographic losses
3,4,5-Trimethoxy-benzaldehyde		12.5 9.5 11.2 11.2 9.1	10.7	No unchanged 3,4,5-trimethoxybenzaldehyde
β-D-Glucosyringaldehyde		69.2 74.6	71.9	

Sample donated by Dr. A. C. Neish, National Research Council, Saskatoon.

The chromatogram of the product of oxidation of the β-D-glucovanillin showed one other spot only which had the same R_f value as the starting material. This may mean that no other serious side reaction is occurring as was the case with the two methylated derivatives.

In the light of both the small recovery of phenolic aldehydes, especially syringaldehyde, from their fully methylated derivatives and of the amounts obtained from the wood, it seems likely that these nuclei are not joined by means of phenolic alkyl ether linkages if the liberation of the carbonyl grouping is the major primary reaction. On the other hand, should these nuclei be involved in phenolic glycosidic linkages, nothing can be said about the relative rates of release of the two functional groupings. It would seem that under these circumstances, whereby both aldehydes are released at the same rate, evidence is presented that suggests that in the aspen protolignin, a larger number of syringyl than guaiacyl nuclei exist.

EXPERIMENTAL

Aspen Wood Meal

Native Saskatchewan aspen sapwood (*Populus tremuloides*) was ground in a Wiley mill (20 mesh), extracted* with ethanol–benzene (4:1) for 48 hr., then with ethanol for 36 hr., thoroughly washed with hot water for eight hours, and air-dried. Anal.: Klason lignin, 16.5; moisture, 7.65; ash, 3.77%.**

Oxidation and Chromatographic Procedures

The general methods of microoxidations of plant material, the chromatographic separation of the oxidation products, and the spectrophotometric determination of the concentration of aldehydes were those described in detail by Stone and Blundell (14). All oxidations were made using 35–50 mgm. samples of wood meal and around 10 mgm. samples of pure compounds. The chromatograms were developed for two to two and one half hours using a solvent of *n*-butyl ether saturated with water. The presence of the aldehyde spots were revealed by spraying with the ferric chloride – potassium ferricyanide reagent (1). The standard concentration vs. optical density curves were those described previously (13). All results of the wood oxidations are expressed as percentage yields by weight based on the amount of Klason lignin in the ash-free oven-dried sample. No corrections were made for chromatographic loss so the results represent minimum values.

For those experiments involving a prior alkaline treatment, only the wood meal and the sodium hydroxide solution were heated initially. After the mixture was cooled, the microbombs were opened, the nitrobenzene added, and the bombs again sealed and heated under standard conditions.

Synthesis of Model Substances

3,4,5-Trimethoxybenzaldehyde.—Syringaldehyde was methylated with dimethyl sulphate in alkaline solution according to the standard procedure (4).

**The extractions and washings were carried out by Mr. A. J. McNamara in these laboratories.*
***The high ash content is believed due to the use of a copper condenser during the extensive extractions.*

3,4,5-Trimethoxybenzaldehyde was recovered in 44.5% yield, m.p. 73–74°C., reported, 74–75°C. The oxime was prepared in high yield, m.p. 81–84°C., reported, 82–84°C.

β-D-Glucosyringaldehyde

Tetraacetyl-β-D-glucosyringaldehyde.—The method used was similar to that reported by Kratzl and Billek (8). Acetobromo-D-glucose (1.5 gm.), potassium carbonate (0.6 gm.), and syringaldehyde (0.67 gm.) were dissolved in a mixture of acetone (13 ml.) and water (7.7 ml.). After six hours at room temperature, the acetone was removed under reduced pressure and the residue extracted with benzene. After washing with dilute potassium hydroxide and drying over sodium sulphate, the benzene solution was concentrated under reduced pressure and the resulting tetraacetyl-β-D-glucosyringaldehyde recrystallized from benzene, yield, 1.3 gm.

Deacetylation of Tetraacetyl-β-D-glucosyringaldehyde

The method of Zemplén and Pacsu (15) was followed. The crude product (1.3 gm.) obtained in the preceding step was warmed on a water bath with methanol (3.3 ml.) and $N/10$ sodium hydroxide (0.33 ml.). From the resulting solution, an orange-yellow colored precipitate resulted after one to two minutes, yield, 0.7 gm. After recrystallization twice from ethanol–water (4:1), m.p. 201–204°C., reported, 210–211°C.

ACKNOWLEDGMENT

The authors wish to thank the Saskatchewan Research Council for both the award of a Graduate Research Fellowship to one of them (K. R. K.) and for a research grant which supported this investigation.

THE REACTION OF METHYL RADICALS WITH CH_3CHO AND CH_3CDO[1]

By P. Ausloos[2] and E. W. R. Steacie

ABSTRACT

Azomethane has been photolyzed in the presence of CH_3CHO and CH_3CDO, and the results compared with the direct photolysis of the aldehydes. The activation energies found were 6.8 and 7.8 kcal./mole, respectively, for the reactions

$$CH_3+CH_3CHO \rightarrow CH_4+CH_3CO \quad [1]$$
$$CH_3+CH_3CDO \rightarrow CH_3D+CH_3CO. \quad [2]$$

The results furnish evidence that only an acyl hydrogen is captured. Evidence has also been found for the occurrence of wall reactions and the disproportionation reaction

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO.$$

INTRODUCTION

By decomposing di-*t*-butyl peroxide in the presence of CH_3CHO, Volman and Brinton (6) obtained a value of 7.5 ± 0.3 kcal. for the activation energy for hydrogen abstraction by methyl from CH_3CHO. This value lies well below most previous estimates. Its acceptance has explained a number of anomalies in the acetaldehyde photolysis, and the value is therefore of considerable importance.

Up to the present no value has been obtained for the activation energy of the companion reaction

$$CH_3+CH_3CDO \rightarrow CH_3D+CH_3CO.$$

Also, there has been no definite proof whether it is an acyl or a methyl hydrogen which is captured in the reaction (4), although the acyl hydrogen is far more probable on general grounds.

The purpose of the present work was to compare the rates of abstraction from CH_3CHO and CH_3CDO, to obtain a check on the activation energy of the abstraction reaction using a different source of methyl radicals, and to determine whether an acyl or a methyl hydrogen is captured in the abstraction reaction. Azomethane has been used as a source of methyl radicals, since it can be photolyzed at wave lengths greater than 3400 Å where acetaldehyde is transparent. It can thus be photolyzed without complications due to the simultaneous photolysis of the aldehyde. The photolysis of CH_3CHO and CH_3CDO has also been investigated very briefly at 3130 Å in order to compare the results with those obtained with azomethane–acetaldehyde mixtures at longer wave lengths. By using relatively low pressures of acetaldehyde and higher intensities ($1–5 \times 10^{13}$ quanta per cc. per sec.) than have usually been used in the past, it is possible to obtain measurable amounts of ethane and thus to determine values of $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$ in the photolysis of acetaldehyde itself.

EXPERIMENTAL

Acetaldehyde-*d* was prepared by Dr. L. C. Leitch (5) of this laboratory by the reaction sequence

$$CH_3CH_2NO_2 \overset{D_2O}{\rightleftarrows} CH_3CD_2NO_2$$

$$CH_3CD_2NO_2 \xrightarrow[0°C.]{H_2SO_4(6M)} CH_3CDO + HDO + N_2O.$$

Mass-spectrometer analysis indicated that the CH_3CDO contained about one per cent CH_2DCDO and less than five per cent CH_3CHO.

The light source was a Hanovia S-500 medium pressure mercury arc. The cylindrical quartz reaction cell, 10 cm. long, 5 cm. diameter, was completely filled by a nearly parallel light beam. Four types of filter were used to limit the incident radiation to longer wave lengths:

Corning clear chemical glass 774 (0–53),
Corning 586 (7–37),
Corning 738 (0–52), and
Corning 970 (9–53).

The apparatus was essentially similar to that used in previous investigations. The methane, N_2, CO fractions were taken off at liquid nitrogen temperature and CO determined by passing over hot CuO. Further analysis was done with a mass spectrometer. The ethane fraction was separated at −170°C., and occasionally checked by mass-spectrometer analysis.

RESULTS AND DISCUSSION

(*A*) *The Reaction of CH_3 with CH_3CHO*

When azomethane is photolyzed in the presence of CH_3CHO the following reactions may be considered:

$$CH_3NNCH_3 + h\nu \rightarrow 2CH_3 + N_2 \quad [3]$$
$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [4]$$
$$CH_3 + CH_3NNCH_3 \rightarrow CH_4 + CH_2NNCH_3 \quad [5]$$
$$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO \quad [1]$$
$$CH_3CO \rightarrow CH_3 + CO \quad [6]$$
$$CH_3 + CH_3CO \rightarrow CH_3COCH_3 \quad [7]$$
$$2CH_3CO \rightarrow CH_3COCOCH_3 \quad [8]$$
$$CH_3 + CH_3CO \rightarrow CH_4 + CH_2CO \quad [9]$$
$$2CH_3CO \rightarrow CH_2CO + CH_3CHO \quad [10]$$

If reaction [9] is neglected for the moment, then

$$\frac{k_1}{k_4^{\frac{1}{2}}} = \left(\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}} - \frac{k_5}{k_4^{\frac{1}{2}}} [CH_3NNCH_3] \right) \Big/ [CH_3CHO].$$

The values of $k_5/k_4^{\frac{1}{2}}$ which are required in the calculations have been taken from an experimental Arrhenius plot for azomethane alone (1).

The results of runs at different temperatures, intensities, and concentrations are given in Table I. As can be seen from Fig. 1 (Curve *B*), a plot of $\log R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$ [Ald] against $1/T$ gives a straight line, except at temperatures below

75°C. where curvature is evident. (The units of k throughout are cm.^{3}, molecules, sec.)

From the first four runs at 27°C., it may be concluded that $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$[Ald] decreases with decreasing intensity as shown by Fig. 2. This can be explained by the occurrence of the disproportionation reaction [9]. Evidence for the

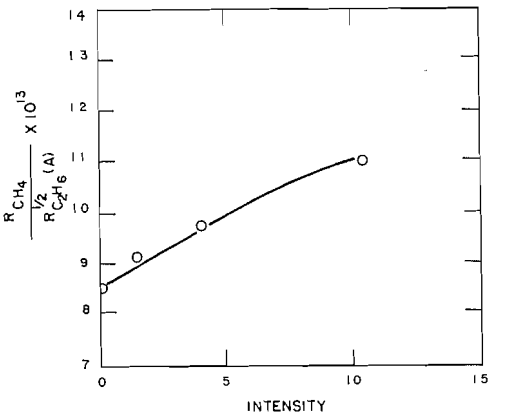

FIG. 2. The effect of intensity at 27°C. on the photolysis of azomethane in the presence of CH_3CHO.

occurrence of this reaction has been found in the photolysis of acetone (2) and biacetyl (3) as well. When the curve in Fig. 2 is extrapolated to zero intensity, a value of 8.4×10^{-13} is obtained for $k_1/k_4^{\frac{1}{2}}$. This is still higher than the value obtained by extrapolation of the linear portion of curve B in Fig. 1. This is therefore not due to reaction [9], and it is suggested that wall effects occur as well at low temperatures, as is the case with acetone and biacetyl.

From the slope of curve B in Fig. 1 at temperatures above 75°C. an activation energy difference $E_1 - \frac{1}{2}E_4$ of 6.8 kcal. is obtained. Since $E_4 = 0$, $E_1 = 6.8$ kcal. This is in excellent agreement with the value found by Volman and Brinton, whose results are also given in Fig. 1. The lower value for E_1 may therefore be considered to be established.

(B) The Photolysis of CH_3CHO

A few experiments were also made on the direct photolysis of CH_3CHO. A Corning Filter No. 970 (opaque at wave lengths below 2900 Å) was used, so that the light absorbed by acetaldehyde consisted mainly of the 3130 Å group of lines. The results are given in Table II. The rate of hydrogen formation has not been included since it was always too small to measure with any great accuracy. An Arrhenius plot of $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[CH_3CHO]$ is given in Fig. 1 (Curve

A). A curved line is obtained which at higher temperatures appears to become parallel to the line obtained by photolyzing azomethane in the presence of CH_3CHO. The curvature may largely be explained by the direct formation of some methane in the primary step. However, in the light of the azomethane results it is probable that the curvature also results in part from reaction [9] and from wall reactions. In spite of these complications the results indicate that at higher temperatures methane mainly results from reaction [1].

(*C*) *The Reaction of CH_3 with CH_3CDO*

When azomethane is photolyzed in the presence of CH_3CDO the same reaction scheme holds as for CH_3CHO, except that in place of [1] we have

$$CH_3+CH_3CDO \rightarrow CH_3D+CH_3CO. \qquad [2]$$

Also we may consider the possible reaction

$$CH_3+CH_3CDO \rightarrow CH_4+CH_2CDO. \qquad [11]$$

If it is assumed that only an acyl hydrogen is captured, then

$$\frac{R_{CH_3D}}{R_{C_2H_6}^{\frac{1}{2}}[CH_3CDO]} = \frac{k_2}{k_4^{\frac{1}{2}}},$$

and

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[CH_3NNCH_3]} = \frac{k_5}{k_4^{\frac{1}{2}}}$$

The values of $k_2/k_4^{\frac{1}{2}}$ and $k_5/k_4^{\frac{1}{2}}$ given in columns 9 and 10 of Table III have been calculated in this way. In Fig. 3 curve *F*, the triangles represent the values of $\log k_5/k_4^{\frac{1}{2}}$, while the line drawn through them represents the results from the photolysis of azomethane alone. It is evident, therefore, that reaction [11] does not occur to an appreciable extent (i.e. not over five per cent of [2]) since all the CH_4 found can be accounted for by abstraction from azomethane. The small amount of CH_3CHO present in the CH_3CDO is not sufficient to alter the results appreciably.

The fact that no C_2H_5D or $C_2H_4D_2$ could be detected in the ethane fraction is further proof that no hydrogen atoms are captured from the methyl group of CH_3CDO. Also no CH_2D_2 was found in the methane fraction, which, as Blacet and Brinton point out (4) excludes a mixed mechanism.

An Arrhenius plot of $k_2/k_4^{\frac{1}{2}}$ (curve *E*) gives an activation energy of 7.9 kcal. for reaction [2], as compared with 6.8 kcal. for [1].

A very small amount of curvature is present in the $\log k_2/k_4^{\frac{1}{2}}$ plot at low temperatures. Since this plot involves CH_3D, the curvature cannot result from the disproportionation of methyl with acetyl, since all the acetyl radicals are CH_3CO. It is therefore probably to be explained by wall reactions.

No curvature was found in the $k_5/k_4^{\frac{1}{2}}$ plot (curve *F*). In this case the reaction

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO \qquad [9]$$

would cause such curvature. Its absence is presumably due to the much smaller rate of abstraction from CH_3CDO as compared with CH_3CHO (a factor of 20). This results in a much smaller concentration of acetyl, and the effect of reaction [9] is apparently negligible.

Curve *F*—Arrhenius plot of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$[Azomethane] for the photolysis of azomethane in the presence of CH_3CDO.

(*D*) *The Photolysis of CH_3CDO*

The photolysis of CH_3CDO was briefly investigated. A Corning 970 filter was used so that absorption was mainly of the 3130 Å group of lines. The results are given in Table IV. The fraction coming off at −195°C. consisted of CO, CH_4, and CH_3D. No CH_2D_2, D_2, or H_2 was found by mass-spectrometer analysis, so that they amounted to less than one per cent of the products. The ethane fraction consisted mainly of C_2H_6 (~60%); considerable amounts of deuterated ethanes were also present. Only the total ethane has been given in Table IV.

In Fig. 3 (curve *D*) an Arrhenius plot of $R_{CH_3D}/R^{\frac{1}{2}}_{Ethane}$[$CH_3CDO$] is given. A large curvature is present at low temperatures, while at higher temperatures the plot becomes parallel to the one found when azomethane is photolyzed in the presence of CH_3CDO. This appears to indicate that at high temperatures CH_3D is mainly formed by reaction [2], while at low temperatures the occurrence of the primary step

$$CH_3CDO + h\nu \rightarrow CH_3D + CO \qquad [12]$$

explains largely the excess of CH_3D responsible for the curvature in the Arrhenius plot.

Considerable CH_4 is formed in addition to CH_3D. This may be accounted for by the presence of about five per cent CH_3CHO in the CH_3CDO sample. Since abstraction by methyl is about 20 times faster from CH_3CHO than from CH_3CDO, even five per cent of CH_3CHO has a large effect. In Fig. 1 (curve *C*) an Arrhenius plot is given for this methane, i.e. a plot of $R_{CH_4}/R_{Ethane}^{\frac{1}{2}}$[Aldehyde]. Since the exact amount of CH_3CHO present is somewhat uncertain, but its percentage is constant, we have used the total aldehyde concentration. The actual value of the ratio $R_{CH_4}/R_{Ethane}^{\frac{1}{2}}[CH_3CHO]$ will therefore be approximately 20 to 25 times higher than the figures plotted in Fig. 1, and the results will therefore coincide approximately with the linear portion of curve *A* as they should. From the slope of curve *C* a value of 6.4 kcal. is obtained for E_1, in excellent agreement with the value of 6.8 kcal. obtained by photolyzing azomethane in the presence of CH_3CHO.

It may be noted that the deviation from linearity is much less for curve *C* than for curve *A*. This is to be expected since the relatively fast abstraction by methyl from CH_3CHO as compared with CH_3CDO, causes a small amount of CH_3CHO to have an important effect on the abstraction reaction. There is, however, no reason to suppose that reaction [11] will be more important for CH_3CHO than for CH_3CDO.

If CH_4 was also produced by abstraction from the methyl group

$$CH_3+CH_3CDO \rightarrow CH_4+CH_2CDO, \qquad [13]$$

a higher activation energy than 6.8 kcal. would be expected, and CH_2D_2 should also be produced. It may therefore be concluded that reaction [13] does not occur to an appreciable extent. However, no explanation can be given for the production of a considerable amount of C_2H_5D and $C_2H_4D_2$.

Since there is no appreciable abstraction from the methyl group in CH_3CDO, in spite of the higher acyl C—D bond strength, it is evident that no appreciable abstraction from the methyl group in CH_3CHO will occur.

ACKNOWLEDGMENT

The authors are indebted to Dr. R. E. Dodd for valuable advice, to Dr. L. C. Leitch for the preparation of the acetaldehyde-*d* sample, and to Miss F. Gauthier and Miss G. Fuller for the mass-spectrometer analysis.

THE PHOTOLYSIS OF BIACETYL[1]

By P. Ausloos[2] and E. W. R. Steacie

ABSTRACT

The photolysis of biacetyl has been reinvestigated. The results are, in general, in excellent agreement with those of Blacet and Bell. Curvature occurs at low temperatures in the Arrhenius plot of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$[Biacetyl], and this is attributed to wall reactions, and to the disproportionation reaction

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO.$$

Azomethane–biacetyl mixtures have been photolyzed to give further information on these points. An activation energy of 8.5 kcal. has been found for the reaction of methyl radicals with biacetyl.

INTRODUCTION

The photolysis of biacetyl has been thoroughly investigated by Blacet and Bell (4, 3). It has, however, been thought to be worth reinvestigating the reaction, especially in the low temperature region, to see if there were anomalies similar to those which occur with acetone. In particular we were interested in the possibility of complications due to wall effects and to the possible occurrence of the disproportionation reactions

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO$$

and

$$CH_3CO+CH_3CO \rightarrow CH_3CHO+CH_2CO.$$

In addition azomethane was photolyzed in the presence of biacetyl to obtain a further check on the activation energy of the reaction of methyl radicals with biacetyl.

EXPERIMENTAL

The reaction cell was a quartz cylinder 10 cm. long and 5 cm. diameter, with a volume of about 170 cc. A Hanovia S-500 medium pressure mercury arc was used for most of the experiments. For a few runs a B.T.H. ME/D 250 w. compact source lamp was used to obtain higher intensities. The reaction cell was completely filled by a nearly parallel light beam. The intensity was varied by means of neutral density filters of chromel deposited on quartz. No other filters were used, except where mentioned. The remainder of the apparatus was essentially similar to that described in previous papers from this laboratory.

Reagent grade biacetyl (Eastman white label) was used, and was distilled in vacuum with the rejection of a large head and tail fraction.

The analysis of the products was done in the usual way by taking off the CO, CH_4 or CO, CH_4, N_2 fraction at liquid nitrogen temperature. In CO, CH_4 samples the CO was determined by hot copper oxide. The samples containing nitrogen were analyzed with a mass spectrometer. The C_2H_6 fraction was

taken off at −175°C., and the ketene fraction at −135°C. Both fractions were occasionally checked with a mass spectrometer.

RESULTS

Table I gives the results of runs at temperatures between 27 and 200°C., and relative intensities varying by a factor of 20, where a relative intensity of 1 corresponds to an absorbed intensity of about 2×10^{14} quanta/sec. The amount of ketene formed was measured in only a few experiments. Velocity constants throughout are expressed in units of cm.^{3}, molecules, sec.

Table II gives the results obtained by photolyzing azomethane in the presence of biacetyl. For these runs a Corning 738 filter was used, which cut off wave lengths below 3400 Å.

The results in the last columns of Tables I and II, together with the results of Blacet and Bell, are plotted in Fig. 1. Table III and Fig. 2 show the effect of varying the intensity by a factor of 200 at 27°C. and constant biacetyl concentration.

● Photolysis of azomethane in presence of biacetyl.

DISCUSSION

To explain their results Blacet and Bell proposed the following secondary reactions:

$$CH_3CO \rightarrow CH_3+CO \quad [1]$$
$$CH_3+CH_3CO \rightarrow CH_3COCH_3 \quad [2]$$
$$2CH_3 \rightarrow C_2H_6 \quad [3]$$
$$CH_3+CH_3COCOCH_3 \rightarrow CH_4+CH_2COCOCH_3 \quad [4]$$
$$CH_2COCOCH_3 \rightarrow CH_2CO+CH_3CO \quad [5]$$
$$CH_3+CH_3COCOCH_3 \rightarrow CH_3COCH_3+CH_3CO \quad [6]$$
$$CH_3+CH_2COCOCH_3 \rightarrow C_2H_5COCOCH_3 \quad [7]$$
$$2CH_3CO \rightarrow CH_3COCOCH_3 \quad [8]$$

Activation Energy of the Abstraction Reaction

If ethane and methane are formed only by reactions [3] and [4], then

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[\text{Biacetyl}]} = \frac{k_4}{k_3^{\frac{1}{2}}},$$

so that a straight line may be expected on plotting the L.H.S. against $1/T$. The results given in Table I and Fig. 1 confirm this for the high-temperature region. However, at low temperatures a curvature becomes apparent in the Arrhenius plot. We have also shown Blacet and Bell's results in Fig. 1. Although their original plot was not drawn so as to show curvature, it is evident that if the two highest temperature points are ignored it is possible to draw a line through their remaining points which is strikingly similar to ours. The two plots thus drawn have the same slope and lead to an activation energy difference $E_4-\frac{1}{2}E_3$ of 8.5 kcal., or assuming $E_3 = 0$, $E_4 = 8.5$ kcal.

Wall Reactions

Fig. 1 also shows the results of experiments in which azomethane was photolyzed in the presence of biacetyl. The effective wave length was 3660 Å. Biacetyl also absorbs slightly under our conditions, but the amount decomposed was negligible compared with azomethane decomposed. This is shown by the very small amount of CO formed at room temperature. At this temperature CO is a measure of the amount of biacetyl photolyzed because of the unimportance of reactions [5] and [6]. At higher temperatures CO is formed by [5] and [6] from radicals resulting from the photolysis of azomethane.

When azomethane is photolyzed in the presence of biacetyl, the following reactions have to be taken into account to explain the formation of methane and ethane.

$$CH_3NNCH_3+h\nu \rightarrow 2CH_3+N_2 \quad [9]$$
$$2CH_3 \rightarrow C_2H_6 \quad [3]$$
$$CH_3+CH_3NNCH_3 \rightarrow CH_4+CH_2NNCH_3 \quad [10]$$
$$CH_3+CH_3COCOCH_3 \rightarrow CH_4+CH_2COCOCH_3 \quad [4]$$

whence

$$\frac{k_4}{k_3^{\frac{1}{2}}} = \left(\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}} - \frac{k_{10}}{k_3^{\frac{1}{2}}}[CH_3NNCH_3]\right) \Big/ [CH_3COCOCH_3].$$

The values of $k_{10}/k_3^{\frac{1}{2}}$ have been taken from an experimental plot for the photolysis of azomethane alone (1). From Fig. 1 it is evident that the results agree

excellently with those from the photolysis of biacetyl itself. It is also apparent that curvature is still present in the Arrhenius plot, although there is none in the plot for azomethane itself. It is suggested that the curvature results from wall effects at lower temperatures where the diffusion of radicals to the wall is of more importance. More conclusive evidence for this will be discussed in a forthcoming paper (2).

Disproportionation of Acetyl

It is suggested that the reactions

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO \qquad [11]$$

and

$$2CH_3CO \rightarrow CH_2CO+CH_3CHO \qquad [12]$$

also occur. If this is so, the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[CH_3COCOCH_3]$ will become intensity dependent, i.e.

$$\frac{R_{CH_4}}{R^{\frac{1}{2}}_{C_2H_6}} = \frac{k_4}{k_3^{\frac{1}{2}}}[CH_3COCOCH_3] + \frac{k_{11}}{k_3^{\frac{1}{2}}}[CH_3CO].$$

To check this two series of runs were carried out at relative intensities which differed by a factor of 20. Fig. 1 shows that variation in intensity has little effect at temperatures above 100°C. At 27° however $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[CH_3COCOCH_3]$ decreases appreciably with intensity as may be expected if reaction [11] occurs, since CH_3CO radicals will be more stable at room temperature.

The amount of ketene formed was also measured at a few temperatures. From 200° to 137°C. a sharp decrease in ketene was observed (Table I) in agreement with the results of Blacet and Bell who measured the ketene formed at 200°, 150°, and 100°C. They explain the formation of ketene by reaction [5]. If this has an appreciable activation energy the drop in ketene with decreasing temperature is to be expected. If reactions [11] and [12] are neglected, the ratio takes the form

$$\frac{[CH_2CO]}{[CH_4]} = 1/\left(1+\frac{k_7}{k_5}[CH_3]\right).$$

Since $E_5 \gg E_7$, this predicts a drop in the ratio of ketene to methane with decreasing temperature, as is observed from 200° to 137°C. There are, however, three anomalies all of which point to the occurrence of [11] or [12]. (*a*) There is always an increase in the ratio CH_2CO/CH_4 with increasing intensity. (*b*) At temperatures below 137°C., the rate of ketene formation begins to increase again. At room temperature the ratio CH_2CO/CH_4 is larger than unity. (*c*) Mass-spectrometer analyses indicated the presence of acetaldehyde as a reaction product.

In order to obtain more definite information on these points, a series of runs were made in which the intensity was varied over a wider range (by a factor of 200). For these runs the temperature was 27 ± 1°C., and the biacetyl pressure was 2.3 cm. The results are given in Table III and Fig. 2. Fig. 2 indicates a considerable increase in the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[CH_3COCOCH_3]$ with increasing

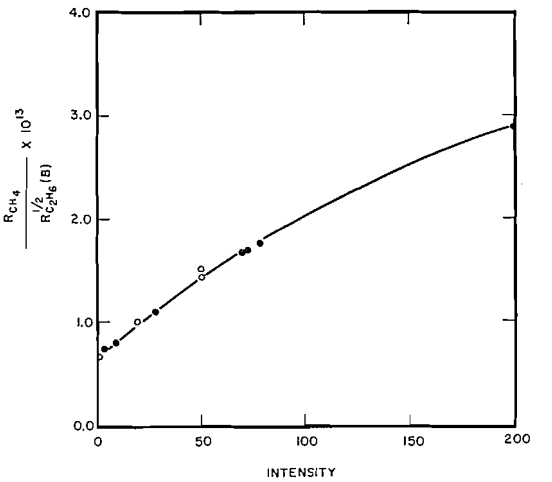

FIG. 2. Effect of intensity.
● B.T.H. lamp. Pressure 2.3 cm.
○ Hanovia lamp. Temperature 27°C.

intensity. If the curve in Fig. 2 is extrapolated to zero intensity a value of 0.65×10^{-13} is obtained for the ratio. This is higher than the value which would be expected from an extrapolation of the straight-line portion of the Arrhenius plot in Fig. 1. The curvature in Fig. 1 is thus in part but not solely due to disproportionation of acetyl radicals. The residual curvature is probably due to diffusion effects accompanying wall reactions.

The fact that the ratio CH_2CO/CH_4 becomes considerably higher than 1 at high intensities indicates that there is a further source of ketene in addition to reaction [11]. As pointed out previously the presence of acetaldehyde suggests reaction [12]. The direct production of acetaldehyde in the primary step

$$CH_3COCOCH_3 + h\nu \rightarrow CH_3CHO + CH_2CO$$

is unlikely on the basis of Blacet and Bell's results in the presence of iodine. Also, the fact that acetaldehyde has been observed in the acetone photolysis as well (2) suggests a common origin such as reaction [12].

A rough quantitative check on the validity of assuming reactions [11] and [12] can be made as follows. From reactions [11], [12], and [3] the relationship can be deduced

$$\frac{R^*_{CH_4}}{R^{\frac{1}{2}}_{CH_3CHO} R^{\frac{1}{2}}_{C_2H_6}} = \frac{k_{11}}{k_{12}^{\frac{1}{2}} k_3^{\frac{1}{2}}}$$

where $R^*_{CH_4}$ represents the amount of excess methane necessary to account for the increase in the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[CH_3COCOCH_3]$ above the limiting value 0.65×10^{-13}. Although the acetaldehyde concentration could not be quantitatively determined, it is evident that

$$R_{CH_3CHO} = R_{CH_2CO} - R^*_{CH_4}.$$

The values of $k_{11}/k_{12}^{\frac{1}{2}} k_3^{\frac{1}{2}}$ calculated in this way are given in the last column of Table III, and are independent of intensity.

In conclusion, it may be pointed out that the results given here indicate complications at low temperatures in all systems in which acetyl radicals are present, and in particular that such complicating processes will be intensity dependent. The analogous case of acetone is discussed in a forthcoming paper (2).

SOME COMPLICATING FACTORS IN THE PHOTOLYSIS OF ACETONE[1]

By P. Ausloos[2] and E. W. R. Steacie

ABSTRACT

The photolysis of acetone has been investigated at room temperature using low pressures and high intensities. In addition an investigation was made of the photolysis of azomethane–acetone mixtures. The results indicate that the curvature at low temperatures of Arrhenius plots of $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$[Acetone] is due to two causes (*a*) a reaction between methyl radicals and adsorbed acetone and (*b*) to the occurrence of the disproportionation reaction

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO.$$

Confirmatory evidence for wall effects was obtained from experiments at low pressures and higher temperatures.

INTRODUCTION

The photochemical decomposition of acetone has been thoroughly investigated, especially by Noyes and his co-workers. In the temperature region from 120° to 200°C. it has been established that all the methane and ethane formed can be accounted for by the reactions:

$$CH_3+CH_3COCH_3 \rightarrow CH_4+CH_2COCH_3 \quad [1]$$

$$CH_3+CH_3 \rightarrow C_2H_6 \quad [2]$$

It has, however, been shown (6, 8, 9) that at lower pressures reaction [2] becomes dependent on a third-body. Whence at higher pressures

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[\text{Acetone}]} = \text{Constant} = \frac{k_1}{k_2^{\frac{1}{2}}}$$

and at low pressures

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[\text{Acetone}]^{\frac{1}{2}}} = \text{Constant}.$$

For the activation energy difference, $E_1-\frac{1}{2}E_2$, a value of 9.7 ± 0.1 kcal. has been generally accepted (12). This value has been deduced from experiments at temperatures above 100°C., and at pressures between 25 and 200 mm.

In the lower temperature region there are complications in the kinetics. Curvature has been observed in the Arrhenius plot between room temperature and 125°C. (7, 12). Several suggestions have been made as to the cause of the discrepancy (11). In the first place the presence of an appreciable amount of acetyl radicals constitutes the most striking difference between the low- and the high-temperature photolysis. The diffusion of radicals out of the light-beam and possible wall effects have also to be considered. As far as diffusion is concerned, Nicholson (10) has shown that although it is important in some

cases, the effect is still too small to account for the curvature in the Arrhenius plot at low temperatures.

The purpose of the present work was in the first place to study the reaction of methyl radicals with acetone in the absence of complications due to acetyl radicals. For this purpose azomethane was used as a source of methyl radicals. It has the advantage of absorbing at longer wave lengths where acetone is transparent. The second object of the work was to investigate the photolysis of acetone under special conditions (high intensities and low pressures), to obtain information regarding wall reactions and reactions of acetyl radicals.

EXPERIMENTAL

Azomethane was prepared by Dr. L. C. Leitch as described in previous papers from this laboratory. Acetone was obtained from the Eastman Kodak Co. Both compounds were thoroughly degassed and stored behind mercury cutoffs.

Two different types of apparatus were used. Apparatus I was of the conventional type which has been described elsewhere (1). A Hanovia S-500 medium pressure mercury arc was used as a light source. The cylindrical quartz reaction cell (5 cm. diameter, 10 cm. long) was completely filled with a nearly parallel light beam.

Apparatus II which was used for low pressure experiments was essentially the same as that described by Dodd and Steacie (6). The lamp was a B.T.H. ME/D 250 w. compact source. In some experiments a "packed" reaction vessel was used. For these the cell which was 70 cm. long contained two inner quartz tubes concentrically mounted. The surface/volume ratio of the packed cell was 7.1 cm^{-1}. The cell was completely filled by a parallel beam of light. An empty cell was also used, which was 100 cm. long.

In experiments with azomethane–acetone mixtures a Corning filter No. 7380 was used to limit radiation to wave lengths greater than 3400 Å. For other experiments a Corning No. 986 filter was used.

The N_2–CH_4 fractions of the products were removed at liquid nitrogen temperature and analyzed by the mass spectrometer. On a few occasions checks were made for CO in the N_2–CH_4 fraction from the photolysis of azomethane–acetone mixtures by passing the gas over hot copper oxide. The quantity of CO was invariably negligible. The CO–CH_4 fractions from the acetone photolysis were analyzed by combustion over hot copper oxide. The ethane fraction was separated at −175°C. and occasionally checked with the mass spectrometer.

RESULTS FROM RUNS AT NORMAL PRESSURES USING APPARATUS I

The results for the photolysis of azomethane and of azomethane–acetone mixtures are given in Tables I and II. In Fig. 1 Arrhenius plots are given for $k_1/k_2^{\frac{1}{2}}$ and $k_3/k_2^{\frac{1}{2}}$, where reaction [3] is

$$CH_3+CH_3NNCH_3 \rightarrow CH_4+CH_2NNCH_3. \qquad [3]$$

The units of k throughout are $cm.^3$, molecules, and sec.

Some experiments were also carried out in which acetone was photolyzed at room temperature and various intensities. The results are given in Table III.

The relative intensity was varied by a factor of 165, where an intensity of 1 corresponds to approximately 5×10^{11} quanta per cc. per sec. The light intensity was varied by means of neutral density filters of chromel on quartz. The higher intensities are much higher than those used in most previous investigations at low temperatures. The values of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[\text{Acetone}]$ have been plotted in Fig. 2.

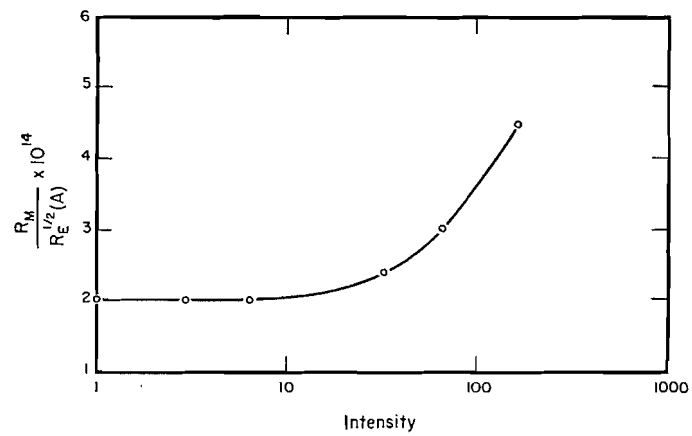

FIG. 2. The photolysis of acetone at 27°C. and 57 mm. with varying intensity.

In addition to the products listed, the highest intensity runs produced a very small amount of a material of intermediate volatility, which could be separated at −125°C. In order to obtain a larger amount of this fraction a run was made at the highest possible incident intensity using a cylindrical cell of 1 liter volume. Mass-spectrometer analysis of the −125°C. cut from this run showed that it consisted mainly of ketene and acetaldehyde.

DISCUSSION

The methane and ethane formed by photolyzing azomethane in the presence of acetone may be accounted for by the following reactions:

$$CH_3NNCH_3 + h\nu \rightarrow 2CH_3 + N_2$$
$$2CH_3 \rightarrow C_2H_6 \quad [2]$$
$$CH_3 + CH_3NNCH_3 \rightarrow CH_4 + CH_2NNCH_3 \quad [3]$$
$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3 \quad [1]$$

From this scheme

$$\frac{k_1}{k_2^{\frac{1}{2}}} = \frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[\text{Acetone}]} - \frac{k_3[\text{Azomethane}]}{k_2^{\frac{1}{2}}[\text{Acetone}]}.$$

The values of $k_3/k_2^{\frac{1}{2}}$ required in the calculations have been taken from an experimental Arrhenius plot for azomethane (2). A few runs were repeated in the low-temperature region to check again the absence of curvature at low temperatures in the Arrhenius plot for azomethane. Fig. 1 shows the complete absence of curvature and the results coincide exactly with those previously obtained (2).

Fig. 1 also gives an Arrhenius plot for $k_1/k_2^{\frac{1}{2}}$, calculated from results with azomethane–acetone mixtures. The dotted line in the figure was obtained by extrapolation of the high-temperature results of Trotman-Dickenson and Steacie on the photolysis of acetone itself. It is evident that the results agree exactly at high temperatures, but that there is appreciable curvature at low temperatures in the results obtained with azomethane–acetone mixtures. At 27°C. a mean value of about 1.6×10^{-14} was found for $k_1/k_2^{\frac{1}{2}}$. This is in excellent agreement with the value of 1.55×10^{-14} found by Nicholson (10) in the direct photolysis of acetone at similar intensities. Since no acetyl radicals are present in the photolysis of azomethane–acetone mixtures, the curvature in the plot at low temperatures and low intensities cannot be due to reactions involving acetyl. Diffusion of radicals out of the light beam is not a possible explanation in the present case, since the cell was filled with light and the cell volume was used in the calculations. It is therefore suggested that wall reactions are involved, and specifically that methyl radicals react with adsorbed acetone to form methane. It may be mentioned that analogous curvature in Arrhenius plots has been found when azomethane was photolyzed in the presence of biacetyl (3) and methyl ethyl ketone (5).

Fig. 2 shows that in experiments on the photolysis of acetone alone the ratio $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[\text{Acetone}]$ does not vary with intensity in the low intensity region. Most previous work was done at still lower intensities. The constant low-intensity value (2×10^{-14}) lies well above the value obtained by extrapolating Trotman-Dickenson and Steacie's Arrhenius plot (12) to lower temperatures. The extrapolated value is in good agreement, however, with the value of 1.6×10^{-14} found by photolyzing azomethane–acetone mixtures. Interference by reactions of acetyl is excluded in this intensity range as the cause of the curvature in the Arrhenius plot. The evidence again strongly favors wall reactions as the cause of the discrepancy.

At higher intensities, however, a sharp increase of $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[\text{Acetone}]$ becomes apparent. This suggests the formation of methane in a radical–radical reaction. Further, since the effect only occurs at low temperatures, the

participation of acetyl is strongly indicated. It is therefore suggested that the additional methane arises by the disproportionation reaction,

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO. \quad [4]$$

The intensity dependence of methane formation can be explained on this basis, as well as the ketene formation at high intensities. The small amounts of acetaldehyde found by mass-spectrometer analysis may be accounted for by the similar reaction

$$2CH_3CO \rightarrow CH_2CO+CH_3CHO. \quad [5]$$

Evidence for both these reactions has been found also in the photolysis of biacetyl (3). Reaction [5] has also been suggested in the photolysis of acetaldehyde (4).

RESULTS FROM EXPERIMENTS AT LOW PRESSURES USING APPARATUS II

The results of a few experiments at low pressures using a "packed" reaction vessel are given in Table IV, and are plotted in Fig. 3 and compared with the

results of Dodd and Steacie (6). For these experiments the *incident* intensity was kept constant and the pressure was varied from 25 to 0.05 mm. The values of ϕ_{CO} in the last column of Table IV were determined in the usual way at higher pressures. The absorbed intensity at lower pressures was obtained by a Beer's law extrapolation.

Table V gives the results of experiments at 27°C. and varying intensities at four different pressures (from 0.6 to 4.7 mm.). The results are given in Fig. 4 in the form of a plot of $\log R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ against the logarithm of the *incident*

intensity. The lowest incident intensity is about eight times the lowest intensity used for the runs at usual pressures (Table III).

Since we were interested in possible wall reactions, the experiments given in Table IV were done. It is evident from Fig. 3 that the results agree excellently with those of Dodd. They confirm the fact that while the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ [Acetone]$^{\frac{1}{2}}$ falls with decreasing pressure in agreement with the assumption that the recombination of methyl radicals is becoming pressure-dependent,

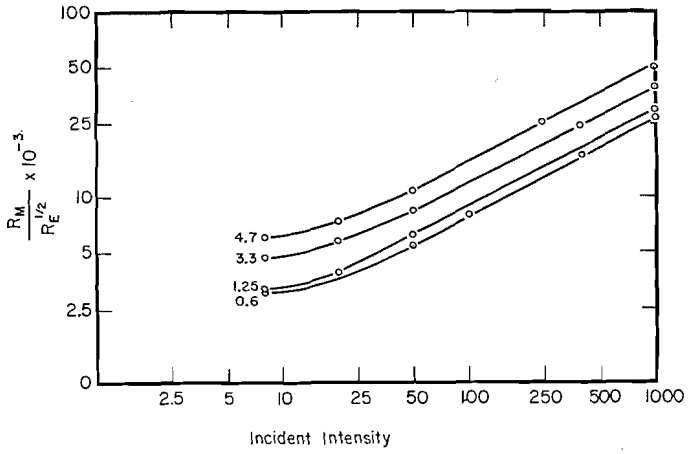

FIG. 4. Photolysis of acetone at 27°C. and low pressures, with varying intensity. The figures on the curves refer to the pressure in mm.

nevertheless at low pressures the ratio rises again instead of becoming constant. This increase commences at higher pressures in the packed cell, and there is no doubt that it is due to a wall reaction which produces methane. The only reasonable possibility seems to be a reaction between methyl radicals and adsorbed acetone. The results appear to indicate that the ratio decreases again at the lowest pressures, but it is difficult to be sure that this effect is real.

It may be mentioned that there is a gradual drop in the ratio $(\frac{1}{2}CH_4+C_2H_6)/CO$ with decrease in pressure in the packed vessel. No such effect was observed in the unpacked cell. We are unable to offer any convincing explanation of this.

The experiments at high intensities and room temperature, given in Table V, were done to obtain more information about the occurrence of reaction [4].

In this temperature region we are primarily concerned with the reactions:

$$CH_3+CH_3COCH_3 \rightarrow CH_4+CH_2COCH_3 \quad [1]$$

$$2CH_3 \rightarrow C_2H_6 \quad [2]$$

$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO \quad [4]$$

$$2CH_3CO \rightarrow CH_3CHO+CH_2CO \quad [5]$$

$$CH_3+CH_3CO \rightarrow CH_3COCH_3 \quad [6]$$

$$2CH_3CO \rightarrow CH_3COCOCH_3 \quad [7]$$

As a *very rough approximation*, at constant temperature and pressure but varying intensity, we may put $[CH_3CO] \propto [CH_3]$, and thus $[CH_3CO] \propto I_{abs}^{\frac{1}{2}}$. Whence, if all methane is formed by [1] and [4], we have *at low pressures*

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}} = \frac{k_4}{k_2^{\frac{1}{2}}}[\text{Acetone}] + \frac{k_4}{k_2^{\frac{1}{2}}}[CH_3CO]$$

so that at constant low pressure and varying intensity

$$\frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}} = k'+k''I_{abs}^{\frac{1}{2}}$$

Since for constant acetone pressure $I_{\text{incident}} \propto I_{\text{abs}}$, $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$ will become constant at low incident intensities and proportional to $I^{\frac{1}{2}}$ at high intensities. Fig. 4 gives a plot of $\log R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}$ against log intensity for four different low pressures. At high intensities a series of straight lines is obtained with a slope of $\frac{1}{2}$, while at low intensities the ratio approaches a constant value. This furnishes further strong support for the postulation of reaction [4].

CONSTITUTION OF A HEMICELLULOSE FROM WHEAT BRAN[1]

By G. A. Adams[2]

ABSTRACT

The hemicellulose prepared from wheat bran by alkaline extraction was an acidic polysaccharide containing arabinose (50.0%), xylose (38.5%), and uronic acid (9.0%). Graded hydrolysis with 0.02 *N* oxalic acid preferentially released 65% of the arabinose with only a small simultaneous production of xylose. Hydrolysis of the full methylated hemicellulose yielded 2,3,4-tri-*O*-methyl-, 2,3-di-*O*-methyl-, 2-*O*-methyl-, and free D-xylose; 2,3,5-tri-*O*-methyl-, 2,5-di-*O*-methyl-, and probably 3- and 5-*O*-methyl-L-arabinose. These data, together with those from periodate oxidation, strongly suggested that the molecule was a highly branched araboxylan. Viscosity measurements and reducing power determinations indicated a degree of polymerization of 300.

Investigations in this laboratory of the polysaccharides of the wheat plant have included those of patent white flour (10), straw (1), and leaf (2). The present paper concerns the hemicelluloses of wheat bran. Early studies on bran by Schulze (12) established xylose and arabinose as major constituents, and more recently, Norris and Preece (9) have demonstrated that glucuronic acid is a minor component. It was now of interest to examine the constitution of this hemicellulosic material in greater detail.

A suitable starting material appeared to be "bee-wing" bran which has an unusually high pentosan content (3) and consists mainly of the outer coatings of the wheat grain with very little starch.

The bran, after extraction with alcohol:benzene (2:1) and ammonium oxalate, contained 46% pentosan and 5.6% lignin. Extraction with dilute alkali gave a crude water-soluble hemicellulose in 37% yield having a pentosan content of 68% and a lignin content of 3%. Acid hydrolysis showed that arabinose and xylose were the main sugars present along with minor amounts of glucose, galactose, and uronic acid. To test the possibility that these sugars represented separate pentosans and hexosans, fractionation methods designed to separate polysaccharides were applied. The copper complexing method which is more or less specific for segregating xylans (5) gave no precipitate with the crude bran hemicellulose. Extraction with 70% ethanol, as used by Aspinall *et al.* (4) for separating an arabinose-rich pentosan from esparto grass, removed only a small portion of bran hemicellulose which varied insignificantly in composition from the original material. When the crude hemicellulose was acetylated and the acetate fractionated from chloroform solution with petroleum ether, most of the product was recovered within a narrow solvent mixture range. Deacetylation and hydrolysis showed that the main fractions contained arabinose and xylose in a ratio of 1.0:0.78; glucose and galactose were present only in the more soluble fractions. Hence it appeared that the hexosans were not a part of the hemicellulose molecule. The same finding was reported pre-

viously for wheat straw (1) and wheat leaf hemicellulose (2). Lack of separation of araban from xylan by the methods just described strongly suggested that the sugars were combined chemically within the same molecule.

Hydrolysis of the hemicellulose with 0.02 *N* oxalic acid preferentially removed L-arabinose units. The stability of the xylose residues to the acid treatment showed that they were in the usual pyranoside form, while the ready removal of 65% of the arabinose units indicated that they were predominantly in the furanoside configuration and also were located towards the outside of the molecule. Slow release of arabinose units after hydrolysis for two and one-half hours in 0.02 *N* oxalic acid indicated that about 35% of the total amount of this sugar was part of the central core of the hemicellulose molecule and was doubly attached to other sugar units.

The main purified hemicellulose fraction was methylated initially with dimethyl sulphate and sodium hydroxide and finally with methyl iodide and silver oxide to a methoxyl value of 38.4% (calculated for $C_7H_{14}O_4$: (OCH_3, 38.8%); $[\alpha]_D^{25}$ −80.4° (*c*, 1.1% in chloroform). Fractionation using chloroform – petroleum ether yielded 10 fractions; of these, a fully methylated product (OCH_3, 38.8%), comprising 32% of the total, was selected for further study. Methanolysis followed by acid hydrolysis yielded the following products: (I) methylated uronic acid (not studied further in this investigation); (II) D-xylose (three parts); (III) 2-*O*-methyl-D-xylose (four parts); (IV) 3- and 5-*O*-methyl-L arabinose (three parts) (?); (V) 2,3-di-*O*-methyl-D-xylose (four parts); (VI) 2,5-di-*O*-methyl-L-arabinose (seven parts); (VII) 2,3,4-tri-*O*-methyl-D-xylose (five parts); (VIII) 2,3,5-tri-*O*-methyl-L-arabinose (six parts).

The methylation data indicated a highly branched structure. Almost 40% of the arabinose appeared on hydrolysis as 2,3,5-tri-*O*-methyl-L-arabinose and therefore existed as end groups in the original hemicellulose. Although the monomethyl arabinose units were not positively identified, their presence indicated branch points in the molecule where other groups were attached. Arabinose linked 1,3- in the original hemicellulose appeared as 2,5-dimethyl arabinose to the extent of about 45% of the total. It was not possible to determine whether these units indicated a structure in which several arabinose units were joined or one in which both arabinose and xylose units occurred. However, the graded hydrolysis data supported the view that about 70% of the arabinose units were joined together in short branches or side chains which were removable with only a slight release of xylose. The decreased rate of acid hydrolysis, which yielded a resistant portion containing about 35% of the arabinose, was not considered due to the pyranose form of arabinose since no direct evidence for this type of structure was found among the methylated sugars. The branching character of the bran hemicellulose involved also the xylose component. The 2-*O*-methyl-D-xylose and unmethylated D-xylose represented single and double branch points respectively. However the number of xylose end groups accounted for only half of these branch points (Table IV) and the assumption must be made that the remainder were linked to arabinose units. The presence of a high proportion of the methylated xylose as 2,3-dimethyl xylose proved that the xylose units were linked 1,4- and were in the pyranose form. The

change in rotation of the methylated polysaccharide on hydrolysis, from highly negative (−82°) to positive (+69.2°), indicated that the sugar units were primarily in the β configuration.

Although a specific structure for this hemicellulose cannot be formulated, methylation data showed that the following sugar residues were present:

D-xyl. $p1\ldots$; $\ldots$ 4-D-xyl. $p1\ldots$; $\begin{matrix}\ldots 3-\\ \ldots 4-\end{matrix}$D-xyl. $p1\ldots$; $\ldots$ L-arab. $f1\ldots$; $\ldots$ 3-L-arab. $f1\ldots$; and in addition $\begin{matrix}\ldots 2-\\ \ldots 5-\end{matrix}$ L-arab. $f1\ldots$; and $\begin{matrix}\ldots 2-\\ \ldots 3-\end{matrix}$ L-arab. $f1\ldots$ are indicated.

Periodate oxidation results supported the methylation data as further evidence for a highly branched structure. The consumption of approximately 0.59 mole of periodate per mole of sugar showed that about half of the sugar residues did not consume periodate and hence had a high proportion of branch attachments. The original sugar residues which yielded 2,3-di-*O*-methyl-D-xylose, 2,3,4-tri-*O*-methyl-D-xylose, and 2,3,5-tri-*O*-methyl-L-arabinose would consume periodate and, based on the proportion present as shown by the methylation data, should consume 0.62 mole of periodate per sugar unit. The yield of formic acid (0.18 mole) calculated from the amount of trimethyl xylose present was in reasonable agreement with the measured yield (0.22 mole per sugar unit). The relatively large amounts of formic acid produced indicated a high proportion of end groups. Mild acid degradation of the hemicellulose, which initially released a large proportion of the arabinose, caused a 10% increase in periodate consumption and a 40% increase in formic acid production. Such effects could be caused by simple degradation of a xylan chain or by removal of arabinose end groups linked to xylose units which in turn became new end groups. Hydrolysis of the unoxidized portion of the hemicellulose released xylose and arabinose in about equal amounts; all the xylose and that portion of arabinose which yielded monomethyl arabinose (see Table IV) represented branched units in the original hemicellulose.

Estimations of the molecular weight of the bran hemicellulose were obtained by viscosity measurements and reducing power determinations. With the exception of the viscosity measurements in water, the results agreed reasonably well and suggested that the molecule contained about 300 sugar residues. This is the same order of magnitude as was suggested for the soluble pentosan of wheat flour (10).

Although wheat bran hemicellulose resembles that of straw (1) and leaf (2) in having the same component sugars, some marked differences are apparent. The wheat bran molecule is much larger, more highly branched, and contains more arabinose than xylose, with the arabinose unit being branched. Although positive proof has not been obtained that a mixture of araban and xylan is not present, the available data indicate that wheat bran hemicellulose is a highly branched araboxylan. The purified cellulase enzyme of *Myrothecium verrucaria* which readily hydrolyzed wheat straw xylan did not attack bran hemicellulose; this observation supported the view that no free xylan was present. Removal

of 70% of the arabinose units by mild acid hydrolysis of the hemicellulose did not initiate enzyme action, thus indicating that the predominantly xylan residue was sufficiently different in structure from wheat straw xylan to resist enzymatic attack.

EXPERIMENTAL

The following solvents (v/v) were used to separate the sugars and their derivatives: (*A*) ethyl acetate – pyridine – water (2:1:2); (*B*) methyl ethyl ketone – water (2:1); (*C*) ethanol–benzene–water (47:200:15); and (*D*) N-butanol–ethanol–water (40:11:19). The R_g values refer to 2,3,4,6-tetra-*O*-methyl-D-glucose.

Preparation of Hemicellulose from Wheat Bran

The bran* was extracted exhaustively with benzene–alcohol (2:1) followed by ethanol to remove pigments, lipids, and waxy substances. Water-soluble materials were removed by two four-hour extractions at 85°C. Pectic substances were extracted by ammonium oxalate (0.5%) at 85°C. in two three-hour extraction periods. The residue was thoroughly washed with warm water and dried with ethanol and ether.

Air-dry extracted bran (160 gm.) was extracted with stirring for 20 hr. at room temperature with 8 liters of 4% potassium hydroxide in an atmosphere of nitrogen. After recovery by filtration on cloth, the residue was subjected to a further extraction for 48 hr. The combined alkaline filtrates were brought to pH 7.0 with acetic acid and then concentrated under reduced pressure at 30°C. to one-tenth their original volume. Only a faint trace of precipitate appeared in the neutral solution. The thick brown solution was dialyzed in cellophane tubes against running water for 48 hr. The dialyzed solution was again concentrated under reduced pressure to one-half its original volume. The hemicellulose was recovered by adding 1 volume of the solution to 4 volumes of ethanol which was rapidly stirred and by allowing the mixture to stand. The precipitated hemicellulose was centrifuged off and dried with ethanol and ether to yield a fluffy gray powder (60 gm.). Acid hydrolysis of the crude hemicellulose followed by chromatographic separation of the sugars (solvent *A*) showed the presence of xylose, arabinose, and glucose, with small amounts of galactose and uronic acids.

Purification Treatments on Crude Hemicellulose

Ethanol (70%) extraction.—Crude hemicellulose (25 gm.) was extracted under reflux with 1000 ml. of 70% ethanol for 24 hr. A fine precipitate which appeared on cooling the alcoholic solution was removed by centrifuging. Concentration of the solution at 30°C. to small volume yielded a light brown precipitate (wt. 0.7 gm.). After hydrolysis with 1% sulphuric acid and chromatographic separation of the sugars, the ratio of xylose to arabinose was 1.0:0.78, which was the same as that of the original hemicellulose. Hence no segregation of araban-rich material was achieved.

**The "bee-wing" bran was donated by Flour Mills of America Inc., Rosedale Mill, 914 Division St., Kansas City, Kansas, U.S.A.*

Copper complexing.—Crude hemicellulose (20 gm.) was dissolved with shaking in 4% sodium hydroxide (1250 ml.) and, to this solution, Fehling's solution (1250 ml.) was added with stirring. Even on prolonged standing no insoluble copper hemicellulose complex formed. Variation in ratio between the alkaline hemicellulose solution and Fehling's solution from 1:1 to 4:1 failed to yield an insoluble compound. By acidification, dialysis, and precipitation with ethanol, the original hemicellulose sample was recovered with its xylose to arabinose ratio unchanged.

Acetylation of crude hemicellulose.—Crude hemicellulose (50 gm.) was dispersed in 1000 ml. of formamide, stirred for two hours at 65°C., cooled to room temperature (20°C.), and 1000 ml. of dry pyridine added. After one hour's stirring, acetic anhydride (400 ml.) was added in 100 ml. quantities over a period of four hours. The acetylated product was recovered by pouring into ice water. After recovery and thorough drying, the partly acetylated hemicellulose was dissolved in pyridine and reacetylated with acetic anhydride. The acetylated product was recovered as before, yield 67.4 gm., acetyl content 38.3%.

Fractionation of hemicellulose acetates.—Acetylated hemicellulose (65 gm.) was dissolved in 3000 ml. of chloroform and filtered through sintered glass (porosity M). To the chloroform solution of the acetates, petroleum ether (b.p. 65–110°C.) was added with vigorous stirring. After the formation of a distinct cloudiness, the material was allowed to settle, removed by centrifuging, and dried *in vacuo*. A total of nine fractions were recovered with the bulk of the material precipitating in a fairly narrow solvent range. Fractions 3–5 inclusive comprised 80% of the acetates with fraction 4 being approximately 60%.

Analysis of the acetylated fractions.—The nine fractions were deacetylated with sodium hydroxide in acetone, precipitated with ethanol, and dried. Acid hydrolysis followed by quantitative chromatography (solvent *A*) showed that all fractions contained arabinose and xylose in an approximate ratio of 1.0:0.78. In addition, fractions 7, 8, and 9 contained small amounts of glucose and galactose. Fractions 2–6 inclusive contained approximately 9% uronic acid while fractions 7–9 contained about 3.5%. Since fraction 4 comprised 60% of the original hemicellulose and contained no hexose sugars, it was selected for the main constitutional studies. Its composition was as follows: ash, nil; nitrogen, nil; lignin, 0.9%; methoxyl, 1.06%; uronic acid anhydride, 9.00%; D-xylose, 38.5%; L-arabinose 50.0%; and $[\alpha]_D^{25}$ −83° (*c*, 1% in potassium hydroxide (2%)).

Graded Acid Hydrolysis

A concentration of 0.02 *N* oxalic acid was found to give preferential release of arabinose and was therefore selected as the most satisfactory concentration for graded hydrolysis of the hemicellulose. Three separate lots of hemicellulose (50 mgm.) were hydrolyzed with 0.02 *N* oxalic acid (5 ml.) at 98°C. with heating periods of two and one-half, four, and six hours respectively. After hydrolysis each solution was analyzed chromatographically for arabinose and xylose content (Table I). The unhydrolyzed portions (acid degraded hemi-

celluloses I, II, and III) were recovered by complete precipitation with ethanol without any attempted fractionations, dried *in vacuo*, and weighed. These materials were completely hydrolyzed with 1% sulphuric acid and the proportion of arabinose and xylose determined by chromatographic analysis (Table II).

Enzyme Hydrolysis

The original bran hemicellulose and acid degraded hemicelluloses I and II were made up to 1% concentration in 1/25 *M* sodium chloride and the pH adjusted to 5.0 with hydrochloric acid. The purified cellulase enzyme of *Myrothecium verrucaria* in 1/25 *M* sodium chloride solution was added to the extent of 100 μgm. protein per ml. of substrate and incubated for 12 hr. at 30°C. with agitation. At the end of the incubation period, 2 volumes of hot ethanol were added to the substrate, the solution filtered, and the filtrate concentrated to a small volume at 40°C. Chromatographic examination of the solution showed only a trace of arabinose and xylose.

Methylation

Hemicellulose (20 gm.) was methylated with dimethyl sulphate and sodium hydroxide (40%) by a method previously described in detail (1). After each of two successive methylation treatments, the partly methylated crude product was recovered by neutralization, dialysis, and evaporation. After the material had been sufficiently methylated (nine treatments) to become soluble in methyl iodide, it was subjected to further methylation by Purdie's reagent. After four methylations with this reagent the methoxyl content was 38.3%. Further methylations increased the methoxyl content only slightly. The final

product was a friable yellow solid, yield 21.2 gm.; OCH_3, 38.4% (theoretical value for dimethyl xylan, 38.7%); $[\alpha]_D^{25}$ −80.4° (*c*, 1.1% in chloroform).

Fractionation.—The methylated hemicellulose (20.2 gm.) was extracted under reflux for a period of two hours with solvent mixtures of chloroform – petroleum ether (b.p. 30–60°C.). After filtration and removal of the solvent, the recovered product was dried *in vacuo* at 40°C. The results of the fractionation are given in Table III. Since fraction 8 comprised a large proportion of the product and was fully methylated, it was used in the subsequent studies of the methanolysis products.

TABLE III

FRACTIONATION OF METHYLATED BRAN HEMICELLULOSE

Fraction	Chloroform: petroleum ether solvent mixture	Yield, %	OCH_3, %	$[\alpha]_D^{25}$
1	0 : 100	0.52	22.6	− 5.48
2	20 : 180	0.41	23.3	−11.05
3	25 : 175	1.03	30.6	−11.30
4	30 : 170	1.85	37.1	−32.4
5	35 : 165	6.24	38.6	−81.0
6	40 : 160	25.79	38.7	−87.1
7	45 : 155	22.9	38.7	−80.0
8	50 : 150	32.50	38.8	−82.1
9	55 : 145	5.67	37.7	−80.0
10	100 : 0	1.23	35.0	−79.5

Methanolysis.—Fraction 8 (100 mgm.) was heated with methanolic hydrogen chloride (10 ml.; 8%) in a sealed tube in a boiling water bath for 16 hr. After removal of the solvent, the methyl glycosides were hydrolyzed with hydrochloric acid (10 ml.; 0.5 *N*) for eight hours at 100°C. The free methylated sugars ($[\alpha]_D^{25}$ +69°) were recovered and separated chromatographically on filter paper using solvent *B*. The sugar spots were developed with aniline phthalate spray. Authentic specimens of 2-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 2,3,5-tri-*O*-methyl-L-arabinose, and 2,3,4-tri-*O*-methyl-D-xylose were used as reference compounds. A total of eight sugar derivatives were located on the chromatogram and the following tentative identifications were made based on color reactions and positions relative to the reference compounds: methylated uronic acid (I); D-xylose (II); a monomethyl pentose corresponding to 2-*O*-methyl-D-xylose (III); monomethyl pentose (IV);

TABLE IV

COMPOSITION OF HYDROLYZATE FROM METHYLATED HEMICELLULOSE

Component sugar	Molar composition, %	Simple molar ratio
D-Xylose (II)	9.5	3
Monomethyl pentose (III)	12.0	4
Monomethyl pentose (IV)	9.0	3
Dimethyl pentose (V)	12.5	4
Dimethyl pentose (VI)	22.0	7
Trimethyl pentose (VII)	15.0	5
Trimethyl pentose (VIII)	18.0	6

dimethyl pentose corresponding to 2,3-di-*O*-methyl-D-xylose (V); dimethyl pentose (VI); a trimethyl pentose corresponding to 2,3,4-tri-*O*-methyl-D-xylose (VII); a trimethyl pentose corresponding to 2,3,5-tri-*O*-methyl-L-arabinose (VIII). The free methylated sugars were extracted from quantitative chromatograms with water and analyzed by the alkaline hypoiodite method (5). The results are given in Table IV.

Separation of the Methylated Sugars

To provide sufficient material for separation and identification of the products of methanolysis, a large quantity was prepared as follows: Fraction 8 (6.4 gm.) was refluxed with 285 ml. of methanolic hydrogen chloride (8%) until the rotation became constant ($[\alpha]_{25}^{D}$ +9.2°). After neutralization with silver carbonate, the methyl glycosides and uronosides were recovered as a brown sirup (6.7 gm.). Saturated barium hydroxide (75 ml.) was added to the sirup and the mixture heated for three hours at 60°C. on a steam bath. Excess barium hydroxide was removed with carbon dioxide and the solution heated for 15 min. at 85°C. Because of the volatility of the trimethyl pentosides, the solution was evaporated at room temperature in a current of air.

Recovery and Separation of Trimethyl Pentoses

Extraction of the methanolysis mixture with *n*-pentane removed the trimethyl pentosides almost quantitatively. They were hydrolyzed with 0.5 *N* hydrochloric acid and the free methylated sugars (1.86 gm.) were recovered in the usual way. Chromatography on filter paper showed that the two trimethyl pentoses contained a trace of a dimethyl pentose. A portion of the trimethyl pentose sirup (0.65 gm.) was separated chromatographically on large sheets of filter paper using solvent *C*. The individual sugars were recovered by elution with water and each solution concentrated to a small volume. Addition of methanol and clarification with charcoal yielded clear yellowish sirups VII and VIII.

Separation of Remaining Sugars

Although solvent *B* separated methylated uronic acids (barium salt form) and methylated sugars satisfactorily in small amounts, the uronic acid streaked into the xylose and two monomethyl pentose spots when the sirup was chromatographed in preparative quantities (conversion of the barium salt to the free acid did not improve the separation). The free xylose and monomethyl pentose areas on the paper which were overrun with uronic acid were cut out, eluted with water, and chromatographed again using solvent *A*. This procedure gave satisfactory separation of the methylated uronic acid (I), free xylose (II), and the two monomethyl pentoses (III) and (IV). The dimethyl pentoses were separated from each other satisfactorily in the first chromatogram using solvent *B*.

Examination of the Methylated Sugar Fractions

Fraction I.—This material was a methylated uronic acid complex which gave a cherry red spot on the paper chromatogram. It was not examined further in the present study.

Fraction II.—The sirup, on standing, crystallized almost completely. Recrystallization from glacial acetic acid yielded a crop of D-xylose crystals, m.p. 145–146°C. unchanged on admixture with an authentic sample, and $[\alpha]_D^{25}$ +19° (*c*, 1.0% in water). Chromatographic examination (solvent *A*) showed only xylose present. This fraction was therefore established as D-xylopyranose.

Fraction III.—On clarification with charcoal in methanol, a clear yellow sirup was obtained which partially crystallized on standing. Chromatography showed only one component with the same R_g value as 2-*O*-methyl-D-xylose (R_g 0.22–0.24, solvent *B*). On demethylation with hydrobromic acid (48%) (9), D-xylose was the only sugar produced. Recrystallization from methanol solution yielded 2-*O*-methyl-D-xylopyranose, m.p. 133°C., $[\alpha]_D^{25}$ + 34.8° (*c*, 1% in water). Analysis: calculated for $C_6H_{12}O_5 : OCH_3$, 18.9%; found: OCH_3, 18.8%. Treatment of this sugar with aniline in ethanol gave crystalline 2-*O*-methyl-N-phenyl-xylosylamine, m.p. 123°. The X-ray diffraction pattern of the crystals was identical with that of an authentic sample of 2-*O*-methyl-N-phenyl-xylosylamine.

Fraction IV.—This sirup was re-chromatographed on filter paper (solvent *B*) until only one spot was present. (R_g 0.37–0.38, solvent *B*; 0.68–0.69, solvent *D*). On spraying with aniline oxalate reagent a reddish color characteristic of pentose sugars was obtained. Demethylation with hydrobromic acid (48%) yielded only arabinose. The sirup (104 mgm.) was distilled (b.p. 140–150°C. at 0.05 mm.) to yield a product (74 mgm.) having methoxyl content 19.3% (calculated for $C_6H_{12}O_5 : OCH_3$, 18.9%) and $[\alpha]_D^{25}$ −4° (*c*, 1.75% in water). Hence the sirup was a monomethyl arabinose. Oxidation with lead tetraacetate (11) yielded 2 moles of formic acid and no formaldehyde. These results are most readily interpreted as indicating the presence of a mixture of 3- and 5-methyl arabinose.

Fraction V.—After repeated chromatographic separations, a sirup was recovered which had $[\alpha]_D^{25}$ +24° (*c*, 1.0% in water); η_D^{25} 1.4733; OCH_3, 34.8% (calculated for $C_7H_{14}O_5 : OCH_3$, 34.8%). With solvent *B* the R_g value was 0.67–0.68 and only a single pink spot was found with aniline phthalate spray on the paper chromatogram. Demethylation of the sirup (12 mgm.) with hydrobromic acid yielded only xylose. Oxidation of the sirup (80 mgm.) with bromine yielded a lactone which was converted into the corresponding crystalline amide with methanolic ammonia. On recrystallization from ethyl acetate 2,3-di-*O*-methyl xylonamide was recovered, m.p. and mixed m.p. 134°. The X-ray diffraction pattern was identical with that of authentic 2,3-di-*O*-methyl xylonamide. A crystalline anilide was prepared having m.p. 123–124°C. and an X-ray diffraction pattern identical with that of 2,3-di-*O*-methyl-N-phenyl-xylosylamine. Fraction V was, therefore, 2,3-di-*O*-methyl-D-xylose.

Fraction VI.—This sirup gave only one spot on chromatographic examination (R_g 0.80–0.81 solvent *B*; 0.88–0.89, solvent *D*); $[\alpha]_D^{25}$ −26° (reported value −18° (6)); OCH_3, 34.4% (calculated for $C_7H_{14}O_5 : OCH_3$, 34.8%). Demethylation yielded only one sugar which was identified as arabinose on paper chromatogram. Oxidation of the free sugar (173 mgm.) with bromine for 48 hr. at

room temperature yielded a lactone (126 mgm.). Distillation of the sirupy lactone (b.p. (bath) 130°–135°C. at 0.05 mm.) yielded a product which crystallized on seeding with a crystal of 2,5-di-*O*-methyl-L-arabonolactone, m.p. and mixed m.p. 60°C. The X-ray diffraction pattern was the same as that of 2,5-di-*O*-methyl-L-arabonolactone. Treatment of the lactone (33 mgm.) with methanolic ammonia gave the corresponding amide which on recrystallization from absolute ethanol yielded 2,5-di-*O*-methyl-L-arabonamide (24 mgm.), m.p. 130–131°. To another portion of the lactone (48 mgm.) phenylhydrazine (18 mgm.) in methanol (5 ml.) was added and the mixture refluxed two and one-half hours. After removal of the solvent, the sirup crystallized and recrystallization from alcohol–ether yielded a pure product (34 mgm.), m.p. 165–167° undepressed on admixture with an authentic sample of 2,5-di-*O*-methyl-L-arabinose phenylhydrazide. The X-ray diffraction pattern was identical with that of the authentic sample. Fraction VI, therefore, was 2,5-di-*O*-methyl-L-arabinose.

Fraction VII.—Purification of this sirup by paper chromatography using solvent *C* yielded a single sugar which gave a pink spot on spraying with aniline phthalate (R_g value was 0.86–0.88 solvent *C*). Demethylation showed xylose to be the only component sugar. On standing the sirup partially crystallized. Recrystallization from ethyl ether containing a small amount of petroleum ether yielded 2,3,4-tri-*O*-methyl-D-xylopyranose, m.p. 89–90°C. undepressed on admixture with an authentic sample, and $[\alpha]_D^{25}$ +20° (*c*, 1.0% in water); OCH_3, 48.2% (calculated for $C_8H_{16}O_5$: OCH_3, 48.4%).

Fraction VIII.—The sirup had an R_g 1.10–1.12 (solvent *B*) identical with that of 2,3,5-trimethyl arabinose; $[\alpha]_D^{25}$ −36°; OCH_3, 48.7% (calculated for $C_8H_{16}O_5$: OCH_3, 48.4%). Oxidation of the sugar with bromine yielded the corresponding lactone which on refluxing with methanolic ammonia was converted into the corresponding amide. Recrystallization of the amide yielded 2,3,5-tri-*O*-methyl-L-arabonamide, m.p. and mixed m.p. 137–138°C. and $[\alpha]_D^{25}$ +18 (*c*, 1.0% in water); OCH_3 44.7% (calculated for $C_8H_{17}O_5N$: OCH_3, 44.9%). The X-ray diffraction pattern showed that the product was 2,3,5-tri-*O*-methyl-L-arabonamide.

Periodate Oxidation

Bran hemicellulose (fraction 4) and acid degraded hemicelluloses I and II (100 mgm. each) were oxidized with 100 ml. of sodium metaperiodate (1%). All oxidations were done in the dark at 16°C. with shaking. Analyses for periodate consumption and formic acid production were made at various time intervals (5). The results are given in Table V.

In a separate experiment 50 mgm. of the original hemicellulose was oxidized to completion with periodate. On freezing and thawing of the solution, the unoxidized portion of the hemicellulose precipitated out and, when washed with ice water and dried with ethanol and ether, yielded a white product (wt. 40 mgm.). Hydrolysis of this polysaccharide with 1% sulphuric acid and separation of the sugars by chromatography yielded arabinose (38%), xylose (52%).

TABLE V

PERIODATE OXIDATION OF BRAN HEMICELLULOSE

	Time, hr.						
	48	72	96	120	144	168	192

**Corrected for periodate consumed in formic acid production.*

Estimation of Degree of Polymerization

Viscosity measurements.—Viscosity measurements were made on three preparations, bran hemicellulose in water solution and in cupriethylenediamine solution, and bran hemicellulose acetate in acetone solution. The solutions used contained 0.50, 0.25, 0.125, 0.0625, and 0.0317% of the component. The measurements were made in Oswald-Cannon-Fenske viscometers in a water bath at 25°C.±0.02°C. Intrinsic viscosity $[\eta]$ was obtained by plotting η_{sp}/c against c (gm./liter). The results were calculated from Staudinger's equation using a K_m factor of 5.0×10^{-4} as proposed for xylans by Husemann (8). The degree of polymerization (P) for the hemicellulose in cupriethylenediamine solution and for the acetate in acetone solution was approximately 300. On the other hand, the value of P for hemicellulose in water was approximately 1000; this value suggested probable association of the molecules.

Reducing power.—The copper reduction method of Somogyi (13) was used for determination of reducing power of three samples of bran hemicellulose (29.6, 39.0, and 45 mgm. respectively). Increasing the reaction period from 30 min. to one hour did not affect the results. Based on the reducing power estimation, the hemicellulose contained one reducing group per 300±10 sugar units. A similar measurement based on estimation of reducing power by alkaline hypoiodite oxidation (5) gave a result of one reducing group for each 250 units.

ACKNOWLEDGMENTS

The author wishes to thank Dr. J. K. N. Jones, Queen's University, for samples of 2,5-di-*O*-methyl-L-arabonolactone, 2,5-di-*O*-methyl-L-arabonamide,

and 2,5-di-*O*-methyl-L-arabinose phenylhydrazide. Dr. D. R. Whitaker of this Division kindly supplied the purified cellulase enzyme.

STUDIES IN THE POLYOXYPHENOL SERIES

VII. THE OXIDATION OF VANILLIN WITH SODIUM CHLORITE AND CHLORINE DIOXIDE[1]

By R. M. Husband,[2] C. D. Logan,[3] and C. B. Purves

ABSTRACT

Vanillin almost instantly reduced 1.2 to 1.5 moles of aqueous chlorine dioxide at 20°C. or 5°C. and any pH between 1.2 and 6.5, and a white crystalline substance with the composition of a dihydroxyvanillin, $C_7H_5O_4(OCH_3)$, was isolated in roughly 25% yield independently of the pH. When oxidized with aqueous sodium chlorite at 20°C. and pH 0.5, these crystals gave another crystalline substance with the composition of a dihydroxyvanillic acid, $C_7H_5O_5(OCH_3)$. Although both these substances decomposed readily to red oils and then to brown powders free of methoxyl groups, seven well characterized derivatives were prepared. The results showed that the substances were unsaturated, monohydroxy, diketone tautomers of a dihydroxyvanillin and the corresponding dihydroxyvanillic acid, but precise structures could not be assigned. Parallel oxidations of vanillin with aqueous sodium chlorite at 20°C. and pH 6 proceeded at a negligible rate, but near pH 5 a reaction that often seemed autocatalytic produced about 19% of 5-chlorovanillin. At pH 4 the aldehyde $C_7H_5O_4(OCH_3)$ was isolated in 19% yield; at pH 1 this aldehyde (15%) was mixed with 7.7% of the corresponding acid $C_7H_6O_5(OCH_3)$, but at pH 0.5 the latter alone was produced (28%). Chlorine dioxide and sodium chlorite therefore differed markedly in their oxidizing action and in the effect of pH upon it. When acting on vanillin, both oxidants also produced deep red, unstable oils with quinone-like properties and often containing chlorine.

INTRODUCTION

The earliest study of the action of chlorine dioxide on an organic substance was published in 1881 by Fürst (4), who noticed that the gas reacted rapidly with ethylene exposed to bright sunlight. Schmidt and his collaborators (17, 18, 19) used aqueous chlorine dioxide to remove lignin (a condensed phenolic ether) from wood, and extended Fürst's observation to many unsaturated aliphatic compounds and to phenols. Catalytic amounts of vanadium trichloride were sometimes used in these oxidations (19). The work of Fuchs and Honsig (3), later extended by Sarkar (15), showed that phenolic ethers and esters were oxidized by aqueous chlorine dioxide at a much slower rate than the phenols themselves, and that the oxidation products included carbon dioxide, oxalic acid, maleic acid, and small amounts of undefined, chlorinated compounds. With the exception of thio compounds and those containing reactive methylene groups, all saturated aliphatic substances examined, including polysaccharides and reducing sugars, were stable to aqueous chlorine dioxide. All of the above research was of a qualitative nature, and the hydrogen ion concentration was in no case controlled.

Since an acidified solution of sodium chlorite displayed the same selectivity as an oxidant, and spontaneously decomposed to chlorine dioxide, the assump-

tion was often made that chlorine dioxide was the active agent in this case also. Jeanes and Isbell (7), however, observed that sodium chlorite oxidized aldose sugars quantitatively to the aldonic acids at a rate which increased as the pH decreased from 8, but that aqueous chlorine dioxide did so only with very great difficulty at any pH in the above range. Although chlorites and chlorine dioxide are now used to bleach cellulose pulps free from residual lignin, the above résumé shows that detailed knowledge concerning their oxidizing action on phenols and phenolic ethers is still exceedingly scanty. Information concerning vanillin, for example, is restricted to the remark that it is oxidized by chlorine dioxide (3, 15), and to the fact that a small yield of 2,4-furane dicarboxylic acid is formed in oxidations carried out with aqueous sodium chlorite near pH 3 (13). The present research had the object of extending these observations.

RESULTS AND DISCUSSION

The concentration of dilute aqueous solutions of sodium chlorite, buffered within 0.1 unit at various pH values and kept at 20°C., was determined from time to time by an iodometric method responsive to chlorite, chlorine dioxide, and hypochlorite, but not to chlorate. These solutions were stable for many hours except at pH 1, when loss by the volatilization of chlorine dioxide might sometimes have been appreciable. As the plots A in Fig. 1 show, aqueous

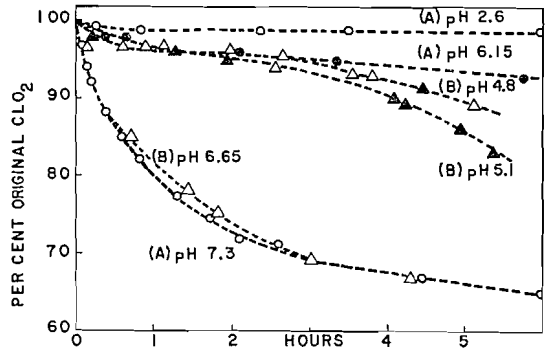

FIG. 1. Rate of decomposition of chlorine dioxide at 20°C. in aqueous 10% sodium acetate – acetic acid buffers. Plots A, 13.5 mM. of chlorine dioxide; plots B, 20 mM. to 25 mM., per liter.

solutions containing about 13.5 mM. of chlorine dioxide per liter were fairly stable on the acid side of pH 6, but at pH 7.3 decreased rapidly in strength owing to the formation of equimolecular amounts of chlorite and chlorate ion. The change was complete within 12 hr. More concentrated, 0.02 to 0.025 *M*, solutions of chlorine dioxide decomposed rather slowly when kept on the acid side of pH 4.5, but near pH 5 the decomposition assumed an autocatalytic form before becoming very rapid at pH 6.65 (plots B). This decomposition was among those reviewed by Taylor, White, Vincent, and Cunningham (22, 23) in their study of the inorganic chemistry of chlorine dioxide and chlorites. Taube and Dodgen (21) used radioactive chlorine to reveal the mechanisms involved when the oxidation state of the halogen changed.

A selection from more than thirty plots of the rate of reduction of the oxidant by vanillin is presented in Figs. 2 and 3, in which full lines refer to reductions of excess sodium chlorite, and broken lines to those of chlorine dioxide. Although the plots were corrected for the spontaneous decomposition of the oxidant, the rate of this decomposition might not be the same in the blank and in the presence of vanillin, since the residual concentrations at any time would be different. Moreover, most of the reductions were strongly exothermic, and it was difficult to keep the temperature at 20°C. during the initial period; the inorganic system was complex, and any quinone formed from the vanillin would interfere with the iodometric method used to determine the residual oxidant. Figs. 2 and 3, although reproducible, thus indicate merely the net change in the redox systems present, and details of the relevant estimations are omitted from this article.

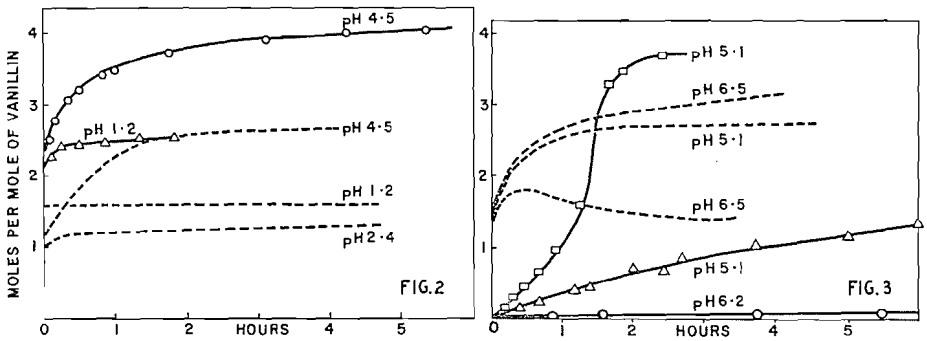

FIG. 2. Apparent rate of reduction of oxidant at 20°C. Solid lines: vanillin, 15 mM., and sodium chlorite, 60 mM. per liter. Broken lines: vanillin, 4 mM. and chlorine dioxide, 21 mM. to 29 mM. per liter.

FIG. 3. See legend for Fig. 2. Upper broken line at pH 6.5 uncorrected for chlorine dioxide blank. Upper solid line at pH 5.1, 65 mM. of sodium chlorite per liter; lower solid line at pH 5.1. 60 mM. per liter.

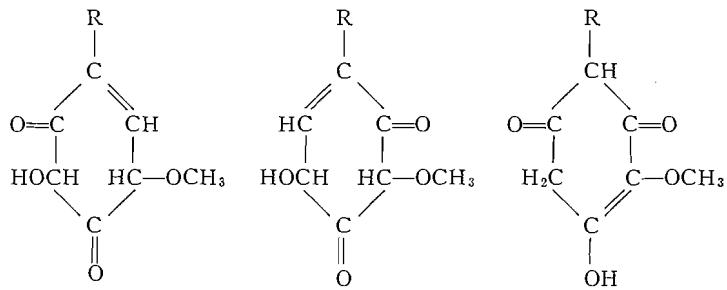
At pH 1.2, 1 mole of vanillin apparently reduced about 2.5 moles of sodium chlorite within a few minutes, and the reaction then became extremely slow. Although the initial rapid reduction was preserved at pH 4.5, a secondary reaction was now marked. When this experiment was repeated at 4°C., the initial reduction was almost unaffected, but the secondary one took more than two hours, instead of less than 20 min., to increase the total consumption of chlorite to 3.0 mole (not shown). The lower plot at pH 5.1 in Fig. 3 was obtained with the same concentration (60 mM. per liter) of sodium chlorite, but a slight increase in concentration to 65 mM. per liter produced the upper plot, whose form suggested an autocatalytic reaction. A reaction at pH 4.6 and 3°C. became apparently autocatalytic within two minutes, but this behavior was never observed on the alkaline side of pH 5.4, even when the concentration of chlorite was increased (not shown). In experiments carried out at pH 5.1 and 6°C., the initial, nearly linear portion corresponding to the consumption of about 1 mole of chlorite required 2.5 hr., instead of 1 hr.; and 4 hr., instead of about 1.5 hr., elapsed before the total consumption was 3.0 mole per mole of

vanillin. At 20°C. and on the alkaline side of pH 5.1, the linear portion of the plot decreased in slope very rapidly, until the consumption of 0.2 moles of chlorite required 14.25 hr. at pH 6.2. No odor of chlorine dioxide was ever noticed at any acidity in these oxidations until more than 2 moles of sodium chlorite per mole of vanillin had been utilized.

Figs. 2 and 3 (broken lines) also show that vanillin almost instantaneously reduced about 1.5 moles of chlorine dioxide at all pH values between 1.2 and 6.5. A slower secondary reduction was evident on the alkaline side of pH 4.5, but could not be even approximately assessed at pH 6.5 because the observed data (upper plot) gave an absurd result (lower plot) when corrected for the large and uncertain blank. The proper correction would probably have placed this plot close to that for the reduction at pH 5.1. This experiment differed from those carried out at pH values less than 6 in that a little by-product chlorate was formed, but aqueous potassium chlorate was found to have no action on vanillin at pH 6.9, 5.7, or even 2.6. When the plots in Figs. 2 and 3 were compared, it became evident that vanillin reduced approximately 1 mole more of sodium chlorite than of chlorine dioxide between pH 1 and pH 4.5 and at all times; between pH 5 and 6.5, however, the relationship was reversed. The course of the initial oxidation with sodium chlorite was highly sensitive to pH, whereas that with chlorine dioxide was apparently independent of this factor. The two oxidants were therefore by no means equivalent.

Much time was spent in attempts to isolate a crystalline product from the clear, bright red solutions that resulted when vanillin was oxidized with aqueous chlorine dioxide at pH 1 or pH 2.3. Such solutions, and also the unstable red oils isolated from them by evaporation or by extraction with ether, assumed a pale yellow color when reduced by sulphurous acid or by hydrogenation under mild conditions, and the red color was regenerated by the addition of benzoquinone or by the access of air. Condensations with aniline, *p*-anisidine, hydroxylamine, *o*-phenylenediamine, and diazotized anilines provided small yields of brown or black powders. The whole mass of observations suggested that the initial product of the oxidations was an unstable, methoxylated quinone that readily changed to brown, amorphous substances of lower methoxyl content. Eventually small yields of a white substance, melting at 101°C. and crystallizing as tufts of very fine needles or as prisms, were isolated. Success in isolating these crystals depended upon extracting the solution of the oxidized vanillin at the proper time with ether, upon maintaining a low temperature, and upon speed in freeing the extract from water and any traces of acid. Buffers employing sulphuric, phosphoric, or citric acid had to be used, because acetic acid was readily extracted from the aqueous solution by the ether and accelerated the decomposition of the product. The final procedure made it possible to isolate the purified crystals from oxidations at pH 1, pH 4, and pH 5.8 in a uniform yield of 25% to 30% by weight. In addition to these crystals, the ether extract contained considerable amounts of an unstable, chlorinated oil whose orange color quickly darkened on standing. Neither this oil nor the aqueous residue, which turned black when warmed to expel the ether, were examined further.

The crystalline product possessed the formula $C_7H_5O_4(OCH_3)$ and was extracted less readily by ether from solution in aqueous sodium bisulphite than from a more concentrated solution in water. Ammoniacal silver nitrate (Tollen's solution) was quickly reduced by the crystals, which also yielded a crystalline mono-2,4-dinitrophenyl hydrazone and a crystalline monosemicarbazone. This evidence for the presence of an aldehyde group was confirmed by oxidizing the substance at pH 0.5 with chlorous acid to a crystalline acidic substance, $C_7H_5O_5(OCH_3)$, decomposing at 143° to 144°C., and giving a nearly quantitative yield of a crystalline monoester when boiled with methanol containing a trace of sulphuric acid. Although two acidic groups were revealed in the acid by a potentiometric titration against standard sodium hydroxide, a marked buffering effect between pH 9 and pH 11 suggested that one of these groups was phenolic or enolic. When added to saturated sodium bicarbonate solution, the aldehyde displayed a slight acidity that was also attributed to a phenolic unit. Since both substances were derived from vanillin, $C_7H_5O_2(OCH_3)$, the aldehyde was at first regarded as a dihydroxy vanillin, and the acid as the corresponding dihydroxyvanillic acid.



R = CHO or COOH

I II III

Both the aldehyde and acid, however, failed to give a distinctive color in the ferric chloride test for phenol. When examined by the Zerewitinoff method with methyl magnesium iodide, the aldehyde was found to contain only one atom, instead of the expected three atoms, of active hydrogen, and to add 3 moles, instead of the expected 1 mole, of the Grignard reagent. In similar fashion, the acid contained only 2 moles of active hydrogen and added 3 moles of the reagent. These observations suggested that the aldehyde and acid existed as ketonic tautomers analogous to the keto forms in which metapolyhydric phenols like resorcinol and phloroglucinol tended to react. Structures I, II, and III, which were metadiketones derived from 5,6-, 2,5-, and 2,6-dihydroxyvanillin, thus came into consideration.

Although the acid (R = COOH) slowly added two atoms of bromine per mole, an attempt to hydrogenate it over a palladium catalyst and with two atmospheres pressure of hydrogen ended with no absorption of the gas. Since double bonds conjugated with ketone or carboxyl groups tended to be hydrogenated less readily than isolated double bonds (5), the observation gave

support to Structures I and II rather than to Structure III. Hydrogenation of the aldehyde (R = CHO) under the same conditions required 2 moles per mole and yielded a distillable oil with the formula $C_7H_9O_4(OCH_3)$ which might have been a mixture of *cis–trans* isomers. Since this oil failed to form a phenylhydrazone and contained two atoms of active hydrogen, it appeared that the aldehyde had been reduced to a benzyl alcohol group, and that the double bond was then reactive enough to absorb the second mole of hydrogen. The replacement of the palladium by a platinum catalyst caused the consumption of a third mole of hydrogen, possibly by the reduction of the aldehyde to a methyl unit, as was shown to occur when vanillin was hydrogenated under the same conditions. An attempt to demonstrate the presence of ketone groups in the acid (R = COOH) by preparing a 2,4-dinitrophenyl hydrazone failed.

Methylation of the acid with silver oxide and methyl iodide gave a practically quantitative yield of a colorless, distillable oil with the composition, $C_7H_3O_3(OCH_3)_3$, expected for the monomethyl ether-monomethyl ester. An attempt to saponify this ester with hot 5% aqueous sodium hydroxide, however, produced a crystalline substance which contained no methoxyl groups and had the composition of a tetrahydroxybenzoic acid, $C_7H_2O_2(OH)_4$. When titrated potentiometrically with alkali, this substance gave a plot similar to that obtained in the titration of the original acid (R = COOH) and the presence of one carboxyl and one acidic hydroxyl group was inferred. The substance probably existed in a ketone form analogous to one or other of the Structures I, II, or III, because it contained only three atoms of active hydrogen per mole, instead of the five expected for a tetrahydroxybenzoic acid. This substance was also obtained in good yield when an attempt was made to methylate the original acid (R = COOH) with sodium hydroxide and dimethyl sulphate. Such easy demethylations of the acid and its monoether-monoester seemed consistent with the alternative structures advanced, since both the methyl ether and the phenolic hydroxyl positions would probably be highly activated by neighboring functional groups. The methylation of the acid (R = COOH) with diazomethane in ether yielded, not the expected monomethyl methyl ester, but unstable colorless needles melting with decomposition at 116° to 118°C. and having the formula $C_7H_3O_3(OCH_3)_3(CH_2N_2)_2$. Since treatment of the monomethyl methyl ester with diazomethane gave the same substance, it was thought probable that two molecules of diazomethane had added to the two ketone groups. The usual result of such addition is ring expansion with loss of nitrogen; but in this case the adduct was stable enough to be isolated. One mole of the diazomethane, of course, might have added to the double bond. An attempt to methylate the aldehyde (R = CHO) with diazomethane yielded 46% by weight of an unstable orange glass with the methoxyl content required for the adduct $C_7H_4O_3(OCH_3)_2(CH_2N_2)_2$, but the substance decomposed before further data could be secured.

Dr. D. A. Ramsay, of the National Research Council of Canada, kindly determined the infrared absorption of the acid (R = COOH) in the form of a mull in Nujol. He attributed a broad band from wavelength 3400 $cm.^{-1}$ to 3000 $cm.^{-1}$ to hydroxyl groups in a state of hydrogen bonding; the absence of a

sharp band in the region 3600 cm.$^{-1}$ to 3700 cm.$^{-1}$ indicated that no unbonded hydroxyl groups were present. Three bands at 1724 cm.$^{-1}$, 1704 cm.$^{-1}$, and 1689 cm.$^{-1}$ were consistent with a structure containing one carboxyl group and one unconjugated and one conjugated ketone group. Two bands at 1651 cm.$^{-1}$ and 1612 cm.$^{-1}$ suggested the presence of two, rather than only one, ethylenic linkages, and the bands at 1450 cm.$^{-1}$ and 1379 cm.$^{-1}$ might be correlated with the methoxy group. Although the remaining bands in the spectrum were difficult to interpret, the absorption at 835 cm.$^{-1}$ was consistent with triple substitution around a double bond ($R_1R_2C{=}CHR_3$) because such substitution was usually accompanied by absorption in the region 810 cm.$^{-1}$ to 840 cm.$^{-1}$. Thus the absorption in the infrared supported structures I, II, and III, but failed to discriminate sharply between them; the authors' preference for Structure I therefore rested on nothing more than the observation that vanillin was substituted as a rule in the fifth or sixth, rather than in the second, position. Baker and Brown (2), for example, obtained 5-hydroxyvanillin (3,4-dihydroxy-5-methoxy-benzaldehyde) in 3.6% yield by an Elbs oxidation of vanillin by potassium persulphate in alkaline solution.

Attempts to elucidate the nature of the aldehyde (R = CHO) were greatly hampered by its instability. Although the pure white crystals could be preserved for some time in a desiccator containing a dehydrating agent, a cold aqueous solution assumed a deep red color within a few hours. The same change occurred very quickly in cold, aqueous sodium bicarbonate. When a trace of pyridine or piperidine was added to a solution of the crystals in ether, a red oil quickly separated. This oil initially had a methoxyl content approaching that of the original aldehyde (16.9%), but when kept either *in vacuo* or in aqueous solution quickly changed to a brown, amorphous substance almost free of methoxyl groups and insoluble in ether, although still soluble in water. Attempts to acetylate the aldehyde with acetic anhydride and pyridine under various conditions gave red solutions from which no well-defined acetate could be recovered. A freshly prepared aqueous solution of the aldehyde had a marked tanning action on the skin, and much of the solute was absorbed by hide powder in the standard test for tannins. Aqueous solutions of the acid (R = COOH) were considerably more stable than those of the aldehyde, but nevertheless soon decomposed to red substances.

As already mentioned, the initial oxidation of vanillin by aqueous sodium chlorite, unlike that by chlorine dioxide, was greatly dependent upon the pH of the system (Figs. 2 and 3). At pH 0.5, the sodium chlorite oxidation yielded 40% by weight (28% of theory) of the acid (R = COOH), at pH 1.0 a mixture of the aldehyde (R = CHO) and acid resulted, and at pH 4.0 25% (19% of theory) of the aldehyde was the only product identified. Sodium chlorite therefore differed from chlorine dioxide in oxidizing the aldehyde group of vanillin when the pH was sufficiently low, as Jeanes and Isbell (7) had previously observed in their oxidations of glucose. The other product isolated when vanillin was oxidized with sodium chlorite was 5-chlorovanillin, which was carefully differentiated from the 6-chloro isomer. Experiments carried out at pH 4.7 and pH 5.05 near 5°C., and at pH 6.0 and higher at room temperature,

produced 4%, 17% to 19%, a trace, and 0%, respectively, of 5-chlorovanillin. A sharp maximum in yield therefore occurred near pH 5, or in the region where the rate of oxidation plot (Fig. 3) often suggested an autocatalytic reaction. The yield was negligible at pH 6 or more because the whole reaction was negligible, and trial showed that 5-chlorovanillin itself was rapidly oxidized to a dark colored oil in media more acidic than pH 5. The production of the 5-chloro derivative was attributed to a side-reaction peculiar to sodium chlorite; none was observed in the experiments with chlorine dioxide, but this oxidant was too active, even at pH 5, to permit any 5-chlorovanillin formed to survive unchanged.

EXPERIMENTAL

The vanillin used was recrystallized from aqueous alcohol until it melted correctly at 82° to 83°C. Sodium chlorite, of analytical grade, was kindly presented by the Mathieson Alkali Company of New York. The Coleman pH Electrometer was frequently standardized against 0.05 *M* potassium acid phthalate, whose pH at 25°C. was accepted as 4.0 (6, 11).

Reduction of Sodium Chlorite by Vanillin (Figs. 2 and 3)

The buffers used consisted of dilute sulphuric acid for pH 1, 10% acetic acid for pH 2.2, and 5.2% sodium acetate plus the appropriate amount of acetic acid for the higher pH range. Frequent tests during each experiment showed that these buffers maintained the original pH to within one-tenth of a unit. Vanillin, 0.913 gm. (6 mM.), was dissolved in 200 cc. of the buffer contained in a glass-stoppered, amber bottle maintained at 20°±0.1°C. in a thermostat. An equal volume of 0.12 *M* sodium chlorite, also at 20°C., was added at zero time with thorough mixing. A blank containing no vanillin was simultaneously prepared. At intervals a 10 cc. aliquot was removed and was mixed with about 90 cc. of water containing 10 cc. of aqueous 10% potassium iodide and 20 cc. of 20% sulphuric acid. The liberated iodine was titrated with 0.025 *N* sodium thiosulphate with a starch solution as indicator, and the result when corrected for the corresponding blank was expressed as moles of sodium chlorite reduced. One mole was considered equivalent to 4 liters of *N* iodine (22, 23). Concordant results were obtained by treating the 10 cc. aliquot with 15 cc. of the potassium iodide solution and 15 cc. of 30% acetic acid according to Jeanes and Isbell (7), but acidification with only 10 cc. of 20% sulphuric acid was insufficient.

5-Chlorovanillin

Three grams (19.7 mM.) of vanillin, dissolved in 200 cc. of an adequate sodium acetate buffer at pH 5.05, was mixed near 5°C. with 77.5 cc. of 1.04 *M* aqueous sodium chlorite (80.5 mM.). The separation of a buff-colored solid from the cold solution was essentially complete after 42 hr. and the clear, dark red color of the filtrate could be discharged to orange-yellow by sulphur dioxide. A 1.03 gm. sample of the solid was extracted with ether in a Soxhlet apparatus and, when concentrated, the red ether extract slowly deposited cubical crystals. The remainder of the product consisted of dark red, viscous oils which were soluble in benzene, and of amorphous, insoluble solids.

After several recrystallizations from benzene, the above crystals, now shining white leaflets, had the elementary analysis and the Rast molecular weight of a chlorovanillin. Their melting point, 164° to 165.4°C., was correct for 5-chlorovanillin, and was not depressed by admixture with an authentic sample: admixture with authentic 6-chlorovanillin (m.p. 170°C.) depressed the value below 143°C. Acetylation of 0.14 gm. of the crystals with 2 cc. of acetic anhydride and one drop of concentrated sulphuric acid gave a 90% yield of pure 3-methoxy-4-acetoxy-5-chlorobenzal diacetate melting correctly at 118°C. (corrected). Authentic samples of the above diacetate, and also of the 6-chloro isomer (m.p. 144°C.) were prepared according to the method of Raiford and Lichty (14) for comparison. The yield of pure 5- chlorovanillin was 0.62 gm. or 17% of theory, and was 19% in a duplicate experiment.

Preparation and Analysis of Aqueous Chlorine Dioxide

To avoid the risk of explosions, chlorine dioxide gas was always prepared in dilution with an equimolecular amount of carbon dioxide by Schacherl's method (16), as described in detail by Sarkar (15). This method involved heating a mixture of potassium chlorate, 25 gm., oxalic acid dihydrate, 20 gm., and 80 cc. of cold 33% (by volume) sulphuric acid to 30° to 60°C. The evolution of gases from larger-scale preparations occasionally became too violent to be easily controlled. An all-glass apparatus coated with black paint was used, and the effluent mixture of gases was scrubbed with a saturated solution of sodium chlorite to replace any chlorine with chlorine dioxide. The effluent chlorine dioxide was absorbed in ice-cold, distilled water contained in a glass-stoppered, amber bottle until a concentration of 0.2 *M* to 0.3 *M* was attained.

These solutions were tested for their content of chlorine or hypochlorous acid by titrating aliquots iodometrically in a phosphate buffer at pH 7, and then by continuing the titration to the end point in dilute sulphuric acid. The first titration measured only one of the five oxidizing equivalents of the chlorine dioxide, *plus* those of any chlorine or hypochlorous acid, while the second or "acid" titration determined only the remaining four oxidizing equivalents of the chlorine dioxide. Five-fourths of the "acid" titration therefore gave the molar equivalent of the chlorine dioxide, and the difference between one-fourth and the first titration corresponded to the content of chlorine and hypochlorous acid. In practice, this content never exceeded 2 mM. per liter, or was almost within the experimental error. Since the solutions were usually diluted to 0.03 *M* to 0.07 *M* in chlorine dioxide before use, they were considered to be free of chlorine. Routine estimations could then be performed in acid solution as described for sodium chlorite solutions, 1 mole of chlorine dioxide being assumed to liberate five atoms of iodine.

The rapid deterioration of 0.0134 *M* chlorine dioxide in a buffer at pH 7.3 (Fig. 1, plot A) was followed by titrating 10 cc. aliquots iodometrically in acid solution. After 12 hr. at 20°C., 16.57 cc. of 0.0246 *N* sodium thiosulphate was required, corresponding to 0.0082 *M* chlorine dioxide. Another 10 cc. aliquot was analyzed by the method of Kolthoff and Furman (9) to include chlorate by being boiled for one minute with 1.3 gm. of ferrous sulphate. Excess potas-

sium iodide was then added to reduce the ferric iron formed, and the liberated iodine was titrated with 35.5 cc. of the standard sodium thiosulphate. After correction for the ferrous sulphate blank (1.55 cc.) and for the chlorine dioxide (16.57 cc.), the chlorate corresponded to 17.4 cc. or was 0.0071 *M*. This value was in fair agreement with the figure of 0.0067 *M* calculated for the complete decomposition of chlorine dioxide into equimolecular amounts of chlorite and chlorate.

Reduction of Chlorine Dioxide by Vanillin (Figs. 2 and 3)

The buffers were those used in the parallel reductions of sodium chlorite. In a typical experiment, 100 cc. of 0.008 *M* vanillin in the desired buffer, contained in a glass-stoppered, amber bottle, was brought to 20°±0.05°C. in a constant temperature bath. A blank containing no vanillin was prepared. At zero time, cold, approximately 0.03 *M* aqueous chlorine dioxide, 100 cc., was added to the solution and the blank, and the stoppered bottles were quickly shaken. The heat of the initial reaction raised the temperature of the vanillin solution close to that of the bath almost immediately. From time to time, the residual oxidant in 10 cc. aliquots was determined iodometrically as chlorine dioxide. The apparent chlorine dioxide content of the blanks was plotted against time (cf. Fig. 1), and the difference between these plots and the corresponding values for the solution was accepted as the chlorine dioxide reduced by the vanillin.

Preparation of Aldehyde $C_7H_5O_4(OCH_3)$

(*a*) With chlorine dioxide. Thirty grams (0.2 mole) of vanillin was dissolved in 1400 cc. of a 0.4 *M* citric acid – 0.8 *M* disodium hydrogen phosphate buffer for pH 4.0 made up according to McIlvaine's proportions (10) but with four times the recommended concentrations. After this solution had been chilled, 820 cc. of 0.41 *M* aqueous chlorine dioxide (0.4 mole) was added near 0°C., and the flask was cooled efficiently to dissipate the considerable heat of the reaction. The solution immediately became dark red but this color changed in about two hours to a golden yellow. At this stage the excess chlorine dioxide was removed by passing nitrogen gas through the solution, which was then extracted with 2 liters of ether. Toward the end of the extraction the solution gradually became opaque and dark red-brown in color. The yellow ether extract was dried over anhydrous sodium sulphate and was concentrated to about 150 cc. on a steam bath. When this concentrate was further evaporated *in vacuo* without warming or access of moisture, it became very cold and deposited white crystals, which were recovered on a filter and were freed from traces of an orange-brown oil by washing with a small amount of cold, anhydrous ether. Concentration and "freezing out" were repeated three or four times to give a total yield of 9.0 gm. (25%) of the crystals, and the final mother liquor contained 7.1 gm. of a chlorine-containing, orange oil which darkened on standing. Benzene was the best solvent found for recrystallization, and the pure prisms melted at 104° to 105°C. Found: C, 52.1, 52.4; H, 4.4, 4.4; OCH_3, 16.7, 16.7%; mol. wt. (Rast) 182. Calc. for $C_7H_5O_4(OCH_3)$: C, 52.1; H, 4.4; OCH_3, 16.9%; mol. wt. 184.

The substance evolved 1.06, 1.01 atoms of active hydrogen in the Zerewitinoff (12) estimation, and 3.83, 3.90 moles of the Grignard reagent was consumed per gram mol. wt. Pyridine was the solvent for the sample and butyl ether for the methyl magnesium iodide.

(*b*) With sodium chlorite at pH 4. Two grams of vanillin was dissolved in 100 cc. of the McIlvaine standard buffer, pH 4.0, but used in four times the usual strength. When 5 gm. of sodium chlorite in 25 cc. of distilled water was added, the solution turned orange, green, and then yellow, and the presence of chlorine dioxide became apparent for the first time at the yellow stage. The aldehyde was isolated as already described in a yield of 0.5 gm. or 19%, m.p. 104° to 105°C., not depressed by admixture with a sample prepared with chlorine dioxide. None of the acid $C_7H_5O_5(OCH_3)$ (see below) could be isolated.

2,4-Dinitrophenylhydrazone of Aldehyde $C_7H_5O_4(OCH_3)$

A 0.20 gm. sample, dissolved in a few cc. of alcohol, was stirred with 60 cc. of filtered Brady's solution containing 4 gm. of the dinitrophenylhydrazine per liter. After about 20 sec. the solution became opalescent, and after one hour the bright yellow deposit was collected and thoroughly washed with water. Yield 0.37 gm. or 97% of theory, and m.p., 192° to 193° (uncorrected). Found: N, 15.7, 15.8%. Calc. for $C_{14}H_{12}N_4O_8$: N, 15.4%.

Semicarbazone of Aldehyde $C_7H_5O_4(OCH_3)$

The sample (0.05 gm.) was mixed in a small centrifuge tube with 0.05 gm. of semicarbazide hydrochloride and 0.75 gm. of anhydrous sodium acetate. A few cubic centimeters of water was added with stirring, and the semicarbazone separated as the original substance dissolved. The white precipitate, after being washed in water and dried at 50°C. *in vacuo*, was recovered in quantitative yield. Found: N, 16.9; 17.1%. Calc. for $C_9H_{11}N_3O_5$: N, 17.4%. The semicarbazone melted at 163° (uncorrected) with decomposition.

Hydrogenation of Aldehyde $C_7H_5O_4(OCH_3)$

(*a*) The sample, 1.84 gm. (0.01 mole) was dissolved in 30 cc. of anhydrous dioxane, and 20 mgm. of a palladium catalyst (20) was added. The mixture when shaken in an Adkins hydrogenator at room temperature and about 35 p.s.i. hydrogen pressure absorbed 2 moles per mole in two hours, and no more was consumed in an additional hour.

After filtration, the colorless solution was evaporated in a vacuum to a slightly discolored, viscous oil weighing 1.85 gm. This oil when distilled at 120°C. and 125μ pressure yielded a colorless product with refractive index η_D^{20} 1.4670. Found: C, 51.5, 51.4; H, 6.4, 6.3; OCH_3, 16.6, 16.7%. Calc. for $C_7H_9O_4(OCH_3)$: C, 51.1; H, 6.4; OCH_3, 16.5%. A Zerewitinoff estimation (12) showed the presence of 2.03, 1.97 atoms of active hydrogen per mole.

(*b*) A microscale hydrogenation was carried out in apparatus described by Johns and Seiferle (8). When the apparatus was tested with pure vanillin and a platinum oxide catalyst, 1.98 moles of hydrogen per mole was used. The aldehyde group in vanillin had therefore been reduced to a methyl group.

Samples of the aldehyde, $C_7H_5O_4(OCH_3)$, 6.04 mgm. and 6.13 mgm., required 2.23 cc. and 2.27 cc. of hydrogen at S.T.P., corresponding to consump-

tions of 3.03, 3.04 moles, respectively, per calculated mol. wt. of 184. A repetition of the hydrogenation on a larger scale gave a colorless glass unaffected by aqueous sodium bicarbonate and by 2,4-dinitrophenylhydrazine, and giving no distinct color with ferric chloride solution.

Methylation of Aldehyde $C_7H_5O_4(OCH_3)$ with Diazomethane

A solution of 1 gm. of the aldehyde in anhydrous ether was mixed with excess of an ether solution of diazomethane prepared from 10 gm. of nitrosomethylurea (1). A pale yellow precipitate, 0.46 gm., settled, which after recovery became dark orange in color. The substance decomposed when heated to 80°C., was insoluble in petroleum ether and benzene, but dissolved in methanol, ethanol, and acetone. All attempts at recrystallization yielded an orange glass. Found: OCH_3, 22.1, 22.2%. Calc. for $C_7H_4O_3(OCH_3)_2(CH_2N_2)_2$: OCH_3, 22.0%. The residue from the ether was also a yellow glass that became dark on exposure to air.

Preparation of the Acid $C_7H_5O_5(OCH_3)$

(*a*) At pH 0.5. Thirty grams (0.2 mole) of vanillin, dissolved in 1500 cc. of aqueous sulphuric acid (pH 0.5), was mixed with 72 gm. (0.8 mole) of sodium chlorite dissolved in 150 cc. of water. The solution became dark red, but this color gradually faded to orange and then to golden yellow. After 45 min. the chlorine dioxide formed in the reaction was removed by bubbling nitrogen through the solution, which was then saturated with sodium chloride and extracted with ether. The ether extract was dried over anhydrous sodium sulphate and concentrated to about 150 cc. When the remaining ether was evaporated *in vacuo* at room temperature, a total of 12 gm. (28% of theory) of white crystals was recovered from 17 gm. of a residual yellow oil. Qualitative tests revealed a high chlorine content in this oil, but when exposed to the air it quickly changed to a dark, viscous tar.

The crystals were washed with cold, anhydrous ether, and when recrystallized from a mixture of ether and low-boiling petroleum ether formed large, colorless, glistening plates melting with decomposition at 143° to 144°C. (uncorrected). Found: C, 48.0, 48.1; H, 4.1, 4.1; OCH_3, 15.6, 15.5%. Calc. for $C_7H_5O_5(OCH_3)$: C, 48.0; H, 4.0; OCH_3, 15.5%. The total Grignard reagent consumed in a Zerewitinoff (12) estimation was 4.80, 4.87 moles, and 2.01, 1.97 atoms of hydrogen were evolved, per calculated mol. wt. of 200. A 50 mgm. sample was neutralized to a potentiometric end point near pH 8 by 5.60 cc. of 0.0914 *N* caustic soda, corresponding to a neutralization equivalent of 98.

The acid was insoluble in petroleum ether and benzene, but dissolved in alcohol, water, chloroform, and ether.

(*b*) At pH 1.0. A solution of 10 gm. of vanillin in 500 cc. of distilled water adjusted to pH 1 with sulphuric acid was mixed with another made from 19 gm. of sodium chlorite and 50 cc. of water. After 2.5 hr., during which time the color changes already described occurred, the mixture was saturated with salt and extracted with ether. The crystalline product, 2.8 gm., recovered from the ether was separated by extraction with benzene into the benzene-soluble aldehyde $C_7H_5O_4(OCH_3)$ (1.8 gm. or 15% of theory) melting at 104° to 105°C.

and the benzene-insoluble acid $C_7H_5O_5(OCH_3)$ (1.0 gm. or 7.7%), melting at 143° to 144°C. Neither melting point was depressed when samples of each product were mixed with the appropriate authentic specimen.

(*c*) From the aldehyde $C_7H_5O_4(OCH_3)$. The oxidation (*a*) was repeated at pH 0.5 with 2 gm. (0.013 mole) of the aldehyde dissolved in 100 cc. of aqueous sulphuric acid, 4.5 gm. (0.05 mole) of sodium chlorite being used. After removing the by product chlorine dioxide, the colorless aqueous solution was extracted with ether. A quantitative yield of the acid remained, and the melting point of this product was not depressed by admixture with an authentic sample. Found: OCH_3, 15.4, 15.5%. Calc. for $C_7H_5O_5(OCH_3)$: OCH_3, 15.5%.

Methylation of the Acid $C_7H_5O_5(OCH_3)$

(*a*) With diazomethane. An excess of an ethereal solution of diazomethane was added to a solution of 1 gm. of the acid dissolved in ether. Large, colorless needles, melting at 116° to 118°C. with decomposition, separated from the solution after a short time. No solvent was found from which the product could be recrystallized without decomposition. Found: C, 46.5, 46.2; H, 5.0, 5.1; OCH_3, 29.9, 29.9; N, 17.8, 17.8%. Calc. for $C_7H_3O_3(OCH_3)_3 \cdot 2CH_2N_2$: C, 46.5; H, 5.2; OCH_3, 30.0; N, 18.1%.

(*b*) With methanol. One gram of the acid was heated under reflux for 10 hr. with 10 cc. of dry methanol containing two drops of concentrated sulphuric acid. Concentration of the solution under vacuum brought about the separation of a crystalline mass melting at 115° to 118°C. with previous softening. Recrystallization from a low-boiling petroleum ether – ether mixture yielded a product which melted at 125° to 126°C. after being washed with water and dried. Found: OCH_3, 29.2, 29.1%. Calc. for $C_7H_4O_4(OCH_3)_2$: OCH_3, 29.0%.

This ester, when re-methylated with diazomethane, yielded the substance $C_7H_3O_3(OCH_3)_3 \cdot 2CH_2N_2$ with the proper melting point of 115° to 117°C., undepressed by admixture with the specimen prepared directly from the acid $C_7H_5O_5(OCH_3)$.

(*c*) With dimethyl sulphate. A solution of the acid, 1.4 gm., and sodium hydrosulphite, 0.2 gm., in a small amount of water was methylated by the alternate addition, with continuous stirring, of 2 cc. volumes of dimethyl sulphate and 5 cc. volumes of 30% sodium hydroxide. The total volumes added were 10 cc. and 20 cc., respectively. After the mixture had been kept near 100°C. for an additional two hours, acidification and continuous extraction with ether yielded 1.2 gm. of a red oil. This oil partly crystallized one day later, and after recovery the crystals were recrystallized from a very small volume of ethyl acetate. The product, still slightly pink in color, decomposed at 172° to 175°C. with discoloration and the evolution of gas. Found: C, 45.4, 45.0; H, 3.27, 3.23; OCH_3, 0.0%. Calc. for $C_7H_6O_6$: C, 45.2; H, 3.2%. The substance evolved 2.95 atoms of hydrogen per mol. wt. 186 in a Zerewitinoff estimation (12). A 15.15 mgm. sample, when titrated to a potentiometric end point near pH 8, consumed 6.80 cc. of 0.0239 *N* sodium hydroxide. The neutralization equivalent was therefore 93.

(*d*) With silver oxide and methyl iodide. A mixture of the following substances was heated under reflux for four hours on a steam bath: 4.0 gm. of the

acid $C_7H_5O_5(OCH_3)$, 50 cc. of anhydrous acetone, 50 cc. of methyl iodide freshly distilled over phosphorous pentoxide, 12 gm. of dry silver oxide, and 8 gm. of regenerated Drierite. The acetone was included because the acid was insoluble in methyl iodide. The product, recovered by filtration of the reaction mixture and evaporation of the filtrate, consisted of a viscous, slightly yellow oil weighing 4.40 gm. One gram of this oil when distilled boiled at 92°C. and 120μ pressure, and the colorless product had the refractive index, η_D^{20}, 1.4940. Found: C, 52.4, 52.5; H, 5.3, 5.2; OCH_3, 40.7, 40.7%. Calc. for $C_7H_3O_3(OCH_3)_3$: C, 52.6; H, 5.3; OCH_3, 40.8%.

This oil, when re-methylated with diazomethane, yielded the crystals $C_7H_3O_3(OCH_3)_3 \cdot 2CH_2N_2$. Although the substance melted with decomposition at 110° to 112°C. instead of 116° to 118°C., and could not be recrystallized, a mixed melting point with a sample prepared directly from the acid $C_7H_5O_5(OCH_3)$ was not depressed.

Another portion of the above oil was heated on a steam bath with 5% aqueous sodium hydroxide; the solution was acidified and extracted with ether. The extract yielded a crystalline product whose melting point of 172° to 174°C. was not depressed by admixture with the crystals, $C_7H_6O_6$, obtained in the attempt to methylate the acid $C_7H_5O_5(OCH_3)$ with dimethyl sulphate and sodium hydroxide.

ACKNOWLEDGMENT

Two of us (R. M. H. and C. D. L.) wish to thank the Brown Company for the two Fellowships, and the Canadian Pulp and Paper Association for the total of two summer stipends, awarded to them during the research.

STUDIES IN THE POLYOXYPHENOL SERIES

VIII. THE OXIDATION OF SUBSTANCES RELATED TO VANILLIN WITH SODIUM CHLORITE AND CHLORINE DIOXIDE[1]

By C. D. Logan,[2] R. M. Husband,[3] and C. B. Purves

ABSTRACT

The research confirmed the fact that chlorine dioxide and sodium chlorite were not equivalent in their oxidizing properties. At 22° C. or less, the oxidation of pyrogallol by aqueous sodium chlorite at pH 6 was very slow, but became very rapid on the acid side of pH 3.5. The amorphous, colored products probably did not include purpurogallin. Under similar circumstances *p*-hydroxybenzaldehyde was unaffected at pH 6; 22% was oxidized to *p*-benzoquinone (Dakin's reaction) at pH 5, and this amount increased to 39% at pH 1. The yield of benzoquinone was about 24% regardless of pH within the above range when aqueous chlorine dioxide was the oxidant. Sodium chlorite at pH 0.9 produced a 91% yield of methoxy-*p*-quinone from methoxy-*p*-hydroquinone; at pH 4 this product was mixed with 56% of 4,4′-dimethoxydiquinone, but near pH 6 a slower oxidation did not proceed beyond 4,4′-dimethoxyquinhydrone. Aqueous chlorine dioxide yielded at least 92% of monomeric methoxyquinone at all pH values between 1 and 6, probably in accord with the equation,

$$3\ \text{hydroquinone} + 3\ ClO_2 \longrightarrow 3\ \text{quinone} + 2\ HCl + HClO_3\ (+3\ O + 3\ H).$$

The simultaneous formation of hydrogen peroxide was suspected, but not proved. In sharp distinction to the behavior of free phenols, veratraldehyde was not oxidized by aqueous chlorine dioxide between pH 6 and pH 3, but at pH 1 a slow reaction yielded up to 15% of veratric acid. Sodium chlorite produced about 92% of the same acid at pH 1 and pH 4, but its action was negligible at pH 5. Since by-product chlorine dioxide was ineffective at pH 4, it was possible to confirm the validity of the Jeanes–Isbell equation for the reduction of chlorous acid:

$$C_6H_3(OCH_3)_2CHO + 3\ HClO_2 \longrightarrow C_6H_3(OCH_3)_2COOH + 2\ ClO_2 + HCl + H_2O.$$

The oxidation of acetylated vanillin was complicated by the occurrence of deacetylation. Red, chlorinated oils with quinoidal properties were also formed in most of the above oxidations.

INTRODUCTION

Although aqueous solutions of sodium chlorite and of chlorine dioxide have often been considered to be equivalent in their bleaching action, a recent research (11) showed that they oxidized vanillin in somewhat different ways. Oxidations with chlorine dioxide at 20° C. seemed to be independent of the hydrogen ion concentration between pH 1 and pH 6 and did not alter the aldehyde group in vanillin. Sodium chlorite, however, had no effect at pH 6, produced about 19% of 5-chlorovanillin at pH 5, appeared to duplicate the behavior of chlorine dioxide at pH 4, and produced derivatives of vanillic acid at pH 3 or less. In order to determine the characteristics of the two oxidants more fully, their action on several other phenolic substances has now been studied.

Schmidt, Hagg, and Sperlin (27) observed that an excess of chlorine dioxide in presence of a vanadium chloride catalyst produced about 25% yields of

both oxalic acid and maleic acid from pyrogallol, one of the most readily oxidizable phenols. The present research employed a sixfold to sevenfold molar proportion of sodium chlorite buffered to within one-tenth of a pH unit, and the consumption of chlorite (Fig. 1) was followed by determining the amount remaining after various times. Iodometric methods of estimating chlorite in presence of pyrogallol proved unsuitable, and the method eventually used depended upon the quantitative oxidation of sodium bisulphite by chlorous acid to sodium sulphate (12), which was determined gravimetrically as the barium salt. This tedious method gave reproducible results (plot for pH 2), although complications introduced by the chlorine dioxide also formed made their absolute value uncertain.

When the solutions of pyrogallol and sodium chlorite were mixed at pH 3.5 or less, about 2.5 moles of oxidant per mole was rapidly consumed (plots for pH 2); the mixture slowly developed an orange color, an orange precipitate appeared but then quickly redissolved to leave a clear yellow solution. The production of chlorine dioxide became apparent only at this stage, which corresponded to the consumption of more than two molar equivalents of chlorite. Between pH 3 and pH 6, the solutions of pyrogallol and of sodium chlorite turned orange to orange-red when mixed, and dark-brown, amorphous solids separated within a few minutes. The rate at which the chlorite was consumed, however, decreased rapidly as the pH increased (plots at pH 4.5 and 5). Other experiments, not reproduced in Fig. 1, showed that a decrease in temperature to 5° C. or less had the same general effect on the shape of the rate-plots as an increase in pH; at pH 3 and 5° C. amorphous solids were still present after 200 hr., and at pH 6 and 5° C. 10 hr. were required for the reduction of 0.1 mole of chlorite per mole of pyrogallol.

The literature concerned with condensations of pyrogallol caused by other oxidants was reviewed by Erdtman (4) who concluded that vicinal, asymmetrical and symmetrical dipyrogallol (the 2,3,4,2′,3′,4′, the 2,3,4,3′,4′,5′, and the 3,4,5,3′,4′,5′-hexahydroxy derivatives of biphenyl) were among the first products formed by oxidation in alkaline, neutral, and acidic media, respectively. Henrich (10), who also suggested a mechanism for such condensations, apparently confused the vicinal with the symmetrical dipyrogallol. Purpurogallin (8), a well defined, crystalline product in certain oxidations, was probably derived from the asymmetrical derivative. The further oxidation and condensation of pyrogallol gave rise to amorphous, ill-defined "humic acids" not dissimilar in character to the colored solids that separated during the present experiments. All attempts to isolate a single chemical individual from these solids failed. Purpurogallin in particular was probably not present, because a pure, crystalline sample was very readily oxidized to soluble substances by sodium chlorite at pH 2 and 10° C. (Fig. 1). Even at pH 4.6, almost seven molar equivalents of the oxidant were consumed within 32 hr. (not shown).

The next experiments employed buffered solutions kept at 20° C. and containing 5 mM. of *p*-hydroxybenzaldehyde and about 20 mM. of chlorine dioxide per liter. Plots of the rate of reaction have not been reproduced,

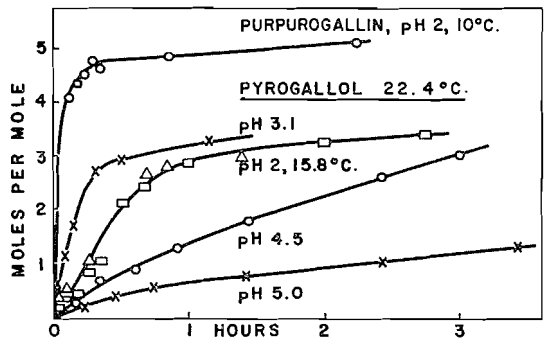

FIG. 1. Rate of oxidation of 0.015 *M* aqueous solutions of purpurogallin and pyrogallol with 0.097 *M* to 0.101 *M* sodium chlorite. Temperature 22.4° C. unless specially noted.

because quinones were formed that interfered with the iodometric method used to determine the remaining chlorine dioxide. The plots suggested that between 1 and 1.3 moles of oxidant per mole was reduced almost instantaneously at pH 5.4 or pH 6, but that the reduction decreased in rate and increased in extent as the pH was lowered, until two hours at pH 1.1 were required for the consumption of about 2.5 moles. No secondary consumption of oxidant was evident at any pH. As expected, one of the products of these oxidations was *p*-benzoquinone, but extraction of the liquors with ether yielded nothing but red tars when sodium acetate – acetic acid buffers had been employed. The substitution of citric acid and sulphuric acid buffers obviated this difficulty.

Although the quinone in the ether extract could be determined fairly accurately by iodometry (33) when the oxidation had been carried out near pH 5 or pH 6, oxidations in more acidic media contained interfering substances, and the method was discarded. Estimations based upon the reduction of the quinone to the hydroquinone by zinc and acid, and on the isolation of the crystalline dibenzoate of the hydroquinone, also failed to give quantitative results. Kimijima and Kishino (17), who encountered similar analytical

difficulties, finally added an excess of aqueous hydroquinone to the residue obtained by evaporating the ether extract, and weighed the crystalline quinhydrone that separated. This simple method gave good checks in the present work. Comparison of the data in columns 2 and 3 of Table I shows that the production of benzoquinone was practically complete in 30 min., and that the yield was almost independent of the pH of the oxidation. The slight decrease in yield observed at pH 2.2 and pH 1 was probably connected with the increase in other oxidations evidenced by the increase in the consumption of chlorine dioxide and in the depth of color of the reaction mixture.

In contrast to the almost instantaneous oxidation of *p*-hydroxybenzaldehyde by chlorine dioxide at pH 6 and 20° C., duplicate experiments with an excess of aqueous sodium chlorite showed that no appreciable reaction occurred. From pH 5 to pH 3, the two oxidants gave similar yields of benzoquinone (Table I, columns 4 and 5), but at pH 1 the yield with sodium chlorite was almost twice as great. No chlorine dioxide was evolved during the early part of the oxidation with sodium chlorite, and no red oil was isolated as a by-product. Red oils were obtained in addition to the quinone when chlorine dioxide was the oxidant, and were probably of a quinoidal nature since their color was completely discharged by reduction with sodium hydrosulphite, or with zinc and acid. The oils, which darkened quickly and became tars, were probably nuclear condensation products of a quinone, or of a hydroxylated quinone. Analogous products were described by Erdtman (4, 6).

The last two oxidations were examples of a general reaction discovered by Dakin (2) for free *o*- or *p*-phenols whose side chains contained an unsaturated carbon atom in the alpha position. In the case of *p*-hydroxybenzaldehyde, oxidation with an alkaline solution of hydrogen peroxide produced a nearly quantitative yield of hydroquinone, together with formic acid from the aldehydic group. Wacek and his collaborators (30, 31) discussed the probable mechanism of such oxidations, and isolated the monoformyl ester of hydroquinone as an intermediate when the oxidation was carried out with peracetic acid in acetic anhydride. The same type of oxidation could be effected by a few other peroxides (2), and also by ozonides decomposing in alkali (30) but not by the other common oxidants tried. In order to avoid the possibility of a Dakin reaction, methoxy-*p*-hydroquinone was chosen for study.

The oxidation of methoxyhydroquinone with twice the molar amount of aqueous chlorine dioxide at room temperature proved to be less complicated, for within 20 min. a heavy, yellow precipitate of methoxyquinone separated from solution. By extraction of the mother liquor with ether, the yield was increased to about 92% of theory from oxidations carried out at pH 1, pH 2.2, and pH 7.5, and iodometric titrations of the aqueous residues suggested that they retained another 7% of quinone-like substances. When the assumption was made that the yield of methoxyquinone was actually quantitative, it became possible to investigate the inorganic reactions involved in the reduction of the chlorine dioxide. To do this, 20 mM. samples of methoxyhydroquinone were oxidized in buffered solutions with 34 mM. to 38 mM. of chlorine dioxide, and after reaction was complete the excess of the gas was expelled

from solution by a stream of nitrogen into bubblers containing aqueous potassium hydroxide. All of the methoxyquinone formed was removed from the original liquor, whose content of "total chlorine" was determined by reducing an aliquot with ferrous sulphate and precipitating chloride as the silver salt. In all cases save run 7 (Table II, column 4) the "total chlorine"

corresponding to 20mM. of the hydroquinone amounted to 20.1 ± 0.7 mM., or 1 mole of chlorine dioxide had supplied only two oxidizing equivalents, instead of the five equivalents found in an iodometric determination. The value of 23 mM. of "total chlorine" found in run 7 probably included chloride originating as chlorite, since the spontaneous decomposition of chlorine dioxide to chloride and chlorite was appreciable at pH 5.8 (11).

With the possible exception of run 7, no significant amount of chlorite was found in the oxidation liquors, and the "total chlorine" therefore originated exclusively in chloride and chlorate. A direct determination of chloride ion by precipitation as silver chloride in presence of nitric acid gave results (columns 5 and 6, runs 1, 2, 3) whose irreproducibility was traced to the action of the acid on the chlorate. The chloride ion was then precipitated with aqueous silver acetate, and any silver carbonate was removed from the precipitate by a subsequent extraction with dilute nitric acid. This method also was unsatisfactory (runs 4 to 7). The estimation of chloride in presence of chlorate was reproducible when silver acetate in 10% acetic acid was the precipitating agent, and these values agreed with those obtained by titrating the chloride ion in neutral solution with standard silver nitrate according to Mohr (18).

Experiments 8 to 11, which were considered reliable, showed that 63% to 65% or substantially two-thirds, of the "total chlorine" was present as chloride. Since chlorite was absent, the remaining one-third could be attributed to chlorate, and the equation for the oxidation of methoxyhydroquinone by chlorine dioxide could be written:

$$3\,C_6H_3(OCH_3)(OH)_2+3\,ClO_2\rightarrow 3\,C_6H_3(OCH_3)O_2+2\,HCl+HClO_3(+3\,O+3\,H).$$

Although this equation strongly suggested that hydrogen peroxide was formed, no reliable method could be found for detecting and estimating this substance in the reaction mixture. Hydrogen peroxide, however, is known to be a frequent by-product of the oxidation of hydroquinones to quinones, especially in alkaline solutions (13, 14).

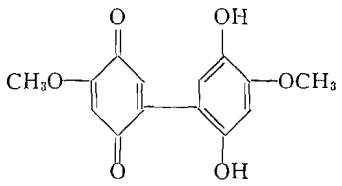
The unsatisfactory oxygen and hydrogen balance in this equation made it desirable to complete the over-all chlorine balance by determining the excess halogen absorbed by the sodium hydroxide in the bubblers. Hypochlorite was absent, and therefore no free chlorine or chlorine monoxide gas had been transferred with the excess chlorine dioxide. Estimations for chloride gave a positive result of 2 mM. to 3 mM. in each case, but control experiments with pure sodium chlorite and sodium chlorate solutions of the relevant concentration, either alone or mixed, showed that the chlorite yielded 3 mM. of apparent chloride. The small chloride content of the bubblers was accordingly considered to be spurious. If this conclusion was correct, the traces of chloride found by Taylor and his collaborators (28) among the decomposition products of sodium chlorite in acid solution could perhaps be explained in the same way. Columns 7, 8, and 9 of Table II show that 50% of the chlorine was present as chlorite, and the remaining 50% was therefore chlorate. Since the above workers (28) demonstrated that no appreciable interaction occurred among the salts of the chlorine oxy-acids in alkaline solution, the fact that the chlorite and chlorate were in equimolecular amount was proof that the only form in which the halogen had entered the bubblers was as chlorine dioxide.

The total amount of halogen in the bubblers (column 7), plus that recovered in the reaction (column 4), amounted to 91% to 94% (column 10) of the chlorine dioxide originally used (column 2). Since the recovery of methoxyquinone was also about 92%, it seemed likely that up to 8% of chlorinated quinones had been formed during the oxidation. Such by-products would have remained in the reaction vessel, and their content of halogen might have escaped estimation as "total chlorine" (column 4).

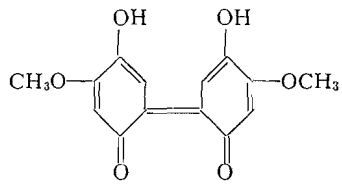
A 91% yield of methoxyquinone was also obtained by oxidizing the hydroquinone at pH 0.9 with a fourfold molar amount of aqueous sodium chlorite, the initial red color of the liquor swiftly changing through green to yellow. The speed of this oxidation suggested that chlorous acid was the active agent, because the spontaneous decomposition of chlorous acid to chlorine dioxide in a control experiment was relatively slow. When this oxidation was repeated at pH 2.2, the initial red solution rapidly became opaque and after a few minutes deposited a 30.4% yield of the crystalline, purple 4,4′-dimethoxy diquinhydrone (Structure I*a* or I*b*) previously investigated by Erdtman (5). If the oxidation was allowed to proceed for about 10 min., the purple precipi-

tate of the diquinhydrone suddenly changed into a heavy, brown-yellow curd, and simultaneously the production of chlorine dioxide became apparent. A recrystallization of this precipitate gave a 30% yield of brilliant yellow needles which proved to be Erdtman's 4,4′-dimethoxydiquinone (II), and which when heated to about 210° C. underwent an intramolecular condensation to the red, crystalline isomer (III). Erdtman obtained the coupled products (I), (II), and (III) by oxidizing methoxyhydroquinone with ferric chloride or chromic acid, and suggested appropriate reaction mechanisms (3, 5).

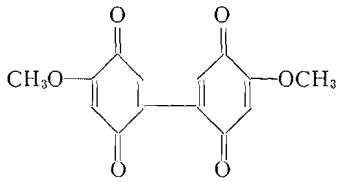
In addition to the 30% yield of the diquinone (II) from the oxidation at pH 2.2, some monomeric methoxyquinone was extracted from the mother liquors. There were therefore two competing oxidations. At pH 4.0, the yield of the diquinone was 56% of theory; at pH 5.2, about 25%, and no methoxyquinone could be recovered. Near pH 6, the oxidations yielded precipitates of the purple diquinhydrone (I*a* or I*b*) but the transformation to the yellow diquinone (II) did not occur, presumably because the oxidation potential of aqueous sodium chlorite at pH 6 was insufficient.



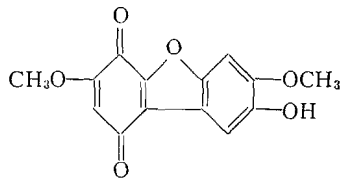
I*a* Purple. Decomp. 220° C.



I*b*



II. Yellow



III. Red. Decomp. 250° C.

The experimental portion of this article does not record oxidations of salicylaldehyde, protocatechualdehyde, protocatechuic acid, and syringaldehyde with chlorine dioxide because no definite products were isolated. In each case the oxidation instantly produced a solution whose deep red color could be partially or completely discharged by zinc dust and acid, and which presumably contained unstable quinones. Syringaldehyde immediately reduced 1.1 to 1.5 molar equivalents of chlorine dioxide at 20° C.; at pH 2 or less the slow secondary reduction was minor, but at pH 4.5 a total of about 3 molar equivalents was consumed within two hours. When 1.5 moles per mole was used at pH 1 and near 5° C., the liquor, initially red, soon turned yellow, and then yielded a yellow oil when extracted with ether. This oil, like the aqueous residue, became deep red when kept.

In sharp contrast to the behavior of the free phenols hitherto discussed, the reduction of chlorine dioxide by a phenolic ether, veratric aldehyde, was

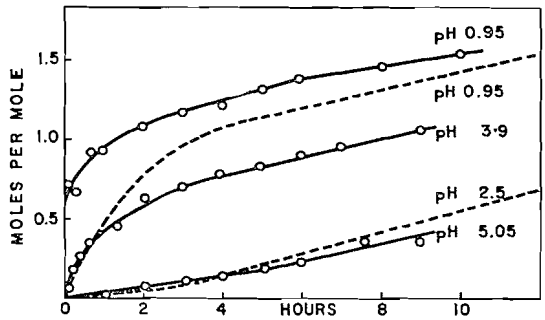


FIG. 2. Rate of oxidation of 0.001 *M* or 0.002 *M* solutions of veratraldehyde in 20% aqueous ethanol at 20° C. with approximately fourfold molar concentrations of oxidant. Solid lines, sodium chlorite; dotted lines, chlorine dioxide oxidations.

negligible at 20° C. and pH 6 to pH 3, was very slow at pH 2.5 (Fig. 2, broken lines), and even at pH 0.95 was not rapid. The liquors from oxidations carried out at pH 1, when extracted with ether, yielded yellow oils that were separated into acidic, aldehydic, and neutral fractions. The last two fractions were yellow-red oils whose color could be readily reduced by zinc and acid. They were not examined further. The acid fraction never exceeded 15% in yield, and contained veratric acid together with a chloro acid with the melting point, 185° to 187° C., of 5,6-dichloroveratric acid (24). Unfortunately, the amount of this acid was too minute to be definitely identified.

Fig. 2 (solid lines) also shows that the initial action of aqueous sodium chlorite on veratraldehyde at pH 0.95 was very rapid but, as in all other cases, became negligible on the alkaline side of pH 5. Yields of 91% and 92% of pure, crystalline veratric acid were isolated from experiments carried out at pH 1 and pH 4, respectively, and even more of the acid was produced, because some remained dissolved in the buffer. This method of preparing veratric acid was probably as convenient as any reported in the literature. Furthermore, since the yield at pH 4 could be assumed to be nearly quantitative, and since chlorine dioxide at this pH and 20° C. had no appreciable action on veratraldehyde for many hours, the reaction afforded a sound basis for studying the inorganic chemistry involved in the reduction of sodium chlorite without interference from the by-product chlorine dioxide.

Veratraldehyde, 10 mM., was oxidized with 29.4 mM. to 60.3 mM. of aqueous sodium chlorite in the apparatus previously used for the quantitative study of the reduction of chlorine dioxide by methoxyhydroquinone. The passage of nitrogen through the reaction liquor in experiments 1 and 2 (Table III) was slow, and eight or nine hours were required to transfer all of the chlorine dioxide into the traps containing aqueous potassium hydroxide. Subtraction of the "total chlorine" remaining in the reaction liquor (column 4) from the millimoles of sodium chlorite used (column 2) gave the amount of halogen expected in the traps. This amount was almost exactly recovered as "total chlorine" from the traps, and almost exactly 50% was present as chlorite, the remainder being assumed to be chlorate. The over-all chlorine

balance was therefore satisfactory, and no volatile chlorine compound except chlorine dioxide had reacted with the alkali.

Of the "total chlorine" (column 4) found in experiments 1 and 2, 1.8 mM. was not accounted for as chloride and chlorite and was attributed to chlorate (column 7). On this assumption, a small amount of chlorine dioxide had decomposed during its long sojourn in the reaction mixture, and in consequence the amounts reported for chlorite consumed (column 8), chlorine dioxide (column 9), and for chloride (column 5), were not accurate. The observed molar ratios of 3.24: 1.87: 1.20 (with 1.0 for veratraldehyde) were nevertheless similar to those determined by Jeanes and Isbell (15) when they oxidized glucose with aqueous sodium chlorite in a sealed tube; that is, in contact with the by-product chlorine dioxide.

In order to confirm this interpretation of the data, in experiments 3 to 6 the chlorine dioxide was removed by a brisk current of nitrogen gas as soon as it was formed. Almost no chlorate was found in the reaction mixture and the content of chlorite plus chloride accounted satisfactorily for the "total chlorine" (columns 4 to 7). The mole ratios of chlorite: chlorine dioxide: chloride: veratraldehyde in experiments 4, 5, and 6 were 2.9 ± 0.02: 1.87 $\pm$ 0.01: 1.0 ± 0.01: 1.0, or were close to those required by the equation

$$RCHO + 3\ HClO_2 \rightarrow RCOOH + 2\ ClO_2 + HCl + H_2O.$$

Experiment 3, in which slightly less than 3 moles of sodium chlorite per mole of veratraldehyde was used, gave chlorite consumed: chlorine dioxide: chloride in the similar mole ratio of 2.86: 1.88: 1.0. The above equation was suggested by Jeanes and Isbell (15), and its validity for the oxidation of glucose was supported by the kinetic studies of Launer and Tominatsu (19, 20). Since 3 moles of sodium chlorite, corresponding to 12 oxidizing equivalents when determined iodometrically, were replaced by 2 moles of chlorine dioxide with

10 equivalents, the net response was only 2 equivalents, or one-sixth of the expected amount. The values in Fig. 2 giving the moles of sodium chlorite reduced at any time had therefore to be increased sixfold. Extrapolation to zero time of the later, nearly linear portion of the plot for the oxidation at pH 3.9 (solid line) pointed to an apparent consumption of about 0.5 mole of sodium chlorite per mole of veratraldehyde, in agreement with the very rapid initial oxidation at pH 0.95. The true consumption was therefore close to the proper value of 3 moles, and the later portions of the plots probably represented an iodometric response to the gradual decomposition of acidified sodium chlorite to chlorine dioxide and chlorate (28). This correction was not applied to the apparent consumption of chlorite by phenolic substances (e.g. Fig. 1) because in these cases the by-product chlorine dioxide was reduced to an unknown extent.

As expected, the rate plot for the oxidation of acetyl vanillin by aqueous sodium chlorite at 20° C. and pH 4.2 was similar to that of veratraldehyde at pH 3.9 (Fig. 2), although somewhat more of the oxidant was consumed and the yield of acetyl vanillic acid was only 78%. Small amounts of an unidentified, chlorinated product were also recovered. The above results were duplicated in an oxidation at pH 1. Acetyl vanillin failed to reduce aqueous chlorine dioxide at all at pH 2.3, pH 3.75, and pH 4.5, but at pH 1.1 an apparent consumption of 1.4 mole per mole occurred within one minute and did not increase thereafter. A 4% yield of 6-chlorovanillic acid was isolated; also a yellow oil with quinoidal properties, and 17% of an unresolved mixture that probably consisted of vanillic and chlorovanillic acid. Small amounts of vanillin and acetyl vanillic acid were recovered in some experiments. It appeared that at pH 1.1 most of the acetyl vanillin had first been hydrolyzed to vanillin, which had then been oxidized as described in the previous article (11). A portion, however, had probably been chlorinated and oxidized prior to deacetylation, because vanillin itself tends to become substituted in the 5-, rather than in the 6-position (25).

It was interesting to note that chlorine dioxide regained the capacity to oxidize acetyl vanillin at pH 5.65, the apparent consumption of 0.5 mole of oxidant being complete within one hour. At pH 6.0 about 1 mole per mole was reduced within 25 min. Yields of 35% and 25%, respectively, of acetyl vanillic acid were isolated, and the other product was unchanged acetyl vanillin. The oxidation of the aldehyde group therefore competed with the decomposition of the chlorine dioxide to chlorite and chlorate, which was rather rapid near pH 6 (15). The by-product chlorite, however, could hardly be responsible for the oxidation, because chlorite at pH 6 and 20° C. was incapable of oxidizing vanillin (15).

EXPERIMENTAL

Materials and Methods

Commercial *p*-hydroxybenzaldehyde, vanillin, and resublimed pyrogallol, also synthetic syringaldehyde kindly given by Dr. P. A. Pearl, of the Institute of Paper Chemistry, Appleton, Wis., were recrystallized to constant melting

point. Purpurogallin was prepared by oxidizing pyrogallol with a neutral solution of sodium iodate (7, 8), and the bright orange crystals were definitely identified by their decomposition point of 272° C., and by the correct melting points of their tetraacetate (9, 22) and trimethyl ether (8, 22), 187° C. and 177° C., respectively. Pure veratraldehyde was prepared by methylating vanillin (1), and the oxidation of vanillin with alkaline hydrogen peroxide as described by Dakin (2) yielded 70% of recrystallized methoxy-*p*-hydroquinone (3). This substance melted at 88° to 89° C., and not at 84° C., as found by Will (32). The acetylation of vanillin (23) yielded acetyl vanillin with the correct melting point of 77° C.

The sodium chlorite of Analytical Grade was the gift of the Mathieson Alkali Company of New York, and aqueous solutions of chlorine dioxide were prepared and standardized as described previously (11). All oxidations were carried out in the dark or in amber colored bottles in order to minimize the photochemical decomposition of chlorine dioxide. The previous iodometric methods were used to follow most of the oxidations.

Reduction of Sodium Chlorite by Pyrogallol (Fig. 1)

In a typical experiment, sodium chlorite, 4.61 gm. (0.05 mole, corrected for a purity of 98.1%) and pyrogallol, 0.945 gm. (0.0075 mole) were separately dissolved in 250 cc. volumes of 0.4 *M* phosphate buffer of the desired pH and were brought to 22.3° ± 0.1° C., or 15.8° ± 0.2° C. in a constant temperature bath. The solutions were then mixed, and kept at the desired temperature; small aliquots were removed at intervals and checked for constancy in pH.

In order to follow the reduction of the sodium chlorite, 25 cc. aliquots, which could not be more than 0.05 *M* in chlorite or pyrogallol, were discharged into 10 cc. of 4% aqueous sodium bisulphite. Concentrated hydrochloric acid, 1 cc., was added, and the mixture was boiled for 15 min. to expel all sulphur dioxide that had not been oxidized to sulphate (12). A few drops of concentrated nitric acid were then added to destroy the amorphous organic material that usually separated at some stage of the oxidation of pyrogallol, and after being boiled for some time longer, the mixture was diluted to 200 cc. with distilled water. The sulphate was estimated according to the standard procedure as the barium salt. After correction for the blank (about 0.1 gm.), 1 mole of sodium chlorite was assumed to be equal to 2 moles of barium sulphate. The experiments with purpurogallin were conducted in the same way.

Oxidation of p-Hydroxybenzaldehyde to Benzoquinone (Table I)

Samples of the aldehyde, 1.22 gm. or 0.01 mole, were dissolved in 50 cc. volumes of water adequately buffered with citric acid – sodium hydroxide to pH 6.0, 5.0, 3.0, and 2.2; sulphuric acid was used as the buffer for pH 1. After being mixed with 65 cc. of 0.48 *M* aqueous chlorine dioxide (0.031 mole), the mixtures were cooled to keep their temperature below 30° C. One hour or one-half hour later, the mixtures were flushed with nitrogen to expel chlorine dioxide, were saturated with sodium chloride, and were extracted with 250 cc. volumes of ether. Each extract was cautiously evaporated and the residue was dissolved in 25 cc. of distilled water; an equal volume of water containing

1.2 gm. of hydroquinone was added, and some time later the precipitate of the green, crystalline quinhydrone was recovered, dried, and weighed (17).

The experiments were repeated with the substitution of 50 cc. of water containing 0.04 mole of sodium chlorite for the aqueous chlorine dioxide. When desired, the above ether extract was dried, evaporated, and extracted with petroleum ether to recover the yellow needles of quinone. These crystals were readily reduced with sodium hydrosulphite and were identified as hydroquinone with the correct melting point of 171° C. (16).

Oxidation of Methoxyhydroquinone with Chlorine Dioxide (Table II)

(*a*) A solution of 2.8 gm. of methoxyhydroquinone (0.02 mole) in 28 cc. of 10% acetic acid (pH 2.2) was mixed with 80 cc. of 0.464 *M* aqueous chlorine dioxide (0.037 mole) at room temperature. After about 20 min. the green-yellow flocculent precipitate was recovered and dried; yield, 1.8 gm., m.p. 143° to 144° C. More of the product, 0.7 gm., was obtained by extracting the filtrate with ether, and the total yield was 92% of theory. After recrystallization from petroleum ether, the bright yellow substance had the melting point, 144° to 145° C., reported by Erdtman (3) for methoxyquinone.

The aqueous residues, now free of chlorine dioxide, required 27.8 cc. of 0.1 *N* sodium thiosulphate in an iodometric titration, an amount which suggested the presence of 1.39 millimoles (7%) of quinone-like substances.

(*b*) The all-glass apparatus used for studying the inorganic chemistry of the oxidation consisted of a 500 cc. round-bottom flask with an inlet for nitrogen reaching nearly to the bottom and an exit for chlorine dioxide. This exit conveyed the gas through two absorption vessels containing 20% aqueous potassium hydroxide. The best results were obtained when the inlet to the test tube which served as the second vessel was drawn out to a fine capillary.

The apparatus was immediately assembled after the mixture of 0.02 mole of methoxyhydroquinone and sodium chlorite described in (*a*) had been prepared in the 500 cc. flask. After 20 min., when the oxidation was known to be complete, the flask was covered with a dark cloth and nitrogen was passed through the apparatus at a rate slow enough for the chlorine dioxide to be completely absorbed in the alkali. This operation took up to eight hours. The two alkaline solutions were then combined and made up to 500 cc. with water. Methoxyquinone was removed from the reaction liquor, and the filtrate was also made up to 500 cc.

The method described by Treadwell (29) was used to determine total chlorine. A 100 cc. aliquot was boiled for 15 min. with 50 cc. of 10% aqueous ferrous sulphate in order to reduce any chlorite and chlorate to chloride. It was necessary to neutralize the alkaline aliquots before carrying out this reduction. After the mixture had been cooled, the brown precipitate was redissolved by adding nitric acid, and the chloride was determined gravimetrically as silver chloride. As previously noted, the chloride present as such in the reaction vessel could be determined most satisfactorily by the Mohr (18) method, a 100 cc. aliquot being carefully neutralized with sodium carbonate and then titrated with standard 0.1 *N* silver nitrate, with potassium chromate as the indicator.

To estimate chlorite, a 10 cc. aliquot of the alkaline solution was treated with excess potassium iodide and sulphuric acid, and the liberated iodine was titrated with 0.04 *N* sodium thiosulphate. One mole of chlorite was equivalent to four atoms of iodine. The chlorate was found by subtracting the chlorite content from the total chlorine present. Since the chlorine dioxide reacted with the potassium hydroxide to form 1 mole of chlorite and 1 mole of chlorate,

$$2\ ClO_2 + 2\ KOH \rightarrow KClO_2 + KClO_3 + H_2O,$$

the chlorine dioxide absorbed was twice the amount of chlorite formed (28).

Oxidation of Methoxyhydroquinone with Sodium Chlorite

(*a*) A solution of the hydroquinone (0.01 mole) in 10 cc. of 10% acetic acid (pH 2.2) was mixed with another containing 0.04 mole of sodium chlorite. A few minutes later, the purple precipitate (0.41 gm. or 30.4%) could be recovered on a filter and recrystallized from pyridine. The powder decomposed at 220° C. If the filtration was delayed for about 11 min., the product was a yellow powder isolated in 30% yield and insoluble in ether, alcohol, and other organic liquids tried with the exception of boiling acetic anhydride. Recrystallization from this solvent gave brilliant golden needles which turned red on heating to about 210° C. and melted at 250° C. The melting point and other properties agreed with those recorded by Erdtman (5) for 4,4′-dimethoxydiquinone.

(*b*) The experiment was repeated with the same quantities, but the 10% acetic acid was replaced by dilute sulphuric acid to adjust the pH to 0.9. In this case the mixture quickly turned red, and then a green precipitate settled which rapidly became yellow. The product (1.01 gm.) was recovered, and also a further 0.24 gm. by extracting the mother liquor with ether. This substance, isolated in a total yield of 91%, had the melting point, 146° C., of methoxyquinone, and a mixed melting point with an authentic sample was not depressed.

Oxidation of Veratraldehyde with Chlorine Dioxide (*Fig. 2*)

(*a*) Experiments on the rate of oxidation were carried out as described for those with *p*-hydroxybenzaldehyde, but the buffer solutions were made up in 20% aqueous ethanol because veratraldehyde was insoluble in water.

(*b*) Veratraldehyde, 4.98 gm. (0.03 mole), dissolved in 400 cc. of 20% alcohol buffered to pH 1.0 with sulphuric acid, was mixed with 0.06 mole of 0.38 *M* chlorine dioxide. No immediate change occurred and no obvious amount of heat was generated, but on standing an amber and finally a red color appeared. The solution was extracted with ether after 10 hr. and the extract in turn extracted, first with saturated sodium bisulphite solution to remove aldehydes, and then with saturated sodium bicarbonate to remove acids.

After recovery from the bicarbonate liquor, the crude acidic fraction, 0.90 gm., was extracted with petroleum ether to remove 0.40 gm. of a mixture of chlorinated acids that could not be thoroughly resolved. One small fraction of colorless needles melted sharply at 185° to 186° C. and might have been 5,6-dichloroveratric acid (24). The remaining 0.5 gm. when repeatedly re-

crystallized from benzene gave crystals whose melting point of 180° to 181° C. was not depressed by admixture with an authentic sample of veratric acid.

Oxidation of Veratraldehyde with Sodium Chlorite (Fig. 2, Table III)

(*a*) The rate of oxidation was determined in 20% aqueous ethanol buffered to the desired pH, and the consumption of chlorite was followed by iodometry. In larger scale experiments, 25 cc. of an aqueous solution contained 10.9 gm. of sodium chlorite (0.12 mole) was mixed with 125 cc. of water plus 18 cc. of ethanol buffered to pH 1.0 with sulphuric acid and containing 5 gm. (0.03 mole) of veratraldehyde. A pale pink precipitate, 5.1 gm., settled out of the solution almost immediately. A single recrystallization from dilute acetic acid yielded 4.9 gm. (91%) of colorless plates whose melting point of 180° to 181° C. was undepressed by admixture with pure veratric acid.

(*b*) The apparatus, the technique, and the analytical methods were the same as those employed in studying the oxidation of methoxyhydroquinone with chlorine dioxide. Veratraldehyde, 1.662 gm. (0.01 mole), dissolved in 30 cc. of an adequate sodium acetate – acetic acid buffer at pH 4.0, was mixed with 50 cc. of water containing 0.04 mole of sodium chlorite. The reaction vessel was aerated with nitrogen, either at a slow or fast rate, but never rapidly enough to bring about an incomplete absorption of by-product chlorine dioxide in the potassium hydroxide bubblers. Crystalline veratric acid separated almost immediately in 92% yield. This product was removed as soon as the absorption of chlorine dioxide was complete, the filtrate and the alkaline absorption liquors were separately diluted to volumes of 500 cc., and aliquots were analyzed.

Oxidation of Acetylvanillin with Chlorine Dioxide

A solution of acetylvanillin, 0.04 mole, buffered to pH 1.0 with 4% sulphuric acid, was mixed with 0.08 mole of aqueous chlorine dioxide. Eight hours later, when its color had turned orange-yellow, the solution was extracted with ether, the extract was shaken with barium carbonate to remove any entrained sulphuric acid, and was then dried over anhydrous sodium sulphate. The residue from the ether was extracted with petroleum ether, which removed a small quantity of a yellow oil, and then with boiling benzene. The latter extract on cooling deposited 0.31 gm. (4%) of colorless needles melting at 207° C. Found: OCH_3, 15.3, 15.1%. Calc. for $C_8H_7O_4Cl$: OCH_3, 15.3%. A mixed melting point with 6-chlorovanillic acid prepared according to Raiford and Potter (26) was not depressed.

When extracted with bisulphite, the benzene mother liquor yielded a small amount of vanillin, and, when re-extracted with sodium bicarbonate, the sodium salts of some acids. The free acids, amounting to 1.45 gm. after several recrystallizations from ether, melted from 185° C. to 187° C. with decomposition, and contained chlorine. Found: OCH_3, 17.1, 17.3%. Calc. for $C_8H_7O_4Cl$: OCH_3, 15.3%; for $C_8H_8O_4$: OCH_3, 18.5%. Vanillic acid melts at 208° to 210° C. (21) and the 6-chloro derivative at 207° C. In other runs small amounts of acetylvanillic acid were identified.

Oxidation of Acetylvanillin with Sodium Chlorite

Acetylvanillin, 4.0 gm. (0.021 mole), dissolved in 50 cc. of alcohol and 50 cc. of 4% sulphuric acid (pH 1), was oxidized with a solution of 7.3 gm. (0.08 mole) of sodium chlorite in 25 cc. of water. After 3.5 hr. the mixture was chilled to 5° C. and was diluted with water. The crystals which deposited melted at 147° to 147.5° C. and a mixed melting point with authentic acetylvanillic acid was not depressed. Yield, 3.4 gm. or 78.5% of theory. An oxidation carried out in a sodium acetate – acetic acid buffer at pH 4.2 gave the same yield.

ACKNOWLEDGMENT

Two of us (R.M.H. and C.D.L.) wish to thank the Brown Company for the two Fellowships, and the Canadian Pulp and Paper Association for the three summer stipends, awarded to them during the research.

PRÉPARATION DE DÉRIVÉS DU PAPAVÉRINOL ET DES HYDROXYLAUDANOSINES[1]

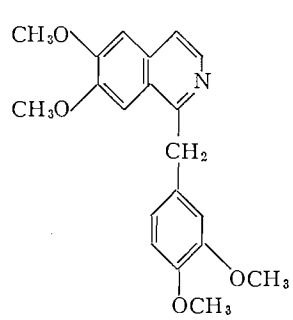
PAR JEAN-LOUIS FERRON ET PHILIBERT L'ECUYER

SOMMAIRE

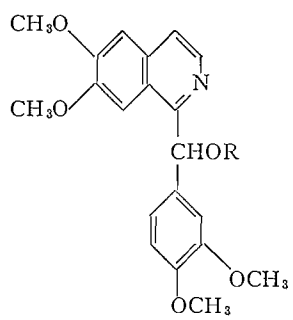
La préparation du papavérinol et des hydroxylaudanosines a été améliorée en apportant diverses modifications au mode opératoire déjà suivi. Par la méthode de Williamson, les éthers *n*-propylique, *n*-hexylique, *n*-décylique, et benzylique du papavérinol ont été obtenus avec d'excellents rendements. Par l'action des chlorures d'acide appropriés sur les hydroxylaudanosines en présence de pyridine, l'acétyl-salicylate, le benzoate, le butyrate, l'isovalérate, et le caproate de l'α-hydroxylaudanosine et le butyrate et le benzoate de la β-hydroxylaudanosine ont été synthétisés.

INTRODUCTION

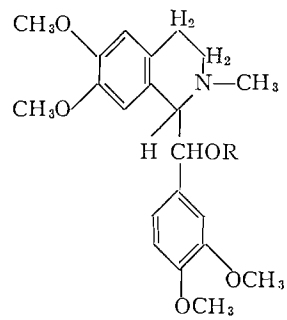
Plusieurs travaux ont éte publiés concernant la préparation de dérivés ou d'homologues de la papavérine (1); un seul a été consacré à la synthèse de bases quaternaires et d'esters du papavérinol (II, R = H) (3), aucun à celle de dérivés des hydroxylaudanosines (III, R = H). Le présent travail avait pour but la synthèse d'éthers du papavérinol et d'esters de l'α- et de la β-hydroxylaudanosine.



(I)



(II)



(III)

Nous avons préparé le papavérinol en oxydant la papavérine en solution acétique à l'aide de l'acétate mercurique selon la méthode de Gadamer (1), mais nous l'avons isolé et purifié par l'intermédiaire du perchlorate ce qui permet pratiquement de doubler le rendement.

Les hydroxylaudanosines sont facilement synthétisées par la réduction catalytique du méthochlorure de papavérinol (2), obtenu par la transformation du méthiodure à l'aide du chlorure d'argent. Nous avons préparé ce méthiodure avec un rendement de 86% en faisant réagir le papavérinol et l'iodure de méthyle sous pression et en purifiant le produit par l'intermédiaire du perchlorate.

En appliquant la méthode de Williamson (4) pour la préparation des éthers nous avons réussi avec d'excellents rendements la synthèse de quelques éthers du papavérinol en faisant bouillir à reflux une solution benzénique d'un

[1]*Manuscrit reçu le 29 septembre 1954.*
Contribution du Département de Chimie de l'Université Laval, Québec, Qué.

halogènure d'alkyle ou d'aryle en présence du sel de sodium du papavérinol. Nous avons ainsi obtenu les éthers *n*-propylique, *n*-hexylique, et *n*-décylique (II, R = C_3H_7, C_6H_{13}, et $C_{10}H_{21}$) identifiés sous forme de perchlorate, et l'éther benzylique (II, R = $CH_2C_6H_5$) caractérisé sous forme de picrate. Les rendements varient de 85 à 100%.

D'autre part, par l'action de chlorures d'acide sur les hydroxylaudanosines en présence de pyridine comme agent de condensation nous avons synthétisé quelques esters. L'acétyl-salicylate de l'α- et les benzoates de l'α- et de la β-hydroxylaudanosine (III, R = $C_6H_4(OCOCH_3)CO$ et C_6H_5CO) ont été obtenus à l'état solide. Les autres esters, le butyrate de la β- et l'isovalérate et le caproate de l'α-hydroxylaudanosine (III, R = C_3H_7CO, Me_2CHCH_2CO, $CH_3(CH_2)_4CO$), qui se séparent à l'état liquide, ont été purifiés sous forme de picrates. Les rendements varient de 25 à 50%.

PARTIE EXPÉRIMENTALE

Papavérinol

A de la papavérine (25.0 g., 0.073 mole) dissoute dans l'eau (125 ml.) et l'acide acétique (25 ml.) est ajoutée une solution d'acétate mercurique (50 g., 0.156 mole) dans l'acide acétique dilué (150 ml. d'acide 1 : 5). Après être laissé à la température ambiante pendant 24 h. le mélange est maintenu dans un bain d'eau à 70°C. pendant deux heures, refroidi, débarrassé par filtration de l'acétate mercureux et additionné d'acide chlorhydrique dilué (250 ml. d'acide 1 : 4). On porte la suspension sur bain-marie et on sature à chaud par un courant lent d'hydrogène sulfuré. Le précipité de sulfure de mercure est filtré et lavé à l'acide acétique dilué (50 ml. d'acide 1 : 4) et le filtrat alcalisé à la soude et extrait au chloroforme. Le résidu de papavérinol brut obtenu après l'évaporation à sec de la solution chloroformique sur bain-marie est dissous dans l'alcool éthylique (150 ml.) et la solution acidulée (pH2) à l'acide perchlorique à 70%. La perchlorate de papavérinol précipite sous forme de sel jaune pur de p.f. 201–202°C. Rendement: 96.7% (32.5 g.). Calculé pour $C_{20}H_{22}O_9NCl$: C, 52.7%; H, 4.9. Trouvé: C, 52.5%; H, 4.83%.

Le papavérinol est libéré en alcalisant à la soude la suspension du perchlorate dans l'eau chaude. Il est ensuite extrait au chloroforme et la solution chloroformique est séchée et évaporée à sec. Le résidu fournit après une cristallisation dans l'alcool éthylique le papavérinol pur de p.f. 138°C. Rendement: 86% (22.5 g.).

Méthiodure de papavérinol

Du papavérinol (10.0 g., 0.028 mole) et de l'iodure de méthyle (30 ml., 0.48 mole) sont chauffés pendant quatre heures dans une bouteille à pression dans un bain d'eau à 80°C. Le mélange est refroidi, l'excès d'iodure de méthyle est récupéré par distillation, et le résidu broyé dans l'acétone (environ 50 ml.). La suspension est filtrée et le méthiodure lavé avec une quantité additionnelle d'acétone (50 ml.). Rendement: 89.5% (12.6 g.).

Hydroxylaudanosines

Du méthiodure de papavérinol (78 g., 0.153 mole) dans l'alcool à 50% (250 ml.) est transformé en méthochlorure par réaction sur bain-marie avec du

chlorure d'argent fraîchement précipité (30 g., 0.2 mole). Le méthochlorure est cristallisé dans l'alcool éthylique, p.f. 205–206°C. Rendement: 97% (60.0 g.). Ce méthochlorure (0.168 mole) en solution dans l'alcool méthylique aqueux (400 ml., 5 : 3) est réduit catalytiquement à 55°C. sous pression (2–3 atmosphères) en présence de 3.0 g. d'un mélange hydroxyde de palladium – carbonate de calcium à 20% de $Pd(OH)_2$. Le catalyseur est filtré, le filtrat concentré sous pression réduite, dilué à environ 100 ml., et rendu alcalin par la soude à 30%. Les hydroxylaudanosines précipitées sont filtrées, séchées, et cristallisées dans l'alcool absolu (200 ml.). L'α-hydroxylaudanosine pure de p.f. 138°C. est obtenue après une seule cristallisation. Rendement: 41.7% (23.0 g.). Les eaux-mères saturées par un courant de gaz chlorhydrique sec donnent le chlorhydrate de la β-hydroxylaudanosine de p.f. 235°C. dont la base elle-même de p.f. 109°C. est libérée. Rendement du chlorhydrate: 24.5% (15.0 g.).

Ethers du papavérinol

On fait réagir à reflux, pendant 10 h., du papavérinol (1.0 g., 0.003 mole) avec un morceau de sodium (environ un gramme) dans du benzène anhydre (25 ml.). On retire l'excès de sodium, on ajoute le bromure d'alkyle ou d'aryle (1 ml.), et on chauffe de nouveau à reflux pendant cinq heures additionnelles. On chasse ensuite sous vide partiel le benzène et l'excès de bromure et on dissout dans l'éther (10–15 ml.). L'extrait éthéré est filtré, évaporé à sec sur bain-marie, et le résidu dissous dans l'alcool éthylique (10 ml.). On précipite ensuite, suivant le cas, soit sous forme de perchlorate en acidulant à pH 2 avec de l'acide perchlorique à 70% ou sous forme de picrate en ajoutant une solution saturée d'acide picrique dans l'alcool (10 ml.). On filtre, lave le précipité avec quelques millilitres d'alcool, et on cristallise le perchlorate dans un mélange alcool–dioxane (4 : 1) et le picrate dans l'alcool. Les rendements varient de 85 à 100%.

Les résultats de ces synthèses sont donnés dans le tableau I.

	Benzoate	49	—	130	187	Alcool – éther de pétrole	Dioxane	$C_{28}H_{31}O_6N$ (ester) $C_{34}H_{34}O_{13}N_4$	70.4	70.8	6.5	6.6	7.9	8.0

Tous les pourcentages sont ceux qui ont été déterminés à l'analyse des picrates sauf pour les benzoates et l'acétyl-salicylate dont les pourcentages de carbone et d'hydrogène ont été obtenus à l'analyse des esters libres.

Esters des hydroxylaudanosines

De l'hydroxylaudanosine (0.5 g.), de la pyridine (0.5 ml.), et du chlorure d'acide (0.5 ml.) sont chauffés sur bain-marie pendant quelques minutes et laissés à la température ambiante pendant 12 h. La gomme formée est triturée dans l'eau (5 ml.) et agitée avec l'éther (trois fois avec 10 ml.) jusqu'à l'obtention d'une solution limpide. Les extraits éthérés sont rejetés et la partie aqueuse est diluée à environ 15 ml. et filtrée. Le filtrat est neutralisé par un excès de bicarbonate de sodium. Le benzoate et l'acétyl-salicylate précipitent à l'état solide et sont purifiés directement par cristallisation dans un solvant approprié. Les autres esters se séparent sous forme d'huile et sont identifiés par la formation d'un picrate. L'ester est dissous dans l'alcool éthylique (5 ml.). Cette solution alcoolique est séchée sur du sulfate de sodium anhydre, filtrée, et le picrate de l'ester est précipité par l'addition d'une solution alcoolique saturée d'acide picrique (5 ml.). Le picrate est filtré, lavé avec quelques millilitres d'alcool, et recristallisé dans un solvant approprié. Les rendements varient de 25 à 50%.

Les résultats des synthèses de ces esters sont donnés dans le tableau II.

REMERCIEMENTS

Les auteurs remercient le Conseil National des Recherches et l'Office des Recherches de la Province de Québec pour l'aide financière accordée à l'un d'eux (J.-L. F.) sous forme de bourse ou d'octroi de recherches.

ESSAI DE SYNTHÈSES PSEUDOPHYSIOLOGIQUES DE 6,7-DIMÉTHOXYISOQUINOLÉINES[1]

PAR JEAN-LOUIS FERRON ET PHILIBERT L'ECUYER

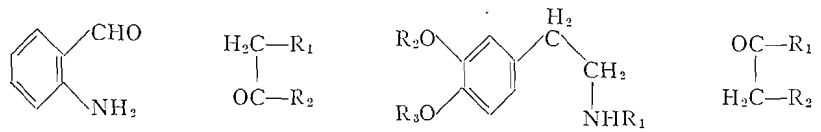
SOMMAIRE

L'acide diméthyl dihydrocaféique, l'eugénol glycol, le méthyleugénol glycol, et l'aldéhyde homovératrique ont été synthétisés par une nouvelle série de réactions. En aucun cas, il a été possible d'isoler une autre base que l'amine de départ lors des essais de condensation, dans des conditions pseudophysiologiques, de l'homovératrylamine et de la N-méthylhomovératrylamine avec divers aldéhydes et cétones bien que la récupération de la base ne dépasse jamais 84%. En dépit de certaines prétentions il semble donc que pour toute fin pratique ce mode de condensation soit irréalisable avec ces amines et d'autres du même genre à moins que les groupements hydroxyles de l'amine ne soient à l'état libre.

INTRODUCTION

A la suite de la synthèse de la tropinone par Robinson (12) plusieurs préparations d'alcaloides ont été effectuées *in vitro* à partir de substances supposées être des produits de dégradation des acides animés. Ces synthèses pseudophysiologiques s'effectuent simplement en laissant séjourner à la température ambiante les substances de départ dans des solutions tampons.

Parmi les substances synthétisées de cette façon il convient de mentionner la lobelamine (16), la pseudopelletiérine (16), la rutécarpine (18), la téloidinone (13), et le tétrahydroharmane (5). Dans le groupe de la quinoléine Schöpf et Lehmann (15) ont réussi la préparation de quinoléines mono- et bi-substituées en position 2 et 3 à partir de l'*o*-aminobenzaldéhyde (I) et de cétones (II, R_1 = H ou groupe alkyle; R_2 = CH_3 ou groupe aryle) ou d'acides β-cétoniques (II, R_1 = CO_2H; R_2 = groupe alkyle ou aryle). Dans la série de l'isoquinoléine



(I) (II) (III) (IV)

Schöpf et Bayerle (14) ont réalisé la condensation de l'acide acétique avec deux amines: la β-(3,4-dihydroxyphényl)-éthylamine (III, R_1 = R_2 = R_3 = H) et la N-méthyl-β-(3,4-dihydroxyphényl)-éthylamine (III, R_1 = CH_3; R_2 = R_3 = H) tandis que Schöpf et Salzer (17) ont réussi la synthèse de la 1-(3′4′-méthylènedioxybenzyl)-6,7-dihydroxytétrahydroisoquinoléine (V, R_1 = R_2 = OH; R_3R_4 = CH_2O_2) à partir du pipéronal (II, R_2 = H; R_1 = 3,4-méthylènedioxyphényl) et de la β-(3,4-dihydroxyphényl)-éthylamine (III, R_1 = R_2 = R_3 = H).

A la suite de ces travaux Schöpf (14) a émis l'hypothèse que la réussite des synthèses physiologiques de dérivés de la tétrahydroisoquinoléine à partir des

[1]*Manuscrit reçu le 29 septembre 1954.*

(V) (VI) (VII)

β-phényléthylamines exige la présence de groupements hydroxyles libres en position "*para*". Par contre, Hahn et Schales (6), alléguant que la présence dans la nature d'un grand nombre d'alcaloides méthylés contredisait la prétention de Schöpf, ont entrepris la condensation de l'homopipéronal avec l'homopipéronylamine et ont affirmé avoir isolé la 1-(3,4-méthylènedioxybenzyl)-6,7-méthylènedioxytétrahydroisoquinoléine (V, $R_1R_2 = R_3R_4 = CH_2O_2$).

Späth et ses collaborateurs (20) par ailleurs rapportent qu'ils ont tenté de répéter les travaux de Hahn et Schales (6) et qu'ils n'ont pas réussi à isoler le produit de condensation. Ils concluent que les prétentions de Hahn et Schales sont fausses. Späth, de plus, attribue à l'instabilité en milieu acide de l'homovératraldéhyde et de la base de Schiff intermédiaire (VI) la faillite de ces essais de condensation dans ces conditions aussi bien que le faible rendement obtenu en effectuant la synthèse de la tétrahydropapavérine à chaud en présence d'acide chlorhydrique concentré (19).

En face de l'hypothèse de Schöpf, des prétentions de Hahn, et des avancés de Späth, il convenait d'étudier et de tenter d'éclaircir ce problème. Nous avons essayé quatre séries de synthèses physiologiques avec l'homovératrylamine (III, $R_1 = H$; $R_2 = R_3 = CH_3$) et la N-méthylhomovératrylamine (III, $R_1 = R_2 = R_3 = CH_3$) comme amines de départ:

(1) condensation de l'homovératrylamine avec l'homovératraldéhyde;
(2) condensation de la N-méthylhomovératrylamine avec l'homovératraldéhyde;
(3) condensation de la N-méthylhomovératrylamine avec la benzaldéhyde;
(4) condensation de la N-méthylhomovératrylamine avec la formaldéhyde, l'acétone, et l'acétaldéhyde.

Nous avons préparé l'homovératrylamine en suivant la méthode de Fries et Bestian (4) qui consiste à décomposer l'azide de l'acide diméthyldihydrocaféique. Celui-ci avait déjà été préparé (11) par la réduction de l'acide non saturé par l'amalgame de sodium. Nous l'avons facilement obtenu en rendements quantitatifs par la réduction catalytique de l'acide caféique en présence de chlorure de palladium dispersé sur du noir animal.

La N-méthylhomovératrylamine a été synthétisée en suivant la méthode de Buck (1). Son picrate a un p.f. de 175°C. et non de 162–163°C. comme le donne l'auteur.

L'aldéhyde homovératrique a déjà été synthétisé par ozonisation du méthyleugénol suivie de la réduction de l'ozonide correspondant (7). Nous l'avons préparé par l'oxydation du méthyleugénol glycol au tétraacétate de plomb. Quant à ce glycol, il peut s'obtenir par l'oxydation du méthyleugénol au permanganate de potassium (9). Nous avons préféré le préparer par la méthylation du groupement phénolique de l'eugénolglycol à l'aide de l'iodure de méthyle.

Enfin, nous avons synthétisé avec un rendement de 90% l'eugénolglycol par l'oxydation de l'acétate d'eugénol à l'acide performique, suivie de la saponification des groupements acétyle et formyle. Freudenberg (3) avait préparé ce glycol à partir de l'eugénol par une série de quatre réactions difficiles avec un rendement final de seulement 43%.

PARTIE EXPÉRIMENTALE

Acide diméthyldihydrocaféique

De l'acide diméthylcaféique (41.6 g., 0.2 mole) est dissous dans la soude (100 ml. de solution à 10%) et la solution est réduite catalytiquement sous pression (2–3 atmosphères) à la température ambiante en présence d'un mélange chlorure de palladium – noir animal (5.0 g. à 8% de chlorure de palladium). Le catalyseur est récupéré par filtration et le filtrat acidulé. L'acide qui précipite est filtré, bien lavé à l'eau, et séché. Rendement: 99% (41.8 g.) d'acide pur de p.f. 97°C.

N-Méthylhomovératrylamine

Cette amine est préparée à partir de l'homovératrylamine (9.82 g., 0.055 mole) et de l'aldéhyde benzoique (5.75 g., 0.055 mole) selon le mode opératoire décrit par Buck (1). Rendement: 69% (11.95 g. d'iodhydrate). La N-méthylhomovératrylamine forme un picrate de p.f. de 175°C.; Buck (1) donne 162–163°C. Calculé pour $C_{17}H_{20}O_9N$: C, 48.1%; H, 4.7%.

Eugénolglycol

De l'acétate d'eugénol (31.7 g., 0.15 mole), de l'acide formique à 90% (320 ml.), et du peroxyde d'hydrogène à 30% (32 ml.) sont introduits dans un ballon. Une réaction exothermique s'amorce immédiatement et la température monte lentement à 40°C. On maintient le mélange réactionnel à cette température (±1°C.) d'abord par immersion intermittente dans un bain d'eau froide et ensuite, lorsque la vitesse de la réaction a diminué, par introduction dans un bain d'eau à 40°C. On laisse à cette température pendant deux heures et ensuite à la température ambiante pendant 12 h. On distille les acides formique et performique sous vide partiel, on dissout le résidu dans l'alcool méthylique (100 ml.), et on saponifie en faisant bouillir à reflux pendant 30 min. avec de l'hydroxyde de potassium (40 g. en solution dans 50 ml. d'eau et 100 ml. de méthanol). L'alcool et l'eau sont ensuite évaporés sous vide partiel et le résidu dissous dans l'acide chlorhydrique dilué (75 ml. d'acide 2 : 1). La solution acide est extraite à l'acétate d'éthyle (cinq portions de 100 ml.), les extraits combinés sont séchés sur du sulfate de sodium anhydre, filtrés, et concentrés. Le glycol brut est distillé sous pression réduite. Rendement: 90% (27.9 g.) de glycol pur de p.é. 146°C./0.0003 mm. Le glycol a été identifié

par la formation du tribenzoate de p.f. 100°C. Calculé pour $C_{31}H_{25}O_7$: C, 73.1%; H, 4.9%. Trouvé: C, 72.9%; H, 5.2%.

Méthyleugénolglycol

On dissout du sodium (3.3 g.) dans l'alcool méthylique anhydre (25 ml.) et à la solution de méthylate de sodium, on ajoute une solution d'eugénol glycol (27.9 g., 0.14 mole) dans du méthanol anhydre (100 ml.) et de l'iodure de méthyle (46 g., 0.32 mole). On fait bouillir la solution à reflux jusqu'à ce qu'elle devienne acide au tournesol. L'alcool est alors distillé sur bain-marie et le résidu dissous dans l'eau (environ 50 ml.). La solution aqueuse est rendue alcaline par addition de quelques millilitres de soude concentrée et extraite à l'alcool amylique (trois portions de 100 ml.). L'extrait est séché, l'alcool amylique chassé sous vide partiel, et le méthyleugénol glycol distillé sous pression réduite. Rendement: 74.5% (22.3 g.) de p.é. 134°C./0.0003 mm.

Aldéhyde homovératrique

Du méthyleugénol glycol (19.97 g., 0.094 mole) est dissous dans le benzène (250 ml.) et introduit dans un ballon à trois tubulures muni d'un agitateur mécanique et d'un condensateur à reflux. A cette solution bien agitée on ajoute à l'ébullition du tétracétate de plomb (41.5 g., 0.094 mole) en portions de 2 à 3 g. Lorsque l'oxydation est terminée (15–20 min.) la suspension est refroidie, l'acétate de plomb filtré, le filtrat lavé à l'eau, séché sur du sulfate de sodium anhydre, et concentré. Le résidu d'aldéhyde homovératrique est distillé sous pression réduite. Rendement: 67.5% (11.34 g.); p.é. 125°C./1.5 mm.

L'aldéhyde a été identifié par la préparation de la *p*-nitrophénylhydrazone de p.f. 158–159°C. (8) et de la 2,4-dinitrophénylhydrazone de p.f. 172°C. Calculé pour $C_{16}H_{16}O_6N_4$: C, 53.3%; H, 4.5%. Trouvé: C, 53.6%; H, 4.3%.

Essais de synthèses physiologiques

Les expériences ont été faites en mélangeant les réactifs de départ dans des solutions tampons. Trois séries de solutions tampons ont été préparées. Les pH ont été vérifiés par mesure électrométrique et les valeurs ont été trouvées exactes à ±0.05. Voici ces mélanges tampons:

SÉRIE A: Phosphate disodique et acide citrique (10)

No	pH	Na_2HPO_4 0.2 *M*	$C_6H_8O_7$ 0.1 *M*
1	4.2	8.28 ml.	11.72 ml.
2	5.2	10.72 ml.	9.28 ml.
3	6.2	12.63 ml.	7.37 ml.

SÉRIE B: Phthalate acide de potassium et hydroxyde de sodium (2)

No	pH	NaOH 0.2 *M*	$KHC_8H_4O_4$ 0.2 *M*
1	4.2	3.65 ml.	50.0 ml.
2	5.2	29.75 ml.	50.0 ml.
3	6.6	47.00 ml.	50.0 ml.

SÉRIE C: Acide acétique et acétate de sodium (21)

No	pH	CH_3CO_2H 0.2 *N*	CH_3CO_2Na 0.2 *N*
1	5.2	4.0 ml.	16.0 ml.

Dans le tableau I où sont compilés les résultats observés, ces mélanges tampons sont identifiés par la lettre de la série suivie du numéro de la solution.

A chacune des solutions tampons mentionnées dans le tableau sont ajoutés de l'amine pesée exactement (environ 0.5 g.) et, suivant le cas, de la cétone

**Dans ces trois essais l'extraction en milieu acide a été faite à l'éther.*

ou de l'aldéhyde pesé exactement (environ 0.5 g.). Les mélanges sont d'abord agités vigoureusement et ensuite laissés au repos à la température ambiante pendant sept à huit jours, tout en agitant quotidiennement durant environ une heure. On extrait alors les solutions acides au chloroforme ou à l'éther selon le cas (trois fois avec 5 ml.). Les extraits chloroformiques ou éthérés sont décantés, séchés sur du sulfate de sodium anhydre, filtrés, et évaporés à sec sur bain-marie. Les résidus laissés par l'évaporation du solvant sont pesés et dissous dans de l'alcool absolu (5–10 ml.) et on ajoute une solution saturée d'acide picrique (9–12 ml.).

Les portions aqueuses sont alcalisées à la soude 30% et extraites au chloroforme (trois fois avec 5 ml.). Les extraits chloroformiques sont décantés, séchés sur du sulfate de sodium anhydre, et filtrés, puis le chloroforme est évaporé sur bain-marie. Le résidu considéré comme étant uniquement de l'amine de départ est pesé. Ce résidu est dissous dans l'alcool absolu (5–10 ml.). L'addition d'une solution alcoolique saturée d'acide picrique (5–10 ml.) fait précipiter un picrate qu'on filtre et recristallise dans un mélange dioxane–éthanol (1 : 4) jusqu'à constance du point de fusion.

Les résultats de ces expériences apparaissent au tableau I. On y trouve: (1) la nature des réactifs; (2) celle de la solution tampon; (3) le pH des solutions; (4) les poids de l'aldéhyde ou de la cétone et ceux de l'amine de départ; (5) le poids de l'extrait obtenu après alcalinisation à la soude; (6) le poids du picrate pur obtenu de l'extrait fait en milieu alcalin; (7) le point de fusion du picrate; (8) le pourcentage de récupération de l'amine. Ces pourcentages sont calculés en faisant le rapport du poids de l'amine brute récupérée sur le poids de l'amine de départ. Il n'est pas tenu compte des extraits faits en milieu acide, parce qu'ils n'ont jamais fourni de picrate lorsque traités par l'acide picrique.

CONCLUSIONS

Bien que la récupération de l'amine de départ ne soit jamais de 100% (une quantité variable d'amine disparaît au cours de l'essai de condensation), dans aucun cas il nous a été possible de déceler la présence d'une autre base que celle de départ dans les produits de la réaction. L'identité du picrate isolé et de celui de l'amine de départ a été vérifiée par la détermination de points de fusion mixtes et par l'analyse des picrates provenant des essais 3, 7, et 11. Il nous semble évident que, s'il y a condensation entre le composé carbonyle et l'amine, elle doit être négligeable et, en tous cas, insuffisante pour être décelée.

Voici donc les conclusions qui découlent de ces expériences:

(1) La condensation de la N-méthylhomovératrylamine avec les aldéhydes exclue la possibilité de la formation d'une base de Schiff instable comme produit intermédiaire, ce qui ne permet pas d'invoquer l'instabilité d'une telle base comme raison de la faillite des condensations pseudophysiologiques avec les N-méthyl-3,4-dihydroxyphényléthylamines éthérifiées.

(2) Comme certains essais de condensation ont été tentés avec des aldéhydes stables (formique, acétique, et benzoique), l'instabilité de l'aldéhyde ne peut pas non plus, dans ces cas, être le véritable facteur d'insuccès.

(3) Ces résultats négatifs confirment le point de vue de Schöpf qui veut que les groupements oxydriles dans l'homovératrylamine doivent être libres pour que la condensation avec les aldéhydes ou les cétones puisse se faire dans des conditions pseudophysiologiques.

A COMPARISON OF THE PROPERTIES OF PENTAACETATES AND METHYL 1,2-ORTHOACETATES OF GLUCOSE AND MANNOSE[1]

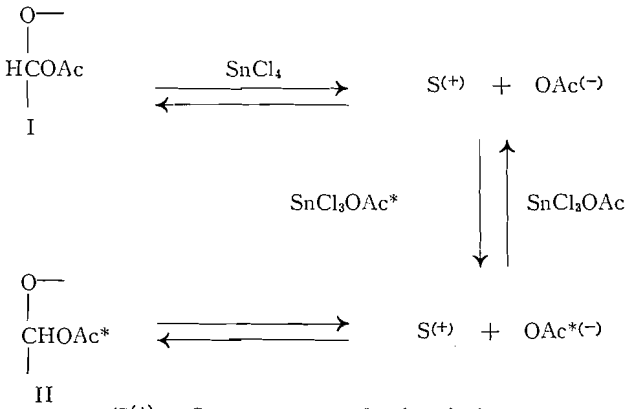
By R. U. Lemieux[2] and Carol Brice

ABSTRACT

The rates of exchange of acetate—concurrent with anomerization—between the C1-acetoxy groups of the pentaacetates (0.05 *M*) of D-glucose and D-mannose and stannic trichloride acetate (0.05 *M*) in chloroform containing stannic chloride (0.05 *M*) were determined at 40°C. using isotopically labelled acetate. 1,2-*trans*-α-D-Mannose pentaacetate underwent exchange seven times more rapidly than the β-1,2-*cis*-anomer but eight times less rapidly than 1,2-*trans*-β-D-glucose pentaacetate. The latter compound was 450 times more reactive than the α-1,2-*cis*-anomer. In accordance with these results, the D-mannose pentaacetate underwent mercaptolysis in ethyl mercaptan containing zinc chloride at rates intermediate to those found for the D-glucose pentaacetates. The main product from the mannose pentaacetates was in each case ethyl 1,2-*trans*-α-D-1-thiomannopyranoside tetraacetate (60–70% yield). Tetra-*O*-acetyl-β-D-glucopyranosyl chloride with silver acetate gave β-D-glucose pentaacetate when the reaction was carried out in dry acetic acid but gave 2,3,4,6-tetra-*O*-acetyl-α-D-glucose in 90% aqueous acetic acid. Tetra-*O*-acetyl-β-D-glucopyranosyl chloride with methanol and silver carbonate gave a sirupy product with the properties expected for methyl 1,2-ortho-*O*-acetyl-α-D-glucopyranose triacetate. The substance was hydrolyzed by 0.005 *N* hydrochloric acid in 95% dioxane 18 times more rapidly than the corresponding derivative of β-D-mannose. The significance of these observations toward an understanding of the effect of configuration on reactivity is discussed.

INTRODUCTION

The technique developed by the authors (11), in which the exchange—concurrent with anomerization (13)—of acetate between the C1-acetoxy group of a sugar acetate and $SnCl_3OAc^*$ (labelled in the carboxyl group with carbon-14), was applied to the pentaacetates of D-mannose and D-glucose. In these experiments the non-radioactive sugar acetate (I) is treated in chloroform solution with equimolar amounts of stannic chloride and the radioactive



($S^{(+)}$ = Sugar acetate carbonium ion)

stannic trichloride acetate. At various times thereafter, the prevailing sugar derivatives (II) are isolated and their radioactivity is determined. It was shown (11) for the D-glucose pentaacetates that the exchange is specific for the C1-acetoxy group. The same situation is assumed for the D-mannose pentaacetates. The reaction rates obtained obviously are a measure of relative ease of bringing about dissociation of the C1 to acetoxy group bonds of the various sugar acetates whether or not anomerization takes place prior to the dissociation.

The exchange data obtained for the pentaacetates of D-mannose and D-glucose at 40°C. are plotted in Fig. 1. It is seen that, at least for the initial

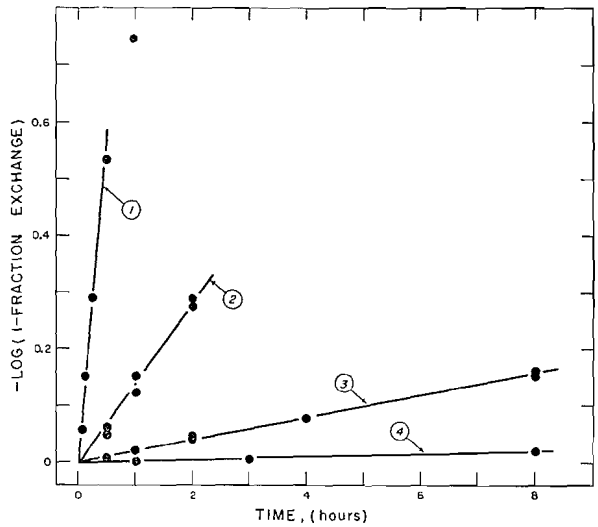

FIG. 1. Rates of exchange of sugar acetates (0.05 *M*) with labelled stannic trichloride acetate (0.05 *M*) in the presence of stannic chloride (0.05 *M*) in chloroform solution.

stages, the exchange reactions follow the simple exponential law expected for simple isotopic exchange reactions (2). The data from duplicate runs starting with the mannose pentaacetates are plotted in order to illustrate the reproducibility of these experiments. The relative rates of exchange at 40°C. obtained by comparing the slopes of the curves in Fig. 1 are listed in Table I.

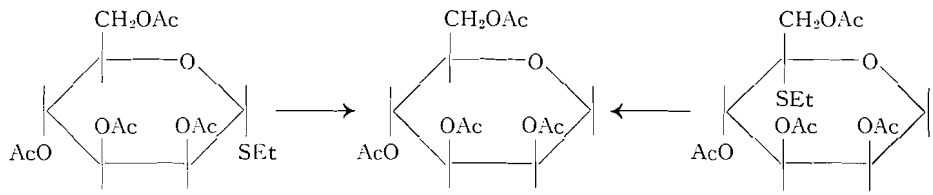
TABLE I

RELATIVE RATES OF EXCHANGE OF THE C1-ACETOXY GROUP OF SUGAR ACETATES (0.05 *M*) WITH $SnCl_3OAc^*$ (0.05 *M*) IN THE PRESENCE OF $SnCl_4$ (0.05 *M*) IN CHLOROFORM AT 40°C.

Pentaacetate of	Relative rates of reaction
1,2-*cis*-α-D-glucose	1
1,2-*cis*-β-D-mannose	8
1,2-*trans*-α-D-mannose	56
1,2-*trans*-β-D-glucose	450

Thus, as found in other similar investigations (7), the rate of C1 to acetoxy group dissociation of sugar acetates is strongly affected by the relative configurations of all the asymmetric centers in the molecule.

The stereochemical route of the reaction of a sugar acetate with ethyl mercaptan catalyzed by zinc chloride (9) is readily established since the acetylated ethyl 1-thioglycosides which are formed are highly resistant to anomerization. Thus, the mercaptolysis of a sugar acetate can yield information on neighboring group participation in replacements of the C1-acetoxy group. Mercaptolysis of either α- or β-D-mannose pentaacetate for 50 hr. at 0°C. gave ethyl α-D-1-thiomannopyranoside tetraacetate. The yield was 70% from the β-D-pentaacetate and 60% from the α-D-anomer. Inspection of the residual sirups, after deacetylation, by preparative paper chromatography led in each case to the isolation of ethyl β-D-1-thiomannopyranoside in approximately 0.15% yield. Therefore, as was previously found (9) for the D-glucose pentaacetates, both the D-mannose pentaacetates yield essentially only the 1,2-*trans*-1-thioglycoside. Fried and Walz (3) have established the pyranoside structure for ethyl β-D-1-thiomannopyranoside tetraacetate. We have established the pyranoside structure of the α-D-anomer (III) by reductive desulphurization to form styracitol tetraacetate (IV). The latter compound was also obtained by reductive desulphurization of ethyl β-D-2-thiofructopyranoside tetraacetate (V). The retention of configuration obtained on mercaptolysis of



the α-D-mannose pentaacetate indicates the participation of a neighboring group in the first stage of the reaction. The fact that 1,2-*trans*-tetra-*O*-acetyl-α-D-mannopyranosyl halides yield 1,2-orthoacetates under the conditions of the Koenigs–Knorr reaction (1, 15 p. 83) supports this contention. The simple Walden inversion obtained on mercaptolysis of β-D-mannose pentaacetate may be the result of an S_N2 type replacement. However, other possible mechanisms, such as anomerization prior to mercaptolysis or the formation of intermediate carbonium ions which have a tendency to form the α-D-thiomannoside cannot at present be excluded.

Lemieux (9) found that β-D-glucose pentaacetate undergoes mercaptolysis much more rapidly than does the α-D-anomer. It was seen above with reference to Table I that a similar wide difference in reactivity exists for these compounds in undergoing exchange of the C1-acetoxy group with stannic chloride acetate. It was therefore of interest to compare the relative rates at which the D-mannose pentaacetates undergo mercaptolysis with those found for the exchange reactions. The rates of mercaptolysis were measured as described

previously (9) and the data are plotted in Fig. 2 where the data for the D-glucose pentaacetates are also included. It is important to note at this point

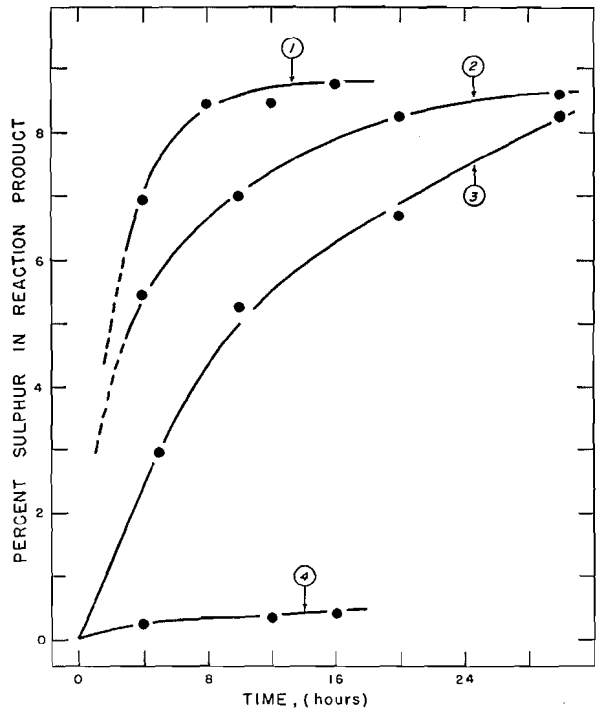


FIG. 2. A comparison of the rates of mercaptolysis (9) of sugar acetates at 0°C.
Plot 1—β-D-glucopyranose pentaacetate (9)
2—β-D-mannopyranose pentaacetate
3—α-D-mannopyranose pentaacetate
4—α-D-glucopyranose pentaacetate (9)

that these rates of mercaptolysis are only a very rough measure of the rates of ethyl 1-thioglycoside tetraacetate formation because of the presence of side reactions which yield materials with higher sulphur contents. It will be seen below that this is particularly true for the D-mannose pentaacetates. The plots in Fig. 2 show that, unlike the D-glucose pentaacetates, the D-mannose pentaacetates undergo mercaptolysis at not widely different rates. These results are roughly in agreement with those expected on the basis of the relative rates of exchange listed in Table I and show that the rates of exchange can be used as an indication of the ease of replacing the C1-acetoxy group of sugar acetates.

The data plotted in Fig. 3 show that an increase in temperature from 0°C. to 20°C. for the mercaptolysis of the D-mannose pentaacetates is accompanied by a large increase in the extent of side reactions. One of the by-products possessed, after deacetylation, the formula $C_{12}H_{26}O_4S_3$. The material may be epimeric to the 2-deoxy-2-ethylthio derivative of D-glucose diethyl thioacetal which was obtained in small yield on the mercaptolysis of the D-glucose pentaacetates (9).

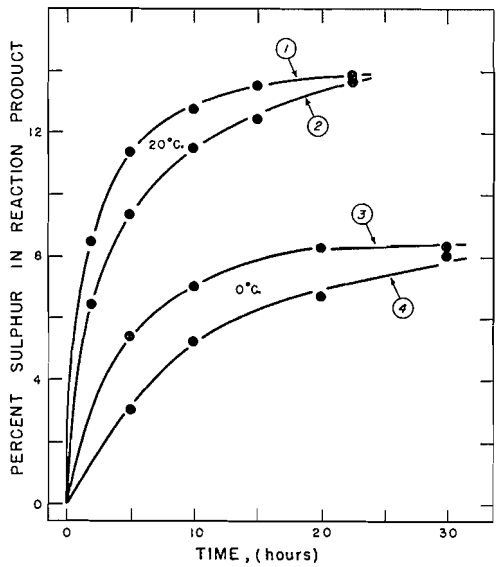

FIG. 3. The effect of temperature on the mercaptolysis of β-mannose pentaacetate (plots 1 and 3) and of α-mannose pentaacetate (plots 2 and 4).

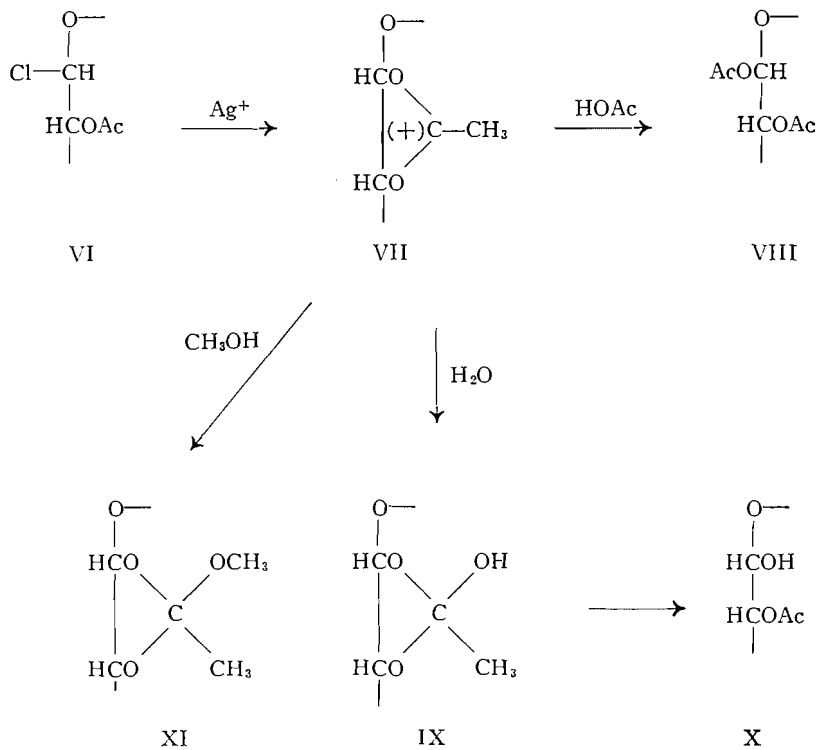
The high reactivity of β-D-glucose pentaacetate as compared to the α-anomer in undergoing dissociation of the C1 to acetoxy group bond catalyzed by acids



has been attributed to participation of the C2-acetoxy group in the case of the 1,2-*trans*-β-D-anomer (9, 11). We now wish to present further evidence for the participation based on the behavior of tetra-*O*-acetyl-β-D-glucopyranosyl chloride (VI) under conditions for solvolysis. This substance is readily obtained in high yield by reacting β-D-glucose pentaacetate with an equivalent amount of titanium tetrachloride in benzene for only five minutes at 40°C. The authors have described the nature of this reaction in a previous publication (11). The chloride (VI) reacted extremely rapidly with silver acetate in dry acetic acid to form β-D-glucose pentaacetate (VIII). However, when water was present in the reaction mixture, the product was strongly dextrorotatory, soluble in water, and readily yielded crystalline 2,3,4,6-tetra-*O*-acetyl-α-D-glucose (X). This was to be expected on the basis of the conclusions reached by Isbell and Frush (8). Winstein and Roberts (19) have recommended the procedure as a general test for carbonium ions derived through neighboring acetoxy group participation. Thus, the orthoacid (IX) was an intermediate in the reaction. It is of interest to note that the fact that this substance rearranged at least in part to the tetraacetate (X) indicates that 1,3,4,6-tetraacetyl-α-D-glucose (12) should possess a tendency to rearrange to the 2,3,4,6-tetraacetate (X). Schlubach and Wolf (17) have prepared the tetraacetate (X) by reaction of tetra-*O*-acetyl-β-D-glucopyranosyl chloride with silver carbonate in moist acetone.

When tetra-*O*-acetyl-β-D-glucopyranosyl chloride (VI) was reacted with silver carbonate in dry methanol, a highly acid-labile sirupy product was obtained which possessed the properties expected for methyl 1,2-ortho-*O*-

TABLE II

RATES OF HYDROLYSIS OF SUGAR ORTHOACETATES

The orthoester, 50 mgm., was dissolved at zero time in 3.16 ml. of 0.005 *N* hydrochloric acid in 95% dioxane and the solution was observed at room temperature, 23.5°C., in a 2 dm. tube.

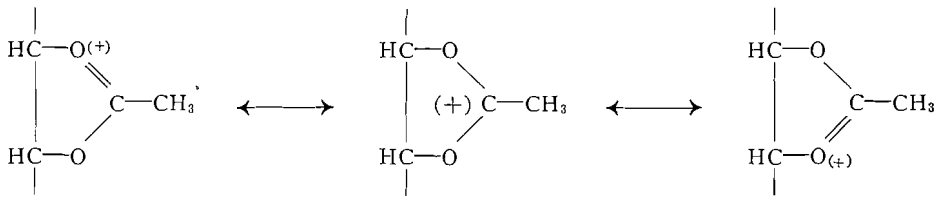
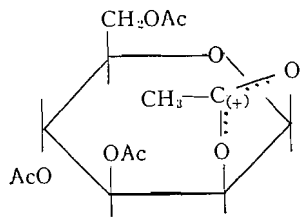
acetyl-α-D-glucopyranose triacetate (XI). That is, although acid hydrolysis gave four acetyl groups per methoxyl group, only three of the acetyl groups could be detected by saponification. Furthermore, the substance was extremely sensitive to acid hydrolysis—a fact which is characteristic of sugar orthoesters (15). Thus, there can be no doubt that the substance was methyl 1,2-ortho-*O*-acetyl-α-D-glucopyranose triacetate (XI). Unfortunately, the substance has not crystallized.

The rates of hydrolysis of both the D-glucose orthoacetate (XI) and the well-known methyl 1,2-ortho-*O*-acetyl-β-D-mannopyranose triacetate (1) in 95% dioxane 0.005 *N* with respect to hydrochloric acid were determined polarimetrically. The data, given in Table II, show that the D-glucose derivative is hydrolyzed 18 times faster than the D-mannose compound. This is reminiscent of the relative reactivities noted above for the 1,2-*trans*-pentaacetates of D-glucose and D-mannose. Winstein and co-workers (18) have established the inherent stability of 1,2-cyclic carbonium ions of structure XII. Consequently, it seems likely that the hydrolysis of 1,2-cyclic orthoacetates proceeds by way



XII

of such ions and that the higher reactivity of both β-D-glucose pentaacetate and the D-glucose orthoacetate (XI) as compared to the corresponding derivatives of D-mannose is due in each case mainly to a greater stability of the 1,2-cyclic ion (VII) from D-glucose than for the corresponding ion (XIII) from D-mannose. This could be the result of a steric inhibition to resonance in the D-mannose carbonium ion (XIII) which is not present in the D-glucose carbonium ion. It is of interest to note that the presently described methyl 1,2-



XIII

ortho-*O*-acetyl-α-D-glucopyranose triacetate (XI) appears to be about five times more sensitive to acid hydrolysis than the corresponding derivative of D-glucuronic acid methyl ester (5).

The greater reactivity of β-D-mannose pentaacetate over α-D-glucose pentaacetate both toward exchange (see Fig. 1) and mercaptolysis (see Fig. 2) may well be due to a weakening of the C1 to acetoxy group bond in the mannose derivative through the steric strain which should arise from the presence in this compound of four large substituents on one side of the ring. It has been suggested (6, 14) that the anomalous A-values which are obtained when Hudson's rules of isorotation are applied to anomeric mannose derivatives may be due to the occurrence in these compounds of internal strains which force the molecules into unusual conformations.

EXPERIMENTAL

Rates of Exchange

Stannic chloride, freshly distilled in a dry atmosphere, 3.30 gm. (12.6 mM.), was dissolved in 50 ml. of pure dry chloroform. Dry radioactive silver acetate, 1.045 gm. (6.25 mM.), 163,000 counts per min., was added and the mixture was refluxed in a dry apparatus for 20 min. The silver chloride was removed by filtration and was washed twice with 20 ml. volumes of the dry chloroform. The combined filtrates were diluted to 100 ml. The sugar acetate, 0.489 gm. (1.25 mM.), was dissolved in about 3 ml. of dry chloroform in 25 ml. volumetric flask. At zero time, exactly 20 ml. of the $SnCl_3OAc^* - SnCl_4$ solution was added at 40°C. and the solution was diluted to 25 ml. After the various reaction times, a 4 ml. sample was removed and plunged into 50 ml. of cold water. The mixture was extracted three times with chloroform. The chloroform extracts were washed in succession with sodium bicarbonate solution then with water, combined, and dried over sodium sulphate. The chloroform was removed *in vacuo* to yield a sirup which was dried at 60°C. in a high vacuum. The sample was converted to barium carbonate for counting at infinite thickness (11). Evidence was obtained (11) that stannic chloride reacts quantitatively with silver acetate. Therefore, complete exchange of the C1-acetoxy group of the sugar acetate with the stannic trichloride acetate thus formed would be expected to yield sugar acetate with a radioactivity of $163{,}000 \times 167/2 \times 16 \times 197 = 4300$ counts per min. when counted as barium carbonate. The results plotted in Fig. 1 were calculated on this basis.

Rates of Mercaptolysis

The rates of mercaptolysis were determined as previously described (9).

Mercaptolysis of β-D-Mannose Pentaacetate

Pure, dry β-D-mannose pentaacetate, 2.00 gm., was dissolved at 0°C. in 10 ml. of dry ethyl mercaptan which contained 1.00 gm. of anhydrous zinc chloride. The solution was left at 0°C. for 48 hr. and the product was isolated as previously described (9). Crystallization from ethanol gave 1.36 gm. (68% yield) of crude ethyl α-D-1-thiomannopyranoside tetraacetate, m.p. 98–106°C. The substance was pure, m.p. 107–108°C., $[\alpha]_D + 101°$ (*c*, 0.6 in chloroform), after two recrystallizations. These constants are in close agreement with those reported by Fried and Walz (3), m.p. 107–108°C., $[\alpha]_D^{25} + 104°$ (*c*, 0.88 in chloroform).

The mother liquors from the crystallizations were combined and evaporated to sirup, 0.75 gm., which was deacetylated with sodium methylate in dry methanol. Inspection of the product by partition chromatography on paper using butanol–ethanol–water (5 : 1 : 4) showed the presence of seven zones. The approximate R_f values were: I, 0.04; II, 0.12; III, 0.17; IV, 0.51; V, 0.64; VI, 0.75; VII, 0.87. The zones were detected on the paper by the periodate–permanganate spray reagent developed in this laboratory (10). Substance III appeared to be mannose and, as is shown below, substances IV and V were the β- and α-ethyl 1-thiomannopyranosides, respectively.

The deacetylated product was dissolved in water and the solution was extracted three times with ether. A very small amount of material, m.p. 108–110°C., was deposited on evaporation of the ether. The melting point was not depressed by the substance described below which was obtained in the same manner from α-D-mannose pentaacetate. The substances responsible for zones IV and V in the above chromatograms were isolated by preparative paper chromatography of the material which remained in the aqueous phase. The compounds were acetylated with sodium acetate and acetic anhydride for crystallization. Zone IV gave 2.7 mgm. of a substance, m.p. 159–160°C., which must be (see below) ethyl β-D-1-thiomannopyranoside tetraacetate, m.p. 161–162°C. Zone V gave 49 mgm. of pure ethyl α-D-1-thiomannopyranoside tetraacetate, m.p. 106–107°C.

When the mercaptolysis was carried out at room temperature for 23 hr., the yield of crude ethyl α-D-1-thiomannopyranoside tetraacetate was 60%.

Mercaptolysis of α-D-*Mannose Pentaacetate*

Mercaptolysis of 2.00 gm. of α-D-mannose pentaacetate under the above conditions led to the direct isolation of 1.18 gm. (59% yield) of crude ethyl α-D-1-thiomannoside tetraacetate, m.p. 98–104°C. The residual sirups were treated as described above. The same pattern was obtained on paper chromatography. The ether extraction gave enough of the by-product for purification and analysis. After recrystallization from water, the material melted at 110.5–111°C. Calc. for $C_{12}H_{26}O_4S_3$: C, 43.61; H, 7.93; S, 29.1%. Found: C, 43.61; H, 7.88; S, 28.1%. Zone IV gave, after acetylation, 3.0 mgm. of a substance, m.p. 157–160°C. This material was combined with the same material described above for a measurement of the specific rotation. The value, −65° (*c*, 0.05 in chloroform), is in good agreement with that, $[\alpha]_D$ −67° (*c*, 0.67 in chloroform), reported for ethyl β-D-1-thiomannopyranoside tetraacetate, m.p. 161–162°C. (3).

1,5-Anhydro-D-*mannitol* (*Styracitol*)

The ethyl α-D-1-thiomannopyranoside tetraacetate, 300 mgm., was treated with 6 ml. of settled Raney nickel in 30 ml. of 70% aqueous ethanol and the mixture was refluxed for 4.5 hr. The catalyst was removed by filtration and washed with hot ethanol. The combined filtrates were evaporated *in vacuo* to sirup which was deacetylated in methanol solution with dry ammonia. Solvent removal gave a sirup which soon crystallized. Recrystallization from methanol

gave 100 mgm. of material, m.p. 154.5–155°C., $[\alpha]_D - 50°$ (*c*, 0.9 in water). The constants for styracitol are, m.p. 155–156°C., $[\alpha]_D - 50°$ (*c*, 1 in water) (3).

Reductive desulphurization of ethyl β-D-2-thiofructopyranoside (20), 1.00 gm., under the above conditions and deacetylation of the product gave a sirup which crystallized after repeated extractions with ether. Recrystallization from methanol gave 91 mgm. of pure styracitol, m.p. 154–155°C., $[\alpha]_D - 50.5°$ (*c*, 0.4 in water). The melting point was unaffected by the styracitol from the α-D-thiomannoside.

Tetra-O-acetyl-β-D-glucopyranosyl Chloride (VI) (11, 16)

A solution of pure dry β-D-glucose pentaacetate, 10 gm., in 50 ml. of dry benzene was mixed at 40°C. with 50 ml. of benzene which contained 5 gm. (3 ml.) of titanium tetrachloride. After five minutes, when some yellow precipitate still remained, the mixture was poured into 150 ml. of ice water. After the mixture was vigorously shaken, the benzene layer was isolated and washed first with aqueous sodium bicarbonate solution and then with water. The benzene solution was dried for a few minutes over sodium sulphate and then evaporated *in vacuo* to a sirup. The sirup was dissolved in ether and Skellysolve F was added to turbidity. On standing at 0°C., 6.5 gm., 68% yield of essentially pure tetra-*O*-acetyl-β-D-glucopyranosyl chloride, m.p. 90–95°C., $[\alpha]_D - 20.3°$ (benzene), was deposited. Recrystallization from the same solvents yielded pure material, m.p. 95–97°C., $[\alpha]_D - 22°$ (*c*, 1 in chloroform). Schlubach (16) has reported tetra-*O*-acetyl-β-D-glucopyranosyl chloride to melt at 99–100°C. with $[\alpha]_D^{17} - 13.0°$ (*c*, 1 in chloroform).

2,3,4,6-Tetra-O-acetyl-α-D-glucopyranose (X) (4, 17)

Tetra-*O*-acetyl-β-D-glucopyranosyl chloride, 0.5 gm., was added to 10 ml. of dry acetic acid which contained 0.5 gm. silver acetate and the mixture was shaken at room temperature. Judging from the rate at which silver chloride was formed, the reaction was complete within one or two minutes. After 10 min., the silver salts were removed by filtration and the filtrate was evaporated to sirup, 0.539 gm., which crystallized completely. The material was pure β-D-glucopyranose pentaacetate (VIII) after one recrystallization from ethanol.

The reaction was repeated with the exception that 90% aqueous acetic acid was substituted for the glacial acetic acid. The product was strongly dextrorotatory, $[\alpha]_D + 110°$ (90% aqueous acetic acid), and crystallized readily from ether–Skellysolve F. The material, m.p. 89–96°C., $[\alpha]_D + 138°$ (*c*, 0.44 in chloroform), melted at 96–98°C. after one recrystallization from the same solvents. Calc. for $C_{14}H_{20}O_{10}$: acetyl, 49.5%. Found: acetyl, 51.1%. Georg (4) has reported 2,3,4,6-tetra-*O*-acetyl-α-D-glucose to melt at 99–100°C. with $[\alpha]_D + 135°$ (*c*, 4 in chloroform). When the reaction was carried out in ordinary glacial acetic acid, the product, $[\alpha]_D + 59°$ (acetic acid) was found to contain about equal amounts of 2,3,4,6-tetra-*O*-acetyl-D-glucose and β-D-glucose pentaacetate.

Methyl 1,2-Ortho-O-acetyl-α-D-glucopyranose Triacetate (XI)

Tetra-*O*-acetyl-β-D-glucopyranosyl chloride, 1 gm., was shaken with 50 ml. of dry methanol which contained 1.5 gm. of freshly prepared dry silver carbonate for 50 min. at room temperature. The solids were removed by filtration and washed with benzene. The combined filtrates were evaporated below 12°C. to a sirup which was dissolved in benzene. The solution was clarified by filtration and evaporated to a sirup, $[\alpha]_D+65°$ (*c*, 0.9 in chloroform) which was dried in a high vacuum at room temperature. Calc. for methyl 1,2-ortho-*O*-acetyl-α-D-glucopyranose triacetate, $C_{15}H_{22}O_{10}$: methoxyl, 8.56%; acetyl by saponification, 35.64%; acetyl by acid hydrolysis, 47.51%. Found: methoxyl, 8.30%; acetyl by saponification, 37.3, 37.3%; acetyl by acid hydrolysis, 47.6, 46.3%.

ACKNOWLEDGMENT

The microanalyses were performed by J. A. Baignee of this laboratory.

A MECHANISM FOR THE ANOMERIZATION OF ACETYLATED ALKYL GLYCOPYRANOSIDES[1]

By R. U. Lemieux[2] and W. P. Shyluk

ABSTRACT

Unequivocal evidence that the anomerization of acetylated alkyl glycopyranosides can proceed by way of an intramolecular mechanism was obtained through the observation that a racemic mixture of methyl β-glucopyranoside tetraacetate with the D-isomer labelled in the methoxyl group with carbon-14 is anomerized both by titanium tetrachloride and boron trifluoride without transfer of radioactive methoxyl groups to the L-isomer. It is submitted that these intramolecular anomerizations are best rationalized as the result of an unsuccessful attempt by the environment to bring about glycosidic cleavage and proceed by way of an ion-pair intermediate in which the anion is derived from the aglycon group.

INTRODUCTION

In 1928, Pacsu reported that methyl β-D-glucopyranoside tetraacetate was transformed to the α-anomer by refluxing a solution of the substance in chloroform containing either stannic chloride (20) or titanium tetrachloride (21). Titanium tetrachloride was the more effective catalyst and the method has found wide application for the preparation of alkyl glycosides anomeric to the form obtained by the Koenigs–Knorr reaction with stable 1,2-*cis*-*O*-acetylglycosyl halides (11, 14, 21, 22, 24). In 1944, Lindberg (10) showed that the *O*-acetylated ethyl β-glycopyranosides of D-glucose and cellobiose are rearranged to the α-anomer by heating a solution in benzene with hydrogen bromide and mercuric bromide. In 1948, Lindberg (11) reported the anomerization of a number of *O*-acetylated alkyl β-D-glucopyranosides in chloroform solution with boron trifluoride as catalyst. Recently, Reeves and Mazzeno (25) have used titanium tetrachloride to anomerize a variety of β-D-glucopyranoside tetrabenzoates.

In 1944, Montgomery *et al.* (17) found that a solution of methyl α-D-arabinopyranoside triacetate in a mixture of 4% sulphuric acid in 7 : 3 acetic anhydride – acetic acid changed in rotation from −19° to −114° in one minute and declined to an equilibrium value of −25° at the end of 20 min. When the experiment was interrupted at the rotation peak of −114°, a 14% yield of methyl β-D-arabinopyranoside triacetate was obtained. In more recent years, Lindberg has studied the polarimetric rates for the reactions of a variety of β-D-glucosides (12, 13, 14), β-D-galactosides (1), and β-D-xylosides (2) in 10 : 3 mixtures of acetic anhydride – acetic acid with sulphuric acid as catalyst. In most cases there was a rapid increase in rotation followed by a decrease to a constant value. The reaction products at maximum rotation gave ethyl, isopropyl, and tertiary butyl α-D-glucopyranoside tetraacetates in 60, 70, and

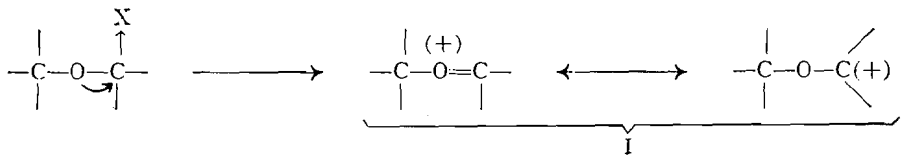
30% yields, respectively (12), and ethyl α-D-galactopyranoside tetraacetate in 55% yield (1). Thus, it was apparent that the initial rapid rise in rotation was related to the formation of the α-anomer. It is to be noted that Lemieux *et al.* (9) have shown that these polarimetric rates are complex expressions which are not susceptible to simple interpretation. For example, it was found (9) that although the change in rotation on the acetolysis of methyl β-D-glucopyranoside tetraacetate did not clearly pass through a maximum, the α-glucoside content did pass through a maximum in 60% yield. Montgomery *et al.* (18) have observed that methyl α-D-glucopyranoside tetraacetate was formed when the β-anomer was treated with an excess of phenol which contained either zinc chloride or *p*-toluenesulphonic acid.

It was apparent that the anomerization of acetylated alkyl glycosides proceeds by way of an intramolecular mechanism since the only attractive alternative mode of reaction was by way of intermediate carbonium ions and this was unlikely because of the presence in the environment of a large excess of nucleophilic substances when the reaction takes place under conditions for acetolysis or phenolysis. Lindberg (12) concluded that the reactions are intramolecular on the basis that he was able to isolate isopropyl α-D-glucopyranoside tetraacetate and ethyl α-D-cellobioside heptaacetate in 66 and 75% yields, respectively, on isomerizing a mixture of isopropyl β-D-glucopyranoside tetraacetate and ethyl β-D-cellobioside heptaacetate using titanium tetrachloride in chloroform. However, considering the rather low yields obtained, this evidence was not compelling in the absence of information on the relative rates for the anomerization of the two β-glycosides since it was possible that one of the anomerizations was substantially finished before the other was well under way. Unequivocal evidence appeared desirable since Lemieux and Brice (6) have found that stannic chloride rapidly dissociates β-D-glucopyranose pentaacetate to acetate and carbonium ions during the process of bringing about anomerization. Obviously, a similar situation could be anticipated for the interaction of the related acetylated glycosides and titanium tetrachloride. We have now obtained unequivocal evidence that acetylated methyl glucopyranosides are not dissociated under conditions for anomerization and that the anomerization must therefore proceed by way of an intramolecular mechanism. This was accomplished by anomerizing a racemic mixture of methyl β-glucopyranoside tetraacetate with the methoxyl group of the D-isomer labelled with carbon-14. Both boron trifluoride and titanium tetrachloride were used as catalysts. Analysis of the products by the method of isotopic dilution showed in both cases that all the radioactivity was in the methyl α-D-glucopyranoside tetraacetate portion.

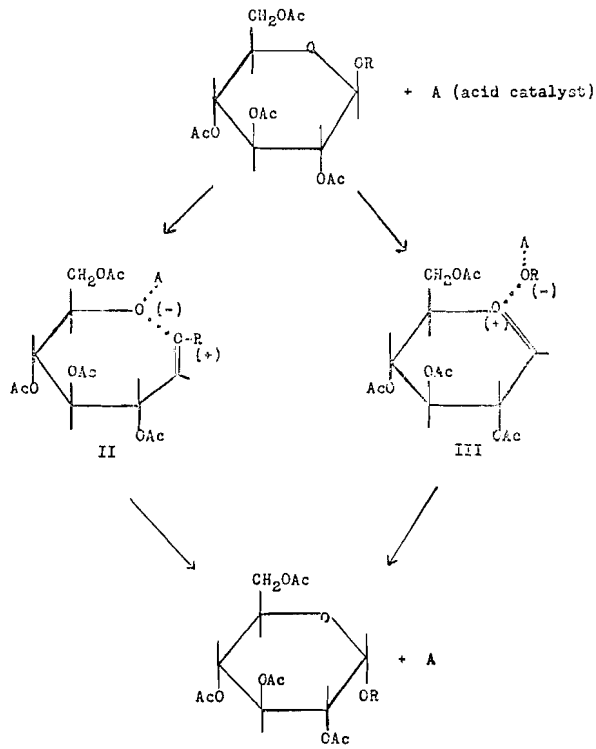
Lindberg (12) has proposed that the anomerizations proceed by way of a ring-opening–ring-closing mechanism. The ring-opening stage was considered to lead either to a carbonium ion or a dipolar ion depending on whether or not the acid catalyst was positively charged. As was indicated above, such a mechanism is unlikely in view of the ability of the anomerization to proceed under conditions for acetolysis or phenolysis. The present authors believe that a more plausible mechanism can be postulated based on the recent discovery

by Winstein and associates (27, 28) of ion-pair intermediates in a wide variety of rearrangements.

The great ease with which an electronegative substituent (X) can be replaced from the α-carbon of an ether has long been recognized and has been attributed to the participation of the ether oxygen in the dissociation of the carbon to X bond which results in the formation of a resonance stabilized carbonium ion (I). Several investigators (4, 6, 12, 19, 23) have suggested the

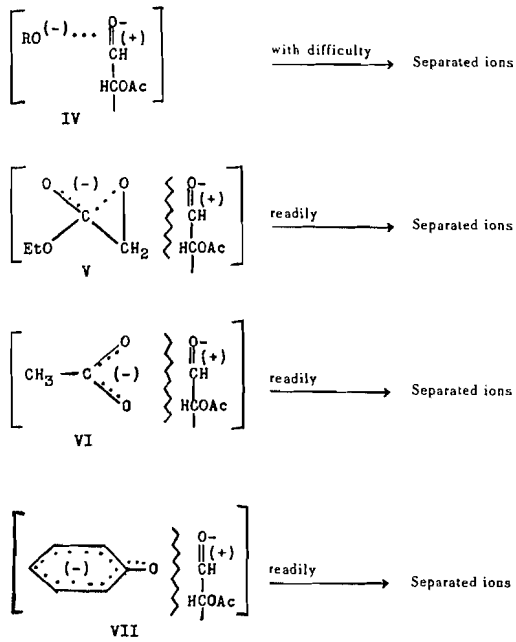


occurrence of an intermediate carbonium ion of this type in replacements at the anomeric center of sugar derivatives. On this basis and the fact that, as pointed out by Winstein and Schreiber (28), the ion-pair phenomenon can in principle be present in all processes which involve neighboring group participation, the anomerization of glycosides can be envisaged to proceed by way of either one of the two possible ion-pair intermediates represented by the formulas II and III. The postulation of the ion-pair (II) would be a refinement of the mechanism proposed by Lindberg (12). However, the present authors submit that the available evidence favors the ion-pair III. First of all, it is noteworthy that Hickinbottom (5) has shown 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride to undergo anomerization as well as glucoside formation when dissolved in methanol. There can be no doubt that in this case the C1 to chlorine bond was the bond to be disrupted and the occurrence of anomerization in the presence of methanol precludes the presence of a solvated carbonium ion intermediate. Therefore, an ion-pair of the type depicted by structure III was most probably an intermediate for the reaction. Secondly, evidence for an intermediate of type III is provided by the effect of changes in the aglycon on the behavior of the compound under conditions for anomerization. The isotopic dilution analysis for methyl α-D-glucopyranoside tetraacetate in the product from the anomerization of the β-anomer which is described in the experimental portion of this paper shows that when titanium tetrachloride was used as catalyst, the yield of α-anomer was 76%. Reynolds (26) found that carboethoxymethyl β-D-glucopyranoside tetraacetate is not anomerized when treated with titanium tetrachloride in chloroform but instead is converted to tetra-*O*-acetyl-α-D-glucopyranosyl chloride in high yield (75%). Pacsu (21) has shown that β-D-glucopyranose pentaacetate is converted to the latter compound by titanium tetrachloride. Lemieux and Brice (6) have shown that the first reaction product is tetra-*O*-acetyl-β-D-glucopyranosyl chloride. Unsuccessful attempts to anomerize phenyl β-D-glucopyranoside tetraacetate are mentioned in the literature (15, 18). However, no experimental details were reported. We have found that phenyl β-D-glucopyranoside tetraacetate is



much more resistant to change by titanium tetrachloride than is methyl β-D-glucopyranoside tetraacetate and has little, if any, tendency for anomerization. Thus, while the conversion of methyl β-D-glucopyranoside tetraacetate to the α-anomer using an equimolar amount of titanium tetrachloride in boiling chloroform was complete within one hour, the much more drastic conditions of a threefold greater amount of titanium tetrachloride and six hour reaction time did not change more than 52% of phenyl β-D-glucopyranoside tetraacetate. When the product from the latter reaction was treated with silver acetate in acetic acid, little silver chloride was formed. This product, 60% yield by weight, specific rotation −5.9° in chloroform, was found by chromatography to comprise at least 81% starting material and 8% α-D-glucopyranose pentaacetate. Therefore, little, if any, phenyl α-D-glucopyranoside tetraacetate was formed. This result was not due to an unexpectedly high reactivity of the latter compound since under the same conditions for anomerization this substance was recovered in 95% yield. Reeves and Mazzeno (25) have recently shown that *O*-nitrophenyl β-D-glucopyranoside tetrabenzoate is more prone to glycosidic cleavage than to anomerization by titanium tetrachloride by finding that the substance was converted to tetra-*O*-benzoyl-α-D-glucopyranosyl chloride in 44% yield. Lemieux *et al.* (7) have recently shown that the anomerization of β-D-glucopyranose pentaacetate in a 0.5 *M* solution of sulphuric acid in 1 : 1 acetic acid – acetic anhydride mixture at 25°C. proceeds only to a very small extent by way of an intramolecular mechanism. On the other hand,

Lemieux *et al.* (9) have shown that under the same conditions methyl β-D-glucopyranoside tetraacetate passes into the α-form approximately four times



more rapidly than it is cleaved to form β-D-glucopyranose pentaacetate. These experimental facts appear to be best rationalized by assuming that both anomerization and glycosidic cleavage result from an attack by the acid catalyst at the aglycon group. When the aglycon group is derived from an anion such as alkylate ion (IV) where charge localization is high, a large proportion of the interactions can reasonably be expected to lead to a fairly stable ion-pair of structure III which can collapse to the α-glycoside instead of leading to separated ions. On the other hand, it is reasonable that ion separation leading to glycosidic cleavage should be extensive when the anion of the ion-pair can dissipate the negative charge through resonance as in the case for the carboethoxymethylate (V), acetate (VI), and phenolate (VII) ions.

EXPERIMENTAL

Methyl β-D-Glucopyranoside Tetraacetate

The substance was prepared labelled with carbon-14 in the methoxyl group by the procedure of Lemieux and Shyluk (8). β-D-Glucopyranose pentaacetate (1.77 mM.) was added to 9 ml. of dry benzene which contained 1.8 mM. of stannic chloride and 1.77 mM. of radioactive methanol. The solution was kept at 40°C. for one hour and the reaction product was isolated in the usual way (8). The substance was pure, m.p. 104.5–105°C., after three crystallizations from methanol and when counted as barium carbonate at infinite thickness possessed a radioactivity of 98,000 counts per minute.

Methyl β-L-Glucopyranoside Tetraacetate

L-Glucose, 1 gm., was converted to sirupy tetra-*O*-acetyl-L-glucopyranosyl bromide by the procedure of Bárczai-Martos and Kőrösy (3). The sirup was reacted with dry methanol, 30 ml., in presence of silver carbonate, 2 gm., at room temperature for 10 hr. The product was isolated in the usual manner and crystallized from 3 ml. of methanol to yield 1.06 gm. of crude methyl β-L-glucopyranoside tetraacetate, m.p. 103–104.5°C. The substance was pure after three recrystallizations from methanol, m.p. 104.8–105.2°C., $[\alpha]_D^{25}+19.3$ (*c*, 1 in chloroform).

Methyl α-L-Glucopyranoside Tetraacetate

Methyl β-L-glucopyranoside tetraacetate, 700 gm., was dissolved in 45 ml. of pure chloroform and the solution was saturated with dry boron trifluoride (11). The reaction mixture was allowed to stand at room temperature for 24 hr. and was then poured into saturated aqueous sodium bicarbonate solution and the product was isolated in the usual way. The substance, 350 mgm., was pure after three recrystallizations from ethanol, m.p. 102–102.5°C., $[\alpha]_D^{25}-130.5$ (*c*, 1 in chloroform).

Anomerization Catalyzed by Boron Trifluoride

Methyl β-D-glucopyranoside tetraacetate labelled in the methoxyl group with carbon-14, 11.04 mgm., 98,000 c.p.m., and non-radioactive methyl β-L-glucopyranoside tetraacetate, 9.98 mgm., were dissolved in 2 ml. of pure chloroform and the solution was saturated with boron trifluoride. After 24 hr. at room temperature, the reaction product was isolated in the usual manner (11). A sample of the sirupy product, 8.3 mgm., was mixed with 101 mgm. of pure methyl α-D-glucopyranoside tetraacetate for crystallization from ethanol. After six recrystallizations from ethanol, the substance melted at 101.5–102.5°C. and possessed a radioactivity of 3560 c.p.m. when counted as barium carbonate at infinite thickness. The radioactivity was unchanged, within experimental error, by further recrystallization. The radioactivity expected on the basis of an intramolecular mechanism and quantitative yield was 3860 c.p.m. The product of the anomerization, 7.8 mgm., was mixed with 99.5 mgm. of pure methyl α-L-glucopyranoside tetraacetate for crystallization from ethanol. After seven recrystallizations the melting point was 102–102.5°C. and the radioactivity was insignificant, 6 c.p.m.

Anomerization Catalyzed by Titanium Tetrachloride

Methyl β-D-glucopyranoside tetraacetate labelled in the methoxyl group with carbon-14, 10.9 mgm., 98,000 c.p.m., was dissolved in 0.3 ml. of pure chloroform which contained an equal amount of non-radioactive L-isomer. The solution was mixed with 0.3 mgm. of 0.2 *M* titanium tetrachloride in chloroform and the container was sealed for heating at 61°C. for five hours. The product was isolated in the usual way (21) and dissolved in 50 ml. of chloroform. The resulting solution was divided into two equal portions which were evaporated to yield two samples of dry sirupy product each weighing 11 mgm. One sample was diluted with 86.8 mgm. of non-radioactive methyl α-D-glucopyrano-

side tetraacetate for crystallization as described above in the anomerization using boron trifluoride. After seven recrystallizations, the material, m.p. 102–103°C., possessed a radioactivity of 4420 c.p.m. The radioactivity expected on the basis of an intramolecular mechanism and quantitative yield was 5840 c.p.m. The other sample of reaction product was mixed with 85.9 mgm. of methyl α-L-glucopyranoside tetraacetate and the mixture was recrystallized six times from ethanol to yield material, m.p. 101.5–102.5°C., which possessed insignificant radioactivity, 16 c.p.m.

Rate of Anomerization Catalyzed by Titanium Tetrachloride

At zero time, equal amounts, 0.6 ml., of 0.2 *M* solutions of methyl β-D-glucopyranoside tetraacetate and titanium tetrachloride in pure chloroform were mixed in glass tubes which were immediately sealed and placed in a water bath controlled at 61°C. After each of the various reaction times, a tube was placed in about 50 ml. of saturated aqueous bicarbonate solution contained in a stainless steel beaker and smashed with a heavy steel rod. The product was isolated by extraction with chloroform in the usual manner. The rotations of the product, measured in chloroform, were as follows: after 30 min. reaction time, +90°; 60 min., 112°; 90 min., 111°; 120 min., 113°.

Attempt to Anomerize Phenyl β-D-Glucopyranoside Tetraacetate

Dry phenyl β-D-glucopyranoside (8) tetraacetate, 424 mgm. (1 mM.) was added to a solution of 3 mM. of titanium tetrachloride in 10 ml. of pure chloroform and the mixture was refluxed for three hours. The brown colored solution was added to ice-water mixture and the resulting mixture was extracted four times with chloroform. The chloroform extracts were washed once with sodium bicarbonate solution, then with water, dried, and evaporated to a sirup which possessed a strong odor of phenol. The product was dissolved in 10 ml. of dry acetic acid which contained silver acetate (1 mM.) and the mixture was shaken at 60°C. for one hour. There appeared to be little reaction. The silver salts were removed by filtration and the filtrate was added to water before extraction with chloroform. The washed and dried chloroform extract was evaporated to a crystalline residue, 252 mgm. yield (60% by weight), $[\alpha]_D$ −5.9° in chloroform. Chromatography on Magnesol–Celite (5 : 1) according to the procedure of McNeely *et al.* (16) afforded 204 mgm. of essentially pure starting material, m.p. 123–125°C. and 20 mgm. of α-D-glucopyranose pentaacetate which was identified by mixed melting point, infrared spectra, and rotation.

When phenyl α-D-glucopyranoside tetraacetate (18), 424 mgm., was treated under the above conditions, the material was recovered in essentially pure condition, m.p. 110–112°C., $[\alpha]_D$ +161° in chloroform in 95% yield.

ACKNOWLEDGMENT

The authors are grateful to Carol Brice for valuable technical assistance and to A. C. Neish for kindly donating the L-glucose used in this work.

THE SOLVOLYSIS OF THE *ALPHA*- AND *BETA*-3,4,6-TRI-*O*-ACETYL-D-GLUCOPYRANOSYL CHLORIDES[1]

By R. U. Lemieux[2] and G. Huber[3]

ABSTRACT

3,4,6-Tri-*O*-acetyl-β-D-glucopyranosyl chloride was found to undergo solvolysis in acetic acid to form 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose as the main reaction product. The much less reactive anomeric α-chloride also appeared to undergo solvolysis with extensive inversion of the anomeric center. It is submitted that the tendencies for inversion obtained in these ionic reactions are due to the conformations imposed on the intermediate ions through distribution of the positive charge to the ring oxygen and the consequent introduction of double-bond character to the carbon-1 to ring-oxygen bond.

INTRODUCTION

It is now clear that the retention of configuration which is obtained in the replacement of the halogen atom of 1,2-*trans*-acetohalogenosugars (fully *O*-acetylated 1,2-*trans*-glycopyranosyl halides) by acetate is due to the participation of the C2-acetoxy group in the dissociation of the C1 to halogen bond (9, 10, 11). The high degree of inversion which usually is obtained in reactions of 1,2-*cis*-acetohalogenosugars could of course be the result of an S_N2 displacement-type mechanism. Isbell and Frush (8) have rationalized the formation of methyl β-D-glucopyranoside tetraacetate from α-acetobromoglucose in about 94% yield on this basis. This view has recently been challenged by Newth and Phillips (15) who suggested instead that these reactions proceed by way of carbonium ions with the positive charge distributed to the ring oxygen. Lindberg (14) had earlier produced kinetic evidence that the reaction of α-acetobromoglucose with water in acetone catalyzed by mercuric acetate was ionic in type. Chapman and Laird (5) have pointed out that some of the arguments used by Newth and Phillips are not acceptable and reported evidence that the reaction of 1,2-*cis*-acetohalogenosugars with amines usually is bimolecular in poorly solvating media. The present authors have recently shown (13) that the reactions of both the α- and β-3,4,6-tri-*O*-acetyl-D-glucosyl chlorides with acetic acid containing silver acetate proceed with inversion of the anomeric centers to a high degree. It was pointed out (13) that these results were in accordance with the idea that these reactions are of the S_N2 type. According to Hassel and Ottar (7) the β-chloride would be much less reactive than the α-anomer should these reactions in fact be of the S_N2 type. This investigation was undertaken to test this speculation made by Hassel and Ottar (7). However, the data obtained show that in all probability the reactions of the 3,4,6-tri-*O*-acetyl-D-glucosyl chlorides with acetic acid are of the S_N1 solvolytic type and that the β-chloride is far more reactive than the α-anomer.

Table I summarizes the results of kinetic studies with 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride (I). Experiments 1 and 2 show that the substance reacts rapidly when dissolved in acetic acid. The facts that the reaction product was strongly dextrorotatory, contained only a trace of chlorine, and afforded 1,3,4,6-tetra-*O*-acetyl-α-D-glucose in 72% crude yield show that the reaction proceeded to a large extent with inversion of the anomeric center. The results of experiments 3 and 4 show that the rate and stereochemical route of the reaction were unaffected by the presence of potassium acetate in the reaction mixture. Thus, it is clear that the rate of reaction is dependent only on the ionizing power of the solvent and therefore the reaction must be of the S_N1 solvolytic type. This conclusion is supported by the observation (experiments 5 and 6) that rendering the solvent less polar by dilution with benzene resulted in a substantial decrease in rate of reaction. Therefore, when 3,4,6-tri-*O*-acetyl-β-D-glucosyl chloride is dissolved in acetic acid the chlorine atom is replaced by acetate *by way of an intermediate carbonium ion with a strong tendency for inversion of the anomeric center.*

In contrast to the β-anomer, 3,4,6-tri-*O*-acetyl-α-D-glucosyl chloride (II) was too unreactive to allow the measurement of its rate of reaction in acetic acid. A comparison of the result of experiment 1 of Table II with that of experiment 2 of Table I shows that the α-chloride (II) is about 100 times less reactive than the β-anomer (I). In order to obtain convenient reaction rates in homogeneous solution, the Lewis acid mercuric acetate was used to catalyze the reaction. A comparison of the results of experiments 3 and 4 of Table II shows that the addition of benzene to the reaction mixture lowered the reaction rate by an extent comparable to that observed for the β-chloride. This observation cannot be taken as compelling evidence for an S_N1 mechanism. Never-

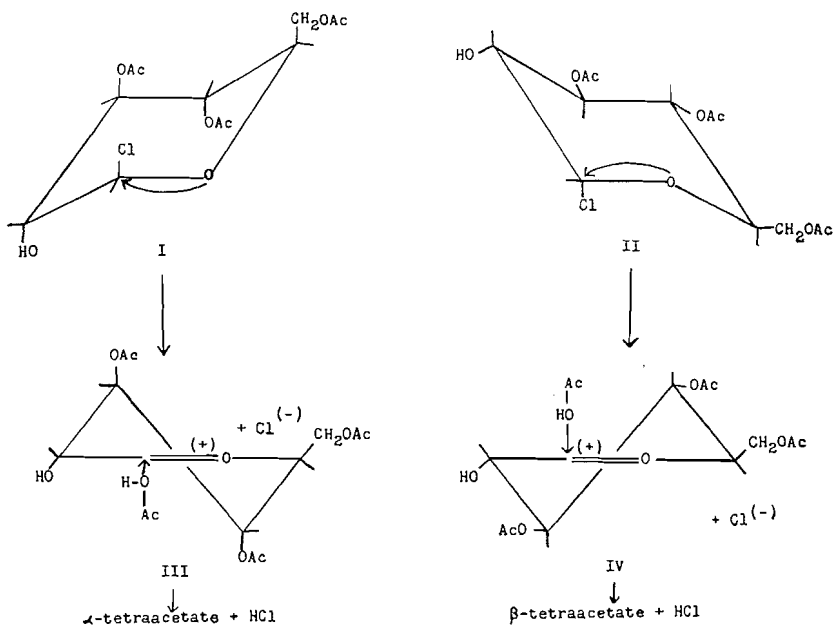
theless, the fact that it leads to the same conclusion as was reached by Lindberg (14) and Newth and Phillips (15) in kinetic studies with α-acetobromoglucose in solvating media leaves little doubt that the reaction proceeds by way of an intermediate carbonium ion. The polarimetric data listed in Table II and the fact that 1,3,4,6-tetra-*O*-acetyl-β-D-glucose could be isolated from the product in 72% crude yield show clearly that the reaction proceeds with a high degree of inversion at the anomeric center. Therefore, it can be concluded that *like its β-anomer* 3,4,6-tri-*O*-acetyl-α-D-glucosyl chloride *undergoes solvolysis with extensive inversion* at the anomeric center.

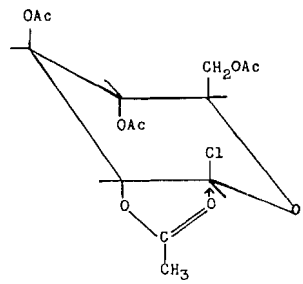
The fact that the reactions of the chlorides (I and II) proceed mainly with inversion shows the reactions to be essentially free of neighbor group participation. The ability of the reactions to proceed readily by way of ionic mechanisms must therefore be related to stabilization of the carbonium ion by interaction with the ring-oxygen atom (5, 15). The fact that this interaction must introduce double-bond character to the lactol carbon to ring-oxygen bond renders possible an interesting rationalization of the results which in turn gains support from a stereodynamic standpoint. The ability of an S_N1 reaction to proceed with a high degree of inversion must be related to the conformation of the carbonium ion. The introduction of double-bond character to the C1 to ring-oxygen bond renders possible two fairly rigid carbonium ions (III and IV) which differ only in conformation as has been suggested for cyclohexene (1). The orientations of the substituents in these ions are such that it can be reasonably expected that ion III prefers to accept an anion on the α-side of the ring and that ion IV is more open to attack on the β-side of the ring. Thus, the stereochemical routes followed in the solvolyses of the chlorides can be rationalized on the assumption that the β-anomer (I) dissociates to the ion III while the α-anomer yields the ion IV. This assumption is supported by the fact that these reaction routes are those to be expected on the basis of the stereochemical

requirements for elimination established by Barton and Miller (3). Thus, the preferred conformation for dissociation of the β-chloride (I) would be as shown where the ring-oxygen atom has a *p*-orbital in the same plane as the chlorine atom. This postulation appears particularly attractive when it is considered that it allows rationalization of the higher reactivity of the β-chloride (I) over the α-anomer (II) on the basis that the presence of the C3-acetoxy group, CH_2OAc group, and chlorine atom in axial orientation (2) can be expected to result in steric assistance to dissociation. That is, it appears likely that the achievement of the conformation I by the β-chloride through kinetic disturbance should result in considerable steric pressure by the C3-acetoxy and CH_2OAc groups on the chlorine atom and thus aid in its dissociation. Hassel and Ottar (7) have discussed the steric interaction which can be expected (4) between opposing groups in axial orientation in the sugar molecules. The postulate also appears attractive for the reason that the dissociation of I to ion III involves much less reorientation of the pyranose ring than the conversion of I to ion IV and as seen above ion III appears necessary to explain the stereochemical route of the reaction. The α-chloride (II) can be expected for similar reasons to react in the conformation shown to form the ion IV. The implication of these ideas on the mechanism of the anomerization of derivatives of glucose is dealt with in another communication (12).

Lemieux (9) has suggested that the high difference in reactivity which exists for the anomeric D-glucopyranose pentaacetates (which can be as great as 450 (10)) and the acetochloroglucoses (9, 10) is due mainly to anchimeric assistance to dissociation by the C2-acetoxy group in the case of the more reactive 1,2-*trans*-β-anomer. The facts that the β-chloride (I) is about 100



times more reactive than the α-chloride (II) and that the reaction was clearly free of neighboring group participation require that this idea be qualified. Nevertheless, the facts that inversion can be expected in the absence of participation of the C2-substituent and that the reactions of β-glucopyranose pentaacetate and β-acetochloroglucose proceed with very high degree of retention of configuration show clearly that C2-acetoxy group participation is extensive and must therefore provide an important driving force for the dissociation (16). This conclusion is strongly supported by the fact that 1,2-*cis*-β-mannopyranose pentaacetate is less reactive than the 1,2-*trans*-α-anomer in spite of the fact that the latter compound is the more stable substance (11). It is of definite interest to note that the higher reactivity of the β-chloride (I) over the α-chloride (II) is probably due to steric considerations which resemble those responsible for the higher reactivity of β-mannopyranose pentaacetate over α-glucopyranose pentaacetate (11). Winstein and Roberts (17) have pointed out that dissociation with participation of a neighboring acetoxy group probably requires an axial–axial orientation as shown in formula V for β-D-acetochloroglucose. This consideration lends considerable weight to the idea that the β-chloride (I) undergoes dissociation in the conformation shown.



V

In contrast to reactions in acetic acid, the reactions of the glucosyl chlorides I and II with silver acetate in dry ether led to extensive racemization of the anomeric center. Gakhokidze (6) has reported the preparation of 1,3,4,6-tetra-*O*-acetyl-β-D-glucose by reaction of the β-chloride (I) under these conditions. We have now shown by isotopic dilution analysis that the product contains 43.3% of the 1,3,4,6-tetra-*O*-acetyl-α-D-glucose. Reaction of the α-chloride II gave only a 44.6% yield of the Walden inversion product. These results are in accordance with expectation for an ionic reaction under these reaction conditions since solvation of the carbonium ion by ether (8) would lead to an equilibrium mixture of the various possible conformations for the carbonium ion.

EXPERIMENTAL

Methods

The kinetic studies and the determinations of radioactivity were carried out as previously described (10, 11). Each experiment was done in duplicate.

Isolation and Analysis of Reaction Products

Table I, experiment 2—the solvent was removed *in vacuo* and the residue was crystallized from ether to give a 72% yield of crude 1,3,4,6-tetra-*O*-acetyl-α-D-glucose, m.p. 88–92°C. The melting point after one recrystallization, 96–98°C., was not depressed by the pure α-tetraacetate, m.p. 97–98°C. (13).

Table I, experiment 7—hydrogen sulphide was passed into the reaction mixture to precipitate mercuric sulphide and the filtrate was evaporated *in vacuo* to a sirup which was monochloroacetylated as previously described (13). The product was crystallized from ethanol to give a 90% yield of crude 2-*O*-monochloroacetyl-α-D-glucopyranose tetraacetate (13), m.p. 130–136°C., $[\alpha]_D$ +96° (chloroform). The substance was characterized by mixed melting point determination after purification.

The products from experiments 5 and 6 of Table I contained about 0.4% chlorine. Therefore, the reactions were essentially free of anomerization of the β-chloride (13).

Table II, experiment 2—hydrogen sulphide was used to precipitate mercuric sulphide and concentration of the filtrate *in vacuo* gave a sirup which was crystallized from ethanol. The yield was 72% of a substance, m.p. 132–135°C., whose melting point was not depressed by 1,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose (13), m.p. 137–138°C.

The 3,4,6-tri-*O*-acetyl-D-glucosyl chloride, 1 mM., was shaken with 2 mM. silver acetate in 10 ml. dry ether for 16 hr. The product, isolated in the usual manner, was diluted with a known amount of radioactive 1,3,4,6-tetra-*O*-acetyl-D-glucose (13) of known radioactivity for isotopic dilution analysis. Starting with the β-chloride (I), the α-tetraacetate was isolated by crystallization and from the radioactivity it could be calculated that it comprised 43.3% of the reaction product. The reaction product from the α-chloride (II), was shown to contain 44.6% β-tetraacetate using this procedure.

THE EFFECT OF CHLORINE SUBSTITUTIONS AT THE C_2-ACETOXY GROUP ON SOME PROPERTIES OF THE GLUCOSE PENTAACETATES[1]

By R. U. Lemieux,[2] Carol Brice, and G. Huber[3]

ABSTRACT

The effects were studied of substituting one, two, and three chlorine atoms at the C2-acetoxy group of the α- and β-D-glucopyranose pentaacetates on the rates both of anomerization and of dissociation of the C1 to acetoxy group bond in 1 : 1 acetic acid – acetic anhydride 0.5 *M* with respect to sulphuric acid at 25°C. In the case of the α-anomers, the rates of anomerization appeared about equal to the rates of dissociation as measured by isotopic exchange. The β-anomers dissociated more rapidly than they underwent anomerization. The difference in rate decreased rapidly, however, with the introduction of chlorine atoms indicating that the tendency for C2-acyl group participation in the dissociation is reduced by the chlorine substitutions. Evidence was obtained that only a very small fraction, if any, of the C1-acetoxy group of β-glucose pentaacetate passes into the α-anomer without becoming completely dissociated. It is pointed out that the data for the anomerizations can be rationalized on the basis of ionic mechanisms, if specific conformations are allocated to the intermediate carbonium ions.

INTRODUCTION

The high reactivity of β-D-glucopyranose pentaacetate as compared to the α-anomer in undergoing dissociation of the C1 to acetoxy group bond through the agency of acid catalysts has been demonstrated under the following conditions: mercaptolysis using zinc chloride in ethyl mercaptan (4), exchange of acetate with stannic trichloride acetate in chloroform (5), replacement by chlorine using titanium tetrachloride in chloroform (5), methanolysis using stannic chloride as catalyst in either benzene or chloroform (9), and phenolysis using toluene sulphonic acid as catalyst (14, 18). Lemieux (4) has pointed out that the high reactivity of the 1,2-*trans*-β-anomer is in all probability related to participation of the C2-acetoxy group in the dissociation. Direct evidence for the participation was recently obtained through the preparation of methyl 1,2-ortho-*O*-acetyl-α-D-glucopyranose triacetate by reacting tetra-*O*-acetyl-β-D-glucopyranosyl chloride with methanol in the presence of silver carbonate (6).

It was now of interest to study the effect of varying substituents at the C2-position on the dissociation of the C1 to acetoxy group bond. The anomeric monochloroacetyl, dichloroacetyl, and trichloroacetyl derivatives of the 1,3,4,6-tetra-*O*-acetyl-D-glucopyranoses (7) were chosen for this purpose since the C2-substituents in these compounds vary widely in electronegativity. A study was made of the behavior of these substances under the conditions for anomerization using 0.5 *M* sulphuric acid in 1 : 1 acetic acid – acetic anhydride

since Bonner (1) has shown these conditions to affect only the anomeric center and to be particularly well-suited for kinetic measurements. Painter (17) has also very recently made an extensive kinetic study of the behavior of the glucose pentaacetates in acetic acid – acetic anhydride mixtures which contained sulphuric acid.

The evidence, based mainly on qualitative infrared spectra (1), that anomerization of the glucose pentaacetates under these conditions leads to a product which contains only the α- and β-pentaacetates was substantiated by isotopic dilution analysis. The analytical results, listed in Table I, showed a composition for the equilibrium mixture which was in good agreement with the composition expected from its rotation. Bonner (1) has reported the equilibrium mixture to contain about 83% α- and 17% β-anomer. This conclusion was based on the rotation of the equilibrium product measured in chloroform. On the other hand, Painter (17) calculated the point of equilibrium from the kinetic data and concluded that the equilibrium mixture contains 87% α- and 13% β-anomer. We have substantiated both of these conclusions (see Table I)

TABLE I

ANALYSIS OF THE REACTION MIXTURE AT VARIOUS TIMES DURING THE ANOMERIZATION OF PENTA-*O*-ACETYL-β-D-GLUCOPYRANOSE

The anomerizations were carried out in 1 : 1 acetic acid – acetic anhydride 0.5*M* with respect to sulphuric acid at 25°C.

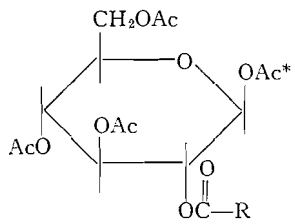
§By difference from the content of α-anomer.

but cannot explain the discrepancy. Since it is possible that the composition of the equilibrium product is altered during the isolation, Painter's method for obtaining the point of equilibrium was used in the present work.

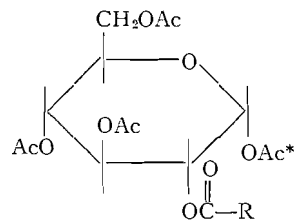
Table I lists the results of isotopic dilution analyses performed on reaction products isolated at a variety of times during the course of reaction before equilibrium was achieved. These results establish that the anomerizations do not proceed by way of isolable intermediates.

Lemieux and Brice (5) have shown that β-glucose pentaacetate is dissociated by stannic chloride in chloroform solution much more rapidly than it is converted to the α-anomer. The same situation was to be expected under the

present conditions of acetolysis. In order to measure the rates of dissociation under the present conditions, all but one of the compounds used in these studies (i.e., compounds I*a*, I*b*, I*c*, I*d*, II*a*, II*b*, II*d*) were prepared labelled with carbon-14 in the carbonyl group of the C1-acetoxy group and the rates at which the substances lost radioactivity by exchange of the C1-acetoxy group with



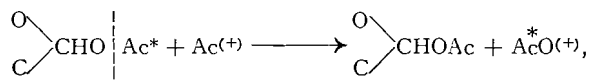
I*a*, R = CH_3
I*b*, R = CH_2Cl
I*c*, R = $CHCl_2$
I*d*, R = CCl_3



II*a*, R = CH_3
II*b*, R = CH_2Cl
II*c*, R = $CHCl_2$
II*d*, R = CCl_3

acetoxy groups from the environment were determined. The loss of radioactivity may of course have been brought about in two ways:

(*a*) by exchange of acetyl groups as acetyl carbonium ion,



and,

(*b*) by exchange of acetoxy groups as acetate ion,

There can be no doubt that the environment can serve as a source of either acetyl carbonium ions or acetate ions. Although direct evidence for the relative importance of the two routes is at present not available, the behavior of the glucose pentaacetates under the variety of reaction conditions listed above clearly demonstrates the C1 to acetoxy group bond to be the most acid-labile linkage in these compounds. Furthermore, the results obtained in the present study can be clearly rationalized only on the assumption of exchange by way of C1 to acetoxy group bond cleavage. Therefore, it is considered completely safe to conclude that the only important route for exchange was that which involved acetoxy groups.

The C1-acetoxy group-labelled β-D-glucose pentaacetate was subjected to anomerization at 25°C. in 1 : 1 acetic acid – acetic anhydride 0.5 *M* with respect to sulphuric acid. The reaction was stopped after 3, 5, and 10 min., the D-glucose pentaacetates were separated by chromatography on Magnesol–Celite (5 : 1) (12) and their radioactivities were determined. The results are listed in Table II. It is seen that as expected (5) the β-pentaacetate underwent exchange much more rapidly than it underwent anomerization. The radioactivity found in the α-anomer will be considered later on.

The fact that a sufficiently accurate value for the velocity constant for the exchange of the β-anomer can be obtained simply by determining the radioactivity of the reaction product after various periods of time is shown by the data listed in Table III. It is seen that this procedure yields a value of 0.46 min.$^{-1}$ for the velocity constant instead of the value of 0.41 min.$^{-1}$ given in Table II. The velocity constants given in Table III are all based on the radioactivity of the isolated reaction products. The plots in Figs. 1 and 2 illustrate the reproducibility of the experimental data from which these constants were calculated.

The data in Table III show that β-D-glucose pentaacetate undergoes exchange about 80 times more rapidly than the α-anomer. This result is consistent with the conclusions previously reached (4, 5) regarding the relative reactivities of these substances. Electronic theory would predict that the introduction of chlorine atoms at the C2-acetoxy groups of the glucose pentaacetates would affect strongly the ease for dissociation of the C1 to acetoxy group bond. Lemieux (4) has pointed out that there should be a strong direct effect in the case of the β-anomer due to reduction in the nucleophilic properties of the carbonyl oxygen of the C2-acetoxy group which would be brought about by each successive substitution of chlorine atoms. Thus, the chlorine substitutions should result in a decreasing tendency for participation in the dissociation and,

since the participation is the source of strong activation, a strong decrease in reactivity. That this is in fact the case is clear from the fact that the introduction of three chlorine atoms brought about a 390-fold reduction in reactivity. This should be compared to the case for the α-anomer where the introduction of three chlorine atoms brought about only a 50-fold reduction in reactivity. Here, the effect of the chlorine substituents on the dissociation must be exerted indirectly by induction transmitted *via* the C2-carbon atom. The introduction

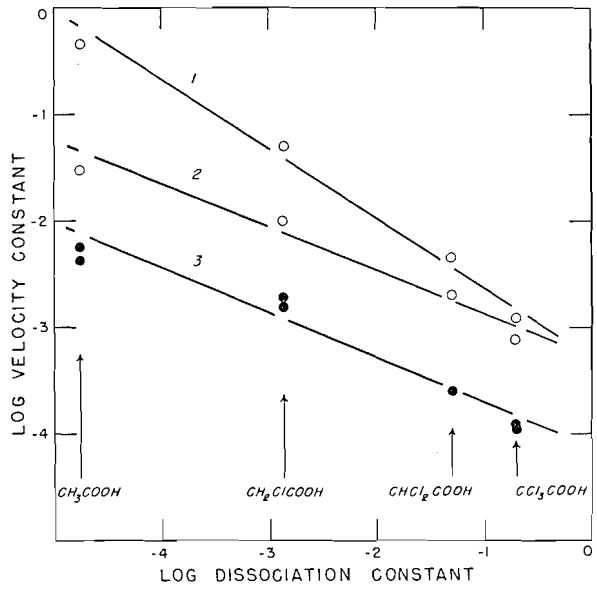

FIG. 3. Plots of log velocity constants (see Tables III and IV) against log dissociation constant for the acid derived from the C2-substituent of an acylated 1,3,4,6-tetra-*O*-acetyl-D-glucose. The dissociation constants are those published by Mason and Kilpatrick (13).

of chlorine atoms at the C2-acetoxy groups of the glucose pentaacetates of course adds greatly to the bulk of these groups. Consequently, it might be expected that these alterations would greatly affect the steric picture. The logarithms of the velocity constants for the exchange reactions are plotted in Fig. 3 against the logarithms of the dissociation constants for the acids present as esters at the C2-position. It is seen that the deviation from Hammett's linear free energy relationship (2) is not great. Consequently, it is apparent that in both series of compounds the steric requirements for reaction were not seriously affected by the introduction of chlorine atoms. Further support for this conclusion is given later on.

The results of polarimetric rate studies on the anomerization of the glucose derivatives (I*a*–I*d* and II*a*–II*d*) are listed in Table IV. The plots in Fig. 4 are

illustrative of the data from which the content of Table III was calculated. A consideration of the results shows that the point of equilibrium was affected only slightly by introducing chlorine atoms in the C2-acetoxy group of the glucose pentaacetates. Consequently, the velocity constants for the forward and reverse reactions were affected about equally by each successive substitution. This comprises strong evidence that the substitutional changes affected the rates of anomerization mainly through electronic phenomena and that the increase in the size of the group through substitution of chlorine for hydrogen had a relatively small effect. This conclusion should be compared with the views recently expressed by Newth and Phillips (15) who contended that the trichloroacetyl group in 2-*O*-trichloroacetyl-β-D-glucopyranosyl chloride exerts a strong shielding effect on the C1-chlorine atom.

It seems clear (10, 11) that acetylated alkyl glycopyranosides undergo anomerization under conditions for acetolysis by way of an intramolecular mechanism. Lemieux *et al.* (10) have studied the anomerization of methyl

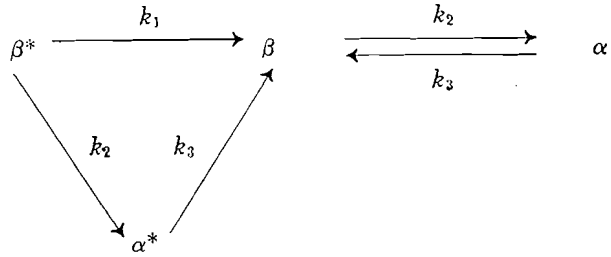
β-D-glucopyranoside tetraacetate under the conditions used herein for the anomerization of the glucopyranose pentaacetates. Since it must be expected that the anomerization of β-D-glucopyranose pentaacetate would have a tendency to follow the same path as the anomerization of methyl β-D-glucopyranoside tetraacetate, any consideration of the mechanism of the latter reaction must first deal with the possibility that the reaction proceeds by way of an intramolecular mechanism.

C1-Acetoxy-group-labelled β-D-glucopyranose pentaacetate was subjected to anomerization and the α-anomer which had formed after various intervals of time was isolated by chromatography and its radioactivity was determined. The data which were obtained are listed in Table II. It is seen that the α-anomer appeared to gain radioactivity directly from the β-anomer since the initially formed α-anomer was more radioactive than samples isolated later on. It is possible that this result was due to the presence of a small amount (about 0.2%) of radioactive α-compound in the starting material. However, it is considered more probable that the result indicates the occurrence of intramolecular anomerization. It was found that the extent of the intramolecular route, if in fact present, was very small by comparing the experimental values

shown in Table II with those expected from calculations based on the assumption that anomerization occurred entirely by way of an intramolecular mechanism. The calculations were based on the following scheme where k_1 is the velocity constant for dissociation of the β-anomer (k_β of Table III), $k_2 = k_{\beta\to\alpha}$, and $k_3 = k_{\alpha\to\beta}$. The reconversion of radioactive α-form to radioactive β-form



need not be considered since this would merely raise our calculated values for the radioactivity of the α-form at any given time by a negligible amount. The rate of formation of α^* can be expressed as,

$$d[\alpha^*]/dt = -d[\beta^*]/dt - d[\beta]/dt.$$

Since the rate of disappearance of β^* is expressed by

[1] $$-d[\beta^*]/dt = (k_1+k_2)\,[\beta^*]$$

and the rate of formation of β is given by

$$d[\beta]/dt = k_1[\beta^*]+k_3[\alpha^*],$$

then

$$d[\alpha^*]/dt = k_2[\beta^*]-k_3[\alpha^*].$$

Integration of equation [1] yields

$$[\beta^*] = [\beta^*]_0\, e^{-(k_1+k_2)\,t}.$$

Therefore,

$$d[\alpha^*]/dt = [\beta^*]_0\, k_2 e^{-(k_1+k_2)\,t} - k_3[\alpha^*].$$

Integration of this linear differential equation using the integrating factor $R = \exp \int k_3\, dt$ yields the expression,

$$[\alpha^*]_t = [\beta^*]_0 \frac{k_2}{k_3 - k_1 - k_2} (e^{-(k_1+k_2)\,t} - e^{-k_3 t}),$$

from which the concentration of α-anomer, $[\alpha^*]_t$, which was formed from radioactive β-anomer after any given time t can be calculated. The concentration of α-anomer, $[\alpha^*]+[\alpha]$, at any given time can be calculated from the integrated expression for reversible first-order reactions,

$$[\alpha^*] + [\alpha] = [\beta^*]_0 \frac{k_2}{k_2 + k_3} (1 - e^{-(k_2+k_3)\,t}).$$

Therefore, the radioactivity of α-anomer, C_t, isolated at time t would be,

$$c_t = c_0[\alpha^*]_t/([\alpha^*]+[\alpha]),$$

where c_0 is the original radioactivity of the β-anomer. The calculated values

for c_t after 3, 5, and 10 min. are given in Table V. A comparison of these results with the values actually obtained which are listed in Table II shows clearly that intramolecular anomerization is an unimportant reaction route.

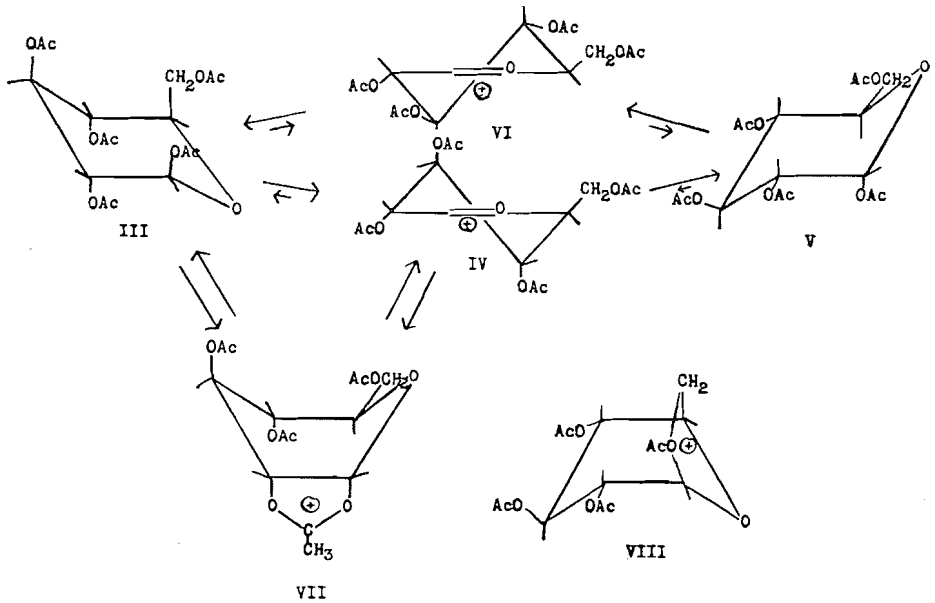
Bonner (1) has proposed a mechanism for the anomerization under the present reaction conditions which would involve a cyclic six-membered intermediate formed between the sugar acetate and a carbonium ion derived from acetic anhydride. Examination of the data in Tables III and IV shows that within experimental error* the velocity constants for anomerization of an α-anomer (compounds II*a*, II*b*, and II*d*) are equal in value to the velocity constants for exchange. This situation is required by Bonner's mechanism or any other S_N2 type mechanism which can be formulated. However, Painter (17) has recently published the results of an extensive kinetic study of the anomerization of the D-glucopyranose pentaacetates in mixtures of acetic acid – acetic anhydride catalyzed both by sulphuric acid and by perchloric acid and concluded from a consideration of the results that the anomerizations proceed by way of sugar acetate carbonium ions. Our present evidence that the rate of anomerization for the α-form was essentially equal to that of dissociation of the C1 to acetoxy group bond might appear to contradict this conclusion. However, Lemieux and Huber (8) have obtained evidence that other similar reactions of derivatives of D-glucopyranose proceed by way of carbonium ions with extensive inversion of the anomeric center. This result was rationalized on the basis of the assumption that the double-bond character introduced at the C1 to ring-oxygen bond imposed a conformation on the ion which rendered the ion more likely to form the inverted product.

We submit that the following mechanisms for the anomerization of the D-glucopyranose pentaacetates is an attractive rationalization of the experimental data thus far obtained. First of all, as was seen above, intramolecular anomerization is undoubtedly unimportant for the *beta* to *alpha* transformation. As it was indicated above, the data for the *alpha* to *beta* anomerization can be rationalized by assuming that the α-pentaacetate (V) dissociates to the

**The experimental error is rather large. For example, if Bonner's value for the equilibrium constant for the anomerization of the glucose pentaacetates is used to calculate the velocity constants, the value of $k_{\alpha\rightarrow\beta}$ becomes 0.0056 min.$^{-1}$ instead of 0.0042 min.$^{-1}$ as listed in Table III.*

carbonium ion (VI) which by virtue of its conformation tends to form the β-pentaacetate (III) on interaction with the environment. The *beta* to *alpha* transformation can be assumed to proceed by way of the carbonium ion (IV) which because of its conformation can be expected (8) to preferentially form the α-pentaacetate. However, as it was seen above the present data show clearly that the β-anomer (III) is rapidly dissociated to the 1,2-α-cyclic carbonium ion (VII). Since direct replacements with retention of configuration are not known, the α-pentaacetate cannot be expected to be formed by direct interaction of this ion with the environment. However, the discovery by Hurd and Holysz (3) that the 1,2-cyclic ketals are formed in the reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide with dialkyl cadmium shows that the 1,2-α-cyclic carbonium ion (VII) can be formed from other carbonium ions. Since the reverse must be expected, the anomerization must follow to some extent the route III → VII → IV → V. The relative importance of these



theoretically plausible routes for the *beta* to *alpha* conversion cannot be assessed. Lemieux and Brice (5) have proposed similar reaction routes for the anomerization of β-glucopyranose pentaacetate in chloroform catalyzed by stannic chloride. It was pointed out that the rearrangement of the 1,2-α-cyclic ion (VII) to the 1,6-β-cyclic ion (VIII) is a further stereochemically possible step for the reaction.

In summary, evidence was obtained to show that the substitution of chlorine atoms at the C2-acetoxy group of β-D-glucopyranose pentaacetate greatly reduces the tendency for this group to participate in dissociation of the C1 to acetoxy group bond. Thus, the fact that the velocity constants for dissociation were 15, 5, and 1.5 times that for β → α anomerization when the C2-substituent was acetoxy, monochloroacetoxy, and trichloroacetoxy, respectively,

renders clear the reason why β-D-acetochloroglucose and 2-*O*-trichloroacetyl-β-D-glucosyl chloride triacetate yield mainly β-D-glucose pentaacetate (6) and 2-*O*-trichloroacetyl-α-D-glucose tetraacetate (7) respectively, on reaction with silver acetate in acetic acid. The results comprise direct evidence in support of the contention (4) that participation of the C2-acetoxy group provides an important driving force for dissociation of a β-C1-substituent. The fact that 2-*O*-trichloroacetyl-β-D-glucopyranose tetraacetate underwent dissociation six times more rapidly than the α-anomer together with the previous observation (8) that 3,4,6-tri-*O*-acetyl-β-D-glucosyl chloride is more reactive than the α-anomer shows that the high reactivity of β-D-glucopyranose pentaacetate (4, 5) and β-D-acetochloroglucopyranose (6) as compared to their α-anomers is not entirely due to C2-acetoxy group participation. Lemieux and Huber (8) have suggested that the higher reactivity of a β-compound may be related to the presence of *cis* C3- and C5-substituents.

EXPERIMENTAL

Methods

The samples were converted to barium carbonate for measurement of the radioactivities at "infinite thickness" in a windowless counter operating with helium–isobutane. Appropriate resolving-time and background corrections were made. Duplicate determinations did not differ by more than 3%.

The polarimetric measurements were made using a 2 dm. polarimeter tube and precision polarimeter. The temperature was controlled within ±0.1°C.

The rates of reaction were measured as follows. The glucose derivative, 2 mM., was dissolved in 8 ml. of 50 : 50 acetic acid – acetic anhydride in a 20 ml. volumetric flask. Sulphuric acid, 1.026 gm. of 95.5% acid, 10 mM., was added to 8 ml. of the solvent mixture and the solution was cooled. The solutions, brought to 25°C., were mixed at zero time and the volume was adjusted to 20 ml. with solvent mixture. This could be done very rapidly by using syringes. The polarimetric rates were determined in the usual way (1). In order to follow the rate of disappearance of radioactivity, 2 ml. samples were removed at various time intervals and plunged into 50 ml. of water. The product was isolated by extraction with chloroform. The chloroform extract was washed with bicarbonate solution, then with water and dried over sodium sulphate. The chloroform was removed *in vacuo* and the sample was dried over phosphorus pentoxide in high vacuum before analysis.

In order to determine the radioactivities of both the β- and α-forms in a reaction mixture to yield the data listed in Table II, the major component was isolated by crystallization and the minor component was isolated by chromatography of the combined mother liquors on Magnesol–Celite (5 : 1) according to the procedure of McNeely *et al.* (12). The materials were recrystallized several times to achieve a very high degree of purity.

The isotopic dilution analyses listed in Table I were carried out by adding a sufficiently large radioactive sample of the anomer to be estimated to a sample of reaction product to allow the substance to be isolated from the resultant mixture by fractional crystallization. The amount of the anomer in the

reaction mixture was calculated from the expression,

$$\% \text{ anomer} = (100x/y)\,[(c_i - c_f)/c_f],$$

when x gm. of radioactive anomer of c_i c.p.m. was added to y gm. of reaction product to be analyzed and c_f was the radioactivity in counts per minute of the pure anomer isolated from the mixture.

The specific reaction rates listed in Tables II and III were calculated from the polarimetric data using the integrated rate expression,

$$k_\alpha + k_\beta = (2.303/t) \log [(\alpha_0 - \alpha_e)/(\alpha_t - \alpha_e)].$$

The rate of exchange, R, for a simple exchange reaction can be calculated from the relationship,

$$R = -\frac{[A][B]}{[A]+[B]} \cdot \frac{1}{t} \ln(1-F),$$

where $[A]$ is the concentration of the exchangeable group in one reactant (in the present case sugar acetate), $[B]$ is the concentration of the exchangeable group in the other reactant (in the present case the acetic acid and acetic anhydride), and the fraction exchange at time t is,

$$F = (c_t - c_0)/[(c_\infty - c_0)].$$

c_0, c_∞, and c_t are the radioactivities of the sugar acetate at zero time, infinite time, and time t, respectively. In the present case, the dissociation of the sugar acetate undoubtedly controlled the rate of exchange. Therefore, the specific rate of exchange, k, can be calculated from the relationship,

$$k = \frac{R}{[A]} = -\frac{[B]}{[A]+[B]} \cdot \frac{1}{t} \ln(1-F).$$

Since $[B]$ was great as compared to $[A]$, the specific reaction rates listed in Table II were calculated from the expression,

$$k = (2.303/t) \log(c_0 - c_\infty)/[(c_t - c_\infty)],$$

which is sufficiently accurate for the present purposes. Analysis showed the presence of 180 acetoxy groups in the environment per mole of glucose derivative. Thus, the radioactivity at infinite time would be expected to be 1/181 of the original radioactivity. In practice, the agreement with this value was very good (compare Tables II and V).

Materials

The radioactive acetate was labelled in the carboxyl group with carbon-14.

C1-Acetoxy-labelled penta-*O*-acetyl-β-D-glucopyranose was prepared by treating acetobromoglucose with radioactive silver acetate in dry acetonitrile (5). The product was recrystallized from ethanol until pure. Radioactive penta-*O*-acetyl-α-D-glucopyranose was prepared by anomerization of the β-anomer using stannic chloride in chloroform solution (5, 16). Purification was by recrystallization from ethanol.

The C1-acetoxy-labelled chloro-compounds were prepared by acylating the C1-acetoxy-labelled α- and β-1,3,4,6-tetra-*O*-acetyl-D-glucoses under the conditions described in a previous publication (7). The compounds were recrystallized from ethanol until pure. The C1-acetoxy-labelled glucose tetraacetates were prepared as follows. A mixture of radioactive silver acetate, 1.7 gm., 3,4,6-tri-*O*-acetyl-α-D-glucosyl chloride, 3.24 gm., and 75 ml. of dry ether which contained one drop of acetic acid was shaken for 12 hr. at room temperature. The silver salts were removed by filtration. Evaporation gave 3.1 gm. of product, m.p. 131–135°C. Pure 1,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose, m.p. 137–138°, was obtained after two recrystallizations from ethanol. The 1,3,4,6-tetra-*O*-acetyl-α-D-glucose was prepared in the same manner starting from 3,4,6-tri-*O*-acetyl-β-D-glucosyl chloride except that the reaction time was extended to 24 hr. and purification was achieved by crystallization from ether – petroleum ether.

THE ACETOLYSES OF THE *ALPHA* AND *BETA* METHYL D-GLUCOPYRANOSIDE TETRAACETATES[1]

By R. U. Lemieux,[2] W. P. Shyluk, and G. Huber[3]

ABSTRACT

The acetolyses of the *alpha* and *beta* methyl D-glucopyranoside tetraacetates in 1 : 1 acetic acid – acetic anhydride 0.5 *M* with respect to sulphuric acid were followed at 25°C. by isotopic dilution analysis of products isolated after various intervals of time. The reaction of the α-glucoside was found to proceed mainly with inversion of the anomeric center. On the other hand, the β-glucoside was found to undergo acetolysis with retention of configuration concurrent with anomerization. It was shown that the polarimetric changes observed in the course of the reactions could be satisfactorily accounted for on the basis of these reaction routes. Reaction mechanisms are suggested.

Montgomery *et al.* (15) investigated the use of either sulphuric acid or zinc chloride in acetic acid – acetic anhydride as a reagent for the acetolysis of glycosides. It was shown that in many cases the glycoside was converted to a mixture of the anomeric sugar acetates in high yield and the procedure has been widely used for the cleavage of acetal bonds in carbohydrate chemistry. Studies on the acetolysis of the anomeric methyl D-arabinopyranoside triacetates showed these reactions to be highly complex (15). A solution at 20°C. of methyl α-D-arabinopyranoside triacetate in a mixture of 4% sulphuric acid in 7 : 3 acetic anhydride – acetic acid changed sharply in specific rotation from −19° to −114° in one minute and declined to an equilibrium value of −25° at the end of 20 min. The hexaacetate of *aldehydo*-D-arabinose and β-D-arabinopyranose tetraacetate were isolated in yields of 50% and 12%, respectively, from the product. However, when the experiment was interrupted at the rotation peak of −114°, a 14% yield of methyl β-D-arabinopyranoside triacetate was obtained. Thus, it was apparent that the rapid initial rise in rotation was due to the anomerization of the α-anomer to the more stable β-form. This possibility was strengthened by the observation that methyl β-D-arabinopyranoside triacetate under the same conditions gave a solution which changed in specific rotation from −184° to a constant equilibrium value of −17° in three minutes. The hexaacetate and the β-tetraacetate could be isolated in 56% and 11% yields, respectively, after 24 hr. The occurrence of the hexaacetate in the reaction products suggested that the C1 to ring-oxygen bond may cleave in preference to the C1 to methoxyl group bond. This idea was substantiated by the acetolysis of the β-arabinoside under the milder conditions of 0.16% sulphuric acid in 7 : 3 acetic anhydride – acetic acid mixture. Both the anomeric forms of methyl hemiacetal pentaacetates (I) were isolated in good and approximately equal yields. It is to be noted that

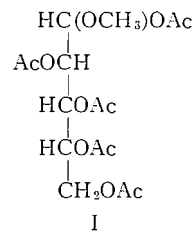
the high levorotation which was achieved in the



I

case of the α-D-arabinoside indicates that the susceptibility to ring cleavage is a property of the β-D-anomer.

More recently, Lindberg (1, 2, 13) has obtained further evidence that the acetolysis of an unstable *O*-acetylated alkyl glycopyranoside is accompanied by anomerization. This was shown to be so for a variety of glucosides (13), galactosides (1), and a xyloside (2) when treated in 10 : 3 acetic anhydride mixture containing sulphuric acid. Lindberg (13) obtained evidence for the presence of peracetylated *aldehydo*-sugar in the product of these reactions. A theory for the mechanism of the anomerization was formulated (13) on the basis of the presence of these open-chain compounds in the products and the polarimetric rates observed.

The present authors undertook to elaborate in detail the course of the acetolysis of both the α- and β-methyl D-glucopyranoside tetraacetates with the hope that the results would provide a firmer basis for work in this complex field. The glucosides were subjected to acetolysis at 25°C. in 1 : 1 acetic acid – acetic anhydride mixture 0.5 *M* with sulphuric acid since these conditions were chosen by Bonner (3) in a thorough kinetic study of the anomerization of the glucopyranose pentaacetates. Furthermore, Bonner's results were closely reproduced in this laboratory (9) in a study of the behavior of the glucopyranose pentaacetates and related compounds under conditions of acetolysis and it was desirable that the results of this study be of use in the present work.

First of all, it is of interest to note the polarimetric changes which occurred when the acetylated glucosides were subjected to the conditions for acetolysis. The results of typical runs are plotted in Fig. 1. Superficially, these results would appear to indicate that the two glucosides reacted at about equal rates, a result in complete disagreement with what could be expected on the basis of the rather great difference in reactivity noted for the glucopyranose pentaacetates under these conditions where β-anomer was found to dissociate 80 times more rapidly than the α-form (9). Thus, it was clear from the beginning that in all likelihood these polarimetric rates were complex expressions which were not susceptible to simple interpretation.

Methyl α-D-glucopyranoside tetraacetate was subjected to the acetolysis and reaction products were isolated after a variety of intervals of time. The methoxyl contents of these samples were determined by the procedure of Hoffman and Wolfrom (5). Care had to be taken in the interpretation of these values since in view of the above described experiences of Montgomery *et al.*

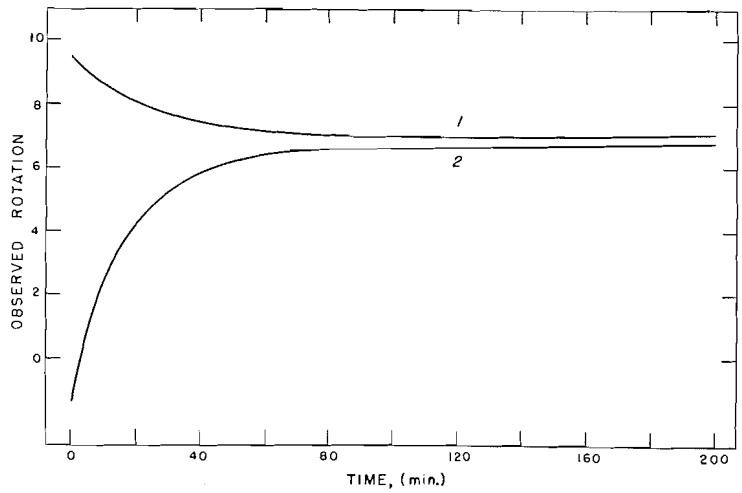


FIG. 1. Polarimetric rates for the acetolysis of the *alpha* (curve 1) and *beta* (curve 2) methyl D-glucopyranoside tetraacetates in 1 : 1 acetic acid – acetic anhydride 0.5 *M* with respect to sulphuric acid at 25°C.

(15) it was possible that these samples contained *aldehydo*-glucose methyl hemiacetal hexaacetate as well as methyl α-D-glucopyranoside tetraacetate. The following analytical method was designed to test for this possibility. The reaction products were saponified to liberate methanol from the acetylated hemiacetal group, and the methanol was removed from the reaction mixture by distillation for estimation by conversion to formaldehyde with potassium permanganate and determination of the formaldehyde by the chromotropic acid colorimetric method (4). The results are listed in Table I. The differences

**Amount of methyl α-D-glucopyranoside tetraacetate in the product.*
†Amount of D-glucose methyl hemiacetal hexaacetate in the product.
‡Determined by isotopic dilution analysis.

between these methoxyl values and the total methoxyl content could be attributed to the starting material methyl α-D-glucopyranoside tetraacetate since, even though the anomerization of the glucosides is probably reversible, the amount of methyl β-D-glucopyranoside tetraacetate present at any time was undoubtedly negligible for the present purposes. This conclusion was substantiated by isotopic dilution analysis of the products isolated after 30 and 90 min. reaction times for their methyl α-D-glucopyranoside tetraacetate contents. The results, listed in Table I, show a good agreement between the methyl α-D-glucopyranoside tetraacetate contents when determined in both ways.

The reaction of methyl α-D-glucopyranoside tetraacetate (B) under the conditions for acetolysis could therefore be represented by the scheme

$$E \xleftarrow{k_6} B \xrightarrow{k_3} C$$

wherein glucosidic cleavage yields a glucopyranose pentaacetate (C) with the velocity constant k_3 and ring cleavage yields the *aldehydo*-glucose methyl hemiacetal hexaacetate (E) with the velocity constant k_6. On this basis, the fraction of B (C_B) in the product at any given time was

$$[1] \qquad C_B = e^{-(k_3+k_6)t}.$$

The rate of the appearance of E is expressed by

$$dC_E/dt = C_B k_6 = k_6 e^{-(k_3+k_6)t},$$

and integration of this expression yields

$$[2] \qquad C_E = \frac{k_6}{k_3+k_6}(1-e^{-(k_3+k_6)t}).$$

Using expression [1], the value for k_3+k_6 could be calculated from the data in Table I and found to be 0.0082 min.$^{-1}$ (average value). Knowing k_3+k_6 and values for C_E at a variety of times (see Table I), the value of k_6 could be calculated using expression [2]. Thus, as shown in Table I, the average values $k_3 = 0.0075$ min.$^{-1}$ and $k_6 = 0.0007$ min.$^{-1}$ were obtained for the acetolysis of methyl α-D-glucopyranoside tetraacetate in 1 : 1 acetic acid – acetic anhydride mixture 0.5 *M* with respect to sulphuric acid at 25°C.

It was now of interest to determine which of the anomeric D-glucopyranose pentaacetates was the first product of the main reaction path. A decision was reached by accounting for the polarimetric change which took place in the course of the reaction. For the reaction sequence

$$E \xleftarrow{k_6} B \xrightarrow{k_3} C \underset{k_5}{\overset{k_4}{\rightleftharpoons}} D,$$

where C and D are the two D-glucopyranose pentaacetates, the change in the

fraction of C (C_C) in the product with time is expressed by

$$dC_C/dt = C_B(k_3+k_6) - C_Bk_6 - C_Ck_4 + C_Dk_5.$$

Since $C_Dk_5 = k_5(1-C_B-C_C-C_E)$, this expression can be converted to

$$dC_C/dt = C_Bk_3 - C_Ck_4 + k_5 - C_Bk_5 - C_Ck_5 - C_Ek_5.$$

Substitution of expressions [1] and [2] for C_B and C_E yields the following equation,

$$dC_C/dt = (k_3-k_5)e^{-(k_3+k_6)t} - C_C(k_4+k_5) + k_5 - [k_5k_6/(k_3+k_6)](1-e^{-(k_3+k_6)t}).$$

Integration using the integrating factor $\exp \int (k_4+k_5)\,dt$ and solving for the integration constant yields the following expression for the fraction of C at any given time:

$$[3] \qquad C_C = \frac{k_3-k_5}{(k_4+k_5)-(k_3+k_6)}\left[e^{-(k_3+k_6)t} - e^{-(k_4+k_5)t}\right] + \frac{k_5}{k_4+k_5}\left[1-e^{-(k_4+k_5)t}\right] + \frac{k_5k_6}{(k_3+k_6)(k_4+k_5)}\left[e^{-(k_4+k_5)t}-1\right] + \frac{k_5k_6}{(k_3+k_6)(k_4+k_5-k_3-k_6)}\left[e^{-(k_3+k_6)t} - e^{-(k_4+k_5)t}\right].$$

The value of C_C at any given time could be calculated using this expression since the four velocity constants were known. As was mentioned above, Bonner (3) has published velocity constants for the anomerization of the D-glucopyranose pentaacetates under the present conditions for acetolysis and the values were reproduced by Lemieux *et al.* (9). The average values obtained by the latter workers, $k_{\beta\to\alpha} = 0.0306$ min.$^{-1}$ and $k_{\alpha\to\beta} = 0.0043$ min.$^{-1}$, were used in the present calculations. The amount of the other D-glucopyranose pentaacetate (C_D) was calculated by difference,

$$C_D = 1-(C_B+C_C+C_E).$$

Thus, the change in the composition of the reaction mixture could be calculated on the basis that β-D-glucopyranose pentaacetate was the first product (C) of the reaction in which case $k_4 = k_{\beta\to\alpha}$ and $k_5 = k_{\alpha\to\beta}$ or, on the other hand, on the basis that the α-pentaacetate was formed first and $k_4 = k_{\alpha\to\beta}$ and $k_5 = k_{\beta\to\alpha}$. The results of these calculations are plotted in Fig. 2.

The contribution to the rotation of the reaction mixture at any given time made by the small amount of by-product E must have been small and, therefore, the rotation of the reaction mixture (α_t) was essentially completely due to the presence of the three other components (B, C, and E). Since at unit concentration (0.1 *M*) methyl α-D-glucopyranoside tetraacetate, β-D-glucopyranose pentaacetate, and α-D-glucopyranose pentaacetate were found by extrapolation to possess rotations of +9.45°, +0.49°, and +8.76°, respectively, it could be expected that the rotation of the reaction mixture at any given time would be closely approximated by the expression

α_t = 9.45 × fraction of α-glucoside + 0.49 × fraction of β-pentaacetate + 8.76 × fraction of α-pentaacetate.

**Calculated on the basis that β-D-glucopyranose pentaacetate is the first reaction product.*
†Calculated on the basis that α-D-glucopyranose pentaacetate is the first reaction product.
‡Calculated using the expression $k = (2.303/t) \log [(\alpha_0 - \alpha_\infty)/(\alpha_0 - \alpha_t)]$.
§The rotation of the D-glucose methyl hemiacetal hexaacetate was neglected.

The results of calculations made on this basis are given in Table II. Furthermore, Table II contains the polarimetric velocity constants which can be calculated from these results. A comparison of the calculated polarimetric velocity constants with that observed shows that, while the results obtained on the basis that the β-pentaacetate was the first product agree fairly well with those observed, the results of calculations based on the assumption that the α-anomer was formed first are in strong disagreement. Thus, it was clear that the acetolysis of methyl α-D-glucopyranoside tetraacetate proceeds mainly with inversion of the anomeric center to yield β-D-glucopyranose pentaacetate. It is noteworthy in this respect that α-D-glucopyranose pentaacetate undergoes mercaptolysis (7) and acetolysis (9) with inversion of the anomeric center—a stereochemical route which has long been recognized for the reaction of acetylated α-D-glucopyranosyl halides under conditions for the Koenigs–Knorr type of reaction (6, 10, 16).

The above information on the acetolysis of methyl α-D-glucopyranoside tetraacetate allowed the consideration of the more complex reaction of the β-anomer under the same reaction conditions. The reaction was followed by isolating samples of the reaction product after various intervals of time and determining the amounts of unreacted methyl β-D-glucopyranoside tetraacetate, methyl α-D-glucopyranoside tetraacetate, β-D-glucopyranose pentaacetate, and α-D-glucopyranose pentaacetate in the material by isotopic dilution analysis. This was accomplished by adding weighed amounts of radioactive samples of these materials to a weighed sample of a reaction product, separating the four components by chromatography on Magnesol–Celite (14), determining the radioactivity of the pure compounds thus isolated, and calculating the fraction of each substance in the reaction product using the expression

$$\text{fraction in reaction product} = (x/y)[c_i - c_f)/c_f]$$

where x gm. of radioactive sample of c_i c.p.m. was added to y gm. of reaction product and c_f was the radioactivity in counts per minute of substance isolated. The results from these analyses are listed in Table III where the methoxyl

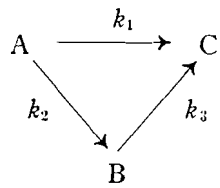
By isotopic dilution analysis.

contents found for each of the reaction products are also given. First of all, it is to be noted that for the first part of the reaction the methyl D-glucopyranoside tetraacetate contents expected from the methoxyl values were in good agreement with those found by isotopic dilution analysis. Secondly, it is to be noted that the analyses for the four components accounted very well for all of the reaction products. Therefore, it could be concluded that the α-glucoside and the two glucose pentaacetates were the only isolable reaction products formed in appreciable amounts and that the reaction could be represented by the following scheme wherein A, B, and C are the methyl β-D-glucopyranoside tetraacetate, methyl



α-D-glucopyranoside tetraacetate, and D-glucopyranose pentaacetate, respectively. For this reaction scheme,

[4] $$-dC_A/dt = (k_1+k_2)C_A$$

and therefore,

[5] $$C_A = e^{-(k_1+k_2)t}.$$

Knowing C_A at a variety of times (Table II) and using equation [4], an average value for k_1+k_2 could be calculated (see Table III). The rate of change in the amount of B at any given time is expressed by

$$dC_B/dt = -(dC_A/dt)-(dC_C/dt)-(dC_D/dt).$$

Since $$dC_C/dt = C_Bk_3+C_Dk_5-C_Ck_4$$

and $$dC_D/dt = C_Ak_1+C_Ck_4-C_Dk_5,$$

then $$dC_B/dt = k_2C_A-k_3C_B$$

$$= k_2e^{-(k_1+k_2)t}-C_Bk_3.$$

Integration using the integrating factor $\exp \int k_3\,dt$ and solving for the integration constant yields

[6] $$C_B = \frac{k_2}{k_3-(k_1+k_2)}\,[e^{-(k_1+k_2)t}-e^{-k_3t}].$$

The value for k_3 under the present reaction conditions was determined in the above described study of the acetolysis of methyl α-D-glucopyranoside tetraacetate. Thus, k_3 and k_1+k_2 being known, using equation [6] and the values for C_B given in Table III, values for k_2 could be calculated. The results of these calculations are given in Table IV.

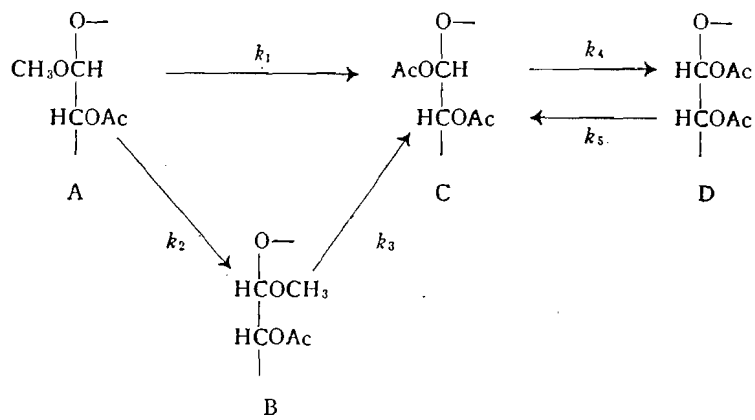
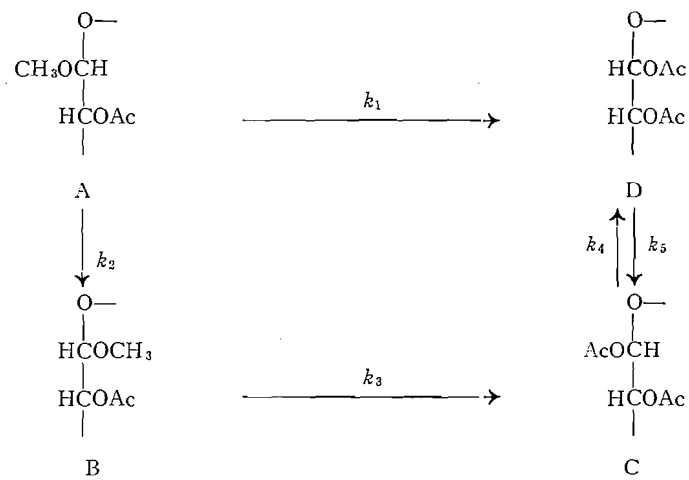
Scheme 1



Scheme 2



It was now of interest to attempt a decision on whether or not one of the anomeric D-glucopyranose pentaacetates was formed preferentially on the acetolysis of methyl β-D-glucopyranoside tetraacetate. A decision was reached by showing that the reaction (scheme 1) which possesses β-D-glucopyranose pentaacetate (C) as the first product of the reaction can account for the experimental data listed in Table III much more satisfactorily than that (scheme 2) which has α-D-glucopyranose pentaacetate as the initial product.

Equations [5] and [6] which relate the amounts of the substances A and B, respectively, in the reaction product after a given reaction time apply to both the schemes 1 and 2. The rate of change of the fraction of compound C (C_C) in the reaction product for scheme 1 is given by the expression,

$$dC_C/dt = C_A k_1 + C_B k_3 + C_D k_5 - C_C k_4.$$

Since

[7] $$C_D = 1-(C_A+C_B+C_C),$$

$$\frac{dC_C}{dt} = (k_1-k_5)\, e^{-(k_1+k_2)t} + k_5 + \frac{k_2(k_3-k_5)}{k_3-(k_1+k_2)}\,[e^{-(k_1+k_2)t} - e^{-k_3 t}] - (k_4+k_5)\, C_C.$$

Integration using the integrating factor $\exp \int (k_4+k_5)dt$ and solving for the integration constant yields

[8] $$C_C = \frac{k_1-k_5}{k_4+k_5-(k_1+k_2)}\,[e^{-(k_1+k_2)t} - e^{-(k_4+k_5)t}] + \frac{k_5}{k_4+k_5}\,[1-e^{-(k_4+k_5)t}] + \frac{k_2(k_3-k_5)}{k_3-(k_1+k_2)}\left[\frac{e^{-(k_1+k_2)t} - e^{-(k_4+k_5)t}}{k_4+k_5-(k_1+k_2)} - \frac{e^{-k_3 t} - e^{-(k_4+k_5)t}}{k_4+k_5-k_3}\right].$$

For scheme 2, the rate of change of the fraction of compound C (C_C) in the reaction product with time is expressed by

$$dC_C/dt = C_B k_3 + C_D k_5 - C_C k_4.$$

Integration of this expression after the appropriate substitutions have been made in the general manner outlined above for scheme 1 yields the following equation:

[9] $$C_C = \frac{k_2(k_3-k_5)}{k_3-(k_1+k_2)}\left[\frac{e^{-(k_1+k_2)t} - e^{-(k_4+k_5)t}}{k_4+k_5-(k_1+k_2)} - \frac{e^{-k_3 t} - e^{-(k_4+k_5)t}}{k_4+k_5-k_3}\right] + \frac{k_5}{k_4+k_5}\,[1-e^{-(k_4+k_5)t}] - \frac{k_5}{k_4+k_5-(k_1+k_2)}\,[e^{-(k_1+k_2)t} - e^{-(k_4+k_5)t}].$$

Thus, for scheme 1, the composition of the reaction product after any given time could be calculated using equations [5], [6], [7], and [8] and the same could be done for scheme 2 by employing equations [5], [6], [7], and [9]. The results of these calculations are plotted in Fig. 3 as are the experimental values given in Table III. It is seen that scheme 1 closely describes the reaction while scheme 2 does not. Therefore, it is clear that under the conditions for acetolysis, methyl β-D-glucopyranoside undergoes glycosidic cleavage to a large extent with retention of configuration to yield β-D-glucopyranose pentaacetate simultaneously with anomerization. The data listed in Table V show that the polari-

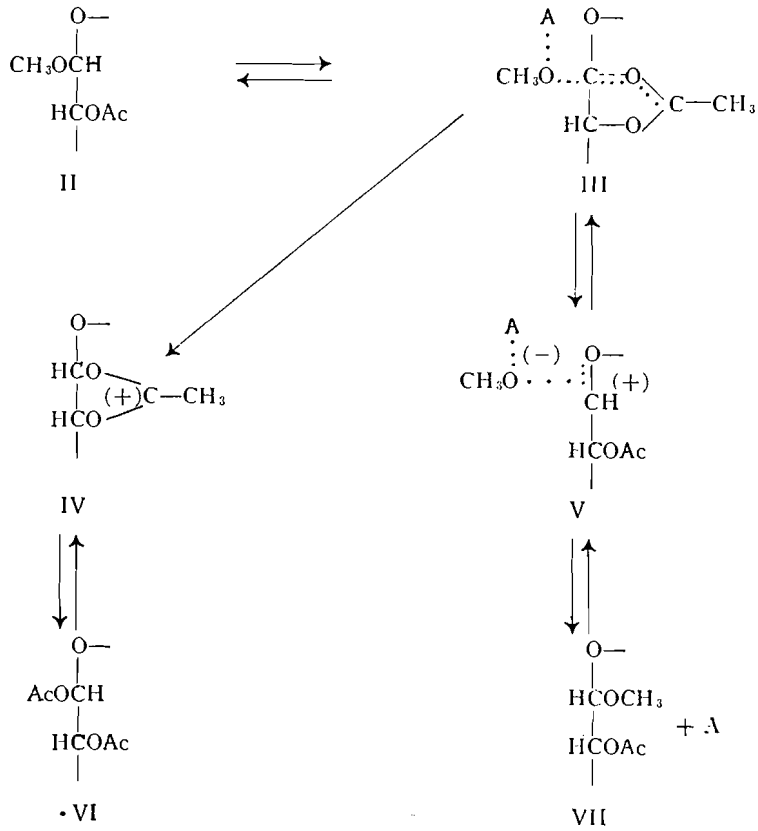
†*The rotation for the equilibrium mixture of the α- and β-D-glucopyranose pentaacetates.*

metric change expected on the basis of scheme 1 is in good agreement with that observed. It is also seen, however, that the polarimetric rate based on scheme 2 is not greatly different from that based on scheme 1 and that therefore a definite decision on the reaction route would be achieved through polarimetric studies only with great difficulty.

In accordance with the mechanism proposed by Lemieux and Shyluk (12) for the anomerization of acetylated alkyl glycopyranosides, the behavior of methyl β-D-glucopyranoside tetraacetate (II) would be accounted for as follows. Under the influence of the acid catalyst (A), the transition state III is achieved. It is deemed necessary to postulate the participation of the C2-acetoxy group in the loosening of the C1 to methoxyl group bond in view of the strong activation this participation appears to provide to the reaction (7, 8). Also, it would otherwise be difficult to rationalize the apparent high degree of anomerization which occurs when methyl α-D-arabinopyranoside triacetate



is subjected to acetolysis with the high lability of the ring structure as displayed by the β-anomer (15). Winstein and Heck (17) have shown that the 1,2-cyclic carbonium ion derived from participation of an acetoxy group shows little tendency for participation in an ion-pair. Consequently, it is conceivable that the transition state III can readily lead to the ion-pair V (12). The collapse of the ion-pair could then result in the formation of the α-glucoside (VII). In the event that the collision leading to the transition state III brought about separation of the ions, the 1,2-cyclic ion (IV) would result—an ion which is known to lead to β-D-glucopyranose pentaacetate as is required by the experimental data.

The acetolysis of methyl α-D-glucopyranoside tetraacetate with inversion of the anomeric center could, of course, be rationalized as a reversal of the above process. That is, the reaction would take place by VII ⟶ V ⟶ III ⟶ IV ⟶ VI. However, in view of the fact that evidence exists that 3,4,6-tri-*O*-acetyl-α-D-glucopyranosyl chloride appears to undergo solvolysis in acetic acid with a preponderance of inversion at the anomeric center (11) it is conceivable that the acetolysis of methyl α-D-glucopyranoside tetraacetate proceeds mainly by dissociation to a carbonium ion which possesses a strong tendency to form β-D-glucopyranose pentaacetate on interaction with the environment.

In conclusion, it is of interest to consider the implication of these results on the procedure used by Lindberg in his studies on the mechanism of the anomerization of acetylated alkyl glycopyranosides (1, 2, 13). First of all, the significance attached by Lindberg to the velocity constants which were calculated from polarimetric data only is questionable. The fact that the polarimetric change which accompanies a complex reaction is not readily amenable to interpretation is well illustrated by the data obtained for the acetolysis of methyl α-D-glucopyranoside tetraacetate. Inspection of Fig. 1 might lead one to believe that the reaction was essentially over in 90 min. The fact was, however, that the reaction was only 53.5% complete at this time. Thus, the common practice of following a carbohydrate reaction polarimetrically to the first point of inflection would in this case have led to nearly the worst possible mixture of starting material and reaction products. The course of the polarimetric change in the acetolysis of acetylated alkyl β-glucopyranosides is obviously determined by a wide variety of factors such as the relative rates of acetolysis and anomerization of the β-glucoside, the relative rates of glycosidic cleavage and ring cleavage for the α-glucoside, the relative rates of glycosidic cleavage, the stereochemical routes of the glucosidic cleavages which need not be the same for all glucosides and the relative rotatory powers of all the reaction products formed. Secondly, Lindberg attached considerable importance to presence of peracetylated *aldehydo*-sugars in the reaction products. It is to be noted in this respect that the present data indicate the formation of these products to be the result of a property of the more stable 1,2-*cis*-glycoside, a conclusion which is in accordance with the above mentioned experimental results obtained by Montgomery *et al.* (15) on the acetolysis of the methyl D-arabinopyranoside triacetates. This is reasonable since the acetolysis of the ring must be expected to be more important in the case of the acetylated 1,2-*cis*-glucosides where anchimeric assistance for glucosidic cleavage through participation of the C2-acetoxy group is not possible. The following deductions are of interest in this respect. The cleavage of the C1 to methoxyl group bond of a methyl D-glucopyranoside tetraacetate may occur either before or after the pyranose ring has undergone acetolysis. If the fission occurred before the ring was opened the product should be a D-glucopyranose pentaacetate; if afterward, the product can be expected to be *aldehydo*-D-glucose heptaacetate. Bonner (3) has shown the pyranose ring of the glucose pentaacetates to be stable under conditions for acetolysis and Lindberg's

experiments (13) indicate the same stability for the heptaacetate. Therefore, the identification by Lindberg (13) of only about 8% heptaacetate in the product from the acetolysis of methyl α-D-glucopyranoside tetraacetate suggests that for this compound the preferred reaction route was direct acetolysis of the C1 to methoxyl group bond. The C1 to acetoxy group bond of β-D-glucopyranose pentaacetate has been shown to be highly susceptible to dissociation as compared to the corresponding bond in the α-anomer (7, 8). It would therefore be surprising indeed if conditions which readily cleave the C1 to methoxyl group bond of methyl α-D-glucopyranoside tetraacetate would not dissociate much more readily the corresponding bond in the β-anomer as is suggested by Lindberg's arguments in support of his theory for the mechanism of the anomerization of acetylated glycopyranosides.

EXPERIMENTAL

The techniques used in carrying out the reaction and isolating samples after the various reaction times were the same as previously reported (9). In order to remove the chloroform, the material was twice dried *in vacuo* from solution in benzene before drying in a high vacuum first for several days at room temperature and then for several hours at 60°C.

The methods used to prepare the radioactive compounds have already been described (8, 12). The isotopic dilution analyses were carried out by adding weighed amounts, about 10 mgm., of the radioactive compounds to a weighed sample of the reaction product before chromatographic separation, purifying the compounds from the chromatogram by several recrystallizations, and then determining the radioactivities of the pure compound as was described in a previous communication (9). The amount of the reaction product used depended on the amount of the material to be analyzed which was present in the sample. Usually, about one gram of reaction product was used. The mixture was applied to the top of a column of Magnesol–Celite (5 : 1) 120 gm., 50 mm. in diameter, and the chromatogram was developed with 1500 ml. of benzene–ethanol (250 : 1) (14). The methyl β-D-glucopyranoside tetraacetate was found about one third of the way down the column and the remainder of the compounds were in the bottom quarter of the column. The α-D-glucopyranose pentaacetate occurred first and was well separated from the methyl α-D-glucopyranose tetraacetate which occurred next. The latter compound was not, however, well separated from the β-D-glucopyranose pentaacetate and was usually obtained by crystallization from the mother liquors from the isolation of the β-pentaacetate.

The contents of alkali-labile methoxyl groups listed in Table I were determined as follows. The sample, about 100 mgm., was dissolved in 1 ml. of diethylene glycol. Two milliliters of *N* sodium hydroxide solution was added and the solution was left at room temperature for one hour. The solution was then washed into a standard micro-Kjeldahl distillation apparatus for distillation in the usual manner. The distillate was collected in a 10 ml. volumetric flask kept in ice water. After about 9 ml. of distillate was collected, the solution was diluted to 10 ml. and the methanol in 1-ml. aliquots was determined by the

procedure described by Boos (4). A standard curve was set up by treating solutions which contained known amounts of methanol in the same manner. The results were reproducible within ± 5%.

ACKNOWLEDGMENT

The authors are indebted to Mr. J. A. Baignee of this laboratory for the microanalyses.

NOTE

SUBUNITS IN THE MOLECULE OF BOVINE PLASMA ALBUMIN[1]

By Manfred E. Reichmann[2] and J. Ross Colvin

Oxidation of intramolecular disulphide bridges in proteins, followed by determination of the molecular weight of the products, has been shown to be a valid method of investigating subunit structure in these substances. Sanger has shown (8) that such oxidation, if carried out at room temperature and for a short period only, irreversibly separates the molecule of insulin into component chains by oxidizing the cystine residues to cysteic acid, without attacking the primary polypeptide backbone. Anfinsen and co-workers (1) have confirmed the applicability of the method by their studies on ribonuclease. We wish to give a preliminary report of the results of an application of the same technique to bovine plasma albumin (B.P.A.).

After 20 min. oxidation of crystalline B.P.A. (Armour and Co.) by performic acid at room temperature, followed by hydrolysis, the cystine and cysteine spots disappeared from the chromatogram of the hydrolyzate (9). Repeated determinations of free α amino groups with Sanger's reagent (5, 7) showed that no α amino groups in other than aspartic acid residues could be detected in either native or oxidized B.P.A. These observations confirm those of Van Vunakis and Brand (10) and indicate that no significant hydrolysis of a peptide bond occurred during oxidation.

The weight average molecular weight of three preparations of oxidized B.P.A. at pH 7.4 in 0.2 *M* sodium chloride and 0.08 *M* borate buffer was determined by previously described light-scattering techniques (6) as $32{,}000 \pm 2000$. Under the same conditions, native B.P.A. gave a molecular weight of 77,000 in good agreement with previous results reported by Edsall *et al.* (3). Osmotic pressure measurements in the same buffer gave a number average molecular weight of 30,000 for oxidized B.P.A. and 66,000 for native B.P.A., the latter estimate being the same as that recently published by Gutfreund (4).

The difference between the molecular weights obtained by light-scattering and osmotic pressure data has usually been attributed to the presence of a small fraction of high molecular weight material in the samples (3). We have detected this fraction in our samples of native B.P.A. by sedimentation in the ultracentrifuge but have been unable to find evidence for it in the oxidized material. During our preparations of oxidized B.P.A., this small fraction of high molecular weight therefore seems to have been lost, and its disappearance accounts adequately for the otherwise surprising agreement between the light-scattering molecular weight of oxidized B.P.A. and that obtained by osmotic pressure.

In contrast to previous suggestions of a single polypeptide chain for B.P.A. (2) these results demonstrate that the molecule is made up of at least two subunits (chains) which seem to be held together by —S—S— cross-links. The component parts are not dissociable, however, by variation of the pH of the solution (6). Full details of this work will be reported later in this journal.

Symposium on Physical Adsorption of Gases by Solids

FOREWORD

The papers that follow were presented at a symposium on "Problems Relating to the Physical Adsorption of Gases by Solids", held at the Royal Military College, Kingston, Ontario, September 10 and 11, 1954, under the auspices of the Physical Chemistry Subject Division of the Chemical Institute of Canada. A few of the papers presented are not being published here, owing either to prior commitments or to the authors' choice. The conveners of the symposium were of the opinion that it would be useful at this time to bring together various points of view on experimental methods and theoretical interpretations currently being applied to the study of physical adsorption of gases by solids. To this end they arranged a program of contributions concerned with the state of physically adsorbed films, the structure and energetics of solid surfaces, and theoretical aspects of adsorption phenomena. No record of discussion was kept as the attendant editing would have significantly delayed publication of these proceedings.

On behalf of the conveners of the symposium I should like to acknowledge the generous co-operation of the National Research Council, of the authorities of the Royal Military College, and of the Editor of the Canadian Journal of Chemistry.

SOME PROBLEMS IN SURFACE CHEMISTRY

An Invited Address by PROFESSOR SIR ERIC RIDEAL, F.R.S.

In 1917, Langmuir advanced the view that in heterogeneous catalytic reactions, chemisorbed reactants were involved. Work since that time has fully substantiated that view and at the present time enquiry is centering around the problem of distinguishing between two possible modes of reaction for the catalytic formation of a product by the interaction of two reactants, A and B, at the surface of a catalyst. These may be depicted as

$$\begin{matrix} A & B \\ | & | \\ M & M \end{matrix} \rightarrow C \qquad \text{or} \qquad \begin{matrix} A & B \\ | & \vdots \\ M & M \end{matrix} \rightarrow C$$

where — denotes a chemisorbed species and ---- a molecule in the gas phase or in the van der Waals field.

During the last quarter of a century we have been interested in the process of chemisorption and have attempted to examine it by a variety of methods.

Three of these have been successful in throwing a great deal of light on the process. These are very briefly (*a*) the use of a single wire on which the accommodation coefficient of a rare gas in the absence and presence of a chemisorbed layer is measured; a field explored in great detail by Dr. J. K. Roberts, (*b*) the contact potential method in which two crossed wires are employed, one as an electron emittor and the other as an acceptor, the acceptor being coated at will by a chemisorbed layer; a method taken up by Dr. R. C. L. Bosworth and more recently (*c*) Mr. M. McD. Baker has had some success in utilising the photoelectric threshold and its change on the adsorption of gases to investigate chemisorption. I might deal briefly with the main features of the results of these investigations.

In the first place, it was found that chemisorption took place readily on clean wires frequently with no detectable energies of activation and that many cases of apparently slow adsorption could be attributed either to a displacement of a previously adsorbed gas or to a slow diffusion into the interior. This does not preclude the fact that there are well established cases of activated adsorption e.g. hydrogen and oxygen on diamond, oxygen on silver and hydrogen on copper, but it does serve to emphasise the danger of attributing all slow processes to an activation energy for adsorption especially where clean metals are involved. It is only natural that activation energies are involved when adsorption on and reaction with oxides and the like are under consideration.

The second important point which emerged was that the molar heat of adsorption was not constant but varied as a function of the surface coverage from $\theta = 0$ to $\theta = 1$. These molar heats of adsorption can be determined directly, calorimetrically, even on a wire or preferably on a metallic mirror following Beeck's method, or calculated from the adsorption isotherms taken over a suitable temperature range. The form of the ΔH, θ curve was of some interest in that ΔH was found to be neither independent of nor a linear function of θ as might be at first sight anticipated but consisted in those cases which were carefully examined of three distinct portions, a high ΔH for a small region of $\theta = 0$ to *ca.* $\theta = 0.1$, a linear portion ΔH gradually falling from $\theta = 0.1$ to *ca.* $\theta = 0.6$, and a more rapid fall after this point sinking to quite low values as θ approaches unity. It is evident that this fact can be interpreted by two entirely different concepts, firstly that the adsorbing surface is heterogeneous in character or that there exist both repulsive fields between the ad-atoms or ad-radicals and that the bonding energy falls with increasing surface coverage.

The first view, viz. the assumption of heterogeneity of the surface, gained a good deal of support in the United States; we, however, were inclined to the alternative view, namely, that the phenomenon of chemisorption of gases at metallic surfaces bore a closer similarity to those phenomena dealing with the modification of the thermionic and photoelectric properties of metallic surfaces in the presence of adsorbed monolayers. It was also easy to show that if the ad-atoms or ad-radicals did indeed resemble dipoles and as a result repulsive fields existed between them, then the general form of the ΔH, θ curve for a dissociating gas such as hydrogen could be accounted for; if, in addition to this

hypothesis, the ad-atoms or ad-radicals could undergo surface diffusion and thus space themselves uniformly over the surface at a speed at least commensurate with the rate at which the experiment of gas admission was being conducted. Dr. Roberts' work is widely known on both sides of the Atlantic and for that reason I have given only the briefest summary of the more important conclusions derived from his investigations. It is interesting to note that recently the accommodation coefficient method of attack has been queried as to its accuracy but I am glad to see that recent work of Dr. Tompkins at Imperial College has fully substantiated Roberts' work.

Dr. Bosworth's work does not appear to be so well known so I am taking the liberty of giving this in slightly more detail.

Langmuir and Kingdon studied the impact of caesium atoms onto a tungsten surface and noted that when the surface was relatively bare every caesium atom evaporated as an ion. The electron work function of tungsten, ϕ, is 4.53 volts whilst the ionisation potential of caesium, I, is 3.88 volts, thus the passage of the electron from the donor caesium atom to the acceptor tungsten is facilitated. When, however, the caesium layer begins to populate the surface more thickly, this layer continues to lower the work function of the surface until, when ϕ has sunk to 3.88 volts, any further incident caesium atom will evaporate as an atom and not as an ion. We might regard the surface phase as consisting of a mixture of ad-atoms and ad-ions, their proportion being given by

$$\frac{n_{ions}}{n_{atoms}} = \frac{f_1}{f_2} e^{-(I-\phi)e/kT}$$

where f_1 and f_2 are the statistical weights of the ion and atom respectively in their ground states; or, we may regard the surface as consisting entirely of ad-atoms, the polarisation or dipole moment of which varies for a bare surface from that equivalent to an adsorbed ion to much smaller values as the surface becomes more crowded, evaporation from the surface taking place in the two stable states viz. atom and ion in a ratio defined by the energetics of the system. Langmuir obtained the following values for the dipole moment of caesium on tungsten:

θ	μ(Debyes)
0.0	14.6
0.5	6.1

Bosworth investigated potassium on tungsten in a similar manner and obtained:

θ	μ(Debyes)
0.012	23
0.025	21
0.10	13
0.50	6.0
1.0	2.8

We can note that the lattice constant of potassium is 5.25Å and if we regard it as a sphere with unit positive charge placed on an ideal plane conductor, the external field produced by an ion and its mirror image would be equivalent to

that of a dipole of electric moment

$$5.25 \times 4.77 = 25 \text{ Debyes},$$

a value very close to that obtained experimentally for extremely dilute films. Bosworth extended this investigation to oxygen on tungsten and computed the following tentative values:

θ	μ(Debyes)
0.05	3.4
0.10	3.0
0.20	2.1
0.40	1.0
0.60	0.8
0.80	0.8

Here again we note that there is a fall in the apparent polarisation as the surface becomes more densely populated. It is interesting to compare the work functions of stable close packed monolayers of electronegative gases on tungsten as determined by this method. ϕ for W = 4.56 volts at 300°A. Then at the same temperature we find ϕ for WO 6.34, WN 5.92, WH 5.82, WD 5.80. For a thick oxide film WO_x ϕ = 6.24 volts.

Bosworth also measured the rate of surface diffusion as a function of the surface concentration of potassium on tungsten. The energies of activation for the surface diffusion were found as expected to be relatively large for dilute films falling to smaller values for more concentrated films. I cite the following values:

θ	E (electron volts)	θ	E (electron volts)
0	0.72	0.1	0.59
0.015	0.69	0.25	0.52
0.025	0.67	0.5	0.35
0.05	0.63	1.0	0.29

From these data it is possible to calculate the spreading forces and these can be compared with say the spreading forces of formic acid adsorbed on mercury.

Potassium on tungsten		Formic acid on mercury	
Ad-atoms per sq. cm. ($\times 10^{-14}$)	F (dynes/cm.)	Molecules per sq. cm. ($\times 10^{-14}$)	F (dynes/cm.)
0.06	0.23	0.8	14
0.12	0.96	1.5	22
0.24	3.5	3.0	38
0.48	10	4.6	52
0.60	14.3		
1.20	38		
1.50	60		
2.40	142		
3.0	187		
4.8	322		

The spreading forces for the strong dipolar system potassium on tungsten are far greater than those for formic acid on mercury. For very dilute monolayers where the distances are too great for appreciable dipolar interaction we note

that the spreading forces which are kinetic thermal in origin for the two systems are of the same order of magnitude. As the surface concentration rises the increased spreading forces for the potassium can be shown to be due to the electrostatic dipole repulsion but for concentrated films the values obtained fall below those calculated, another confirmation that the magnitude of the dipole is falling with concentration.

It is difficult to attain such a high accuracy when wires or thin ribbons of metal are employed as can be attained with metallic mirrors. It also militates against the accuracy of the method when other extraneous metal has to be present or when local high temperatures as in thermionic emittors are employed. For this reason Mr. M. McD. Baker has been engaged in exploring the possibilities of using photoelectric thresholds in conjunction with freshly formed metallic mirrors derived by vaporisation from suitable filaments. So far we have confined our attention to the 1800 line of mercury and have used a silica window to our vessel. We hope to extend the method further into the ultraviolet so that we can examine chemisorption on such metals as copper. Mr. Baker has examined the chemisorption of hydrogen and of carbon monoxide on a variety of metals. It is interesting to note that the $\Delta\phi, \theta$ curve pursues a curve similar to the $\Delta H, \theta$ curve, namely on several metals there is an initial relatively large rise in $\Delta\phi$ indicating a large dipole, this is followed by a steady linear rise and then the curve bends over indicating that the magnitude of the dipole in the closely packed film is very small.

Finally by means of the method of contact potentials it is possible to measure the latent heats of evaporation. The experimental evidence suggests that on tungsten oxygen evaporates as molecules formed by the combination of two chemisorbed atoms i.e. a bi-molecular surface action whilst nitrogen evaporates in a unimolecular manner i.e. either as N_2 or WN. The values obtained for these two chemisorbed gases on tungsten were as follows:

ΔV (volts)	Nitrogen, E (kcal./mole)	Oxygen, E (kcal./mole)
−0.10	—	150
−0.20	28	147
−0.40	26	130
−0.60	23	113
−0.80	20	90
−1.00	19	83
−1.20	18	76
−1.70	—	67

It is from these experiments difficult to avoid the conclusions that monolayers chemisorbed on uniform metallic surfaces vary markedly in properties as their surface concentration is varied. Dilute monolayers are relatively firmly held and have large dipoles and large energies of activation for migration. As the packing density increases the polarisation of the dipoles decreases, the lateral mobility increases, the spreading force increasing and the energy of activation for migrations decreasing and, at the same time, the forces holding the ad-atom or ad-radical to the surface suffer a considerable diminution.

It is interesting to determine the energy changes associated with the ionisation of sodium, i.e. the reaction

$$Na^+ \rightarrow Na + \epsilon,$$

from Bosworth's data. For gaseous sodium vapour $E = 5.1$ electron volts; in a closely packed monolayer on tungsten it is $E = 1.7$ electron volts, whilst in a very dilute monolayer it is $E = -0.4$ electron volts.

It does not seem to be unreasonable to apply similar considerations to, say, hydrogen on nickel. We may regard a nickel surface when sparsely populated as capable of dissociating hydrogen. The resulting surface hydride is relatively polar and the reaction is strongly exothermic. The repulsive forces between the ad-atoms ensure an even distribution over the surface. For these, the rate of recombination and re-evaporation as molecules is extremely slow and the equilibrium pressure of hydrogen above a nickel surface for small values of θ is vanishingly small. As θ increases the interaction energy decreases and the reaction becomes increasingly less exothermic whilst the repulsive forces and the energy of activation for lateral migration become reduced, with the result that evaporation proceeds more readily and, as we have found with Trapnell, relatively large equilibrium pressures of hydrogen are necessary for θ to attain unity. We might also assume that there may be substrates with which the interaction energy for hydrogen sinks to such low values that surface dissociation ceases *before* θ reaches unity resulting in a mixed atomic and molecular film.

We have not succeeded in attempts to discover the mechanism of the surface migratory process. We could imagine it to take place by three different methods. If we regard each metallic atom as though it were a crater with the ad-atom in it then a migration might consist of a process of hopping from one crater to the next. Again there may be preferred directions, e.g. at an angle of 45° on the surface of a cubic crystal or a direction in which the lips of the crater are lower giving rise to directional migration.

Finally, we may conceive the existence of migratory levels involving the supply of energy to raise the ad-atom into the migratory level and then the supply of a much smaller energy of activation in the travel over the migratory level. The energies for migration in the migratory levels being naturally smaller the greater distance the level is from the metal atom surface and the greater the original energy of activation necessary to raise the ad-atom to that level.

This concept of chemisorption involves, as we have seen, electron transfer, either the ad-atom or ad-radical being the electron donor or acceptor, and I need only at this point draw your attention to the ever increasing amount of work now being devoted to the electronic structure of metals and to the production of p and n lattice defects to modify the electronic structure of catalysts.

Finally, I would like to express my gratitude for the kindness which the National Research Council is always extending to me especially in so far that they have made my attendance at this meeting possible. I would also like to congratulate all those who have taken part in getting this meeting together.

The meetings of the Faraday Society, deservedly some of us think, hold a high reputation in the world of science. The reason for the success of those meetings can be summed up in two words—hard work. I think those of us present here who have attended meetings of that society would consider this meeting as good as the best.

INVESTIGATION OF THE PHYSICALLY ADSORBED STATE BY MEANS OF DIELECTRIC MEASUREMENTS[1]

By E. W. Channen[2] and R. McIntosh[3]

ABSTRACT

Dielectric data obtained for a variety of adsorbates on porous silica gel and on nonporous rutile are summarized. Four methods of computing the polarizabilities or dielectric constants of the adsorbed matter are outlined and applied using the primary experimental data of capacitance change and volume adsorbed. All four methods contain somewhat arbitrary assumptions and at best are semi-empirical. None predicts values of the electrical constants of the adsorbed species which appear reasonable in all cases. It is concluded that an interpretation of the phenomena revealed by the primary data is not possible until improved methods of computing the polarizability of adsorbed material are developed.

INTRODUCTION

Attempts to elucidate the state of physically adsorbed films of vapors on solids have been reported particularly by Higuti (7), Kurbatov (12), and by McIntosh and his associates (13, 14, 17, 18, 20). These investigators have discovered the very interesting fact that when the change of capacity of the test cell is plotted against the volume of gas adsorbed, a sudden change of the slope of this plot is observed at some particular quantity of adsorbed matter. Typical observations for a variety of adsorbates on a porous adsorbent, silica gel, and on nonporous rutile are given below. The interpretation of this kind of data and of the variation of the slopes of such plots with temperature is, however, a very difficult matter.

In order to attempt an interpretation it appears necessary to evaluate the polarizability of the adsorbed species. The dielectric which is being examined is, of course, a heterogeneous one, and it is necessary to account correctly for such factors as the arrangement of the particles in the bed, the spaces between particles occupied by gaseous matter, and the contribution of the adsorbed matter. Up to the present the simpler situation of powdered solid and intervening space between particles has not been satisfactorily treated, although both Böttcher (1) and Kamiyoshi (9) have succeeded in developing formulae which yield reasonable values of the dielectric constant of the solid provided its dielectric constant is not above about 20.

In the present paper the general nature of the experimental findings is reviewed and information from further studies recorded. A comparison is then made of the values of the polarizability of the adsorbed matter or of the apparent dipole moments of polar adsorbates deduced by a number of procedures. It is thus shown that the values obtained are markedly dependent upon the method of computation. As each procedure involves an empirical step and usually also an arbitrary assumption in the method by which the

[3]*Professor of Chemistry.*

polarizability of the adsorbed matter is separated from that of the whole system, it has not been possible generally to assess the advantages of one method over the others. An obvious test is to rely upon the answer obtained for a nonpolar adsorbate, such as butane. In this case, however, owing probably to the low dielectric constant of the adsorbate, discrimination among the methods is not readily achieved. The contribution of the paper, therefore, is to point out the nature of the problem and to emphasize that the methods outlined are far from satisfactory. As these methods include that used by Kamiyoshi (10), it must be concluded that all values of the polarizability or of the permanent moment so far published are unlikely to be reasonable approximations to the effective molecular constants of adsorbed molecules.

SUMMARY OF EXPERIMENTAL OBSERVATIONS

The experimental observations made in this laboratory are briefly summarized below. As Higuti (7) and Kurbatov (12) have also reported the type of result to be found using porous adsorbents, the validity of the findings appears established.

I. *Porous Silica Gel*

(*a*) All adsorbates studied reveal two well-defined linear sections of the plots of capacitance change versus volume of gas adsorbed. (*b*) These linear sections are separated by a short transition region, so that extrapolation of the two lines defines a critical value of the volume adsorbed at which a change of the apparent polarizability of the adsorbed phase occurs. (*c*) The second linear section always has a lower slope than the first. (*d*) Depending upon the adsorbate, the critical value of the volume adsorbed may or may not change with temperature over the range of temperature which has been studied. (*e*) The critical value of the volume adsorbed does not agree with the value of V_m computed by the B.E.T. method. (*f*) Addition of water to the gel before admission of the second adsorbate may influence both the values of the slopes and the critical quantity of adsorbate. (*g*) The variation of the slopes of the linear sections with temperature depends upon the particular adsorbate. Nonpolar butane shows a negligible temperature dependence of the slopes. Polar adsorbates, such as ethyl chloride and water, show a negligible dependence on temperature of the slope of one section, while the slope of the other section may vary either as is normal for a polar substance or anomalously.

Details may be found in earlier publications, but typical plots for several adsorbates are shown in Fig. 1 as illustrations of the usual findings.

II. *Nonporous Rutile*

The measurements are more difficult to make using this adsorbent because of its low adsorptive capacity (specific surface to N_2 80 square meters) and the lower quantity which packs into the beds. The relative precision with which capacities are measured and the essentially similar results obtained with a different assembly (19) indicate that the results reported here are valid. It should be emphasized that linear sections of the usual type of plot are excellent, and in our opinion, it is justifiable only to draw straight lines through

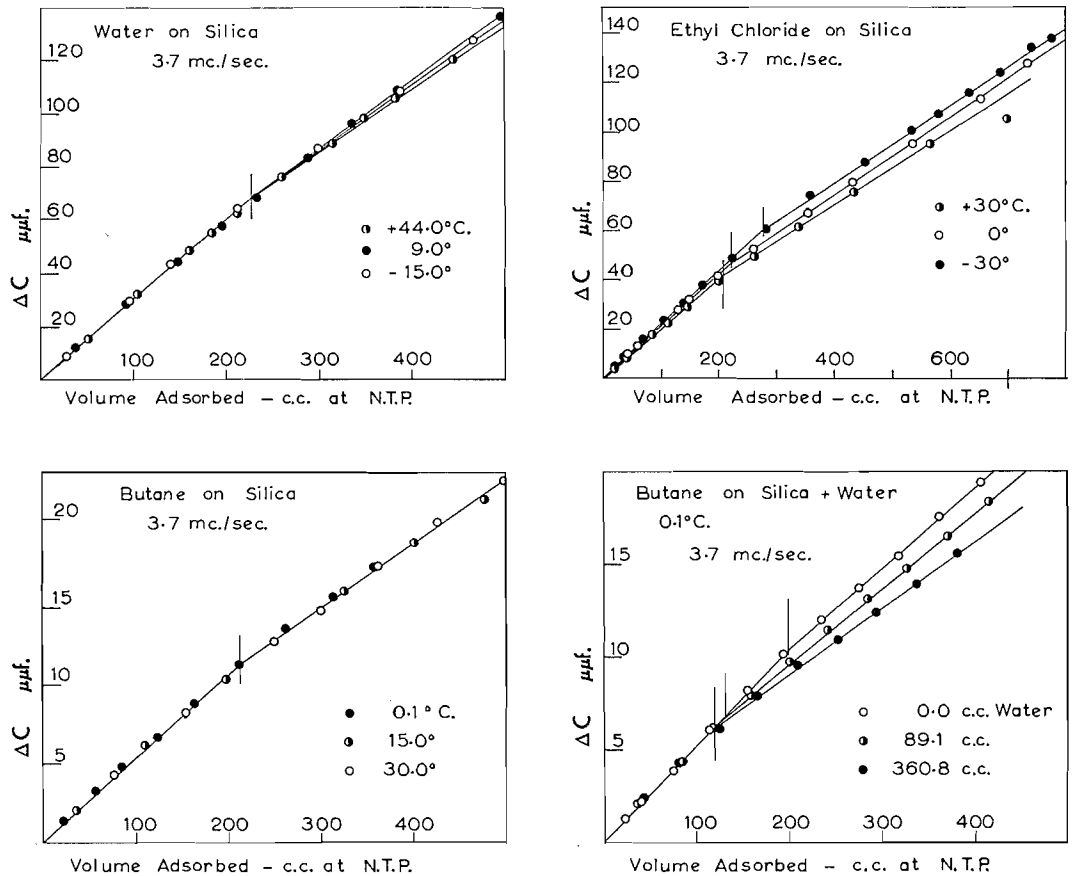

FIG. 1. Plots of capacitance change versus volume adsorbed for various adsorbates on silica.

the experimental points of the several sections of the graphically represented data.

The experimental observations may again be briefly summarized. (*a*) Nonpolar butane shows no discontinuity of the slope of the usual capacitance change versus volume adsorbed plot. (*b*) Three polar adsorbates, namely, ethyl chloride, sulphur dioxide, and ammonia, reveal two linear sections in the plots. (*c*) In these cases the second linear section possesses a higher slope than does the first, a fact which is in striking contrast with the behavior of polar adsorbates on porous silica. (*d*) The temperature coefficients of the slopes are negligible over the narrow temperature range of some thirty degrees which was feasible for the adsorbates other than dichlorofluoromethane. (*e*) The critical value of the quantity adsorbed at which the apparent polarization of the adsorbate changes is in good agreement with the value of V_m computed by use of the B.E.T. (4) or Hüttig equations (8). (*f*) Critical examination of these primary data shows that the sudden change cannot be accounted for by the gaseous matter between particles. (*g*) Dichlorofluoromethane[4] does not

[4]*The data for dichlorofluoromethane were obtained by Mrs. E. Petrie in this laboratory.*

exhibit the sudden change of apparent polarization at 20.2°C., but does so at −19.6°C., owing to a negligible temperature coefficient along the first section and a negative coefficient along the second. Representation of typical data is made in Fig. 2.

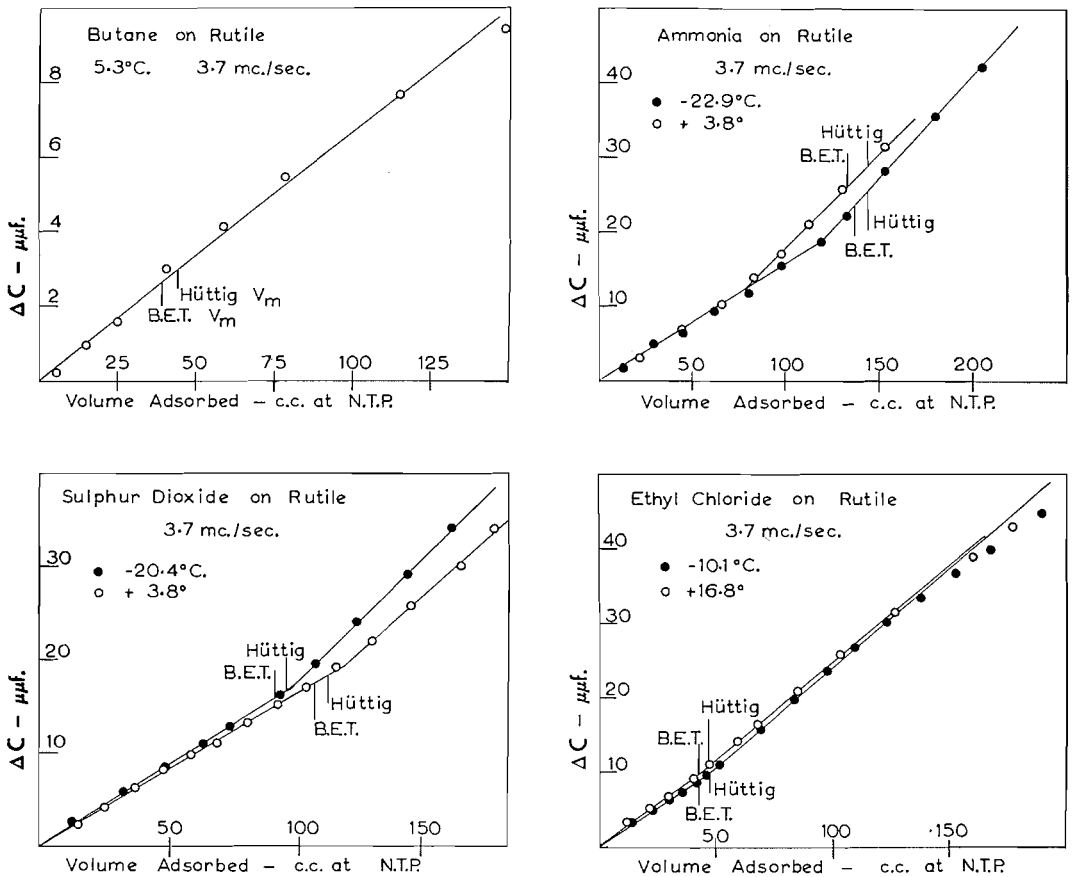

FIG. 2. Plots of capacitance change versus volume adsorbed for various adsorbates on rutile.

A comparison of these results with those obtained using silica suggests that porous structure has a bearing upon the results found. Moreover, the agreement between the values of V_m deduced from theories of adsorption and the critical values found from the electrical measurements using the nonporous adsorbent suggests that the change of apparent polarization occurs on the completion of the first molecular layer in the case of that adsorbent. It should be noted from the C values of the B.E.T. or Hüttig plots that the heat of adsorption in the first layer is quite large for these adsorbates.

General Theoretical Considerations

If the value of the directing field at the site of an adsorbed molecule were known, some theoretical knowledge is available to aid in the interpretation of the behavior of the adsorbed matter. McIntosh, Rideal, and Snelgrove (14)

showed that the orientational contribution to the total polarization of an adsorbed dipole constrained to rotate in the plane of the adsorbing surface is $\mathbf{E}_r(\mu^2/3kT)$, where $\mathbf{E}_r$ is the directing field. Kurbatov (12) treated the case of a dipolar molecule which can undergo rotational oscillations in three dimensions, and also the case of a rotating molecule constrained to rotate within a given cone angle. For the first case he established the important result that although the orientation of the oscillator may make an important contribution to the measured polarization, the temperature coefficient of the orientational effect will be negligible if there is a reasonable restoring force to the equilibrium position of the oscillator with no field applied. In the second case the usual inverse temperature relation should be observed. Snelgrove and McIntosh (18) applied this type of treatment to molecules constrained to move in the plane of the adsorbing surface with similar results. Although we have now shown (5) that equation [e] of their paper should be modified to the form

$$[a] \qquad \overline{\mathbf{m}} = \frac{\mu^2 \mathbf{E}_r}{3kT}\,(1-e^{-1/2\beta^2}) \qquad [a]$$

the important result is still valid, namely, that a higher polarizability than is to be expected for a nonpolar adsorbate and a negligible temperature variation of the orientational part of the polarization may be found. It is therefore not surprising that values of the polarizability of adsorbed molecules in excess of that predicted on the basis of refractive index data (or more properly, high frequency dielectric data) should be deduced from any method of computation which may be employed, even when the primary data appear independent of temperature. On the other hand, in our opinion, one should not expect to find an apparent permanent moment for an adsorbed nonpolar species. This statement is based upon the view that although a dipole may be induced in a nonpolar adsorbate by the field of the solid, the random orientation of the adsorbing surfaces should cause the net effect of these induced dipoles to be zero. Moreover, since the direction of the induced dipole depends upon the direction of the field from the surface, there is no tendency for the induced dipole to orientate with the applied field. When, therefore, a nonpolar adsorbate is found to possess a polarizability markedly in excess of α_0, the distortion polarizability, when the primary data have been treated by some procedure such as those to be discussed below, we believe that this result merely demonstrates the inadequacy of the treatment. A discussion of four procedures which we have employed with the type of data recorded above will now be given. These four procedures are (1) extension of Böttcher's powder method, (2) Böttcher's solution formulae applied to the adsorbate–adsorbent system, (3) a cluster model of the powder in conjunction with Böttcher's several methods, (4) the procedure due to Kamiyoshi.

METHODS OF OBTAINING DIELECTRIC QUANTITIES

I. *Extension of Böttcher's Powder Method*

The extension of Böttcher's powder method has been described earlier (14). It is useful, however, to review the assumptions which are made in it.

It is assumed (*a*) that the average field within the composite dielectric is given by the Clausius–Mosotti field $\frac{1}{3}(\epsilon+2)\mathbf{E}$, where ϵ is the average dielectric constant of the system and $\mathbf{E}$ is the applied field, (*b*) that the field in the interstices is given by the Onsager cavity field, namely, $[3\,\epsilon/(2\,\epsilon+\epsilon_g,)]\,\mathbf{E}$, where ϵ is the dielectric constant of the composite dielectric and ϵ_g is the dielectric constant of the gas at the equilibrium pressure over the solid, (*c*) that the average field in the composite system is given by adding the average internal fields in each constituent on a volume fraction basis, (*d*) that the total polarization of the composite dielectric is given by adding the polarization of each constituent on a volume fraction basis. It should be noted that an assumption concerning the density of the adsorbate is required, and there is thus an adjustable parameter in the final equation

$$[b]\qquad \frac{\epsilon+2}{3}-\frac{\epsilon}{2\epsilon+\epsilon_g}(\epsilon_g+2)\,\delta_3=\frac{\epsilon_i-1}{4\pi C_1}+\frac{\epsilon-\epsilon_i-(\epsilon_g-1)\frac{\epsilon}{2\epsilon+\epsilon_g}(\epsilon_g+2)\,\delta_3}{4\pi C_2}$$

TABLE I

DIELECTRIC CONSTANTS OR POLARIZATIONS PER CM.^{3} FOR ADSORBATES ON SILICA BY THE EXTENSION OF BÖTTCHER'S POWDER METHOD

Temp., °C.	First linear section	Second linear section	Refractive index squared	Dielectric constant from Onsager equation
Butane—dielectric constant				
0.1	1.80	1.61	1.81	—
15.0	1.78	1.58	1.79	—
30.0	1.74	1.55	1.77	—
Ethyl chloride—dielectric constant				
0.1	8.66	4.36	1.90	10.9
15.0	7.89	4.14	1.87	10.0
30.0	7.50	3.99	1.84	9.4
Methyl chloride—dielectric constant				
0.1	9.40	5.05	1.86	12.0
Water—polarization per cm.^{3}				Polarization from Onsager equation
−15.0	1.069	0.947		0.915
9.0	1.052	0.944		0.908
44.0	1.052	0.937		0.896

where δ_3 is the volume fraction occupied by gaseous matter, ϵ_i is the dielectric constant of the powder before addition of adsorbate, and C_1 and C_2 are respectively the volume average polarizabilities of the solid and of the adsorbate. The correction terms for gaseous matter given here are of some significance in dealing with rutile systems. McIntosh, Rideal, and Snelgrove (14) have pointed out how dielectric measurements might be employed to establish the value of the density of the adsorbed phase for nonpolar adsorbates, or for polar adsorbates at very high measuring frequencies. Without such knowledge the arbitrary assumption that the adsorbate has the density of liquid at the particular temperature has been made.

TABLE II

DIELECTRIC CONSTANTS* FOR ADSORBATES ON RUTILE BY THE EXTENSION OF BÖTTCHER'S POWDER METHOD

Temp., °C.	First linear section	Second linear section	Refractive index squared	Dielectric constant from Onsager equation
Butane				
5.3	2.05	—	1.80	—
Ethyl chloride				
0.6	6.2	7.2	1.90	10.9
−10.1	6.1	7.8	1.92	11.7
−19.2	6.2	9.2	1.94	12.3
Ammonia

−22.9	15.6	69	1.84	16.7
Sulphur dioxide				
3.8	7.8	10	2.03	11.6
−20.6	8.2	16	2.09	13.4

**The number of significant figures stated is to show any variation with temperature. Absolute values of the dielectric constant of the adsorbate are not known.*

In conjunction with equation [*b*] the relation

$$[c] \qquad \frac{\epsilon_2-1}{\epsilon_2+2} = \frac{4\pi}{3} C_2$$

has been employed to give the dielectric constant of the adsorbate. The use of this formula follows from the definition of C_2 based upon assumption (*d*).

The application of this method to systems consisting of porous silica and various adsorbates seems reasonable, in view of the fact that the result obtained for the dielectric constant of the silica from the measured ϵ_i is about 6. On the other hand, as may be seen from Table I the value obtained for water is too high, and cannot reasonably be accounted for on the basis of experimental error. Application to systems of rutile and adsorbate is questionable, because the measured value of ϵ_i yields a wrong value for the dielectric constant of rutile (negative) while the known value is about 114 (11). It is not surprising, therefore, that the value of the dielectric constant of ammonia is found to be greater than that of bulk liquid. The use of the field in a spherical cavity is one source of error, since this approximation is poor when the dielectric constant of the powder particles is large (2). Values for several adsorbates are given in Table II.

II. *Solution Method*

Böttcher (3) has also treated the case of solutions. The requisite equations are:

$$[d] \qquad \frac{\epsilon+2}{3}\mathbf{E} = \sum_k \frac{4}{3}\pi a_k{}^3 N_k \mathbf{E}_{i_k} + \left(1 - \sum_k \frac{4}{3}\pi a_k{}^3 N_k\right)\frac{3\epsilon}{2\epsilon+1}\mathbf{E},$$

$$[e] \qquad \frac{\epsilon-1}{4\pi}\mathbf{E} = \sum_k \left(N_k \alpha_k \mathbf{E}_{i_k} + N_k \frac{\mu_k{}^2}{3kT}\mathbf{E}_{r_k}\right),$$

[f] $$\mathbf{E}_{i_k} = \left\{1+\frac{\mu_k^2}{3kT}\left(\frac{f_k}{1-f_k\alpha_k}\right)\right\}\mathbf{E}_{r_k}.$$

Here, a_k, α_k, and N_k are respectively the radius, the distortion polarizability, and the number of molecules per unit volume of the kth type of molecule. $\mathbf{E}_{i_k}$ and $\mathbf{E}_{r_k}$ are respectively the internal field and the directing field at the kth type molecule. If these equations for solution systems are combined with the equations of the Böttcher powder method, it follows that a constant C_2' for the adsorbed matter is now defined by the relation

[g] $$\left(\frac{4}{3}a_2^3C_2'N_2\right)\mathbf{E}_{i_2} = \alpha_2N_2\mathbf{E}_{i_2}+\frac{\mu_2^2}{3kT}N_2\mathbf{E}_{r_2}.$$

It can then be shown that

[h] $$\frac{\epsilon-\epsilon_i}{4\pi C_2'} = \frac{\epsilon+2}{3}-\frac{3}{2\epsilon+1}\left[\delta_4+\frac{4}{3}\pi a_3^3N_3\left\{\left(1+\frac{f_3}{1-f_3\alpha_3}\frac{\mu_3^2}{3kT}\right)\frac{1}{1-f_3\alpha_3}\right\}\right]$$
$$-\frac{\epsilon_i-1}{4\pi C_1'}+4\pi N_3\frac{1}{1-f_3\alpha_3}\frac{3\epsilon}{2\epsilon+1}\left\{\alpha_3\left(1+\frac{f_3}{1-f_3\alpha_3}\frac{\mu_3^2}{3kT}\right)+\frac{\mu_3^2}{3kT}\right\}\frac{1}{4\pi C_2'}$$

where δ_4 designates the volume fraction of free space and the subscript 3 designates the gaseous molecules. The symbols C_1' and C_2' refer to the solid and the adsorbed matter, respectively.

[i] $$\text{Also } f_k = \frac{1}{a_k^3}\left(\frac{2\epsilon-2}{2\epsilon+1}\right).$$

By this combination of equations the field within the solid is regarded as independent of the volume fraction of adsorbate and of gas, as in the extension of the powder method. Since the value of ϵ changes only slightly with increasing quantity of adsorbate, this approximation is not very serious.

Thus a plot of

$$\frac{\epsilon+2}{3}-\frac{3\epsilon}{2\epsilon+1}\left[\delta_4+\frac{4}{3}\pi a_3^3N_3\left\{\left(1+\frac{f_3}{1-f_3\alpha_3^3}\frac{\mu_3^2}{3kT}\right)\frac{1}{1-f_3\alpha_3}\right\}\right]$$

versus

$$\epsilon-\epsilon_i-4\pi N_3\frac{1}{1-f_3\alpha_3}\frac{3\epsilon}{2\epsilon+1}\left\{\alpha_3\left(1+\frac{f_3}{1-f_3\alpha_3}\frac{\mu_3^2}{3kT}\right)+\frac{\mu_3^2}{3kT}\right\}$$

should yield a straight line of slope $1/4\pi C_2'$. The values of α were taken from refractive index data, while the values of a were assigned from the van der Waals' constants of the adsorbate (6, 16). The value of C_2' obtained from the data is independent of the value assigned the volume fraction of the solid, δ_1, for changes of the order of 30%. Thus the apparent electrical characteristics of the adsorbate are not dependent upon whether or not a "free space" term should be included for the solid constituent.

Finally, the relation between dipole moment of the adsorbate and C_2' is given by

[j] $$\frac{\mu_2^2}{3kT} = \left\{1-\frac{\alpha_2}{a_2^3}\left(\frac{2\epsilon-2}{2\epsilon+1}\right)\right\}\left\{C_2'\frac{4\pi a_2^3}{3}-\alpha_2\right\}\Big/\left(1-C_2'\frac{4\pi}{3}\frac{2\epsilon-2}{2\epsilon+1}\right).$$

Some justification for using a solution model may be derived from the fact that the adsorbent has a large specific surface, so that its subdivision is great, and the system approximates to a mechanical mixture on the molecular scale. Further, the term $(\mu_2^2/3kT)\mathbf{E}_{r_2}$ is valid for a dipole constrained to rotate in the plane of the adsorbing surface (14), but would not be valid for a rotational oscillator. A likely source of failure is the spherical form of the model implicit in the equations, a criticism already mentioned in the preceding section. It should also be noted that the treatment implies a field within the solid independent of the numbers N_2 and N_3 of adsorbed and gaseous molecules.

It can be seen from equations [*d*], [*e*], and [*f*] that the selected values of α and a will influence the number obtained. In the case of a nonpolar adsorbate, the relation

$$[k] \qquad C_2'\frac{4\pi}{3}a_2^3 = \alpha_2$$

should apply, and may be used to test the measure of agreement between experiment and theory when the value of a_2 is taken from the van der Waals' equation of state. For butane the value of α_2 from refractive index data is 8.2×10^{-24} cc. per molecule. The experimental values of C_2' for butane on silica and rutile gave values of 5.7×10^{-24} and 7.1×10^{-24} cc. per molecule, respectively. It may be remarked that adjustment of the parameter a_2 may be made in a similar fashion to that mentioned in the preceding section. Examples of the numerical values of μ for various adsorbates on silica and rutile are recorded in Table III. The value of ϵ required in the calculations was taken about midway along the appropriate linear section of the plots.

TABLE III

APPARENT DIPOLE MOMENTS FOR ADSORBATES ON SILICA AND RUTILE BY THE "SOLUTION" METHOD OF COMPUTATION

Substance	Temp. (°C.)	Adsorbent	Molar volume	α per molecule from refractive index data $\times 10^{24}$	Apparent dipole moment $\times 10^{18}$	Gaseous dipole moment $\times 10^{18}$
NH_3	−22.9	TiO_2	8.80	2.02	0.53	1.47
NH_3	+ 3.8	TiO_2	8.80	2.02	0.56	1.47
SO_2	+ 3.8	TiO_2	14.0	5.56	0.0	1.61
C_2H_5Cl	+ 0.6	TiO_2	22.0	6.47	0.57	2.02
C_2H_5Cl	0.0	SiO_2	22.0	6.47	0.52	2.02
C_4H_{10}	0.1	SiO_2	30.4	8.20	α_2 from $C_2' = 5.7 \times 10^{-24}$	
C_4H_{10}	5.3	TiO_2	30.4	8.20	α_2 from $C_2' = 7.1 \times 10^{-24}$	

The most noteworthy feature of this method of computation is the terms arising from the presence of gaseous matter in the composite dielectric. This remark applies only to the rutile systems, where the relative quantities of adsorbate and gaseous material are such as to make the contribution from the

gas important. In the cases of ethyl chloride and sulphur dioxide the discontinuities evident in the slopes of the plots of the primary data disappear, or a lower polarizability is deduced for the second linear region. This suggests that an overcorrection is being made. As the correction terms are negligible for the first linear sections, the values of μ for these sections are given in the table.

III. *The "Cluster" Method*

It was pointed out that the application of Böttcher's formula to powdered rutile did not yield the correct value of the dielectric constant of crystalline rutile, namely, 114. As the specific surface of the sample is 80 square meters, the ultimate particles would be invisible and the particles seen are aggregates or clusters of these. Further, in packing the cell it was found that the volume fraction of solid always lay in the range 0.16–0.18. For powders of particle size of the order 0.005 cm. the volume fraction of solid is ordinarily in the range 0.4 to 0.6. The existence of clusters could explain this difference in the volume fraction of solid in the beds of rutile. By assigning a value for the volume fraction of the ultimate particles within the clusters, the volume fraction of the clusters themselves, considered as a homogeneous phase, can be calculated. By an application of Böttcher's powder method, the mean dielectric constant of the clusters can then be calculated. From this number, in conjunction with the previously assigned value of the volume fraction of solid within clusters, a second application of Böttcher's procedure yields the dielectric constant of the ultimate particles of solid.

This procedure was applied for two different values of the volume fraction within the clusters. The one corresponded with hexagonal close-packing of spheres, and gave a dielectric constant of 180 for the solid rutile. The other corresponded with cubical close-packing of spheres, and gave a dielectric constant of 50. If both the cluster model and Böttcher's equation are correct, the arrangement within the clusters must be something between the hexagonal and cubical close-packing arrangements. The volume fraction within the clusters can then be empirically adjusted to yield the correct value of the dielectric constant of the rutile.

Having established the distribution of the powder alone in this way, the dielectric data for the adsorbed gases may be treated in either of two ways on making the further assumption that the adsorbed matter is contained within clusters. These are: (*a*) Calculate the mean dielectric constant of the clusters as a function of the volume of adsorbed gas and then, using those results, calculate the dielectric constant by the extension of the powder method described earlier. (*b*) Calculate the mean dielectric constant of the clusters as in (*a*) above and then apply the solution method to the clusters to obtain the property of the adsorbed phase.

Method (*a*) yielded values of ϵ_2 approaching infinity. Method (*b*), led, in the case of butane, to a value of $\alpha_2 = 11.6 \times 10^{-24}$cc. per molecule, compared with 8.2×10^{-24} from refractive index measurements. This corresponds with a prediction of a permanent moment of 0.5×10^{-18} e.s.u. for a nonpolar

adsorbate. As already argued, such a prediction illustrates some inadequacy of the treatment. The apparent permanent moments of ethyl chloride and ammonia, as shown in Table IV, are in fair agreement with the known moments. On the other hand, a virtually infinite moment was deduced for sulphur dioxide. Furthermore, although both procedures (*a*) and (*b*) gave excellent straight lines over the entire range of quantity adsorbed they obscured the discontinuity of the slope of the primary data. On these grounds the method must be considered invalid.

Kamiyoshi's Method

Kamiyoshi (9, 10) starting with Rayleigh's formula for a cubical array of spheres (15) obtained expressions for the apparent dielectric constants of two types of region regarded as making up the composite dielectric. These regions were considered to consist of spheres of dielectric constant ϵ_0 in space and of spheres of dielectric constant 1 in a medium of dielectric constant ϵ_0. Then, on the assumption that the over-all dielectric constant may be obtained by combining these two types of region as a system of condensers in series and in parallel, a formula was deduced which would yield the value of the dielectric constant of the solid. Similar treatment would yield a value of the dielectric constant of solid plus adsorbed phase. If a porous adsorbent was employed an empirical correction factor had to be introduced to obtain the correct value of the dielectric constant of the solid, much as the packing factor was selected in the "cluster" treatment outlined earlier. Such an empirical factor had to be introduced in the case of rutile.

When the dielectric constant of adsorbent plus adsorbate is deduced by this method, some further means of separating the contributions of the two constituents must be employed. Kamiyoshi (10) used a solution model and the Debye equations for dilute solutions. Theoretically, this general procedure is hardly preferable to any of those with which we have already dealt. However, as each is semiempirical, Kamiyoshi's method was employed using ethyl chloride and butane on rutile. With ethyl chloride the value of μ_2 was found to be 1.41×10^{-18} e.s.u. In the case of butane, however, a permanent moment of about 1.6×10^{-18} e.s.u. was deduced, and on the arguments put forward earlier this demonstrates the inapplicability of the method. This is not an isolated example, since Kamiyoshi himself has reported apparent permanent moments of 0.57 and 0.47×10^{-18} e.s.u. for carbon tetrachloride and for benzene, respectively, adsorbed on silica gel (10). Owing to the tediousness of the computations by this method other data were not tested in view of these unsatisfactory results. An application of our modified solution treatment was not attempted because in this case the value of ϵ for the solid plus adsorbate varies appreciably over the range of quantity adsorbed.

GENERAL CONCLUSIONS

The interesting phenomena which may be observed on measuring capacity increments with increasing quantity of adsorbate on a solid have been shown to be of fairly general occurrence and to be specific to the adsorbent as well

as the adsorbate. Up to the present however, no satisfactory way of obtaining the apparent electrical properties of adsorbed matter has been developed, and until this is achieved no great clarification of the observations appears likely.

TABLE IV

APPARENT DIPOLE MOMENTS FOR ADSORBATES ON RUTILE BY THE "CLUSTER" METHOD OF COMPUTATION

Substance	Temp., °C.	Apparent dipole moment $\times 10^{18}$	Gaseous dipole moment $\times 10^{18}$

THE GROWTH OF CRYSTALLINE LAYERS ON FOREIGN SURFACES[1]

By J. H. Singleton and G. D. Halsey, Jr.

ABSTRACT

When the bulk phase of an adsorbent is solid, it has been shown that adsorption often proceeds only to a finite limit as the pressure reaches saturation. A theory is developed for this finite limit, in terms of the excess forces at the surface and the incompatibility of the crystal lattices of the adsorbent and adsorbate. It is applied to the stepwise adsorption of krypton on graphitized carbon black. An extrapolation formula applicable to smooth isotherms at high coverages is developed and shown to be analogous to the Harkins–Jura equation. It is applied to argon adsorbed on carbon black, on xenon preadsorbed on carbon black, on silver iodide, and on anatase. The energies obtained are compared with a theoretical estimate based on the Kirkwood–Müller equation. A theory for calculating isotherms on preadsorbed layers is developed and compared with the data for argon on xenon.

In the temperature range of ordinary physical adsorption measurements, the adsorbate is usually a liquid in the bulk phase. It appears that, at least in the typical case, adsorption proceeds without limit as the pressure approaches saturation. At lower temperatures we have shown (8, 9) that there is a definite upper limit to the thickness of the adsorbed layer in a number of cases. The technique used involved following the change in the argon isotherm as the preadsorbed layer of the adsorbate was thickened. For the adsorption of xenon on anatase or silver iodide, only one or two atomic layers of the rare gas on the surface produced the saturation pressure of the bulk crystal. In the case of krypton on a graphitized carbon black, a definite upper limit was established between five and six layers.

It is clear that for growth to continue, a supersaturated atmosphere of xenon would be required, and that the degree of supersaturation would be related to the ability of the foreign surface to act as a nucleating agent for, in this case, xenon. Difficulties inherent in working with supersaturated vapors make it desirable to develop a theoretical method of calculating the degree of supersaturation from equilibrium data below saturation.

A Theory Predicting a Finite Adsorption Limit

The adsorption of argon on graphitized carbon black has been interpreted as evidence of surface homogeneity, because of the quasi-stepwise character of the isotherm. Our measurements with krypton at 77°K. on the same adsorbent show much more pronounced steps. Champion and Halsey (1) have modified the treatment of Hill (5) for adsorption on a uniform surface. His theory is essentially a generalization to n layers of the crude treatment of adsorption with lateral interaction given by Fowler and Guggenheim (2). He took into account the condensation energy of the adsorbate but neglected

[1]*Manuscript received September 16, 1954.*
Contribution from the Department of Chemistry, University of Washington, Seattle, Wash., U.S.A. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

the van der Waals forces transmitted from the surface to each succeeding layer. When these forces are included the isotherm that results is composed of a series of steps.

In an attempt to suppress these steps, and thus produce an ordinary smooth isotherm on a uniform surface, Champion and Halsey introduced the idea of an incompatibility between the crystal lattices of the adsorbent and the adsorbate. It was possible to make the steps disappear, but in order to have adsorption continue out to several layers it was necessary to increase the van der Waals forces and to change their decay law unreasonably. Thus, the theory developed was found not to apply to ordinary adsorption in the liquid range; however, it will now be applied to the problem of finite adsorption limits.

Hill's equations were modified to read

$$[1] \quad p/p_0 = [(\theta_n - \theta_{n+1})/(\theta_{n-1} - \theta_n)] \times \exp\{(-E_n/kT) + (w/kT)(-2g_n\theta_n - 1)\}.$$

Here, p/p_0 is the partial pressure in equilibrium with the adsorbed layers, θ_n the coverage in the nth layer, E_n the excess energy of adsorption transmitted to the nth layer, and w the lateral interaction energy. The last two are taken positive in sign for attractive interaction, which is the opposite of the usual thermodynamic convention. The compatibility factor, g_n, can vary from zero to unity. If it has the value zero, the lateral interactions are completely suppressed. If the factor is unity, it is implied that the lattices are completely compatible, and so the full energy of lateral interaction is operative. It will appear that the degree of incompatibility necessary to suppress growth beyond a few layers is not large. Since w is approximately equal to one half the energy of sublimation of the bulk crystal, and since g_n will always be near unity, calculations using equation [1] will lead to a completely stepwise isotherm (1). In order to find the positions of the risers of the steps in terms of p/p_0, the value one half is given to θ_n, unity to θ_{n-1}, and zero to θ_{n+1}. This yields a simple expression for the pressure at the nth step:

$$[2] \quad \ln(p/p_0)_n = -E_n/kT + (w/kT)(1 - g_n).$$

This equation can be put into usable form by making two assumptions; first that the energy E_n is given by the cube law (1, 6)

$$[3] \quad E_n = E_1/n^3,$$

and second that g_n has the constant value g in all layers. Thus

$$[4] \quad \ln(p/p_0)_n = -E_1/n^3kT + (w/kT)(1 - g).$$

We shall now use the positions of the steps for the second and third layers in the isotherm for krypton on graphitized carbon black to evaluate the parameters. The data so fitted are shown in Fig. 1. The values used to achieve this fit are $E_1/kT = 7.9$ and $(w/kT)(1-g) = 0.09$. The heat of sublimation of solid krypton is about 2.5 kcal. and T is 70°K. Thus g is 0.99 or almost unity. This value of g causes the isotherm to cross the axis $p/p_0 = 1$ at between four and five layers, whereas the actual crossing was one layer higher.

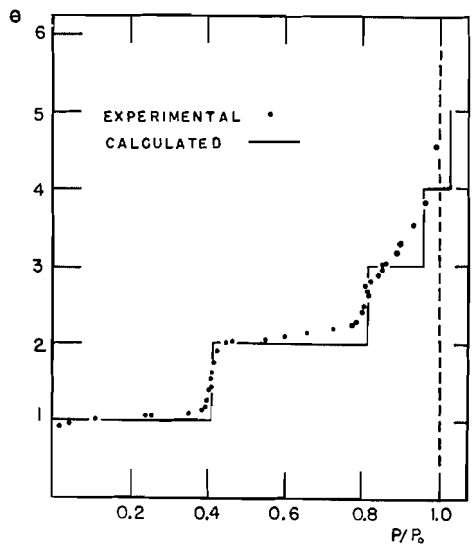

FIG. 1. Comparison of steps calculated from equation [4] with experimental isotherm points of krypton on graphitized carbon black at 77.1°K.

It appears that a very slight disturbance of the structure of the bulk crystal, at least as is reflected in its energy, is enough to halt the growth of the adsorbed phase at a definite limit. Note that this disturbance is nowhere nearly equal to the heat of fusion (which is about 12% of the heat of sublimation) so that the surmise that the adsorbed phase is "liquid" is definitely wrong.

An Extrapolation Formula

If the coverage on the surface is many layers thick, the integral layer number n in equation [4] can be replaced by the continuous variable, θ, the total coverage. An isotherm equation results:

$$\ln(p/p_0) = -E_1/\theta^3 kT - (w/kT)(1-g). \quad [5]$$

With $g = 1$, this equation reduces to a special case of an equation successfully applied to adsorption from the liquid phase:

$$\ln(p/p_0) = -E_1/kT\theta^r. \quad [6]$$

As we observed above, for the liquid, compatibility does not seem to present a problem. The present equation is analogous to the equation used by Harkins and Jura (4) in connection with their relative method of evaluating surface area:

$$\ln(p/p_0) = A - B/v^2. \quad [7]$$

Here A and B are constants and v is the volume adsorbed and is thus proportional to θ. The change in power of θ from the Harkins value of two to three in equation [5] attaches a definite meaning to the constants. The analogue of A in equation [5] is a measure of incompatibility. The interpretation of E_1 will be discussed in the next section.

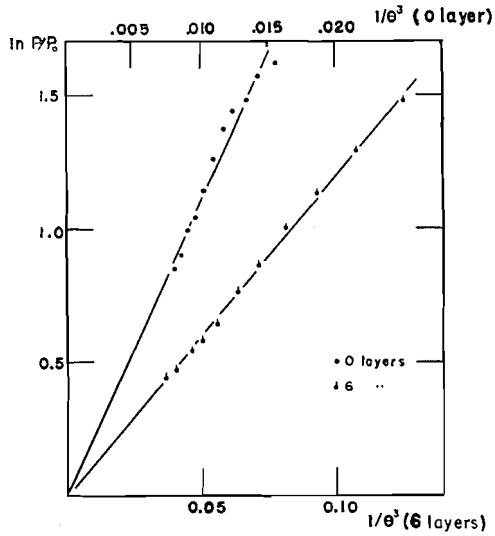

FIG. 2. Extrapolation from data for argon adsorption on graphitized carbon black using equation [5] (0 and 6 layers of preadsorbed xenon: 77.1°K.).

The data for the adsorption of argon on the graphitized carbon black, and for the adsorption of argon on six layers of xenon preadsorbed on the black are plotted according to equation 5 in Fig. 2. Note that the points for the six layers of xenon extrapolate to the origin, which shows that the solid argon is fully compatible with the preadsorbed xenon. It appears that the points for the bare carbon surface also extrapolate at least very near to the origin,

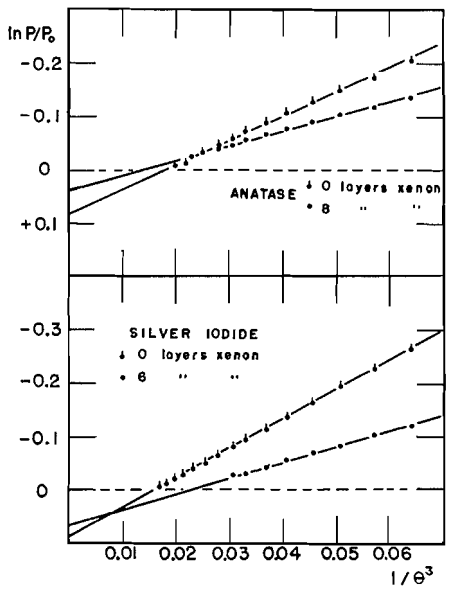

FIG. 3. Extrapolation from data for argon adsorption on anatase and silver iodide, using equation [5] (0 and 8, 0 and 6 layers of preadsorbed xenon, respectively: 77.1°K.).

although, because of the bumpiness in the isotherm, the straight line plot is not perfect.

In Fig. 3, some data that do not intercept the origin are presented. Argon is thus not compatible with either anatase or silver iodide. On both surfaces the intercept on the $\ln(p/p_0)$ axis is at about 0.09, which corresponds to a supersaturation ratio of 1.1. Note that when the surfaces are coated with as much xenon as they will support, the intercept is reduced, and the supersaturation ratio decreases to 1.05 for silver iodide and 1.08 on anatase. Thus the xenon forms sort of a "graded seal". In harmony with the greater thickness of xenon layer on silver iodide, the decrease in the supersaturation ratio is greater.

Comparison of E_1 with the Kirkwood–Müller Formula

When the extrapolation formula (5) is used to evaluate E_1 it is clear that the value found is unlikely to agree with E_1 values found experimentally using data over the first-layer range. Short-range forces, heterogeneity, crystal lattice periodicity, and incompatibility all operate to affect the real value of E_1. The E_1 evaluated using data at high coverages represents only the long-range surface forces, with local disturbances more or less averaged out. It is thus more nearly the ideal quantity to compare with theoretical estimates of the London force than calorimetric data are. Steele and Halsey (10) have calculated the energy of interaction of a single rare gas atom at a distance D from the surface using the following expression, which is based on a treatment due to Kirkwood and Müller (7):

$$[8] \qquad \epsilon^* = (N_2 mc^2 \pi/D^3)\{\alpha_1\alpha_2/[(\alpha_1/\chi_1)+(\alpha_2/\chi_2)]\}$$

N_2 is the number of atoms per cm.^{3} in the solid, mc^2 is the mass of the electron multiplied by the velocity of light squared, and α and χ are the atomic polarizability and atomic susceptibility respectively. The subscript one refers to the adsorbed atom and two refers to the adsorbent atoms.

Following Hill (6), we must now modify this expression so that it applies to an adsorbed atom surrounded by the other atoms of the adsorbed phase. E_n is defined as the excess energy available to the adsorbed atom in the nth layer because of the presence of the adsorbent n layers away. Because the absolute pressure, p, is divided by the reference-state pressure p_0, the energy must be corrected by the extent to which the adsorbed layers deviate from the bulk structure. Part of this deviation has been taken care of by the g factor of equation [5]. However, in introducing a semi-infinite slab of adsorbent n layers away, a similar slab of adsorbate has been removed. Therefore one must subtract this energy of self interaction from equation [8] to obtain the expression for E_n.

$$[9] \qquad E_n = \epsilon^* - (N_1 mc^2 \pi/D^3)(\alpha_1\chi_1/2)$$

N_1 is the number of atoms per cm.^{3} in the solid adsorbate. The distance D must now be evaluated in order to calculate E_1. Since the E_1 determined

using the extrapolation formula equation [5] refers to large distances from the surface, the appropriate distance is that between adjacent parallel planes of atoms in the bulk adsorbate. For the close-packed rare gas crystals, this is equal to $\sqrt{\frac{2}{3}}$ times the lattice parameter.

Comparison of the Calculated and Experimental Values of E_1

The constants used to calculate E_1/kT are presented in Table I. The temperature was 77°K. The density given was used to calculate the lattice parameter. It will appear in the analysis of the argon isotherms on xenon which follows below, that the argon isotherm on six atomic layers of xenon is sufficiently close to the calculated isotherm for an infinitely thick layer of xenon to calculate E_1/kT on this basis. The calculated value is 2.55 compared to the measured value 1.20. For argon on the bare carbon surface the calculated value is 13.8 compared to 11 measured. For the case of krypton on carbon, which was analyzed using the formula, equation [4], the calculated value is 15.3, compared to the measured value 7.9.

The calculated value for argon on silver iodide is 9.7; the experimental value is 11. No estimate of the diamagnetic susceptibility of anatase could be found. Since the theory is admittedly quite crude, the agreement, although not perfect, is satisfactory.

TABLE I

	Density (gm./ml.)	Atomic susceptibility $\times 10^{29}$	Atomic polarizability $\times 10^{24}$
Argon	1.65[a]	3.24[c]	1.623[e]
Krypton	2.994[a]	4.65[c]	2.46[e]
Xenon	3.56[a]	7.04[c]	4.00[e]
Silver iodide	5.67[b]	13.6[d]	9.28[f]
Carbon black	2.25[b]	3.79[d]	1.02[f]

A Theory for Adsorption on Top of Preadsorbed Layers

The two different preadsorbates that we have studied exhibited layer formation in the case of xenon and solution in the case of krypton when argon was subsequently adsorbed. It was possible to develop a crude theory for solution in preadsorbed layers (9) by modification of the regular solution theory of Fowler and Guggenheim (3) to include the free energy of adsorption. The essential assumption added to those of the bulk solution theory was that the presence of component B did not affect the molar contribution of component A to the adsorption energy, and vice versa. This amounted to assuming that

the two species were the same size; an equivalent assumption will be required here for a given total coverage $\theta_A+\theta_B$; the adsorption free energy was calculated from a weighted average of the energy for the pure components. It was then possible to calculate the mixed isotherms from the isotherms for the single components and the bulk solution data.

We shall now develop an analogous theory for the case (that of argon on xenon) where the essentially non-volatile component B forms an insoluble and distinct layer under the volatile A. The problem is to calculate intermediate isotherms for A from the isotherm for the surface bare of B, and the isotherm for the surface covered with an infinite number of layers of B. We shall see that this latter isotherm can be calculated although it may not be possible to measure it directly. Suppose that there are N_A molecules of A and N_B molecules of B adsorbed on the surface. (These numbers can be related to θ by dividing by the number of molecules in a monolayer.) We shall denote the isotherm for A on b layers of B by $(p/p_0)_b$ and the isotherm for pure B on the otherwise bare surface by $(p/p_0)_B$. The free energy of the adsorbent and its surface is a constant, F_s. (Note that since the reference state is a solid there is essentially no volume change associated with the adsorption process and that therefore F, the Helmholtz free energy, equals G, the Gibbs free energy, and so no distinction need be made.) Then, the total free energy of the surface plus N_A molecules of A and N_B molecules of B is

$$[10] \qquad F = F_s+kT\int_0^{N_B}\ln(p/p_0)_B dN+kT\int_0^{N_A}\ln(p/p_0)_b dN.$$

Then the chemical potential of A

$$[11] \qquad \mu_b^A = \partial G/\partial N_A = \partial F/\partial N_A = kT\ln(p/p_0)_b,$$

independent of F_s and the isotherm for component B.

We shall now divide the contributions to μ_b^A into two terms; one from the underlying solid and one from a slab b layers thick of component B. If we assume that these b layers are exactly equivalent to the same number of layers of A in reducing the contribution of the surface forces, then the first term in μ_b^A is the chemical potential of argon on the bare surface μ_0^A evaluated at $b+\theta_A$ layers. To this term must be added the term for the slab of B of thickness b layers. This is equal to the contribution from a slab of infinite thickness $\mu_\infty^A(\theta_A)$ minus the contribution from beyond $b+\theta_A$ layers, $\mu_\infty^A(\theta_A+b)$:

$$[12] \qquad \mu_b^A = \mu_0^A\,(b+\theta_A)+\mu_\infty^A(\theta_A)-\mu_\infty^A(b+\theta_A)$$

This relationship can be put in terms of the isotherm data by using equation [11], but actually it is more convenient to carry out the calculations in terms of the μ's. Note that for the relationship equation [12] to hold, the monolayer thickness of B must equal that of A, or else it will have a different effect in reducing the surface forces. This restriction corresponds to the restriction of regular solution theory that the molecules must be of the same size.

Calculation of the Limiting Isotherm $(p/p_0)_\infty$

If the known isotherm for argon on six layers of xenon, and thus μ_6^A is substituted into equation [12] a difference equation in the unknown μ_∞^A results. As a first approximation, the value of μ_6^A at $6+\theta_A$ can be used in place of $\mu_\infty^A(6+\theta_A)$ to calculate $\mu_\infty^A(\theta_A)$. This better value can then be used in the equation for a second approximation, etc. Throughout, the extrapolation formula equation [5] is used to obtain values beyond the experimental range. The result of this calculation is shown as an isotherm in Fig. 4. It is compared with

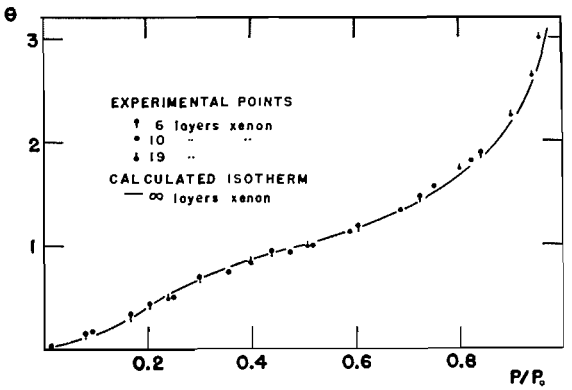

FIG. 4. Comparison of the limiting isotherm for argon on preadsorbed xenon, calculated according to equation [12], with experimental points taken at 77.1°K. (graphitized carbon black).

experimental points taken in the presence of enough xenon to make 6, 9.7, and 19.4 atomic layers. One can calculate from the extrapolation formula that going from 6 to 10 layers should change the upper part of the isotherm noticeably, and that the isotherm for 20 layers should be indistinguishable from the limiting curve. It would appear, then, that growth does stop between 6 and 10 layers. However, the continued change in the isotherm near a monolayer of argon, upon going from 6 to 10 layers of xenon, suggests that the surface arrangement of the xenon is different in the last few layers.

Calculation of the Intermediate Isotherms

In Fig. 5 isotherms calculated from the limiting isotherms are presented. They are compared with some of the experimental data. Although agreement is not quantitative, the general features of the data are well reproduced. Note that the calculated pressures are above the observed values, in keeping with the fact that the atomic layers of xenon are presumably thicker than the argon layers.

Previously (8), we had adjusted the monolayer volume of xenon by a 20% increase from the "point B" value, because when this volume was preadsorbed, a small "point B" appeared in the argon isotherm. No similar adjustment was made in the argon v_m, and therefore the isotherms here are presented in terms of the estimated "point B" volume. However, the calculated isotherm on one layer of xenon shows a "point B" of 0.1 monolayer. This at least suggests

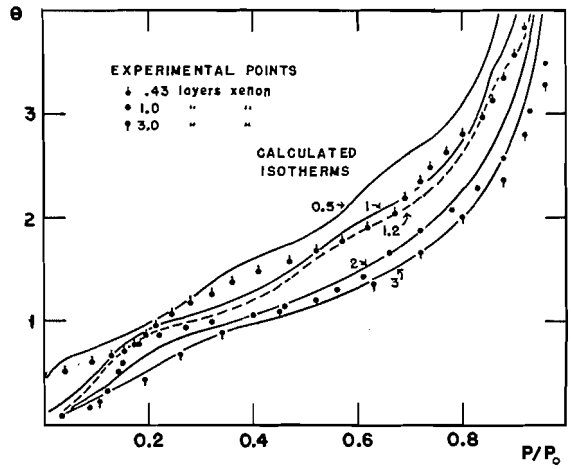

FIG. 5. Calculated isotherms for argon on preadsorbed xenon, using equation [12], compared with experimental points taken at 77.1°K. (graphitized carbon black).

that the true argon v_m should be larger also. This is in keeping with other independent estimates we have made of the area of this carbon black, all of which are larger than the B. E. T. area.

USE OF INTERPOLATION THEORY IN THE ANALYSIS OF GAS ADSORPTION ISOTHERMS

I. THEORY[1]

By J. M. Honig and P. C. Rosenbloom

ABSTRACT

The theory presented in this paper permits the determination of extremal bounds for a given adsorbate–adsorbent system within which the adsorption isotherms must fall if certain assumptions pertaining to the nature of the adsorption process are applicable. The use of interpolation theory in estimating lower and upper bounds on physical quantities of interest in adsorption theory is also discussed.

INTRODUCTION

The object of this paper is to present a new mathematical approach to the problem of surface heterogeneity and its effect on the physical sorption of gases by solids. In previous work of this type (1–5, 9, 13–16, 18) it has been customary to interpret a given isotherm in terms of a particular distribution of adsorption energies among the surface sites of the adsorbent. Several difficulties associated with this correlation procedure have by now emerged (6, 10, 11): First of all, the isotherm equation is quite insensitive to the choice of distribution function which characterizes the energy heterogeneity. Secondly, it is necessary to introduce a large number of simplifying assumptions in order to make the correlations mathematically feasible. It is often difficult to ascertain to what extent the simplifications are really applicable, the more so because the adsorption theories in themselves furnish no pertinent criteria. In view of these difficulties it would be instructive to estimate the maximum variation in the adsorption isotherm as the energy distribution is allowed to vary over all conceivable mathematical functions consistent with the physical requirements. Further, it is desirable to have at hand some method of checking the validity of the restrictive assumptions.

The present paper is devoted to a study of these subjects. It will be shown that by random selection of one or more points from a set of isotherm data one can construct lower and upper bounds which define the maximum possible variation in the isotherm data consistent with the simplifying restrictions. Failure of the remaining points to remain within these bounds is a clear indication that the restrictive postulates and the data are incompatible, at least over certain ranges of surface coverage. Lastly, the theory lends itself to a determination, without resorting to curve fitting procedures, of lower and upper bounds on quantities of interest in adsorption theory.

The mathematical theory is based on a publication by Rosenbloom (12) to which the reader is referred for verification of the theorems cited in the next

This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

sections. The relevant parts of this theory are also summarized and made plausible in an appendix. Examples illustrating the application of this theory to experimental data will be presented elsewhere.

FUNDAMENTAL CONCEPTS

A. The following assumptions are used as a basis for further discussions (see also (7)): (*a*) Adsorption occurs on a fixed number of surface sites; (*b*) adsorption is limited to a monolayer; (*c*) each site is associated with a fixed adsorption energy; (*d*) no lateral interactions occur between adsorbed molecules; (*e*) each adsorbed particle is held rigidly to its site of adsorption; (*f*) the distribution of adsorption energies remains unaltered in the adsorption process. Using these assumptions it can be shown (1, 2, 4, 5, 9, 13–16, 18) that the fraction of surface sites covered, θ, is related to the gas pressure, p, and to the temperature T by the expression

$$[1] \qquad \theta(p, T) \equiv \frac{n}{n_m} = \int_0^\infty \frac{dF(\epsilon)}{1+[\beta(\epsilon, T)/p]\, e^{-\epsilon/kT}}.$$

Here ϵ is the adsorption energy associated with a given site and $dF(\epsilon) = f(\epsilon)\, d\epsilon$ is the fraction of all sites associated with adsorption energies in the range ϵ to $\epsilon+d\epsilon$. The quantity $\beta(\epsilon, T)$ is related (5) to the ratio of internal partition functions of molecules in the gas phase and on the surface; n and n_m are the quantities of adsorbate present on the surface at equilibrium and when the surface is covered by a monolayer.

It is shown (7) that by use of the substitutions

$$[2] \qquad \begin{aligned} &\eta = \epsilon-\epsilon_0 \geqslant 0, \\ &\alpha_0 = \alpha(0, \epsilon_0, T), \\ &\alpha(\eta, \epsilon_0, T) = \beta(\eta+\epsilon_0, T)\, e^{-\epsilon_0/kT}, \\ &y = \alpha_0/p+1, \\ &\lambda = (\alpha_0/\alpha)\, e^{\eta/kT}-1, \end{aligned}$$

the integral [1] can be converted into the simple form

$$[3] \qquad L(y, T) = \int_0^\infty \frac{dG(\lambda, T)}{\lambda+y}.$$

In equation [3], $L(y, T) \equiv \theta_1(\alpha_0/(y-1), T)$ and

$$[4] \qquad \begin{aligned} G(T) &= \int_0^\infty dG(\lambda, T) \equiv \int_0^\infty g(\lambda, T)\, d\lambda \\ &= \int_0^\infty (\alpha_0/\alpha)\, e^{\eta/kT} f(\eta+\epsilon_0)\, d\eta \\ &= \int_0^\infty (\lambda+1) dF(\epsilon). \end{aligned}$$

Note that the above substitutions were introduced in order to take into account

the possible dependence of β on ϵ, and the possibility that the lowest adsorption energy on the surface may have the value $\epsilon_0 > 0$.

B. According to theory (12), if L is a function of the form [3] and if $F(\epsilon)$ is a nonnegative, nondecreasing function such that $G(0) = 0$ then the function L must satisfy certain restrictive inequalities. Let us consider the class of all functions of the form [3] which are subject to $k+1$ restrictions

$$[5] \qquad L(y_i, T) = C_i, \qquad i = 0, 1, 2, \ldots k,$$

where $y_0 < y_1 < \ldots < y_k$ and where the C_i are given constants. Then there exist two uniquely determined functions L_a and L_b in this class such that for any other functions in this class the following inequalities hold:

$$[6] \qquad \begin{aligned} &L_a(y, T) \leqslant L(y, T) \leqslant L_b(y, T) \text{ for } y_k < y,\ y_{k-2} < y < y_{k-1},\ y_{k-4} < y < y_{k-3}, \text{ etc.;} \\ &L_a(y, T) \geqslant L(y, T) \geqslant L_b(y, T) \text{ for } y_{k-1} < y < y_k,\ y_{k-3} < y < y_{k-2}, \text{ etc.} \end{aligned}$$

Thus, in alternate intervals between the selected reference values y_i of equation [5], L_a and L_b represent extremal functions, each forming lower and upper bounds alternately in the consecutive intervals marked off by the y_i. L_a and L_b thus represent an interlacing structure on an L vs. y diagram.

Of the $k+1$ restrictions used in equation [5], k are obtained by arbitrary selection of k reference points $\theta(p_i, T)$ from the experimental isotherm data. An additional restriction arises from the normalization requirement

$$[7] \qquad 1 = \int_0^\infty dF(\epsilon) = \lim_{p\to\infty} \theta(p, T) \equiv \theta(\infty, T) = L(1, T).$$

C. Having examined the existence of extremal bounds, we now turn to a discussion of the conditions under which $L(y, T)$ assumes the limiting form L_a or L_b. It can be shown (see (12) and appendix) that the extremal functions L_a and L_b are obtained from equation [3] if $G(\lambda, T)$ is chosen to be a step function

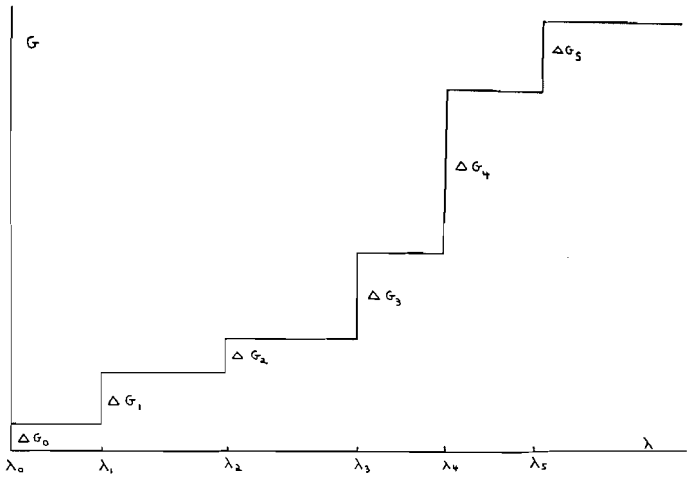

FIG. 1. The step function G.

with at most $k+1$ jumps at the points $\lambda_0, \lambda_1, \ldots, \lambda_k$. (See Fig. 1). In the open intervals $\lambda_i < \lambda < \lambda_{i+1}$ $(i = 0, 1, \ldots, k)$, $dG(\lambda, T) \equiv 0$; hence in these regions the integral vanishes identically. At each of the points of discontinuity, λ_i, however, the function G increases by an amount ΔG_i as shown in the figure, and the denominator in the integral [3] assumes the value λ_i+y. Thus, an increment $\Delta G_i/(\Delta_i+y)$ is associated with every stepwise increase in G; equation [3] is accordingly reduced to a summation of the form

$$[8] \qquad L_{a,b}(y, T) = \sum_{i=0}^{k} \frac{\Delta G_i}{\lambda_i+y}.$$

It is evident from equation [8] that the use of Stieltjes integrals lends itself particularly well to the type of interpolation theory described here. For a rigorous discussion of the theory and properties of such integrals the reader is referred to standard texts (17). In this connection it might be noted that the distribution density function $g(\lambda, T) = \partial G(\lambda, T)/\partial\lambda$, which corresponds to the step function G described above, is a linear combination of $k+1$ Dirac delta functions located at $\lambda = \lambda_i$.

D. To determine L_a or L_b uniquely it is now necessary to fix (*a*) the number of terms in the summation [8], (*b*) the size of the jumps ΔG_i, and (*c*) their location on the λ scale. (*a*) The theory of Reference 12 requires that we count each step in the function G that occurs in the open interval $0 < \lambda < \lambda_k$ with weight 2 and that we assign weight 1 to a jump by G at either end point 0 or λ_k. Let us define the *order* of a function of the form [8] as the total weight of all the steps. The theory of extremals (12) then demands that the order of L_a or L_b be at most $k+1$. This requirement determines the number of properly weighted terms to be included in the summation. (*b*, *c*) The values of λ_i and of ΔG_i may be determined from the conditions of constraint [5] imposed on the system. Detailed computational procedures for this step will be provided in the next two sections for the cases $k = 1$ (order two) and $k = 2$ (order three). The extension to larger k values is straightforward, but the mathematical complications become excessive in the higher order calculations.

It may be noted that L_a and L_b are continuous functions of the variable y. Since these extremals are also affected by the choice of reference values y_i, it is clear that any experimental errors in the reference points $\theta(p_i, T)$ will displace the calculated limiting curves from their correct positions. The magnitude of this effect can be computed by the standard calculational procedures.

E. To sum up: It is possible to specify two limiting isotherms L_a and L_b which delineate the greatest possible variations in θ as $F(\epsilon)$ assumes all functional relationships which leave the integral [1] convergent. The specification of L_a and L_b requires that $G(\lambda, T)$, related by equation [4] to the distribution $F(\epsilon)$ of energies over the surface sites, be a step function. This choice converts the Stieltjes integral [3] into a summation. The number of terms in that sum, the size of the jumps in G, and their location in the λ spectrum are all determined by the imposition of conditions of constraint. The latter are obtained from the normalization condition for $F(\epsilon)$ and by selection of a limited number of reference points from the experimental data, through which the limiting isotherms

are required to pass. If the remaining experimental points fall outside the prescribed bounds, the observed isotherm data are not compatible with assumptions (*a*)–(*f*).

SECOND ORDER THEORY

In the second order theory the two constraints on L are given by $L(1, T) = 1$ and $L(y_1, T) = C_1$. (See equations [7] and [5].) There are two extremal distribution functions G which can be specified to be of order two. One of these, G_a, is constant everywhere except for a jump ΔG_1 at some point λ_1 in the range $0 < \lambda < \lambda_m$. The second distribution, G_b, is likewise constant everywhere except for a jump ΔG_0 at $\lambda = 0$ and another jump ΔG_m at $\lambda = \lambda_m$. In these relations λ_m represents the maximum value of λ encountered for the adsorption system under study.

Using the first of these distributions functions in equation [8] one obtains

$$L_a(y, T) = \Delta G_1/(y+\lambda_1) \tag{9}$$

while use of the second distribution function in equation [8] yields

$$L_b(y, T) = \Delta G_0/y+\Delta G_m/(y+\lambda_m). \tag{10}$$

The constants ΔG_0, ΔG_1, ΔG_m, and λ_1 can be determined by application of the two conditions of constraint which the extremal functions must satisfy. Thus from [9] one finds

$$\begin{aligned} L_a(1, T) &= 1 = \Delta G_1/(1+\lambda_1), \\ L_a(y_1, T) &= C_1 = \Delta G_1/(y_1+\lambda_1). \end{aligned} \tag{11}$$

Similarly, from equation [10]

$$\begin{aligned} L_b(1, T) &= 1 = \Delta G_0+\Delta G_m/(1+\lambda_m), \\ L_b(y_1, T) &= C_1 = \Delta G_0/y_1+\Delta G_m/(y_1+\lambda_m). \end{aligned} \tag{12}$$

Solution of the two sets of simultaneous equations leads to

$$\begin{aligned} \lambda_1 &= (C_1y_1-1)/(1-C_1), \\ \Delta G_1 &= (C_1y_1-C_1)/(1-C_1), \end{aligned} \tag{13}$$

and

$$\begin{aligned} \Delta G_0 &= [1+\lambda_m-C_1(y_1+\lambda_m)]\, y_1/\lambda_m(y_1-1), \\ \Delta G_m &= (C_1y_1-1)(y_1+\lambda_m)(1+\lambda_m)/\lambda_m(y_1-1). \end{aligned} \tag{14}$$

Substitution of equations [13] into [9] results in the extremal isotherm

$$L_a(y, T) = [1+(y-1)(1-C_1)/C_1(y_1-1)]^{-1}. \tag{15}$$

Similarly, use of equations [14] in [10] yields the second extremal isotherm

$$\begin{aligned} L_b(y, T) = \lambda_m^{-1}(y_1-1)^{-1}\{&(y_1/y)[1-C_1y_1+\lambda_m(1-C_1)] \\ &+[(y_1+\lambda_m)/(y+\lambda_m)]\,[C_1y_1-1+\lambda_m(C_1y_1-1)]\} \end{aligned} \tag{16}$$

As a final step, it is only necessary to introduce the relations for y, L, and C_1 from equations [2], [3], and [5]. This gives us the explicit relations

$$\theta_a = p\theta_1/[p_1(1-\theta_1)+p\theta_1], \tag{17}$$

$$\theta_b = \frac{p_1/\alpha_0}{\lambda_m}\left\{\left(\frac{\alpha_0/p_1+1}{\alpha_0/p+1}\right)[(1+\lambda_m)(1-\theta_1)-\theta_1(\alpha_0/p_1)] + \left(\frac{\alpha_0/p_1+1+\lambda_m}{\alpha_0/p+1+\lambda_m}\right)(\lambda_m+1)[\theta_1(\alpha_0/p_1+1)-1]\right\}. \tag{18}$$

In the above relations $\theta_1 \equiv \theta(p_1, T)$ where θ_1, p_1 is the reference point, arbitrarily selected from the isotherm data, through which the limiting curves θ_a and θ_b are required to pass; $\lambda_m = [\alpha_0/\alpha(\eta_m, \epsilon_L, T)] \exp(\epsilon_m-\epsilon_0)/kT-1$.

The labor of evaluating θ_b can be considerably reduced by selecting a reference pressure p_1 such that $\alpha_0/p_1+1 << \lambda_m$. Then in the pressure range for which $\alpha_0/p+1 << \lambda_m$, equation [18] reduces to

$$\theta_b(p, T) = [p-p_1+(\alpha_0+p_1)\theta_1]/(\alpha_0+p). \tag{19}$$

It is readily verified that the exact functions [17] and [18] interlace at the common points $(0, 0)$, (θ_1, p_1), and $(1, \infty)$, as required. Equation [19] fails to meet the first requirement, which merely means that this limiting function, together with [17] bounds a wider region than equations [17] and [18] and thus furnishes less precise information.

It is instructive to determine which of the two limiting isotherms represents the lower and the upper bounds in the two regions $p < p_1$ and $p > p_1$. A mathematical analysis of this problem will be deferred to a later paper. One can, however, arrive at a decision by use of a qualitative argument. It is seen that θ_a represents the Langmuir adsorption isotherm; this is consistent with the assumption that the associated function $g(\lambda, T)$ vanishes everywhere except for a Dirac delta peak at $\lambda = \lambda_1$. The energy density distribution function $f(\epsilon)$ has a corresponding peak at $\epsilon = \epsilon_1$. In most experimental work, however, one encounters a much wider distribution in ϵ. In particular, at very low pressures the sites associated with adsorption energies near ϵ_m will be filled much more extensively than those associated with energies $\epsilon_1 < \epsilon_m$. It is thus to be expected that at these low pressures the experimental isotherm will be greater than the calculated Langmuir isotherm associated with the energy ϵ_1. By selecting a p_1 from the higher pressure range and by noting the interlacing properties discussed earlier it follows that

$$\theta_a < \theta < \theta_b \quad \text{for} \quad 0 < p < p_1,$$
$$\theta_a > \theta > \theta_b \quad \text{for} \quad p_1 < p < \infty. \tag{20}$$

THIRD ORDER THEORY

In this section we deal briefly with the problem of finding upper and lower bounds on $L(y, T)$ when three conditions of constraint are placed on $L(y, T)$. These are: $L(1, T) = 1$, $L(y_1, T) = C_1$, and $L(y_2, T) = C_2$. There exist two extremal distribution functions $G(\lambda, T)$ which can be specified to be of order

three. The first, G_a, is everywhere constant except for two jumps ΔG_m and ΔG_1 located at $\lambda = \lambda_m$ and at a point $0 < \lambda_1 < \lambda_m$. The second, G_b, is everywhere constant except for two jumps ΔG_0 and ΔG_2 located respectively at $\lambda = 0$ and at a point $0 < \lambda_2 < \lambda_m$. Use of the two distribution functions in equation [8] yields

[21] $$L_a = \Delta G_1/(y+\lambda_1)+\Delta G_m/(y+\lambda_m),$$

[22] $$L_b = \Delta G_0/y+\Delta G_2/(y+\lambda_2).$$

Application of the conditions of constraint to equation [21] results in the set of equations

$$\Delta G_1 = (y_1+\lambda_1)(y_2+\lambda_1)[C_1(y_1+\lambda_m)-C_2(y_2+\lambda_m)]/(\lambda_m-\lambda_1)(y_2-y_1),$$

$$\Delta G_m = (y_1+\lambda_m)(y_2+\lambda_m)[C_2(y_2+\lambda_1)-C_1(y_1+\lambda_1)]/(\lambda_m-\lambda_1)(y_2-y_1),$$

[23] $$\lambda_1 = \frac{C_2y_2(y_1-1)(y_2+\lambda_m)-C_1y_1(y_2-1)(y_1+\lambda_m)+(y_2-y_1)(1+\lambda_m)}{C_1(y_2-1)(y_1+\lambda_m)-C_2(y_1-1)(y_2+\lambda_m)+(y_1-y_2)(1+\lambda_m)}.$$

Similarly, the use of the conditions of constraint in [22] yields the unknowns:

$$\Delta G_0 = y_1y_2[C_1(y_1+\lambda_2)-C_2(y_2+\lambda_2)]/\lambda_2(y_2-y_1),$$

[24] $$\Delta G_2 = (y_1+\lambda_2)(y_2+\lambda_2)(C_2y_2-C_1y_1)/\lambda_2(y_2-y_1),$$

$$\lambda_2 = \frac{(y_1-1)(C_2y_2^2-1)-(y_2-1)(C_1y_1^2-1)}{(y_2-1)(C_1y_1-1)-(y_1-1)(C_2y_2-1)}.$$

The extremal isotherms θ_a and θ_b can now be found by setting $L = \theta$, $C_1 = \theta_1$, $C_2 = \theta_2$, $y = \alpha_0/p+1$ in equations [23] and [24] and substituting these quantities into [21] and [22]. It is evident that the limiting isotherms are very unwieldy.

Fortunately one obtains a much simpler formulation whenever it is possible to select two reference pressures p_1 and p_2 which satisfy the inequality

[25] $$1 << \alpha_0/p_i << \lambda_m.$$

If one now restricts the range of pressures to values $\alpha_0/p \ll \lambda_m$ then θ_a reduces to

[26] $$\theta_a = \frac{(\theta_2-\theta_1)\,p+[\theta_1p_2(1-\theta_2)-\theta_2p_1(1-\theta_1)]}{(\theta_2-\theta_1)\,p+[p_2(1-\theta_2)-p_1(1-\theta_1)]}.$$

Likewise, using assumption [25], but imposing no restriction on p, it can be shown that θ_b reduces to

[27] $$\theta_b = \frac{\theta_1\theta_2(p_1-p_2)}{[(\alpha_0+p)/\alpha_0p]\,p_1p_2(\theta_1-\theta_2)+(\theta_2p_1-\theta_1p_2)}.$$

At sufficiently low pressures this limiting expression reads

[28] $$\theta_b = \frac{\theta_1\theta_2(p_1-p_2)}{p_1p_2(\theta_1-\theta_2)/p+(\theta_2p_1-\theta_1p_2)}.$$

It can be shown that the exact relations [21] and [22] interlace at $(0, 0)$, (θ_1, p_1), (θ_2, p_2), $(1, \infty)$ as required. The approximate functions [26] and [27] or

[28] do not meet at (0, 0) or (1, ∞) and thus bound a wider region on the θ vs. p diagram than the exact functions. In fact, it follows from [26] and [28] that

$$[29] \qquad \lim_{p\to 0} \theta_b = 0, \qquad \lim_{p\to 0} \theta_a = \frac{\theta_1 p_2(1-\theta_2) - \theta_2 p_1(1-\theta_1)}{p_2(1-\theta_2) - p_1(1-\theta_1)}.$$

Equation [29] shows that $\lim_{p\to 0} \theta_a$ may be either positive or negative depending on the magnitudes of the terms involved in the fraction. One cannot decide as to which isotherm represents the upper and the lower bound in the various intervals until after numerical values have been substituted for the parameters.

In comparing the results of the second and third order theories, it is seen that use of the equations [26] and [28] does not require specification of numerical values for α_0 or λ_m. Moreover, equation [28] is independent of the choice of n_m, as may be verified by substitution of $\theta = n/n_m$ on both sides. For these reasons equations [26] and [28] are quite useful in the actual computation of limiting isotherms. On the other hand, these relations are only approximate and should be applied only to cases where it is known that the restrictive assumption [25] is applicable and where for all experimental pressures, $p \ll \alpha_0$.

APPENDIX

In this appendix we shall try to expound the relevant ideas of the article of reference 12, which is written primarily for mathematicians, in a less technical and more intuitive language. For this purpose let us consider an analogous problem with finite sums instead of integrals. Suppose we consider all sets of numbers $g_1 \ldots g_n$ which satisfy the inequalities

$$[30] \qquad g_j \geqslant 0, \qquad 1 \leqslant j \leqslant n,$$

and the set of equations

$$[31] \qquad \sum_{j=1}^{m} a_{ij} g_j = C_i, \quad i = 1, \ldots, k$$

where the a_{ij} and the C_i are given constants. Here the sequence $g_1 \ldots g_n$ corresponds to the nonnegative function $g(\lambda, T)$ of equation [4], while the constraints [31] correspond to the conditions $L(y_i, T) = C_i$ of equation [5]. In fact, $L(y_i, T)$ of equation [3] is the result of a linear operation (integrating $(y_i+\lambda)^{-1} g(\lambda, T)$) applied to g; the form of a linear operation applied to a finite sequence g_i is given by the left-hand side of [31]. The function $G(\lambda, T)$ corresponds to the sequence of the sums g_1; g_1+g_2; . . . ; $g_1+\ldots+g_n$. Let us now interpret conditions [30] and [31] geometrically.

If we think of $(g_1 \ldots g_n)$ as a point in n-dimensional space, then the linear equations [31] represent hyperplanes while the linear inequalities [30] represent half-spaces. Thus [30] and [31] together represent the intersection of a finite number of hyperplanes and half-spaces, i.e., a convex polyhedron. As an example, we may consider the three-dimensional space defined by three mutually perpendicular axes g_1, g_2, g_3. The inequalities $g_1 \geqslant 0$, $g_2 \geqslant 0$, $g_3 \geqslant 0$ represent

three mutually intersecting half-spaces which define a semi-infinite volume in space: this is our polyhedron P. The polyhedral volume may be made finite by the specification of another half-space, such as $g_1+g_2+g_3 \leqslant 1$; the resulting polyhedron now has vertices at (0, 0, 0), (1, 0, 0), (0, 1, 0), and (0, 0, 1), each vertex being formed by the intersection of three triangularly shaped bounding planes. Note that the bounding faces are described by replacing the inequality signs with equalities. If we now intersect the polyhedron with the plane $z = \frac{1}{2}$ the polyhedron will be projected onto this plane and form a triangle with vertices at $(0, 0, \frac{1}{2})$, $(\frac{1}{2}, 0, \frac{1}{2})$, $(0, \frac{1}{2}, \frac{1}{2})$. This example illustrates the general principle that the intersection of an n-dimensional polyhedron with a hyperplane results in a polyhedron of $n-1$ dimensions.

Suppose now we wish to find the maximum of a linear function

$$F(g) = \sum_{j=1}^{n} a_j g_j \text{ on } P.$$

If M is the maximum, then $F(g) \leqslant M$ for all points in P, while $F(g) = M$ for at least one point. In other words, the whole polyhedron lies on one side of the hyperplane, $F(g) = M$, and has at least one point in common with this hyperplane. Such a hyperplane is called a *supporting hyperplane.* It is intuitively obvious in ordinary three-dimensional space, and is easy to prove in any n-dimensional space, that a supporting hyperplane must contain at least one vertex of the polyhedron.

In three-dimensional space at least three of the bounding faces (planes) meet at a vertex. Similarly, in n-dimensional space at least n of the bounding faces meet at a vertex; algebraically, in the defining equations and inequalities of the polyhedron, at least n of the equality signs must hold. If we apply this to the polyhedron P defined by the half-spaces and hyperplanes [30] and [31], we see that since we already have k equality signs in [31], then at least $n-k$ of the equality signs in [30] must hold at a vertex, i.e., at most k of the g_i's can be different from 0 at a vertex. Therefore, the maximum of a linear function on P is attained at some point with at most k nonvanishing co-ordinates, where k is the number of linear constraints in the definition of P. Note that in the sequence corresponding to $G(\lambda, T)$, a nonvanishing g_j corresponds to a jump from $g_1+ \ldots +g_{j-1}$ to $g_1+\ldots+g_j$, so that this sequence has at most k jumps at a vertex. The same reasoning applies to the problem of minimizing $F(g)$ on P.

The maximizing vertex will be unique if no edge of the polyhedron is parallel to the supporting hyperplane. This geometrical condition can be expressed algebraically in terms of the nonvanishing of certain determinants formed from the numbers a_{ij} and g_j.

The above reasoning can be extended to certain infinite dimensional spaces. Physicists are already familiar with one infinite dimensional space, Hilbert space, as representing the state of a mechanical system in quantum mechanics. In the present problem under consideration, the space involved has as its "points" the functions $G(\lambda, T)$ of bounded variation (17) on the interval $[0, \lambda_m]$. The "polyhedron" P is now defined by the conditions

[32] $G(\lambda, T)$ is nondecreasing in $[0, \lambda_m]$

and

[33] $$L(y_i,T) = \int_0^{\lambda_m} K(y_i, \lambda)\, dG(\lambda, T) = C_i, \quad i = 0, 1, \ldots, k.$$

Here [32] corresponds to [30] and [33] to [31], with the kernel $K(y_i, \lambda)$ playing the role of the matrix (a_{ij}). We have replaced k by $k+1$ constraints in order to make the conditions agree with [5]. In our physical problem $K(y, \lambda) = 1/(y+\lambda)$. The set of functions $G(\lambda, T)$ satisfying [32] and [33] form a convex polyhedron P in the infinite dimensional space. The "vertices" of P are represented by G's which have at most $k+1$ jumps. The generalization of the "edge" criterion for uniqueness is as follows:

If $K(y, \lambda)$ is Cartesian, i.e., if the number of zeros of any linear combination $\sum_{i=1}^{r} a_i K(y_i, \lambda)$ in the interval $[0, \lambda_m]$, where $y_1 < y_2 \ldots < y_r$ is at most equal to the number of sign changes in the coefficients, then the G which makes a given integral of the form $\int_0^{\lambda_m} K(y, \lambda)\, dG(\lambda, T)$ a maximum or a minimum under the conditions [32] and [33] is a *uniquely determined* step function. Furthermore, if the kernel is Cartesian, then we can narrow down the positions of the jumps of the extremal G. This is expressed in the condition that its *order* must be at most $k+1$. The details of the proofs are beyond the scope of this brief summary. The kernel $K(y, \lambda) = 1/(y+\lambda)$ can easily be proved to be Cartesian by the use of problem 87 (8), and the standard formula for a Vandermonde determinant. (See also problem 48 (8).)

It is quite likely that this method can be applied to other problems of inference from empirical data.

ACKNOWLEDGMENT

The authors are pleased to acknowledge the assistance of Mr. Chi Chang in verifying some of the derivations.

THERMODYNAMIC CONSIDERATIONS OF SURFACE REGIONS
ADSORBATE PRESSURES, ADSORBATE MOBILITY, AND SURFACE TENSION[1]

By E. A. Flood and Max Huber[2]

ABSTRACT

The flow of water through the micropore system of activated carbon has been described in previous papers as a hydrodynamic flow of liquid water under high pressure gradients due to surface forces. It is shown below that these high pressures are probably real and that the temperature coefficient of the flow rate is closely related to the temperature coefficient of the viscosity of liquid water. Surface tension is discussed.

If two volumes consisting of a single fluid substance have the same total Gibbs free energy[3] per unit mass and the same temperature, but have different positions in a scalar potential field, they will, in general, have different intrinsic thermodynamic potentials, different pressures and densities. They will, of course, be in a state of neutral equilibrium with respect to transformations into one another, the pressures and positions in the field remaining constant during the transformations.

The condition that these two systems remain in reversible equilibrium with one another as the pressures are varied is that $v_1 dp_1 = v_2 dp_2$, the positional coordinates x_1 and x_2 and the other variables remaining constant. This condition is necessary and sufficient regardless of whether the potential field is a function of pressure p_1 or not.

If a path of variation of the equilibrium pressure $p_1(n)$ is known as a function of the mass of material constituting the second system, as this mass varies from zero to n and the systems are in reversible equilibrium throughout this path, then the change in Gibbs free energy ΔF_1 at x_1 can be determined and must be equal to ΔF_2 at x_2 along this path of variation of the equilibrium pressure. Thus we can write for the process of filling the two volumes

$$\Delta F = \int_{x_1, p=0, n=0}^{x_1, p=p_1, n=n} v_1(n) dp_1(n) = \int_{x_2, p=0, n=0}^{x_2, p=p_2, n=n} v_2(n) dp_2(n)$$

and hence also

$$p_2 = \int_0^{p_1} \frac{\rho_2}{\rho_1} dp_1 \equiv \left| \frac{\rho_2}{\rho_1} \right| \cdot p_1.$$

The positional 'potential difference' between the two volumes $\Omega(x_2 - x_1)$ may be obtained from the following:

$$\Delta F = \int_{0, n=0, x_1}^{p_1, n, x_1} v_1(n) dp_1 + \int_{n, p_1, x_1}^{n, p_2, x_1} \left(\frac{\partial F}{\partial p} \right)_{x,n} dp + \int_{n, p_2, x_1}^{n, p_2, x_2} \left(\frac{\partial F}{\partial x} \right)_{p,n} dx$$

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3485. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

[2]*National Research Council of Canada Postdoctorate Fellow.*

[3]*The total Gibbs free energy, F, may be defined by* $F = F_0 + \omega = n\mu_0 + n\Omega$ *where* F_0 *is the Gibbs intrinsic free energy,* ω *the potential of position, n the mass,* μ_0 *the intrinsic thermodynamic potential, and* Ω *the potential of position of unit mass.*

and

$$\int_{n,p_1,x_1}^{n,p_2,x_1} v_1 dp_1 + \int_{n,p_2,x_1}^{n,p_2,x_2} f(x)dx = 0$$

where v_1 is written for $(\partial F/\partial p)_{x,n}$ and $f(x)$ for $(\partial F/\partial x)_{p,n}$. Accordingly,

$$\Omega(x_2-x_1, p_2) = -\frac{1}{n}\int_{n,p_1,x_1}^{n,p_2,x_1} v_1 dp_1 = \int_{n,p_2,x_1}^{n,p_2,x_2} f(x)dx$$

and

$$\Omega(x_2-x_1, p_1) = -\frac{1}{n}\int_{n,p_1,x_2}^{n,p_2,x_2} v_2 dp_2 = \int_{n,p_1,x_1}^{n,p_1,x_2} f(x)dx.$$

If the last two expressions for Ω are the same, Ω is independent of p, and v is independent of x or of the field.

In the case of equilibrium between a uniform reference volume and an assembly of elementary volumes of the same substance where the elementary volumes of the assembly have varying values of the x co-ordinate, i.e., varying values of the force function of the field, the conditions for reversibility are essentially similar and if $p_1(n)$ is known as a function of the mass of material in the whole assembly, then we may write

$$[1] \qquad \bar{p}_a = \int_0^{p_1} \frac{\bar{\rho}_a}{\rho_1} dp_1 \equiv \left|\frac{\bar{\rho}_a}{\rho_1}\right| . p_1$$

where $\bar{p}_a$ and $\bar{\rho}_a$ represent respectively the volumetric mean pressure and density of the assembly of volumes, $\Sigma v_{a_i} = v_a$.

In adsorption reactions $p_1(n)$ is given by the isotherm, where n is the mass adsorbed and p_1 the equilibrium pressure. If v_a, the adsorbate volume, is known, $\bar{\rho}_a$ and $|\bar{\rho}_a/\rho_1| . p_1$ and hence $\bar{p}_a$ can be calculated.

If the adsorbate can be regarded as an assembly of volumes of a single component and if $p_1(n)$ represents a path of thermodynamic reversibility, $\bar{p}_a$ as calculated from [1] will give the mean volumetric hydrostatic pressure of the adsorbate.

Under the usual methods of measuring adsorption isotherms, $p_1(n)$ cannot represent a path of thermodynamic reversibility if it is anywhere a decreasing function of n.

It is to be emphasized that Equation [1] is independent of the mechanism of adsorption and is equally applicable to adsorbate systems with or without menisci of various kinds, provided only that $p_1(n)$ represents a reversible path and that the adsorbate behaves as a single component substance in a scalar potential field.

From the above relations it is easily shown (4) that the change in volumetric average state of stress of the adsorbent as a result of adsorption of n moles of gas may be expressed as follows:

$$\delta\bar{p}_c{}^v = \left(1+\frac{v_a}{v_c}-\frac{v_a}{v_c}\cdot\alpha\right)\delta p_1$$

where $\bar{p}_c{}^v$ is the volumetric mean state of stress of the adsorbent; v_a and v_c are

the void volume and solid volume of the adsorbent respectively; and α is defined by $\bar{p}_a{}^v = \int (\bar{p}_a/\rho_1)\, dp_1 = \alpha \,.\, p_1$.

From Hooke's Law for isotropic bodies

$$\frac{\delta l}{l} = -\frac{1}{3}\beta\delta\bar{p}^l$$

where $\delta l/l$ is the length change per unit length, β is the bulk compressibility, and $\delta\bar{p}^l$ is the change in linear average state of stress along the length l. If the change in solid stress were due wholly to a change in hydrostatic pressure, $\delta\bar{p}^l$ would be equal to $\delta\bar{p}^v$. This would be the case if no surface field existed and the interaction of gas and solid were confined to an increase in hydrostatic pressure δp_1. Thus the change in state of stress of the solid may be thought of as consisting of two parts, one a change in hydrostatic stress, δp_1, and a second, $\delta(\bar{p}_c{}^v)'$, due to interaction. Accordingly, we may write

$$\delta\bar{p}_c{}^v = \delta p_1 + \delta(\bar{p}_c{}^v)' \quad \text{and} \quad \delta\bar{p}^l = \delta p_1 + \delta(\bar{p}^l)'$$

where, in general, $\delta(\bar{p}_c{}^v)'$ and $\delta(\bar{p}^l)'$ are not equal. Let

$$\delta(\bar{p}^l)' = K\,\delta(\bar{p}_c{}^v)',$$

then

$$\delta\bar{p}^l = \left(1 + K\frac{v_a}{v_c} - K\frac{v_a}{v_c}\cdot\alpha\right)\delta p_1;$$

and putting $v_a/v_c = \phi$, the adsorption extension is given by

$$\frac{\partial l}{l} = -\frac{1}{3}\beta(1 + K\phi - K\phi\alpha)\,\delta p_1. \qquad [2]$$

It is found that $\delta l/l$ as calculated by Equation [2] describes the data very well in the cases examined, as shown in Figs. 1 to 5.

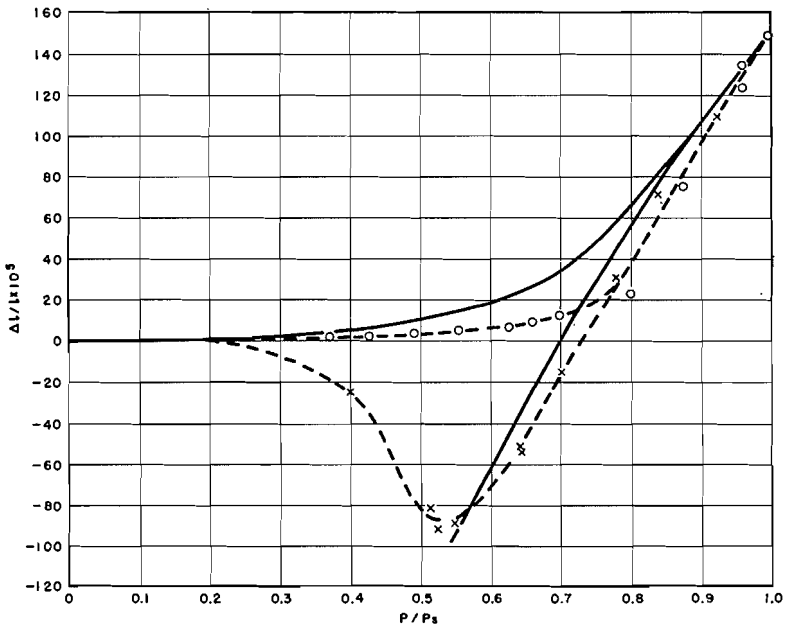

FIG. 1. Adsorption extension: Water vapor on carbon, data of Haines and McIntosh (7). Broken line drawn through experimental points. O, adsorption; ×, desorption. Solid line calculated from $\delta l/l = \frac{1}{3}\beta\phi K\alpha p_1 = 3.43 \cdot 10^{-7} \cdot \alpha p_1$. ($\beta K = 4.76 \cdot 10^{-7}$ p.s.i.; $\phi = 2.16$.)

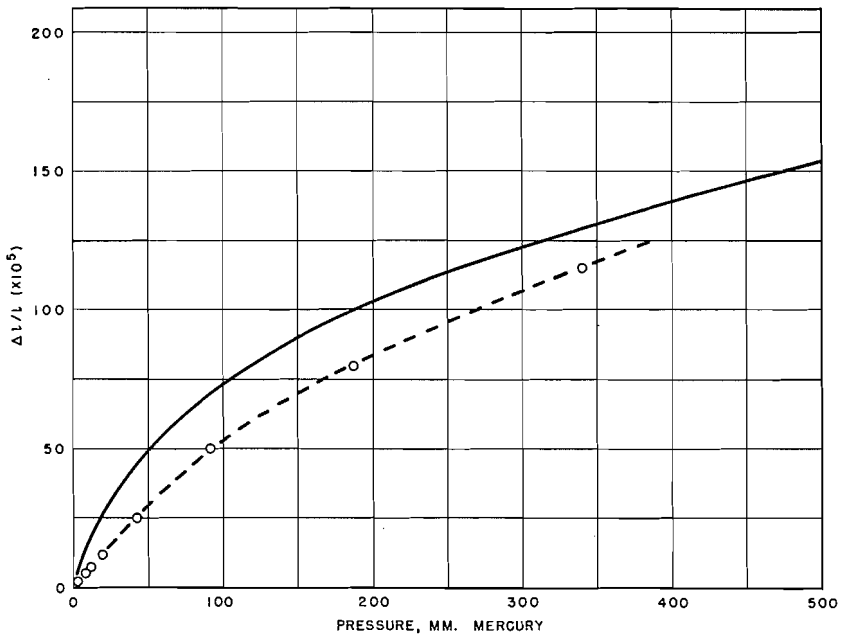

FIG. 2. Adsorption extension: Dimethyl ether on carbon, data of Haines and McIntosh (7). Broken line drawn through experimental points. Solid line calculated from $\delta l/l = 3.43 \cdot 10^{-7} \cdot \alpha p_1$.

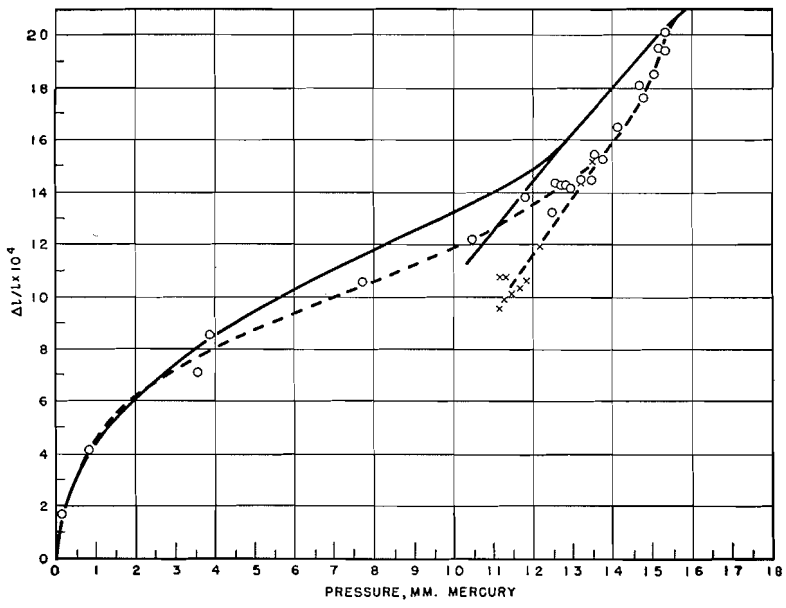

FIG. 3. Adsorption extension: Water vapor on porous glass, data of Amberg and McIntosh (1). Broken line drawn through experimental points. ○, adsorption; ×, desorption. Solid line calculated from $\delta l/l = \frac{1}{3}\beta\phi\, X\alpha p_1 = 3.69 \cdot 10^{-7} \cdot \alpha p_1$. ($\beta K = 5.76 \cdot 10^{-7}$ p.s.i.; $\phi = 1.92$.)

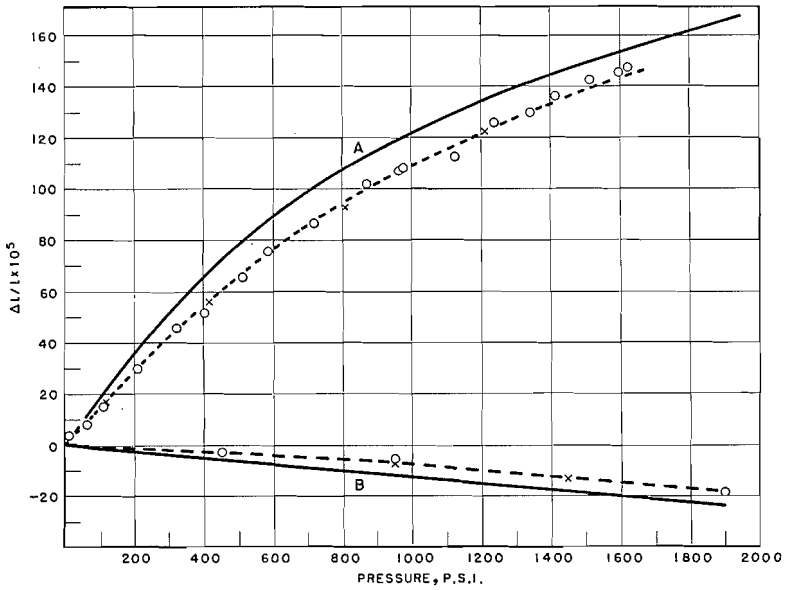

FIG. 4. Adsorption extension: Carbon rod No. 1 (25°C.) (cf. (4)). *A*, nitrogen; *B*, liquid water. Broken line drawn through experimental points. ○, adsorption; ×, desorption. Solid line calculated from $\delta l/l = \frac{1}{3}\beta(1+\phi K-\phi K\alpha)p_1$. ($\beta = 3.3\cdot 10^{-7}$ p.s.i.; $K = 2.91$; $\phi = 1.65$.)

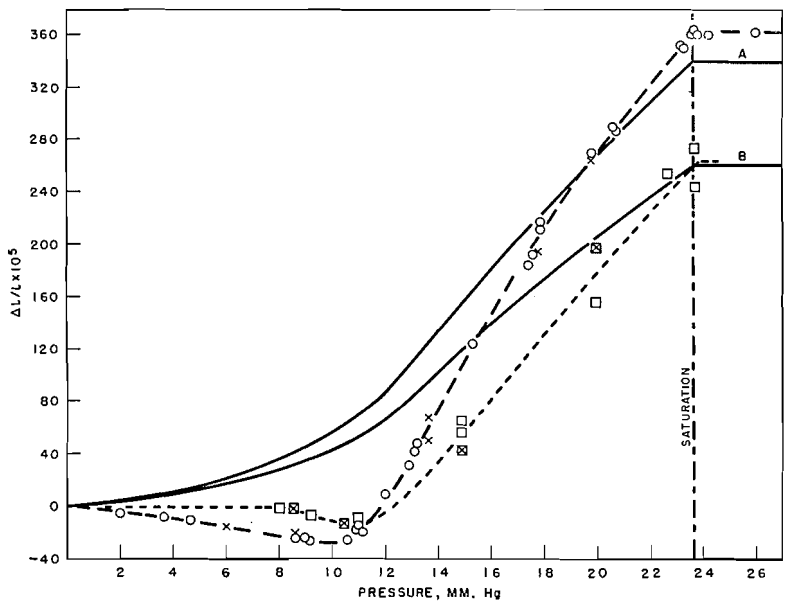

FIG. 5. Adsorption extension: Water vapor on Carbon rod No. 1 (25°C.) (cf. (4)). *A*, axial extensions; *B*, radial. Broken line drawn through experimental points. Solid line calculated. Axial, *A*, as for Fig. 8. Radial, *B*, as for Fig. 8, but $K = 2.23$.

The above relations may also be applied to permeability problems. It can be shown that if surface forces within a small capillary condense a dilute vapor to densities exceeding the saturation value and so cause a dense liquid film to form on the surface, and if the liquid film is greater than a few molecules deep, the flow rate can be written

$$Q_m = \frac{-A}{\eta_l}\rho_a \cdot \frac{dp_a}{dx} = \frac{-A}{\eta_l}\frac{\rho_a^2}{\rho_1}\frac{dp_1}{dx} = \frac{A}{\eta_l}\left|\frac{\rho_a^2}{\rho_1}\right|\frac{\Delta p_1}{L},$$

where p_1, p_a = pressures of gas and adsorbate, respectively; ρ_1, ρ_a = densities of gas and adsorbate, respectively; Q_m = flow in gm./min.; η_l = liquid viscosity.

It has been shown that this formula represents the flow rate of water through the micropore system of some carbons fairly well (5).

This formula indicates that at equal values of the pressure and concentration gradients, the relative flow rates at two temperatures (25° and 35°C.) can be expressed by

$$\frac{Q_{m25}}{Q_{m35}} = \frac{\eta^{35}}{\eta^{25}}\frac{T^{25}}{T^{35}} \text{ or } \frac{K_{25}}{K_{35}} = \frac{p_s^{35}}{p_s^{25}}\left(\frac{T^{25}}{T^{35}}\right)^2\frac{\eta^{35}}{\eta^{25}}$$

where $K = \frac{\text{cc.}}{\text{min.}}\frac{p_1}{\Delta p}$ and p_s^{35} = saturation pressure at 35°C.

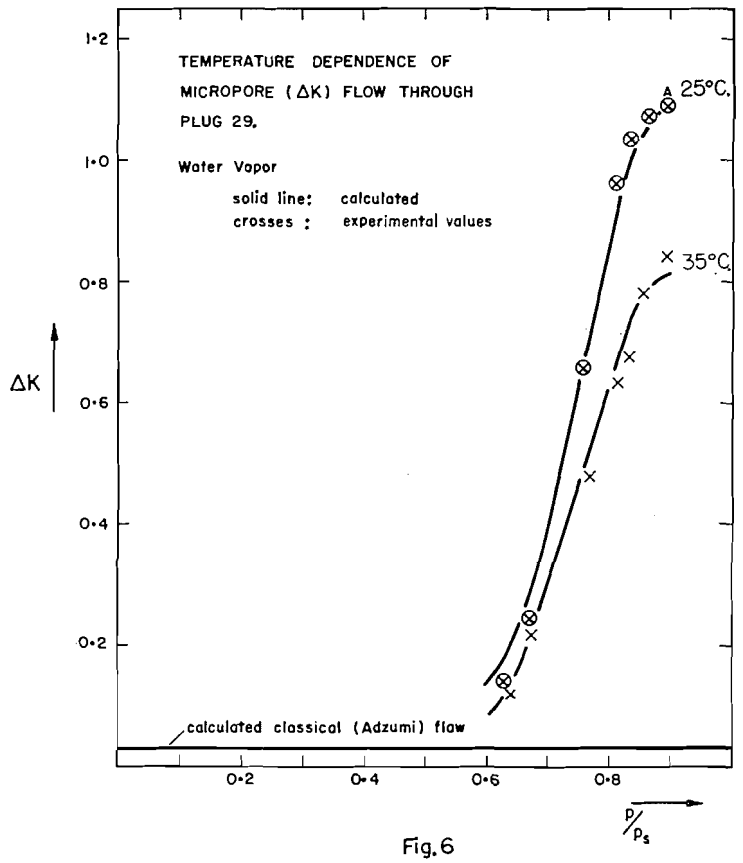

Fig. 6

Fig. 6 shows calculated and observed water flow rates for an active carbon where the macropores have been filled with a lead alloy, thus largely removing macropore flow. The constant A is calculated from the flow at 25°C. at the point $p/p_s = 0.89$. The curves at 25°C. and 35°C. are calculated using this value of A. Incidentally, A is almost identical with the calculated value based on pore size distributions reported by Emmet for similar carbons, and is nearly the same as the constant for unfilled carbon rods, when allowance is made for increased path lengths.

Between the region of classical hydrodynamic and/or effusive flow through large pores ($>10^{-5}$ cm.) and the region of slow diffusive flow through pores of molecular dimensions ($<10^{-7}$ cm.) where diffusion coefficients involve large activation energies and are often highly specific (cf. Barrer (2)), we should expect a pore size region (10^{-7} to 10^{-5} cm.) where the flow mechanisms are essentially classical but where fluid densities and pressure gradients within the pores are considerably increased by the surface forces. Our results strongly suggest that this is indeed the case.

Surface Tension of Fluid Interfaces

There appear to be some differences of opinion as to whether the Helmholtz free energy per unit surface and 'surface tension' are the same thing or not (cf. Shuttleworth (10)). Some authors treat the surface film as a separate thermodynamic system distinct from the material lying on either side of it, while other authors consider that the 'surface free energy' is the change in Helmholtz free energy of the whole system when it is changed in such a way that the surface increases while the volume of the whole system remains constant.

In a fluid interface, the pressure in every elementary volume must be the same in all directions. Following Tolman (11) we may think of the interface as made up of laminae parallel with the surface and we must suppose a pressure gradient along the normal to this surface. If the gradient extends a distance h along x, the normal to the interface, and if $\bar{p}(x)$ is the mean value of the stress intensities of the various laminae parallel with the surface, the stress intensities being averaged over the interval h, then $\bar{p}(x) \cdot h$ is the surface force exerted by unit length of the surface region. If $\bar{p}(x)$ is negative, $-\bar{p}(x) \cdot h$ is literally a positive 'surface tension'. In this case, if h is constant and $\bar{p}(x)$ is a function of T only, then $(\partial A/\partial\sigma)_T = -\bar{p}(x) \cdot h = \gamma$, and γ is unambiguously the Helmholtz free energy, A, per unit of surface area σ.

If we consider a spherical or cubical shell of thickness h where the mean parallel stress intensity in the surface shell is $\bar{p}(x)$, and p_0 is the uniform pressure outside of the body while p is that inside, then balancing forces, the pressure difference across the surface is given by

$$p - p_0 = (2[p_0 - \bar{p}(x)]h)/r \quad \text{or} \quad \Delta p \approx 2\gamma/r,$$

where r is either the radius of the sphere or one half the side length of the cube.

The reversible work of forming a drop of liquid within a large constant volume of gas is $\frac{1}{3}\gamma\sigma$ as shown by Gibbs (6). An assembly of drops (or cubes)

of various sizes contained within a constant volume does work w (not reversible in this case) when small drops are converted to larger drops, the work being very nearly equal to $\frac{1}{3}\gamma\sigma$. If we had defined the surface tension as $(\partial w/\partial\sigma)_{T_v}$ for this process, this 'surface tension' would be only one third of the actual surface tension. In this case, as in the case considered by Gibbs, the work consists of two parts, the work done by the surface, $\gamma\Delta\sigma$, less the work done on the interior mass, $v\Delta p$. In some cases we cannot measure surface tension directly and cannot distinguish between the work done by the surface and the work done simultaneously on or by the interior mass. 'Surface free energies' in such cases are 'surface differential free energies' of whole systems wherein surface tension proper may play only a very small part. It is only when the system consists wholly of a single kind of surface layer that $(\partial A/\partial\sigma)_T$ is reasonably unambiguous and that γ, the tension of the surface, measures the Helmholtz free energy of that surface. Evidently, in the case of liquids the 'surface tension' rather than the 'surface free energy' is the more directly observable quantity; and if there be any meaning to such distinctions, then as pointed out by Brown (3), the surface free energy is to be regarded as the 'useful fiction' and the surface tension the 'reality' rather than the other way about.

When a liquid is separated from its vapor by a flat fluid surface of tension the following conditions prevail. The Gibbs free energy of every lamina is the same and independent of their positions along x, the normal through the surface. The hydrostatic pressures are the same in the bulk liquid and in the gas, and densities of bulk liquid and vapor are constant. But within the interface density and pressure gradients exist. Thus, specific volumes, $v(x)$, and pressures, $p(x)$, of laminae are variable functions of x within the interfacial region. If we take x_0 as the end of the liquid region whose pressure is p_0, and $x = x_0$ to $x = h$ as the interfacial region, and if $\Omega(x)$ is the potential of field and $f(x)$ the force function of the field, we have the following necessary relations:

$$\Omega(x) = \int_{x_0}^{x} \frac{d\Omega(x)}{dx}\,dx = \int_{x_0}^{x} f(x)\,dx = \int_{x_0 p_0}^{x p_0} \left(\frac{\partial F}{\partial x}\right)_p dx$$

and

$$p(x) = p_0 + \int_{x_0}^{x} \frac{dp(x)}{dx}\,dx \quad x_0 \leqslant x \leqslant h.$$

The functions $v(x)$, $p(x)$, $\Omega(x)$, $f(x)$ etc. must conform to the following equations:

$$dF = \left(\frac{\partial F}{\partial x}\right)_p dx + \left(\frac{\partial F}{\partial p}\right)_x dp = f(x)\,dx + v(x)\,dp(x) = 0$$

and

$$\int_{x_0}^{h} \frac{d\Omega}{dx}\,dx = \int_{x_0}^{h} f(x)\,dx = -\int_{x_0}^{h} v(x)\frac{dp(x)}{dx}\,dx = 0,$$

$$\int_{x_0}^{h} \frac{dp(x)}{dx}\,dx = 0; \quad \int_{x_0}^{h} p(x)\,dx = \bar{p}(x).h = -\gamma.$$

These equations impose considerable restrictions on possible forms of the

various functions. Thus if $\Omega(x)$ have a single extreme, say a maximum at x_m, the minimum pressure must occur at x_m, and since the mean value of the magnitude of $dp(x)/dx$ in the interval x_0 to x_m must equal that in the interval x_m to h, and since from physical considerations the mean value of $v(x)$ must be greater in the later interval, $v(x)$ must have a maximum in the interval $0-x_m$,

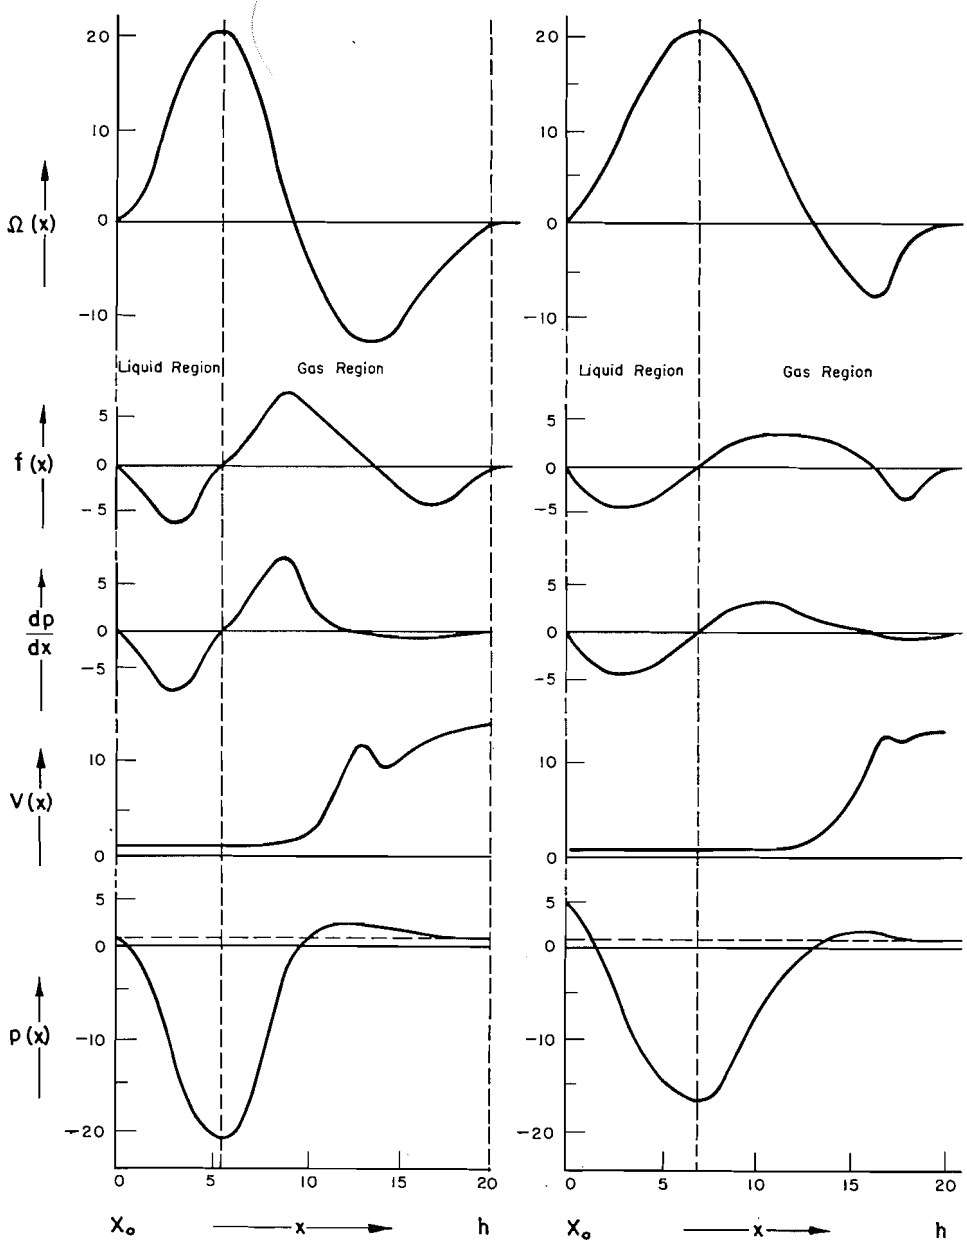

Fig. 7

i.e., in the region of lowest pressures. Accordingly $\Omega(x)$ cannot have a single extreme[4] when surface tensions have appreciable positive values and when vapor densities are low. Assuming a simple form for $\Omega(x)$ having a maximum and a minimum, and choosing a physically plausible form $v(x)$, the relations which must subsist between the various functions can be illustrated approximately (see Fig. 7*a*). Evidently, this surface adsorbs its own vapor (cf. Wyllie (12)). For convenience of illustration the difference between the specific volumes of liquid and vapor has been taken much less than is the case with liquid–vapor systems such as water. The magnitudes of the negative pressures are also much smaller with respect to vapor pressures than is the case in ordinary systems of appreciable surface tension. In the case of the water interface $-\bar{p}(x) \cdot h \approx 70$ dynes cm.$^{-1}$ at room temperature. If the thickness of the interface, h, lies between 10 and 1 Å, the mean negative pressure or mean stress intensity must lie between 700 and 7000 atm. Evidently such large tensile stresses cannot be sustained in the more dilute regions of the fluid interface and hence, practically the whole contribution to $p(x)$ must come from the region where the fluid has high tensile strengths, high densities, and low compressibilities, i.e., from the liquid region of the interface. The maximum tensile stress in this region will exceed the mean tensile stress by factors depending on the relative thicknesses of these regions, the factor being the greater, the smaller the ratio of the thickness of the dense region to the thickness of the whole interface. In the case illustrated in Fig. 7*a* the factor is about five and correspondingly, the maximum tensile stress is between 35,000 and 3500 atm. for total film thicknesses between 1 and 10 Å. The film thickness as measured by the Rayleigh method will be the region of rapid change of refractive index and thus will be the region of rapid increase in specific volume. The thickness of the water interface as measured by Raman and Ramdas (8) using the Rayleigh method is about 1 Å. If the relative thicknesses of the various regions are as illustrated, the total film thickness is somewhat less than 10 Å and the maximum tensile stress of the order of 4×10^3 atm. It seems very improbable that this figure can be much too low since it is comparable with the measured tensile strength of some metals.

Capillary Rise and Depression

As a variation of the 'flat' interface illustrated by Fig. 7*a* we may suppose the whole system raised or lowered in a potential field independent of surface potential fields. If we impose the condition $dF = 0$ for this variation the conditions are analogous to capillary rise or depression.

In order that $dF = 0$, the relative changes in liquid and gas pressures will be more or less proportional to densities. Accordingly the $p(x)$ curve must be distorted so that

$$\int_{x_0}^{h} \frac{dp(x)}{dx} \cdot dx \neq 0 .$$

However, for small rises or depressions $\bar{p}(x)$ and $\Omega(x)$ will not be changed appreciably, since the magnitudes of $\bar{p}(x)$, $p(x_m)$ etc. are large compared with

[4]*That is,* $\frac{d\Omega(x)}{dx} = 0$ *at more than one value of* x *between* x_0 *and* h.

the pressure changes introduced by the rise or depression. For large depressions, analogous to the effect of curvature on very small droplets, the pressure changes may be comparable with $\bar{p}(x)$. In such cases to retain constancy of surface tension either $\Omega(x)$ must change or the surface thickness or both must change. A natural assumption is that the tendency of the surface to adsorb its own vapor becomes less on surfaces concave toward the dense phase and hence that $\Omega(x)$ is changed. Fig. 7*b* illustrates a 'capillary depression' of the hypothetical system illustrated by Fig. 7*a*, the values of $\bar{p}(x)$ and h being unchanged, but $v(x)$, $p(x)$, and $\Omega(x)$ distorted so that there is a net pressure difference between liquid and vapor.

The energy of a vapor is in general much greater than the energy of the corresponding liquid. The heat energy or TS energy change from liquid to gas is somewhat greater than the corresponding internal energy change (i.e., by $p_0\Delta v$). In order that a positive potential of position exist in the interface $[\Delta(E+p_0v)/\Delta x]\ \Delta x$ must exceed $(T\Delta S/\Delta x).\ \Delta x$. Since $p_0\Delta v$ is small, especially in the dense region of the interface, we may ascribe the positive potential of position to an increase in energy without a compensating increase in entropy. In the more dilute region the negative potential of position may be ascribed to the large increase in entropy associated with the large volume change, the entropy in this region becoming too large with respect to the energy. The energy of a single phase (lamina in this case) of one component cannot vary continuously at constant μ, T, and P; consequently, strictly continuous density (energy) gradients must be associated with pressure gradients, i.e., potential gradients. Evidently surface potentials are in the main due to the very sharp density gradients in the neighborhood of the surface. Accordingly changes in surface conditions which tend to reduce density differences and which tend to equalize compressibilities will tend to reduce surface potentials. Thus, it would appear that the 'surface tension' of the flat surface is near the maximum and that either increasing or decreasing the equilibrium pressures by very large values will in the limit result in a vanishing surface tension. In the case illustrated in Fig. 7*b*, the mean potential of the matter in the surface region is increased by the distortion (cf. Rice (9)).

A primary objective of the inquiry outlined above is to obtain some notion of the physical factors controlling rates of flow of fluids through porous adsorbents. Evidence has been obtained that in the case of pores which are fairly large compared with molecular dimensions (10^{-7} to 10^{-5} cm.), flow mechanisms are essentially those of classical laminar flow, but are controlled by density and pressure gradients (both parallel and normal to the direction of flow) that are functions of the surface forces. Generally, these gradients are not directly observable and accordingly must be measured indirectly or inferred from measurements of adsorbate pressures, surface tensions, surface potentials, or other average properties. Where we can determine density gradients we can calculate corresponding pressure gradients and can make considerable progress in relating net flow rates to the physical structures of ultra fine grained porous adsorbents.

THE DETERMINATION OF PORE SIZE DISTRIBUTION AND SURFACE AREA FROM ADSORPTION ISOTHERMS[1]

By E. M. Voigt[2] and R. H. Tomlinson

ABSTRACT

Theoretical isotherms have been developed which when compared to experimental isotherms showing hysteresis, allow the calculation of pore size, pore size distribution, and surface area of the sorbent. Interpretation of some experimental isotherms obtained with porous vycor glass shows that this system can best be represented by the "ink bottle" pore model with a Gaussian distribution of pore sizes. The mean pore radius of the porous glass is about two thirds of the Kelvin radius, and the surface area greater than that obtained from the B.E.T. theory. The Kelvin radius is interpreted as a weighted average, but the B.E.T. surface area appears more fundamentally different.

INTRODUCTION

The B.E.T. (4) theory which has been widely used for interpretation of adsorption phenomena fails to account for the types IV and V isotherms of the Brunauer classification (3). The more complete B.D.D.T. theory (3), which takes capillary condensation into account, applies only to those systems where there is no distribution in pore size or where the variation from an average pore size is not too great.

Several attempts have been made to interpret adsorption, particularly at high relative pressures where hysteresis is encountered, in terms of pore distribution and capillary condensation. The radii of cylindrical capillaries which fill at a given partial pressure may be evaluated by means of the Kelvin equation:

$$\ln (P/P_0) = -2\gamma V_1/R R_0 T$$

where P = pressure,
P_0 = vapor pressure at the temperature T,
γ = surface tension,
V_1 = molal volume of the adsorbed liquid at the temperature T,
R = capillary radius,
R_0 = the gas constant,
T = absolute temperature.

The particular radius corresponding to the point of inflection on the hysteresis loop is known as the Kelvin radius. This radius may be interpreted as the radius of that pore having the most probable volume. If, however, there is a distribution of pore radii, the pore which has the most probable volume will have a greater than average radius. Whether the adsorption or desorption branch of the isotherm should be used for the determination of the Kelvin radius will be considered below. A more basic capillary condensation equation has recently been derived by Kistler (8):

$$[1] \qquad dA/dV = -\ln(P/P_0)R_0T/M\gamma,$$

where A = pore area,
V = pore volume.

It may be seen that this relation reduces to the Kelvin equation for cylindrical capillaries or spherical pores.

From the experimental isotherm it is possible to obtain directly a plot of the pore volume distribution curve. Kubelka (10) has used a plot of

$$d(V_a/V_t)/d \log D \text{ vs. } \log D,$$

where V_a is the total volume adsorbed at a given relative pressure,
V_t is the total volume adsorbed at the saturation pressure,
D is the pore diameter as calculated from the Kelvin equation for the relative pressure corresponding to V_a.

The curves obtained resemble typical probability curves and Kubelka interpreted their maxima as corresponding to the capillary diameter that occurs most frequently in the adsorbent. Schuchowitski (13) has criticized Kubelka's plot on the basis that it did not differentiate between adsorption and capillary condensation. Foster (7) overcame this objection by plotting a function similar to that of Kubelka, but using only the hysteresis region of the isotherm. In either case, however, the peak of the distribution curve merely corresponds to the point of inflection on the original isotherm, and hence the "average" pore radius calculated from these methods is the Kelvin radius discussed above.

Wheeler (15) has suggested an integrated theory combining multilayer adsorption and capillary condensation. Following the suggestion of Wheeler, Shull (14) has assumed that multilayer adsorption reduces the pore size by an amount t at any given pressure. Thus one must use a modified Kelvin equation which relates the maximum pore that will be filled owing to capillary condensation at any given relative pressure:

$$\ln (P/P_0) = -2\gamma V_a/(R-t)R_0T,$$

where t = thickness of the adsorbed film. It was concluded that a plot of $V_c - V$ against $R-t$, where $R-t$ was evaluated by means of the above equation, should correspond to the integral:

$$V_c - V = \pi \int_R^\infty (R-t)^2 L(R)dR,$$

where $L(R)dR$ is the total length of pores whose radii fall between R and $R+dR$.

By assuming various forms of the distribution function $L(R)dR$, families of curves were obtained. Each member of a given family corresponded to a value of the most probable pore size. These theoretical curves could then be compared with experimental isotherms plotted in the same manner. That member of a given family of the theoretical curves which most closely represented the experimental curve would allow one to choose the type of distribution and mean pore radius of the pores in the experimental system. Whereas the method of Wheeler and Shull is adequate for many systems, it makes no allowance for the influence of pore shape. In any system having a distribution of pores, most of the total void volume will arise from those pores which are

greater than average in radius. It follows that volumes of sorbed material as obtained from capillary condensation measurements might well be more adequately represented by a $f(R^3)$ ('ink bottle') type of pore volume function than a $f(LR^2)$ (cylindrical type) volume function. The present work evaluates the theoretical form of capillary condensation isotherms for various pore shapes, sizes, and distributions. Further, it has been possible to obtain information about the thickness of the adsorbed film, and the surface area of the sorbent. The theory is discussed with reference to some experimental isotherms obtained by Barrer (2) and Emmett (6) for porous vycor brand glass.

THEORETICAL

Distribution of Capillary Condensation Radii

The Kistler equation [1] in the appropriate form indicates the relative pressure at which condensation will occur on a meniscus in a capillary of a given shape. Such condensation would also occur on an adsorbed layer covering the concave surfaces of a porous system. If such condensation leads to a reduction in the radius of curvature of the surface, condensation will continue on this surface at constant pressure as long as the radius of curvature continues to reduce. In this discussion a pore will be considered as any void region in a porous material which by virtue of this process completely fills at constant relative pressure. Also the pore radius will be considered as the radius of curvature of that surface on which the above pore filling process started to occur.

If a given porous system has a distribution of pore radii, one may expect that at a given partial pressure, pores of radius equal to or less than the value determined by the appropriate form of the Kistler equation [1] will be completely filled. That is, if the volume of a pore in the porous system is expressed by the function

$$V = f_1(R),$$

and if the number of pores having radii falling between R and $R+dR$ is given by

$$dn = f_2(R)dR,$$

then the volume of all pores with radii between R and $R+dR$ is

$$dV = Vdn = f_1(R) \times f_2(R)dR,$$

and the ratio of the sum of the volumes of all pores whose radii are equal to or less than R to the total volume of all the pores is given by

$$[2] \qquad V/V_c = \int_{\infty}^{R} (f_1(R) \times f_2(R)dR) / \int_{0}^{\infty} (f_1(R) \times f_2(R)dR).$$

In order to solve equation [2] it is necessary to obtain explicit functions for $f_1(R)$ and $f_2(R)$. Various pore models may be assumed.

(*a*) The cylindrical type pore model for which

$$f_1(R) = K_1LR^2,$$

where K_1 = shape factor ($K_1 = \pi$ for cylinders),

and L = length of pore.

(*b*) The 'ink bottle' type pore model for which

$$f_1(R) = K_2R^3,$$

where K_2 = shape factor ($K_2 = \frac{4}{3}\pi$ for spheres).

It is most reasonable to assume that the distribution in pore size is either Maxwellian or Gaussian, although in some porous systems other types of distribution may occur.

(*a*) For a typical Maxwellian distribution

$$f_2(R) = \frac{4N}{\sqrt{\pi}}\frac{R^2}{\alpha^3}\exp\left(-\frac{R^2}{\alpha^2}\right),$$

where N = number of pores per unit mass,
and α = a constant.

(*b*) For a typical Gaussian distribution

$$f_2(R) = NA\exp\left[-\frac{\beta^2}{\alpha^2}(R-\alpha)^2\right],$$

where A = normalization constant

$$= \int_0^\infty \exp\left[-\frac{\beta^2}{\alpha^2}(R-\alpha)^2\right]dR,$$

β = constant.

With both of these distributions α may be interpreted as the most probable radius, and β which occurs in the Gaussian function is a measure of the distribution width.

Four solutions to equation [2] may be obtained using the four possible combinations of the above pore models and distributions.

(*a*) Cylindrical type pore model with Maxwellian distribution of pore radii

$$[3] \qquad \frac{V}{V_c} = \frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}dx - \frac{4}{3\sqrt{\pi}}x^3e^{-x^2} - \frac{2}{\sqrt{\pi}}xe^{-x^2},$$

where $x = R/\alpha$.

(*b*) Cylindrical type pore model with Gaussian distribution of pore radii

$$[4] \qquad \frac{V}{V_c} = \frac{(\frac{1}{2}+\beta^2)\int_{-\beta}^{z} e^{-z^2}dz + e^{-\beta^2}(\beta-\frac{1}{2}\beta) - e^{-z^2}(\beta+\frac{1}{2}z)}{(\frac{1}{2}+\beta^2)\int_{-\beta}^{\infty} e^{-x^2}dz + (\beta-\frac{1}{2}\beta)\,e^{-\beta^2}},$$

where $z = \beta(R-\alpha)/\alpha$.

(*c*) 'Ink bottle' type pore model with Maxwellian distribution of pore radii

$$[5] \qquad \frac{V}{V_c} = 1-\left[\frac{x^4}{2}e^{-x^2}+x^2e^{-x^2}+e^{-x^2}\right],$$

where $x = R/\alpha$.

(*d*) 'Ink bottle' type pore model with Gaussian distribution of pore radii

$$[6]\quad \frac{V}{V_c} = \frac{-\frac{1}{2\beta^3}e^{-z^2}(1+3\beta^2+3\beta z+z^2)+\frac{1}{2\beta^3}e^{-\beta^2}(1+\beta^2)+\left(1+\frac{3}{2\beta^2}\right)\int_{-\beta}^{z}e^{-z^2}dz}{\frac{1}{2\beta^3}e^{-\beta^2}(1+\beta^2)+\left(1+\frac{3}{2\beta^2}\right)\int_{-\beta}^{\infty}e^{-z^2}dz},$$

where $z = \beta(R-\alpha)/\alpha$.

Values of the functions V/V_c versus R have been plotted in Figs. 1–6 corresponding to each of the various systems represented by equations [3, 4, 5, 6]. Each curve in a given figure is representative of a different value of the parameter α (the most probable pore size). Two families of curves have been plotted for each pore model with a Gaussian distribution, since these systems have a further parameter β. As β may have any positive value these are merely representative of a large number of families which may be plotted for these systems. The plot of V/V_c versus R for a particular value of α (and β for Gaussian distribution) will be known as a theoretical or normalized capillary condensation isotherm for the given pore model and distribution.

Distribution of Pore Radii Including the Thickness of the Adsorbed Layer

In addition to capillary condensation true adsorption contributes to the total amount of the sorbed material in a porous system. Since all adsorption in any pore must precede capillary condensation, the capillary condensation radii distributions evaluated in the previous section must be representative of pores which are reduced in radius by an amount equal to the thickness of the

adsorbed layer. If it is assumed that at saturation the adsorbed material is equally distributed on all surfaces, the ratio of the volume filled by capillary condensation to the total volume of the system is given by

$$V_c/V_t = \int_0^\infty f_1(R)f_2(R)dR \Big/ \int_0^\infty f_1(R)f_2'(R)dR,$$

where $f_2'(R) = f_2(R)$ with $R-\alpha$ replaced by $R-(\alpha+t)$,
and t = thickness of adsorbed layer at saturation if equally distributed on all surfaces.

Thus for the Gaussian distributions

$$[7] \qquad \frac{V_c}{V_t} = \frac{\int_0^\infty R^n \exp\left[-\frac{\beta^2}{\alpha^2}(R-\alpha)^2\right]dR}{\int_0^\infty R^n \exp\left[-\frac{\beta^2}{\alpha^2}\{R-(\alpha+t)\}^2\right]dR},$$

where $n = 2$ for the cylindrical type pore model,
and $n = 3$ for the 'ink bottle' type pore model.

Solving equation [7] we obtain:

(*a*) cylindrical pore model

$$[8] \qquad \frac{V_c}{V_t} = \frac{\beta e^{-\beta^2} + (1+2\beta^2)I}{\beta\omega e^{-\beta^2\omega^2} + (1+2\beta^2\omega^2)I(t)};$$

where $\omega = \frac{a+t}{a}$, $I = \int_{-\beta}^{\infty} e^{-x^2}\,dx$ with $x = \frac{\beta}{a}(R-a)$, and $I(t) = \int_{-\beta\omega}^{\infty} e^{-x^2}\,dx$.

(*b*) 'Ink bottle' pore model

$$[9] \qquad \frac{V_c}{V_t} = \frac{(\beta^2+1)\,e^{-\beta^2} + (3\beta+\beta^3)I}{(\beta^2\omega^2+1)\,e^{-\beta^2\omega^2} + (3\beta\omega+\beta^3\omega^3)I(t)}.$$

Determination of Surface Area

The surface area of a given porous system may be represented by:

$$S_w = \int_0^\infty f_3(R)f_2(R)dR;$$

S_w = surface area per unit weight of porous material,
$f_3(R)$ = the surface area of a pore whose volume is $f_1(R)$,
$f_2(R)$ = the particular distribution function determined above in which α is set equal to $\alpha+t$.

Thus the surface area per unit mass of sorbent for the 'ink bottle' model with Gaussian distribution of pore radii is given by

$$[10] \qquad S_w = \int_0^\infty K_3R^2AN \exp\left[-\frac{\beta^2}{\alpha^2}(R-R_0)^2\right]dR,$$

where $R_0 = a+t$ (when assumption of equal distribution of adsorbed material is justified),
K_3 = shape factor ($K_3 = 4\pi$ for spherical pores).

To solve equations of type [10] requires a knowledge of the shape factor K_3 and the number of pores per unit mass N. Since these quantities can not be

evaluated from sorption data alone without further assumptions, it is considered simpler to evaluate the surface area of the porous material from V_m, the volume of adsorbed material required to form a monolayer on the surface of the sorbent. This calculation allows the use of more generally recognized assumptions.

It is apparent that the evaluation of V_m is analogous to the determination of the thickness of the adsorbed layer, except that in this case the value of the thickness may be assumed to be one molecular diameter. Thus

$$[11] \qquad \frac{V_t - V_m}{V_t} = \frac{\int_0^\infty R^n \exp\left[-\frac{\beta^2}{\alpha^2}\{R-(R_0-m)\}^2\right] dR}{\int_0^\infty R^n \exp\left[-\frac{\beta^2}{\alpha^2}\{R-R_0\}^2\right] dR},$$

where m = thickness of monolayer = 1 molecular diameter of adsorbate. Solving equation [11] for:

(*a*) Cylindrical pore model ($n = 2$)

$$[12] \qquad \frac{V_t - V_m}{V_t} = \frac{\eta\, e^{-\eta^2} + (1+2\eta^2)\, I(\eta)}{\tau\, e^{-\tau^2} + (1+2\tau^2)\, I(\tau)};$$

where $\eta = \frac{\beta}{\alpha}(R_0 - m)$, and $\tau = \frac{\beta}{\alpha}R_0$, $I(\eta) = \int_{-\eta}^{\infty} e^{-x^2} dx$ and $I(\tau) = \int_{-\tau}^{\infty} e^{-x^2} dx$.

(*b*) 'Ink bottle' pore model ($n = 3$)

$$[13] \qquad \frac{V_t - V_m}{V_t} = \frac{(\eta^2+1)\, e^{-\eta^2} + (3\eta+\eta^3)\, I(\eta)}{(\tau^2+1)\, e^{-\tau^2} + (3\tau+\tau^3)\, I(\tau)};$$

where $I(\eta)$ and $I(\tau)$ have the same meaning as in [12].

Surface area may then be evaluated in the usual manner from the relation

$$[14] \qquad S_w = \frac{V_m}{22400}\, x\, N_a\, x\, A_m,$$

where S_w = surface area per gram of adsorbent,
N_a = Avogadro's number,
A_m = surface area covered by a molecule as obtained from the equation

$$A_m = 4 \times 0.866\left[\frac{M}{4\,\gamma\, 2 \times N_a\, x\, \rho_l}\right]^{2/3},$$

where M = molecular weight of adsorbate,
ρ_l = density of the liquefied adsorbate at temperature of the isotherm.

EXPERIMENTAL INTERPRETATION

In order to find the distribution of capillary condensation radii in an experimental system, it is necessary to obtain the experimental values of V/V_c and plot these against R, where R is calculated from the Kistler equation [1] in the appropriate form for the relative pressure corresponding to V. That is, for the

Cylindrical pore model: adsorption—Cohan equation,
desorption—Kelvin equation;
KR^3 pore model: adsorption—Kelvin equation.

(For discussion see below.) The pore model and distribution parameters may then be obtained from the theoretical isotherm that gives the best fit to the experimental curve. Before it is possible to obtain these quantities from the experimental isotherm it is necessary to understand the mechanism of adsorption hysteresis. In some cases hysteresis is not reproducible. Zsigmondy (16) has suggested that this type of hysteresis probably results from the effects of surface impurities. Where the branches of the hysteresis loop are entirely reproducible, two main theories have been proposed. The 'ink bottle' theory of Kraemer (9) which has been adopted by McBain (11) suggests that during adsorption, capillary condensation occurs on a relatively large meniscus in the 'bottle' part of the pore, and that desorption must occur from the smaller meniscus of the 'neck' of the ink bottle pore. Although this theory has not yet been proved Rao (12) has shown that in a qualitative way it will explain his experimental data. Proponents of this theory have considered the adsorption branch of the isotherm as most significant in determining pore radius. The 'ink bottle' hypothesis does not necessarily imply that each 'bottle' has only a single neck, for the arguments would be equally valid for any porous network having larger pores connected by smaller ones.

Cohan (5) has suggested a theory of hysteresis which turns out to be very similar to the 'ink bottle' theory, except that it is subject to a more quantitative treatment because of a simpler pore model. Cohan considers the pores to be cylindrical in shape and that adsorption capillary condensation occurs as an annular ring on the wall of the pore rather than on a normal meniscus as required by the Kelvin equation. For these conditions the Kelvin equation must be modified, and Cohan has shown that this modified equation is identical in form to the Kelvin equation except for the disappearance of the numerical factor 2. This modification of the Kelvin equation can also be obtained directly from the Kistler equation [1]. Therefore radii calculated with Cohan's equation, using the adsorption branch of the isotherm, are one half those obtained when the normal Kelvin equation is used.

Desorption, on the other hand, occurs from the surface of a normal meniscus in a completely filled capillary, and the vapor pressure over the meniscus could therefore be represented by a normal Kelvin expression. Whereas Cohan has been able to obtain quantitative relations between adsorption and desorption for the cylindrical pore model, it is to be expected that in most systems the pore radii will vary from point to point along their lengths and the 'ink bottle' model will more nearly represent most porous systems. No quantitative expressions, however, have yet been developed to relate the adsorption and desorption pressures in the more complicated but realistic 'ink bottle' system.

There is, however, a good visual test which allows one to choose between the Cohan and the 'ink bottle' models. The difference may be seen when the weight adsorbed, after the contribution of reversible adsorption is subtracted, is plotted against the log of the relative pressure.[3] For the Cohan mechanism,

[3]*The reversible adsorption in the pressure region where hysteresis occurs may be approximately estimated from the slope of the top of the hysteresis loop which Amberg and McIntosh (1) have shown to be reversible.*

adsorption and desorption branches of the isotherm should then be entirely symmetrical since the form of the adsorption, as well as the desorption branch, is determined by the *same* pore radii distribution. Their relative positions, however, are determined by differences in the shapes of the menisci. In the case of the 'ink bottle' model the shapes of the menisci are the same and it is the largest pore neck which determines the relative pressure at which desorption occurs in a given pore. The amount desorbed, however, depends more on the volume of the pore than on the volume of the necks leading into it. The position and shape of the adsorption branch is then fixed by the distribution of pore sizes whereas the position and shape of the desorption branch is related to the radii distribution of the largest necks connecting the pores. Since there may be several necks to a given pore, the probability that all of these are much smaller than the mean radius of the necks is greatly reduced, and hence one would expect the desorption branch of the isotherm to represent an apparent distribution of pore necks with greatly reduced numbers of small necks. This difference will manifest itself in a much steeper desorption isotherm, particularly in the lowest relative pressure region where hysteresis is observed.

Whereas this test may allow one to establish the Cohan mechanism, it can only show in a qualitative way the possible validity of the 'ink bottle' model. A quantitative test of the 'ink bottle' model may be obtained by comparison of experimental and theoretical isotherms, but as yet this comparison applies to only the adsorption branch.

Further, it is necessary to interpret the form of the experimental isotherm in terms of the physical processes which give rise to it. If the partial pressure of a sorbable gas over a sorbent is increased, this pressure increase may lead to one, two, or three types of physical sorption:

(*a*) Complete filling of pores whose radii are equal to or less than the value required by the Kistler equation [1] in a form corresponding to the model.

(*b*) Adsorption on the surfaces of pores whose radii are larger than the value required for Kelvin condensation.

(*c*) Capillary condensation into the corners of pores which are too large to completely fill at the given partial pressure.

Types (*a*) and (*b*) are self-explanatory, but type (*c*) is best illustrated with reference to a specific model. For a boxlike pore capillary condensation may occur into the corners, but the addition of each layer of sorbate increases the radius of curvature of the menisci so that further condensation requires an increase in pressure. Gas condensed in this manner would show no hysteresis, and would be difficult to distinguish from multilayer adsorption. When, however, the corners of the boxlike pore are completely filled and only a single spherical hole remains, further condensation reduces the radius of curvature of the meniscus and the slightest increase in pressure will result in complete filling of the pore. This pore filling process is the type (*a*) condensation which results in the 'ink bottle' type hysteresis.

The value of V used in the theoretical isotherms corresponds to type (*a*) sorption only, while V_c is the value of V at saturation pressure. Since type (*a*) sorption always leads to hysteresis, the maximum value that V may have at any

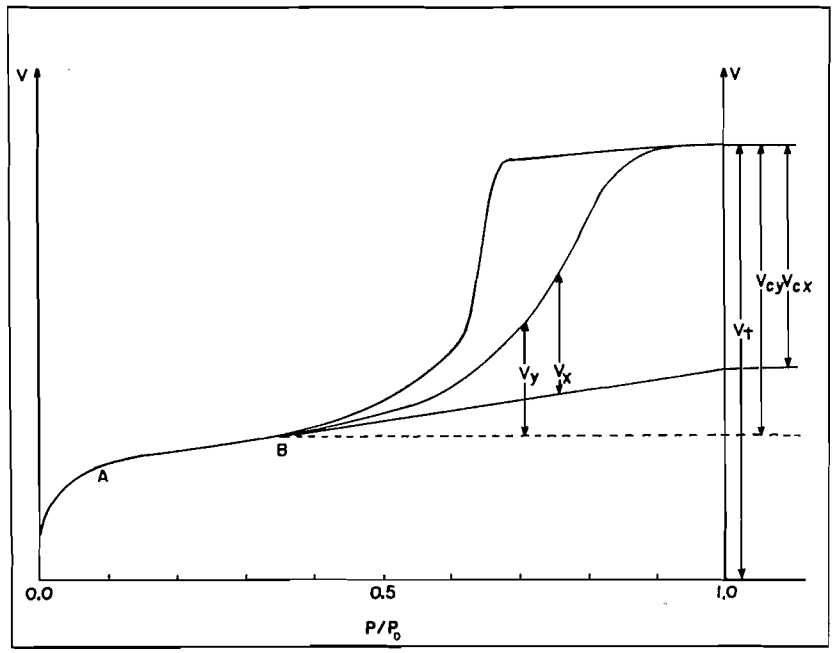

FIG. 7. Typical adsorption–desorption isotherm showing hysteresis.

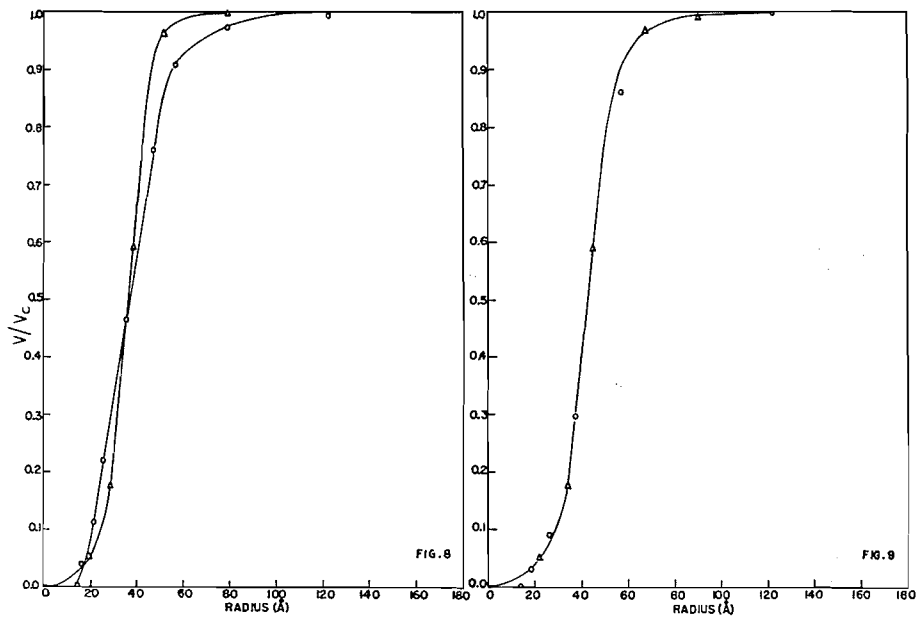

FIG. 8. Comparison of theoretical and experimental isotherms: experimental values from Emmett (6) using ratio of V_c/V_{cy} (FIG. 7).
Δ Selected Gaussian isotherm of cubic type with $\beta = 1$ and $\alpha = 10$Å (equation 6).
FIG. 9. Comparison of theoretical and experimental isotherms: experimental values from Emmett (6) using ratio of V_x/V_{cx} (Fig. 7).
Δ Selected Gaussian isotherm of cubic type with $\beta = 1$ and $\alpha = 22.5$Å (equation 6).

given relative pressure is equal to the total amount sorbed less the amount sorbed at the relative pressure where hysteresis becomes significant. Thus if only type (*a*) sorption occurs in pressure regions where hysteresis is observed then a plot of V/V_{cy} (see Fig. 7) should correspond to the theoretical isotherm. This ratio taken from Emmett's experimental isotherm for nitrogen on porous glass (6) has been found to fit best the theoretical isotherm (equation 6) for $\beta = 1$ and $\alpha = 13$ Å (see Fig. 8). If, however, sorption other than type (*a*) is contributing to the total sorption in the pressure region where hysteresis occurs, it is necessary to know what shape the adsorption isotherm would have had if capillary condensation had not contributed. Test extrapolations of the region A–B (see Fig. 7) of the experimental isotherm for porous glass show that the actual form of this extrapolation makes relatively small differences in the fit of the 'experimental' V/V_c and the theoretical isotherms. Thus the ratio V_x/V_{cx} (see Fig. 7) taken for the same nitrogen isotherm as above still fits the theoretical isotherm (equation 6) with $\beta = 1$ and $\alpha = 15$ Å (Fig. 9). Comparison of Figs. 8 and 9 shows that the fit of the 'experimental' isotherm to the theoretical isotherm is better in the case of Fig. 9 although the actual distributions and mean pore radii are not significantly different. Since this choice is not critical for the porous glass system the ratio V_x/V_{cx} (Fig. 7) has been used in this work as the experimental value comparable to the ratio V/V_c of the theoretical isotherm. In Table I the types of distribution, pore model, mean capillary condensation radius, and distribution width β are summarized for the experimental isotherms obtained by Barrer (2) and Emmett (6) for porous vycor glass.

TABLE I

MEAN PORE SIZE AND PORE SIZE DISTRIBUTION IN POROUS GLASS CALCULATED FROM VARIOUS ISOTHERMS

Substance adsorbed	Type of distribution	Character of volume function	Distribution width, β	Mean capillary condensation radius, α(Å)	Adsorbed layer thickness, t, (Å)	Mean radius after addition of adsorbed layer thickness, R_0, (Å)
Argon (Ref. 6)	Gaussian	Cubic	1	17.5	6.4	23.9
Nitrogen (Ref. 6)	Gaussian	Cubic	1	15.0	4.5	19.5
Butane (Ref. 6)	Gaussian	Cubic	2	15.0	(2.2)	19.9*
Oxygen (Ref. 2)	Gaussian	Cubic	1	18.0	6.18	24.2
Ammonia (Ref. 2)	Gaussian	Cubic	½	15.0	10.7	25.7

**Layer thickness assumed to be one molecular diameter (4.9 Å).*

DISCUSSION

The typical comparison between an experimental isotherm and a theoretical isotherm shown in Figs. 8 and 9 indicates that the adsorption isotherm in the

region where hysteresis is observed can for the porous system investigated be very closely represented by equation [6]. This tends to justify the assumptions which lead to this equation, i.e.

(*a*) There is a Gaussian distribution of pore radii;

(*b*) The pore volumes can be represented by an R^3 (ink bottle) function;

(c) All pores of radius equal to or less than that which is evaluated from the appropriate form of the Kistler equation [1] will be completely filled at a given partial pressure, i.e., the assumption that capillary condensation is the predominant factor in the region of hysteresis is valid.

From Table I it is apparent that the type of distribution, as well as the character of the volume function found for each gas, is very self-consistent. However, slight differences are found with respect to the values obtained for the parameters β and α. This can possibly be ascribed to the fact that the system has a most probable pore size comparable to the molecular dimensions. Thus, the size and shape of the adsorbed molecule may be expected to become influencing factors.

The fit of the 'experimental' and theoretical isotherm, as might be expected, is slightly better in the case of Fig. 9 than Fig. 8, although the actual distribution and mean radius obtained are not significantly different. It is apparent that with the relatively large contributions of capillary condensation found with porous glass it is the pressure and shape of the hysteresis region of the isotherm rather than the contribution of reversible sorption which are most significant in determining the fit of the 'experimental' and theoretical isotherms.

There are several differences between the theory introduced above and that described by Shull (14). Shull has only considered the cylindrical pore model whereas a better correlation between theoretical and experimental isotherms has been found with the 'ink bottle' model for the porous glass system. The present approach can, however, be used in cases where the cylindrical pore model might be desirable. Furthermore, it has been found convenient in this work to evaluate a normalized isotherm (V/V_c) rather than the inverted isotherm ($V_c - V$) used by Shull. The normalized isotherm not only allows the cancellation of arbitrary constants from the theoretical relations but also simplifies the necessary curve fitting. Shull has also used his method to determine pore sizes from isotherms where *hysteresis does not occur*. The theoretical curves evaluated either by Shull or in this work may well represent some part of any experimental isotherm—as a matter of fact, they may in their strictly mathematical form be used for the evaluation of any physical phenomenon showing such functional correlation. But, in the interpretation of such results, it must not be forgotten that any parameters, dependent or independent, appearing in the equations are now mathematical symbols only and therefore have no relation to the physical functions with which they were associated in the original theory. Thus, the evaluation of a mean or average pore size for a system that does not show hysteresis is inadvisable.

In the theoretical section, only the families of curves corresponding to $\beta = 1$ and $\beta = 2$ have been plotted for the Gaussian distribution. Since there is

no limitation on the possible values of β, there is an infinite number of such families that can be drawn. Presumably an experimental isotherm which will not fit one of the theoretical isotherms which have been plotted in the theoretical section may fit a member of a family of isotherms for a different value of β. It must be pointed out here, however, that Maxwellian distributions have the disadvantage of not by themselves allowing a decision regarding pore shape. For example, if the volume adsorbed can be represented by the integral of an expression $R^4e^{-\alpha^2R^2}dR$, one cannot interpret whether this expression is either (*a*) $K_1LR^2 \times R^2e^{-\alpha^2R^2}dR$ or (*b*) $K_2R^3 \times R\,e^{-\alpha^2R^2}\,dR$. The former case (*a*) would indicate a cylindrical pore volume whereas (*b*) would correspond to the 'ink bottle' pore. To distinguish between these two possibilities it is necessary to use further criteria such as the visual test described above.

In order to obtain the total pore radius, it is necessary to find the thickness of the adsorbed layer which must be added to the capillary condensation radius. This may be calculated from equation [9] which is the applicable relation for the previously established pore model and distribution. If, for the nitrogen isotherm of Emmett, all the gas sorbed at the relative pressure where hysteresis becomes significant were equally distributed on the surfaces of the pores, the thickness of the resultant adsorbed layer could be evaluated from the ratio V_{cv}/V_t (Fig. 7). Using the previously obtained value of α (i.e. 15 Å) a value of 4.5 Å is obtained for the layer thickness. That is, if the layer is equally distributed, the amount adsorbed at the partial pressure where hysteresis becomes significant is approximately the amount required to form a monolayer (i.e. 4 Å) on all surfaces. The values of t obtained for different sorbates together with the mean pore radius including the thickness of the adsorbed layer are listed in Table I. In the case of ammonia it is seen that t is approximately equal to three molecular diameters. Barrer (2) has pointed out that the high affinity of the ammonia molecule for the sorbent causes considerable swelling and hence the mean capillary radius obtained from the ammonia isotherm does not appear excessively large. For butane the calculated layer thickness is less than one molecular diameter and therefore the surface cannot be completely covered at the pressure where hysteresis occurs. Since condensation begins only after monolayer formation it has been assumed that the distribution of butane is not equal on all surfaces, and that the thickness of the adsorbed layer is equal to one molecular diameter at the pressure at which a pore fills by condensation. All above radii are seen to have values considerably less than the Kelvin values of 30–40 Å given by Emmett (6), which do not yet include the thickness of the adsorbed layer. This difference was to be expected, however, since it was realized at the outset that the Kelvin radius calculated from the relative pressure at the inflection point on the isotherm corresponded to the radius of the pore which has the most probable volume. That is, the Kelvin radius is the radius such that

$$d(dV/dR)/dr = 0.$$

If, therefore, the volume distribution function is known, the Kelvin radius may be calculated directly. For the model found applicable to the porous glass

system, the Kelvin radius is such that

$$\frac{R}{dR}\left[R^3\exp\left\{-\frac{\beta^2}{\alpha^2}(R-\alpha)^2\right\}\right] = 0,$$

whence the Kelvin radius = 1.82 α when $\beta = 1$.

Barrer (2) and Cohan (6) arrived at values similar to those obtained in this work by using the desorption branch of the isotherm. Barrer has corrected for the thickness of the adsorbed layer by the addition of two molecular diameters of the adsorbate. The highly polar molecules, however, give inconsistent values. Since these radii are calculated from the partial pressure corresponding to the point of inflection on the isotherm they must correspond to weighted values in the same sense as the Kelvin radii discussed above. The weighted radius obtained from the desorption isotherm happens to almost correspond to the mean radius obtained from the adsorption isotherm after allowance is made for the distribution in pore size. However, the pore model corresponding to the desorption isotherm has not been found applicable so that the apparent similarity seems largely fortuitous.

The model which most closely resembled the actual system was the 'ink bottle' model. This conclusion appears in direct opposition to that arrived at by Amberg and McIntosh (1), who decided that the cylindrical pore model was applicable to this same system. This difference is partly one of definition in so far as they have shown the pores to have a length to diameter ratio of about two, which these authors would consider 'ink bottle' rather than cylindrical type pores. Although this seems to be only a minor point of disagreement the relative forms of the expected adsorption and desorption isotherms are quite different for the two systems. The test described above which compares the relative shapes of the adsorption and desorption isotherms of the two models seems to eliminate the Cohan mechanism and is also qualitatively in agreement with the 'ink bottle' mechanism. The excellent correspondence between the theoretical cubic type isotherms and experimental adsorption isotherms over the complete applicable pressure range strongly indicates a basic equivalence between the 'ink bottle' model and the porous glass system.

When the smaller pore radii evaluated from the above methods are accepted, it is apparent that for a given pore volume a greater pore surface area should be expected. This may be calculated from V_m, the quantity of sorbate required to complete a surface monolayer. The value of V_m may be obtained from equation [11], which is the appropriate equation for the pore model established for the porous glass. Numerically, these values of V_m are greater than those obtained from the B.E.T. isotherm with the exception of ammonia (see Table II). In order to reconcile the differences, it is necessary to re-examine the postulates leading to the different V_m's. The V_m evaluated in this work corresponds to one of the several definite models used, rather than the V_m of the real system.

In order to evaluate the mean pore radius of the distribution it was necessary to assume the appropriate form of the Kistler equation [1]. In porous glass, where the pores have been formed in a solid non-crystalline mass by a preferential leaching process, it would appear that after the smoothing out of surfaces

by adsorption, condensation would occur on nearly spherical surfaces. This, as pointed out in the introduction, leads to the Kelvin relation. For capillary condensation causing hysteresis in the 'ink bottle' model this factor appears to be a maximum. Whereas altering this factor may change our conclusions with respect to the mean radius, it does not affect the conclusions with respect to the pore model and distribution. Any smaller value of the constant of the applicable form of the Kistler equation [1] would lead to a smaller mean pore radius and larger values of V_m and surface area.

For the V_m of the B.E.T. theory to be valid, it is necessary that the surface of the porous glass be homogeneous. Barrer (2) has already shown that the heats of sorption on the porous glass do not confirm this assumption and furthermore, the B.E.T. isotherm only fits the experimental data for the porous glass at low relative pressures. Kistler (8) has presented further arguments against the acceptance of the B.E.T. V_m.

TABLE II

COMPARISON OF CALCULATED V_m'S AND SURFACE AREAS WITH THOSE OBTAINED BY B.E.T. METHOD FOR POROUS GLASS

Substance adsorbed	V_m as determined from equation [13] (cc. at S.T.P. per gram material)	Total surface area of system as calculated from V_m ($m.^2$ $gm.^{-1}$ material)	B.E.T. V_m (cc. at S.T.P. per gram material)	B.E.T. surface area ($m.^2$ $gm.^{-1}$ material)
Argon (at 90°K.) (Ref. 6)	37.5	157	26.5	111.5
Nitrogen (Ref. 6)	34.1	143	29.0	121
Butane (Ref. 6)	24.6	212	8.6	74.5
Oxygen (at 79°K.) (Ref. 2)	46.7	178	36.5	139
Ammonia (Ref. 2)	40.6	138	59.9	204

In view of these factors the surface areas shown in Table II which are calculated from the V_m obtained in this work by means of equation [14] are considered more representative of the porous glass than those obtained using the B.E.T. V_m. The variations in the surface areas obtained for the different gases may well result from variations in the pore structure of the sorbent which were neglected in the present theory. This approach, then, appears to be generally applicable to other porous systems except where appreciable amounts of reversible capillary condensations might occur (type *c* physical adsorption defined above). Even with fibrous networks or compacted solids, however, one would expect hysteresis to result from the filling of nearly spherical type pores. In such systems the 'pore radius' would require a different interpretation with respect to the pore structure. Furthermore, the reversibly sorbed material would not be equally distributed on all surfaces and the evaluation of the surface area by the method described above would lead to inaccurate results.

SURFACE ENERGIES OF THE ALKALI HALIDES[1]

By G. C. Benson and G. W. Benson[2]

ABSTRACT

Previous theoretical calculations and experimental measurements of the surface energies or enthalpies of the alkali halides are reviewed briefly. A new attempt to determine the surface enthalpy associated with the {100} face of sodium chloride from a calorimetric study of the effect of particle size on the heat of solution is described. The result (305 ergs/cm.^{2} at 25°C.) appears to be larger than might be predicted on the basis of the classical Born-Mayer theory.

1. INTRODUCTION

The surface energies of ionic crystals have been considered theoretically a number of times during the past thirty years but very little work has been done on their experimental determination. A satisfactory comparison of experimental data with various theoretical models has not yet been achieved. Such a comparison is highly desirable since it would yield information concerning the force fields and distortion of the lattice near the surface of the crystal. Furthermore, at moderate pressures the surface energy differs only negligibly from the surface enthalpy and Jura and Garland (6) have shown that, in simple cases, a knowledge of this quantity at one temperature, together with the contribution of the surface to the specific heat of the crystal as a function of temperature, makes possible a calculation of all the surface thermodynamic properties.

In our laboratory a study of the surface energies of the alkali halides is in progress and the present paper is a report on the current status of this project. A brief review of some theoretical aspects of the problem is given in Section II. This is followed by a summary of the attempts of previous authors to determine the surface energies of the alkali halides calorimetrically. A description of our experimental work is given in Section IV and the preliminary results for sodium chloride are discussed in the last section.

II. SURFACE THERMODYNAMIC QUANTITIES AND THEORETICAL CALCULATIONS OF THE SURFACE ENERGIES OF THE ALKALI HALIDES

The variables, entropy, volume, and composition, are no longer sufficient to specify the thermodynamic state of a solid body having a significant extent of surface, and introduction of other variables becomes necessary. In the simplest case one new variable, the area A, is required and a term γdA is added to the usual expression for the differential of the energy of the system. In terms of more convenient variables, differential surface properties may be defined as derivatives with respect to A at constant temperature T, pressure p, and composition n. On this basis γ is identical with the surface Gibbs free energy $(\partial G/\partial A)_{T,p,n}$.

Experimentally, surface properties are generally determined by comparing measurements on systems having different specific areas. The quantities obtained are really integral surface properties but when stated per unit area are identified with the differential properties. This involves the added assumption that γ is independent of A.

Theoretical calculations of the surface energy are usually based on atomistic models at zero pressure and temperature. In this case the surface energy, enthalpy, and various free energies become identical and are separately equal to the increase in potential energy of interaction between the ions when a new surface is formed by division of an infinite crystal as illustrated in Fig. 1.

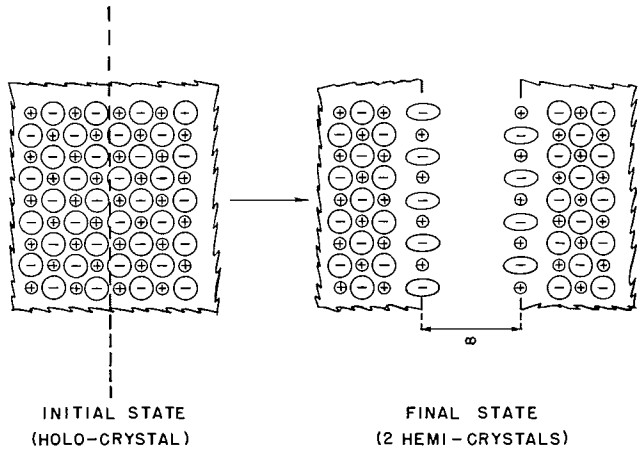

FIG. 1. Formation of two new surfaces by division of a holocrystal into two hemicrystals.

Thus the surface energy per unit area is given by

$$[1] \qquad E_s = (2\,U_{\text{hemi}} - U_{\text{holo}})/2A$$

where U_{holo} and U_{hemi} are the total energies of interaction for the initial crystal and for one of the hemicrystals respectively. A is the area of one of the newly created surfaces.

In classical calculations these energies are evaluated by adding up interactions between pairs of ions, assuming that these interactions can be represented as a sum of coulombic, dipole–dipole, dipole–quadrupole, and repulsive terms. Various types of distortion in the region of the surface such as changes in lattice spacing and polarization of the ions have been considered, and it is generally concluded that significant distortion is limited to one or two layers at the surface and makes a contribution of 10 to 20% to the surface energy.

The dependence of the calculated surface energies on the various types of interactions and distortion assumed in the model is shown in the cycle of values given in Table I. It will be noted that the recent calculation of Shuttleworth gives almost the same value as that of Born and Stern, though a number of refinements have been made in the model. One feature which appears in Shuttleworth's calculations is the relative importance of the van der Waals' attractive terms. Although these forces contribute only a few per cent to the

cohesive energy of the crystal, their contribution to the surface energy is 50% of the net value.

TABLE I

THEORETICAL VALUES OF THE SURFACE ENERGY OF A {100} FACE OF SODIUM CHLORIDE

Author	Description of model	E_s, erg/cm.^{2}	Ref.
Born and Stern 1919	Coulombic and inverse 10th power repulsive forces	150	1
Lennard-Jones and Taylor 1925	Coulombic and inverse 9th (Na—Na), 10th (Na—Cl), and 11th (Cl—Cl) power repulsive forces	96	7
Dent 1929	Same as L.-J. and T. but included polarization and a 5% contraction at the surface	77	3
Shuttleworth 1949	Coulombic, attractive van der Waals' and exponential repulsive forces; also included a correction for surface distortion	155	11

Recently a quantum mechanical calculation of the surface energy of LiF has been described by van der Hoff and Benson (5). In this an attempt is made to consider the electronic density distributions of the ions in more detail and to avoid the introduction of semiempirical force laws. The value of the cohesive energy of the crystal calculated by this model is in good agreement with that calculated in a classical fashion, but the surface energy is about two to three times larger than the classical value.

III. PREVIOUS EXPERIMENTAL MEASUREMENTS OF THE SURFACE ENERGIES OF THE ALKALI HALIDES

Sutherland (12) has given an excellent review of previous attempts to determine the surface energy, enthalpy, or free energy of a solid. A method which seems very likely to yield useful results in this field is the determination of the surface enthalpy from the effect of particle size on the heat of solution. Lipsett, Johnson, and Maass (8) measured this effect for sodium chloride in water. Their original result was 400 ergs/cm.^{2} at 25°C., but the salt in this experiment was exposed to water vapor for a period of time before the solution process. In a second paper (9) by the same authors, a new technique to avoid this exposure is described and a revised value of 386 ergs/cm.^{2} reported. Boyd and Harkins (2) performed similar experiments and obtained a value of 395 ergs/cm.^{2} The areas in both these sets of experiments were obtained from photomicrographs and are generally considered to be too small. Hence the values of the surface enthalpy are probably high. Wertz (13) working in Harkins' laboratory used a gas adsorption technique for measuring the area of the salt and obtained a value of 130 ergs/cm.^{2} for the surface enthalpy. Unfortunately this work was discontinued after a single determintion and the value cannot be considered as well established. In all these measurements the surface area of the salt used was in the range 1–5 square meters per gram

and no attempt was made to establish that the heat effect per unit weight was proportional to the specific surface area.

IV. EXPERIMENTAL DETERMINATION OF THE SURFACE ENTHALPY OF SODIUM CHLORIDE

It is apparent from the brief survey of theoretical and experimental work given in the two preceding sections that further investigation of the calorimetric method of determining the surface enthalpy would be of value. With this purpose in view, we have constructed an adiabatic calorimeter suitable for measuring heats of solution at 25°C.

The calorimeter vessel (190 cc. capacity) is constructed from a corrosion resistant stainless steel. It is hung by nylon loops inside an evacuated space surrounded by a water jacket. The temperature of the latter can be varied to maintain adiabatic conditions. The sample of salt sealed in a thin-walled glass bulb is held in a guillotine arrangement. Breaking the bulb and stirring the contents of the calorimeter is accomplished by an intermittent rotation of the whole assembly through 180°. Further details of the design and operation of the calorimeter will be given in another publication.

Emersleben (4) has deplored the failure of most workers to give information regarding particle size when reporting heats of solution and has criticized Wüst and Lange (14) in connection with their results for sodium chloride. It thus seemed desirable to carry out some measurements on "coarse" salt. At the same time this served to establish the accuracy of the calorimetric procedure.

The coarse salt was Merck reagent recrystallized three times from conductivity water. It was given a final drying in the sample bulb under vacuum at 300°C. for 12 hr. before being sealed off under a few millimeters pressure of helium. Attempts to measure the area of this salt by the usual B.E.T. nitrogen adsorption method at 78°K. indicated that the area was negligibly small (i.e. less than 0.1 square meter per gram, which corresponds to an average particle size exceeding 30μ). Equilibrium conductivity water was used in all solution experiments and no attempt was made to remove dissolved gases. Measurements were made in the concentration range 0.05 to 1.4 molal. The results appear to be more consistent internally than those of previous workers and fall between the values reported by Wüst and Lange (14) and by Lipsett, Johnson, and Maass (8, 9). The reproducibility of the present results is estimated to be about 0.1% down to 0.2 molal. Below this concentration the errors increase and are of the order of 0.5% at the lowest concentration studied. The solid curve in Fig. 2 was plotted from a table of our smoothed data. The calorie used in stating these values is defined as 4.1840 absolute joules. A more detailed analysis of the coarse salt results will be given in the paper on the operation of the calorimeter.

The fine salt was prepared in an apparatus similar to that described by Young and Morrison (15) but some changes were made in the method of heating the salt. Also contact between the salt and brass parts of the apparatus was eliminated. Some signs of non-stoichiometry have been observed for salt prepared

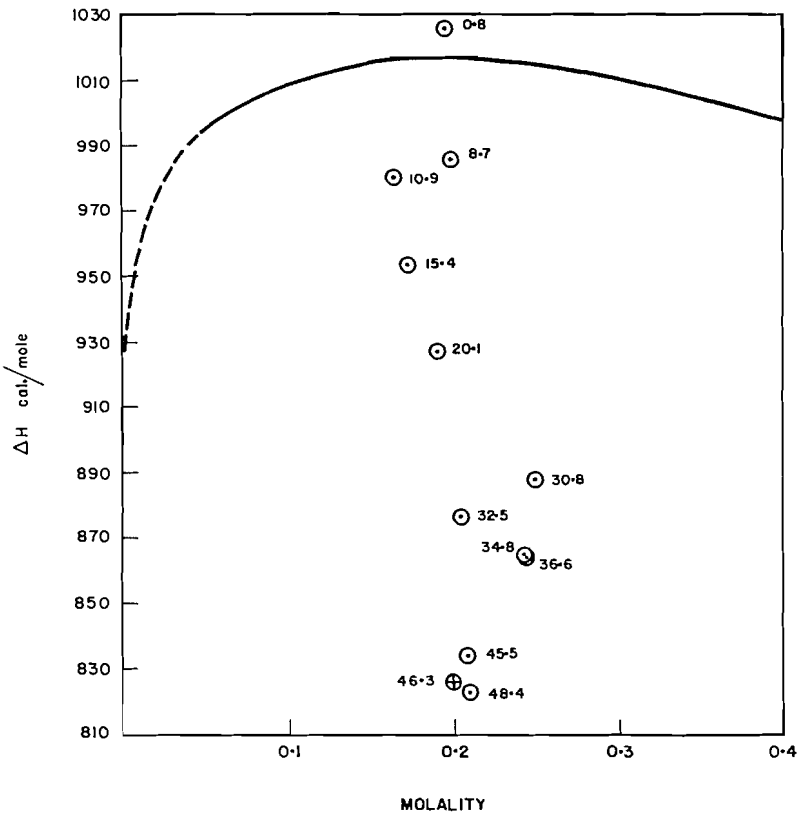

FIG. 2. The curve represents the $\triangle H$ for solution of coarse sodium chloride in water at 25°C. plotted as a function of molality. The results obtained for fine salt are indicated by the points labelled with the areas in square meters per gram. The point marked with a cross is for unsintered salt; all other points are for sintered samples.

by this method. Samples collected at high precipitator voltages sometimes have a slight blue color and give alkaline solutions when dissolved in water. This blue color probably indicates the presence of colloidal sodium produced by electrolysis or bombardment in the electrostatic precipitator. A careful check was kept on the pH of solutions of the fine salt and none of the material used in the present work showed this effect.

Care was taken to minimize any exposure of the fine material to water vapor. B.E.T. areas were measured on the actual samples to be dissolved in the calorimeter. The original preparation yielded material with a surface area of about 48 square meters per gram. It was found that controlled sintering offered a convenient method of producing samples with lower specific surfaces. Thus samples of fine salt were heated under vacuum for 14 hr. at temperatures from 70 to 200°C. before the area was measured. Below 100°C. the sintering was negligible, while at 200°C. nearly the whole area could be destroyed in the 14-hr. period.

Heats of solution measured with the fine salt are indicated by the points in Fig. 2 labelled with the specific areas of the samples. The point marked with a

cross was obtained with the original unsintered material; all other samples were sintered. The fact that one area is higher than the unsintered material is due to a slight non-uniformity of the original preparation.

V. DISCUSSION OF THE RESULTS

Excluding the smallest area sample, the points for fine salt fall below the curve for coarse salt, indicating a positive particle size effect. A plot of the deviation $(\Delta H)_s$ against surface area, given in Fig. 3, shows a definite linear

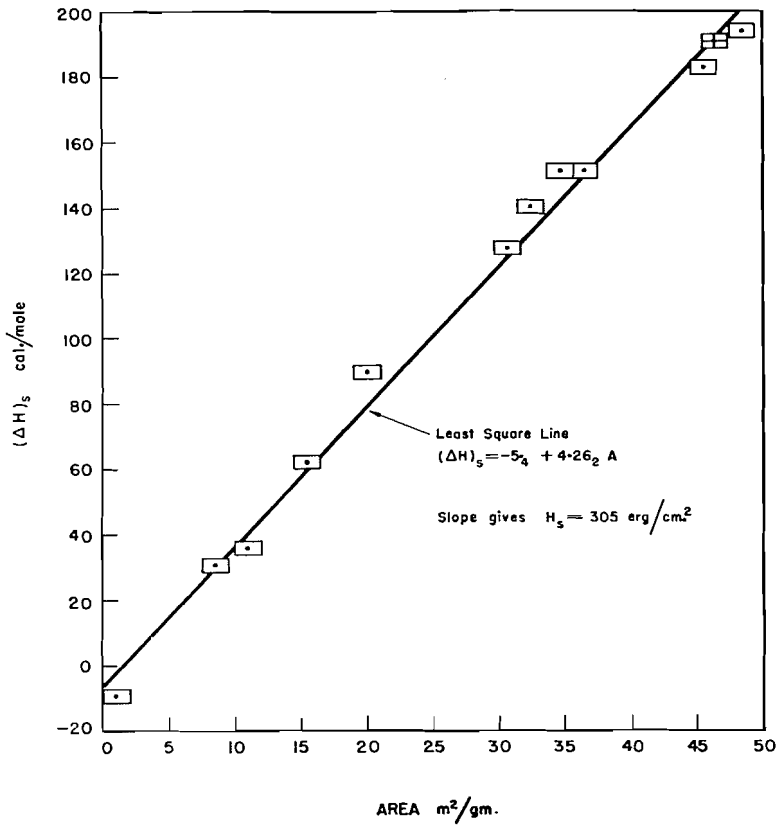

FIG. 3. Plot of the variation of the $\triangle H$ for solution of sodium chloride in water at 25°C. as a function of the surface area of the sample. The point marked with a cross is for unsintered salt; all other points are for sintered samples. The length and breadth of the rectangles correspond to ±1 square meter per gram and ±2 cal./mole respectively.

trend but does not go through the origin. The slope of the least square line corresponds to a surface enthalpy $H_s = 305$ ergs/cm.^{2} at 25°C. Electron micrographs of the salt prepared by Young and Morrison show that the crystals are predominantly cubic; hence the above value of H_s should be associated with the {100} face of sodium chloride.

It is difficult at present to place limits on the accuracy of this result. The B.E.T. method applied to materials like sodium chloride is generally considered to give the surface area to about 5 to 10% though the reproducibility of the

measurement is much better than this. The accuracy of the individual calorimetric determinations of $(\Delta H)_s$ is of the order of 2 or 3 cal./mole but variations from sample to sample are higher than this. The most disturbing feature is the negative value of $(\Delta H)_s$ obtained for the smallest area sample. This is further confirmed by the negative intercept of the least square line. Unfortunately the measurements were made in the order of decreasing area and the sign and magnitude of the intercept was not apparent for sime time. Since then spot tests done on the fine salt have indicated the presence of nitrate and nitrite impurities. Presumably these were formed in the Cottrell precipitator. Since all the data reported came from one preparation of fine salt, it is quite possible that a reasonable correction could be made by moving the line with fixed slope until it passes through the origin. This assumes the impurities are fairly homogeneously distributed in the original preparation. In this case the surface enthalpy is unchanged but it is for impure sodium chloride. The influence of these impurities on the surface enthalpy will depend to a large extent on their nature and on whether they are preferentially concentrated in the surface region.

The electron micrographs mentioned above also showed a broad distribution of particle size. Extremely small crystals may be expected to show deviations arising from the effects of edges and corners. Even for larger crystals surface structure such as steps and kinks may lead to irregularities in the apparent surface energy. In addition there is the further possibility of effects arising from strain energy in the small crystals. The present results with sintered samples indicate that if these effects are present and make significant contributions to the heat of solution they are proportional to the extent of surface and for practical purposes could be lumped with the ideal surface contribution. However, comparison of the result with a theoretical model requires a more detailed knowledge of these various factors.

Until the uncertainties outlined in the preceding two paragraphs are investigated further, the value 305 ergs/cm.^{2} must be considered as provisional. Nevertheless, a comparison of this value with the theoretical and previous experimental results summarized in Sections II and III is of interest. Our value is roughly 85 ergs/cm.^{2} lower than the values reported by Lipsett, Johnson, and Maass and by Boyd and Harkins. This is in line with the criticism of their area determination. Wertz's result is considerably lower but is based on an isolated measurement. The value of H_s at 0°K. is related to that at 298°K. by the equation

$$[2] \qquad H_s(0°) = H_s(298°) - \int_0^{298} C_s dT$$

where C_s is the surface contribution to the heat capacity. Patterson and Morrison (10) are studying this last term in detail but their results are incomplete as yet. At present all that can be deduced from [2] is that $H_s(0°)$ should be smaller than 305 ergs/cm.^{2} It seems rather doubtful that the temperature correction will reduce this to the classically calculated value of 155 ergs/cm.^{2}

An equivalent way of stating the present result is

$$[3] \qquad (\Delta H)_s = 11.8/l \text{ cal./mole}$$

where l is the length in microns of the edge of an average sized cubic particle. Emersleben (4) has given a theoretical value of 13.0 for the numerical coefficient. Although the derivation is based on a model assuming an ideal lattice and only coulombic forces, the expression does provide a useful approximation in the present case.

ACKNOWLEDGMENTS

The authors are indebted to Dr. H. P. Schreiber and Dr. F. W. Thompson for preparing the samples of fine salt and to Mr. P. D'Arcy for assistance with the calorimetric measurements. They also wish to thank Dr. J. A. Morrison and Dr. D. Patterson for many stimulating discussions of surface problems.

A LOW TEMPERATURE PARTICLE SIZE EFFECT ON THE HEAT CAPACITY OF SODIUM CHLORIDE[1]

By D. Patterson,[2] J. A. Morrison, and F. W. Thompson[2]

ABSTRACT

An effect of particle size upon the heat capacity of sodium chloride has been found in the temperature range 9° to 21°K. The experiments were done with three NaCl samples of specific surfaces between 38 and 59 sq. meters per gm. The observed effect has the temperature dependence predicted by theory but its magnitude is three to four times larger than expected. It is unlikely that adsorbed gases have made any significant contribution in the experiments. The accuracy with which the specific heat and surface area differences have been determined is not high enough to show definitely whether or not the surface specific heat is an extensive property of the surface.

INTRODUCTION

The existence of an effect of particle size on the thermodynamic properties of a solid is evident from the Einstein model which considers the solid as an assembly of oscillators identified with the atoms. Atoms on the free surface are less strongly bound than those in the interior so that their frequency is lowered, producing a change in thermodynamic properties which is proportional to the surface area. With the Debye or Born – von Karman models, however, the oscillators are identified with the normal modes of vibration of the whole solid. The effect of free boundaries is then not localized in the frequencies of oscillators associated with the surface but is spread throughout the frequency spectrum. Nevertheless, it may be shown that in particular cases the effect of finite particle size reduces to a contribution to the thermodynamic quantities which is extensive in the surface area, plus other contributions (e.g. edge contribution) which can ordinarily be neglected.

Brager and Schuchowitsky (2, 3), Montroll (8), and Stratton (11) give the following relation (low temperature form) for the heat capacity of small particles of rectangular cross-section and with perfect faces,

$$C_v = 464.5\ (T/\theta_D)^3 + B(T/\theta_D)^2 + \ldots \text{ cal./gm. atom deg.} \qquad [1]$$

where θ_D is the Debye characteristic temperature and B is a constant proportional to the specific surface area. According to [1] the surface contribution becomes more important at low temperatures since it is decreasing as T^2 while the volume contribution does so as T^3. If the density of modes in the frequency spectrum is too low, equation [1] breaks down and the specific heat is no longer an extensive property of the surface. This may occur if the particles are too small or if the temperature is too low, i.e. if $(h\nu_0/2kT) > (2N/\pi)$ (ν_0 is the maximum frequency of the solid lattice and N^3 is the number of atoms in the particle).

[2]*National Research Laboratories Postdoctorate Research Fellow.*

Specific heat measurements on several samples of TiO_2 between 12° and 270°K. showed an effect of particle size above 50°K. (4) which could be explained to an order of magnitude as an effect on the optical modes of vibration of TiO_2 (10). However, the low temperature increase predicted by equation [1], which has to do with the acoustical modes, was not found. Since there were no grounds for doubting the theory, it was decided that the low temperature effect must have been masked by other effects. Therefore, it seemed worthwhile to try further experiments using the simpler solid, NaCl, about which more is known theoretically, and also to carry the experiments to as low a temperature as possible. With the NaCl, an increase of the specific heat with decreasing particle size has now been found at low temperatures. The temperature dependence of the effect is that required by theory but the magnitude is three to four times greater than anticipated.

Apart from the intrinsic interest in the effect itself, two other considerations exist. Recently there has been some discussion (1, 5, 6, 7) as to whether or not thermodynamic properties associated with solid surfaces are extensive properties of the surface in a real case, as has been predicted by [1]. An answer to this should be found in experiments such as the present ones, but unfortunately the accuracy achieved so far is not high enough to permit definite conclusions to be drawn. A further interest lies in the possibility of obtaining information about surface structure from measurements of particle size effects, but for this purpose the experiments must extend over a wide temperature range.

EXPERIMENTAL

Materials

The small particles of NaCl (mean specific surfaces between 38 and 59 sq. meters per gm.) were prepared by the method described by Young and Morrison (12) and by a recent modification of this method. The methods involve volatilizing NaCl in a platinum crucible and sweeping the crystals formed from the vapor into an electrostatic precipitator with a stream of dry nitrogen. The samples were handled in an inert gas atmosphere in either a dry box or a desiccator. Each sample was about 30 gm.

The specific surfaces of the samples were determined by nitrogen adsorption at liquid nitrogen temperatures. Determinations on the whole calorimetric samples and on aliquots (0.5 to 2 gm.) agreed to 10% or better.

Calorimetric Measurements

The details of the calorimetric method are given fully in a preceding paper (9) so that here it is only necessary to discuss special effects associated with the experiments on the small particles.

In the experiments with bulk NaCl (9) it was found that thermal equilibrium within the calorimeter vessel could be readily attained over the temperature range 2.5° to 20°K. with 10^{-6} moles of helium in the vessel. Further, this amount of helium did not make a significant contribution to the specific heat of the system. On the other hand, with the small particles of NaCl in the

calorimeter vessel, 10^{-6} moles of helium did not allow thermal equilibrium to be established in a reasonable time below about 9°K. Apparently the helium was being adsorbed on the large surface presented by the small particles. One set of experiments was done with 10^{-4} moles of helium in the calorimeter vessel but here also equilibrium times became much too long below 9°K. The heat capacity of this additional helium was very much less than it would have been if the helium had been present as a gas. This suggests that the helium was being strongly adsorbed in a localized array on the surface.

In principle, specific heat measurements such as these can be pursued to temperatures below 9°K. simply by increasing the amount of helium until some is left in the gas phase at the lowest temperature desired. Practically, however, correcting for the effect of helium on the specific heat would prove difficult. The additional results which might be obtained would hardly justify the labor involved in determining the heat capacity of the adsorbed helium, the heat of adsorption, etc., over a range of temperature and of concentration.

RESULTS AND DISCUSSION

Since the heat capacity of NaCl changes by about a factor of 20 in the range 9° to 20°K., the small observed dependence of the heat capacity upon particle size cannot be shown conveniently in a graph of the primary data.

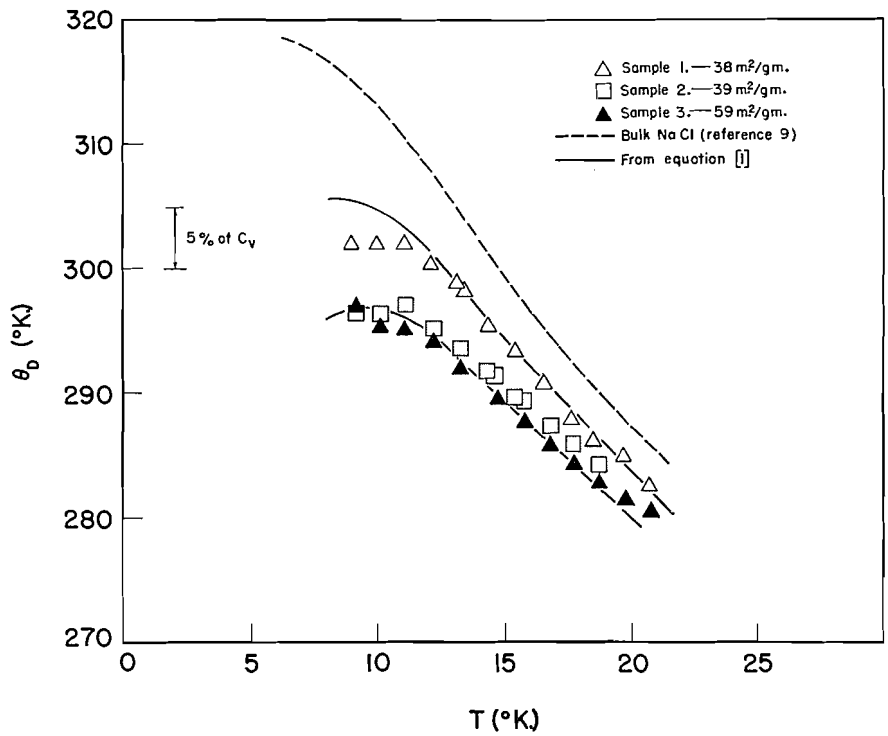

FIG. 1. The Debye characteristic temperature (Θ_D) for small particles of NaCl as a function of temperature.

Rather, recourse is had to a plot of the 'apparent' Debye characteristic temperature corresponding to each measured specific heat versus the absolute temperature. All of the results shown in this form in Fig. 1 were obtained with about 10^{-6} moles of helium in the calorimeter vessel. The significant point is that each of the three samples of small particles of NaCl has a larger specific heat (lower θ_D) than that of the bulk over the temperature range 9° to 21°K. As will now be shown, the temperature dependence of the specific heat is of the expected form.

The theoretical predictions are based on the Debye model, although it is recognized that it does not hold exactly for bulk NaCl, i.e. θ_D is a function of temperature. The consequences of the model are given by equation [1]. The two full curves of Fig. 1 have been calculated using the equation with the constant B fitted from the experimental points for samples 1 and 3 at 15°K. There is a certain arbitrariness involved in this fitting but it seemed most reasonable to select fixed points abut the middle of the temperature region. Although there appears to be a small systematic deviation at the higher temperatures for sample 3 and at the lower temperatures for sample 1, the curves reproduce the experimental results quite well. The deviation at the lower temperatures is probably due to the difficulty of attaining thermal equilibrium.

The actual values of B for samples 1 and 3 deduced from the experiments are 1.28 and 2.60 cal./mole deg. respectively whereas Montroll's theory (8) gives 0.42 and 0.64. The magnitude of the particle size effect is, therefore, three to four times larger than predicted. While no quantitative explanation for this difference can be offered as yet, the observed values might be increased by several things, e.g. by the presence of adsorbed gases or by surface roughness and non-stoichiometry. The effect of adsorbed gases must, however, be insignificant in these experiments. The excess of the specific heat of sample 1 over that of bulk NaCl is approximately 0.0055 cal./deg. at 20°K. Were this amount to be contributed by adsorbed atoms or molecules behaving as fully excited oscillators, nearly 10% of the surface would need to be covered. Such a surface concentration would seem unlikely because the weakly bound oscillators would readily desorb at room temperature. Any gases not removed by pumping at this temperature would be held to the surface so tightly as to have high frequencies of oscillation, at least of the order of 10^{13} sec.$^{-1}$. Oscillators of frequency higher than about 10^{12} sec.$^{-1}$ would make no significant specific heat contribution below 20°K.

Surface roughness and non-stoichiometry may well explain the difference in results between samples 1 and 3 and sample 2. The former two were made in the same apparatus, the only difference in their preparations being the temperature of volatilization of the NaCl. Sample 2 was prepared in another apparatus with a somewhat higher potential in the electrostatic precipitator, and it shows a particle size effect which is much too large compared with that for samples 1 and 3. Sample 2 must have contained an excess of sodium as the pH of its solution in water was about 9 compared with pH's of 6 to 6.5 for the solutions of the other two samples. Since the specific heat for this sample has the same temperature dependence as that for the other two, one might specu-

late that the excess sodium was in the surface. However, no attempt has been made yet to deduce quantitatively the effect of such a surface excess.

The ratio of the B's for samples 1 and 3 is 2.03, while the ratio of their surface areas is 1.55. The difference, approximately 25%, is just within the probable combined experimental error in determining the differences in specific heat and in surface area. The experiments, therefore, do not allow a definite decision as to whether or not the surface specific heat is an extensive property of the surface.

REVERSIBILITY IN PHYSICAL ADSORPTION[1]

By E. L. Pace, K. S. Dennis, S. A. Greene, and E. L. Heric

ABSTRACT

The question of reversibility and equilibrium is considered in relation to the physical adsorption of gases on finely divided solid surfaces. Conclusions are drawn from calorimetric measurements of (1) adsorption isotherms, (2) integral, differential, and isosteric heats of adsorption, and (3) heat capacity of the adsorbed phase for surface coverages of the order of a monolayer or less. In line with the preceding, results are presented and discussed for calorimetric studies involving (1) heats of adsorption and heat capacities of methane adsorbed on rutile between 80 and 140°K., (2) heats of adsorption of argon on rutile between 60 and 90°K., and (3) the zero point entropy of krypton adsorbed on rutile at a coverage of about 0.57 of the monolayer capacity.

INTRODUCTION

The following paper will be directed towards the question of reversibility and equilibrium as related to the physical adsorption of gases on finely divided solid surfaces. Surface coverages under consideration will, in general, be of the order of a monolayer or less. The conclusions will be drawn from calorimetric measurements of (1) adsorption isotherms, (2) integral, differential, and isosteric heats of adsorption, and (3) heat capacity of the adsorbed phase.

Some methods used in establishing the reversibility of the adsorption process are essentially empirical in character. Those deserving mention here are (1) the reproducibility of the adsorption isotherm and its invariance with time and (2) comparison of the heat of adsorption with the heat of desorption at the same surface coverage and temperature. In the case of the adsorption isotherms, difficulties arise because of the slowness of the equilibrium process and the necessary measurement of very low pressures with precision. These difficulties have been emphasized in the recent work of Young *et al.* (10) with *n*-heptane on various solid surfaces and Crowell and Young (1) with the argon–graphite system. If heats of adsorption and desorption agree within the experimental error, this agreement is an indication that the adsorption and desorption paths are the same. The method, however, is not generally feasible at low equilibrium pressures because of the slow rate of the desorption process of the adsorbate. This second method has been used under suitable conditions by Pace *et al.* (8) in a study of the methane–rutile system and by Morrison and co-workers (5) in studies of argon adsorbed on rutile.

Some methods of establishing reversibility are fundamentally thermodynamic in character. It is possible by these methods to derive the same thermodynamic quantity from independent measurements of adsorption isotherms, heats of adsorption, and heat capacity at several coverages and temperatures.

[1]*Manuscript received September 16, 1954.*
Contribution from Morley Chemical Laboratory, Western Reserve University, Cleveland, Ohio. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

From the adsorption isotherm, we can obtain the isosteric heat (q_{st}) from the expression

[1] $$q_{st} = RT^2(d \ln P/dT)_{N_s}$$

in which P is the equilibrium pressure of the adsorbate, N_s is the number of adsorbed moles, and T is the absolute temperature. The isosteric heat q_{st} is related to the molar heat content of the gas (H_G) and differential molar heat content (considering adsorbed gas as one component system) of the adsorbed gas ($\bar{H}_s$) by the expression

[2] $$q_{st} = H_G - \bar{H}_s.$$

The experimental integral heat of adsorption (Q_{N_s}) is also related to q_{st} since

[3] $$Q_{N_s} = \int_0^{N_s} q_{st} dN_s.$$

A differential heat of adsorption can be defined in terms of the integral heat as $(dQ_{N_s}/dN_s)_T$. It can be evaluated either as the slope of the integral heat curve or by direct experimental measurement. If the increment of added gas is small enough, $(\Delta Q_{N_s}/\Delta N_s)_T$ is essentially the same as $(dQ_{N_s}/dN_s)_T$. It is also obvious that the differential heat of adsorption is identified thermodynamically with the isosteric heat. Kington and Aston (4) have pointed out that calorimetrically measured quantities can be interpreted without ambiguity in terms of the reversible thermodynamic properties of the system.

The heat capacity of the adsorbed phase can be measured directly and also can be derived from the temperature coefficient of the various heats of adsorption from the expressions

[4] $$(dQ_{N_s}/dT)_{N_s} = N_s(C_{PG} - C_{N_s})$$

and

[5] $$(dq_{st}/dT)_{N_s} = C_{PG} - \bar{C}_{N_s}.$$

In the preceding expressions, C_{PG} is the molar heat capacity of the gas, C_{N_s} is the molar heat capacity of the adsorbed gas, and $\bar{C}_{N_s}$ is the differential molar heat capacity.

Finally, the zero point entropy evaluated from heat capacity, heat of adsorption, and heat capacity measurements provides the most complete criterion for the reversibility of the adsorption process. The zero point entropy S_0 is calculated from

[6] $$S_0 = S_G(T, P_0) - \int_0^T (C_{N_s}/T)\, dT - Q_{N_s}(T)/T - R/N_s \int_0^{N_s} \ln P/P_0 dN_s$$

in which $S_G(T,P_0)$ is the molar entropy of the gas at temperature T and reference pressure P_0 and P is the equilibrium pressure of the adsorbate. A value of zero for S_0 would be a strong indication that the adsorption process was an equilibrium one. A non-zero value would have ramifications in terms of the configuration of the adsorbed phase, surface barriers, etc. Morrison and

co-workers (2, 5) have used this particular method very effectively in their study of the argon–rutile system.

In line with the preceding observations we are presenting the results of some calorimetric studies on (1) heats of adsorption and heat capacities of methane adsorbed on rutile between 80 and 140°K., (2) heats of adsorption of argon on rutile between 60 and 90°K., and (3) the entropy of krypton adsorbed on rutile at a coverage of about 0.57 of the monolayer capacity.

EXPERIMENTAL

The methane–rutile system was studied with a low temperature adiabatic calorimeter, the general features of which have been previously described (9). The adsorbate was Research Grade methane of 99.5% minimum purity obtained from the Phillips Petroleum Company. It was purified further by a one-step fractional distillation. The rutile was obtained from the National Lead Company. The monolayer capacity was 0.0311 moles of methane by the B.E.T. method.

The argon–rutile system was studied with a Nernst-Giauque type calorimeter. Some of the details concerning this calorimeter are to be found in the literature (7). The rutile sample, obtained from the National Lead Company, was from a different batch than for the preceding study. It was 94.3% titanium dioxide, the remainder being adsorbed or coordinately bound water. The monolayer capacity was 0.0541 moles of argon.

The entropy of the krypton–rutile system was determined with an adiabatic calorimeter which was almost identical with the one used for the methane–rutile study. The krypton was obtained from Matheson Company. The analysis supplied with the gas indicated a total impurity of 0.08 mole per cent. The rutile sample was taken from the same batch as that used in the argon–rutile system. Its monolayer capacity was 0.0283 moles of krypton.

The details involved in obtaining the calorimetric data on isotherms, heats of adsorption, and heat capacity, have been described adequately elsewhere (2, 5, 8, 9).

DISCUSSION

It has been pointed out that a certain internal consistency should exist between the heat capacity derived from the temperature coefficient of the integral heat of adsorption and the directly measured quantity if the adsorption is reversible. The heat capacity of methane adsorbed on rutile was measured at coverages of 0.00887, 0.01763, 0.02641, and 0.03463 moles of methane corresponding to the fractions 0.28, 0.56, 0.84, and 1.11 of the monolayer. Integral heats of adsorption were measured at 110, 120, 130, and 140°K. and the temperature coefficient used to evaluate values of c_{N_s}($c_{N_s} = N_s C_{N_s}$). The results are presented in Table I. The direct measurement of the heat capacity at some coverages was not extended to temperatures as high as those used for the integral heats. In these cases, the heat capacity curve was extrapolated for the purpose of comparing results. The heat capacities from the two sources agree well within the experimental error. Therefore, the adsorption

appears to be reversible for the methane–rutile system above 110°K. at all coverages.

The results of a study of the differential heats of adsorption of argon adsorbed on a rutile surface for coverages to a maximum of the order of a monolayer are summarized in Fig. 1. The measurements were carried out at temperatures of 63.5, 69.5, 73.0, 78.5, and 86.5°K. A warm thermal drift was encountered at 69.5°K. at low coverages which made the evaluation of the differential heat very uncertain. Therefore, the data at this temperature are not shown. The data at 73, 78.5, and 86.5°K. were used with directly measured heat capacities to reduce the results to a single curve at 63.5°K. The differential heats measured experimentally at 63.5°K. did not fall on the preceding curve, even though, unlike the measurements at 69.5°K., no prolonged thermal drift was observed within the limits of the sensitivity of the calorimeter (0.001 calorie per minute). The values which were obtained gave the two lower curves in Fig. 1. The path of adsorption in this case appears to depend on the size and the order of the increments of gas which are added. When the values of the differential heat at 63.5°K. are used with those at higher temperatures to determine an average value for the heat capacity of the adsorbed phase, the results are entirely unreasonable. Consequently, we conclude that the adsorption has taken place reversibly for the argon–rutile system only at temperatures above 73°K.

The results of a zero point entropy determination for a system consisting of 0.01627 moles ($\theta = 0.57$) of krypton adsorbed on rutile with a monolayer capacity of 0.0283 moles are presented in Table II. The value is 0.4 ± 1.0 cal. deg.$^{-1}$ mole^{-1}.

The precision in the value of the zero point entropy would allow one to draw two conclusions without a clear decision as to which is correct.

One conclusion is that the zero point entropy is zero at absolute zero for the adsorbed gas (assuming no surface perturbation) and hence, the adsorption process is reversible. This conclusion has been reached by Morrison and co-workers (2, 5) in their study of the argon–rutile system. The other conclusion is that the zero point entropy is a small, positive value. The appearance

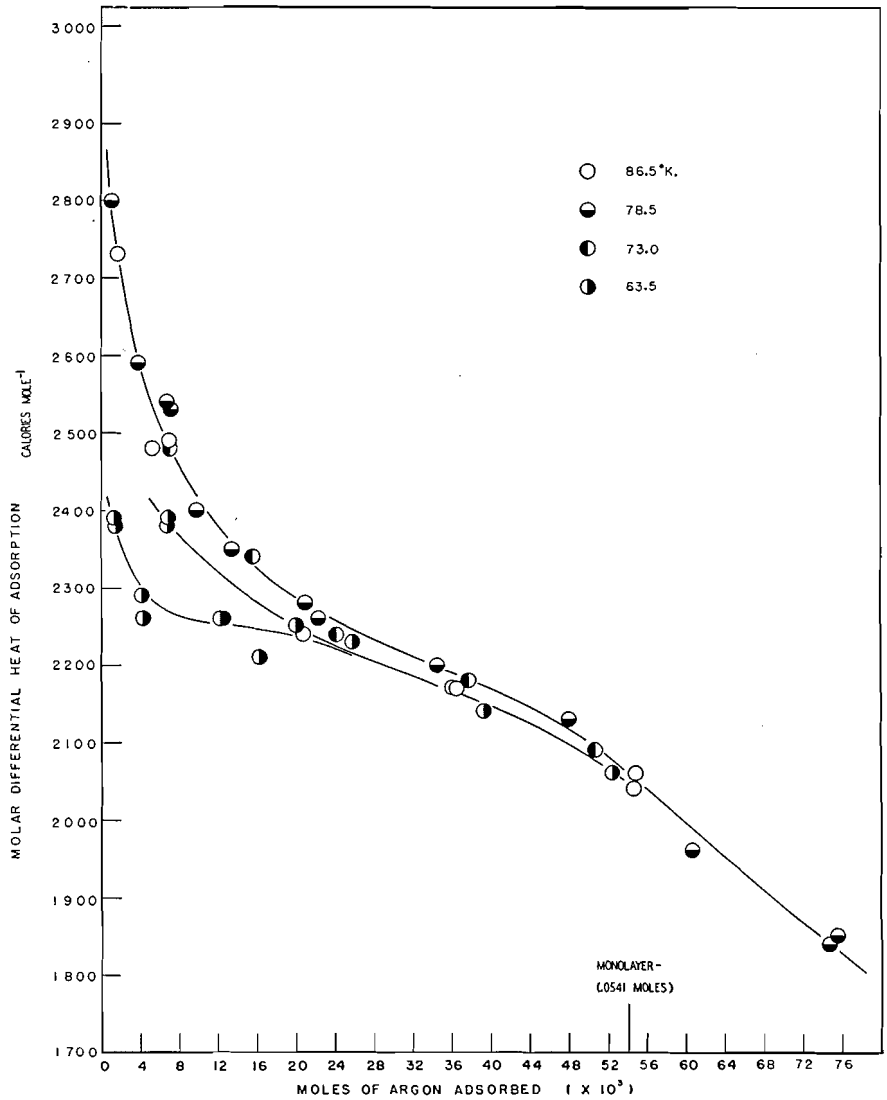

FIG. 1. Differential heat of adsorption of the argon–rutile system.

of such an entropy could arise from an appreciable number of molecules being present in a reasonably homogeneous but not completely filled group of sites at very low temperatures. The coverage which has been studied experimentally is a favorable one from this standpoint. At the lowest temperature of the heat capacity measurements, the group of sites at the peak of the distribution function, comprising about 10% of the total sites, is incompletely filled. Calculations of the type described by Hill (3) based on a unimolecular localized model show that this group of sites contributes a small configurational entropy (about 0.3 cal. deg.$^{-1}$ mole^{-1}) which is essentially temperature independent

between 10 and 125°K. The details concerning this calculation will be presented in a forthcoming publication (6) and so will not be discussed further here. Consequently, a zero point entropy of the order of that observed would result with a continuous energy distribution provided that the energy barriers in the surface are not surmounted by the adsorbed molecules within the experimental time of approximately 15 min. required for a heat capacity measurement. A rough calculation shows that, for energy barriers in the surface of the order of several hundred calories at the lowest experimental temperature, the time of passage over the barriers is of the same order as the time of the experiment. Without the "freezing in" of the adsorbed molecules, the observed zero point entropy could be accounted for by the existence of the distribution of energy among the sites, such that 10% of the sites is contained in a peak of width smaller than RT at the lowest experimental temperature. This possibility must also be considered in view of the fact that the rutile consists of acicular crystals in which 100 and 110 planes predominate.

INTERACTION ENERGIES OF ORGANIC MOLECULES WITH RUTILE AND GRAPHON SURFACES FROM HEATS OF IMMERSION[1]

By J. J. Chessick, A. C. Zettlemoyer, F. H. Healey, and G. J. Young

ABSTRACT

The heats of immersion of rutile in a series of short chain organic liquids are found experimentally to be an approximate linear function of the dipole moment of the wetting liquid. The significance of the relation is discussed in terms of the polar van der Waals force contribution which is primarily dependent on dipole moment. The average distance of approach of a dipole to the rutile surface and the effective surface force field extending from the rutile surface are calculated.

The net adsorption energy, which is calculated directly from heat of immersion data, is related to the energy contributions resulting from the various polar and nonpolar van der Waals forces active in the adsorption process: These energy contributions which make up the total adsorption energy are calculated for the interaction of an alcohol and a hydrocarbon with both a heteropolar (rutile) and a homopolar (Graphon) surface. On the basis of the results obtained, the effects of chain length and functionality of the liquids on the heat of immersion are discussed.

INTRODUCTION

The heats of immersion of rutile and Graphon in a variety of organic liquids were reported in a previous paper (3). In particular the heats of immersion found with rutile for a series of *n*-butyl derivatives were shown to be a linear function of the dipole moments of the wetting liquid. From the slope of the line the average electrostatic field strength of the rutile surface at the position of the dipole was calculated. From this value, the distance from the rutile surface to the dipole center could be estimated.

In the present paper the heat of immersion measurements are extended to include organic liquids with a wider range of dipole moment. From the estimated field strength the approximate contributions of the various van der Waals forces to the total interaction energy are calculated. In addition, the similarities in the heats of wetting of several heteropolar solids in a variety of liquids relative to their respective heats of wetting in water are considered.

EXPERIMENTAL

Apparatus

The calorimeter, associated equipment, and general techniques were the same as those previously reported (3, 9). Special attention was given to the drying of the liquids and the interior of the calorimeter as well as to maintaining anhydrous conditions during the course of each run.

Solids

The titanium dioxide (rutile), du Pont Ti-pure R-300, Lot 5550, was activated at 400°C. and 1×10^{-5} mm. pressure for two hours before the samples

[1]*Manuscript received September 16, 1954.*
Contribution from Chemistry Department, Lehigh University, Bethlehem, Pa. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

were sealed off for heat of immersion determinations. The surface area as measured by the conventional B.E.T. method from nitrogen adsorption data was 7.3 square meters per gram.

The Graphon, Lot No. L-2808, supplied by the Godfrey L. Cabot Company, had a surface area of 95 square meters per gram. The activation of the Graphon samples was carried out at 25° and 1×10^{-5} mm. pressure for 24 hr. More rigorous activation conditions for the Graphon did not influence the heat of immersion values appreciably (8).

Liquids

The properties and purification of most of the wetting liquids have been reported (3). The three new wetting liquids, *n*-butyl iodide (b.p. 129–131°), *n*-butyraldehyde (b.p. 73–75°), and 1-nitropropane (pract.) were stored and fractionally distilled over anhydrous magnesium sulphate before use.

RESULTS AND DISCUSSION

Heats of immersion of rutile and Graphon in a variety of organic liquids are given in Table I. Many of these values have been reported in a previous paper (3) where it was pointed out that the heat of immersion of rutile in a series of straight chain compounds was a linear function of the dipole moment of the wetting liquid. Heat data for the additional liquids shown in Table I fall close to the same line presented previously (3).

Octane	−140±5	−127±0

In systems which wet spontaneously (no contact angle) nearly the entire heat effect on immersion of the clean solid surface is due to the adsorption of

molecules in the first layer. Experimental proof comes from the fact that the heat of immersion per unit area of solid having a preadsorbed monolayer of the wetting liquid is usually very close to the value obtained on immersing a unit area of the liquid surface, h_L. A good approximation of the heat effect due to the adsorption of a monolayer is therefore given by $(h_{I(SL)}-h_L)$, where $h_{I(SL)}$ is the heat of immersion of the clean solid surface. This heat effect is directly related (5) to the net energy of adsorption, (E_A-E_L), by the equation

$$h_{I(SL)}-h_L = +N_A(E_A-E_L). \quad [1]$$

In this case (E_A-E_L) is the net integral energy of adsorption for a molecule in the monolayer and N_A is the number of molecules adsorbed per cm.^{2} in the monolayer. The net energy of adsorption thus represents the energy involved in removing a molecule from the bulk liquid and adsorbing it onto the surface. If it is assumed that interactions between molecules in the liquid are the same as in the adsorbed state, it follows that (E_A-E_L) represents only the interaction between the surface and an adsorbed molecule and does not include interactions between adsorbed molecules and themselves.

The total interaction energy between adsorbed polar molecules and a heteropolar surface consists of four principal parts: E_W, the nonpolar van der Waals contribution; E_α, the contribution due to the polarization of the adsorbate by the surface; E_μ, the contribution arising from the interaction between a permanent peripheral dipole in the adsorbate and the electrostatic field of the dielectric surface; and $E_{\text{int.}}$, the contribution arising from interaction between adsorbed molecules, thus:

$$E_A-E_G = E_w+E_\mu+E_\alpha+E_{\text{int.}}. \quad [2]$$

With the assumption that the interactions in the adsorbed state are the same as in the liquid state, then

$$E_{\text{int.}} = E_L-E_G \quad [3]$$

and

$$E_A-E_L = E_w+E_\mu+E_\alpha. \quad [4]$$

The various expressions developed for these energies are summarized by de Boer (1). The most useful forms of these equations for the purpose of this paper are

$$E_\alpha = \frac{-F^2\alpha_1}{2} \quad [5]$$

$$E_w = \frac{N_v}{4r^3}\alpha_1\alpha_2\frac{I_1I_2}{I_1+I_2} \quad [6]$$

$$E_\mu = -F\mu. \quad [7]$$

In these equations α_1 and α_2 are the polarizabilities of the adsorbate and adsorbent respectively, I_1 and I_2 the corresponding ionization energies, N_v the number of atoms of the dielectric per cm.^{3}, r_0 the nearest surface ion, μ the dipole moment, d the distance of charge separation in the dipole, and F is the average electrostatic force field of the surface.

The net energy of adsorption for a monolayer, $N_A(E_A - E_L)$ is plotted in Fig. 1 as a function of the dipole moment for a number of straight chain compounds on rutile. The $N_A(E_A - E_L)$ values were calculated from the heat of

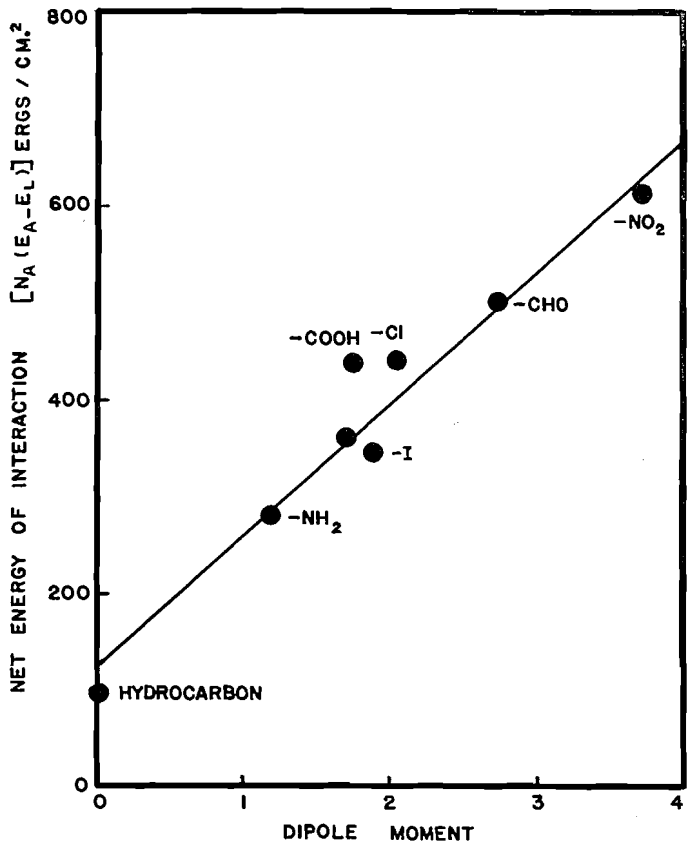

FIG. 1. Net interaction energy as a function of dipole moment of various polar molecules on rutile.

immersion data in Table I and a knowledge of h_L using equation [1]. The dipole moments are those of Smyth (7). If it is assumed that the differences in the total adsorption energy arise primarily from E_μ, then, according to equation [7], the slope of the line in Fig. 1 is a measure of the average electrostatic field strength of the rutile surface immersed in the liquids. Exact agreement of the heat data for all the liquids studied would be expected if the polarizabilities, cross-sectional areas, and distance from dipole to surface were the same. Since polar molecules at monolayer coverage no doubt have the polar end directed toward the rutile surface, these properties of the molecules probably do not differ markedly. The average effective field strength of the rutile surface was calculated to be 2.72×10^5 e.s.u.

The contributions of the various interaction energies to the net adsorption energies for hexane and *n*-butyl alcohol on the heteropolar surface, rutile, and the homopolar surface, Graphon, are given in Table II. Since Graphon has no

electrostatic surface field, E_μ and E_α are both zero and the total adsorption energy is due primarily to dispersion forces alone. Any "image" force between the alcohol and Graphon must be negligible since the heats of wetting of Graphon were found to be independent of the dipole moment of the liquid. The values of E_w for the Graphon systems were taken to be equal to the net adsorption energy $N_A(E_A - E_L)$ and were not calculated because of both the approximate nature of the equation and the lack of reliable values for the physical constants of the surface atoms.

TABLE II

CONTRIBUTION OF VARIOUS VAN DER WAALS' FORCES TO THE ADSORPTION ENERGY

System	Interaction energies (ergs/cm.^{2})		
	E_w	E_α	E_μ
Hydrocarbon on rutile	62	30	0
Hydrocarbon on Graphon	67	0	0
Alcohol on rutile	94	21	246
Alcohol on Graphon	66	0	0

The values of E_α and E_μ for alcohol on rutile were directly calculable from equations [5] and [7] respectively from the knowledge of the field strength. The polarizabilities of the OH and CH_2 groups were calculated from molar refraction data. The alcohol was assumed to be oriented perpendicularly to the surface at monolayer coverage. Calculation of the contribution to E_α due to the polarizability of the nearest CH_2 group showed this contribution to be negligible ($\sim$0.01 ergs/cm.^{2}) since the distance of approach of this group from the surface is prohibitively large (*ca.* 3.5 Å). The value of E_w was obtained here and in the case of the hydrocarbon on rutile by subtracting $E_\mu + E_\alpha$ from the net adsorption energy. The value of E_w calculated for alcohol on rutile by equation [6] agrees in magnitude with the value already obtained, but the approximate nature of the equation and the lack of knowledge of the physical constants of the surface atoms permit only an order of magnitude to be calculated.

For the hydrocarbon on rutile, an average distance of approach of 2.3 Å was estimated from considerations of bond distances and the geometry of the hydrocarbon molecule assuming a horizontal orientation. To calculate E_α from equation [5] the field strength corresponding to this distance was estimated from the exponential function of Hückel discussed in a later section. The calculation was made for the contribution for each CH_2 or CH_3 group since the number of carbon atoms in a monolayer is approximately the same for each of the hydrocarbons irrespective of the orientation of these molecules. For this reason also, E_α will be about the same for any of the hydrocarbons regardless of chain length.

For all the systems listed in Table II with the exception of alcohol–rutile, the contribution of the dispersion force is very nearly the same. Apparently the OH groups of the alcohol interact more strongly than the CH_2 or CH_3 groups of the hydrocarbon owing, primarily, to the closer average distance of approach of the OH group to the surface. It is important to note that the *direct* influence

of the surface is negligible for the second layer in these calculations because of the large distance of second layer molecules from the surface, and thus the use of the term $(h_{I(SL)}-h_L)$ to approximate the heat of adsorption in the first layer appears to be justified.

Variation of Field Strength with Distance of Approach

An equation for the field strength above an ion in a solid composed of singly charged ions has been given by Hückel (4) as

$$F = \frac{8\pi\epsilon}{r_c^2} \exp\left(-\pi\sqrt{2}\frac{r_0}{r_c}\right)$$

where ϵ is the electronic charge, r_c is the closest interionic spacing in the crystal, and r_0 is the distance from the center of a surface ion. The slope of Fig. 1 gave an independent measure of the field strength which was substituted in Hückel's equation to determine whether a reasonable value of r_0 would result even though adsorption did not necessarily occur above an ion site and the crystal was made up of doubly charged ions. Using a value of 1.96 Å for the r_c distance in rutile (6) the value of r_0 was calculated to be 2.08 Å. Estimates of the distance from the center of the alcohol dipole to the center of the surface oxide ions range from 2.06 to 2.37 Å depending on the assumed orientation.

If the exponential term in Hückel's equation is used to obtain the variation of the field with distance from the surface, it is found the field strength is negligible at the distance (*ca.* 3.5 Å) of the first CH_2 group of an alcohol molecule oriented perpendicular to the surface. Thus there is essentially no contribution to E_α from the carbon chain.

A consideration of the factors in the equation for the various contributing energies emphasizes the dominant role of the OH group for adsorption of an alcohol on rutile. The hydrocarbon portion of the molecule is too far from the surface to have any significant influence on the interaction energy. Thus, it would be reasonable to expect that chain length would have a negligible effect on the heat of immersion or net adsorption energy. This is indeed the case; the lower alcohols have essentially the same heat of immersion values as *n*-amyl alcohol. The same result, of course, would be expected with other relatively short-chain polar homologues. Similarly, for hydrocarbons on a polar or nonpolar surface, the CH_2 and CH_3 groups contribute in an approximately equal manner to the total adsorption energy. Regardless of orientation, the number of these groups is very nearly the same and here too, as was found experimentally, the heats of immersion would be expected to be independent of chain length.

Relative Heats of Immersion

It was pointed out in the previous paper (3) that rutile and barium sulphate had identical relative heats of immersion in water and in alcohol even though the actual values for the two solids were widely different. Harkins (2) had also

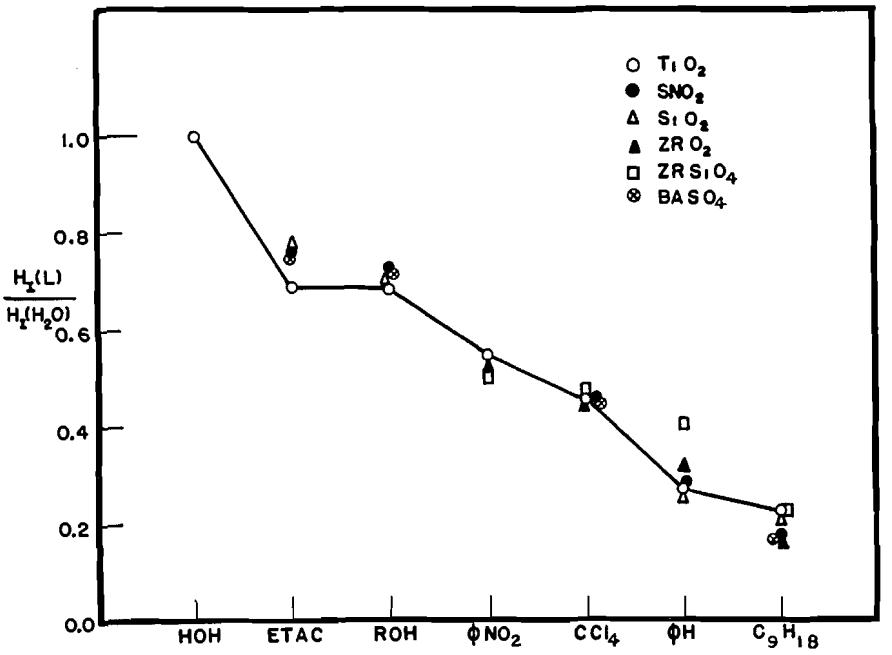

FIG. 2. Relative heats of immersion of several hydrophilic solids in various organic liquids.

noted this similarity in the relative heat of immersion values for a number of different solids and liquids. Fig. 2 shows a plot of the heats of immersion of various solids in liquids relative to their heats of immersion in water. The line was drawn through the values for titanium oxide, and the close agreement for the group of solids indicates that their relative interactions with the different liquids is the same. All of the solids are heteropolar and hydrophilic, and probably all present primarily an outer surface of oxygen ions. The similar behavior is, however, still surprising since such properties as polarizability, characteristic energies, and field strength all vary. A further study of the influence of crystal parameters on the various interaction forces is being undertaken to attempt to explain the differences in the absolute heats of wetting of the different solids.

The relative heats of wetting given in Fig. 2 show only a general correlation with dipole moment since the cross-sectional areas of the molecules are not the same and therefore the surface concentration of dipoles per square centimeter varies; also the polarizabilities are different. Thus nitrobenzene, with a very high dipole moment, has a relatively low heat of wetting indicating that the benzene ring is blocking off a considerable portion of the surface.

Because of the similarity in relative heats of wetting the results obtained with one solid should be applicable to all solids of the same type. Therefore, once heats of immersion of a reference solid in a series of liquids have been measured only one heat of immersion value for a new solid of the same type need be obtained in order to predict the values in the other liquids.

THERMODYNAMIC PROPERTIES OF HYDROCARBONS ADSORBED ON RUTILE II[1]

By H. P. Schreiber[2] and R. McIntosh[3]

ABSTRACT

Integral molar heats and entropies of adsorbed methane and propane on rutile have been computed from data of isotherms at 103.2° and 110.2°K. for methane and 166.3° and 224.6°K. for propane. Some resemblance has been found between these functions and those for argon, nitrogen, and oxygen adsorbed on rutile, reported by Drain and Morrison. The integral molar entropy of adsorption made possible a test of the model of a localized film without interactions on a heterogeneous substrate. The model was found to be a reasonable representation of the state of adsorbed methane up to about 0.5 of the monolayer and of propane up to about 0.3 of the monolayer. A unique heat of adsorption curve for the adsorption of methane, ethane, propane, and *n*-butane has been derived and its significance is briefly discussed. The curve has been employed to derive functions for the distribution of energies among the adsorption sites of the substrate.

INTRODUCTION

In a recent publication, hereafter referred to as I (8), the differential molar thermodynamic functions of methane, ethane, propane, and *n*-butane adsorbed on rutile were presented. These functions were computed from adsorption isotherms determined in a manner especially developed to provide accurate thermodynamic data. The results were of comparable accuracy with similar data obtained by calorimetry (7). It was therefore decided to attempt a calculation of the integral thermodynamic functions of the adsorbates, and to utilize them in combination with a simple model of a localized film in the manner developed by Drain and Morrison (1). Only the data for methane and propane were sufficiently detailed to make the additional calculations feasible, and the discussion is largely limited to these two systems.

The value of the integral thermodynamic functions has been amply stressed by Hill (4). A more significant description of the state of the adsorbed phase may be obtained from them, and the values of the integral molar entropy permit comparison with assumed models, the properties of which are computed by statistical methods. In this paper the integral heats and entropies of adsorption of methane and propane are presented and discussed.

RESULTS AND DISCUSSION

Thermodynamic Analysis

The integral molar thermodynamic functions of the adsorption process are obtained when the spreading force, ϕ, of the film is chosen as one of the independent variables describing the adsorbed phase. In order to evaluate these functions, ϕ must be known accurately over wide ranges of surface concentra-

tion. The values of ϕA were obtained according to the methods described by Hill, Emmett, and Joyner (6). The required equation is

$$[1] \qquad \phi A = R\,T \int \frac{V}{p}\,d\,p$$

where V is the volume of gas adsorbed per gm.,
p is the equilibrium pressure,
A is the surface area per gm. considered independent of T, and R and T have their usual significance.

In regions of higher equilibrium pressures the integration was performed graphically. In the low pressure region the isotherms could be represented analytically by the equation

$$[2] \qquad V = a\,p + b\,p^{\frac{1}{2}}$$

where a and b are constants, and the integration was performed using this relation. Values of ϕA were obtained at 103.2, 118.2, and 133.2°K. for methane, and at 166.3, 183.4, 197.6, and 224.6°K. for propane. The integral molar heats of adsorption were obtained from

$$[3] \qquad (H_g - H_s)_\phi = \frac{R \ln(p_2 - p_1)_\phi}{1/T_1 - 1/T_2}$$

and the integral molar entropies of adsorption from

$$[4] \qquad H_g - H_s + R\,T \ln p/p^\circ = T(S_g - S_s).$$

The subscripts g and s refer to the gas and the adsorbed phase, respectively. In several instances the integral heat of adsorption was evaluated from

$$[5] \qquad H_s - H_g = q_{st} - \frac{T}{\Gamma}\left(\frac{\partial \phi}{\partial \Gamma}\right)_T$$

where q_{st} is the isosteric heat of adsorption and Γ equals V/A. This serves as a check upon the correctness of the ϕ values (6). In all cases the value of $H_s - H_g$ so obtained agreed to within 150 cal. mole^{-1} with the values obtained from equation [4]. The rather large uncertainty is due to the fact that the errors in determining q_{st} and ϕ are combined here. It can be concluded, however, that the ϕ values are free from gross errors. In general, the integral thermodynamic functions are less well defined than their differential counterparts. This is because the correlation of the correct equilibrium pressure with some particular value of ϕ is less certain than the correlation of the equilibrium pressure at some particular value of the volume adsorbed. This is especially true at low equilibrium pressures. Thus the error in the integral heats of adsorption is $\pm$ 100 cal. mole^{-1} and in the integral molar entropies 1.0 cal. mole^{-1} degree^{-1}.

In order to make the entropy relationships easier to interpret, the integral and differential molar entropies of the adsorbed molecules themselves were evaluated and recorded herein. The entropy of the gas phase, necessary for this evaluation, was obtained by making appropriate corrections for the

pressure to the entropy in the standard state, taken as 1 atmosphere pressure and the temperature in question. The entropy in the standard state was taken from the literature (9).

Methane

The integral heat of adsorption of methane at 110.2°K. is shown in Fig. 1A as a function of θ. For comparison, the corresponding isosteric heat curve is also represented. The two curves show an expected similarity. The integral heat values did not vary with temperature in the range 103.2 to 133.2°K. The shape of the heat curves is that generally considered to be characteristic of physical adsorption on a heterogeneous substrate.

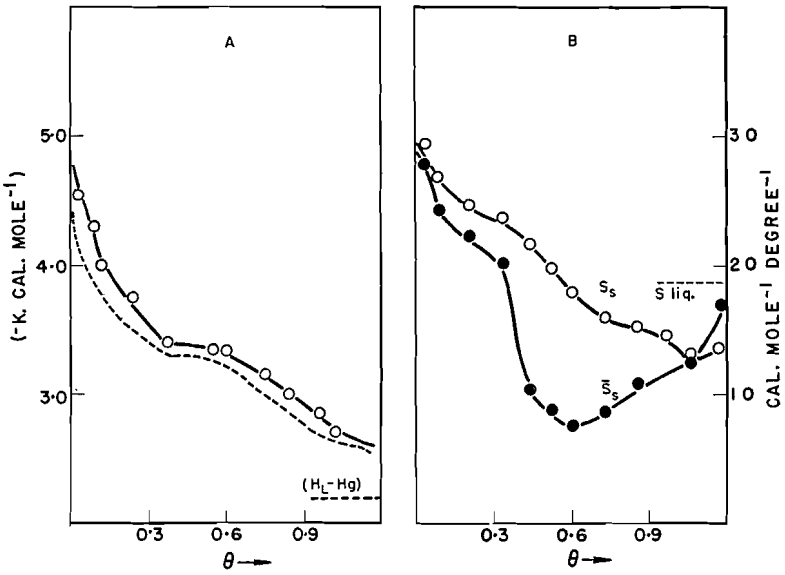

FIG. 1. A. Integral (—) and isosteric (— — —) heat of adsorption of methane on rutile at 110.2°K.

B. Integral molar (S_s) and differential molar ($\bar{S}_s$) entropy of methane adsorbed on rutile at 103.2°K.

The integral and differential molar entropies of methane adsorbed at 103.2°K. are shown in Fig. 1B. At first, both S_s and $\bar{S}_s$ decrease continuously with surface coverage, but the curve of the integral entropy exhibits a shallow minimum in the vicinity of $\theta = 1.0$. A deeper minimum occurs in the plot of $\bar{S}_s$ near $\theta = 0.6$. Both S_s and $\bar{S}_s$ are initially greater than the entropy of bulk liquid, but approach that value at high surface concentrations. The general shape of the curves is that which has been derived by Hill, Emmett, and Joyner(6) on the basis of the B.E.T. model for high values of the constant C. In this case the value of C was approximately 85. The results are similar to those reported by Drain and Morrison (1) for argon on rutile. Thus the initial decrease in the entropy may be interpreted as being caused by restrictions in the configuration of the adsorbate as the number of sites available for adsorption decreases. The increasing values of S_s beyond $\theta = 1$ is then due to the formation of multilayers.

Propane

The integral molar heats of adsorption for propane at average temperatures 174.8 and 210.3°K. are shown in Fig. 2, along with the corresponding isosteric heats of adsorption. It was pointed out in I that the shape of the isosteric heat curve might suggest a phase change in the adsorbed film at 185°K. This is again suggested by the integral heat of adsorption curve.

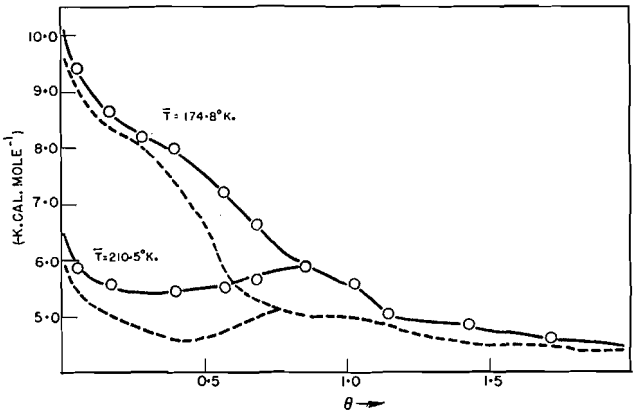

FIG. 2. Integral (—) and isosteric (— — —) heat of adsorption of propane on rutile.

Below 185°K. the integral heat of adsorption curve is of similar shape to that for methane, but at higher temperatures the plots are distinctly different. The junction of the two branches of the plot occurs near 0.8 θ instead of 0.6 θ as indicated by the plot of the isosteric heat of adsorption.

It was suggested in I, on the basis of the plots of $\bar{S}_s - S_g$ at 183.9 and 197.6°K., that the adsorption of propane differed from the adsorption of

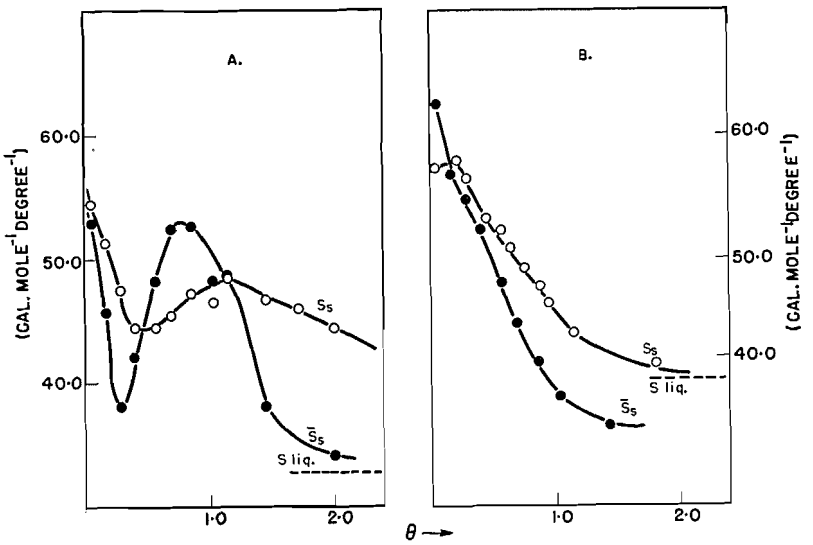

FIG. 3. A. Integral molar (S_s) and differential molar ($\bar{S}_s$) entropy of propane adsorbed on rutile at 166.3°K.
B. At 224.6°K.

methane and ethane. This view may be more closely examined with the aid of Figs. 3A and 3B, in which both S_s and $\bar{S}_s$ for propane are plotted at 166.3 and 224.6°K., respectively. It is evident from Fig. 3A that the curves of S_s and $\bar{S}_s$ for propane at the lower temperature are similar to the curves for methane. On the other hand, both S_s and $\bar{S}_s$ at 224.6°K. vary with θ in an entirely different manner. This fact again suggests a change in the physical state of adsorbed propane near 185°K. Unfortunately, the entropy values are dependent upon the heats of adsorption, and so cannot provide independent evidence of the validity of the postulated phase change.

While the entropy curves for propane at 166.3°K. are of the same general shape as those shown in Fig. 1B, some differences should be noted. The minimum value of S_s occurs near 0.4 θ, rather than near the monolayer. A comparable finding has been reported by Drain and Morrison (2) in the cases of oxygen and nitrogen adsorbed on rutile. It is difficult to interpret these differences in the entropy relationships. Contributions to the entropy from internal degrees of freedom of the adsorbed molecules as well as molecular interactions no doubt influence the shape of the curve.

Test of Localized Film Model

The values of the integral molar entropy permit a more detailed examination of the systems along lines developed by Drain and Morrison (1, 2). These authors showed that the assumption of a localized film upon a heterogeneous substrate led to theoretical values of S_s which agreed well with the experimentally measured values up to a surface coverage of 0.6 θ in the case of argon. The model was also successful in accounting for the behavior of oxygen and nitrogen, although the diatomic molecules offered a much more complex problem for treatment.

In the present case no detailed statistical treatment has been carried through. In the first place, the accuracy of the S_s values suffices only for semi-quantitative interpretation. Secondly, the increased complexity of the molecules makes the statistical problem virtually intractable. Finally, the problem of surface heterogeneity can only be satisfactorily resolved if isosteric heat of adsorption data can be derived for 0°K. Therefore heat capacity data are necessary, which will permit reduction of the q_{st} to 0°K. These data were not available.

In view of these limitations, it has been assumed that methane, adsorbed at 103.2°K., and propane, adsorbed at 166.3°K., form localized films. To reduce difficulties in interpretation, discussion is essentially limited to surface coverages well below the monolayer, where molecular interactions can be neglected. The postulate of the existence of a heterogeneous substrate may be supported by the usual arguments (1, 11). The assumed presence of localized films may also be justified. If the temperature region in which some degree of localization is considered to persist is taken as

$$\frac{\Delta U}{10R} < T < \frac{\Delta U}{R} \quad (3,11)$$

where ΔU is the energy barrier between neighboring sites, and if ΔU is

considered to be considerably less than 50% of the net heat of adsorption, the films of methane and propane may be considered as localized films. At 0.3 θ, for example, the net heat of adsorption of methane is 1300 cal. mole^{-1} and 3600 cal. mole^{-1} for propane. Hence, taking values of ΔU between 200 and 500 cal. mole^{-1} for methane, and between 500 and 1000 cal. mole^{-1} for propane, the assumption of localized films at the designated temperatures appears justified.

On the basis of the assumed model it becomes meaningful to split the molar entropy of the adsorbate into configurational and non-configurational parts according to the equation

[6] $$S_s = S_c + S_{nc}.$$

Both S_c and S_{nc} may be calculated from theory and Hill (5) has given the necessary formulae. The computations involve a knowledge of a distribution function for the energies of the sites of the heterogeneous surface, of the temperature dependence of the partition function of the adsorbate, and of the dependence of the partition function on the energy ϵ, of the adsorption site. Owing to the complexity of the methane and propane systems, S_c has been calculated by the use of the approximate equation due to Drain andMorrison (1)

[7] $$S_c = (\pi^2/3)\, R\, (d \ln V/d \ln p)$$

which is valid for energy distributions that are wide compared with RT. S_{nc} was then evaluated by means of equation [6]. The behavior of the quantities so calculated is the sole criterion of the applicability of the chosen model. On the basis of the findings of Drain and Morrison (1, 2) it would seem that for simple molecules, the variation of S_s with θ should initially be determined largely by configurational effects. Furthermore, at a given temperature and over the initial range of surface coverage, the dependence of S_{nc} on surface coverage should be determined largely by the variation of the vibrational frequency ν of the adsorbed molecules with the site energy ϵ. If $\nu \alpha \epsilon^n$ where n

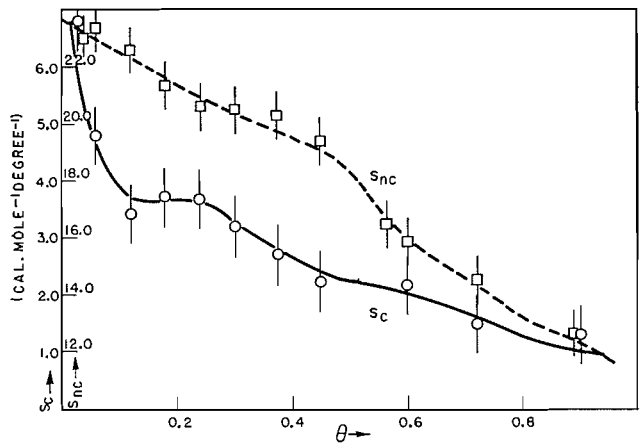

FIG. 4. Configurational molar (S_c) and non-configurational molar (S_{nc}) entropy of methane adsorbed on rutile at 103.2°K.

is of the order of unity, as suggested by Drain and Morrison, S_{nc} may be expected to vary only slightly with θ.

Methane

The configurational and non-configurational entropies of adsorbed methane are shown as functions of θ in Fig. 4. Comparison of Fig. 4 with Fig. 1B shows that the S_c curve for methane resembles the curve for S_s up to 0.5 θ. Moreover, the greater part of the variation of S_s with θ is accounted for by the change of S_c in this range of surface coverage. Beyond 0.5 θ the S_s and S_c plots begin to diverge and S_{nc} varies rapidly with θ. In this region, molecular interactions should become significant and the postulated model no longer is suitable. Therefore the model of a localized film without interaction on a heterogeneous surface seems an acceptable representation of the state of the adsorbed methane up to 0.5 θ.

Propane

The values of S_c and S_{nc} for adsorbed propane are represented in Fig. 5. Comparison with Fig. 3A again reveals that there is some resemblance in the

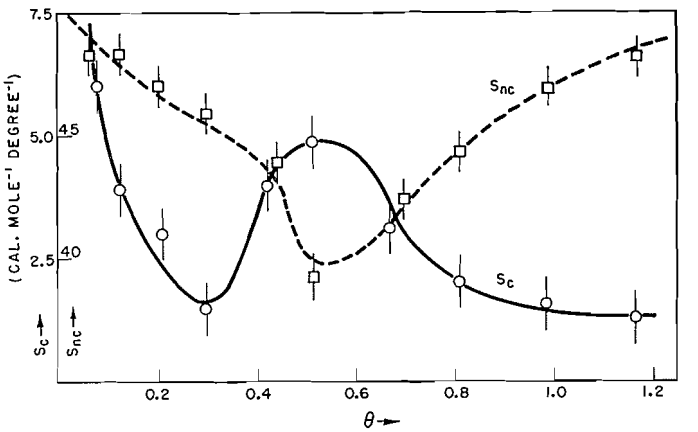

FIG. 5. Configurational molar (S_c) and non-configurational molar (S_{nc}) entropy of propane adsorbed on rutile at 166.3°K.

behavior of S_s and S_c up to about 0.3 θ. However, the variation of S_{nc} is greater than in the case of methane. This is not surprising, in view of the fact that Drain and Morrison found that even for nitrogen and oxygen the complications caused by added rotational and vibrational degrees of freedom were of importance. It should also be noted that S_{nc} for propane, unlike that for methane, has a minimum value near 0.5 θ and then increases rapidly. Thus, up to 0.5 of the monolayer the variations of the S_{nc} functions of the two adsorbates are similar, and the increasing rate of change between 0.4 and 0.5 θ may be due, as has been suggested in the case of methane, to interactions. The rapid increase of S_{nc} in the case of propane beyond this region indicates failure of the model from other causes.

The Surface Heterogeneity of the Rutile Adsorbent

The effects of surface heterogeneity can be taken into account quantitatively in a model describing physical adsorption. Specifically, Sips has shown (10) that a function giving the distribution of energies among adsorption sites can always be obtained from a given isotherm. Drain and Morrison have evaluated such distribution functions (2) and, using them, have carried out successful statistical analyses for nitrogen, oxygen, and argon adsorbed on rutile. They found that up to monolayer capacity, the various isosteric heats of adsorption were linear functions of each other, so that a unique heat of adsorption function could be reduced to 0°K. Since the distribution function of the energies

B. Distribution of energies among the adsorption sites for methane and propane adsorbed on rutile. Broken line extrapolations are normalizing factors giving areas under the curves equal to the respective monolayer capacities.

of the adsorption sites is derived from the isosteric heat of adsorption curve, it also followed that the distribution functions had the same shape, although the range of energies varied with each adsorbate. They interpreted these findings as meaning that the same sites were involved in the adsorption of all three gases, but that the forces of interaction varied.

The same treatment has been followed in this study involving the four saturated hydrocarbons. Owing to the lack of heat capacity data, it was not possible to correct the isosteric heat of adsorption curves to the absolute zero as Drain and Morrison were able to do. The data for each vapor were compared at the common reduced temperature $T/T_c = 0.53$. This temperature corresponded to the temperature of the lowest isotherm in each case and also the temperature at which the relative value of ΔU and $R\,T$ was about equal. Again it was found possible to construct a unique isosteric heat of adsorption curve for the four hydrocarbons up to nearly the monolayer capacity. The curve is represented in Fig. 6A. Only certain values for ethane between 0.3 θ and 0.6 θ depart appreciably from the curve.

The unique heat of adsorption curve leads to a family of distribution curves of the same shape but of widths in the ratios 1:2.5: 4:15.4, if the width of the methane curve is taken as unity. Two of these curves, those for methane and propane, are shown in Fig. 6B.

An interpretation of the existence of a unique heat of adsorption curve along the lines given in the case of the simpler molecules by Drain and Morrison is not ruled out. However, in the present case this interpretation tends to lose its simplicity because, for example, it is difficult to imagine that a "site" for the adsorption of methane should also serve as a "site" for the adsorption of butane. If the existence of common isosteric heat curves is established for other series of complex molecules, the significance of curves such as that in Fig. 6A should be reconsidered.

AN APPARATUS FOR THE MEASUREMENT OF DIELECTRIC CONSTANTS OF ADSORBED GASES AT FREQUENCIES UP TO 100 Mc./sec.[1]

By M. H. Waldman[2] and R. McIntosh[3]

ABSTRACT

The design of an apparatus suitable for the measurement of dielectric constants at frequencies up to 106 Mc./sec. is shown. The apparatus was used to measure changes in capacitance with volume adsorbed for the system sulphur dioxide – rutile at about 3.5°C. and for frequencies of 13, 36, and 106 Mc./sec. The results failed to reveal any dispersion due to the adsorbed matter in this frequency range. The dielectric behavior observed is the same, within experimental error of a few per cent, as that found by Channen and McIntosh for the same system at 3.7 Mc./sec.

INTRODUCTION

From the work of Snelgrove, Greenspan, and McIntosh (6) and Waldman, Snelgrove, and McIntosh (7), who measured dielectric constants of gases on silica gel and rutile at radio frequencies, it became evident that it would be desirable to investigate these dielectric constants at much higher frequencies. The reasons for making high frequency measurements were:

(1) The method of calculating the dielectric constants from the primary data involved the knowledge of the density of the adsorbed matter. If the frequency of the applied field were made so high that the adsorbed dipole could no longer follow the changes in the field, then the adsorbate would act as nonpolar material and the densities could be determined by applications of laws for nonpolar dielectrics. The determined density could then be used in the low frequency calculations.

(2) It would be of interest to see whether the Debye dispersion range (2) of the adsorbed matter would correspond to the dispersion range, in magnitude and position in the frequency spectrum, of the bulk liquid, or whether the dispersion phenomena characteristic of a rotational oscillator would be observed.

Although the frequency at which dispersion would be found was unknown, the design and construction of a cell that would allow reliable measurement of dielectric constants at high frequencies up to about 100 Mc./sec. was attempted. Previous to this, cells were used which consisted of three co-axial cylinders with the center cylinder at high potential while the other two were grounded. The space between the cylinders was packed with the solid dielectric. The change in capacity in this test cell due to adsorption of gas on the solid was

[1]*Manuscript received September 16, 1954.*

[3]*Professor of Chemistry.*

measured by adjusting a precision condenser connected in parallel with the test cell.

This method was quite suitable for the radio frequencies used, but the corrections to be applied for the lead connections between the two condensers became excessive for frequencies higher than about four megacycles/second.

It became clear, then, that the main requirement was to construct a cell with the shortest possible leads between the test cell and the measuring condenser so that lead corrections would be negligible. A modification of an apparatus due to Hartshorn and Ward (4) was used. In principle, these authors made the measuring condenser part of the test cell. In the present case, a very slight modification of the original test cell accomplished the same result. The innermost cylinder was made movable so that by raising or lowering this cylinder the capacity of the whole condenser was increased or decreased. The powder, of course, was packed only in the space between the two outermost cylinders. The changes in capacitance due to the movement of the innermost cylinder merely had to be calibrated against a standard condenser at low frequencies. Since the dielectric in the space between this cylinder and the next larger one was Teflon, its capacity would not alter with frequency.

The Principle of the Hartshorn and Ward Method

To grasp the principle of operation, consider an ideal circuit as envisaged by Hartshorn and Ward (4). Schematically, this may be shown as in Fig. 1.

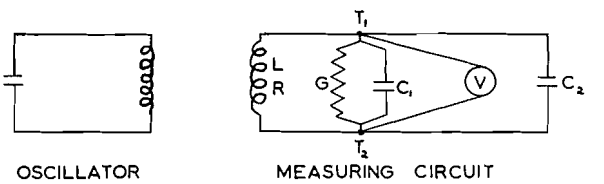

FIG. 1.

The only voltages considered are those between T_1 and T_2 which are common to all the components of the measuring circuit. C_1 is the test condenser containing the sample, and C_2 is the measuring condenser which is used to compensate for changes in capacity in C_1 and also to obtain the resonance curves.

Current considerations in the above circuit lead to an expression for C in terms of C_r, the resonance capacity, G, the conductance across the cell, and q, the square of the ratio of the voltage at resonance to the voltage at the particular capacity measured, as follows

$$[a] \qquad C = C_r \pm \frac{G\sqrt{(q-1)}}{\omega}$$

where ω is the frequency, in radians per second, of the circulating current Assuming G does not change, this expression shows that the resonance curve should be symmetrical about C_r as shown below.

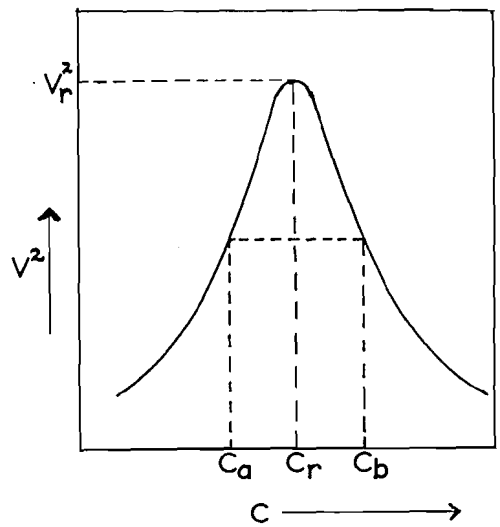

FIG. 2.

Thus, if one measures two values of C, C_a and C_b, for the same value of V^2 (or q) the resonance capacity may be calculated by

[b] $$C_r = \tfrac{1}{2}(C_a + C_b),$$

while the conductance of the system is given by

[c] $$G = \frac{(C_a - C_b)}{2\sqrt{(q-1)}}.$$

The above considerations are for an ideal circuit where the leads have zero impedance. In practice, the leads to the various components never have zero impedance. As Hartshorn and Ward have pointed out, the only quantities which require further consideration are the resistance and inductance in the leads to C_1 and C_2. The residual resistance and inductance are designated as R' and L'.

Taking R' and L' into consideration, it may be shown that the combination is equivalent to a capacitance C_p in parallel with a conductance G_p where C_p and G_p are given, after certain reasonable approximations, by

[d] $$C_p = C_t\,(1 + L'C_t\omega^2 - R'^2C_t^2\omega^2)$$

and

[e] $$G_p = G_t\,(1 - 2L'C_t\omega^2 - R'^2C_t^2\omega^2) + R'C_t^2\omega^2.$$

If both L' and R' are not very small [d] should be written

[f] $$C_p = \frac{C_t(1 - L'C_t\omega^2)}{(1 - L'C_t\omega^2)^2 + R'^2C_t^2\omega^2}.$$

If R' is found to be negligibly small but L' quite large, then [f] may be written

[g] $$C_p = \frac{C_t}{1 - L'C_t\omega^2};$$

[f] is, of course, the most rigorous expression for C_p.

The equations [*d*], [*f*], or [*g*] are used to correct for asymmetry in the resonance curve. Once the curve is made symmetrical, G_p may be calculated by use of [*c*].

In fact, in cases where R' is negligible, L' may be accurately found by determining the value of L' necessary to make an asymmetric curve symmetrical by use of [*g*]. With reasonable care in construction R' should be negligibly small at all frequencies so that [*g*] may indeed be used to correct for asymmetry.

If, on trial, it is found that the resonance curve is completely symmetrical without correction, then it may reasonably be assumed that the L' and R' are both negligibly small.

Further, even if there were appreciable lead corrections in this system the manner of operation would cause them to be cancelled out.

Consider equation [*d*]. Any L and R in the leads could be lumped with the L' and R' of the cell. We have for the first condition, before gas is adsorbed

$$C_{p_1} = \epsilon C_{t_1}(1+\omega^2 L'\epsilon C_{t_1} - R'^2\omega^2\epsilon^2 C_{t_1}^2)$$

where ϵ is the dielectric constant of the bare powder in the cell and C_{t_1} is the low frequency capacity of the empty cell determined from low frequency measurements and the reading of the calibrated micrometer.

After gas is adsorbed we have

$$C_{p_2} = \epsilon' C_{t_2}(1+\omega^2 L'\epsilon' C_{t_2} - R'^2\omega^2\epsilon'^2 C_{t_2}^2)$$

where ϵ' is the composite dielectric constant of the system and C_{t_2} would be the capacity of the empty cell at this setting.

By the method of operation $C_{p_1} = C_{p_2}$, since resonance is re-established at the same frequency and for the same coil. Since the correction term is thus the same in both cases, $\epsilon C_{t_1} = \epsilon' C_{t_2}$. C_{t_1} and C_{t_2} are determined directly from the positions of the piston as measured by the micrometer and ϵ is separately determined at low frequency by bridge methods. Thus, correct values of ϵ' may be measured by this method. This assumes that ϵ, the dielectric constant of the powder does not change with frequency in this frequency range. The evidence at hand indicates that this assumption is correct.

In order to show that the operation of the cell is such that lead corrections vanish, it is best to consider a diagram of the cell. This is shown in Fig. 3.

Design and Operation of the Cell

As may be seen, the cell consists of a cylinder with a thick flange, on top of which a lid may be bolted. The cylinder and its flange were machined out of a single block of brass. Inside this cylinder and resting on a block of Teflon on the bottom is a smaller cylinder with a short lug at the top to which a high potential lead may be soldered. Since the wall of the outer cylinder is well grounded, we thus have a condenser of two coaxial cylinders.

Fitting snugly inside the second cylinder is a cylinder of Teflon. Since the fit is quite snug, the second cylinder must be rigidly fixed if the Teflon cylinder is rigidly fixed. This is accomplished in two ways. (1) The Teflon disc

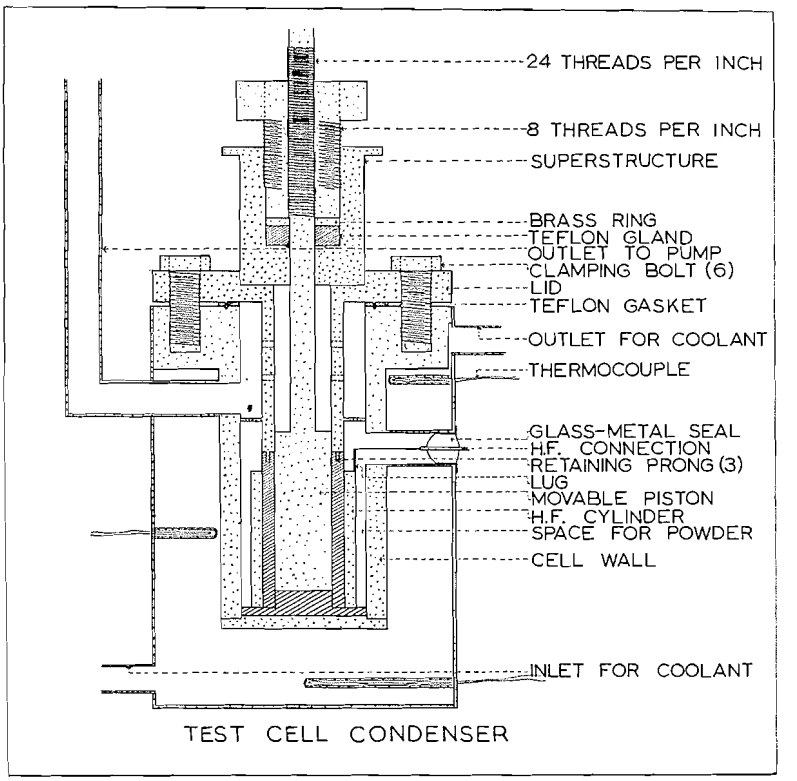

FIG. 3. Test cell for high frequency measurements.

at the bottom of the large cylinder has a raised circular portion over which the Teflon cylinder fits tightly. (2) The cell lid has a long sleeve extending down with three prongs cut out of the end of the sleeve. These prongs fit into three matching slots cut into the Teflon cylinder so that when the lid is tightly clamped the Teflon cylinder is held fixed.

Passing down through the sleeve and the Teflon cylinder is a brass piston on a long rod. The rod and the piston were machined out of a single piece of brass to ensure that they rotated about a common axis without a trace of wobble. Further, the piston was made to maintain good contact with the sleeve at all times as it was moved up or down. It will be noticed that the sleeve itself has a collar near the lower end that makes good contact with the walls of the outer cylinder. Thus, the piston is always grounded to the walls of the outer cylinder by a ground connection, the length of which does not change as the piston is moved. It will now be clear that this movable piston makes a variable condenser system with the second high potential cylinder. Small holes were drilled through the sleeve and collar to allow free passage of gas.

To ensure that no leakage would occur while the piston was moved, a superstructure was built on top of the lid. This superstructure consisted of a brass cup solidly soldered to the lid, and of a large heavily threaded brass bolt

pressing down on a brass ring resting on top of a Teflon gland at the bottom of the cup. The piston rod passed through the bottom of the cup, the Teflon gland, the brass ring, and the bolt. When the large bolt was screwed down tightly, the Teflon gland was squeezed out and made a very effective seal. If the operating temperature was lowered appreciably below room temperature, the large bolt had to be tightened further to prevent leaks. To accomplish the movement of the rod the inside of the bolt and the top part of the rod were threaded and the piston could be screwed up and down by the use of a small rachet wrench. The movement of the piston was measured by a micrometer (not shown) which could be read to 0.0001 in. also fastened to the top of the lid.

Taken as a whole, the cell is really a single variable condenser consisting of two parts, one of which is fixed, and one variable. The two parts have a common high potential plate so that, in effect, there is no high potential lead between them. Their respective grounds go to a common point and are very nearly the same short length.

The height of the fixed condenser part was 3.5 cm. The inside radius of the outer cylinder was 1.58 cm. with a gap of 0.27 cm. Thus, the volume of the space in which the powder was packed was 8.46 $cm.^3$ and the capacity when empty was 10.53 $\mu\mu f$. When filled with powder the capacity of the space increased to about 33.5 $\mu\mu f$. which value varied depending on the density of packing. When completely assembled the cell had a total capacity of about 50 $\mu\mu f$. with the piston resting on the bottom. The cell was operated at about 47 to 48 $\mu\mu f$. capacity to allow resonance curves to be taken at all points of operation. The total movement of the piston was 1 in. which could be measured accurately to 0.0002 in. The total change in capacity brought about by this 1 in. movement of the piston was 7.5 $\mu\mu f$.

With 48 $\mu\mu f$. total capacity, resonance could be obtained at 106 Mc./sec. with an inductance consisting of a straight piece of copper wire 2.5 cm. long connected across the cell from the high potential lead to ground. The lowest frequencies at which resonance could be made to occur would presumably be limited by the ability to wind a coil with enough turns of wire. In practice the cell was used at a frequency of 13 Mc./sec. by use of 10 turns of copper wire on a form 3.15 cm. in diameter.

To maintain a constant temperature, an outer jacket, through which coolant could be circulated, was built around the entire cell as shown in the diagram. In this case, it was felt to be more convenient to cause a low boiling liquid to boil in this outer jacket and condense in a coil immersed in a dry ice – acetone bath above the cell, and thus to maintain the temperature of the cell at that of the refluxing liquid. The temperature could be varied quite easily by altering the pressure at which boiling occurred. The temperature was checked by means of three thermocouples set into the boiling chamber. By this means the temperature could be kept constant to 0.1°C. with a temperature gradient of less than 0.2°C. from the bottom to the top of the cell.

It is worthwhile, now, to consider a certain aspect of the voltmeter used. This was a vacuum tube voltmeter employing two balanced tubes, as described

by Greenspan (3). The circuit diagram is given by Hartshorn and Ward (4). From this diagram it can be seen that the operation of the voltmeter is that of a Wheatstone bridge of which the plate resistances of the two tubes form two equal arms and the two tubes form the other two arms. The internal resistance of tube I is altered by the input voltage from the test cell to the grid of this tube. This will cause an unbalanced condition with respect to tube II and current will flow through the galvanometer. In most cases the swing of the galvanometer in response to this current is very large, and the galvanometer spot travels far off the scale. For determining resonance capacities alone, this causes no trouble, since the capacity of the test cell is changed till the galvanometer spot has swung through its farthest limit and has returned to the same position on the scale. When it is desired to determine an entire resonance curve, for the purpose of measuring the G of the circuit, however, the actual number of scale divisions traversed by the spot must be known. To accomplish this, just before the spot moves off the scale it is returned to the low point of the scale by altering the bias on tube II. Since the internal resistance of the tube is a function of the bias (viz. operation of tube I), changing the bias of tube II would also change its internal resistance. This would change an arm of the Wheatstone bridge that was supposed to have remained constant. Therefore, depending on the number of times the spot had to be returned to scale during a measurement, the top part of the resonance curve would have been determined at a different bias than the bottom part. Furthermore, owing to the change in the tube resistance, the top part of the curve would have been determined at a different amplification factor of the tube. This disadvantage could, of course, be overcome by operating the apparatus at such a low sensitivity that the whole curve could be taken on one scale length,

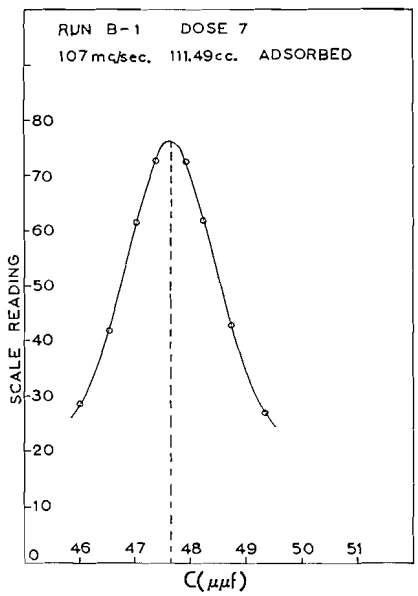

FIG. 4. Resonance curve for run B-1 addition 7.

or by using a scale of great length. Both alternatives were impractical. It was possible to show, from considerations of the galvanometer circuit, that the required change in bias on the grid of tube II did not change the tube constants to an appreciable extent.

It now was shown that the residual inductance and resistance of the cell were negligible. Plots of V^2 versus C_t were obtained for a variety of frequencies and these curves were found to be perfectly symmetrical, even at the highest frequency used. These symmetrical curves were obtained for the empty cell and for the cell packed with powder and with gas adsorbed. A typical curve taken from one of the runs is shown in Fig. 4.

Table I demonstrates the symmetry of the curve. As was pointed out earlier, such symmetry in the resonance curve can only mean no corrections need be made because of residual resistance and inductance.

TABLE I

46.77	48.61	47.69
46.43	48.93	47.68

It had next to be confirmed that true values of the dielectric constant could be obtained at all frequencies. For this test, glass was used as the dielectric, since its dielectric constant remained unchanged in the frequency range. The following procedure was used.

First, with the empty cell the resonance capacity was measured using a coil giving resonance at 73 Mc./sec. The top was removed and a piece of glass, cut into a half cylinder that partly filled the space to be occupied by the powder, was inserted into that space. The top was carefully replaced and the plunger moved until resonance was again obtained. Now the coil was changed to one that would allow resonance at 13 Mc./sec. Resonance was obtained with the glass in and the plunger nearly in the same position as it was at 73 Mc./sec. The top was removed, the glass taken out, the top replaced, and the plunger moved until resonance was again obtained. Thus the capacity change due to insertion of the glass could be compared for the frequencies of 13 Mc./sec. and 73 Mc./sec. since the position of the glass semicylinder was the same for both frequencies.

As an added assurance, this value was checked against the value obtained at 10.2 kc./sec. using a bridge method of measuring the capacity. The glass semicylinder was not an exact fit so that it was not possible to insert it in exactly the same way as for the high frequency trial. To compensate for this error, 10 trials were made by the bridge method and an average taken. Table II shows the remarkably close agreement in the result of all three tests and adequately shows that the cell will give true readings.

RESULTS

The cell was used to measure the change in capacity when sulphur dioxide was adsorbed on nonporous rutile at frequencies of 13, 36, 106 Mc./sec. and the single temperature of 3.5°C.

From the primary data at these frequencies (a typical set is represented in Fig. 5), no appreciable frequency dependence could be detected. The plot is seen to have the same general characteristics as those shown by a similar

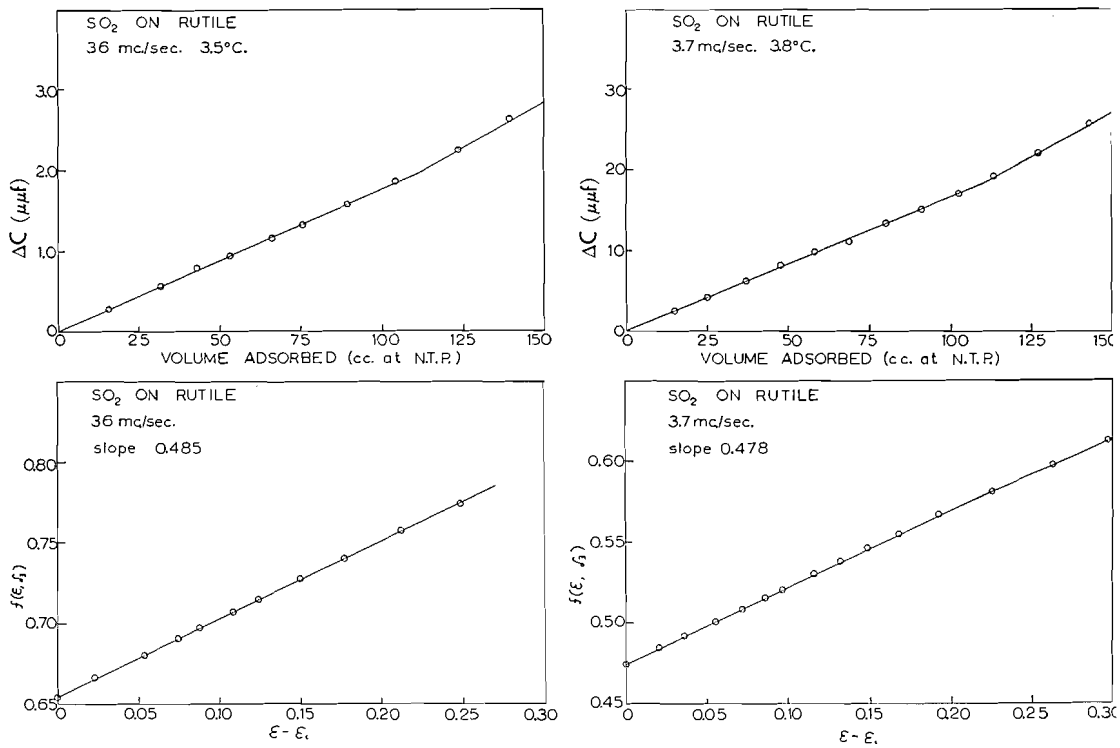

FIG. 5. Plots of ΔC versus volume adsorbed and functional plots for sulphur dioxide adsorbed on rutile.

plot given by Channen (1) at 3.7 Mc./sec. with the apparatus described by Snelgrove, Greenspan, and McIntosh (6). The characteristic change in the slope of the plot was also found here as observed by Channen and McIntosh for sulphur dioxide.

It is desirable to compare results obtained in this assembly with those obtained by Channen. Unfortunately, this comparison can not be made using

the primary data, owing to the difference in cell geometry and packing densities of the powder. A comparison using some functional plot must be made. The various functional plots that it is possible to use are discussed elsewhere in a paper by Channen and McIntosh (1). The one used here is the original function derived by McIntosh, Rideal, and Snelgrove (5) with a small correction for the material in the gas phase which was not necessary for silica systems. Using this method, the results obtained in this investigation agree very well with those of Channen, as a comparison of the slopes of the first linear sections of the functional plots given in Table III reveals.

TABLE III

Frequency (Mc./sec.)	Temp., °C.	Slope
13.0	3.2	0.471
36.0	3.5	0.485
106.0	3.7	0.469
3.7	3.8	0.478

From equation [*c*] one may obtain an expression for the power factor (or the loss tangent) of the adsorbed vapor in the form

$$[h] \qquad \tan \delta = \frac{(\Delta C_i - \Delta C_0)}{2\, C_{r_i} \sqrt{(q-1)}}$$

where $\tan \delta$ is the loss tangent.

ΔC_i is the change in capacity needed to go from one side of the resonance curve to the other at any chosen q after the ith addition of gas.

ΔC_0 is the change in capacity under the same conditions but for the bare powder.

C_{r_i} is the resonance capacity at the ith addition of gas.

There was no detectable loss tangent at any of the frequencies used. This result is not, in itself, conclusive, since the adsorbed phase is such a small fraction of the total system that, though the adsorbed phase itself may have an appreciable loss tangent, its contribution to the loss tangent of the system as a whole may be undetectable.

CONCLUSIONS

The above results show that the apparatus, as designed, works well at frequencies up to 106 Mc./sec. However, measurements at these frequencies have not shown any marked change in behavior of the adsorbed molecules from their behavior at low frequencies. Nevertheless, the conviction remains that some anomalous behavior, particularly the phenomenon of dispersion, must exist in some higher frequency range.

Since neither the cell capacitance nor the inductance used to obtain resonance can be greatly reduced, the principle employed in the construction of this apparatus has probably been pushed to near its upper frequency limit. If it is desired to investigate a higher frequency range, some other method, such as transmission lines or wave guides, will have to be tried.

ON THE CALCULATION OF THERMAL TRANSPIRATION[1]

By S. Chu Liang

ABSTRACT

The equation proposed earlier has been derived from a new kinetic concept. It is shown to be a reasonable approximation of this new consideration. The equation is also shown to be mathematically consistent with the general fact that when the thermomolecular pressure difference is plotted against the normally measured pressure, a single maximum is obtained. The curves calculated from this equation are shown to agree closely with those from the Weber equation using van Itterbeek and de Grande's data. The practical use of the equation is discussed.

INTRODUCTION

The problem of the effect of thermal transpiration on pressure, or the thermomolecular pressure difference, was observed and investigated by a number of workers both experimentally and mathematically (1, 4, 9). Although a practical solution was not obtained, the problem was neglected for many years. It was not even mentioned in most publications where it was obviously important.

Recently, Weber and his co-workers reinvestigated this problem and showed the extent to which a pressure measurement may be affected (11, 12). More recently, the problem was again brought to the general attention of this continent. Its practical importance was demonstrated by Liang (6) in the the case of vapor pressure measurement, and by Crowell and Young (2) in the case of physical adsorption.

Until very recently, the only available equation by which the thermal transpiration effect may be calculated was a semiempirical one obtained by Weber and his co-workers. The equation was derived along the line given by Maxwell with modifications suggested by Weber, and took the general form

$$[1] \qquad \ln \frac{p_1}{p_2} = \frac{1}{2} \ln \frac{T_1}{T_2} - \frac{1+2n}{2(1+n)} \left[B \ln \frac{y_1+m}{y_2+m} + C \ln \frac{y_1+m'}{y_2+m'} + D \ln \frac{y_1+m''}{y_2+m''} \right]$$

in which $y = R/\lambda$, R being the tube radius and λ the mean free path of the gas; n was related to the viscosity η by the equation

$$[2] \qquad \eta/\eta_0 = (T/T_0)^{\frac{1}{2}+n};$$

B, C, D, m, m', and m'' were constants calculated from another three semiempirical constants, k_1, k_2, and μ, which in turn were evaluated from the experimental data. Weber and Schmidt (13) calculated the constants for helium. van Itterbeek and de Grande (10) found that the values of k_1, k_2, and μ were functions of the nature of the gas and that separate determinations for different gases must be made. They extended the equation accordingly to cover the cases of hydrogen, deuterium, and neon.

[1]*Manuscript received September 16, 1954.*
Contribution from Research Laboratory, Dominion Tar & Chemical Co., Ltd., 3547 Allard Street, Ville LaSalle, Quebec. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

Los and Fergusson (8), in attempting to extend the Weber equation to the cases of nitrogen and argon, discovered that equation [1] was not applicable to argon. They also showed that by following the same general argument as Weber, mathematically, another equation of the general form

$$[3] \quad \ln\frac{p_1}{p_2} = \frac{1}{2}\ln\frac{T_1}{T_2} - \frac{1+2n}{2(1+n)}\left[B\ln\frac{y_1+m}{y_2+m} + \frac{C}{2}\ln\frac{y_1^2+m'y_1+m''}{y_2^2+m'y_2+m''} - \frac{D-\frac{1}{2}Cm''}{d}\left(\tan^{-1}\frac{y_1+\frac{1}{2}m'}{d} - \tan^{-1}\frac{y_2+\frac{1}{2}m'}{d}\right)\right]$$

is possible, where $d = (m''-\frac{1}{4}m'^2)^{\frac{1}{2}}$. The constants, while differing from those of equation [1], may be calculated in a similar fashion to that employed by Weber. This, of course, raises the intrinsic problem whether equation [1] or equation [3] should be employed when a new gas is being considered.

In the meantime, a different empirical formula was suggested by the present writer (5) in the form

$$[4] \quad R = p_1/p_2 = [\alpha(X/f)^2+\beta(X/f)+R_m]/[\alpha(X/f)^2+\beta(X/f)+1]$$

for the purpose of calculating the thermal transpiration effect R. Equation [4] was obtained by plotting R vs. p_2, the normally measured pressure. $X = p_2.d$, d being the tube diameter. $R_m = (T_1/T_2)^{\frac{1}{2}}$ and f is the "pressure shifting factor" which was used to correlate the different gases and was arbitrarily defined as $f_{N_2} \equiv 1$. The constants α and β were obtained by fitting the curve to the experimental data. Equation [3] was later modified slightly (7) to take a more readily usable form

$$[5] \quad p_1/p_2 = [\alpha_{He}(\phi_g X)^2+\beta_{He}\phi_g X+R_m]/[\alpha_{He}(\phi_g X)^2+\beta_{He}\phi_g X+1]$$

by referring to helium as the standard, and defining $\phi_{He} \equiv 1$. Equation [5] has been found to be applicable to at least eight gases, namely, helium, neon, hydrogen, argon, nitrogen, krypton, xenon, and ethylene; and it is expected to be equally applicable to others.

Equation [5] can be reduced readily to

$$[6] \quad \frac{p_2-p_1}{p_2} = \frac{\Delta p}{p_2} = \frac{1-R_m}{\alpha_{He}(\phi_g X)^2+\beta_{He}\phi_g X+1}.$$

The practical advantage of equation [6] over the Weber equation and its variation (equations [1] and [3]) is immediately obvious. It is therefore desirable to investigate whether there is any reasonable basis for its existence; and to examine whether, mathematically, it conforms to all the known facts. Such is the primary purpose of this communication.

DERIVATION OF EQUATION [5]

The purely mathematical approach to the problem has been exhausted by Chapman and Cowling (1). The final solution includes a cluster integral which is too complicated to solve for practical purposes. The recent thermodynamic approach made by de Groot (3) following the Onsager theory of reciprocal relations is deceptively simple. The many terms included in the final solution

are so far from the conventional thermodynamics that its usefulness for practical purposes is rather doubtful. The physical approach outlined by Maxwell has been followed up by Weber and his associates (11, 12) to reach useful but cumbersome results. It is thus decided that an entirely independent approach, a new kinetic approach, however empirical it may be, should be adopted.

We shall now consider the system composed of two regions at T_1 and T_2, connected by a tube of diameter d, and filled with *one* gas. After infinite time of waiting, the pressures are p_1 and p_2. We shall proceed to solve the relation between p_1 and p_2. At the offset, it should be pointed out that the system under consideration is not, and will never be, in thermodynamic equilibrium. Consequently, the conventional thermodynamics is of no great help. When the pressures between two regions of different temperatures reach "equilibrium", a stationary state, not an equilibrium, is established. The boundary conditions are that, at high pressures, i.e. $\lambda \ll d$, $p_1 = p_2$, and at low pressures, i.e. $\lambda \gg d$, $p_1/p_2 = (T_1/T_2)^{\frac{1}{2}}$. Furthermore, at high pressures the collisions for the transfer of energy take place predominantly in the gaseous phase while at low pressures the collisions take place predominantly via the wall. In the intermediate pressure region, the two types of collisions are both important, to varying degree as a function of the pressures. We assume that the collisions may be divided into the two types, each exerts its influence independently on the pressures, and the resultant effects are additive. Thus,

$$[7] \qquad p_1 = [N_G p_2 + N_W p_2 (T_1/T_2)^{\frac{1}{2}}]/(N_G + N_W),$$

where N_G and N_W are the number of collisions via the gaseous phase and wall respectively. It must be emphasized that N_G and N_W are not necessarily the physical numbers, but that they may be the equivalent numbers. The assumption of additivity may therefore be justified.

It follows readily that $N_G = k_1 p_1 p_2$ as N_G depends on the concentrations of molecules in both regions, where k_1 is a proportional constant; and $N_W = k_2 p_2$ (or $k_2' p_1$) where k_2 (or k_2') is *pressure dependent.*

Further, we will assume that p_1 may be represented by a polynomial of p_2, or

$$[8] \qquad p_1 = a p_2 + b p_2^2 + \ldots$$

Solving equation [7] by substituting the functions for N_G and N_W we have

$$[9] \qquad \frac{p_1}{p_2} = \frac{k_1 p_1 + k_2 (T_1/T_2)^{\frac{1}{2}}}{k_1 p_1 + k_2}.$$

Substituting equation [8] into equation [9], bearing in mind k_2 as a function of p's, we obtain

$$[10] \qquad \frac{p_1}{p_2} = \frac{k(p_2)(a p_2 + b p_2^2 + \ldots) + (T_1/T_2)^{\frac{1}{2}}}{k(p_2)(a p_2 + b p_2^2 + \ldots) + 1},$$

in which $k(p_2) = k_1/k_2$. Equation [10] may be rewritten in the form

$$[11] \qquad \frac{p_1}{p_2} = \frac{A p_2^2 + B p_2 + (T_1/T_2)^{\frac{1}{2}}}{A p_2^2 + B p_2 + 1},$$

when taking only the first two terms of equation [8]. By following the argument put forward earlier (5, pp. 150–151), equation [11] is transformed into equation [5].

DISCUSSION

Comparison with Weber Equation

The merit of the Weber equation cannot be denied. It has served well as far as accuracy is concerned. The starting point of Weber's treatment is very sound in principle. The approach of considering a stationary state established by the balance of an axial flow and a tangential flow is quite rigorous. That the original Maxwell treatment is inadequate to solve this problem has been adequately discussed in textbooks on the kinetic theory of gases and needs no further amplification. Weber, therefore, has to modify some of the Maxwellian terms, and an approximation is made. When the equation for the hydrodynamical region is applied to the molecular region, Weber is forced to make a further modification. Much of the original rigorousness is lost after the successive approximations, although the mathematical expression does not become any simpler. The complete solution (equations [1] and [3])is cumbersome yet still empirical. Actually, equations [1] and [3] are simple in appearance but unwieldy in use. For y_1 and y_2 are functions of λ's which are in turn functions of p_1 and p_2. Thus to calculate p_1 for a given value of p_2, the operation becomes extremely complicated. The alternative solution found by Los and Fergusson makes it even less attractive.

The present treatment gives a very simple formula and thus eliminates all the difficulties involved in the Weber equation. Besides, it leaves no ambiguity when a new gas is to be considered. The agreement between equation [6] and the experimental values is to be shown in the discussion to follow.

It might be questioned whether or not the rigorous starting mathematical treatment of Weber is a strong point in its favor. Actually, if the theoretical treatment is of interest, then those treatments given by Chapman (1) and de Groot (3) should be followed but not that of Weber.

Comparison with Experiments

For all the published cases known to the writer, T_2 and p_2 represent the conditions at room temperature, and T_1 and p_1 those at lower temperatures; the discussion will therefore be confined to this understanding.

Generally, when Δp is plotted against p_2,* the curve exhibits a single maximum. Equation [6] will be examined for this point. At Δp = maximum or $d(\Delta p)/dp_2 = 0$,

[12] $$\alpha_{\mathrm{He}}(\phi_g X)^2_{\max} = 1,$$

$$X_{\max} = (p_2 \,.\, d)_{\max} = (1/\alpha_{\mathrm{He}}\,\phi_g{}^2)^{\frac{1}{2}},$$

or

[13] $$(p_2)_{\max} = \frac{1}{\alpha^{\frac{1}{2}}_{\mathrm{He}}.d} \cdot \frac{1}{\phi_g}.$$

**In Weber's type treatment, the customary way is to plot Δp against $\bar{p}$, where $\bar{p} = \frac{1}{2}(p_1+p_2)$. The net result is the same.*

Equation [12] is of considerable practical importance. It not only indicates that equation [6] gives a single maximum, but also gives the pressure at which the maximum exists. Furthermore, for a given tube, $\alpha_{He}^{\frac{1}{2}}.d$ is constant, for various gases; the value of $(p_2)_{max}$ is therefore a function of ϕ_g *only*. Experimentally, the value of $(p_2)_{max}$ can be determined more accurately for a larger difference between T_1 and T_2. Once it is determined, it may be used for the cases of small temperature difference when direct determination often involves high uncertainty. The accuracy in the determination of $(p_2)_{max}$ may also be increased by using tubes of small diameter, which correspond to high values of $(p_2)_{max}$, and the $(p_2)_{max}$ so obtained may then be used for the cases of tubes of large diameters.

Since $\phi_{He} \equiv 1$, by measuring $(p_2)_{max}$ for helium accurately, α_{He} may be obtained with good accuracy. This makes it possible for ϕ_g for other gases to be obtained with low experimental uncertainty.

Equation [6] also makes it possible for the experimental results obtained with the same gas, same T_1 and T_2, but different tube diameter, to be cross-checked. Thus, if

$$Y = (\Delta p) \,.\, d,$$

the equation [6] gives

$$[14] \qquad \frac{Y}{X} = \frac{(\Delta p) \,.\, d}{p_2 \,.\, d} = \frac{1-R_m}{\alpha_{He}(\phi_g X)^2+\beta_{He}(\phi_g X)+1}.$$

Or, if Y is plotted versus X, measurements of different tube diameters will fall in a single curve.

The foregoing considerations are examined with the published experimental results. The equation is known to be applicable to the conditions for $T_1 = 78°$ and 195°K. (5, 6, 7). In order to test its applicability over wide temperature variations, the data of van Itterbeek and de Grande (10), which cover the temperature range of $T_1 = 20$–90°K. in a reasonably systematic way, are used. The constants for equation [5] at various temperatures are determined, and the curves so calculated are compared with the experimental data and also with the curves obtained according to the Weber equation by the original authors. The agreement is in general very close. One such comparison, the 69°K. results, is shown in Fig. 1. The open and closed points are the two sets of published data for $d = 1.236$ and 0.860 mm. respectively. The full lines are the curves calculated from equation [5]. In the case of helium, the dotted curve represents that calculated from the Weber equation. In the cases of neon and hydrogen, the difference between the Weber equation and equation [5] is too small to be shown. Thus, for all practical purposes, the two solutions, both empirical, are equal.

Substituting equation [12] into equation [14] gives

$$[15] \qquad \frac{Y_{max}}{X_{max}} = \frac{1-R_m}{2+\beta_{He}\phi_g X_{max}} = \frac{1-R_m}{2+\beta_{He}/\alpha_{He}^{\frac{1}{2}}}.$$

Equation [15] gives the value of Y_{max}/X_{max} for all gases. Thus, once the constants α_{He} and β_{He} are determined, the value of Y_{max}/X_{max} in all gases for all

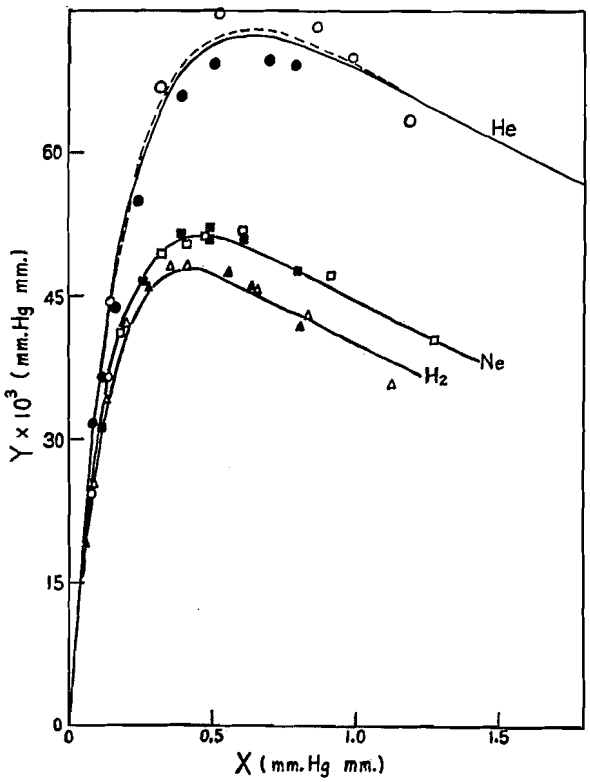

FIG. 1. Comparison of the curves calculated from the present equation and the Weber equation with experimental data (van Itterbeek and de Grande) for helium, neon, and hydrogen, at $T_1 = 69°K$. Tube diameter: open points, $d = 1.236$ mm.; closed points, $d = 0.860$ mm. Full lines, equation [5]; dotted line, the Weber equation.

tube sizes and at all temperature differentials may be evaluated readily. Table I gives one set of values of Y_{max}/X_{max} for helium, neon, and hydrogen at $T_1 = 69°K$. as an example.

TABLE I

Y_{max}/X_{max}— FOR HELIUM, NEON, AND HYDROGEN AT 69°K.

Gas	Y_{max} (mm. Hg mm.)	X_{max} (mm. Hg mm.)	Y_{max}/X_{max}
Helium	0.0730	0.63	0.116
Neon	0.0513	0.445	0.115
Hydrogen	0.0480	0.41	0.117

From equation [15], one may also obtain

$$[16] \qquad B = \beta_{He}\phi_0 = \frac{1-R_m}{Y_{max}} - \frac{2}{X_{max}}.$$

Thus, the B value for each gas may be calculated from experimental data for

each individual gas through the use of equation [16]. The ratio B_g/B_{He} gives ϕ_g which may thus be determined experimentally.

It should be emphasized that the thermal transpiration effect is a function of the nature of the tube. This has been pointed out previously (5) and has since been verified experimentally (8). The accommodation coefficient undoubtedly plays an important role. Thus Los and Fergusson have found that the effect produced in a metal tube differs from that in a glass tube.

The question of what role the length of the tube plays has been raised on many occasions. It is sufficient to say that as long as the length of the tube is such as to permit the establishment of the two regions at T_1 and T_2, the length is immaterial. If the tube is too short, then the two distinct regions cannot be established. In that case, of course, the basic conditions are not met, and it becomes a different problem altogether.

ACKNOWLEDGMENT

The author wishes to acknowledge his indebtedness to Dr. J. A. Morrison of the National Research Council of Canada who first interested him in this problem.

THE ADSORPTION OF ARGON ON SOME VACUUM DEHYDRATED SALTS[1]

By H. W. Quinn,[2] R. W. Missen,[3] and G. B. Frost

ABSTRACT

Isotherms for the adsorption of argon on amorphous products formed by the vacuum dehydration of several hydrated salts have been determined. These have shown that the adsorption is physical and that dehydration results in the formation of products of large capillary volume. The probable distribution of capillary diameters has been estimated and correlated with the effect of water vapor at low pressures in catalyzing the crystallization of the amorphous intermediates. Consideration of these findings, in the light of data for the heats of transition from the amorphous to the crystalline state, suggests that the X-ray amorphous character is not entirely due to the capillary structure but that other changes occur. The possible nature of these is discussed.

INTRODUCTION

When certain hydrated salts are dehydrated under vacuum or at very low pressures of water vapor, products are obtained which do not diffract X-rays. These products crystallize into the lattice of one of the crystalline lower hydrates in the presence of water vapor above certain limiting pressures which are specific for each salt but which depend on temperature. Crystallization also occurs when the amorphous material is heated at moderate temperatures for various periods. Hydrated salts known to behave in this manner are copper sulphate pentahydrate, zinc sulphate heptahydrate, manganous sulphate tetrahydrate, nickel sulphate hexahydrate, magnesium sulphate heptahydrate, and manganous oxalate dihydrate. There are probably others.

Discussion of the possible mechanism of formation of amorphous material under vacuum dehydration and its subsequent crystallization in the presence of water vapor has been given elsewhere (5, 9). It appears that as the parent lattice loses co-ordinated water molecules at the reaction interface, a skeleton lattice is formed which probably collapses at once into either a microcrystalline state (the microcrystals being below the limit in dimensions required for X-ray diffraction), or into some state of ionic randomness resulting in a disordered lattice of higher energy than its normal crystalline counterpart. The effect of water in inducing crystallization may be due to a catalytic effect whereby macrocrystals are formed from microcrystals (8), or to the effect of adsorbed water dipoles in lowering interionic attractive forces and diffusing into the strained lattice, thus increasing the mobility of the disordered ions and enabling them to orient themselves into an energetically stable arrangement.

The limiting pressures of water vapor above which the formation of an amorphous intermediate is not observed vary from small fractions of a millimeter to a few millimeters. Observed values are given in Table I.

TABLE I

Salt	t, °C.	Approximate limiting pressure (mm.)
$MnC_2O_4.2H_2O$	60	0.2
$CuSO_4.5H_2O$	40	0.25
$MnSO_4.4H_2O$	50	1.2
$ZnSO_4.7H_2O$	40	1.5
$NiSO_4.6H_2O$	60	2.0
$MgSO_4.7H_2O$	40	4.5
$MgSO_4.7H_2O$	50	8.0
$MgSO_4.7H_2O$	60	12.5

The rate of dehydration of manganous oxalate dihydrate at a series of low pressures of water vapor has been determined by Volmer and Seydel (11) and by Topley and Smith (10). Similar rate determinations for the dehydration of copper sulphate pentahydrate have been made by Frost and Campbell (4), who interpreted these rates in terms of the formation of amorphous material and its subsequent crystallization. Wheeler (12) and Ford (3) have studied the rates of dehydration of the other salts mentioned and found that all were qualitatively similar in the dependence of rate on the water vapor pressure in the vicinity of the reaction interface.

Certain salts do not yield amorphous products on vacuum or low pressure dehydration. Nickel nitrate hexahydrate and magnesium nitrate hexahydrate undergo a series of crystalline phase changes. The rate of dehydration of chrome alum has been determined by Cooper and Garner (1) who made measurements of the rate of growth of nuclei on crystal surfaces. The product obtained on vacuum dehydration shows a definite pattern of X-ray diffraction lines, and the dependence of dehydration rate on water vapor pressure is quite different from that observed for hydrated salts which yield X-ray amorphous products. On vacuum dehydration, this salt appears to form a crystalline lower hydrate of large internal surface due to capillary formation, whereas dehydration in the presence of water vapor at low pressure yields normal crystal aggregates.

Ford (3) has shown that the dependence of rate of dehydration on water vapor pressure of cobalt chloride hexahydrate is very similar to that of chrome alum, and that the mechanism of dehydration is probably the same for the two salts.

Frost, Moon, and Tompkins (5) have calculated values for the heat of transition from the amorphous to crystalline forms of copper sulphate monohydrate and zinc sulphate monohydrate from measurements of the heat of solution of the amorphous and crystalline forms. Jamieson (7) has made similar determinations for magnesium sulphate monohydrate and nickel sulphate monohydrate. He also found that the heat of solution of vacuum dehydrated cobalt chloride differed from that of the normal crystalline monohydrate. Since all these salts

when dehydrated under vacuum have higher heats of solution than their macrocrystalline counterparts, regardless of whether or not X-ray diffraction lines are shown, it will be more convenient in what follows to use the term "active" rather than "amorphous" to describe them. Values of the heats of transition are as follows:

$$ZnSO_4 \cdot H_2O \text{ (active)} \rightarrow ZnSO_4 \cdot H_2O \text{ (cryst.)}; \quad \Delta H = -7600 \text{ cal. mole}^{-1},$$
$$CuSO_4 \cdot H_2O \text{ (active)} \rightarrow CuSO_4 \cdot H_2O \text{ (cryst.)}; \quad \Delta H = -7170 \text{ cal. mole}^{-1},$$
$$MgSO_4 \cdot H_2O \text{ (active)} \rightarrow MgSO_4 \cdot H_2O \text{ (cryst.)}; \quad \Delta H = -6550 \text{ cal. mole}^{-1},$$
$$NiSO_4 \cdot H_2O \text{ (active)} \rightarrow NiSO_4 \cdot H_2O \text{ (cryst.)}; \quad \Delta H = -4720 \text{ cal. mole}^{-1},$$
$$CoCl_2 \cdot H_2O \text{ (active)} \rightarrow CoCl_2 \cdot H_2O \text{ (cryst.)}; \quad \Delta H = -1390 \text{ cal. mole}^{-1}.$$

In view of the fact that the formation of these energy active products is a reaction step in the dehydration mechanism, and since the conversion of these products into crystalline forms depends in a very marked way on the action of water molecules adsorbed at very low pressures, it appeared desirable to study the adsorption of other gases on these intermediates. It was thought that a knowledge of such factors as the types of isotherms, the adsorptive capacity, the capillary structure, and the heats of adsorption might throw light on the nature of these products and on their role in the reaction mechanism. Preliminary experimental work has indicated a small but definite adsorption of hydrogen, carbon monoxide, and carbon dioxide. This paper, however, deals entirely with the adsorption of argon on various vacuum dehydrated salts.

EXPERIMENTAL METHOD

Recrystallized samples of hydrated salts were placed in a container which consisted essentially of two concentric cylinders of 100-mesh copper gauze, the sample being contained in the annular space between the inner and outer cylinders. The thickness of the sample so contained was about four millimeters. Dehydrations under vacuum were then carried out for several hours, usually at 40°C., preliminary experiments having indicated the time required to reach the stoichiometric monohydrate composition. Adsorption and desorption measurements were made following dehydration without disturbing the sample, the usual volumetric technique being used. Following these measurements, requisite weighings were made to determine the weight loss on dehydration and small samples removed for the making of X-ray powder photographs.

Crystalline copper sulphate monohydrate was prepared by placing pentahydrate crystals in the adsorbent container and allowing them to stand in an oven at 110°C. and atmospheric pressure for 60 hr. The final weight corresponded to the monohydrate composition and X-ray lines characteristic of the crystalline monohydrate were obtained.

Cobalt chloride hexahydrate, when dehydrated under vacuum as described above, yielded a crystalline product corresponding to the monohydrate composition. It is known, however, that under such conditions a sequence of changes occurs which involves the co-ordination of chloride ion and the

ultimate loss of hydrogen chloride. In order to determine the extent of this reaction, a 5-gm. sample was dehydrated, the water being trapped, and the hydrogen ion and chloride ion concentrations determined. It was found that approximately 0.025% of the weight loss was due to the formation of hydrogen chloride. Some slight heterogeneity in composition may therefore have been introduced from this source.

Isotherms were obtained at liquid air temperatures and at the boiling points of liquid oxygen and liquid nitrogen. The temperatures of these refrigerants were determined during the course of the adsorption measurements by means of a resistance thermometer.

RESULTS

Argon adsorption isotherms were obtained for several dehydrated salts. These are shown in Fig. 1. These isotherms were obtained at liquid air temperature (approximately 85°K.) with the exception of that for copper sulphate

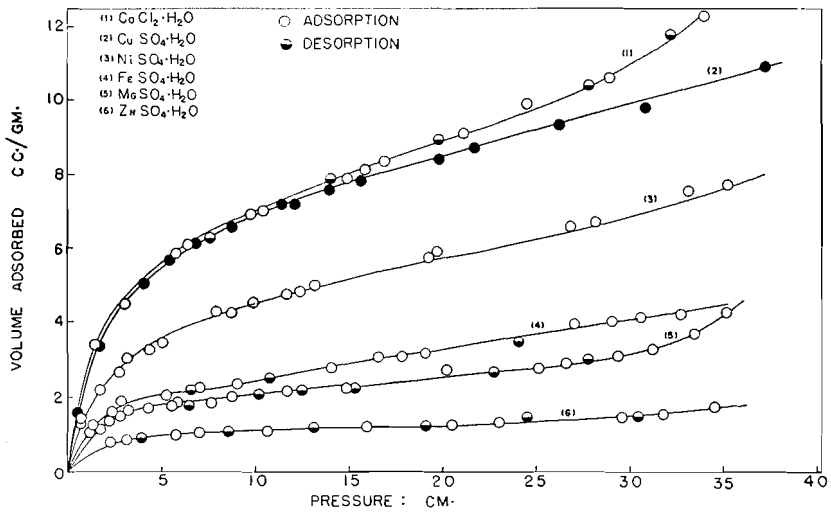

FIG. 1. Adsorption isotherms for argon on several vacuum dehydrated salts at approximately 85°K.

which was obtained at 90°K. All samples were of approximately the same weight and were all dehydrated at 40°C. to the monohydrate composition with the exception of nickel sulphate which retained about 1.5 mole of water. The final products showed no X-ray diffraction lines except in the case of cobalt chloride, where weak diffraction lines were observed.

It will be observed that the isotherms are similar in type. There is very little difference in adsorptive capacity between the active crystalline form of cobalt chloride and the X-ray amorphous copper sulphate. However, the adsorptive capacity of the other salts, which are also X-ray amorphous, varies widely.

In Figs. 2 and 3 are shown isotherms for active and macrocrystalline copper sulphate monohydrate at 78°K. and 90°K. respectively, both adsorption and desorption points being shown. The adsorptive capacity is much greater for the active form and there is a pronounced hysteresis loop in the isotherm at

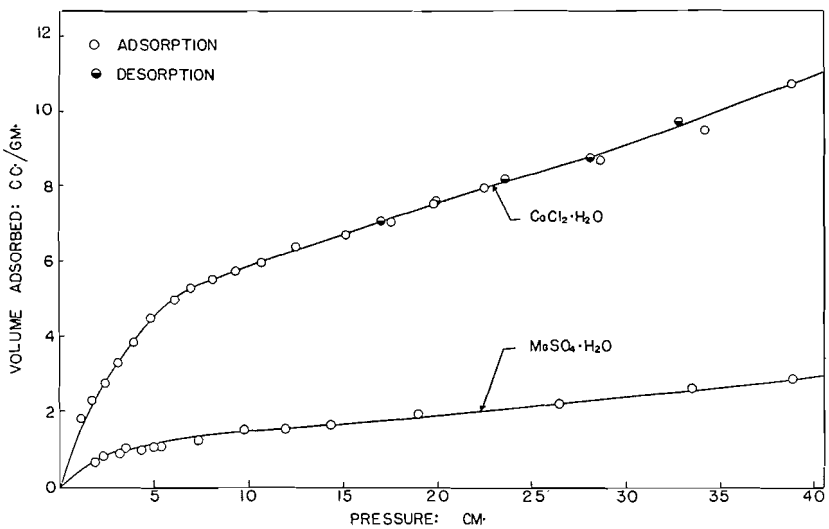

FIG. 5. Comparison of adsorption and desorption isotherms for active cobalt chloride and active magnesium sulphate at 90°K.

78°K. The sharp rise of the isotherm for the crystalline monohydrate at 78°K. is to be attributed to the condensation of argon at its saturation pressure.

The isotherms obtained for active cobalt chloride and for active magnesium sulphate at 78°K. are shown in Fig. 4. Those obtained at 90°K. are shown in Fig. 5. Pronounced hysteresis loops were obtained in the 78°K. isotherms, that for magnesium sulphate extending over a greater range of pressure.

Surface area values were calculated from the foregoing isotherms using both the B.E.T. method and the Hüttig method (2). These values are given in Table II.

TABLE II

SURFACE AREAS

Adsorbent	Method	T, °K.	V_m (cc. per gm.)	Area (sq. m. per gm.)
$CuSO_4.H_2O$ (C)	B.E.T.	78	1.04	3.94
$CuSO_4.H_2O$ (C)	B.E.T.	90	0.99	3.82
$CuSO_4.H_2O$ (A)	B.E.T.	78	7.04	26.7
$CuSO_4.H_2O$ (A)	B.E.T.	90	7.25	28.1
$CuSO_4.H_2O$ (A)	Hüttig	90	7.71	29.8
$CoCl_2.H_2O$ (A)	Hüttig	78	9.48	35.9

$FeSO_4.H_2O$ (A)	Hüttig	85	2.47	9.4

The adsorption data obtained from the isotherms at 78°K. for active copper sulphate, crystalline copper sulphate monohydrate, active cobalt chloride, and active magnesium sulphate were tested for specificity in the usual manner, by plotting the relative volume adsorbed (v/v_m) against the relative pressure (p/p_0). The results obtained are shown in Fig. 6. There is a marked absence of any specific effect for values of v/v_m up to and somewhat greater than unity;

TABLE III

DISTRIBUTION OF CAPILLARY DIAMETERS

Salt	Pressure, cm.	P/P_0	V/V_m	Diameter, Å	Position on hysteresis loop
$CoCl_2.H_2O$	8.5	0.31	1.29	18	Lower limit
	10.4	0.38	2.05	22	Sharp break in desorption curve

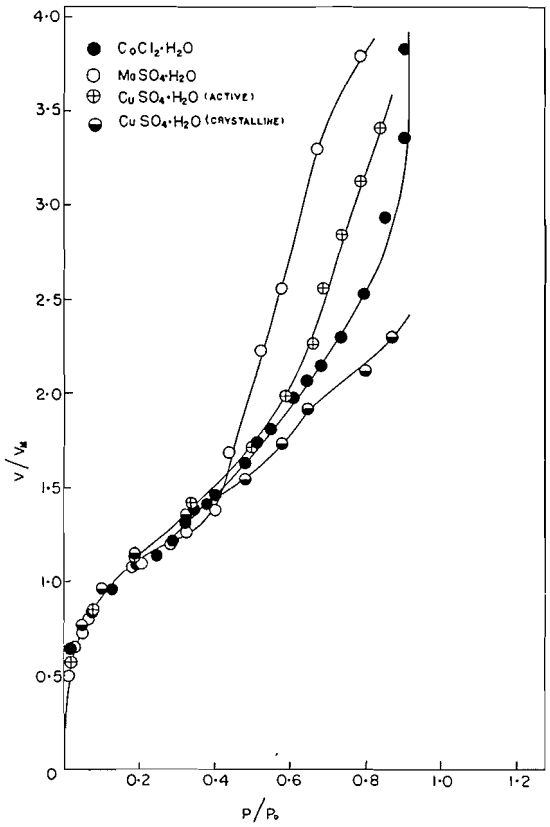

FIG. 6. Comparative specificity curves for three active and one macrocrystalline salt.

in other words, in this region, all the adsorbents differ in adsorptive capacity only by reason of differences in surface area. At higher values there is a marked divergence indicating a distinct difference in the distribution of capillary sizes.

Capillary diameters have been calculated assuming the validity of the Kelvin equation. Some values obtained are given in Table III.

From Table III, it will be observed that active magnesium sulphate contains capillaries which are much smaller in diameter than the smallest calculated for either active copper sulphate or active cobalt chloride, although it does have at its upper limit capillaries which are equal in diameter to the maximum size shown by copper sulphate. Active cobalt chloride, on the other hand, has capillaries which are nearly twice as large as the maximum size exhibited by the other two salts.

Differentiated structure curves, obtained by plotting dv/dr against r, are shown in Fig. 7. For cobalt chloride, the greatest contribution to the total capillary volume is made by capillaries of diameter of approximately 20 Å. For copper sulphate, these curves show two peaks at capillary diameters of approximately 28 Å and 53 Å. For magnesium sulphate there are also two peaks at 11 Å and 26 Å.

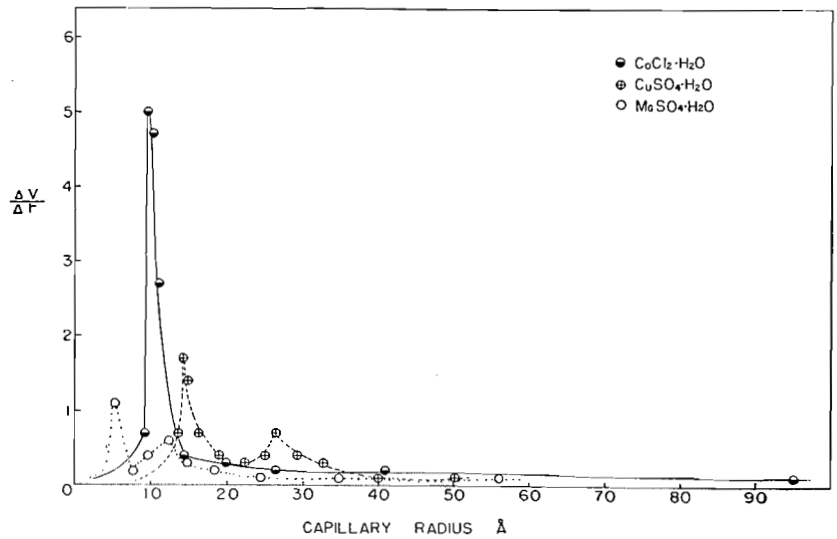

FIG. 7. Differentiated structure curves.

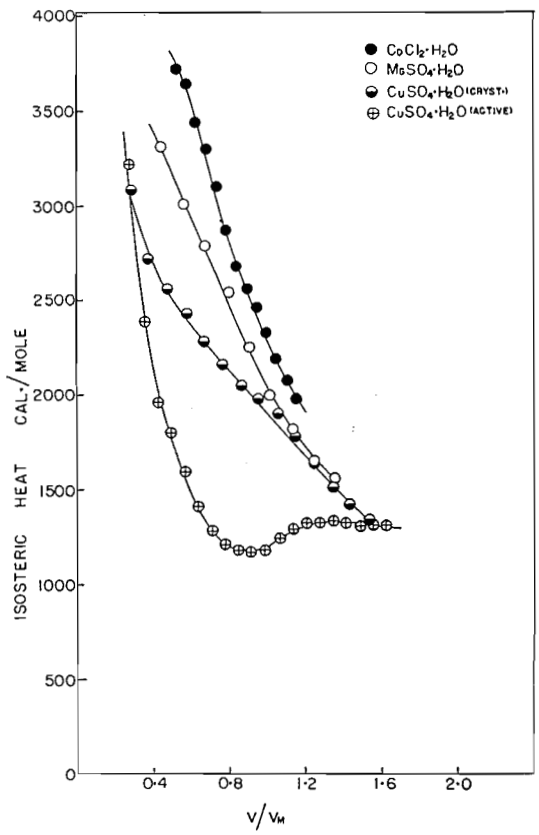

FIG. 8. Change in isosteric heat of adsorption with relative surface coverage.

Although the most frequently occurring capillary diameter for cobalt chloride is smaller than the diameters calculated for copper sulphate, the differentiated structure curve shows that the total number of these is approximately three times greater than that of the 28 Å diameter capillaries and somewhat over five times the number of the 53 Å capillaries of copper sulphate. For magnesium sulphate, the number of capillaries of either diameter which occurs most frequently is comparable with that of either diameter for copper sulphate. However, with magnesium sulphate, these diameters are very much smaller. It follows that the total capillary volume of magnesium sulphate is much smaller than that of either copper sulphate or cobalt chloride. Since there is a significant number of capillaries of wide diameter in copper sulphate, it is a little difficult, from the differentiated structure curves alone, to correlate its total capillary volume with that of cobalt chloride. However, the surface areas of these two active salts are nearly the same and, therefore, their capillary volumes must be comparable.

Isosteric heats were calculated from the isotherms at 78°K. and 90°K. The values obtained, plotted against v/v_m, are shown in Fig. 8. In all cases, there is a rapid decrease in isosteric heat with the extent of adsorption. The values calculated for active copper sulphate decrease much more rapidly than those for the other salts and at lower values of v/v_m. In the vicinity of the value of v/v_m corresponding to the formation of a monolayer, these values pass through a minimum. It was not possible to carry the adsorption measurements into a range of pressure from which the existence of minima for the other salts could be ascertained.

DISCUSSION

The adsorption of argon on these vacuum dehydrated salts follows, in the main, the pattern of the adsorption of non-polar gases on gel-like structures, the over-all heats of adsorption being of the order of magnitude which has been observed for such systems. However, there are some points of interest which it appears desirable to bring out in discussion.

It has been shown that, for the three salts most carefully studied, vacuum dehydration yields products of large capillary volume. The capillary volumes of active copper sulphate and of active cobalt chloride have been shown to be comparable, although the former is an X-ray amorphous product and the latter is a crystalline product of large internal surface. Active magnesium sulphate is X-ray amorphous but has a smaller internal surface.

The over-all spread in capillary diameter for the three active salts is from about 11 Å to nearly 200 Å. The diameters most likely to occur are much greater than those observed for dehydrations of the zeolitic type where the capillary diameters are less than 5 Å. It follows, therefore, that the loss in water is accompanied by a considerable contraction in volume in the reaction zone and that this contraction in volume continues as the reaction interface moves into the dehydrating lattice. Garner and Pike (6) have observed the shapes of the dehydration nuclei formed on the faces of copper sulphate pentahydrate crystals and have shown that dehydration occurs most rapidly along certain

crystal planes. Cooper and Garner (1) photographed, at various stages of growth, the nuclei formed on the dehydration of crystals of chrome alum. It was shown that, as the nuclei grow, radial cracks develop around a star-shaped hole at the center of the nucleus. In the absence of direct observation, it may be reasonably assumed that some like process occurs in the cases under consideration. The observed differences in most probable capillary diameter are likely due to differences in crystallographic character. If the parent lattice and the crystalline end product of dehydration differ in crystal parameters and in specific volume, the capillaries are likely to be large. Relative rates of dehydration along preferred planes may be a contributory factor in the distribution of capillary sizes.

The relative adsorptive capacity of the various adsorbents studied is clearly related to the capillary structure. Active magnesium sulphate with a surface area of approximately seven square meters per gram and probable distributions of capillary diameter about the values of 11 Å and 25 Å presents a much smaller total capillary volume than active copper sulphate or active cobalt chloride. The adsorptive capacities of the latter two salts are about the same, whereas that of magnesium sulphate is very much smaller.

This immediately suggests a correlation between the internal surface and the characteristic limiting pressures of water vapor above which amorphous intermediates do not occur. Cobalt chloride hexahydrate dehydrates at zero pressure of water vapor into a crystalline product of large internal surface. Active copper sulphate with nearly the same adsorptive capacity adsorbs a sufficient quantity of water at approximately 0.25 mm. pressure to induce crystallization; active magnesium sulphate of much lower adsorptive capacity shows a much greater stability in the amorphous state and does not crystallize below pressures of 4.5 mm. Of the salts for which isotherms are shown in Fig. 1, active nickel sulphate fits well into this correlation; active zinc sulphate does not. However, this salt behaves in a more complex fashion on dehydration and requires closer study. Although an isotherm has been reported for the dehydration product of ferrous sulphate heptahydrate, it is probable that this salt undergoes a series of crystalline changes on low pressure dehydration and consequently does not fit into the sequence under discussion. The behavior of manganous oxalate dihydrate with respect to this correlation should be of interest.

It has been pointed out that the heat of solution of vacuum dehydrated cobalt chloride hexahydrate is greater by 1390 cal. per mole than that of the normal crystalline monohydrate. This difference may be ascribed in part to the large internal surface. Since however, both active cobalt chloride and active copper sulphate have about the same capillary volume, it might be expected that the heat of solution relative to the crystalline form (or, therefore, the energy liberated on the amorphous to crystalline transition) of active copper sulphate should be of the same order as that observed for cobalt chloride. This is far from being the case, the value being over 7000 cal. per formula weight. All of the values for the X-ray amorphous to crystalline transitions, given earlier in this paper, are higher than those which might be expected from the

surface area or capillary data found, unless it is assumed that large differences in surface energy exist.

This suggests that some change, other than increased surface or capillary volume, occurs during vacuum dehydration. If there is a lack of conformity at the reaction interface between the dehydrating lattice and its crystal end product, it is possible that the ions of the lattice will collapse into whatever energy levels happen to be available, ordered arrangement being realized (as was suggested at the outset) as mobility is given to the ions by the adsorption and inward diffusion of water dipoles. A state of internal strain would therefore result which would manifest itself by a relatively high energy release on crystallization.

If such a state of internal strain were also a source of surface inhomogeneity, it might be expected that some specificity in adsorption would be observed for the active salts with reference to their crystalline counterparts. From Fig. 6, it is clear that no marked specific effects occur with active copper sulphate in reference to the crystalline monohydrate, at least up to the formation of the monolayer. However, the isosteric heat of adsorption falls off much more rapidly with increased adsorption for active copper sulphate than for the crystalline monohydrate and a minimum is observed at approximately the completion of the monolayer. The existence of such minima has, of course, been predicted theoretically and observed experimentally for certain ionic crystals. In the present work, no minimum has been observed for crystalline copper sulphate monohydrate, although a slight extrapolation of the adsorption isotherms suggests that one occurs just beyond the range of calculated values. It is possible that the more rapid drop in isosteric heat values and the location of the minimum in a lower range of adsorption for active copper sulphate has significance in terms of the possible ionic disorder of the surface and the effect of this on the induced dipoles of the adsorbed atoms. However, this possibility must remain in the region of speculation until more comprehensive experiments have been made.

THE FORMATION OF THIN FILMS OF IRON OXIDE[1]

By E. J. Caule and M. Cohen

ABSTRACT

It is assumed that the free energy of a thin film of iron oxide is a function of its thickness. The effect on the dissociation pressure is calculated and the condition for stability of thickness is stated. A possible method for measuring the free energy change involved in oxide film formation on metal surfaces is presented which is based on measurements of the e.m.f. of the dry cell metal|oxide|oxygen.

INTRODUCTION

At ordinary temperatures and pressures the system iron+oxygen is unstable and will go spontaneously to one or more of the various iron oxides. For example, the equilibrium dissociation pressure of α Fe_2O_3 is about 10^{-80}mm. pressure of oxygen. Hence, when the process of oxidation halts it is natural to assume that kinetic conditions have imposed a very slow speed on the process, slow enough to give the appearance of a halt.

The influence of resistance to change can be seen very clearly in the formation of iron oxide films on massive iron at pressures of around, say, 3 cm. oxygen and at temperatures around 370°C. In this region the clear-cut result is obtained, by a variety of methods, that the rate of increase of the film thickness is inversely proportional to the thickness. The most reasonable interpretation of this result is that the rate is controlled by the diffusion of the reagents through the film. Subsidiary experiments on transport processes, such as conduction, in oxides have checked this conclusion directly.

This simple diffusion mechanism holds over a very wide range of film thicknesses—under the conditions mentioned above, from 800 Å up to thicknesses of the order of fractions of a millimeter where the film begins to lift from the metal and to scale off the surface. The range from 0 to 800 Å behaves anomalously, not following the diffusion law. Fig. 1 shows an oxidation for which the diffusion law is valid; the weight increase varies linearly with the square root of the time which follows from the varying of the rate of increase with the thickness. Fig. 2 can be regarded as a "blown-up" view of the anomalous region in Fig. 1; the data were obtained from observation of interference colors and the ordinate is plotted directly as Angstrom units since the interference colors can be correlated with film thickness. It is seen that the anomalous region has been divided into two stages. At any rate, from Fig. 1 it is clear that given a certain thickness iron oxide will limit the rate of its own further growth.

It is tempting to apply this conclusion to the data on iron oxidation at room temperature. At room temperature and below, iron will take up oxygen to form a film in the manner shown in Fig. 3. It is seen that the rate slows

practically to zero in the time shown. It is natural to assume that the process here is exactly the same as the high-temperature diffusion process, modified and reduced in scale by the drop in temperature, since the diffusion process has been found to have an activation energy of about 40 kcal. This paper will present an alternative explanation of the low-temperature phenomena, which can be extended to explain the initial section of the high-temperature curve. It will be claimed (*a*) that the film initially formed on iron at any temperature attains an equilibrium thickness, whose magnitude is a function of temperature and pressure, and (*b*) that a process of recrystallization transforms the initial oxide to a second variety not possessing an equilibrium thickness and that in this second form the diffusion process of the type shown in Fig. 1 takes place. Unless, then, process (*b*) occurs, growth of the film will cease entirely at a certain thickness which is truly stable in the absence of the second phase.

The most striking fact to consider is that all of the iron oxide phase is concentrated at an interface, where it is subject to peculiarly unbalanced forces. From this consideration comes the first assumption, that the free energy of the iron oxide per unit of weight or volume is a function of the thickness.

Let the free energy of the oxide phase, F_{ox}, be divided into two parts, one the free energy of the equivalent amount of iron oxide in the bulk phase, F_b, and the other the amount of free energy attributable to the existence of the oxide at an interface, F_s.

[1] Then $F_{ox} = F_b + F_s$.

[2] Similarly, $\mu_{ox} = \mu_b + \mu_s$.

The number of moles, N, of oxide can be related to the thickness, r, by the following equation:

[3] $$N = r.A.\rho/M$$

where A is the area considered, ρ is the density, and M the molecular weight. From [3] there is obtained:

$$dN = (A\rho/M).dr.$$

Consequently μ_s in [2] above can be expressed as a function of r:

$$[4] \qquad \mu_s = \frac{\partial F_s}{\partial N} = \frac{M}{A\rho} \cdot \frac{\partial F_s}{\partial r}.$$

At a fixed pressure of oxygen, p_{O_2}, the condition for equilibrium is

$$[5] \qquad 4\mu_{Fe} + 3\mu_{O_2} = 2\mu_{ox}.$$

This assumes that the oxide formed is Fe_2O_3, which below 550°C. is very probable.
Hence

$$4\mu_{Fe} + 3\mu^0_{O_2} + 3RT \ln p = 2\mu_{ox} = 2\mu_b + 2\mu_s,$$

from which

$$[6] \qquad 4\mu^0_{Fe} + 3\mu^0_{O_2} - 2\mu^0_b = 2\mu_s - 3RT \ln p.$$

But the left-hand side of this equation is then $-\Delta F^0$, which is equal to $RT \ln K$.
Hence

$$[7] \qquad RT \ln K = 2\mu_s - 3RT \ln p.$$

For bulk oxide equation [7] reduces to $K = p^{-3}$ which gives the equilibrium pressure when the free energy is not dependent on the thickness of film. Here, because of the introduction of $2\mu_s$, p will not have the value it would have for bulk oxide. If μ_s has a positive value, p will have to have a more positive value—and correspondingly for a negative value of μ_s.

There is a second important factor to be considered, namely, the slope of the μ_s vs. r curve. (*a*) If $\partial\mu/\partial r$ is negative in a range, no equilibrium can be established in the range at a given value of applied oxygen pressure, since an increase in r will result in a lower value of μ and thus a lower value of equilibrium pressure. (*b*) On the other hand, a positive value of $\partial\mu/\partial r$ in a certain range does permit the system to come to equilibrium at definite values of p which then define values of r. From the above considerations there are seen

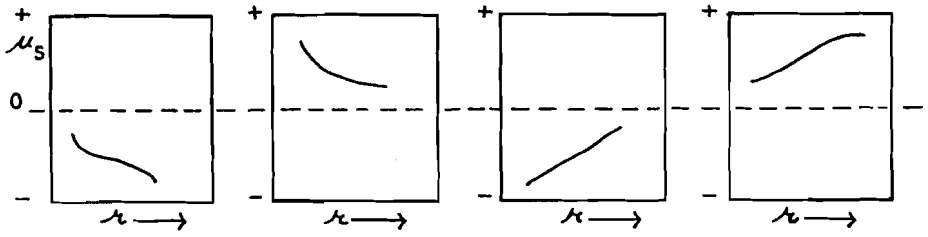

FIG. 4.

(i) $\mu_s < 0$, $\frac{\partial\mu}{\partial r} < 0$ — No equilibrium $p < p_b$

(ii) $\mu_s > 0$, $\frac{\partial\mu}{\partial r} < 0$ — No equilibrium $p > p_b$

(iii) $\mu_s < 0$, $\frac{\partial\mu}{\partial r} > 0$ — Equilibrium possible $p < p_b$

(iv) $\mu_s > 0$, $\frac{\partial\mu}{\partial r} > 0$ — Equilibrium possible $p > p_b$

to be four possibilities which are shown in Fig. 4. In the caption to this figure, p_b represents the dissociation pressure of the bulk oxide. It will be seen that the most probable situation is represented by (iv).

In the discussion so far the definition of μ_s has been by means of the differential equation [4]. It is important that it be emphasized that μ_s includes not only the free energy connected with the formation of the top layer of oxide but also the "reorganization" energy of the inner layers and of the metal–oxide interface.

Another major assumption must now be made in order to account for the experimental facts; the primary stable film is considered to be not a normal oxide, but one of higher total free energy content, perhaps amorphous in character. There are several reasons for this condition, one of which is that it is extremely difficult to obtain a definite and recognizable electron diffraction pattern from such thin films. Another is to be found in the results of high-temperature oxidation; a striking graph from a series of experiments is shown in Fig. 5, where there is clearly an induction period between stages 1 and 2.

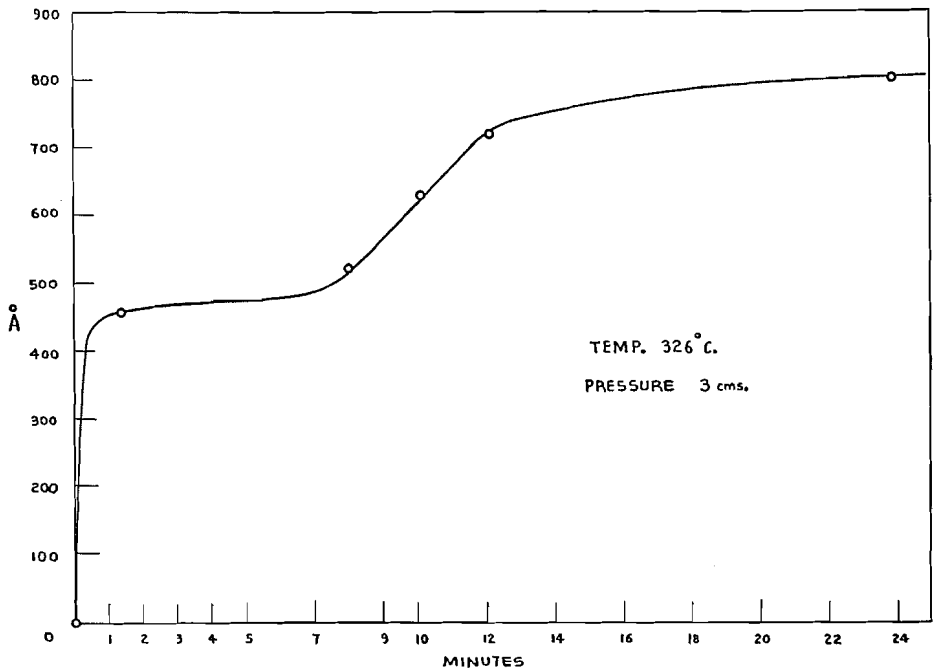

FIG. 5. Color measurement of thickness as function of time.

Mott (2) has obtained the same result for copper, by a method of direct weighing of oxygen uptake. In general, our results indicate that stage 2 can be explained on the basis of a nucleation and recrystallization process occurring to the oxide, assumed amorphous, formed in stage 1. The induction period demonstrates that the oxide in stage 1 is stable in the absence of the type of oxide formed in stage 3, which is the normal bulk crystalline α-ferric oxide.

At low temperatures the transformation does not occur readily and stable films are left on the metal.

The assumptions brought into the discussion so far could be tested if there were a direct method of measuring free energy as a function of thickness. Normally one of the most direct measurements is that of e.m.f., which is, of course, related to free energy by: $\Delta F = -n\mathcal{F}E$. There is a possibility of such a measurement here since the oxidation of iron is electrical in character and a current normally does flow in the oxide (3). An over-all equation showing the transfer of electrons can be written: $4(Fe-3e)+3(O_2+4e) \rightarrow 2Fe_2O_3$. In Mott's theory of oxidation (2) electrons are emitted from the metal through the oxide to combine with adsorbed oxygen on the oxide surface; the negative ions then set up a field across the oxide which pulls iron ions through the oxide. Unfortunately the electron current, which normally is in the external circuit, is here in the cell itself together with the ion current. This rules out direct measurement of the cell e.m.f. and destroys any simple analogy to cells containing liquid solutions.

There have been many measurements made, notably by Hackerman (1), of the contact potential difference between a noble reference electrode and an electrode of iron or other metal undergoing oxidation. The resultant readings, while showing that changes are taking place, have not been able to be interpreted. It is possible to set up a circuit which in most respects simulates the oxidizing system and produces an e.m.f. analogous to contact potential. Fig. 6 shows the proposed analogue.

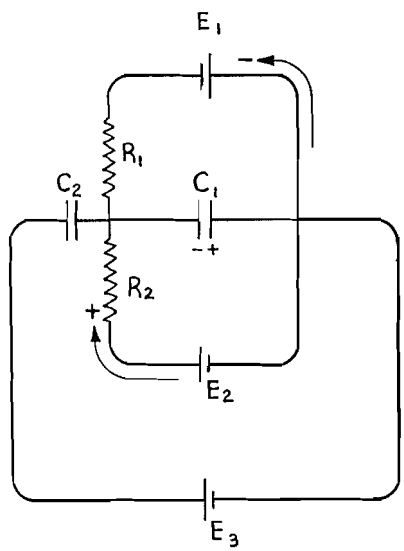

FIG. 6. Electrical analogue to pair of contacting metals, one of which is oxidizing in oxygen.

In this circuit the contact potential would appear across C_2, which is a condenser of very low capacity similar to the electrodes ordinarily used in contact potential measurements. Condenser C_1 represents the capacity of

the oxide film. R_1 is the resistance to electron flow of the oxide film, and R_2 is the resistance to positive ion flow of the same film. E_1 is the e.m.f. responsible for electron flow and according to Mott (2) is to be equated to $W+E^0-\phi$ where W is the binding energy of an adsorbed oxygen ion, E^0 is the electron affinity of oxygen, and ϕ is the work function of the metal against vacuum. E_2 is the e.m.f. equivalent to the free energy change of removing an iron ion from the metal and bringing it to the outer layer of the oxide. It is equal to $L-W_{Fe}$, where L is the sublimation energy of an iron ion and W_{Fe} is the binding energy in the external layer. E_3 is the contact potential difference between iron and the reference metal.

Before the system comes to equilibrium, growth occurs by the passage of a current around the circuit including E_1 and E_2. Growth will stop when this current drops to zero. The condenser C_1 allows simulation of the building-up of the charge on the surface of the oxide which is a feature of Mott's theory. The potential actually measured across C_2, the "contact potential", is the algebraic sum of e.m.f.'s around the circuit—it is the negative of the voltage which must be inserted to cause no current to flow when the capacity of C_2 is altered (which is the common method of measurement of contact potentials by the vibrating plate method). At equilibrium, then, the measured contact potential will be E_3-E_1 or E_3-E_2 since E_2 and E_1 must be equal and opposed. At other non-equilibrium stages, the measured contact potential will be E_3-E_2+potential drop across R_1.

The free energy change involved in the oxide growth is proportional to the algebraic sum of E_1+E_2. At equilibrium this sum is zero; consequently the relative magnitudes must change as the thickness increases.

The analogue is not too useful as yet but further study may prove its validity and increase its usefulness. The assumptions involved in the early part of this paper may be extreme and based on faulty experimental data, since accurate oxidation experiments are difficult to do. They too await further trial and proof.

HEATS OF ADSORPTION OF KRYPTON ON HIGHLY GRAPHITIZED CARBON BLACK[1,2]

By C. H. Amberg, W. B. Spencer, and R. A. Beebe

ABSTRACT

Calorimetric heats have been determined at −183°C. for the adsorption of krypton on a highly graphitized sample of carbon black. This adsorption system is of particular interest because of the extreme step-wise nature of the isotherm. Both the heat-coverage curve and the isotherm appear to be indicative of a high degree of homogeneity of the adsorbing surface.

INTRODUCTION

Graphitized carbon blacks are among the very few known solid adsorbents which appear to exhibit energetically homogeneous adsorbing surfaces. Schaeffer, Smith, and Polley (21) have described the preparation of a number of these blacks. These authors (19) found a development of steps in the argon isotherms at −195°C. on carbon blacks heat treated at successively higher temperatures up to 3000°C. (notably the 'Spheron 6' and 'P-33' series), which they interpreted as indicative of increasing homogeneity of the surface. Steps were also observed with oxygen and to a lesser extent with nitrogen as the adsorbate. Champion and Halsey (8) have predicted step-wise isotherms on homogeneous surfaces on theoretical grounds. They made use of Hill's isotherm equations (14) modified so as to include the influence of the surface force field of the adsorbent up to the nth layer. Conversely, they have shown that the smoothing out of such steps on a homogeneous surface requires untenable assumptions, and they have therefore concluded that the more common smooth type of isotherm must be due to surface heterogeneity.

A number of publications from this laboratory concerning chiefly the adsorption of nitrogen and argon on carbon surfaces show evidence of a maximum value in the heat-coverage curve at the monolayer (3, 6, 7). The evolution of what is thought to be a homogeneous surface is particularly well demonstrated by the adsorption of argon on a series of Spheron blacks (7). With heat treatment to increasingly higher temperatures causing both the removal of oxygen and also increasing graphitization, the initial high section of the heat-coverage curve is gradually both lowered and flattened out, whilst the rise due to lateral interaction between the adsorbed molecules thus becomes more clearly delineated and the maximum value at the monolayer shows a slight increase. This behavior is reflected in the second layer, but to a lesser extent, probably because adsorption into separate layers is less pronounced at that stage.

[1]*Manuscript received September 16, 1954.*

Contribution from the Chemistry Department, Amherst College, Amherst, Mass. This work was supported by the U.S. Office of Naval Research. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

[2]*Work on the adsorption of sulphur dioxide and ammonia on carbon surfaces, presented together with this material at the Kingston meeting, is described in O.N.R. Reports Nos. 4 and 5 from this laboratory and will be submitted for journal publication in the near future.*

Further indication that there may be an increase in surface homogeneity with heat treatment is given by the growth of crystallites as determined by X-ray diffraction (19). Furthermore, taking the black P-33 (2700°) as an example, the particles appear to have a structure approaching that of graphite judging from their interplanar distance, which is 3.42 Å (19) as compared to 3.35 Å for graphite (17). Planar regions, probably exposed basal planes of the graphite type, may be distinguished on the surface of the carbon black particles in the electron microscope and these may well be a decisive factor in producing those phenomena which we attribute to a homogeneous surface.

In this connection, Crowell and Young (10) have shown that the potential energy calculated for an argon atom adsorbed on the basal plane of graphite is quite insensitive to position at a given distance from the surface. The experimental evidence from adsorption work also points towards surface homogeneity in the case of graphite. Thus, for instance, Gulbransen and Andrew (12) found a distinct step for the initial part (up to $P/P_0 = 0.4$) of a krypton isotherm on graphite.

Undoubtedly, the removal of oxygen from the carbon particle at the earlier stages of the heat treatment plays its part in removing more 'active' sites and thus rendering the surface more homogeneous, an effect particularly noticeable with polar adsorbates. A number of adsorption and heat of wetting studies have dealt with this subject (4, 24).

Along with plausible indications mentioned above, there is as yet little *direct* experimental evidence available to link the 'operationally defined' degree of homogeneity of a surface to its fine structure. The well known work of Rhodin (20) on the adsorption of nitrogen on single crystal copper surfaces, also discussed by Halsey (13), presents one of the most telling demonstrations of the difference between homogeneous and heterogeneous surfaces. On single crystal faces, which were demonstrably flat on the atomic scale, clean and undistorted, the isosteric heat of adsorption curves started with nearly constant values at lower coverage up to about $\theta = 0.5$. On polycrystalline copper Rhodin found disproportionately high initial heats along with the masking of lateral interaction effects in the adsorbate. This must have been caused largely by the presence of intercrystalline boundaries.

We are indebted to Dr. G. D. Halsey for calling our attention to the extreme step-wise type of isotherm for the system krypton – P-33 (2700°) first obtained in his laboratory (23). As Dr. Halsey suggested, it would obviously be interesting to obtain calorimetric heats of adsorption for this system. Because we had been building up a considerable backlog of adsorption data for a number of adsorbates on graphitized carbon blacks, it seemed to us worthwhile to add the krypton – P-33 (2700°) system to the list for the purpose of comparison and contrast.

EXPERIMENTAL

Materials

The adsorbent used was the highly graphitized P-33 carbon black, heat treated to 2700°C. It was kindly supplied by Dr. W. R. Smith of Godfrey L.

Cabot Inc., Boston. Its characteristics have been previously described in detail by Polley, Schaeffer, and Smith (19). It has a B.E.T. nitrogen surface area of 12.5 square meters per gram. The calorimeter was loaded with 10.18 gm. of this material.

Spectroscopically pure krypton furnished by the Air Reduction Sales Company was used as the adsorbate.

All runs were done at liquid nitrogen or liquid oxygen temperatures. The former were read with an argon vapor pressure thermometer and the latter with an open-ended oxygen vapor pressure thermometer.

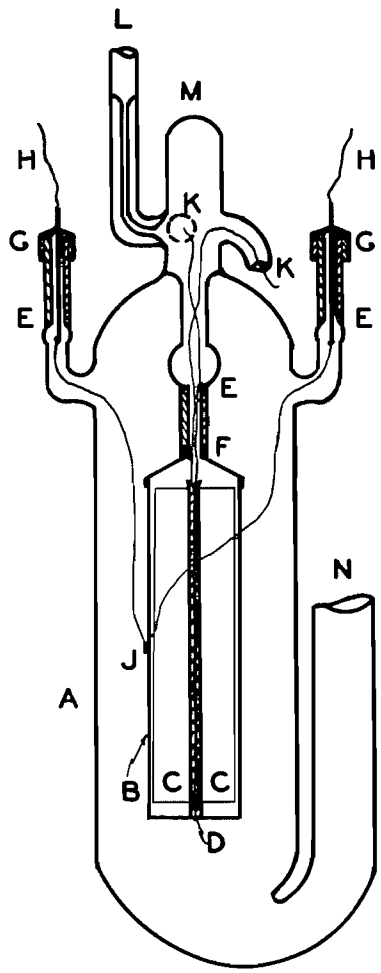

FIG. 1. Calorimeter.
A, Glass jacket; *B*, platinum cylinder; *C*, platinum fins; *D*, heater; *E*, Kovar-pyrex seals; *F*, Kovar-platinum seal; *G*, brass caps; *H*, thermocouple leads; *J*, copper–constantan thermal junction; *K*, heater leads (side arms not fully shown); *L*, inlet tube; *M*, top seal; *N*, connecting tube to pump and helium reservoir.

Apparatus and Procedure

The apparatus used for the determination of isotherms was of the conven-

tional type which has been described in previous publications from this laboratory (6).

Equilibrium pressures were read on a calibrated McLeod gauge up to 19 mm. mercury and above that on the constant volume mercury manometer using a Gaertner travelling microscope. Agreement between the two in overlapping regions was within 1%.

The calorimeter used in the present work is shown in Fig. 1. It consists of a platinum cylinder *B*, 7 cm. long, 2 cm. in diameter and of 0.25 mm. wall thickness. Into this was close-fitted a set of six platinum fins, *C*, symmetrically spaced about a central platinum tube of 3 mm. diameter which serves as the housing for heater, *D*. A clearance of 2 mm. is provided between the fins and the bottom of the cylinder to facilitate gas distribution. A platinum lid was silver soldered onto the cylinder after having been joined, at *F*, to a Kovar-pyrex seal, *E*. The Kovar inlet tube is 19 mm. long and has an inside diameter of 5.5 mm. Surrounding the platinum cylinder is a glass jacket, *A*, the spacing between the two being about one centimeter. One copper–constantan thermal junction, *J*, is silver soldered onto the outside of the platinum cylinder. The thermocouple wires (B&S No. 30 and No. 31 for copper and constantan respectively) are connected to short sections of heavier wire (B&S No. 18) and these in turn are sealed through side arms in the jacket as shown on the diagram at *G*. The heater leads are similarly sealed through side arms at *K* (not fully shown in the diagram).

Gas inlet *L* consists of a short section of 3 mm. capillary tubing, which was completely immersed in the constant temperature bath during runs; it is joined onto regular 8 mm. tubing. Thermal transpiration was thus minimized because of the relatively large diameter of the inlet tube in the region of the temperature gradient. The top of the instrument, *M*, was open for the purpose of inserting the adsorbent and installing the heater and was subsequently sealed off. The 15 mm. tube, *L*, is connected through stopcocks to the vacuum manifold as well as to a helium reservoir. Thus the calorimeter jacket may be pumped out during measurements or else helium may be admitted to it, if rapid heat exchange is desired, as it is between separate admissions of adsorbate.

The 160 ohm heater was wound from B&S No. 34 enamel covered 'Advance' wire. The coil was covered with a thin layer of aluminum foil which was held in place by four narrow strips of platinum shaped so as to provide a sliding fit with the heater housing.

The reference thermal junction was housed in an 8 mm. glass tube which, in turn, was held in a copper cylinder of 2 cm. inside diameter by a rubber stopper. The whole unit, not shown in the diagram, was wired to the calorimeter jacket. For runs at −195° the inner glass tube was filled with pump oil. This, however, was discarded for runs at liquid oxygen temperature with no apparent change in performance of the thermocouple.

Before each run the whole calorimeter was outgassed overnight at 200°. Next, the Dewar vessel containing liquid nitrogen or oxygen was raised around the apparatus and the system allowed to establish temperature equilibrium over a period of two to three hours. To accelerate this process, helium was

admitted to the jacket to a pressure of about one centimeter or higher. Finally, the jacket was pumped out and the instrument was then ready for measurements.

The methods used for the measurement of electrical energy input during calibrations and for amplification and recording of the thermal e.m.f. have been described in previous publications from this laboratory. A Perkin–Elmer d-c. breaker–amplifier was used in conjunction with an Esterline–Angus automatic recorder. The procedure outlined by Beebe and Dell (4) was followed.

RESULTS AND DISCUSSION

The results of two separate runs are shown in Figs. 2 and 3. Fig. 2 represents the isotherm of krypton on P-33 (2700°) at −183° plotted as volume adsorbed versus relative vapor pressure. Values for the saturation vapor pressures of solid krypton were taken from the data of Keesom, Mazur, and Meihuizen (16).

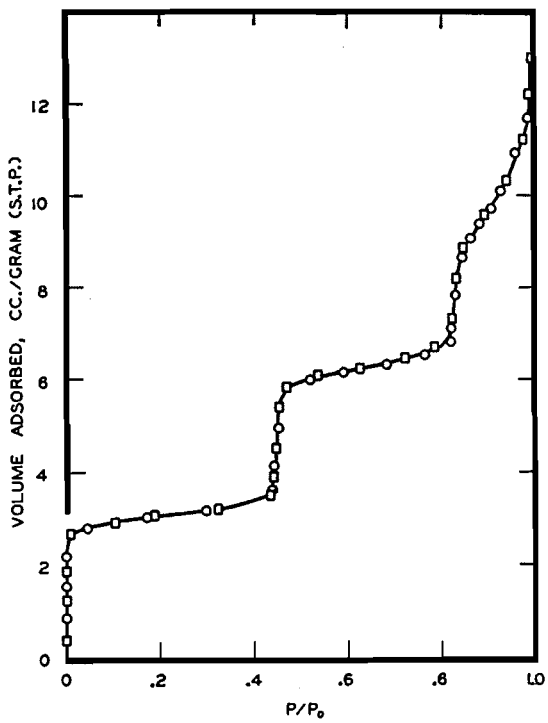

FIG. 2. Isotherm, adsorption of krypton on P-33 (2700°) carbon at −183°C.: ○, run 1; □, run 2.

The highly pronounced step-wise character of this isotherm had already been demonstrated by Singleton and Halsey at the boiling temperature of liquid nitrogen (23). There is no appreciable difference in the sharpness of comparable steps at the two temperatures. We have also determined a krypton isotherm on Spheron (2700°) which is known to be less highly graphitized than

the P-33 (2700°) sample. As expected the isotherm on Spheron (2700°) had a somewhat less step-wise character.

Singleton and Halsey argued that the adsorption of krypton in their case reached a definite limiting value at the saturation pressure of bulk solid krypton somewhere between the fifth and sixth layers. This was supported by a model (22) which predicts a limiting value between the fourth and fifth layers at saturation. We have repeated their calculation for the −183° isotherm with the same result. Unfortunately, our data near saturation are not sufficiently definitive to decide between an isotherm which crosses the $P/P_0=1$ ordinate or one which proceeds to a very large value at saturation. The latter was assumed to be the case with the systems studied by Beebe, Beckwith, and Honig (2) who employed vapor pressures of liquid krypton extrapolated to below the triple point.

In Fig. 3 the calorimetric heats for krypton on P-33 (2700°) at −183° are plotted as a function of the volume adsorbed. As corrections for the heats of compression are negligible, the calorimetric heats may be said to represent the true isosteric heats of adsorption.

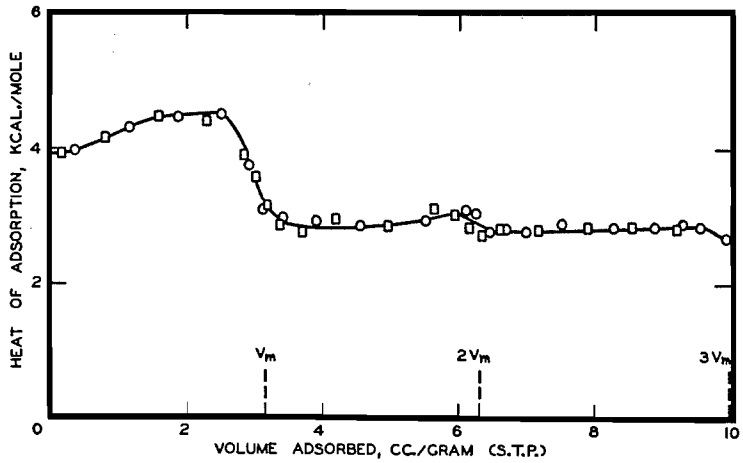

FIG. 3. Heats of adsorption, krypton on P-33 (2700°) carbon at −183°C.: ○, run 1; □, run 2.

The curve shows the expected rise due to lateral interaction between adsorbate molecules in the first layer, amounting to about 600 cal./mole adsorbed. A steep drop of about 1600 cal./mole occurs at the completion of the monolayer and the curve levels off at 200 cal. above the heat of sublimation of krypton. The latter was calculated by means of the Clapeyron equation from vapor pressures given by Mathias, Crommelin, and Meihuizen (18). (The analogous figures for argon on Spheron (2700°C.) (7) are about 400 cal./mole for the rise in the first layer and 800 cal./mole for the steep drop. These figures, of course, are not strictly comparable, since the two carbon surfaces represent a different degree of homogeneity.) The same pattern is reflected in the second adsorbed layer of krypton, although to a much smaller extent. The maximum

rises only 200 cal. above the minimum value in the second layer and the well defined drop into the third layer amounts to some 250 cal. A small rise in the second layer for argon was observed, but the descending part following it is more gradual than with krypton; this conforms well to the picture of less sharp separation into adsorbed layers in the case of argon. There is an indication of a third step into the fourth layer in our case. Since, however, heat values at coverages higher than those reported show an unreasonably large scatter (undoubtedly owing to condensation effects in the calorimeter) not too much reliability can be claimed for the third drop at the end of the curve.

The heats of adsorption and the isotherm of krypton on P-33 (2700°) were also measured at −195°. Our isotherm agreed well with that given by Singleton and Halsey (23) except in the first low pressure region, where our pressure values were somewhat higher. This was due to our not having waited longer than two hours for the attainment of equilibrium. Our attention was focused on the measurement of the heat evolved during the first few minutes following the admission of a gas increment to the system and the exact equilibrium pressure was not a critical quantity in our heat determination. The observed heats in the first layer at −195° are more or less constant with coverage, which leads one to suspect initial non-selective adsorption on the most readily accessible part of the carbon black, followed by a subsequent redistribution of the krypton too slow to be detected by our calorimeter (5). Beginning with the first steep drop in the heat curve, agreement between the heats of adsorption at the two temperatures was excellent. This is plausible, as one would not expect a very large temperature coefficient of the heat of adsorption; thus, for instance, the heats of vaporization of liquid krypton differ by only 0.14% over the 13° range, as calculated from the equation given by Mathias, Crommelin, and Meihuizen (18).

For the same reason it appears valid to employ the integrated form of the Clausius–Clapeyron equation over this temperature range in order to calculate the isosteric heats for an intermediate temperature from the two isotherms. It is worthy of note that the agreement was quite good beyond a coverage of 3.0 cc./gm., if we compared the heats obtained by calorimetry with those calculated from the isotherms. However, the calculated heats in the region 0–3.0 cc./gm. are far from being in agreement with the calorimetric values; this was to be expected because of the known errors in the pressure measurements in the region of low coverage.

Differential and integral molar entropies were calculated from the calorimetric heats and the isotherm at −183° (1) using the equations given by Drain and Morrison (11). The entropy-coverage curves follow the characteristic pattern found, for instance, by Hill, Emmett, and Joyner for the system nitrogen–Graphon (15). Crossing of the two curves takes place at the monolayer, where there is a minimum in the integral entropy curve. Although the curves as calculated do not actually cross at the completion of the second layer, a second minimum in the differential entropy approaches the integral curve very closely and the curves could be said to cross within the limit of error of these calculations.

In conclusion it may be said that both the isotherm and heat data point again to a highly homogeneous surface in the case of P-33 (2700°).

In view of the X-ray and electron micrograph data cited in the Introduction one might argue that the surface of these carbon particles consists chiefly of crystallites whose basal planes are arranged in directions parallel to the plane faces of the irregular polyhedra of the kind detectable by means of the electron microscope. This still leaves unanswered the question of why a surface, where lattice defects, crystallites in the surface oriented in directions other than parallel to it, and edge effects are bound to be significant factors in its topography, shows practically none of the experimental signs of heterogeneity such as smoothed out isotherms (such as type II of the B.E.T. classification) and monotonically decreasing heat of adsorption curves in the first and higher layers. One must remember, that the original P-33 particle before heat treatment consisted of a random arrangement of crystallites. It is not likely that these have arranged themselves to form a perfect surface of basal planes. Even if that were so, one might still expect boundaries between adjacent planes to be the seats of higher energy sites. Possibly the explanation is to be sought in terms of favorable packing of the crystallites even within the imperfectly ordered particle. It should be pointed out in this connection that although the distance between nearest neighbours in the hexagonal structure of the basal plane of graphite is 1.42 Å, or slightly less than half the distance between basal planes, the distance across the hexagon is of the same order of magnitude as that between planes. Thus a non-polar adsorbate atom or molecule placed over the center of a carbon hexagon may well be subjected to forces similar to those operative over the edges of a 'bundle' of planes oriented in a direction normal to a geometric plane which is tangential to the surface. In other words, if the distance between carbon neighbors on the surface nowhere exceeds the interplanar distance of 3.35 Å by a significant amount, the model of Crowell and Young (10) (or in a simpler form by Crowell (9)) may still be applicable for argon and other adsorbates which approach the surface less closely. Adsorbates with a closer approach may well be more sensitive to irregularities in the surface. It is therefore not surprising to find that a graphitized carbon black shows the symptoms of homogeneity to a more marked degree for krypton than it does for argon. It would be interesting to have data available for adsorbates of smaller atomic or molecular cross-section, such as neon or helium, on a highly graphitized carbon surface.

ACKNOWLEDGMENTS

The authors are indebted to Dr. G. D. Halsey for making available, prior to its publication, his manuscript containing krypton adsorption data (23). Our thanks are also due to Dr. J. M. Holmes for his helpful suggestions in working out some of the experimental details of this investigation.

PHYSICAL ADSORPTION STUDIES IN CARBON BLACK TECHNOLOGY[1]

By M. H. Polley, W. D. Schaeffer, and W. R. Smith

ABSTRACT

The adsorption isotherms of *n*-butane and butene-1 on typical furnace and channel carbon blacks were determined over a range of temperatures, 55°–250°C. The adsorption of *n*-butane on carbon black surfaces is attributed to physical adsorption; however, the extent of surface covered per unit area of carbon black is considerably greater at a given temperature than for a silica. Butene-1 is also physically adsorbed on the furnace blacks. The presence of approximately 3% chemisorbed oxygen on the surface of the channel blacks induces an isomerization of butene-1 to *cis*-butene-2. When oxygen is first chemisorbed on a furnace black surface, then that surface also interacts with butene-1. Those blacks which participate in the isomerization of butene-1 respond or "interact" in a cyclic heat treated Butyl rubber – carbon black masterbatch.

INTRODUCTION

In the field of carbon black technology, the properties that carbon black imparts to inks, lacquers, and rubber compounds are largely dependent upon the extent of surface and the nature of the carbon black employed. Of course, the extent of carbon surface is easily measured by low temperature nitrogen adsorption or by evaluation of electron micrographs. The former estimates the total surface area, while the electron micrograph pictures the external surface area. The nature of the carbon black surface, on the other hand, is not as easily defined but may be characterized by the concentration and type of chemisorbed complexes that reside on the carbon black surface. It is often the nature of the carbon black surface that is responsible for the marked effects some carbon blacks produce in application. The presence of chemisorbed complexes accounts for such effects as slowing the rate of cure in rubber compounds or developing flow in lithographic inks.

One industrial development in which the nature of the carbon black surface plays an important role is in the cyclic heat treatment of Butyl rubber. This process was developed by the Esso Laboratories and is described by Gessler and co-workers (2, 3, 5, 8). The cyclic heat treatment of Butyl rubber produces increased modulus, increased tensile, increased elasticity, and increased abrasion resistance. The processing involved is simply the heat treatment of a carbon black – Butyl rubber masterbatch at 160°C. followed by milling for five minutes. This is repeated for the desired number of cycles. The improvement in reinforcement properties is associated with the chemisorbed oxygen present on the channel black surface. Furnace blacks or "devolatilized" channel blacks did not show corresponding improvement. However, if a furnace black was first oxidized before it was compounded in Butyl rubber, it then responded to the cyclic heat treatment process. It was postu-

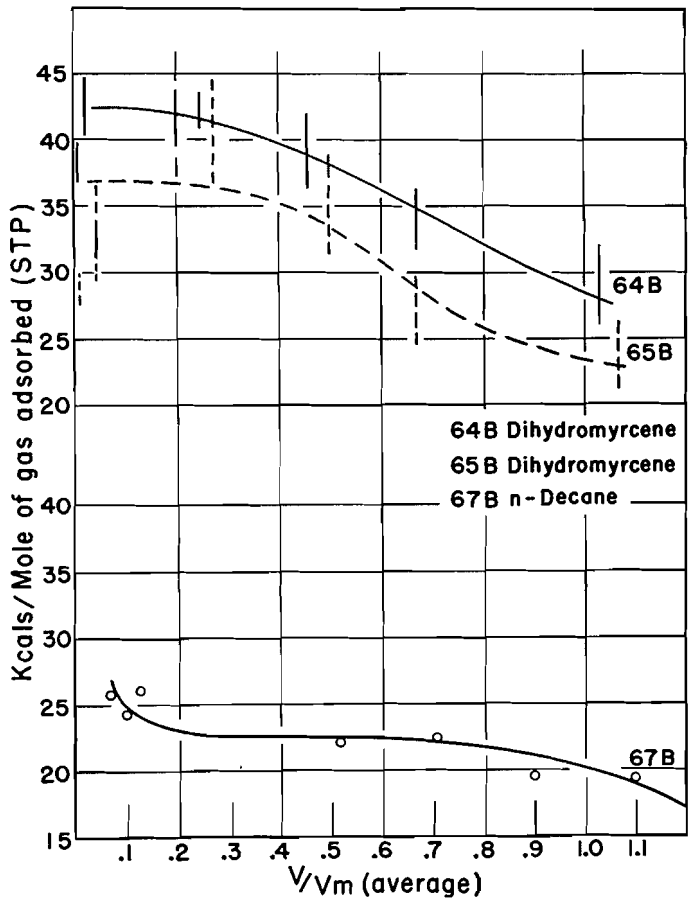

FIG. 2. Differential heats of adsorption at 100°C., Spheron 6.

lated that this cyclic heat treatment produces: (1) enhanced anchorage of polymer-to-carbon clusters or particles, and (2) subsequent milling disaggregates these carbon clusters by virtue of the enhanced anchorage, making new surface available for further polymer–carbon linkage.

If the reinforcement developed was due to this polymer–black interaction as suggested, then could this interaction be studied more simply by gas phase adsorption of hydrocarbons analogous to the Butyl polymer? Earlier studies (1) on the heats of adsorption of the four- and five-carbon hydrocarbons on carbon blacks at 0°C. were typical examples of *physical* adsorption. No interaction was apparent between any of the adsorbed molecules and the carbon blacks studied. In Fig. 1, the isotherms for *cis*-butene-2, butene-1, and *n*-butane on Spheron 6 carbon black are shown. Spheron 6 is a channel black having about 3% chemisorbed oxygen on the surface. If these isotherms were plotted against relative pressure, they would be nearly superimposed. Later work (4) with *n*-decane and dihydromyrcene at 100°C. did show evidence of some sort of interaction of the dihydromyrcene with Spheron 6 that was absent with the "devolatilized" Spheron 6, absent with the "ion-exchanged" Spheron 6, and absent with furnace black. The heats of adsorption in Fig. 2 illustrate the presence of this interaction, possibly a cyclization of the dihydromyrcene. Unfortunately, the reaction product was not identified.

The present work describes adsorption research continued with the four-carbon hydrocarbons, *n*-butane and butene-1, at higher temperatures than those used earlier. The temperatures were chosen to coincide with those employed in the Butyl heat cycling process.

EXPERIMENTAL

The carbon blacks chosen for study were similar types to those used by the Esso Laboratories and could be separated into two main groups, i.e., those that do not respond to the heat cycling process and those that do. With the first group of blacks no interaction would be expected between the butene-1 and the carbon black surface. With the second group, if the response to heat cycling is due to polymer–carbon linkage, then there may be evidence of interaction between the butene-1 and the chemisorbed oxygen on the carbon black surface.

The apparatus and procedures were similar to those used in earlier experiments (1). A constant temperature bath containing various refluxing liquids provided temperatures of 55°, 109°, and 179°C.

RESULTS

Fig. 3 illustrates the type of adsorption isotherm that is obtained for butene-1 on a variety of adsorbents at 109°C. or roughly 115° above the boiling point of the butene-1. The "devolatilized" Spheron 6 is simply a standard channel black which has been heated to 957°C. for one hour in a vacuum to remove most of the chemisorbed oxygen. The surface area was 109.7 sq. meters per gram. The Vulcan 3 and Vulcan 9 are oil furnace blacks containing less than 1% chemisorbed oxygen. They differ principally in surface area—the Vulcan

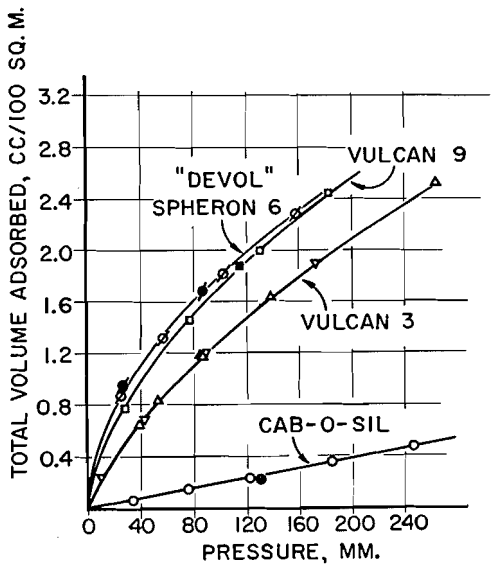

FIG. 3. The adsorption of butene-1 at 109°C., open points—adsorption; solid points—desorption.

3 having an area of 77 sq. meters per gram and the Vulcan 9 having an area of 134 sq. meters per gram. The Cab-O-Sil is a 99% pure silica formed in a high temperature flame process. Its surface area is 152 sq. meters per gram. To eliminate these surface area differences, the volume adsorbed has been expressed as cc. (S.T.P.) per 100 sq. meters. Surprisingly enough, the volume of gas adsorbed at 109°C. is as much as one sixth that of the volume adsorbed at 0°C. for the carbon blacks. Like the 0°C. data, these isotherms were completely reversible and reproducible. Pressure equilibration was fairly rapid—generally in about 10–15 min. Although not illustrated on this graph, the *n*-butane isotherm on the Vulcan 3 sample lies very close to the butene-1 curve for the same black. The most interesting feature in this set of isotherms is the large difference in the magnitude of adsorption of butene-1 on a non-polar carbon black surface as opposed to a polar silica surface. Our earlier work (6) with butene-1 on silica gel at 0°C. revealed heats of adsorption nearly identical with that of carbon black, and the silica gel isotherms when plotted per unit area were only about 10% lower than that of the carbon black. However, Emmett (7) found for *n*-butane on a silica alumina catalyst an adsorption of 0.04 cc. per 100 sq. meters at 100°C. and one atmosphere pressure. This is even a lower order of magnitude than the data for the Cab-O-Sil.

In the second group of pigments, i.e., those that do show a response to the Butyl heat cycling process, standard Spheron 6 is the most familiar. Fig. 4 shows that the adsorption per unit area has just about doubled in volume from the values of the blacks in the previous graph. The solid desorption points on the upper curve give evidence of hysteresis. The lower isotherm, which was a repeat run on the same Spheron 6 sample, shows the poisoning effect of the first experiment. In addition, the pressure equilibration time is now greater

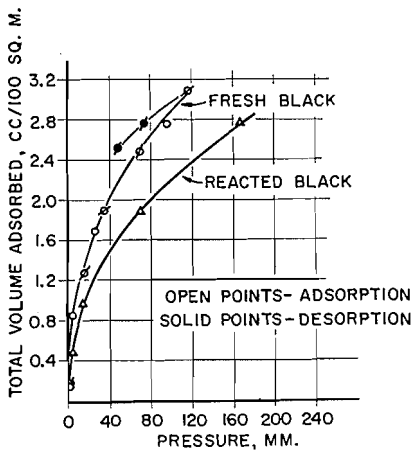

FIG. 4. The adsorption of butene-1 on Spheron 6 at 109°C.

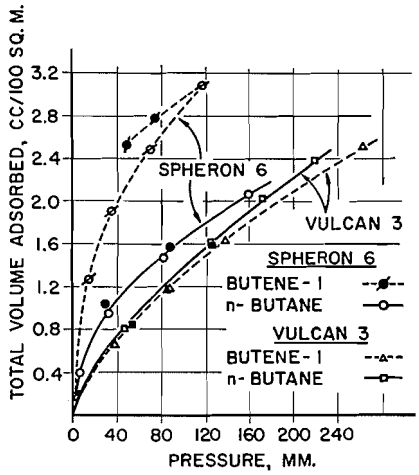

FIG. 5. The effect of unsaturation at 109°C., open points—adsorption; solid points—desorption.

than one hour. These isotherms do not represent true equilibrium points, as the final pressure reading was generally taken at some 95% of equilibrium. Considering this fact, the agreement of the two runs on fresh black in the upper curve is quite good. Thus, with hysteresis, poisoning, and slow pressure equilibration, it appears that there is evidence of some type of interaction occurring between the butene-1 and the chemisorbed oxides present on the Spheron 6 surface. This interaction is not evident when *n*-butane is adsorbed on Spheron 6. The effect of unsaturation on the adsorption isotherms for the Spheron 6 channel black as compared to the Vulcan 3 furnace black is shown in Fig. 5. The non-polar Vulcan 3 surface scarcely can differentiate between the two adsorbates, butene-1 and *n*-butane.

If this interaction was not seen at 0°C. either in the isotherms or in the heats of adsorption measurements, then at what point does it become evident? Fig. 6 illustrates the effect of temperature on the adsorption of butene-1 on Spheron 6. The desorption points are not plotted on the 0°C. isotherm, but at the high pressures they were coincident with the adsorption curve. Hysteresis is seen at 55°C. though the reaction is very slow at this temperature. Desorption points were not obtained on the 179° and 250°C. runs, but in these experiments the reaction rate had increased markedly.

Two other carbon blacks, in addition to Spheron 6, have been tested in Butyl rubber and did respond to the heat cycling process. They are oxidized Vulcan 3 and an experimental channel black. These two carbon blacks shown in Fig. 7 have about 3% chemisorbed oxygen on the surface, while the oxidized Printex U has about 9%. Volatile analysis experiments now in progress have shown differences in the type of volatile matter that is contained on these various surfaces.

Mass-spectrometer analysis has confirmed the purity of the original butene-1 and also has identified the desorbed gas from the butene-1-standard Vulcan 3

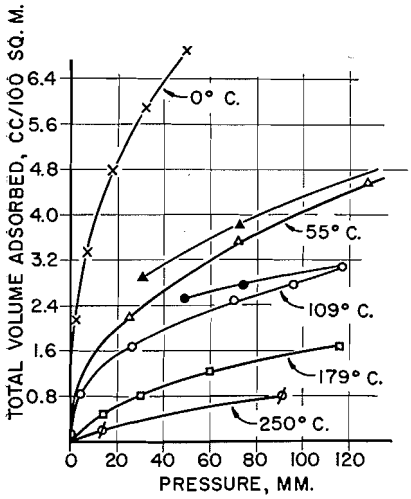

FIG. 6. The effect of temperature on the adsorption of butene-1 on Spheron 6.

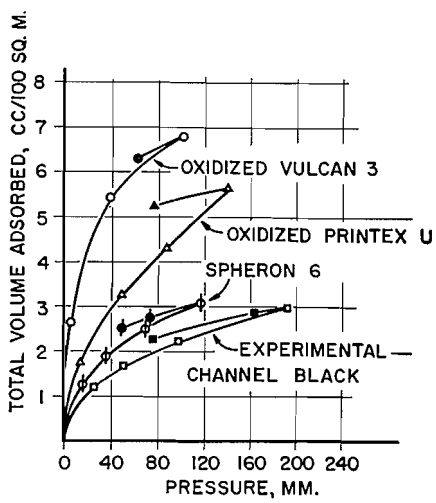

FIG. 7. The adsorption of butene-1 at 109°C.

isotherm as pure butene-1. The reaction product of the butene-1-Spheron 6 isotherm contained a mixture of butene-1 and *cis*-butene-2. Thus, the interaction is an isomerization reaction.

The nature of the carbon black – polymer association in the heat-cycled Butyl rubber is still undefined, yet, here, by a relatively simple adsorption experiment, it has been possible to predict the performance of a carbon black in a heat-cycled Butyl rubber compound.

ACKNOWLEDGMENT

The authors wish to thank Mr. Murray Bazinet of the National Research Corporation, Cambridge, Mass., for the mass-spectrometer analyses.

CHARCOAL SORPTION STUDIES

III. THE ADSORPTION OF ETHYLENE AND PERFLUOROETHYLENE BY AN ACTIVATED CHARCOAL[1]

By H. L. McDermot, J. C. Arnell, and B. E. Lawton

ABSTRACT

The adsorption of ethylene and perfluoroethylene by an activated charcoal has been measured over a range of temperatures. Integral and differential heats have been calculated and compared for the two gases. The heats of adsorption of perfluoroethylene are consistently higher than those of ethylene, but only by an amount to be expected from the difference in molecular weights. The absolute entropy of adsorbed ethylene has been calculated and found to be in agreement with a model in which the adsorbed molecules are mobile and possess at least two degrees of rotational freedom.

INTRODUCTION

The factors influencing the adsorption of hydrocarbons on carbon surfaces have been exhaustively studied by Beebe and his co-workers (1, 2). Beebe *et al.* (2) measured the heats of adsorption calorimetrically for the adsorption of a series of hydrocarbons on a non-porous carbon black. The hydrocarbons chosen were paraffins and olefins containing four or five carbon atoms, and included geometrical isomers and one positional isomer. It was found that for any given coverage the differential heat of adsorption was directly proportional to the number of carbon atoms in the hydrocarbon, but was independent of the presence of unsaturation in the compound or of the arrangement of the carbon atoms in the molecule. In a subsequent paper, Beebe *et al.* (1) showed that the heat of adsorption per carbon atom of the adsorbate was diminished with respect to the value found for the linear isomers, if the molecular arrangement of the adsorbate was such that one of the carbon atoms projected into space when the others were in the plane of the surface. For example at a coverage of $\theta = 0.2$, the differential heat of adsorption of neopentane was reported by these workers to be 1.6 kcal. per carbon atom compared with a value of 2.5 kcal. per carbon atom for *n*-pentane. The work of Beebe's group has demonstrated that with the exception of neopentane and cyclohexane the differential heat of adsorption per carbon atom of hydrocarbon at a coverage of $\theta = 0.2$ lies between 2.5 and 2.65 kcal. per carbon atom.

The present work was undertaken to make a careful study of the adsorption of a simple hydrocarbon on a carbon surface and to investigate the effect of replacing all the hydrogen atoms of the hydrocarbon by fluorine atoms. To this end adsorption isotherms are presented for the adsorption of ethylene and perfluoroethylene by an activated charcoal. Thermodynamic quantities for the adsorbed phase have been calculated by the methods outlined by Hill (6).

Contribution from the Defence Research Chemical Laboratories, Ottawa, Canada. Also issued as DRCL Report No. 178. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.

PROCEDURE

The charcoal employed in this study was a zinc chloride activated maple charcoal of extremely low ash content whose properties have been reported elsewhere (10).

The ethylene was procured from the Ohio Chemical Co. It was reported to be 99.5% pure and was used without any further purification. The perfluoroethylene was made by the pyrolysis of polytetrafluoroethylene and purified by low temperature fractional distillation.

The charcoal was prepared for adsorption measurements by evacuation at 200°C. for at least 12 hr. The perfluoroethylene isotherms were measured by a gravimetric method. A sample of charcoal weighing approximately half a gram was placed in a bulb fitted with a stopcock and a tapered joint so that the sample could be removed from the system and weighed. The adsorption isotherm was measured by admitting gas to the charcoal, allowing the system to equilibrate, and then removing the sample from the system and weighing it. The weight of gas adsorbed was simply the difference between this weight and that of the evacuated sample. With the exception of the isotherm at 273.2°K. for which an ice bath was used, simple water thermostats were used for the measurements at all the other temperatures. Isotherms were measured at 273.2°, 290.5°, 295.8°, 302.0°, and 308.5°K. The isotherms are plotted in Fig. 1 and are reversible within the experimental error of the measurements.

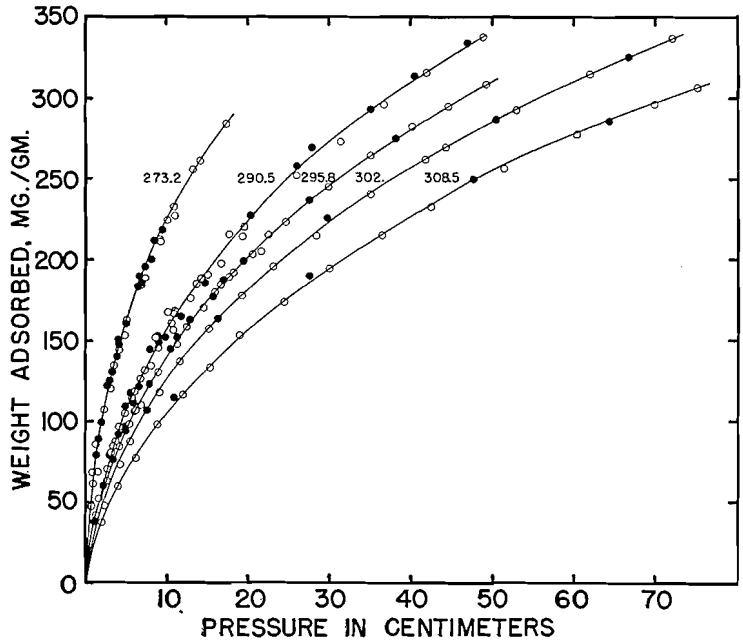

FIG. 1. Adsorption isotherms for perfluoroethylene on charcoal. Open symbols denote adsorption. Closed symbols denote desorption.

To achieve greater precision than was attained in the perfluoroethylene isotherms, the ethylene isotherms were measured volumetrically in a standard

volumetric adsorption system. A slightly larger sample of charcoal was used than that employed in the perfluoroethylene measurements, but its treatment prior to adsorption measurements was the same. An ice bath was used for measurement of the isotherm at 273.2°K. To attain the lower temperatures an ethylene glycol – water bath was used which was cooled by a copper coil through which liquid air was circulated at a rate controlled by a vapor pressure regulator. Sulphur dioxide was used in the regulator at 260.8°K. and methyl chloride at 245.4°K. The ethylene isotherms displayed a small amount of hysteresis over the pressure range studied. The adsorption points were somewhat scattered and slightly displaced in the direction of higher pressures with reference to the desorption points. It was also observed that on adsorption the system required extremely long periods of the order of eight hours to equilibrate compared with short periods of about 15 min. on desorption. The short equilibration times on desorption and the exact reproducibility of the desorption points taken over many separate runs are believed to be convincing proof that the adsorption points are not at true equilibrium, but represent metastable states due perhaps to slow diffusion of gas into the granules of the charcoal. Accordingly the adsorption points have not been plotted in Fig. 2, which

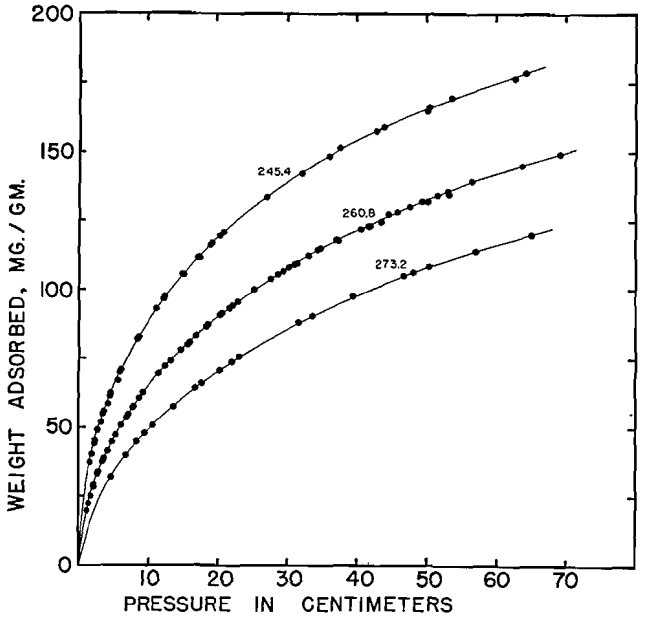

FIG. 2. Adsorption isotherms for ethylene on charcoal.

shows the desorption points for the isotherms at 273.2°, 260.8°, and 245.4°K. The absence of corresponding hysteresis effects in the perfluoroethylene–charcoal system can possibly be accounted for by the following: (1) the gravimetric method is not as sensitive as the volumetric, and (2) removal of the adsorption cell from the thermostat for weighing tends to obscure hysteresis effects if the bath temperature is lower than room temperature.

Thermodynamic quantities were calculated by the methods outlined by Hill (6). Isosteric heats and integral heats were calculated by means of the equations

$$Q_{ST} = \left(\frac{\partial \ln p}{\partial T}\right)_v RT^2,$$

$$H_G - H_S = \left(\frac{\partial \ln p}{\partial T}\right)_\phi RT^2,$$

$$\phi = RT \int_0^p \frac{V}{p}\, dp,$$

where Q_{ST} is the isosteric heat, $H_G - H_S$ is the integral heat, and the other symbols have their usual meaning. The fraction of the surface covered, θ, was estimated from the area of the charcoal as measured by the low temperature adsorption of nitrogen and from the areas of the adsorbate molecules as calculated from their liquid densities. The isosteric and integral heats are plotted as a function of θ in Figs. 3 and 4 respectively. As a check on the internal consistency of the calculations, the isosteric heat was computed also by means of the equation

$$Q_{ST} = H_G - H_S + \frac{T}{V}\left(\frac{\partial \phi}{\partial T}\right)_v$$

and compared with the isosteric heat calculated in the usual manner. The measure of agreement reached in the case of ethylene is shown in Fig. 5. The difference between the integral molar entropy of the adsorbed phase and that

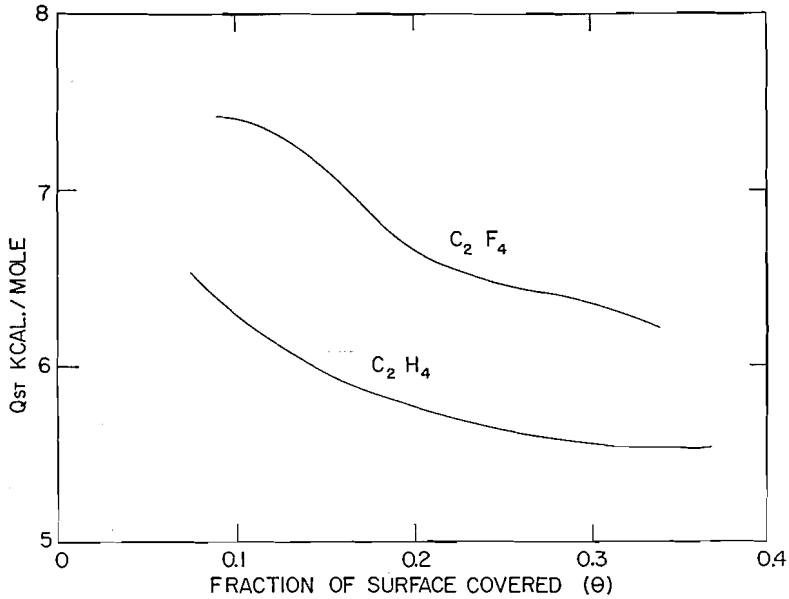

FIG. 3. Isosteric heats for the adsorption of ethylene and perfluoroethylene by charcoal.

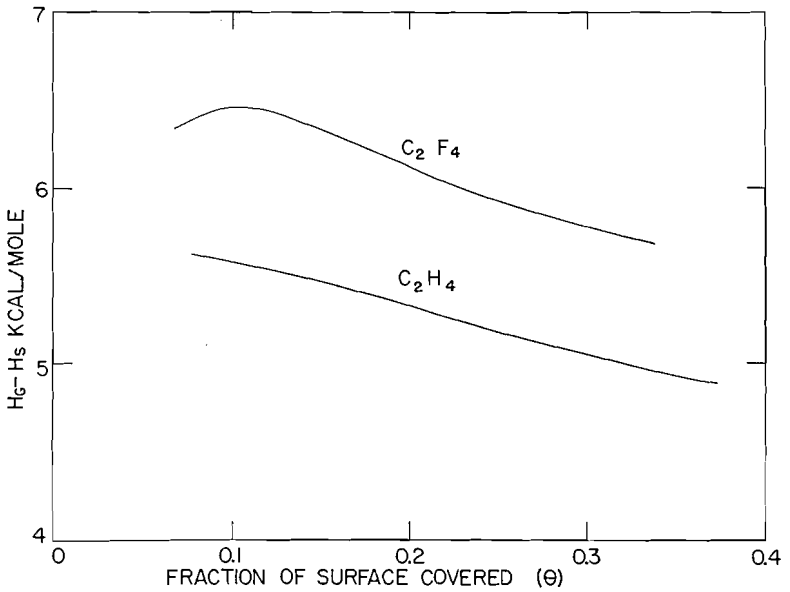

FIG. 4. Integral heats for the adsorption of ethylene and perfluoroethylene by charcoal.

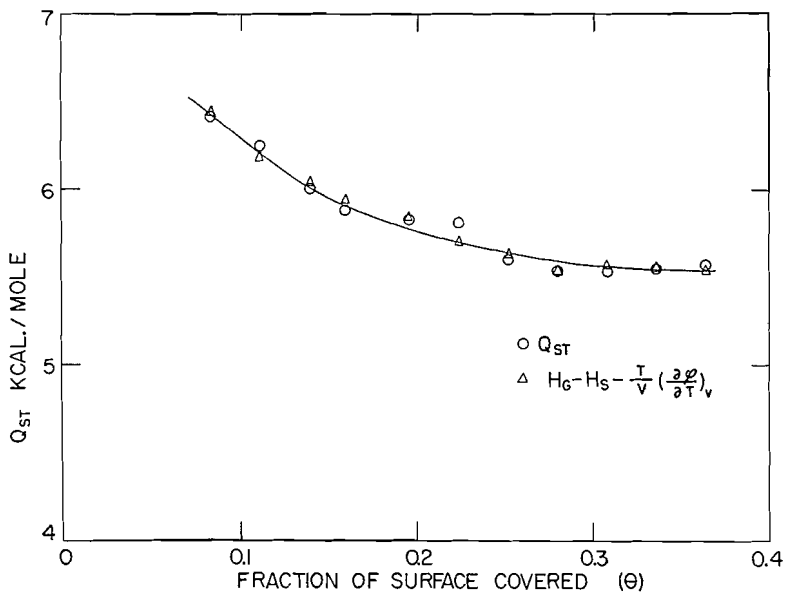

FIG. 5. Isosteric heats calculated in two different ways for the adsorption of ethylene by charcoal.

of the gas at the equilibrium pressure was computed from the equation

$$S_G - S_S = (H_G - H_S)/\bar{T},$$

where $\bar{T}$ is the mean temperature of the isotherms. The quantity $S_G - S_S$ is plotted as a function of θ for both gases in Fig. 6.

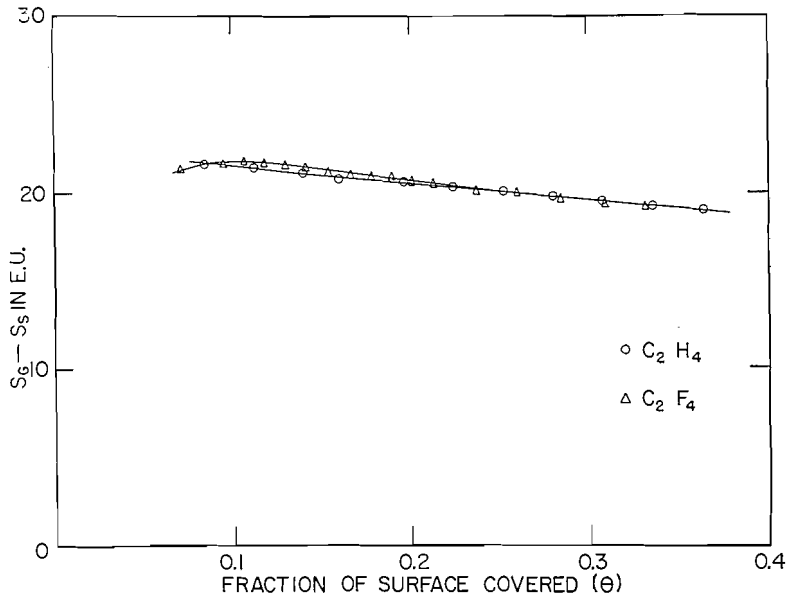

FIG. 6. Integral molar entropy changes accompanying the adsorption of ethylene and perfluoroethylene by charcoal.

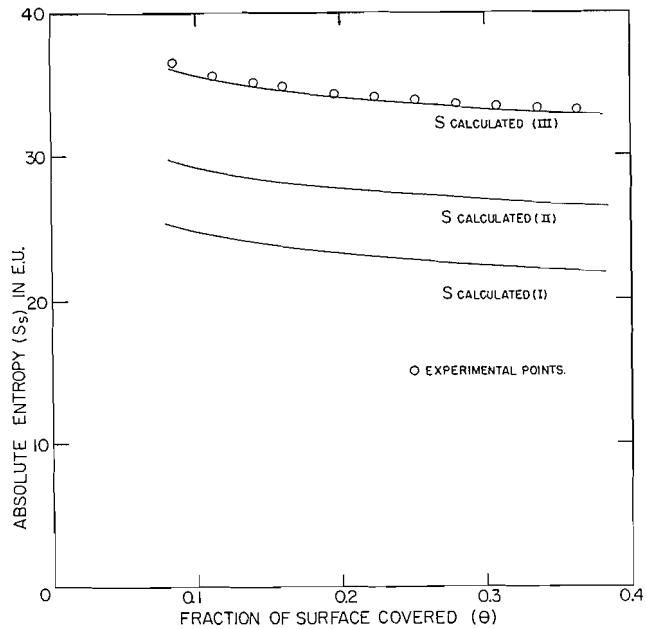

FIG. 7. Absolute entropy of ethylene adsorbed by charcoal. Circles denote experimental points. Solid lines are calculated values.

The absolute entropy, S_S, of the adsorbed ethylene was calculated from the quantity $S_G - S_S$ using the value of 51.1 e.u. (4) for the entropy of the gas at a pressure of 1 atm. and at the temperature $\bar{T}$. Experimental values of S_S are

presented in Fig. 7 along with theoretical curves based on three adsorption models.

DISCUSSION

Experimental values of the entropy of adsorbed ethylene are presented in Fig. 7 along with theoretical curves based on three adsorption models. The theoretical curves were calculated by means of the following equations derived from simple statistical thermodynamics

$$S_{\text{trans}} = R \ln \frac{2\pi mkTeA}{h^2} + 2,$$

$$S_{\text{rot}} = R\left[\ln \frac{1}{\pi\sigma}\left\{\frac{8\pi^3 (I_A^a\, I_B^b\, I_C^c)^{1/n} kT}{h^2}\right\}^{\frac{1}{2}n} + \frac{n}{2}\right]$$

where S_{trans} is the translational entropy, A is the area available per molecule, S_{rot} is the rotational entropy, $a+b+c = n$ is the number of degrees of rotational freedom possessed by the molecule, I_A, I_B, and I_C are the moments of inertia, and σ is the symmetry number. The area available per molecule, A, was calculated from the relationship $A = \Sigma/N$, where Σ is the area of the adsorbent. The first curve, labelled $S_{\text{calculated}}$(I), represents the case where the adsorbed molecules possess two degrees of translational freedom and one degree of rotational freedom in the plane of the surface. In the second model, $S_{\text{calculated}}$(II), the molecules are endowed with two degrees of translational freedom and two degrees of rotational freedom in the plane of the surface. The third curve, $S_{\text{calculated}}$(III), is calculated by assigning the molecules two degrees of translational freedom and all three degrees of rotational freedom.

Kemball (9) has suggested that a molecule that has lost one degree of translational freedom may acquire in its place a vibrational degree of freedom which may result in an entropy contribution of from 0 to 5 e.u. The following equations given by Kemball (9) have been used to estimate the entropy contribution due to vibration of the ethylene molecule:

$$\nu = L\, V_m^{-\frac{1}{3}}\, T_m^{\frac{1}{2}}\, M^{-\frac{1}{2}}$$

$$\text{and } S_{\text{vib}} = R[(h\nu/kT)(e^{+h\nu/kT}-1)^{-1} - \ln(1-e^{-h\nu/kT})],$$

where ν is the frequency, L is a constant having the value 2.8×10^{12}, V_m is the molecular volume, and T_m is the melting point. At 259°K., S_{vib} was calculated to be 4.1 e.u.

If interaction exists between the adsorbed molecules, an entropy contribution may be expected from this source. However in the present experiments, it is hoped that the coverage is sparse enough to lead to negligible interaction between adsorbed molecules. Some evidence exists to show that this is indeed the case. Graham (5) has suggested that adsorption systems may be characterized by the form of the curve obtained by plotting the quantity $\theta/(1-\theta)p$, which he calls the equilibrium function, against θ, the fraction of the surface covered. If this is done for ethylene and perfluoroethylene it is found that the equilibrium function decreases steadily with increasing θ. According to Graham, this type of behavior is characteristic of adsorption on a non-uniform surface with no interaction between adsorbed molecules. Consequently, it is believed that the contributions arising from molecular

interaction may be neglected up to the highest coverage attained in these experiments, although they would undoubtedly become important at higher coverages. If Kemball's suggestion is accepted, then the theoretical values presented in Fig. 7 must all be increased by 4.1 e.u. It is at once apparent that $S_{\text{calculated}}$(III) will be appreciably above the experimental values over the whole range of coverage investigated and that $S_{\text{calculated}}$(I) will still be considerably below the experimental values. Thus on this basis Model III may be ruled out and it may be inferred that insufficient degrees of freedom were assigned to the molecule in the case of Model I. Model II with the addition of a weak vibration remains as the final choice, and indeed the values so calculated account for 93% of the experimentally measured entropy. The difference between $S_{\text{calculated}}$(II) plus 4.1 e.u. and the experimental values is 2.4 e.u. over the coverage studied. The experimental values are accurate to approximately 1 e.u. and the method of calculating the vibrational entropy is an approximate one. Therefore, the agreement noted above is satisfactory. de Boer (3) has also calculated entropies of hydrocarbons adsorbed on charcoal and concluded that the adsorbed films are mobile. Although the authors of this paper believe this is true on the basis of their own findings, they do not feel that de Boer was justified in reaching this conclusion. In the first place his calculations were based for the greater part on work done by Ray and Box (11), which although adequate for the purpose intended is not accurate enough for making thermodynamic calculations. Secondly, de Boer calculated differential entropies, which Hill (7) has pointed out are unsuitable for comparison with those calculated from statistical–mechanical models.

The heats of adsorption and the entropies of adsorption for ethylene and perfluoroethylene have been compared in Figs. 3, 4, and 6. Over the range of coverage studied the heat of adsorption of perfluoroethylene is consistently higher than that of ethylene, although the entropies are almost identical at the temperatures chosen. For example, at $\theta = 0.2$ the differential heat of adsorption of ethylene was found to be 2.65 kcal. per carbon atom compared with 3.10 kcal. per carbon atom for perfluoroethylene. These values are in approximate agreement with values found by Beebe *et al.* (1, 2) for the adsorption of a number of hydrocarbons by carbon surfaces. In the discussion which follows, it will be shown that the mode of adsorption is the same for the two gases and that the differences in the heat of adsorption may be accounted for solely in terms of the difference in molecular weight between the two compounds. The physical properties of ethylene (8) and perfluoroethylene (12, 13) are listed below.

	Critical temp., °K.	Mean temp. of adsorp., °K.	Ads. temp. / Critical temp.	Heat of vaporization, kcal./mole	B.P., °K.	Entropy of vaporization, e.u.
Ethylene	283	259	0.92	3.33	169	19.7
Perfluoro-ethylene	307	297	0.97	4.10	197	20.8

It is seen that the mean temperatures of adsorption are close to 95% of the critical temperatures of the two gases. Since the forces which determine the critical temperature of the gas are similar to those active in physical adsorption, the agreement between the entropy curves of Fig. 6 at roughly the same fraction of the critical temperature is interpreted as meaning that the mechanisms of adsorption are identical for the two gases. This is believed to be exactly analogous to the agreement of the entropies of vaporization at the boiling points, which occur at approximately 60% of the critical temperatures.

The quantity $H_G - H_S - H_L$ is plotted in Fig. 8 as a function of θ. The curves fall close to each other indicating that the forces responsible for the

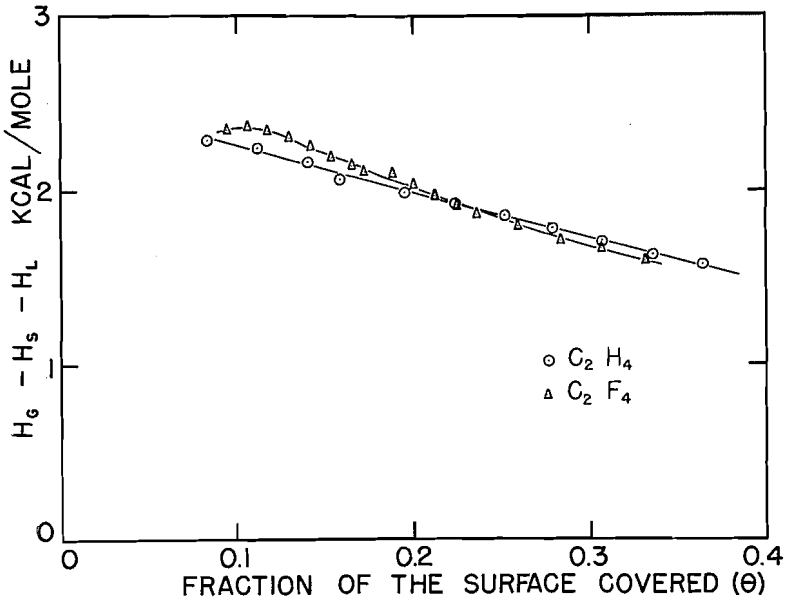

FIG. 8. The difference between the integral heat of adsorption and the heat of vaporization for ethylene and perfluoroethylene.

increase in the heat of vaporization of perfluoroethylene over that of ethylene are also responsible for the observed increase in the heat of adsorption. Since these two substances obey Trouton's rule quite closely, it may be assumed that the liquids are monomeric and that the increase in the heat of vaporization of perfluoroethylene over that of ethylene is simply a result of its higher molecular weight. Consequently, the heat of adsorption of perfluoroethylene is larger than that of ethylene by an amount that would be expected from its higher molecular weight. It is concluded therefore that there is no specific interaction between the fluorine atoms of the fluorocarbon and the carbon surface.

THE ADSORPTION OF ALIPHATIC ACIDS FROM AQUEOUS SOLUTIONS BY POROUS CARBONS[1]

By John L. Morrison[2] and David M. Miller[3]

ABSTRACT

The maximum adsorptions of the lower members of the mono- and di-carboxylic acids from aqueous solutions were determined for coconut charcoals of different degrees of activation. Based on these results, a method for estimating pore size was applied to the more finely porous charcoals. To corroborate the pore sizes estimated from acid adsorption, pore size – area distributions were calculated from measurements of the water vapor sorption isotherms of the charcoals. An alternation in the maximum amounts of adsorbed acids was observed with the more active charcoals. Acids with an even number of carbon atoms had larger adsorptions than acids with an odd number. The alternation was much more marked for the di- than for the mono-carboxylic acids. A remarkable correlation between the alternation of adsorptions and of melting points of both acid series was observed. An explanation for the general phenomenon of alternation based on rotational motion of molecules in the solid state is given as an alternative to the widely held one based on tilting of molecular chains.

A determination of the nature of the adsorbed layer is one of the principle objectives of adsorption studies. In the selective adsorption by a porous adsorbent of one component from a binary liquid mixture, two alternatives have been considered possible, either molecular layer adsorption (6, 10, 11) or capillary condensation (4, 5, 8). The present work concerning the adsorption of aliphatic acids from aqueous solutions by porous carbons appears to be an example of the first alternative.

Linner and Gortner (11) measured the adsorption isotherms of 31 organic acids from water solutions by one sample of Norite charcoal, and by applying the Langmuir equation, they calculated the maximum amounts adsorbed at higher concentrations. In the case of acid adsorption, the present work exclusively involves the direct measurement of the maximum amounts adsorbed. As Linner and Gortner suggest, this is "a more valid method of comparing the effect of molecular structure on adsorption".

EXPERIMENTAL

The coconut shell charcoal samples were obtained from the Standard Chemical Co. Ltd., Montreal. They consisted of two series of seven samples, each sample removed from the steam activator at approximate intervals of 24 hr. Some data on the series Charcoals 1 to 7 have already been given (10) and data for the series charcoals 1B to 7B are given in Table I.

[2]*Determined by J. L. Morrison.*

Acid Adsorption

The data of Lemieux and Morrison for the adsorption of the aliphatic acids from acetic to valeric by Charcoals 1 to 7 are used here. The measurements on caproic acid and the dicarboxylic acids oxalic to adipic on the same charcoal series are new, as are all the measurements on Charcoals 1B to 7B.

Caproic acid was C. P., Fisher Scientific Co.; the other monocarboxylic acids and malonic, succinic, and adipic acids were chemically pure grade from Eastman Kodak Co.; oxalic acid was recrystallized from technical grade, Central Scientific Co.; glutaric acid was prepared from trimethylene bromide (14).

The procedure already described (10) was followed with slight modifications for the dicarboxylic acids. The adsorptions were carried out in 250-ml. ground glass stoppered flasks which were sealed by paraffin wax. At least two days were allowed for equilibration. The measurements on the B series were made at 25.0 ± 0.1°C., and the dicarboxylic acids were equilibrated at room temperature.

Owing to the large solubilities of malonic and glutaric acids, smaller amounts of solution and larger charcoal samples than above were used. Here 25 ml. portions of acid solution were added to 4 gm. of Charcoals 1 to 4 and to 3 gm. of Charcoals 5 to 7. They were allowed to stand until gas evolution ceased (seven to eight days). Then two 10-ml. samples were titrated. The two procedures checked for succinic acid within the experimental error.

The adsorptions at four or five concentrations were determined and averaged for each charcoal. The average deviation for the monocarboxylic acids adsorbed on the B series was ±2.0%, and for the dicarboxylic acids, excluding glutaric, ±3.6%. Glutaric acid had a deviation of ±9.2%. In all cases, the deviations decreased with increasing charcoal activity; for example, with Charcoal 7, glutaric acid deviated by ±4.7% and the average of the other dicarboxylic acids was ±2.6%.

Water Adsorption

To obtain an independent measure of the charcoal pore sizes, the water vapor adsorption isotherms were measured by the method of Wiig and Juhola

(23). As in their case, dibutyl phthalate manometers were used. Because they exhibited a very small vapor pressure (approx. 5×10^{-4} cm. Hg) on the McLeod gauge, they were replaced by Apiezon Oil B manometers for repeat determinations on two charcoals. No difference was found in the isotherms.

At least two hour and often overnight periods were used in the measurement of each point of an isotherm. Six to nine points were determined on each of the adsorption and desorption branches for each charcoal. The isotherms were measured at 22.9 ± 0.1°C.

RESULTS AND DISCUSSION

Acid Adsorption

All the data fitted Langmuir isotherms, as is generally observed for this type of system (6, 10, 11). Hansen, Fu, and Bartell (6) have shown that porous sugar charcoal in constrast with nonporous carbons exhibits a Langmuir isotherm with a value of 1 for the maximum number of adsorbed layers. The maximum amounts of the various acids adsorbed by the two charcoal series are given in Table II. Included for convenience are the corresponding results obtained by Lemieux and Morrison (10).

TABLE II

MAXIMUM NUMBER OF MILLIMOLES ACID ADSORBED PER GRAM CHARCOAL

Acid adsorbate	Charcoal number (first series)						
	1	2	3	4	5	6	7
Acetic	2.15	2.55	2.85	3.22	3.25	3.70	4.00
Propionic	1.63	2.04	2.47	2.91	2.93	3.46	3.75
Butyric	1.24	1.66	2.06	2.63	2.74	3.43	3.84
Valeric	0.88	1.31	1.75	2.40	2.41	3.18	3.66
Caproic	0.75	1.10	1.32	1.96	2.04	2.63	3.00
Oxalic	1.27	1.56	1.74	2.00	2.15	2.40	2.54
Malonic	0.60	0.78	1.09	1.40	1.52	1.62	1.87
Succinic	0.61	0.91	1.22	1.70	1.78	2.18	2.29
Glutaric	0.23	0.42	0.82	1.10	1.15	1.49	1.69
Adipic	0.43	0.68	0.99	1.48	1.44	1.88	2.08

	Charcoal number (second series)						
	1B	2B	3B	4B	5B	6B	7B
Acetic	1.90	2.14	2.59	2.74	2.89	3.15	3.36
Propionic	1.39	1.89	2.34	2.50	2.78	3.11	3.27
Butyric	1.01	1.71	2.24	2.45	2.82	3.19	3.39
Valeric	0.74	1.58	2.04	2.31	2.68	3.13	3.33
Caproic	0.44	0.98	1.46	1.73	2.15	2.54	2.70

Maximum adsorption occurs at about the following concentrations for the various acids: caproic—0.03 *M*, oxalic—0.09 *M*, malonic—4.8 *M*, succinic—0.5 *M*, glutaric—3.0 *M*, and adipic—0.05 *M*.

Pore Size from Acid Adsorption

The *less activated* members of the two charcoal series exhibit an inversion of Traube's rule when it is applied to the maximum number of moles of mono-

carboxylic acid adsorbed. Although some workers (5, 8) interpret this by a capillary condensation mechanism, we interpret it on the basis of oriented unimolecular adsorption and a sieving of the molecules according to chain length. Moreover, the fact as seen in Figs. 2 and 3 that for the less activated charcoals the *change* in the amount adsorbed for successive acids is comparable to the absolute adsorptions suggests that most pores are comparable in size to the length of the acid molecules. This suggestion led to a method for estimating the pore size of very finely porous carbon.

Qualitatively, the results indicate that Charcoals 1, 2, and 1B have "an even distribution of pore sizes" (10). On this basis, assume that the pores are like a set of open-ended regular cones; also assume vertical orientation of the monocarboxylic acids at the water–charcoal interface. The model is given in Fig. 1. The amount adsorbed will be proportional to the number of cones n,

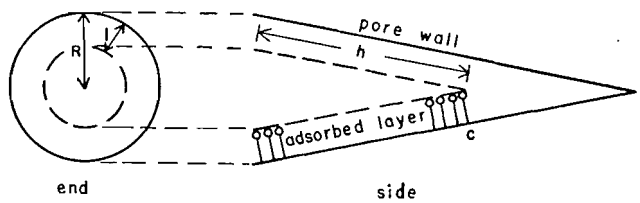

FIG. 1. Cone model of a charcoal pore. R—pore radius, l—acid chain length, h—slant height of cone radius $(R-l)$, c—"cutoff" radius.

and the lateral area of the cones of radius $(R-l)$ and slant height h, where R = pore radius and l = acid chain length. Thus

$$x_m = knh\ \pi(R-l), \qquad [1]$$

where x_m is the maximum number of millimoles adsorbed per gm. charcoal, and k is a proportionality constant.

For different acid chain lengths, the change in x_m for the same charcoal will be

$$dx_m/dl = -knh\pi. \qquad [2]$$

Here, the product nh is assumed constant as a first approximation. By substituting for nh in Equation [1] we obtain

$$R = 1-x_m/(dx_m/dl). \qquad [3]$$

In Figs. 2 and 3, the x_m values have been plotted against acid chain length, the latter having been estimated from the liquid molar volume by assuming a common cross-sectional area of 24.3 Å^2 for the acid molecules (19, 22). The pore radii given in Table III were obtained from plots similar to Figs. 2 and 3 after a correction varying from 1.2 to 3.1% was made for the alternation effect (to be discussed later). This correction placed the first three acids, acetic to butyric, on the same straight lines respectively for Charcoals 1,2, and 1B, with valeric lying somewhat above in each case.

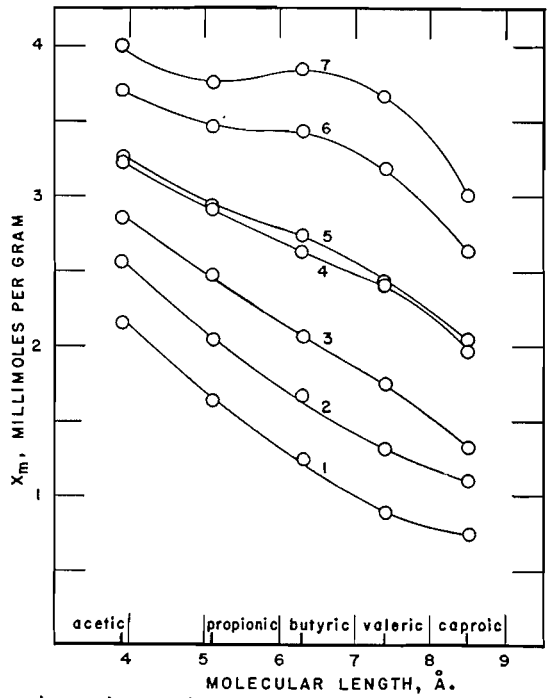

FIG. 2. The change in maximum adsorption of monocarboxylic acids with chain length for the first charcoal series.

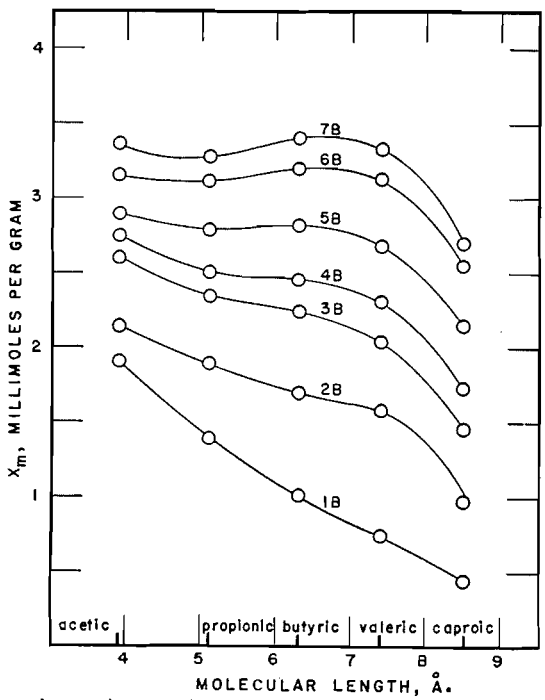

FIG. 3. The change in maximum adsorption of monocarboxylic acids with chain length for the B charcoal series.

The radii in Table III are the largest radii of the cones in the model, and depend on the molecular chain lengths chosen for the acids. In a later section it will be shown that these radii may be low by about 2Å.

TABLE III

PORE RADII (Å) OF CHARCOALS BY ACID ADSORPTION

Acid	Charcoal number			
	1	2	3	1B
Acetic	9.7	10.9	13.9	9.1
Propionic	9.7	10.9	14.2	9.1
Butyric	9.7	10.9	13.6	9.1
Valeric	9.9	11.2	13.9	9.5

The approximation assumption that the product '*nh*' in Equation [1] is constant apparently has some validity because of the constancy of the radii of particular charcoals for the first three acids. If the product '*nh*' is approximately constant, then, on the cone model, either or both of two possibilities are suggested. The number of pores, n, may be the same to all acids, in which case the apical angle would have to increase with increasing pore radius at such a rate as to keep h approximately constant, *or*, the apical angle may remain constant, in which case the number of pores would have to decrease with increasing pore radius.

Pore Radii from Water Adsorption

The water vapor adsorption isotherms are most conveniently reported in Table IV. These data are taken from smoothed curves drawn through the experimental points when the amount adsorbed was plotted against the relative water vapor pressure.

The area of charcoal occupied by water rather than the weight adsorbed, at various relative pressures, was considered the more valid parameter by which to compare the water adsorption radii with the acid adsorption radii. The distribution of pore areas for various pore radii was found in the following way.

The equation of Kistler, Fischer, and Freeman (9),

$$[4] \qquad \frac{dA}{dW} = \frac{2.303\,RT}{M\sigma\cos\theta}\log\frac{P_0}{P}$$

was applied to the desorption branch of the water isotherms (2). Here, A is the area occupied by W grams of water of molecular weight M, and surface tension σ, at a relative pressure of P/P_0. R is the gas constant and the $\cos\theta$ term was added by us to take account of the partial wettability of charcoal by water. The distribution of area with the weight of water was obtained by graphical integration.

Following Fineman, Guest, and McIntosh (2) and Wiig and Juhola (23), the Kelvin equation was used to calculate the pore radius R at various relative

Note: A = adsorption; D = desorption.

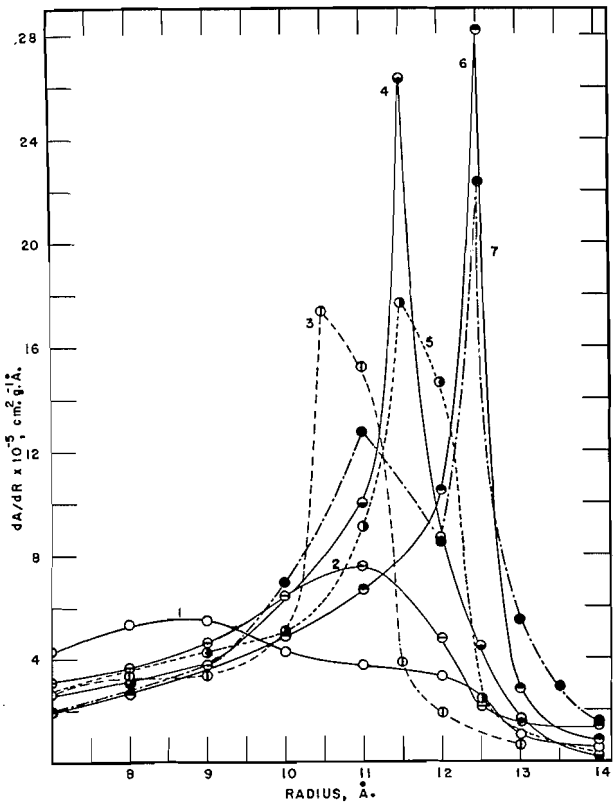

FIG. 4. The distribution of pore area with radius for the first charcoal series.

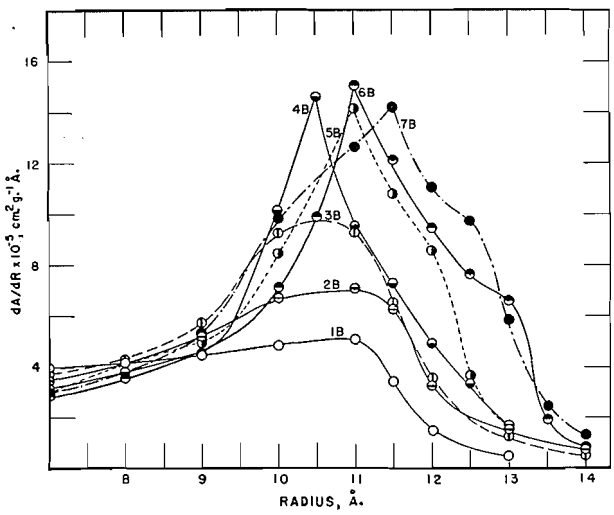

FIG. 5. The distribution of pore area with radius for the B charcoal series.

pressures, and thus at various adsorbed weights. In both expressions, the $\cos\theta$ term for partial wettability was given the value of 0.65 following the work of McDermot and Arnell (12). Areas were connected to radii by their relations to the adsorbed weights. Then, by graphical differentiation of the plots of the cumulative areas at various pore radii (Milligan and Adams (15) did the same for weights), the area – pore radius distribution curves were obtained for each charcoal. These are given in Figs. 4 and 5.

Two observations may be made. Confirming the qualitative picture of the pores of Charcoal 1 and 1B given by the acid adsorption results, it is seen that these charcoals have a fairly even pore size distribution. Also, the values of the radii from water adsorption compare reasonably well with those from acid adsorption.

Water–Acid "Cutoff" Areas

The combined water and acid adsorption data give another confirmation of the proposed model. Contrary to the suggestion (4, 5) that the acids are leaving the water solution to fill the charcoal pores, density measurements (16) indicate that water from the binary mixture can penetrate further into the charcoal than any of the acids.[4]

The areas reached by water were compared with those reached by the various acids. The latter were calculated by assuming vertical orientation and a cross-sectional adsorption area of 24.3 Å^2 (10, 19, 22) for the acid molecules. The excess area penetrated by water compared with that penetrated by a particular acid was approximately the same for the first four charcoals of each charcoal series. The "cutoff" radii (at *c* in Fig. 1) corresponding to the excess water penetration areas were determined from the composite Kistler–Kelvin data and are given in Table V. The radii are the average of Charcoals 1 to 4 and 1B to 4B.

TABLE V

"CUTOFF" RADII FOR WATER PENETRATION

Acid	Cutoff radius, Å	Acid chain length, Å
Acetic	6.5 ± 0.5	3.9
Propionic	7.7 ± 0.5	5.1
Butyric	8.7 ± 0.3	6.3
Valeric	9.5 ± 0.5	7.4
Caproic	10.3 ± 0.4	8.5

The differences between successive "cutoff" radii are consistent with the differences in acid chain lengths. However, the "cutoff" radii are about 2Å greater than the acid lengths. This is not unreasonable in such a dynamic system. If these radii are approximately correct, they increase the estimated acid pore radii given in Table III by about 2Å. The revised values are more

[4]*Such penetration would reduce the apparent selective acid adsorption but a calculation for the most extreme case, valeric acid solution on Charcoal 1, showed that the effect was about 8% which is within the experimental error.*

compatible with the water radii results, considering that the acids give *external* pore radii.

Alternation in Acid Adsorption

Alternation in the maximum adsorption of the successive members of the monocarboxylic series to valeric acid was observed for Charcoals 5 to 7 (Fig. 2) and Charcoals 3B to 7B (Fig. 3). The dicarboxylic acids exhibited a much more marked alternation in adsorption, as shown in Fig. 6. These

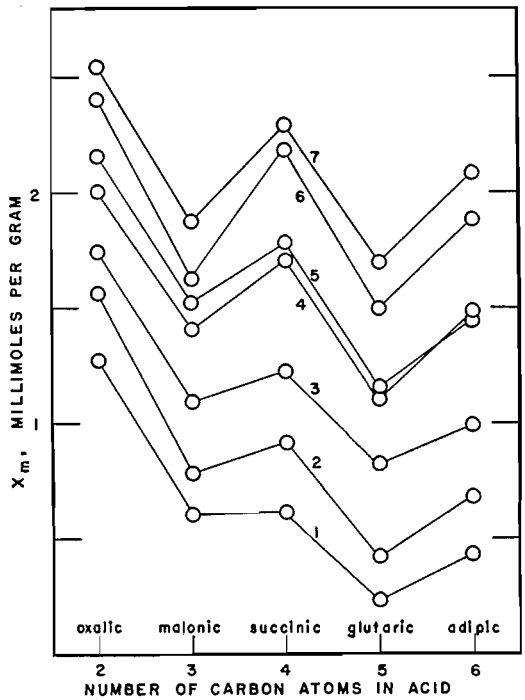

FIG. 6. The change in maximum adsorption of dicarboxylic acids with number of carbons in the chain for the first charcoal series.

observations greatly extend earlier ones made by Linner and Gortner (11) for the same acids on a single Norite charcoal. In their case, the monocarboxylic acids showed a slight alternation, without alternately larger and smaller values, while the dicarboxylic acids gave sufficient alternation to exhibit such a fluctuation. However, the authors remarked that "the results in themselves are not particularly striking".

The alternation increases with increasing charcoal activity. In the lesser activated charcoals, the alternation is markedly reduced, being practically non-existent for the monocarboxylic acids, but still quite definite for the dicarboxylic acids. Apparently for these charcoals progressive sieving of the longer molecules masks the alternation effect, and where the alternation is less marked as in the case of the monocarboxylic acids, the effect becomes negligible. However, alternation is not really absent even for Charcoals 1 and 1B

and corrections were made for the effect when the pore radii were estimated from the acid adsorption data.

Alternation in many of the physical properties of a number of long chain homologous series of compounds is well known and appears to be a characteristic of the solid state (18). In Fig. 7, the adsorptions of the two acid series on

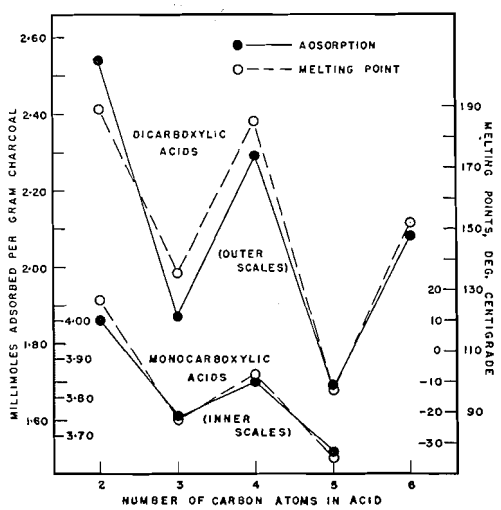

FIG. 7. A comparison of the alternation in melting points of mono- and di-carboxylic acids with their maximum adsorptions by Charcoal 7.

Charcoal 7 are compared with their melting points (3, 18). The scales of the two acid series were displaced so that each series would appear separately. The arbitrary elements in the figure are the adsorption and temperature scales which were adjusted so that a successive pair of acids approximately overlapped. However, the scale *intervals* are respectively the *same* for each acid series pointing to a remarkable correlation between the *alternations* in adsorption and in melting point.

On the basis of X-ray evidence, Malkin (13) suggests that alternation is a property of crystals with tilted molecular chains, "alternate planes of odd chains being less closely packed" than those of even chains. In support of his explanation is the fact that the dicarboxylic acid chains have an unusually large tilt in their crystals (1). Malkin's hypothesis requires association of the molecules along the long axis of the chain. However, the present adsorption results do not point to such association on the carbon surface. The internal consistency of the results appears to rule out that any *mixture* of associated and unassociated molecules is adsorbed. Dimers or higher associations may be ruled out by the calculations which, by assuming monomers, gave pore radii from the acid adsorptions that were consistent with those obtained from water vapor adsorption. Also, the monocarboxylic acids in water solutions give normal freezing point depressions (7). The molal freezing point of oxalic acid is 3.40°C. at 0.02 molal concentration and that of succinic 1.99° at 0.01

molal. So that although the aliphatic acids are known to associate in nonpolar solvents (18), they do not do so in water. Thus, it is difficult to reconcile the present observations with Malkin's explanation, and we must seek an alternative one. In fact, Malkin's hypothesis has been "vehemently criticized" as Smith has pointed out in his review (21).

Referring to Charcoal 7 in Fig. 6, the straight line drawn through oxalic, succinic, and adipic acids is nearly parallel to that drawn through malonic and glutaric acids. The same holds approximately for Charcoals 4 to 6. Since Charcoal 7 probably is equally open to all the acids with the possible exception of caproic, it appears that the addition of *two* methylene groups to the acid chain increases the molecular adsorption area (or section area) by a constant amount. However, the addition of *one* methylene group either decreases or increases the section areas by a much larger but also approximately constant amount.

Quantitatively, the addition of one methylene group as such (calculated for Charcoal 7 and with a cross sectional area of 24.3 $Å^2$ per molecule) increases the section area by about 2.4 $Å^2$. On the other hand, the fluctuations cause changes in the section areas of 12.3 $Å^2$ per fluctuation. It would appear that alternation is a reflection of the amount of space occupied by the carboxyl groups on the carbon surface, which in turn may be determined by their relative orientation in the chain.

In other words, the even acids in which the terminal carboxyl groups are *trans* to each other fit together closer than the odd acids in which the carboxyls are *cis*. The basic reason for this may have very little to do with tilt, but rather may be due to rotation of the chains along their long axis. It seems reasonable that the *cis* arrangement would sweep out larger areas than the *trans* arrangement. A similar explanation may apply to melting point alternation.

In the case of the monocarboxylic acids the similar but smaller effect would be explained by the fact that one of the terminal groups is smaller—a methyl replacing a carboxyl group.

Rotation of molecules in the solid state is not an uncommon phenomenon. Pauling says that "in general it is to be expected that rotational motion of molecules and complex ions of sufficiently low moment of inertia will set in below the melting point of the crystals" (17). Moreover, he points out that "the moment of inertia along a staggered chain about an axis along the chain would be very small". Further, Rideal and Tadayon (20) have shown the ease of motion of aliphatic acids in the solid state.

The rotational hypothesis is better able to account for the much greater alternation of the acids of shorter chain length (18) than is Malkin's hypothesis. The longer the chain, the more readily it will be able to accommodate *cis* rotations, and the less the carboxyl groups will dominate the rotational motion. Over a certain range of chain lengths we might expect a transition from one dominant type to the other. Such a transition is very apparent in the case of the monocarboxylic acids, both from melting point and adsorption evidence.

Caproic Acid

Caproic acid behaves anomalously compared with the lower monocarboxylic acids. At higher charcoal activities, its adsorption falls off sharply, as shown in Figs. 2 and 3. Linner and Gortner (11) observed a similar falloff in the adsorption of caproic acid on Norite charcoal. A possible explanation may be that its molecular chain length is sufficient to be sieved appreciably even by the highly activated charcoals.

An alternative explanation is suggested by the adsorption of caproic acid on Charcoals 1 and 2. In Fig. 2, the falloff in adsorption is not as great as would be expected from caproic acids behaviour with the other charcoals. This may mean that caproic acids' is partially curled up, thus reducing its effective chain length and permitting it to penetrate finer pores. At the same time, the concomitantly higher molecular adsorption area would reduce the number of moles adsorbed.

The anomalous adsorption behavior of caproic acid is paralleled by its melting point behavior. In a plot of the melting points of the monocarboxylic acids (3) against the number of carbons, a straight line drawn through valeric acid parallel to the melting point axis divides the plot into two parts which are approximately mirror images. Thus, while valeric acid is the last member of one group, caproic acid is the first member of the other group of acids. Considering the close parallel already observed between the alternations in adsorption and melting point, it is not surprising to find caproic acid behaving anomalously. On the basis of the rotational hypothesis given above, it is suggested that over the interval valeric to caproic acids, molecular rotation in the crystal changes from carboxyl dominance to hydrocarbon chain dominance.

ACKNOWLEDGMENTS

The authors thank Dr. J. C. Arnell for supplying and making certain measurements on some of the charcoals. They also acknowledge financial assistance from the National Research Council.

THE RATE OF ADSORPTION OF SOME LOW BOILING GASES ON A MODIFIED SARAN CHARCOAL[1]

By J. R. Dacey and D. G. Thomas[2]

ABSTRACT

The pyrolysis at 300°C. of vinylidene chloride monomer adsorbed on Saran charcoal alters the pore structure of the charcoal so that low boiling gases such as nitrogen are adsorbed slowly. The rates of adsorption of nitrogen, argon, and methane have been measured. They were found to vary with pressure and temperature, and from the temperature variation an activation energy may be calculated. A new method of determining this energy is described which involves changing the temperature during only one adsorption experiment.

INTRODUCTION

Previous work had shown that pressed Saran (polymerized vinylidene chloride) gave, when pyrolyzed *in vacuo*, a porous charcoal in which the pores were comparable in size with the size of simple hydrocarbon molecules (3). The pores were not cylindrical for although large bulky molecules such as neopentane were only adsorbed slowly, flat molecules such as benzene were adsorbed very rapidly as were thin molecules such as *n*-pentane. It seemed therefore as though there were slot-like constrictions in the charcoal, perhaps arising from the presence of graphitic platelets. The molecules which were adsorbed slowly diffused into the charcoal by an activated process, and the energy of activation, E, could be measured. It was suggested that E corresponded to the energy required to move a molecule from one position to another over the carbon surface, though for larger molecules, the energy required to squeeze through a small constriction may also play a part. Unfortunately the kinetic experiments, which were performed at temperatures ranging from about -50°C. upwards, were not always precisely reproducible even with consecutive runs on the same piece of charcoal. After each run it was necessary to heat the charcoal in order that the desorption should occur in a reasonable time, and it was thought that changes in the charcoal might take place during this heating, accounting for the irreproducibility. To offset these difficulties an attempt was made to block the interstices of the charcoal to a controlled extent, so that smaller and lighter molecules would be adsorbed slowly at low temperatures, desorption occurring at room temperature. The charcoal was successfully blocked, but the behavior was still not reproducible. At the same time a modified method of determining E during one adsorption run was devised.

EXPERIMENTAL

Materials

Charcoal

Saran charcoal was prepared in the manner previously described (3). Oxygen was used initially in an attempt to block the charcoal, which was

[1]*Manuscript received September 16, 1954.*
Contribution from the Department of Chemistry, Royal Military College of Canada, Kingston, Ontario. This paper was presented at the Symposium on Problems Relating to the Adsorption of Gases by Solids, held at Kingston, Ontario, September 10–11, 1954.
[2]*Present address: Bell Telephone Laboratories, Murray-Hill, New Jersey, U.S.A.*

hung from a quartz spiral and heated at 300°C. in an atmosphere of oxygen. There was, however, no change of weight and the sorption of benzene was still very rapid, so the method was abandoned.

Monomeric vinylidene chloride was adsorbed rapidly at room temperature. By pumping at 300°C. all the monomer was desorbed. But if the charcoal was heated at 300°C. in the presence of excess monomer vapor for an hour or so, some reaction took place, for pumping did not then remove all the monomer. Further heating and pumping caused further weight loss. One such sample with a 10% weight increase adsorbed benzene at a measurable rate (10% of the weight of the sample adsorbed in 25 min.) and gave a saturation value of 0.29 cc./gm. assuming the adsorbate to have the normal liquid density. Heating to redness essentially restored the charcoal to its original condition. Another piece, treated so that the weight increase was only 7%, adsorbed *n*-hexane more slowly (5% in one hour) than benzene (5% in 22 min.) at 20°C., and 2-methyl-pentane not at all.

Sample No. 3, on which most of the work was done, was heated at 300° in the presence of monomer for four and one-half hours and after pumping at 500°C. for 20 min. there was a weight increase of 16%. In this condition even nitrogen was not adsorbed at liquid air temperature and so the sample was pumped at red heat for five minutes, reducing the weight increment to 11%. Nitrogen was now slowly adsorbed at 90°K. (3% in one hour), but although desorption took place within a few minutes at room temperature the rate of adsorption steadily decreased from run to run. One per cent was adsorbed in 11 min. in the first run, but the third run required 19 min. to adsorb the same amount.

A further pumping at red heat for 10 min. reduced the weight increment to 9.0% and speeded the adsorption of nitrogen. Except for occasional heatings at 300°C., which increased the rate of adsorption without affecting the weight of the charcoal, the sample was examined in this condition.

Nitrogen — was commercially obtained 99.99% pure.
Methane — was commercially obtained 99.7% pure.
Argon — was commercially obtained 99.99% pure.
Benzene — was Analar grade dried with phosphorus pentoxide.

Apparatus and Procedure

The techniques used were similar to those described in a previous paper (3). About 0.07 gm. of charcoal was suspended from a quartz spiral, and the adsorption was followed by measuring the increase in length of the spiral. The extension of the spiral was 15 cm. for the original 0.07 gm. of charcoal. Pressures were measured with a mercury manometer. For pressures above one atmosphere a large manometer was used and taps were held in with special clamps. As the quantity of gas adsorbed during a run was small compared with the amount in the apparatus, the pressure remained virtually constant.

Temperatures were measured with a platinum resistance thermometer calibrated at the National Bureau of Standards. Commercial oxygen and nitrogen were liquefied, and when the liquefied gases were mechanically stirred in a Dewar Flask, they were found to remain at a constant temperature, to

within $\pm 0.01°$, over the period necessary to measure the rate of adsorption (about one hour). For temperatures slightly above the boiling point of liquid oxygen a Dewar Flask of Freon 12 was manually thermostatted by dropping liquid air into a copper tube immersed in the stirred Freon. Solid carbon dioxide and a bath of acetone cooled by occasionally adding solid carbon dioxide was also used as a thermostat. With the manually controlled thermostats the temperature control was only good to $\pm 0.1°$ but was adequate for our purpose.

The rate of adsorption increased rapidly with temperature and as before it was concluded that an activated diffusion process was the rate controlling factor. The activation energy, E, could be obtained by plotting the logarithms of the slopes of the initial straight part of the plot of amount adsorbed versus the square root of the time against the reciprocal of the absolute temperature. However, since the desorption process which was carried out at room temperature seemed to cause some change in the charcoal it was thought desirable to obtain the E value by changing the temperature during a run. This method of determining E was developed and tested for validity using neopentane on ordinary Saran charcoal as is described below.

The Determination of E by Changing the Temperature During One Run

For the initial stages of adsorption, that is before an appreciable quantity of the diffusing material has arrived at the center of the adsorbate, it can be shown that,

$$Q = kC_0 D^{\frac{1}{2}} t^{\frac{1}{2}} \qquad [1]$$

where Q is the total quantity of material adsorbed, k is a constant, C_0 is the surface concentration, D is the diffusion constant, and t is the time of adsorption (1, 2).

Consider now two runs performed at temperatures T_A and T_B. In Fig. 1 we see using equation [1],

$$Q_y = kC_{0_A} D_A^{\frac{1}{2}} t_{A_1}^{\frac{1}{2}} = kC_{0_B} D_B^{\frac{1}{2}} t_{B_1}^{\frac{1}{2}}$$

or

$$Q_y^2 = k^2 C_{0_A}^2 D_A t_{A_1} = k^2 C_{0_B}^2 D_B t_{B_1}.$$

Similarly

$$Q_x^2 = k^2 C_{0_A}^2 D_A t_{A_2} = k^2 C_{0_B} D_B t_{B_2}.$$

We thus have two values for $Q_x^2 - Q_y^2$ at temperatures T_A and T_B and we may equate these:

$$k^2 C_{0_A} D_A (t_{A_2} - t_{A_1}) = k^2 C_{0_B} D_B (t_{B_2} - t_{B_1})$$

or if

$$C_{0_A} = C_{0_B}$$

$$\frac{D_A}{D_B} = \frac{t_{B_2} - t_{B_1}}{t_{A_2} - t_{A_1}} = \frac{1/\tau_A}{1/\tau_B}, \qquad [2]$$

where τ_A and τ_B are the times required to adsorb between the limits Q_x and Q_y at the temperatures T_A and T_B respectively.

Suppose now that we begin the adsorption at T_B until Q is reached (Fig. 1), and at Q abruptly change the temperature to T_A. We may then observe the

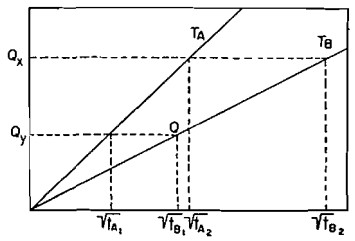

FIG. 1.

time τ_A required for adsorption from Q_y to Q_x at T_A, and we may safely predict the time τ_B by extrapolating the initial straight line plot at temperature T_B.

The energy of activation for the diffusion process may now be obtained from:

$$\log_{10}\frac{\tau_A}{\tau_B} = \frac{E}{2.3R}\left(\frac{1}{T_A}-\frac{1}{T_B}\right).$$

It is apparent that so long as we remain in the region for which equation [1] is valid, several temperature changes may be made and the same analysis applied.

It was observed that for neopentane the rate of adsorption changed 4% on changing the relative pressure at constant temperature from 0.1 to 0.2. When the relative pressure was increased from 0.2 to 0.9 the rate increased by only 2%. We therefore conclude that above a relative pressure of about 0.2 when adsorbing hydrocarbons the surface approaches saturation and C_0 remains almost constant. With neopentane our measurements were made with a relative pressure above 0.2. With nitrogen the saturation concentration is not closely approached until higher relative pressures are reached. This is discussed further below.

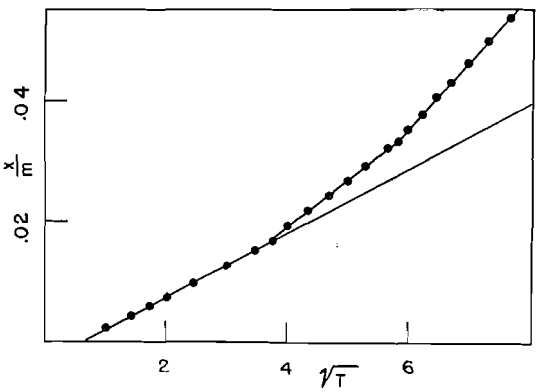

FIG. 2. The rate of adsorption of neopentane. The temperature was changed twice during the run.

This method was tested for the adsorption of neopentane on Saran charcoal. The results are plotted in Fig. 2. The first portion of the curve was obtained at 0°C. and this straight line was extrapolated to higher values of x/m, the ratio of the weight of the adsorbent to adsorbate. After 12 min. the temperature was increased to 9.9°C. $\tau_0°$ and $\tau_{9.9}°$ were taken between the values of x/m of 0.025 and 0.035. A third portion of the curve was obtained by increasing the temperature to 19.9°C. after 32 min. $\tau_0°$ and $\tau_{19.9}°$ were now obtained between $x/m = 0.045$ and $x/m = 0.055$. The E calculated from the first and second parts of the curve was 7700 cal./mole, and that calculated from the first and third was 7600 cal./mole. In most such cases the E values agreed to within 5%. For satisfactory results it was necessary to have fairly slow adsorption so that the x/m values used were less than 0.3 of the saturation value. Best results were obtained if the temperature changes did not exceed 10°C.

RESULTS

We have already indicated that by suitable treatment with monomeric vinylidene chloride the charcoal could be blocked to different degrees and that the adsorption in these different states was controlled by the shape and size of the adsorbed molecules.

Sample No. 3, after treatment with the monomer as described above, was saturated with nitrogen at 90.4°K. and gave 0.29 cc./gm. as the available pore volume assuming the nitrogen to have the normal liquid density. In the untreated charcoal the corresponding figure is 0.46 cc./gm. Since during its treatment with monomer the original charcoal had increased its weight by about 0.1 gm./gm., and as one may assume that the density of the material remaining in the charcoal is of the order of unity, we conclude that the adsorbed monomer does not block off large volumes but rather only blocks off that volume which it occupies, this being consistent with the picture of slot-like pores offered in the previous paper (3). This is supported by the behavior of benzene on another piece of charcoal which had also adsorbed about 0.1 gm./gm. The volume available to benzene was 0.28 cc./gm., whereas the original charcoal had 0.40 cc./gm. available to benzene.

The experiments described below were carried out on sample No. 3 which adsorbed nitrogen slowly and benzene and larger molecules not at all.

Nitrogen

For nitrogen the variation of C_0 with relative pressure was investigated in some detail. The pressure was changed in the middle of the run but the temperature was not altered; the time of passage between two values of x/m was determined in a manner similar to that described above. From the relation $\tau_A/\tau_B = C_{0_A}^2 D_A / C_{0_B}^2 D_B$ assuming that the coefficient of diffusion is independent of pressure, we can arrive at a relative value of C_0 at the two pressures. A typical run is shown in Fig. 3. By several such experiments at a series of overlapping pressures it is possible to build up a relative isotherm. Such an isotherm is shown in Fig. 4 which was calculated from data obtained at −183°C. except for one run at −196°C. where the relative pressure was changed from 0.29 to 0.99. It is seen to be of the Langmuir type without a large uprising as

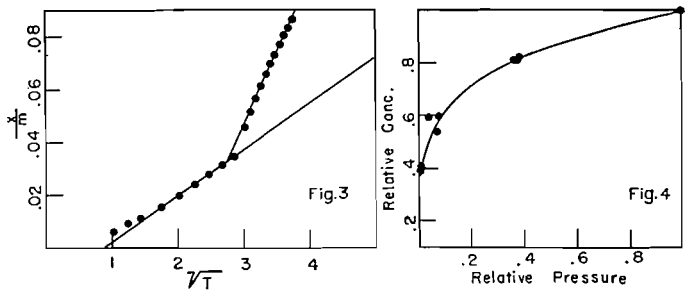

FIG. 3. The rate of adsorption of nitrogen. The pressure was changed during the run.
FIG. 4. The relative isotherm for nitrogen on the outer surfaces.

$p/p°$ approaches unity. At $p/p° = 0.2$ the surface was found to be only 75% saturated so it seemed best for the determination of E to make runs at different temperatures with $p/p°$ close to unity where the surface concentration should remain reasonably constant if the differences in temperature were not too great. The results of several such runs together with other runs in which $p/p°$ did not equal unity are presented in Table I. A typical experimental run is shown in Fig. 5.

**Heat of adsorption on Saran charcoal at saturation pressure = 3200 cal./mole (3).*

Argon

Argon at liquid nitrogen and oxygen temperatures was adsorbed at a rate comparable with the rate at which nitrogen was adsorbed. In Table I are given

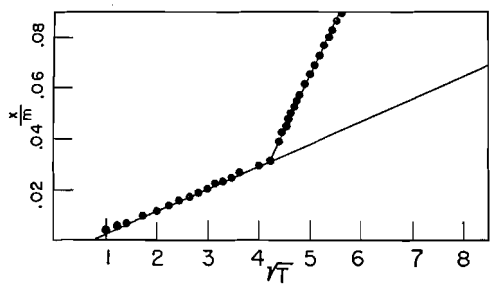

FIG. 5. The rate of adsorption of nitrogen. The temperature was changed during the run while the surface concentration remained constant.

the results of two runs on Sample 3. Between these runs methane had been adsorbed and the charcoal had been heated to 400°C. which had caused a loss in weight of 0.3%. A saturation value at 90.09°K. gave a pore volume of 0.26 cc./gm., assuming the normal liquid density for the adsorbed argon. This is in fair agreement with the nitrogen value.

Methane

Methane was adsorbed slowly. At first adsorption was studied above the critical temperature of methane (190.7°K.), then near its boiling point (111.7°K.). The results are given in Table I.

DISCUSSION

When vinylidene chloride is adsorbed on Saran charcoal it may be removed readily by pumping at room temperature and therefore does not polymerize. However, if the system is heated to 300°C. it cannot be removed. The adsorbed vinylidene chloride therefore polymerizes inside the capillaries of the charcoal. This polymer on further heating undoubtedly loses hydrogen chloride and would no doubt all eventually decompose leaving only carbon.

The additional carbon–polymer complex does not block off large voids in the original carbon because as was shown above the total pore volume was reduced by an amount roughly equivalent to the space required for the weight increase observed.

The carbon–polymer complex probably blocks off many of the entrances into the porous structure of the original carbon. At the same time the many entrances which must remain unblocked are reduced in size. This is clear from the fact that on the original charcoal both nitrogen and benzene were rapidly taken up while on the modified sample nitrogen was taken up slowly but benzene not at all. We therefore conclude the modification carried out as described above alters the slot-like constrictions which existed in the original sample, probably closing some of them completely while reducing the size of the others so that a benzene molecule cannot enter while a methane molecule can.

Unfortunately, a carbon with pores so small that small molecules could be adsorbed slowly at low temperatures and desorbed at room temperature did not overcome the difficulty of subtle changes occurring which altered the rates of adsorption from run to run. This phenomenon was attributed, in the case of

ordinary Saran charcoal, to the heating necessary for desorption but it appears now that the act of adsorption and desorption without heating above room temperature is sufficient to bring about small structural changes in the adsorbent.

However, despite this difficulty, methods were devised as described above, which make it possible to estimate the value of the energy of activation. The E values for nitrogen cannot be said to be entirely consistent though except for run 25 it appears that when the relative pressure is high, so that the changes in surface concentration brought about by the temperature changes are not great, E has a value of approximately 2000 cal./mole. For those runs in which the relative pressure has been kept nearly constant, at the two temperatures, at a comparatively low value, the E values are below 2000 cal. Presumably this is because the increase in temperature at the low coverage produces a large decrease in surface concentration which is not fully compensated for by the increase in pressure. This is to be expected if the heat of adsorption at low surface coverage is greater than the heat of vaporization of the liquid.

In considering the data on argon it must be noted that between runs 33 and 38 methane had been adsorbed and the charcoal had been heated to 400° which had caused a 0.3% loss of weight. This treatment seems to have substantially altered the adsorption kinetics. E has increased and the rate decreased, however, if E alone had changed, the slope of the x/m vs. $\sqrt{t}$ plot should have decreased by a factor of 1300 where in fact it has only decreased by a factor of 5.3. It seems that although in run 38 the diffusion process requires a higher activation energy the steric limitations have become much less stringent.

Considering Table I, the data on methane, the first two runs show that at low coverage the surface concentration is very sensitive to temperature changes, which is to be expected since at low coverage the heat of adsorption will be high. Thus the E values for these runs are of little significance, but for run 37, in which the pressures were kept near the saturation pressure, the E value should be more meaningful.

DÉDOUBLEMENT DES α- ET β-HYDROXYLAUDANOSINES[1]

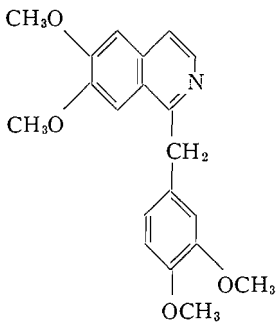
PAR JEAN-LOUIS FERRON ET PHILIBERT L'ECUYER

SOMMAIRE

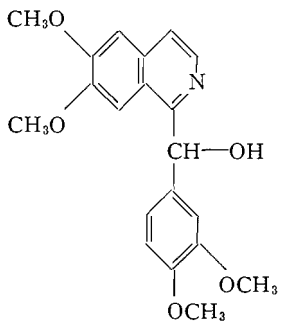
Les hydroxylaudanosines, α- et β-, ont été dédoublées en leurs énantiomorphes et les constantes physiques de ces derniers déterminées. Dans des conditions identiques le papavérinol ne s'est pas dédoublé en ses antipodes optiques; au contraire, il a donné de la papavéraldine lors des essais de dédoublement avec les acides *d*-tartrique, *l*-malique, et *d*-camphresulfonique.

INTRODUCTION

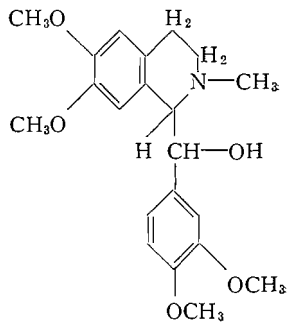
Le papavérinol (II) et les hydroxylaudanosines (III) sont obtenus, le premier par l'oxydation de la papavérine (I) et les dernières par la réduction



(I)



(II)



(III)

du méthochlorure de papavérinol (4). Ils possèdent respectivement un et deux carbones asymétriques laissant ainsi prévoir l'existence de deux et de quatre isomères optiques. Les quatres énantiomorphes des hydroxylaudanosines réunis deux à deux donnent deux formes racémiques connues sous le nom d'α- et de β-hydroxylaudanosines. D'autre part le papavérinol se présente également à l'état racémique. Le but du présent travail était de dédoubler ces diverses formes racémiques.

Parmi les multiples procédés utilisés pour le dédoublement des substances racémiques nous avons choisi la méthode de Ingersoll (2) qui se prête le mieux au dédoublement de l'une ou l'autre des trois catégories de formes racémiques possibles. Par cette méthode nous avons dédoublé l'α- et la β-hydroxylaudanosine en utilisant les acides *d*- et *dl*-tartriques comme agents de dédoublement. Ce même procédé appliqué au papavérinol avec les acides *d*-tartrique, *l*-malique, et *d*-camphresulfonique n'a permis l'isolement d'aucun sel. Le dédoublement ne s'est pas effectué. Une base de p.f. 210°C. a cependant été obtenue lors des essais de dédoublement avec les deux premiers acides et c'est la même qui précipite dans les deux cas; car il n'y a aucun abaissement du point de fusion si on mélange les deux échantillons en proportions égales. Cette substance possède une fonction cétonique comme le montre la formation d'une

[1]*Manuscrit reçu le 29 septembre, 1954.*
Contribution du Département de Chimie de l'Université Laval, Québec, Qué.

2,4-dinitrophénylhydrazone. Elle a été définitivement identifiée comme étant la papavéraldine. Comme le point de fusion du méthiodure du composé isolé (148–150°C.) différait considérablement de celui qui est donné par Menon (5), nous avons synthétisé la papavéraldine selon la méthode de Taylor (6) et préparé son méthiodure. Son p.f. est bien 148–150°C. et il ne varie pas lorsqu'on mélange le méthiodure avec celui qu'on obtient à partir de la base isolée au cours des essais de dédoublement du papavérinol.

Cette transformation du papavérinol en papavéraldine est sans doute due à une oxydation atmosphérique du genre de celle que subit la dihydroyobyrine pour donner la yobyrone (3).

Les pouvoirs rotatoires ont été déterminés sur des solutions à 1% pour le *d*-tartrate de la *d*-α-hydroxylaudanosine, le *l*-tartrate de la *l*-α-hydroxylaudanosine, le *d*-tartrate de la *d*-β-hydroxylaudanosine, et le *l*-tartrate de la *l*-β-hydroxylaudanosine ainsi que pour les bases optiquement actives obtenues par la neutralisation de chacun de ces sels et les pouvoirs rotatoires spécifiques ont été calculés.

PARTIE EXPÉRIMENTALE

Dédoublement de l'α-hydroxylaudanosine

De l'α-hydroxylaudanosine (4.00 g., 0.011 mole) et de l'acide *d*-tartrique (1.605 g., 0.011 mole) sont dissous dans l'alcool éthylique absolu (40 ml.) à l'ébullition. Par refroidissement à la température ambiante on obtient une gomme dont la cristallisation s'amorce lentement et se continue pendant une semaine. Le *d*-tartrate bien cristallisé est alors filtré, lavé avec quelques millilitres d'alcool absolu, et le filtrat (*a*) mis de côté pour l'isolement de l'autre isomère. Le sel (4.965 g.) est cristallisé une première fois dans l'alcool à 85% (50 ml.) contenant un peu d'acide *d*-tartrique pour empêcher la dissociation du sel et laissé pendant une semaine à la température ordinaire en contact avec les eaux-mères. Les cristaux sont alors filtrés et le filtrat (*b*) est ajouté au filtrat (*a*). Le *d*-tartrate de la *d*-α-hydroxylaudanosine (2.145 g.) est lavé avec quelques millilitres d'alcool éthylique à 85% et recristallisé dans le même solvant (30 ml.). Cette deuxième cristallisation fournit le sel pur de p.f. 208–209°C. Rendement: 60% (1.68 g.). Calculé pour $C_{21}H_{27}O_5N.C_4H_6O_6$: C, 57.4%; H, 6.4%. Trouvé: C, 57.5%; H, 6.3%. $[\alpha]_D = +76.2°$ (*c*, 1.004 dans l'eau). Le sel est ensuite dissous dans l'eau (35 ml.) et la solution rendue alcaline par addition d'un excès de soude 3*N*. La base précipite et fournit après une cristallisation dans l'alcool absolu (6–7 ml.) la *d*-α-hydroxylaudanosine pure de p.f. 151°C. Rendement: 60% (1.19 g.). $[\alpha]_D = +84.2°$ (*c*, 1.057 dans le chloroforme).

Les filtrats réunis (*a* et *b*) sont évaporés à sec sur bain-marie, le résidu est dissous dans l'eau (30–35 ml.), et la solution alcalisée par un excès de soude 3*N*. La base précipitée est extraite au chloroforme. La solution chloroformique est séchée, filtrée, puis évaporée à sec sur bain-marie. Le résidu (2.84 g., 0.007 mole) est traité à l'ébullition par de l'acide *dl*-tartrique (2.28 g., 0.014 mole) dans l'alcool absolu (20 ml.). Par refroidissement, un sel cristallise. On le laisse séjourner une semaine à la température ambiante. Le *l*-tartrate (3.32 g.) est

ensuite filtré, lavé avec quelques millilitres d'alcool à 85% (35 ml.) contenant un peu d'acide *dl*-tartrique. Recristallisé dans l'alcool à 85%, le *l*-tartrate de la *l*-α-hydroxylaudanosine est obtenu à l'état pur, p.f. 207°C. Rendement: 52% (1.49 g.). $[\alpha]_D = -75.9°$ (*c*, 1.001 dans l'eau). Le sel est ensuite dissous dans l'eau (35 ml.) et la solution neutralisée à la soude *N*. La base qui précipite est filtrée et lavée à l'eau. Une cristallisation dans l'alcool (4–5 ml.) donne la *l*-α-hydroxylaudanosine pure de p.f. 151°C. Rendement: 47% (0.95 g.). Calculé pour $C_{21}H_{27}O_5N$: C, 67.5%; H, 7.3%. Trouvé: C, 67.6%; H, 7.1%. $[\alpha]_D = -86.4°$ (*c*, 1.209 dans le chloroforme).

Un mélange à parties égales des deux inverses optiques, la *d*- et la *l*-α-hydroxylaudanosine, a un p.f. de 138°C. qui est le p.f. de la base racémique, l'α-hydroxylaudanosine.

Dédoublement de la β-hydroxylaudanosine

On procède avec les mêmes quantités de substances exactement comme précédemment lors du dédoublement de l'α-hydroxylaudanosine. Le *d*-tartrate de la *d*-β-hydroxylaudanosine (3.32 g.) précipite d'abord. Une première cristallisation dans l'alcool absolu (35 ml.) et une deuxième dans l'alcool éthylique à 95% (30 ml.) fournit le sel pur de p.f. 190–191°C. Rendement: 61.5% (1.76 g.). $[\alpha]_D = -19.5°$ (*c*, 1.000 dans l'eau).

La base obtenue par neutralisation du sel est cristallisée une fois dans l'alcool à 50% (10 ml.) et donne la *d*-β-hydroxylaudanosine pure de p.f. 104°C. Rendement: 47% (0.94 g.). Calculé pour $C_{21}H_{27}O_5N$: C, 67.5%; H, 7.3%. Trouvé: C, 67.2%; H, 7.3%. $[\alpha]_D = +11.2°$ (*c*, 1.030 dans le chloroforme).

Le *l*-tartrate est obtenu par l'action de l'acide *dl*-tartrique (1.74 g., 0.012 mole) sur la base *l*-impure (2.16 g., 0.006 mole) dans l'alcool absolu (15 ml.). Le sel qui se dépose par refroidissement est laissé au contact des eaux-mères pendant une semaine à la température ambiante. Le sel (1.82 g.) est ensuite filtré et lavé avec quelques millilitres d'alcool absolu. Après une cristallisation dans l'alcool à 90% (25 ml.) il donne le *l*-tartrate de la *l*-β-hydroxylaudanosine pur de p.f. 189–190°C. Rendement: 50.5% (1.44 g.). Calculé pour $C_{21}H_{27}O_5N.C_4H_6O_6$: C, 57.4%; H, 6.4%. Trouvé: C, 57.1%; H, 6.4%. $[\alpha]_D = +20.0°$ (*c*, 1.000 dans l'eau).

L'alcalisation de la solution aqueuse du sel par la soude 3*N* donne la *l*-β-hydroxylaudanosine. Celle-ci après une cristallisation dans l'alcool à 50% (8–10 ml.) est pure et a un p.f. de 103°C. Rendement: 34% (0.68 g.). $[\alpha]_D = -12.3°$ (*c*, 1.056 dans le chloroforme).

La détermination du point de fusion d'un mélange à parties égales des deux antipodes, la *d*- et la *l*-β-hydroxylaudanosine, donne 109°C. qui est le p.f. de la β-hydroxylaudanosine racémique.

Essais de dédoublement du papavérinol

Du papavérinol (1.121 g., 0.003 mole) et de l'acide *d*-tartrique (1.00 g., 0.006 mole) sont dissous dans l'alcool éthylique absolu (10 ml.) à l'ébullition et laissés à la température ambiante durant quatre mois. Le produit cristallin qui s'est alors déposé est filtré, lavé avec quelques millilitres d'alcool absolu, et séché. Cette substance (0.46 g.) insoluble dans l'eau et soluble dans le chloro-

forme donne par cristallisation dans le dioxane (5 ml.) un produit (0.28 g.) de p.f. 210°C. Un autre essai à partir de 2.0 g. de papavérinol et de 0.946 g. d'acide *d*-tartrique a donné après 22 jours 0.463 g. de produit brut. Si cependant l'acide *l*-malique (0.38 g. pour 1.0 g. de papavérinol) est employé, la quantité du produit de p.f. 209°C. obtenu n'est que de 0.10 g. La même substance a été isolée au cours de ces trois essais. C'est ce qu'ont montré les déterminations de points de fusion mixtes. Cette substance basique forme une 2,4-dinitrophénylhydrazone de p.f. 250–251°C. Calculé pour $C_{26}H_{25}O_8N_5$: C, 58.3%; H, 4.7%. Trouvé: C, 58.3%; H, 4.4%. C'est donc une cétone. Un méthiodure de p.f. 148–150°C. (déc.) a également été préparé. Il cristallise dans l'alcool éthylique. Calculé pour $C_{21}H_{25}O_5NI$: C, 50.7%; H, 4.8%. Trouvé: C, 50.1%; H, 4.6%.

Comme le point de fusion (148–150°C.) du méthiodure ne correspondait pas à celui (133–135°C.) qui est donné par Menon (5), de la papavéraldine a été préparée par la méthode de Taylor (6). Cette papavéraldine synthétique a également un p.f. de 210°C. seule ou mélangée au composé isolé. Le point de fusion de son méthiodure est aussi le même que celui du méthiodure de la base isolée, soit 148–150° (déc.), et il n'est pas affecté par le mélange des deux sels. Calculé pour la papavéraldine $C_{20}H_{19}O_5N$: C, 68.0%; H, 5.4%. Trouvé pour le composé isolé: C, 67.7%; H, 5.9%. Il s'ensuit donc que la base isolée est la papavéraldine.

KINETICS OF THE CUPRIC ACETATE CATALYZED HYDROGENATION OF DICHROMATE IN AQUEOUS SOLUTION[1]

By E. Peters and J. Halpern

ABSTRACT

In aqueous solution, cupric acetate was found to act as a homogeneous catalyst for the reduction of dichromate by hydrogen, i.e.

$$Cr_2O_7^{--} + 3\,H_2 + 8\,H^+ \xrightarrow{[Cu(OAc)_2]} 2\,Cr^{+++} + 7\,H_2O.$$

The paper describes a kinetic study of this reaction. Rates were determined at temperatures between 80° and 140°C. and hydrogen partial pressures up to 27 atmospheres. The rate is independent of the dichromate concentration but varies directly with the partial pressure of hydrogen and is nearly proportional to the concentration of cupric acetate. The activation energy is 24,600 calories per mole. Cupric acetate, apparently acting as a true catalyst, activates the hydrogen through formation of a complex with it. An extension of the mechanism proposed earlier for the reaction of cupric acetate itself with hydrogen also accounts for the kinetics of the dichromate reaction.

INTRODUCTION

Dakers and Halpern (3) have recently shown that cupric acetate reacts homogeneously in aqueous solution with molecular hydrogen as follows:

$$2Cu(OAc)_2 + H_2 + H_2O \rightarrow Cu_2O + 4HOAc. \qquad [1]$$

The kinetics of this reaction are described in an earlier paper (3). The rate can be expressed by the equations:

$$-d[Cu(OAc)_2]/dt = k_2'[Cu(OAc)_2]\,P_{H_2} = k_2[Cu(OAc)_2]\,[H_2] \qquad [2]$$

where P_{H_2} is the partial pressure of hydrogen above the solution.

k_2', apparently independent of the hydrogen pressure and solution composition, was given by:

$$k_2' = 6.15 \times 10^{10} \exp[-24{,}200/RT]\ \text{atm.}^{-1}\ \text{min}^{-1}. \qquad [3]$$

To account for this kinetic behavior the reaction was postulated (3) to proceed through the following sequence of steps, the first step being rate determining:

$$Cu(OAc)_2 + H_2 \xrightarrow[\text{slow}]{k} Cu(OAc)_2 \cdot H_2 \qquad [4]$$

followed by:

$$Cu(OAc)_2 \cdot H_2 + Cu(OAc)_2 + H_2O \xrightarrow[\text{fast}]{} Cu_2O + 4HOAc. \qquad [5]$$

Cupric acetate thus appears to have the property of being able to activate molecular hydrogen homogeneously, through the formation of a complex with

This work was supported by a grant from the National Research Council of Canada and a Fellowship award to one of the authors (E. P.) from the Consolidated Mining and Smelting Company of Canada Ltd.

it, as represented in equation [4]. Only two other instances of comparable homogeneous activation of hydrogen, one involving cuprous acetate (1, 2, 8) and the other dicobalt octacarbonyl (5, 9) as the activating species, have previously been reported. This appears to be the first time that this type of activation has been observed in aqueous solution. The detailed mechanism of the process and its relation to the more common phenomenon of heterogeneous catalytic activation of hydrogen have not been resolved.

The reaction sequence represented in equations [4] and [5] above implies that cupric acetate should also be capable of functioning as a homogeneous catalyst for the reactions with hydrogen of other compounds which are thermodynamically reduced more readily than cupric acetate itself, but which do not react with hydrogen in the absence of a catalyst for kinetic reasons.

In accord with this it was found that the homogeneous reduction of dichromate salts by molecular hydrogen in aqueous solution, represented by the equation:

$$Cr_2O_7^{--} + 3H_2 + 8H^+ \rightarrow 2Cr^{+++} + 7H_2O, \qquad [6]$$

would proceed only in the presence of dissolved cupric acetate, the latter apparently acting as a true catalyst. The present paper describes a kinetic study of this reaction, undertaken with a view to obtaining further information about the mechanism of the hydrogen activation process.

EXPERIMENTAL

Sodium dichromate, cupric acetate, sodium acetate, and acetic acid, all of Reagent Grade, were supplied by Nichols Chemical Company. The solutions were prepared by dissolving weighed quantities of these chemicals in distilled water. Commercial hydrogen gas, supplied in cylinders by Canadian Liquid Air Company, was used without further purification.

The experiments were conducted in the stainless steel autoclave described in an earlier paper (3). Three liters of solution of desired composition were placed in the autoclave which was then sealed, flushed with nitrogen, and heated to the reaction temperature, maintained to within ±0.3°C. Hydrogen was introduced and maintained at a desired partial pressure with a standard gas pressure regulator. The solution was stirred with an impeller of 2.5 in. diameter which rotated at 900 r.p.m. Samples of the solution were withdrawn periodically for analysis. The concentration of unreacted dichromate was measured with a Beckman DU Spectrophotometer using the 3500 Å absorption peak. Cupric acetate concentrations were determined electrolytically.

RESULTS

In the absence of cupric acetate, no reaction between dichromate and hydrogen could be detected up to temperatures of 160°C. and hydrogen partial pressures of 30 atm. When cupric acetate was present, the reduction of dichromate proceeded measurably at temperatures as low as 80°C. Spectrophotometric identification of the product, chromic acetate, confirmed that the stoichiometry of the reaction is represented by equation [6].

**Stirring velocity reduced to 600 r.p.m. In all other experiments stirring velocity was 900 r.p.m.*

decreased linearly with time, corresponding to zero order kinetic behavior, i.e.

$$-d[Cr_2O_7^{--}]/dt = k_0. \quad [7]$$

Values of the zero order rate constant, k_0, determined from the slopes of the rate plots were reproducible to within $\pm 5\%$ (see Table I).

Further evidence for zero order kinetic behavior is provided by the results in Fig. 2 and Table I, which show k_0 to be independent of the initial $Cr_2O_7^{--}$ concentration. The fact that the rate was unchanged when the stirring velocity was varied from 600 to 900 r.p.m. indicates that the reaction was not limited by solution of hydrogen.

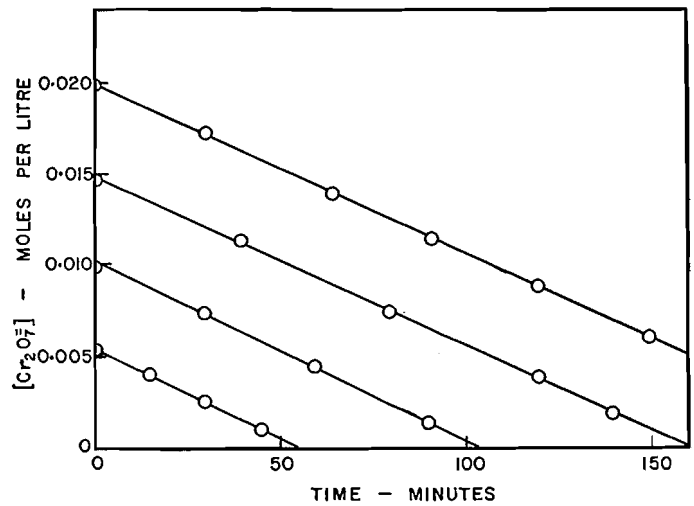

FIG. 2. Rate curves for the reduction of dichromate by hydrogen. $[Cu(OAc)_2]$, 0.10 M./liter. Temperature, 100°C. H_2 partial pressure, 13.6 atm.

Fig. 1 shows that the concentration of cupric acetate remained constant as long as dichromate was undergoing reaction. This was always found to be the case and is in accord with the view that cupric acetate is a true catalyst for the dichromate reaction. Only when the reduction of dichromate was complete, did the cupric acetate react with hydrogen to form cuprous oxide according to equation [1]. The first order kinetic behavior of this reaction, shown in Fig. 1, is in quantitative agreement with that reported earlier (3). Apparently the reduction of cupric acetate is not affected by the previous dichromate reaction or by the presence of small amounts of chromic salts in the solution.

The dependence of the rate of the dichromate reaction on the concentration of cupric acetate provides further support for the catalytic role of the latter. The results in Figs. 3 and 4 show that the rate increases in a nearly linear manner with increasing cupric acetate concentration, i.e.

$$k_0 = k_3 [Cu(OAc)_2]. \quad [8]$$

Actually the relation is seen to be not quite linear, k_3 showing a tendency to fall off slightly with increasing $[Cu(OAc)_2]$. Thus at 100°C. and 13.6 atm. of

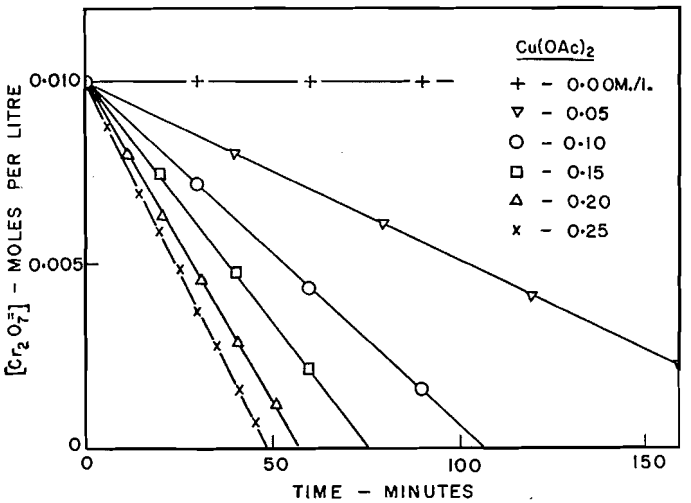

FIG. 3. Rate curves for the reduction of dichromate at different concentrations of cupric acetate. Temperature, 100°C. H_2 partial pressure, 13.6 atm.

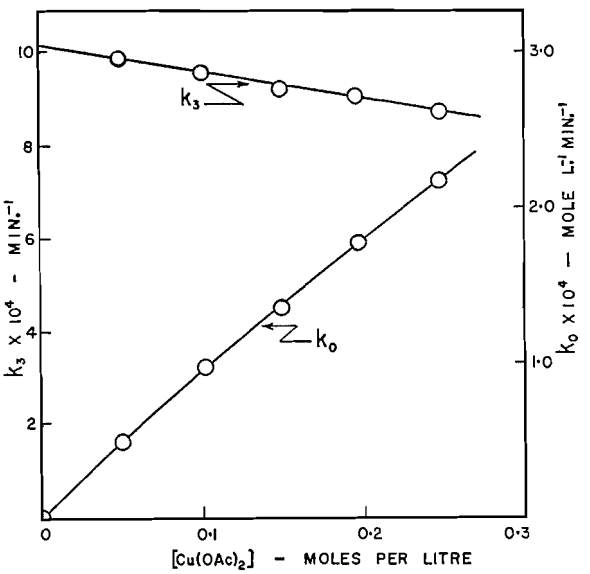

FIG. 4. Dependence of the rate of reaction of dichromate on the concentration of cupric acetate. Temperature, 100°C. H_2 partial pressure, 13.6 atm.

hydrogen, the value of k_3, extrapolated to zero [$Cu(OAc)_2$] (see Fig. 4), is given by:

$$k_3^0 = 0.00101 \text{ mole } Cr_2O_7^{=}/\text{mole } Cu(OAc)_2/\text{min.} \qquad [9]$$

At the highest cupric acetate concentration investigated, i.e. 0.25 M./liter, the value of k_3 was found to be 0.00087 or about 14% lower. The significance of this decrease will be discussed later.

The reduction of dichromate was studied at hydrogen partial pressures ranging from zero to 27.2 atm. The results, plotted in Fig. 5, show the rate to be directly proportional to the partial pressure of hydrogen throughout this

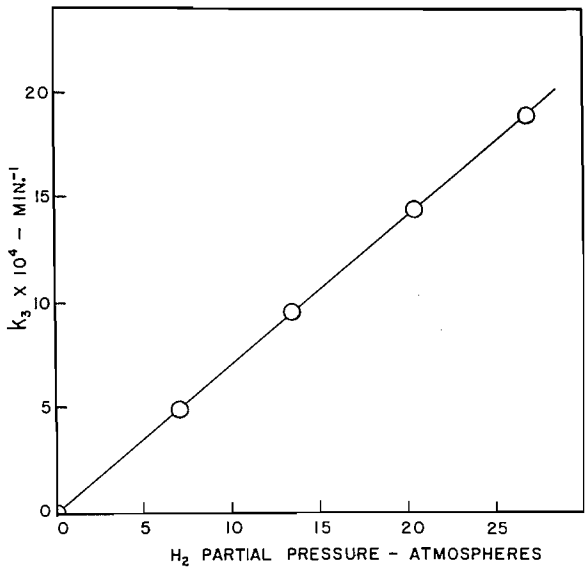

FIG. 5. Dependence of the rate on the hydrogen partial pressure. Temperature, 100°C.

range. Assuming that the solubility of hydrogen follows Henry's Law (3, 7), this relation also implies that the rate is proportional to the concentration of molecular hydrogen in solution.

The kinetics of the reaction are thus seen to conform to the bimolecular rate equation:

$$-d[Cr_2O_7^{--}]/dt = k_4'[Cu(OAc)_2]P_{H_2} = k_4[Cu(OAc)_2]\,[H_2]. \qquad [10]$$

The following relations are also seen to hold:

$$k_3 = k_4'\,P_{H_2} = k_4[H_2] \qquad [11]$$

and

$$k_4' = \alpha k_4 \qquad [12]$$

where α is Henry's constant denoting the solubility of hydrogen.

There is evident a formal similarity between equation [10] and equation [2], which expresses the rate of reaction of cupric acetate with hydrogen. Relations similar to equations [11] and [12] also apply in the case of the cupric acetate reaction (3).

The rate of the dichromate reaction was measured at temperatures ranging from 80° to 140°C. The results were found to give a good Arrhenius plot shown in Fig. 6. The activation energy, calculated from the slope of this plot, is 24,600±600 cal. per mole, in good agreement with the value of 24,200±800 cal. per mole reported earlier for the reaction of cupric acetate itself with hydrogen (3). It should be noted that in the series of experiments where the temperature was varied, the partial pressure of hydrogen, and not its con-

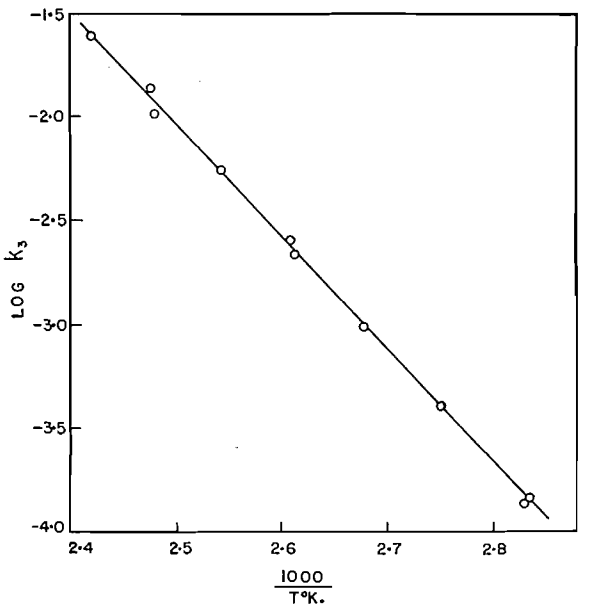

FIG. 6. Arrhenius plot for the cupric acetate catalyzed reaction of dichromate with hydrogen.

centration in solution, was held constant. The apparent activation should therefore be corrected for the change in solubility of hydrogen with temperature. This correction is probably small.

In most of these experiments the solutions contained, in addition to sodium dichromate and cupric acetate, 0.25 M./liter of sodium acetate and 0.5 M./liter of acetic acid. The pH was thus buffered at a value of about 4.5 and changed very little during the course of reaction. That these values are not critical is indicated by the results in Table I which show that wide variations in the acetate and acetic acid concentrations were substantially without effect on the rate.

DISCUSSION

The kinetic similarity of the dichromate and cupric acetate reactions supports the view that both have the same rate controlling step. In each case the pattern of kinetic behavior suggests that the rate is determined by a bimolecular process involving one molecule of cupric acetate and one molecule of hydrogen. The hydrogen must become activated in this step so that its subsequent reaction with either reducible substrate to give the observed reaction products is rapid.

A reaction mechanism incorporating such a rate controlling step has already been proposed for the reduction of cupric acetate (see equations [4] and [5]). An analogous mechanism can be written for the dichromate reaction, i.e.

$$3Cu(OAc)_2 + 3H_2 \xrightarrow[\text{slow}]{k} 3Cu(OAc)_2 \cdot H_2 \qquad [13]$$

followed by:

$$3Cu(OAc)_2 \cdot H_2 + Cr_2O_7^{--} + 8H^+ \xrightarrow[\text{fast}]{} 2Cr^{+++} + 7H_2O + 3Cu(OAc)_2. \quad [14]$$

The role of cupric acetate is seen to be that of a true catalyst, since it is regenerated as long as dichromate is undergoing reduction.

At 100°C., the rate constant for the cupric acetate reaction, k_2', was found to be 4.45×10^{-4} atm.$^{-1}$ min.$^{-1}$ (3). From equation [9], the value of the corresponding rate constant for the dichromate reaction, k_4', extrapolated to zero cupric acetate concentration, is seen to be 7.45×10^{-5} atm.$^{-1}$ min^{-1}. The ratio $k_2' : k_4'$ is thus found experimentally to be 5.95, in agreement with the theoretical value of 6.0, corresponding to the fact that the reduction of $Cr_2O_7^{--}$ involves six electrons as compared with one for $Cu(OAc)_2$.

Thus measurements of the dichromate reaction rate and of the cupric acetate reaction rate both yield the same value of k. It has previously been shown (3) that this value corresponds to a frequency factor of 4.8×10^{13} liter mole^{-1} min.$^{-1}$, or an equivalent activation entropy, $\Delta S_c^{\ddagger}$, of -6.5 e.u. These values are normal (3, 4, 6) for a simple bimolecular process such as that represented by equation [13].

The reaction mechanisms which have been proposed for both the dichromate and cupric acetate reactions thus appear to be in quantitative agreement with the kinetic results. In particular, this agreement may be taken as supporting the conclusion that cupric acetate rather than one of its reduction products (i.e. cuprous acetate or cuprous oxide) is the species responsible for activating molecular hydrogen. Other evidence for the same view has previously been presented (3). In the present case the evidence appears fairly conclusive, since no cupric acetate is reduced until all the dichromate has reacted. This is of special interest in view of Calvin's earlier work (1, 2), showing that cuprous acetate activates hydrogen homogeneously in quinoline solutions. It appears that the mechanism of activation in the two systems is not the same.

It is probable that the observed slight decrease in k_4' (and hence in the apparent value of the ratio $k_4' : k_2'$) with increasing cupric acetate concentration arises from a secondary effect of cupric acetate, the most likely one being a lowering of the solubility of hydrogen (i.e. of α). The mechanism which has been proposed above suggests that k_4 is independent of the concentration of hydrogen. At constant partial pressure, any change in α would therefore be reflected in k_4'. A lowering of the solubility of hydrogen in water is a well-known effect of many salts (7).

k_2', which is also proportional to α, should vary in a similar manner with the cupric acetate concentration. That the earlier work (3) did not reveal this variation is not surprising, since the values of k_2' were determined by measuring the rate of disappearance of cupric acetate, usually down to very low concentrations. The first order kinetics of this reaction would tend to mask a small change in the rate, apparent only in the first stages (i.e. when most of the cupric acetate was still unreacted). Recently more accurate determinations have been made of the initial rate of the cupric acetate reaction. The results

confirm that k_2' varies, in a similar manner to k_4', with the cupric acetate concentration, and thus that the ratio $k_2' : k_4'$ retains a constant value close to 6.

CONCLUSIONS

Further evidence has been provided that cupric acetate activates molecular hydrogen homogeneously in aqueous solution. One consequence of this is its ability to function as a true homogeneous catalyst for the hydrogenation of other compounds. An extension of the mechanism, proposed earlier (3) for the reaction of cupric acetate itself with hydrogen, also appears to explain the kinetics of the catalytic hydrogenation of dichromate.

THE OXIDATION OF 3-(N-BENZYLACETAMIDO)-1,2-PROPANEDIOL TO N-BENZYLACETAMIDOACETALDEHYDE AND RING CLOSURE OF THE LATTER TO ISOQUINOLINE[1]

By Arlen W. Frank[2] and C. B. Purves

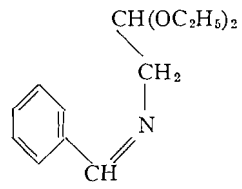
ABSTRACT

Fischer's synthesis of isoquinoline by the oxidative cyclization of benzylaminoacetaldehyde diethyl acetal with 20% oleum was found to give a yield of 8.5%, but his isolation of the intermediate aldehyde could not be repeated. The N-acetyl derivative, N-benzylacetamidoacetaldehyde, however, was synthesized as a somewhat unstable oil, b.p. 129–131° (0.12 mm.), and was cyclized in 7.5% yield to isoquinoline. This synthesis involved the hydrogenation of 3-benzylideneamino-1,2-propanediol to 3-benzylamino-1,2-propanediol, b.p. 152–155° (0.5 mm.); hydrochloride, m.p. 92–94.5°. The N-acetyl derivative, 3-(N-benzylacetamido)-1,2-propanediol, b.p. 188° (0.12 mm.), was then oxidized with sodium metaperiodate; the behavior of other intermediates in the synthesis toward periodate, and also lead tetraacetate, was studied. The following additional compounds were thought to be new: 3-veratrylideneamino-1,2-propanediol, m.p. 123–125°; 3-veratrylamino-1,2-propanediol, b.p. 207–214° (0.4 mm.); the hydrochloride, m.p. 151–152°; 3-(N-benzylacetamido)-1,2-diacetoxypropane, b.p. 196–199° (0.7 mm.), and N-benzylacetamidoacetaldehyde 2,4-dinitrophenylhydrazone, m.p. 315–316°.

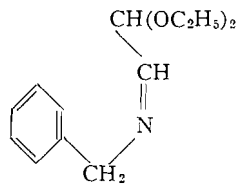
INTRODUCTION

The synthesis of isoquinolines from substituted benzylideneaminoacetals (I) or benzylaminoacetals (II) suffers from the fact that the azomethine link is unstable in the sulphuric acid or polyphosphoric acid required for cyclization. While this difficulty is not great when simple aldimine Schiff bases are cyclized, it becomes serious with the more complex ketimine Schiff bases (12). In order to eliminate this difficulty, the azomethine group has been reduced to the more stable secondary amine (III), which has then been cyclized with sulphuric acid in the presence of an oxidizing agent.

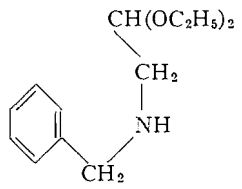
In 1893 Fischer (10) reported that the oxidative cyclization of benzylaminoacetaldehyde with fuming sulphuric acid gave isoquinoline, isolated in low but unstated yield as the platinichloride. Since sulphur dioxide was evolved



I



II



III

and no isoquinoline was obtained when cyclization was attempted with concentrated instead of fuming sulphuric acid, it appeared that one of the inter-

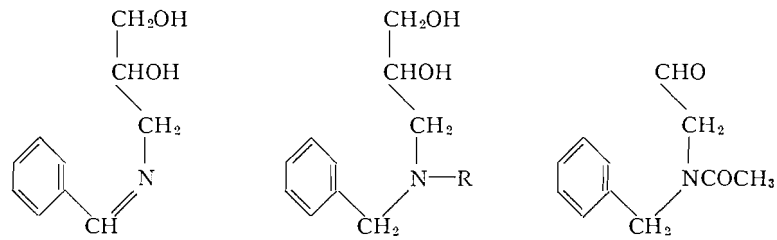
mediates, probably 1,2-dihydroisoquinoline, was oxidized by the sulphur trioxide. Fischer's method, however, was obviously inapplicable to many compounds substituted in the benzene ring because of the ease with which such compounds were sulphonated. An alternative method, developed by Rügheimer and Schön (28) consisted of cyclization in concentrated sulphuric acid containing arsenic pentoxide as an oxidizing agent. Although veratrylaminoacetal yielded 21% of 6,7-dimethoxyisoquinoline (11), the method failed when applied to myristicinylaminoacetal (26) and to N-(α-veratrylveratryl)-aminoacetal (2). Attempts to isolate the intermediate 1,2-dihydroisoquinolines in the cyclization of benzyl- (10), myristicinyl- (29), piperonyl- (20), and N-methylpiperonylaminoacetal (31) were uniformly unproductive. In addition to sulphuric acid in various concentrations, other cyclizing agents such as concentrated hydrochloric acid and phosphorus oxychloride were tried without success.

Despite these disappointing results, the synthesis seemed to merit further study, because it offered a simple and direct way of preparing isoquinoline derivatives such as the alkaloid papaverine from readily available substances (2). In all save one of the cases cited, cyclization had to await the hydrolysis of the acetal to a free aldehyde (or to a vinyl derivative), and if the delay happened to be lengthy there would be opportunity for undesired side-reactions. The exception was Fischer's claim (9) that benzylaminoacetaldehyde could be isolated as a pale yellow, crystalline hydrochloride by evaporating to dryness a solution of the corresponding acetal (III) in concentrated hydrochloric acid. The free base was reported to be a colorless, ether soluble oil which strongly reduced Fehling's solution and which gave the low but unstated yield of isoquinoline when cyclized (10). Neither the base nor its hydrochloride was analyzed or assigned any physical characteristics other than those just stated, and the synthesis has apparently never been repeated nor applied successfully to any other compound in the benzylaminoacetal class. A reinvestigation of the original work was therefore undertaken.

Despite many attempts, Fischer's hydrochloride was invariably isolated as a black, gummy solid which could not be purified by recrystallization. Neutralization of these hydrochlorides gave no recognizable benzylaminoacetaldehyde, and Fischer's claim to have obtained it was finally considered to be in error. On the other hand, cyclization of the black, solid hydrochloride with 20% oleum at room temperature for 24 hr. did give isoquinoline, which was isolated as the picrate in 8.5% yield based on the original benzylaminoacetal. Stronger acid (30–35% SO_3) probably resulted in sulphonation, since the yield of isoquinoline decreased to only 0.07% of theory. The experiment with 20% oleum was then repeated with the acetal itself, and the yield of isoquinoline was 3.5%. When a solution of the acetal (III) in concentrated sulphuric acid was heated for 30 min. at 160–170° and the basic portion of the product was distilled in steam, a copious amount of oil was recovered but no isoquinoline picrate could be isolated from it. Under these conditions, benzylideneaminoacetal (I) was cyclized to isoquinoline in 50% yield (24). An experiment was also carried out using arsenic pentoxide instead of sulphur trioxide as the

oxidizing agent, but only an impure picrate was recovered in small yield. A condensation with concentrated sulphuric acid at 100° for four hours yielded an amorphous yellow solid softening at 185° to 190°, and containing 9.7% of nitrogen (calc. for isoquinoline: N, 10.9%); another condensation with 72% sulphuric acid for four days at room temperature gave a viscous yellow liquid with 8.3% of nitrogen. Neither of these substances was the 1,2-dihydroisoquinoline postulated by Fischer as an intermediate in the cyclization. A base, prepared by cyclizing benzylaminoacetal in cold concentrated sulphuric acid, according to Fischer's directions, was probably impure isoquinoline. The details of these negative experiments have been omitted from this article.

The failure to confirm Fischer's preparation of benzylaminoacetaldehyde made it desirable to develop a new synthesis for this class of compounds, and advantage was taken of the fact that the structure IV (and from this, V) could be readily obtained by condensing benzaldehyde with 3-amino-1,2-propanediol. The analogous veratryl derivatives were also prepared. Oxidation



IV V (R = H or $COCH_3$) VI

of IV or V (R = H) with sodium periodate or lead tetraacetate would then be expected to cleave the 1,2-glycol units giving the aldehydes corresponding to the acetals I and III. No previous reference was found to the oxidation of a Schiff base like IV by periodate, other than the oxidation of mannose phenylhydrazone and of glucose phenylosazone (15), the latter giving a pyrazolone in which, of course, the C=N bonds were stabilized by resonance. Benzylidenimine was known to be dehydrogenated with lead tetraacetate in acetic acid to benzonitrile (8), and the imines produced by the oxidation of 2-aminoalcohols were considered to be further oxidized to nitriles (8, 18). McCasland and Smith (18) recently reviewed the rather extensive literature dealing with the action of both oxidants on the aminoalcohols themselves.

It was expected that the azomethine bond in 3-benzylideneamino-1,2-propanediol (IV) would be untouched by periodate in neutral or basic solution, but might be readily hydrolyzed in an acidic medium. An aqueous solution of IV, however, was reported as strongly basic (5), a property not characteristic of a Schiff base, and also at once developed the odor of benzaldehyde. The compound, therefore, appeared to exist in aqueous solution as a mixture of the Schiff base (and its cyclic oxazolidine form (4)), benzaldehyde, and 3-amino-1,2-propanediol in equilibrium. In keeping with this view, the compound IV, like 3-amino-1,2-propanediol (21), reduced 2 moles of periodate per mole both at

pH 8 and pH 4, and 1 mole of ammonia was liberated. It was interesting to note that when 1 mole of periodate per mole of Schiff base was used, no less than 0.55 mole of ammonia was formed; the N—C—C—O link in 3-amino-1,2-propanediol was therefore somewhat more sensitive than the glycol unit to cleavage by the periodate. Although Mead and Bartron (21) found that ammonia could not be reliably determined by the direct titration of solutions in which formaldehyde was present, accurate results were obtained in the present experiments by distilling the ammonia as in the standard Kjeldahl method.

In order to avoid hydrolysis, 3-benzylideneamino-1,2-propanediol was then oxidized with lead tetraacetate dissolved in benzene or in glacial acetic acid. Two moles per mole of diol was rapidly consumed in the former solvent, but in the latter the rate of consumption was slow enough to be followed by iodometry (13). The rate plot (Fig. 1) showed that 1 mole of the tetraacetate was

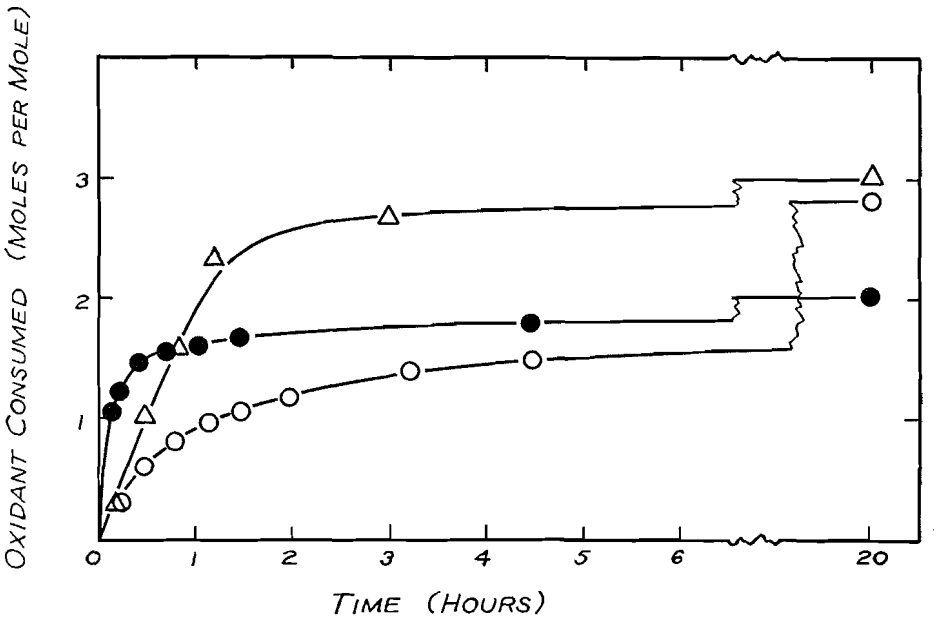


FIG. 1. Oxidation of the aminediols with excess 0.05 *M* lead tetraacetate in acetic acid at 26°.
△3-Amino-1,2-propanediol
●3-Benzylideneamino-1,2-propanediol
○3-(N-Benzylacetamido)-1,2-propanediol (3.04 moles tetraacetate consumed after 47 hr.)

consumed fairly quickly, while the second mole required about 20 hr. Fig. 1 also shows that under the same conditions 3-amino-1,2-propanediol required 3 moles of the tetraacetate, of which 1 mole was expended in slowly oxidizing one of the products, formic acid, to carbon dioxide (8, 23). Although it was plain that the consumption of 2 moles, instead of 1 mole, by IV was not caused by the solvolysis of the Schiff base group, no good explanation was found for

the anomaly. The fact that exactly 2 moles of lead tetraacetate were utilized, instead of a fractional amount, suggested that a specific, ionic reaction was occurring, rather than a non-specific, free-radical process such as addition or dehydrogenation (3, 8). These oxidations were not pursued because they were not likely to yield the desired product, benzylaminoacetaldehyde.

An easy hydrogenation of the Schiff base (IV) yielded 3-benzylamino-1,2-propanediol (V, R = H), which was found to reduce 2 moles of periodate per mole at pH 4, but only 1 mole when the solvent was 5% sulphuric acid. This behavior was not unexpected, because Tompsett and Smith (30) observed that periodate produced formaldehyde from aminoalcohols like ethanolamine and serine in neutral, but not in acid solution. The consumption of periodate by 2-aminocyclohexanol also decreased with decrease in pH (18). It seemed likely that the conversion of the amine to the ammonium salt in acid media prevented the formation of a cylic ester with the periodate ion, which was probably an essential intermediate in the oxidation (6). Attempts were made to use the above results on a preparative scale by destroying any excess periodate in the acidic reaction mixture with ethylene glycol, and then extracting the neutralized liquor with ether. No N-benzylaminoacetaldehyde could be recovered from the black gums produced. Attempts to prepare this compound by deacetylating its N-acetyl derivative (see below) also ended in failure.

3-(N-benzylacetamido)-1,2-propanediol (V, R = $COCH_3$) was then prepared, either directly from 3-benzylamino-1,2-propanediol (V, R = H) by acetylation in aqueous solution, or indirectly by the partial deacetylation of the O,O,N-triacetyl derivative. The consumption of periodate by the product (V, R = $COCH_3$) was 1.3 mole per mole after 30 min., and did not increase during 24 hr. One mole of lead tetraacetate was consumed rapidly, but a slow utilization of a further 2 moles during 47 hr. also occurred (Fig. 1). In other aminoglycols the introduction of an N-acyl group such as acetyl, benzoyl, or carbobenzyloxy prevented the oxidation from exceeding 1 mole (7, 14, 22). The oxidation of 3-(N-benzylacetamido)-1,2-propanediol with periodate, however, led to a successful preparation of N-benzylacetamidoacetaldehyde (VI), which was a colorless oil soluble in chloroform but not in ether, and which darkened quite rapidly. The crystalline 2,4-dinitrophenylhydrazone of the aldehyde was prepared and characterized.

When a solution of N-benzylacetamidoacetaldehyde (VI) in concentrated sulphuric acid was heated for 30 min. at 160–170°, the product included 7.5% of isoquinoline, but this yield decreased to 3% when the heating was only for five minutes. Cyclization in 20% oleum for 24 hr. at room temperature also gave isoquinoline picrate, but in extremely low yield. The odor of benzaldehyde was absent in these experiments, whereas in the Pomeranz (24) cyclization of benzylideneaminoacetal (I) a considerable amount of benzaldehyde was produced in a hydrolytic side-reaction. This difference suggested that the present reaction involved cyclization to 1,2-dihydroisoquinoline, or its N-acetyl derivative, followed by dehydrogenation or deacetylation. All attempts to isolate these supposed intermediates, or N-benzylaminoacetaldehyde, however, were in vain.

EXPERIMENTAL[3]

Materials and Analytical Methods

Glycidol (2,3-epoxy-1-propanol), prepared from 3-chloro-1,2-propanediol with alcoholic potassium hydroxide (25), was dissolved in aqueous ammonia (16) and the solution distilled 24 hr. later to give an 88.5% yield of 3-amino-1,2-propanediol as a colorless oil boiling at 154–156° (14 mm.). On redistillation the product boiled sharply at 153° (13 mm.). The picrolonate melted with charring at 216–218°.

Lead tetraacetate was prepared by adding red lead (Pb_3O_4) to a hot mixture of acetic acid and acetic anhydride, as described by McClenahan and Hockett (19). The consumption of the tetraacetate was followed iodometrically (13), and that of the periodate either iodometrically in acid solution, or by the arsenite–iodine titration near pH 9 (14). In order to determine the ammonia liberated in the oxidation of 3-benzylideneamino-1,2-propanediol (IV), samples, 0.03675 and 0.04360 gm., were dissolved in 20 ml. of 0.05 *M* sodium metaperiodate. After one hour at room temperature, the solutions were transferred to a semimicro Kjeldahl distilling apparatus, diluted with 10 ml. of 45% aqueous sodium hydroxide and steam distilled for 10 min., the distillates being collected in 25 ml. volumes of 0.8% aqueous boric acid containing five drops of methyl purple indicator. The distillates when titrated required 7.52 and 8.94 ml. of 0.02660 *N* hydrochloric acid, respectively, or 98, 98% of the theoretical amount. These results were corrected from blanks containing only sodium metaperiodate.

Benzylaminoacetaldehyde Diethyl Acetal (III)

The details, lacking in Rügheimer and Schön's (27) description, were as follows. A mixture of 53.5 gm. (0.35 mole) of chloroacetaldehyde diethyl acetal and 77.0 gm. (0.72 mole) of benzylamine was heated for 1.5 hr. at 145–150° with mechanical stirring. During this time the solution became deep red in color, gases were evolved, and benzylamine hydrochloride separated in a mass of white crystals. After cooling, water was added to dissolve the salt, the solution was made alkaline with 500 ml. of 10% sodium carbonate and extracted with ether. The extract was washed with water, dried over anhydrous sodium sulphate, and evaporated. The residual oil when distilled at 15 mm. pressure yielded 45.8 gm. (59%) of benzylaminoacetal boiling at 150–160°; redistillation of this fraction furnished a pure sample boiling correctly (9, 27) and sharply at 156° (15 mm.). Found: N, 6.22, 6.20%. Calc. for $C_{13}H_{21}O_2N$: N, 6.27%.

In attempts to prepare Fischer's benzylaminoacetaldehyde hydrochloride (9), 4.5 gm. of the above acetal was dissolved cautiously in 20 ml. of ice-cold, concentrated hydrochloric acid. After being heated for one hour at 50–60°, the solution was evaporated to dryness under reduced pressure. No crystalline material could be recovered from the black residue.

In a typical cyclization to isoquinoline the black hydrochloride from 4.5 gm. of the acetal was gradually added to 20 ml. of ice-cold oleum (20% SO_3),

[3]*Melting points were not corrected.*

solution being immediate and with the evolution of hydrogen chloride. After 24 hr. at room temperature, the wine-red solution was poured onto 50 gm. of crushed ice, diluted with 50 ml. of water, and extracted with ether. The aqueous layer was made strongly alkaline by adding 40 gm. of sodium hydroxide dissolved in 200 ml. of water, and was distilled in steam until 300 ml. of distillate was collected. Extraction of the distillate with ether removed an oil which was diluted with a little ethanol and added to a hot solution of picric acid, 2.5 gm., in 75 ml. of water. The picrate which separated, when recovered, washed with ethanol, and dried, weighed 0.61 gm. (8.5%) and melted at 225–227.5°. A mixed melting point with authentic isoquinoline picrate prepared from commercial isoquinoline was not depressed. When the mother liquors were concentrated to small volume 0.53 gm. of crude picric acid was all that separated.

3-Benzylideamino-1,2-propanediol (IV)

Condensation of 77.7 gm. of 3-amino-1,2-propanediol with 98.0 gm. of benzaldehyde in 40 ml. of ethyl acetate (5) gave a 70% yield of the above substance as white needles, m.p. 80–82°, from ethyl acetate. The reported melting point was 75–79° (17), but the almost quantitative yield, m.p. 72–78°, found by Bergmann *et al.* (5) was never attained. Found: N, 7.80, 7.80%; neutralization equivalent, 177, 178. Calc. for $C_{10}H_{13}O_2N$: N, 7.82%; neut. equiv., 179. This equivalent probably referred to the 3-amino-1,2-propanediol formed by hydrolysis during the titration.

The oxidations with aqueous sodium metaperiodate were carried out with a 0.05 *M* solution and 10 to 30 mgm. samples of the Schiff base. One mole of the Schiff base yielded 0.98, 0.98 mole of ammonia when excess periodate was used; 0.56, 0.55 mole with 1.0 mole of periodate, and 0.49, 0.49 mole with 0.9 mole. The oxidations with lead tetraacetate (Fig. 1) employed a 0.05 *M* solution in glacial acetic acid or benzene and 10 to 30 mgm. samples of the Schiff base.

3-Veratrylideneamino-1,2-propanediol

The preparation was adapted from that of the benzylidene derivative. A mixture of 66.4 gm. (0.40 mole) of veratraldehyde, 31.9 gm. (0.35 mole) of 3-amino-1,2-propanediol and 20 ml. of ethyl acetate was stirred until all the veratraldehyde dissolved. Within a few minutes, the solution suddenly became quite hot and solidified to a white, crystalline mass. After being washed thoroughly with ethyl acetate and dried *in vacuo*, the product weighed 78.8 gm. (94.5%) and melted at 121–124°. Two recrystallizations from ethyl acetate left the melting point almost unchanged (123–125°). Found: C, 60.2, 60.3; H, 7.2, 7.0; N, 5.71, 5.78; OCH_3, 25.6, 25.6%. Calc. for $C_{12}H_{17}O_4N$: C, 60.2; H, 7.2; N, 5.86; OCH_3, 25.9%.

3-Benzylamino-1,2-propanediol (V, R = H)

A mixture of 17.9 gm. (0.1 mole) of 3-benzylideamino-1,2-propanediol, 200 mgm. of Adams' platinum oxide catalyst (1), and 100 ml. of ethanol was shaken under 2–3 atm. pressure of hydrogen until the consumption of the gas

ceased (three to five hours). The liquor was decanted and the recovered catalyst used in two or three similar hydrogenations until it became inactive. The combined ethanolic solutions obtained from 104.2 gm. of the Schiff base were filtered and then evaporated to an oil which was distilled at 0.5 mm. pressure, the yield being 93.1 gm. boiling at 130–160°. Redistillation furnished 80.7 gm. (76.5%) of a viscous, colorless oil boiling at 152–155° (0.5 mm.). Found: C, 65.7, 65.7; H, 8.1, 8.1; N, 7.44, 7.48%; neut. equiv., 181, 182, 181. Calc. for $C_{10}H_{15}O_2N$: C, 66.3; H, 8.3; N, 7.73%; neut. equiv., 181.

A solution of the amine in an excess of hydrochloric acid was extracted with ether to remove any non-basic impurities, and was then evaporated to dryness under diminished pressure. The residue of 3-benzylamino-1,2-propanediol hydrochloride melted at 92–94.5° after two recrystallizations from isoamyl alcohol. Found: N, 6.28, 6.29%. Calc. for $C_{10}H_{16}O_2NCl$: N, 6.43%.

A 50 mgm. sample of the amine was dissolved in 15 ml. of 0.05 *M* sodium metaperiodate and at intervals 2-ml. aliquots were analyzed iodometrically. The consumption of periodate, 2.11 moles per mole after 30 min., was practically unchanged at 2.06 mole after one hour. In a second oxidation, a 50 mgm. sample was dissolved in 10 ml. of 10% sulphuric acid and 10 ml. of the 0.05 *M* periodate. After 15 min., 1 hr., 3 hr., and 17 hr. the consumption of periodate was 0.74, 1.10, 1.12, and 1.24 mole per mole, respectively.

3-Veratrylamino-1,2-propanediol Hydrochloride

3-Veratrylideneamino-1,2-propanediol, 23.9 gm. (0.1 mole) was dissolved in 100 ml. of ethanol and hydrogenated over 200 mgm. of platinum oxide catalyst as already described for the corresponding benzylidene Schiff base. The product from three such hydrogenations was dissolved in 100 ml. of water, 50 ml. of concentrated hydrochloric acid was added, and the solution extracted with ether to remove any non-basic impurities. Evaporation of the aqueous residue to dryness under reduced pressure left the white, crystalline hydrochloride. After one recrystallization from ethanol the yield was 64.7 gm. (89.5%) and the m.p., 151–152°. Found: N, 5.02, 5.01; OCH_3, 22.1, 22.3%. Calc. for $C_{12}H_{20}O_4NCl$: N, 5.04; OCH_3, 22.3%.

The free base, 3-veratrylamino-1,2-propanediol, distilled with some decomposition at 207–214° (0.4 mm.) as a pale yellow, viscous oil.

3-(N-Benzylacetamido)-1,2-diacetoxypropane

A mixture of 79.7 gm. (0.44 mole) of 3-benzylamino-1,2-propanediol (V, R = H), 400 ml. of acetic anhydride, and 40 gm. of fused sodium acetate was heated for several hours under reflux near 100°, and the solution was then decanted into 1300 ml. of water. After standing overnight to decompose the acetic anhydride, the clear solution was extracted with ether and the extract washed, twice with dilute hydrochloric acid and thrice with water. The residual oil remaining after evaporation of the dried extract was distilled, giving 81.8 gm. (61.5%) of product boiling at 196–199° (0.7 mm.). Found: C, 62.4, 62.5; H, 6.8, 6.9; N, 4.49, 4.47%. Calc. for $C_{16}H_{21}O_5N$: C, 62.5; H, 6.9; N, 4.56%. The compound was soluble in ether and water.

3-(N-Benzylacetamido)-1,2-propanediol (V, R = $COCH_3$)

(*a*) *From 3-(N-Benzylacetamido)-1,2-diacetoxypropane*

The above O,O,N-triacetyl derivative was selectively deacetylated by a procedure adapted from that used by Carter *et al.* (7) to de-O-acetylate hexa-acetyl inosamine to N-acetyl inosamine.

A 9.2 gm. (0.03 mole) sample, dissolved in 100 ml. of anhydrous methanol, was mixed with 150 ml. of methanol which had been saturated with ammonia gas at 26°. After being kept for 40 hr. at room temperature, the solution was evaporated to dryness under reduced pressure, and the residue was held at 150° and 0.4 mm. pressure until the acetamide was removed by distillation. The still residue when fractionated yielded 5.1 gm. (76%) of product boiling at 190–193° (0.3 mm.). Found: N, 5.78, 5.79%. Calc. for $C_{12}H_{17}O_3N$: N, 6.28%.

(*b*) *From 3-Benzylamino-1,2-propanediol Hydrochloride*

The hydrochloride from 49.5 gm. of the base was dissolved in 500 ml. of water, mixed with 83 ml. of acetic anhydride, and 39.0 gm. of sodium acetate trihydrate dissolved in 100 ml. of water was added at once. This solution was shaken for six hours at room temperature, then extracted with ether to remove any triacetyl derivative, and evaporated to dryness. The residue was mixed with chloroform and filtered to remove the inorganic salts. The chloroform filtrate was shaken thoroughly with water, both phases were transferred to a liquid–liquid extractor, and the aqueous layer was extracted with chloroform for 24 hr. The residual oil remaining after evaporation of the chloroform amounted to 35.5 gm. (58%). A small sample distilled as an extremely viscous yellow oil at 182–188° (0.12 mm.), for the most part at 188°. Found: C, 64.2, 64.3, 64.2; H, 7.6, 7.7, 7.7; N, 6.15, 6.11%. Calc. for $C_{12}H_{17}O_3N$: C, 64.5; H, 7.7; N, 6.28%. This compound was soluble both in water and in chloroform. One mole reduced 1.30 mole of sodium metaperiodate in neutral solution within 30 min., and this amount did not increase after 24 hr.

N-Benzylacetamidoacetaldehyde (VI)

A mixture of 11.3 gm. (0.05 mole) of 3-(N-benzylacetamido)-1,2-propanediol, 16.3 gm. (0.076 mole) of sodium metaperiodate, and 280 ml. of water was shaken vigorously for six hours and then extracted with chloroform. The residual oil from the evaporation of the extract was distilled at 0.4 mm. pressure, the fraction boiling at 136–139° weighing 5.6 gm. (58%). The sample redistilled for analysis had the boiling point 129–131° (0.12 mm.). Found: C, 69.1, 68.8; H, 6.9, 6.8; N, 7.29, 7.31, 7.33%. Calc. for $C_{11}H_{13}O_2N$: C, 69.1; H, 6.9; N, 7.33%. The aldehyde was a colorless oil after distillation, but darkened rapidly even when stored in a desiccator over potassium hydroxide or calcium chloride. The substance was soluble in chloroform, but was insoluble in ether and only slightly soluble in water.

The 2,4-dinitrophenylhydrazone of VI was prepared by adding the aldehyde in slight excess to an acid solution of 2,4-dinitrophenylhydrazine in ethanol. Brick red crystals, which separated slowly, were recovered after 24 hr. and were recrystallized from phenol containing a little ethanol. After being dried overnight *in vacuo* at 78° to remove any traces of phenol, the crystals melted

with effervescence at 315–316°, becoming black above 305°. Found: N, 18.5, 18.9%. Calc. for $C_{17}H_{17}O_5N_5$: N, 18.9%. The derivative was quite insoluble in ethanol, ethyl acetate, and other organic liquids tried, but dissolved in nitrobenzene and in hot phenol.

In a typical cyclization to isoquinoline, 1.21 gm. of N-benzylacetamidoacetaldehyde (VI) was dissolved cautiously in 10 ml. of ice-cold concentrated sulphuric acid and the solution heated for 30 min. at 160–170°. After cooling, the solution was poured onto 50 gm. of crushed ice, and the isoquinoline was recovered as in the cyclization of benzylaminoacetal. The picrate weighed 0.141 gm. (7.5%) and melted at 226–228°. A mixed melting point with an authentic sample of isoquinoline picrate, m.p. 226–227.5°, was not depressed.

ACKNOWLEDGMENT

One of us (A. W. F.) wishes to thank the National Research Council of Canada for the Studentship he was privileged to hold in 1953–54.

AN ADIABATIC CALORIMETER FOR THE TEMPERATURE REGION BELOW 20°K.—THE SPECIFIC HEAT OF SODIUM CHLORIDE[1]

By J. A. Morrison, D. Patterson,[2] and J. S. Dugdale[2,3]

ABSTRACT

A simple adiabatic calorimeter for specific heat measurements at very low temperatures is described. Liquid helium is made in the cryostat by the Simon expansion method. The calorimeter and adiabatic shield are cooled below 13°K. by conduction of heat along the lead wires rather than by conduction with exchange gas. The working thermometer is a carbon resistor which has been calibrated against a helium gas thermometer. The assembly has been used to determine the specific heat of rock salt between 2.5° and 20°K. The results are compared with the theoretically derived values of the specific heat and Debye characteristic temperature for sodium chloride.

INTRODUCTION

In recent years there has been an increasing interest in the specific heat of substances at very low temperatures to try to determine, for example, the electronic contribution to the specific heat or the effect of superconductivity on the heat capacity of metals (8). In many cases the substances used have been of such a form—blocks or large single crystals—as to permit use of very simple calorimeter assemblies (11) in which the calorimeter vessel exchanges heat continuously with its surroundings. Such assemblies work satisfactorily where thermal equilibrium times are short, i.e. of the order of seconds. The present apparatus was designed especially for experiments with samples of small particles where it was anticipated that equilibrium times of the order of minutes would be encountered. Hence, it seemed obligatory to make the assembly of the adiabatic type. This had the further advantage of achieving uniform and continuous operation throughout the temperature region 2.5° to 20°K. Although designed primarily for samples of small particles, the assembly may be used equally well for experiments on bulk solids as will be shown by the results for bulk sodium chloride.

Accurate values of the specific heat of bulk NaCl were needed for comparison with the specific heat of small particles of NaCl. Existing measurements by Clusius *et al.* (5) were not adequate as they went no lower than 11°K. At the same time, however, the results which have been obtained are of interest for comparison with theoretical values of the specific heat deduced from a Born–von Karman treatment of NaCl crystal (7), and with quantities deduced from elastic constants. As will be seen, the agreement between the experimental and theoretical results is gratifying.

APPARATUS AND EXPERIMENTAL TECHNIQUE

The Cryostat

The essentials of the calorimeter assembly are shown diagrammatically in Fig. 1. The outer part of the cryostat (the liquid nitrogen and liquid hydrogen stages) was patterned after a cryostat used for adsorption experiments which

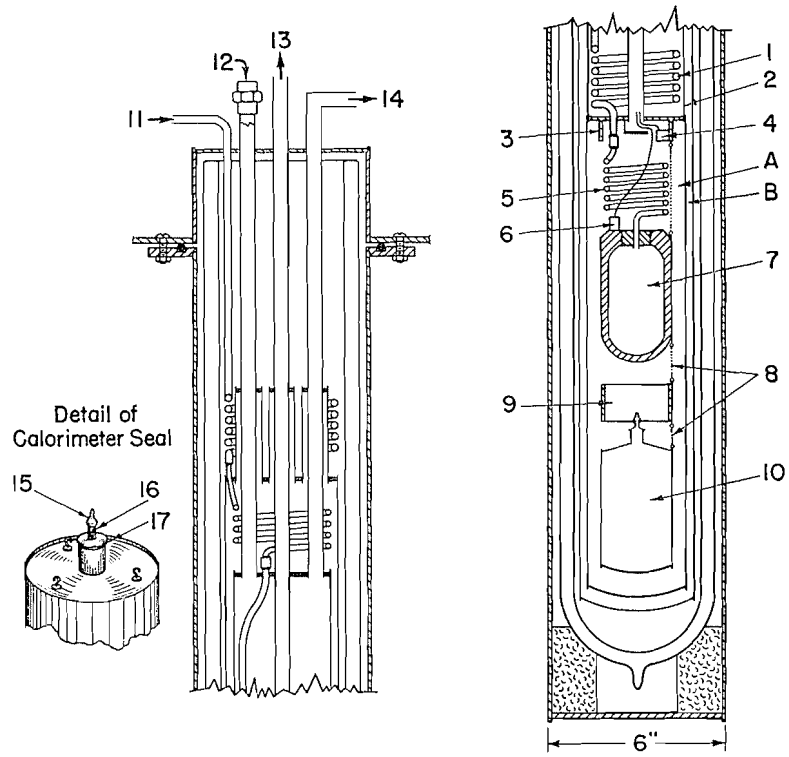

FIG. 1. The calorimeter assembly. A and B: vacuum spaces; 1: coil of copper tubing, 1 meter long, $\frac{3}{16}$ in. O.D., 0.035 in. wall thickness; 2: liquid hydrogen container; 3: anchoring ring for lead wires; 4: hydrogen vapor pressure thermometer; 5: coil of copper nickel tubing, 1 meter long, $\frac{1}{8}$ in. O.D., 0.018 in. wall thickness; 6: helium vapor pressure thermometer; 7: helium bomb (copper); 8: Nylon suspension cords; 9: adiabatic shield ($\frac{1}{16}$ in. thick copper), 10: calorimeter vessel; 11: high pressure helium line; 12: liquid hydrogen filling tube; 13: vacuum line; 14: gaseous hydrogen vent line; 15: soft glass seal; 16: platinum tube; 17: Wood's metal seal.

has been adequately described elsewhere (9). In order to reach temperatures below 10°K. a liquid helium stage has been added, the liquid helium being made by the Simon expansion method (12). The helium bomb, 7, of about 150 cm.^{3} internal volume, is hung by Nylon cords from the liquid hydrogen container, 2. An expansion of helium from a pressure of 130 atm. to 1 atm. with a starting temperature of 13°K. attained by pumping on the liquid hydrogen in 2 produces about 50 cm.^{3} of liquid helium which has proved to be adequate for 12 or more hours of experiments.

Previous experience showed that the use of exchange gas at liquid helium temperatures caused certain experimental difficulties. On the one hand, it

proved difficult to secure a satisfactory vacuum and on the other hand desorption of helium from the surface of the calorimeter vessel caused a perceptible fall in its temperature. Consequently, in these experiments no exchange gas was used below about 13°K. Temperatures below this were reached by conduction of heat from the calorimeter along the lead wires. This was, of course, a slow process and required three to five hours for liquid helium temperatures to be reached, but the advantages of the method greatly outweigh this disadvantage.

The Calorimeter and Shield

The adiabatic shield, 9, and the calorimeter vessel, 10, are hung below the helium bomb by Nylon cords, 8. Since the major heat exchange between the calorimeter vessel and shield was along lead wires, an elementary form of shield was permissible. However, experience showed that radiation exchange with the jacket was significant when extremes of temperature were reached, e.g. calorimeter at 4° and surrounding can at 20°. Therefore, a detachable cylindrical radiation shield (not shown in the diagram) of 0.001 in. thick copper foil which surrounded the calorimeter vessel was attached to the shield.

The lead wires from outside (No. 36 B. and S.D.S.C. copper) are brought in through the central tube and first make thermal contact with the anchoring ring, 3. Similar copper leads go between the bomb and the shield and make good thermal contact with each. Between the anchoring ring and the bomb, and between the shield and the calorimeter constantan leads (No. 30 B. and S.D.S.C. 15 cm. long) are used in order to reduce thermal conduction. The copper to constantan junctions were put close together at isothermal points in order to minimize thermal e.m.f.'s. Residual e.m.f.'s in the circuits were of the order of 0.1 μv. and were quite steady.

Adiabatic control was accomplished by manual regulation of the current passed through a heater wound on the shield. Temperature differences between the shield and calorimeter vessel were detected by a difference thermocouple made from two alloy wires—Ag – 0.37% Au/Au – 2.4% Co.* This thermocouple has adequate sensitivity even at the lowest temperature ~2.5°K. (e.g. 5 μv./deg. at 4°).

Since it was desired to do experiments with samples of particles of bulk density as low as 0.1, it was necessary to use a large calorimeter vessel (approximately 300 cm.^{3}). At the same time the mass of the vessel had to be kept small and this was accomplished by making the vessel of thin copper (0.007 in.) with light reinforcing rings on the cylindrical side. The bottom and top were made slightly conical for added strength. Light vertical vanes (0.001 in. copper) were attached to the inside wall of the vessel in order to enhance gross conduction of heat from the outer wall to the center of the sample.

Filling the Calorimeter

The method of putting samples into the calorimeter requires comment because of the possible significance of adsorbed gases in the specific heat

Cf. Keesom, W. H. and Matthijs, C. J. Physica, 2: 623. 1935.

measurements. It was important to be able to evacuate the filled calorimeter vessel and to seal it securely with a small amount of helium gas inside to assist in heat exchange. As may be seen from the diagram, the vessel is provided with a port approximately one-quarter inch in diameter through which the sample is admitted under an inert gas atmosphere. Connection to a vacuum line is made through a platinum-soft glass seal, 15,16, the platinum tube being fastened to the calorimeter vessel with Wood's metal, 17. Finally the glass tube is sealed off close to the platinum seal. In practice, the amount of glass in the seal averaged 100 mgm. with variations from experiment to experiment not exceeding 10 mgm. These variations were of no significance in the specific heat measurements.

Thermometer and its Calibration

The most important aspect of the calorimetry is the matter of a working thermometer and the temperature scale. It turns out that the accuracy of the specific heat measurements is determined by the accuracy with which the temperature scale can be fixed. No completely satisfactory thermometer exists for this temperature region, but recently carbon resistors have been tried. One of these (Ohmite, nominal value 10 ohms, $\frac{1}{2}$ watt) was used for the present assembly. The resistor was attached to the bottom of the calorimeter vessel with a light copper clip. Thermal contact between the thermometer and the calorimeter was established through the thermometer leads (No. 28 B. and S.D.C.C. copper) wrapped twice around and lacquered to the cylindrical side of the vessel. Experiment showed that the time lag between the heater (200 ohms of No. 40B. and S.D.G.C. manganin, wrapped on the side) and the thermometer was less than two seconds. Resistances of the thermometer were determined with a Mueller bridge in which the current was varied from 10 μa. to 65 μa., depending upon the temperature.

The attractive feature of using carbon resistance thermometers is the possibility of having to calibrate them only at the two ends of the temperature region, intermediate temperatures being obtained by a suitable interpolation formula. Two interpolation formulas have been suggested and as will be seen, one is much preferable to the other for the thermometer used in these experiments. Clement and Quinnell (4) have proposed the formula

$$\log R+(K/\log R) = A+(B/T) \qquad [1]$$

while Brown, Zemansky, and Boorse (3) have suggested a four-constant formula

$$\log R = A+(B/T)+(C/T^2)-KT^2. \qquad [2]$$

The constants of the formulas were determined in the following way. First, the indications of the carbon thermometer were compared with temperatures deduced from the hydrogen vapor pressure thermometer, 4, at several points in the range 14° to 20°. For the comparisons, exchange gas was admitted to space A and at least half an hour was allowed for equilibrium at each point. The vapor pressure thermometer was filled with normal hydrogen and tem-

peratures were deduced from the appropriate vapor pressure equation given by Woolley *et al.* (14). At the lower end of the temperature region the carbon thermometer was compared with the helium vapor pressure thermometer, 6. These comparisons had to be made with space A evacuated and therefore temperature differences between the bomb and shield and between the shield and calorimeter had to be taken into account. The latter was determined each time by means of the difference thermocouple but the former had to be deduced from a separate experiment in which a vapor pressure thermometer was attached to the calorimeter vessel. Small temperature differences (a few hundredths of a degree) were found which were due to small amounts of energy appearing in the calorimeter vessel as a result of vibration. It was not possible in practice to eliminate vibration completely. The observed vapor pressures of helium were converted to temperatures on the 'agreed' scale (13). The constants of the interpolation formulas were computed using comparison data at about 4°, 14°, and 20°K. for formula [1] and at about 4°, 14°, 17°, and 20°K. for formula [2]. The constants shifted each time that the thermometer was cooled from liquid nitrogen or higher temperatures. At 20°K. or below no shift in the constants could be detected over a period of two days.

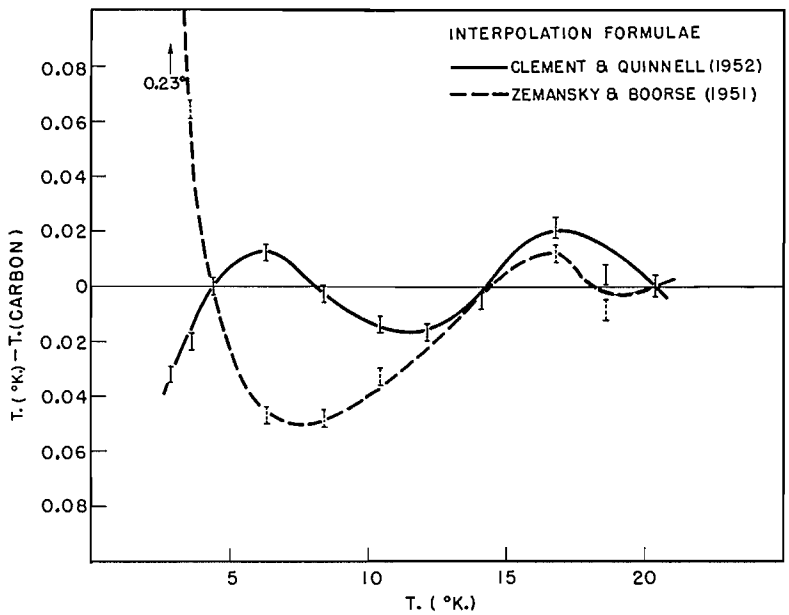

FIG. 2. Deviation of the carbon thermometer scale from the thermodynamic scale.

Finally in a separate experiment the carbon thermometer was compared with a helium gas thermometer (2 cm.^{3} bulb, 0.4 cm.^{3} external volume, ice point pressure approximately eight meters) attached to the calorimeter vessel. The results of the comparison are shown in Fig. 2 as a deviation plot. The deviations of formula [1] are relatively modest over the whole temperature

range but formula [2] becomes seriously off at the low temperature end. The difficulty would appear to be that the constant C in formula [2] turns out to be negative, which leads to a maximum in the R–T relation at low temperatures (at about 1.7° K. in this case). It was found most convenient to work out the experimental results on the scale given by formula [1] and as a last step to convert them to the thermodynamic scale using Fig. 2.

The matters of the precision and accuracy of the method are best discussed in connection with the specific heat results for NaCl.

THE SPECIFIC HEAT OF SODIUM CHLORIDE

Experimental Details

For these experiments two samples were used—pieces broken from a single crystal made by the Harshaw Chemical Company and fused lumps (Merck reagent grade). The Merck NaCl was fused in a platinum crucible and then poured onto a sheet of platinum in an inert gas atmosphere. Each sample was placed in the calorimeter under a helium atmosphere. The calorimeter vessel was evacuated to a pressure of 10^{-6} mm. Hg at room temperature and finally sealed off with 10^{-6} moles of helium inside as exchange gas. This amount of helium was so small as to not contribute to the specific heat even if it were all desorbed during one temperature increment. The samples were each about one-half mole and on the average contributed about one-third of the total specific heat. Temperature increments between 0.5° and 1° were used throughout. The equilibrium times following admission of energy to the calorimeter vessel varied from about 30 sec. at the lowest temperatures to about five minutes at 20°K.

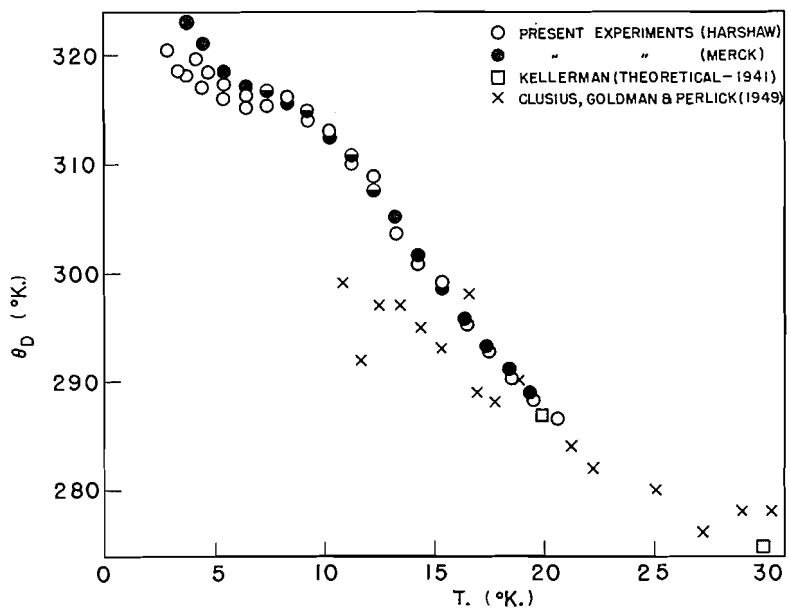

Fig. 3. The Debye characteristic temperature (θ_D) for NaCl as a function of temperature.

Results and Discussion

The results of the experiments are summarized in Fig. 3 in the form of a plot of the apparent Debye characteristic temperature, θ_D, versus the absolute temperature. θ_D was computed for each experimental value of the specific heat by means of the equation

[3] $$C_V = 464.5\ (T/\theta_D)^3 \text{ cal./gm. atom deg.}$$

The difference between C_p and C_V could reasonably be neglected in this temperature region. One notes that as T is reduced below 20°K. θ_D increases at first fairly rapidly but below about 8°K. much more slowly. This behavior is in agreement with the work of Blackman (2) who showed that an exact fit of the Debye model (θ_D practically a constant) was only to be expected at temperatures of the order of $\theta_D/50$ or less. The measured specific heat at 20°K. agrees almost exactly with the theoretical value deduced by Kellerman (7).

A limiting value of θ_D at 0°K. can be deduced from the elastic constants of the crystal. Kellerman (7) gives the value of 313° which he computed by the Hopf–Lechner method (6) using theoretically derived elastic constants. Recently Overton and Swim (10) have determined the elastic constants of NaCl down to 60°K. and have estimated the values at 0°K. by extrapolation. Using their values of the elastic constants and a simpler method of calculation due to Bhatia and Tauber (1), one derives the value of 321° for θ_D at 0°K., which agrees with θ_D deduced from the experiments at the lowest temperatures within the experimental uncertainty.

The agreement between the results for the two samples of NaCl is of interest as one might expect that imperfections in the fused sample could have a measurable effect on the low temperature specific heat.

Using the criterion that the specific heat should be a smooth function of the temperature, it was established that the precision of measurement of the total heat capacity was 0.3% at worst. That is, for any one set of experiments the results were consistent with a smoothed function to this extent. The accuracy, however, depends on the fixing of the temperature scale in an absolute sense. The possible errors involved in this can be estimated. Under the unfavorable condition of the NaCl contributing only one third to the total specific heat, it would appear that the accuracy of the results for NaCl is 1% or better from 20° down to about 7°K. Below the latter temperature the accuracy decreases to about 5% at the lowest temperature reached. Furthermore, the experimental and theoretical results for NaCl agree within these limits.

THE PHOTOLYSIS OF ACETONE IN THE PRESENCE OF HYDROGEN BROMIDE[1]

By M. J. Ridge[2] and E. W. R. Steacie

ABSTRACT

The presence of hydrogen bromide during the photolysis of acetone sharply inhibits the yields of carbon monoxide, ethane, and volatile methyl radical derivatives as measured by the function ($CH_4+2C_2H_6$). The observed effects can be explained on the assumption that both acetyl and methyl radicals react rapidly with HBr.

INTRODUCTION

The photolysis of acetone has been extensively used as a source of methyl radicals. The subsequent reactions of these with other substances are accessible to study when mixtures of acetone and a substrate are photolyzed. These methods have recently been applied by Raal and Steacie (6) to halogen-substituted hydrocarbons. It has, however, been discovered that the photolysis of acetone in the presence of certain chlorine-substituted hydrocarbons is accompanied by complicating side reactions leading to the formation of hydrogen chloride (2, 7). Cvetanovic and Steacie (3) have studied the photolysis of acetone in the presence of hydrogen chloride and have shown that methyl radicals react rapidly with hydrogen chloride which is largely regenerated by the abstraction of hydrogen atoms from acetone by chlorine atoms.

The work of Anderson and Kistiakowsky (1) indicates that methyl radicals react rapidly with hydrogen bromide also. However, there are reasons for believing that the photolysis of acetone in the presence of hydrogen bromide may not proceed entirely analogously with the hydrogen chloride case. In the oxidation of hydrocarbons the presence of hydrogen bromide profoundly modifies the reaction, the effect being attributed to the abstraction of a hydrogen atom from hydrogen bromide by peroxy radicals. Hydrogen chloride does not exert the same effect.

EXPERIMENTAL

Apparatus

The optical system was as previously described and included a G.E. 935 phototube so that the intensity of the incident light could be controlled (7). The light source was a Hanovia S-500, medium pressure lamp. The experiments were carried out using a Corning 0.53 filter (Pyrex) with a "cut-off" below 2800 Å. The analysis system was of the type usually used in this laboratory and included a Le Roy-Ward still, McLeod gauge, Toepler pump, and a gas burette. Since hydrogen bromide reacts slowly with mercury, a reaction

[1]*Manuscript received August 3, 1954.*

[2]*On leave of absence 1952–53 from the Division of Tribophysics, Commonwealth Scientific and Industrial Research Organization, Melbourne, Australia.*

system was adopted in which taps greased with silicone grease were employed and contamination by mercury vapor was reduced to a minimum.

The acetone was prepared as previously described (7). Hydrogen bromide was prepared by adding bromine to tetralin. The crude hydrogen bromide was passed through a red phosphorus column to eliminate excess free bromine, and through a bubbler filled with a concentrated aqueous solution of hydrogen bromide in order to remove bromides of phosphorus. The gas was then subjected to three bulb to bulb distillations from acetone dry ice to liquid air temperatures, first and last thirds being rejected. The fraction retained was kept frozen in liquid nitrogen and samples were taken by warming to dry ice temperature. The frozen solid was quite white.

Preliminary Experiments

In view of the "tail-off" towards longer wave length in the absorption spectrum of hydrogen bromide, some preliminary experiments were carried out to determine the effect on hydrogen bromide of light of the wave lengths passed by the filter.

Hydrogen bromide, 635 mm., was admitted to the reaction vessel at 150°C. Within the experimental error the intensity of the emergent beam as determined by the phototube was unaffected by the admission of the reagent. In the pressure region of the photolysis experiments absorption could therefore be safely neglected.

Hydrogen bromide, 101 mm., was illuminated for four hours at 150°C. The fraction uncondensable at −196°C. was found to be negligibly small. In general, preliminary experiments indicated that decomposition of hydrogen bromide could be neglected. This conclusion is borne out in the experiments by the virtual absence of hydrogen among the products.

RESULTS

Products of the Photolysis of Acetone in the Presence of Hydrogen Bromide

The major products (Table I) were methane and carbon monoxide. A trace of hydrogen was detected in the run with 50 mm. hydrogen bromide, but none at all in the run with 20 mm. hydrogen bromide. In none of the remaining experiments (in which the analyses were carried out by conventional gas analysis methods) was there any indication of the presence of hydrogen, and

TABLE I

PRODUCTS OF THE PHOTOLYSIS OF ACETONE IN THE PRESENCE OF HYDROGEN BROMIDE

Run	Temp., °C.	Time, hr.	Concentration, micromoles/cc.		Products, micromoles			
			Acetone	Hydrogen bromide	Methane	Carbon monoxide	Hydrogen	Ethane
100	150	4	1.854	1.987	4.99	1.24	0.07	0.05
112	201	4	1.888	0.748	10.75	4.85	None detected	0.04

it may therefore be disregarded as a significant product. With the quantities of hydrogen bromide employed here, ethane has been reduced to almost negligible proportions.

Effect of Concentration of Hydrogen Bromide

The effect of hydrogen bromide over a range of concentrations is shown in Table II. The experiments were carried out with 50 mm. acetone at 150°. Throughout the series the light intensity was maintained constant.

TABLE II

THE EFFECT OF CONCENTRATION OF HYDROGEN BROMIDE ON THE PHOTOLYSIS OF ACETONE
Time of irradiation 4 hr.; Temp. 150°C.

Run	Concentration, micromoles/cc.		Products, micromoles			
	Acetone	Hydrogen bromide	Methane	Carbon monoxide	Ethane	$\frac{CH_4+2C_2H_6}{CO}$
105	1.900	—	4.29	7.76	4.29	1.66
110	1.889	0.068	9.99	3.88	0.07	2.61
106	1.901	0.190	7.41	1.95	0.02	3.82
107	1.891	0.372	5.80	1.34	0.02	4.36
109	1.889	0.778	4.83	0.76	0.02	6.4
108	1.904	1.934	4.32	0.82	0.02	5.3
104	1.900	3.870	4.47	0.90	0.02	5.0
111	1.892	—	4.23	7.45	4.01	1.65

Table II shows that the addition of hydrogen bromide to acetone has resulted in a striking reduction of the carbon monoxide, volatile methyl radical ($CH_4+2C_2H_6$) and ethane yields, the ethane yield being in most cases too small for accurate measurement. For small concentrations of hydrogen bromide the effect is strongly dependent upon hydrogen bromide concentration but becomes independent of hydrogen bromide at higher concentrations.

Another striking effect of hydrogen bromide is the inhibition of the carbon monoxide yield. The addition of only 20 mm. of hydrogen bromide (run 109) reduced the carbon monoxide yield to 10% of its value in the absence of hydrogen bromide. This behavior is contrary to that of hydrogen chloride, which produces no effect upon the carbon monoxide yield (3).

The Effect of Temperature on the Inhibition by Hydrogen Bromide

This is shown in Table III. At each temperature two photolyses were carried out at the same light intensity. One of these was a blank with acetone alone.

Throughout the series the time of irradiation and concentration of reagents were maintained constant, except with runs 194 and 195 where longer exposures were used so as to increase the amount of products. An attempt to maintain the illumination constant over the whole series had to be abandoned owing to difficulties arising from the fogging of the cell windows, which became more pronounced as the temperature was raised. Experiment pairs with the same number outside the bracket were carried out at the same light intensity.

in the same way from the function ($CH_4+2C_2H_6$). The ratio of the carbon monoxide deficiency to the yield of carbon monoxide for the acetone photolysis is nearly unity up to 120°C. and then falls off as the temperature increases, but even at 300°C. it is still 0.14. Over the whole range the value of $-\Delta CH_3/\Delta CO$ is of the order of magnitude of unity.

The absolute values of the carbon monoxide deficiency and the volatile methyl radical deficiency are significant only as showing a general tendency, since illumination was maintained constant only over the pairs 113, 114; 105, 109; and 119, 120. It is seen that they rise to maximum at 150° and then fall away again.

The Effect of Time of Irradiation in the Presence of a Small Amount of Hydrogen Bromide

Table V shows the effect of increasing times of irradiation on 100 mm. of acetone at 150° in the presence of 0.3 mm. of hydrogen bromide. The results of an experiment with the same pressure of acetone in the absence of hydrogen

bromide are included for comparison. Although the carbon monoxide yields show more scatter than usual, it appears that even this amount of hydrogen bromide has inhibited the carbon monoxide yield to some extent.

The effect of the addition of 0.3 mm. of hydrogen bromide has been to increase the methane yield at the expense of the ethane yield, the ratio $CH_4+2C_2H_6/CO$ remaining constant. The ratio $R_{CH_4}/R_{C_2H_6}$ (R_{CH_4} = rate of methane formation etc.) shows a drop as the time of irradiation is increased, presumably indicating that hydrogen bromide is slowly spent as the photolysis proceeds. However, the magnitude of the effect produced is such that a large part of the HBr reacting must be regenerated.

DISCUSSION

The effect of hydrogen bromide on the photolysis of acetone is particularly striking. As little as 1.5 mm. in 50 mm. of acetone at 150° practically eliminates the ethane yield (run 110, Table II), reduces the carbon monoxide yield to almost half its value in the absence of hydrogen bromide, brings about a considerable increase in the yield of methane and an increase in the ratio

$(CH_4+2C_2H_6)/CO$ to a value well over 2. The last effect is a plain indication that the reaction is not a simple case of photodecomposition of acetone to give methyl radicals and carbon monoxide, followed by the abstraction of hydrogen from the hydrogen halide by the methyl radicals, as appears to be the case in the photolysis of acetone – hydrogen chloride mixtures (3).

That hydrogen abstraction (2) is, however, involved

$$CH_3+HBr = CH_4+Br \qquad [2]$$

is fairly clear from the results of the photolyses for various lengths of time, with very small additions of hydrogen bromide (see Table V). In this case the carbon monoxide yield was only slightly affected and the ratio $(CH_4+2C_2H_6)/CO$ remained the same as for acetone alone, the drop in the ethane yield on addition of hydrogen bromide being accounted for by a corresponding increase in the methane yield. From the same series of experiments it is likewise clear that the reaction

$$Br+CH_3.CO.CH_3 = HBr+CH_2.CO.CH_3 \qquad [4]$$

occurs sufficiently rapidly compared with other reactions of bromine atoms for the hydrogen bromide to be partly regenerated, as has already been discussed. This result is of significance for the photolysis of acetone in the presence of bromine substituted hydrocarbons, as it indicates that the formation of even small quantities of hydrogen bromide will result in serious complications as far as interpretation of the results and derivation of activation energies concerned.

Hydrogen bromide in greater concentration brings about a marked reduction in the volatile methyl radical yield $(CH_4+2C_2H_6)$; for example, at 150° the addition of 9.8 mm. hydrogen bromide to 50 mm. acetone reduces the volatile methyl radical yield to less than half its value in the absence of hydrogen bromide (run 107, Table II). This indicates that methyl radicals are either undergoing reactions not leading to methane or ethane production, or that the photolysis of acetone is so interfered with by the presence of hydrogen bromide, that there is a reduction in the number of methyl radicals produced.

A striking feature of the effect of hydrogen bromide is the sharp suppression of the carbon monoxide yield. This is almost certainly due to a rapid reaction of acetyl radicals with HBr to form acetaldehyde.

Table IV shows that the ratio $-\Delta CH_3/-\Delta CO$ is approximately unity over the range of temperature studied. If the values most likely to be in error are omitted, viz. for 300° where the degree of inhibition is small, and for 50° where the amount of products is small, the average value is 1.1. However, this ratio, as calculated from the figures of Table III, alone is of limited significance. It is, however, consistent within the experimental error with a mechanism in which the loss of CH_3 and of CO is due to loss of acetyl radicals.

Attempts were made to detect acetaldehyde among the products of photolysis of acetone – hydrogen bromide mixtures, but these were not successful. It is felt, however, that this is not a serious objection as there was a considerable amount of tarry products and acetaldehyde may well have been lost in these.

The Reaction Mechanism

The observed effects are therefore accounted for by the following reaction scheme:

$$\begin{aligned} CH_3.CO.CH_3+h\nu &= CH_3.CO+CH_3 && [I\phi] \\ CH_3.CO &= CH_3+CO && [1] \\ CH_3+HBr &= CH_4+Br && [2] \\ CH_3.CO+HBr &= CH_3.CHO+Br && [3] \\ Br+CH_3.CO.CH_3 &= HBr+CH_2.CO.CH_3 && [4] \\ CH_3+Br &= CH_3Br && [5] \end{aligned}$$

Since the light used in these experiments was largely 3130 Å, we assume that the initial decomposition of acetone proceeds predominantly to a methyl and an acetyl radical (5). The acetonyl radical will presumably disappear by association to form bromoacetone or methyl ethyl ketone.

From the above scheme

$$d[CH_3.CO]/dt = I\phi - k_1[CH_3.CO] - k_3[CH_3.CO]\,[HBr] = 0. \qquad I$$

Also $$d[CO]/dt = k_1[CH_3.CO],$$

$\therefore$ $$[CH_3.CO] = d[CO]/dt./k_1. \qquad II$$

Substituting II in I and rearranging

$$I\phi = d[CO]/dt + k_3/k_1.[HBr].d[CO]/dt.$$

Identifying $I\phi$ with R_{CO}, the rate of carbon monoxide formation for acetone alone, and setting R^*_{CO} equal to $d[CO]/dt$, the rate of carbon monoxide formation in the presence of hydrogen bromide, we obtain on rearranging:

$$R_{CO}/R^*_{CO} - 1 = k_3[HBr]/k_1$$

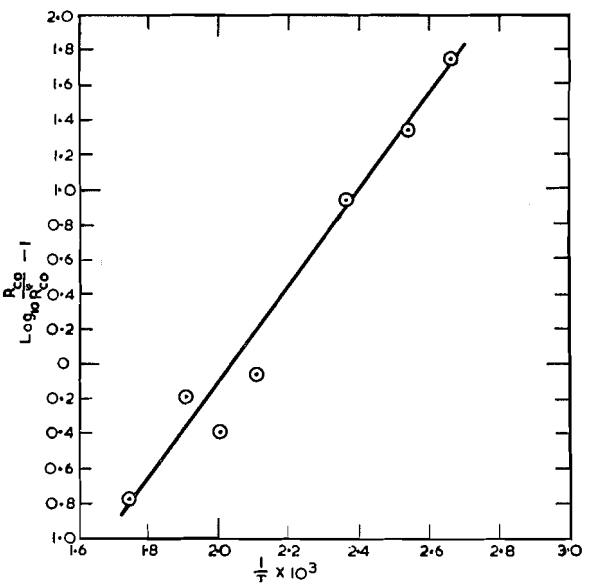

FIG. 1. $\text{Log}_{10} R_{CO}/R^*_{CO} - 1$ vs. $1/T \times 10^3$.

Fig. 1 shows log $R_{CO}/R^{*}_{CO}-1$ plotted against $1/T$. The points lie about a straight line with a slope corresponding to about -13 kcal./mole for the difference E_3-E_1. The activation energy of reaction (1) is not known precisely but has been estimated at from 10 to 18 kcal./mole (4). E_3 is unlikely to be more than 5 kcal./mole. Thus, in view of the drastic approximations made in the above derivation the value of -13 kcal./mole for E_3-E_1 is a reasonable one, and to this extent supports the mechanism suggested.

If the inhibition of the acetone photolysis by hydrogen bromide is due entirely to the reaction of acetyl radicals the yield of $(CH_4+2C_2H_6)$ for the inhibited reaction cannot be less than the carbon monoxide yield of the corresponding uninhibited reaction. However, reference to Table II shows that the volatile methyl radical yield of the inhibited reaction falls appreciably below the carbon monoxide yield for acetone alone. This may be attributed to reaction (5). As noted previously with the experiments with 0.3 mm. hydrogen bromide, hydrogen bromide is gradually spent despite the regenerative reaction. With the higher concentrations of hydrogen bromide used in the experiments over a range of temperatures, the production of bromine atoms must become appreciable.

ACKNOWLEDGMENT

We wish to thank Miss F. Gauthier and Dr. F. P. Lossing of this laboratory for the mass spectrometric analyses, and Drs. R. J. Cvetanovic and R. M. Heggie for many interesting discussions.

THE EFFECT OF PRECIPITATION CONDITIONS ON THE FLOW PROPERTIES OF SILICA DISPERSIONS[1]

By A. F. Sirianni and I. E. Puddington

ABSTRACT

The pH of the solutions in which silica is precipitated from sodium silicate has a marked effect on the flow properties of pastes prepared by subsequently dispersing the silica in liquid hydrocarbons. The yield value of this non-Newtonian suspension exhibits a pronounced maximum when silica precipitated at about pH 5 is used. An explanation based on the properties of the solid–liquid interface is proposed.

INTRODUCTION

When a dilute solution of sodium silicate is treated with acid, a sol of silicic acid is formed. On standing, this sol sets to a firm, transparent gel. Although the mechanism of this change is still a subject of investigation, it appears to be due to the formation of polymers from the liberated silicic acid and the cross-linking of these aggregates to form a three-dimensional structure. The time required for the sol–gel transformation to occur is termed the time of set and it is a function of the hydrogen ion concentration in the system when silica concentration and temperature are kept constant. The time of set and certain mechanical properties of the gel can also be altered by the use of chemical additives (12, 13). A number of substances show this effect, including alcohols, aldehydes, ketones, and sugars.

Since the time of set is an indication of particle–particle interaction, it might be expected that factors that change the time of set materially may also influence the other properties of the gel that depend on interaction between particles. A recent and interesting use to which silica has been put is its addition to liquid hydrocarbons to produce highly thixotropic pastelike dispersions. Since thixotropy is caused by the interaction of solid phase particles, it seemed probable that the conditions of preparation of the original silica gel would influence the properties of the paste. The present communication describes part of the work undertaken in this connection, viz., the effect, on the flow-properties of the hydrocarbon–silica dispersions, of altering the pH at which gels of constant concentration are prepared.

EXPERIMENTAL

The silica aqua gels were prepared by adding sulphuric acid to an appropriate concentration of *N* grade sodium silicate produced by the Philadelphia Quartz Company. The following procedure was typical: 100 gm. of 41° Baumé silicate were diluted to 450 cc. with distilled water in a 2 liter beaker. The silicic acid was precipitated during vigorous agitation by the addition of about 550 cc. of dilute sulphuric acid. The pH of the sol was taken with a Beckman pH meter before gelation occurred, the quantity of acid being adjusted to give

[1]*Manuscript received in original form August 11, 1952, and as revised, October 25, 1954.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3481.

gels that varied in pH from 1.0 to 8.6. Variations in the time of set of these sols were similar to those observed by other investigators. The concentration of SiO_2 in all the gels was approximately 2.8%.

The gels were allowed to age for 24 hr. at 25°C., after they had set. They were then washed until substantially free from soluble salts. This was normally accomplished with four 1-liter portions of distilled water, the gel and wash water being mixed in a Waring Blendor before filtering. In a few experiments the gel was extracted until no sulphate could be detected in the wash water. As subsequent experiments indicated no significant difference between these gels and those washed by the first procedure, the simpler method was used. Changes in pH of the gel during the setting period were small and in the expected direction (7).

Silica may be dispersed in non-aqueous media and still retain much of the structure developed during the sol–gel transformation by either of the following methods. In the first, the water in the aqua gel is exchanged with a solvent miscible both with water and with the liquid medium in which the silica is to be dispersed. This may be done conveniently by a process of exhaustive extraction. In the present work acetone was used as the solvent. The exchange was carried out in a continuous liquid extractor fitted with a fractionating column to deliver substantially dry acetone to the sample. Solvent replacement was considered complete when a test sample of silica did not shrink when placed in high boiling liquid hydrocarbon and the solvent flashed off. Silica–hydrocarbon dispersions could now be prepared by adding an appropriate quantity of silica–acetone gel to the hydrocarbon, flashing off the acetone, and subjecting the system to mild homogenization.

The second method consists in first producing a silica aerogel by the method of Kistler (8) followed by dispersing a known amount of the aerogel in the hydrocarbon using a shearing device.

The flow properties of the pastes produced by these methods could be examined using conventional apparatus.

The pastes from solvent exchanged silica were made up to contain 5.76% of silica by weight in a highly paraffinic oil having a viscosity of about 0.65 poise at 38°C. Pastes prepared from aerogels contained 5.0% of silica by weight. Owing to the similarity of refractive index of the two phases, the dispersions were quite transparent. Viscometric measurements were made using an extrusion plastometer that was equipped with a capillary having an orifice 0.089 cm. in diameter and 2.45 cm. in length. Compressed nitrogen provided a source of variable pressure. The samples were degassed by being placed in a vacuum desiccator for about 20 min. and were charged into the viscometer under reduced pressure to lessen the danger of entrapping air bubbles.

From the outflow time, weight of material extruded, and pressure used, the rates of shear and apparent viscosity were calculated for the various samples using Poiseuille's equation. The results were examined by plotting the apparent viscosities against the reciprocal of the rate of shear and by calculating the residual viscosity and coefficient of thixotropy or yield value from the intercept at infinite shear and the limiting slope of the graph at high shear rates.

RESULTS AND DISCUSSION

Typical data showing the changes in the yield value of the silica–oil dispersions with the variation of the pH at which the silica was precipitated are shown in Fig. 1. During a period of several years, more than 60 individual

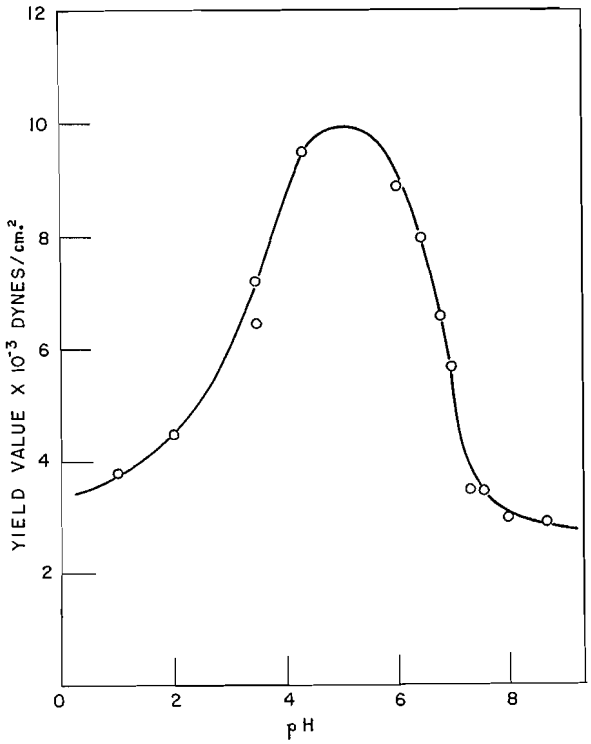

FIG. 1. Dependence of the yield value of silica–hydrocarbon pastes on the conditions under which the silica is precipitated.

experiments have been conducted using the silica obtained from several samples of sodium silicate and using both the solvent exchange and aerogel techniques in the preparation of the silica–oil pastes. With minor variations the flow properties of the dispersions follow the pattern indicated in Fig. 1. The maximum in the curve obtained with pastes prepared via the aerogel technique is usually displaced slightly to the left. However, by redispersing samples of the silicas in water, it was found that the pH of the dispersions prepared from the aerogels was higher than comparable samples prepared from solvent exchanged silica. The change in acidity apparently occurs during the preparation of the aerogel and compensates for the apparent displacement of the maximum.

Comparison of the residual viscosities of these systems (1, 5, 15) indicates an apparent increase in the axial ratio of individual particles of silica in the vicinity of pH 5. This, however, may actually be an increased porosity in particles of cross-linked gel at this pH. No differences could be detected in the

various samples of silica when the pastes prepared from them were examined with the electron microscope. To determine whether or not this apparent change in shape factor could account for the maximum found in the yield value, three silica aqua sols, adjusted to pH 5.0, 6.6, and 2.5 respectively, were prepared and allowed to gel. After the gels had aged for 24 hr., each was divided into three portions, extra water was added, and each portion agitated until a smooth slurry was produced. One of the portions from each batch was retained as a control and to each of the others acid or alkali was added to adjust the pH of the slurries to 2.9 and 7.1 for the first batch, 5.0 and 4.0 for the second, and 5.0 and 7.0 for the third. After a further 24 hr. period of aging, the silica samples were washed, solvent exchanged with acetone, and dispersed in oil as previously described. When the flow properties of these nine dispersions were examined and the yield values plotted as a function of conditioning pH it was found that a reasonably smooth curve very similar in shape to Fig. 1 could be drawn through the points. The apparent viscosity at infinite shear was virtually independent of the conditioning pH values in each of the three batches. These results would seem to indicate that the phenomenon is due predominantly to the surface properties of the silica rather than to the shape of the particles.

The maximum in yield value apparently bears no relation to the minimum time of set of silica gels since this occurs at about pH 8 (13), nor is it related to the rigidity of the aqua gels (11). It does appear to occur in a region where elastic recovery of the aqua gel is high and very near the isoelectric point determined by Batchelor (2).

Schneiderwirth (14) has noted that aqueous dispersions of insoluble alkaline earth salts show a maximum in thixotropy at pH 5 and the apparent viscosity of aqueous suspensions of TiC and TiN have been observed to pass through a maximum at pH 6 (16). Mukherjee and Mitra (10) have reported a very pronounced maximum in the viscosity of suspensions of bentonitic clay at about pH 6.5 and Hauth (6) has noted a similar phenomenon with aqueous alumina. Thus maxima in apparent viscosity with changes in pH do not appear to be uncommon with aqueous inorganic suspensions. No record of a similar occurrence with non-aqueous media was found, however.

Since the maximum in yield value must be associated with a high degree of flocculation and instability of the system, this is to be expected at or near an isoelectric point. Although it has been pointed out recently (9) that while the usual double layer considerations may apply in a number of non-aqueous systems they would not be expected in such apolar liquid media as hydrocarbons. Garner, Nutt, and Mohtadi have been able to demonstrate electrokinetic phenomena with carbon dispersed in highly non-polar systems (4). Electrokinetic effects could not be observed with these dispersions of silica after suitable dilution. However, it is perhaps not unreasonable that a partial layer of acid or alkali sorbed on the silica surface on either side of the isoelectric point would confer a degree of stability to the system in proportion to the percentage of surface covered, with a consequent reduction in the yield value. This effect may be enhanced by the presence of oil soluble polar compounds in the liquid phase.

Chaudhury (3) has suggested the possible influence of the free energy at the solid–liquid interface on the stability of colloidal systems. The effect of screening ions on the surface energy of quartz and its relation to the rheological properties of aqueous clay and sand suspensions has been emphasized recently in a review by Weyl (17). That the effect may be even more pronounced in non-aqueous media is also indicated. Certainly the initiation of flow in a thixotropic paste involves the creation of fresh solid–liquid interfaces, since electrical properties of pastes indicate solid–solid contact in the unsheared condition. High interfacial surface energies might be expected to contribute to the high yield values of the less stable systems, while the possible reduction of surface energies due to the adsorption of ions is in keeping with the greater stability found with the systems where the silica was precipitated above and below pH 5. Many examples can be cited where spontaneous adsorption of molecules dissolved in the liquid phase has increased the stability of suspensions in hydrocarbon media. This process presumably takes place with a substantial reduction of the free energy of the solid–liquid interface.

ACKNOWLEDGMENT

Preliminary experimental data contained in this paper were obtained when work was in progress under an industrial agreement between Imperial Oil Limited and the National Research Council. Our thanks are due Imperial Oil for permission to publish the results.

THE PHOTOLYSIS OF MIXTURES OF ACETONE AND SOME HALOGENATED HYDROCARBONS[1]

By M. J. Ridge[2] and E. W. R. Steacie

ABSTRACT

The composition of the products of photolysis of acetone in the presence of methyl chloride, methyl bromide, methylene chloride, and methylene bromide has been determined. These reactions are attended by complications not found with the photolysis of acetone–hydrocarbon mixtures. Failure to take into account reactions resulting from the formation of halogen hydrides and to allow for the presence of ethylene invalidates the values obtained by Raal and Steacie for the activation energy for hydrogen abstraction by methyl radicals from some halogenated hydrocarbons.

INTRODUCTION

The photolysis of mixtures of acetone and some halogenated hydrocarbons has been investigated by Raal and Steacie (4), who found ethane, methane, and carbon monoxide as volatile products. Assuming that all methane arose from hydrogen abstraction by methyl radicals from acetone and the particular halogenated hydrocarbon, and that all ethane arose from the combination of methyl radicals, Raal and Steacie obtained values for the activation energy of a number of reactions of the type

$$CH_3+CH_3X = CH_4+CH_2X$$

where X = Cl, Br, or F.

However, the photolysis of acetone in the presence of carbon tetrachloride and chloroform has been studied by Cvetanovic *et al.* (1) and with both substrates hydrogen chloride was found among the reaction products. In view of the rapid hydrogen abstraction from hydrogen chloride by methyl radicals (2), the formation of hydrogen chloride during the course of the reaction invalidates the kinetic treatment applied by Raal and Steacie to the photolysis of acetone in the presence of chloroform.

The present paper describes the results of an investigation into the composition of the products of the photolysis of acetone in the presence of methyl chloride, methylene chloride, methyl bromide, and methylene bromide.

EXPERIMENTAL

The apparatus was of the same general design as that used by Cvetanovic and Steacie (2), with provision for the exclusion of mercury vapor from the reaction cell. Silicone grease was used as a stopcock lubricant. When constant illumination over a series of runs was required, the current through the lamp was adjusted to give constant intensity of the emergent light as measured by a phototube reading. In fact, the current through the lamp required to be con-

stantly increased as the exposure continued, owing to the deposition of opaque matter on the windows of the reaction cell (chiefly on the front window).

Two filters were used alternatively, viz.:

(*a*) A Corning 7.54, with a "cutoff" below 2300 Å.

(*b*) A Corning 0.53, with a "cutoff" below 2800 Å (Pyrex Filter).

Analysis of products was carried out by means of a modified Ward still (3) in conjunction with standard gas analysis methods. Analyses of fractions from the Ward still were also carried out by means of the mass spectrometer.

RESULTS

Acetone – Methyl Chloride Mixtures

The results of a number of experiments with acetone – methyl chloride mixtures are given in Table I. The products are those to be expected from the photolysis of acetone or from hydrogen abstraction by methyl radicals from

†No illumination.
—Product not determined.

methyl chloride. However, ethylene is also an important product. Tests for the presence of hydrogen chloride among the reaction products were made by the method previously described (1). A series of experiments was made at 150°C. When methyl chloride was irradiated alone, or when mixtures of acetone and methyl chloride were maintained at 150°C. for 15 hr. without irradiation, no

hydrogen chloride was detectable. Hydrogen chloride was, however, always found in irradiated mixtures of acetone and methyl chloride.

The following conclusions may be drawn:

(*a*) The formation of ethylene and HCl shows that the reaction is complex and invalidates the kinetic treatment of Raal and Steacie (4).

(*b*) The presence of mercury vapor has no effect.

(*c*) Runs 56 and 57 show that the quantum yield of CO is not affected by the presence of a large amount of methyl chloride.

(*d*) No appreciable quantity of gaseous products is formed on irradiating methyl chloride alone.

(*e*) The presence of a large excess of CO_2 (runs 64 and 65) does not affect the results. Surface effects or effects due to excited molecules are therefore unimportant.

A few experiments were also made with deutero-acetone and methyl chloride. The C_1 fraction consisted of CO, CD_3H, and CD_4. The absence of CH_4 and CH_3D is further evidence that no direct decomposition of CH_3Cl is occurring. The ethylene fraction was mainly $C_2D_2H_2$. This rules out the possibility of ethylene resulting from disproportionation of CH_2Cl or dimerization followed by decomposition. Ethylene presumably results from the decomposition of complex products perhaps formed from CH_2Cl and CH_3COCH_2.

Acetone – Methylene Chloride Mixtures

Similar experiments were carried out with methylene chloride. Appreciable amounts of hydrogen chloride were found among the reaction products. Traces of HCl were found, however, when methylene chloride alone was irradiated.

Acetone – Methyl Bromide Mixtures

Similar experiments were carried out with acetone – methyl bromide mixtures. The results for a typical run were:

Temperature:	150°C.
Filter:	"*b*"
Acetone:	100 mm.
Methyl bromide:	100 mm.
Time:	nine hours

Products	μM.
CH_4	24.37
CO	16.48
C_2H_6	1.11
C_2H_4	0.19

Ethylene was thus again formed, but in much smaller amount than with methyl chloride. Hydrogen bromide was not positively identified, since the unilluminated mixture gave a slight positive reaction.

The complications are thus not as pronounced as with methyl chloride, but the results of Raal and Steacie (4) should be regarded with some suspicion.

Similar results were obtained with methylene bromide.

ORGANIC DEUTERIUM COMPOUNDS
XIII. THE MECHANISM OF THE NEF REACTION SYNTHESIS OF ETHANAL-1-*d*[1]

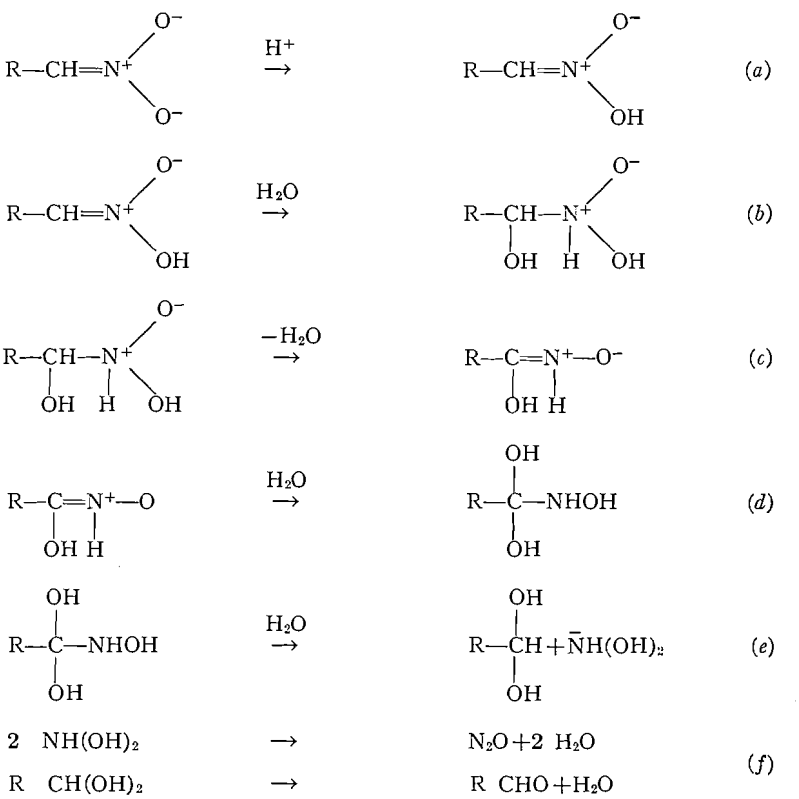
By Leonard C. Leitch

ABSTRACT

The mechanism of the Nef reaction was investigated with nitroethane-1,1-d_2. The isolation of 95 mole % ethanal-1-*d* in 70% yield renders a mechanism proposed by Mahler untenable, but supports others submitted by van Tamelen and Thiede and by Nametkin.

INTRODUCTION

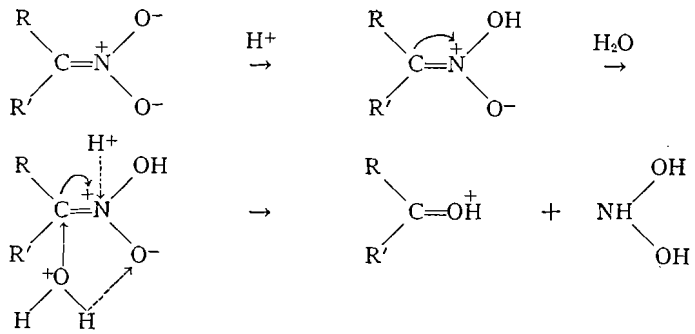
The conversion of a primary nitroparaffin into an aldehyde or of a secondary nitroparaffin into a ketone is known, after its discoverer, as the Nef reaction (9). Its scope was later investigated by Johnson and Degering (4) when nitroparaffins became readily accessible from the nitration of aliphatic hydrocarbons. Mahler (7) defined the optimum conditions for the preparation of propionaldehyde from 1-nitropropane and suggested "the highly tentative mechanism" shown below.



[1]*Manuscript received October 25, 1954.*
Contribution from the Division of Pure Chemistry, National Research Laboratories, Ottawa, Canada. Issued as N.R.C. No. 3489. Presented at the 126th meeting of the American Chemical Society, New York City, September, 1954.

This mechanism hinges on the addition of a mole of water in one direction, its elimination in another, then addition of a second mole of water, followed by hydrolysis. The addition of water in the manner indicated is improbable on account of the charge distribution between carbon and nitrogen. Also, this mechanism cannot account for the formation of ketones from secondary nitroparaffins.

An alternative mechanism which is shown below was recently advanced by van Tamelen and Thiede (11).

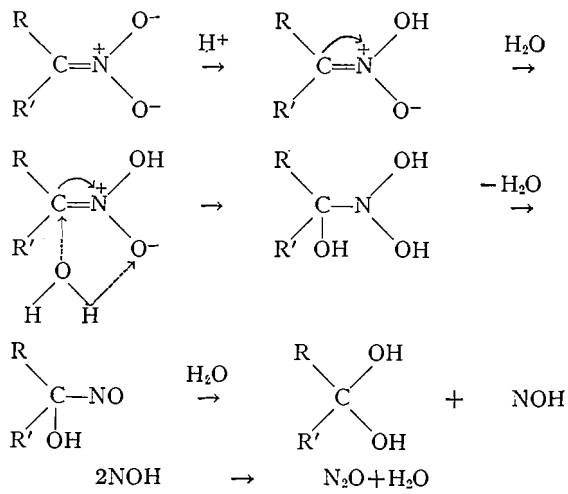


These authors point out a parallel between the Nef reaction and the hydrolysis of oximes and present evidence strongly in favor of this scheme.

The correctness or otherwise of these mechanisms may be readily tested using deuterated nitroethane as a tracer; for, if the reaction proceeds as proposed by Mahler, nitroethane-1,1-d_2 ($CH_3CD_2NO_2$) should give normal acetaldehyde because the hydrogen at C-1 is lost as water in step (*c*) and acetaldehyde is formed by hydrolysis in step (*e*). On the other hand acetaldehyde deuterated in the functional group should result if the reaction follows the course suggested by van Tamelen and Thiede (11).

Nitroethane-1,1-d_2 was prepared by exchanging nitroethane with deuterium oxide as described for nitromethane in a previous paper (5) but in the presence of a weak base. After two exchanges the bands at 1330, 1255, 1132, 994, and 811 cm.$^{-1}$ in the infrared spectrum of $CH_3CH_2NO_2$ were reduced in intensity while new bands corresponding to $CH_3CD_2NO_2$ appeared at 1305, 1289, and 1025 cm^{-1}. The mass spectrum of nitroethane shows no parent peak, but measurement of the peak intensity due to $CH_3\overset{+}{C}D_2$ indicated that the compound contained about 45 mole % $CH_3CD_2NO_2$ and unknown amounts of CH_3CHDNO_2 and $CH_3CH_2NO_2$. There was no peak corresponding to three deuterium atoms in the molecule so deuteration therefore does not extend to the H in the methyl group. The deuterated nitroethane was subjected to the Nef reaction essentially as described by Johnson and Degering (4) except that the acetaldehyde itself was isolated instead of its semicarbazone. The mass spectrum of the acetaldehyde indicated it was largely CH_3CDO. The mechanism of the Nef reaction as proposed by Mahler (7) is therefore incorrect. On the other hand, the present work supports the alternative and simpler mechanism of van Tamelen and Thiede (11).

A minor shortcoming of their interpretation of the Nef reaction is its failure to account for the appearance of a transient blue color in the reaction mixture prior to the evolution of nitrous oxide. Nametkin (8) attributed this color to the formation of a nitroso intermediate.* It is possible to modify the mechanism of van Tamelen and Thiede (11) to include a nitroso intermediate as shown below.



The Nef reaction is well adapted to the synthesis of ethanal-1-*d* and other aldehydes deuterated only in the formyl group on account of its simplicity and the high isotopic purity of the product, which is over 95% if we base our results on the theoretical calculation of Brinton and Blacet (3) for the mass ratio CDO/CHO obtained by mass spectrometry.

The apparent discrepancy between the deuterium content of the nitroethane and that of the acetaldehyde prepared from it may be readily reconciled by reference to data in a paper by Wynne-Jones (12). According to this author the relative rates of ionization of the hydrogen and deuterium atoms in nitroethane are in the ratio 10:1. Therefore, assuming the deuterated nitroethane contained 50% of the isotopic species, CH_3CHDNO_2, its ion, $CH_3CD{=}NO_2^-$ will be present to the extent of 45%; this, added to the 45% from $CH_3CD_2NO_2$, would lead to acetaldehyde containing 90% CH_3CDO.

Ethanal-1-*d* has been synthesized by Blacet and Brinton (2) in five steps starting from butyne-2. Another synthesis from diacetyl was reported recently by Loewus *et al.* (6). The first is tedious and leads to a product of low isotopic purity, while the second requires lithium aluminum deuteride which is both difficult to obtain and very expensive. Moreover, these methods are not suitable for the synthesis of other aldehydes deuterated in the functional group because the starting materials are not readily accessible.

**This information was kindly supplied by Dr. W. E. Noland, Department of Chemistry, University of Minnesota, Minneapolis, Minn.*

The ethanal-1-*d* reported in this work has since been used by others in these laboratories in spectroscopic and photochemical studies (1, 10).

EXPERIMENTAL

Nitroethane-1,1-d_2, $CH_3CD_2NO_2$

A mixture of nitroethane (25 ml.) and deuterium oxide (25 ml.) containing 10 mgm. of dissolved anhydrous sodium acetate was heated overnight in a sealed tube in a rocking furnace at 90°C. The tube containing the deep-yellow reaction mixture was opened, attached to a vacuum line, frozen, and evacuated. The supernatant layer of deuterated nitroethane was distilled off through a U-tube containing Drierite and condensed in a trap at −78°C. The yield of colorless liquid was 19.0 ml. The loss is due to the formation of a water-soluble product by a side reaction which was not further investigated.

The exchange was repeated with an equal volume of fresh deuterium oxide and sodium acetate. The yield of nitroethane-1,1-d_2 analyzing 45 mole % $CH_3CD_2NO_2$ was 11.0 ml.

Ethanal-1-d, CH_3CDO

Nitroethane-1,1-d_2 (3.0 ml.) was dissolved in 20 ml. of ice-cold 10% sodium hydroxide in a small separatory funnel. The solution was added slowly dropwise to one of 6 ml. sulphuric acid dissolved in 40 ml. of water, which was kept at 0 to 5°C. and stirred continuously. The addition of the sodium nitroethane solution produces a characteristic blue color in the sulphuric acid which fades as nitrous oxide is evolved. Any acetaldehyde entrained in the nitrous oxide was condensed in a U-tube cooled to −40°C. with dry ice and acetone. Stirring was continued for 15 min. after all the sodium salt solution had been added. When the reaction mixture was heated the acetaldehyde distilled and condensed in the U-tube. The product was then distilled from the U-tube into a graduated trap on the vacuum line. Yield: 0.8 ml. The mass spectrum gave the following principal peaks:

46	($CH_2D.CDO$)	3.82
45	(CH_3CDO)	136.0
30	($\overset{+}{C}DO$)	200.8
29	($\overset{+}{C}HO$)	24.83

Evidently, ethanal-1-*d* is largely produced in this reaction rather than normal acetaldehyde.

There is no advantage in dissolving the deuterated nitroethane in sodium deuteroxide. In fact, this leads to a higher peak at 46 due to CH_2DCDO produced by the exchange:

$$CH_3CDO + D^+ \rightleftarrows CH_2DCDO + H^+.$$

ACKNOWLEDGMENTS

The author is grateful to Dr. D. A. Ramsay for the interpretation of the infrared absorption spectra and to Miss F. Gauthier for the mass analyses.

THE BIOGENESIS OF ALKALOIDS

XIV. A STUDY OF THE BIOSYNTHESIS OF DAMASCENINE AND TRIGONELLINE

By Edward Leete,[2] Léo Marion, and Ian D. Spenser[2]

ABSTRACT

Tryptophan-3-C^{14} was prepared from methyl labelled sodium acetate and fed to mature *Nigella damascena* L. plants. Radioactivity was translocated throughout the plant, but no activity was detected in the damascenine isolated from it. Similarly the radioactive tryptophan was fed to pea seedlings and trigonelline detected in the plant extracts. This was also inactive, and these results are discussed.

It has been suggested (25) that trigonelline (the methyl betaine of nicotinic acid) arises from proline by ring opening to δ-aminovaleric acid and thence to nicotinic acid by reaction with a one carbon fragment such as formic acid. Klein and Linser (18, 19) injected various amino acids into the hollow stems of *Dahlia variabilis* and other plants which produce trigonelline and they claimed that the amount of trigonelline increased, relative to that in control plants, after the feeding of ornithine, proline, glutamic acid, or δ-aminovaleric acid. No increase was observed after feeding arginine, tyrosine, aspartic acid, or other amino acids. Hexamethylene tetramine produced increases in the amount of alkaloid, possibly by acting as a source of formic acid. These results have been critically examined by James (15) who raised doubts about the supposed increases in the amount of alkaloid.

Barger (3) was the first to place damascenine (the methyl ester of 2-methylamino-3-methoxybenzoic acid) amongst the alkaloids derived from tryptophan by the oxidation of indole to anthranilic acid followed by hydroxylation and methylation. In animals and molds it has been conclusively proved that 3-hydroxyanthranilic acid and nicotinic acid arise in the course of tryptophan metabolism (4, 6, 14, 20). Many biological reactions which occur in plants have been shown to be similar to if not identical with those occurring in animals and molds. It was thus conceivable that tryptophan might be the source not only of damascenine, but also of trigonelline. It was therefore decided to feed tryptophan labelled with C^{14} in the 3-position of the indole nucleus to plants producing damascenine and trigonelline. If tryptophan were the precursor of these alkaloids radioactivity would be expected in the carboxyl group of both trigonelline and damascenine.

The preparation of tryptophan-3-C^{14} in 5% yield from carboxyl labelled benzoic acid in 11 steps has been reported (14). In the present work methyl labelled sodium acetate was converted to pyruvamide-3-C^{14} by the method described in the literature (2, 24) for the preparation of pyruvamide-2-C^{14} from carboxyl labelled sodium acetate. This was converted to the phenylhydrazone and quantitatively hydrolyzed to pyruvic acid phenylhydrazone

[1]*Manuscript received November 4, 1954.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3496.
[2]*National Research Council of Canada Postdoctorate Fellow.*

which was esterified with diazomethane and cyclized to methyl indole-2-carboxylate (7). The ester was hydrolyzed and the indole-2-carboxylic acid decarboxylated in quinoline in the presence of cupric oxide. The indole-3-C^{14} was converted via gramine to tryptophan-3-C^{14} (1, 13, 23). The over-all radiochemical yield from pyruvamide to tryptophan was 6%. Direct ring closure of pyruvic acid phenylhydrazone to indole-2-carboxylic acid failed completely (11) while cyclization of pyruvamide phenylhydrazone to indole-3-carboxamide was accomplished in 12% yield only. Attempts to synthesize pyruvic acid phenylhydrazone according to Japp and Klingemann (16) in two steps from methyl iodide and ethyl methylmalonate (10) or from methyl iodide and ethylacetoacetate (9) led to the desired product in poor yields only.

The labelled tryptophan was fed to mature five-month-old *Nigella damascena* plants via the roots and after eight days the damascenine isolated from the whole plant by ether extraction. The amino acid was also fed to five-week-old pea seedlings and after seven days trigonelline was detected in the extracts of the aerial parts of the plant. No trigonelline was found in the roots. Neither alkaloid, however, was radioactive.

EXPERIMENTAL[3]

Synthesis of Tryptophan-3-C^{14}

Pyruvamide-3-C^{14}.—This was prepared from methyl labelled sodium acetate by the same method as that described for the synthesis of pyruvamide-2-C^{14} (2, 24).

Pyruvic acid-3-C^{14} phenylhydrazone.—Pyruvamide-3-C^{14} (0.834 gm., 0.0096 mole) of activity 2.78×10^8 disintegrations per minute was dissolved in water (30 ml.) and a solution of freshly distilled phenylhydrazine (0.95 ml., 0.0096 mole) in 2 *N* hydrochloric acid (5 ml.) was added. The mixture was kept at 0° for one hour and the product filtered off and washed with water (100 ml.). It was wetted with a little methanol, dissolved in boiling water (100 ml.), 2 *N* hydrochloric acid (150 ml.) added, and the solution kept on the steam bath for two hours. The solution was cooled and the crystalline pyruvic acid-3-C^{14} phenylhydrazone filtered, m.p. 173–174°, wt. 1.382 gm., yield 81%.

Indole-3-C^{14}-2-carboxylic acid.—The pyruvic acid phenylhydrazone was suspended in ether and treated with excess diazomethane. The solvent and excess reagent were removed by distillation, the residual ester dissolved in glacial acetic acid (6 ml.), and after cooling concentrated sulphuric acid (0.7 ml.) was added. The resulting solution was kept at 80° for one hour when crystallization of ammonium acetate was complete. It was filtered, the filtrate cooled, water (250 ml.) and 2 *N* ammonium hydroxide (50 ml.) added, and the mixture kept at 0° for 48 hr. The supernatant liquor was sucked off and the crude methyl indole-2-carboxylate transferred to a sublimation tube and distilled at 120–140° at 0.001 mm. The white sublimate together with a small amount of yellow oil was washed out with methanol, taken to dryness, and hydrolyzed with hot *N* sodium hydroxide (10 ml.). 2 *N*-Hydrochloric acid (12 ml.) was added, the mixture cooled for 36 hr., and the acid filtered. After

[3]*All melting points are corrected.*

drying over concentrated sulphuric acid the crude indole-2-carboxylic acid, m.p. 176–179°, wt. 0.371 gm., was obtained in 29.7% yield based on pyruvic acid phenylhydrazone.

Indole-3-C^{14}.—The active indole-2-carboxylic acid was refluxed with cupric oxide (20 mgm.) in quinoline (6 ml.) in an atmosphere of nitrogen for 16 hr. The mixture was cooled, diluted with ether (200 ml.), filtered, and the filtrate washed with aqueous sodium hydroxide and then with dilute hydrochloric acid. The ether solution was dried over sodium sulphate and evaporated *in vacuo* at room temperature. It left a residue consisting of crude indole-3-C^{14} (0.290 gm.).

DL-Tryptophan-3-C^{14}.—The crude active indole was converted to gramine by reaction with formaldehyde and dimethylamine. The gramine (0.214 gm.) was diluted with inactive gramine to give a weight of 1.59 gm. which in a Mannich reaction yielded tryptophan-3-C^{14} acetate (with 1 mole of acetic acid of crystallization), wt. 1.342 gm., with a specific activity of 1.24×10^4 disintegrations per min. per mgm., or 4.02×10^6 disintegrations per min. per millimole, representing an over-all radiochemical yield of 6% from pyruvamide.

Pyruwamide Phenylhydrazone

In the course of the radioactive synthesis this compound was not isolated. Pyruvamide (1.09 gm., 0.0125 mole) in water (10 ml.) was added to a warm solution of phenylhydrazine (1.35 gm., 0.0125 mole) in 2 *N* hydrochloric acid (6.3 ml.). A bulky crop of crystals separated almost immediately. After being allowed to stand for 10 min. the product was filtered off and recrystallized from hot water containing a little sodium hydroxide. Pyruvamide phenylhydrazone separated as shiny plates (1.95 gm., 88% yield), m.p. 143–144°. The literature reports m.p. 144° for this compound prepared by another method (12). Calc. for $C_9H_{11}ON_3$: C, 61.00; H, 6.26; N, 23.72. Found: C, 61.21; H, 6.33; N, 23.34%. The substance is only very slowly hydrolyzed by 2 *N* aqueous sodium hydroxide, but is readily converted to pyruvic acid phenylhydrazone by dilute aqueous hydrochloric acid.

Indole-2-carboxamide.—Ring closure of pyruvamide phenylhydrazone could not be effected by means of a mixture of acetic and sulphuric acids, nor by dry ethanolic hydrogen chloride. Boron trifluoride gave the product in poor yield. Pyruvamide phenylhydrazone (0.89 gm., 0.005 mole) in glacial acetic acid (3 ml.) was treated with boron trifluoride dietherate (1 ml.). The mixture was heated for 20 min. on the water bath, cooled, poured into water and the suspension extracted with ether. The dried ether extract was distilled at 0.01 mm., yielding two products. The first fraction was an oil (0.31 gm.) which on standing for two months set to a glass and was not further investigated. The second fraction, a crystalline sublimate (0.10 gm., 12% yield), m.p. 234.5–235.5°, was the desired product. Calc. for $C_9H_8ON_2$: C, 67.48; H, 5.03. Found: C, 67.53; H, 5.09%.

Administration of the Tryptophan-3-C^{14} *to Nigella damascena L.*

Nigella damascena L. seeds were germinated in soil and allowed to grow for five months. Eighteen mature plants were transferred to a hydroponics set up

with the roots dipping into the nutrient solution. The nutrient solution contained, per liter, potassium nitrate (505 mgm.), calcium nitrate tetrahydrate (1180 mgm.), magnesium sulphate heptahydrate (495 mgm.), potassium dihydrogen phosphate (272 mgm.), ferrous sulphate heptahydrate (2 mgm.), plus traces of micronutrients (B, Mn, Zn, Mo, Cu). After two weeks in the nutrient solution new roots were being produced and some of the plants were flowering. At this stage the tryptophan-3-C^{14} acetate (580.1 mgm., with a specific activity of 4.02×10^6 disintegrations per min. per millimole, and a total activity of 7.21×10^6 disintegrations per min.) was equally divided between the plants. The tryptophan was taken up by the plant as shown by the day to day decreasing activity in the nutrient solution. The first day after feeding the total activity remaining in the nutrient solution was 5.9×10^6, second day 4.4×10^6, third day 2.9×10^6, fourth day 2.0×10^6, fifth day 0.8×10^6, sixth day 0.2×10^6, seventh day 0.1×10^6 disintegrations per min.

Isolation of Damascenine

On the eighth day the plants were harvested, dried at 50–60°, and ground in a Wiley mill. The ground material (18.8 gm.) was extracted with ether for three days in a Soxhlet extractor. This ether extract had a total activity of 1.07×10^4 disintegrations per min. The green solution was evaporated to dryness and a small sample of the residue chromatographed on Whatman No. 1 paper (buffered to pH 8 with phosphate – citric acid), with a mixture of *n*-butanol (80 ml.) and water (15 ml.) as the developing solvent. Authentic specimens of 3-hydroxyanthranilic acid, damascenine (obtained from *Nigella damascena* seeds according to the procedure of Ewins (8)), and damasceninic acid were run on the same chromatogram and had R_F values of 0.15, 0.88, and 0.76 respectively. The hydroxyanthranilic acid was detected by its pronounced fluorescence in ultraviolet light and the other two compounds with Dragendorff's reagent (21). Only damascenine was found in the plant extract. The residue from the ether extract of the plant was dissolved in *N* hydrochloric acid (100 ml.) and the solution extracted with ether. The aqueous layer was made alkaline with ammonia and the alkaloid extracted with ether. The fluorescent extract was dried and the ether removed by distillation under diminished pressure leaving a residue which was distilled *in vacuo*. Damascenine distilled as a colorless oil, b.p. 120° at 0.001 mm., wt. 5.6 mgm. This was completely non-radioactive.

The ground plant was further extracted with methanol, but no more alkaloid was obtained. The methanol extract was radioactive (1.6×10^5 disintegrations per min.) presumably owing to the extraction of uncombined radioactive tryptophan from the plant. After extraction with ether and methanol the plant had a total activity of 2.1×10^5 disintegrations per min.

Administration of Tryptophan-3-C^{14} to Garden Peas

Garden peas (Laxton's Progress) treated with fungicide (Semesan) were allowed to germinate in soil. After two weeks 48 plants were transferred to a hydroponic solution of the same composition as that used for the *Nigella*

damascena and the labelled tryptophan acetate (573.7 mgm. with a specific activity of 4.02×10^6 disintegrations per min. per millimole) was administered as in that case. The rate at which the amino acid was taken up by the plant was followed by determining the total activity of the nutrient solution every day. The plants were harvested on the seventh day and the roots and the aerial parts worked up separately. No trace of trigonelline was found in the roots. The aerial parts of the plant (64.9 gm. fresh weight) were extracted with water. The extract, having a total activity of 1.4×10^5 disintegrations per min., was treated with 20% lead acetate solution to precipitate the protein and then with hydrogen sulphide to remove the excess lead. The filtrate (having a total activity of 0.5×10^5 disintegrations per min.) was concentrated to 250 ml., made alkaline with ammonia, and treated with an excess of ammonium reineckate (3 gm. in 10 ml. of methanol) to precipitate the choline. The precipitate was centrifuged off after cooling overnight and the solution acidified with 1.0 *N* hydrochloric acid and kept cold for 24 hr. The precipitated reineckate was filtered off, washed with *n*-propanol, and dissolved in acetone. This acetone solution contained negligible radioactivity; it was chromatographed on Whatman No. 1 paper using the one phase system 95% ethanol–5% ammonia of d. 0.880 (5) which separates choline (R_F 0.45) from trigonelline (R_F 0.22), and the chromatogram developed with Dragendorff's reagent (21). The trigonelline spot on the chromatogram was not radioactive. Trigonelline reineckate was decomposed with silver sulphate and barium hydroxide (17), but only a trace of free base was obtained.

DISCUSSION

If the synthesis of damascenine and of trigonelline occurred in the plants while they were in contact with the radioactive tryptophan, the results would indicate that tryptophan was not utilized for the production of the bases. Since damascenine and trigonelline are methylated derivatives of 3-hydroxyanthranilic acid and of nicotinic acid respectively, both well established tryptophan metabolites in animals and in molds (4, 6, 14), and since methylation in plants has been shown to be a general and facile process, the present results would lead to the conclusion that tryptophan metabolism in the plants studied differs radically from that prevailing in animals and molds.

In feeding experiments with mature plants, there is the danger that alkaloids are no longer being actively produced at the time of the experiment. In our experiments, however, the labelled amino acid was fed while the plants were flowering and producing seeds. In both *Nigella damascena* (8) and peas (22) the alkaloid is present in the seeds, and while it is conceivable that it may be translocated there from other parts of the plant and that actual synthesis no longer takes place at the time, this seems unlikely.

ACKNOWLEDGMENT

The authors are indebted to Professor H. K. Mitchell of the California Institute of Technology for a sample of 3-hydroxyanthranilic acid and wish to acknowledge his courtesy.

ABSORPTION SPECTRA OF METALS IN SOLUTION[1]

By H. Blades[2] and J. W. Hodgins[3]

ABSTRACT

Measurements of the absorption spectra were made on solutions of alkali and alkaline earth metals in ammonia, methylamine, ethylamine, and mixed solvents. In ammonia, a single absorption band was measured which is common to all the metals examined. In the amines and in mixtures of ammonia with methylamine, however, bands were found which were characteristic of the metal employed. A hypothesis has been advanced to explain the existence of the different types of energy traps responsible for the variations in spectra.

INTRODUCTION

The alkali metals and some of the alkaline earth metals dissolve in liquid ammonia without reaction; it is thought that simple dissolution occurs, yielding metal ions and electrons which are trapped or solvated in the liquid (5). Various physical properties have been examined which are consistent with this postulate, although a concise model has not yet been formulated for the electron traps. For example, the expansion exhibited on dissolving the metal has been attributed to the formation of holes in the liquid which represent energy barriers for the escape of electrons (8). The electrical conductivity in dilute solution is greater than can be explained by simple ionic transport, but less than would be expected by electronic conduction (5). Magnetic susceptibility measurements indicate that the metal is ionized, but some difficulty is experienced in explaining the variation of the susceptibility with temperature (3). The measurements of paramagnetic resonance absorption are consistent with the existence of trapped electrons (4). Finally, the absorption spectra of a number of the solutions have been measured, and the observation made that in ammonia there is a single absorption maximum whose position is independent of the particular metal in solution (1, 9). This maximum is in a region where none appears in the spectrum of bulk sodium metal; and in the spectrum of atomic sodium, very strong absorption occurs at 5889 Å (*D* line), which does not appear in the solution spectrum. Since the maximum observed is also absent from the spectrum of sodium ion and of liquid ammonia, it has been ascribed to the trapped electrons.

Primary amines will also dissolve some of the metals; sodium, cesium, potassium, lithium, and calcium are soluble in methylamine, while ethylamine dissolves at least lithium and potassium. Although these solutions have been examined less exhaustively than the ammonia solutions, their behavior is similar. Thus the variation of electrical conductivity with concentration in metal solutions in methylamine is similar to that in anhydrous ammonia (2), and the absorption spectra, although exhibiting maxima at a different wave

length, were shown to be independent of the metal for a limited number of solutions (1).

The experimental observations of the absorption spectra are limited to quite early work done with a visual spectrophotometer (1) and to some work by Vogt (9). Because the solutions in methylamine had maxima in the absorption spectrum at visible wave lengths, these were observed by the early workers, but the peaks for ammonia solutions were missed as they occur in the near infrared. Vogt describes the spectra of lithium and sodium in ammonia solutions of unspecified concentration. The dearth of spectrophotometric data is probably explained by the difficulty of manipulating the solutions, their very high absorbance, and the awkward spectral region in which the absorption maximum for ammonia is located.

In the present paper, absorption spectra are presented for solutions of lithium, sodium, potassium, and calcium in ammonia and in methylamine, lithium and potassium in ethylamine, sodium and potassium in mixed ammonia and methylamine, and sodium in mixed ammonia and ethylamine.

EXPERIMENTAL PROCEDURE

The main experimental problems associated with the measurement of liquid ammonia and amine spectra arise from the instability of the solutions, their low boiling points (which necessitate constant refrigeration), and the very high molar absorbancy index which make dilute solutions and very thin cells necessary.

The spectra were determined in two parts, the region from 0.3 to 1.0μ on a Beckman D.U. ultraviolet spectrophotometer and from 1.0 to 2.5μ on a Beckman IR-2 infrared spectrophotometer. Quartz cells of thickness 10, 1.0, and 0.1 mm. as supplied by the American Instrument Company were used. In both instruments the effective band width is considerably smaller than the half-height width of the maxima being investigated so that the shape of any spectrum was not affected by the dispersion of the instruments.

The cell was contained within a thick-walled Lucite box with quartz windows on either side for the passage of the light beam. The absorption cell was removed from the light path by moving it upwards. It was kept at the desired temperature by a stream of cold dry air, which entered the box by the ducts shown in Fig. 1 (at *G*). The air was dried with silica gel and cooled by liquid air. The outside windows of the box were kept clear of frost by jets of warm dry air.

The cold box made a light-tight fit into either spectrophotometer, and fogging of the instrument optics was prevented by the warm dry air which continually swept the volume outside the box. Temperature was controlled manually both by regulating the flow of air through the box and by regulating the temperature of the air entering it. A thermocouple cemented on the cell wall near the face showed fluctuations of two to three degrees.

The apparatus for manipulating the solvents and preparing the solutions is shown schematically in Fig. 1. Solvents were stored in a detachable trap *A*. Solutions were prepared in trap *B* by various methods and were transferred to

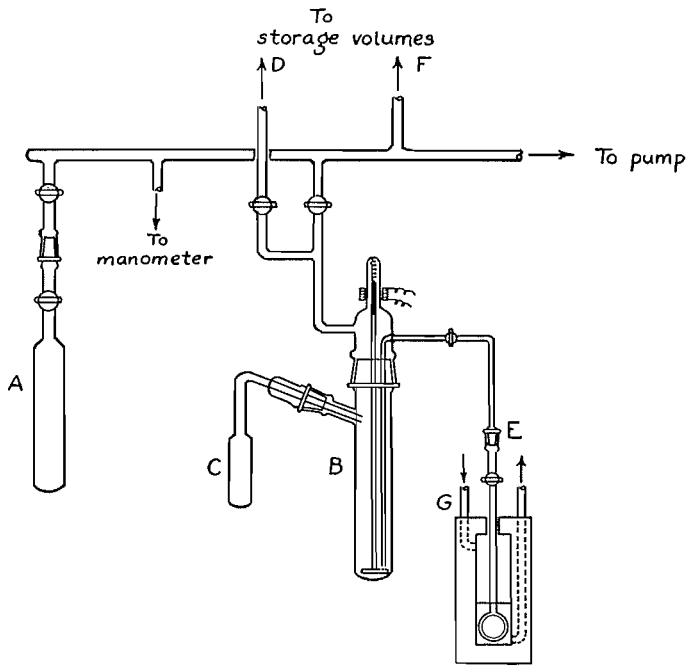

FIG. 1. Apparatus for preparing solutions and filling absorption cell.

the cell by admitting nitrogen from *D* thus forcing the liquid through the siphon into the cell. Excess liquid in the neck of the cell was removed by pumping off the nitrogen and distilling the solvent back into *B*.

The cell was disconnected at the ground glass joint *E* for measurements in the spectrophotometer. At the completion of these measurements the cell could be reconnected at *E* and the solvent distilled off. Another solvent could then be distilled into the cell thus avoiding the necessity of forcing over-all combinations of metals and solvents.

A saturated solution of potassium in methylamine was found to be quite stable, could be successfully forced over, and was just the correct concentration for spectral measurements in the 0.1 mm. cell. Solutions were thus prepared simply by placing a piece of potassium in trap *B* and distilling in a suitable quantity of methylamine. It thus became possible by the procedure described above to obtain spectra for any solvent in which potassium was more soluble than in methylamine.

A similar procedure could be used for sodium solutions although for this metal the combination of a saturated solution in methylamine and the 1.0 mm. cell was most convenient.

For more soluble metals it was necessary to resort to a dilution technique where a piece of the metal was placed in trap *C* and solvent added by distillation. Trap *C* could then be rotated on its ground glass joint until drops of solution poured from *C* into *B* where a relatively large volume of solvent diluted the drop to a suitable concentration.

Since lithium and calcium metal are relatively stable in the air, solutions of these metals were prepared either by the above dilution procedure or by placing a small piece of the metal in trap *B*. However, solutions of these metals are much less stable than those of sodium and potassium and hence greater difficulty was experienced in forcing them over.

When a solvent was distilled into the thin cells containing metal residue the first few drops of solution were sufficient to cover the whole cell face since the liquid rose by capillary action. Thus the concentrations of solutions prepared in this manner were not reproducible. Mixed solvents were condensed from a large gas storage bulb *F* in order to prevent preferential condensation. Table I

TABLE I

METHODS OF PREPARATION OF THE SOLUTION

Metal	Solvent	Method of preparation
Li	Methylamine	Small piece of metal placed in trap, or by diluton
Li	Ammonia	Residue from methylamine
Li	Ethylamine	Dilution
Na	Methylamine	Saturated solution
Na	Ammonia	Residue from methylamine
Na	Mixed solvent	Residue from methylamine
K	Methylamine	Saturated solution and dilution of saturated solution
K	Ammonia	Residue from methylamine
K	Ethylamine	Saturated solution
Ca	Ammonia	Small piece of metal placed in cell
Ca	Methylamine	Saturated solution

shows the specific fashion in which the various solutions were prepared. Solvents were distilled, before use, in a Podbielniak type of column and at a pressure of 300 to 400 mm. Hg. All the amines as received had ammonia fractions in them but the separation of this fraction was quite sharp on the still used. Only a middle fraction was used for the experiment. The solvents were dried over one of the alkali metals but ultimately it was found that lithium was the best drying agent probably because it is the most soluble.

No attempt was made to purify the metals used. It was observed, however, in the case of sodium and calcium that these metals did contain something which made it difficult to produce a solution in methylamine. This material could be removed in one of two ways. The metal could be fused in trap *B* under vacuum (feasible only for sodium) or a solution could be first made in ammonia and the ammonia subsequently evaporated. The latter method was

used for calcium, but either method left the metal in a finely divided state which caused some trouble because metal particles tended to remain suspended in the liquid.

The absorption spectra of liquid ammonia and methylamine are shown in Fig. 2. From these spectra it can be seen that little difficulty will be encountered from solvent contribution to solution spectra, down to about 7000 cm^{-1}. At frequencies above this almost any cell thickness is acceptable while below this a cell 0.1 mm. in thickness is desirable. Spectra of sodium solutions in the mixed solvent and in ammonia have a band at about 7350 $cm.^{-1}$ which for ease of preparation were measured in the 1.0 mm. cell. Consequently, measurements of this band are more uncertain than most of the spectra reported.

Considerable variation of absorbance was observed from solution to solution even in the case of those which were originally saturated. This was probably due to change in concentration which occurred when the liquid was forced over. It is possible that sufficient water and oxygen remained adsorbed on the surface of the vessels to affect the dilute solutions slightly, particularly in the region between the windows.

Variations in absorbance were also observed when the temperature of a specific solution was changed, particularly in the case of the saturated solutions. This variation followed no regular pattern and if the solubility changed with temperature and some suspended particles of metal were present such behavior would be predicted. However, when the temperature was held steady, absorbance measurements on solutions in pure solvents were reproducible throughout the time required for determination of the spectrum.

No detectable fading was observed in sodium or potassium solutions in methylamine up to −20°C. Lithium and calcium solutions in methylamine tended to fade at temperatures as low as −40°C. Solutions in ammonia were stable without exception but in this case the temperature was not allowed to rise above −40°C.

MATERIALS USED

Ammonia	Matheson	Anhydrous
Methylamine	Matheson	Anhydrous
Ethylamine	Matheson	Anhydrous
Sodium	Merck	Reagent grade
Potassium	Baker and Adamson	Reagent grade
Lithium	Metalloy	Low sodium, reagent grade
Calcium	Purest grade	Dominion Magnesium Limited

EXPERIMENTAL RESULTS

The spectra of lithium, sodium, potassium, and calcium in ammonia are identical, having a single broad band with a maximum at 6650 $cm.^{-1}$ (−60°C.)* and a half-height width of 2950 cm^{-1}. The specific observations are shown in

When a band was not determined at −60°C. a value has been estimated using the temperature coefficients given below.

**Low frequency maximum only.*

Table II. Calcium does not appear there because the solution used was too concentrated, so that it was possible only to show that no additional bands appeared and that the maximum was located similarly to the other three metals.

In methylamine different bands were observed for the various metals. This is illustrated in Fig. 4. Lithium and calcium have a single band each, which is the same for both metals and appears at 7680 cm.$^{-1}$ (−60°C.). Sodium has a single band at 15,300 cm^{-1}. Potassium has two bands close together with the

WAVE NUMBER, ($cm.^{-1}$)

result that the observed position of either band is somewhat affected by the other. It seems likely, however, that the high frequency band is identical with that found for sodium.

The effect of concentration on the potassium spectrum was investigated by adjusting the concentration, in three separate cells of 10, 1.0, and 0.1 mm. thickness, to give nearly constant absorbance. This will produce a change in concentration of about 100-fold. The resulting spectra are shown in Fig. 5. It will be noted here that the relative height of the two maxima varies with concentration and this indicates that absorption occurs by two independent processes.

In ethylamine only lithium and potassium were successfully dissolved. Their spectra are shown in Fig. 7. Two different bands are observed, the high frequency band being very similar to the high frequency band produced in methylamine. The low frequency band as observed for lithium, however, has a much greater half-height width than the comparable bands observed in methylamine.

The spectrum of sodium in a mixed solvent of methylamine and ammonia (molar ratio 1 : 1), shown in Fig. 8, exhibits two main absorption bands. The position of the high frequency band was established at 14,700 cm.$^{-1}$; its

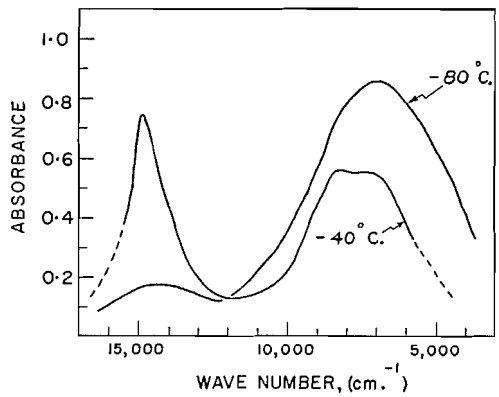

FIG. 8. Sodium in mixed ammonia–methylamine.

precise location was made difficult by the large variation of absorbance with temperature. The position and half-height width of the low frequency band are shown in Table II. From these it can be seen that this band is essentially the same as that observed for pure ammonia. Although its position is slightly shifted, its half-height width indicates that it does not contain a new hidden band. The temperature dependence of the absorbance at the maximum is shown for both bands in Table III.

The absorption spectrum of potassium in mixed methylamine and ammonia (molar ratio 1 : 1) reveals one band. The location and half-height width of this band serves to identify it with the low frequency band observed for sodium in the mixed solvent. This spectrum was obtained in the 0.1 mm. cell so that the concentration of potassium is probably about 10 times that of the corresponding sodium solution.

A solution of sodium in a mixture of ethylamine and ammonia (molar ratio 1 : 1) was examined for its absorption spectrum. This showed two bands, one at 7500 cm.$^{-1}$ and one at 14,800 cm^{-1}. The high frequency maximum can

TABLE III

EFFECT OF TEMPERATURE ON THE ABSORBANCE AT THE MAXIMA FOR THE MIXED SOLVENT

probably be ascribed to sodium effectively dissolved in ethylamine although no solution is formed in the pure solvent.

From the data in Table II it might be expected that the position of the band in the spectrum of sodium in methylamine would be affected by both temperature and concentration. The effect of temperature on a specific solution for which the absorbance remained fairly constant is shown in Table IV. A plot of these data gives a temperature coefficient of −13 cm.$^{-1}$/degree. If the data in Table II for sodium in methylamine are now adjusted to a single temperature, using the above temperature coefficient it can be demonstrated that a change in position of the maximum is produced as the absorbance (i.e. concentration) is changed. The variation is 330 cm.$^{-1}$/unit of absorbance.

TABLE IV

THE EFFECT OF TEMPERATURE ON THE POSITION OF THE MAXIMUM FOR A SOLUTION OF SODIUM IN METHYLAMINE

Temperature, °C.	Position of maximum	Absorbance at maximum
−14	14,710	1.89
−25	14,810	1.80
−28	14,930	1.73
−50	15,150	1.53
−50	15,250	1.55
−58	15,270	1.45
−73	15,490	1.39
−73	15,380	1.65
−74	15,490	1.48

The position of the maximum for potassium in ammonia varies with temperature in a similar fashion, and the temperature coefficient for this system is -9 cm.$^{-1}$/degree.

The temperature coefficients for the half-height widths are 12 cm.$^{-1}$/°C. for potassium in ammonia and 14 cm.$^{-1}$/°C. for sodium in methylamine. As would be expected these coefficients are positive but the data are not precise enough to test the fit of a plot of $\sqrt{T}$ against band width.

The spectra of sodium and potassium in methylamine were observed for saturated solutions in a 1.0 mm. and a 0.1 mm. cell respectively. An attempt was made to determine the solubility of these two metals in methylamine. This was done by preparing saturated solutions at -80°C. and filling a small bulb with the solution in a manner similar to that used for filling the absorption cells. The solvent was then evaporated and the residual metal determined by measuring the hydrogen evolved on reacting it with water. The method of preparation of sodium solutions was such that the production of small particles of suspended metal was very likely. While this is not important in the measurement of spectra it does make analysis for the metal in solution difficult. Solutions were allowed to stand for some time before a sample was drawn off for analysis but this does not preclude the possibility of particles being swept off the delivery tube. With potassium the problem was not so severe because the metal was not in a finely divided state and particles were much less likely to be formed. Thus figures obtained for potassium are more likely to be accurate. The best estimates of concentration were 8×10^{-4} moles/liter and 1.9×10^{-3} moles/liter for saturated solutions of sodium and potassium respectively. It is suspected that the figure for sodium is somewhat high. A value of about 10^4 is thus observed for the molar absorbancy index of sodium in methylamine. The molar ratio of potassium to methylamine as used in the 0.1 mm. cell was thus about 5×10^{-5}; that for sodium to methylamine as used in the 1.0 mm. cell was probably 10^{-5} or less.

DISCUSSION

Originally it was hoped that information about the electron traps in liquid ammonia and amines could be obtained by observing spectra in mixtures of ammonia and an amine. It had been established that the spectrum in ammonia had a band at about 6000 cm.$^{-1}$ (9) and that a corresponding band occurred for methylamine at about 15,000 cm.$^{-1}$ (1). If traps exist in the structure of the liquid rather than in the form of a molecular orbital about a given molecule of solvent then it was reasoned that, in mixtures, intermediate bands between the two parent bands would appear. Indeed there was the possibility of only the intermediate band appearing.

The present observations confirm previous conclusions regarding the spectra in ammonia but the spectra for potassium, lithium, and calcium in methylamine are new and unexpected. At first glance it would appear that it is necessary to postulate a trap which will involve the metal ion as well as the solvent. But since identical bands appear for more than one metal (i.e. 7680 cm.$^{-1}$ band for lithium and calcium and the 15,500 cm.$^{-1}$ band for sodium and potassium) it is

evident that a given metal ion does not produce a unique trap. This is adequate evidence for rejecting a metal ammoniate or solvent metal complex as the location of the trap. It will be shown below that it is possible to fit all the observed facts into the presently held theory that the electron trap is formed by a hole in the liquid which has a more or less regular structure.

It is suggested by Lipscomb (6) that the density of metal ammonia solutions is consistent with the hypothesis of a hole in the liquid of 3 Å radius. The solvent molecules at the edge of such a hole will have their more positive ends, in this case the three hydrogen atoms, directed inwards thus forming a region of low potential in which the electron is trapped. By analogy with *F* centers and impurity phenomena in solids such a trap might be expected to have an excited state with an attendant energy transition which is manifested by the absorption spectrum.

The positive end of the ammonia molecule is made up of three hydrogen atoms and is symmetrical so that the array of molecules at the edge of any hole will be identical. This will make the configurational co-ordinates and consequently the transition levels for each hole identical, with the result that a single maximum is observed for all the solutions in liquid ammonia. As the temperature is changed the intermolecular association will be disturbed with the result that the configuration of the hole is slightly altered. This leads to a slight change in the transition levels in the trap and is manifested by a shift in the position of the absorption maximum.

The methylamine molecule is not symmetrical about the nitrogen atom and hence it is possible that two different aspects of the molecule may be presented at the boundary of a trap. These two orientations may or may not be mixed depending on how readily they fit around the hole, the size of the hole, and on what other forces are at work in the rest of the liquid. On the basis of this model the methylamine spectra can be broken into two groups, called for convenience, amine bands and aliphatic bands. The former represents the condition where the methylamine molecules are oriented so that an ammonia-like trap is produced. This case is probably represented by the spectra of calcium and lithium where a band is observed at about 7680 cm^{-1}. The small difference in position of the maximum from that observed in ammonia is accounted for by the effect of the methyl group on the intermolecular forces and hence on the configurational co-ordinates. Aliphatic bands arise from traps in which the methyl group takes part in the formation of the trap boundary. Such a trap would be expected to have quite different configurational co-ordinates and a different set of transition levels. Such a situation is in fact observed for the sodium and potassium spectra in methylamine where a band appears at about 15,500 cm^{-1}.

In potassium solutions in methylamine an intermediate band is produced which must arise from a third trap because the relative height of the two bands observed varies with concentration and temperature. Such behavior would not be observed if two transition levels in a single oscillator were being represented. The fact that there is a discrete additional band and not a diffuse broadening of the original implies that a fixed combination of the two possible orientations exists.

Aliphatic bands in ethylamine are represented by the spectrum of potassium in solution. A mixture of the orientations producing aliphatic and amine traps is probably represented by the lithium spectrum in ethylamine. The single band is very much broadened and close inspection shows that the broadening is largely on the high frequency side which is what would be expected for mixed traps where the amine orientation predominated.

The particular trap which is formed in the amines depends on the metal ion which is present in the solution. This implies that the metal ions have a relatively long range effect on the orientation of solvent molecules so that one trap or the other is formed depending on the strength of this influence. Thus as the potassium solutions were made more dilute the number of pure aliphatic traps tended to increase at the expense of the other mixed trap. In very dilute lithium solutions in methylamine (Fig. 6) there is definite evidence that a weaker band at about 15,000 cm.$^{-1}$ exists which was not observed in the more concentrated solutions. In even more dilute solutions this band presumably would become relatively stronger and in fact Gibson and Argo (1) report a definite band in that position. It would appear that aliphatic traps would normally form in methylamine but the influence of certain metal ions favors the amine type trap to a degree depending on their concentration.

Further evidence for the long range effect of the metal ions is presented by the concentration effect on the position of the maximum in sodium solutions in methylamine. Here it was observed that even in very dilute solutions a variation in concentration shifted the position of the maximum to a significant degree.

It will be shown below that the difference in depth of traps of the two kinds is only about 0.1 ev., so that even a very weak influence from the metal ion may be sufficient to favor the orientation producing one trap or the other.

In mixed ammonia and methylamine, the following six types of trap may be expected:

Amine type	Mixed type	Aliphatic type
1. Pure ammonia	3. Ammonia+methylamine (amine oriented)	6. Pure methylamine
2. Pure methylamine	4. Ammonia+methylamine (aliphatic oriented)	
	5. Methylamine (amine oriented) +methylamine (aliphatic oriented)	

In pure methylamine, a trap of type 5 above is represented only in the potassium spectrum; from this it can be predicted that traps of type 4 and 5 will be rare in the mixed solvents. In fact no corresponding bands have been observed.

Traps of types 1 and 2 have maxima which lie quite close together (Table V). In the mixed solvent an intermediate band is observed, probably due to traps of type 3. A similar band could of course be produced from the sum of two

TABLE V

AVERAGE VALUES, INDEPENDENT OF METAL, FOR BAND POSITION AND HALF-HEIGHT WIDTH FOR THE LOW FREQUENCY BANDS

Measurement	Solvent		
	Ammonia	1:1 Ammonia methylamine	Methylamine
Band maximum	6650	7310	7680
Half-height width, $cm.^{-1}$	3080	3460	4420

separate bands each representing the spectrum observed in the pure solvents, but such a band would be wider than either of the two parent bands. This, however, is not observed since the band width also is intermediate as shown in Table V. It is therefore concluded that the intermediate band observed results from the formation of combination traps involving both solvents.

The band of the pure aliphatic type is observed only for sodium in the mixed solvents. A corresponding band does not appear in the potassium solution. This is consistent with the pattern in pure methylamine where it is observed that potassium has a stronger directing influence towards the formation of amine type bands than does sodium.

The relative depths of traps of the two kinds, i.e. those involving the amine group only and those involving only the aliphatic group, can be estimated from the effect of temperature on the height of the two maxima appearing in the sodium solution in mixed methylamine and ammonia. Heights of these two maxima as a function of temperature are given in Table III. By plotting the absorbance of the two maxima against temperature it can be shown that the one maximum gains at the expense of the other when the temperature is changed.

If it is assumed that the activation energy for the formation of traps is zero, we may write:

[1] $$B/A = a\, e^{-(E_b - E_a)/RT}$$

where A = concentration of traps of the amine type,
B = concentration of traps of the aliphatic type,
a = constant,
E_a = energy of formation of Trap A,
E_b = energy of formation of Trap B.

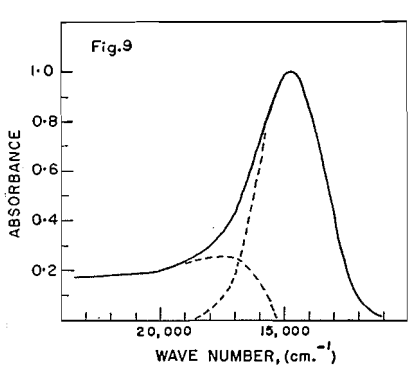
If it is further assumed that Beer's Law holds for the maxima, it follows that

$$B^1/A^1 \propto B/A$$

where B^1 = absorbance at maximum of high frequency band when the concentration of aliphatic traps is B,
A^1 = absorbance at maximum of low frequency band when the concentration of amine traps is A.

Thus the plot of $\log B^1/A^1$ against $1/T$ should permit an estimation of $E_b - E_a$.

Such a plot is shown in Fig. 10 and from this a value of -0.17 ev. is obtained for $E_b - E_a$. Traps of mixed amine and ammonia types are thus slightly deeper than the aliphatic type. Because of the great similarity of these bands it is suggested that ammonia traps, methylamine traps of the amine type, and mixtures of the two will have approximately the same depth. The difference in depth between traps in ammonia and methylamine for a metal such as sodium then is about 0.2 ev.



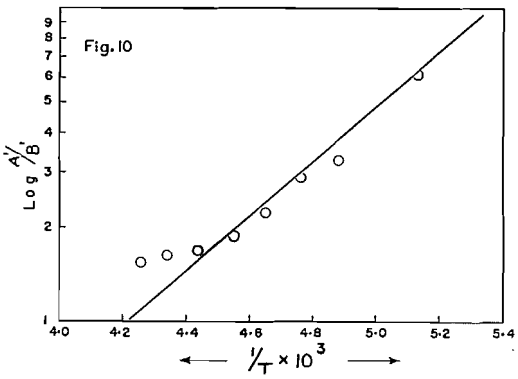


FIG. 9. Sodium in methylamine.
FIG. 10. Effect of temperature on peak height in spectrum of sodium in mixed ammonia–methylamine.

The separation of the two bands for spectra in methylamine and ammonia is about 1 ev. This value is much larger than the difference between the potential energies of the two traps so that it must be concluded at least for the low frequency bands that the absorption process involved in producing the bands is not one resulting in dissociation of the traps but rather is a transition between two energy levels of the trap.

Fig. 9 shows a more detailed representation of the absorption spectrum of sodium in methylamine. If this spectrum be compared with that found for potassium in ammonia (Fig. 3) it will be noted that for the high frequency band in methylamine there is a rather high level of continuous absorption on the high frequency side. In ammonia the level of absorption falls off much more quickly in the corresponding region.

By analogy with F centers in alkali halide crystals (7) it is suggested that the continuous absorption in the solution spectrum in methylamine represents a dissociation continuum which begins in the neighborhood of the main band. This implies a dissociation energy of about 2 ev. for the high frequency trap.

SUMMARY

1. A single band in the absorption spectra at 6650 cm.$^{-1}$ was found for all the solutions of metals in liquid ammonia which were studied.

2. The absorption spectra of solutions of metals in methylamine have a single band with the exception of potassium which has two. The position of the single band may be at one of two points, 15,300 cm.$^{-1}$ or 7680 cm.$^{-1}$ (-60°C.) depending on the metal.

3. The absorption spectrum of potassium in ethylamine has a single maximum in the 15,300 cm.$^{-1}$ region.

4. A solution of sodium in mixed methylamine–ammonia solvent has an absorption spectrum with two bands, one in the 15,300 cm.$^{-1}$ and one in the 7300 cm.$^{-1}$ region.

5. From the sodium in methylamine absorption spectrum it is argued that a dissociation continuum begins in the neighborhood of the band, which permits the estimation of 2 ev. for the depth of traps represented by bands in the 15,300 cm.$^{-1}$ region. From temperature effects in the mixed solvent it was shown that the trap represented by the band in the 7300 cm.$^{-1}$ region is about 0.2 ev. deeper.

6. Since the separation in trap depth is much less than the separation of the two bands it is argued that the absorption bands result from energy transitions and not from dissociation of the trap.

ACKNOWLEDGMENT

The foregoing investigation was part of the work performed at the Royal Military College under D.R.B. Research Grant No. 357. This opportunity is welcomed for thanking the Defence Research Board for its fine cooperation and financial assistance.

SOME OBSERVATIONS ON CYANIC ACID AND CYANATES[1]

By M. W. Lister

ABSTRACT

Various reactions of cyanic acid and the cyanate ion have been examined. Cyanic acid, in the presence of added hydrochloric or nitric acid, decomposes quantitatively according to the equation: $HNCO+H_3O^+ \rightarrow CO_2+NH_4^+$. The rate constant for this reaction was measured over a range of temperature and ionic strength, and was found to be 0.86 mole liter^{-1} min.$^{-1}$ at unit ionic strength and 1.5°C. The activation energy is 14½ kcal. The effect of ionic strength on the reaction with hydrochloric acid closely parallels that on the activity coefficients of the acid itself. Without added acid cyanic acid decomposes by a first order reaction: $HNCO+2H_2O \rightarrow NH_4HCO_3$, followed by a rapid second stage: $NH_4HCO_3+HNCO \rightarrow NH_4NCO+H_2CO_3$. This reaction has a rate constant of 0.011 min.$^{-1}$ at 0°C., and an activation energy of 16 kcal. There is also a few per cent of some side reaction. Cyanate ions in alkaline solution decompose thus: $OCN^-+2H_2O \rightarrow NH_4^++CO_3^{--}$. This reaction was examined over a range of temperature and ionic strength: it is first order with $k = 3.0 \times 10^{-3}$ min.$^{-1}$ at 100°C. (0.3 ionic strength) and 23½ kcal. activation energy. The rate is somewhat dependent on hydroxide concentration, when this is fairly low. The reaction is catalyzed by carbonate, but not by a number of other anions that were examined. The rate of the catalyzed reaction is proportional to the carbonate concentration, but independent of cyanate, at least over a considerable range. The ionization constant of cyanic acid has been measured by a method that avoids errors from hydrolysis; the value obtained was 2.0×10^{-4}. The oxidation of cyanate by hypochlorite and by chlorine was examined more briefly.

Past workers have established with reasonable certainty the qualitative aspects of the decomposition reactions of cyanic acid and the cyanate ion. However, quantitative measurements have not been too systematic, and it is hoped that the present work will give a more complete picture. Besides the decomposition reactions in aqueous solution, which are really hydrolyses, some observations are included on the oxidation of the cyanate ion.

1. DECOMPOSITION OF CYANIC ACID IN ACID SOLUTION

This acid decomposes fairly rapidly in dilute aqueous acid according to the equation:

$$HNCO+H_3O^+ \rightarrow CO_2+NH_4^+.$$

Cyanuric acid only results to any great extent in concentrated solution. The ammonium ions could react with cyanate ions to give urea; but this reaction is much slower, so that in acid solution it is negligible. Quantitative measurements on this reaction are rather limited. Taufel, Wagner, and Dunwald (8) report a reaction first order with respect to cyanic acid, and with a rate constant of 2.4×10^{-3} min.$^{-1}$ at 25°C. We have studied this reaction over a range of conditions with the following results.

Experimental Method

A good grade of potassium cyanate was recrystallized from a mixture of 10% water, 50% ethyl alcohol, and 10% methyl alcohol. A solution of this salt in water was made up; a sample was pipetted into a flask immersed in a

[1]*Manuscript received October 26, 1954.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ont.

bath at the temperature being investigated. A sample of hydrochloric acid of known concentration was similarly pipetted out and to this was added sodium chloride solution to give the desired ionic strength. This also was brought to the correct temperature. The solutions were mixed and after a given time the reaction was stopped by adding excess sodium hydroxide. The actual reaction temperature was read from a thermometer graduated in 0.1°C. immersed in the reaction mixture.

The ammonia formed was estimated by distilling it into a known amount of standard acid, and titration. The distillation was brief enough so that only a very small amount of ammonia was formed by decomposition of cyanate during this operation; however as this reaction was also measured (see Part 3), this error could be allowed for. The solution was always distilled for the same length of time. Traces of ammonium ion initially present in the cyanate (or elsewhere) were estimated in a reagent blank run. The cyanate initially present was calculated from the strengths of the stock solutions, which were determined by silver nitrate titration (see Part 3 for details). At subsequent times it was assumed that the cyanate concentration was given by the initial concentration minus the ammonium ion formed. It was checked that if the reaction was allowed to go to virtual completion the ammonium ion formed was equal to the initial cyanate; i.e. side reactions are negligible. The same point was checked in another way. A potassium cyanate solution, containing some carbonate from its decomposition, was titrated with hydrochloric acid, and the pH followed. An inflection point was found at a pH of about 7.8. At this point the carbonate is just converted to bicarbonate. After this the pH meter was removed, and bromcresol green added. The solution was warmed and acid run in to maintain the color of the indicator at yellowish-green. Eventually the color did not change even on boiling, and at this point the reaction is just complete.

$$KOCN + 2HCl + H_2O \rightarrow KCl + NH_4Cl + CO_2$$

This is a method of estimating cyanate in the absence of interfering substances, and the results agreed with those of silver nitrate titration. Hence side reactions during the titration with acid are negligible.

Results

This reaction was examined at various temperatures and ionic strengths. Table I gives results all at an ionic strength of 1.0. This ionic strength is derived on the assumption that no cyanic acid is ionized; the value for the ionization constant obtained later shows that the fraction ionized would be less than 0.001. The reaction itself will not change the ionic strength.

Table I also gives values of the rate constant assuming that the reaction is first order with respect to cyanic acid and hydrogen ions; i.e. that

$$-dx/dt = kxy$$

where x = (HNCO), y = (H^+), and k is the rate constant. The most convenient integrated form of this equation is

$$k = \frac{1}{ct} \ln \frac{x_0(x-c)}{x(x_0-c)}$$

where x_0 and y_0 are the initial values of x and y, and $c = y_0 - x_0$. k was calculated from this equation. The values of k so obtained are reasonably constant, though at 25°C. the rate is too great for very accurate measurements. It can readily be checked that no other rate equation fits the results anything like as well. Run 12 differs from the others in being done with nitric acid; it gives

TABLE I

the same rate as with hydrochloric acid, showing that chloride has no catalytic effect.

Table II shows the effect of altering the ionic strength. These runs are all at 1.5°C. The constants were calculated as before, except for Run 8 where cyanic acid was in slight excess. Here if $b = x_0 - y_0$, then

$$k = \frac{1}{bt} \ln \frac{x(x_0-b)}{x_0(x-b)},$$

but as b is small this can be expanded as a series:

$$k = \frac{1}{t}\left[\frac{x_0-x}{x_0(x-b)} - \frac{b}{2}\frac{(x_0-x)^2}{x_0^2(x-b)^2} + \ldots\right].$$

For Run 8, k was calculated from this formula.

The results of these runs give the following average values for the constants. Firstly at an ionic strength of 1.0 we get:

T	1.5	13.1	25.5	°C.
k	0.86	2.44	7.45	moles liter^{-1} min.$^{-1}$

These give an activation energy of 14.5 kcal./gm-mol.

At 1.5°C. the dependence of k on the ionic strength, μ, is as follows:

μ	0.2	0.5	1.0	2.0	3.0
k	0.73	0.73	0.86	1.07	1.25 moles liter^{-1} min.$^{-1}$

TABLE II

Run No.	Ionic strength	Initial (H^+), M	Time, sec.	(HNCO), M	k, moles l.$^{-1}$ min.$^{-1}$
8	0.2	0.0944	0	0.0986	—
			15	0.0969	0.740
			60	0.0923	0.759
			120	0.0866	0.738
			240	0.0781	0.700
			480	0.0642	0.713
9	0.5	0.293	0	0.0986	—
			15	0.0934	0.764
			30	0.0889	0.726
			120	0.0667	0.713
			240	0.0470	0.704

			30	0.0857	1.024
			60	0.0726	1.140
			120	0.0564	1.074
			240	0.0351	1.057
11	3.0	0.285	0	0.0987	—
			15	0.0903	1.260
			30	0.0839	1.173
			60	0.0695	1.302
			120	0.0515	1.261

It is interesting to note that this change closely parallels that of the activity

coefficient (f) of hydrochloric acid at similar ionic strengths (7):

μ	0.2	0.5	1.0	2.0	3.0
$\log f$	−0.116	−0.121	−0.091	0.008	0.120
$\log k$	−0.137	−0.137	−0.066	0.029	0.097

The next question is whether this is the same reaction as that examined by Taufel *et al.* (8). Cyanic acid itself could provide hydrogen ions; from the rate constants given above and that obtained by these authors, the observed rates would be the same if the pH were 3.5, which is a reasonable value for partially hydrolyzed cyanic acid. However if cyanic acid provided the hydrogen ions the rate would not appear to be first order, as reported by Taufel *et al.* In fact the reaction should follow the equation:

$$x_0/x - \ln(x_0/x) = 1 - 2k.k_a t$$

where x is the cyanic acid concentration, initially x_0, k is the rate constant, and k_a the ionization constant. It was therefore decided to investigate the decomposition of cyanic acid in the absence of added acid.

2. DECOMPOSITION OF CYANIC ACID WITHOUT ADDED ACID

The reaction here goes in two stages:

$$HNCO + H_2O \rightarrow NH_3 + CO_2,$$
$$NH_3 + HNCO \rightarrow NH_4^+ + NCO^-.$$

The first stage is, of course, the slower.

Experimental Method

Cyanic acid solution was prepared in the usual way by passing the gases formed by heating cyanuric acid through a red-hot tube and thence into ice-cold water (e.g. 1, 10). A slow stream of nitrogen was used to carry over the gas. The resulting solution of cyanic acid was used as soon as possible. It was contained in a flask immersed in a water bath of the desired temperature, and samples for analysis were taken at intervals.

The chief difficulty in following this reaction is to find an analytical method that distinguishes between cyanic acid and cyanate ions. As it is necessary to stop the reaction by the addition of alkali, only an acid–base titration seemed to offer much hope of a successful method. It was found that if a sample of partially decomposed cyanic acid were run into excess sodium hydroxide solution, and the mixture titrated with standard acid, then the pH of the mixture showed two inflection points, at 7.8 and at 5.1. The first inflection comes when carbonate ions have just been converted into bicarbonate; in effect this is the pH of ammonium bicarbonate solution. The second is due to the fact that at pH 5.1 most of the carbonate is now carbonic acid while the buffering action of cyanate is only just beginning. This is not a very well marked inflection, but it is quite distinguishable.

The procedure was therefore as follows. The sample was run into a known volume of standard sodium hydroxide solution, and this mixture was titrated with hydrochloric acid with the help of a pH meter. The volumes required to give pH 7.8 and 5.1 were noted. After this the pH meter was removed, brom-

cresol green was added, and the solution was heated. Hydrochloric acid was run in until the bromcresol green maintained a green color even on boiling; the volume of acid required was noted. It will be seen that the difference between the gram molecules of the sodium hydroxide and hydrochloric acid gives the number of gram molecules of the following constituents: (1) pH 7.8: HNCO+CO_2; (2) pH 5.1: HNCO; (3) bromcresol green end point: HNCO+2(NCO^-). From this the concentrations of cyanic acid, cyanate ion, and carbon dioxide can be found separately. There is a small correction to apply at pH 5.1, since about 4% of cyanate is already cyanic acid, and about 4% of the carbon dioxide is still present as bicarbonate. If any cyanuric acid (pK_a = 6.75(2)) is present it will appear as carbon dioxide in this scheme of analysis, but will not interfere with the analyses for cyanic acid or cyanate.

TABLE III

Run No.	Temp., °C.	Time, min.	(HNCO), *M*	(NCO^-), *M*
1*x*	5.0	0	0.0796	0.0305
		27	0.0298	0.0555
		62	0.0080	0.0646
		95	0.0025	0.0655

		80.5	0.0302	0.0609
6*x*	12.0	0	0.1191	0.0182
		11	0.0532	0.0496
		21	0.0246	0.0580
		31	0.0120	0.0632
		41.5	0.0049	0.0601

The results are given in Table III. A plot of log(HNCO) against time shows that the reaction is first order. The equation, $x_0/x - \ln(x_0/x) = 1+2k.k_a t$, derived above, is definitely not followed. These runs give the following first order rate constants:

Run	1*x*	2*x*	3*x*	5*x*	6*x*	
T	5.0	5.0	0.0	0.0	12.0	°C.
k	1.82	1.73	1.12	1.07	3.71	$\times 10^{-2}$ min.$^{-1}$

These constants make the activation energy about 16 kcal./gm-mol. Owing to the fact that the pH changes in the titration are not very sharp, these

constants are only moderately accurate. These results show that the $HNCO + H_3O^+$ reaction will be faster at pH less than about two; above pH 2 the $HNCO + H_2O$ reaction will be faster. The pH's of these reaction mixtures were followed during the runs, but are not worth reporting in detail, except to say that they ran from about 2.5 to 4.5, and agreed reasonably well with the analytical results.

It was found that the bromcresol green titer fell slowly during a run. If the reaction is solely

$$2HNCO + H_2O \rightarrow NH_4NCO + CO_2$$

this titer should not change. These experiments indicate that there is a few per cent of some other, or perhaps subsequent, reaction involving cyanate. The formation of urea is too slow (see, for example, Ref. 9) to account for the change; possibly some cyanuric acid is formed. However on the present evidence all that can be said is that such reactions, if present, would decrease the bromcresol green titer. This matter deserves further study.

3. DECOMPOSITION OF CYANATE IONS

This reaction has been investigated at 80°C. by Masson and Masson (4), who examined the decomposition of salts such as barium cyanate which give insoluble carbonates, and sodium cyanate which give soluble carbonates. The first salt reacts thus:

$$Ba(NCO)_2 + 2H_2O \rightarrow BaCO_3 + CO(NH_2)_2.$$

Ammonium ions are no doubt an intermediate. With sodium cyanate they find that the reaction approximates to

$$4NaOCN + 6H_2O \rightarrow 2Na_2CO_3 + (NH_4)_2CO_3 + CO(NH_2)_2.$$

They believe that the relative proportion of ammonium carbonate and urea is not essential from the reaction mechanism, but the chance result of the relative reaction rates. They found that the reaction was catalyzed by sodium ammonium carbonate ($NaNH_4CO_3$), and less so by sodium carbonate. They attribute the catalysis to the $NH_4CO_3^-$ ion, though it seems dubious to postulate this as a unit.

Taufel *et al.* (8) made a few measurements on the decomposition at 100°C. in the presence of excess alkali, which prevents urea formation by removing ammonium ions. They found a first order reaction with $k = 2.7 \times 10^{-3}$ min^{-1}.

The present work deals with the decomposition in the presence of excess sodium hydroxide (in most cases), over a variety of conditions, and in some runs with added carbonate or other ions to discover if they catalyze the reaction.

Method and Apparatus

The reaction was carried out in a flask fitted with a thermometer and a side tube for sampling. The flask was deeply immersed either in boiling water or, for lower temperatures, in a water thermostat of conventional design.

The reaction mixture was made up from stock solutions of potassium cyanate, sodium hydroxide, and sodium nitrate to bring the ionic strength to a known value. In some runs sodium carbonate or other salt was added to investigate the catalytic effect, and the amount of sodium nitrate was adjusted to maintain the ionic strength. Since the over-all reaction is

$$OCN^- + OH^- + 2H_2O \rightarrow NH_4OH + CO_3^{--},$$

it is, of course, impossible to keep constant ionic strength throughout the reaction, but the reactions were started at known values.

The reaction was followed by pipetting out a sample, which was rapidly cooled and to which then a few drops of phenolphthalein were added and dilute acetic acid run in until the color was just discharged. Litmus paper was put in, and acetic acid was added drop by drop until the litmus was pink. This brings the pH to 5–6, and cyanate can now be titrated with silver nitrate without interference from carbonate or ammonia. Sodium chromate was used as indicator.

The results are given in Table IV. Within experimental error the results all conform to a first order reaction, and accordingly the first order constants are also given in Table IV. There seems to be a slight dependence on hydroxide concentration when this is small, but not at higher concentrations. Run 3 illustrates this point very well. In this run the hydroxide was completely used up when the cyanate concentration fell to 0.09 *M*. At about this point the rate increased rapidly, showing that other reactions are important once ammonium ions are present; but the point at 0.095 *M* cyanate (0.005 *M* hydroxide) is in line with the earlier points, showing that even at this low hydroxide concentration the rate had not increased very much. It was checked that when excess hydroxide was present all the carbon from cyanate appeared as carbonate. Hence side reactions only occur when ammonium ions are present.

Runs 1, 5, and 6 give a value of $23\frac{1}{2}$ kcal./gm-mol. for the activation energy. This is doubtless for the first stage of the reaction

$$OCN^- + 2H_2O \rightarrow NH_4^+ + CO_3^{--}$$

after which the ammonium ion reacts with hydroxide.

The next matter to be investigated was the catalytic effect of carbonate found by Masson and Masson for the reaction without added alkali. It was suspected at first that this might simply arise from the higher ionic strength

of the solutions containing carbonate. Accordingly sodium sulphate was added to two runs; it was chosen as a 2:1 salt like sodium carbonate. A run was also carried out at high sodium nitrate concentration. The results are given in Table V. It will be seen that no very great change in k results; and there is no difference between nitrate and sulphate, so the small change probably is due to changing ionic strength.

Table VI gives the effect firstly of added carbonate, and secondly of adding some other ions derived from weak acids. The results show that acetate and borate do not catalyze the reaction, so that the catalytic effect of carbonate is not reproduced by the anion of any weak acid. This is perhaps only to be expected, since hydroxide ions were present in every run, and are also anions of a weak acid.

In the runs with carbonate there is a marked catalytic effect and in addition the rate of the reaction no longer fits a first order equation. In fact in runs 11,

12, and 13, (HNCO) gives a linear plot against time. Run 10 is more or less intermediate, but on the whole fits a logarithmic plot best. In Runs 12 and 13 there is some sign that the rate falls off at low concentrations, but over most of the range the rate is constant. If we calculate the rate at various carbonate concentrations, the results are as follows:

Run	—	10	11	12	13	
(CO_3^{--})	low	0.105	0.21	0.49	0.76	M
Rate	3.0	3.9	4.4	5.6	7.15	$\times 10^{-4}$ moles liter^{-1} min.$^{-1}$

The first rate given above is that calculated from runs without added carbonate for a cyanate concentration about the average of those used in these runs. It roughly indicates what part of the rate is to be ascribed to the uncatalyzed reaction. In the other runs the carbonate concentrations are the averages during the run. These rates give a reasonably linear plot against (CO_3^{--}); that is, the catalyzed reaction conforms to the equation

$$-d(OCN^-)/dt = K_1(OCN^-)+K_2(CO_3^{--}).$$

The results make $K_2 = 6.2 \times 10^{-4}$ min^{-1}. This value of K_2 is obtained by calculating the rate due to the uncatalyzed reaction for all successive pairs of points in Runs 10–13, subtracting this from the observed rate, and dividing the difference by the carbonate concentration. The average result is that given above. Masson and Masson (4) propose an equation for the reaction without excess sodium hydroxide, which is in effect:

$$-d(OCN^-)/dt = \{K_1+K_2(CO_3^{--})\}(OCN^-),$$

but it does not seem possible to fit the present results to this equation. While the catalysis of this reaction by carbonate seems well established, it is not easy to propose a detailed mechanism; that is, to explain the nature of the interaction between cyanate and carbonate.

These results mean that the reaction

$$OCN^-+OH^-+2H_2O \rightarrow NH_4OH+CO_3^{--}$$

must be autocatalytic to a certain extent. The reason that this is not apparent from the results of Table IV (without added carbonate) is that the catalytic contribution is small in these runs: K_1 is about five times as large as K_2, and the runs were terminated after usually about 40% of the cyanate had decomposed.

4. IONIZATION CONSTANT OF CYANIC ACID

This quantity has been previously measured by Taufel *et al.* (8) using the color of bromphenol blue to give the pH of a cyanic acid solution; and by Naumann (5) from the conductivity of a solution containing equimolar amounts of potassium cyanate and hydrochloric acid. The values reported are (i) 2.2×10^{-4}, probably at 0°C.; and (ii) 1.2×10^{-4} at 0°C. Since the decomposition of cyanic acid is relatively rapid even at 0°C., it seemed desirable

to repeat this measurement by a method that avoids as far as possible the risk of error from hydrolysis. Accordingly a roughly 0.1 *M* solution of potassium cyanate was titrated with 0.1004 *M* hydrochloric acid, the pH being followed on a pH meter. The total concentration of cyanate was found by continuing the titration to the bromcresol green end point as described above. A value of the ionization constant, K_a, can be calculated from each pH reading. In this method any carbonate present in the cyanate can be measured and allowed for; the results given in Table VII are calculated on the

TABLE VII

Run 1, Temp. 27°C.											
Vol. HCl	0.72	1.09	1.47	1.99	2.50	3.03	4.03	4.96	6.00	7.07	7.91
pH	7.85	6.42	5.99	5.55	5.27	5.10	4.90	4.80	4.69	4.55	4.51
pK_a(calc.)	—	(3.52)	(3.80)	3.76	3.71	3.70	3.71	3.75	3.76	3.72	3.75
Vol. HCl to bromcresol green end point = 89.97 ml. Mean pK_a = 3.73.											
Run 2, Temp. 10°C.											
Vol. HCl	0.74	1.26	1.51	2.01	2.50	3.00	3.51	3.98	5.00	6.00	
pH	7.85	6.35	6.08	5.64	5.37	5.17	5.01	4.90	4.70	4.59	
pK_a(calc.)	—	3.68	3.79	3.75	3.72	3.68	3.65	3.64	3.59	3.60	
Vol. HCl to bromcresol green end point = 81.60 ml. Mean pK_a = 3.68.											

assumption that pK_a for carbonic acid is 6.46. Any hydrolysis of cyanic acid would show up as an upward drift in the calculated K_a values. As before it was assumed that the ammonium bicarbonate stage was just reached at a pH of 7.85. The best average for pK_a is 3.70, so K_a is 2.0×10^{-4}. It was checked by a rough calorimetric measurement that cyanic acid absorbs heat on ionization though the amount is small. This means that pK_a must fall as the temperature rises, so the difference between the two runs in Table VII must be due to experimental error.

5. OXIDATION OF CYANATE

This section briefly reports some observations on the oxidation of cyanate by the hypochlorite ion and by chlorine and on the similar oxidation of cyanide to cyanate.

The oxidation of cyanide by hypochlorite is known, though it does not seem to have been much investigated. It does however form the basis of a German patent for producing cyanate by passing chlorine into an alkaline cyanide solution, though this could go through cyanogen chloride. It was observed in the present work that potassium cyanide containing sodium hydroxide was oxidized quantitatively to cyanate by sodium hypochlorite. In the presence of hydroxide concentrations down to about 0.1 *M*, equal amounts (within experimental error) of cyanide and hypochlorite were used up in this reaction; that is, side reactions to the main reaction

$$CN^- + ClO^- \rightarrow OCN^- + Cl^-$$

are not present to more than 1% at the most. Attempts to measure the speed of the reaction were unsuccessful: the reaction was stopped by adding hydrogen

peroxide to destroy hypochlorite, but even when this was done only five seconds after the start of the reaction at 3°C., the reaction was already virtually complete. This perhaps merely proves that hypochlorite ions react with cyanide faster than with hydrogen peroxide, but the latter is certainly a rapid reaction.

With low concentrations of sodium hydroxide, cyanate is oxidized by hypochlorite. Under these conditions 1 gm-mol. of cyanide reacts with about 2.5 gm-mol. of hypochlorite; a typical example is the following experiment:

	Concentration, *M*			
Ion	Initial	Final	Difference	
CN^-	0.128	0	0.128	
ClO^-	0.577	0.231	0.346	
OH^-	0.019	0		
CO_3^{--}	0.015	0.034	0.128	carbonate
HCO_3^-	0	0.109		

The concentrations under 'initial' are those immediately on mixing, calculated on the assumption of no reaction. Under 'final' are the results of analyses after the reaction. Hence the reaction is, at least mainly:

$$2KCN+5NaOCl+H_2O \rightarrow 2KHCO_3+5NaCl+N_2$$

or, if we assume that cyanate is formed first, this is then oxidized:

$$2KOCN+3NaOCl+H_2O \rightarrow 2KHCO_3+3NaCl+N_2.$$

This last reaction occurred when cyanate and hypochlorite were mixed directly, as shown by the following experiment:

	Concentration, *M*		
Ion	Initial	Final	Difference
OCN^-	0.316	0	0.316
ClO^-	0.547	0.029	0.518

This gives a hypochlorite to cyanate ratio of 1.64. This is somewhat greater than 1.5, probably because at the end of the reaction the remaining hypochlorite was in a hot solution, containing bicarbonate, from which nitrogen was being evolved. Probably some hypochlorous acid was decomposed, or also evolved.

With fairly low concentrations of sodium hydroxide, the oxidation of cyanate appeared to have an induction period. In the following experiment cyanide (initial concentration 0.130 *M*) was mixed with hypochlorite and samples were taken at intervals and analyzed for hypochlorite. The concentration of sodium hydroxide was initially 0.038 *M*.

Time	0	0.75	2	3.67	5	32	min.
(NaOCl)	0.562	0.414	0.412	0.223	0.217	0.222	*M*
Temp.	22	33	34	40	43	—	°C.

The temperature was read from a thermometer immersed in the liquid, and it is probably because of lag in the thermometer that the temperature appears to rise between 3.67 and 5 min. though the reaction is already virtually complete. Note that here 2.61 hypochlorite ions vanished for each cyanide ion. The length of the induction period, as measured by the time for rapid nitrogen evolution to develop, was as follows (other conditions as in the last experiment):

Induction time	10 sec.	3–3.5 min.	long
(NaOH)	0.019	0.038	0.065 *M*

Similar experiments were made on mixtures of cyanate and hypochlorite. In Run 1 below, the hypochlorite concentration was followed by samples taken at intervals; initially the cyanate concentration was 0.316 *M*, and the sodium hydroxide concentration was 0.0735 *M*. The initial time is the time of mixing:

Run 1	Time	0	0.4	1.5	4.2	7.0	12.0	13.1	min.
	(NaOCl)	0.547	0.543	0.542	0.540	0.538	0.530	0.029	*M*

The temperature in this and similar runs was followed with the results in Table VIII.

TABLE VIII

Run	(NaOH) initial, *M*	Time, min.	Temp., °C.	Run	(NaOH) initial, *M*	Time, min.	Temp., °C.
1	0.0735	0.5	19.8	3	0.057	0.2	19.7
		8.0	19.9			1.0	19.9
		9.5	20.0			2.0	20.0
		11.0	20.2			2.3	22.0
		12.0	20.2			2.6	53.5
		12.7	54.5			2.8	54.8
		13.5	53.5			3.25	54.3
		15.0	51.0			4.0	53.5
2	0.0695	0.2	19.2	4	0.042	0.2	19.5
		2.0	19.8			0.5	41
		4.0	19.9			0.7	53
		6.0	20.0			0.8	54.5
		6.2	35			1.0	54.3
		6.5	45			2.0	53.0
		6.75	54.5				
		7.0	54.2				
		8.0	52.0				

There is evidently an induction period in all these runs, as was also apparent from the sudden evolution of gas after a certain time. The time required for rapid gas evolution to develop was:

Run	1	2	3	4	
(NaOH) initial	0.0735	0.0695	0.057	0.042	*M*
Induction time	12.3	6.2	2.4	0.3	min.

The explanation of this would seem to be that the oxidation of cyanate by hypochlorite ions is slow, but that hypochlorous acid oxidizes it rapidly.

As soon as the hydroxide is used up, the potassium bicarbonate formed is acid enough to liberate hypochlorous acid; cyanic acid is too strong an acid to be formed.

Similar experiments were made on the reaction between chlorine and cyanate. The reaction is fairly rapid in solution at room temperature. The results are not very clear-cut, probably because more than one reaction can occur. The products were found to be chloride, carbon dioxide, nitrogen, and ammonium chloride or hydrochloric acid depending on the relative amounts of chlorine and cyanate. No urea was detected by the xanthydrol test (3). With smaller amounts of chlorine the reaction approximated to

$$4KOCN+3Cl_2+4H_2O \rightarrow 4KCl+4CO_2+N_2+2NH_4Cl.$$

In one experiment 4.69 millimoles of potassium cyanate and 3.44 of chlorine disappeared (a ratio of 1.36 to 1); no acid and 1.74 millimoles of ammonium ion were formed: the above equation would lead one to expect 2.34 of ammonium ion, so about three quarters of the expected amount was formed. In another experiment 3.29 millimoles of potassium cyanate disappeared, and 0.86 of ammonium ion and 3.86 of acid appeared. If we assume the above equation, followed by attack of chlorine on ammonium chloride, to give nitrogen and hydrochloric acid, this reaction would have used up 4.01 millimoles of chlorine; actually 4.47 disappeared. Several other similar experiments were made, but the results were all about the same: the analyses for the products and reagents did not agree to better than 10% with the predictions of the equation above, allowing for subsequent reaction of chlorine and ammonium ions. It is not difficult to suggest side reactions, and the most that can be said is that this equation probably represents the main reaction. Normand and Cumming (6) report that bromine gives a reaction precisely analogous to the one suggested for chlorine. Here presumably the attack of bromine on ammonium ions, or other side reactions, is slower so that the reaction is more clear-cut.

NOTES

UNIT CELL, SPACE GROUP, AND INDEXED X-RAY DIFFRACTION POWDER DATA FOR THE C_{15} LUPINE ALKALOIDS, *l*-THERMOPSINE ($C_{15}H_{20}N_2O$), *dl*-LUPANINE ($C_{15}H_{24}N_2O$), AND *d*-HYDROXYLUPANINE ($C_{15}H_{24}N_2O_2$)[1]

By W. H. Barnes, D. M. Donaldson,* and D. C. Phillips

Thermopsine, $C_{15}H_{20}N_2O$, is the "blank-*cis*" (1) precursor of α-isosparteine, $C_{15}H_{26}N_2$, the structure of which (in the form of the monohydrate) has been studied in this laboratory (2). Lupanine, $C_{15}H_{24}N_2O$, is the first "*cis–trans*" hydrogenation product of the "blank-*trans*" isomer of thermopsine, namely anagyrine. As a preliminary step in possible structure investigations, the unit cell constants of *l*-thermopsine, *dl*-lupanine, and *d*-hydroxylupanine have been determined from precession photographs obtained with Mo K_α radiation (λ = 0.7107 Å), and the space group of each has been established. The density (at ~22°C.) of *l*-thermopsine and of *dl*-lupanine was measured by flotation in aqueous solutions of potassium iodide, while solutions of carbon tetrachloride and benzene were employed as the flotation liquid for *d*-hydroxylupanine.

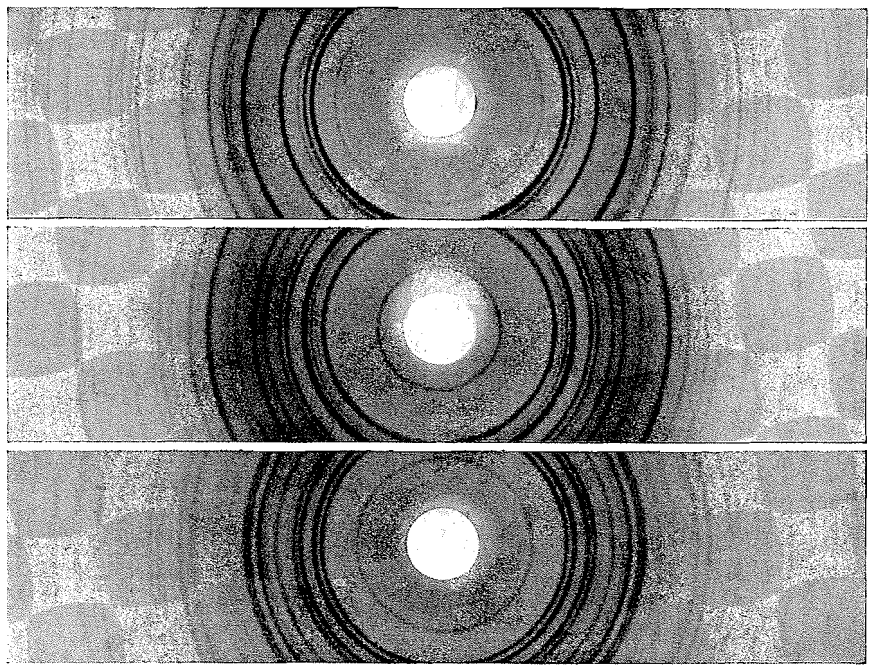

FIG. 1. X-ray diffraction powder photographs of A, *l*-thermopsine; B, *dl*-lupanine; C, *d*-hydroxylupanine. (Camera diameter: 114.6 mm.; radiation: Co K_α, λ = 1.790 Å)

X-ray diffraction powder patterns were obtained with a camera of 114.6 mm. diameter, Straumanis film mounting. Co K_α radiation ($\lambda = 1.790$ Å); the apparatus "cutoff" was 20 Å. Film shrinkage corrections were applied in the case of the precession photographs, but were too small to be significant for the powder films.

The single-crystal data are shown in Table I, and the powder data in Tables II, III, and IV, where B and BB designate lines that were broader and much broader, respectively, than the general average for the pattern examined and an asterisk (under d(Obs.)) indicates a line, the presence of which is probable, but which was too faint ($I/I_1 < 1$) for accurate measurement. The small-2θ end of each film is reproduced in Fig. 1, where, incidentally, the advantage of a capillary-tube container for the specimen (*l*-thermopsine, *dl*-lupanine) over a glass-fiber and adhesive (Household Cement) mount (*d*-hydroxylupanine) is apparent in the generally improved sharpness of the lines in the first and second patterns compared to the third.

BY W. H. BARNES

X-ray diffraction powder photographs of narcotine ($C_{22}H_{27}O_7N$) were taken some time ago in connection with the collection of data for the identification of a number of narcotics (1, 3). The free base, unlike its hydrochloride salt, gave a satisfactory and reproducible pattern. Owing to the pressure of special

[1]*Issued as N.R.C. No. 3488.*

problems that developed with certain narcotics during the survey (2, 3), it was impractical to obtain single-crystal data for the authentication of the powder patterns of the majority of the compounds which, like narcotine, presented no difficulties. Since that time, however, unit cell and space group data for narcotine have become available (4) and it has, therefore, become desirable to index the powder pattern. According to Lovell (4), narcotine is orthorhombic,

space group $P2_12_12_1$, with $a = 7.90$ Å, $b = 15.4$ Å, $c = 32.6$ Å. Retaining this orientation, the powder pattern, indexed on the basis of these data for all reflections corresponding to $d > 3.00$ Å, is given in Table I, where B identifies an unusually broad line and an asterisk (under d(Obs.)) indicates the probable presence of a line which was too faint ($I/I_1 < 1$) or diffuse for accurate measurement. The agreement between d(Obs.) and d(Calc.) is very satisfactory, particularly in view of the large number of possible reflections with the consequent difficulty of deciding precisely which contribute most probably to a given line on the film, and because the maximum error in the single-crystal numerical data is estimated as of the order of 1% (4).

NOTE ON THE VOLATILITY OF LITHIUM OXIDE

BY A. E. VAN ARKEL, U. SPITSBERGEN, AND R. D. HEYDING

Preliminary experiments in this laboratory on the reactions of lithium oxide with various metals in the presence of oxygen at 1000°C. were complicated by the apparent volatilization of Li_2O. Although there is considerable disagreement in the earlier literature in respect of the vapor pressure of Li_2O, recent reports by Brewer and Margrave (2) indicate that the vapor or decomposition pressure would probably be too low at 1000°C. to result in any significant losses. Moreover, during experiments on molten Li_2O at 1570°C. there was no indication that the vapor pressure was appreciable (1).

To confirm these observations, small magnesia boats containing powdered Li_2O were heated *in vacuo* at 1000°C. for extended periods of time. A small initial decrease in weight was observed and was found to be a function only of the quantity of oxide employed in the experiment. Such losses can be attributed to the decomposition of impurities which in these experiments amounted to some four per cent of the oxide and were in all probability hydroxide and carbonate. Following this initial decomposition no appreciable decrease in weight could be detected.

Similar small losses occurred when the same experiments were repeated using dry oxygen rather than a high vacuum. On the other hand the oxide disappeared rapidly in the presence of oxygen containing small amounts of water vapor. Brewer and Margrave also observed erratic losses when wet gases were passed over Li_2O at 1200°C. and have suggested the formation of a volatile 'hydenide'.

space group $P2_12_12_1$, with $a = 7.90$ Å, $b = 15.4$ Å, $c = 32.6$ Å. NOTE ON THE VOLATILITY OF LITHIUM OXIDE

BY A. E. VAN ARKEL, U. SPITSBERGEN, AND R. D. HEYDING

Preliminary experiments in this laboratory on the reactions of lithium oxide with various metals in the presence of oxygen at 1000°C. were complicated by the apparent volatilization of Li_2O. Although there is considerable disagreement in the earlier literature in respect of the vapor pressure of Li_2O, recent reports by Brewer and Margrave (2) indicate that the vapor or decomposition pressure would probably be too low at 1000°C. to result in any significant losses. Moreover, during experiments on molten Li_2O at 1570°C. there was no indication that the vapor pressure was appreciable (1).

To confirm these observations, small magnesia boats containing powdered Li_2O were heated *in vacuo* at 1000°C. for extended periods of time. A small initial decrease in weight was observed and was found to be a function only of the quantity of oxide employed in the experiment. Such losses can be attributed to the decomposition of impurities which in these experiments amounted to some four per cent of the oxide and were in all probability hydroxide and carbonate. Following this initial decomposition no appreciable decrease in weight could be detected.

Similar small losses occurred when the same experiments were repeated using dry oxygen rather than a high vacuum. On the other hand the oxide disappeared rapidly in the presence of oxygen containing small amounts of water vapor. Brewer and Margrave also observed erratic losses when wet gases were passed over Li_2O at 1200°C. and have suggested the formation of a volatile 'hydenide'.

A series of very simple experiments to indicate the dependence of the volatility of Li_2O on the presence of water vapor has now been completed. A small platinum crucible containing the oxide was heated inductively in a system designed to permit the introduction of water vapor at relatively low pressures. A water cooled platinum disk was placed a few centimeters from the crucible to allow recovery of some of the condensable volatile material. The results may be indicated briefly as follows:

Time, hr.	Temp., °C.	v.p. H_2O, mm. Hg	Total loss in weight (%)
1.0	1000	Pumps on	5.7
2.5	1040	Pumps on	3.3
12.0	1000	Pumps on	4.4
16.0	1000	Pumps on	5.8
2.0	1040	10^{-8}	3.2
2.5	1040	10^{-4}	6.4
2.0	1040	10^{-3}	12.2
0.5	1020	10^{-2}	18.1

The rates of evaporation are necessarily qualitative since surface areas of the oxide samples were observed to alter considerably during the course of the experiments, and water vapor pressures are accurate only in order of magnitude.

Debye–Scherrer diagrams of the material collected on the target corresponded to the pattern of anhydrous lithium hydroxide. We cannot exclude the possibility that the powder initially deposited was not LiOH, but was subsequently converted to hydroxide during handling in spite of the precautions imposed. Nor do these experiments prove the nature of the volatile species. Nevertheless, since Smith and Sugden have shown that gaseous LiOH is stable at 2000°C. (3), there is reason to believe that the hydroxide was the primary product in these reactions. If such is the case, the apparent volatility of Li_2O at high temperatures in systems in which traces of water vapor are present can be ascribed to the simple reaction $Li_2O_{(s)}+H_2O_{(g)} \rightarrow 2LiOH_{(g)}$ in which the favorable change in free energy is mainly due to the large change in entropy associated with the formation of a second mole of gas.

The factors affecting the stability of gaseous LiOH are analogous to those affecting the stability of gaseous VCl_4 and $CrCl_4$. Provided the conditions of the system are such that the vapor pressure of the lower chloride (VCl_3 or $CrCl_3$) is negligible, the gaseous tetrachloride will not dissociate because the dissociation can proceed only with a decrease in entropy.

ATISINE: THE FUNCTIONAL GROUPS[1]

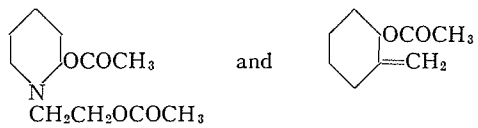
By O. E. Edwards and Tara Singh[2]

The suggestion is implicit in the structure recently suggested for dihydroatisine (9) that atisine and isoatisine are oxazolidines rather than vinylamines. This possibility was ignored in our earlier consideration of the environment of the nitrogen in these alkaloids (2) because both bases gave methane equivalent to two active hydrogens when heated with methyl Grignard reagent at 100° in anisole. Since the value of this evidence has been questioned by Dr. Wiesner (private communication) it was decided to accumulate further evidence bearing on the question.

Infrared spectra of atisine, isoatisine, and dihydroatisine were compared at identical concentrations in chloroform. The intensity of the C=C stretching band in all three was identical, while an extra OH stretching band appeared in the latter. This indicates oxazolidine rather than vinylamine structures for the bases.

Pelletier and Jacobs (7) have very recently reached the same conclusion after examining the properties of several oxidation products of atisine and isoatisine.

On the basis of the oxazolidine structures, the bases should give monoacetate with no free hydroxyl, or diacetates with one free hydroxyl. Jacobs and Craig (5) obtained a diacetate hydrochloride from atisine hydrochloride. However, we have obtained instead a triacetate hydrochloride by the action of acetic anhydride or acetic anhydride – pyridine mixture on atisine or isoatisine hydrochlorides. The amorphous sensitive base liberated from this hydrochloride showed no hydroxyl absorption in the infrared. On hydrolysis with potassium hydroxide in aqueous methanol it gave isoatisine nearly quantitatively. However, on hydrolysis with sodium carbonate solution at room temperature atisine was obtained. Thus the triacetate is a derivative of atisine, probably containing the following partial structures:



The formation of the triacetate from isoatisine involves the first example of the isomerization of isoatisine to atisine. So far, attempts to obtain crystalline mono- or di-acetates from atisine or isoatisine have failed.

Wiesner's structures do not readily account for the extra active hydrogen found in isoatisine and distilled atisine (2). These results seem to demand the presence of hydrogen on the carbons α to the masked aldehyde or ketone carbons.

Jacobs and Craig (5) showed that atisine gave 0.71 mole fraction of acetic acid in the Kuhn–Roth determination. There is some possibility that the exocyclic methylene might isomerize to give a C-methyl prior to oxidation by the chromic acid, although the experience of other workers with gelsemine (3) and bakankosine (1) makes this seem unlikely. Thus it proved desirable to investigate further the source of the acetic acid.

It has now been found that isoatisine, the $C_{20}H_{29}ON$ base (2), and the lactam tricarboxylic acid from isoatisine (4) give 0.52, 1.13, and 0.57 mole fraction of acetic acid in the Kuhn–Roth determination indicating one, two, and one C-methyl respectively.

The infrared spectrum of a film of atisine has a band at 1375 cm.$^{-1}$, which is also present in the spectra of chloroform solutions of isoatisine and the $C_{20}H_{29}ON$ base. These bands can be ascribed with certainty to a methyl group (6). A comparison of the apparent integrated absorption intensities (8) of this band in the last two bases indicated that two methyl groups are present in the C_{20} base if isoatisine has one, in agreement with the suggested mode of formation of this base (2) and with the results of the Kuhn–Roth determination. The infrared spectrum of a perfluorohydrocarbon mull of the lactam tricarboxylic acid from isoatisine contained a methyl band at 1380 cm^{-1}.

Thus all the evidence is consistent with the conclusion that atisine has one methyl group.

It is most probable that it is this C-methyl group which becomes the 1-methyl substituent on the phenanthrene derivatives obtained by selenium dehydrogenation of atisine derivatives. In this respect the structure suggested by Wiesner is satisfactory.

EXPERIMENTAL

Infrared spectra were determined on a Perkin–Elmer model 21 double beam spectrophotometer with a sodium chloride prism. In order to obtain a more reliable value for the integrated absorption intensity, a trace was made with two cells containing chloroform. The chloroform in one cell was then replaced by a chloroform solution of the compound and the spectrum recorded. The background trace was taken as the 0% absorption line for the calculations. Method 1 of Ramsay (8) was used and the value 1.57 was taken for K. Percentage absorption values are cited in brackets after the position of peaks in wave numbers.

Atisine

Obtained as a resin from ether solution. Infrared spectrum (65.8 mgm. per ml., 0.1 mm. cell): 3590 (20), 1655 (13).

Isoatisine

M.p. 152°. Found: C-methyl, 2.27. Calc. for $C_{22}H_{33}O_2N$: one C-methyl, 4.38. Infrared spectrum (30.6 mgm. per ml. in chloroform, 0.1 mm. cell): at 1375 cm.$^{-1}$ $\log_{10}(I_0/I) = 0.049$, $\Delta\nu_{\frac{1}{2}}^{c} = 10.5$ cm^{-1}. $A = 1800$. At a concentration of 63.2 mgm. per ml., 0.1 mm. cell: 3600 (19), 1652 (11).

Dihydroatisine

Infrared spectrum (64.8 mgm. per ml., 0.1 mm. cell): 3600 (21), 3470 (19), 1655 (12).

The $C_{20}H_{29}ON$ Base

M.p. 82–84°. Found: C-methyl 5.65. Calc. for $C_{20}H_{29}ON$: two C-methyls, 10.04. Infrared spectrum (30.0 per ml. in chloroform, 0.1 mm. cell): at 1376 cm.$^{-1}$ $\log_{10}(I_0/I) = 0.054$, $\Delta\nu_{\frac{1}{2}}^{a} = 17$ cm^{-1}. $A = 3300$. At 1710 cm.$^{-1}$ (62) and 1649 cm.$^{-1}$ (24).

Lactam Tricarboxylic Acid from Isoatisine

This was prepared by the method of Huebner and Jacobs (4). After two recrystallizations from aqueous methanol the tiny plates melted at 253–255° (dec.) when immersed at 230°. Found: C-methyl, 2.10. Calc. for $C_{21}H_{29}O_7N$: one C-methyl, 3.69. Infrared spectrum (perfluorohydrocarbon mull): a broad band centered about 1700 cm.$^{-1}$ (COOH); 1610 (lactam); 1515, 1465, 1450, 1405 (CH_2's); 1380 (CH_3).

Triacetylatisine Hydrochloride

(*a*) A suspension of atisine hydrochloride (0.15 gm.) in 3 cc. of acetic anhydride was boiled for 10 min. The crystals dissolved to give a light orange solution. The reagent was removed under reduced pressure, and the residue crystallized from methanol–ether. The 104 mgm. of crystals melted at 230° dec. After two recyrstallizations the melting point was 235°. The infrared spectrum was identical with that of the products from (*b*) and (*c*).

Atisine was left overnight in solution in acetic anhydride. The reagent was removed under reduced pressure, methanol added, and the solution again taken to dryness. The residue was converted to its hydrochloride. The crystalline product melted at 233°. After one recrystallization it melted at 242° dec., and did not depress the melting point of the triacetate hydrochloride.

(*b*) From 145 mgm. of isoatisine, treated as in (*a*), was obtained 96 mgm. of acetate hydrochloride. After one recrystallization from very concentrated methanol solution on addition of ethyl acetate, it melted at 241° dec. It showed no mixed melting point depression with product from (*c*) and had the same infrared spectrum.

(*c*) A suspension of 918 mgm. of finely divided atisine hydrochloride in 20 cc. of 50% pyridine – acetic anhydride was refluxed for five minutes. The solution was cooled to 0°, giving 984 mgm. of fine needles, m.p. 230° dec. After two recrystallizations from methanol – ethyl acetate the melting point was 241° when immersed at 210°. $[\alpha]_D^{22} -18 \pm 1°$ ($c = 2.0$ in ethanol). Found: C, 63.67, 63.76, 64.16; H, 8.49, 8.50, 8.11; Cl, 7.11, 7.17. Calc. for $C_{28}H_{42}O_6$ NCl: C, 64.16; H, 8.08; Cl, 6.77. I.R. spectrum: 3580 (40), 3440 (39), 3350 (40), 1740 (90), 1679 (40), 1650 (51), 1333 (29), 1320 (25), 1309 (29), 1250 (92), 1210 (46), 1128 (29), 1111 (23), 1094 (25), 1071 (45), 1060 (51), 1039 (53), 1020 (57), 985 (34), 973 (35), 955 (25), 948 (55), 902 (38), 843 (16), 831 (16). Isoatisine hydrochloride treated in the same way gave a good yield of the same triacetate hydrochloride.

Triacetyl Atisine

Cold potassium hydroxide solution was added to a cold solution of the triacetyl hydrochloride in water. The precipitate was extracted quickly into petroleum ether (30–60°), the solution dried, and the solvent removed under reduced pressure. The clear gum would not crystallize from ether or petroleum ether. Infrared spectrum (film): 3080 (18), 2945 (85), 2890 (75), 1740 (92), 1652 (35), 1582 (45), 1450 (57), 1415 (44), 1375 (76), 1329 (31), 1310 (31), 1240 (97), 1182 (32), 1155 (27), 1113 (31), 1070 (45), 1028 (78), 985 (57), 947 (33), 901 (49), 827 (25).

Saponification of the Triacetate

(*a*) A sample of the amorphous triacetate prepared as described above was hydrolyzed for four hours at room temperature followed by 0.5 hr. reflux in aqueous methanol containing potassium hydroxide. The solvent was largely removed under reduced pressure, the residue taken up in water and extracted with ether. The base crystallized readily and completely from concentrated ether solution. M.p. 149°; mixed m.p. with isoatisine 151°.

(*b*) A solution of 69 mgm. of triacetate hydrochloride and 100 mgm. of sodium carbonate in 2 cc. of water soon became milky. It was clarified by addition of methanol and left for 24 hr. at room temperature. The mixture was worked up as in (*a*) giving 39 mgm. of base. This would not crystallize. Its infrared spectrum (film) had every peak coincident with that of atisine except for a very small extra peak at 1727 cm^{-1}. It gave a hydrochloride, m.p. 300° dec., which when mixed with atisine hydrochloride melted at 302° dec.

ACKNOWLEDGMENT

The authors wish to thank Dr. R. N. Jones and Mr. R. Lauzon for taking the infrared spectra.

ORGANIC FLUORINE COMPOUNDS

I. AN IMPROVED SYNTHESIS OF HEXAFLUOROACETONE[1]

BY A. T. MORSE, P. B. AYSCOUGH, AND L. C. LEITCH

ABSTRACT

The synthesis of hexafluoroacetone reported recently by Brice, Lazerte, Hals, and Pearlson has been improved in several particulars. Teflon was depolymerized to tetrafluoroethylene which was then dimerized to give a 50% yield of perfluoroisobutene in one step. Oxidation of the latter at 35–40°C. with aqueous potassium permanganate gave a 75% yield of hexafluoroacetone hydrate. The vapor pressure of hexafluoroacetone was measured between −60° and −28°C.

Hexafluoroacetone was first obtained by Fukuhara and Bigelow (2) among the products of the direct fluorination of acetone. It was subsequently prepared by Henne, Shepherd, and Young (3) by the oxidation of the chlorofluoroolefin $(CF_3)_2C=CCl_2$. While the yield of ketone is satisfactory, the preparation of the olefin is tedious and involves hydrofluorination at one stage. Brice, Lazerte, Hals, and Pearlson (1) recently obtained a 26% yield of hexafluoroacetone by the oxidation of perfluoroisobutene prepared by the thermal isomerization of perfluorocyclobutane. The latter was presumably prepared by polymerization of tetrafluoroethylene at 500°C. as reported by Miller (5).

It occurred to us that perfluoroisobutene might be obtained in one step from tetrafluoroethylene. The use of teflon was later suggested to us in a letter from Dr. W. H. Pearlson of the Minnesota Mining and Manufacturing Company, St. Paul, Minn. A furnace, described by one of us in an earlier paper (4), having three independent elements which permit the temperature to be controlled at different points appeared to be suitable for the preparation of perfluoroisobutene. Teflon was depolymerized at 450°C. to tetrafluoroethylene in the first section of the furnace and then dimerized to a mixture of perfluorobutenes by heating the monomer to 700°C. in the second and third sections. A 62% yield of fluorobutenes consisting of 85% perfluoroisobutene was thus obtained; the 2-isomer was formed to the extent of only 15%. These figures were arrived at by comparing the infrared spectrum of our product with the spectra of the pure compounds reported in the paper by Pearlson and co-workers (1).

The perfluorobutenes were oxidized with alkaline permanganate in the apparatus illustrated in the experimental part at 35 to 40°C. instead of in an auto-

[1]*Manuscript received November 16, 1954.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Ontario, Canada. Issued as N.R.C. No. 3512.

clave at 100°C. as reported by Pearlson and co-workers. The yield of hexafluoroacetone hydrate was 70 to 80% of the theoretical amount. The dehydration to hexafluoroacetone was carried out according to the directions of Henne and co-workers (3). These authors reported the formation of a white solid during the dehydration of hexafluoroacetone hydrate which gave a semicarbazone melting very near hexafluoroacetone semicarbazone prepared from the hydrate. In the present work this substance was also detected when the hexafluoroacetone was fractionated on the vacuum line. It gives a mass spectrum identical with that of hexafluoroacetone. When sealed in a glass tube it can be sublimed by merely applying the heat of the hand. The sub-

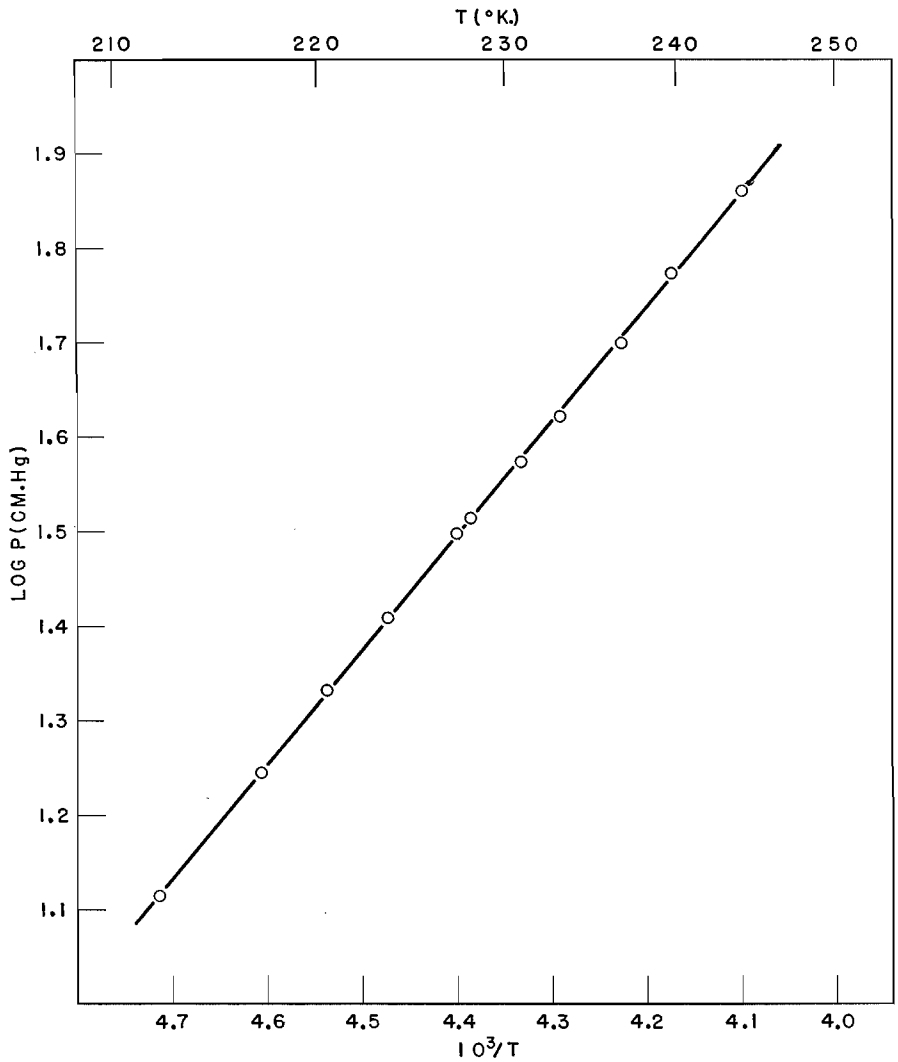

FIG. 1. Vapor pressure of hexafluoroacetone.

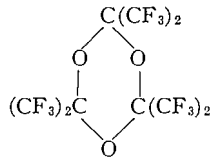
stance is considered to be a polymeric form of hexafluoroacetone and is provisionally assigned the structure I.



I

The vapor pressure of a sample of hexafluoroacetone purified by fractionation on the vacuum line was measured by the static method described in an earlier paper (4). The line shown in Fig. 1 gives the expression

$$\log p \text{ (mm.)} = 6.8060 - [(1.2074 \times 10^3)/T]$$

for the vapor pressure of hexafluoroacetone between −60°C. and −28°C.

EXPERIMENTAL

Perfluoroisobutene

The furnace used in this experiment was referred to in the Introduction. Teflon (200 gm.) cut into small pieces was placed at one end of the reactor while the other end was connected to a 150 ml. spiral trap cooled to −78°C. The section of the furnace containing the teflon was slowly heated to 450°C. while the temperature of the other two units was kept at 700–725°C. After two hours the temperature of the first section was raised to 550°C. to complete the depolymerization of the teflon. At the end of the experiment the trap contained 110 ml. of yellow liquid which was fractionated on the vacuum line. Forty milliliters of material with a very high vapor pressure, consisting chiefly of perfluoropropene, were distilled off. The remainder (70 ml.), which had a vapor pressure of 40 mm. at −78°C., was collected in another trap. Yield: 125 gm. By infrared analysis this product was found to contain 85% perfluoroisobutene, i.e. 106 gm., and 15% perfluorobutene-2.

Hexafluoroacetone Hydrate

The apparatus used in the oxidation is shown in Fig. 2. Potassium permanganate (300 gm.) and 1200 ml. of water were placed in the 3-liter reaction flask *B*. The fluoro-olefin (95 ml., 165 gm.) was condensed into the trap *A* which was then connected to the bubbler immersed in the permanganate solution. The contents of the flask were agitated by means of a magnetic stirrer. The temperature of the fluoro-olefin was raised to about 10°C. and maintained there while the vapor bubbled slowly into the permanganate solution. The rate of flow could be readily controlled by varying the temperature of the bath surrounding the olefin. Hexafluoroacetone hydrate produced by the oxidation remained in solution while unchanged perfluoroisobutene was returned to the flask by the cold finger *C* which was kept at −80°C. The carbon dioxide which was produced simultaneously passed into the atmosphere, any fluoro-olefin which it carried over being condensed in a second trap (*D*)

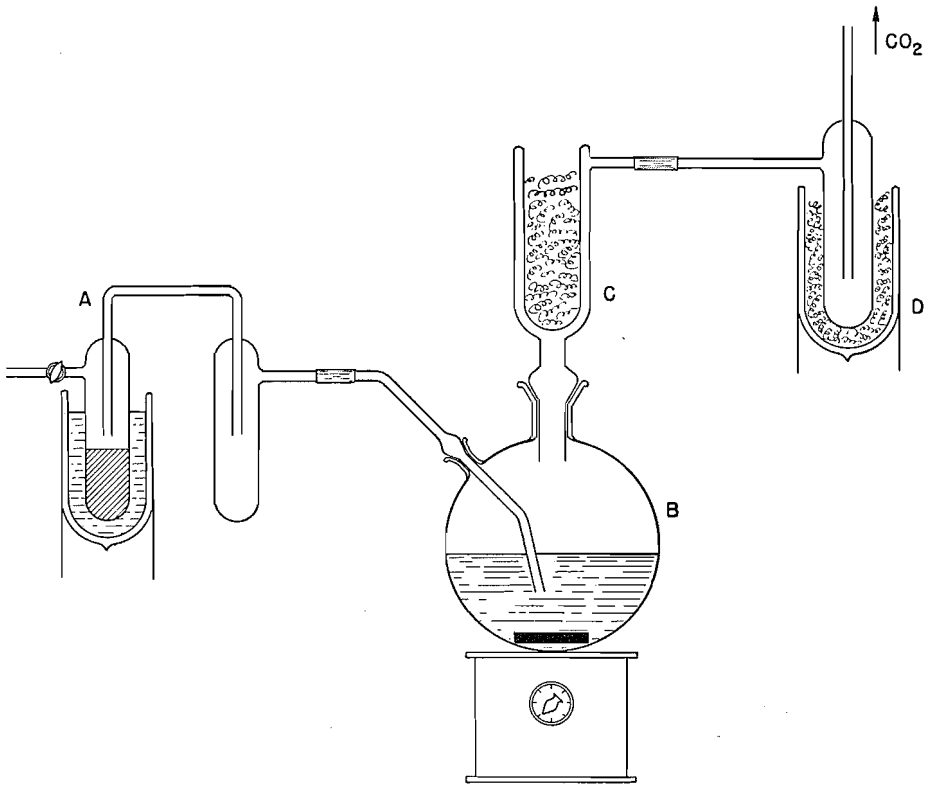


FIG. 2. Apparatus for the oxidation of perfluoroisobutene to hexafluoroacetone.

maintained at −80°C. Reaction was slow at first but became more rapid as the temperature increased to 35–40°C. The fluoro-olefin was absorbed at the rate of 20–25 gm. per hour.

The reaction mixture was then treated with sulphur dioxide to remove excess permanganate and the mixture filtered with suction. The precipitate on the filter was washed with 500 ml. of water and discarded. The combined filtrates were extracted with ether in a continuous extraction apparatus for 24 hr. The ether extract was separated, dried over sodium sulphate, and freed of solvent. The residue was fractionated under reduced pressure. The yield of hexafluoroacetone hydrate, b.p. 55–6°C. at 80 mm., n_D^{20} 1.3179 was 108 gm. (72% of the theoretical amount).

Hexafluoroacetone

The hydrate was treated with phosphorus pentoxide as directed by Henne, Shepherd, and Young (3). A middle fraction of 5.0 ml. from a total of 7.5 ml. of hexafluoroacetone was collected separately on the vacuum line. It distilled at a constant pressure of 32.6 mm. at −78°C. The vapor pressure of this fraction was measured at several temperatures, between −60°C. and −28°C. by the static method (4), and the values plotted logarithmically in

Fig. 2. The mass spectrum of the product was identical with that of Pearlson and co-workers (1).

ACKNOWLEDGMENT

The authors are extremely grateful to Dr. W. H. Pearlson of the Minnesota Mining and Manufacturing Company for a generous sample of hexafluoroacetone and suggestions.

THE SYNTHESIS OF HEMOPYRROLE-DICARBOXYLIC ACID AND OF SOME DIPYRROMETHENES[1]

By S. F. MacDonald and R. J. Stedman[2]

ABSTRACT

The pyrrole II*e* was obtained through the known II*c* and hydrolyzed to III*b*. This last could be partially decarboxylated to hemopyrrole-dicarboxylic acid III*c* or, with formic acid, converted into the dipyrromethene VII*b*. The isomeric dipyrromethene VII*a* was obtained analogously.

Of the two key pyrroles related to the uroporphyrins, cryptopyrrole-dicarboxylic acid I*a* has already been synthesized (10). The synthesis of the second of these, hemopyrrole-dicarboxylic acid III*c*, is now reported.

With ethyl cyanoformate and hydrogen chloride, the pyrrole II*c* (10), for which an improved preparation is given, gave the glyoxylic ester II*d*. Consistently high yields were obtained only when the usual conditions (cf. (6)) were modified to ensure that the intermediate ketimine hydrochloride crystallized. The glyoxylic ester was catalytically reduced in acetic–sulphuric acid over palladium black (cf. (9)) to II*e*, which Treibs and Ott have obtained from II*c* by a different route (13). When this reduction was attempted with W-6 Raney nickel in refluxing ethanol (cf. (12)), with hydrogen (cf. (15)) at 130–150° and 3000 to 4000 lb. per sq. in. in ethanol over copper chromite (1), or with zinc dust in boiling acetic acid, the only product isolated was II*c* identified by melting point and mixed melting point, the positive Ehrlich's reaction in the cold, and, in the first case, by analysis for C, H, and N. The loss of an acyl group on catalytic reduction was unexpected but is not without analogy (cf. (8)).

Alkaline hydrolysis of II*e* resulted in III*a* or in III*b*, differing in their Ehrlich's reactions. These structures were confirmed by decarboxylating the latter to the known hemopyrrole-carboxylic acid IV*a*. With water at 100°, III*b* gave a dicarboxylic acid which could not be directly shown to be III*c* rather than IV*b*, for the latter is known only as a half-ester (7*b*). Under these conditions I*a* had been obtained from I*b* (10) and IV*b* would be expected to lose its α-carboxy group. Further, the dimethyl ester of the dicarboxylic acid gave a strongly positive Ehrlich's reaction in the cold, behavior consistent with III*c* but not with IV*b*. However, the dicarboxylic acid was shown definitely to be hemopyrrole-dicarboxylic acid III*c* by conversion of its dimethyl ester into V*e* (see below) with phosgene and methanol (cf. (7*c*)).

As the preparation of the intermediates might have proved more convenient using the higher-melting methyl esters, methyl α-oximino-β-ketoadipate and benzyl acetoacetate were combined in the Knorr synthesis to give V*a*, which

was converted into V*b*, V*c*, V*d*, and V*e*. The structures of these were confirmed by relating V*d* and V*e* to the ethyl esters for which there was independent analytical proof. Thus II*d* could be hydrolyzed either to VI*a* or VI*b*, and the latter gave V*d* with diazomethane; similarly II*e* was hydrolyzed to III*b*, which was converted into V*e* with diazomethane.

Two better methods were found for converting ethyl β-keto-α-carbethoxy-adipate into ethyl β-ketoadipate (cf. (5, 14)), an intermediate in the preparation of II*a*: the triester was allowed to stand with sulphuric acid, and alcohol added to the mixture, or the triester was boiled with water (cf. (4, 2)). To obtain the methyl β-ketoadipate of Bardhan (3) required in the synthesis of V*a*, β-carbomethoxy-propionyl chloride and the ethoxymagnesium derivative of ethyl malonate gave methyl δ,δ-dicarbethoxylevulinate, which was converted into β-ketoadipic acid with hydrochloric acid (cf. (5)), and the acid esterified.

Both the pyrroles I*b* and III*b* reacted normally with formic acid and hydrogen bromide at 100° (cf. (7*d*)) to give the dipyrromethenes VII*a* and VII*b* respectively. At lower temperatures, the hydrobromides of I*a* and III*c* were the predominant products (16).

EXPERIMENTAL

2-Methyl-5-carboxypyrrole-4-(propionic acid) Diethyl Ester, IIc

Up to 500 gm. of the benzyl ester II*a* have been hydrogenated in 1 liter of ethanol in a 3 liter autoclave as previously described (10). The mixture of crude acid II*b* and catalyst (277 gm.) from 378 gm. of the benzyl ester II*a* was dry distilled in two lots at 230° rising to 260° (air bath temperatures) under the water-pump vacuum (initially and finally 15 mm.). The pyrrole II*c* rapidly

solidified in the air condenser. It was recrystallized from pentane by extraction (Soxhlet) giving 155 gm. (63% from the benzyl ester), m.p. 67-67.5° (cf. (10)).

2-Methyl-5-carboxypyrrole-3-(glyoxylic acid)-4-(propionic acid) Triethyl Ester, IId

The pyrrole II*c* (45 gm.) in ethyl cyanoformate (45 ml.), dry ether (150 ml.), and chloroform (50 ml., dry and alcohol free) was stirred in an ice–salt bath and protected from moisture while dry hydrogen chloride was passed in for three hours. Dry air was then passed through without cooling until the mixture was largely crystalline. Ether (100 ml.) was added, the mixture kept at 0° overnight, the ketimine hydrochloride filtered off, washed with ether, dried *in vacuo*, and dissolved in ice-water (3 liters). After several hours, the glyoxylic ester was filtered off and washed with water. It was dissolved in alcohol, filtered with charcoal, and the charcoal washed with alcohol. After the filtrate and washings (110 ml.) were diluted with 85 ml. of water and allowed to stand at 25° then at 0°, 53 gm., m.p. 78–79°, were collected. The mother liquors diluted with 100 ml. of water and allowed to stand as above gave 4.8 gm., m.p. 77–78° (total, 92% as used for reduction). For analysis, the ester was recrystallized twice and dried *in vacuo*, forming colorless needles, m.p. 78.5°–79°. Ehrlich's reaction slowly positive hot. Found: C, 57.64; H, 6.72; N, 4.01%. Calc. for $C_{17}H_{23}O_7N$: C, 57.78; H, 6.56; N, 3.96%.

2-Methyl-5-carboxypyrrole-3-(acetic acid)-4-(propionic acid) Triethyl Ester (Ethyl α-Carbethoxyhemopyrrole-dicarboxylate), IIe

The glyoxylic ester II*d* (24 gm.) in acetic acid (100 ml.) and sulphuric acid (3.75 ml.) was shaken for six hours with palladium black (1.2 gm., freshly prepared (17)) under hydrogen (60 lb. per sq. in.) at 27°. After the theoretical uptake in two hours, absorption nearly ceased. The filtrate and washings from the catalyst were added to ice-water (3 liters) containing sodium bicarbonate (70 gm.), seeded, and left at 0° overnight. The solid was filtered off, washed, and dried. The acidified filtrate was extracted once with ether, and the ether evaporated from the extract.

Three reductions, using 57.8 gm. glyoxylic ester, were worked up together. When the solid was extracted with pentane (Soxhlet) most of the product crystallized from the pentane. More was obtained by combining the partially hydrolyzed pentane-insoluble material with the residue from the ether extract, esterifying it with 5% ethanolic hydrogen chloride at 25° overnight, pouring it into ice water, and extracting the dried solid with pentane (Soxhlet). Yield 44 gm. (79%), long colorless needles, m.p. 63–64°, or prisms, m.p. 64–65°. Ehrlich's reaction negative cold but positive hot. For analysis, it was recrystallized three times from aqueous ethanol and dried *in vacuo*, needles m.p. 63–64°. Found: C, 59.98; H, 7.26; N, 4.26%; mol. wt. (Rast) 333. Calc. for $C_{17}H_{25}O_6N$: C, 60.16; H, 7.43; N, 4.13%; mol. wt. 339.

When less active palladium black was used, the yield fell to about 50%.

This pyrrole and the isomeric ethyl α-carbethoxycryptopyrrole-dicarboxylate (10) were not clearly distinguished by their melting points or by their infrared

spectra in carbon disulphide. However, their mixed melting point showed a depression.

α-Carboxyhemopyrrole-dicarboxylic Acid, IIIb

The triethyl ester II*e* (2 gm.) in ethanol (25 ml.) and 10% sodium hydroxide (25 ml.) was heated for two and a half hours on the steam bath in an open flask. The solvent was removed *in vacuo*, the residual gum dissolved in water (25 ml.), warmed, and filtered with charcoal, and the product (1.27 gm., 84%), a yellow powder m.p. 144–145° (decomp.), precipitated with sulphur dioxide at 0° and washed with ice-water. After three recrystallizations from acetone (dried over potassium carbonate) (thimble) it formed small very pale violet needles, m.p. 155–156° (decomp.), Ehrlich's reaction strongly positive cold. Found in material dried *in vacuo*: C, 51.29; H, 5.36; N, 5.54%. Calc. for $C_{11}H_{13}O_6N$: C, 51.76; H, 5.13; N, 5.49%. It is stable when kept under nitrogen, or *in vacuo* over phosphorus pentoxide.

Hemopyrrole-dicarboxylic Acid, IIIc

The crude tricarboxylic acid III*b* (0.802 gm., m.p. 148°) in water (3 ml.) was heated under nitrogen on the steam bath to solution and cessation of effervescence (*ca.* 15 min.). After the solution was cooled to 0°, the product (0.544 gm., 84%) was collected and washed with a little ice-water, as very pale pink prisms, m.p. 150–150.5° (decomp.), Ehrlich's reaction positive cold, no insoluble picrate was formed in wet ether. After three recrystallizations from water (4 ml.) the melting point was unchanged. Found in material dried *in vacuo* and stored over nitrogen: C, 56.78; H, 6.26; N, 6.82%. Calc. for $C_{10}H_{13}O_4N$: C, 56.86; H, 6.20; N, 6.63%.

Dimethyl Hemopyrrole-dicarboxylate[3]

Hemopyrrole-dicarboxylic acid III*c* (3.05 gm.) was allowed to stand overnight with a cooled ethereal solution of diazomethane. After removing the ether *in vacuo*, the crystalline residue was distilled (135°, 5×10^{-5} mm.). The ester (3.33 gm., 96%) formed yellow crystals, m.p. 50–51°, raised to 51°–52.5° by resublimation, Ehrlich's reaction strongly positive cold. Found: C, 60.39; H, 7.35; N, 6.03%. Calc. for $C_{12}H_{17}O_4N$: C, 60.23; H, 7.16; N, 5.86%.

Unless protected from light and stored *in vacuo* or under nitrogen, the product turns red.

Conversion of Dimethyl Hemopyrrole-dicarboxylate to 2-Methyl-5-carboxypyrrole-3-(acetic acid)-4-(propionic acid) Trimethyl Ester, Ve

Dimethyl hemopyrrole-dicarboxylate (2.11 gm., distilled in high vacuum at 110–115°) was dissolved in dry ether (70 ml.), cooled in ice-water, and treated with a rapid stream of phosgene for 15 min. The solution initially became cloudy, but rapidly cleared and darkened. After one and a quarter hours at room temperature the ether and excess phosgene were removed by a stream of dry air, and the crystalline residue was briefly dried *in vacuo* and dissolved in dry methanol (50 ml.). Evaporation under reduced pressure after 60 hr. gave a

[3]*This preparation is due to Dr. K. H. Michl.*

dark gum which rapidly crystallized and was freed from hydrogen chloride by drying *in vacuo* over potassium hydroxide. Recrystallization from 15 ml. of methanol and 30 ml. of water (charcoal) gave the trimethyl ester (2.30 gm., 87%) as light brown crystals, m.p. 91°–91.5°.

A further crystallization from methanol–water gave light yellow plates, melting point unchanged, undepressed by authentic Ve (see below), and indistinguishable from it by its infrared spectrum in carbon disulphide. The Ehrlich's reaction was positive hot. Found, in material recrystallized from pentane (thimble) and dried at 60° *in vacuo*: C, 56.77; H, 6.55; N, 4.83%. Calc. for $C_{14}H_{19}O_6N$: C, 56.56; H, 6.44; N, 4.71%.

Hemopyrrole-carboxylic Acid, IVa, from α-Carboxyhemopyrrole-dicarboxylic Acid, IIIb

The tricarboxylic acid III*b* (0.583 gm., m.p. 155°) in glycerol was heated under nitrogen at 200° for 15 min. After the mixture was poured into water (100 ml.) and extracted with ether (4 × 25 ml.), the extract was washed with water (25 ml.), dried over sodium sulphate, and the ether evaporated. The crystalline residue on sublimation (100°, 5×10^{-4} mm.) gave cream colored crystals (0.224 gm., 58%), m.p. 120–125°. After three crystallizations from water it formed cream colored rectangular plates, m.p. 127–128° (lit. 130–131° (7*a*)), Ehrlich's reaction positive cold. Found in material stored under nitrogen: C, 64.60; H, 8.06; N, 8.65%. Calc. for $C_9H_{13}O_2N$: C, 64.65; H, 7.83; N, 8.38%.

Methyl Hemopyrrole-carboxylate

Hemopyrrole-carboxylic acid (77 mgm., m.p. 128–129°, from III*b*) was added to ethereal diazomethane (from 2 gm. nitrosomethylurea) under nitrogen. After one hour the ether solution was washed with dilute hydrochloric acid, the acid neutralized with sodium bicarbonate and washed with ether, the ether washed twice with water and dried over sodium sulphate. The dark crystalline residue left after evaporation of the ether was sublimed (50–60°, 10^{-3} mm.) giving methyl hemopyrrole-carboxylate as colorless prisms (31.5 mgm., 38%), m.p. 48–51°; after recrystallization from aqueous methanol, colorless plates, m.p. 49–51°, were obtained.

The methyl ester picrate, long chocolate-brown prisms, m.p. 118.5–120° (lit. 121–122° (7*a*)) was obtained from the ester with picric acid in wet ether.

The methyl ester, regenerated from the picrate with ether and aqueous sodium bicarbonate, melted at 50–53° (lit. 57° (7*a*)) after sublimation.

α-Carbethoxyhemopyrrole-dicarboxylic Acid, IIIa

The triethyl ester II*e* (1.94 gm.) in 20 ml. of ethanol and 14.2 ml. of 0.889 *N* sodium hydroxide (2.2 equiv.) was heated for two hours in an open flask on the steam bath. After it was taken to dryness *in vacuo*, the residual gum was dissolved in 9 ml. of water and the product precipitated with sulphur dioxide at 0° and washed with ice-water. After it was suspended in 12 ml. of water at 100° for 15 min., filtered at 0° and washed, the cream colored product (1.16 gm., 72%) melted at 232–234° (decomp.). For analysis, it was recrystallized four times from acetone (thimble) giving very light brown elongated prisms, m.p. 237–238° (decomp.), Ehrlich's reaction very weak cold but strongly

positive hot. Found in material dried *in vacuo* at 60°: C, 55.49; H, 5.82; N, 5.09%. Eq. wt. 140.6. Calc. for $C_{13}H_{17}O_6N$: C, 55.12; H, 6.05; N, 4.94%. Eq. wt. 141.6.

2-Methyl-3-carbobenzoxy-4-(2-carbomethoxyethyl)-5-carbomethoxypyrrole, Va

Sodium nitrite (45 gm.) in water (75 ml.) was slowly added at $\leqslant 8°$ with stirring to methyl β-ketoadipate (101.3 gm.) in acetic acid (350 ml), and the excess nitrite was destroyed with ammonium sulphamate. This solution and zinc dust (300 gm.) were added slowly with stirring and cooling to benzyl acetoacetate (121 gm.) and ammonium acetate (100 gm.) in acetic acid (250 ml.) at 60–70°. After one hour at 90° the solution was decanted into ice-water (6 liters) and the zinc washed with hot acetic acid (50% then glacial). After the oil which separated had solidified, it was filtered off, well washed with water, and dried *in vacuo*, m.p. 120–126°. Recrystallization from ethanol (400 ml.) gave the product as pale yellow crystals (118 gm., 61%), m.p. 128–130°. For analysis, it was recrystallized three times from ethanol giving nearly colorless rectangular plates, m.p. 130–130.5°, Ehrlich's reaction positive hot. Found in material dried at 60° *in vacuo*: C, 63.71; H, 5.56; N, 3.74%. Calc. for $C_{19}H_{21}O_6N$: C, 63.50; H, 5.89; N, 3.90%.

2-Methyl-3-carboxy-4-(2-carbomethoxyethyl)-5-carbomethoxypyrrole, Vb

The benzyl ester V*a* (112 gm.) in 800 ml. of ethanol was hydrogenated for eight hours at 130° and 1100 lb. per sq. in. over 10 ml. of Raney nickel. When filtered off and washed with ethanol, the product (87 gm., containing nickel) was suitable for decarboxylation. A portion (14 gm.) was ground and filtered with 1 liter of ice-cold *N*/10 sodium carbonate, the product precipitated from the filtrate with carbon dioxide, filtered, and washed, giving 9 gm., m.p. 243–244° (decomp.). After two recrystallizations from ethanol and one from methanol, it formed colorless plates, melting point unchanged, Ehrlich's reaction positive hot. Found in material dried *in vacuo*: C, 53.76; H, 5.87; N, 5.36%. Calc. for $C_{12}H_{15}O_6N$: C, 53.53; H, 5.62; N, 5.20%.

2-Methyl-4-(2-carbomethoxyethyl)-5-carbomethoxypyrrole, Vc

The crude acid V*b* (73 gm., containing nickel) was distilled in two portions under the vacuum of a water pump at 230° rising to 245° (air-bath temperature) into an air condenser. The pale yellow waxy product was recrystallized from pentane (thimble) to give pink prisms (39 gm. 66% from the benzyl ester), m.p. 71–72°. This was suitable for the next stage. Two further recrystallizations gave the pyrrole as cream colored prisms, m.p. 72.5–73.5°. Ehrlich's reaction was slowly positive in the cold. Found in material dried *in vacuo*: C, 58.64; H, 6.86; N, 6.45%. Calc. for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22%.

2-Methyl-5-carboxypyrrole-3-(glyoxylic acid)-4-(propionic acid), VIb

The ethyl ester II*d* (5.295 gm.) was heated in an open flask on the steam bath for two and one-half hours with 60 ml. of ethanol and 60 ml. of 10% sodium hydroxide. After removal of the residual solvent *in vacuo*, the gum was dissolved in 50 ml. of water, filtered, and the product precipitated with excess hydrochloric acid at 0°. The tricarboxylic acid VI*b* (2.81 gm., 70%) obtained

as a white powder by washing the precipitate with water and drying it *in vacuo* had a melting point of 197–198° (decomp.), which was depressed by admixture of 2-methyl-5-carbethoxypyrrole-3-(glyoxylic acid)-4-(propionic acid) VI*a* (see below). Ehrlich's reaction was slowly positive in the cold.

Precipitation by sulphur dioxide instead of hydrochloric acid gave a product containing sodium.

2-Methyl-5-carboxypyrrole-3-(glyoxylic acid)-4-(propionic acid) Trimethyl Ester, Vd

(*i*) *From the Triethyl Ester IId by Hydrolysis and Re-esterification*

The glyoxylic acid VI*b* (2 gm.) was added in portions to diazomethane (from 14 gm. of nitrosomethylurea) in ether. After it had stood for three hours, the ethereal solution was washed with dilute hydrochloric acid, with aqueous sodium bicarbonate, and with water, dried over sodium sulphate, and evaporated to dryness. The residue, which crystallized slowly at 0°, was recrystallized from methanol (12 ml.) – water (18 ml.), and had the melting point 106–107.5° (1.82 gm., 78%). After three recrystallizations from aqueous methanol, it formed long colorless prisms, m.p. 108–109° or, with slow heating, 114–115°. The Ehrlich's reaction was positive hot. Found in material dried *in vacuo* at 60°: C, 53.63; H, 5.10; N, 4.57%. Calc. for $C_{14}H_{17}O_7N$: C, 54.01; H, 5.51; N, 4.50%.

Subsequent preparations gave only the higher melting form, colorless rectangular plates, m.p. 114.5–115°, and undepressed by admixture of the lower melting form. Ehrlich's reaction was positive hot. Found: C, 54.22; H, 5.48; N, 4.69%.

(*ii*) *From 2-Methyl-4-(2-carbomethoxyethyl)-5-carbomethoxypyrrole, Vc (Preparative Method)*

The pyrrole V*c* (32.6 gm.) was dissolved in 35 ml. of methyl cyanoformate (b.p. 97.5–98.5°), 38 ml. of chloroform (dry and alcohol free), and 120 ml. of dry ether, cooled in ice-salt with the exclusion of moisture, stirred, and treated with a rapid stream of dry hydrogen chloride for three hours. Solid separated during the reaction; the mixture was evaporated to dryness by a stream of dry air passed into the mixture, without cooling, for four hours. Dry ether (120 ml.) was added and, after 12 hr. at 0°, the ketimine hydrochloride was collected as a yellow powder, washed with ether, and dried under water pump vacuum. The hydrochloride was powdered and added portionwise, with stirring, to ice-water (3 liters). The glyoxylic ester was collected, washed with water, and dried *in vacuo* after the initially clear yellow solution had been allowed to stand for four hours at 0°. The crude product was dissolved in methanol (160 ml.), warmed with charcoal, filtered, and recrystallized by the addition of water, giving colorless plates (39.0 gm., 86.5%) m.p. 111°-113°, sufficiently pure for hydrogenation.

2-Methyl-5-carboxypyrrole-3-(acetic acid)-4-(propionic acid) Trimethyl Ester, Ve

(*i*) *By Reduction of the Glyoxylic Ester (Preparative Method)*

The glyoxylic ester V*d* (36.4 gm., m.p. 111–113°, prepared by method (*ii*))

in acetic acid (120 ml.) and sulphuric acid (6.49 ml.) with palladium black (2.3 gm., freshly prepared) was shaken at 28° under hydrogen (60 lb. per sq. in.) for four hours. After the theoretical uptake in two hours, absorption nearly ceased. The filtrate and acetic acid washings from the catalyst were evaporated to dryness under reduced pressure on the steam bath after the addition of anhydrous sodium carbonate (13.5 gm.). The residue was taken up in dry benzene (320 ml.), which was distilled, initially at atmospheric pressure, and finally to dryness under water pump vacuum. The rapidly solidifying gum was dissolved in dry methanolic hydrogen chloride (160 ml. of 10%), warmed to 55° in a water bath, and allowed to cool in the bath overnight. The crystals that rapidly separated when the solution was poured into ice-water (2.5 liters) were collected after one hour at 0°, well washed with water, and dried *in vacuo*. The crude product was recrystallized from methanol (180 ml.) – water (320 ml.) to give the pyrrole (27.0 gm., 78%) as pale pink plates, m.p. 92°.

(*ii*) A sample prepared in the same way by reducing glyoxylic ester (m.p. 114–115°, prepared by method (*i*)) and recrystallized twice from aqueous methanol formed colorless plates, m.p. 92°, giving a positive Ehrlich's reaction (hot). Found in material dried *in vacuo*: C, 56.32; H, 6.41; N, 4.93%. Calc. for $C_{14}H_{19}O_6N$: C, 56.56; H, 6.44; N, 4.71%.

The melting point of this specimen was not depressed by admixture of material prepared by method (*i*).

(*iii*) *From the Ethyl Ester IIe Via the Tricarboxylic Acid IIIb*

The tricarboxylic acid III*b* (0.116 gm., m.p. 144–145°) was esterified with diazomethane (from 2 gm. of nitrosomethylurea). After one hour the ether was washed with dilute hydrochloric acid, with aqueous sodium bicarbonate, and with water, and dried over sodium sulphate. The gum which remained after evaporation of the ether rapidly crystallized. Recrystallization from methanol (2 ml.) – water (9 ml.) gave the product (64 mgm., 47%), m.p. 91–92°. The melting point was unchanged after recrystallizations from aqueous ethanol and aqueous methanol. Found, in material dried *in vacuo*: N, 4.81%. The identity of this product and the analytical sample of (*ii*) above was confirmed by their mixed melting point and by their infrared spectra in carbon disulphide.

2-Methyl-5-carbethoxypyrrole-3-(glyoxylic acid)-4-(propionic acid), VIa

The triethyl ester II*d* (7 gm.) in ethanol (45 ml.) and 0.889 *N* sodium hydroxide (50 ml., 2.23 equiv.) was heated in an open flask on the steam bath for 35 min. The solvent was removed *in vacuo* and the partially crystalline residue dissolved in water (25 ml.) and made strongly acid with hydrochloric acid at 0°. The crude product was filtered off and washed with ice-water. Two recrystallizations from water (20 ml.) gave 2.17 gm. (37%), m.p. 195–196° (decomp.), eq. wt. 148.0 (calc. 148.6). Large pale pink prisms, m.p. 198–199°, Ehrlich's reaction positive hot, were obtained after two further recrystallizations. Found in material dried *in vacuo*: C, 52.20; H, 5.16; N, 5.03%. Calc. for $C_{13}H_{15}O_7N$: C, 52.52; H, 5.09; N, 4.71%.

As in the case of VI*b*, the crude product contained sodium when precipitated by sulphur dioxide.

Diethyl β-Ketoadipate

(*i*) To diethyl β-keto-α-carbethoxyadipate (809.5 gm.) (14) cooled in an ice–salt bath, sulphuric acid (810 ml.) was added at $\leqslant 20°$ with stirring. After 12 hr. at 27°, absolute ethanol (1500 ml.) was added with stirring, together with solid carbon dioxide to keep the temperature at $\leqslant 10°$. After 20 hr. at room temperature, the solution was poured into ice-water (8 liters) and extracted with benzene (3 × 500 ml.). The extracts were washed twice with dilute sulphuric acid, thrice with dilute sodium bicarbonate, twice with water, and dried over sodium sulphate. Distillation through a Vigreux column gave the diester (330 gm. 54%), b.p. (0.4 mm.) 112–120°, η_D^{25} 1.4390.

(*ii*) Three liters of water and 1406 gm. of ethyl β-keto-α-carbethoxyadipate were gently boiled with vigorous stirring under a 12 in. Vigreux column for four and one-half hours. A hydrometer showed 180 gm. (theory 225 gm.) of ethanol in the 1.8 liters of distillate. The undistilled residues from two such runs were combined. The ester was separated and combined with the ether wash (1 liter) of the water layers, washed with saturated sodium bicarbonate, four times with water, and with 4 × 250 cc. of cold saturated sodium carbonate which was then back-washed with ether. The organic layer was clarified with anhydrous sodium sulphate, washed three times with water, three times with dilute sulphuric acid, and four times with water, clarified with an anhydrous sodium sulphate, filtered, the ether removed on the steam bath, and the residue distilled to 150° at 0.2 mm. The fractionation of the distillate at 0.2 mm. with a 12 in. lagged Vigreux column was followed refractometrically; the product (1367 gm., 65%, η_D^{26} 1.4390) consisted of the main fraction (1280 gm., b.p. 108–119°, nearly all 117–119°) together with that obtained by refractionating the 95–108° cut.

Methyl δ,δ-Dicarbethoxylevulinate

The ester (214 gm., 81%) b.p. 140° (0.4 mm.) was obtained according to the method used for the triethyl ester (14) from 145.5 gm. of β-carbomethoxypropionyl chloride, 162 gm. of malonic ester, and 23.4 gm. of magnesium. For analysis, it was slowly distilled through a 3 in. Vigreux column and collected at 115° (0.25 mm.), as a colorless liquid, η_D^{27} 1.4486, giving a violet-brown color with ferric chloride. Found: C, 52.60; H, 6.51%. Calc. for $C_{12}H_{18}O_7$: C, 52.55; H, 6.61%.

Dimethyl β-Ketoadipate

β-Ketoadipic acid (281.5 gm.) from the above ester and hydrochloric acid (cf. (5)) gave the dimethyl ester (3) (126 gm., 38%) b.p. (0.6 mm.) 100–104°, η_D^{27} 1.4416, when esterified with 250 ml. of methanol containing 93 gm. of hydrogen chloride.

5,5′-Dimethylpyrromethene-3,3′-(diacetic acid)-4,4′-(dipropionic acid) Hydrobromide, VIIa

The tricarboxylic acid I*b* (1 gm., crude m.p. 143°) (10) was heated on the steam bath with 98% formic acid (5 ml.) and 30% hydrogen bromide in acetic acid (2.5 ml.) under reflux for 40 min. After two hours at 10° the product

was filtered off and washed with cold formic acid. The brown powder, 0.535 gm. (53%), m.p. 200–201° (decomp.), gave orange-yellow micro needles (0.385 gm.), melting point unchanged, on recrystallizing from formic acid (8 ml.). Found in material dried *in vacuo*: C, 49.22; H, 5.08; N, 5.45; Br, 15.39%. Calc. for $C_{21}H_{25}O_8N_2Br$: C, 49.13; H, 4.91; N, 5.46; Br, 15.57%.

It is stable when kept *in vacuo* over phosphorus pentoxide and protected from light.

5,5′-Dimethylpyrromethene-3,3′-(dipropionic acid)-4,4′-(diacetic acid) Hydrobromide, VIIb

The crude tricarboxylic acid III*b* (1.02 gm., m.p. 145°) was heated under reflux on the steam bath with 98% formic acid (5 ml.) and 30% hydrogen bromide in acetic acid (2.5 ml.) for one hour. The reaction mixture was evaporated to dryness under reduced pressure and acetic acid (15 ml.) added to the rapidly crystallizing brown residue. After one hour at 0°, the methene hydrobromide was collected, washed with cold acetic acid, and dried *in vacuo*. The orange-powder (0.641 gm., 62%), m.p. 217°–218° (decomp.), was recrystallized from formic acid (4 ml.) to give small orange elongated prisms (0.405 gm.), m.p. 218–218.5° (decomp.). The melting point was unchanged by further recrystallization. Found in material dried *in vacuo*: C, 49.38; H, 4.95; N, 5.36; Br, 15.55%. Calc. for $C_{21}H_{25}O_8N_2Br$: C, 49.13; H, 4.91; N, 5.46; Br, 15.57%.

The hydrobromide was stored *in vacuo* over phosphorus pentoxide, and protected from light.

SIMPLE PYRROLES AS BASES[1]

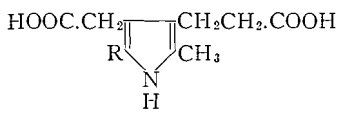
By R. J. Stedman[2] and S. F. MacDonald

ABSTRACT

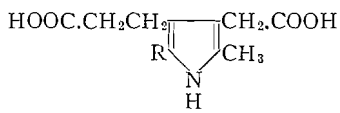
Some simple pyrroles form stable hydrobromides. Their formation may interfere with some reactions, but offers analytical possibilities.

Although the basic nature of dipyrromethenes and of porphyrins is well-known, that of simple pyrroles has been largely ignored. Discussions have been limited to rationalizing the instability of salts of pyrrole itself (1, 10). However, the acidic (7) and basic properties of simple pyrroles are very dependent on the substituents present. Solubility in mineral acid has been noted (13), shown spectroscopically to be due to salt formation (3), and used to separate mixtures by partition (9). Chloroaurates and chloroplatinates (13, 2) as well as picrates are known, but apparently only two salts of simple pyrroles with mineral acids have been described: the deliquescent or unstable hydrochloride of cryptopyrrole (2,4-dimethyl-3-ethylpyrrole) (6), and an unstable hydrobromide of 2-bromomethyl-3-methyl-4-ethyl-5-carbethoxypyrrole (8).

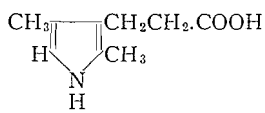
When the preparation of a dipyrromethene from I*b* was attempted with formic acid and hydrogen bromide at 55° (12), the product which separated was the hydrobromide of I*a*, cryptopyrrole-dicarboxylic acid. The hydrobromide could also be prepared directly from I*a* in ether, to which it again reverted with aqueous pyridine. α-Carboxy-hemopyrrole-dicarboxylic acid, II*b*, behaved like I*b*, and both hemopyrrole-dicarboxylic acid, II*a*, and cryptopyrrole-carboxylic acid, III, behaved like I*a*. The hydrobromides were stable to recrystallization and to drying in vacuum. The behavior of other pyrroles with hydrogen bromide has not been studied.



I*a*, R = H
b, R = COOH



II*a*, R = H
b, R = COOH



III

These hydrobromides should prove useful analytically, for pyrroles such as I*a* are very soluble in water and neither the acids nor the methyl esters are

[1]*Manuscript received November 8, 1954.*

precipitated by picric acid, the classical reagent for separating pyrrole mixtures. In a preliminary experiment the pyrrole mixture resulting on the reduction of uroporphyrin, previously obtained as an oil (5), was readily precipitated from ether with hydrogen bromide in acetic acid, and the hydrobromides converted into a solid mixture of pyrroles.

EXPERIMENTAL

Hydrobromide of Cryptopyrrole-dicarboxylic Acid

(*i*) *From Cryptopyrrole-dicarboxylic Acid, Ia*

The pyrrole (0.192 gm.) was dissolved in acetic acid (2 ml.) and dry ether (5 ml.). The addition of hydrogen bromide (0.5 ml. of a 30% solution in acetic acid) caused the separation of an oil which crystallized on scratching. More ether was added, and the product (0.231 gm., 87%), m.p. 134–136° (decomp.), filtered off and washed with ether. By recrystallization from acetic acid (2 ml.) – ether (2 ml.), it was obtained as pale pink plates, m.p. 137–138° (decomp.), unchanged on further recrystallization. Ehrlich's reaction was strongly positive cold. Found in material dried *in vacuo*: C, 41.11; H, 4.61; N, 4.70; Br, 27.59%. Calc. for $C_{10}H_{14}O_4NBr$: C, 41.11; H, 4.83; N, 4.80; Br, 27.36%.

(*ii*) *From α-Carboxycryptopyrrole-dicarboxylic Acid, Ib*

The crude tricarboxylic acid (4 gm., m.p. 140.5°) was suspended in 98% formic acid (8 ml.) and warmed at 55° with hydrogen bromide (4 ml. of a 30% solution in acetic acid) to solution and cessation of effervescence (*ca.* 20 min.) (cf. (12)). The solvent was removed *in vacuo* at 50°, the partially crystalline residue shaken with acetic acid (140 ml.) at 50° and, after two hours at 25°, some dipyrromethene removed by filtration and washed with acetic acid. The pyrrole hydrobromide (3.18 gm., 69%), a yellow powder m.p. 136–138° (decomp.), was precipitated from the combined filtrate and washings by dry ether (200 ml.) and washed with acetic acid – ether (1:1). After recrystallization from acetic acid (25 ml.) – ether (25 ml.) it formed pale tan plates (2.71 gm.), m.p. 137–138° (decomp.), undepressed by admixture with the hydrobromide obtained under (*i*). Ehrlich's reaction was strongly positive cold. Found in material dried *in vacuo*: C, 41.24; H, 4.87; N, 4.67; Br, 27.27%. The infrared spectra in Nujol mull of the products obtained under (*i*) and (*ii*) confirmed their identity.

The material (0.246 gm., 6%), insoluble in acetic acid, was recrystallized from formic acid to give the yellow 5,5′-dimethyl pyrromethene-3,3′-diacetic acid-4,4′-dipropionic acid hydrobromide, m.p. 200–200.5° (decomp.), undepressed by admixture with authentic material (12).

Cryptopyrrole-dicarboxylic Acid, Ia, from its Hydrobromide

The pyrrole hydrobromide (292 mgm., 1 millimole) was dissolved in aqueous pyridine (0.5 ml. of a 16.5% w/v solution, 1.05 millimole). After one hour at 0°, the pale pink plates (86 mgm., 41%) were filtered off and washed with a little ice cold water. The m.p. (128–129°) was undepressed by authentic cryptopyrrole-dicarboxylic acid of m.p. 128–129° (11), and identity was confirmed by infrared spectra in Nujol mull.

Hydrobromide of Hemopyrrole-dicarboxylic Acid

(*i*) *From Hemopyrrole-dicarboxylic Acid, IIa*

This hydrobromide (0.716 gm., 95%) m.p. 158–159°, was obtained as a gray powder from 0.545 gm. of the pyrrole II*a* in 5 ml. of acetic acid with 1 ml. of hydrogen bromide in acetic acid, as was the isomer above. After two recrystallizations from 7 ml. of acetic acid it formed violet prisms, m.p. 160–161°. Ehrlich's reaction was strongly positive cold. Found in material dried *in vacuo*, C, 41.18; H, 5.01; N, 4.57; Br, 24.81%. Calc. for $C_{10}H_{14}O_4NBr.\frac{1}{2}CH_3.COOH$: C, 41.01; H, 5.01; N, 4.35; Br, 24.81%.

The distillate from a solution of the hydrobromide (30 mgm., subjected to prolonged drying *in vacuo*) in 0.75 ml. of water gave a positive test for acetic acid when treated with lanthanum nitrate, iodine, and ammonia (4).

(*ii*) *From α-Carboxyhemopyrrole-dicarboxylic Acid, IIb*

The crude tricarboxylic acid II*b* (0.5 gm., m.p. 149°) was heated at 70° for a few minutes with 1 ml. of formic acid and 0.5 ml. of hydrogen bromide in acetic acid. The solvent was removed *in vacuo* at 25°, leaving a gum which rapidly crystallized. Recrystallization from 7 ml. of acetic acid gave a yellow powder (0.278 gm., 48%), m.p. 157–159°. After two further crystallizations it formed pale yellow prisms, m.p. 159–160.5°. Contamination by dipyrromethene was detected by the visible spectrum. Ehrlich's reaction was strongly positive in the cold. Found in material dried *in vacuo*: C, 41.40; H, 5.04; N, 4.66; Br, 24.64%. The melting point was undepressed by the product of (*i*) above, and the infrared spectra in Nujol mull confirmed their identity.

Hydrobromide of Cryptopyrrole-carboxylic Acid

Cryptopyrrole-carboxylic acid, III, (0.501 gm., m.p. 140–141°) in 10 ml. of dry ether was treated with hydrogen bromide (1 ml. of a 30% solution in acetic acid). The oil which was immediately deposited rapidly crystallized and the product (0.716 gm., 96%) was collected after one hour at room temperature, washed with dry ether, and dried *in vacuo*. The crude material, a greenish powder, m.p. 148–150° (decomp.) was recrystallized from 7 ml. of acetic acid, giving small green prisms (0.365 gm.), m.p. 151–151.5°. The color persisted after two further recrystallizations and the melting point was unchanged. The Ehrlich's reaction was strongly positive in the cold. Found in material dried *invacuo*: C, 43.86; H, 5.90; N, 5.83; Br, 32.28%. Calc. for $C_9H_{14}O_2NBr$: C, 43.56; H, 5.69; N, 5.65; Br, 32.21%.

Cryptopyrrole-carboxylic Acid, III, from its Hydrobromide

The pyrrole hydrobromide (193 mgm.; 0.78 millimole) was dissolved in 1 ml. of water and treated with pyridine (0.80 ml. of a 7.9% w/v aqueous solution, 0.80 millimole). The free pyrrole was immediately deposited and was collected after one hour at 0° as a brown powder (95.5 mgm., 73%), washed with cold water, and dried *in vacuo*. Sublimation at 100° in a high vacuum gave a colorless product, m.p. 141–142°, undepressed by admixture of authentic cryptopyrrole-carboxylic acid.

PHOTOLYSIS OF ACETONE IN THE PRESENCE OF MERCURY DIMETHYL[1]

By H. G. Oswin, R. Rebbert, and E. W. R. Steacie

ABSTRACT

The reactions between $CH_3+CH_3—Hg—CH_3$ were investigated in a system in which acetone was used as the source of CH_3 radicals. Similarly d_6-acetone was used to investigate the reactions of CD_3 radicals and $CH_3—Hg—CH_3$. Activation energies for the hydrogen abstraction reactions were calculated, and no significant difference was found between the CD_3 and CH_3 reactions, being respectively 10.0 and 10.2 kcal./mole. Under conditions of constant intensity and acetone concentration, reaction rates appear to be dependent on mercury dimethyl concentrations. In the case of the acetone-d_6 system, quantities of $C_2D_3H_3$ were found in the reaction products. This is discussed as possible evidence of such a reaction as:

$$CD_3+CH_3—Hg—CH_3 \rightarrow CD_3—CH_3+Hg+CH_3.$$

INTRODUCTION

The photolysis of mercury dimethyl was recently investigated (4) and an activation energy for the reaction

$$CH_3+Hg(CH_3)_2 \rightarrow CH_4+CH_3—Hg—CH_2 \qquad [1]$$

was derived. The work presently described was carried out to determine whether this value is in fact independent of the source of methyl radicals.

Acetone and deuterated acetone are suitable sources of methyl radicals, and can be photolyzed in a wavelength region above 2800 Å, where mercury dimethyl does not absorb. Under these conditions there will be two competing reactions producing methane,

$$CH_3+Hg(CH_3)_2 \rightarrow CH_4+CH_3—Hg—CH_2 \qquad [1]$$

$$CH_3+CO(CH_3)_2 \rightarrow CH_4+CH_3—CO—CH_2. \qquad [2]$$

To obtain the rate of reaction [1], the rate of reaction [2] is subtracted from the over-all rate of formation of methane. The disadvantage of this method is that the rate constant of reaction [2] is considerably larger than [1], and consequently contributes far more to the over-all methane formation rate.

Deuterated acetone has been used successfully to investigate similar reactions (3, 6), and under the circumstances should give a clearer picture of the two competing reactions; in this case:

$$CD_3+Hg(CH_3)_2 \rightarrow CD_3H+CH_3—Hg—CH_2 \qquad [3]$$

$$CD_3+CO(CD_3)_2 \rightarrow CD_4+CD_3—CO—CD_2. \qquad [4]$$

Hence the ratio of CD_4 to CD_3H (determined mass spectrometrically) should give a more accurate measure of the relative rates. A correction can be made for CD_3H formed by reactions of the type

[1]*Manuscript received November 9, 1954.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3508.

$$CD_3+HCD_2—CO—CD_3 \rightarrow CD_3H+CD_2—CO—CD_3 \quad [4a]$$

and $$CD_2H+CD_3—CO—CD_3 \rightarrow CD_3H+CD_2—CO—CD_3 \quad [4b]$$

from the rates found in the photolysis of the deuterated acetone sample alone.

EXPERIMENTAL TECHNIQUE

A conventional high-vacuum apparatus was employed, containing a suitable cell, mixing bulb, and micro-gas analysis equipment. All stopcocks were lubricated with silicone grease to minimize the amount of mercury dimethyl dissolving.

A suitable filter (Corning 0/53) was used to absorb radiation of shorter wavelength than 2800 Å. This eliminates direct energy absorption by mercury dimethyl, a fact which was established by carrying out a few preliminary blank runs with only mercury dimethyl present.

Mercury dimethyl was prepared in the previously described manner (4). Reagent grade acetone was first dried and distilled *in vacuo* before using.

A sample of deuterated acetone was prepared (3) and analyzed mass spectrometrically. It was found that the total hydrogen content of the sample consisted of 96% of the deuterium isotope.

In the case of the experiments with deuterated acetone, the various fractions of the reaction products were analyzed mass spectrometrically. By this method, CO, CD_4, and CD_3H can be determined in the C_1 fraction. In the C_2 fraction only C_2D_6 can be analyzed accurately, estimates of the succeeding compounds C_2D_5H, $C_2D_4H_2$ etc. becoming progressively less accurate.

RESULTS

(a) *"Light" Acetone and Mercury Dimethyl*

The case of "light" acetone will be considered first.

The temperature range investigated here was restricted between 433° and 511°K., the lower limit being imposed by small rates of reaction [1] at low

TABLE I

No.	Temp., °C.	Acetone (mm.)	Mercury dimethyl (mm.)	Rates of formation of products (molecules/cc./sec. × 10^{11}) CH_4	C_2H_6	CO	$(k_2/k_5^{\frac{1}{2}}) \times 10^{13}$
Photolysis of acetone alone

184	212	49.2	48.2	29.4	5.18	20.6	6.59
181	238	51.4	50.9	45.5	4.92	24.2	10.4

temperatures. The upper limit is determined by the increased thermal decomposition of mercury dimethyl above this temperature range.

Table I lists the reaction rates for pure acetone and acetone–mercury dimethyl mixtures. Values of log $(k_1/(k_5)^{\frac{1}{2}})$ were calculated where k_5 is the rate constant for methyl recombination.

$$CH_3+CH_3 \rightarrow C_2H_6 \qquad [5]$$

These values are shown plotted against $10^3/T°K.$ in Fig. 1.

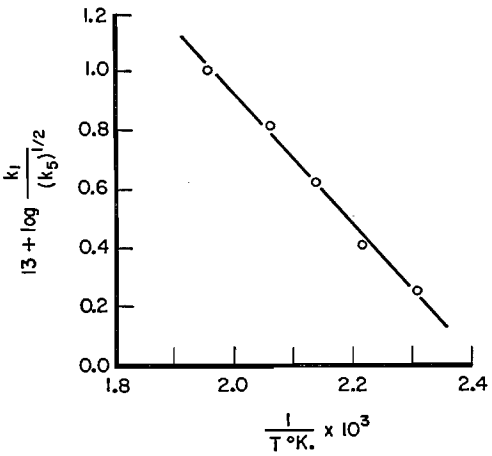

FIG. 1

The regression equation of log $(k_1/(k_5)^{\frac{1}{2}})$ on T is

$$\log (k_1/(k_5)^{\frac{1}{2}}) = -(2238/T°K.)-7.59$$

from which it is found that

$$E_1-\tfrac{1}{2}E_5 = 10.2\pm1.0 \text{ kcal. per mole.}$$

TABLE II

EFFECT OF MERCURY DIMETHYL ON PRODUCTS AT CONSTANT INTENSITY

No.	Temp., °C.	Pressure of acetone (mm.)	Pressure of $Hg(CH_3)_2$ (mm.)	R_{CO}	$\frac{1}{2}R_{C_1}+R_{C_2}$
176	144	42.4	0	2.32	1.94

21	125	78	49	1.10	1.29	7.58	6.24
8	125	88	53	2.08	2.05	18.8	4.97

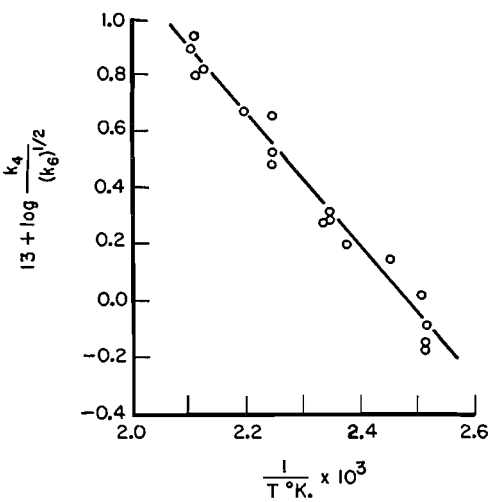

FIG. 2

Very small quantities of C_3 products were found, but these were too small to allow accurate analysis, and would probably contain appreciable proportions

of C_2 compounds. By volume this fraction usually amounted to between one per cent and three per cent of the C_2 fraction.

A preliminary check on the conditions of the experiment can be obtained from a calculation of the activation energy for the reaction:

$$CD_3 + (CD_3)_2CO \rightarrow CD_4 + CD_3—CO—CD_2. \qquad [4]$$

Fig. 2 shows a plot of log $(R_{CD_4}/(R_{C_2D_6})^{\frac{1}{2}})$ [acetone] against $10^3/T°K$.

The regression equation of this relationship is given by

$$\log (k_4/(k_6)^{\frac{1}{2}}) = -(2373/T°K.) - 9.254,$$

where k_6 is the rate constant for the methyl recombination:

$$2CD_3 \rightarrow C_2D_6. \qquad [6]$$

From the above expression

$$E_4 - \tfrac{1}{2}E_6 = 10.9 \pm 1.0 \text{ kcal. per mole.}$$

The activation energy for reaction [3]

$$CD_3 + CH_3—Hg—CH_3 \rightarrow CD_3H + CH_3—Hg—CH_2$$

was calculated from a plot of

$$\log (R_{CD_3H}/(R_{C_2D_6})^{\frac{1}{2}}) \text{ [mercury dimethyl] versus } 10^3/T°K.$$

The plot shown in Fig. 3 may be represented by

$$\log (k_3/(k_6)^{\frac{1}{2}}) = -(2196/T°K.) - 7.336.$$

Hence $E_3 - \frac{1}{2}E_6 = 10.0 \pm 1.0$ kcal. per mole.

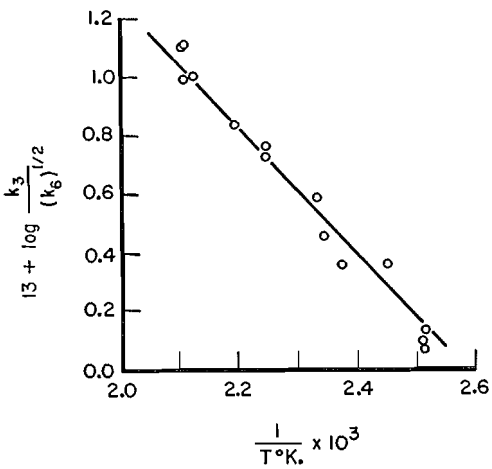

FIG. 3

Also listed in Table III are the rates of formation of $C_2D_3H_3$. Although the accuracy of these figures may be no better than $\pm 50\%$, the quantities are still

too large to be accounted for by such reactions as

$$CD_2H + CH_2D \rightarrow C_2D_3H_3.$$

The presence of $C_2D_3H_3$ will be discussed later.

DISCUSSION

The value of 10.9 kcal./mole found for E_4 lies between the previous values of 10.6 and 11.6 kcal./mole obtained respectively by Majury and Steacie (3) and Whittle and Steacie (6). In view of the different experimental conditions, the present value of 10.9 is probably not as accurate as these others. However, Whittle and Steacie in support of the higher value suggest that the lower value of 10.6 kcal./mole is due to non-linearity of the Arrhenius plot at lower temperatures; since the present work was carried out at the lower temperatures also, it is not surprising that it agrees more with the value of 10.6 kcal./mole.

The recent figures of McNesby and Gordon (2) for the acetone–acetone-d_6 photolysis indicate that there is no measurable difference in activation energy for the abstraction of hydrogen from acetone by CH_3 and CD_3 radicals. It seems reasonable to assume therefore that there should be no significant difference between the activation energies for reactions [1] and [3], as is indicated by the values of 10.2 ± 1.0 and 10.0 ± 1.0 kcal./mole presently obtained.

Activation energies previously obtained (5) for hydrogen abstraction reactions, using mercury dimethyl as a source of methyl radicals, are generally in good agreement with those obtained in acetone systems. It was assumed in this work that the only sources of CH_4 and C_2H_6 were by hydrogen abstraction and recombination of methyl radicals. However, several features of the present work with acetone and mercury dimethyl must be considered in this respect.

(1) In the presence of an equal amount of mercury dimethyl, the rate of formation of CO from acetone is reduced by 10% over the range 144°–238°C. (see Table II).

(2) Table II also indicates that the quantum yield of methyl radicals recovered as CH_4 and C_2H_6, in the presence of mercury dimethyl, is decreased at the lower temperatures and increased at the higher temperatures, eventually exceeding two CH_3 radicals per CO formed.

(3) Mixtures of deuterated acetone and mercury dimethyl yield appreciable quantities of $C_2D_3H_3$ (see Table III), although only CD_3 radicals are formed in appreciable amount by direct light absorption.

Holroyd and Noyes (1), investigating the photolysis of mercury dimethyl alone at 2600 Å, established these points:

(4) At 175°C., there is an increase in $R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[DM]$ with increasing light absorption.

(5) At 175°C., more than two methyls appear as methane and ethane per quantum absorbed.

(6) The quantum yield of ethane formation is nearly independent of the amount of methane formed, and is approximately the same at 30°C. and 175°C. There is a slight increase with decreasing light absorption.

In reference to point (1), there are two possible causes of a decrease in CO formation:

(*a*) decreasing extinction coefficient of acetone, in the presence of mercury dimethyl; but in view of the pressures used, it is unlikely that this effect would be appreciable;

(*b*) transfer of energy from an excited acetone molecule or CH_3CO radical; this may or may not induce decomposition of the mercury dimethyl molecule.

Both of these possibilities would result in an increased or decreased primary production of methyl radicals, but would not affect the modes of formation of methane and ethane. If the transfer of energy to mercury dimethyl resulted in subsequent decomposition, it would explain the presence of CD_3–CH_3 in the reaction products, but could not account for all of it.

Observation (5), that more than two methyls appear per quantum absorbed, has been offered by Holroyd and Noyes as evidence of the reaction:

$$CH_3+CH_3—Hg—CH_3 \rightarrow C_2H_6+CH_3+Hg. \qquad [7]$$

The observed formation of CD_3–CH_3 in the present work also indicates that reaction [7] may occur. This reaction together with the suggested explanations of the R_{CO} decrease could explain qualitatively the reported observations. In view of the possibility of energy transfer, the quantities of CD_3–CH_3 formed cannot be used for an accurate estimation of the importance of reaction [7].

If reaction [7] is an additional mode of formation of ethane, then the relation holds

$$\frac{k_1}{k_5^{\frac{1}{2}}}[DM] = \frac{R_{CH_4}}{R_{C_2H_6}\beta^{\frac{1}{2}}} - \frac{k_8}{k_5^{\frac{1}{2}}}[RH]$$

$$= 1 - \frac{k_7}{k_1}\frac{R_{CH_4}}{R_{C_2H_6}}\left(1+\frac{k_8}{k_1}\frac{[RH]}{[DM]}\right)$$

where k_8 is the rate constant for the abstraction of hydrogen from an added hydrocarbon RH. Hence from the photolysis of mercury dimethyl alone, it is possible to determine the two parameters $k_1/k_5^{\frac{1}{2}}$ and k_7/k_1 from variations in the formation of CH_4 and C_2H_6 over an extensive range of light absorption. From Holroyd and Noyes data, k_7/k_1 would be between zero and unity at 175°C. At room temperature no methane is formed and

$$C_2H_6 = 1+\frac{k_7}{k_5^{\frac{1}{2}}}\frac{[DM]}{I_a^{\frac{1}{2}}}$$

which is in qualitative agreement with the drift with light absorption observed by Holroyd and Noyes.

Inasmuch as reaction [7] does occur, it should have a very low activation energy and an unusually small steric factor; unfortunately no more than these qualitative conclusions can be drawn.

Analysis of the present and previous (4) data, assuming reaction [7] occurs, shows that in view of the amounts of CH_4 and C_2H_6 found at higher temperatures, k_7 can have no more than a slight temperature coefficient. Arbi-

trarily taking $E_1 - E_7 = 10$ kcal. and $k_7/k_1 = 0.37$ at 175°C., it is found that values of $k_1/k_5^{\frac{1}{2}}$ and $E_1 - \frac{1}{2}E_5$ become practically identical for mercury dimethyl alone, and the present experiments with acetone – mercury dimethyl mixtures. Other values for hydrogen-abstraction reactions remained virtually unaffected by this treatment.

Although this treatment has no more than a qualitative significance, it would seem that a second mode of ethane formation could exist in the mercury dimethyl photolysis without affecting the observed agreement with the acetone work.

ACKNOWLEDGMENT

We should like to thank Miss F. Gauthier, Miss J. Fuller, and Dr. F. P. Lossing for the mass-spectrometer analysis, and Dr. R. J. Cvetanovic for very helpful discussions.

STUDIES ON CARRAGEENIN: COMPARISON OF FRACTIONS OBTAINED WITH POTASSIUM CHLORIDE AND BY SUCCESSIVE EXTRACTION AT ELEVATED TEMPERATURES[1]

By D. A. I. Goring and E. Gordon Young

ABSTRACT

Carrageenin was fractionated with potassium chloride and by successive extractions at elevated temperatures. Measurements were made of sulphate content, optical rotation, gel strength, intrinsic viscosity, sedimentation rate, and ionic mobility. The results indicated three components extractable at 30°C., 60°C., and 100–120°C. The 60°C. extract had a high gel strength while the components extracted at 30°C. and 100–120°C. showed low gelling tendencies. The two non-gelling components were concentrated in the supernatant liquid when fractionated with potassium chloride.

INTRODUCTION

Carrageenin, the polysaccharide extractable from the red alga Irish moss (*Chondrus crispus*), has been shown to consist mainly of D-galacto-4-sulphate residues joined in the 1–3 position (11). Other monosaccharides have been found in carrageenin as usually prepared (2, 9, 11, 19, 24). The chemical individuality of these preparations however was not established. Cook, Rose, and Colvin (3) observed in the ultracentrifuge two components in commercial carrageenin. Smith and Cook (21) and Smith, Cook, and Neal (22) were able to separate these components in aqueous solution with potassium chloride. They applied the term κ-carrageenin to the precipitated component and λ-carrageenin to the component remaining in solution. These components differed in sulphate content, optical activity, rates of sedimentation and of diffusion, and intrinsic viscosity. Neither Cook *et al.* (3) nor Goring (6) could detect any clear separation of components electrophoretically.

Rose (18) found no evidence for chemically distinct components but cold and hot water extracts have been reported to differ in optical rotation and gelling tendencies (15). The usual hot water extract of carrageenin will act as a suspending agent in milk only when mixed at 60°–70°C. Hess and Siehrs (10) noted that when the residues of a hot water extraction were re-extracted with steam at 105°–120°C., a substance was obtained which suspended cocoa in milk when mixed at 10°–20°C.

These observations indicated that fractionation of the polysaccharides in Irish moss was feasible and that these fractions differed in certain properties. The purpose of the present work was to compare the properties of fractions separated by (*a*) potassium chloride and (*b*) re-extraction of the plant at increasing temperatures. Measurements were made of sulphate content, optical rotation, gel strength, intrinsic viscosity, sedimentation rate, and electrophoretic mobility.

[1]*Manuscript received October 4, 1954.*
Contribution from the Maritime Regional Laboratory, National Research Council, Halifax, Nova Scotia. Issued as N.R.C. No. 3515.

PREPARATION AND FRACTIONATION

All preparations were made from one lot of *Chondrus crispus* harvested at Prospect, Nova Scotia, in September, 1952. The plants were washed, air-dried, and milled to pass a 40-mesh screen. Manipulations were carried out as quickly as possible and toluene was added as a preservative when necessary. Samples were stored at −13°C. No excessive bacterial contamination was found at any time either microscopically or by plating.

The solvent used throughout for extraction and fractionation was aqueous sodium acetate of ionic strength (I) 0.02.

The various fractions were studied exclusively as the sodium salt. A 0.5% solution of the crude polysaccharide was dialyzed with internal mechanical stirring against aqueous sodium acetate for 24 hr. at 10°C. The acetate was then removed by dialysis against a solution of 50–100 mgm./liter sodium hydroxide in distilled water. If the concentration of sodium hydroxide was 1% of the concentration of carrageenin in the solution, the final pH of the dialyzate was 8–9. Dialysis against distilled water caused the pH to fall and degradation to occur which brought about a marked drop in viscosity.

Sodium carrageenate was obtained by freeze-drying the dialyzed solution. The water content of this material was 1–4%.

Fractionation with Potassium Chloride

Following the method of Smith *et al.* (21, 22), potassium chloride was added to the solutions of carrageenin. On centrifugation a gel separated and the supernatant liquid was decanted. These fractions are subsequently termed *gel* and *sol* respectively. Fractionation was difficult with carrageenin of high intrinsic viscosity because of more or less complete gelation. A more effective fractionation was possible after the solutions had been heated to 90°C. for 15 min. and cooled. The intrinsic viscosity of the purified polysaccharide was unchanged by this treatment.

Preliminary fractionations confirmed in general the results of Smith and co-workers (21, 22). The fractionation with potassium chloride, which was studied in detail, is shown in Fig. 1. Dried, ground *Chondrus crispus* was extracted with 0.02 M aqueous sodium acetate at 100°C. for five minutes in a Servall Dumore blendor. The solution was clarified by centrifugation and the crude polysaccharide was precipitated by pouring into five volumes of ethanol. The yield on the basis of dry weight was 65%.

The crude polysaccharide was redissolved at a concentration of 0.5% and the solution heated to 90°C. for 15 min. Part of the solution was dialyzed and freeze-dried to give the unfractionated material (Fig. 1). The remainder was fractionated by adding a 10% solution of potassium chloride dropwise with vigorous stirring until a concentration of 0.4% was established. This caused the separation of a *sol* fraction, S1, and a *gel* fraction, G1. Part of G1 was dialyzed and refractionated to give S2 and G2. Fractions were finally dialyzed and freeze-dried to give the sodium salt. The ratio G1/S1 was 2.36 and G2/S2 was 2.43. These *gel*/*sol* ratios were considerably larger than the values reported by Smith *et al.* (21, 22). The higher concentration of carrageenin used by us

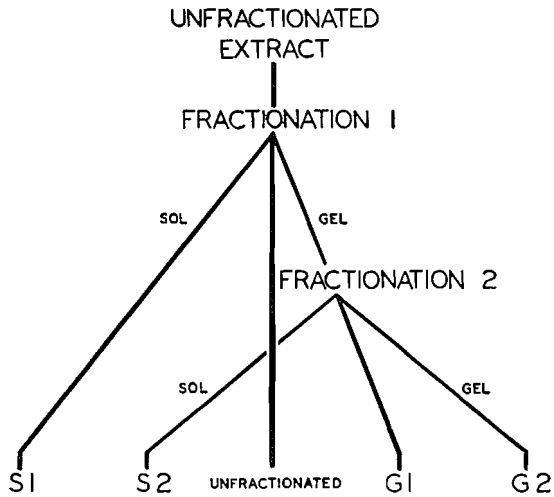

FIG. 1. Fractionation with potassium chloride.

(0.5% compared to 0.05–0.2%) could account for this difference. The equality of G1/S1 and G2/S2 showed that the fractionation was not as clean-cut as that obtained by Smith *et al.* (22) with more dilute solutions.

Successive Extraction at Increasing Temperature

Two series of extractions were made. These are designated Extraction E and Extraction F.

Extraction E.—Forty grams of dried, ground *Chondrus crispus* were stirred in 1400 cc. of aqueous sodium acetate at 30°C. for two hours. After centrifuging the clear supernatant liquid was dialyzed and freeze-dried. The residue was re-extracted at 60°C. for 15 min. After separation, a further extraction was made at 120°C. for 15 min. The final residue was discarded. As controls, portions of the 30°C. and 60°C. extracts were subjected to identical treatment at 120°C. Notation of the extracts and yields expressed as percentages of the total yield are given in Table I.

TABLE I

EXTRACTION E. SUCCESSIVE EXTRACTIONS OF IRISH MOSS AT 30°C., 60°C., AND 120°C.

	Temp., °C.	Time, min.	Yield, % of total	Notation of fraction
	30	120	25	E 30
	60	15	55	E 60
	120	15	20	E 120
Controls	30–120	15	—	EC 30–120
	60–120	15	—	EC 60–120

Extraction F.—Extraction F was similar to Extraction E except that temperatures were 60°C., 100°C., and 120°C. Portions of the 60°C. extract were subjected to the higher temperatures to provide controls. Notation and yields are given in Table II.

TABLE II

EXTRACTION F. SUCCESSIVE EXTRACTIONS OF IRISH MOSS AT 60°C., 100°C., AND 120°C.

ANALYTICAL PROCEDURES

Measurement of Concentration

The concentration, c, was based on the weight of purified material dried at 50°C. *in vacuo*. For sulphate content, gel strength, optical rotation, and refractive increment, concentrations were computed by direct weighing. For viscosity, sedimentation, and electrophoresis a refractometric determination was made with a Bellingham and Stanley refractometer. The mean value of dn/dc at 5461 Å for six different samples was 0.132 ($\pm$0.002) gm.$^{-1}$ cm.^{3}

Optical Rotation

The specific rotation was measured at a concentration of 0.3% in a 20 cm. tube at room temperature (23°C.) in a Rudolph polarimeter with a sodium lamp.

Sulphate

Sodium carrageenate was hydrolyzed by refluxing for three hours in 6 N hydrochloric acid. The solution was diluted and filtered. Sulphate was determined in the filtrate as barium sulphate. Measurements were done in duplicate and the mean deviation was $\pm$0.7%.

Ionic Mobility

Electrophoresis was observed at 25°C. in a Tiselius apparatus fitted with the Longsworth scanning device. The buffer was sodium acetate (pH = 5.5, I = 0.05) made up according to Green (7). The usual technique was modified as previously described (6). The mobility, U, was the mean for the rates of migration of ascending and descending boundaries.

Viscosity

The intrinsic viscosity, $[\eta]$, was determined with Ubbelohde capillary viscometers as previously described (6). A correction for degradation on storage was not necessary because it was found that the viscosity was constant over long periods for the sodium salt obtained from a solution at pH 8–9. Measurements were made at 25°C. in acetate buffers (pH = 5.5; I = 0.05).

Some variation of intrinsic viscosity with rate of shear has been observed in carrageenin of high molecular weight (14). The intrinsic viscosity observed must, therefore, be considered to obtain only for the mean rate of shear for solvent flow (1100 sec.$^{-1}$) in the viscometers used.

Gel Strength

Gel strength was measured with the apparatus shown in Fig. 2. A motor-driven cylindrical plunger (0.8 cm. in diameter) descended at 0.15 cm./sec. on the surface of the gel contained in a 5 ml. beaker as used in the Beckman

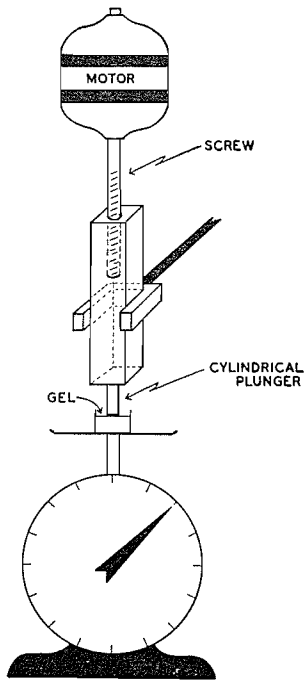

FIG. 2. Apparatus for measurement of gel strength.

pH meter. The beaker rested on a 500 gm. dietary spring balance. The breaking point was the maximum reading of the balance before penetration. This point was quite sharp and readily determined.

The solvent was a solution of potassium chloride ($I = 0.05$) in acetate buffer (pH = 5.5; $I = 0.05$). Gels were made by allowing a 2% solution of the polysaccharide to set overnight at a temperature of 20°C. Immediately before measurement the gel was inverted in the beaker, exposing a fresh surface. A stainless steel disk placed initially in the bottom of the beaker facilitated this operation. Measurements were done in triplicate and the mean deviation was $\pm 5\%$.

Sedimentation

Sedimentation was observed in an analytical Spinco ultracentrifuge at 42°C. to inhibit gelation. The rotor and cells were kept at 50°C. overnight. The filled cells and the rotor were then equilibrated at 50°C. for one hour. In the machine, the rotor was equilibrated under vacuum for one hour. At intervals during the run the temperature was taken with the fixed couple. The difference between the readings for the fixed and free couples was taken at

the end of the run. On an average the free couple reading exceeded the fixed couple reading by 0.6°C. By this method excellent temperature control was achieved. The range of fixed couple readings in any one run was 0.8°C. and the average temperature was 42.3 (±0.4)°C. for 66 runs. Thus, the range during any one run was small and the temperature for a series of runs was essentially constant.

As shown in Fig. 3, the graphs of $\log_{10} r$ vs. time were linear for all concentrations studied. Although the concentrated solutions were gel-like, no variation of the sedimentation constant, s, with time occurred as reported for thymus nucleoprotein (20).

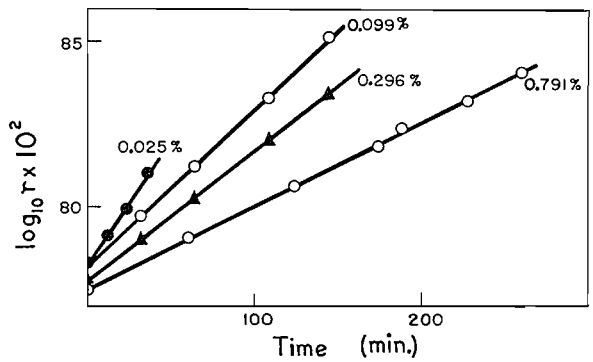

FIG. 3. Graphs of $\log_{10} r$ vs. time for S1.

Sedimentation constants were corrected (1) to water at 40°C. This correction implies that the molecular shape in the buffer is unaltered in water. With a polyelectrolyte such as sodium carrageenate this is not the case. Therefore the s°_{40} value gives the rate of sedimentation in water for a molecule having the same shape as sodium carrageenate in the buffer used.

Areas of the peaks were measured on enlargements with a planimeter. For the two components observed, dn/dc was assumed equal and relative concentrations were assumed to be proportional to areas. The relative area of the fast "shoulder" varied with the total concentration of carrageenin and was sometimes difficult to estimate. To permit comparison, all measurements of area were done on runs at the same concentration of carrageenin (0.007 gm. cm.$^{-3}$).

The variation of s°_{40} with c was studied for the fractions shown in Fig. 1 and Table II. As may be seen in Fig. 6, s°_{40} usually increased rapidly for low values of the concentration. Graphs of $\sqrt{s}$, $1/s$, and $\log_{10} s$ vs. c and sc vs. s failed to give a straight line. The graph of $\sqrt{(1/s)}$ vs. c was linear but the intercept was too near the origin to permit interpretation. The method of Jullander as used by Greenwood (8) was found to be applicable. On the same graph s°_{40} vs. c and $s^\circ_{40}\,\eta_{rel}$ vs. c are plotted. As shown in Fig. 4, the double extrapolation permits a reasonably unambiguous determination of $(s^\circ_{40})_{c=0}$. For these fractions the values of $(s^\circ_{40})_{c=0}$ were also obtained by the method of Newman, Loeb, and Conrad (16). Agreement between the two methods was ±1%.

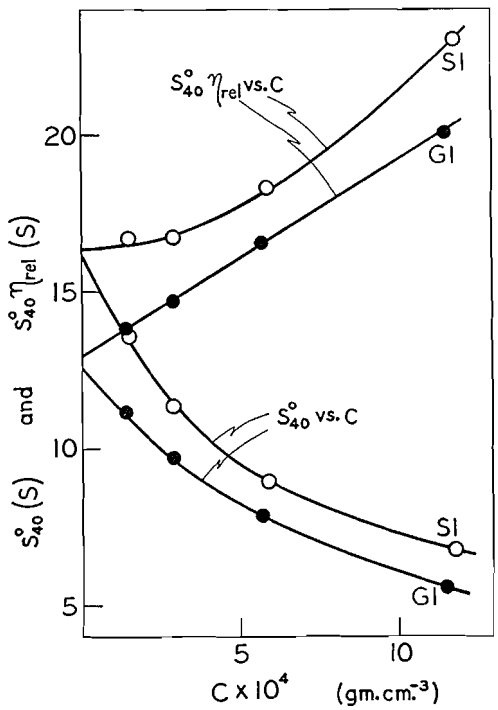

FIG. 4. Graphs of s°_{40} vs. c and $s^{\circ}_{40}\,\eta_{rel}$ vs. c for S1 and G1.

The molecular weight, M, was computed by the method of Mandelkern and Flory (12) from

$$[1] \qquad M = \left(\frac{(s^{\circ}_{40})_{c=0}\,[\eta]^{\frac{1}{3}}\,\eta_0 N}{2.5 \times 10^6(1-\bar{v}\rho)}\right)^{3/2}$$

where η_0 is the viscosity of the solvent, N is Avogadro's number, $\bar{v}$ is the partial specific volume of the solute, and ρ is the density of the solvent. The partial specific volume determined by Cook *et al.* was used (3).

Certain experimental factors limited the validity of the absolute values of M. The intrinsic viscosity was measured at 25°C. in an ionic strength of 0.05 whereas sedimentation was observed at 40°C. in an ionic strength of 0.2. Cook *et al.* (3) have noted that $[\eta]$ does not change markedly for such a range in ionic strength and temperature. Also, for one of the undegraded fractions studied, the decrease in $[\eta]$ for rates of shear from 100 sec.$^{-1}$ to 1000 sec.$^{-1}$ was 13%. However since $[\eta]$ occurs in Equation 1 only as a cube root such errors are small.

As noted by Smith *et al.* (22) a more serious discrepancy lies in the assumption of a random, uncharged coil implicit in the Mandelkern-Flory treatment. The carrageenin molecule is charged and although its shape in solution is not known with certainty, viscometric (13) and light scattering (4) results suggest

that it is rod-like. However, experimental conditions were identical for all fractions and therefore the relative values of M were considered to indicate the approximate changes in molecular weight from fraction to fraction.

RESULTS

Fractionation with Potassium Chloride

The electrophoretic and ultracentrifugal diagrams of the fractions (Fig. 1) are shown in Tables III and IV respectively. The corresponding values for the sulphate content, $[\eta]$, gel strength, M, and $[\alpha]_D$ are given in Table V. Included in Table IV are the relative concentrations of the minor component observed in sedimentation.

Successive Extraction at Increasing Temperature

The ultracentrifugal data for Extractions E and F (Tables I and II) are given respectively in Tables VI and VIII. The corresponding values of $[\alpha]_D$, gel strength, $[\eta]$, and sulphate content are given in Tables VII and IX.

DISCUSSION

In families of polymeric substances there are two major categories of molecular differences. In the first the molecules of any single polymer may differ in chain length to give a polydispersity of molecular weight. In the second the difference is of molecular type. For example, sulphated polysaccharides may differ in type of linkage, sugar residues, branching, or degree of sulphation. In the present work we are concerned mainly with the second category, i.e. with components rather than polydispersity of molecular weight. Therefore

properties independent of molecular weight were most important in identifying components.

As mentioned previously, the fractionations were probably not sharp and it is likely that all the fractions were, to some extent, mixtures of components. However, marked differences were noted in some of the properties from fraction to fraction. It was therefore possible to infer that in some fractions a component with certain physical properties predominated. The results indicated three components. The differences in the various properties of these components are discussed in detail in the sections below.

Gel Strength

Large differences were noted in the gel strengths of different fractions compared with the relatively small decrease in the controls (EC 60–120 in Table VII and FC 100 and FC 120-A in Table IX). Further S1, with a molecular weight twice as great as the strongly gelling G2, had nearly zero gel strength. Thus it appeared that the gel strength depended more on structural factors than on molecular weight.

For successive extractions at increasing temperatures (Tables VII and IX) a pronounced maximum in gel strength was noted in the 60°C. extracts. This supports the early reports (15) of a non-gelling cold extract. The decrease in gel strength for re-extractions at 100–120°C. agrees with the findings of Hess and Siehrs (10). These results suggest that there are three components extractable at approximately 30°C., 60°C., and 100–120°C., the 60°C. extract having a strong gelling tendency.

The extract fractionated with potassium chloride was made at 100°C. and therefore would contain some of each of the three components. The fractionation would be expected to concentrate the single gelling component in the *gel* fractions while the *sol* fractions would contain the two non-gelling components. Provisionally the components extractable at 30°C., 60°C., and 100–120°C. will be called respectively Components A, B, and C.

Sedimentation

In nearly all the fractions (Tables IV, VI, and VIII) a varying proportion of a minor fast-moving component was noted. A similar component has been noted by Cook *et al.* (3) and Smith *et al.* (21, 22). Usually the minor component was more concentrated in extracts made at 100°–120°C. (Tables VI and VIII) and, as later discussed, F 120-B was composed largely of this material. Its proportion was not increased in the controls and thus it probably did not originate from heat treatment of the other components.

The minor component was probably the non-gelling Component C. This is supported by the increased concentration of the minor component in the sol fractions (Table IV). However, its proportion was small. Thus, the main component of the *sol* fractions would be A.

Differences in the three components are further illustrated by the concentration dependence of s°_{40}. As shown in Fig. 5, the graphs of s°_{40} vs. c for F 60 and F 120-A were coincident from $c = 0.002$ to $c = 0.01$ gm. cm.$^{-3}$ despite the marked decrease in $[\eta]$ and M on degradation. Below $c = 0.002$ gm. cm.$^{-3}$

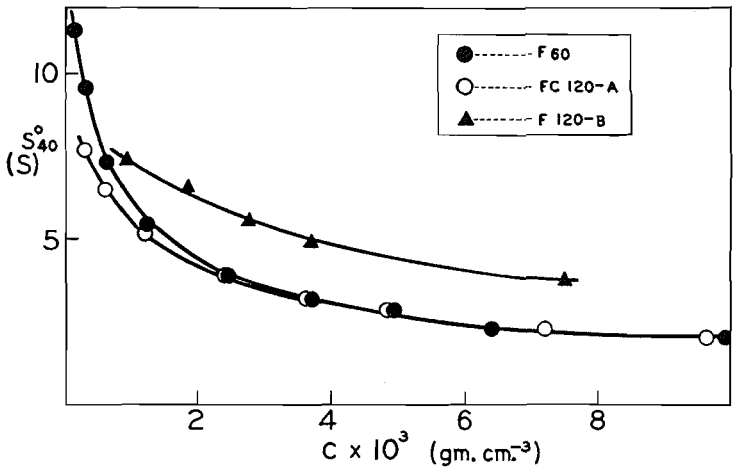

FIG. 5. Graphs of s°_{40} vs. c for F 60, FC 120-A, and F 120-B (Table IX).

the heavier molecule sedimented more quickly. However, F 120-B shows a faster sedimentation over most of the concentration range with a smaller dependence of s°_{40} on c. A similar though smaller effect was noted for F 120-A. These results suggest that F 120-A and F 120-B are composed largely of the quickly sedimenting Component C. The molecular weight of F 120-B is considerably less than that of F 60. The difference in sedimentation behavior must therefore be associated with a difference in shape or intermolecular interaction.

A lesser distinction in sedimentation is noted for G1 and the main component of S1, as shown in Fig. 6. The concentration dependence is similar but

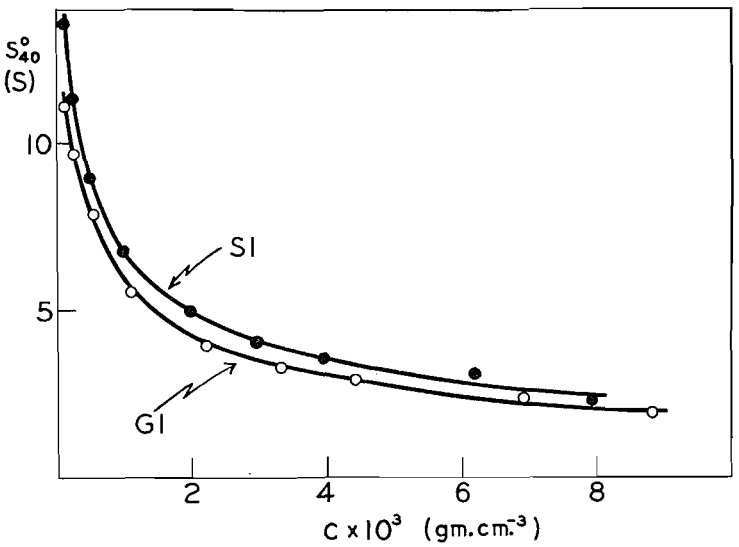

FIG. 6. Graphs of s°_{40} vs. c for S1 and G1 (Fig. 1).

s°_{40} for S1 is higher than that for G1. This small increase in s°_{40} occurred in all fractions rich in Component A. This might be expected since the molecular weights for the *sol* fractions (Table V) were greater than those for the *gel* fractions in agreement with the data of Smith *et al.* (21, 22). However, the coincidence of s°_{40} vs. c for F 60 and FC 120-A shows that a change in chain length alone does not alter s°_{40} at $c \geqslant 0.002$ gm. cm.$^{-3}$ Therefore, the slightly greater value of s°_{40} for Component A probably arises from a small structural variation in the polysaccharide rather than a difference in chain length.

Sulphate Content

The sulphate content was remarkably constant for most fractions at 23–26%. Also, the controls (Tables VII and IX) showed that a negligible loss in sulphate occurred on heating to 100–120°C. A decrease in sulphate content was noted for F 100 and F 120-A (Table IX). This suggests that a lower sulphate content was a property of Component C.

The sulphate contents of the *sol* fractions were higher than those of the *gel* fractions (Table V). This effect was smaller but in the same direction as that observed by Smith and Cook (21). The low sulphate content of Component C concentrated in the *sol* fractions could have masked the difference in sulphate between Components A and B.

Optical Rotation

On heating, the change in $[\alpha]_D$ for the controls was negligible (Tables VII and IX). But low values of $[\alpha]_D$ were observed in all fractions in which the quickly sedimenting component was concentrated (e.g. S1 in Table V or F 120-B in Table IX) indicating a low rotation for Component C.

The equality of $[\alpha]_D$ for E 30 and E 60 (Table VII) suggested that the rotations of Components A and B were essentially equal. The low rotation of the *sol* fractions could then be due to the increased concentration of Component C.

Electrophoresis

As observed by previous workers (3, 6) the electrophoretic diagrams (Table III) showed no clear indication of separate components. The peak asymmetry increased with gel strength. This effect was due to a non-classical distribution of concentration at the boundaries (described in detail elsewhere (5)) and could not definitely be associated with polydispersity. Because of the uncertainty in interpretation of the patterns, electrophoresis was not attempted on all the fractions.

The mobility of the *sol* fractions was slightly greater than that of the *gel* fractions. This trend was probably due to the smaller sulphate content (Table V) of the *gel* fractions.

Viscosity

The intrinsic viscosity of E 60 (Table VII) was greater than that of E 30 and a marked decrease in $[\eta]$ occurred for the extracts and controls of Extraction F at 100–120°C. (Table IX). As noted by Rose (18) this decrease is probably due to the degradation of the polysaccharide by the high tempera-

tures used. Because of the ease of degradation of carrageenin (6, 13) the intrinsic viscosity could not be used as a means of identifying components.

CONCLUSIONS

The results of the potassium chloride fractionation agree well with those of Smith *et al.* considering the different sources of material in the two investigations. In both, the *sol* fractions showed a higher molecular weight, sedimentation constant, and sulphate content and a lower specific rotation (Tables IV and V). The small divergences in detail from the results of these workers could be due to either (*a*) different degrees of degradation on preparation of the carrageenin or (*b*) different proportions of the two non-gelling components in the sol fractions.

The significant properties of the three components are summarized in Table X. Sulphate content and $[\alpha]_D$ were found to be independent of the

TABLE X

A SUMMARY OF THE PROPERTIES OF THE THREE COMPONENTS EXTRACTABLE FROM *Chondrus crispus*

Component	Temp. of extraction, °C.	Relative conc., % of extractable material*	Gelling tendency	$[\alpha]_D$	Sulphate content (%)
A	30	35	Nil	45–50	26
B	60	50	Strong	45–60	22–26
C	100–120	15	Weak	<30	<20

**The proportion of Component C was derived from the areas of the quickly sedimenting components in Extraction F. The remainder was assumed to consist entirely of Components A and B. An approximate A/B ratio was obtained by assuming the main component of S1 and S2 to be entirely A.*

decrease in molecular weight which occurred on extraction at higher temperatures. The gel strength showed some decrease on degradation but this was small compared with the large differences between the gelling and non-gelling extracts. These properties therefore pertain to the molecular *type* of the component. The figures given for the proportion of a component, $[\alpha]_D$, or the sulphate content obtain only for the sample of Irish moss examined although the trends noted may be general.

From the results it is clear that Components A and B made up the bulk of the extractable polysaccharide. The marked distinction between the two components lies in the ability of B to form a gel. The gelling tendency might be related to different degrees of branching in the molecules. An appreciable change in the concentration dependence of the sedimentation would then be expected. As shown in Fig. 6, the sedimentation behavior of the two components was similar. On the other hand, O'Neill (17) has recently discovered 24% of 3,6-anhydro-D-galactose in a *gel* fraction whereas the corresponding *sol* fraction contained considerably less (23). The gelling tendency may therefore be associated with this structural difference in the chain rather than a difference in shape due to branching.

The minor component, C, comprised only a small percentage of the extractable material although a greater proportion may be available with prolonged extraction. The low sulphate content suggests that it was a desulphated product of one of the major components. This could give rise to the small concentration dependence of s°_{40} due to the decrease in interaction (Fig. 5). However, the controls showed no loss in sulphate, which indicated that the material differed in this respect from Component A or B.

ACKNOWLEDGMENTS

The authors wish to thank Dr. A. N. O'Neill for his help in the measurements of optical rotation, and H. F. Roberts, F. G. Mason, and Miss M. C. Chepeswick for technical assistance.

THE PHOTO-OXIDATION OF AZOMETHANE[1]

By G. R. Hoey[2] and K. O. Kutschke

ABSTRACT

The photo-oxidation of azomethane has been studied at low oxygen pressures (0.02 to 1 mm.) in the temperature range *ca.* 25°C. to 161°C. The primary process in the normal photolysis of azomethane is essentially unaffected by the presence of oxygen. Carbon monoxide is probably a secondary product of the oxidation of methyl radicals. Carbon dioxide formation is quite small, and therefore neither methyl radicals nor $CH_3N{=}N{-}CH_2$ radicals are oxidized appreciably to carbon dioxide. Nitrous oxide, which is a major product of the oxidation, is most likely formed from the oxidation of $CH_3N{=}NCH_2$ radicals. The suggested mechanism of N_2O formation is:

$$CH_3N{=}N{-}CH_2+O_2 = CH_3N{=}NCH_2O_2$$
$$CH_3N{=}N{-}CH_2O_2 = CH_3+N_2O+H_2CO.$$

The reaction of methyl radicals with oxygen was found to proceed with a negligible activation energy and a steric factor of the order of 10^{-2}. Evidence for the occurrence of the reactions

$$2CH_3O_2 = 2CH_3O+O_2$$
$$2CH_3O = CH_3OH+H_2CO$$

at room temperature was obtained.

INTRODUCTION

The photolysis of azomethane has been studied extensively, and the mechanism appears to be well established. The main reactions involved in the photolysis are (15, 23):

$$CH_3N{=}NCH_3+h\nu = 2CH_3+N_2$$
$$CH_3+CH_3N{=}NCH_3 = CH_4+CH_3N{=}NCH_2$$
$$CH_3+CH_3N{=}NCH_3 = (CH_3)_2N{-}NCH_3$$
$$CH_3+CH_3 = C_2H_6$$
$$CH_3+CH_3N{=}NCH_2 = CH_3N{=}NC_2H_5$$
$$CH_3+(CH_3)_2N{-}NCH_3 = (CH_3)_2N{=}N(CH_3)_2.$$

The quantum yield of nitrogen formation is close to unity at the longer wavelengths, and independent of temperature. Since Φ_{N_2} is independent of the pressure of azomethane, and unaffected by the presence of carbon dioxide, the possibility of an excited molecule mechanism is unlikely (23). There is no evidence for a stable $CH_3N{=}N$ radical. Azomethane has been shown to be a convenient source of radicals for reactions of the type

$$CH_3+RH = CH_4+R$$

where RH is a hydrogen donor compound (1, 15). In view of these features of the photolysis, azomethane would be expected to be a convenient source of radicals for a study of the reaction of methyl radicals with oxygen.

Marcotte and Noyes (18) have investigated the photolysis of acetone in the presence of oxygen at low oxygen pressures and low light intensities. Their

[1]*Manuscript received November 18, 1954.*

[2]*National Research Laboratories Postdoctorate Fellow 1952–1954.*

results indicated that the reaction between a methyl radical and oxygen, which they assumed to yield a formyl radical and a water molecule, proceeds with negligible activation energy and a low steric factor (*ca.* 10^{-4}). Christie (8), working in Noyes' laboratories, has since shown that, for experimental conditions similar to those of Marcotte and Noyes, methyl radical oxidation leads to formaldehyde and water with a further acetone molecule supplying the additional hydrogen. On the basis of Christie's results, the earlier scheme must be considered oversimplified; in particular the products of methyl radical interaction with oxygen postulated by Marcotte and Noyes seem rather doubtful.

Martin and Noyes (19) have extended the study to mixtures of mercury dimethyl and oxygen, and methyl iodide and oxygen. The relative amounts of CO and CO_2 were different than for acetone. Formaldehyde is a major product with methyl iodide – oxygen mixtures at room temperature (2, 19) and with acetone at temperatures above 120°C. (8, 14), whereas with mercury dimethyl with temperatures above 100°C., it does not seem to be a major product (19). It would be interesting to compare results obtained with azomethane and oxygen with those obtained by Noyes and co-workers using similar experimental conditions.

There has been no study reported in the literature on the thermal oxidation of azomethane. Scheer and Taylor (22) photolyzed azomethane in the presence of propane and oxygen. They observed a slow oxidation of propane in the temperature range 35° to 200°C., and cool flames at 250°C.

EXPERIMENTAL

PART I

The azomethane was prepared by Mr. R. Renaud of these laboratories (21). It was purified by a trap to modified Ward still (16) distillation, and the fraction collected between −78°C. and −110°C. was stored as a gas in a blackened flask behind a mercury cutoff. The oxygen was prepared by heating potassium permanganate and purified by passage through two traps at liquid nitrogen temperature. Commercial carbon dioxide was degassed at −196°C. Carbon monoxide was prepared by heating a $ZnO–CaCO_3$ mixture (27) and purified by passage through a trap at −196°C.

A Hanovia S-500 mercury arc was used as the light source. The beam, which was collimated by a quartz lens, completely filled the reaction cell. A Corning violet ultra filter No. 586, 6 mm. in thickness, was used in all the experiments. This filter limited the incident intensity mainly to the 3340 Å and 3660 Å wavelengths. The relative extinction coefficients of these wavelengths are such that the absorbed light intensity is effectively the 3660 Å wavelength (15). The incident light intensity was varied by the use of neutral density filters.

The quartz cell was 10 cm. long and 5 cm. in diameter with a volume of 180 cc. The cell was surrounded by an aluminum block furnace, and the temperature was controlled manually to ±1°C. The total volume of the reaction system, including reaction cell, U-tube manometer, stirrer, and McLeod gauge, was 400 cc.

Oxygen pressures as low as 0.02 mm. were used in this work. An oxygen consumption of at least 0.15 mm. was necessary for analysis of the products. Since constant oxygen pressures were desired at pressures less than 0.15 mm., small oxygen doses (0.003 mm.) were added during the run as frequently as necessary to maintain constancy of pressure. The number of doses required was determined in trial runs.

The run was interrupted at regular intervals (two to five minutes), at which time a premeasured oxygen dose was pumped into the reaction mixture through an iron, glass-enclosed float, and sufficient time allowed for mixing of the gases. The rate of oxygen disappearance was found to depend on the temperature and on the oxygen pressure. To compensate for this, the number of doses per run, and consequently the exposure time per dose (rather than the size of the oxygen dose), was varied. Mixing of the gases was effected by a glass propeller type stirrer with a glass-enclosed copper core at the bottom; the stirrer was driven by an induction motor. At oxygen pressures greater than 0.15 mm., 0.02 mm. doses were added during the exposure without interrupting the run.

Gas analyses were carried out for N_2, CH_4, CO, O_2, CO_2, and N_2O. After each run the reaction mixture was passed through a modified Ward still at -196°C. The non-condensables, N_2, CH_4, CO, and O_2, were analyzed by means of a Cu–CuO furnace at a temperature of about 230°C. The oxygen formed CuO. The CO was oxidized to CO_2 and was frozen out at a cold finger. The remainder, N_2 and CH_4, was collected and analyzed for N_2 and CH_4 mass spectrometrically. The CO_2 and the N_2–CH_4 mixture were measured directly, and the oxygen was determined by difference. The CO_2 and N_2O were distilled from the Ward still at -160°C., and were collected for mass spectrometric analysis. Ethane was not detected in any of the experiments in which oxygen was present.

Azomethane was used as an actinometer. A value of unity (23) for the quantum yield of nitrogen formation in the absence of oxygen was used for the temperature range 25° to 161°C. The data in the literature are in accord (4, 7, 15) with such a value although the individual values are quite often less than unity and nearer 0.9. If, in fact, $\Phi_{N_2} < 1$ in the absence of oxygen, the values of the quantum yields quoted here are too large by about 10%.

Formaldehyde was not detectable at the Ward still or by mass spectrometric analysis. This, however, is not conclusive evidence that formaldehyde is not a major product of the oxidation as the formaldehyde may have polymerized. To check this point, an amount of formaldehyde roughly comparable to that expected in the experiments described in Part II was introduced into the reaction system in the presence of azomethane. Polymerization of the formaldehyde evidently occurred as formaldehyde was not detected by the two methods mentioned above. Analysis of formaldehyde in the presence of azomethane in aqueous media was not accomplished since an acid catalyzed hydrolysis forms formaldehyde and methyl hydrazine from azomethane (28). Methods which were unsuccessful owing to this interference by azomethane were Lebbin's resorcinol test, Schiff's test, and the polarographic method (25). Thus, it

cannot be stated whether or not formaldehyde is a major product of the reaction.

The products remaining after distilling off the azomethane at −90°C. were analyzed mass spectrometrically. Water and methanol were identified positively and formed most of the fraction.

PART II

Experiments of long duration were performed at room temperature in order to collect sufficient products for chemical analysis. Large oxygen pressures were used and oxygen was not added during the run. The azomethane pressure was maintained constant during the run at 6.6 mm. by circulating the gases through two traps in the reaction system held at the temperature of dry ice.

After the run, the gases were passed to the Ward still. The non-condensables and CO_2 were analyzed as described in Part I. N_2O was not detected by mass spectrometric analysis. The azomethane was separated from the Ward still at −90°C.; no product was detected between these fractions. This fraction was shown to be azomethane with trace quantities of methanol and water by mass spectrometric analysis. These results were verified by the infrared absorption of the fraction. The remainder, which will be designated as the "liquid products", was separated from the Ward still at room temperature.

The liquid products were analyzed by the following methods. Mass spectrometric analysis showed the presence of methanol and water only. The methanol was analyzed by the method of Elving and Warshowsky (10) and by infrared analysis. The two methods agreed to within 20%. The acid, which was shown to be formic acid by its infrared absorption, was titrated directly using phenolphthalein as the indicator. Peroxides were determined by the method of Nozaki (20).

The liquid products were also placed in contact with metallic sodium. The hydrogen given off was a measure of the total active hydrogen present (amount of $H_2 = \frac{1}{2} \times$ amount of active hydrogen). The quantum yield of water formation was assumed to be

$$\Phi_{H_2O} = (\Phi_{\text{active hydrogen}}) - (\Phi_{CH_3OH} + \Phi_{HCOOH} + \Phi_{\text{peroxides}}).$$

RESULTS AND DISCUSSION

The lack of variation of Φ_{N_2} with the experimental conditions of temperature and oxygen pressure (Fig. 1) and of azomethane pressure (Table I) strongly suggests that nitrogen is formed solely in a primary process. Since ethane was not detected at any temperature at an oxygen pressure as low 0.02 mm., the possibility of a direct molecular rearrangement into ethane and nitrogen (6) may be discounted. This is in agreement with the conclusion reached by Davis, Jahn, and Burton (9) who observed complete suppression of hydrocarbon products and no inhibition of the nitrogen yield when the photolysis was carried out in the presence of nitric oxide (10 mm.). On the basis of this evidence, the primary process is taken as [1], proceeding with a quantum efficiency close to unity in the presence of oxygen.

$$CH_3N_2CH_3 + h\nu \rightarrow 2CH_3 + N_2. \qquad [1]$$

Pressure of oxygen = 0.9±0.1 mm.; temp. = 123°C.; $I_a = 10^{12}$ quanta/cc./sec.
[a]*CO_2 added.*
[b]*CO added.*

The photo-oxidation, under conditions such that methane is found, is postulated to proceed in part through the following steps:

$$CH_3 + A \rightarrow CH_4 + CH_3N_2CH_2 \quad [2]$$
$$CH_3 + A \rightarrow CH_3A \quad [3]$$
$$CH_3 + O_2 \rightarrow CH_3O_2 \quad [4]$$
$$CH_3A + O_2 \rightarrow CH_3AO_2 \quad [5]$$
$$CH_3N_2CH_2 + O_2 \rightarrow CH_3N_2CH_2O_2. \quad [6]$$

Reaction [2] has been well substantiated (1, 15, 23) and reaction [3] has been shown to proceed at a somewhat greater rate (15). Reaction [5] has been included to account for $-\Phi_{O_2} \geqslant 2$ at low oxygen pressure Fig. 2; i.e. every methyl radical must, directly or indirectly, lead to the consumption of one molecule of oxygen. The sole fate of methyl radicals produced in the primary process must be reaction with oxygen when Φ_{CH_4} is negligible. This condition is met at all oxygen pressures studied at room temperature, and at a progressively higher oxygen pressure as the temperature is increased (Fig. 3). A similar phenomenon is observed in the photo-oxidation of acetone (8, 14, 18).

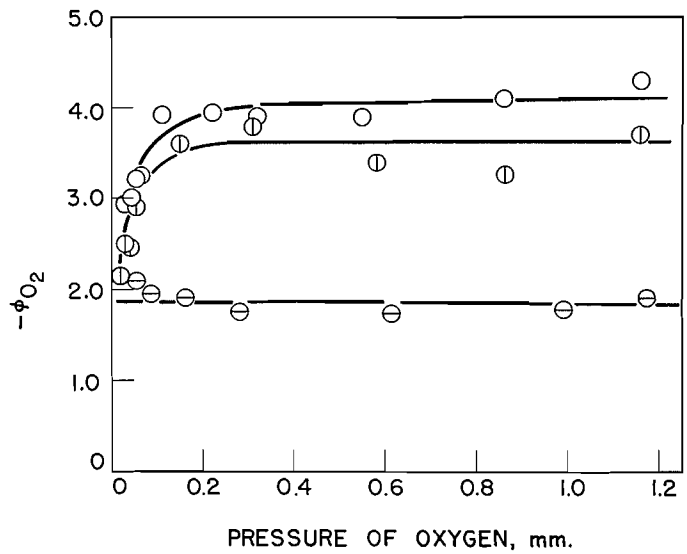

FIG. 2. Dependence of $-\Phi_{O_2}$ on oxygen pressure:
$I_a = 5 \times 10^{11}$ quanta/cc./sec.; pressure of azomethane, 101 mm.; ○, 161°C.; ⊕, 123°C.; ⊖, *ca.* 25°C.

Nitrous oxide is a major product at the higher temperatures employed. An upper limit to Φ_{N_2O} is attained at oxygen pressures such that Φ_{CH_4} is negligible (Figs. 3 and 4); the value of this limit is temperature dependent (Fig. 3). At

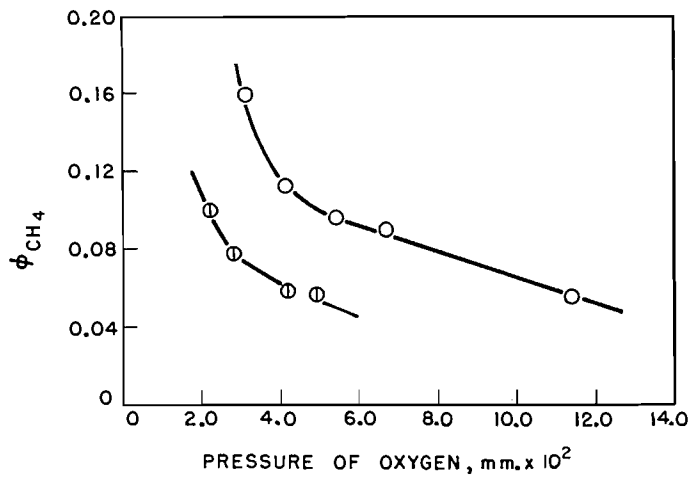

FIG. 3. Dependence of Φ_{CH_4} on oxygen pressure:
$I_a = 5 \times 10^{11}$ quanta/cc./sec.; pressure of azomethane, 101 mm.; ○, 161°C.; ⊕, 123°C.

oxygen pressures such that this limit is attained, a radical resulting from the oxidation of a methyl radical must initiate a sequence of reactions which eventually produces nitrous oxide. A plausible scheme is

$$CH_3O_2 \rightarrow R + ? \quad [7]$$
$$R + CH_3N_2CH_3 \rightarrow RH + CH_2N_2CH_3 \quad [8]$$
$$CH_3N_2CH_2 + O_2 \rightarrow CH_3N_2CH_2O_2 \quad [6]$$
$$CH_3N_2CH_2O_2 \rightarrow CH_3 + N_2O + H_2CO \quad [9]$$
$$R \rightarrow \text{no } N_2O \quad [10]$$

where R is some oxygenated radical. Reaction [10], a chain termination not involving azomethane or oxygen, is included to account for the dependence of Φ_{N_2O} on the concentration of azomethane (Table I). Insufficient data are available to determine whether [10] is of the first or second order in radical concentration. Since [8] and possibly [9] will probably require an activation energy, the temperature dependence of Φ_{N_2O} is qualitatively explained.

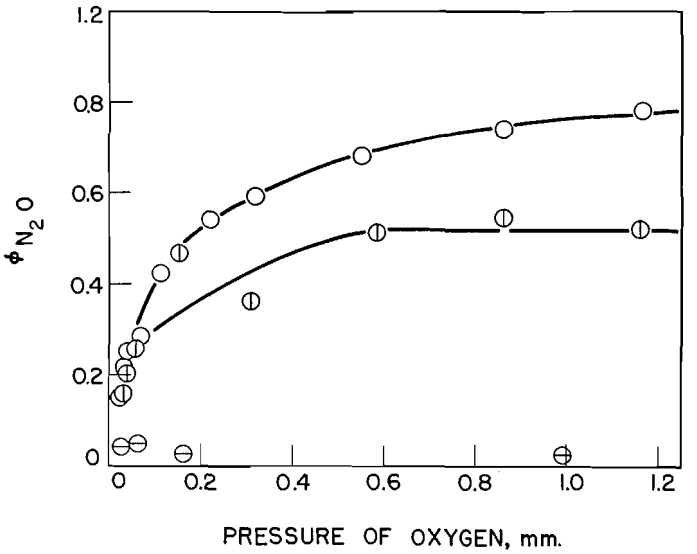

FIG. 4. Dependence of Φ_{N_2O} on oxygen pressure:
$I_a = 5 \times 10^{11}$ quanta/cc./sec.; pressure of azomethane, 101 mm.; ○, 161°C.; ◑, 123°C.; ⊖, *ca.* 25°C.

Although it has been assumed that nitrous oxide is produced in a chain propagating reaction, [9], which may occur in steps, the over-all yield of this product is low, $\Phi_{N_2O} < 1$. Unless fates other than [6] and [9] are postulated for $CH_3N_2CH_2$ and $CH_3N_2CH_2O_2$ respectively, it seems necessary to employ efficient chain termination reactions for the radicals R. Methyl radicals disappear rapidly in a system containing azomethane, presumably by addition to the nitrogen–nitrogen double bond to form tetramethyl hydrazine (15). It is, therefore, conceivable that azomethane acts as a sink for oxygenated radicals in a two stage addition process; the over-all reaction may be written

$$2R + CH_3N_2CH_3 \rightarrow CH_3NRNRCH_3. \quad [11]$$

The correct general form of $-\Phi_{O_2}$, Φ_{CH_4}, and Φ_{N_2O} as a function of (O_2) and of $(CH_3N_2CH_3)$ is obtained from a steady state treatment of the mechanism.

Under conditions such that Φ_{CH_4} is negligible, i.e. Φ_{N_2O} and $-\Phi_{O_2}$ have attained their limiting values, the mechanisms predict that

$$-\Phi_{O_2} = 2+2\Phi_{N_2O}.$$

Substitution of the observed values of Φ_{N_2O} leads, at 123°C., to $-\Phi_{O_2} = 3.1$ (experimental = 3.6), and at 161°C. to $-\Phi_{O_2} = 3.6$ (experimental = 4.0). The proposed mechanism, though obviously oversimplified, is in near accord with the data.

The relative rates of [2] and [4] may be determined from a relationship between Φ_{CH_4} and Φ_{N_2O} derived from the following assumptions: (i) two methyl radicals are produced in the primary process; (ii) methyl radicals are consumed only by [2], [3], and [4]; (iii) each methyl radical formed in other than the primary process is accompanied by the production of one molecule of nitrous oxide.

$$(2+\Phi_{N_2O})/\Phi_{CH_4} = (k_2+k_3)/k_2+k_4(O_2)/k_2(A)$$

In Fig. 6 a linear relation is shown between $(2+\Phi_{N_2O})/\Phi_{CH_4}$ and (O_2) at constant (A) for two temperatures. The slopes of these lines lead to $k_4/k_2 = 6.8 \times 10^4$ at 123°C. and 3.3×10^4 at 161°C. Extrapolation to $(O_2) = 0$ yields $(k_2+k_3)/k_2 = 5.0$ at 123° and 6.5 at 161°C.; the values obtained from the data of Jones and Steacie (15) for these intercepts are 6.2 and 6.0 respectively. This degree of agreement is considered adequate. The Arrhenius activation energy difference, E_2-E_4, is equal to 6.9 kcal./mole and the collision theory steric factor ratio, p_4/p_2, is 17; $E_2 - \frac{1}{2}E_E$ equals 7.3 kcal./mole and $p_2/p_E^{\frac{1}{2}}$ equals 4×10^{-4} (1), where the subscript E refers to the combination of two methyl radicals producing ethane, the latter proceeding with negligible activation energy and approximately unit collision efficiency (11). Hence $E_4 \backsim 0.4$ kcal./mole and $p_4 \backsim 7 \times 10^{-3}$.

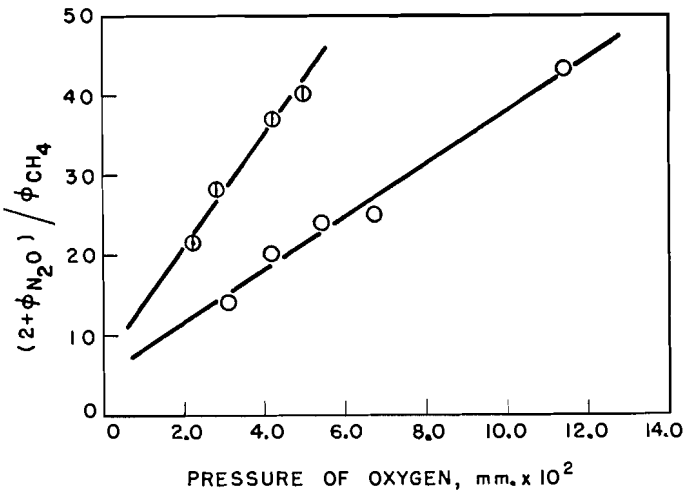

FIG. 6. Dependence of $(2+\Phi_{N_2O})/\Phi_{CH_4}$ on oxygen pressure:
$I_a = 5 \times 10^{11}$ quanta/cc./sec.; pressure of azomethane, 101 mm.; ○, 161°C.; ◑, 123°C.

Using acetone photolysis as a source of methyl radicals, Marcotte and Noyes (18) obtained $E_4 \backsim 0$ and $p_4 \backsim 10^{-1}$ by a method essentially similar to that employed here. The general agreement of the present determination with the earlier work in which more extensive data were reported at four temperatures is taken as support for the over-all reaction [9]. From an investigation of the photo-oxidation of methyl iodide, Blaedel, Ogg, and Leighton (5) estimated $E_4 \sim 3$ kcal./mole, while van Tiggelen (24) obtained an approximate value $E_4 \sim 1.5$ kcal./mole in a study of the acetone photosensitized oxidation of methane. Thus, there is general agreement that reaction [4] is rapid and that both the activation energy and steric factor are low.

The identity of the primary products of the oxidation of methyl radicals is still a matter of conjecture, however; thus [7] has been explicitly written as

$$CH_3O_2 \rightarrow HCO + H_2O \qquad [12]$$
$$\rightarrow HCHO + OH. \qquad [13]$$

Other reactions of peroxymethyl radicals which have been suggested are (12, 17, 26)

$$CH_3O_2 + R'H \rightarrow CH_3O_2H + R' \qquad [14]$$
$$CH_3O_2 + CH_3O_2 \rightarrow 2CH_3O + O_2. \qquad [15]$$

Reaction [12] is now considered unlikely (8, 14, 19) and reaction [15] should not be of great importance in the low concentration range under discussion at present. The positive identification of methanol and water among the liquid products suggests that R radicals may be identified tentatively with CH_3O_2, CH_3O, and OH. Further speculation regarding the detailed reactions of these radicals are, on the basis of the present data, unwarranted.

Small quantities of carbon monoxide and dioxide are found, the latter in almost insignificant amounts and apparently independent of conditions ($\Phi_{CO_2} < 0.1$). The carbon monoxide yield roughly parallels that of nitrous oxide as a function of oxygen pressure (Figs. 4 and 5) but is smaller by a factor

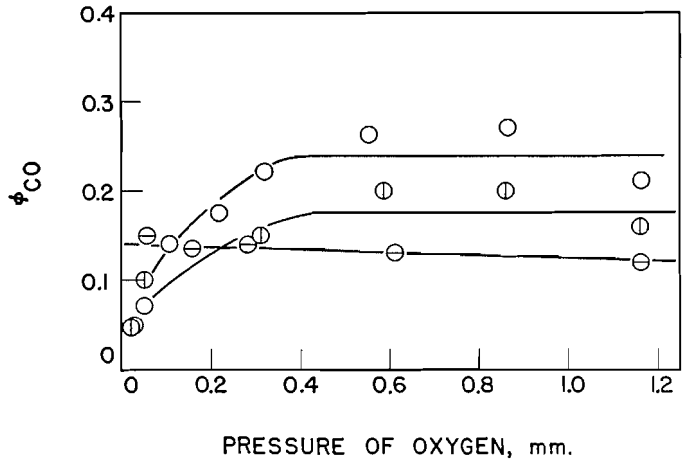

FIG. 5. Dependence of Φ_{CO} on oxygen pressure:
$I_a = 5 \times 10^{11}$ quanta/cc./sec.; pressure of azomethane, 101 mm.; ○, 161°C.; ◑, 123°C.; ⊖, *ca.* 25°C.

of approximately two. The variation of Φ_{CO} as azomethane concentration is decreased by a factor of 15 with a constant rate of production of radicals is small and in the opposite direction to that of Φ_{N_2O} in the same circumstances (Table I). This suggests that carbon monoxide arises from an oxidation of methyl radicals and that the intermediate stages do not involve the substrate. The variability (18, 19) in the CO/CO_2 ratio when various methyl radical sources are used suggests that both these products arise in an indirect manner (14). This is supported by Hentz (13) who observed an induction period for the production of carbon monoxide in the acetone–oxygen system. It might be pointed out that the low yield of carbon dioxide observed here is compensated by the production of nitrous oxide. Indeed, if the acetonyl radical were to react with oxygen in the manner postulated here for $CH_3N_2CH_2$ (i.e. [6] and [9]), the product would be carbon dioxide.

The experiments described in Part II of the Experimental section are reported in Table II as averages taken over a number of experiments. The salient facts are: (i) Φ_{N_2} and $-\Phi_A$ do not differ significantly from unity; (ii) $-\Phi_{O_2}$ lies

between one and two; (iii) methanol, water, and formic acid are major products; (iv) a material balance is not even approximately attained if one nitrogen molecule is accompanied by the production of two single carbon radicals; (v) the oxygen concentration and the absorbed intensity, and hence the radical concentration, were high, while the temperature and azomethane concentration were low.

As pointed out previously, the experimental arrangement was such that formaldehyde probably could not have been detected as a product. If the total apparent decrement in the carbon balance is assumed to be formaldehyde, $\Phi_{H_2CO} \sim 1$. It is not readily apparent how an explanation of the results can be advanced if Φ_{H_2CO} is not at least as great as Φ_{CH_3OH} since the nearly unit yield of azomethane disappearance renders abstraction reactions unimportant. If this assumption is made, however, the mechanism might be expected to reduce to the radical–radical interactions suggested by Vaughan *et al.* (3), viz. [1], [4], and [15] followed by

$$2CH_3O \rightarrow CH_3OH + H_2CO. \qquad [16]$$

This is in qualitative accord with the data if it is noted that small amounts of oxygen will be required to oxidize some of the products of [16] to the water, acid, and carbon oxides found.

ACKNOWLEDGMENTS

The authors are indebted to Dr. E. W. R. Steacie for advice and encouragement throughout this work. They also wish to thank Dr. L. C. Leitch and Mr. R. Renaud for azomethane samples, Miss F. Gauthier and Miss M. J. Fuller for the mass spectrometric analyses, and Mr. R. Lauzon for the infrared absorption measurements.

THE PREPARATION OF DICYANODIACETYLENE

By F. J. Brockman

ABSTRACT

The preparation of dicyanodiacetylene as reported by Moureu and Bongrand has been investigated more fully and a procedure developed whereby yields as high as 36% have been obtained.

INTRODUCTION

In 1920 Moureu and Bongrand (1) reported what was undoubtedly the first synthesis of dicyanodiacetylene. By the action of aqueous potassium ferricyanide on the cuprous derivative of propriolonitrile (cyanoacetylene) they obtained trace quantities of a solid with characteristic properties. This preparation has been investigated more fully and a procedure developed whereby yields as high as 36% have been obtained. The product was characterized as dicyanodiacetylene (C_6N_2) by elementary analysis and molecular weight determinations and by conversion on hydrogenation to hexamethylenediamine. Although the yield of hexamethylenediamine (isolated as the picrate) was low (8.5%), this low yield appeared to be due to decomposition of the dicyanodiacetylene in the presence of the hydrogenation catalyst (Adams' platinum oxide).

Dicyanodiacetylene is an unstable, volatile, white solid with a marked irritating odor. By sublimation in a stream of carbon dioxide gas it may be obtained as fine, elongated crystals melting at 64.5–65.5°C. X-ray diffraction lines obtained from a single crystal rotation pattern are listed in Table I, together with their estimated relative intensities.

2.83	20	1.58	10

*Wave length 1.5418 Å.

Attention should be drawn to the unusual composition and structure of dicyanodiacetylene. Being composed solely of carbon and nitrogen it can be

[1]Manuscript received September 27, 1954.
Contribution from the Central Research Laboratory, Canadian Industries (1954) Ltd., McMasterville, Quebec.

considered as a subnitride of carbon. It is also one of the longest, completely linear molecules described and should be a very interesting compound for structural study.

EXPERIMENTAL

Preparation of Cuprous Propriolonitrile

Cuprous chloride (9.9 gm., 0.10 mole) was dissolved in 10 cc. of 14% aqueous ammonia under an atmosphere of nitrogen and diluted with 900 ml. of water. To this solution at approximately 25°C. was added with agitation propriolonitrile (1) (1.5 gm., 0.029 mole) over a three minute period. After being stirred for an additional five minutes the olive green precipitate was separated by decantation and filtration and washed twice with 30 ml. of 1.5% aqueous ammonia. The product after drying under vacuum, first over sulphuric acid and finally over phosphorus pentoxide, weighed 3.7 gm. (110% yield on propriolonitrile). Cuprous propriolonitrile is subject to detonation by heat and shock.

Preparation of Dicyanodiacetylene

A solution of 7.8 gm. (0.0234 mole) potassium ferricyanide in 20 ml. of water was added over a five minute period to a stirred suspension of cuprous propriolonitrile (1.5 gm., 0.012 mole) in 25 ml. of water and 25 ml. of benzene. The temperature of the reaction mixture was maintained at 5 to 6°C. throughout. Agitation was continued for two minutes after addition was complete and the reaction mixture then centrifuged, the centrifuge bottles and cups being chilled before use in an ice-water bath. After centrifuging for five minutes at 2000 r.p.m., the benzene layer (17 ml.) was removed. The lower aqueous layer and a heavy sludge-like precipitate were again cooled, extracted with a further 20 ml. of benzene, and the centrifuging procedure repeated. Owing to the formation of a fine black precipitate at this stage, only 10 ml. of benzene extract could be separated by this means. By filtration of the residual mixture through filter-aid, a further 15 ml. of extract was obtained. The combined benzene extracts were dried over sodium sulphate and most of the benzene removed by fractionation at atmospheric pressure through a short (8 cm.) Vigreux column. The resulting dark brown concentrate (2 ml.) was taken to dryness in a slow stream of carbon dioxide, the condensate being collected in a small ice-cooled receiver. After removal of all the benzene, dicyanodiacetylene was sublimed from the residue by continuing the volatization procedure. The sublimate was further purified by resublimation in a stream of carbon dioxide. The white crystalline product thus obtained, m.p. 64.5–65.5°C., weighed 0.180 gm. (30.5% yield). Calc. for C_6N_2: C, 72.0; N, 28.0; mol. wt., 100. Found: C, 72.15; N, 27.42; mol. wt. (depression of f.p. of benzene) 97. An additional 0.035 gm. of product, m.p. 64–64.5°C., was obtained by distilling most of the solvent from the benzene distillates using a column packed with glass spirals and working up the concentrate as described above. The total yield isolated was 0.215 gm. (36% yield on cuprous propriolonitrile).

Dicyanodiacetylene gradually turns brown at room temperature, but may be stored at 0°C. This discoloration is more rapid in the presence of water or

in ether solution and occurs at once in alcohol. Petroleum ether, b.p. 28–35°C., may be used as an extraction solvent in place of benzene. Ether is unsatisfactory owing to the instability of dicyanodiacetylene in this medium and chloroform is not recommended since it is difficult to separate from the by-product sludge.

Hydrogenation of Dicyanodiacetylene to Hexamethylenediamine

The hydrogenation was carried out in a small high pressure hydrogenation unit equipped with a 110 ml. glass liner. Dicyanodiacetylene (0.27 gm., 0.0027 mole) was dissolved in 20 ml. of acetic anhydride and Adams' platinum oxide (0.10 gm.) added just prior to the sealing up of the mixture in the hydrogenation unit. (Although dicyanodiacetylene is reasonably stable in acetic anhydride solution, decomposition occurs in the presence of Adams' catalyst as evidenced by the gradual appearance of a dark brown color.) After being flushed out with hydrogen, the apparatus was charged to a pressure of 800 p.s.i. and the shaker started. The pressure fell off to 725 p.s.i. in 15 min. and more slowly to 710 p.s.i. over a three and one-half hour period. No further drop in pressure had occurred at the five hour mark and the reaction was stopped. The reaction temperature remained at approximately 30°C. throughout the hydrogenation. The solvent was removed from the dark brown reaction mixture by vacuum distillation, and the residual oily gum, containing acetylated hexamethylenediamine, was hydrolyzed by refluxing for five hours with 20% aqueous sulphuric acid (5 gm.). The hydrolyzate was made alkaline to a pH of 13–13.5 with 20% aqueous sodium hydroxide to liberate hexamethylenediamine from its salt and the resulting solution distilled to dryness under aspirator vacuum. To the distillate was added 1.4% aqueous picric acid (40 ml.) and the precipitate of hexamethylenediamine picrate removed by filtration. The product, m.p. 219°C., weighed 0.13 gm. (8.5% yield on dicyanodiacetylene). After recrystallization from water, the material melted at 221–222°C. (lit. 220°C.). It was further identified as hexamethylenediamine

ALLOYS OF INDIUM: THE SYSTEM INDIUM–LEAD–TIN[1]

By A. N. Campbell, R. M. Screaton,[2]
T. P. Schaefer,[3] and C. M. Hovey[4]

ABSTRACT

There is no ternary eutectic in the system: indium–lead–tin: the eutectic trough extends from the lead–tin eutectic to the tin–indium eutectic. The liquidus surface has been outlined. The structures of all alloys of the above system have been investigated, at room temperature, by the X-ray and microscopic techniques. A one-phase region extends across the ternary diagram from the limits of the β-phase in the indium–tin system to the limits of the β-phase in the lead–indium system. This indicates that the intermetallic β-phases of the two systems (lead–indium and tin–indium) have the same lattice structure, viz. face-centered tetragonal. Heterogeneity has been detected by direct experiment in the system lead–indium, whereas it had previously only been deduced. Hardness tests, both Brinell and Vickers, have been made on the alloys.

The only previous work that has been reported on the above system is that of Grymko and Jaffee (5), who dealt primarily with the corrosion-resistance properties of the indium–lead–tin solders; they state, however, that the liquidus of one alloy containing 37.5 weight per cent lead, 37.5 weight per cent tin, and 25 weight per cent indium, lies at 181° C. and the solidus at 134° C. The component binary systems, viz.: lead–tin, indium–lead, and indium–tin, have all been investigated and very little remains in doubt. To save unnecessary discussion, the equilibrium diagrams are given in Figs. 1, 2,

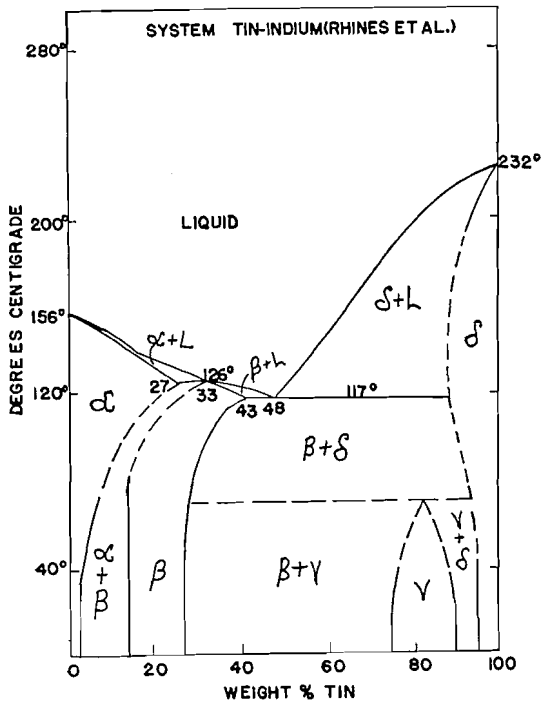

FIG. 3.

and 3. Fig. 1 is due to Stockdale (11) and represents the system lead–tin. The only point of interest in this system is a mysterious evolution of heat at 150° C., which occurs in all lead rich alloys; this is not due to any ordinary phase change.

Fig. 2 represents the system indium–lead: it is due to Davis and Rowe (1). This system shows a minimum freezing temperature, lying 1° C. below the melting point of pure indium, and three solid phases, an α-phase with the lead structure, a γ-phase with the indium structure, and an intermediate β-phase, for which Klemm (7) claims a face-centered tetragonal structure; further discussion of this structure is reserved until the discussion of our own work. The most complicated system is that of indium–tin (Fig. 3) due to Rhines (9). It is seen that this system exhibits four solid structures, one of which, however, the γ-phase, exists only at relatively low temperatures and therefore cannot be in equilibrium with melt. The α-phase possesses the structure of indium, the δ-phase that of tin, while the β-phase, according to Orlamunder (7) has a tetragonal, face-centered lattice. For the low-temperature γ-phase, Valentiner (12) proposed a body-centered tetragonal structure, but Fink (4) thought this phase was simple hexagonal: however, Ferguson and Screaton (3) believe it to be simple hexagonal with one atom per unit cell.

PART 1. THE LIQUIDUS SURFACE

Materials Used

The lead contained the following impurities:

Antimony	0.005%
Silver	0.002%
Total foreign metals	0.05%

The indium was given to us by the Consolidated Mining and Smelting Company of Canada Limited and had the following impurities:

Tin	0.015%
Nickel	0.0015%
Lead	0.015%
Copper	0.002%
Cadmium	0.001%
Iron	0.0005%

The tin analysis gave:

Iron	0.0020%
Antimony	0.0023%
Lead	Trace
Copper	Trace
Tin	99.9957% (by difference)

Methods of Chemical Analysis

The method of sampling differed in the study of the liquidus from that used in the study of the completely solid system. In no case did we rely on the original weighed composition since oxidation, though slight, is preferential, occurring chiefly to the lead. For the study of the liquidus, samples of liquid alloy were drawn up into a 1/16 in. diameter alundum tube. The alloy solidified in the tube after mounting a short distance; the tube was then broken and the whole of the sample analyzed, in case there should have been segregation of the alloy during solidification. Alloys with low indium content were dissolved, with the help of platinum foil, in hydrochloric acid, and the tin content determined by titration with iodine (10). Lead was estimated by the standard method of precipitation as sulphate. Prolonged attempts were made to determine indium directly, both polarographically and by precipitation with 8: 4 hydroxyquinoline but neither method was satisfactory in the presence of lead and tin. In the end, therefore, indium was obtained by difference. This may seem a doubtful procedure when the indium content is small but it should be remembered that the composition never differed much from that of the original weight composition. In alloys of high indium content, tin was determined as metastannic acid, which was subsequently ignited to the dioxide and weighed as such. All these analytical methods are well known.

Determination of Equilibrium Curves and Surfaces

The method of thermal analysis was used to determine these. The melts

were contained in alundum crucibles and temperature was measured with a mercury-in-glass thermometer, reading from 0 to 201° C. in 1/10°. The thermometer was calibrated against a standard platinum resistance thermometer: temperature was therefore accurate to ± 0.2° C.

The method of linear cooling was used, the rate of cooling being 1° per 1.5 minutes. The molten alloys were well stirred and kept at a temperature at which they were entirely liquid, for two hours, to ensure homogeneity. Starting with the composition of the lead–tin eutectic, as given by Stockdale (11), indium was added progressively and a cooling curve taken and an analysis made after each addition. An examination of the cooling curve showed whether or not the mixture had the trough composition. If it did not have, there was primary crystallization of a single phase and a preliminary point of inflection on the cooling curve. This was corrected, when necessary, by adding small quantities of tin (lead was never necessary). It soon became apparent that the eutectic trough, starting from the lead–tin eutectic, was heading smoothly for the indium–tin eutectic. Therefore, this was checked by starting from the indium–tin eutectic and adding lead. In this way, we were able to show that even the smallest addition of lead raised the solidification temperature of the indium–tin eutectic and therefore the possibility of a ternary eutectic lying very close to the indium–tin eutectic was excluded.

We thought it advisable to check the statement that there is a minimum freezing point in the lead–indium system, lying, according to the literature, 1° below the melting point of indium. For this purpose, we used a Beckmann thermometer with which we determined the freezing point of pure indium. Small weighed quantities of lead were then added and the freezing point determined each time. The procedure was repeated until a minimum freezing temperature was obtained. The freezing temperature of the lowest freezing alloy was then determined absolutely on the 200° thermometer. We obtained a depression of about 0.15° C. (constant) after the addition of 2.5 weight per cent lead.

Because of the occurrence of one peritectic in the lead–indium system and two in the indium–tin system, we expected peritectic halts along the eutectic trough of the ternary system. We first investigated the binary peritectics but we found the heat effects slight and difficult to observe, at least by our technique. When the third metal was added to these binary peritectic compositions, the heat effect was quenched entirely. Experimentally, then, we found no peritectic halt on the eutectic trough. Our investigation of the completely solid alloy at room temperature shows that there must be one, and only one, peritectic halt on the trough, but we do not know its temperature and composition.

To complete the study of the liquid surface, some points on the areas representing equilibrium of liquid with single solid phases were necessary (chiefly in the region where α-lead separates from the melt) and these were obtained by making up alloys of suitable composition and applying thermal analysis, using, however, a chromel–alumel thermocouple, since the temperatures involved were somewhat higher.

Experimental Results

Discussion of the Liquidus Surface

The experimental results show that there is no ternary eutectic in this system; the eutectic trough extends from the lead–tin eutectic to the tin–indium eutectic.

Our value for the eutectic temperature of the binary system lead–tin, 183.3° C., is in good agreement with Stockdale's value (11). We have, however,

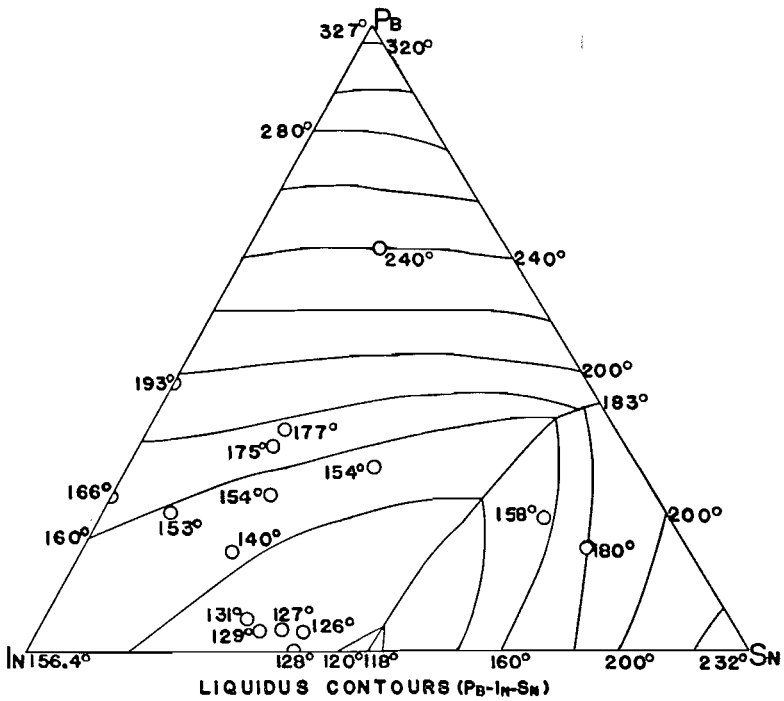

FIG. 4.

repeated the eutectic of the tin–indium system several times, using the composition given by Rhines (9) and we obtain values for this eutectic temperature lying between 118.7° C. and 118.9° C., as against Rhines's own value of 117° C. This may be due to our having had at our disposal very pure indium. In the lead–indium system, we confirm the existence of a minimum freezing temperature lying, however, only 0.15° C. below the melting point of pure indium.

Fig. 4 is a projection diagram of the liquid surface, with isothermal lines.

PART 2. ROOM TEMPERATURE ISOTHERM

The structure of the completely solidified alloy was studied by the X-ray and microscopic techniques. As a subsidiary aid in the study of structure and because of its intrinsic practical importance, the hardness was determined in various regions of the composition triangle: both Brinell and Vickers hardness tests were applied.

Experimental

All alloys were heat-treated by cooling them gradually over a period of twenty-four hours, from a temperature at which they were completely liquid down to room temperature. This was achieved by coupling a slow, constant speed, electric motor through a system of gears to a "Variac", which governed the input to the furnace. After the potential fell to zero, an automatic switch cut out the circuit. Twenty-three hours were required to rotate the Variac through its complete range. Obviously, such an apparatus does not decrease temperature linearly since the power input is proportional to the square of the voltage; in other words, cooling was more rapid at higher than at lower temperatures, but this is rather a desirable feature.

The purity of the materials is described under the first Section, where, also, it is stated that all alloys were analyzed and the methods of analysis are given. The method of treatment of alloys for the study of the solid system was as follows: A total weight of 40 gm. of the desired composition was charged into a crucible and preheated to about 60° above the liquidus temperature, as read from the appropriate equilibrium diagram (see preceding section). After fusion and repeated stirring with an alundum rod, the melt was cooled to roughly three degrees above the temperature of the liquidus surface, the whole process occupying about three hours. The continuous cooling mechanism was now set in motion and the alloy annealed down to room temperature.

From the ingot prepared as above the oxide film was removed with a lathe. A specimen for microscopic examination, approximately 7 mm. in width and 4 mm. thick, was also prepared on the lathe. Turnings for chemical analysis were taken from the immediate vicinity of the prepared surface. No demarcation marks, denoting gross phase separation during cooling, could ever be detected by a vertical saw-cut; moreover, the general agreement between final analysis and original composition of charge favors this conclusion.

A strip for X-ray examination was cut from the surface of the prepared specimen, with a sharp thin-bladed knife: it was possible to reduce the thickness of this strip as low as 0.2 mm. Powder pictures of such strips were taken on a North American Phillips X-ray unit, using a simple Debye camera of

57.3 mm. diameter. Copper radiation and a nickel filter were used. The exposure time varied from one to three hours depending on the composition and size of the specimen. The above procedure was necessary because indium and alloys rich in indium are almost as soft as putty. Filings could not be prepared readily because of the "smearing" properties of these alloys. The small degree of cold-working by the knife-edge would only cause a slightly preferred orientation of the grains and this effect was neutralized by rotation of the specimen during exposure to X rays.

Our treatment of the specimens prior to microscopic examination is described in detail, because no satisfactory methods of polishing and etching the indium alloys in question are to be found in the literature. Preparatory to polishing, the surface was lightly rubbed on a fine mill-file, held stationary, the teeth being cleaned after each stroke. The final polish was given on a wheel-driven silk cloth (selvyt), using the "light" variety of powdered magnesium oxide as polishing agent. If the sample contained large quantities of lead, tarnishing tended to occur but it was found that this could be prevented by the use of soap. Too much water on the cloth increased the tarnishing but a heavily tarnished layer could be removed by dabbing the surface with glacial acetic acid. Polishing was carried on close to the center of the wheel until the surface had a lustrous appearance, as far as possible scratch-free.

An etching reagent consisting of seven parts of glycerol, two parts of concentrated nitric acid, and one part of glacial acetic acid gave the best results over the whole concentration range, but the nitric acid content was varied for different samples to achieve the best effect. This reagent was described by Villela and Beregekoff (13) for lead alloys. Etching took place by immersion for 5 to 30 sec. at approximately 40° C. To ensure that the true structure of the sample did not remain latent, the specimen was alternately lightly polished and etched. This also decreased the danger of cold-working from overpolishing and the deterioration of a delicate microstructure from overetching.

Hardness tests were made by the Brinell ball and Vickers' diamond hardness tests. Because of the softness of these alloys, a special Brinell machine was constructed, which had a unit ratio of load in kgm. to the square of the diameter of the ball in mm., as specified in "Metals Handbook" (8). A load of 5.5 kilograms was applied to a steel ball of 2.35 mm. diameter, for 30 sec. The Vickers-Armstrong machine was of a standard type.

The method of procedure was as follows: Alloys, some fifteen in number, representing both the pure phases and the heterogeneous regions, of the binary systems, were prepared and, after heat-treatment in the manner described, the powder pattern and microstructure of each alloy were determined. A small quantity of third component was then added to each alloy; the alloy was then remelted, heat-treated, and examined by the two techniques mentioned, attention being directed to the appearance of a new phase. Because of the great similarities in lattice structure of β-lead–indium and β-tin–indium, it was thought that a continuous series of solid solutions might exist, forming a band over the diagram, and this was found to be the case.

Experimental Results

Table IV contains the compositions of all alloys studied, together with their hardness figures, on both scales. Table V gives approximate figures which will permit the single-phase, two-phase, and three-phase areas to be plotted.

TABLE IV

COMPOSITION AND HARDNESS

Fig. 5 is a graphical representation of these data—the room temperature isotherm. We give no X-ray data since no new phase occurs in the three component alloy and the X-ray data for all binary phases are now to be found in the literature. We reproduce, however, certain photomicrographs since, without them, a paper of this kind is practically valueless to workers in the field: the etching reagent was always that described previously, unless other-

wise stated. It will be noted on Fig. 5 that a single phase region extends across the isotherm from β-indium–tin to β-indium–lead. This is the most interesting of the results and it indicates that the two phases (of the binary systems) are of closely similar structure. The invariant triangle in which β-indium–tin, γ-indium–tin, and α-lead are in equilibrium occupies a large part of the isotherm.

In Fig. 6, the hardness numbers, both DPH and Bhn, are plotted for the binary systems designated. For the indium–tin system there is no indication of the formation of the intermediate β-phase but in the plot of the indium–tin alloys a maximum appears at the composition of the γ-phase. Fig. 7 is a plot of hardness contours for the ternary system.

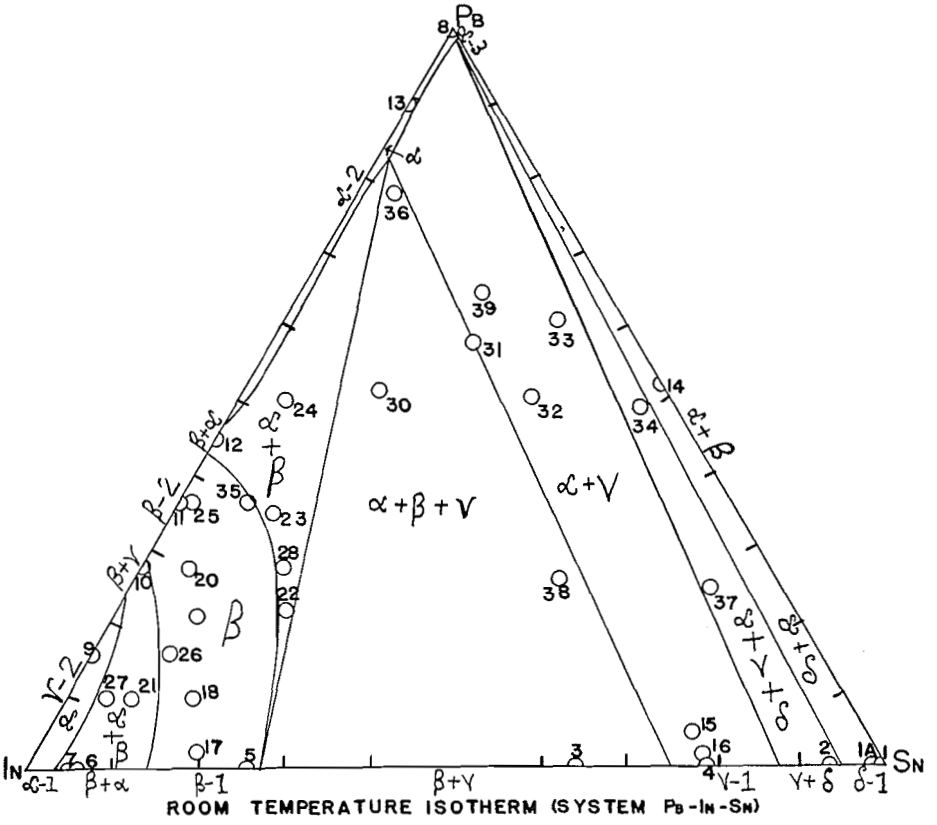

FIG. 5.

There follows a description of the individual photomicrographs. To facilitate discussion the phases designated by Greek letters are distinguished by Arabic numerals, thus, 1 for In–Sn, 2 for Pb–In, and 3 for Pb–Sn.

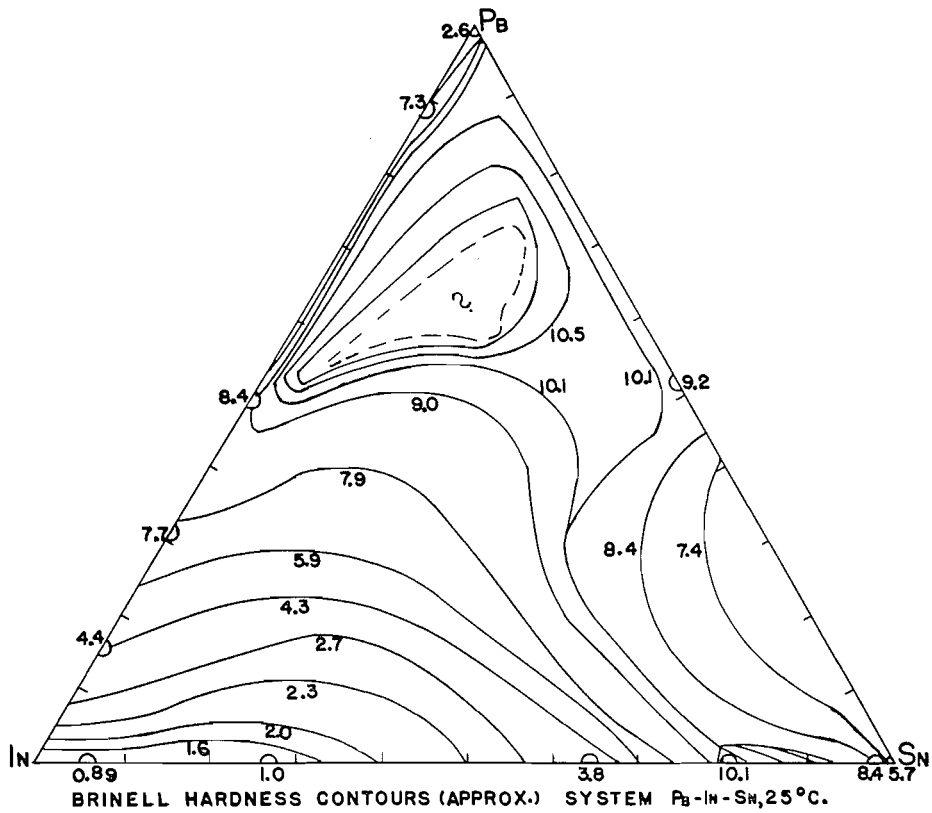

FIG. 7.

TABLE V

Nature of phase	Type of lattice	Composition of points defining area
Single-phase areas		
α-Lead	Face-centered cubic	(1) 1.5% Sn, 98.5% Pb (2) 53.1% In, 46.9% Pb (3) 1% Sn, 25% In, 74% Pb
δ-Tin	Body-centered tetragonal	Does not occur as a single phase in the ternary system; stable up to 5% In in In–Sn system
α-In	Face-centered tetragonal	(1) 3% Sn, 97% In (2) 23% Pb, 77% In (3) 3% Sn, 10% Pb, 87% In
γ-Tin–indium	Simple hexagonal	Does not occur as a single phase in the ternary system: (1) 75% Sn, 25% In (2) 88% Sn, 12% In
β-Lead-indium	Face-centered tetragonal	This phase extends down to β-In–Sn and is isostructural with it. The following points define the band: (1) 28% Pb, 72% In (2) 43% Pb, 57% In (3) 78% In, 13% Pb, 9% Sn (4) 14% Sn, 86% In (5) 27% Sn, 73% In (6) 61% In, 19% Sn, 20% Pb (7) 45% In, 8% Sn, 37% Pb
β-Tin–indium	Face-centered tetragonal	
Two-phase areas		
α-Lead + δ-Tin		(1) 100% Sn (2) 95% Sn, 5% In (3) 1.5% Sn, 97.5% Pb, 1% In
α-Lead + γ-Tin–indium		(1) 1.5% Sn, 97.5% Pb, 1.0% In (2) 95% Sn, 5% In (3) 88% Sn, 12% In (4) 16% In, 1% Sn, 83% Pb
α-Lead + β-Lead–tin		(1) 27% Sn, 73% In (2) 43% Pb, 57% In (3) 47% Pb, 53% In (4) 16% In, 1% Sn, 83% Pb
α-Indium + β-Lead–tin		(1) 14% Sn, 86% In (2) 3% Sn, 97% In (3) 3% Sn, 10% Pb, 87% In (4) 23% Pb, 77% In (5) 28% Pb, 72% In (6) 8% Sn, 77% In, 15% Pb
Three-phase areas		
α-Lead + δ-Tin + γ-Tin–indium		(1) 88% Sn, 12% In (2) 95% Sn, 5% In (3) 1.5% Sn, 97.5% Pb, 1% In
α-Lead + β-Lead–indium + γ-Tin–indium		(1) 75% Sn, 25% In (2) 27% Sn, 73% In (3) 23.5% Sn, 19% In, 57.5% Pb (4) 16% In, 1% Sn, 83% Pb

Interpretation of Photomicrographs

A number of representative photomicrographs are given, in order to indicate the type of microstructure obtained, and particularly such as are not to be found in the literature. Fig. 8 shows the difference in etching characteristics

between the γ-1 and δ-1 phases, the γ-1 being light, i.e. not attacked to the same extent as the δ-1 phase. Fig. 9 shows the grain boundaries in the γ-1 phase (the dark spots are probably spurious effects arising from polishing). That the γ-phase is the one actually present is proved by the powder photograph of this sample, which was identical with that obtained by Ferguson

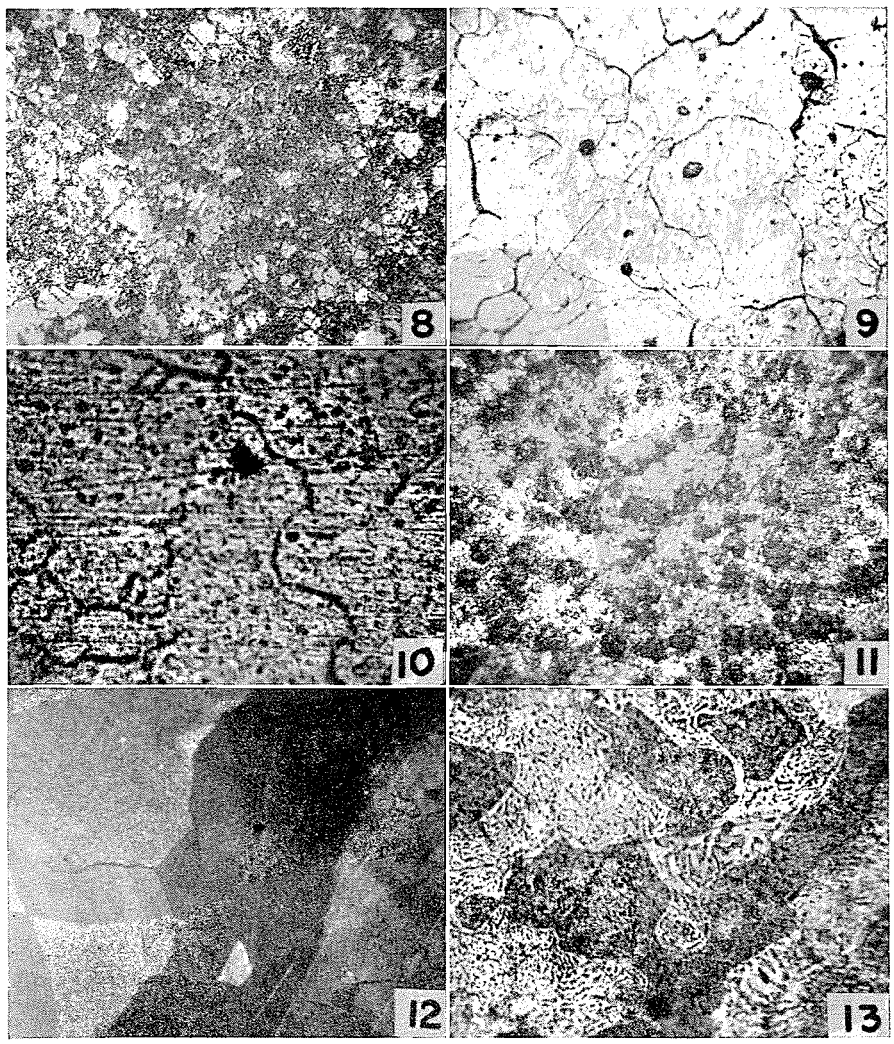

FIG. 8. Alloy 2, × 250. Note the difference in etching characteristics of γ-1 (light) and δ-1 (dark).
FIG. 9. Alloy 4, × 135. Grain boundaries in γ-1; black spots are probably spurious, although some β-1 may be present.
FIG. 10. Alloy 5, × 135. Grain boundaries in β-1, exhibiting the characteristic pitted appearance of this phase.
FIG. 11. Alloy 10, × 250. Repolished and re-etched after three months at room temperature; β-2 in a background of γ-2.
FIG. 12. Alloy 11, × 135. Repolished and re-etched after three months at room temperature; grain boundaries in β-2.
FIG. 13. Alloy 14, × 250. Lead grains (dark) in the Pb–Sn eutectic.

and Screaton (3) and showed the lines of the simple hexagonal lattice of γ-1. Grain boundaries in the β-1 phase are visible in Fig. 10 and were obtained by polishing in an electrolyte consisting of equal parts of 70% perchloric acid and

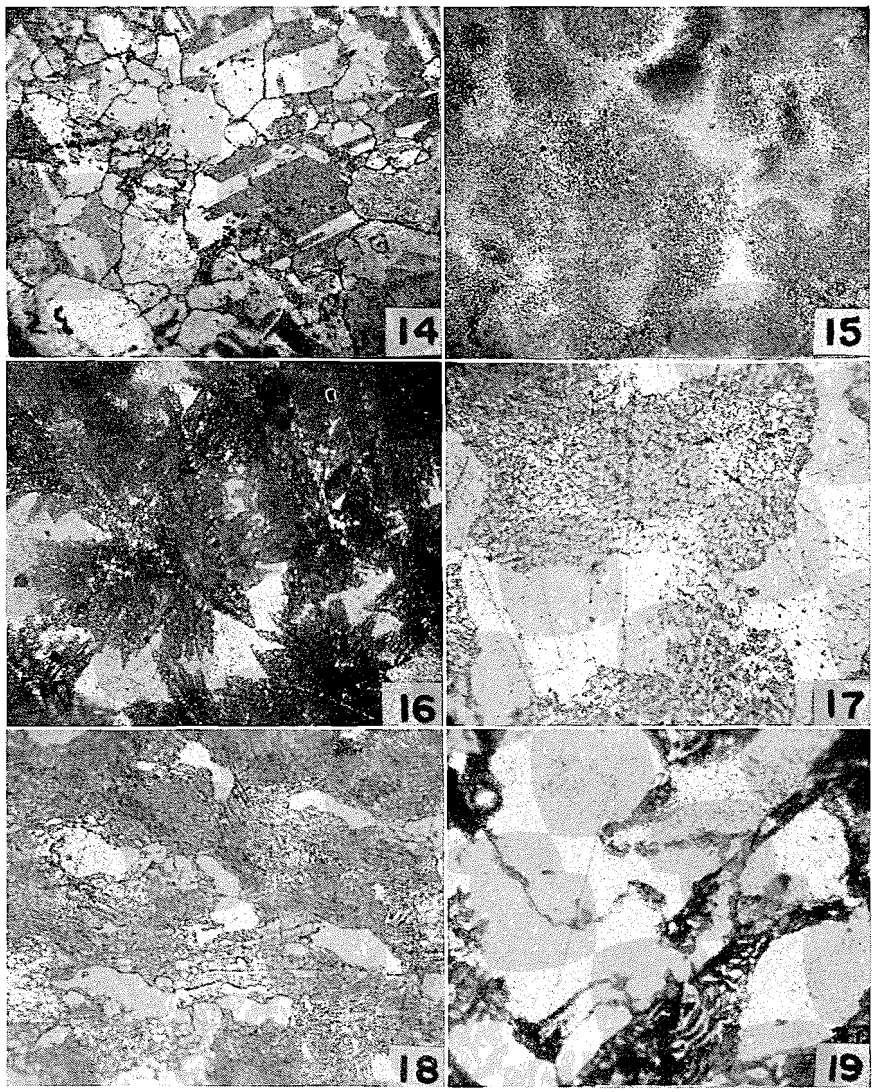

FIG. 14. Alloy 25, × 250. Repolished and re-etched after one month at room temperature; grains of β with twinning bands.
FIG. 15. Alloy 23, × 135. Repolished and re-etched after one month at room temperature; showing α-2 and β.
FIG. 16. Alloy 30, × 250. The dendritic growth of β is here well marked; α-2 and γ-1 are also present (light areas) as proved by X-ray photograph.
FIG. 17. Alloy 32, × 250. A region of the alloy where α-2 is present with eutectic of α-2 and δ-1; now breaking up with the disappearance of δ-1 and appearance of γ-1.
FIG. 18. Alloy 39, × 250. As cast; α-2 (light) in a eutectic matrix of α-2, and δ-1. Note difference (Fig. 13) in appearance of lead crystals when indium is present.
FIG. 19. Alloy 38, × 250. α-2 (light), β-(black), γ-1 (gray).

glacial acetic acid, the sample being made the anode with an aluminum plate serving as cathode (current density 0.3 amp. per cm.^{2}), followed by the usual etch. Note the pitted appearance of the surface. Fig. 11 shows the heterogeneity in alloy 10, Fig. 12 the grain boundaries in alloy 11. The eutectic in the lead–tin system (Fig. 13) has a lamellar structure, the lead etching darkly in the absence of indium. Twinning bands are to be seen in the grains of alloy 25, shown in Fig. 14: they arose from the cold-working caused by polishing. In Fig. 15, the microstructure of an alloy defining the phase boundary between the one- and two-phase regions, as seen on the isotherm, is exhibited. The interpretation is obvious, when one notes that the α-2 phase, lead structure, etches very weakly (appearing light) in the presence of indium. The X-ray photographs substantiate this argument. With alloy 30, Fig. 16, we enter the invariant triangle. The dendritic growth of the β-phase here manifests itself clearly, and this explains the difficulty in distinguishing it from certain other phases in the binary systems, as found by Davis and Rowe (9, in discussion). Such a growth can apparently produce interfluence between the phases. The γ-1 (gray) and α-2 (light) phases are also present and this is corroborated by the X-ray photograph.

As we leave the invariant triangle and enter the adjacent two-phase region where γ-1 and α-2 are stable, the microstructures take on the appearance of Fig. 17 which depicts a region of alloy 32 in which the eutectic (δ-1 and α-2) is in the process of breaking up into α-2 and γ-1. The structure of a cast alloy in this region is portrayed in Fig. 18, alloy 39; the X-ray photograph shows lines for α-2 and δ-1. Note that the lead phase appears light and is delineated by the dark structure of the eutectic. The three phases β (black), γ-1 (light gray), and α-2 (light) occur in Fig. 19, representing alloy 38.

DISCUSSION

Ferguson and Screaton (3) do not agree with Valentiner (12) on the structure of β-indium–tin but, since the lattice of β-indium–lead is established as face-centered tetragonal and since this is the stable lattice right across the diagram, it appears as if Valentiner's view is correct.

Previous workers have failed to detect, by microscopic examination, any evidence of heterogeneity in the lead–indium system, although they had deduced the existence of an intermediate β-phase from X-ray data. Our photomicrograph of alloy 10 (Fig. 11) shows the heterogeneity. The trouble is due to the fact that both α-indium and β-indium–lead have face-centered tetragonal lattices. Davis and Rowe (9, in discussion) do not state their etching reagent. It is probable that the acetic acid in ours was the factor of success, since it tends to remove tarnished films.

For stable intermetallic phases in an alloy the rule is that the intermetallic compound is usually harder than the hardest of its components. This is exemplified by the graph of hardness vs. composition for the indium–tin system, where the peak on the curve lies in the γ region: the β-phase is softer than pure tin and just slightly harder than pure indium. In general, an intermetallic "compound" has some composition within the boundaries of its stable

existence and corresponding to a definite chemical formula. Since compounds, according to Hume-Rothery (6) correspond to definite valence electron to atom ratios, one can hence attribute much of their hardness to their tendency to form homopolar bonds. The results support this view. The γ-phase, of simple hexagonal structure, is almost twice as hard as the body-centered tetragonal lattice of pure tin. Since the hexagonal lattice would have more planes for deformation slipping than the tetragonal, some other forces must be operative, e.g. homopolar bonding.

Alloys containing the γ-indium–tin phase could not be dissolved completely in acids, unless platinum was used to promote solution by galvanic action. Whatever the cause of this passivity, the phenomenon is interesting from the point of view of corrosion studies.

ACKNOWLEDGMENT

We are indebted to Professor R. B. Ferguson, Associate Professor of Crystallography, for much helpful advice in carrying out the X-ray measurements.

HYDROGEN PEROXIDE AND ITS ANALOGUES

VI. INFRARED SPECTRA OF H_2O_2, D_2O_2, AND HDO_2 [1]

By Osias Bain[2] and Paul A. Giguère

ABSTRACT

The absorption spectrum of hydrogen peroxide was re-examined with a prism instrument in the region 1.5 to 25μ. A pair of well-resolved perpendicular bands arising from torsional oscillation of the OH groups were found centered about 460 and 575 cm.$^{-1}$. The overtone band at 3.8μ was shown to be a hybrid with prominent rotational structure and some indications of doubling. Its assignment to the combination $\nu_2+\nu_6$ implies a positive anharmonicity. Four new overtone bands were observed in liquid hydrogen peroxide. The infrared spectrum of deuterium peroxide was measured for the first time in the solid and vapor states. The vapor bands are quite different in appearance from those of hydrogen peroxide. One of the fundamentals, the asymmetric O—D stretching at 2661 cm.$^{-1}$, was resolved sufficiently to allow calculation of the rotational constants of the isotopic molecule. Mixtures of the two peroxides containing around 40% of HDO_2 were also investigated; from the results the frequency of the as yet unobserved symmetric modes ν_1 and ν_2 could be estimated with fair certainty. The O—O stretching vibration at 11μ was too weak to be located definitely in the spectra of the gaseous peroxides. The structural parameters of the H_2O_2 molecule are now established as follows:

$$r_{O—O} = 1.49\pm0.01 \text{ Å}$$
$$r_{O—H} = 0.97\pm0.01 \text{ Å}$$
$$\alpha_{OOH} = 100°\pm2°$$

The O—H and O—D stretching bands were studied in solutions of the three isotopic peroxides in carbon tetrachloride.

Previous investigations of the molecular spectrum of hydrogen peroxide (2, 6, 10, 30, 34) have served to confirm the structure now accepted for that molecule but, otherwise, they have left unanswered a number of important questions, such as the assignment of the weak band at 3.8μ and the frequency of the four symmetric modes, especially ν_4 the torsional oscillation. In an effort to solve some of these problems the infrared spectrum of that compound was measured again under a wider range of conditions than covered heretofore. In addition, the completely deuterated peroxide was prepared and its spectrum in the vapor state was recorded for the first time. Mixtures of these two isotopic peroxides were used to obtain valuable information on the hybrid molecule HDO_2. Unfortunately, study of the latter was severely limited by interference from the parent molecules H_2O_2 and D_2O_2, always present in large proportions, in addition to traces of H_2O, D_2O, and HDO. Finally the spectra of the three peroxides dissolved in a non-polar solvent have helped elucidate the region of the O—H and O—D stretching fundamentals. While the subject remains far from exhausted the new results have made possible calculation of the force constants of the molecule (11) and an appreciable refinement in our knowledge of the structural parameters.

EXPERIMENTAL

The material used for obtaining the spectra was prepared as described before;

[1]*Manuscript received November 22, 1954.*

the hydrogen peroxide, 99.5%, by fractional distillation of Becco's 90% commercial product, and the deuterium peroxide, 90–93%, by dissociation of heavy water vapor, 99.6% pure, in the electrodeless discharge (16). The tendency of these peroxides to decompose spontaneously gave rise to numerous difficulties in selecting suitable containers and window material. For the latter, plates of highly polished silver chloride were found to be quite satisfactory. Spectra of the solid peroxides were studied without too much difficulty because of the slower decomposition rate at low temperature. An absorption cell of the type described by Wagner and Hornig (31) was used. One drop of liquid peroxide was squeezed between two precooled silver chloride plates and the whole was quickly inserted in the holder. After the cell was evacuated the temperature was lowered further with dry ice and acetone. Atmospheric humidity had to be kept low enough to prevent condensation on the windows.

The liquid peroxides could not be studied so easily. Even with very smooth silver chloride plates some slight decomposition always occurred at room temperature and the oxygen produced forced out the thin film of liquid. In the overtone region glass spacers were used and the thickness, measured by an interference method (28), was about 0.1 mm. Below 1μ a glass cell 1 cm. thick was used so that four new combination bands could be detected in both hydrogen and deuterium peroxides (Table I). Solutions in carbon tetrachloride could only be studied in the near infrared up to approximately 4μ where the solvent is still sufficiently transparent. A very thick absorption cell was needed then because of the low solubility of the peroxides. (No data are available on the solubility of hydrogen peroxide in carbon tetrachloride but, from the relative intensity of the various absorption bands, it seems to be of the same magnitude as that of water (7), namely 8–10 mgm. per 100 gm. of solvent.) A glass tube, 10 cm. long, closed by silver chloride windows made tight by means of Koroseal gaskets was entirely satisfactory. For the vapor a Perkin-Elmer 1-meter multiple reflection cell made of cast aluminum was tried at first. In practice the sample of liquid peroxides could not be heated much above 70°C., where the vapor pressure is of the order of 30 mm. Hg. To prevent condensation on the mirrors and windows the cell had to be kept at 90°C. Under such conditions, decomposition was so rapid, even with a flow system, that a steady concentration of peroxide could not be secured and the water vapor produced blotted large sections of the spectrum. Therefore a glass cell of 1.25 meter path-length was built as shown in Fig. 1.

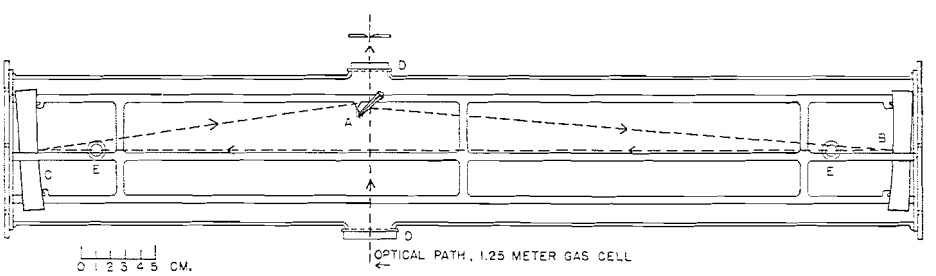

FIG. 1. Diagram of the 1.25 meter absorption cell made of Pyrex glass.

The cell proper is made out of a 60 cm. length of Pyrex tube 10 cm. diameter. The ends, slightly flared and ground flat, are closed by disks of 1S aluminum, 3 mm. thick and well polished. (Very pure aluminum, when properly cleaned, is fairly inert towards hydrogen peroxide.) The two front-aluminized, spherical mirrors, B and C, 8 cm. diameter and 117.5 cm. focal length (such as used in the Perkin-Elmer spectrometer) are mounted in a frame of three thick glass rods held together by rings of bent glass rods. Light, stainless steel springs press the spherical mirrors against lumps of glass fused onto the main rods. Two small plane mirrors, 1.8 × 2.5 cm. cut from microscope slides and bevelled on one side, are mounted diagonally and back-to-back in a holder of thin glass rods fused onto the glass frame. (They could be replaced by a single wedge-shape piece.)

The optical alignment proved to be a delicate operation, but once made it was permanent. To that end the optical assembly was taken out of the glass tube and placed at right angle in the convergent beam of the spectrometer. Mirrors A and B were first lined up so that the reflected beam was collimated and centered about the main axis of the cell. This was achieved by a trial and error method. The lumps of glass, against which the spherical mirrors rest, were softened with a torch and "worked" to the correct position. Mirror C was then similarly adjusted so as to focus the reflected beam on the entrance slit of the monochromator after reflection on the other face of the "wedge" mirror, A. Such an arrangement does not alter appreciably the convergence of the infra-red beam. With the optimum alignment of the mirrors, as much as 80% of the incident light was transmitted after traversing the cell. The openings of the cell, closed either by the aluminum disks or by silver chloride windows, D, could be made tight without difficulty by means of Koroseal gaskets. However, this material is somewhat troublesome in that the plasticizer (a mixture of tritolyl phosphates) distills off on heating *in vacuo*. These esters were identified by their infrared spectra (8) in the 11–15μ region. By keeping the pressure above 15 mm. Hg in the cell at all times this undesirable phenomenon could be reduced appreciably.

To keep the cell at 85–90°C. it was wrapped with insulated nichrome wire and covered with asbestos paper and aluminum foil. The extent of decomposition of the peroxide vapor after one passage through this cell was of the order of 15%, as compared with 85% with the all-metal cell. Various techniques were tried to introduce the peroxide vapor. A static system with the liquid peroxide in a side tube and the absorption cell evacuated was unsatisfactory on account of decomposition. Continuous pumping of the cell through a dry-ice trap and a reducing valve adjusted so that the pressure in the cell remained at 15 mm. Hg resulted in a steady state as indicated by the reproducibility of the intensity spectra. Evacuation of the absorption cell was not necessary, however. The device shown in Fig. 2 was found useful: the sample of liquid peroxide in tube A is surrounded by a vapor jacket B in which a suitable liquid (for instance carbon tetrachloride) is boiled under atmospheric pressure. A regulated stream of dry nitrogen is bubbled through a small tube closed by a fritted glass disk. The stream of gas saturated with peroxide vapor is passed at constant rate

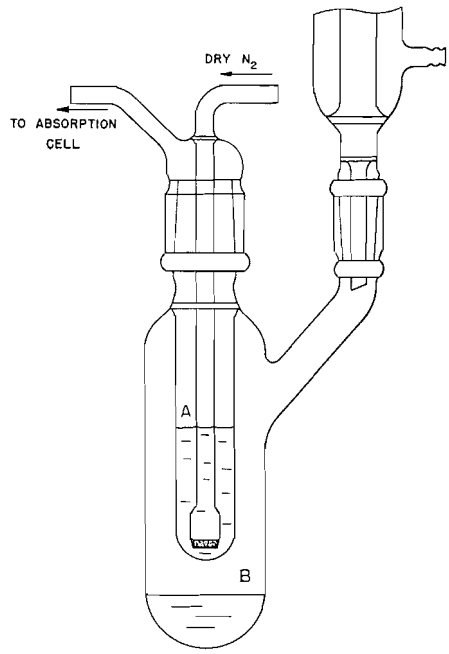

FIG. 2. Device for filling the absorption cell with peroxide vapor.

through the absorption cell and then through a dry-ice trap. The infrared spectrometer was a Perkin-Elmer, model 12C, with automatic scanning and recording on a Speedomax. During this investigation the monochromator was converted to double-pass with notable increase of resolving power and reduction of scattered light. Absorption by atmospheric gases was kept at a tolerable level by circulation of dry nitrogen through the two housings of the instrument.

INTERPRETATION OF THE SPECTRA

From the structural point of view the molecules H_2O_2 and D_2O_2 may be described as slightly asymmetric, prolate tops. The degree of prolateness is characterized by the function

$$\beta = (I_{B,C}/I_A) - 1, \qquad [1]$$

where $I_{B,C}$ is the harmonic mean of the two large moments of inertia and I_A is the minor moment of inertia of the molecule. The rotational constants of H_2O_2 have been measured previously (10, 34) and from these, β turns out to be 11.2. Similar calculations for D_2O_2, assuming the same structural parameters, lead to $\beta = 6.4$. As for their asymmetry (I_B/I_C), it cannot be evaluated with the same certainty because of insufficient data, but estimates of the individual moments of inertia (3, 10) show that it must be less than 5%, even in the case of D_2O_2, unless the azimuthal angle ϕ is very different from 90°. The spectra of these molecules will therefore exhibit two different types of band structures; (*a*) perpendicular bands, corresponding to the symmetric vibrations, ν_1 to ν_4, (10) for which the change of electric moment is essentially perpendicular to the

top axis, and, (*b*) hybrid bands of predominantly parallel character arising from the asymmetric vibrations ν_5 and ν_6. The former, presumably rather weak in infrared, will have a single broad maximum with a rotational structure easily resolvable under the dispersion of a prism instrument. Indeed, the spacing of their rotational levels is 18 cm.$^{-1}$ for H_2O_2 and about half as much for D_2O_2.

On the other hand, the strong parallel component of the hybrid bands will show separate *P*, *Q*, and *R* branches but the rotational structure will not be perceptible because of too fine spacing: 1.65 cm.$^{-1}$ for H_2O_2 and 1.47 cm.$^{-1}$ for D_2O_2. The contour of these bands may be predicted from the equation of Gerhard and Dennison (9). Thus the separation of the *P* and *R* maxima, dependent on the various moments of inertia and the temperature, is calculated to be 43 and 45 cm.$^{-1}$ respectively for H_2O_2 and D_2O_2 at 70°C. Similarly the intensity of the zero *Q* branch relative to the total intensity of the parallel band should be 9% for H_2O_2 and 12% for D_2O_2. Finally, the perpendicular component of these hybrid bands may be expected to alter the over-all intensity distribution, particularly near the center, with more or less definite indications of a coarse rotational structure.

Spectra of the Vapor

(A) *The Torsional Oscillation Mode*

The outstanding feature in the present study of hydrogen peroxide vapor is certainly the band system of medium intensity extending from 16μ to beyond the transmission limit of KBr optics. For deuterium peroxide the corresponding band lies mostly outside the present range of our instrument; we hope to investigate it soon with CsBr optics. The tracing shown in Fig. 3 was recorded with a

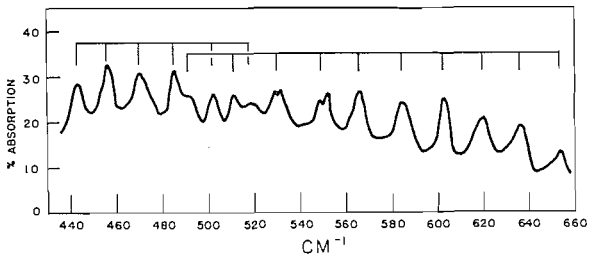

FIG. 3. The torsional oscillation band in hydrogen peroxide vapor.

slit equivalent to a resolved width of frequency band ranging from 4.4 to 6.7 cm.$^{-1}$. On the basis of location and relative intensity there is little doubt that this band arises from the torsional oscillation, or hindered internal rotation, mode ν_4. Qualitatively this oscillation may be expected to result in a fairly large change of the electric moment of the molecule perpendicular to the top axis. Analysis of the rotational structure (Table II) shows a spacing averaging 18 cm.$^{-1}$ on the short wavelength side, dropping suddenly to 16–15 cm.$^{-1}$ somewhere around 480 cm.$^{-1}$. This convergence is in opposite direction to that in the second (10) and third harmonics (34) of the O—H stretching vibrations and, for that reason, it is unlikely that we have here a single, or unsplit

TABLE II

APPROXIMATE FREQUENCIES AND TENTATIVE ASSIGNMENTS OF THE PRINCIPAL MAXIMA IN THE 17–22μ BANDS OF HYDROGEN PEROXIDE

vibrational transition. This, coupled with the irregular spacing observed between 485 and 520 cm.$^{-1}$, points strongly to the presence of two separate bands. From intensity distribution the center of the short wavelength component is tentatively located at 575 cm.$^{-1}$ and the other, around 465 cm.$^{-1}$. Obviously these figures, especially the latter, are rather uncertain because of the low intensity of incident radiation and the small number of maxima observed.

That this band is doubled confirms the previous interpretation of a similar feature in overtone bands namely, a double minimum in the torsional oscillation. Indeed, the other explanations considered seem most unlikely. For instance, it is doubtful that one of the two bands could be due to transition from an excited state such as $2\nu_4 - \nu_4$ because both components have about the same intensity and "borrowing" by coupling of levels is not expected in this case. Also, the high-frequency band is too intense to be an harmonic of some fundamental situated in the far infrared. The large doublet splitting, about 110 cm.$^{-1}$, is not surprising as the torsional oscillation is much more closely associated with the double minimum than the other vibrational levels. (Compare the inversion splitting of ν_1 and ν_2 in NH_3 (18) for instance.) It also confirms that one of the potential barriers must be fairly low. According to the model of Penney and Sutherland (26) rotation of the two O—H groups about the O—O bond is restricted by an asymmetric potential function having a high and low barrier in the *cis*- and *trans*-positions respectively. The height of the first, V_1, was estimated by them at 1 electron volt and that of the second V_2, at about half of that value. No complete theoretical treatment of the asymmetric potential function has been reported yet although various approximations have been suggested (22, 27). From electron density calculations Lassettre and Dean (19) arrived at values of 94° to 113° for ϕ, the azimuthal angle, with heights of potential barriers ranging from 8 to 21 kcal./mole for V_1 and from 2 to 10 kcal./mole for V_2. Therefore, the potential function generally assumed for the torsional oscillation in molecules such as ethylene,

$$V = \tfrac{1}{2}V_0(1-\cos 2\phi), \qquad [2]$$

where V_0 is the barrier of periodicity π, is not strictly applicable to the case of

hydrogen peroxide. If a periodicity of 2π is to be preserved, then a cosine function of the following form is the simplest possible one:

[3] $$V = \tfrac{1}{2}(V_1 - V_2)\cos\phi + \tfrac{1}{2}(V_1 + V_2)\cos^2\phi.$$

From this the position of the minima is given by

[4] $$\phi \text{ min.} = 2n\pi \pm \cos^{-1}[(V_2 - V_1)/2(V_2 + V_1)],$$

and a ratio of V_1/V_2 of about 3 is required to make $\phi = 105°$, the average estimated by Lassettre and Dean. In principle the energy levels could be found by replacing the potential function in the Schrödinger equation by V from [3], and would be given by the periodic eigenvalues of "a" in the following Mathieu-type equation:

[5] $$(d^2M/dx^2) + (a - b\cos 2x - c\cos^2 2x)M = 0,$$

[6] where $$a = 32\pi^2 I_r E/h^2,$$

[7] $$b = (16\pi^2 I_r/h^2)(V_1 - V_2),$$

[8] and $$c = (16\pi^2 I_r/h^2)(V_1 + V_2).$$

At present the lengthy calculations to determine how the eigenvalues of "a" depend on V_1 and V_2 do not seem justified for lack of enough accurate data.

Pending rigorous solution of the wave equation for the asymmetric function [3] various simplifications are necessary in correlating the experimental results. Thus, assuming a symmetrical twofold barrier [2], an average value of 520 cm.$^{-1}$ for the torsional frequency leads, through solution of the Mathieu equation, to a value of $V_0 = 6$ kcal./mole. About the same value was obtained from the perturbed oscillator treatment (20). A recent investigation of the microwave spectrum of hydrogen peroxide (24) has yielded a much lower value, *ca.* 320 cal./mole, also on the assumption of a symmetrical potential function. It is possible that this spectrum could be interpreted as well in terms of a function with a high and a low barrier.

On the other hand the difference between the calorimetric entropy at 25°C. and the calculated statistical entropy of hydrogen peroxide (13) corresponds to an hypothetical barrier $V_0 = 3.5$ kcal./mole. On the same basis the treatment suggested by Pitzer (27) for molecules with slightly asymmetric tops attached to a rigid frame yields the more reliable value 4.7 kcal./mole. Thus it appears fairly certain that the *trans*-barrier is appreciably lower than the *cis*-one. However, it could hardly be as low as suggested by the microwave spectrum because then an important fraction of the H_2O_2 molecules would possess a torsional energy greater than V_2 at moderate temperatures, and their symmetry would be effectively C_{2h} (23). In that respect it is unfortunate that the low volatility and thermal unstability of hydrogen peroxide make it impossible to measure the infrared spectrum or the heat capacity of the vapor as a function of temperature.

(*B*) *The O—O Stretching Mode*

Repeated scrutiny of the 11μ region in the spectrum of H_2O_2 vapor has failed to reveal any definite indication of the O—O vibration ν_3. Under the maximum

equivalent path-length attainable, absorption amounted to less than 3% in the range 830–920 cm.$^{-1}$ while it was complete for ν_6, the OH bending mode. (In D_2O_2 and HDO_2 the situation is less favorable because of the strong ν_6 band near by.) This remarkable fact, which, alone, is sufficient to rule out any tautomeric form of the molecule such as H_2O—O, has not been fully appreciated in previous investigations. One of us (10) reported a very weak maximum "hardly noticeable" in the vapor and assigned to it a value of 877 cm.$^{-1}$ largely on the faith of the corresponding Raman shift (6). As for the band of medium intensity found by Bailey and Gordon at 870 cm.$^{-1}$ (2), it must have resulted from condensation on the windows of the absorption cell as confirmed otherwise (10) by the resemblance of their spectra in both phases.

Indeed, it is a peculiarity of this frequency that it is much stronger, relatively speaking, in the condensed states than in the vapor. Such enhanced activity must be due to strong molecular association as it is not likely that the configuration of the free molecule is appreciably different from that in the liquid or the solid. X-ray investigations of the crystal structure of hydrogen peroxide (1) and its addition compound with urea (21) have shown azimuthal angles of about 94° and 106° respectively. Even when the hydrogen atoms of H_2O_2 are replaced by much heavier groups, as in SF_5—O—O—SF_5, the azimuthal angle remains nearly the same (107°±5° (17) from electron diffraction by the vapor). According to the C_2 model of H_2O_2 ν_3 must yield a perpendicular band with a single maximum, which makes its location still more problematic. The intensity, at any rate relatively low, would depend on the azimuthal angle, becoming zero for $\phi = 180°$. A consequence of this situation is that the frequency of ν_3 is not yet known accurately, having been measured so far only in the liquid and solid where it may be altered slightly by molecular interaction. Cf. the case of hydroxylamine (12). For that reason measurement of the Raman spectrum of hydrogen peroxide vapor would be a desirable, if difficult investigation.

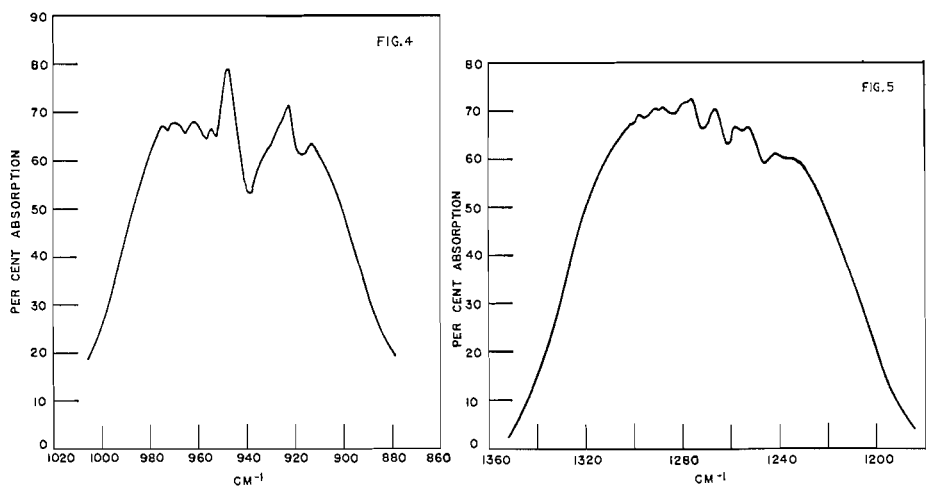

FIG. 4. The asymmetric OD bending frequency in deuterium peroxide vapor.
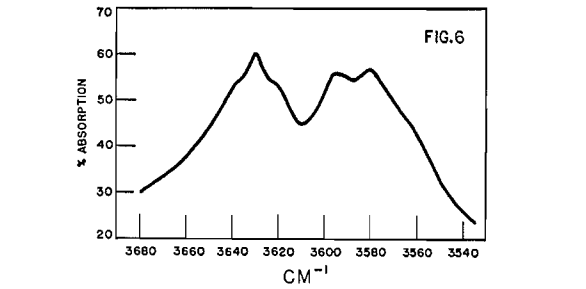
FIG. 5. The OH bending vibration ν_6 in gaseous hydrogen peroxide.

(C) The OH and OD Bending Modes

The asymmetric bending modes ν_6 are the most intense in the spectra of both peroxides, their central Q branch occurring at 1266 cm.$^{-1}$ in H_2O_2 and 947 cm.$^{-1}$ in D_2O_2. The first one was recorded with a fluorite prism and the second, with a rock salt prism; in both cases the resolution was about 4 cm.$^{-1}$. As predicted by the equation of Gerhard and Dennison (9) the Q branch is much stronger in D_2O_2 (Fig. 4) than in H_2O_2 (Fig. 5). It was not possible to evaluate the separation of the P and R maxima because of some coarse structure arising presumably from the perpendicular component. No regularity could be detected in this rotational structure, possibly on account of doubling of the bands. The prominent maxima on the low frequency side, specially in the case of D_2O_2, at 923 cm.$^{-1}$, resemble the satellite bands reported by Williams (32) in his study of formic acid. In general appearance both bands show pronounced asymmetry, the intensity gap between the P and Q branches missing in D_2O_2. Since other bands of both peroxides feature the same unequal intensity distribution it is doubtful if it arises from another coincident vibration, ν_2 in this case. Rather we believe there is an appreciable frequency difference between ν_2 and ν_6 on the basis of the following indirect evidence.

The spectrum of HDO_2 measured in that region showed very clearly the Q branch of the OOD bending vibration at 981 cm.$^{-1}$. By analogy with the



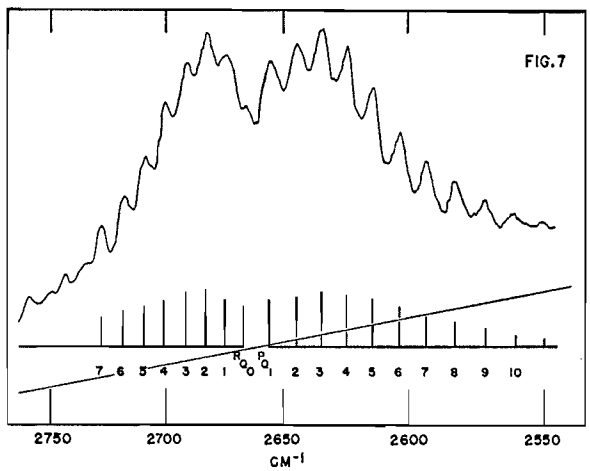


FIG. 6. The O—H stretching band ν_5 in hydrogen peroxide vapor.
FIG. 7. Rotational structure of the stretching band ν_5 in deuterium peroxide. (The sloping line corresponds roughly to the background.)

bending frequency in HDO, which occurs about halfway between those in H_2O and D_2O, we infer that ν_2 should be around $981+(981-947) = 1015$ cm.$^{-1}$ in D_2O_2. In fact a slight absorption was noticeable at 1007 cm.$^{-1}$ in the vapor of both D_2O_2 and HDO_2. The corresponding OOH bending mode could not be identified with certainty in H_2O_2 but, from the isotope shift, it may be expected to lie around 1350 cm.$^{-1}$ in that molecule. Consideration of various combination bands leads to the same conclusion, as explained below.

(D) The O—H and O—D Stretching Modes

Recording of the asymmetric stretching bands ν_5 was done under medium absorption with a LiF prism and a spectral half-width resolution of 9.7 cm.$^{-1}$ for H_2O_2 (Fig. 6) and 4.9 cm.$^{-1}$ for D_2O_2 (Fig. 7). Here the two peroxides show still greater differences than for the bending modes. While both bands have the same parallel contour, the coarse rotational structure of the perpendicular component is prominent in D_2O_2 but is missing completely in H_2O_2 although the resolution was sufficient to bring it out. This situation is reminiscent of the overtone band of hydrogen peroxide $\nu_1+\nu_5$ under high dispersion (10) in contrast with the corresponding band finely resolved in hydrogen persulphide (33). Still, the present circumstance may be fortuitous—overlapping by water vapor bands or doublet splitting—as there is no obvious reason why the perpendicular component should be much stronger in D_2O_2 than in H_2O_2.

The frequencies of the various maxima in Fig. 7 are listed in Table III together with the calculated rotational constants A′ and A″. The accuracy of these figures is estimated to be 4%. The band center was found from the equation of Dieke and Kistiakowsky (5) to be at 2661 cm.$^{-1}$. For the H_2O_2 band the center was taken at the absorption minimum, 3610 ± 5 cm.$^{-1}$. Like the others these values are not corrected for vacuum.

(E) Overtone Bands

An interesting result of this investigation is the resolution of the hybrid band at 3.8μ in H_2O_2 vapor, the origin of which had remained uncertain until

now. With its definite parallel-type contour and prominent rotational structure (Fig. 8) it can only arise from combination of the two bending modes $\nu_2+\nu_6$ since both $2\nu_2$ and $2\nu_6$ would be predominantly perpendicular. Besides

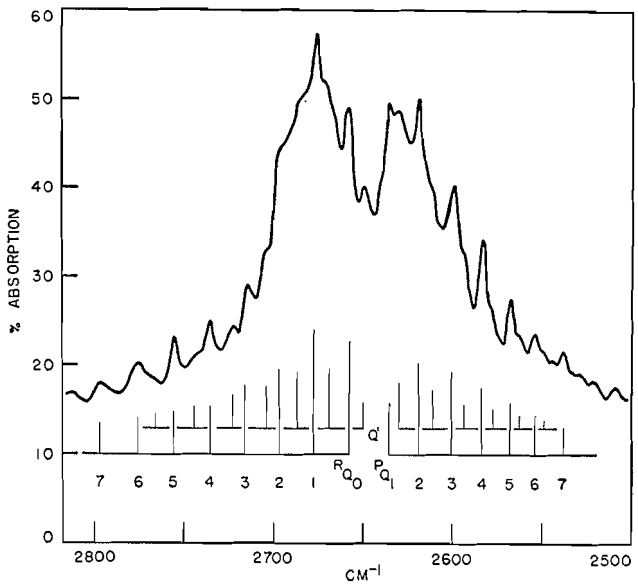

FIG. 8. Overtone band at 3.8μ in gaseous hydrogen peroxide.

they should be very weak, and for different reasons: $2\nu_6$, because even harmonics of unsymmetrical frequencies are usually missing in non-linear molecules, and $2\nu_2$, because of the weakness of its first harmonic. The present assignment leads to an unexpected anharmonicity as the frequency of the combination band, 2647 cm.$^{-1}$, is higher, instead of lower, than the sum of its components, about 2615 cm.$^{-1}$ if the above deduced value for ν_2 is correct. The difference cannot be due entirely to uncertainty in the latter estimate. Indeed, an increase of more than 30 cm.$^{-1}$, making ν_2 greater than 1380 cm.$^{-1}$, would hardly leave any shift for this frequency in the condensed phases. In fact it has been observed at 1400 cm.$^{-1}$ in the Raman effect of the pure liquid (29). That the unusual anharmonicity associated with $\nu_2+\nu_6$ is real is further confirmed by the frequency of this band in the Raman spectrum, *ca.* 2815 cm.$^{-1}$ (29).

Recordings of this band made under maximum absorption revealed some secondary peaks between the main ^PQ and ^RQ sub-bands particularly at 2650 and 2723 cm.$^{-1}$. These could be due to absorption from the first excited level of ν_4 although we are inclined to consider them as indications of doubling in view of their fair intensity and the presence of the same feature in the other two resolved overtones. The separation of the doublet at the center, 10 cm.$^{-1}$ from the minima of intensity, seems plausible in that conjecture. The irregular convergence of the rotational structure (Table IV) is probably exaggerated by the low resolving power available. Consequently the rotational constants derived therefrom would be much less accurate than those from the two over-

Note: The primed symbols refer to the secondary band.

tones of the O—H stretching frequencies (10, 34). Incidentally when the latter are compared with the present band the difference in general appearance is striking. In particular no ^PQ or ^RQ branches are missing near the center (Fig. 8). The reason for such differences is not clear at present. For the corresponding band in D_2O_2 at 5μ absorption was too low to reveal any structure. Similarly, the combination $\nu_1+\nu_5$ appeared as a hybrid band at 5240 cm.$^{-1}$. Finally a few very weak maxima were noticed in H_2O_2 vapor at 4465, 4835, and 4955 cm.$^{-1}$. The first of these can be assigned unambiguously to $\nu_3+\nu_5$ which gives a reasonable anharmonicity, 35 cm.$^{-1}$. As for the other two, their separation is far too great for the P and R branches of a single band, so that they must arise from different combinations among the various possibilities listed in Table I.

Spectra of the Condensed States

(F) Liquid and Solid

Strong molecular association in the peroxides makes a spectroscopic study of their condensed states of special interest. On the other hand, and for the same reason, little information may be expected from it in connection with the structure of the free molecule. In the region covered by the LiF prism six weak maxima were found in liquid H_2O_2 (Figs. 9 and 10) and four in liquid D_2O_2 (Table I). Of the latter, two are rather uncertain (at 6110 and 7215 cm.$^{-1}$) as they were observed in a dilute solution (15–20%) and the maxima are probably shifted appreciably by dilution (compare Figs. 9 and 10). For crystalline H_2O_2 the present measurements agree quite well with those of Taylor (30) except for the combination band reported by him at about 2740 cm.$^{-1}$ which we found at a higher frequency and resolved into two peaks at 2840 and 2930 cm.$^{-1}$. Thus the temperature shift is really in the same direction as for the fundamentals ν_2 and ν_6 so there is no objection to an assignment to that combination; this leads to a positive anharmonicity as for the vapor band. The weaker component at 2930 cm.$^{-1}$ may be due to $2\nu_2$ and/or to a ternary combination with a lattice mode. In crystalline D_2O_2 the frequency of ν_4 shows the normal isotope shift with the low-frequency band in H_2O_2. Therefore it is likely that the value given by Taylor for this mode in liquid D_2O_2, (538 cm.$^{-1}$) is too high. Attempts to check this point were unsuccessful. No splitting of the bending OD frequencies could be detected contrary to H_2O_2, although the peak at 1000 cm.$^{-1}$ (Fig. 11) appears slightly asymmetric.

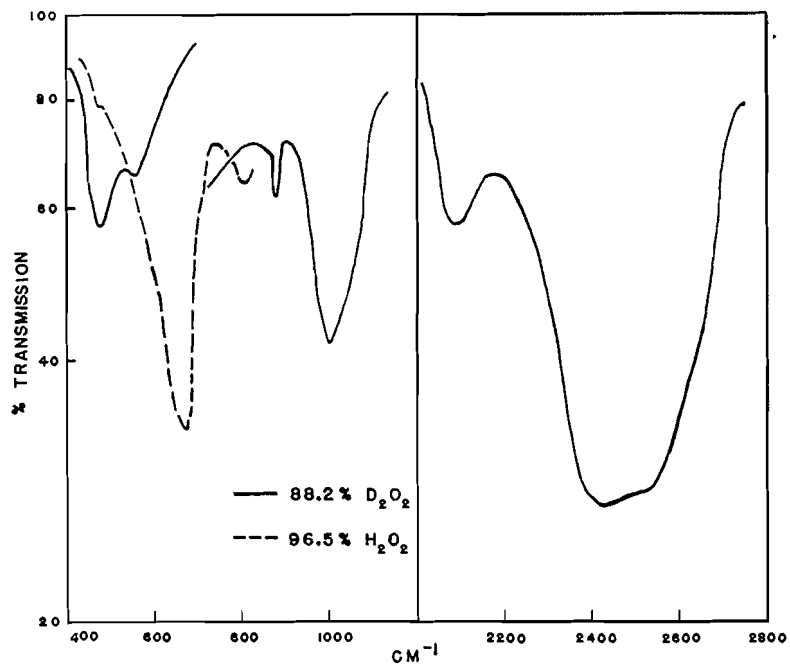

FIG. 11. Absorption spectra of crystalline H_2O_2 and D_2O_2.

(G) Solutions in Carbon Tetrachloride

Just as in the case of water (7) the absorption spectra of H_2O_2 and D_2O_2 dissolved in a non-polar solvent have provided valuable information on the O—H and O—D stretching modes. Mixtures of the two peroxides were particularly useful in that respect. It must be remembered here that an equimolar mixture of H_2O_2 and D_2O_2 will contain approximately 25 mole % of each constituent along with the hybrid compound HDO_2. In addition the molecular species H_2O, D_2O, and HDO will also be present in various amounts depending on the initial concentration of the peroxides. The H_2O_2 used was over 99% pure and the D_2O_2, about 50% in D_2O; the CCl_4 always contained some H_2O.

The results, shown in Table V and Figs. 12 and 13, lead to some interesting correlations the most striking of which is the exact coincidence of the O—H stretching frequency in HDO_2 with ν_5 in H_2O_2 and similarly, of the O—D

frequency in HDO_2 with ν_5 in D_2O_2. In HDO the O—H and O—D frequencies occur midway between the symmetric and asymmetric vibrations of the corresponding parent molecules.* By analogy the same relationship may be expected to abide in the peroxide molecules from which, therefore, it follows that the symmetric and asymmetric modes ν_1 and ν_5 should have nearly the same frequency. This conclusion, in harmony with the loose coupling between these two modes, explains why only one O—H stretching vibration has been observed so far, even in the crystal at low temperatures. The weak band found by Taylor (30) shifted some 135 cm.$^{-1}$ from the main O—H band in the Raman spectrum of the crystal was correctly assigned by him to a combination with a lattice vibration since the same difference appears between other frequencies in the solid. It may be noted here that assignment of the two H_2O_2 bands at 4818 and 4919 cm.$^{-1}$ to combination of one stretching with one bending mode is consistent with the previous conclusions, $\nu_1 \approx \nu_5$ and $\nu_2 \approx \nu_6 + 90$ cm.$^{-1}$.

It is instructive to compare the shifts of the various frequencies in the condensed states of the peroxide molecules with those of water. The figures summarized in Table VI are only approximate on account of the width of the absorption maxima. That the shifts of the O—H stretching frequency in peroxides are only half of those in water molecules might be considered an indication of weaker hydrogen bonds in the former. Other physical properties

**The present results for D_2O and HDO dissolved in carbon tetrachloride agree with those of a recent investigation of HDO vapor (4) as regards the frequency of ν_3 in that molecule.*

TABLE VI

FREQUENCY SHIFTS (IN CM.$^{-1}$) FOR WATER AND PEROXIDE MOLECULES IN CONDENSED PHASES

	H_2O_2	D_2O_2	H_2O	D_2O
Vapor – crystal (at −70°C.)				
ν bend.	−115	−53	−55	−30
ν stretch.	290	190	515	350
Vapor – solution in CCl_4				
ν stretch.	56	50	37	30

have been interpreted in the sense of nearly equal energy of these bonds in both compounds (15, 25). Judging from the shortest O—H · · · O distances in the crystals the difference cannot be very large since these distances are 2.78 Å in solid H_2O_2 (1) and 2.76 Å in ice. However, whereas in the latter all the hydrogen bonds are of equal length and tetrahedrally oriented, in H_2O_2 there are two slightly longer O—H · · · O distances per molecule, namely 2.90 Å. Comparison between the two types of molecules is further complicated by the fact that the shifts of the bending frequency are about twice as great in peroxides as in water. On the other hand the shifts in a non-polar solvent involve mainly van der Waals forces and this is confirmed by the observation that for peroxide and water solutions in carbon tetrachloride the shifts are roughly in the same ratio as the polarizability of the two molecules, 2.31 and 1.48 × 10^{-24} cm.^{3} (15).

Structural Parameters

The above data were used to calculate the force constants and bond lengths and angles in the peroxide molecule. All these have been published elsewhere (11) except for the two following points: First, the resolution of the rotational structure of a D_2O_2 band (Table III) makes possible some refinement of the molecular parameters. Thus the locus of points corresponding to the X_{01}

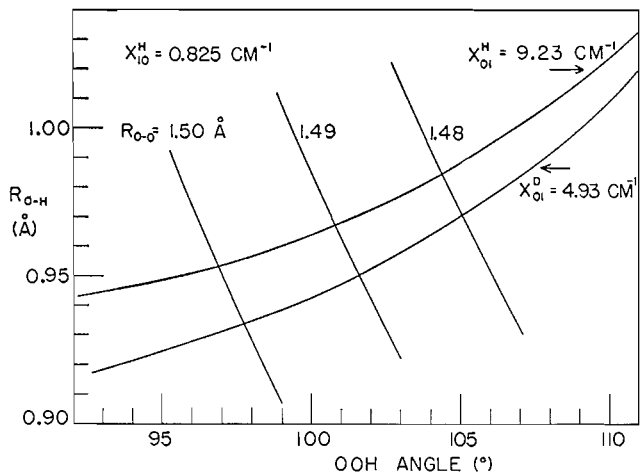

FIG. 14. Locus of O—H distances and OOH angles fitting the rotational constants of H_2O_2 and D_2O_2.

rotational constant for D_2O_2, 4.93 cm.$^{-1}$, has been added to the already published graph in Fig. 14. From the nearness of loci for the two isotopic molecules it is clear that more accuracy is needed for the D_2O_2 constant X_{01} in order to improve the situation significantly. The other point concerns the second rotational constant of H_2O_2 in the ground state, $X_{10} = 0.825$ cm.$^{-1}$ (34) contribution of which was not included in the published calculations. Since it corresponds to the harmonic mean of the two large moments of inertia it is very sensitive to changes in the O—O distance. Calculated values of this constant for $r_{O-O} = 1.48$, 1.49, and 1.50 Å have been plotted in Fig. 14 against r_{O-H} and α_{OOH}, the azimuthal angle being taken as 90°. The intersection of these curves shows that $r_{O-O} = 1.49 \pm 0.01$ Å in exact agreement with the X-ray data on the crystal (1) and within the limits of accuracy of the electron diffraction results (14). This datum is of special interest in connection with the single bond covalent radius of oxygen.

RÉSUMÉ

Le spectre infrarouge du peroxyde d'hydrogène a été mesuré de nouveau avec un appareil à prisme couvrant la région de 1.5 à 25μ. Une bande double, dont les centres sont situés aux environs de 460 et 575 cm.$^{-1}$, apparaît dans la vapeur due à la torsion des groupes OH. La bande rapportée précédemment à 3.8μ a été résolue; elle est attribuée à la combination des modes de déformation $\nu_2+\nu_6$, ce qui implique une anharmonicité positive. Dans le spectre d'absorption du liquide on a observé quatre nouvelles bandes.

On a également mesuré le spectre du peroxyde de deutérium dans les mêmes conditions. On a réussi à résoudre la structure fine d'une des fondamentales, ν_5, à 2661 cm.$^{-1}$, ce qui a permis de calculer les constantes de rotation de la molécule isotopique. Des mélanges des deux peroxydes contenant environ 45% de la molécule hybride HDO_2 ont aussi été étudiés. Enfin on a mesuré l'absorption de ces trois molécules en solutions diluées dans un solvant non polaire. A partir des nouvelles données on a obtenu les constantes de force des diverses liaisons ainsi que les paramètres suivants:

$$r_{O-O} = 1.49 \pm 0.01 \text{ Å},$$
$$r_{O-H} = 0.97 \pm 0.01 \text{ Å},$$
$$\alpha_{OOH} = 100 \pm 2°.$$

A COMPARATIVE STUDY OF THE DEHYDRATION KINETICS OF SEVERAL HYDRATED SALTS[1]

By R. C. Wheeler[2] and G. B. Frost

ABSTRACT

Rates of dehydration under full vacuum, and also as the pressure of water vapor due to the dehydration process was allowed to increase, have been determined for a number of hydrated salts. The dehydration of manganous sulphate tetrahydrate, zinc sulphate heptahydrate, nickel sulphate hexahydrate, and magnesium sulphate heptahydrate has been found to proceed through the formation of amorphous intermediates, the last two of these being very stable. The dehydration of nickel nitrate hexahydrate, magnesium nitrate hexahydrate, and probably of ferrous sulphate heptahydrate and cobalt chloride hexahydrate at very low pressures takes place with the formation of crystalline intermediates. The results obtained are discussed in relation to the dependence of rate of dehydration on water vapor pressure previously reported for copper sulphate pentahydrate and for manganous oxalate dihydrate.

INTRODUCTION

It has been shown in an earlier paper (3) that when powdered samples of copper sulphate pentahydrate are dehydrated under vacuum at moderate temperatures, the dehydration proceeds to the monohydrate stage with a gradual decrease in rate. The product is amorphous in the sense that it does not diffract X-rays. However, if similar samples are placed in a closed and initially evacuated space, and the water vapor pressure due to the dissociation of the hydrate allowed to increase in the vessel, the rate of dehydration at first decreases to a minimum value, then increases to a value much larger than the minimum rate, this being followed, in turn, by a decline. The end product formed under these conditions is crystalline.

The minimum in rate occurs at a water vapor pressure of approximately 0.25 mm. and the periods of acceleration and decline, over a range in pressure of only a few millimeters, these pressures being far below those corresponding to possible phase equilibria. This marked effect of water vapor in a very narrow region of pressure has been observed also by carrying out dehydrations at a series of controlled pressures. The dehydration curves obtained for pressures below 0.25 mm. are quite different than for those above this value, the former showing a gradual loss in weight with time, while the latter show induction periods, the duration of which depends on the pressure.

The behavior of copper sulphate pentahydrate in this respect is similar to that of manganous oxalate dihydrate (6, 7), which for many years was regarded as unique in the dependence of its rate of dehydration on water vapor pressure. On vacuum dehydration this salt hydrate also yields a product which does not diffract X-rays.

Explanations of the form of these rate curves have been discussed elsewhere (1, 3, 4). The initial fall in rate is probably due to the retarding effect of water

[1]*Manuscript received November 16, 1954.*

[2]*Present address: Imperial Oil Fellow in Chemistry, Cambridge University.*

vapor on diffusion through a transition layer of amorphous material formed during the initial stages of dehydration, and the intermediate acceleration in rate, to an increase in porosity occurring on crystallization of the amorphous product in the presence of adsorbed water. The final decline is probably due to the gradually increasing impedance of the crystalline layer.

The purpose of the present work has been to survey the dehydration kinetics of a number of hydrated salts in order to obtain information regarding the generality of these effects. Rate determinations have been carried out for dehydrations at pressures of 10^{-5} mm. or less (designated as vacuum dehydrations in the following) and also while the pressure due to the liberated water vapor increased. For convenience, these latter are referred to as "increasing pressure" dehydrations. Determinations of rates of dehydration at externally controlled and constant pressures of water vapor have not been made in this work, although they give much more detailed information regarding the nature of the processes involved. However, such experiments are very time consuming, and it was desired to obtain comparative data for as many salts as possible.

EXPERIMENTAL METHOD

The salts used were reagent grade materials, recrystallized twice, air-dried, and screened, the "through 60 mesh on 80 mesh" fraction being used.

The essential features of the apparatus have been described (3). Powdered samples were placed in a small basket made of 100-mesh copper gauze, and suspended from a quartz spiral. The water vapor pressure in the system was measured by means of an oil manometer which had a conventional vertical arm and also an inclined arm for fine sensitivity in low pressure ranges. Readings of spiral extension and of pressure were made with a rigidly mounted cathetometer.

Vacuum dehydrations were carried out by allowing small samples (approximately 50 mgm. in most cases) to dehydrate while the pumps were in operation. Readings were plotted as weight-loss versus time. For several salts these curves were found to present points of interest, but they also served to establish the composition of the dehydration product. Increasing pressure dehydrations were carried out in the following manner. The samples were nucleated by allowing dehydration to proceed under vacuum to 10% of the total possible weight loss as determined by vacuum dehydration. The spiral case was then closed off from the pumps and the samples allowed to dehydrate and slowly build up a pressure of water vapor in the system. Readings of weight-loss were commenced at the beginning of the nucleation period, and those of pressure, at the time of closing off the spiral case, both of these being continued at a series of times for several hours. Determinations of rates of dehydration were made by evaluating tangents to the weight-loss versus time curves at a series of time values.

X-ray powder photographs were made using copper K_α radiation. For convenience, the term "X-ray amorphous" is used to describe products for which no diffraction lines were observed.

RESULTS

(1) *Manganous Sulphate Tetrahydrate*

Vacuum dehydration at 40°C. resulted in the smooth continuous weight-loss versus time curve shown in Fig. 1 (lower curve) the end product being of the monohydrate composition.

The results obtained on dehydration at 50°C. as the pressure of water vapor in the system increased are shown in Fig. 2.

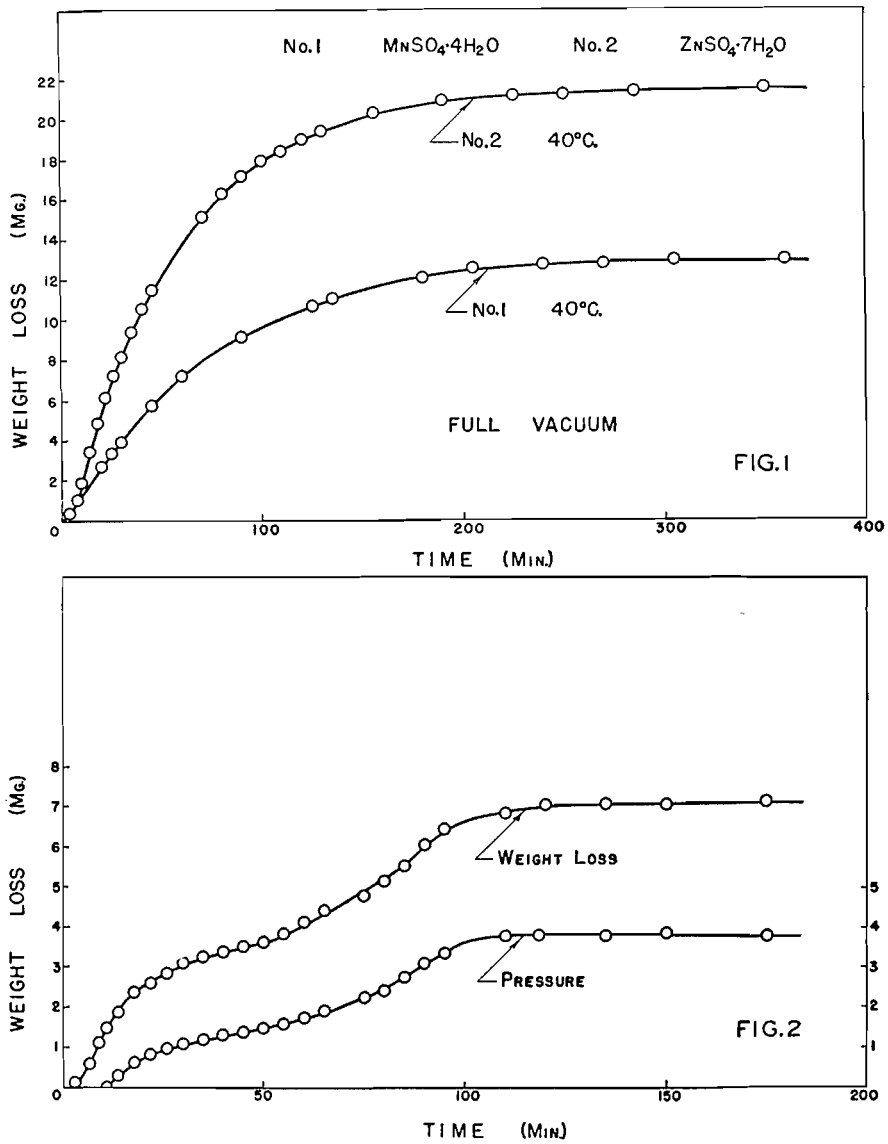

FIG. 1. The dehydration of zinc sulphate heptahydrate and of manganous sulphate tetrahydrate under vacuum.

FIG. 2. The dehydration of manganous sulphate tetrahydrate with increasing pressure of water vapor.

Following the period of nucleation under vacuum, the slope of the weight-loss curve gradually decreases as the pressure in the system becomes greater. The curve flattens somewhat at a weight-loss of about 3.5 mgm. which corresponds roughly to the trihydrate composition. An accelerated rate is then observed followed by a decline, the slope becoming zero at the dihydrate stage. These rates of dehydration plotted against the pressure, are shown in Fig. 3. Although the decline in rate to a minimum value, followed by an accelerated period, is similar to that reported for copper sulphate pentahydrate and for manganous oxalate dihydrate, the actual weight-loss versus time curve (Fig. 2) is slightly different in that a fairly rapid weight-loss persists for some time after the sample is exposed to water vapor, whereas with copper sulphate pentahydrate an induction period occurs almost immediately.

Unfortunately, X-ray data could not be obtained for this salt with the copper target available, since the absorption of the radiation was strong, resulting in fluorescent radiation.

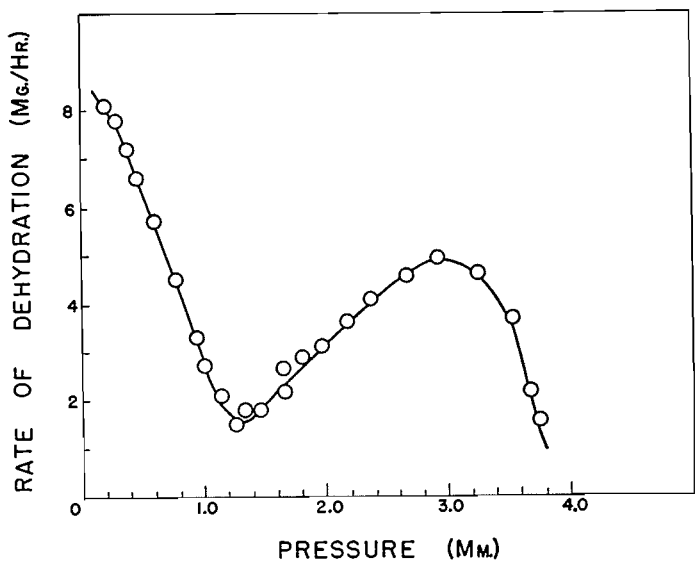

FIG. 3. The change in rate of dehydration of manganous sulphate tetrahydrate with pressure increase.

(2) *Zinc Sulphate Heptahydrate*

Vacuum dehydration at 40°C. again resulted in a smooth continuous curve (upper curve, Fig. 1), the end product being stoichiometrically of the monohydrate composition, and X-ray amorphous.

Measurements made at increasing pressure, and at 40°C., are shown in Fig. 4.

A small but reproducible induction period occurred immediately after nucleation, corresponding to the longer induction period observed for copper sulphate pentahydrate. Following this, the weight-loss curve has a slightly concave portion followed by a slightly convex portion, there being no clearly

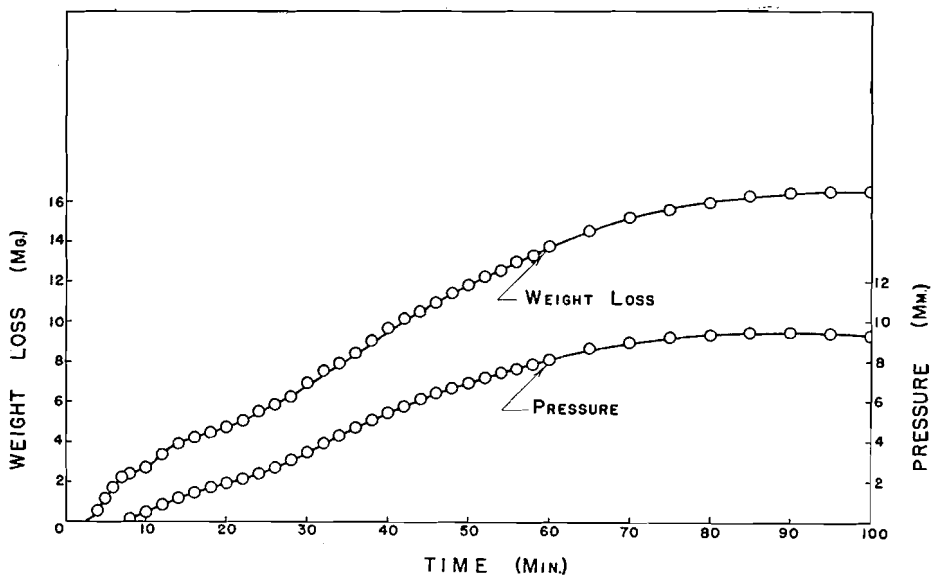

FIG. 4. The dehydration of zinc sulphate heptahydrate with increasing pressure of water vapor.

defined induction period. This resulted in two minima being obtained when the rate of dehydration was plotted against the pressure, as shown in Fig. 5.

X-ray powder photographs of the products obtained from these increasing pressure dehydrations showed a clearly defined diffraction pattern of monohydrate lines. Patterns identical with these were obtained when sealed samples of the amorphous product formed on vacuum dehydration were allowed to stand for several days.

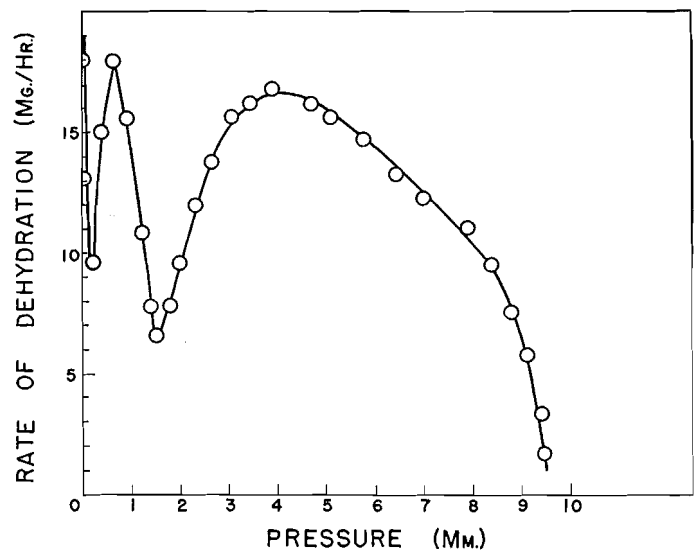

FIG. 5. The change in rate of dehydration of zinc sulphate heptahydrate with pressure increase.

(3) *Ferrous Sulphate Heptahydrate*

Dehydration under vacuum again exhibited a continuous loss of water from the heptahydrate to the monohydrate, the curve being similar to those shown in Fig. 1.

The weight-loss curve obtained on dehydration at increasing pressure at 60°C. is shown in Fig. 6.

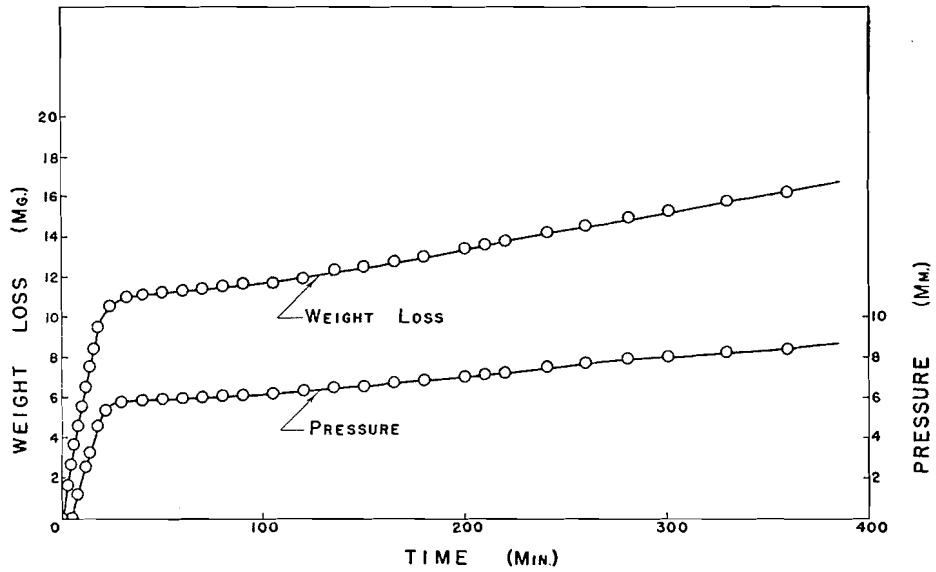

FIG. 6. The dehydration of ferrous sulphate heptahydrate with increasing pressure of water vapor.

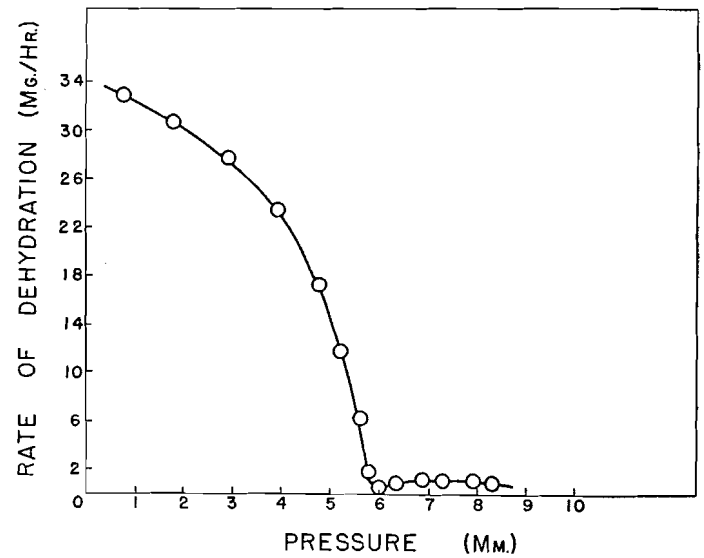

FIG. 7. The change in rate of dehydration of ferrous sulphate heptahydrate with pressure increase.

Following nucleation, rapid dehydration continued to somewhat beyond the tetrahydrate composition where an induction period set in followed by a slow increase in rate. This increase was diminished as the dehydration temperature was lowered, no increase being observed in a 21 hr. period at 40°C. The rate of dehydration at 60°C., plotted against the water vapor pressure, is shown in Fig. 7.

The curve is similar in character to that shown in Fig. 3, although the secondary increase in rate is much smaller, and the minimum occurs at a much higher pressure. It was not possible to obtain X-ray diffraction patterns for this salt for the reason that has been mentioned for manganous sulphate.

(4) *Nickel Nitrate Hexahydrate*

Vacuum dehydrations at several temperatures resulted in curves of different character than those described in the foregoing; the curve obtained at 40°C. is shown in Fig. 8, those obtained at other temperatures being similar. The initial loss of water is rapid and the rate nearly linear. After a weight-loss of about 6 mgm., the curve transforms to a second region which is also nearly linear, and then declines. If the two linear sections are extended to point A (Fig. 8), the point of intersection is found to be at approximately the tetrahydrate composition. The slopes of these linear portions were found to increase with temperature.

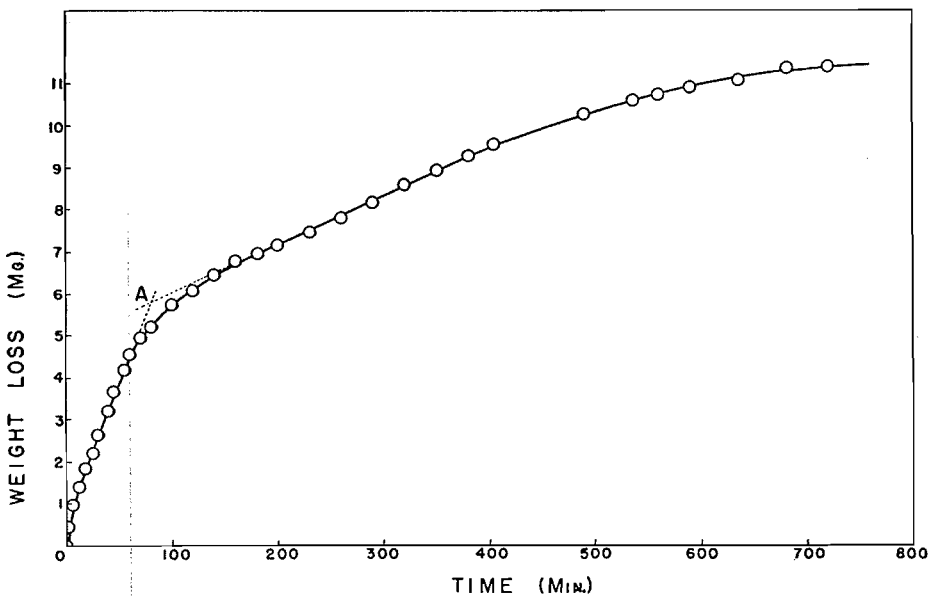

FIG. 8. The dehydration of nickel nitrate hexahydrate under vacuum.

The end product had the dihydrate composition. It appears, therefore, that under vacuum, dehydration takes place fairly rapidly to the tetrahydrate state, followed by the dehydration of this intermediate product to the dihydrate.

Unlike the examples reported in the foregoing, the end product of vacuum dehydration gave a definite X-ray diffraction pattern. However, if the time of preparation for the exposure were made as short as possible, the diffraction lines were very faint. It is possible that an amorphous material of very low stability was produced, subsequent handling being sufficient to cause the commencement of crystallization.

For dehydrations carried out at increasing pressure, an induction period was observed at the tetrahydrate stage followed by a slow and gradual increase in rate, the curves resembling closely those obtained for ferrous sulphate heptahydrate. Close examination of X-ray diffraction patterns obtained indicated the presence of tetrahydrate and dihydrate lines. It appears therefore that the first step in this process is the formation of crystalline tetrahydrate which then nucleates and forms crystalline dihydrate at a much slower rate. The rate of dehydration plotted against pressure is shown in Fig. 9, the curve again resembling that obtained for ferrous sulphate heptahydrate.

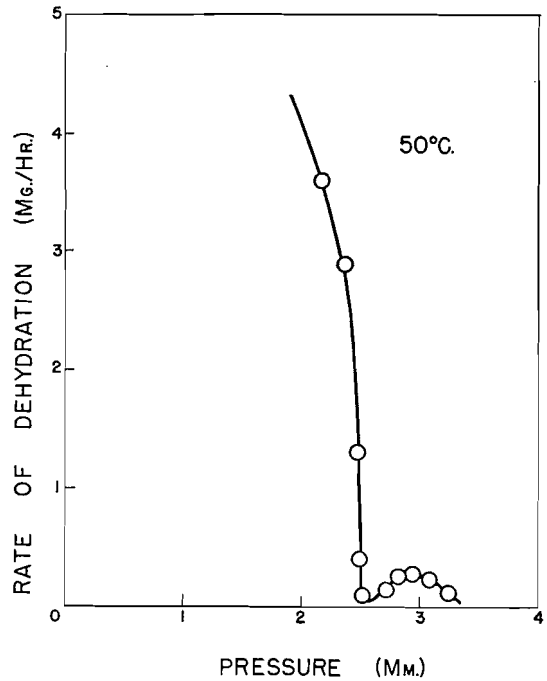

FIG. 9. The change in rate of dehydration of nickel nitrate hexahydrate with pressure increase.

The possibility of the formation of a basic salt in the dehydration process has been disregarded since it was found that the product formed both on vacuum and increasing pressure dehydration gave a pattern of only hexahydrate lines after standing in the room atmosphere for a few hours.

(5) *Magnesium Nitrate Hexahydrate*

Preliminary experiments with this salt indicated that effects occurred which were quite different from those observed for the other salts studied. Conse-

quently a number of dehydrations were carried out at several temperatures. The details of the experiments are given in Table I.

TABLE I

DEHYDRATION DATA FOR MAGNESIUM NITRATE HEXAHYDRATE

9	50	Increasing pressure	1415	35.4	3.42
10	40	Vacuum	35	32.3	1.89

Weight-loss versus time curves for the vacuum dehydration experiments Nos. 1, 3, 5, and 7 of Table I are shown in Fig. 10.

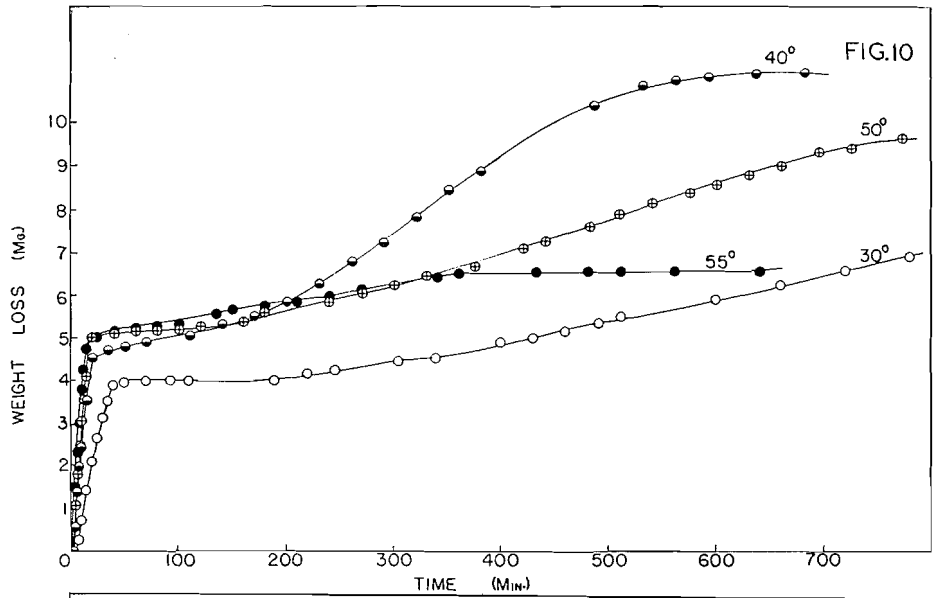
These dehydrations all displayed an induction period setting in at the tetrahydrate composition. These vacuum dehydration curves are, therefore, of the type which has been previously associated with dehydrations at increasing pressure. Furthermore, the period of acceleration following the induction period shows an interesting temperature dependence, the rate at 40°C. being higher than that at 30°C. and then declining as the temperature is raised.

Rate curves plotted against time, for these temperatures, are shown in Fig. 11. These curves show the minima and accelerated rates associated with increasing pressure dehydrations in the foregoing.

The end product of the vacuum dehydrations was found to be crystalline dihydrate, well defined and characteristic diffraction patterns being obtained. Clearly defined tetrahydrate lines were obtained with samples (Expt. 10) partially dehydrated to this stage. It appears quite definite, therefore, that on vacuum dehydration this salt forms crystalline tetrahydrate which then nucleates and forms crystalline dihydrate at rates which are markedly temperature dependent.

Experiments 8 and 9 of Table I were carried out at increasing pressure. Dehydration was observed to take place rapidly to the tetrahydrate stage at which an induction period set in, followed at 50°C. by a slow increase in rate, while at 40°C. no increase could be detected. The rate versus pressure curve obtained at 50°C. was found to be similar to that reported above for nickel nitrate hexahydrate.

Although many basic hydrated salts of magnesium have been reported, the formation of these takes place at dehydration temperatures exceeding 150°C. When the crystalline products obtained in the present experiments were allowed to stand in the humidity of the ordinary room atmosphere reversion to the hexahydrate crystalline form occurred.



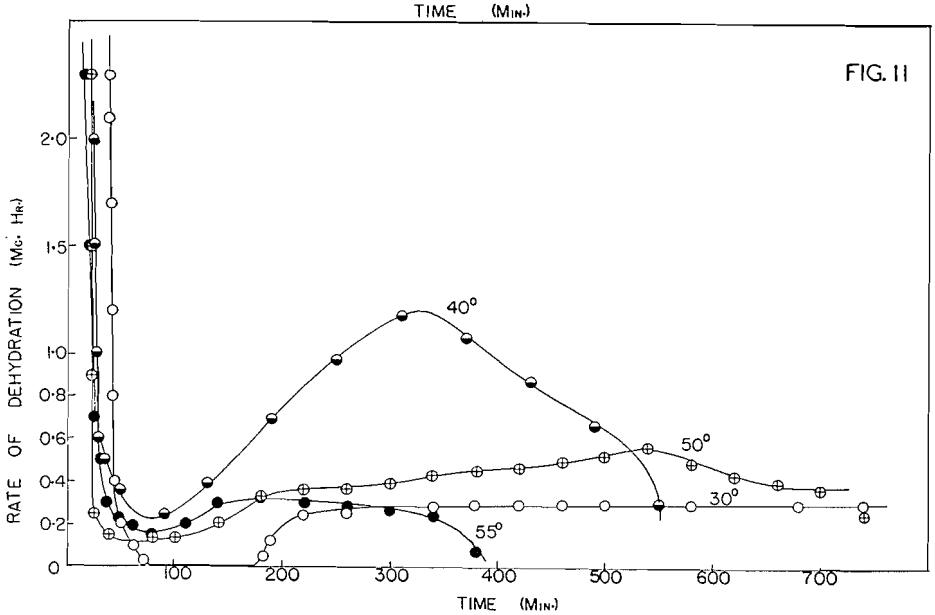


FIG. 10. The dehydration of magnesium nitrate hexahydrate under vacuum at several temperatures.

FIG. 11. The change in rate of dehydration of magnesium nitrate hexahydrate at several temperatures.

Since the dehydration from the tetrahydrate to the dihydrate stage has a temperature coefficient exhibiting a maximum in the region of 40°C., a careful survey of the rates in the temperature range from 30°C. to 55°C. was carried out. In order to make a comparison, the maximum rate of dehydration was found from the rate versus time curves (or from rate versus percentage decomposition curves) and converted to a rate per milligram of sample. (The com-

parison of maximum rates rather than rates obtained at the same percentage decomposition has been made in view of a suggestion by Colvin and Hume (1) that the maximum rates correspond to approximately the same interfacial conditions.) The results of these calculations are given in Table II and are

TABLE II

CALCULATED MAXIMUM RATES

Expt. No.	Temp., °C.	Maximum rate, mgm./hr./mgm.	Point Fig. 12
1	30.4	10.06	A
2	35.1	44.62	B
3	40.2	48.20	C
4	45.0	37.81	D

6	50.1	22.70	F
7	55.1	12.06	G

plotted in Fig. 12. From this figure it is clear that at temperatures above approximately 40°C., the mechanism of the dehydration process is in some way adversely affected by increase in temperature, the rate of dehydration becoming negligible above approximately 55°C.

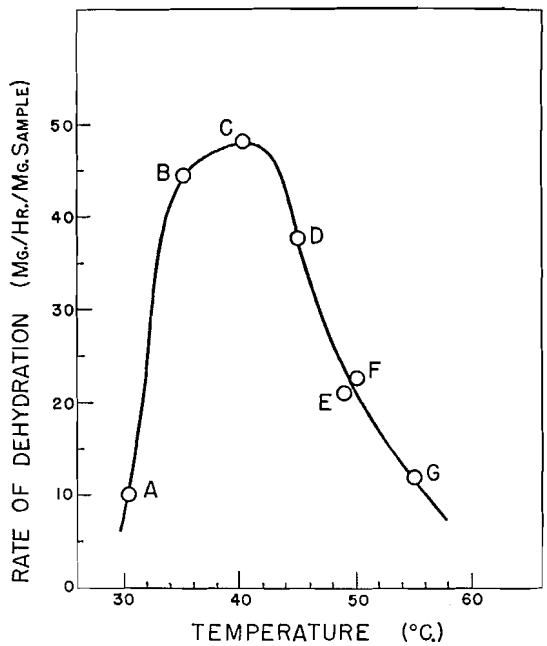

FIG. 12. The dependence of the second stage of the rate process on temperature for magnesium nitrate hexahydrate.

(6) *Magnesium Sulphate Heptahydrate*

Vacuum dehydration of this salt resulted in a smooth continuous curve of the same type as those shown in Fig. 1. The end product had the monohydrate

composition and was X-ray amorphous. Lines characteristic of the crystalline monohydrate appeared when amorphous samples were sealed and heated for two days at 130°C.

However, the behavior of this salt on dehydrating at increasing pressure was very different from that of any of the salts mentioned in the foregoing. It was found that the rate of dehydration gradually decreased with corresponding increase in pressure, no induction periods being observed. The product obtained was X-ray amorphous. The change of rate with pressure increase is shown in Fig. 13.

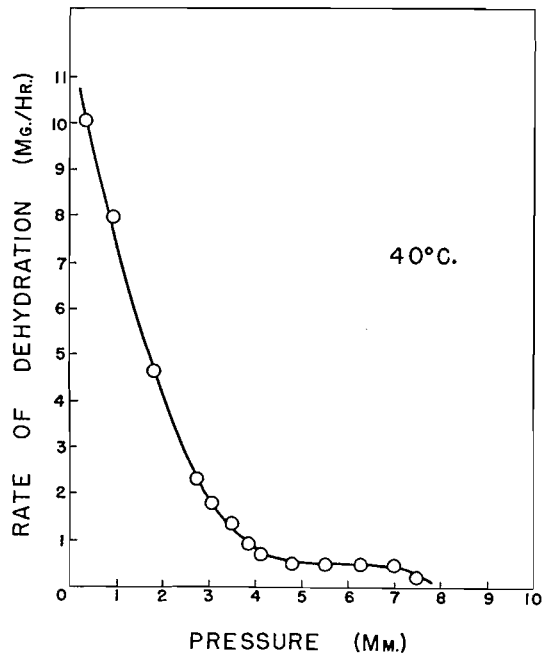

FIG. 13. The change in rate of dehydration of magnesium sulphate heptahydrate with pressure increase.

(7) *Nickel Sulphate Hexahydrate*

This salt was found to behave in similar manner to magnesium sulphate heptahydrate. The product of vacuum dehydration had the monohydrate composition and was X-ray amorphous. The effect of increasing water vapor pressure on the dehydration rate is similar to that shown in Fig. 13. Faint hexahydrate lines were obtained in this sample, indicating incomplete dehydration.

(8) *Cobalt Chloride Hexahydrate*

Vacuum dehydration resulted in curves similar to those obtained for nickel nitrate hexahydrate. These are shown in Fig. 14.

The rate of dehydration proceeds rapidly to the dihydrate stage followed by a much slower rate. Prolonged dehydration yields a product having the mono-

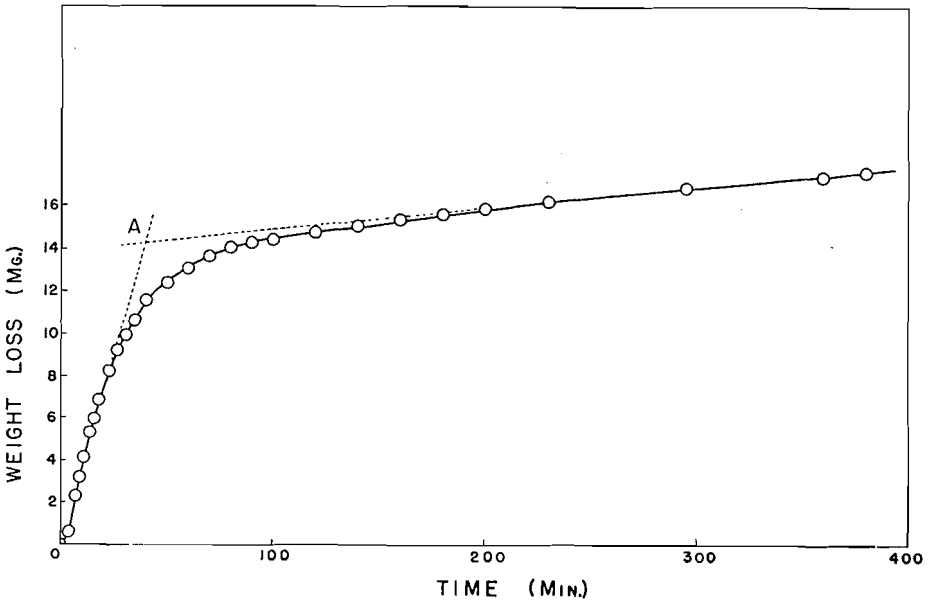

FIG. 14. The dehydration of cobalt chloride hexahydrate under vacuum.

hydrate composition. Unfortunately, the crystalline or amorphous character of the end product could not be definitely determined by X-ray diffraction for reasons which have been mentioned.

On dehydrating at increasing pressure, a rapid loss of water occurred to approximately the dihydrate composition, beyond which no change was observed. The change in rate with pressure increase is shown in Fig. 15.

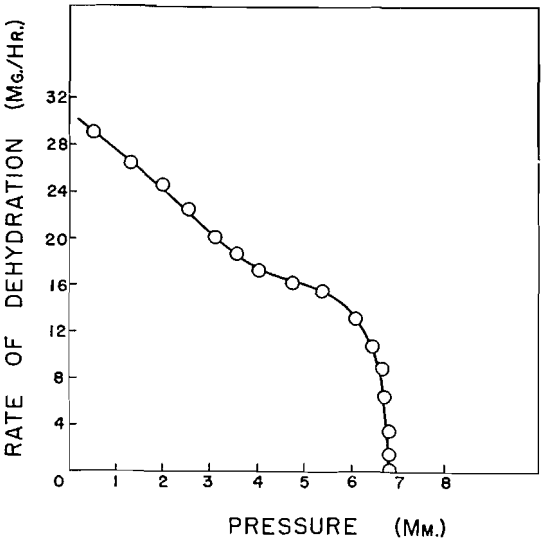

FIG. 15. The change in rate of dehydration of cobalt chloride hexahydrate with pressure increase.

DISCUSSION

Although it has not been possible to determine from X-ray evidence whether or not the product obtained from the vacuum dehydration of manganous sulphate tetrahydrate is amorphous, the similarity of the dehydration curves to those previously reported for copper sulphate pentahydrate (3) and for manganous oxalate dihydrate (6, 7) suggests that the dehydration process is the same in each case and is subject to the same interpretation. However, the minimum in the rate curve for the manganous salt occurs at about 1.2 mm., whereas for copper sulphate pentahydrate it occurs at about 0.25 mm., and for manganous oxalate dihydrate at less than 0.2 mm.

The dehydration process for zinc sulphate heptahydrate is more complex. Since an X-ray amorphous product is formed on vacuum dehydration, it is certain that this forms during the nucleation period. It is possible that the short induction period following nucleation (or therefore the first minimum in the rate curve) is due to the crystallization of this product at very low pressure. No adequate interpretation can be made of the second minimum at higher pressure on the basis of the present data and a more comprehensive study of the dehydration kinetics of this salt hydrate should be made.

Magnesium sulphate heptahydrate is of particular interest in that the dehydration curves obtained indicate that an X-ray amorphous product is formed not only on vacuum dehydration but also in the presence of water vapor at a pressure much higher than those observed for the other salts. The amorphous product is therefore very stable. This result suggests that this salt might be found to behave in a manner similar to copper sulphate pentahydrate if investigated over a wide range of controlled and constant pressures of water vapor. Experiments of this type are being carried out in this laboratory and will be reported in a later paper. The data given for nickel sulphate hexahydrate suggest a similar type of behavior.

The formation of crystalline products in the vacuum dehydration of nickel nitrate hexahydrate and magnesium nitrate hexahydrate indicates that if an amorphous product is formed at all, it must crystallize at extremely low water vapor pressures. Although the decomposition products obtained from ferrous sulphate heptahydrate could not be characterized by X-ray diffraction, the similarity of the dehydration curves to those obtained for nickel nitrate hexahydrate suggests that these products may be also crystalline. The minima observed in the rate versus pressure curves for these salts must be interpreted therefore in a somewhat different manner than has been done for copper sulphate pentahydrate. Instead of a process involving the crystallization of amorphous material, it must be assumed that as nuclei develop on the surfaces of the crystalline intermediates, the development of macrocrystalline aggregates is catalyzed by adsorbed water molecules.

The curves obtained for the dehydration of cobalt chloride hexahydrate are also similar to those obtained for nickel nitrate hexahydrate and it is probable that this dehydration also proceeds through the formation of a crystalline intermediate. However, with this salt the dehydration at increasing pressure does not proceed past the dihydrate stage, the corresponding pressure being

much lower than the equilibrium pressure reported by Derby and Yngve (2) for the hexahydrate – dihydrate – water vapor equilibrium. The behavior of this salt is of interest in comparison with that of magnesium sulphate heptahydrate, and a more comprehensive study of its dehydration kinetics is in progress.

The dehydration of magnesium nitrate hexahydrate is of particular interest, since the sequence of changes occurring on vacuum dehydration is that which is observed for other salts as the pressure of water vapor increases. Dehydration takes place rapidly with the formation of crystalline tetrahydrate which then nucleates and forms crystalline dihydrate. If it is assumed that the development of macrocrystals from these nuclei is catalyzed by water vapor, then this process must occur at the very low pressures prevailing in the transition layer as the water molecules liberated from the hexahydrate lattice pass through the crystalline tetrahydrate layer into the external evacuated space. The rate of escape of water molecules from the dehydrating tetrahydrate lattice will increase with temperature. However, any slight adsorption in the transition layer will decrease with the temperature. The opposition of these two effects may qualitatively explain the over-all dependence of rate on temperature which has been observed. However, any such explanation must be regarded as highly tentative in view of the lack of more comprehensive data. It will be observed from Fig. 10 that the rate of dehydration of the primary hexahydrate lattice increases with temperature in the normal manner, as also does both the primary and secondary rate for nickel nitrate hexahydrate.

It is clear from all the data presented in the foregoing that the effect of water vapor in first decreasing and then accelerating the over-all rate of dehydration, first observed by Topley and Smith for the decomposition of manganous oxalate dihydrate, is quite general and is always associated with an induction period in which a crystalline lower hydrate is formed from an intermediate. The intermediate may be an X-ray amorphous product or it may be crystalline. The nature of the X-ray amorphous product is, therefore, of interest. It may consist of an aggregate of microcrystals with dimensions of only a few unit cells, these being below the limiting size required for X-ray diffraction (about 100 Å). If this is so, the nature of the process whereby macrocrystals are formed in the presence of water molecules from X-ray amorphous intermediates does not differ in any essential way from that in which macrocrystals of the end product are formed from a nucleated crystalline intermediate. However, the heats of transition from the X-ray amorphous to the crystalline states which have been reported for the monohydrates of copper and zinc sulphate (4) are higher than might be expected from consideration of surface energy only, and it is possible that, for these salts at least, some condition other than high state of division results from low pressure dehydration of the primary lattices. The determination of such heats of transition for other salts is in progress.

The limiting pressure of water vapor above which amorphous products crystallize varies greatly from one salt hydrate to another, being virtually zero for nickel nitrate, magnesium nitrate, and cobalt chloride, and ranging to

presumably relatively high values for magnesium sulphate and nickel sulphate. Experiments carried out in this laboratory suggest that this effect is related to differences in the surface areas and capillary structures of the transition layer, although the nature of the amorphous material itself may also be a factor (5).

NOTES

INTERDIFFUSION OF POLYISOBUTYLENE AND CYCLOHEXANE

By J. Kelly and A. T. Hutcheon

Prior to a more extensive study of the diffusion in dilute solutions of polyvinylacetate in acetone, results are reported here for one sample of polyisobutylene in interdiffusion with cyclohexane. The measurements were intended to be an experimental test for this system of the equation (5).

$$[1] \qquad D = \frac{RTP^{-1}\Phi^{\frac{1}{3}}}{\eta_0 N(M[\eta])^{\frac{1}{3}}}$$

in which the product $P^{-1}\,\Phi^{\frac{1}{3}}$ is claimed to be a constant for all polymer systems and the other symbols have their usual significance. Furthermore, the dependence of the diffusion coefficient on concentration serves as a test of the equation (4).

$$[2] \qquad Y = \frac{1+2\Gamma_2 c+3\Gamma_3 c^2}{D} = \frac{1+k_s c}{D_0}$$

since Γ_2 has been obtained from osmotic pressure measurements (2), and k_s from sedimentation (6) data assuming a linear dependence of the frictional coefficient on concentration.

EXPERIMENTAL

The diffusion was carried out in a Neurath cell (7) at 30°C. ±0.02 in a constant temperature air bath on a vibration-free mounting. The diffusion coefficients were calculated by the area-maximum ordinate method (3) from measurements of the refractive index gradient obtained by the scale method of Lamm (10).

The diffusion coefficient was measured at three different initial concentrations and at time intervals of several hours for each concentration, as shown in Table I. Average values of D_A are given for concentrations 0.2636 and 0.3660 gm./100 ml. For the concentration 0.5676 gm./100 ml., there was a decided gradual decrease in the value of D_A with time and for this experiment a corrected value of D was obtained by extrapolation to infinite time of the plot of D versus 1/time. This procedure is necessary when the boundary is not initially sharp (8).

The average and corrected values of D_A and the value of $\Gamma_2 = 0.63$ (2) were used in plotting the function

$$Y = (1+2\Gamma_2 c+3\Gamma_3 c^2)/D$$

against the mean concentration $c_0/2$ in Fig. 1 for $\Gamma_3 = \frac{5}{8}\,.\,\Gamma_2^2$ and $\Gamma_3 = \frac{1}{4}\,.\,\Gamma_2^2$. From the intercept, $1/D_0$, D_0 is calculated to be 3.3×10^{-7} cm.^{2} sec^{-1}.

DISCUSSION

This experimental value may be compared with that calculated from equation 1. Using Flory's data (6)—$\eta_0 = 9.7 \times 10^{-3}$ poises, $[\eta] = 2.76\times10^{-4} M^{0.69}$, $M = 86{,}700$, and $P^{-1}\Phi^{\frac{1}{3}} = 2.65 \times 10^{-6}$ for this particular fraction—D_0 is calculated to be 2.8×10^{-7} cm.²/sec. at 20°C. The value of $D_0 = 3.4 \times 10^{-7}$ cm.²/sec. at 30°C. is obtained from the relation (7)

$$D_0^{30} = D_0^{20} \frac{T_{30}\eta_{20}}{T_{20}\eta_{30}}$$

where T is the absolute temperature and η the viscosity of the solvent. This is in good agreement with the experimental value and better agreement would be obtained using the average value of $P^{-1}\,\Phi^{\frac{1}{3}}$ reported as 2.5×10^6 (1).

From equation 2, the slope of the plot of Y versus concentration is equal to k_s/D_0. From the data of Flory *et al.* on sedimentation (2), k_s is equal to 1.28 for this fraction of polyisobutylene, hence, using the calculated value of D_0, the predicted slope would be $1.28/(3.4 \times 10^{-7}) = 3.8 \times 10^6$. If the observed value of D_0 equal to 3.3×10^{-7} were used, the slope would be 3.9×10^6. The observed slopes in Fig. 1 are 4.6×10^6 for $\Gamma_3 = \frac{5}{8}.\Gamma_2^2$ and 4.1×10^6 for $\Gamma_3 = \frac{1}{4}.\Gamma_2^2$ when Y is plotted against $c_0/2$ from Table II. The suggestion

TABLE II

VALUES OF $Y = (1+2\Gamma_2 c+3\Gamma_3 c^2)/D = (1+k_s c)/D_0$ AS A FUNCTION OF CONCENTRATION

Concentration $c_0/2$, gm./100 ml.	$D_0 \times 10^7$ cm.^{2}/sec.	$Y \times 10^{-6}$ for $\Gamma_3 = \frac{5}{8}.\Gamma_2^2$	$Y \times 10^{-6}$ for $\Gamma_3 = \frac{1}{4}.\Gamma_2^2$
0.132	3.27	3.61	3.58
0.183	3.25	3.86	3.81
0.284	3.29	4.31	4.20

that the third virial coefficient should be less than $\frac{5}{8}.\Gamma_2^2$ (9) and that it is $\frac{1}{4}.\Gamma_2^2$ (2) is therefore supported by these data.

The values of D at the concentration of 0.2636 gm./100 ml. were least precise and if the other values at 0.3660 and 0.5676 gm./100 ml. are weighted more in drawing the lines in Fig. 1, the slope of the line for $\Gamma_3 = \frac{1}{4}.\Gamma_2^2$ would be 3.96×10^6 and D_0 would be 3.23×10^{-7} cm.^{2}/sec., which corresponds to $P^{-1}\,\Phi^{\frac{1}{3}} = 2.5 \times 10^6$ in equation 1, in agreement with Flory's best average value (1). The data are not sufficiently precise to contend for exact values of $P^{-1}\,\Phi^{\frac{1}{3}}$ or Γ_3, but the conclusion that $\Gamma_3 = \frac{1}{4}.\Gamma_2^2$ is more nearly correct than $\Gamma_3 = \frac{5}{8}.\Gamma_2^2$ is inescapable and that it *may* be exactly $\frac{1}{4}.\Gamma_2^2$ is not contradicted by these results.

The above good agreement between theory and experiment is for the diffusion coefficient calculated by the area-maximum ordinate method; there is some discrepancy, in these experiments, between D_A and D_σ (second moment method (6)) unlike the results of Schulz and Meyerhoff (8). The D_σ values generally lie *below* those for the area-maximum ordinate method. The reasons for this discrepancy are not known and will be discussed more fully in a future publication.

ACKNOWLEDGMENT

UNIT CELL, SPACE GROUP, AND INDEXED X-RAY DIFFRACTION POWDER DATA FOR CERTAIN NARCOTICS
VII. MORPHINE HYDROCHLORIDE TRIHYDRATE, AND THE DIHYDRATES OF MORPHINE HYDROBROMIDE, MORPHINE HYDRIODIDE, CODEINE HYDROCHLORIDE, CODEINE HYDROBROMIDE, CODEINE HYDRIODIDE[1]

BY W. H. BARNES AND JUNE M. LINDSEY[2]

Morphine hydrochloride (anhydrous, and trihydrate) and morphine hydriodide dihydrate were the only hydrohalide salts of morphine or of codeine included in the collection of X-ray diffraction powder data completed in this laboratory some time ago as an aid to the identification of certain narcotics (1, 3). It was realized at the time of this survey that morphine hydrobromide, and the hydrochloride, hydrobromide, and hydriodide of codeine should be examined at some future date. Through the kindness of Dr. C. G. Farmilo, specimens of all four hydrohalide salts (in the form of the dihydrates) were obtained in due course, and their unit cell constants, space groups, and powder patterns (indexed for $d > \backsim 3$ Å), together with single-crystal data for morphine hydrochloride trihydrate and for morphine hydriodide dihydrate, have now been determined. At the same time the powder patterns for the last two salts, which are recorded in full elsewhere (3), have been indexed for those reflections corresponding to $d > \backsim 3$ Å. The experimental methods have been described in detail previously (1, 2, 3).

Of the various narcotics studied during the powder-data survey (3), morphine, codeine, and thebaine were selected as the first to be considered for complete structural investigation because of the widespread interest in their stereochemical configuration (11). In view of the fact, however, that their molecules are asymmetric, it was decided to use the corresponding hydrohalide salts in an application of the isomorphous-replacement method to the problem. This eliminated thebaine for which only the free base and the hydrochloride were immediately available.

The six salts of morphine and codeine, which are the subject of the present note, crystallized from water in rosettes, and in sheaves, of needles, elongated

UNIT CELL, SPACE GROUP, AND INDEXED X-RAY DIFFRACTION POWDER DATA FOR CERTAIN NARCOTICS
VII. MORPHINE HYDROCHLORIDE TRIHYDRATE, AND THE DIHYDRATES OF MORPHINE HYDROBROMIDE, MORPHINE HYDRIODIDE, CODEINE HYDROCHLORIDE, CODEINE HYDROBROMIDE, CODEINE HYDRIODIDE[1]

BY W. H. BARNES AND JUNE M. LINDSEY[2]

Morphine hydrochloride (anhydrous, and trihydrate) and morphine hydriodide dihydrate were the only hydrohalide salts of morphine or of codeine included in the collection of X-ray diffraction powder data completed in this laboratory some time ago as an aid to the identification of certain narcotics (1, 3). It was realized at the time of this survey that morphine hydrobromide, and the hydrochloride, hydrobromide, and hydriodide of codeine should be examined at some future date. Through the kindness of Dr. C. G. Farmilo, specimens of all four hydrohalide salts (in the form of the dihydrates) were obtained in due course, and their unit cell constants, space groups, and powder patterns (indexed for $d > \backsim 3$ Å), together with single-crystal data for morphine hydrochloride trihydrate and for morphine hydriodide dihydrate, have now been determined. At the same time the powder patterns for the last two salts, which are recorded in full elsewhere (3), have been indexed for those reflections corresponding to $d > \backsim 3$ Å. The experimental methods have been described in detail previously (1, 2, 3).

Of the various narcotics studied during the powder-data survey (3), morphine, codeine, and thebaine were selected as the first to be considered for complete structural investigation because of the widespread interest in their stereochemical configuration (11). In view of the fact, however, that their molecules are asymmetric, it was decided to use the corresponding hydrohalide salts in an application of the isomorphous-replacement method to the problem. This eliminated thebaine for which only the free base and the hydrochloride were immediately available.

The six salts of morphine and codeine, which are the subject of the present note, crystallized from water in rosettes, and in sheaves, of needles, elongated

[1]*Issued as N.R.C. No. 3524.*
[2]*National Research Laboratories Postdoctorate Fellow.*

in the direction of the *c*-axis. Individual crystals of the codeine hydrohalides, however, were somewhat larger, and of better form, than those of the corresponding salts of morphine. They were of almost square cross-section and could be cut readily to cubical shape of suitable size for single-crystal study. Primarily for these reasons, therefore, codeine hydrobromide dihydrate was selected for the investigation of the structure of the codeine molecule, and the isomorphous codeine hydriodide dihydrate was employed to provide data of assistance in the allocation of signs to the observed structure amplitudes. A brief account of the results of this investigation has been given elsewhere (7) and full details will be published later (8).

An interesting feature of the hydrohalide salts of morphine and of codeine is that the phase normally available from commercial sources (and obtained by crystallization from water or dilute alcohol at ordinary temperatures) is the dihydrate in all cases with the exception of morphine hydrochloride, which crystallizes as the trihydrate. The existence of other hydrates, and of the anhydrous salts, has been reported in the literature (10), and an extensive series of hydration–dehydration studies is now in progress in this laboratory. It is hoped to report X-ray diffraction data for some of these other hydrate phases in a subsequent note in order to supplement existing powder data for *anhydrous* morphine hydrochloride (3).

Single-crystal data, obtained from precession photographs (Cu K_α, λ = 1.5418 Å), for morphine hydrochloride trihydrate, morphine hydrobromide dihydrate, morphine hydriodide dihydrate, and the dihydrates of codeine hydrochloride, hydrobromide, and hydriodide, are summarized in Table I;

TABLE I

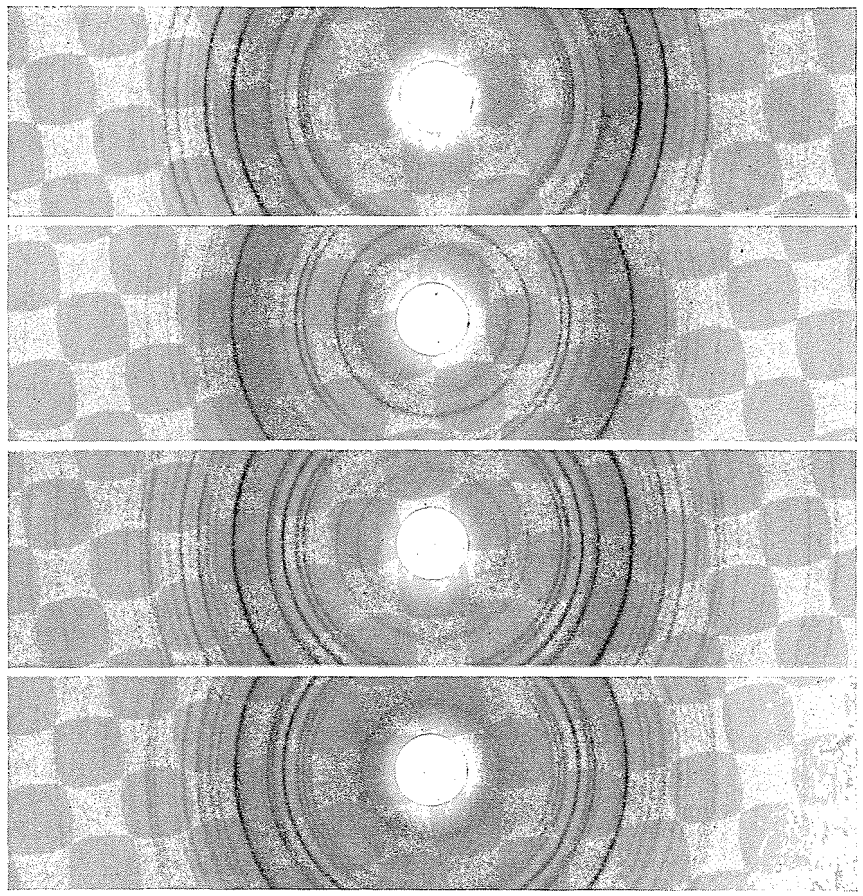

FIG. 1. X-ray diffraction powder photographs of A, morphine hydrobromide dihydrate; B, codeine hydrochloride dihydrate; C, codeine hydrobromide dihydrate; D, codeine hydriodide dihydrate. (Camera diameter: 114.6 mm.; radiation: $Co_{\alpha}K_{\alpha}$, $\lambda = 1.790$ Å).

trihydrate and morphine hydrobromide dihydrate, which will be found elsewhere (3).

It should be mentioned that the orientation chosen for the unit cells is $c < a < b$ in conformity with the convention recommended in Dana's *System of Mineralogy* (4) and in *Crystal Data* (5), and with that adopted for codeine (anhydrous free base) and for codeine monohydrate (free base) in *Barker's Index* (9) and by Groth (6).

Mr. B. J. Cowick assisted with the powder investigations.

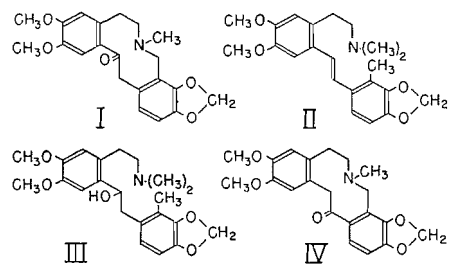
THE IDENTITY OF CRYPTOCAVINE AND CRYPTOPINE[1]

BY A. F. THOMAS,[2] LÉO MARION, AND R. H. F. MANSKE

Cryptocavine ($C_{21}H_{23}O_5N$) has been reported to occur in various fumariaceous plants (2) and to be different from, but isomeric with and closely related to cryptopine I. Its structure IV was deduced (3) from the Emde reduction of the methosulphate followed by dehydration with acetyl chloride which gave anhydrotetrahydromethylcryptocavine, very similar to anhydrotetrahydromethylcryptopine II obtained in the same way from cryptopine (4). Both anhydrotetrahydro derivatives, on oxidation with potassium permanganate, gave the same products, i.e., 5,6-methylenedioxy-*o*-toluic aldehyde and 4,5-dimethoxy-2-β-dimethylaminoethylbenzaldehyde. The slight difference between the anhydrotetrahydro compounds was ascribed to geometrical isomerism (3).



Construction of models of II showed that the *cis*-form would be highly strained with the aromatic rings partly overlapping. Examination, however, of the specimen originally obtained from cryptocavine and one freshly prepared from pure cryptopine showed that the two were identical. Both crystallized from dilute methanol as long colorless silky needles, m.p. 110°, undepressed on

admixture, and both possessed the same absorption in the ultraviolet ($\lambda_{max.}$ 330 mμ, log ϵ, 4.38; $\lambda_{min.}$ 264 mμ, log ϵ, 3.91) and in the infrared. It is perhaps significant that at no time were we able to crystallize Perkin's tetrahydromethylcryptopine III although several preparations were made, and it is noteworthy that Perkin states that II contains solvent of crystallization when freshly prepared, and that the melting points of both II and III were the same (4).

The apparent confirmation of structure IV for cryptocavine (3) made it of interest to examine the *trans*-annular amide formation of this molecule. The perchlorate was prepared (crystallized from aqueous methanol, m.p. 226–228°, dec. Calc. for $C_{21}H_{23}O_5N.HClO_4$: Cl, 7.55. Found: Cl, 7.36, 7.42%), but was found to have an infrared absorption spectrum identical with that of cryptopine perchlorate. The free bases had the same pK_a value (8.09) which was higher than expected in view of the fact that cryptopine had been reported to be a weak base (1). Debye-Scherrer powder photographs of the two bases were the same, as were the infrared absorption spectra in various media. The melting point of a mixture of cryptocavine and cryptopine was not lowered provided that pure cryptopine was used, but it was found that any mixture of the pure bases with the cryptopine sample originally used (3) was indeed liquid at 205° as reported (3). Furthermore, both the Debye-Scherrer photograph and the infrared absorption spectrum of this sample contained all the characteristics of the corresponding photograph and spectrum of pure cryptopine, together with a few minor additional lines and peaks. The latter were all present in the Debye-Scherrer photograph and the infrared spectrum of protopine. Hence the sample of cryptopine originally used for comparison was contaminated with protopine. The melting point of this sample was taken again and found to be not 221°, but 204–208°. It must, therefore, be concluded that cryptocavine is identical with cryptopine, and the designation cryptocavine should be deleted from the literature.

ACKNOWLEDGMENTS

The pure cryptopine used in this work was obtained from the Dyson Perrins Laboratory, through Dr. A. S. Bailey whose courtesy we acknowledge. Our thanks are also due to Mr. R. Lauzon and Dr. R. N. Jones for the infrared spectra and to Dr. Maria Przybylska for the Debye-Scherrer photographs.

THE SYNTHESIS OF OPSOPYRROLE-DICARBOXYLIC ACID[1]

BY D. M. MACDONALD[2] AND S. F. MACDONALD

ABSTRACT

The methyl groups of the pyrroles I*a* and II*a* react with sulphuryl chloride to give dichloromethyl derivatives which hydrolyze to aldehydes. The pyrrole I*a* also forms a trichloromethyl derivative which hydrolyzes to the corresponding acid. Alkaline decarboxylation of the latter gives opsopyrrole-dicarboxylic acid, IV*a*.

To obtain further pyrroles related to the uroporphyrins, we have studied the halogenation of the methyl groups of I*a* and II*a*, and further transformations analogous to those which had been carried out on an isomeric pyrrole (6, 9). The bromination of both I*a* (13) and II*a* (unpublished) proceeds normally giving the α-bromomethyl pyrroles.

With two moles of sulphuryl chloride, both I*a* and II*a* presumably gave dichloromethyl derivatives, which were not purified but hydrolyzed directly to the corresponding aldehydes I*b* and II*b*. The former has also been obtained from I*a* with lead tetraacetate (16). The latter, II*b*, was hydrolyzed to V*a* which was converted to the oxime V*b*.

With three moles of sulphuryl chloride, I*a* presumably gave a trichloromethyl derivative, which hydrolyzed to I*c*. The pyrrole I*d* was obtained from I*c* by thermal decarboxylation, and hydrolysis then gave III, one of the pyrroles which have been postulated as intermediates in the biosynthesis of hemin (12). Opsopyrrole-dicarboxylic acid IV*a*, one of the hypothetical reduction products of the uroporphyrins, was obtained from I*c* by alkaline decarboxylation. The method was not quite parallel to the analogous synthesis of opsopyrrole-carboxylic acid (7), for the greater solubility of the product here necessitated the release of the free acid by ion-exchange rather than by acidification. The dimethyl ester IV*b* was an oil which did not give a crystalline picrate. The structure of IV*a* was confirmed by its degradation to opsopyrrole-carboxylic acid (3-methylpyrrole-4-propionic acid). Further, although the usual methods for converting opsopyrroles to porphyrins failed here, when IV*a* was boiled with formaldehyde and dilute hydrochloric acid, then aerated, a mixture of uroporphyrins resulted, which was shown by paper chromatography to contain octacarboxylic acids only.

Several analogous chlorinations with sulphuryl chloride in ether, including those of the 3-methyl (5), 3-ethyl (10), and 3-propionic acid (7) derivatives of 2,4-dimethyl-5-carbethoxypyrrole, have not been sufficiently stepwise and complete to give good yields of aldehydes or acids. The influence of impurities in the ether there and in the preparations of I*b* and I*c* is unknown. In the case of II*b*, however, whether or not freshly dried ether was used, when the preliminary drying of the solvent ether was with phosphorus pentoxide rather

than with sulphuric acid, the chlorination of II*a* with two moles of sulphuryl chloride was incomplete.[3] The main product, repeatedly isolated after the hydrolysis in 70–90% yield, was 3,3′-di-(carbethoxymethyl)-4,4′-di-(2-carbethoxyethyl)-5,5′-dicarbethoxydipyrromethane. This was identified by melting point and mixed melting point with the methane, m.p. 146°, obtained by boiling II(R = CH_2Br) with water (unpublished).

An improved preparation based on that of Pinner (1, 17, 18) has been worked out for the ethyl acetone-dicarboxylate required in the preparation of I*a*.

EXPERIMENTAL

The ether had been distilled with sulphuric acid and dried over sodium (2). Acetone had been distilled over potassium carbonate, and water had been boiled and cooled under nitrogen.

2-Carboxy-3-(2-carbethoxyethyl)-4-carbethoxymethyl-5-carbethoxypyrrole (*Ic*)

Sulphuryl chloride (10 ml.) was added slowly to a stirred solution of I*a*

[3]*This observation is due to Dr. A. H. Jackson.*

(12.95 gm.) in 200 ml. of absolute ether maintained at $\leqslant 4°$ and protected from moisture. Stirring was continued for 5 min., then for 30 min. with the cooling bath removed. The ether was evaporated *in vacuo* at $\leqslant 20°$, and three 100-cc. portions of ether successively added and evaporated in the same way. Hydrated sodium acetate (40 gm.) in 650 ml. of boiling water was added to the residual oily trichloromethyl derivative, the mixture boiled for three minutes with vigorous stirring and cooled quickly, sodium bicarbonate added to dissolve the precipitate, the solution extracted three times with ether, and the ether washed with 5% sodium bicarbonate (twice with 100 ml.). The combined aqueous layers were filtered, saturated with sulphur dioxide at 20°, and, after one hour at 0°, the crystalline product filtered off and washed with water (twice with 100 ml.). It was dissolved in 500 ml. of boiling ethanol, and water (3.5 liters, heated to 80°) added. After standing overnight the colorless needles were filtered off (8.76 gm., 62%), dried to constant weight over sulphuric acid at 10 mm., m.p. 140–141°, Ehrlich's reaction negative (cold), red (hot). Found in material recrystallized several times from ethanol–water and dried (18 hr., 56°, 0.1 mm.): C, 55.58, 55.62; H, 6.43, 6.25; N, 3.79%. Calc. for $C_{17}H_{23}NO_8$: C, 55.27; H, 6.28; N, 3.47%.

2-Carbethoxy-3-carbethoxymethyl-4-(2-carbethoxyethyl)-pyrrole (Id)

The acid Ic (3.154 gm.) was heated at 240° under nitrogen until the evolution of carbon dioxide ceased, then sublimed (160–220°, 10 mm.). The sublimate was crystallized three times from ether–hexane to remove oil, giving 590 mgm., m.p. 51–51.5°. An additional 120 mgm. (total, 25%) was obtained from the mother liquors by evaporating, subliming, dissolving in ether, filtering with charcoal, evaporating, putting onto an alumina column in a little methanol, eluting with ether until the cold Ehrlich's reaction was negative, washing the eluate with aqueous sodium bicarbonate, drying it with sodium sulphate, evaporating, and recrystallizing five times from ether–hexane. For analysis, it was recrystallized five times from pentane (Soxhlet), and the colorless plates dried (20 hr., 20°, 10^{-5} mm.), m.p. 51–52°, Ehrlich's reaction bluish-red (cold) (slow). Found: C, 59.29, 59.18; H, 7.14, 7.18; N, 4.60%. Calc. for $C_{16}H_{23}NO_6$: C, 59.06; H, 7.12; N, 4.31%.

2-Carboxy-3-carboxymethyl-4-(2-carboxyethyl)-pyrrole (III)

The ester Id (407 mgm.) was refluxed for one hour with 5% potassium hydroxide in 50% ethanol (10 ml.). The cooled solution was put through Amberlite IR–120 (H^+ form, from 20 gm. wet Na^+ form) and eluted with water until the Ehrlich's reaction was negative (cold). The eluate (150 ml.) was concentrated *in vacuo* at *ca.* 20° by swirling on the steam bath until the product crystallized. Filtration and washing with 1 ml. of water gave radiating clusters of thick rods (272 mgm.). A colorless product was obtained after two recrystallizations from acetone (Soxhlet) (143 mgm., 47%), m.p. 178° (decomp.), Ehrlich's reaction bluish-red (cold). For analysis, it was recrystallized four times from acetone and dried overnight (56°, 0.1 mm.). Found: C, 50.08; H, 4.72; N, 6.03%. Calc. for $C_{10}H_{11}NO_6$: C, 49.78; H, 4.60; N, 5.81%.

3-Carboxymethyl-4-(2-carboxyethyl)-pyrrole (Opsopyrrole-dicarboxylic Acid) (IVa)

The pyrrole Ic (0.5 gm.) in 3 ml. of 10% sodium hydroxide was heated under nitrogen in a sealed tube for two hours at 175–180°. The filtered contents of four such tubes were passed through Amberlite IR-120 (H^+ form, from 30 gm. wet Na^+ form), eluting with water (*ca.* 300 ml.) until the Ehrlich's reaction was weak in the cold. The eluate was concentrated (10 mm. *ca.* 20°) by swirling on the steam-bath, then freeze-dried. The colorless residue was extracted into ether (Soxhlet), the ether concentrated to 50 ml., filtered warm, and the product precipitated with hexane as colorless poorly formed needles (882 mgm., 83%), m.p. 139–140°, Ehrlich's reaction bluish-red (cold). For analysis the product was recrystallized four times from ether–hexane and dried (18 hr., 56°, 0.1 mm.). Found: C, 54.79, 54.90; H, 5.69, 5.70; N, 6.94%; eq. wt. 100.3. Calc. for $C_9H_{11}NO_4$: C, 54.81; H, 5.62; N, 7.10%; eq. wt. 98.5.

3-Carbomethoxymethyl-4-(2-carbomethoxyethyl)-pyrrole (Methyl Opsopyrrole-dicarboxylate) (IVb)

Opsopyrrole-dicarboxylic acid (210 mgm.) in ether was allowed to react with excess ethereal diazomethane for 15 min., the ether evaporated, and the residue distilled in a collar flask (138–147° bath temp., 10^{-4} mm.). The yellowish oily product (215 mgm., 90%) was redistilled and the colorless oily middle fraction (135–137° bath temp., 10^{-4} mm.) analyzed, Ehrlich's reaction bluish-red (cold). Found: C, 58.78, 58.67; H, 6.59, 6.39; N, 6.14%. Calc. for $C_{11}H_{15}NO_4$: C, 58.64; H, 6.71; N, 6.22%.

Degradation of Opsopyrrole-dicarboxylic Acid to 3-Methylpyrrole-4-propionic Acid (Opsopyrrole-carboxylic Acid)

The pyrrole IVa (275 mgm.) was heated in a sealed tube for two hours at 150° with 3 ml. of water. The solid left on freeze-drying the combined filtrate and washings from the contents of the tube was extracted with ether (Soxhlet). The ether was concentrated to 20 ml., then replaced by boiling while hexane was added, red amorphous material being filtered off periodically until a slightly cloudy colorless solution was obtained. The product separated, on cooling, as colorless aggregates. After three recrystallizations, 65 mgm. were obtained, m.p. 116°, raised to 117° by sublimation (95–103°, 10^{-2} mm.). Found: C, 62.89, 62.94; H, 7.01, 6.98; N, 9.02%; eq. wt. 148. Calc. for $C_8H_{11}NO_2$: C, 62.73; H, 7.24; N, 9.14%; eq. wt. 153.

Another preparation, after four recrystallizations from chloroform–hexane, had m.p. 115–116°, raised to 118.5–120° after sublimation (Lit.: 119° (not sharp) (11*a*, 4, 7), 117° (8)).

Mixture of Uroporphyrins from Opsopyrrole-dicarboxylic Acid

Opsopyrrole-dicarboxylic acid (100 mgm.) was refluxed for 20 min. in 200 ml. of 0.5% hydrochloric acid and 40 ml. of 1% formaldehyde, cooled, and aerated overnight. The porphyrin was precipitated, filtered off, washed, esterified with methanolic hydrogen chloride, and brought into chloroform in the usual way. The chloroform was washed with 50% aqueous resorcinol (14*b*)

which was subsequently washed with chloroform. The combined chloroform layers were washed free of resorcinol with water, and filtered through a column of alumina (grade V), the porphyrin being eluted with chloroform containing 5% of methanol. After washing with dilute sodium hydroxide and with water, the chloroform was replaced with methanol at the boil, and the solution concentrated to *ca.* 1 ml. giving a mixture of uroporphyrin methyl esters as rods (9 mgm.). Recrystallized six times, it had m.p. 252–258° (4.5 mgm.). Found in 1.5 mgm. sample: C, 60.40; H, 6.84%. Calc. for $C_{48}H_{54}N_4O_{16}$: C, 61.14; H, 5.77%.

A sample was hydrolyzed, and chromatographed on paper with 2,4-lutidine-water in an atmosphere of ammonia (15); the only spot had the same R_f as the uroporphyrin I marker.

Opsopyrrole-dicarboxylic acid did not give porphyrins with chloromethyl ether in alcohol, either on standing or on refluxing (cf. 3) or with formic acid at 100° (cf. 11*a*, 11*b*).

2-Formyl-3-(2-carbethoxyethyl)-4-carbethoxymethyl-5-carbethoxypyrrole (*Ib*)

Sulphuryl chloride (0.477 ml.) was slowly added to the pyrrole I*a* (1 gm.) in 10 ml. of ether, the solution being vigorously stirred, protected from moisture, and kept below 4°. After five minutes, the cooling bath was removed and stirring continued for 30 min. The ether was removed *in vacuo* below 20°, and three 10-ml. portions of ether were successively added and evaporated in the same way. Hydrated sodium acetate (2 gm.) in 50 ml. of boiling water was added to the oily residue of the dichloromethyl derivative, the mixture boiled for three minutes, cooled quickly to 0°, and the crystalline aldehyde filtered off. It was dissolved in 50 ml. of boiling ethanol, and 200 ml. of water (heated to 80°) added. On cooling, the product separated (800 mgm., 77%), m.p. 82–83°. For analysis it was recrystallized three times from ethanol–water and dried (18 hr., 56°, 0.1 mm.) giving nearly colorless needles, m.p. 83.5–84° (Lit.: 84.5° (16)), Ehrlich's reaction red (hot). Found: C, 58.01, 58.00; H, 6.70, 6.39; N, 4.25, 3.88%. Calc. for $C_{17}H_{23}O_7N$: C, 57.76; H, 6.56; N, 3.96%.

2-Formyl-3-carbethoxymethyl-4-(2-carbethoxyethyl)-5-carbethoxypyrrole (*IIb*)

As described for the isomer I*b* above, 10.8 gm. of II*a* (14*a*) in 120 ml. of ether was treated with 5.35 ml. of sulphuryl chloride, the oil evaporated three times with 30 ml. of ether, and boiled with 30 gm. hydrated sodium acetate in 500 ml. of water. The aldehyde was obtained as long needles, m.p. 80–81° (9.87 gm., 88%), after recrystallizing from 500 ml. of ethanol and 2250 ml. of water as for the isomer. For analysis, it was recrystallized five times from ethanol–water and dried (18 hr., 56°, 0.1 mm., nearly colorless needles), m.p. 80.5–81°, Ehrlich's reaction red (hot). Found: C, 57.69, 57.98; H, 6.56, 6.43; N, 4.15%. Calc. for $C_{17}H_{23}NO_7$: C, 57.76; H, 6.56; N, 3.96%.

2-Formyl-3-carboxymethyl-4-(2-carboxyethyl)-5-carboxypyrrole (*Va*)

The corresponding ester II*b* (16 gm.) was heated for two hours with 200 ml. of 10% sodium hydroxide on the steam bath under nitrogen. The cooled solution was passed through Amberlite IR–120 (H^+ form, from 400 gm. wet

Na^+ form) and eluted with water. The eluate (3 liters) was concentrated to 60 ml. (10 mm., bath temp. 60°), and the first crop of the product (10.02 gm.) filtered off. Second and third crops were obtained by concentrating the mother liquors to 20 ml. and filtering (0.37 gm.), then freeze-drying the last liquors. The first crop was extracted into 450 ml. acetone (Soxhlet), the solution concentrated to 150 ml., cooled slightly, and 300 ml. ether added; after colored material was filtered off warm, the first lot crystallized at 0° and was filtered off. The combined second and third crops were treated in the same way with 450 cc. acetone and 300 ml. of ether, colored material separated, and the filtrate combined with the mother liquors from the first lot. Amorphous material was precipitated by adding ether, the solution filtered, and the ether evaporated. The remaining acetone solution was decolorized with charcoal, and two further lots of crystals successively obtained by concentration and cooling. The combined three lots were extracted into 900 ml. of acetone, 2 liters of ether added, and the ether evaporated from the filtered solution while acetone was added to keep the product in solution. After the concentrate was filtered with charcoal, concentrated to 300 ml., and cooled, the product (7.2 gm.) separated as fine needles. The mother liquors were concentrated to 75 ml., giving 1.8 gm. more (total 74%).

For analysis, the product was recrystallized four times from acetone and dried (18 hr., 56°, 0.1 mm.) giving cream-colored needles, decomposing at about 240°, Ehrlich's reaction red (hot). Found: C, 49.45, 49.00; H, 4.22, 4.32; N, 5.02%; eq. wt. 86.3. Calc. for $C_{11}H_{11}NO_7$: C, 49.07; H, 4.12; N, 5.20%; eq. wt. 89.7.

2-Oximinomethyl-3-carboxymethyl-4-(2-carboxyethyl)-5-carboxypyrrole (*Vb*)

A solution of the aldehyde V*a* (8.99 gm.), 8.4 gm. of sodium hydroxide, and 4.7 gm. of hydroxylamine hydrochloride in 500 ml. of water was kept for 18 hr. at room temperature, then heated one and one-half hours on the steam bath. The cooled solution was passed through Amberlite IR-120 (H^+ form, from 200 gm. wet Na^+ form) and eluted with water. The eluate (3 liters) was adjusted to pH 4 with sodium hydroxide and concentrated to 200 ml. on the steam bath under nitrogen at 10 mm., the pH being kept above 2. The first crop, which separated on cooling as radiating needles (6.96 gm.), was recrystallized twice from acetone; a second crop was obtained by concentrating the acetone mother liquors and recrystallizing the solid from acetone. A third crop was obtained by evaporating the aqueous mother liquors to dryness *in vacuo* by swirling on the steam bath, extracting the residue with acetone (Soxhlet), concentrating, extracting the solid which separated with ether (Soxhlet), evaporating the ether until the solution was cloudy, and leaving at 0° overnight. The combined three lots were recrystallized from acetone (Soxhlet) giving 6.64 gm., m.p. 204° (decomp.); concentrating the mother liquor gave 1.68 gm., m.p. 201° (total 86%). For analysis, 120 mgm. were dissolved in 3 ml. acetic acid on the steam bath and 5 ml. of benzol added. The oxime which crystallized after 12 hr. at 0° was recrystallized in the same way giving cream-colored aggregates (17 mgm.), dried (30 hr., 56°, 10^{-3} mm.), m.p. 201° (de-

comp.). Ehrlich's reaction was violet (hot). Found: C, 46.67; H, 4.47; N, 9.75%. Calc. for $C_{11}H_{12}N_2O_7$: C, 46.48; H, 4.26; N, 9.86%.

Although the oxime takes up two moles of hydrogen over palladium black (19) in dilute ammonia, the product has not given consistent analyses.

Ethyl Acetone-dicarboxylate

To 550 gm. of anhydrous citric acid, free of large lumps, in a 5-liter round-bottomed flask protected by a calcium chloride tube, 1100 gm. of 15–18% oleum was added in portions with frequent shaking so that the temperature did not exceed 40°. After standing for three hours at 35–40° with frequent shaking, the solution was cooled below −15° by adding dry ice, and 1 liter of similarly cooled absolute alcohol added in portions with shaking and stirring, the temperature being kept below 0° by adding more dry ice. The mixture was allowed to stand until a clear solution resulted; this required two hours, the temperature rising to 15°. After standing at 0° overnight, the solution was poured into 3.5 liters of ice and water. Three such lots were worked up together. The first was extracted four times with 250 ml. of benzene, the last two extracts being used to extract the second lot, being followed by two extractions with 250 ml. of benzene also used to extract the third lot which was then extracted twice with 250 ml. of fresh benzene. The combined extracts were washed with water, with four lots of 250 ml. of saturated sodium bicarbonate, and with water. After clearing with sodium sulphate and filtering, they were washed twice with 250 ml. of 2% sulphuric acid, four times with 250 ml. of water, cleared with sodium sulphate, filtered, and fractionated through a 12 in. lagged Vigreux column. Yield: 1180 gm. (68%), b.p. (0.8 mm.) 93–96°, η_D^{25} 1.4391.

By the same procedure, except that the initial mixture stood four hours at 40–45°, three lots of 550 gm. of powdered citric acid monohydrate gave 984 gm. (62%) of the ester.

THE MERCURY PHOTOSENSITIZED HYDROGENATION OF PROPYLENE AND THE ACTIVATION ENERGY OF THE REACTION $C_3H_7+H_2 = C_3H_8+H$ [1]

By G. R. Hoey[2] and D. J. Le Roy

ABSTRACT

The reactions initiated in hydrogen–propylene mixtures by $Hg(^3P_1)$ atoms were studied over the temperature range from room temperature to 320°C. At 260° and above, the rate of formation of propane and the rate of pressure decrease are linear functions of the hydrogen pressure. This effect is attributed to the reaction $C_3H_7+H_2 = C_3H_8+H$ and its activation energy is estimated to be equal to or slightly greater than 12.5 kcal. per mole. This is 1.2 kcal. per mole greater than the corrected value for the activation energy of the analogous reaction $C_2H_5+H_2 = C_2H_6+H$. The ratio $k_{combination}/k_{disproportionation}$ is estimated to be approximately 2.0 at room temperature in the case of isopropyl radicals.

INTRODUCTION

Kinetic data are now available for the reaction of methyl (10, 17, 14) and ethyl (18, 9) radicals with hydrogen as well as for the reverse reactions of atomic hydrogen with methane (2) and ethane (1). The present investigation was undertaken for the purpose of obtaining data on the reaction of propyl radicals with hydrogen,

$$C_3H_7+H_2 = C_3H_8+H.$$

The method chosen was similar to that used by Le Roy and Kahn (9) in their study of the analogous reaction,

$$C_2H_5+H_2 = C_2H_6+H. \qquad [a]$$

Their method can be described briefly.

At temperatures below approximately 200°C. the mercury ($^3P_1$) photosensitized hydrogenation of ethylene was interpreted in terms of the following reactions:

$$Hg(^3P_1)+H_2 = 2H+Hg(^1S_0) \qquad [b]$$

$$H+C_2H_4 = C_2H_5 \qquad [c]$$

$$2C_2H_5 = C_4H_{10} \qquad [d]$$

$$2C_2H_5 = C_2H_6+C_2H_4. \qquad [e]$$

In agreement with this mechanism, the rate of pressure decrease was independent of hydrogen pressure. At high temperatures, however, the rate of pressure decrease and the rate of formation of ethane increased linearly with the hydrogen concentration. This effect was attributed to reaction [*a*]. When this reaction is incorporated into the mechanism the predicted slope of the *rate* vs. (H_2) curve is proportional to $k_a/(k_d+k_e)^{\frac{1}{2}}$. From the effect of tempera-

[2]*Present address: Division of Applied Chemistry, National Research Council of Canada, Ottawa.*

ture on the slope Le Roy and Kahn obtained a minimum value of 10.5 kcal. per mole for E_a by neglecting the effect of temperature on $(k_d+k_e)^{\frac{1}{2}}$. Their result was in good agreement with the value of 11.5 ± 1 kcal. per mole subsequently obtained by Wijnen and Steacie (18) from experiments on the photolysis of diethyl ketone in the presence of deuterium.

Moore and Taylor (12), in their investigation of the mercury photosensitized hydrogenation of propylene, confined their measurements to room temperature. Moore (11) later studied the reaction at temperatures up to 200°C., but he did not investigate the effect of hydrogen pressure. In the present investigation we have studied the effect of hydrogen pressure on the mercury photosensitized hydrogenation of propylene over the temperature range from room temperature to 320°C. and we have been able to apply the method of Le Roy and Kahn to obtain a minimum value for the activation energy of the reaction of isopropyl radicals with hydrogen.

EXPERIMENTAL

Two different types of reaction system were used. The first (I) involved a quartz annular cell and furnace and a lamp arrangement similar to that used previously (9). Pressures were measured on a wide bore U-tube manometer. This apparatus was used to obtain a considerable fund of analytical data for 300° and 320°C. but it was not suitable for accurate pressure measurements or for reproducible light intensities.

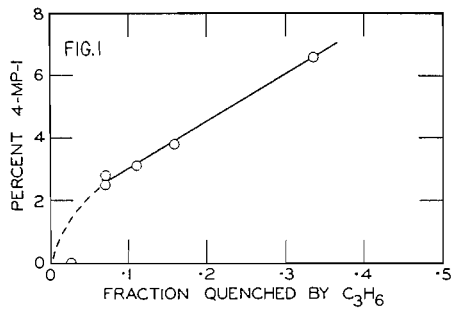
The second reaction system (II) was particularly well adapted for the determination of rates at constant incident light intensity. The cylindrical quartz cell, 5 cm. in diameter and 10 cm. long, had a plane window at one end; the other end of the cell was tapered down to a quartz-to-pyrex graded seal which was sealed to the inner member of a 19/38 standard taper joint. During an experiment gas was circulated through the cell by a mercury piston pump; the gas entered through a 6 mm. tube ring-sealed to the outer part of the 19/38 joint and extending to within a few millimeters of the window. The cell was surrounded by a close fitting aluminum block furnace with a quartz window placed about 7.5 cm. beyond the cell window. The upper half of the furnace could be taken off to remove and clean the cell. The temperature of the furnace was controlled to within ±0.5°C. The lamp used in connection with this cell was of the usual type with rare gas carrier, but since it was entirely outside the heated zone its output was independent of the reaction temperature. With this reaction system more accurate pressure measurements were made possible by using a modified form of the differential manometer described previously (7) with a multiplication ratio of approximately nine. Of the total volume of the system 64.2% was outside the furnace.

Commercial electrolytic hydrogen was purified by passage through platinized asbestos at 500°C. and through silica gel at the temperature of liquid air. The propylene (Ohio Chemical Company) was said to have a purity of 99.5%; it was subjected to several trap-to-trap distillations before being placed in the storage reservoir. The hydrocarbons used for infrared identification were standard samples obtained from the United States Bureau of Standards.

The products were separated into fractions by low temperature distillation (8). The methane in the non-condensable fraction was separated from hydrogen by diffusion of the latter through palladium (8). The olefin content of the C_2, C_3, and C_4 fractions was determined by the method of Pyke, Kahn, and Le Roy (13). Infrared spectra of the C_5 and C_6 fractions were taken. Insufficient C_5 material was obtained for identification except at high temperatures; experiments at 300°C. showed this fraction to contain 2-methyl butene-1 to the extent of approximately 40%, the remainder was an unidentified paraffin. The C_6 fraction was found to contain 2,3-dimethyl butane and 4-methyl pentene-1, as well as an unidentified material comprising, on the average, about 8% of the fraction. No evidence was found for *n*-hexane or 2-methyl pentane; this is in agreement with the observations of Moore (11) and suggests that only isopropyl radicals are formed by the addition of atomic hydrogen to propylene.

RESULTS

A series of experiments was done at room temperature, using cell II, for the purpose of identifying products and studying their possible dependence on hydrogen pressure. In these experiments, and in those described subsequently, the pressure drop was not allowed to exceed 50% of the initial propylene pressure; preliminary experiments had shown that the rate of pressure drop was constant until the pressure drop reached approximately 75% of the initial propylene pressure. For propylene pressures from 10 to 53.6 mm. and hydrogen pressures from 115 to 380 mm. the proportions of the various products, with the exception of 4-methyl pentene-1, were independent of the initial composition of the reaction mixture within the accuracy of the measurements. The average composition of the products was: 2,3-dimethyl butane 46.0%, propane 36.6%, methane 4.9%, unidentified C_6 fraction 4.5%, C_5 2.3%, butane 1%, butene 1%.



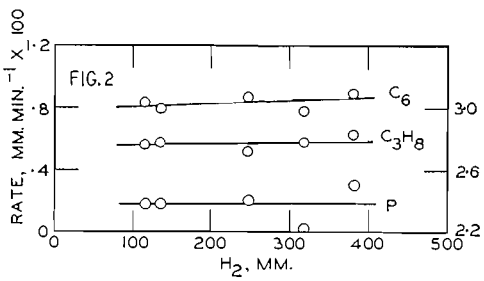


FIG 1. Effect of quenching of $Hg(^3P_1)$ atoms by propylene on the yield of 4-methyl pentene-1.
FIG. 2. Effect of hydrogen pressure on the rate of formation of the C_6 fraction and of propane (left hand scale) and on the rate of pressure decrease (right hand scale) at room temperature. Initial pressures of propylene were from 9.9 to 27.8 mm.

The percentage of 4-methyl pentene-1 increased considerably with the ratio of propylene to hydrogen. In Fig. 1 this percentage is plotted against the fraction of $Hg(^3P_1)$ atoms quenched by propylene, F. The value of F was calculated from the average concentrations of propylene and hydrogen, the

molecular weights of these two gases and of mercury, and the quenching cross sections for collisions of the two gases with $Hg(^3P_1)$ atoms. The quenching cross section for propylene was assumed to be 50×10^{-16} cm.^{2}, i.e. slightly greater than the value found by Steacie (16) for ethylene. The value taken for hydrogen was 8.9×10^{-16} cm.^{2} (16). Since only the ratio of these two quantities is involved in the calculation of F, the numbers would not be changed appreciably by using Darwent's suggested values of 31.0×10^{-16} and 6.0×10^{-16} for propylene and hydrogen, respectively (5).

The form of the curve in Fig. 1 suggests that 4-methyl pentene-1 probably arises through the quenching of $Hg(^3P_1)$ atoms by propylene. No 4-methyl pentene-1 could be detected in the experiment for which F was 0.028 (initial propylene 10 mm., initial hydrogen 380 mm.), which affords some justification for extrapolating the curve through the origin.

The rate of production of C_6 and propane and the rate of pressure drop are shown as functions of the hydrogen pressure in Fig. 2. This graph does not include the data for the experiment for which F was equal to 0.336 (*vide* Fig. 1); because of the considerable amount of quenching by propylene in this experiment the rate of pressure drop was only 1.68×10^{-2} mm. min.$^{-1}$.

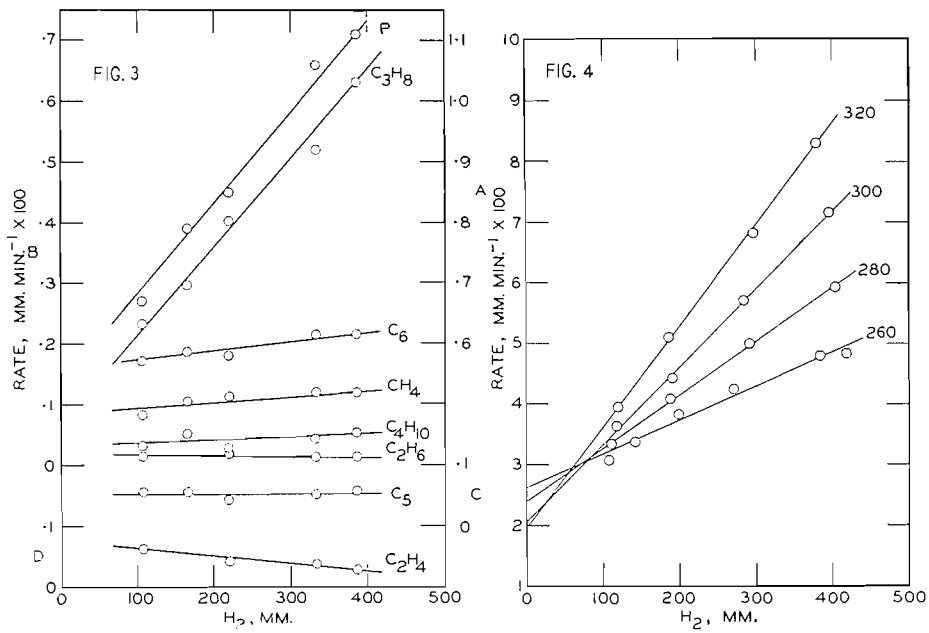

FIG. 3. Effect of hydrogen pressure at 320°C. Scale A: rate of pressure decrease; Scale B: rate of formation of methane, ethane, propane, butane, and C_6; Scale C: rate of formation of C_5; Scale D: rate of formation of ethylene. Initial pressures of propylene were in the range 17.7 to 18.2 mm.

FIG. 4. Effect of hydrogen pressure on the rate of pressure decrease at 260°, 280°, 300° and 320°C., using system II. In most cases the ratio hydrogen : propylene was of the order of 20 : 1 or greater. The ordinates refer to pressures corrected to 25°C., the abscissae to observed pressures at the reaction temperature.

In Fig. 3 are shown the results of a series of experiments using cell I at 320°C. The rate of production of propane and the rate of pressure drop are strongly

dependent on the hydrogen pressure at this temperature, while the rates of formation of the other products are not. Also, the rates of formation of ethane and ethylene are appreciable at 320°, although neither of these products could be detected at 25°C. A small amount of a product higher than C_6 was found at 320°C.; its rate of formation was independent of hydrogen pressure and equal to approximately 0.02×10^{-2} mm. min.$^{-1}$. At 25°C. the rates of formation of butane and butene were the same; at 320°C. the rate of formation of butene (*ca.* 0.012×10^{-2} mm. min.$^{-1}$) was considerably less than that of butane.

Quantitative comparison of the rates of formation of the various products at the two temperatures cannot be made with certainty because different lamps and cells were used. However, relative to the rate of formation of C_6, the rate of formation of methane is 6.3 times as great and of butane 11.5 times as great at 320° as at 25°C. The ratio of C_6 to propane for "zero hydrogen pressure" is 1.5 for 25°, 2.4 for 320°C. Since the C_6 fraction is largely 2,3-dimethyl butane, and since reaction [5] would not be expected to occur at low hydrogen pressures (see below) it would appear that there is little difference in activation energy for the combination and disproportionation of isopropyl radicals.

When a correlation had been established between the rate of pressure drop and the rate of formation of propane at high temperatures, a series of experiments was done to determine with some precision the rate of pressure drop as a function of hydrogen pressure and temperature. These measurements were made with cell II and the differential manometer; the results are shown in Fig. 4.

DISCUSSION

Even at the highest temperatures used, propane and 2,3-dimethyl butane are the major products. In view of the results shown in Figs. 2 and 3 it would appear that the most important reactions leading to their formation are the following:

$$Hg(^3P_1)+H_2 = 2H+Hg(^1S_0) \quad [1]$$

$$H+C_3H_6 = C_3H_7 \quad [2]$$

$$2C_3H_7 = C_6H_{14} \quad [3]$$

$$2C_3H_7 = C_3H_8+C_3H_6. \quad [4]$$

$$C_3H_7+H_2 = C_3H_8+H. \quad [5]$$

From the effect of hydrogen pressure on the rate of formation of propane it is clear that reaction [5] is negligible at room temperature but of increasing importance as the temperature is raised. Although at higher temperatures the rates of formation of methane and butane are greater, and ethane and ethylene appear in appreciable quantities, the formation of these products does not seem to be strongly influenced by hydrogen pressure. Furthermore, in the experiments at 320°C. in which propane was measured there was a good correlation between the rate of formation of propane and the rate of pressure drop. It therefore seems justifiable to interpret the slopes of the curves in Fig. 4 as showing the effect of hydrogen pressure on the rate of formation of propane.

Since, to a good approximation, all the products are saturated it follows that the rate of consumption of propylene will be almost identical with the rate of pressure drop.

The basic mechanism, reactions [1] to [5], inclusive, will be referred to as I. According to I the rate equation for the consumption of propylene is

$$-d(C_3H_6)/dt = I_a\left\{1+\frac{k_3}{k_3+k_4}\right\}+\frac{k_5 I_a^{\frac{1}{2}}}{(k_3+k_4)^{\frac{1}{2}}}(H_2). \qquad [i]$$

The curves in Fig. 4 satisfy an equation of the same form as [i], although mechanism I takes no account of the formation of methane, ethylene, or butane, to mention only three of the additional products found at higher temperatures. Also, mechanism I does not allow for the instability of the propyl radical at high temperatures (4) or for the possible occurrence of reaction [6],

$$H+C_3H_7 = C_3H_8. \qquad [6]$$

The analogous reaction between H atoms and ethyl radicals has been shown to be of some importance, under certain conditions, in the mercury photosensitized hydrogenation of ethylene (15).

If reaction [6], which may involve a third body, is included it is found that [i] still applies provided $k_2(k_3+k_4)(C_3H_6)/(k_5k_6(H_2))$ is appreciably greater than unity. From a consideration of the probable magnitudes of the quantities involved and from our analogous experiments with ethylene (15), it would appear that this condition obtains.

It is easily shown that if the propyl radical decomposes according to reaction [7],

$$C_3H_7 = C_3H_6+H, \qquad [7]$$

this will have no effect on the validity of [i].

If the propyl radical decomposes according to reaction [8],

$$C_3H_7 = C_2H_4+CH_3, \qquad [8]$$

and this is followed by [9],

$$CH_3+H_2 = CH_4+H, \qquad [9]$$

methane and ethylene will be formed at the same rate, viz. $k_8 I_a^{\frac{1}{2}}/(k_3+k_4)^{\frac{1}{2}}$ and a term of this same magnitude will be *added* to [i]; for brevity this term will be referred to as A.

If [8] is followed by [10],

$$CH_3+C_3H_7 = C_4H_{10}, \qquad [10]$$

it can be shown that [i] will be valid provided $(2I_a/A)^2$ is appreciably greater than unity. This condition undoubtedly obtains at the temperatures and light intensity used. Ethylene and butane will each be formed at a rate equal to A.

If [8] is followed by [11],

$$CH_3+H = CH_4, \qquad [11]$$

and if $(2I_a/A)^2$ is appreciably greater than unity it can be shown that the term A must be *subtracted* from [i]. Methane and ethylene will then each be formed at the rate A.

In all of the above cases the mechanisms predict that the steady state H atom concentration should increase with the concentration of H_2. The secondary reaction,

$$H+C_2H_4 = C_2H_5, \qquad [12]$$

would therefore be expected to become more important at high pressures of hydrogen. This probably accounts for the decrease in the yield of ethylene shown in Fig. 3.

Reactions [1] to [11] account in an adequate manner for all of the major products. In addition, some butane will be formed by the combination of ethyl radicals formed in [12]. The 4-methyl pentene-1, formed at low hydrogen concentrations, undoubtedly arises by the combination of propyl radicals with allyl radicals formed in the quenching of propylene by $Hg(^3P_1)$ atoms.

Bywater and Steacie (4) considered reaction [13],

$$H+C_3H_7 = CH_3+C_2H_5, \qquad [13]$$

to be the source of methyl radicals in the mercury photosensitized decomposition of propane at temperatures below 300°C. This reaction could occur if the excited propane formed in [6] were not deactivated. Reaction [6] would be more probable than [13] at the pressures used in these experiments, and since it has been shown that the occurrence of [6] is not likely to affect the validity of $[i]$ it seems justifiable to interpret the slopes of the curves in Fig. 4 in terms of $[i]$.

The logarithms of the slopes of the curves in Fig. 4 are plotted against $1000/T$ in Fig. 5. Least squares plots were used in each case. Since the ordinates in Fig. 4 refer to pressures measured with the whole system at 298°K., and the abscissae to pressures measured with the cell at the reaction temperature, T°K., it follows that the slopes, S, are given by the expression

$$S = \{298 V_c k_5 I_a^{\frac{1}{2}}\}/\{T(V_c+V_b)(k_3+k_4)^{\frac{1}{2}}\}, \qquad [ii]$$

in which V_c is the volume of the cell and V_b that of the rest of the system. Hence,

$$E_5 = -R\, d\{\ln S+\ln(k_3+k_4)^{\frac{1}{2}}+\ln T\}/d(1/T). \qquad [iii]$$

From Fig. 5 the first term is 11.4 kcal. per mole. The second term will be

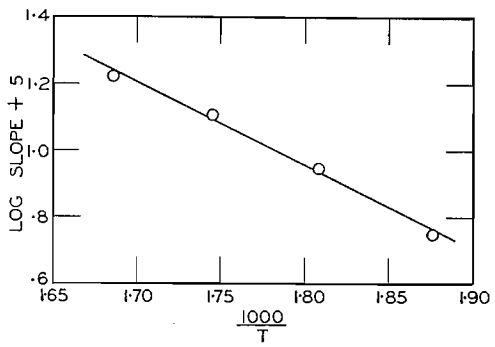

FIG. 5. Arrhenius plot of the slopes of Fig. 4.

neglected; the third is equal to RT. Using the average reaction temperature, 290°C., $E_5 = 12.5$ kcal. per mole.

For the analogous reaction,

$$C_2H_5+H_2 = C_2H_6+H \qquad [14]$$

Le Roy and Kahn found $-R\,d\ln S/d(1/T)$ to be 10.5 kcal. per mole (9). However, they plotted values of $-dP/dt$ reduced to 25°C. against values of P_{H_2} reduced to 25°C. In this case the third term is $RT^2V_b/(298V_c+TV_b)$, rather than RT. In their experiments V_c/V_b was 0.87, and for an average reaction temperature of 290°C. the correction term is 0.8 kcal. per mole. The corrected value of E_{14} is then 11.3 kcal. per mole, in good agreement with the value 11.5±1 kcal. per mole obtained by Wijnen and Steacie (18).

The errors introduced by neglecting the effect of temperature on combination and disproportionation in evaluating E_5 and E_{14} are probably less than 1 kcal. per mole.

An estimate of the value of k_3/k_4 may be obtained from the present data. The experiments of Moore and Taylor (12) suggest a value of 2.5 for this quantity at room temperature. Blacet and Calvert (3) and Durham and Steacie (6) found it to be *ca.* 2.0 at room temperature, while the latter obtained a value of 2.7 at 121°C. If we equate the ratio of hexane to propane at "zero hydrogen pressure" to k_3/k_4 the present results yield the value 1.3 at room temperature, *ca.* 2.1 at 320°C. The increase with temperature is in line with the results of Durham and Steacie. However, our experiments with ethylene (15) have shown that (product of combination)/(product of disproportionation) only approaches $k_{comb.}/k_{disp.}$ when the concentration of olefin is high, because of the influence of reaction [6] or its analogue. Moore and Taylor used a propylene pressure of 40 mm., which should be sufficient to yield a good value of k_3/k_4, but the ratio of propylene to hydrogen was only 1:6 which, in our experience, would result in the presence of a considerable amount of 4-methyl pentene-1 in the C_6 fraction. Their value of 2.5 at room temperature is probably too high for this reason. Our value is probably too low. A value close to 2.0 at room temperature would therefore seem to be established for the ratio of the rate of combination to the rate of disproportionation of isopropyl radicals.

ACKNOWLEDGMENT

COMPRESSIBILITY OF GASES AT HIGH TEMPERATURES

IX. SECOND VIRIAL COEFFICIENTS AND THE INTERMOLECULAR POTENTIAL OF NEON[1]

By G. A. Nicholson[2] and W. G. Schneider

ABSTRACT

The second virial coefficients of neon have been determined in the temperature range 0° to 700°C. and the pressure range 10 to 80 atmospheres. These data were combined with published low temperature (−150° to 0°C.) second virial data, to investigate the intermolecular potentials of neon using both a Lennard-Jones potential, with a 9th and 12th power repulsion term, and also a modified Buckingham exponential–six potential. The agreement between observed and calculated values of $B(T)$ was excellent for both the exponential–six and the Lennard-Jones 12:6 potentials and slightly less satisfactory for the Lennard-Jones 9:6 potential.

VIRIAL COEFFICIENT DETERMINATION

Introduction

The determination of the second virial coefficients of neon consisted essentially of the accurate measurement of the pressure of gas in a pipette followed by the expansion of the gas into a smaller pipette, both pipettes being maintained at constant temperature, and the measurement of the final pressure. A series of experiments were carried out with different initial pressures and at different temperatures, and from the data obtained it was possible to calculate the virial coefficient at any of the experimental temperatures. Full details of the method have already been described in previous papers (10, 11, 14, 6).

Experimental

Stainless steel pipettes with volumes of approximately 220 and 50 ml. were used. Both vessels were maintained at constant temperature in a thermostat: oil was used as thermostat liquid up to 100°C. and a molten eutectic mixture of lithium, potassium, and sodium nitrates for temperatures above 100°C. Temperatures were controlled automatically to ±0.005°C. or better, using a photocell–amplifier–relay circuit in conjunction with a platinum resistance thermometer. A second platinum resistance thermometer was used to measure the temperature of the thermostat liquid.

Pressure measurements were made with a Keyes type of dead weight piston gauge which had been calibrated against the vapor pressure of carbon dioxide at 0°C. This instrument and the corrections to be applied to the measured pressure have already been described (10).

The neon used in these determinations was supplied by Linde Air Products as spectroscopically pure neon. Mass spectroscopic examination of the gas did not reveal any impurities, and subsequent analyses carried out at the beginning and end of each isotherm confirmed this.

[1]*Manuscript received December 6, 1954.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3535.
[2]*National Research Council of Canada Postdoctorate Fellow, 1953–54.*

Isotherms of neon were determined at 0°, 50°, 100°, and at 100° intervals up to 700°C. From these data second virial coefficients and intermolecular potentials have been calculated.

Interpretation of Experimental Results

If both pipettes are at a temperature T, their respective volumes are V_1 and V_2, and the number of molecules present initially in the large pipette at a pressure P_1 is n, then since we are dealing with a permanent gas at high temperatures and relatively low pressures, the isotherms can be fitted to simple virial expressions of the form

$$[1] \qquad P_1V_1/n = A_T+B_TP_1+C_TP_1^2.$$

On expanding the gas into the second pipette, the pressure is reduced to P but n remains constant

$$[2] \qquad P_2(V_1+V_2)/n = A_T + B_TP_2 + C_TP_2^2.$$

Combining equations [1] and [2] and eliminating n we get

$$[3] \qquad \frac{P_1}{P_2} = N+(N-1)\frac{B_T}{A_T}P_1+(P_1N-P_2)\frac{C_T}{A_T}P_1$$

where $N = (V_1+V_2)/V_1$.

The isotherms of neon are linear above 50°C. and the contribution due to the term involving the third virial coefficient can therefore be neglected in equation [3]. It must be considered, however, in calculating virial data for the 0° and 50°C. isotherms because these isotherms were found to have a slight curvature.

Considering the simple case

$$[4] \qquad \frac{P_1}{P_2} = N+(N-1)\frac{B_T}{A_T}P_1,$$

N is the intercept when the pressure ratio P_1/P_2 is plotted against P_1 and the value of B_T/A_T can therefore be derived from the slope of the graph. In order to calculate B_T for each isotherm, A_T must be known. If A_T and B_T are expressed in amagat units, then for the 0°C. isotherm

$$A_0+B_0 = 1.$$

Thus A_0 and B_0 can be determined and A_T is then calculated from the expression

$$A_T = A_0T/273.16.$$

Results

Experimental results are shown in Fig. 1 where the pressure ratio, P_1/P_2 is plotted against the pressure in the large pipette before expansion, P_1.*

**It should be noted that the experimental pressures P_1 along the abscissa are not equally spaced, but become progressively more closely spaced at lower pressures, approximately in the ratio $1/N$, as is obvious from equation [4]. This crowding together of the experimental points at low pressures is of great advantage in determining the limiting slope of the curve since from it the second virial coefficient is derived.*

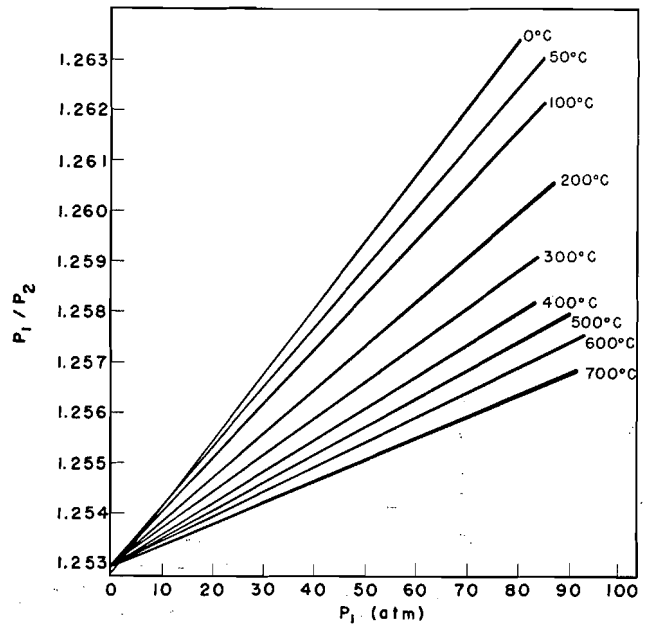

FIG. 1. Plot of pressure-ratios, P_1/P_2, vs. pressure, P_1, for neon.

The scatter of the individual points about the lines would not be noticeable on this scale and so all experimental points have been omitted. In every case, the scatter obtained was of the same order as the accuracy of the pressure measurement. At each temperature at least three expansion runs were carried out, each run usually consisting of eight expansions. The best line to represent the experimental results for each isotherm was fitted by a method of least mean squares (12) and the virial coefficients obtained from these are given in Table I. These data, expressed in amagat units of volume, are converted to cm.^{3}/mole units by multiplying by the normal volume V_N where

$$V_N = 22414.6/A_0 \text{ cm.}^3$$

The variation of the second virial coefficient, B, with temperature is shown graphically in Fig. 2. This graph also shows the results of other measurements carried out on neon (3, 4, 8, 5) and the data are recorded in Table II. There is

good agreement between all the second virial data for neon except those results obtained in the temperature range 0° to 200°C. The data of Michels, Kamerlingh-Onnes, Holborn, and Otto (4), and N.R.C. agree quite closely at 0°C. but the Holborn and Otto (3) result is much higher. However, all the other Holborn and Otto (3) results are in fairly good agreement with N.R.C. results, while those of Michels, Kamerlingh-Onnes, and Holborn and Otto (4) in the temperature range 25° to 200°C. are much lower. It is interesting to note the sudden changes of curvature of the line joining the results of Holborn and Otto (4) at about 0°C. and 200°C. There appears to be no apparent explanation for the discrepancies in the data over the range 0° to 200°C. although the presence of impurities in the gas may be one of the most probable reasons.

ON THE INTERMOLECULAR POTENTIAL OF NEON

The second virial coefficient is related to the energy of interaction between pairs of molecules by the expression

$$B(T) = 2\pi N \int_0^\infty r^2(1-e^{-E(r)/kT})\,dr$$

where $B(T)$ is the second virial coefficient,

N is Avogadro's number,

$E(r)$ is the potential energy of interaction as a function of distance r.

Using this expression it is easy to calculate values for the second virial coefficients provided the potential $E(r)$ is known. The reverse process is not so easy, however, unless a fairly simple expression is used for the term $E(r)$. One such expression is the Lennard-Jones inverse power potential:

$$E(r) = 4\epsilon[(r_0/r)^n - (r_0/r)^6],$$

the special case of this being when $n = 12$, i.e. a 12th power of repulsion and a sixth power of attraction. In the above expression ϵ is the energy at the minimum of the potential energy curve and r_0 is the low-velocity collision diameter. The value of r at the minimum will be designated as r_m. An exp: 6 intermolecular potential

$$E(r) = \frac{\epsilon}{1-6/\alpha}\left[\frac{6}{\alpha}e^{\alpha(1-r/r_m)} - \left(\frac{r_m}{r}\right)^6\right],$$

where ϵ is the depth of the potential energy minimum,

r_m is the position of the minimum,

α is a parameter which measures the steepness of the repulsion energy, has also been used successfully, and it has also been used to predict data on transport properties with fair accuracy.

The experimental results were fitted with a Lennard-Jones 12:6 and 9:6 potential and also an exp:6 potential. For the Lennard-Jones 12:6 potential, integration of the above expression for B leads to $B(T) = b_0\,\beta(\tau)$ where $b_0 = \frac{2}{3}\pi N r_0^3$ and $\tau = kT/\epsilon$. Tables for the function $\beta(\tau)$ have been compiled by Hirschfelder, Bird, and Spotz (9). A method of least mean squares (13) was

used to calculate the best potential parameters. Two sets of virial data were used:

(i) N.R.C. data only.

(ii) N.R.C. data together with the low temperature (0° to −150°C.) data of Holborn and Otto (4) and Kamerlingh-Onnes. Quantum mechanical corrections (2) were applied to all virial data at temperatures of 0°C. and lower before they were used in the calculations. All values shown in Table III have already been corrected.

Good agreement was obtained between the two sets of data for the potential parameters (see Table III) and therefore in subsequent calculations, N.R.C.

data were combined with the low-temperature data of previous workers. Second virial coefficients were calculated from the potential parameters and these are compared with experimental values in Table III. It is apparent from the comparison that the deviations for the 12:6 potential and the exp:6 potential are very similar and neither potential appears to be superior to the other. This is perhaps not surprising in view of the close similarity of the two types of potential energy curves, which are shown plotted in Fig. 3. The 9:6 potential gives a slightly poorer fit to the experimental data in that the sum of squares of the deviations is somewhat higher than for the other two potentials. The over-all fit is nevertheless surprisingly good in view of the rather large difference of this potential (also shown in Fig. 3) compared with the 12:6 and exp:6 potentials.

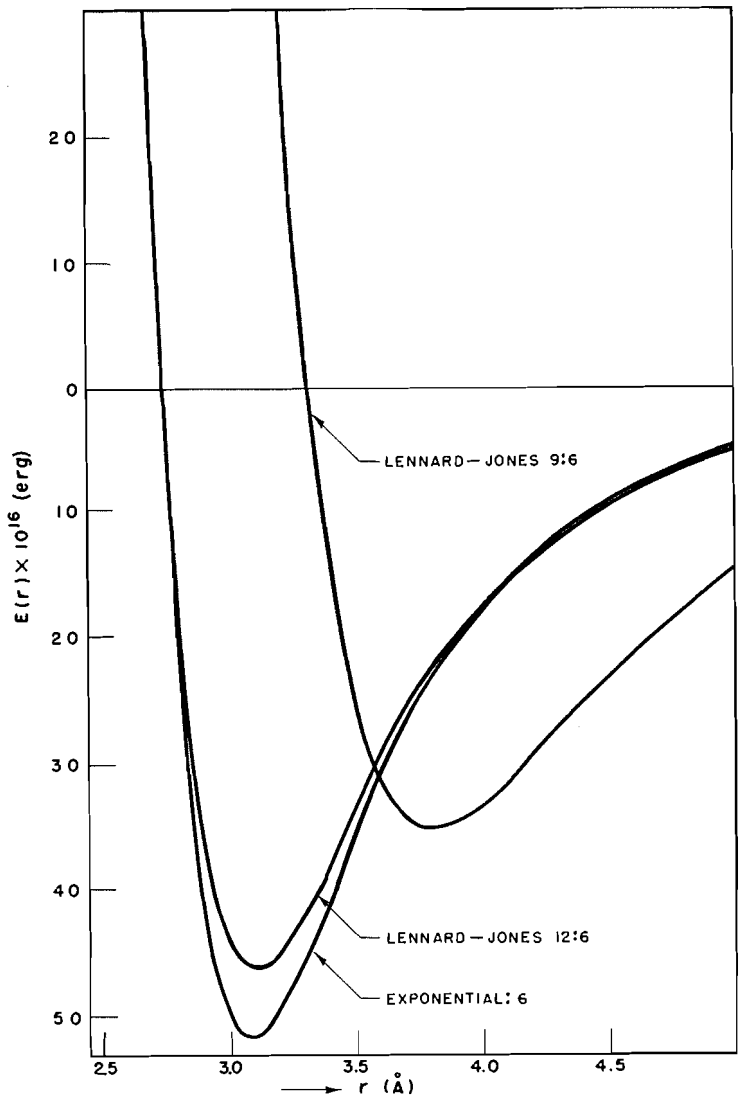

FIG. 3. Comparison of potential energy curves for neon.

Corner (1) has shown recently how calculations of intermolecular potentials may be improved by the use of crystal data in addition to gas property data. He used this method to determine the potentials of neon with repulsion of an exponential type from crystal, second virial, and Joule-Thomson coefficient data. Mason and Rice (7) extended the application of Corner's method to include experimental transport property results for the evaluation of the intermolecular potentials of a number of simple non-polar molecules, including neon. For comparison, the potential parameters obtained by Corner (1) are given in Table IV together with those of Mason and Rice (7) and N.R.C.: these are for an exp:6 potential only. The over-all agreement is very satisfactory.

THE DEGRADATION OF CARRAGEENIN

I. KINETICS IN AQUEOUS SOLUTION AT pH 7[1]

By C. R. Masson

ABSTRACT

The degradation of carrageenin in buffered aqueous solution at pH 7.0 has been studied over the temperature range 60° to 101°C. by following the change in viscosity and reducing properties. Kinetic analysis indicates the occurrence of two reactions: (*a*) an initial rapid degradation representing only about 0.3% of the complete hydrolysis, followed by (*b*) a first-order random degradation having $k = 2.75 \times 10^{13}\ e^{-29,200/RT}$ hr^{-1}. The latter reaction becomes important at temperatures above 60°C. The results indicate that carrageenin is more unstable than would be expected of a simple 1–3 galactan, and that two types of weak linkage are involved in the structure of the polysaccharide.

INTRODUCTION

The polysaccharide carrageenin is a well known naturally-occurring hydrocolloid which, by virtue of its gelling and stabilizing properties in aqueous solution, is of commercial importance (12). Black (1) has recently reviewed the literature on the structure of this polysaccharide. The main units are D-galactose residues joined through carbon atoms 1 and 3 and carrying a half-ester sulphate group on carbon 4. The polysaccharide is obtained by extracting with water the red alga *Chondrus crispus*. In the commercial process, heat is generally employed at some stage during extraction and drying, but, although it has long been known (3) that carrageenin solutions are thermally unstable, no systematic study of the degradation has been reported. Such a study might not only yield results of practical value but might also help to elucidate some aspects of the structure of the macromolecule.

EXPERIMENTAL

Materials

In this Part, only one extract was employed. It was extracted from the dried *Chondrus* at approximately 80°C., decolorized with carbon at 60°C., and precipitated with ethanol from a slightly saline solution. As shown previously (4) it had a number average molecular weight not greater than 74,500. This extract was chosen on account of its relatively low molecular weight, as it was desired to employ reducing end-group titrations as a means of following the degradation. The material is referred to as extract F.

Solutions were prepared as required by "tumbling" at room temperature until homogeneous, and were clarified by means of Selas No. 02 porcelain filters. The sodium salt of the polysaccharide, which was used in all experiments, was prepared by passing the solutions through a column of Amberlite IR 100 exchange resin. Solutions were stored in the refrigerator at 4°C., but even at this temperature a slight decrease in viscosity occurred on standing. Experi-

[1]*Manuscript received December 6, 1954.*
Contribution from the Maritime Regional Laboratory, National Research Council, Halifax, N.S. Issued as N.R.C. No. 3531.

ments were therefore made as soon as possible after the solutions had been prepared.

Measurements

An iodometric method (11) was employed for the titrations of total reducing power.

Viscosities were measured at 25°C. in Ostwald viscosimeters with the characteristics given previously (4). All viscosities were independent of the rate of shear.

Preliminary experiments showed that the decrease in viscosity which occurred on heating an unbuffered solution of carrageenin was accompanied by a decrease in pH. This catalyzed further degradation so that the reaction became quite rapid in the later stages. Buffered solutions were therefore employed in studying the kinetics. *M*/30 sodium phosphate was chosen since the ionic strength was sufficiently high for adequate buffering capacity but low enough to avoid excessive suppression of the viscosity due to the cation effect.

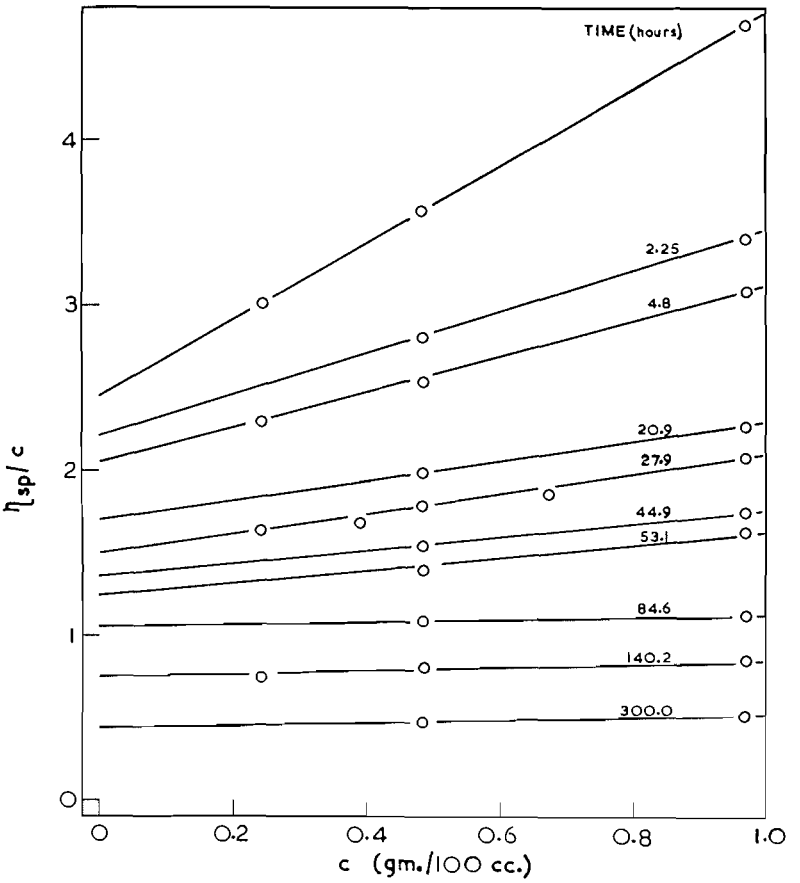

FIG. 1. η_{sp}/c vs. c for a carrageenin solution after various times of heating at 90°C. (Viscosities at 25°C.)

The degradation was studied by heating solutions, of concentration 0.944 gm./100 ml., at various temperatures and measuring the reducing property and intrinsic viscosity of samples withdrawn at various times. The flasks containing the solutions were equipped with reflux condenser, thermometer, and stopper to allow withdrawal of samples, and were placed in baths controlled to within ±0.1°C. Thermal equilibrium was established within one half hour. The experiment at 101°C. was made in an oil bath under gentle reflux and the temperature rose by about 0.5°C. during this experiment. All solutions darkened in color on prolonged heating, although this was slight at 60°C. In addition, small particles of a brown solid occasionally appeared and the solutions were filtered, if necessary, before viscosity measurements were made.

RESULTS

Fig. 1 illustrates the results of a typical experiment. The specific viscosities of the individual samples were measured at various concentrations in $M/30$ phosphate buffer. Extrapolation of the linear plots of η_{sp}/c against c to zero concentration gave values of $[\eta]$ at various times during the experiment. Table I shows the values of $[\eta]$ and of the total reducing power (expressed as

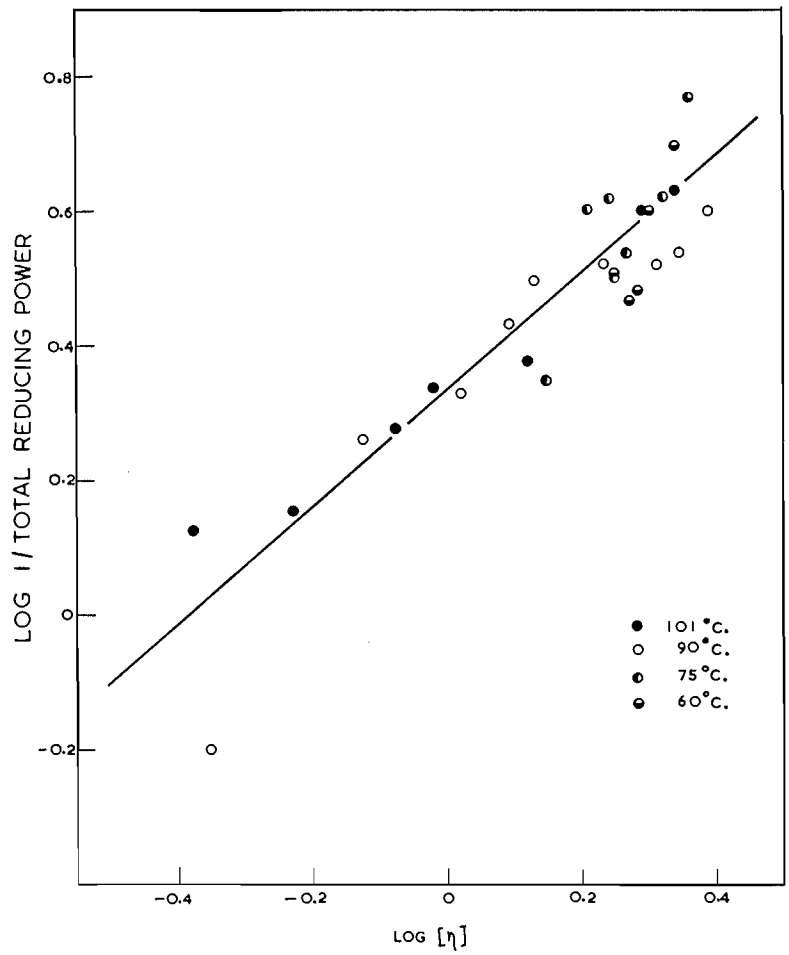

FIG. 2. log [η] vs. log (1/total reducing power) for all runs.

measurements have, however, been performed on dialyzed fractions of the degraded polysaccharide (4). End-group titrations on these fractions showed that the molecular weights calculated on the basis of one reducing end-group per molecule were in reasonable agreement with the accurate values obtained osmometrically. This is illustrated in Table II.

On the basis of this agreement, the titration values shown in Table I have been used to obtain a relationship between $[\eta]$ and M. In Fig. 2 log $[\eta]$ is plotted against log (1/total reducing power) for all the measurements. The scatter is large on account of the insensitivity of the chemical method in this region. For most points, however, the scatter is no greater than expected for an error of ± 0.1 ml. in the titrations. The line through the points corresponds to the relationship

[1] $$[\eta] = 7.59 \times 10^{-6} M^{1.20}.$$

Molecular weights calculated from the intrinsic viscosities by equation [1] are listed in Table I. These values are approximate only, but the relative values may be used to obtain a fairly accurate representation of the course of the degradation.

DISCUSSION

For a first-order, random degradation (2) the velocity constant k is given by the expression

[2] $$1/M_t - 1/M_0 = k\,t/m$$

where M_0 and M_t are the molecular weights at zero time and time t respectively, and m is the molecular weight of the monomer. In Fig. 3, $1/M_t - 1/M_0$ is plotted against t for the four runs. A sharp decrease in molecular weight is observed in the early stages of degradation. After this the plots become linear, indicating random degradation. The initial, non-linear portion of the reaction is exhibited most clearly in the runs at the lower temperatures and does not appear at 101°C. It represents only about 0.3% of the total degradation on the basis of complete hydrolysis.

The slopes of the linear portions of the curves in Fig. 3 give values of k/m. If a tentative value of $m = 250$ is adopted, the following values of k are obtained for the random degradation:

Temp. (°C.)	60	75	90	101
$k \times 10^5$ (hr.$^{-1}$)	0.15	1.13	6.48	20.5

From these data a good Arrhenius plot is obtained, which yields $E = 29.2$ kcal. for the activation energy and $A = 2.75 \times 10^{13}$ (hr.$^{-1}$) for the temperature-independent factor in the equation for the random degradation.

The value of E is of the same order of magnitude as the values found for the degradation of other polysaccharides. Thus Moelwynn-Hughes (8) has reported a value of $E = 30.97$ kcal. for the hydrolysis of maltose polysaccharides. A value of $E = 29$ kcal. has been found (7) for amylose, while for pectin $E = 28 \pm 6$ has been obtained (6).

The values of k are high for a polysaccharide in neutral solution. The labile nature of carrageenin suggests that the observed degradation does not corre-

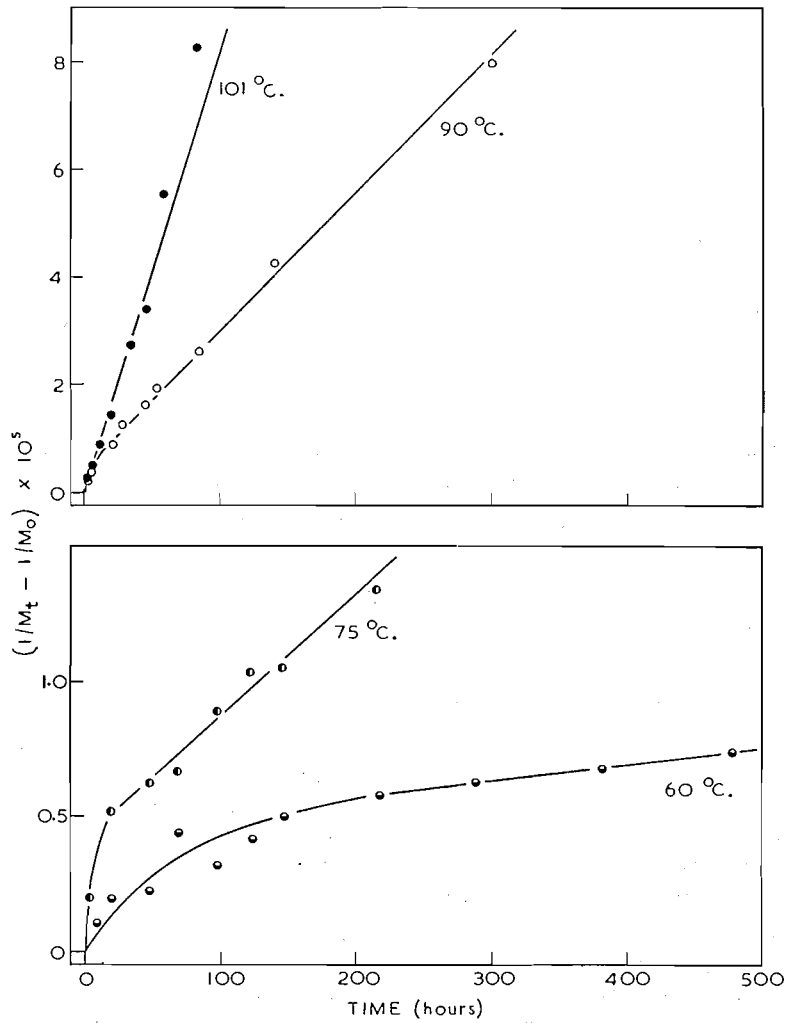

FIG. 3. $1/M_t - 1/M_0$ vs. t for runs at various temperatures.

spond to the scission of 1–3 linked D-galactose residues, but must be attributed to the presence of weaker bonds in the structure. Recent work (9) has revealed the presence of 3,6-anhydro-D-galactose as a constituent of the κ fraction (10) of carrageenin, and strong evidence is available that this compound is split off in the early stages of degradation (5, 9). The high velocity constants may therefore be attributed to this cause.

The random degradation may be interpreted on the basis that the anhydro-D-galactose residues are incorporated either at random or in a regular repeating sequence throughout the structure. The results indicate that long chains of 1–3 linked D-galactopyranose residues are not present in the structure of this extract as the degradation proceeds linearly to low values of $[\eta]$.

At temperatures below 60°C. the rate of random degradation becomes inappreciable. The decrease in viscosity observed for carrageenin solutions at lower temperatures is therefore ascribed to the non-random process noted above. The nature of the weaker linkages responsible for this aspect of the kinetics is at present unknown. A possible interpretation is that bonds responsible for chain-branching or cross-linking are broken in the early stages of degradation, but further work would be required to decide this.

ACKNOWLEDGMENTS

The author wishes to thank Dr. A. N. O'Neill for supplying the carrageen extract and Mr. G. W. Caines for technical assistance.

THE REACTION OF DIETHYL AZODICARBOXYLATE WITH DIHYDROGELSEMINE[1]

By Thelma Habgood and Léo Marion

ABSTRACT

Dihydrogelsemine reacts with diethyl azodicarboxylate yielding a carbinolamine which forms a methyl ether. Both this ether and the carbinolamine base can be oxidized by chromic acid to the same neutral lactam. That there has been no rearrangement of the carbon skeleton during these reactions is shown by reduction of the methyl ether of the carbinolamine with sodium borohydride to dihydrogelsemine and by reduction of the lactam with lithium aluminum hydride to tetrahydrodesoxygelsemine. It is concluded that both dihydrogelsemine and gelsemine contain a methylene group adjacent to $N_{(b)}$, and from the infrared spectrum of the lactam of dihydrogelsemine, $N_{(b)}$ appears to be part of a five-membered ring.

In the course of the investigation of the demethylation of dihydrogelsemine by means of cyanogen bromide (6), the use of diethyl azodicarboxylate as a demethylating agent was explored as an alternate route to dihydro-N-*nor*-gelsemine. It was observed, however, that the action of this reagent on dihydrogelsemine followed a different course. It gave rise to an intermediate which failed to produce formaldehyde when heated with dilute hydrochloric acid, contrary to what was expected from the observations of Diels and Fischer (2) in the preparation of *nor*codeine. The products of the hydrolytic reaction were a new base I and diethyl hydrazodicarboxylate. This seemed to indicate that the azo ester had attacked not the hydrogens of the N-methyl group, but the hydrogen on a carbon adjacent to $N_{(b)}$, and thus afforded a tool with which the alicyclic part of the molecule (5, 7) could be breached.

Because of its unstable character it was not possible to purify the new base I, but on standing in methanol solution in the presence of mild alkali, it was converted into a crystalline methoxy-base II ($C_{21}H_{26}O_3N_2$). The infrared absorption spectrum of this base II (Fig. 1, curve 1) contained two bands (1095 and 1115 cm.$^{-1}$) attributable to ether linkages, together with a band in the NH region and a strong peak at 1713 cm.$^{-1}$ due to the oxindole carbonyl. The base I formed a crystalline perchlorate, $C_{20}H_{23}O_2N_2 \cdot ClO_4$ corresponding to the anhydro-base III, and the infrared absorption spectrum of the salt (Fig. 1, curve 2) indeed showed an absorption band at 1668 cm.$^{-1}$ which has been shown to occur in the spectra of salts containing the $>C{=}N^+<$ grouping (3). The methoxy-base II when treated with perchloric acid gave rise to the same anhydro salt as base I. These facts can be interpreted on the assumption that base I is a dihydrogelsemine carbinolamine, and in support of this, the methoxy-base II gives the silver mirror test, reduces Fehling's solution, and within a few minutes gives a dark orange color with 2,4-dinitrophenylhydrazine. This interpretation was confirmed by the reduction of the methoxy base II

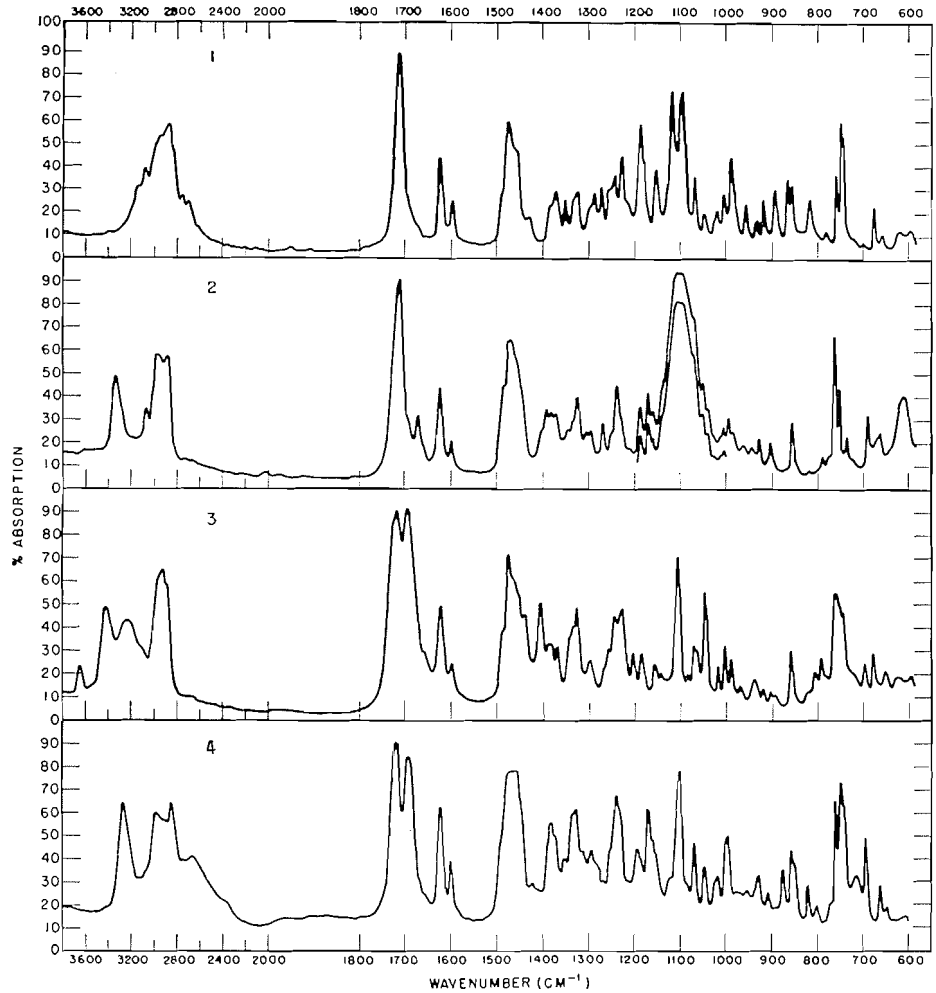

FIG. 1. Infrared absorption spectra in nujol mulls taken on a double beam Perkin-Elmer spectrophotometer, model 21. Curve 1, methoxy base II. Curve 2, perchlorate of base I. Curve 3, dihydrogelsemine lactam. Curve 4, dihydrogelsemine.

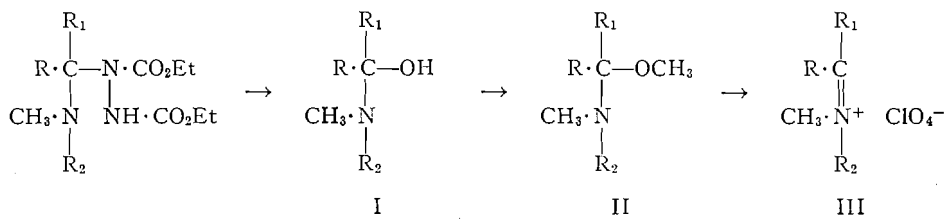
with sodium borohydride which converted it to dihydrogelsemine. Hence the above reactions can be represented by the partial formulae I–III.

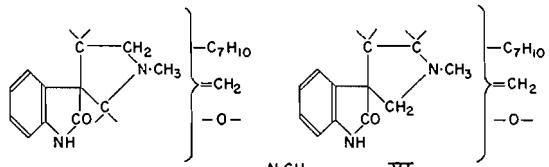


Oxidation of either base I or the methoxy-base II with chromic anhydride in acetic acid gave rise to a neutral product IV ($C_{20}H_{22}O_3N_2$). This product

differed from dihydrogelsemine in having two hydrogens less and one oxygen more. Its neutral properties suggested that it was a lactam, and its infrared absorption spectrum (Fig. 1, curve 3) supported this deduction. It showed a strong absorption band at 1718 cm.$^{-1}$ due to the oxindole carbonyl, and another still stronger peak at 1693 cm.$^{-1}$ attributable to a carbonyl present in a cyclic lactam[2]. The absorption of the new carbonyl in the infrared shows it to be part of a five-membered lactam since the carbonyl of six-membered lactams absorbs at lower frequencies. The lactamic nature of the new carbonyl was confirmed by the action of lithium aluminum hydride which converted product IV into tetrahydrodesoxygelsemine, $C_{20}H_{26}ON_2$, identical with that obtainable directly from dihydrogelsemine (7). Product IV, therefore, contains a carbonyl next to $N_{(b)}$ and dihydrogelsemine must contain a methylene group adjacent to the basic nitrogen. The lactam was hydrolyzed by barium hydroxide, but the resulting amino acid recyclized as soon as its aqueous solution was evaporated to dryness.

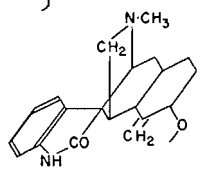
Since gelsemine is known to contain an exocyclic methylene group (4), and since the conversion of gelsemine to dihydrogelsemine has been shown to involve the saturation of this double bond (4), it is legitimate to assume that this reduction does not cause any alteration of the carbon-nitrogen skeleton. Hence, gelsemine also must contain a methylene group adjacent to $N_{(b)}$. Although the action of diethyl azodicarboxylate on gelsemine did not yield any crystalline substance, the amorphous reaction product was converted back to gelsemine by reduction with sodium borohydride, and this lends support to the foregoing conclusion.

In the light of these results, the structures suggested by Robinson (4) and by Prelog and his co-workers (5) to represent gelsemine are untenable. Of the six rings present in gelsemine the nature of three is now established and the base can be represented by one of the partial structures V or VI of which for biogenetic considerations V is preferred. Since one carbon is required for the exocyclic methylene group and one ring is a cyclic ether, a remnant C_7H_{10} is



V

VI



VII

[2]*In this connection it is noteworthy that the infrared spectrum of dihydrogelsemine (in a mull) shows a double peak in the carbonyl region although this base contains only one carbonyl group (Fig. 1, curve 4). The infrared spectrum of N-cyano-*norgelsemine *also contains a double peak in the carbonyl region whereas the spectra of gelsemine and N-cyanodihydro*norgelsemine *show a single absorption band in that region. In the spectrum of the lactam, however, the second peak is stronger than that of the oxindole carbonyl (Fig. 1, curve 3).*

left with which to form the two remaining rings. To represent gelsemine, formula VII is tentatively suggested. It can be derived from one molecule of tryptamine and one of tyrosine which together account for the carbon-nitrogen skeleton of the base. The known reactions of gelsemine can be explained on the basis of this formula in which, however, only one point of attachment of the ether oxygen is suggested, there being no evidence so far as to the size of the cyclic ether.

EXPERIMENTAL[3]

Dihydrogelsemine Carbinolamine

To a solution of dihydrogelsemine (3.643 gm.) in a mixture of acetone (100 ml.) and methanol (10 ml.) diethyl azodicarboxylate (4.0 ml.) (prepared according to the method of Curtius (1)) was added dropwise with swirling. A slight amount of gas was evolved and the solution became warm. After 2.5 hr. the solvent was removed under reduced pressure, and the gummy residue was heated on the steam bath for one hour with 10% hydrochloric acid. No smell of formaldehyde was detected. When cool, the acidic solution was extracted with chloroform to remove neutral compounds consisting of unreacted diethyl azodicarboxylate and of diethyl hydrazodicarboxylate, m.p. 133.2–133.7, either alone or in admixture with an authentic specimen. The acidic solution was alkalized with dilute sodium hydroxide and the precipitated base was extracted with chloroform. On evaporation, the extract left a pale yellow glass difficultly soluble in methanol (3.005 gm.). The basic fraction was benzoylated in chloroform solution with benzoyl chloride (1.6 gm.) under Schotten-Baumann conditions. The chloroform layer was washed with dilute sulphuric acid and the tertiary amine (1.829 gm.) was isolated by alkalization and extraction with chloroform. The tertiary base dissolved in methylene dichloride was chromatographed on alumina. Elution with methylene dichloride and chloroform gave a colorless glass (1.533 gm.). A portion of this base was allowed to stand overnight with methanol, potassium carbonate, and methyl iodide. The mixture was then filtered and the filtrate evaporated to dryness. A residue was left which crystallized from methanol as colorless prisms, softening at 262°, m.p. 264.5–267.5° (decomp.). After two recrystallizations from methanol, the product softened at 258.5° and decomposed at 262.5–264°. It gave no precipitate with silver nitrate solution, was soluble in dilute acids, and could be precipitated from solution by addition of alkali. Calc. for $C_{21}H_{26}O_3N_2$: C, 71.16; H, 7.39; N, 7.91; OCH_3, 8.8; $N\cdot CH_3$, 4.24; one active H, 0.28%. Found: C, 71.17; H, 7.30; N, 7.83; OCH_3, 9.17; $N\cdot CH_3$, 4.28; active H, 0.23%.

Later it was found that the methyl ether could be prepared simply by allowing the tertiary amine fraction to stand overnight in methanol in the presence of potassium carbonate.

The basic methyl ether formed a perchlorate which after two recrystallizations from methanol gave colorless prisms, m.p. 295–295.5°, (dec.) Calc. for $C_{20}H_{23}O_2N_2 \cdot ClO_4$: C, 56.79; H, 5.48; N, 6.63. Found: C, 56.85; H, 5.47; N, 6.72%. It is the perchlorate of the anhydro base and its formation involved

[3]*All melting points are corrected.*

the loss of the elements of methanol. The same salt could be obtained directly from the amorphous unmethylated base.

Reduction of Dihydrogelsemine Carbinolamine Methyl Ether

A solution of the carbinolamine methyl ether (72 mgm.) in methanol (5 ml.) was treated with powdered sodium borohydride (110 mgm.) and allowed to stand for one hour at room temperature. The solvent was evaporated under diminished pressure and the residue was taken up in water and extracted with chloroform. The extract was washed with dilute sulphuric acid, the washings were made alkaline with dilute sodium hydroxide and extracted with chloroform. The base obtained by evaporation of the chloroform (50 mgm.) crystallized on addition of a few drops of acetone, m.p. 219–221°, undepressed by admixture with dihydrogelsemine. The infrared absorption spectrum of the product was exactly superimposable on that of dihydrogelsemine.

Dihydrogelsemine Lactam

The carbinolamine methyl ether (338 mgm.) dissolved in glacial acetic acid (15 ml.) was treated with a solution of chromic anhydride (132 mgm.) in water (1 ml.) and acetic acid (5 ml.). A brown complex was precipitated at first which redissolved. After 18 hr. the excess oxidizing agent was destroyed by addition of a few milliliters of ethanol, and the solution was alkalized with dilute sodium hydroxide. The suspension was extracted with chloroform and the extract washed with dilute sulphuric acid. Evaporation of the chloroform left the neutral lactam (252 mgm.) as a pale yellow foam which was dissolved in benzene and chromatographed on alumina. Elution with ether gave the lactam (186 mgm.) which crystallized as long prisms from methanol. Undried material when heated slowly sintered at 152° and effervesced from 172–180°. When dried at 110° for 10 hr., the lactam had m.p. 157–159.5°. Calc. for $C_{20}H_{22}O_3N_2$: C, 70.98; H, 6.55; N, 8.28. Found: C, 70.70; H, 6.46; N, 8.23%.

Oxidation of Base I

The amorphous base I (338 mgm.) was dissolved in glacial acetic acid (15 ml.) and treated with a solution of chromic anhydride (132 mgm.) in acetic acid (5 ml.) and water (1 ml.). After 18 hr. at room temperature a little ethanol was added to destroy the excess of chromic acid, the solution was diluted with water, alkalized with sodium hydroxide, and extracted with chloroform. The chloroform extract was washed with dilute sulphuric acid and with water, and evaporated to dryness. The neutral product (252 mgm.) was dissolved in benzene and chromatographed on alumina (activity IV) and eluted with ether. A crystalline fraction (116 mgm.) was obtained which after recrystallization from methanol consisted of colorless prisms. After drying it melted at 157–159.5° either alone or in admixture with the dihydrogelsemine lactam obtained by oxidation of the carbinolamine methyl ether.

Reduction of Dihydrogelsemine Lactam

A solution of dihydrogelsemine lactam (260 mgm.) in dry dioxane (12 ml.) was added dropwise to a suspension of lithium aluminum hydride (650 mgm.) in freshly distilled ether (1 ml.). After the vigorous reaction had abated, the

mixture was refluxed for two hours and afterwards the excess reagent was destroyed by the cautious addition of 1:1 methanol–water. The precipitated hydroxides were centrifuged and washed with methanol, the decantate and washings were evaporated under diminished pressure, and the residue dissolved in chloroform. Evaporation of the filtered chloroform solution left a yellow gum (414 mgm.), the benzene-soluble portion of which was chromatographed on alumina. Elution with benzene yielded a colorless oil (190 mgm.) which crystallized from ether as colorless flat prisms, m.p. 142–142.5°, undepressed on admixture with an authentic specimen of tetrahydrodesoxygelsemine (7).

Saponification of the Lactam

Refluxing dihydrogelsemine lactam with potassium hydroxide in ethanol, or with aqueous dilute hydrochloric acid or concentrated hydrochloric acid did not hydrolyze the lactam. Heating with concentrated hydrochloric acid in a sealed tube at 160–180° also failed to bring about hydrolysis.

The lactam (375 mgm.) was heated in a sealed tube for five hours at 150–160° with saturated aqueous barium hydroxide solution (10 ml.). After cooling, the solution was filtered and to the filtrate small pieces of dry ice were added to precipitate the barium. The barium carbonate was centrifuged and washed with hot water. Evaporation of the combined decantate and washings almost to dryness gave 315 mgm. of long platelets which became brown above 200° but did not melt below 310°. Evaporation to complete dryness transformed the solid into a chloroform-soluble substance (185 mgm.) which crystallized from methanol as prisms softening at 155–168°, shown by its infrared absorption spectrum to be identical with the original lactam. The lactam was inert to 95% hydrazine at 125–135°.

Reaction of Gelsemine with Diethyl Azodicarboxylate

Gelsemine (2.569 gm.) in methanol solution was allowed to stand for 18 hr. with diethyl azodicarboxylate (1.754 gm.), and the product worked up exactly as described for dihydrogelsemine. It consisted of a colorless glass which did not crystallize from any of the usual solvents.

A quantity of the product (103 mgm.) dissolved in methanol (15 ml.) was treated with sodium borohydride (302 mgm.) exactly as described above. The product after chromatography on alumina consisted of a colorless foam (34 mgm.) which crystallized from acetone, m.p. 178.5–179°, undepressed on admixture with gelsemine.

ACKNOWLEDGMENT

The authors wish to express their thanks to Dr. R. N. Jones and Mr. R. Lauzon who determined the infrared absorption spectra.

DISINTEGRATION-RATE DETERMINATION BY 4π-COUNTING
PART I[1]

By B. D. Pate[2] and L. Yaffe

ABSTRACT

The response probability of a 4π-counter has been examined and conditions determined for which the response probability is unity to within $\pm 0.1\%$ for a range of nuclides. Variables examined have been the effect of polarization potential, discriminator bias, source location, counting rate, counter gas purity, thickness of conductor on source mount, for particles of various energies and from various modes of disintegration.

GENERAL INTRODUCTION

The determination of absolute disintegration rates in a precise manner is of fundamental importance in nuclear physics and nuclear chemistry. It is also of some application in other fields, e.g. radiobiology, where radioactive tracers are used as a research tool. The experimental methods available have been reviewed a number of times (8, 18, 25, 26). All with the exception of 4π-counting and coincidence counting are subject to sources of error which limit the accuracy attainable to several per cent. Recent results (31) with β–γ and γ–γ coincidence measurements indicate that an accuracy of better than one per cent may be possible. The method, however, is limited to nuclides which emit gamma radiation and whose decay schemes are well known.

4π-Counting, up to this time used mainly in the standardization of material for therapeutic use, has considerably wider applicability and greater potential precision than the majority of other techniques. However, the results of international intercomparison of standards (31) show a scatter of a few per cent, and the limits of error assumed by individual workers are of the same order of magnitude (16, 18, 26, 31, 33).

Errors of this magnitude are certainly not inherent in the method and the present paper is the first of a series which will describe work aimed at improving the accuracy attainable with 4π-counting techniques. While some of the information we shall present is strictly applicable only to the design of chamber we have used, most of it is of interest in connection with any form of 4π gas-ion counting.

4π-Counting in the present form originated in 1944, when Simpson (32) described a counter with a geometry approaching 4π steradians. What was probably the first true 4π-counter was designed by L. Meyer-Schützmeister and described in 1948 by Haxel and Houtermans (17). Since that time a number of counting chambers of a variety of designs have been described (1, 2, 4–7, 16–18, 22, 23, 27, 28, 30, 32, 33, 35–37). A counter system with a geometry of 4π steradians can be achieved in several ways, e.g. with a gaseous source as part of the filling of a gas counter, or with the source dispersed

throughout the phosphor of a scintillation counter. We have confined our attention to a system which has obvious advantages for routine radiochemical work—a chamber composed of two 2π gas-ion counters arranged face to face. The source material is placed between them, in solid form.

The particular advantages of a counter that will respond to radiation emitted over a solid angle of 4π steradians have been appreciated for some years. Since every charged particle that is emitted is registered by the counter system, any event subsequent to charged particle emission which occurs within the resolution time of the instrument will not be registered separately. This has two desirable consequences.

(i) Provided the primary events of the nuclear transition studied include charged particle emission with a total probability of unity, one count will be registered per distintegration. This remains undisturbed by the emission of secondary particles, nuclear gamma radiation, or annihilation radiation, when this occurs within the counter resolving time, as is usually the case. Cases for which some data from the decay scheme are required include those when particle emission occurs with a probability of less than unity (which includes orbital electron capture) and transitions leading to a metastable excited state of the product nucleus. In such cases, the accuracy of the disintegration-rate determination will clearly depend on the accuracy of the nuclear data employed, in addition to that inherent in the counting procedure.

(ii) Scattering of radiation either by source material, source mount, gas, or counter walls is without effect on the observed disintegration rate, since any discharges (subsequent to that corresponding to the primary event) caused by repeated scattering of one particle will occur within the counter resolving time. The same is true of secondary radiation production due to interaction of primary particles with gas, wall, or other material within the counter.

Thus most of the large corrections (38) of uncertain accuracy required to correct data from conventional counter systems (where the geometry is much less than 2π steradians) are eliminated. The only sources of error still to be corrected for in the calculation of disintegration rates from counter data are due to:

(*a*) Failure of the counter to respond once to every ionizing particle, arising from a nuclear disintegration, that reaches the counter gas.

(*b*) Absorption of radiation by the mount on which the source is deposited.

(*c*) Absorption of radiation by the source material itself ('self-absorption').

(*d*) Statistical fluctuations in the disintegration rate of the source and in the background counting rate of the counter. This error can clearly be reduced to within any desired limits by extension of the number of events observed.

This paper considers the first of the above items. Subsequent publications will deal with (*b*) and (*c*) and certain theoretical topics relating to counter behavior.

INTRODUCTION

For the present discussion, it is convenient to define a quantity which we shall call the *response probability* of the counter. This is the probability that a

discharge triggering the recorder be produced when a charged particle or photon originating from a nuclear disintegration reaches the counter gas. (The term "efficiency" is avoided since it has been used by different workers in various contexts.) This probability will have a certain value for a specific form of radiation (e.g. for charged particles ideally it will be unity) but under given conditions however it may deviate from this value. It is the purpose of the remainder of this paper to describe an examination of the variation of the response probability of the counter system used by us.

The response probability is found to be a function of several variables in the conditions under which the counter is operated. Some of these variables can be adjusted to ensure that no deleterious effect on the response probability occurs. Others cannot be controlled in this fashion and one must determine, to the desired degree of precision, the value of response probability as a function of the variable considered. Corrections for the departure from unit probability in the final calculation of disintegration rate can then be made.

The response probability of the counter may be less than unity if:

(*a*) the gas multiplication of the chamber is less than a minimum value;

(*b*) the "effective geometry" of the chamber is less than 4π steradians;

(*c*) the counting rate is so high that the apparatus is unable to resolve successive discharges, and "coincidence-losses" occur.

It may be more than unity, i.e. more than one count be registered per disintegration, when:

(*d*) at higher anode voltages, the discharge phenomena become more energetic. Then photon emission from the excited gas molecules and positive ion bombardment producing secondary and photoelectron emission from the cathode may lead to multiple discharging over a time interval greater than the counter resolution time.

(*e*) the counter gas contains more than a limiting concentration of impurities with an electron affinity. This may lead to the formation of slow moving negative ions which, collected after the electron pulse, may also lead to spurious pulses being observed.

(*a*) *Gas Multiplication*

In order that the passage of an ionizing entity through the chamber shall register a count, the ionization produced, after gas multiplication, collection at the counter anodes, and external amplification, must produce a pulse at the output of the amplifier system larger than the discriminator bias potential applied to the signal. Whether this condition is satisfied depends on the value of the multiplication factor, amplifier gain, capacitance of the chamber anode system and amplifier input, and the bias potential. These quantities may all be measured, but, aside from the discriminator bias, which cannot be reduced below a minimum value, the only one normally varied in the system is the gas-multiplication factor. This must be adjusted, by increasing the polarization potential for example, until the situation described above is obtained. However, the polarization potential cannot be raised indefinitely since above a limiting value the secondary processes described under (*d*) above set in.

Thus it is important to determine whether the gas multiplication can be raised sufficiently to bring the response probability of the chamber close to a value of unity for the radiation producing the least amount of ionization in the chamber. (This is clearly particularly important when beta radiation is to be examined, since the energy spectrum includes a proportion of particles with very low energies, a proportion which increases with decreasing spectrum energy end point.)

One may determine in two ways whether this state of affairs can be brought about.

(i) The change in counting rate as the gas multiplication is varied within the range available may be observed.

(ii) The various quantities described above, including the gas multiplication (as a function of polarization potential), may be measured and the total response probability of the counter under given conditions may be calculated for those energies where specific ionization is at a minimum.

Both these methods have been used in the present investigation.

In addition to being a function of the polarization potential, the gas multiplication is also dependent on several other variables.

(iii) The polarization field strength is a function of position inside the chamber, and therefore the ion collection will be a function of source position both within the normal source-mount plane, and for movements at right angles to this plane. However, at certain polarization potentials, it is expected that a region will exist in the center of the chamber over which the response probability is constant at a value of unity. The operation of the counter will then be insensitive to small movements of the source within this region.

(iv) Since the efficiency of ion collection within the chamber is a rapidly varying function of field strength it is important to ensure that in the vicinity of the source the field strength is at a maximum. This is especially true for soft β emitters which will have a short range in the gas and thus most of the ionization is produced in the immediate source vicinity. The counter design ensures this maximum field strength provided the source mount is conducting to the cathode surface. An insulating mount will disturb the field strength in such a manner that a position of zero field strength occurs at the source position and hence poor ion collection results.

Seliger and Cavallo (30) claimed that the loss in efficiency due to the use of a non-conducting film mounted over an aperture in an aluminum diaphragm was negligible provided the aperture diameter was limited to minimize the field disturbance. However, a later paper (22) agreed with most observers that, for reliable results, the film had to be rendered conducting. This is satisfactorily accomplished by distillation of gold *in vacuo* on to the film. A rapid routine method for estimating the thickness of the gold layer has been described in a previous publication (24). It is of considerable importance to reduce the superficial density of the source mount used as far as possible in order to reduce absorption of radiation (see the next paper in this series). It is thus essential to know the minimum superficial density of gold required for satisfactory counter operation, since it is fruitless to reduce the film super-

ficial density much below this figure. Little quantitative information is available on this point, or on whether one or both sides of the film need be coated. Hawkings (16) has used 25 μgm./cm.^{2} of gold on both sides of a 100 μgm./cm.^{2} Formvar film with success.

(v) The electron-collection process will clearly be affected to some extent if the counter gas contains a significant proportion of electron-accepting impurities. It is therefore of importance to determine the limiting concentration which can be tolerated without the counter operation being affected.

(*b*) *Counter "Geometry"*

The response probability will be reduced from a value of unity if conditions are such that a proportion of the emitted radiation is absorbed (other than by source material, or the mounting film) before it can produce the necessary minimum number of ions required to trigger the recorder. It must, therefore, be verified that, with the aperture sizes used by us, this effect is not serious.

(*c*) *Coincidence Losses*

Operation of the chamber as a proportional counter serves to increase the value of the response probability at high counting rates, by making possible a reduction in the resolution time of the apparatus, compared with that obtained with the counter operated as a Geiger-Müller counter for instance. The use of the 4π-counter over a wide range of counting rates nevertheless demands that the coincidence loss be accurately known as a function of counting rate. Owing to the variety of processes which may cause coincidence losses in the proportional counter and associated electronic equipment this function is best obtained empirically. The availability of thin films, described in a previous publication (24), has made possible a very precise determination of the coincidence loss function by a modification of the conventional multiple source technique.

EXPERIMENTAL PROCEDURES, RESULTS, AND DISCUSSION

The counter chamber used in these experiments is essentially that described by Hawkings *et al.* (16) and is reproduced in Fig. 1. It consists basically of two hemispherical brass cathodes of 7 cm. diameter and two ring-shaped anodes of 0.001 in. diameter tungsten wire. The source mount, which is continuous with the cathodic surface, consists of a plastic film of superficial density 5–10 μgm./cm.^{2} rendered conducting by a layer of gold (2 μgm./cm.^{2}) applied by distillation *in vacuo* to either surface of the film. The film is mounted over an aperture in an aluminum plate 1 mm. thick. The aperture diameter is usually 5 cm. and occasionally 2.5 cm.

The chamber is used in conjunction with a Nicholls high voltage supply (AEP 1007B). The anodes of the chamber are connected in parallel to an Atomic Instrument Co. preamplifier (205-B) which has been modified to obtain a low noise level. The output from this is fed into an Atomic Energy of Canada Ltd. amplifier (AEP 1448) which has non-overload characteristics, and thence after discrimination into a Marconi scaling unit of 1000 (AEP 908).

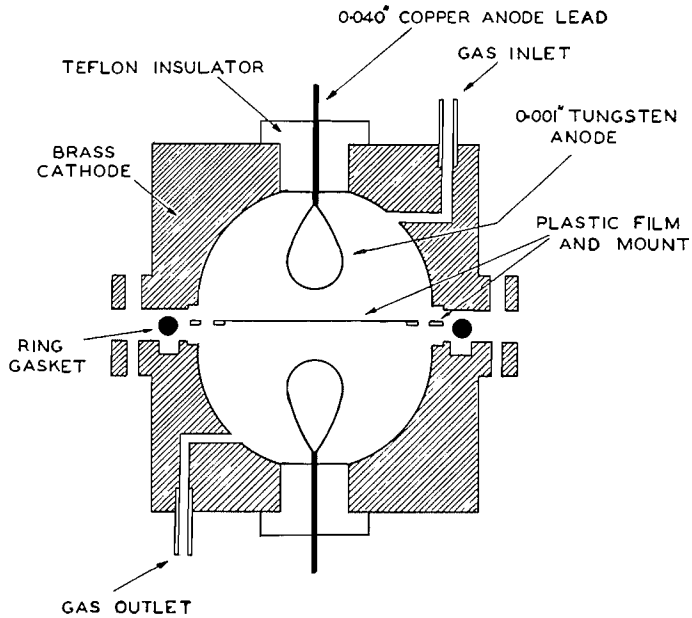

FIG. 1. The 4π-counting chamber.

The over-all gain of the amplifying system is 30,000 and a bias voltage up to 50 v. can be applied by the discriminator to the output signal.

The counter chamber is operated in the proportional region. The counting gas used is C.P. methane at atmospheric pressure dried by passage over silica gel. After insertion of the sample the counter is flushed for about five minutes at a rapid flow rate and the rate then moderated to a standard rate of 0.5 ml. methane per sec.

The stability of the equipment, which was checked with a standard RaD-E-F source and a Ni^{63} source, is excellent. This can also be attested to by the reproducibility of results obtained at different times.

The sources of radioactivity used were all of so high specific activity that source thickness did not affect the results quoted in this paper. Samples approximating "point-sources" were prepared by evaporation of a suitably sized aliquot of stock solution on the mounting film using infrared radiation. One exception to this procedure was the case of Tc^{99m}. This nuclide was co-separated with rhenium in the normal fission product procedure (14) up to the final stage when the Re–Tc mixture was precipitated as the sulphide. The sulphide was slurried with water and a portion evaporated on the film.

The half life, mode of decay, radiation characteristics, and source of supply of the nuclides used are shown in Table I.

(*a*) *Gas Multiplication*

(i) *High Voltage Characteristics of the Counter*

High voltage characteristic curves were obtained in the usual way for a series of sources of β radiation of increasing maximum energy, at a constant

TABLE I

CHARACTERISTICS AND SOURCE OF SUPPLY OF RADIOACTIVE NUCLIDES

Nuclide	Half life	Mode of decay	Maximum energy of particle (Mev.)	Source of supply
Ni^{63}	80 yr.	β^-, no γ	0.067	A.E.C.L.
S^{35}	87 days	β^-, no γ	0.167	A.E.C.L.
Ca^{45}	152 days	β^-, no γ	0.254	A.E.C.L.
Tl^{204}	4.0 yr.	β^-, no γ	0.765	A.E.C.L.
Bi^{210}	5.0 days	β^-, no γ	1.17	Separated from RaD-E-F from A.E.C.L.
P^{32}	14.4 days	β^-, no γ	1.70	A.E.C.L.
La^{140}	40.3 hr.	β^-, γ	2.26	Separated from fission products of uranium irradiated in BEPO, A.E.R.E. Harwell, England
Po^{210}	138 days	α	5.30 (mono-energetic)	Separated from RaD-E-F from A.E.C.L.
Na^{22}	2.6 yr.	β^+, γ	1.8	A.E.C.L.
Co^{60}	5.3 yr.	β^-, γ	0.319	A.E.C.L.
Tc^{99m}	6.0 hr.	IT	0.142 (mono-energetic)	Separated from fission products of uranium irradiated in NRX, Chalk River, Ont.

discriminator bias level. The nuclides employed, with the exception of La^{140} all emit β^- particles without accompanying γ radiation. Their nuclear properties are described in the top half of Table I. Fig. 2 indicates the response of the counter to pure β radiation. Standard deviations on the quantities measured lie within the areas of the points as plotted (as for all succeeding figures in this paper unless otherwise indicated).

The data shown in Fig. 2 indicate that the chamber used in this work is suitable for measurements of β^- emitters with maximum energies at least down to 0.067 Mev. The plateaus obtained in no case show any perceptible slope. The maximum figure which can be calculated on a basis of the statistics of the measurements concerned is less than 0.1% per 100 v. There is, therefore, little ambiguity as to the correct counting rate figure to be used as a basis for calculating the disintegration rate, and little doubt of the fact that substantially all of the particles in the spectrum are being registered. At polarization potentials of about 100 v. in excess of the threshold value, the response probability approximates very closely to unity. However, obviously, any polarization potential on the plateau may equally well be used if for any reason this is desirable.

The displacement observed with increasing particle energy is due to the reduced amount of ionization produced in the region of maximum polarization field strength by the more energetic radiation. The effect is less marked at the

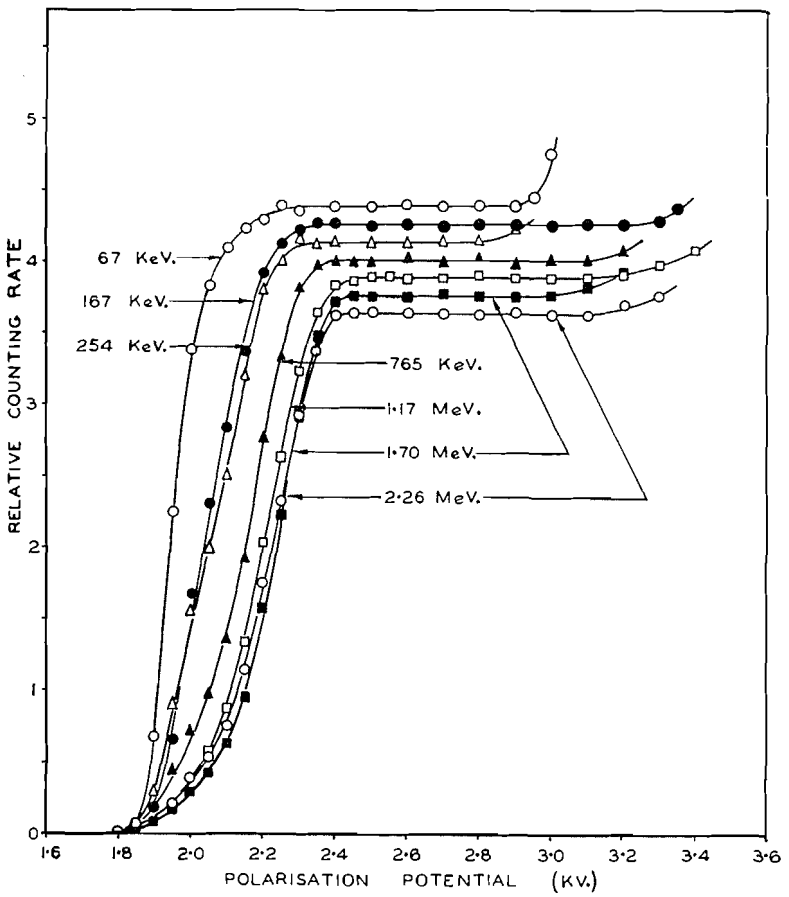

FIG. 2. High voltage characteristics for β radiation of varying maximum energies.

higher end of the energy scale since there is very little variation of specific ionization with energy in this region.

The length of the plateaus observed with β^- emitters is never less than 400 v. and may be as much as twice this. The polarization potential at which multiple pulsing sets in is dependent on many factors such as condition of source and temperature of the chamber.

Fig. 3 shows a series of characteristics obtained using Ni^{63} (maximum energy 0.067 Mev.) taken at increasing discriminator bias values. Fig. 4 shows a similar series using La^{140} (maximum energy 2.26 Mev.). Plateaus taken at increasing bias values are displaced to higher polarization potential values but otherwise are exactly superimposable. Fig. 5 shows characteristics obtained with nuclides decaying by the emission of alpha particles, positrons, negative electrons with gamma radiation, and by isomeric transition. These data indicate that the present chamber makes a satisfactory counter for many forms of radiation. Absolute measurements with α- and β^+- and β^--emitting nuclides with or without accompanying γ radiation are clearly straightforward.

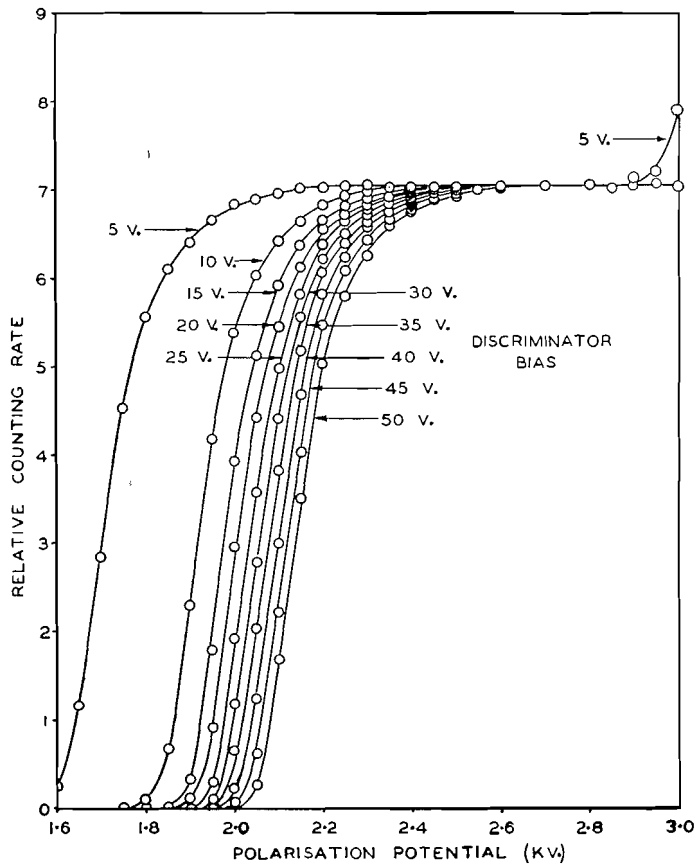

FIG. 3. High voltage characteristics for Ni^{63} β radiation as a function of applied discriminator bias.

With nuclides decaying by means of isomeric transition the same is true if the pertinent nuclear data are available.

Fig. 6 shows the variation of the characteristic with increasing disintegration rate. A series of P^{32} sources of known strength was prepared on 5–10 μgm./cm.^{2} films. The disintegration rates (about 500 d.p.s.) were below the region where coincidence losses were significant. A series of secondary sources was then prepared from these by lamination, the total disintegration rates being calculated by summing those of the component sources. (It will be shown in a forthcoming publication that the absorption of radiation from P^{32} even with 10 or more of these component films can be neglected.) The results of measurements at two values of discriminator bias are shown. The calculated rate for each source used is shown for comparison purposes.

These results show clearly that satisfactory characteristics are retained with our apparatus at least up to a counting rate of 3×10^3 counts per second. The irregular shape of the curves above this figure show that it is meaningless to quote a coincidence loss for a counting arrangement unless this loss is given

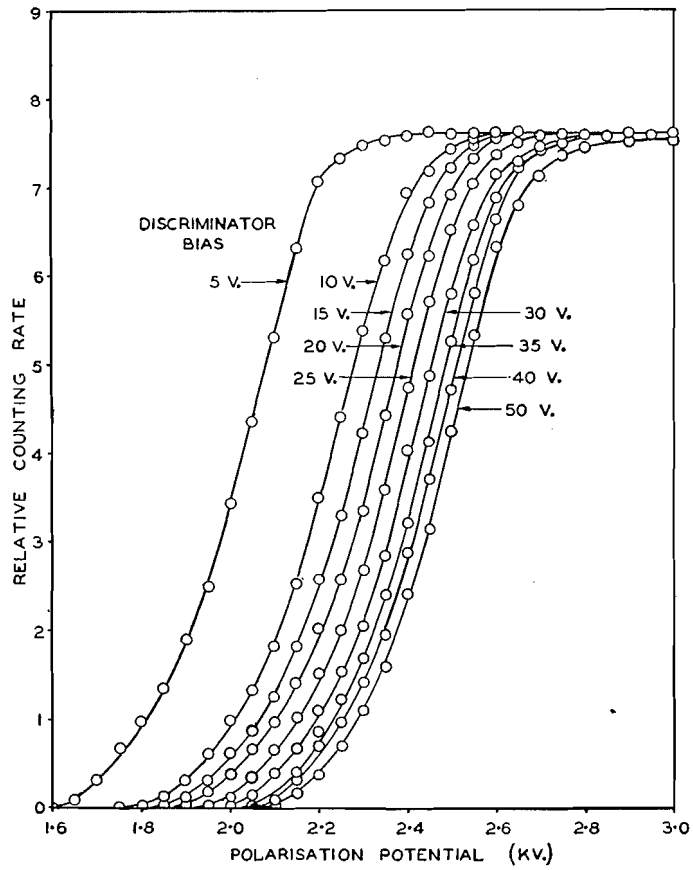

FIG. 4. High voltage characteristics for La^{140} β radiation as a function of applied discriminator bias.

for definite polarization conditions, since coincidence losses in proportional counting are due to a variety of reasons. For example, since the discharge mechanism results in a local and partial reduction of the polarizing field, the counter may enter into successive discharge processes with the effective counter field at different stages of recovery. Also, at higher counting rates, the slow migration of positive ions to the cathode may substantially reduce the polarization field and thus the gas multiplication. In addition to this losses in the electronic circuit may also occur.

(ii) *Response Probability to Charged Particles as a Function of Their Energy*

The ionization produced by most charged particles is more than adequate to ensure a response probability of unity under normal operating conditions. With low energy particles and electrons of about 2 Mev. (where the specific ionization is at a minimum (3)) this may not be so. For example, a small low energy fraction of any spectrum of β radiation will not count with unit probability. This fraction increases as the maximum energy of the spectrum decreases.

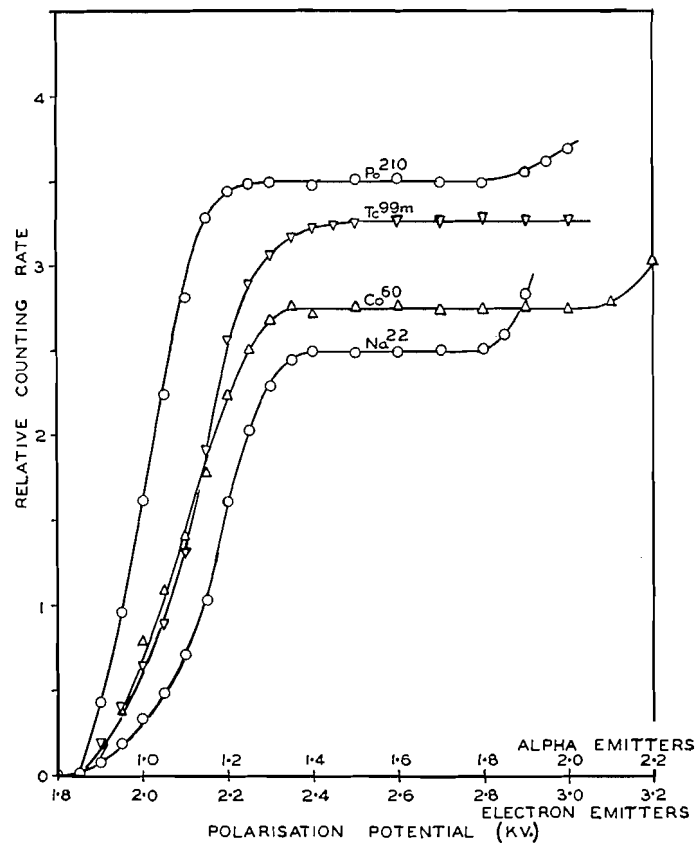

FIG. 5. High voltage characteristics for various forms of radiation.

We have calculated the response probabilities of the counter towards the entire spectrum of the β radiation of Ni^{63} and S^{35} since these were the softest β radiations studied. The calculations are conveniently made in three stages. *First*, the minimum total charge pulse arriving at the counter anode system which will trigger the recording mechanism is calculated from the measured electronic parameters. The corresponding original ionization is then computed.

Amplifier gain	$= 3 \times 10^4$	(measured with a calibrated pulse generator and oscilloscope)
Minimum bias level	= 3 v.	(i.e. a pulse greater than this will trigger the scaler circuit)
Minimum input	= 0.1 mv.	(calculated from above)
Capacitance of chamber anode system and amplifier input	= 25 $\mu\mu$f.	(measured by resonance bridge method)

Therefore, the 0.1 mv. input signal corresponds to a charge arriving at the anode of 2.5×10^{-15} coulombs or 1.6×10^4 electronic charges.

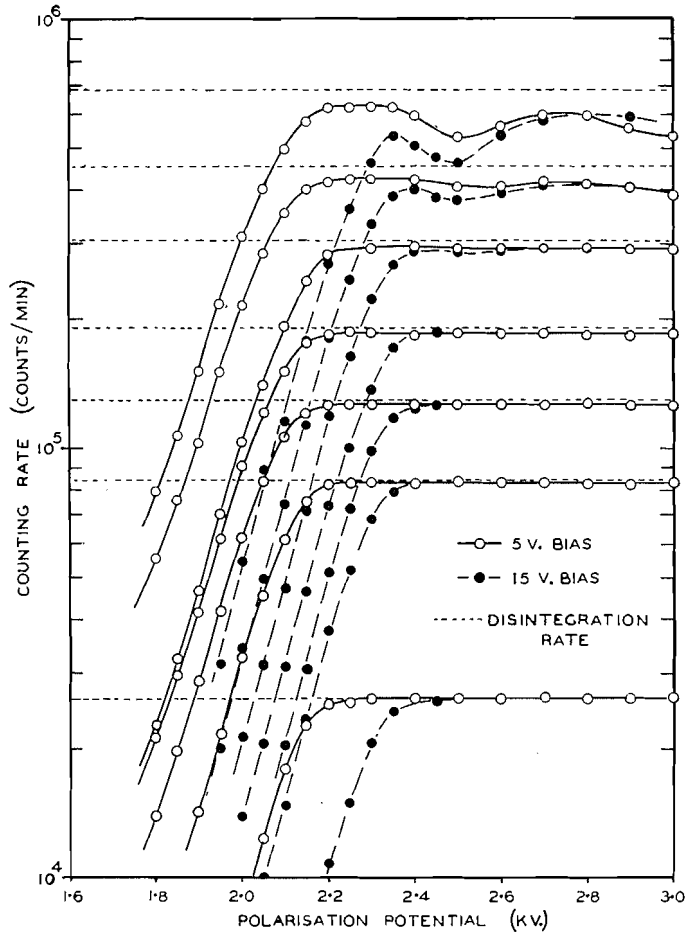

FIG. 6. High voltage characteristics as a function of disintegration rate.

The mean gas multiplication was determined in the following way. Using the alpha particles from Po^{210} the maximum pulse height obtained at the chamber anode system was measured with a cathode ray oscilloscope. Care was taken that pulses were not large enough to produce amplifier saturation or proportional counter distortion. The observed pulse amplitude was independent of polarization potential between 250 and 500 v. Here the chamber is acting as a saturated ion chamber and the gas multiplication is unity. Readings, taken at increasing potentials, were normalized to this value. When the danger of saturation or distortion became apparent a Ni^{63} source was substituted for the Po^{210}. A large range existed where both could be used so that no errors were introduced by the substitution.

The results are shown in Fig. 7. At 2.6 kv. the mean gas multiplication (A) has a value of 2.6×10^3 and at 2.9 kv., $A = 1.6 \times 10^4$. Therefore, at these polarization potentials, the counter will respond to a mean of six and one ion pairs respectively.

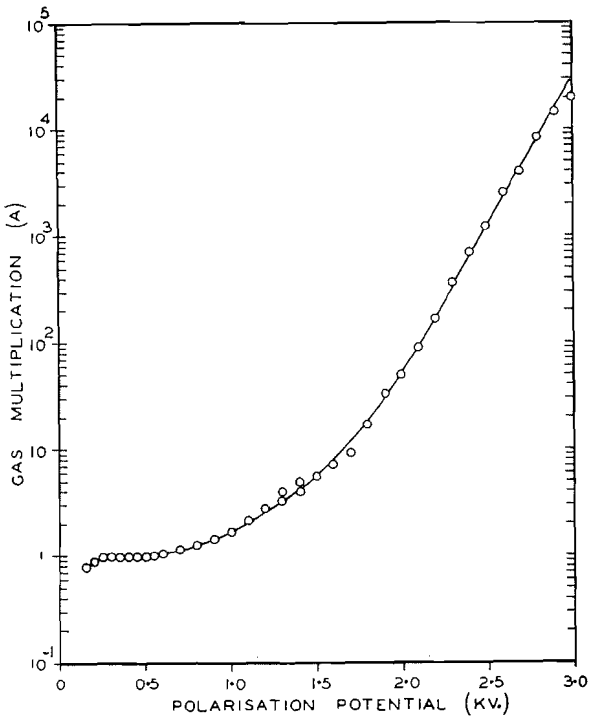

FIG. 7. Gas multiplication function of counter.

Secondly, the probability that a given particle energy will produce a certain minimum number of ion pairs should be calculable if the appropriate data are available. Curran *et al.* (9) note that the mean energy (W) necessary to produce one ion pair increases with particle energy at low energies, but give no quantitative data. They also note that W for both argon and nitrogen (both non-electron acceptors like methane) is substantially independent of energy down to 500 ev. This confirms theoretical predictions made by Fano (11). As a first approximation (adequate for present purposes) one can assume that the value due to Schmeider (29) of $W \sim 30$ ev. applies in the region of interest.

Both the ionization and gas multiplication obtained under given conditions are subject to variance. Let J_0 be the mean number of ion pairs produced in the chamber ($= E/W$ where E is the particle energy dissipated in the gas). The variance of J and of the gas multiplication A have been studied by a number of workers. Fano (12) has shown, on theoretical grounds, that the variance of J, $V_J = FJ_0$ where F (a constant for the particular gas) is found to be equal to 0.3 for atomic H where necessary data for calculation are available.

The variance of A was examined theoretically by Snyder (34) and Frisch (13) who found that $V_A = A$. Thus the total variance V of the output pulse amplitude of a counter expressed as an equivalent variance of the original ionization J will be $V = FJ_0 + J_0$. The observations of Hanna *et al.* (15) at

250 ev., 2.8 kev., and 17.4 kev. indicate that a value of $V = J_0$ describes the experimental results more exactly. Since F is not expected to be very small, the variance of the gas multiplication factor must be less than J_0, confirming the observations of Curran *et al.* (10).

Thus the distribution of pulse amplitudes at the chamber anode for a given energy will be approximately a Poisson distribution. On this basis, then, one can calculate the probability P that at least one or at least six ion pairs be produced, as a function of particle energy, corresponding to the polarization potential values mentioned above.

The probability functions are shown in Fig. 8. Since a minimum of one ion pair will trigger the counter at 2.9 kv., the curve for $J = 1$ represents the counter response probability function under this condition. Similarly, the curve for $J = 6$ gives the response probability at 2.6 kv. Clearly, at low E values these calculations are in error, but certainly show at worst an order of magnitude for P at these energies.

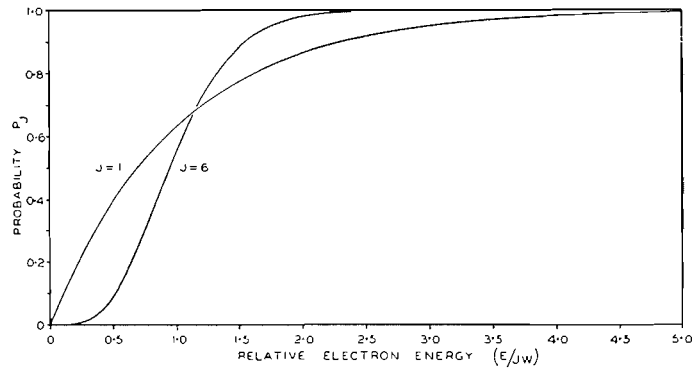

FIG. 8. Counter response probability as a function of electron energy for mean ionizations of one and six ion pairs.

Thirdly, from the probability curves of Fig. 8 it is now possible to obtain a mean response probability for a radiation of any known energy distribution. We have calculated the values for Ni^{63} and S^{35} at applied potentials of 2.6 and 2.9 kv. The relevant probability function has been integrated using energy values from the spectrometer data of Langer *et al.* (21) for S^{35} and Kobayashi *et al.* (19) together with the modified beta decay theory for $\Delta J = 2$, yes transitions (20) in the case of Ni^{63}. The results of the calculations are shown in Table II.

TABLE II

COUNTER RESPONSE PROBABILITY

Nuclide	Applied voltage (kv.)	Mean no. of ion pairs detected	Probability
Ni^{63}	2.6	6	0.9953
Ni^{63}	2.9	1	0.9992
S^{35}	2.6	6	0.9998
S^{35}	2.9	1	0.9999

Owing to their low energy emission Ni^{63} and S^{35} are the two nuclides we have studied which are most likely to have a low response probability. The response probability in the two cases is seen to be very close to unity. This conclusion is also, of course, corroborated by the observations recorded in Fig. 2. The counting rates obtained with all energies remained essentially unchanged even when for example, in the case of S^{35}, the applied potential was increased from 2.4 to 3.2 kv., corresponding to a change in the gas multiplication by a factor of about 160. A minimum in the specific ionization also occurs at a particle energy of about 2 Mev. The specific ionization at this point is about 40 ion pairs per cm. per atmosphere of methane (3) which corresponds to a production of at least 100 ion pairs in the chamber. This is clearly sufficient to ensure a response probability of unity.

(iii) *Response Probability as a Function of Source Position*

We have examined the variation of response probability of the counter for sources of radiation as a function of their location in the source-mount plane in a manner essentially similar to that employed by Hawkings *et al.* (16) for P^{32}. We have determined this for β emitters of varying energy from 0.067 Mev. to 2.26 Mev. at various polarization potentials and bias voltages.

The source was mounted on a small area of 5–10 μgm./cm.^{2} film supported over an aperture of 5 mm. diameter in a slide of aluminum foil. The slide was arranged to move between two parallel wires so that the source could be adjusted to any position along a diameter of the source-mounting diaphragm. This movement, combined with the rotation of the diaphragm, allowed the source to be brought to any point within the plane of the source mount. The whole was screened electrostatically from the electrode system by being sandwiched between two gold-coated 10 μgm./cm.^{2} films. Attenuation of the β radiation by absorption in the small layer of gas trapped between the films could be neglected for purposes of this experiment. The counting rate was observed with the source in 90 different positions, each at two values of polarization potential and two discriminator bias settings. Typical contours of qual response probability are shown in Figs. 9 and 10.

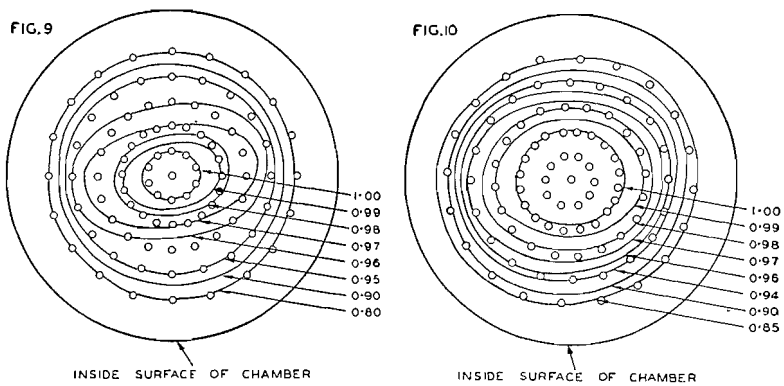

FIG. 9. Contours of equal response probability for Ni^{63} β radiation.
FIG. 10. Contours of equal response probability for La^{140} β radiation.

The contours are essentially similar to those obtained by Hawkings *et al.* (16) for P^{32}. The area over which the response probability is unity for a particular applied voltage and bias level can be seen to be smaller for Ni^{63} than for La^{140}, because of the reduced range of the weaker radiation in the counter gas. Other curves, similar in nature, have been obtained with varying polarization and bias level but are not shown here for reasons of brevity. These curves show an expansion of the contours with increasing polarization and decreasing bias voltage.

From these data it is clear that a source diameter of up to at least 1 cm. can be tolerated by the counter for all particle energies studied without a significant drop in response probability.

It will be seen from Fig. 1 that the counting chamber is constructed in such a manner that both hemispheres are recessed to accommodate an aluminum source-mount diaphragm. This allowed us to investigate the variation of response probability when a source of S^{35} was moved 1 mm. from the medial position towards each anode. (The source-mounting film is customarily affixed to one side of the aluminum diaphragm, and the source material deposited on the side of the film away from the diaphragm.) The results, as shown in Table III, show that a displacement of at least 1 mm. in either direction (the maximum allowed by the counter design) may occur without adversely affecting the counting rate.

TABLE III

EFFECT ON RESPONSE PROBABILITY OF VERTICAL SOURCE DISPLACEMENT

Position	Observed counting rate (counts/min.)
Source central facing upwards	39,070 ± 140
Source displaced 1 mm. towards top anode facing upwards	39,170 ± 140
Source central facing downwards	39,240 ± 140
Source displaced 1 mm. towards bottom anode facing downwards	39,280 ± 140

(iv) *Effect of Variation of Gold Thickness of Source-mount Films*

The effect on counter response probability of variation of gold thickness on films has been investigated in two sets of experiments, one each for Ni^{63} and P^{32} radiation. Sets of VYNS films (all of 5–10 μgm./cm.^{2} superficial density and mounted over diaphragm apertures of 5 cm. diameter) were coated on one side with a range of gold thicknesses. The superficial density of gold applied was measured spectrophotometrically as described previously (24). For each film, a source was applied centrally to the side of the film on which the gold had been deposited. The high voltage characteristic at a constant discriminator bias setting obtained with this arrangement was recorded. A diaphragm with aperture diameter of 2.5 cm. was then placed over the first, forming effectively a system in which a film with the same gold superficial density was mounted over a smaller aperture. The characteristic curve was again determined. The film, on the original diaphragm, was then removed from the counter and 10 μgm./cm.^{2} gold distilled on to it. In one half of the experiments the gold was

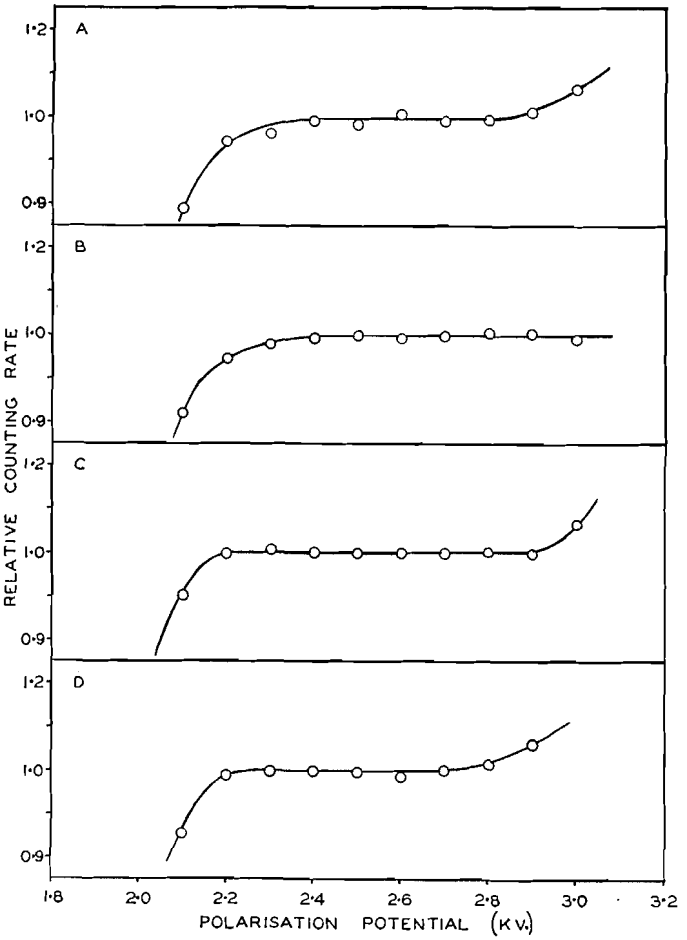

FIG. 11. High voltage characteristics as a function of side of mount to which gold is applied.
A. 5 μgm./cm.² of gold on source side. Ni^{63}
B. 5 μgm./cm.² of gold on reverse side. Ni^{63}
C. 5 μgm./cm.² of gold on source side. P^{32}
D. 5 μgm./cm.² of gold on reverse side. P^{32}

applied to the side of the film carrying the source and in the other half to the reverse side. The voltage characteristic was again determined. Finally, a further 10 μgm./cm.² of gold was applied, this time to the opposite side to the above (both sides now had at least 10 μgm./cm.² of gold) and a fourth characteristic was measured.

The results of the effect of gold thickness are as follows:

1. In all cases the last two characteristics were identical. Identical voltage characteristics were obtained regardless of whether the gold was on the source side, reverse side, or both sides. Representative characteristic curves are shown in Fig. 11.

2. The appearance of the characteristics obtained with increasing thicknesses of gold is shown in Fig. 12 for Ni^{63} and Fig. 13 for P^{32}. In order to render

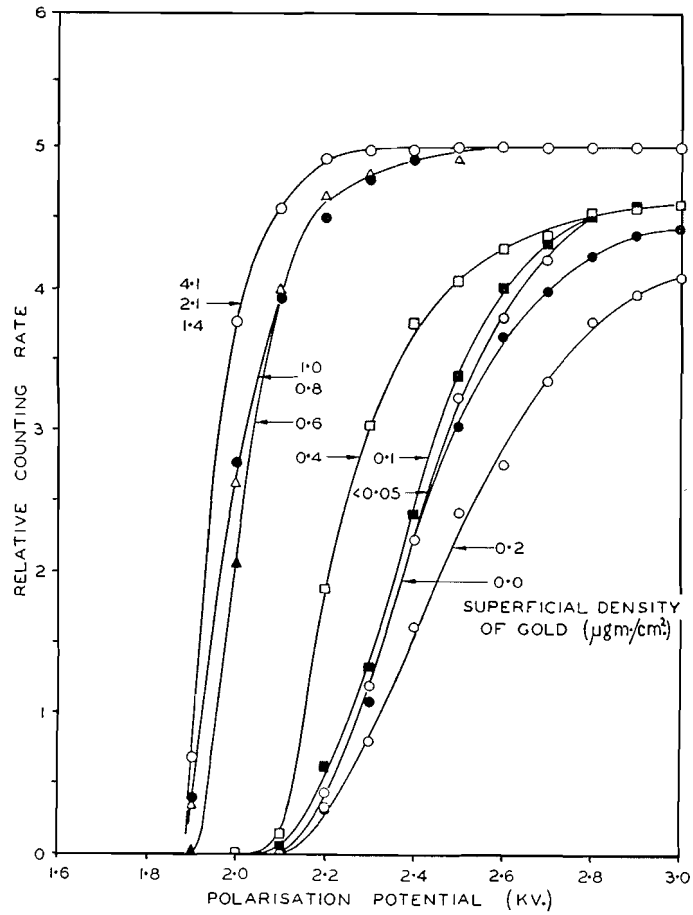

FIG. 12. High voltage characteristics for Ni^{63} as a function of gold thickness on source mount.

the data comparable the counting rates are expressed as a fraction of that found for the source after application of 10 μgm./cm.² of gold to the source mount. The figures plotted apply to a diaphragm aperture of 5 cm. The smaller aperture of 2.5 cm. had the effect of displacing the characteristic for a given gold thickness to a higher polarization potential. However, the gold thickness at which normal characteristics occurred (> 2 μgm./cm.²) was the same for both aperture sizes.

(v) *Effect of Purity of Counting Gas*

The effect of using a counter gas of inferior quality is shown in Fig. 14. This shows a series of characteristics using Ni^{63} as the radioactive source and Technical grade methane as the counting gas. The mass spectrometric analysis of a sample of C.P. methane, giving normal performance, is shown in Table IV. We do not give an analysis for Technical grade methane as this varies from one cylinder to another; the variation in quality is such that some samples may be found to give satisfactory characteristics.

*The authors wish to thank Dr. H. I. Schiff for having performed this analysis.

Experiments performed with synthetically prepared gas mixtures showed that the counter is relatively insensitive to the presence of higher saturated

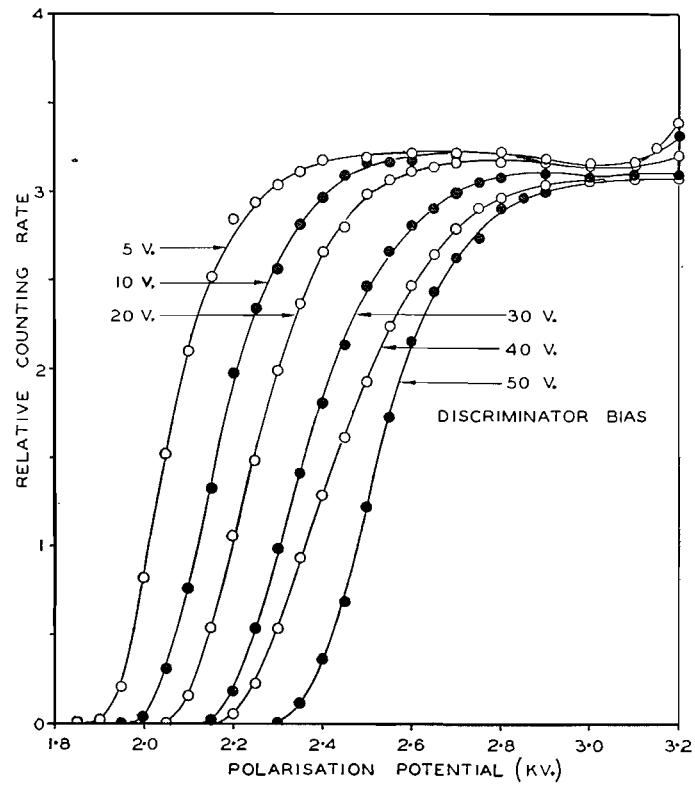

FIG. 14. High voltage characteristics obtained with impure methane for Ni^{63} β radiation.

and unsaturated hydrocarbons in the gas mixtures. The presence of small quantities of air or oxygen, however, is injurious, possibly owing to the electron affinity of the latter.

(*b*) "*Counter Geometry*"

Experimental techniques for determining effect of "counter geometry" are described in section (iv) of (*a*).

Characteristics for Ni^{63} and P^{32} are shown in Fig. 15 for both large and small diaphragm apertures. The gold thicknesses used in this experiment were greater than the limit at which regular behavior commenced.

Several workers (16, 23) have discussed the effect of using a relatively thick metal diaphragm in order to support the source-mounting film or foil. Calculations have been made of the fraction of particles emitted which will be "lost" owing to collision with the diaphragm aperture wall. Experiments have also been performed at a single value of the polarization potential to determine the effect of reduction of aperture size.

Fig. 15 shows clearly that no decrease in counter response occurs when the diaphragm aperture diameter normally used is decreased by one half. Provided that a particle produces the necessary minimum number of ions before being absorbed in the aperture wall, no loss in counts will occur. As the

C. 2.5 cm. diameter aperture. P^{32}
D. 5.0 cm. diameter aperture. P^{32}

FIG. 16. Coincidence loss function of the counter, at 2.6 kv. high voltage and 15 v. discriminator bias.

polarization potential is increased, the probability of this minimum number being produced approaches unity. Thus, the effect of a reduced aperture size is to displace the polarization characteristic to higher polarization potentials and does not reduce the effective counter geometry from 4π steradians.

(*c*) *Response Probability at Higher Counting Rates*

The coincidence loss function of the counting arrangement has been determined using the method previously described to examine the effect of disintegration rate on the characteristic curve of the counter. A series of 12 sources of P^{32} with disintegration rates ranging from between 3×10^2 and 10^4 d.p.s. was prepared and the counting rates of the single and laminated sources obtained. The results, expressed as "coincidence loss" as a function of the observed counting rate, are shown in Fig. 16 plotted on a log–log scale. Some points for the curve were also obtained by studying the departure from exponential decay of a source of Na^{24}.

The results obtained in Fig. 16 clearly illustrate the loss in counting rate of this counter assembly with increasing disintegration rate. The presentation of the data on a log–log plot results in a curve which is linear and thus facilitates extrapolation to lower counting rates. This correction curve can be used with

confidence for our arrangement up to an apparent counting rate of 6×10^5 c.p.m. It is highly probable that most of the losses which occur are not primarily due to the counter but due to the electronic equipment.

SUMMARY

On the basis of the experimental work discussed in this paper, it is estimated that the error due to the departure of the response probability of a 4π-counter from a value of unity may be reduced to less than 0.1%. For our apparatus, the conditions under which this is realized are the following: source-mounting film of 5–10 μgm./cm.^{2} VYNS resin mounted over a diaphragm aperture of 2.5 or 5.0 cm. and coated with at least 2 μgm./cm.^{2} of gold, counting gas C.P. methane, polarization potential 2.6 kv., and discriminator bias 15 v.

The absence of perceptible slope on the high voltage characteristics of the chamber when functioning correctly allows a considerable latitude in the conditions under which the system may be satisfactorily operated. It further allows a rapid verification that the system is so operating. If an increase of 200 v. in the polarization potential or 10 v. decrease in the discriminator bias causes no change in counting rate observed, then a response probability close to a value of unity is indicated.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council of Canada and Atomic Energy of Canada Ltd. for grants-in-aid. We would also like to express our appreciation to Dr. J. D. Jackson, Dr. R. E. Bell, and Mr. R. C. Hawkings for valuable discussions during the work and in the preparation of the manuscript. One of us (B.D.P.) wishes to thank the National Research Council for assistance received in the form of a studentship.

THE COMPRESSIBILITY OF GASES AT HIGH TEMPERATURES

X. XENON IN THE TEMPERATURE RANGE 0° TO 700°C. AND THE PRESSURE RANGE 8 TO 50 ATMOSPHERES[1]

By E. Whalley, Y. Lupien, and W. G. Schneider

ABSTRACT

The virial coefficients of xenon have been measured in the temperature and pressure range described. The results are compared with previous measurements.

The compressibility and the virial coefficients of a number of gases have been previously measured over a wide temperature range using an expansion technique (5). In the present paper measurements of the virial coefficients of xenon from 0° to 700°C. are reported. Temperatures up to 700°C. were employed in the present measurements in order that the virial coefficients could be extended well above the Boyle point. The pressure ranges covered by the measurements were approximately 4 to 20 atm. at 0°C., 8 to 30 atm. at 50°C., and 8 to 50 atm. at the higher temperatures. The xenon gas used in the measurements was supplied by the Linde Company and contained no krypton or other impurities above the limit of detection by a mass spectrometer (about 0.01%). Frequent checks on its purity were made during the runs. The procedure and method of measurement were the same as described previously (5).

RESULTS

The experimental measurements were fitted to the equation of state

$$PV = A+BP+CP^2 \qquad [1]$$

by the method of least squares described previously (6). The values of the virial coefficients A, B, and C, and their standard errors, are summarized in Table I. The units are amagat units. The standard error of the derived coefficients has been defined previously (6) and it is perhaps worth pointing out that it does not necessarily represent the absolute error. The total number of gas expansions carried out in the measurements at each temperature are also given in the table.

At 0°C. the vapor pressure of xenon is approximately 41 atm. (3). It was not possible to fit the measured data above 20 atm. to a virial equation including the fourth virial coefficient, so only measurements below 20 atm. were retained in the final analysis. At 50°C. only measurements below 30 atm. were retained for the same reason. At higher temperatures the maximum pressure was 50 atm. and at all temperatures except for the 0° isotherm the lowest pressure was 8 atm. or lower. For the 0° isotherm, which presented the greatest difficulty in fitting a series equation, the measured pressures were extended down to 4 to 5 atm. This was accomplished with an auxiliary piston

gauge which was designed to operate in the pressure range from 3 to 15 atm. The additional low pressure data, which are very essential for obtaining accurate second virials for highly imperfect gases, greatly facilitated the fitting of the data to a series equation. Moreover, for the isotherms between 0° and 150°, where the curvature of the pressure-ratio vs. pressure plots was greatest, the value of N, the volume ratio of the gas pipettes, was determined separately at each temperature by measurements with helium in the usual way. This further simplified the fitting of the data since the intercept on the zero pressure axis of the pressure-ratio vs. pressure plots is then fixed, and the uncertainty of extrapolation of the data from higher pressures is greatly reduced.

COMPARISON WITH PREVIOUS MEASUREMENTS

The compressibility of xenon has been measured by Beattie, Barriault, and Brierley (1) at M.I.T. in the temperature range 16.65–300°C. and pressure range 20–400 atm., and by Michels, Wassenaar, and Louwerse (4) at Amsterdam in the temperature range 0–150°C. and pressure range 16–2800 atm.

The M.I.T. measurements were fitted (2) to the equation of state

$$[2] \qquad PV = RT+\frac{B_V}{V}+\frac{C_V}{V^2}+\frac{D_V}{V^4}.$$

The second and third virial coefficients B_V and C_V were converted to the corresponding pressure virial coefficients of equation [1] by the relations

$$[3] \qquad A = RT/V_N, \quad B = B_V/RTV_N, \quad C = \frac{C_V-B_V^2/RT}{V_NR^2T^2},$$

where V_N is the normal volume. The Amsterdam measurements below a density of 50 amagat units were fitted to the equation

$$[4] \qquad PV = A_\rho+B_\rho\rho+C_\rho\rho^2+D_\rho\rho^4.$$

The second and third virial coefficients were converted to the corresponding virial coefficients of equation [1] by the relations

$$[5] \qquad B = B_\rho/A_\rho, \quad C = \frac{C_\rho-B_\rho^2/A_\rho}{A_\rho^2}.$$

Both sets of values are compared with the present measurements in Table I. Both quoted values of the virial coefficients to several figures more than justified by their accuracy. They have been rounded off to the values quoted in the table.

The normal volumes of xenon deduced from the three sets of measurements are listed in Table II.

Our results are not in very good agreement with either the M.I.T. or the Amsterdam values, though these agree very well with each other. Apart from the 0° and 50° measurements, our second virial coefficients are uniformly about 0.1×10^{-3} amagat units higher than the others. This would appear to

**Calculated by using the Beattie–Bridgeman equation of state which had been fitted to the isotherm measurements at higher temperatures. No measurements at 0°C. were carried out by these authors. Less weight should be placed on this value than on the others.*

indicate that there is some systematic difference between the measurements. In both the Amsterdam and the M.I.T. measurements the lowest pressures measured were rather high, being from 16.5 to 27.7 atm. for the Amsterdam isotherms, and 20.7 to 46.1 atm. for the M.I.T. isotherms, whereas the lowest pressure used in the present measurements was never greater than 8 atm. Since the second virial coefficient is obtained from a zero pressure slope it would seem that greater accuracy could be obtained from measurements extending to lower pressures. Because xenon is a rather imperfect gas, particularly at the lower temperatures, the measurements should preferably not extend to a too high pressure. The deviations of the experimental from the observed values of $V(PV-RT)$ at constant temperature of Beattie's measurements are not random (Table I, Ref. 2). We have not reported our pressure measurements since they are partly functions of the apparatus, but care was taken in the analysis that the deviations of the calculated from the observed pressure ratios were random, indicating that equation [1] was a good fit to the data. Another contributing cause of the different virial coefficients may be the use of an inverse volume series for the equation of state in the M.I.T. and the Amsterdam measurements, whereas we have used a pressure series.

ACKNOWLEDGMENTS

We wish to thank Mr. W. A. Stevenson for assistance in constructing the apparatus, and Mr. G. David for assistance with the computations.

IDENTIFICATION OF SPRUCE SULPHITE LIQUOR COMPONENTS[1]

By E. A. Kvasnicka and R. R. McLaughlin

ABSTRACT

Spruce sulphite liquor was extracted with butyl acetate. By means of solvent fractionation, chromatography, and countercurrent distribution, vanilloyl methyl ketone, vanillin, dihydroconiferyl alcohol, 3,3′-dimethoxy-4,4′-dihydroxystilbene, and a new phenolic compound, $C_{20}H_{24}O_5$, were isolated and identified.

In the field of lignin chemistry, the oxidation of sulphite waste liquor has aroused considerable interest. A large amount of work has been carried out for the purpose of isolating and identifying the low molecular weight fragments of lignin in such oxidized liquors (22). However, no such comparable effort has been made to investigate the original sulphite waste liquor, though a few constituents have been noted (8, 16, 21, 28). The amount of such compounds is much smaller than in oxidized liquor and consists mainly of degradation products of lignin together with some materials derived from the wood, or their reaction products (32, 35). It follows that the identification of these components could be an important link between the studies of wood extractives and the examination of the constituents of oxidized liquors, and might indicate technical uses of the compounds so identified, or of compounds that could be derived from them.

These considerations induced a thorough investigation of the solvent-extractable components of spruce sulphite liquor in this laboratory. The present paper describes the first part of the results obtained.

Spruce sulphite liquor was extracted with butyl acetate, which removes a larger amount of solids than benzene or ether (11). The extract contains three main groups of components: tannins and conidendrin, other phenols, and neutral compounds (hydrocarbons and esters). It was necessary to perform a crude separation into these groups by solvent fractionation before the further work was done. Conidendrin was separated by its low solubility in ethanol. Extraction of the ethanol-soluble part with ether left a minor amount of conidendrin and the tannins as residue. Extraction of the ether-soluble part with petroleum ether removed mainly hydrocarbons and left as residue the main part of the other phenolic compounds.

The next step was the separation of these groups into the bisulphite-soluble compounds (extraction with 21% sodium bisulphite), acids (10% sodium bicarbonate), and phenols (6% sodium hydroxide). The neutral compounds and a very small amount of phenols with extreme pK values (2) remained after these extractions.

The large number of components in these fractions made separations difficult and required an efficient method to check the course and extent of

[1]*Manuscript received November 30, 1954.*
Contribution from the Department of Chemical Engineering, University of Toronto, Toronto 5, Ontario.

the subsequent steps. Paper chromatography was used extensively for this purpose.

The bisulphite-soluble material was separated by chromatography. Vanillin and 1-(3-methoxy-4 hydroxyphenyl)-propanedione-1,2 were isolated. The latter compound has not yet been reported in spruce sulphite liquor. Its presence in the aqueous filtrates of lignin ethanolysis mixtures (3, 14) shows some relation between the degradation processes during ethanolysis and sulphite cooking.

The alkali-soluble material was separated by fractional acidification, utilizing the difference of the pK values. Further separation was obtained by countercurrent distribution which yielded dihydro-coniferyl alcohol (3-(3-methoxy-4-hydroxyphenyl)-propanol-1) as a new component of spruce sulphite liquor. Hibbert (13) and Schuerch (30) found this compound in the hydrogenolysis products of maple lignin. Kawai (17) isolated it as a degradation product of egonol.

From the same fraction, a new phenolic compound, $C_{20}H_{24}O_5$, m.p. 134°C., was isolated. Its spectrum (UV, IR) is closely related to dihydroconiferyl alcohol and the investigation of its structure is under way.

In addition to the previously reported compounds, a small amount of 3,3′-dimethoxy-4,4′-dihydroxystilbene was isolated by chromatography of the alkali-soluble fraction. Richtzenhain (26) found this stilbene in oxidized sulphite liquors and reported its absence in untreated liquors.

It can be seen that the compounds now isolated from spruce sulphite liquor are known as reaction products of quite different lignin degradation procedures: ethanolysis, hydrogenolysis, and oxidation.

Further investigations will be concerned with the identification of the remaining compounds of the extracts and with the origin of the isolated products.

EXPERIMENTAL PART

1. *Extraction*

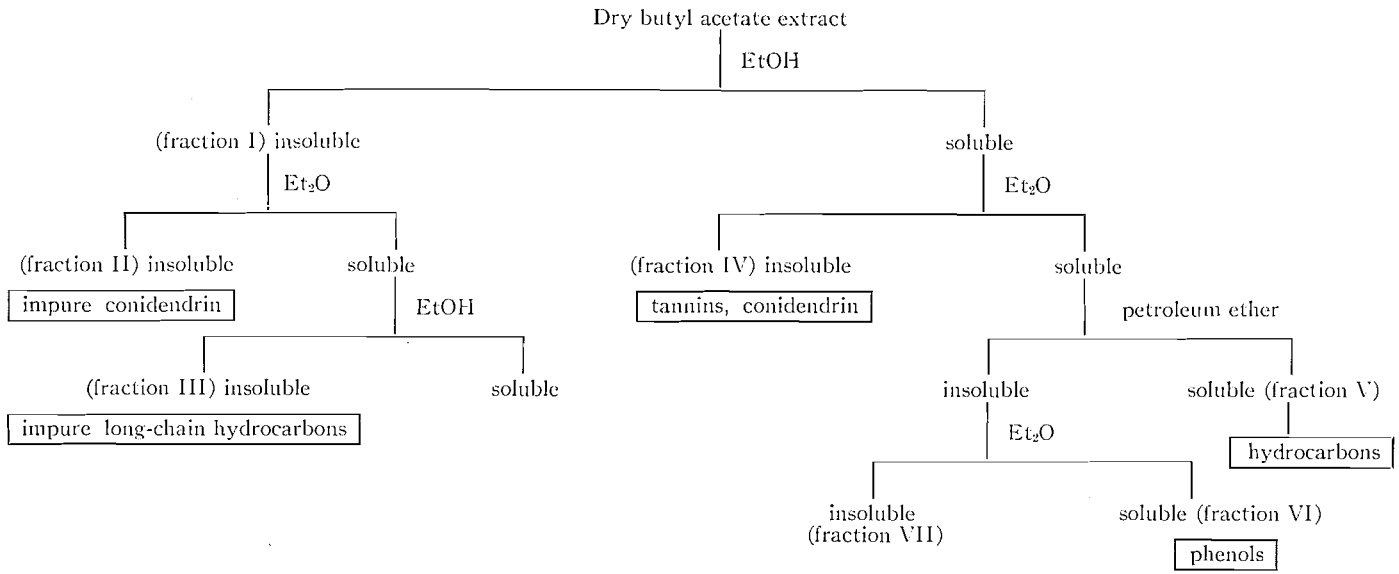
Spruce sulphite waste liquor (SWL) (Cook No. 3001/48, Ontario Paper Co., Thorold, Ont.) was extracted with *n*-butyl acetate by a 21-ft. fast spray type extraction column (4) (countercurrent flow, flow ratio 2: 1/BuOAc–SWL (continuous phase)). This extract was concentrated and the last part of the solvent was removed in a 3-liter glass still under reduced pressure (12 mm., 40°C. bath temp.). Several such extractions gave an average of 1.38 gm. dry extract per liter of sulphite liquor. This amount can be increased at lower flow rates.

2. *Solvent Fractionation* (See Table I)

Fifty grams of dry extract was dissolved in 500 ml. ice-cold dry ethanol. The insoluble material (fraction I) was filtered off. The ethanol was removed under reduced pressure (12 mm.). The residue was shaken twice with 100 ml. portions of ether (30 min.). The insoluble part (fraction IV) was separated. The ether was distilled off under reduced pressure. The residue was extracted

TABLE I

SOLVENT FRACTIONATION OF BUTYL ACETATE EXTRACT



NOTE: Fraction	II	III	IV	V	VI	VII	others and loss
Weight (as % of the dry butyl acetate extract)	12.6	1.3	27.9	17	37.9	0.7	2.6

twice with 100 ml. portions of petroleum ether (b.p. 30–60°C.). The insoluble part (fraction V) was separated and extracted twice with 75 ml. portions of ether. The residue (fraction VII) was filtered off. Fraction I, the ethanol-insoluble material, was shaken with 200 ml. ice-cold ether (five minutes) and filtered. The residue was impure conidendrin (fraction II). The ether filtrate was concentrated to 50 ml. under reduced pressure, cooled to 0°C., and 150 ml. ice-cold dry ethanol added. The resulting precipitate was impure melene (28) (fraction III).

The extractions and separations reported under parts 1 and 2 are based on parts of the theses submitted by Sacks (28) and Kenyon and Kerr (18) in partial fulfillment of the requirements for the M.A.Sc. degree and B.A.Sc. degree at this University.

3. *Group Separation*

After evaporation fractions V and VI were each dissolved in 20 times their volume of butyl acetate. A small amount of conidendrin (1.6 gm.) separated from fraction VI after this procedure.

The solution was extracted successively with sodium bisulphite solution (21%), sodium bicarbonate solution (10%), and sodium hydroxide solution (6%).

The sodium bisulphite extract was acidified with sulphuric acid, heated, aspirated, and cooled. It was extracted with chloroform.

The bicarbonate and sodium hydroxide solutions were also acidified and extracted with chloroform.

The remaining butyl acetate solution was distilled under reduced pressure until the solvent was removed.

The chloroform solutions of the other groups were also evaporated and the weights of extracted materials determined, as shown in Table II.

TABLE II

GROUP SEPARATION OF FRACTIONS V AND VI

Group:	Bisulphite-soluble	Bicarbonate-soluble	Sodium-hydroxide-soluble	Remaining fraction
Fraction V	0.09	0.21	0.42	16.3%
Fraction VI	3.0	0.9	24.0	10 %

NOTE: *All numbers represent per cent by weight of the original dry butyl acetate extract.*

4. *Bisulphite-soluble Compounds*

Paper chromatography (see part 6) was used to give a preliminary indication of the composition of the fraction. No significant differences were found between the bisulphite-soluble components of fractions V and VI. Both contain two principal compounds (compound A—R_F: 0.53, compound B—R_F: 0.73) and minor amounts of other compounds.

Compound A was isolated from a series of paper chromatograms on Whatman No. 3 paper with the same solvent system (see part 6). The position of the spots was detected under the UV lamp, the spot area was marked, and was

cut out. Elution of the spots obtained by chromatography of a total amount of 12 mgm. bisulphite fraction gave 2.5 mgm. of a yellow oil. UV and IR spectra indicated a diketo-compound of the guaiacyl group. A larger quantity of bisulphite-soluble material (200 mgm.) was used for a chromatogram on a 2 × 15 cm. column of 100 mesh silica gel (Mallinckrodt). After development with 600 ml. benzene–methanol (250: 1, v/v), the column material was cut into zones. The material in the yellow zones was eluted with methanol and checked by paper chromatography. The combination of the material of the corresponding zones gave after recrystallization from ethanol–water (1: 3), 21 mgm. of yellow crystals, m.p. 72.5°C.[2]

The mixed melting point with authentic vanilloyl methyl ketone was not depressed. The spectra of the compounds were identical and both gave the same R_F values, color reactions with spray reagents, and the same characteristic nickel salt of the dioxime.

IR spectrum:[3] Maxima at 1720, 1664, 1593, 1510, 1463, 1430, 1376, 1350, 1297, 1262, 1227, 1202, 1172, 1139, 1125, 1117, 1033 cm.$^{-1}$ (CS_2, CCl_4)

The UV spectrum of compound B and its R_F value were identical with those of vanillin. Sublimation of a 50 mgm. sample of bisulphite-soluble material under reduced pressure gave 20 mgm. of crystalline sublimate, identified as vanillin by mixed melting point and paper chromatography.

5. *Sodium-hydroxide-soluble Compounds*

Paper chromatography (see part 6) revealed only minor quantitative differences in the composition of the sodium hydroxide extracts of fractions V and VI. Aside from conidendrin, two principal components (compound C—R_F: 0.20, compound D—R_F: 0.55) and smaller amounts of about 20 other phenolic compounds were indicated.

The course of all the following separation steps was checked by paper chromatography.

Half of the alkali-soluble part of fraction VI was dissolved in 200 ml. 2 *N* sodium hydroxide and the pH adjusted to 12.0 by addition of sodium dihydrogen phosphate. After extraction with chloroform (50 ml.), the water phase was acidified further in steps of 0.25 pH units and extracted again after each step with 50 ml. chloroform, until pH 5 was reached.

Isolation of Compound D

The five chloroform extracts made between pH 12.0 and 11.0 contained almost all of compound D and also some other phenols. These extracts were concentrated to a volume of 15 ml. The further separation was effected by countercurrent distribution between chloroform–ethanol – phosphate buffer solution (pH 12) (29) in a 24 stage circular type Craig apparatus (5). (Volume relation 7.7: 12 (buffer phase)). After 24 transfers, compound D had migrated from tube 1 to tubes 6–9 and these fractions contained only minor amounts of impurities. The solvent of these fractions was removed under reduced pressure

[2]*All melting points are uncorrected.*

[3]*We are grateful to Miss E. M. Kirby of the Ontario Research Foundation for the determination of all infrared spectra.*

(bath temperature below 50°C.) and the residue dissolved in the minimum amount of hot benzene. After cooling, crystals separated (240 mgm.). Recrystallization from benzene gave colorless prismatic crystals, m.p. 134°C.

Analysis: Found: C: 69.98, 69.95; H: 7.05, 6.96; CH_3O: 17.83, 17.90
Calc. for $C_{20}H_{24}O_5$: C: 69.74; H: 7.03; CH_3O: 18.1

Mol. wt.: Found: (Rast): 340
Calc.: 344.39

UV spectrum: (95% EtOH): Max. 229 mμ, 283 mμ
(95% EtOH, 1 mole KOH/l.): max. 247 mμ, 299 mμ

IR spectrum: Maxima at: 1604, 1516, 1453, 1430, 1366, 1266, 1231, 1202, 1180, 1149, 1120, 1094, 1030 cm.$^{-1}$ (melt, supercooled)

The mother liquors of these crystallizations yielded further quantities of compound D after chromatography on Magnesol–Celite (5: 1) (23) with benzene–methanol (250: 1) as eluent.

Isolation of Compound C

The chloroform extracts made between pH 10.75 and 9.75, containing the principal amount of compound C, were concentrated to 15 ml. and subjected to countercurrent distribution in a manner similar to that described above. Solvent system: chloroform – phosphate buffer (pH 11) – ethanol–water (29): volume relation 7.7: 14 (buffer phase). After 34 transfers, the compound had migrated from tubes 1–2 to tubes 18–28. The purest fractions were combined, the solvent removed under reduced pressure, and the residue purified further by chromatography on a Magnesol–Celite (5: 1) column (23) using benzene–methanol (250: 1, v/v) as eluent. The fractions were combined according to the results of paper chromatography. The solvent was removed under reduced pressure and a colorless oil remained (400 mgm.). Its IR spectrum was very similar to the spectrum of eugenol.

The compound was now benzoylated. A sample, 365 mgm., was dissolved in 10 ml. pyridine, cooled, and 0.5 ml. benzoyl chloride added. After 24 hr. at room temperature, the mixture was heated on the steam bath for five minutes, diluted with water, and extracted with chloroform. After drying, the solvent was removed and 720 mgm. crude benzoyl compound isolated. Recrystallization from petroleum ether – benzene yielded white needles, m.p. 62–63°C. A synthesized sample of dihydroconiferyl alcohol dibenzoate gave no depression of the mixed melting point.

Comparison of compound C with a synthesized sample of dihydroconiferyl alcohol (30) gave identical R_F values, spectra, refraction indices, and color reactions.

UV spectrum: (95% EtOH): Max. 228 mμ, 281.6 mμ

IR spectrum: Maxima at 1608, 1513, 1464, 1431, 1368, 1266, 1231, 1202, 1183, 1149, 1119, 1050, 1037 cm.$^{-1}$ (CS_2, CCl_4)

Isolation of 3,3′-Dimethoxy-4,4′-dihydroxystilbene

The alkali-soluble part (5 gm.) of fraction VI was chromatographed on a Magnesol–Celite (5: 1) column (23) (size: 3 × 40 cm.) using benzene–methanol

(200: 1) as eluent. The effluent was collected in 15-ml. portions. In addition to the compounds reported above a strongly fluorescent compound was found in the first fractions (Nos. 6–10) of the effluent. Another chromatogram was made on silica gel (Mallinckrodt, 100 mesh), using the same eluent. The zone with a strong violet fluorescence was cut out, eluted with ethanol, and concentrated. The resulting crystals were collected and recrystallized from ethanol, giving 20 mgm. colorless needles, m.p. 213°C. The mixed melting point with 3,3′-dimethoxy-4,4′-dihydroxystilbene (26) was not depressed. The color reactions were also identical.

6. *Paper Chromatography*

The solvent systems: butanol – 2% ammonia (24), butanol–water and benzene – petroleum ether – water (19) were used to some extent. However, the major part of paper chromatography in this work was carried out with the solvent system: tetrahydrofuran – petroleum ether (b.p. 65–110°C.) – water (3: 7: 5) because of the short travel time for this solvent (about 10 cm. per hour) and the good separation of a large number of compounds (see Table III). Descending chromatography was used.

ferric chloride (1%) – potassium ferricyanide (1%), 1:1
phosphomolybdic acid (4%), followed by treatment with ammonia vapors
diazotized sulphanilic acid (12)
diazotized *p*-nitraniline (34)

Buffered papers: sheets of Whatman No. 1 paper were sprayed with 2% phosphate buffer solutions of pH values between 4 and 10 and dried at room temperature. These papers made possible separations of acids and acidic phenols from each other and from other phenolic compounds with similar R_F values. The R_F values of acidic compounds decrease on the papers with increasing alkalinity gradually to zero, depending on their pK values (20). This method can be used to distinguish between vanillin, acetovanillone, and vanillyl methyl ketone or between hydroferulic acid and dihydroconiferyl alcohol. The method of Reid and Newcombe (25) was also used to distinguish between vanillin and acetovanillone.

ACKNOWLEDGMENTS

A NEW TYPE OF CELLULOSE ETHER

THE PREPARATION AND PROPERTIES OF THE ω-(*p*-AMINOACETOPHENONE) ETHER OF CELLULOSE[1]

By R. R. McLaughlin and D. B. Mutton[2]

ABSTRACT

With the object of preparing a cellulose ether containing diazotizable amino groups, seven different forms of cellulose, or cellulose derivatives, were treated with 10 different reagents under a variety of conditions. Reasons why only one reagent under one set of conditions gave a product with a substantial degree of substitution (0.35) and with satisfactory physical properties are presented. This resulting ether, the ω-(*p*-aminoacetophenone) ether of cellulose, was prepared by the reaction between ω-chloro-*p*-aminoacetophenone and ethanol-washed soda-cellulose (from wood pulp, cotton, paper, or rayon). It can be (*a*) diazotized and coupled with any of the usual reagents to yield cellulose-azo colors, (*b*) xanthated, before or after coupling, and spun as rayon filament; if uncoupled at this point it can be diazotized and coupled, (*c*) dyed directly with acid dyes, (*d*) rendered organo-soluble by nitration, and (*e*) carboxymethylated after coupling to yield colored, water-soluble derivatives. It is insoluble in the usual cellulose reagents, and is as stable to acid and alkaline hydrolysis as cellulose.

INTRODUCTION

The purpose of the work described in this paper was the preparation of cellulose ethers containing primary aromatic amino groups. On diazotization and coupling such ethers should produce azo compounds in which the chromophore groups form part of the molecule of the cellulose derivatives, which should be as stable as cellulose to most reagents. Analogous nitro compounds, because they may be reduced to the corresponding aromatic amines, are also of interest. Ethers rather than esters were investigated because the former are more resistant to hydrolysis.

A number of attempts to prepare colored cellulose derivatives have been reported. In 1926 Peacock (42) obtained what he regarded as a superficial coloring of cotton by treating it with *m*-nitrobenzyl-phenyldimethyl-ammonium chloride, diazotizing, and coupling. A similar result was obtained by Kursanov and Solodkov (33). Charles Gränacher (19, 20, 21, 22, 23) obtained diazotizable cellulose fibers by a superficial etherification of swollen cellulose (alkali cellulose washed free of alkali with water) with such reagents as *p*-nitrobenzyl chloride and 2,4-dinitrochlorobenzene in the presence of lithium carbonate. Repetition of this work by us failed to give a degree of substitution (D.S.) greater than 0.01. A modification of this method applied by Pancirolli (41) to cellulose and starch yielded a *p*-nitrobenzyl ether of starch with a D.S. of 0.04. Repetition of Pancirolli's work led to the successful method described later in this paper.

The usual etherification reaction between alkali cellulose and an organic halide forms the basis for a number of patents (7, 8, 9, 10, 11, 28) wherein

[1]*Manuscript received May 31, 1954.*

[2]*Present address: Industrial Cellulose Research Ltd., Hawkesbury, Ontario.*

reaction conditions are usually described only vaguely, and analytical data are usually lacking. Such an attempt by Niethammer and Konig (39) with 2,4-dinitrochlorobenzene yielded a product with nitrogen content below 1% (D.S. <0.06). Reduction, diazotization, and coupling gave colors that were not intense. Repetition of this work by Andrews, Hyer, and Ray (1), in this laboratory, failed to give any product with a D.S. above 0.04, and variation of the reaction conditions with this reagent by us gave essentially the same results.

Recently Guthrie (25) colored cotton by treating it with an alkaline solution of a dye containing the chloroethyl or sulphatoethyl group, but concluded from the colors obtained that the D.S. was very low (26).

Seiberlich (49), Dinklage (9), and others (28) have reported the formation of a diazotizable cellulose derivative by the nitration of benzyl cellulose and reduction of the product, but the nitrogen content was not given. Our repetition of this work gave inconclusive analytical results and no intensely colored products.

Several other patents (12, 13, 50) refer to diazotizable cellulose ethers but no analytical results are cited.

Though the present work was confined to ethers, it ought to be recorded here that colored cellulose esters have been reported by a number of workers (3, 9, 10, 13, 24, 29, 30, 45), also a diazotizable aminocellulose (47, 48), and several derivatives prepared from oxycellulose (38, 46).

This survey indicates that no well-defined cellulose ether containing aromatic amino or nitro groups with a D.S. > 0.05 has hitherto been prepared. Apparent degrees of substitution below 0.05 might well be ascribed to adsorption.

RESULTS AND DISCUSSION

Preliminary Experiments

Several different forms of cellulose were treated with a number of etherifying agents under a variety of conditions. The etherifying agents used were 2,4-dinitrochlorobenzene, *p*-nitrochlorobenzene, picryl chloride, *p*-chloroaniline, *p*-bromoaniline, *p*-nitrobenzyl chloride, *p*-nitrobenzyl bromide, β-(*o*- and *p*-nitrophenyl) ethyl bromide, γ-(*p*-nitrophenyl) propyl bromide, *p*-amino-ω-chloroacetophenone, and *p*-nitrobenzyl chloromethyl ketone.

Three principal forms of cellulose were used. (1) Cellulose activated by swelling or solution was treated with an etherifying agent in the presence of some acid-binding reagent or solvent. This group included "activated cellulose", prepared according to Gränacher (19, 20, 21, 22, 23), and organo-soluble cellulose acetate, D.S. (of acetyl groups) 1.75 to 2.67. (2) Benzyl cellulose (D.S. 1.0 in benzyl groups, remaining hydroxyl groups blocked by acetylation) was nitrated according to Seiberlich (49) and Dinklage (9). (3) An etherifying agent was treated with an alkali derivative of cellulose such as ordinary alkali cellulose; sodium cellulosate according to the methods of Gaver (17, 18), and of Sugihara and Wolfrom (51); sodium cellulosate from sodium in liquid ammonia (15, 16, 43); and ethanol-washed alkali cellulose, modified after Pancirolli (41). The most commonly used conditions consisted in refluxing a solution (ether,

benzene, dioxan, ethanol, pyridine, or acetone) of the etherifying agent with the particular form of cellulose in use. Some experiments were carried out in the molten etherifying agent, and some at room temperature, with and without shredding, with and without solvent.

Purification of the products was effected by extraction of the unused reagents and the by-products with suitable solvents.

The only cases in which degrees of substitution consistently above 0.05 were obtained were those in which (*a*) molten *p*-nitrobenzyl chloride was reacted with sodium cellulosate (method of Sugihara and Wolfrom) (51), and (*b*) *p*-nitrobenzyl chloride and bromide, and *p*-amino-ω-chloroacetophenone, were reacted with ethanol-washed alkali cellulose.

The reaction with sodium cellulosate produced erratic results, and the products were amorphous powders of low D.P. Using ethanol-washed alkali cellulose, *p*-nitrobenzyl chloride and bromide produced degrees of substitution averaging 0.07–0.10. *p*-Amino-ω-chloroacetophenone, on the other hand, consistently gave products having D.S. between 0.20 and 0.35. This was by far the most successful combination.

In any etherification reaction the driving force, and the solubility, reactivity, and molecular size of the etherifying agent determine the result. For a successful reaction, a sufficient driving force must be available (40) (usually determined by the alkali concentration); the solubility of the reagent must be high enough to permit substantial diffusion to the reaction centers at the cellulose hydroxyl groups; and the reactivity of the reagent must be such that the extremes of a negligible rate of reaction and complete saponification to useless by-products are avoided.

The reason for the negative results obtained with most of the methods and reagents used in this work is probably that all the above conditions were not simultaneously fulfilled in such cases.

When alkali cellulose is washed with ethanol, much of the excess sodium hydroxide is removed, although the sodium hydroxide and water which are bound or preferentially absorbed by the cellulose are not affected to the same extent. Thus, while the proportion of hydroxyl groups in equilibrium with the sodium salt will be slightly decreased (making a lower D.S. possible), the excess alkali which is responsible for the hydrolysis of the etherifying agent will be sharply reduced. This, together with the higher water solubility of *p*-amino-ω-chloroacetophenone (hereinafter referred to simply as "ω"), is likely the reason for the success of the reaction of "ω" with ethanol-washed alkali cellulose.

ω-(p-Aminoacetophenone) Ether of Cellulose

This new ether of cellulose was prepared with D.S. up to 0.35 by reacting ethanol-washed alkali cellulose with an ethanol solution of "ω" (cf. Experimental). The purified product was usually light-yellow and fibrous.

The ratio of sodium hydroxide to the anhydro-glucose units of cellulose was varied by increasing the number of ethanol washings. The effect that this has upon the degree of substitution of the ω-cellulose is shown in Fig. 1, and indicates that the optimum molar ratio is about 1:1.

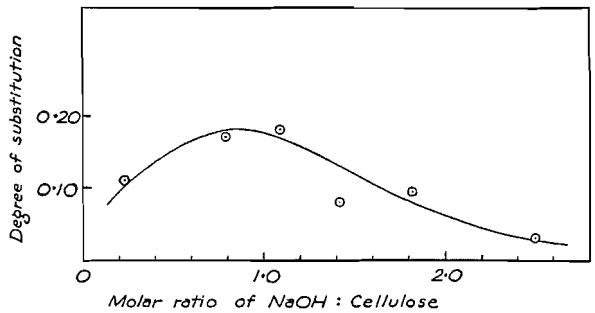

FIG. 1. The effect of the molar ratio of sodium hydroxide to anhydro-glucose units of cellulose upon the degree of substitution of ω-cellulose.

Twenty-eight per cent potassium hydroxide was used for steeping, in place of sodium hydroxide, and the resulting alkali cellulose was washed with ethanol to a potassium hydroxide: anhydro-glucose units molar ratio of 0.66: 1. When treated in the usual way with "ω", the product obtained had a D.S. of 0.20, showing, as was expected, that potassium hydroxide may be used in this reaction.

Since we had concluded that no well-defined cellulose ether containing aromatic amino or nitro groups with a D.S. > 0.05 had previously been prepared, we wished to establish definitely that ω-cellulose was actually a cellulose ether. No one experiment proved this unequivocally. However, the evidence given by the properties of the compound, as described below, make any other interpretation extremely unlikely.

Because of the adsorptive properties of cellulose it was necessary to demonstrate that ω-cellulose is neither a mechanical mixture of cellulose and "ω", nor an adsorption complex. A mechanical mixture of cellulose and "ω" was dialyzed with hot acetone, and the residue was found to be nitrogen-free. On the other hand, the nitrogen content of a sample of ω-cellulose (D.S. 0.28) was unchanged after dialysis for one week with hot acetone.

The stability of ω-cellulose (D.S. 0.21) to alkali with respect to time, temperature, and alkali concentration is shown in Figs. 2, 3, and 4. The levelling-off of all curves at D.S. 0.18 indicates that the ether linkage in ω-cellulose is quite stable to alkali. The slight decrease observed may be due to the removal of some lower molecular weight fractions having a slightly higher-than-average D.S.

In another experiment, boiling with 1% sodium hydroxide solution for six hours lowered the D.S. only from 0.30 to 0.26. The same treatment with 1% sodium carbonate solution had no effect.

The stability of ω-cellulose (D.S. 0.21) to acid with respect to time, temperature, and acid concentration is shown in Figs. 5, 6, and 7. These curves do not level off at a constant D.S. as in the case of the alkaline treatment, but slope gently downward. This indicates that the ether linkage in ω-cellulose is slowly cleaved by acid in a manner analogous to the acid hydrolysis of cellulose. The samples represented by the last two points in Fig. 7 were visibly degraded and could be crumbled to a powder when dry. This experiment indicates either that the ether linkage in ω-cellulose is as stable as the glycosidic linkages

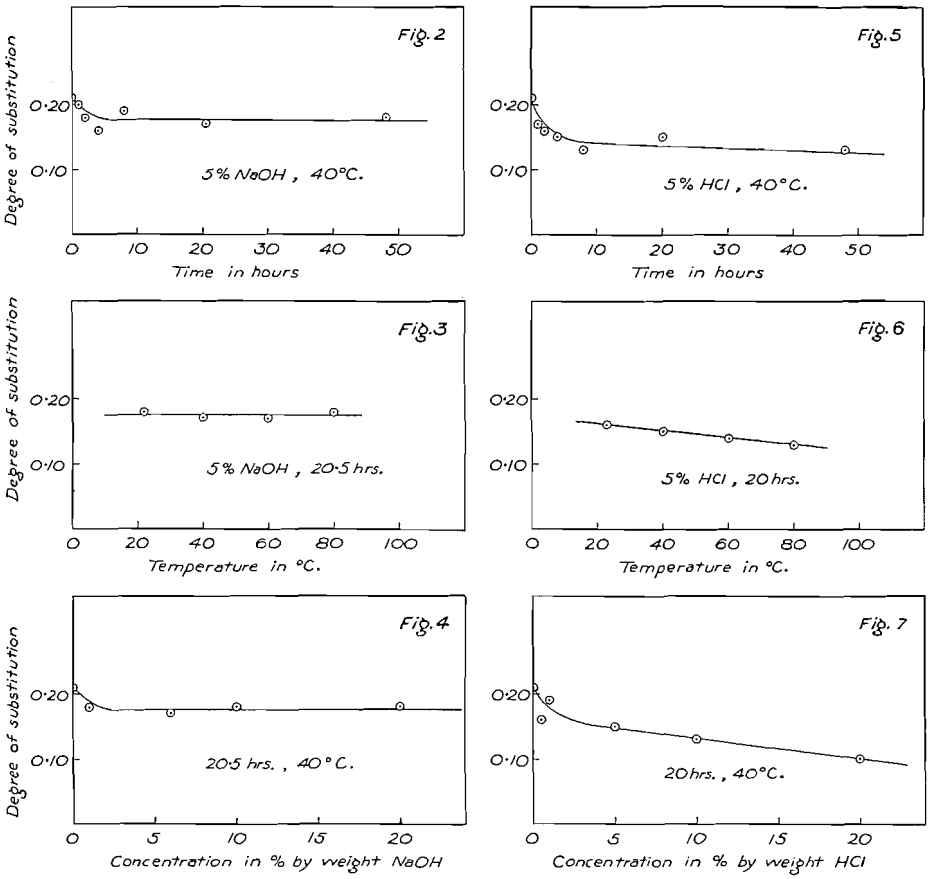

FIG. 2. The effect of time of hydrolysis in 5% sodium hydroxide at 40°C. upon the degree of substitution of ω-cellulose.

FIG. 3. The effect of temperature of hydrolysis in 5% sodium hydroxide for 20.5 hr. upon the degree of substitution of ω-cellulose.

FIG. 4. The effect of concentration of sodium hydroxide during hydrolysis at 40°C. for 20.5 hr. upon the degree of substitution of ω-cellulose.

FIG. 5. The effect of time of hydrolysis in 5% hydrochloric acid at 40°C. upon the degree of substitution of ω-cellulose.

FIG. 6. The effect of temperature of hydrolysis in 5% hydrochloric acid for 20 hr. upon the degree of substitution of ω-cellulose.

FIG. 7. The effect of hydrochloric acid concentration in the hydrolysis at 40°C. for 20 hr. upon the degree of substitution of ω-cellulose.

in cellulose, or else that the low molecular weight portions of the cellulose ether, which probably have a higher D.S., are being hydrolyzed and made water-soluble by the acid treatment.

In another experiment, boiling with 1% hydrochloric acid for six hours did not lower the D.S. (0.30) of a sample of ω-cellulose.

During purification of several batches of ω-cellulose, continued washing with acetone provided a colorless extract. On changing to hot water the washings were again slightly colored (yellow) but presently became colorless.

On changing to acetone the first washings were colored, but also, presently, became colorless. This process could be repeated, apparently indefinitely. During this treatment, the D.S. of the ω-cellulose decreased gradually, in one case from 0.28 to 0.19 over a period of six days' washing. It seems likely that some of the lower-molecular-weight and more highly substituted fraction of the ω-cellulose was slightly soluble in the solvent combination existing when a change of solvent was made.

Samples of ω-cellulose (D.S. 0.33) and the corresponding coupled products were examined by Industrial Cellulose Research, Limited, Hawkesbury, Ont., for the purpose of making viscosity measurements, but were found to be insoluble in cuprammonium or cupriethylene–diamine solutions. Were the product an adsorption complex this behavior would be very unlikely.

It could be envisaged that an initial small D.S. of "ω" groups in cellulose could be followed by a polymerization reaction between the excess "ω" and the amino groups present in the cellulose ether, thus:

Cellulose—O—CH_2.CO.C_6H_4.NH.CH_2.CO.C_6H_4.NH. . . . etc. An analysis for nitrogen would thus indicate a high D.S. whereas it might, in fact, be small. To clarify this point a sample of ω-cellulose (1.53% nitrogen, D.S. 0.21) was treated with nitrous acid at room temperature, heated to boiling, washed, and dried. The product contained 0.52% nitrogen (D.S. 0.07). It thus appears that at least two thirds of the original nitrogen was present as primary amino groups, i.e. that the original D.S. was at least 0.14. This is a minimum value, as it would be higher if there were any introduction of nitroso groups during the treatment with nitrous acid. This point is being further investigated.

Several attempts were made to hydrolyze ω-cellulose and to isolate ω-glucose. Neither the acetolysis procedure of Dickey and Wolfrom (6) nor the methanolysis procedure of Sugihara and Wolfrom (51) produced significant hydrolysis of the ω-cellulose. These failures, however, indicate a significant difference in structure between cellulose and ω-cellulose. Hydrolysis with 72% sulphuric acid was more successful. The hydrolyzate was purified and chromatographed. No ω-glucose was isolated, but a low-molecular-weight carbohydrate fragment containing an aromatic amino group was detected. Investigation of this problem is continuing.

Dr. A. W. Pross of the Central Research Laboratory of Canadian Industries, Limited, McMasterville, Quebec, carried out some work comparing the infrared spectra of cellulose, ω-cellulose, and carboxymethyl cellulose in an attempt to demonstrate compound formation. The results gave some indication that such was the case, but the experimental difficulties involved in these measurements made it impossible to draw any definite conclusions.

ω-Cellulose was diazotized and coupled by standard procedures to form colored azo derivatives. Using β-naphthol, the color of the product varied from a light pink, from ω-cellulose of D.S. 0.01 or less, to a very deep and brilliant red, from ω-cellulose of D.S. 0.20. At high magnification under a microscope the colors appeared to be uniform. Neither alkaline hypochlorite solution, 3% and 30% hydrogen peroxide, nor an acid solution of sulphur dioxide had any visible effect on the color of these derivatives.

An obvious possible application of ω-cellulose-azo compounds is their xanthation and spinning as molecularly-colored rayon. Viscose prepared from coupled ω-cellulose (D.S. 0.01) was spun into isotropic filaments by the method of Hermans (27). The thread, uniform, light red in color, could be stretched more than 100% and was of fair strength. Several yards of filament could be spun without a break, and under the microscope appeared smooth, uniform, and evenly colored. The same procedure was carried out with uncoupled ω-cellulose (D.S. 0.01). Almost colorless filaments were obtained, which could then be diazotized and coupled, or dyed directly with suitable acid dyes. A colored derivative prepared from ω-cellulose (D.S. 0.21) was also xanthated. The product dissolved only with difficulty in 6% sodium hydroxide solution and had to be diluted with more 6% sodium hydroxide solution before being filterable by suction. An attractive, bright-red filament was obtained by spinning the viscose solution as before. As mentioned previously, Industrial Cellulose Research, Limited, found that xanthated ω-cellulose of D.S. 0.33 was insoluble in sodium hydroxide solution. It thus appears that the solubility of the xanthate falls off sharply as the D.S. of ω-cellulose increases. It is possible, however, that this might be at least partially offset by increasing the D.S. of the xanthate groups. This point is being investigated.

It was found possible to render ω-cellulose-azo compounds water-soluble by carboxymethylation. The reaction was carried out on samples ranging in D.S. from 0.01 to 0.33. After purification by dialysis (34), the products were analyzed for D.S. of carboxymethyl group by the method of McLaughlin and Herbst (35). For ω-celluloses of D.S. 0.21 and 0.33, the D.S. of carboxymethyl groups had to be greater than 1.0 to make the product water-soluble. Degrees of substitution up to 1.7 were obtained. Whereas ordinary sodium carboxymethyl cellulose of a low D.S. is soluble in water, a considerably higher degree of substitution seemed to be required to confer complete solubility on the sodium carboxymethyl cellulose prepared from colored ω-cellulose.

Direct dyeing of cellulose is difficult because, unlike wool and silk, it contains no strongly polar groups such as the amino or carboxyl. ω-Cellulose, on the other hand, should possess direct-dyeing properties. A sample of ω-cellulose (D.S. 0.21) was dyed with a number of acid dyes such as croceine scarlet 3BX, croceine orange G, fast light green, and intensive blue. The dyeing procedures were adapted from those of Cain and Thorpe (4) and yielded attractive, intense, uniform colors which were fairly fast to washing. Controls run with shredded cellulose and absorbent cotton gave products from which the dyes were readily and completely removed by washing.

Nitration of ω-cellulose using standard techniques produced a material which was soluble in acetone. On evaporation of the filtered acetone solution a thin, opaque, yellow-brown, brittle film was obtained.

Samples of rayon yarn, paper towelling, surgical gauze, and factory cotton were soaked in 18% sodium hydroxide solution, pressed, washed with ethanol, and subjected to the usual etherification procedure. The D.S. of the samples were: ω-rayon, 0.01; ω-paper, 0.08; ω-gauze, 0.01; ω-cotton, 0.02. Diazotizing

and coupling with β-naphthol gave bright colored materials. The paper was red, the others orange. Direct dyeing with acid dyes was also effective, as before. Tensile strength tests on the rayon by Industrial Cellulose Research, Limited, revealed that, as expected, the tensile strength had been reduced by more than half. However, if the rayon derivative were required this effect can be avoided by etherifying before xanthation and regeneration. The low D.S. shows that the etherification conditions would need to be altered if the high D.S. obtained with shredded cellulose were desired, though intense, uniform colors are produced even with the low D.S. reported.

EXPERIMENTAL

Materials and Methods

For preparing alkali cellulose and for carrying out some of the reactions a Baker-Perkins Model No. 4–AN2 Werner-Pfleiderer shredder was used. A very much smaller model of this machine, having inside dimensions 2 × 2 × 4 in. (1/10th volume), was made later when some of the desired reagents proved to be difficult and expensive to make in the quantities required by the larger machine.

The only practical method of purifying the reaction products was by extraction of the unused reagents and by-products with suitable solvents. The extent of extraction necessary could often be judged by color since most of the reagents and their products of hydrolysis yield colored extracts. Therefore, when several consecutive extracts were colorless, purification was considered complete. In doubtful cases this was confirmed by establishing the constancy of the D.S. during the later stages.

The most convenient method for determining the extent of etherification was to analyze the products for nitrogen introduced as amino or nitro groups. The semimicro-Kjeldahl apparatus and procedure of Redemann (44) was used, with minor modifications. This involved 50 mgm. samples; reduction of any nitro groups with dextrose, according to Elek and Sobotka (14); selenium as a catalyst for digestion; collection of the ammonia evolved in 4% boric acid solution, and titration with 0.02 *N* hydrochloric acid, using a mixed indicator of methyl red and bromocresol green (31).

The *p*-amino-ω-chloroacetophenone used in this work was prepared by the method of Kunckell (32). Acetanilide was subjected to a Friedel and Crafts reaction with chloroacetyl chloride using aluminum chloride as a catalyst. The acetyl group was then removed by hydrolysis with aqueous hydrochloric acid. Pale, lemon-yellow crystals were obtained after repeated recrystallization from ethanol.

p-Nitrobenzyl chloromethyl ketone is a new compound. It was prepared by the chloromethylation of *p*-nitrophenylacetyl chloride after the method of McPhee and Klingsberg (36). Faintly yellow needles were obtained after recrystallization from ethanol (m.p. 94.0–94.5°C.; % nitrogen: calc. for $C_9H_8O_3NCl$: 6.56%; found: 6.59%).

ω-(p-Aminoacetophenone) Ether of Cellulose

Preparation

Ten grams of dry, shredded cellulose were steeped in 20% sodium hydroxide solution, pressed to a press-factor of three, slurried with just enough 95% ethanol to cover the mass, allowed to stand for one minute, and filtered. The ethanol washing was repeated as often as required (usually twice) (see Fig. 1). The product was refluxed for eight hours with 400 cc. of ethanol containing 15 gm. of *p*-amino-ω-chloroacetophenone. The light-yellow fibrous product was filtered, washed with hot acetone, water, and finally with acetone until the extract was colorless.

Hydrolysis with 72% Sulphuric Acid

Hydrolysis by sulphuric acid (37, 52, 53) was carried out as follows: Eight grams of ω-cellulose (D.S. 0.20) was covered with 100 cc. of cold 72% sulphuric acid, and the mixture, which soon became very dark colored, was allowed to stand at room temperature for 18 hr. The mixture was added to 3400 cc. of distilled water and refluxed for five hours. The dark-brown flocculent precipitate that separated on cooling was filtered off, and the red filtrate was neutralized with a hot aqueous solution of barium hydroxide. After removal of the barium sulphate, the yellow filtrate was concentrated to 175 cc. by evaporation at 50 mm. and 50°C. The concentrate was dialyzed through cellophane against three 225 cc. portions of distilled water and the combined dialyzates were reduced in volume to 150 cc. Unsubstituted glucose was removed from the concentrate by fermentation according to the method of Chen *et al.* (5). After the resulting mixture was centrifuged and filtered, the filtrate was evaporated to dryness, yielding a dark-red sirup. This was extracted with 30 cc. of dry, acetone-free methanol and treated with activated carbon to give a dark-red extract. A fraction obtained from this extract by chromatography on a Magnesol: Supercel column (2) (this column freely passed glucose and *p*-amino-ω-hydroxyacetophenone) gave a positive test for primary aromatic amino groups and a positive Molisch's test for carbohydrates. The nitrogen content (1.94%) was, however, too low for ω-glucose (4.47%).

Diazotization and Coupling

Ten grams of ω-cellulose suspended in 300 cc. of water was cooled to 5°C., 50 cc. of 1:1 hydrochloric acid was added, and the mixture cooled to 0°C. Two grams of sodium nitrite in 20 cc. of water was added, and the whole was allowed to stand for five minutes. The diazotized ω-cellulose was filtered off and washed with ice water. It was then added to a cooled solution (5°C.) made by dissolving 7.5 gm. of β-naphthol in 50 cc. of ethanol and adding 30 cc. of 20% sodium hydroxide solution and 300 cc. water. The mixture was vigorously stirred and then allowed to warm to room temperature and stand for half an hour. The colored ω-cellulose was filtered and thoroughly washed with water and ethanol.

Xanthation and Spinning

Five grams of ω-cellulose (D.S. 0.01) diazotized and coupled with β-naphthol was treated as in making alkali cellulose and then xanthated with 1.66 cc.

carbon bisulphide for 2.5 hr. in a small shredder. After the resulting 14 gm. of the red xanthate was added to 40 cc. of 6% sodium hydroxide solution, the mixture was kneaded for one hour. The resulting viscose solution was filtered without much difficulty through a thick, cotton pad and yielded a filtrate containing no undissolved fibers visible under the microscope. Isotropic filaments were spun by the method of Hermans (27) by forcing the viscose solution by low pressure through a fine glass capillary below the surface of a 14% ammonium sulphate solution.

Carboxymethylation

Five grams of ω-cellulose (D.S. 0.21) coupled with β-naphthol was mixed in the small shredder for 30 min. with 1.25 gm. of sodium hydroxide in 6.5 cc. of water; 3.5 gm. of powdered sodium chloroacetate was added, the mixture was shredded for 2.5 hr. and allowed to stand overnight; 1.25 gm. of flake sodium hydroxide was added and shredding was carried out for 30 min.; 3.5 gm. of sodium chloroacetate was added, shredding was continued for two hours, and the mixture was allowed to stand overnight. A sample was removed for analysis, and a third carboxymethylation step was carried out. The sticky, dark-red product was removed from the shredder and dissolved in water. The solution was purified by dialysis, using a cellophane membrane (34).

ACKNOWLEDGMENTS

We are indebted to the Advisory Committee on Scientific Research of the University of Toronto for financial assistance. One of us (D.B.M.) is also indebted to the Spruce Falls Power and Paper Company for fellowships held during the 1949–50 and 1950–51 academic sessions, and to the University of Toronto for the Wallberg Research Fellowship held during the 1951–52 session.

We should also like to thank Industrial Cellulose Research, Limited, Hawkesbury, Ont., for supplying raw materials and carrying out certain tests; and Dr. A. W. Pross, Canadian Industries Limited, McMasterville, Que., for the work on the infrared spectrum of ω-cellulose.

A 27°C. ISOTHERMAL CALORIMETER[1]

By Paul A. Giguère, B. G. Morissette,[2] and A. W. Olmos[3]

ABSTRACT

The need for a Bunsen-type isothermal calorimeter operating as close as possible to the standard thermochemical reference temperature, 25°C., was fulfilled by means of diphenyl ether (m.p. 26.9°C.) as the working substance. The instrument was calibrated electrically by comparison with the ice calorimeter and the constant was found to be 19.01±0.02 cal. per gm. of mercury. From this and other known properties of diphenyl ether the density of the solid at the melting point was estimated at 1.188 gm. per ml. Check determinations based on the heat of vaporization of water showed that for such measurements the mantle of solid ether must first be melted inside by an amount equivalent to the heat to be measured. The calorimeter was operated in a large water-thermostat kept constant to within 0.001°C. With highly purified diphenyl ether there was no noticeable temperature drift during the measurements. Quantities of heat up to 600 cal. could be measured with a reproducibility of the order of 0.2%. The new calorimeter is simpler to operate than the ice calorimeter and its sensitivity is more than three times as great.

INTRODUCTION

As part of a research program on hydrogen and deuterium peroxides (9) it was required to measure some thermochemical properties of these compounds such as the heats of vaporization, heats of solution, and heats of decomposition. Preliminary measurements of these quantities made in this laboratory with the ice calorimeter were reported a few years ago (5). Although generally satisfactory for this kind of work the ice calorimeter suffers from certain drawbacks such as low sensitivity and tedious operation. Furthermore, it is necessary to correct the results to 25°C., the standard temperature for thermochemical data. To minimize the uncertainty of such corrections it would be desirable to work as near as possible to that temperature. A number of Bunsen-type calorimeters operating with various organic compounds have been described in the literature. Coffin (1, 2) has reviewed the question and discussed the requirements for a suitable working substance. Diphenyl methane, m.p. 24.5°C. (11), and diphenyl ether, m.p. 26.9°C. (8, 10), have been used in the past for that purpose. On the basis of availability and stability towards oxidation the second was selected as more promising, a choice vindicated by recent investigations at the National Bureau of Standards (6).

In fact three or four distillations of a commercial product, followed by an equal number of crystallizations, were sufficient to obtain the ether in such a degree of purity that no "premelting" could be detected during the measurements. Another convenient feature of the diphenyl ether calorimeter is that it operates so near the average temperature of the laboratory that all thermal leaks are reduced to a minimum and a simple water-thermostat provides an

entirely satisfactory surrounding. After more than three years of trouble-free operation we are convinced that this simple isothermal calorimeter is ideally suited for the measurement of heat effects accompanying physical or chemical changes at ordinary temperature.

EXPERIMENTAL

Two slightly different calorimeters were built in the course of this investigation. The most successful one will be described here together with suggestions for future improvements.

Construction of the Calorimeter

The calorimeter itself was made entirely of Pyrex glass although the use of a metal tube with appropriate seal for the central well, as suggested by some authors, would no doubt improve the heat transfer to the mantle. The dimensions shown in Fig. 1 are considered optimum; they are by no means

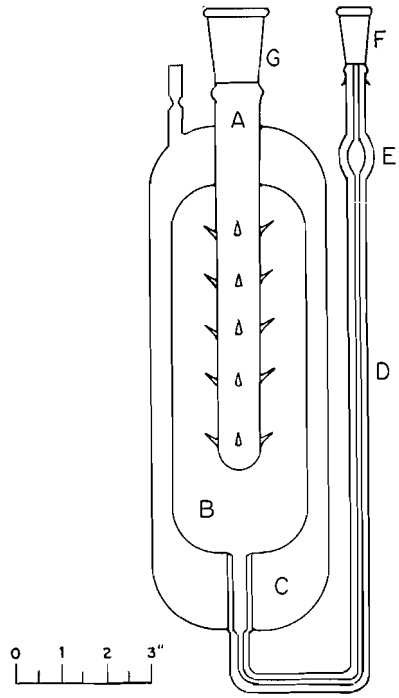

FIG. 1. Optimum dimensions for a diphenyl ether isothermal calorimeter of some 600 cal. capacity.

critical except, possibly, for the glass studs outside the central tube A which are needed to keep the mantle of frozen ether from slipping down. If made too short, they will not allow measurement of large enough amounts of heat; if too long, there is the danger of puncturing the mantle, with resulting heat loss, because the thermal conductivity of glass is appreciably higher than that of diphenyl ether. From the experience gained, 15 to 20 glass studs $\frac{3}{8}$ in. long would be adequate for a calorimeter of the size shown here.

The tube connecting the middle chamber B with the outside was first made S-shaped between the two jackets for greater elasticity. However, the inner seal soon broke merely on heating in an air-oven for drying. On the advice of a professional glass blower that section was replaced by a straight, thick-walled tube which, indeed, gave no trouble thereafter. The small bulb E, $\frac{1}{2}$ in. diameter blown on the capillary tube near the top, was found useful for trapping air bubbles before they reach the middle chamber. After cleaning thoroughly by the standard procedures the outside jacket C was evacuated down to 10^{-5} mm. Hg by means of a diffusion pump while the whole calorimeter was heated to about 100°C. in an oven. Just before sealing off the connecting tube a charcoal trap connected to the line was cooled in liquid air. In the first calorimeter the vacuum jacket had been silvered inside, except for a middle strip, but this was later found unnecessary. An outer shield of aluminum foil with opposite rectangular windows is sufficient to stop any radiant energy. It also affords a clearer view of the inside of the calorimeter, which is of great convenience, and it can be removed to speed up melting of the mantle when necessary.

Purification of the Diphenyl Ether

The starting product, Eastman's C.P., was first crystallized twice and then distilled four or five times under reduced pressure, 1.5 mm. Hg at about 102°C. Each time generous head- and tail-fractions were discarded until finally the distillation temperature remained constant to ±0.5°C. for the whole 800 ml. batch. To fill the calorimeter some 50 ml. of twice-distilled mercury were first introduced into chamber B. Then the calorimeter was mounted in an inverted, inclined position and the capillary tube was connected through the standard joint F to an "adapter tube" similar to those used in vacuum distillation apparatus. The lower end of that tube, reaching near the bottom of a 2-liter flask containing the pure ether, was bent so that it connected both the middle chamber of the calorimeter and the space above the ether to a vacuum pump and a cold trap. First the ether was rid of all dissolved gases by three successive freezings and meltings under reduced pressure. The solubility of air in diphenyl ether is so great that on the first freezing *in vacuo* the liquid seemed to boil violently. After three such operations no more dissolved gas was liberated. Then the bent tube was rotated by 180° about the ground joint and air was admitted above the liquid ether forcing it up into the calorimeter. A small residual bubble of vapor was expelled by blowing steam into the central well and then turning up the calorimeter while still heating it with steam until the mercury had filled the capillary tube up to the ground joint F.

Operation of the Calorimeter

The device for measuring the mercury was of the type developed for the ice calorimeter at the National Bureau of Standards (7). However, a steel needle-valve was not available so that an ordinary glass stopcock had to be used. This was somewhat unsatisfactory because only very little grease could be used on it and frequent cleaning was necessary. The calibrated capillary tube also required repeated cleaning as it was so fine (0.6 mm. diameter) that

mercury tended to stick in it. This part of the measuring device served only occasionally to obtain information on the thermal leak. Weighing of the displaced mercury in tiny beakers was done to the nearest 0.1 mgm. A mantle of solid ether was formed slowly by immersing a cold rod in the central well half-full of mineral oil for better heat transfer. In general one mantle could serve for two or three determinations. Before making a new mantle the old one was always melted completely. An infrared lamp was found very useful for this purpose. Apparently the manner of forming a mantle was of no great importance. Either ordinary ice or dry ice could be used, with rates varying from 20 min. to one hour. Usually it took five hours for a new mantle to come to equilibrium with the liquid ether.

The water-bath surrounding the calorimeter was a large aquarium made of plate-glass. Adequate temperature control was secured by means of a continuously adjustable "Magna-Set" mercury regulator and an electronic relay actuating a 500-watt immersion heater. A Cenco centrifugal stirrer provided efficient agitation. An auxiliary heater, hand-controlled through a Variac, was added for cold periods whereas a circulation of tap water was occasionally needed for operation in the summer. With such an arrangement the temperature could be kept constant indefinitely to within 0.03°C. but this was not quite sufficient. For a better temperature control and a more regular heat leak the principle of "internal insulation" suggested by Tian (12) was resorted to. The calorimeter proper was enclosed in a square box of Plexiglass which, effectively, provided an insulation of three inches of water between the calorimeter and the surrounding thermostat. As a result temperature fluctuations inside the box became smaller than 0.001°C. and the thermal leak of the calorimeter remained constant for a whole day instead of changing from hour to hour. What is important, indeed, is not so much the absolute value of this leak as its constancy, as has been pointed out by other investigators. As a matter of fact it was found preferable throughout this investigation to work with a steady, measurable thermal leak rather than with a vanishingly small one.

The temperature of the water-bath that gave the smallest leak (less than 0.2 cal. per hr.) was 26.90°C., as measured with a Leeds and Northrup certified platinum-resistance thermometer. In order to minimize fluctuations in the melting temperature of the diphenyl ether and, consequently, variations in the heat leak, the level of mercury in the measuring device was kept as constant as possible throughout a run. Another minor source of error stemmed from the small electric bulb used to light the calorimeter from behind. This energy amounted to only 0.3 cal. per hr. and could easily be accounted for.

Calibration of the Calorimeter

Usually such calibrations are carried out by absolute electric measurements. Since an ice calorimeter was available and since the factor of this instrument is known with great accuracy (7) it was decided to use it as reference for calibrating the diphenyl ether calorimeter. Two resistances R_1 and R_2 of about the same value were immersed in the central well of each calorimeter and connected in series. On passing an electric current in the circuit the amount

of heat dissipated in each calorimeter is obviously proportional to the values of R_1 and R_2. Therefore the electric energy need not be measured exactly; even the exact values of R_1 and R_2 are not required. Indeed, if a second series of experiments is made with the resistances interchanged then the calibration factors f of the two calorimeters are related thus,

$$f_e\sqrt{W_e \cdot W_e'} = f_i\sqrt{W_i \cdot W_i'},$$

where W and W' are the weights of mercury displaced in each set of determinations in each calorimeter.

The two resistances were made of 10-ohm windings of No. 34 Advance wire wound on thin glass tubes and connected to leads of No. 26 copper wire. In order to reduce the heat leak, particularly in the ice calorimeter, the leads were connected directly to "thermal shunts" made of sections of insulated brass foil immersed in the surrounding ice-bath. In spite of this precaution the leak of the ice calorimeter was nearly three times greater than normal which, in fact, represented the major uncertainty in these measurements. From the results collected in Table I and the factor for the ice calorimeter,

TABLE I

CALIBRATION OF THE DIPHENYL ETHER CALORIMETER BY COMPARISON WITH THE ICE CALORIMETER

$f_i = 64.640 \pm 0.007$ cal. per gm. of mercury (7), one finds for f_e 19.01 cal. per gm. of mercury with a standard deviation of 0.02 unit. Thus the diphenyl ether calorimeter has a sensitivity 3.4 times that of the Bunsen ice calorimeter. Holmberg (8) had obtained a slightly higher factor, 20.49, and Sachse (10),

a much greater one, 27.20 cal. per gm. of mercury, but the ether used by the latter must have been impure as shown by the melting point, 26.55°C. From the equation

$$f_e = L/\Delta v \,.\, d_m,$$

where L is the heat of fusion of the ether, 24.176 cal./gm. (6), and d_m is the density of mercury, we get 0.08574 for Δv, the change of specific volume of the ether on melting. The density of the liquid is 1.06611 at 30°C. and 1.06117 at 35° (4). Extrapolation to the melting point gives 1.0692 and from the above value of Δv the density of the solid at that temperature is calculated to be 1.188 while the coefficient dt/dp for the melting curve is 0.025° per atm. On the other hand, the triple point of diphenyl ether is known accurately: 26.87±0.01°C. from the measurements at the National Bureau of Standards. Therefore the melting point is 26.89_5°C. Adding to this the pressure effect of the mercury column above the mantle of solid ether (30 cm.) we arrive at the exact value 26.90° observed for the temperature of minimum leak, which confirms the high purity of the ether in the calorimeter. Dodd and Hu Pak Mi (3) found 26.85°C. by direct measurement and a slightly higher value, 26.95°C., from the break in the curve of viscosity vs. temperature.

A first series of calibrations of the new calorimeter based on the heat of vaporization of water had given a somewhat greater factor, 19.10 cal. per gm. of mercury. Since previous investigators have recommended that isothermal calorimeters be calibrated in the same way they are to be used, the cause of this discrepancy was investigated in order to apply it to measurements of the heat of vaporization of hydrogen and deuterium peroxides. For these check measurements a weighed 0.5 gm. sample of distilled, deaerated water in a thin glass tube was immersed in the calorimeter well and connected through a standard joint with a vacuum pump and a cold trap. The calibration factors thus obtained seemed to depend on the rate of evaporation of the water. As a high value of the factor indicates a loss of heat, it was suspected that the vapor left the calorimeter at a temperature lower than 26.9°C. No such difficulty had been encountered in similar measurements with the ice calorimeter so the explanation was thought to rest with the lower thermal conductivity of diphenyl ether. (No data are available on this compound in particular but organic liquids and solids generally have thermal conductivity about ten times smaller than that of ice.) To check this point a few determinations were carried out after first premelting the mantle of solid ether by an amount at least equal to the heat effect to be measured. The results in Table II seem to bear out the above contention, specially the first run where no premelting led to an abnormally high factor, and the second one, where only partial premelting gave an intermediate value. Still, the factors obtained by that method were always appreciably higher than by the more reliable electrical method, an indication that premelting does not provide exact compensation. At any rate the average value of f_e from these determinations, 19.04±0.04 cal. per gm. of mercury, was used only in measurements of heats of vaporization.

TABLE II

CALIBRATION OF DIPHENYL ETHER CALORIMETER BASED ON THE HEAT OF VAPORIZATION OF WATER

CONCLUSION

The diphenyl ether isothermal calorimeter has proved to be a reliable and useful research instrument for measuring thermal phenomena at room temperature. It has the advantage of great simplicity of construction and operation. For over three years it has remained constantly in working condition with very little attention. Operation near room temperature reduces to a minimum, not only the thermal leaks, but also the correction of results to the accepted temperature for thermochemical data. The use of a water-thermostat means considerable simplification over the ice calorimeter. Diphenyl ether is currently available and easily purified; once in the calorimeter it seems indefinitely stable.

The aim of this investigation was to determine some calorimetric properties of hydrogen and deuterium peroxides (to be published in a following paper). Lack of time and equipment did not allow an exhaustive study of the possibilities of the diphenyl ether calorimeter. This is particularly true of the calibration, which should be repeated by an absolute electrical method to take full advantage of the greater sensitivity of the instrument.

RÉSUMÉ

On a mis au point un calorimètre isotherme du type de Bunsen fonctionnant avec l'oxyde de phényle dont le point de fusion est 26.9°C. Le facteur de calibration, 19.01 ± 0.02 cal./g. de mercure, a été déterminé électriquement par comparaison avec le calorimètre à glace. Le nouveau calorimètre est très simple de construction et de manipulation; il est contenu dans un thermostat à eau. Avec le modèle décrit on a pu mesurer jusqu'à 600 cal. avec une précision de l'ordre de 0.2%. Les fuites et corrections sont réduites au minimum parce que la température de fonctionnement est assez voisine de celle du laboratoire.

REACTIONS BETWEEN SOLID CALCIUM CARBONATE AND ORTHOPHOSPHATE SOLUTIONS[1]

By J. S. Clark and R. C. Turner

ABSTRACT

Studies of the reactions between solid calcium carbonate and orthophosphate solutions at low partial pressures of carbon dioxide indicated that hydroxyapatite was the stable product formed in these systems. Hydroxyapatite precipitated directly even though dicalcium phosphate formed initially under certain conditions. The reactions with orthophosphate did not seriously disturb the normal calcium carbonate equilibrium with the solution.

INTRODUCTION

Owing to the importance of calcium carbonate in phosphate fixation (the conversion of soluble phosphates to less soluble forms) in calcareous soils, considerable attention has been given to reactions between phosphate in solution and solid calcium carbonate. Boischot *et al.* (2) and Cole *et al.* (4) showed that, at relatively low concentrations, phosphate was adsorbed on the surface of the calcium carbonate crystals. At higher concentrations there was apparently chemical precipitation of a calcium phosphate. Cole and his co-workers presented evidence that dicalcium phosphate was precipitated and they implied that this compound was an intermediate in the formation of hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$).

The object of the work reported here was (*a*) to show the effect of the surface reaction between phosphate and calcium carbonate on the equilibrium between the solution and solid calcium carbonate, and (*b*) to obtain more information on the kind of reaction which takes place.

EXPERIMENTAL

Equilibration and rate studies of the reactions between solid calcium carbonate and solutions of phosphates at various initial concentrations were made at two partial pressures of carbon dioxide. The partial pressures of carbon dioxide in the systems were obtained by constantly bubbling through the suspensions either air piped in from just outside the laboratory window or a commercial mixture of 5% CO_2 and 95% N_2. The versene method (1) was used for the determination of calcium concentrations except in the rate studies where the flame photometer was found to be more convenient. The molybdenum blue method (5) was used for phosphorus and the glass electrode for pH. The activities of the ions were estimated by means of the Debye Huckel equation (7).

RESULTS

The results of the equilibration experiments are plotted as points in Fig. 1 in which the solubility lines are calculated from published data (6, 8). The

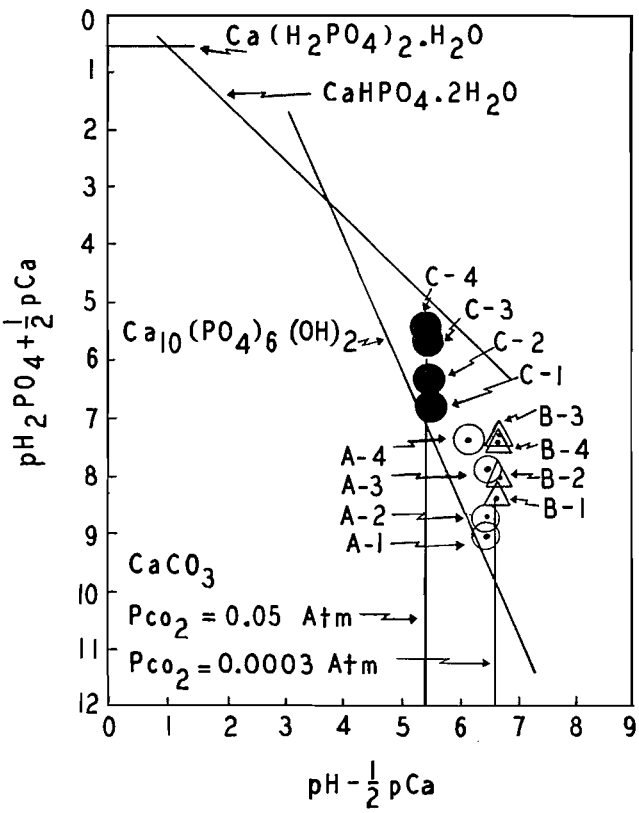

FIG. 1. Solubility diagram.
Legend:
P_{CO_2} = 0.0003 atm. Series A and B, 0.05 atm. Series C.
Initial phosphate concentrations:

A—1 10^{-6} M KH_2PO_4	B—1 5×10^{-6} M H_3PO_4	C—1 10^{-5} M H_3PO_4
A—2 5×10^{-6} M KH_2PO_4	B—2 10^{-5} M H_3PO_4	C—2 2×10^{-5} M H_3PO_4
A—3 10^{-5} M KH_2PO_4	B—3 5×10^{-5} M H_3PO_4	C—3 10^{-4} M H_3PO_4
A—4 10^{-4} M KH_2PO_4	B—4 10^{-4} M H_3PO_4	C—4 2×10^{-4} M H_3PO_4

solubility diagram is discussed fully elsewhere (3); however, a brief explanation of the diagram is included in the appendix.

After the 5% CO_2 and 95% N_2 mixture was bubbled through the suspensions for two weeks, the values of $pH - \frac{1}{2}pCa$, regardless of the initial concentration of phosphate, were reasonably close to the line in the diagram for calcium carbonate at P_{CO_2} (partial pressure of carbon dioxide) equal to 0.05 atmosphere. When air was bubbled through the suspensions for two to five weeks, the average value of $pH - \frac{1}{2}pCa$ was 6.5 compared with a calculated value of 6.6 for P_{CO_2} = 0.0003 atmosphere which is the average partial pressure of CO_2 in the air. There was more variation within a series when air was bubbled through the suspensions but this is probably the result of variations in the carbon dioxide content of the air. As the solubility product of $CaCO_3$ was generally satisfied, it seems unlikely that contamination from the atmosphere, e.g. NH_3 or SO_2, was serious.

The experimental data plotted on Fig. 1 show that although the solutions were virtually at equilibrium with solid calcium carbonate, they were not at equilibrium with a calcium phosphate compound. The fact that the experimental points are above the hydroxyapatite line indicates that equilibrium was reached slowly in these systems; therefore experiments were made to study the progress of the reactions towards equilibrium.

In Table I are presented results of experiments in which samples were removed at intervals while the carbon dioxide – nitrogen mixture was bubbled

through phosphated suspensions of calcium carbonate. In each experiment 20 gm. of $CaCO_3$ was mixed with slightly less than 1 liter of water for 24 hr. by bubbling the gas through the suspensions. A sufficient volume of relatively concentrated phosphate solution was added to give the desired initial concentration and the solution was made up to 1 liter with water. Samples were taken at frequent intervals but only sufficient data to show the progress of the reactions are included in Table I.

It is seen from the second column of Table I that the solution was close to equilibrium with calcium carbonate within 20 min. except at the highest initial concentration of phosphate. With the highest concentration of phosphate, 2.5×10^{-2} *M* H_3PO_4, the values of $pH-\frac{1}{2}pCa$ did not approach that

required for P_{CO_2} equal to 0.05 atmosphere until after about four hours. There was a rapid initial precipitation of phosphate in this system. During the process of rapid precipitation the solution was supersaturated with respect to dicalcium phosphate. This can be seen by plotting the values of $pH_2PO_4 + \frac{1}{2}pCa$ and $pH - \frac{1}{2}pCa$ on the solubility diagram of Fig. 1 or more conveniently by comparing the values of $a_{Ca^{++}}.a_{HPO_4^=}$ in the last column of Table I with the solubility product of dicalcium phosphate. After the rapid precipitation, the phosphate concentration gradually reached a constant value for the remainder of the experiment and the solution was apparently at virtual equilibrium with dicalcium phosphate. With the intermediate initial concentrations of phosphate, 2.2×10^{-3} *M* H_3PO_4 and 1.7×10^{-3} *M* KH_2PO_4, the early rapid decrease in phosphate concentration was followed by a slower prolonged precipitation. Again the rapid precipitation occurred while the solution was supersaturated with respect to dicalcium phosphate, but the solution was definitely not supersaturated with respect to this solid during the slower precipitation. With the lowest initial concentration of phosphate, 2.4×10^{-4} *M* H_3PO_4, the solution was never supersaturated with respect to dicalcium phosphate and there was only a slow rate of decrease of the phosphate concentration during the whole experiment.

In Table II are reported data for experiments in which air was bubbled through the suspensions. For these experiments calcium carbonate was added directly to solutions of the various phosphates. When the phosphate solution

was either H_3PO_4 or KH_2PO_4, about two hours were required for the solution to approach equilibrium with solid calcium carbonate. With K_2HPO_4 solutions, the values of $pH-\frac{1}{2}pCa$ were always reasonably close to the equilibrium value. The values of $pH-\frac{1}{2}pCa$, however, decreased gradually during the early part of these experiments but this was followed by a slow increase. The behavior of the systems in which the initial phosphate concentrations were 1.56×10^{-3} M H_3PO_4 and 1.02×10^{-3} M KH_2PO_4 was similar to that of the intermediate concentrations reported in Table I; the values of $a_{Ca^{++}}.a_{HPO_4^=}$, however, decreased more rapidly at P_{CO_2} equal to 0.0003 atmosphere. When the initial phosphate concentration was 1.01×10^{-3} M K_2HPO_4 there was apparently no reaction for the first two hours even though the solution was supersaturated with respect to dicalcium phosphate. After two hours there was a rapid decrease in the phosphate concentration followed by a slower reaction. With the lowest phosphate concentration, 0.5×10^{-3} M K_2HPO_4, the value of $a_{Ca^{++}}.a_{HPO_4^=}$ never exceeded that for dicalcium phosphate and there was only a slow precipitation, which began after about six hours.

The rate of decrease of the phosphate concentration in the rate experiments reported in Tables I and II was extremely slow after the first rapid reaction. A long reaction period would be required for the solutions to reach equilibrium with hydroxyapatite. There are two possible reasons for this apparently slow reaction: one, that the solution was approaching equilibrium with some calcium phosphate other than hydroxyapatite; two, that it was simply a rate process, the rate being highly dependent on the phosphate concentration. The results in Fig. 2 suggest that the latter possibility is more probably correct

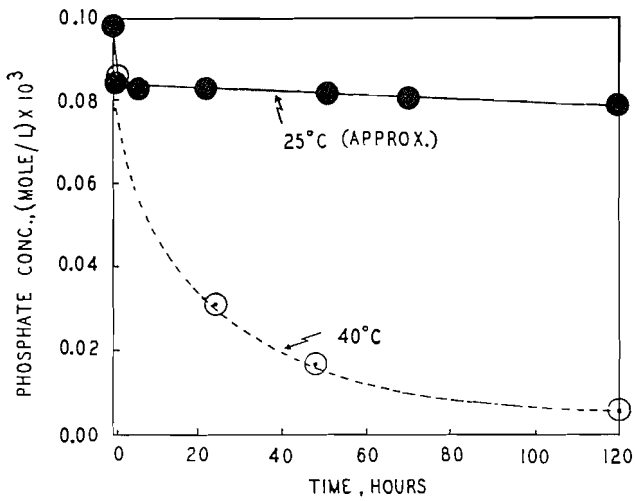

FIG. 2. Effect of temperature on rate of reaction at P_{CO_2} approximately 0.0003 atmosphere.

because the rate of decrease of the phosphate concentration was faster at 40°C. than at room temperature (about 25°C.) when the initial phosphate concentration was 0.098×10^{-3} M K_2HPO_4. The rate of decrease of the phosphate concentration at 40°C. was very slow after five days and, even

though the phosphate concentration was about one-tenth that of the lowest concentration obtained at room temperature, the solution was still supersaturated with respect to hydroxyapatite. In an experiment at 80°C., however, the solution was close to equilibrium with hydroxyapatite within 24 hr.

DISCUSSION

Regardless of the mechanism of the reaction between solid calcium carbonate and dilute solutions of phosphate, the calcium carbonate exerts its normal effect on the solution equilibrium.

It is seen from the diagram of Fig. 1 that, under the conditions prevailing in these experiments, dicalcium phosphate is not thermodynamically stable. As it is generally agreed that tricalcium phosphate does not exist in nature, the thermodynamically stable form is probably hydroxyapatite. If the solution is supersaturated with respect to dicalcium phosphate, however, this compound precipitates because hydroxyapatite forms at a much slower rate. This conclusion is based on the results reported under (*a*) in Table I which shows that about 21×10^{-3} mole of phosphorus was precipitated in less than eight hours, yet the solution was apparently supersaturated with respect to dicalcium phosphate after 31 hr. When the initial concentrations of phosphate were intermediate, (*b*) and (*c*) in Tables I and II, dicalcium phosphate was apparently precipitated in small quantities. The small quantities remained only for a short time, the length of time apparently depending on the quantity present and the rate of precipitation of hydroxyapatite. Judging by the results under (*d*) of Tables I and II, there seems little doubt that hydroxyapatite precipitated directly without the necessity of having to form dicalcium phosphate as an intermediate.

It was mentioned above that the values of the product $a_{Ca^{++}}.a_{HPO_4^{=}}$ decreased more rapidly when air was bubbled through the suspensions than when the 5% carbon dioxide mixture was used, indicating a more rapid approach to equilibrium in the former case. A possible explanation of this is that the rate of precipitation of hydroxyapatite is dependent on the concentration of $PO_4^{\equiv}$ ions which would be lower in the more acid suspensions through which the CO_2–N_2 mixture was passed. This observation along with the resulting increase in the rate of phosphate precipitation with increasing temperature indicates the advisability of making a thorough study of the kinetics of precipitation of hydroxyapatite.

APPENDIX

The solubility diagram of Fig. 1 is based on the fact that the equilibrium formation of a number of solid calcium orthophosphates in aqueous systems may be expressed by the equation

$$m\mathrm{Ca(OH)_2} + n\mathrm{Ca(H_2PO_4)_2} = \text{solid} + y\mathrm{H_2O} \qquad [1]$$

where m and n represent the number of moles of $Ca(OH)_2$ and $Ca(H_2PO_4)_2$, respectively, forming 1 mole of solid and y moles of H_2O. In relatively dilute solutions, $Ca(OH)_2$ and $Ca(H_2PO_4)_2$ may be assumed to be completely dis-

sociated. It follows, therefore, that

$$-m(\mathrm{pH}-\tfrac{1}{2}\mathrm{pCa})+n(\mathrm{pH_2PO_4}+\tfrac{1}{2}\mathrm{pCa}) = k \qquad [2]$$

where "p" represents the negative logarithm of the ion activity, k is a constant, and the activity of OH^- ions is expressed in terms of the ionic product of water, K_W, and the H^+ ion activity. With $(\mathrm{pH}-\frac{1}{2}\mathrm{pCa})$ and $(\mathrm{pH_2PO_4}+\frac{1}{2}\mathrm{pCa})$ as the two co-ordinates, equation 2 represents a straight line with slope m/n.

The constant k in equation 2 can be evaluated from the solubility product of the solid, the second and third dissociation constants of phosphoric acid, K_2 and K_3, and the ionic product of water. For hydroxyapatite, monocalcium phosphate, and dicalcium phosphate equation 2 becomes, respectively, equations 3, 4, and 5 below,

$$-7(\mathrm{pH}-\tfrac{1}{2}\mathrm{pCa})+3(\mathrm{pH_2PO_4}+\tfrac{1}{2}\mathrm{pCa}) = \tfrac{1}{2}(\mathrm{p}K_{sp}{}^{I}-6\mathrm{p}K_2K_3-2\mathrm{p}K_W) \qquad [3]$$

$$(\mathrm{pH_2PO_4}+\tfrac{1}{2}\mathrm{pCa}) = \tfrac{1}{2}\mathrm{p}K_{sp}{}^{II} \qquad [4]$$

$$-\tfrac{1}{2}(\mathrm{pH}-\tfrac{1}{2}\mathrm{pCa})+\tfrac{1}{2}(\mathrm{pH_2PO_4}+\tfrac{1}{2}\mathrm{pCa}) = \tfrac{1}{2}(\mathrm{p}K_{sp}{}^{III}-\mathrm{p}K_2) \qquad [5]$$

where $K_{sp}{}^{I}$, $K_{sp}{}^{II}$, and $K_{sp}{}^{III}$ are the solubility products of the appropriate solid phases. The solubility lines in Fig. 1 were drawn from equations 3, 4, and 5 using published values (8) for the right-hand side of the equation. In the figure, the co-ordinates are arranged so that the chemical potential of $Ca(H_2PO_4)_2$ increases upwards and that of $Ca(OH)_2$ to the right. If the solution is in equilibrium with a given solid phase, the solubility points must lie along the solubility line for that compound. A solubility point to the right or above a solubility line indicates supersaturation or the existence of a metastable solid phase.

If the solution is at equilibrium with solid calcium carbonate, it can be shown that

$$-(\mathrm{pH}-\tfrac{1}{2}\mathrm{pCa}) = \tfrac{1}{2}(\mathrm{p}K_{sp}{}^{IV}-\mathrm{p}K_1{}^{I}K_2{}^{I}-\mathrm{pC}-\mathrm{p}P_{CO_2})$$

where $K_{sp}{}^{IV}$ is the solubility product of $CaCO_3$, $K_1{}^{I}$ and $K_2{}^{I}$ are the first and second dissociation constants of carbonic acid, P_{CO_2} is the partial pressure of CO_2 in the system, and C is the total molal concentration of CO_2 in solution when P_{CO_2} is unity.

THE TERTIARYBUTYLBENZENES

I. ALKYLATION OF 1,4-DI-*t*-BUTYLBENZENE WITH *t*-BUTYL CHLORIDE[1]

By L. Ross C. Barclay and Eileen E. Betts[2]

ABSTRACT

The alkylation of *p*-di-*t*-butylbenzene with excess *t*-butyl chloride in the presence of aluminum chloride in the cold produces a new aromatic hydrocarbon, m.p. 218.5–219°. Evidence is given for the presence of an alicyclic nucleus in this hydrocarbon which analyzes for $C_{22}H_{34}$. The preparation of nitro and amino derivatives from this hydrocarbon is described. The alkylation of benzene under similar conditions yielded some 1,3,5-tri-*t*-butylbenzene, and an improved method of preparation of this hydrocarbon from *p*-di-*t*-butylbenzene is given.

INTRODUCTION

For some time we have been interested in synthesizing 1,3,5-tri-*t*-butylbenzene and in preparing derivatives of this compound required in a study of the influence of the bulky *t*-butyl group on functional group reactions. Recently Bartlett (1) showed that the reaction of *t*-butyl chloride and aluminum chloride with *p*-di-*t*-butylbenzene yields *m*-di-*t*-butylbenzene, 1,3,5-tri-*t*-butylbenzene, and a hydrocarbon of melting point 209–210°. This excellent communication prompted us to publish some of the work conducted in our laboratory on *t*-butylbenzenes.

We found that not only *p*-di-*t*-butylbenzene but also benzene is converted to a mixture of 1,3,5-tri-*t*-butylbenzene and a hydrocarbon of melting point 218–219°, when treated with excess *t*-butyl chloride and aluminum chloride. Bartlett's preparation of 1,3,5-tri-*t*-butylbenzene could not be repeated but an improved method is given in the experimental section (Run II). In these alkylations, 1,3,5-tri-*t*-butylbenzene is formed rapidly, but under the influence of excess aluminum chloride and prolonged reaction time it is converted to the higher melting hydrocarbon. Some interesting properties of this hydrocarbon are reported.

A New High Melting Hydrocarbon and Some Derivatives

A high melting (218.5–219°) aromatic hydrocarbon which analyzed for $C_{22}H_{34}$ was isolated by adding aluminum chloride in portions to a cold (below −5°) solution of *p*-di-*t*-butylbenzene in excess *t*-butyl chloride. This compound was nitrated and the nitro compound reduced to an amine. Attempts to convert the amine into a phenol whose properties could be compared with those of the known 2,4,6-tri-*t*-butylphenol (12) produced a pale yellow compound possessing an ultraviolet absorption intensity much higher than that of phenols. The properties of these derivatives indicate that they are highly hindered. For example, the nitro compound does not show the large increase in absorption in the near ultraviolet characteristic of nitro derivatives of

[1]*Manuscript received November 17, 1954.*
Contribution from the Department of Chemistry, Mount Allison University, Sackville, New Brunswick.
[2]*Recipient of a National Research Council Bursary.*

benzene and in this respect is similar to the sterically hindered nitro compounds studied by Brown and Reagan (4). In addition, the amine derivative does not dissolve in concentrated acid.

Certain general conclusions can be made concerning the structure of the high melting hydrocarbon from the ultimate and spectral analyses. The higher carbon values (or lower hydrogen values) of this compound compared to those of the butylbenzenes suggest a second ring fused onto the benzene ring in the alkylation. This might also explain the high melting point. The infrared spectrum (Fig. 1) shows the presence of *t*-butyl groups. The most characteristic feature is the strong band at 891 cm.$^{-1}$ and the absence of any strong band below this. In this respect it resembles the spectrum of pentamethylbenzene, which may indicate that the hydrocarbon contains a penta-substituted ring. The ultraviolet absorption of this hydrocarbon is very interesting in that it shows similarities to that of certain alicyclics, for example indan. The latter shows characteristic bands at 273.6, 267, and 260 mμ compared to 278, 271, and an inflection at 262 mμ for this hydrocarbon. In addition the very weak band for indan at 291 suggested by Morton and de Gouveia (9) as being due to impurities is present in this compound at 298 mμ.

It should be noted that tetralin also has similar absorption with bands at 274 and 267 and an inflection at 261 mμ but the weak band near 290 mμ is not reported (9). It is possible that this weak band may be of use in identifying the indan nucleus in the high melting hydrocarbon.

Early Research on the Poly-t-butylbenzenes

In 1890 Senkowski (10) reported tri-*t*-butylbenzene, m.p. 128°, along with *p*-di-*t*-butylbenzene, m.p. 70°, and a liquid hydrocarbon from the alkylation of benzene with isobutyl chloride. Smith (11) obtained some of Senkowski's hydrocarbon, m.p. 128°, by the rearrangement of isobutylphenyl ether in benzene solution with aluminum chloride.

In a study of various complexes formed by the Friedel-Crafts reaction, Gustavson (5) found that the action of *t*-butyl chloride and benzene on aluminum chloride at −10° led to the formation of a yellow crystalline compound, aluminum chloride ditributylbenzene hydrochloride, $Al_2Cl_5[C_6H_3-[(CH_3)_3C]_3]HCl$, which was also formed by the reaction of *p*-di-*t*-butylbenzene and powdered aluminum chloride with *t*-butyl chloride.

Ipatieff (6) and co-workers reported mono-, di-, and tri-*t*-butylbenzene (a liquid) from the reaction of isobutylene with a mixture of sulphuric acid and benzene. Koch and Steinbrink (7) alkylated benzene by the method described by Ipatieff and co-workers and obtained *p*-di-*t*-butylbenzene but were unable to prepare a tri-substituted product by this method. Legge (8) attempted to prepare tri-*t*-butylbenzene by the reaction of isobutylene with aluminum chloride or sulphuric acid on benzene but obtained instead a considerable number of unexpected alkylbenzenes and suggested an electronic explanation for the results obtained.

Bartlett and co-workers (1) found small quantities of Senkowski's hydrocarbon (m.p. 129.5–130°) in some residues from the preparation of *p*-di-*t*-

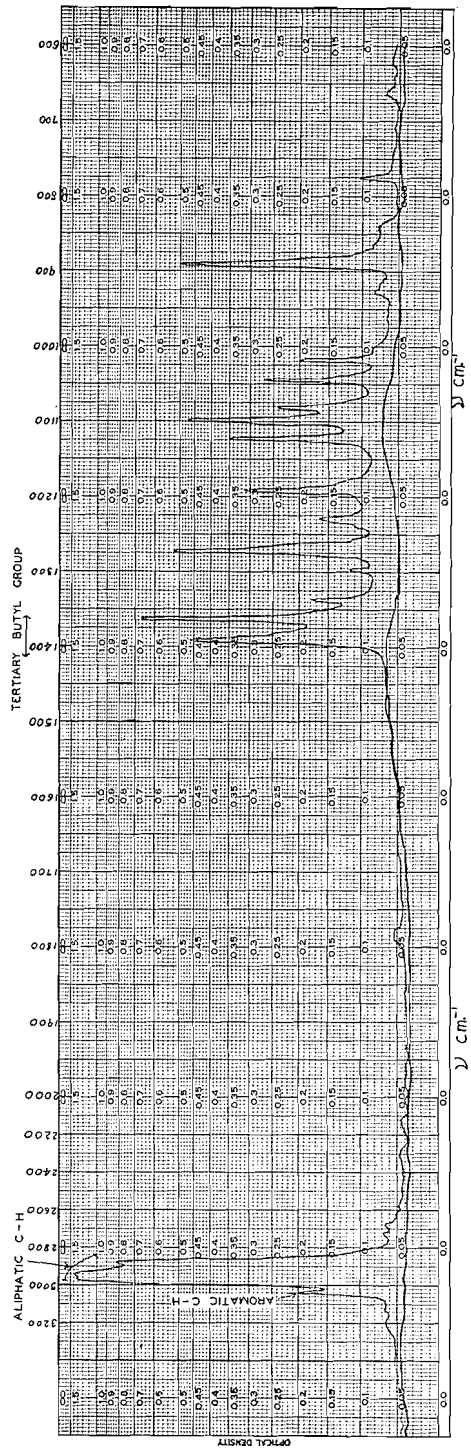

FIG. 1. Infrared spectrum of the high melting (218.5–219°) hydrocarbon in carbon disulphide.

butylbenzene by the Standard Oil Company of Indiana. However, these workers did not establish the structure of this hydrocarbon. It seems unlikely that the structure given to this compound by Smith (11), that is 1,2,4-tri-*t*-butylbenzene, is correct because of the improbability that two *t*-butyl groups can occupy adjacent positions in the benzene ring. Brown and co-workers (3) investigated homomorphs of *o*-di-*t*-butylbenzene and support this view.

EXPERIMENTAL

The melting points recorded were obtained with a Fisher-Johns type apparatus and are uncorrected. Ultraviolet spectra were measured on a Beckmann DU spectrophotometer with cyclohexane, free from aromatics, as solvent.

Alkylation of Benzene and Isolation of 1,3,5-Tri-t-butylbenzene

A solution of pure benzene (36 ml., 0.41 mole) in *t*-butyl chloride (189 ml., 1.7 moles) was cooled to −5° and 59 gm. of aluminum chloride added in small portions over a period of two hours. Aliquots removed after one and three-quarter hours and after all the aluminum chloride was added yielded colorless crystalline material mixed with some liquid on decomposition in ice. On crystallization from ethanol, these aliquots yielded a total of 14 gm. of crystalline material (m.p. 60–65°) consisting of a mixture of *p*-di-*t*-butylbenzene and 1,3,5-tri-*t*-butylbenzene. Careful crystallization from ethanol yielded some of the tri-substituted product, m.p. 73°, which did not depress the melting point of an authentic sample. The remainder of the reaction was decomposed in ice water after a total of six hours' reaction. The hydrocarbon layer was extracted with ether and the ether removed on the steam cone. The viscous residue was placed in a refrigerator overnight and some crystalline material (3 gm.) formed. Crystallization from benzene–ethanol yielded colorless crystals which consisted mainly of the high melting hydrocarbon and which melted at 195–200°.

Alkylation of p-Di-t-butylbenzene

Run I—Preparation of the High Melting Hydrocarbons

p-Di-*t*-butylbenzene (47 gm., 0.25 mole) was dissolved in 300 ml. of *t*-butyl chloride and the solution cooled to −5°, causing much of the hydrocarbon to precipitate. Powdered aluminum chloride (66 gm., 0.5 mole) was added in small portions over a two-hour period to this mixture with vigorous stirring. After about five minutes the hydrocarbon redissolved and there was copious evolution of hydrogen chloride. At the end of six hours' reaction in the cold, the evolution of hydrogen chloride subsided and two layers appeared—a yellow liquid layer on top and a thick dark amorphous mass at the bottom of the flask. The reaction mixture was decomposed in crushed ice and the hydrocarbon layer distilled with steam until oily droplets ceased coming over into the distillate. The solid residue was separated from adhering polymeric liquid products on the suction pump by washing with ethanol to yield 20 gm. of colorless crystalline material, m.p. 205–210°. In later runs it was found more convenient to extract the decomposed reaction product directly with ether and proceed with the isolation by concentration of the ether until the hydro-

carbon crystallized. Repeated crystallizations from 1:1 benzene–ethanol yielded colorless needles, m.p. 218.5–219°.

Run II—Improved Synthesis of 1,3,5-Tri-t-butylbenzene

Seventy-five grams of *p*-di-*t*-butylbenzene was dissolved in 350 ml. of *t*-butyl chloride and the solution cooled to −3°, causing much of the hydrocarbon to precipitate. Seven grams of aluminum chloride was added during the first half hour to the stirred mixture, the temperature being maintained below 0°. Twenty grams of aluminum chloride was then added in 10 min. causing the semisolid reaction mixture to become liquid and the temperature to lower to −7°. After an additional 10 min., the reaction mixture was carefully decomposed in cold water. The organic layer was extracted with ether, which was removed with excess *t*-butyl chloride on the steam cone. The residue solidified on cooling with an ice–salt mixture to yield 70 gm. (75% yield) of colorless solid. After five recrystallizations from ethanol, this material melted at 74.8–75°. The ultraviolet absorption spectrum (Fig. 2) of this product was practically identical to that of authentic 1,3,5-tri-*t*-butylbenzene prepared in small yield in this laboratory by the condensation of pinacolone.

Anal. Found: Molecular weight 247.7, 245.5, 248.8.
Calc. for tri-butylbenzene 246.4.

(4) Nitro derivative of the high melting hydrocarbon (m.p. 266.5–267°).

Run III—Intermediates in the Preparation of the High Melting Hydrocarbon

Essentially the same procedure with the same amounts of reagents as in Run II was used except that additional aluminum chloride (7.5 gm.) was added and the reaction was continued for six hours. Aliquots of the reaction

mixture were removed when the mixture became fluid (after 30 min.) and after 45 min. These were decomposed in water and recrystallized from ethanol. The first aliquot contained a mixture of *p*-di-*t*-butylbenzene and 1,3,5-tri-*t*-butylbenzene. The second aliquot (after 45 min.) contained 1,3,5-tri-*t*-butylbenzene, which after one crystallization melted at 73°. At the end of six hours, the remaining reaction mixture was decomposed, extracted with ether, and the excess *t*-butyl chloride removed with the ether on the steam cone. On standing, the liquid residue deposited some crystalline material which yielded 6 gm. of colorless crystals after crystallization from benzene–ethanol, m.p. 211–212°.

Nitration of the High Melting Hydrocarbon

The hydrocarbon (12.6 gm., m.p. 216–218°) was dissolved in a mixture of glacial acetic acid (580 ml.) and acetic anhydride (345 ml.) at 65°. Fuming nitric acid (5 ml., sp. gr. 1.5) was added drop by drop and the reaction mixture was heated at 90° for three hours. On cooling, the product crystallized as pale yellow crystals, 7.3 gm., m.p. 261–262°. Repeated crystallization from benzene–ethanol changed the melting point to 266.5–267°.

Anal. Found: C, 77.75, 77.52; H, 9.57, 9.49; N, 4.04.

Molecular weight, 343.5.

Preparation and Attempted Hydrolysis of an Amino Derivative

A solution of 5 ml. of concentrated hydrochloric acid in 5 ml. of ethanol was added to a mixture of 0.5 gm. of the nitro derivative with 1 gm. of granulated tin. This mixture was heated on the steam cone under reflux and enough ethanol, saturated with dry hydrogen chloride, was added to give a clear solution. This solution was refluxed for five hours and then allowed to stand for a day. At the end of this time, no crystallization had taken place so that the product was worked up in the usual way by precipitation in water, addition of alkali to dissolve the tin, and extraction with ether. On evaporation of the ether colorless crystals formed, m.p. 247–248°. Crystallization from benzene–ethanol yielded colorless crystals, m.p. 249.2–249.7°.

Anal. Found: C, 85.00, 85.09; H, 11.27, 11.11; N, 4.01.
Calc. for $C_{22}H_{35}N$: C, 84.28; H, 11.26; N, 4.47.

This amine appeared to be almost completely insoluble in concentrated hydrochloric acid but the ultraviolet spectrum, with general absorption maxima at 292($E^{1\%}$ 71.3), 248($E^{1\%}$ 205), and 214 mμ ($E^{1\%}$ 1460), is typical of aromatic amines.

Two grams of this amine was dissolved in 180 ml. of a 1: 5 sulphuric acid – acetic acid solution. The solution was cooled in an ice bath and a solution of 22 gm. of sodium nitrite in 90 ml. of water was added. The reaction mixture was then warmed on the steam cone until evolution of nitrogen ceased, cooled, and extracted with ether. After washing with 10% sodium bicarbonate solution, the excess ether was removed and pale orange crystals formed, m.p. 208–209°. Unsuccessful attempts were made to remove the color from this

product by chromatography on alumina and crystallization with charcoal. The ultraviolet absorption, λ_{max} 265 mμ, $E^{1\%}$ 377, of this compound is much more intense than expected for a phenol and a more detailed study is required before a structure can be suggested for this product.

The Action of Oxidizing Agents on the High Melting Hydrocarbon

Tertiary-butyl groups are known to oxidize with difficulty; for example, Boedtker (2) obtained mainly di-*t*-butylquinone on attempted oxidative degradation of *p*-di-*t*-butylbenzene. Using increased pressure and temperature, Legge (8) succeeded in obtaining terephthalic acid by nitric acid oxidation of *p*-di-*t*-butylbenzene.

Attempts to oxidize the high melting hydrocarbon to a known benzenecarboxylic acid have not been successful. Oxidation with nitric acid in pressure tubes at elevated temperatures yielded acidic material but yields were very small and nitration accompanied oxidation. The use of such oxidizing agents as chromic acid or potassium permanganate in solvents such as acetone, acetic acid, or pyridine has not produced any identifiable benzenecarboxylic acid. It was found, however, that *p*-di-*t*-butylbenzene could be oxidized to terephthalic acid in small yield by heating a powdered mixture of the hydrocarbon with an oxidizing agent such as potassium permanganate in a nitrogen atmosphere at 220°. This procedure has yielded some polycarboxylic acid from the high melting hydrocarbon and, although the degradation was not complete in this case, seems the most promising approach.

ACKNOWLEDGMENTS

This work was conducted with the aid of a grant from the National Research Council of Canada, Ottawa, and in addition one of us (E.E.B.) gratefully acknowledges financial assistance provided by a National Research Council Bursary.

The authors wish to thank Dr. L. Marion for having ultimate analyses done for us at the National Research Council Laboratories. We also thank Dr. R. N. Jones and Mr. R. Lauzon for measuring and interpreting the infrared spectrum.

We are indebted to Dr. R. A. Friedel of the United States Bureau of Mines, Pittsburgh, for his assistance in the interpretation of the ultraviolet spectra and to Dr. S. H. Langer of the same laboratory for measuring the molecular weights.

THE SYNTHESIS OF C^{14}-CARBOXYL-LABELLED ω-THIOETHYL FATTY ACIDS[1]

By Anne E. Almond, Anna Mary Burditt, D. E. Douglas,[2] and Jean Eccles

ABSTRACT

Syntheses on a semimicro scale of thioethyl acetic, ω-thioethyl propionic, and ω-thioethyl butyric acids labelled with carbon-14 in the carboxyl group are described. The compounds were chromatographed on filter paper with butanol–water–ammonia as the developing solvent, and the R_F values determined.

In the course of an investigation, at this Institute, of ω-thioalkyl fatty acids as metabolic inhibitors in isolated tissues, carbon-14-carboxyl-labelled thioethyl acetic, ω-thioethyl propionic, and ω-thioethyl butyric acids were required. Experimental details for the synthesis of these labelled molecules on a semimicro scale are described in this communication.

Although ω-thioalkyl acetic acids have been prepared by alkylation of sodium thioglycollate with the appropriate alkyl halide (6) and these and other ω-thioalkyl fatty acids from the sodium salt of a thiol and a ω-halo fatty acid (3, 7) this latter method was only employed for the preparation of thioethyl acetic acid-1-C^{14}.

A more convenient synthetic method for higher homologues involves cyanidation of an ethyl ω-haloethyl sulphide followed by hydrolysis of the resulting nitrile to the acid. This method is not satisfactory when ethyl chloromethyl sulphide is a reactant, owing to the instability of this molecule (2). Ethyl γ-bromopropyl sulphide forms a Grignard reagent, which may be carbonated to yield ω-thioethyl butyric acid. Ethyl β-chloroethyl sulphide, however, failed to form a Grignard reagent.

A method for the paper chromatography of the acids described has been worked out, to assess the radiopurity of the labelled compounds.*

EXPERIMENTAL

Thioethyl Acetic Acid-1-C^{14}

Acetic acid was liberated from 4.8 mM. of sodium acetate-1-C^{14} (199,700 counts total activity) with hydrogen chloride gas according to a previously described high-vacuum procedure (4), and condensed into a reaction flask fitted with a micro dropping funnel and cold-finger condenser. The acetic acid was brominated in the presence of acetyl chloride (0.1 ml.), red phosphorus (20 mgm.), and a crystal of iodine with bromine (0.5 ml.). The latter was added dropwise, while the mixture was heated under reflux (4).

[2]*In charge, Division of Atomic Chemistry.*
**Recently, a communication (J. Am. Chem. Soc. 76: 3860. 1954) from another laboratory has appeared regarding the antituberculosis activity of some ethylmercapto compounds, including several thioalkyl-fatty acids. No details are given regarding synthetic methods, and presumably carbon-14-labelled compounds were not employed in this investigation.*

After two hours the reaction mixture was hydrolyzed with 2 to 3 ml. of water, and the unreacted bromine removed in a stream of nitrogen. The last traces of bromine were removed with 1 *N* sodium bisulphite. The resulting solution was neutralized to pH 8 with dilute sodium hydroxide, and evaporated *in vacuo*. The residue was dissolved in the minimum amount of water, and 0.62 *M* sodium ethanethiolate (10 ml.) in ethanol was added. The mixture was shaken several times and allowed to stand for 24 hr. and then heated under reflux for three hours, and finally concentrated to dryness *in vacuo*.

The residue was dissolved in water and the aqueous solution extracted continuously with ether for four to five hours. The aqueous layer was acidified to pH 2 with dilute sulphuric acid and extracted continuously overnight with ether. The ethereal solution was dried over sodium sulphate, and evaporated in a stream of nitrogen. The oily residue was distilled from a Späth bulb (bath temperature 100°C.) on the high-vacuum system yielding 0.1555 gm. (21%) of a colorless oil. Specific activity 200 counts per min. per mgm. with 50% counter geometry. $\eta_D^{22°} = 1.4800$.

ω-Thioethyl Propionic Acid-1-C^{14}

Barium carbonate-C^{14} (1 mc. per mM.) was converted to sodium cyanide-C^{14} by Adamson's method (1). To 0.4 mM. of this radiocyanide were added 5 mM. (0.245 gm.) of carrier sodium cyanide, 8 ml. of 80% ethanol, and 5.4 mM. (0.65 ml.) of ethyl β-chloroethyl sulphide. The mixture was heated under reflux for four hours and the solvent was removed *in vacuo*. The remaining oil was hydrolyzed with a solution of 6 *N* hydrochloric acid (5 ml.) and glacial acetic acid (2.5 ml.) in a sealed tube at 100° for 12 hr. The acetic and hydrochloric acids were removed *in vacuo*, and the product dissolved in a few milliliters of water, and extracted exhaustively with chloroform. The chloroform solution was shaken several times with an excess of dilute sodium hydroxide, then with water. The combined alkaline extracts and washings were acidified to pH 2 and extracted four times with chloroform. The combined chloroform solutions were dried over sodium sulphate and filtered. The filtrate was concentrated and the remaining oil was distilled under high vacuum from a Späth bulb. Yield 0.2612 gm. (36%, based on ethyl β-chloroethyl sulphide). Colorless oil. Activity yield: 15.9% from barium carbonate-C^{14}. Specific activity 87,400 c.p.m./mgm. with 50% counter geometry. Calc. for $C_5H_{10}O_2S$: C, 44.76; S, 23.90. Found: C, 44.5; S, 23.8. $\eta_D^{21.5} = 1.4805$.

ω-Thioethyl Propionamide

A sample of non-radioactive ω-thioethyl propionic acid was treated with a slight excess of thionyl chloride, and the mixture heated at 80°C. for 10 min. to complete the reaction. Excess concentrated ammonium hydroxide was added carefully to the resulting acid chloride. The reaction mixture was evaporated to dryness *in vacuo*, and the amide dissolved in isopropyl ether, and recrystallized from the same solvent. Colorless plates, m.p. 64–65°C. Calc. for $C_5H_{11}NOS$: C, 45.08; N, 10.52; S, 24.07. Found: C, 44.3; N, 10.7; S, 24.5.

ω-Thioethyl Butyric Acid-1-C^{14}

(*a*) *Cyanidation of Ethyl γ-Chloropropyl Sulphide and Hydrolysis of the Nitrile*

A mixture of sodium cyanide (0.3 gm.), water (0.5 ml.), ethanol (5 ml.), and ethyl γ-chloropropyl sulphide (0.693 gm.) (5) was heated under reflux for six hours. The ethanol was evaporated *in vacuo*, the residue shaken with water to dissolve salts and then extracted with ether. The ethereal solution was dried with sodium sulphate and evaporated in a bomb tube under a stream of nitrogen. The oily residue was heated with a mixture of 1.5 ml. each of glacial acetic acid and concentrated hydrochloric acid for about three hours at 110°C. The acetic and hydrochloric acids were removed *in vacuo*, and the crude acid purified by the method described above for the preparation of ethyl thioacetic acid. After high-vacuum distillation, the product weighed 0.090 gm. Yield 12%, based on ethyl γ-chloropropyl sulphide. $\eta_D^{22°} = 1.4805$.

(*b*) *Carbonation of the Ethyl γ-Bromopropyl Sulphide Grignard Reagent*

Although ethyl γ-chloropropyl sulphide formed a Grignard reagent only in the presence of ethyl bromide added as promoter, the corresponding bromo-compound was active alone.

Ethyl γ-bromopropyl sulphide was prepared from ethyl γ-hydroxypropyl sulphide and phosphorus tribromide in carbon tetrachloride.

The Grignard reagent was prepared from ethyl γ-bromopropyl sulphide (2.2 gm.), magnesium (0.3 gm.), and dry ether (30 ml.). Carbonation was carried out according to the usual high-vacuum technique with carbon dioxide liberated from 0.9048 gm. (4.6 mM.) of barium carbonate-C^{14} (5.08×10^5 counts total activity) by means of concentrated sulphuric acid. The mixture was allowed to warm slowly to room temperature with occasional shaking after the carbonation at approximately −20°C. was assumed to be complete. The magnesio complex was carefully decomposed with excess of dilute sulphuric acid, and the ether layer was removed. The aqueous phase was extracted four times with ether and the combined ethereal solutions were washed with three portions of 0.5 *N* sodium hydroxide (total 15 ml.) then four times with water. The combined alkaline solution and washings were saturated with sodium sulphate, acidified to pH 2, and extracted with ether.

The ethereal solution was dried over sodium sulphate, and the ether removed leaving an oily residue. This residue was distilled in a Späth bulb under high vacuum at a bath temperature of 100° yielding 0.362 gm. of a colorless oil. Specific activity 570 c.p.m./mgm. Yield 53%, based on barium carbonate. Calc. for $C_6H_{12}O_2S$: C, 48.65; S, 21.60. Found: C, 48.7; S, 21.8. $\eta_D^{22.0°} = 1.4805$; mixed R.I. with the product prepared by the previous method $\eta_D^{22°} = 1.4805$. The identity of the compounds obtained by the two procedures was further established by chromatography on filter paper.

A crystalline amide could not be obtained from this compound with thionyl chloride and ammonia.

Paper Chromatography of the Thioethyl Fatty Acids

Approximately 0.1 mgm. quantities of the labelled acids in excess ammonium

hydroxide were chromatographed on Whatman No. 1 filter paper with butanol–water–ammonia by the ascending technique. Butanol (100 ml.) was shaken with water (25 ml.) and ammonium hydroxide (2 ml.) below room temperature, and the butanol layer separated. An open beaker containing concentrated ammonium hydroxide was placed under the battery jar containing the chromatogram. After approximately 15 hr., the chromatograms were removed and dried.

The paper was sprayed with 0.1% aqueous chloramine-T, dried, and sprayed immediately with starch – potassium iodide solution (0.1 gm. soluble starch and 0.1 gm. potassium iodide per 100 ml.). White spots on a blue background indicated the presence of the thio-acids. Radioautographs were obtained by placing the dried chromatograms before treatment with chloramine-T in contact with Eastman No-Screen X-ray film for approximately two weeks.

The following relative R_F values were observed for the regions of maximum concentration:

R_F $C_2H_5SCH_2COOH = 0.34$

$$\frac{R\ C_2H_5S(CH_2)_2COOH}{R\ C_2H_5SCH_2COOH} = 1.30$$

$$\frac{R\ C_2H_5S(CH_2)_3COOH}{R\ C_2H_5SCH_2COOH} = 1.55$$

A trace of radioactive contaminant with an R_F of 0.12 was present in the ω-thioethyl propionic and ω-thioethyl butyric acids.

ACKNOWLEDGMENT

The authors wish to thank Dr. Wm. Brown, formerly of this Institute, for samples of inactive thioethyl acetic and ω-thioethyl propionic acids.

OXIDE COMPLEXES FORMED IN THE SYSTEMS PLATINUM METALS : ALKALI CARBONATES : OXYGEN[1]

By J. J. Scheer, A. E. van Arkel, and R. D. Heyding[2]

ABSTRACT

On heating mixtures of a platinum metal with an alkali carbonate in different ratios and at different temperatures in an oxygen stream, two kinds of compounds are formed:

(1) the cubic compounds $Na_xPt_3O_4$ and $Na_xPd_3O_4$,

and

(2) a series of oxide complexes with compositions ABO_2 or A_2BO_3, both isomorphous with Na_2SnO_3.

Although all metals of the platinum group form oxides, anhydrous complexes of their oxides have not been described. The observation that at high temperatures platinum crucibles are readily attacked by lithium oxide in the presence of air (1) was the first indication that such complexes might be prepared. On investigating the reactions of lithium oxide – platinum black mixtures in oxygen at 1000°C., Bright reported the formation of a product with the approximate formula Li_2PtO_3 (3). Further study of the X-ray pattern has shown that this product was actually a mixture of two or more compounds.

We have found that lithium oxide and platinum react in oxygen even at 400°C. to form single compounds, and that the same products are obtained from lithium carbonate – platinum mixtures. Because of the ease with which carbonate–platinum mixtures could be handled in comparison to those of the oxide (2), all subsequent reactions were restricted to the carbonate. Like the oxide, the carbonate attacks most crucible materials, and it was necessary to use crucibles cut from fused polycrystalline blocks of magnesium oxide.

By replacing the platinum black in the reaction mixtures by other finely divided platinum metals, a number of lithium complexes with Pd, Rh, and Ir were prepared, and by the substitution of Na_2CO_3 for Li_2CO_3, analogous sodium complexes have been obtained.

EXPERIMENTAL

The platinum metals were used in the form of platinum black, prepared by the procedure described in Gmelin (5) (i.e., reduction with sodium formate); palladium black (5); rhodium and iridium sponge, both 99.95% pure, from British Drug Houses Ltd.

Analytically pure sodium carbonate and lithium carbonate (May and Baker) were preheated in oxygen at 400°C. for about five hours.

Portions of metal and carbonate were weighed into a magnesium oxide boat and mixed intimately. This mixture was heated under a slow stream of oxygen which had been dried over sulphuric acid, silica gel, sodium hydroxide, and,

finally, phosphorous pentoxide. Heating was continued until no further change in weight could be observed.

Debye–Scherrer diagrams of the products were taken in a 9 cm. Unicam camera with Cu K_α radiation.

RESULTS AND DISCUSSION

In the systems Na–Pt–O and Na–Pd–O, the first compounds formed were the cubic phases $Na_xPt_3O_4$ and $Na_xPd_3O_4$ (a_0 = 5.67 Å and 5.64 Å, respectively), the first of which has been described by Waser and McClanahan (8). Experimental and calculated values of $\sin^2\theta$ and of line intensities for one of these structures are given in Table I.

On heating mixtures of the molecular proportions metal : carbonate ::1:1 for about 20 hr. at 600°–1000°C., the A_2BO_3 compounds Li_2RhO_3, Na_2IrO_3, Na_2PtO_3, and Li_2PtO_3 were obtained. These compounds are isomorphous with a series of complexes of quadrivalent elements, Li_2TiO_3, Na_2TiO_3, Na_2SnO_3, and Na_2PbO_3, investigated by Lang (6). Typical X-ray data are given in Table II.

It was not possible to prepare Na_2PdO_3 by this method, although quadrivalent palladium appears to exist in the phase Li_2PdO_3.

The rhodium mixtures first formed the compounds $LiRhO_2$ and $NaRhO_2$, and it seems probable that the latter compound is also transformed into the A_2BO_3 compound Na_2RhO_3, but its crystal structure has not yet been established.

It has been found that both ABO_2 compounds are isomorphous with the A_2BO_3 compounds (Table III). The lattice of the compound $LiRhO_2$ consists of alternating layers of lithium and rhodium atoms separated by oxygen layers. From this structure the crystal of the A_2BO_3 type is formed by the

substitution of one lithium and two quadrivalent rhodium ions for three trivalent rhodium ions in the lattice, leading to the formula $Li_{4/3}\,Rh_{2/3}\,O_2 = 2/3\,Li_2RhO_3$. A very similar substitution has been observed in fluorides of the $NaLaF_4$ type, which may be written as $Na_{3/2}\,La_{3/2}\,F_6$ or $(Na_{3/2}\,La_{1/2})LaF_6$, and are isomorphous with Na_2ThF_6 (9).

According to Lang (6), the structure of Na_2SnO_3 can be described by reference to a monoclinic cell, as well as to a larger orthorhombic cell, three times the volume of the former. In Table IV the parameters of both cells are given for the isomorphous ABO_2 and A_2BO_3 complexes; whether the symmetry is orthorhombic or pseudorhombic will be left undecided.

*Cf. *Lang* (6).

The structure of these compounds is closely related to that of the hexagonal complexes of one of the iron metals, i.e. $LiNiO_2$ (high temperature modification) and $NaNiO_2$ (4), the difference lying in the relative positions of the metal layers. Both groups can be derived from a cubic close packed arrangement of oxygen ions, with the metal ions in the octahedral interstices. By a slightly different arrangement of the metal atoms the cubic structure of $LiFeO_2$ is obtained.

In all of these groups the metal ions are surrounded by six oxygen ions, and in this respect are completely different from the compounds of the $Na_xPt_3O_4$ type, in which all platinum atoms are in the center of square PtO_4 groups. There can be no doubt that the Pt—O bonds are due to dsp^2 hybridization, as in PtO (7); however there are two kinds of platinum ions in the lattice according to the formula $Na_xPt^{2+}_{1+x}Pt^{3+}_{2-x}O_4$. The range of the parameter x has not yet been determined.

We intend to continue this investigation by including the remaining metals of the iron and platinum groups as well as other alkali metals.

THE PURIFICATION OF SEDOHEPTULOSE[1]

By L. Ujejski[2] and E. R. Waygood[3]

ABSTRACT

Methods involving paper and cellulose column chromatography are described for the purification of sedoheptulose phosphate from the mother liquor obtained from *Sedum spectabile* by the procedure of LaForge and Hudson. The beginnings of crystallization with subrectangular arrangement of rod-like longulites of free sedoheptulose have been obtained by chromatographic separation in phenol from an equilibrium mixture of sedoheptulosan and sedoheptulose prepared by treating the former with 3 *N* hydrochloric acid at room temperature. A spraying reagent for carbohydrates containing ketose units is described.

The 7-carbon sugar sedoheptulose has been known since 1917 when it was isolated by LaForge and Hudson (7) from *Sedum spectabile* in the form of a syrup. Ettel (4) in 1932 established its configuration as D-altroheptulose. The free ketose has not yet been obtained in crystalline form, but Pratt *et al.* (9) in 1952 established the formula of the crystalline non-reducing anhydride, sedoheptulosan, as 2,7-anhydro-β-D-altroheptulopyranose.

The intermediate role of the sugar and its phosphorylated derivative in the metabolic processes of plants and animals has been recently investigated in many laboratories (5, 11). The subject matter of the present communication is, however, concerned solely with the purification of the free ketose and its phosphorylated derivative.

The previous assumption that sedoheptulosan and sedoheptulose may be determined by the same color reactions (10) has been proved correct and this also applies to sedoheptulose phosphate.

Sedoheptulose phosphate has been isolated from the 'mother liquor' obtained from leaves of *S. spectabile* by the method of LaForge and Hudson (7). The yellow-green dense liquid was chromatographed on filter paper and most of the yellow impurities remained at the starting line. Sedoheptulose phosphate was detected by orcinol reagent (1) and corresponding spots were eluted and determined spectrophotometrically by the cysteine–sulphuric and the carbazole – sulphuric acid reactions (3). The former reagent gave a transient yellow color which changed to orange after 48 hr., maximum density being at 510 mμ, characteristic of sedoheptulosan (10). Carbazole–sulphuric produced the expected red color, but the mixture did not show the constant ratio D490/D400 = 1.90 characteristic of the anhydride, indicating the presence of impurities. A second chromatographic separation, using 100 spots each containing 200 μgm. initially, produced a glassy yellow-product after elution and evaporation *in vacuo*. Larger amounts were purified on cellulose column

and this procedure also produced a glassy product that, after drying, could be ground to a yellowish white powder, which became sticky on exposure to air. Determination of bound phosphate indicated that this substance was sedoheptulose monophosphate.

Free sedoheptulose was not isolated directly from the mother liquor; however this sugar was separated chromatographically from the equilibrium mixture produced by incubating sedoheptulosan with 3 N hydrochloric acid for 12 hr. at room temperature. Difficulties were encountered since no spraying reagent could be found for sedoheptulosan. Of numerous solvents tried, phenol was found to be preferable for the separation of sedoheptulose from the equilibrium mixture. Chromatographic development in this manner produced two spots with the orcinol reagent. Similar spots were obtained by developing a solution of the equilibrium mixture in ethanol – butanol – $N/20$ hydrochloric acid (110: 10: 20).

It is known that the behavior of phenol as a solvent (6) in paper chromatography differs from other organic solvents giving greater R_f values than could be expected from the water content. "The explanation probably lies in the fact that phenols can form compounds with sugars analogous to these formed by water, so that the distribution of a sugar between the aqueous phenolic solvent and water–cellulose complex will depend not only on the water present in each phase but also on the phenol." (6).

When sedoheptulose phosphate and sedoheptulosan were developed in phenol each gave one spot in different positions with the orcinol reagent, whereas the equilibrium mixture gave two spots in corresponding positions (Fig. 1). The explanation for this lies in the fact that performed sedoheptulose

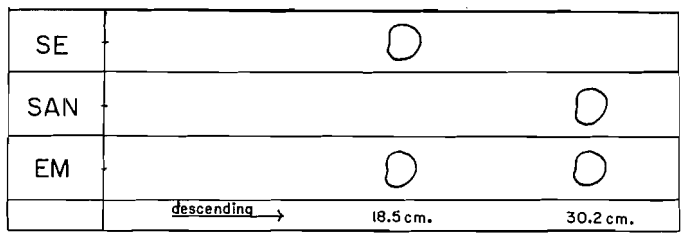

FIG. 1. Paper chromatogram showing the movement of sedoheptulose (SE), sedoheptulosan (SAN), and the equilibrium mixture (EM) in phenol.

in the equilibrium mixture moves slower in this solvent than sedoheptulosan, but the anhydride forms a new equilibrium mixture in its position on the paper in the presence of phenol. The newly formed free sugar is detected by the orcinol reagent but it does not separate from the anhydride during development. Therefore the two spots correspond to sedoheptulose and the newly formed equilibrium mixture of sedoheptulosan and sedoheptulose. This property of separation of sedoheptulose from the equilibrium mixture has served as a basis for its isolation in pure form.

Spots corresponding to free sedoheptulose were cut out, eluted with water, passed through Amberlite anion exchange resin, and evaporated to dryness *in vacuo*. A crystalline substance was obtained which was identified as sedo-

heptulose by its osazone. Complete crystallization of a large quantity of sedoheptulose was not obtained, but only the beginnings of crystallization of sedoheptulose (Fig. 2). The experiments indicated that in order to obtain larger amounts of the substance it would be advantageous to combine both cellulose column and ion exchange chromatography.

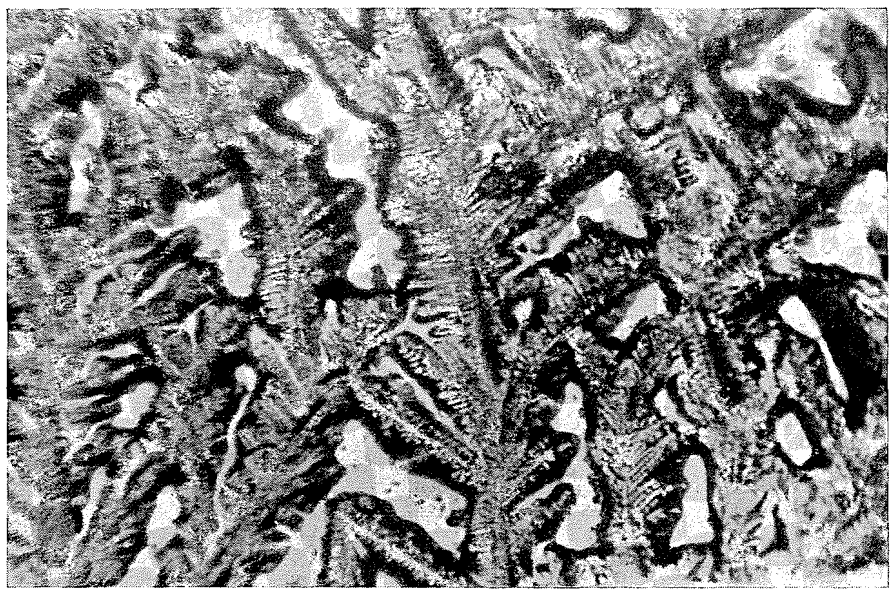

FIG. 2. The subrectangular arrangement of rod-like longulites of free sedoheptulose crystals.

Dische (2) prepared the equilibrium mixture by treating sedoheptulosan with 1% hydrochloric acid on a steam bath for 30 min. and obtained three different spots with the orcinol reagent on his chromatograms in phenol. Noggle (8) used 0.2 *N* hydrochloric acid on a steam bath for 30 min. and detected four spots under the same conditions. He suggested that the first two R_f 0.45 and 0.70 represented sedoheptulose and sedoheptulosan and the other two spots unknown carbohydrates.

It is possible that the heat treatment may produce other anhydrides of sedoheptulose (9). This is supported by Noggle's (8) use of Dowex 50 in the hydrogen form to prepare the equilibrium mixture in place of hot 0.2 *N* hydrochloric acid. Under these conditons he detected only sedoheptulose and sedoheptulosan in the equilibrium mixture. Our separations were concerned only with mixtures produced at room temperature.

In the course of studying various spraying reagents for sedoheptulosan, Dische's reagent (3) was modified and adapted for use on paper. Cysteine and carbazole dissolved in butanol and trichloracetic acid gave a brownish spot with sedoheptulose. This spray had a wide application and gave distinctly colored spots with reducing and non-reducing mono- and poly-saccharides containing ketose units. It was found also that phloroglucinol gave a bluish green spot with sedoheptulose.

EXPERIMENTAL

Purification of Sedoheptulose Phosphate by Chromatography

The purification of sedoheptulose syrup was accomplished either by paper or cellulose column chromatography.

In the former procedure, 20 mgm. of the syrup was dissolved in 1 ml. of water and aliquots of 10 μl. were placed on Whatman No. 1 filter paper and developed for 36 hr. in butanol–ethanol–water (10:1:2). The resulting spots, located by orcinol, were cut out and eluted with 400 ml. water. This solution was evaporated *in vacuo*, redissolved in 1 ml. water, and chromatographed again in butanol – acetic acid – water (4:1:2). Near to the end of the evaporation a yellow-white precipitate appeared which formed a glassy product when dry. Recovery was 80%. The filter papers were previously washed with 0.03 *N* hydrochloric acid, then with water to neutrality, and afterwards with 0.5 *N* sodium hydroxide followed by water to neutrality.

In the latter procedure, 20 ml. of a yellow solution of 1% sedoheptulose sirup in methanol was passed through a column (25 cm. $\times$ 1.5 cm.) of Whatman No. 1 cellulose. The yellow ring that remained on the column was eluted with water until the orcinol reaction became negative. The solution was evaporated *in vacuo* and a glassy yellow-white powder was obtained.The product was readily pulverized in a mortar but eventually became sticky during exposure to air.

In solution, free phosphate was formed after hydrolysis with *N* hydrochloric acid for three hours on a steam bath. The phosphate produced corresponded to a monophosphoric ester of sedoheptulose. Further purification of this material by paper chromatography did not alter its physical properties.

The first methyl alcoholic effluent was colorless and gave no orcinol reaction. After evaporation to dryness a small amount (1%) of amorphous white product was obtained. The substance was sparingly soluble in water, m.p. 138°C., and gave no reaction for sugars. The nature of this product is as yet unknown.

Separation of Crystalline Sedoheptulose from the Equilibrium Mixture

Crystalline sedoheptulosan was used as the starting material using descending paper chromatography with a 90% solution of freshly distilled phenol as the solvent. Sixty milligrams of sedoheptulosan were treated with 0.5 ml. of 3 *N* hydrochloric acid at room temperature for 12 hr., 3.5 ml. water were added; thus 1 ml. contained 15 mgm. of the equilibrium mixture (sedoheptulose and sedoheptulosan). Aliquots of 10 μl. of this solution were developed for 30 hr. on paper. The components of the equilibrium mixture were identified by running parallel spots of sedoheptulose phosphate and sedoheptulosan. Two spots were observed on the path of the equilibrium mixture, one corresponding to sedoheptulose and the other to sedoheptulosan. Apparently sedoheptulose phosphate and sedoheptulose move at the same rate. The identification of sedoheptulosan by the orcinol spray is due to the formation of a new equilibrium mixture in this spot.

Elutions of spots from 3 ml. of a solution containing 45 mgm. of the equilibrium mixture in hydrochloric acid were combined and passed through

Amberlite IR4B(OH) and evaporated *in vacuo*. Fig. 2 shows the beginnings of crystallization and the subrectangular arrangement of rod-like longulites of free sedoheptulose obtained by this separation. Seven milligrams of the free ketose was obtained corresponding to approximately 20% of sedoheptulose in the equilibrium mixture assuming 80% recovery.

Aliquots of 10 μl. of sedoheptulose phosphate as well as the equilibrium mixture were also developed in butanol – ethanol – $N/20$ hydrochloric acid (100:10:20). As with phenol one spot was obtained with sedoheptulose phosphate and two with the equilibrium mixture using the orcinol reagent.

New Spraying Reagent for Carbohydrates Containing Ketose Units

Dische's reagent, a mixture of cysteine, carbazole, and sulphuric acid, was modified as follows:

Cysteine hydrochloride, 1.5 gm., was dissolved in 6 ml. of water, 15 gm. of trichloracetic acid were added, made up to 100 ml. with butanol, and 0.12 gm. of carbazole was added. The sprayed papers were heated for 10 min. at 85°.

The following carbohydrates containing ketose units show brown spots: dihydroxyacetone, fructose, sorbose, hexosediphosphate, ascorbic acid, sedoheptulose, sucrose, turanose, melizitose, stachyose (two spots), and inulin.

THE REACTION OF ACTIVE NITROGEN WITH HYDRAZINE[1]

By G. R. Freeman and C. A. Winkler

ABSTRACT

Hydrazine was completely destroyed by active nitrogen, at both 150°C. and 480°C., up to a hydrazine flow rate of about 22×10^{-6} mole per sec., whereas ammonia production was small at hydrazine flow rates below about 12×10^{-6} mole per sec. Thus it appears that ammonia is formed in secondary reactions only. The results indicate that NH_2 radicals rather than hydrogen atoms may be prominent in secondary reactions. Comparison of the rate of hydrazine destruction with the rate of production of hydrogen cyanide from ethylene indicates that excited nitrogen molecules do not make a large contribution to the chemical reactivity of active nitrogen.

INTRODUCTION

The reaction of active nitrogen with ammonia (5) gave strong indication that more than one chemically reactive species exists in active nitrogen.* It was therefore of interest to study the analogous reaction with the related compound, hydrazine.

EXPERIMENTAL

The apparatus used was essentially the same as that described in earlier papers (3, 6) with one modification. Since hydrazine is a liquid (b.p. 113°C.) with a vapor pressure of 10 mm. at 20°C., it was not convenient to store it as a gas. It was stored as a liquid in a cylindrical bulb (cross sectional area = 28 sq. cm.) which was connected to the flowmeter through a 7 liter ballast volume. The storage bulb was immersed in a thermostat regulated at 20.95 ± 0.05°C. The rate of flow of hydrazine into the reaction vessel was varied by placing jets of different sizes in the flowmeter.

The molecular nitrogen flow rate was 9.2×10^{-5} mole/sec., corresponding to a pressure of 1.5 mm. Hg in the reaction vessel. In some experiments, where hydrogen atoms replaced active nitrogen, the molecular hydrogen flow rate was 8.0×10^{-5} mole per sec., which gave an operating pressure of 1.0 mm. Hg.

Anhydrous hydrazine (99%) was very kindly contributed by the Mathieson Chemical Corp.

The only products from the reactions of hydrazine with either active nitrogen or hydrogen atoms are nitrogen, hydrogen, and ammonia. The condensable products were collected in a trap containing standard sulphuric acid, immersed in liquid nitrogen. After the solution had been melted, the total amount of base in the products was determined by titration to methyl red end point. The hydrazine content of the solution was then determined by

[1]*Manuscript received December 24, 1954.*
Contribution from the Physical Chemistry Laboratory, McGill University, Montreal, Quebec, with financial assistance from the National Research Council of Canada.
**It seems probable that one active species is nitrogen atoms, while some other component such as N_2^* or N_3 might also contribute to the activity.*

titration with iodate (1). The difference between the amounts of total base and hydrazine gave the amount of ammonia.

Some comparative experiments were also made with the ethylene – active nitrogen system. In these, hydrogen cyanide was analyzed by the Liebig–Dénigès method (7).

RESULTS AND DISCUSSION

The yellow afterglow of active nitrogen was observable in the tube leading from the reaction vessel to the cold trap at all hydrazine flow rates until that corresponding to the maximum rate of decomposition of hydrazine was approached (up to about 20×10^{-6} mole per sec.). In the ethylene – active nitrogen reaction, the yellow afterglow was gradually replaced by the cyanogen flame; at 420°C., no nitrogen afterglow could be observed at flow rates of ethylene above about 1×10^{-6} mole per sec. However, at this temperature the cyanogen flame was observable in the tube leading from the reaction vessel to the cold trap at all ethylene flow rates until that corresponding to the maximum rate of production of hydrogen cyanide was approached (up to about 13×10^{-6} mole per sec.). Thus the presence, in the tube leading to the cold trap, of the nitrogen afterglow in the hydrazine reaction, and the cyanogen flame in the ethylene reaction, seem to indicate the persistence of active nitrogen in the two reactions. Since active nitrogen reacts with ammonia to only about 15% the extent to which it reacts with ethylene (5) or hydrazine, the persistence of the yellow afterglow in the ammonia reaction up to flow rates much higher than that corresponding to the maximum rate of destruction

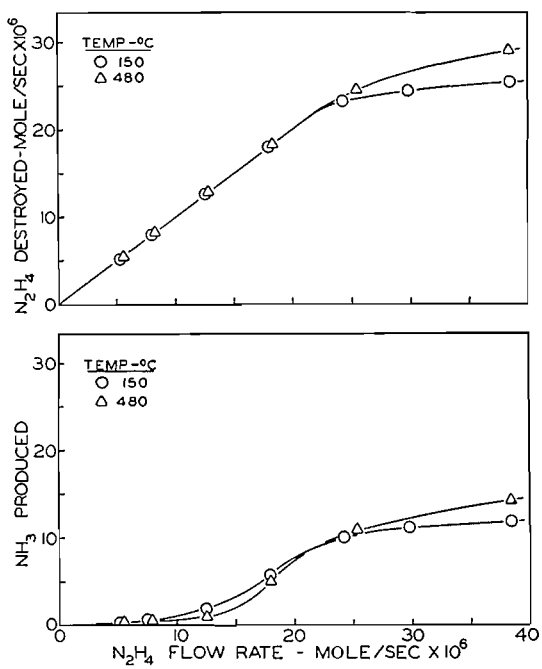

FIG. 1

of ammonia may be taken as further indication of the presence of two active species in active nitrogen.*

The relations between the hydrazine flow rate, the amount of hydrazine destroyed, and the corresponding amount of ammonia produced are shown in Fig. 1 for different temperatures. At both 150°C. and 480°C. hydrazine was completely destroyed up to a flow rate of about 22×10^{-6} mole per sec. The maximum rate of destruction increased by about 14% when the temperature was increased from 150°C. to 480°C.

From the shape of the ammonia production curves, it would appear that ammonia is formed only by reaction of hydrazine with a product of the hydrazine – active nitrogen reaction. The amount of ammonia produced at 480°C. was smaller than the amount produced at 150°C. in the range of lower flow rates, but the reverse was true at the higher flow rates (above about 20×10^{-6} mole per sec.). This was probably due to a greater increase in the rate of the active nitrogen – hydrazine reaction than in the rates of the secondary reactions. Thus there would be less hydrazine available for secondary reactions until all the active nitrogen was consumed. The possibility that ammonia was produced in the initial reaction, and destroyed by subsequent reaction with excess active nitrogen is ruled out because the maximum rate of destruction of ammonia by active nitrogen in the absence of any other reactant would be about 3×10^{-6} mole per sec. under similar conditions (5). It is

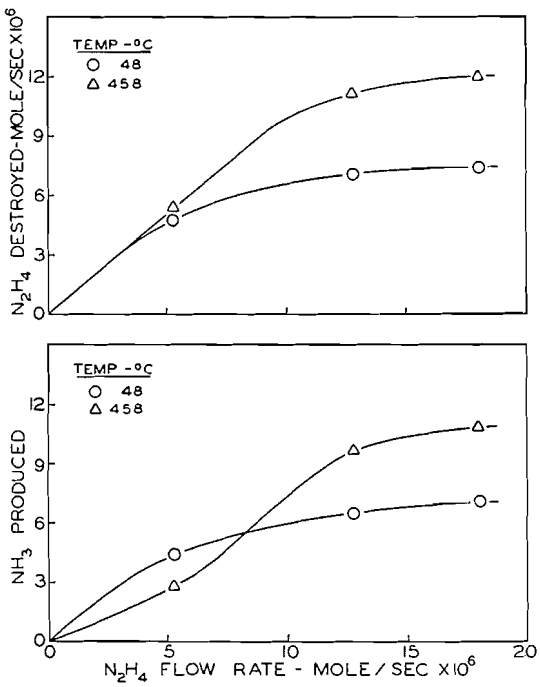

FIG. 2

**This persistence of the yellow afterglow implies the persistence of a species of nitrogen which contains at least 170 kcal. of energy, i.e. a species with sufficient energy to generate $N_2B^3\Pi_g$ molecules.*

probable, also, that the component in active nitrogen capable of reacting with ammonia would be rapidly removed by reaction with hydrazine.

There was a possibility that hydrogen atoms might be formed from the attack of active nitrogen on hydrazine. Although the hydrogen atom – hydrazine reaction has been studied (2, 4), some experiments were made in the present apparatus to permit a more direct estimate of the extent to which hydrogen atom reactions might contribute to the over-all active nitrogen – hydrazine reaction.

The hydrazine – hydrogen atom reaction was studied at 48°C. and 458°C., and the results are shown in Fig. 2. At 48°C., one mole of ammonia was produced for each mole of hydrazine destroyed. At 458°C., $(1-\alpha)$ mole of ammonia was formed for each mole of hydrazine destroyed, where $0 < \alpha < 1$. The value of α decreased, i.e. ammonia production increased, as the hydrazine flow rate was increased, probably in parallel with a decrease in hydrogen atom concentration available for secondary reactions as the hydrazine flow rate was increased (due to direct reaction between H and N_2H_4). This would imply that the decrease in yield of ammonia with increase of temperature was due to attack of hydrogen atoms on ammonia, or on an intermediate from which ammonia might be derived. The results can be explained by the following reactions:

		ΔH(kcal.)*	
$H+N_2H_4$	$\rightarrow H_2+N_2H_3$	$-(8$ to $13)$	[1*a*]
	$\rightarrow NH_3+NH_2$	-39	[1*b*]
$2N_2H_3$	$\rightarrow N_2+2NH_3$	$-(144$ to $154)$	[2]
$H+NH_3$	$\rightarrow H_2+NH_2$	$+4$	[3]
$NH_2+N_2H_3$	$\rightarrow N_2+H_2+NH_3$	$-(117$ to $122)$	[4]
$2NH_2$	$\rightarrow N_2+2H_2$	-90	[5*a*]
$2NH_2+M$	$\rightarrow N_2H_4+M$	-68	[5*b*]
$2H+M$	$\rightarrow H_2+M$	-102.7	[6]
$H+N_2H_3+M$	$\rightarrow N_2H_4+M$	$-(90$ to $95)$	[7*a*]
$H+N_2H_3$	$\rightarrow N_2+2H_2$	$-(113$ to $118)$	[7*b*]

**To calculate heats of reactions, the following dissociation energies and heats of formation were used:*
D_{N_2} = 9.765 ev. = 225.0 kcal. (Hendrie, J. M. J. Chem. Phys. 22: 1503. 1954).
D_{H_2} = 4.455 ev. = 102.7 kcal. (Beutler, H. Z. physik. Chem. B29: 315. 1935).
D_{H-NH_2} = 4.65 ev. = 107 kcal. (Devins, J. C. and Burton, M. J. Am. Chem. Soc. 76: 2618. 1954).
$\Delta H_f(NH_3) = -10.94$ kcal. (Handbook of chemistry and physics).
$\Delta H_f(N_2H_4) = 22.7$ kcal. (Reference (1), this paper).
From these values, the following were calculated:
Average N—H bond energy in NH_3 = 92.5 kcal.
Average N—H bond energy in NH_2 = 85.3 kcal.
Total bond energy in N_2H_4 = 407.7 kcal.
$D_{H_2N-NH_2}$ = 67.7 kcal.
Total bond energy in NH_3 = 277.5 kcal.
If it is then assumed that the average $H_2N—NH_2$ bond energy = 60 kcal., the average $H—N_2H_3$ bond energy = 87 kcal. Therefore, it was assumed that $D_{H-N_2H_3}$ = 90 to 95 kcal. It was also assumed that D_{H-NH} = 90 kcal., and D_{H-N} = 81 kcal. (these values were approximated from the total bond energy in NH_3 and D_{H-NH_2}).

If reaction [1*b*] were the predominant initial reaction, one ammonia molecule

would be formed from each hydrazine molecule destroyed. This would prohibit the reaction

$$NH_2+N_2H_4 \rightarrow NH_3+N_2H_3 \qquad \Delta H = -(12 \text{ to } 17)\text{kcal.} \quad [8]$$

since ammonia production never exceeded hydrazine consumption on a mole basis. At 458°C. and low hydrazine flow rates a large proportion of the ammonia formed by reaction [1*b*] would have to be subsequently destroyed by hydrogen atoms (see Fig. 2). This would seem to require that the ammonia so formed be excited, since the rate of destruction previously observed with hydrogen atoms at 440°C. (5) was much too small to explain the large value of α found at 458°C. and low hydrazine flow rates.

Although reaction [1*a*] is less favorable energetically than reaction [1*b*], its occurrence might be expected by analogy with the corresponding hydrogen atom reaction with ethane,*

$$C_2H_6+H \rightarrow C_2H_5+H_2 \qquad \Delta H = -4.7 \text{ kcal.} \quad [9a]$$

which is generally accepted over the more energetically favorable reaction

$$C_2H_6+H \rightarrow CH_4+CH_3 \qquad \Delta H = -18 \text{ kcal.} \quad [9b]$$

If reaction [1*a*] were the predominant initial reaction, the high value of α at 458°C. and low hydrazine flow rates could be explained readily by the combined effect of reactions [3] and [7*b*]. It is also possible that some N_2H_3 radicals are destroyed on the walls at high temperatures to yield nitrogen and hydrogen but no ammonia. Although the NH_2 radicals might have a significant concentration at high temperatures and low hydrazine flow rates, the hydrazine concentration should be very low because of reaction [1*a*]; hence reaction [8] following upon [1*a*] should not occur to any appreciable extent.

There are two possible exothermic reactions between nitrogen atoms and hydrazine,

$$N+N_2H_4 \rightarrow N_2+H_2+NH_2 \qquad \Delta H = -91 \text{ kcal.} \quad [10a]$$
$$\rightarrow N_2+H_2+NH+H \qquad \Delta H \approx -1 \text{ kcal.} \quad [10b]$$

If N_3 were an active species, it would react in the same manner as N, but the corresponding reactions would be less exothermic by the amount of the N_2—N bond energy in N_3. Since hydrazine reacts rapidly with active nitrogen the most probable mechanism for the reaction, if N and N_3 are assumed to be the reactive species, would seem to be:

		ΔH(kcal.)	
$N+N_2H_4$	$\rightarrow N_2+H_2+NH_2$	-91	[10*a*]
$NH_2+N_2H_4$	$\rightarrow NH_3+N_2H_3$	$-(12 \text{ to } 17)$	[8]
$2N_2H_3$	$\rightarrow N_2+2NH_3$	$-(144 \text{ to } 154)$	[2]
$NH_2+N_2H_3$	$\rightarrow N_2+H_2+NH_3$	$-(117 \text{ to } 122)$	[4]
$2NH_2$	$\rightarrow N_2+2H_2$	-90	[5*a*]
$2NH_2+M$	$\rightarrow N_2H_4+M$	-68	[5*b*]

**The bond strengths involved here were taken from a paper by Szwarc, M. Chem. Revs. 47: 75. 1950.*

If N_2^* were a reactive species, it could react with hydrazine without producing ammonia directly, or it might react to produce ammonia in a secondary reaction with the N_2H_3 radical derived from N atom attack on hydrazine:

$$N_2^* + N_2H_4 \rightarrow 2NH_2 + N_2 \quad [11]$$
$$N_2^* + N_2H_3 \rightarrow NH_3 + N_2 + N. \quad [12]$$

Reaction [12] would be followed by [10*a*]. Each N_2^* would result in the decomposition of only one hydrazine molecule.

Since ammonia is a product of secondary reactions only, it is possible to separate the effect of the secondary reactions from that of the total reaction. The ethylene – active nitrogen reaction at 451°C. was used to estimate the total active nitrogen concentration because hydrogen cyanide production from other hydrocarbons studied thus far has never been found to exceed that from ethylene. The maximum amount of hydrogen cyanide produced was 19.0×10^{-6} mole per sec. It may be assumed that if N_3 were a reactive species, each N_3 would yield one molecule of hydrogen cyanide, and if N_2^* were a reactive species, each N_2^* would yield two molecules of hydrogen cyanide. Therefore, if N_3 and N were the reactive species, the maximum amount of hydrazine decomposed without the production of ammonia should be approximately equal to the maximum amount of hydrogen cyanide produced from ethylene. If, however, N_2^* makes a predominant contribution to the activity of active nitrogen, the maximum amount of hydrazine decomposed without the production of ammonia should be much smaller than the maximum amount of hydrogen cyanide produced from ethylene.

The only product of the active nitrogen hydrazine reactions considered above which could react further with hydrazine is the NH_2 radical. Therefore, each hydrazine molecule decomposed in a secondary reaction (reaction [8], followed by reactions [2] and [4]) would yield two molecules of ammonia. Since, in the hydrogen atom – hydrazine reaction, at low temperature, little, if any, N_2H_3 was destroyed without production of ammonia, it is reasonable to assume that the same is true for the active nitrogen reaction at 150°C. Therefore, by subtracting one half of the amount of ammonia formed at 150°C. from the total amount of hydrazine destroyed at this temperature, for hydrazine flow rates of 24×10^{-6} mole per sec. and higher, it was estimated that 18.8×10^{-6} mole per sec. of hydrazine was destroyed by direct reaction with active nitrogen. This estimate must be increased by an amount corresponding to the amount of hydrazine regenerated by reaction [5*b*]. It was not possible to calculate from the present results the extent to which reaction [5*b*] occurred under the conditions of the reaction reported in this paper. Therefore, it may be concluded only that the maximum rate of destruction of hydrazine by active nitrogen was at least 18.8×10^{-6} mole per sec. The close agreement of this figure with that for hydrogen cyanide production in the ethylene – active nitrogen reaction indicates that N_2^* makes, at best, only a small contribution to the chemical reactivity of active nitrogen, and therefore, that reactions [11] and [12] only occur to a small extent or not at all.

The increase in the maximum amount of hydrazine destroyed when the temperature was increased from 150°C. to 480°C. was presumably due to an increased rate of decomposition of hydrazine in reaction [8].

The long "induction period" in the ammonia production curves (1) indicates that reaction [10*a*] is much faster than reaction [8], which would be expected.

The ammonia production curves tend to level off at a value corresponding to only about 35% of the NH_2 radicals reacting according to reaction [8]. This indicates that the NH_2 radicals are removed quite rapidly by the combined effects of reactions [4], [5*a*], and [5*b*].

THE REACTION OF METHYL RADICALS WITH ACETALDEHYDE[1]

By R. E. Dodd[2]

ABSTRACT

The rates of formation of methane and ethane in the photodecomposition of acetaldehyde have been measured between 391 and 564°K. The rate constant for the reaction

$$CH_3+CH_3CHO \rightarrow CH_4+CH_3CO$$

was found to be

$$k = 10^{10.8}\, T^{\frac{1}{2}}\, e^{-8000/RT} \text{ moles}^{-1} \text{ cm.}^{+3} \text{ sec}^{-1}.$$

The abstraction of hydrogen from acetaldehyde by methyl radicals, reaction [1], was first proposed by Leermakers (10) as a step in the photolysis of acetaldehyde

$$CH_3+CH_3CHO \rightarrow CH_4+CH_3CO. \qquad [1]$$

Undoubtedly it makes an important contribution to the rate of formation of methane, R_M, in the photolysis, and at high temperatures it predominates. For some time the activation energy, E_1, for reaction [1] was identified with the over-all activation energy, E_p, for the high-temperature photolysis. It is now clear that this involved the assumption of too simple a mechanism for the photolysis for which the reported values (1, 8, 10, 11) of E_p lay in the range 8.3–10.0 kcal./mole.

Under conditions where reaction [1] is the only source of methane $R_M = k_1[CH_3][CH_3CHO]$ but any attempt to state the methyl radical concentration in terms of the light absorption involves specific assumption about the possible reactions of the methyl radicals. For an estimate of k_1 it is safer to derive the methyl radical concentration from the rate of formation of ethane, R_E. This involves the one assumption that any ethane formed arises solely from reaction [2]

$$CH_3+CH_3 \rightarrow C_2H_6. \qquad [2]$$

Then $[CH_3] = k_2^{-\frac{1}{2}} R_E^{\frac{1}{2}}$ and hence

$$k_1k_2^{-\frac{1}{2}} = R_M R_E^{-\frac{1}{2}} [CH_3CHO]^{-1}.$$

Since, however, under the conditions of low light intensity which were used, reaction [1] is so much faster than reaction [2] ethane was not detected in the products of photolysis without the aid of the mass spectrometer. Volman and Brinton (13) were able to attain a higher concentration of methyl radicals by the thermal decomposition of di-*t*-butyl peroxide in the presence of acetaldehyde and were thus able to measure R_E and hence $k_1k_2^{-\frac{1}{2}}$. With $E_2 = 0$ (7) they obtained $E_1 = 7.5$ kcal. per mole over a narrow temperature range

and with a rather large percentage conversion of reactant. Ausloos and Steacie (2) have now extended the temperature range using methyl radicals from the photolysis of azomethane and obtained a value $E_1 = 6.8$ kcal. per mole.

Although ethane was first detected by mass spectrometer in the products of the photolysis of acetaldehyde (3, 4, 6) it was not measured so as to give absolute values of R_E to allow calculation of $k_1k_2^{-\frac{1}{2}}$ (with the possible exception of one point (12) at 300°C.). During the course of work on the photolysis of acetone at low pressures (5) it became evident that the right conditions could be obtained for the formation of ethane from acetaldehyde in amount sufficient for measurement in a gas burette. Thus $k_1k_2^{-\frac{1}{2}}$ could be accurately measured in the direct photolysis. The results of experiments under these conditions are presented in this paper. Although it is somewhat higher than the value of E_1 (6.8 kcal. per mole) obtained from further measurements on the direct photolysis by Ausloos and Steacie, a value ($E_1 = 8.0$ kcal. per mole) lower than the over-all activation energy, E_p, is favored.

EXPERIMENTAL

The apparatus used is described in detail elsewhere (5). The reaction cell was of quartz, 100 cm. in length and 1185 cm.^{3} in effective volume. All experiments were with about 10 mm. of aldehyde. The length of vessel allowed sufficient absorption of light at this pressure of aldehyde, and the volume allowed the accumulation of sufficient products without going beyond about five per cent decomposition.

Two sets of experiments were performed: experiments 57–66 with a Corning 9700 filter, whose transmission exceeds 50% at wave lengths greater than 2900 Å; experiments 79–85 with Corning 9863 and 7740 filters, where the transmission exceeds 50% only above 3100 Å. The reduction in intensity in the second set is thus largely at the expense of higher energy quanta between 2900 and 3100 Å. For each set a separate calibration of the photometer was made using, as standard, the carbon monoxide yield from acetone above 125°C. Carbon monoxide, hydrogen, and methane were separated from ethane by a liquid nitrogen trap. Carbon monoxide and hydrogen were burnt on hot copper oxide. The resultant carbon dioxide was measured after the water was trapped with dry ice. The water, representing hydrogen, was measured by difference.

RESULTS AND DISCUSSION

The results are listed in Table I. The ratio $\rho = R_M R_E^{-\frac{1}{2}}[CH_3CHO]^{-1}$ is shown as a function of temperature in Fig. 1, which also includes the similar measurements reported by Ausloos and Steacie (2) for 35 mm. of aldehyde. It is evident that the three sets approach, with increasing temperature, a line of slope corresponding to about 8 kcal. per mole.

The curvature at low temperatures indicates that other sources of methane are becoming significant by comparison with the reduced rate of reaction [1]. Although more possibilities will have to be considered, it is convenient first to discuss the curvature in terms of a primary intramolecular rearrangement

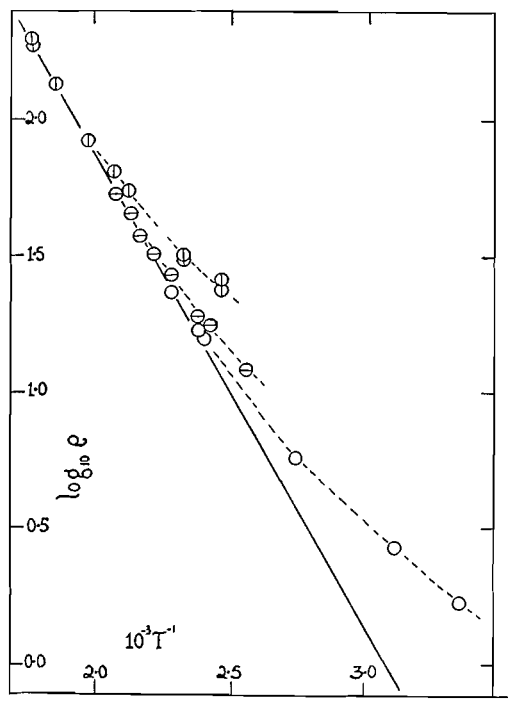

FIG. 1. The temperature dependence of $R_M/R_E^{\frac{1}{2}}$ [CH_3CHO].
⊕ Expts. 57–66; ⊖ Expts. 72–85; ○ Ausloos and Steacie, direct photolysis.

(quantum yield, k_0') so that the relevant steps in the mechanism are:

$$\begin{aligned} &CH_3CHO+h\nu \rightarrow CH_4+CO, && k_0'I_a \\ &CH_3CHO+h\nu \rightarrow CH_3+CHO, && k_0I_a \\ &CH_3+CH_3CHO \rightarrow CH_4+CH_3CO, && k_1 \\ &CH_3+CH_3 \rightarrow C_2H_6. && k_2 \end{aligned}$$

These lead to the equation:

$$\rho = k_1k_2^{-\frac{1}{2}}+k_0'I_aR_E^{-\frac{1}{2}}[CH_3CHO]^{-1}$$

in which, evidently, the last term becomes relatively smaller at high temperatures. The Arrhenius plot for ρ should tend with increasing temperature towards a straight line corresponding to that for $k_1k_2^{-\frac{1}{2}}$, as is the case. Further support is given to this interpretation of the curvature in Fig. 1 by the fact that, so far as my experiments are concerned, the curvature is proportionately less (i.e., commences at lower temperatures) in the set of experiments in which, other things being equal, the light intensity was lower. Furthermore it is possible to estimate the values of the quantum yield, k_0', which will give a straight line Arrhenius plot for $k_1k_2^{-\frac{1}{2}}$. Thus, $k_0' = 0.4$ for the experiments with light of wave length down to 2900 Å and 0.1 for those more closely limited to 3130 Å. These are reasonable values in accordance with the view that k_0' is greater at shorter wave lengths. It is not possible to make the same assessment for the experiments done on the direct photolysis by Ausloos and Steacie (2) since they did not measure I_a: it is probable that the intensities lay between those of the two sets of experiments reported here.

If account is taken of the fact that the formation of ethane is pressure dependent (5, 9) a correction must be applied to k_2 since these experiments were performed at 10 mm. pressure. This amounts to depressing the curves by 0.05 logarithmic units throughout. The two sets of corrected numbers are shown in Fig. 2 where they lie well on the line:

$$\log_{10}(k_1k_2^{-\frac{1}{2}}) = 4.65+\tfrac{1}{4}\log_{10}T-8000/2.3\,RT.$$

With the accepted value for k_2 (at high pressures) (7) this gives:

$$k_1 = 6.3 \times 10^{10}.T^{\frac{1}{2}}.e^{-8000/RT} \text{ moles}^{-1} \text{ cm.}^3 \text{ sec}^{-1}.$$

Included in Fig. 2 are results obtained by Volman and Brinton (13) and by Ausloos and Steacie (2) using methyl radicals derived from the thermal decomposition of di-*t*-butyl peroxide and from the photolysis of azomethane. The agreement in the overlapping temperature range is very good. On the other hand Ausloos and Steacie's figures, taken independently, lie on a line yielding $E_1 = 6.8$ kcal./mole, a difference from 8.0 kcal. which probably lies outside systematic experimental error. But the points at 27 and 51°C. lie above this line and the extra methane has been attributed to wall reactions. It may be suggested that any reaction leading to such amounts of additional methane at these temperatures would still make a significant contribution to the methane formation at higher temperatures and may thus explain the whole of the discrepancy between the two sets of data.

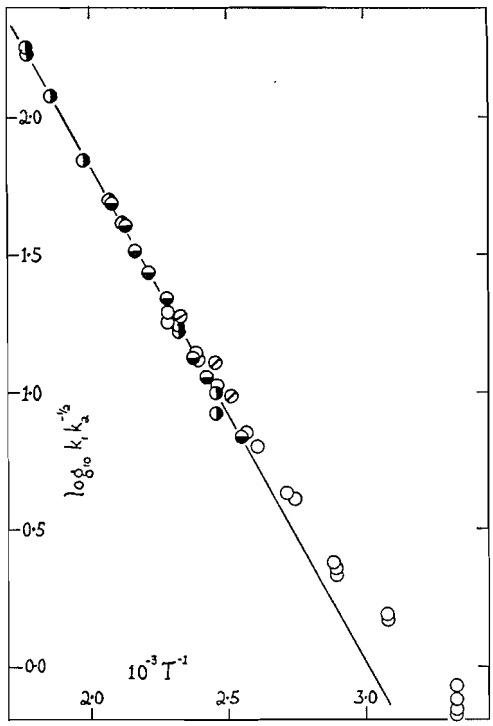

FIG. 2. The temperature dependence of $k_1 k_2^{-\frac{1}{2}}$.
◑ Expts. 57–66; ◒ Expts. 72–85; ○ Ausloos and Steacie, methyls from azomethane; ⊘ Volman and Brinton, methyls from di-*t*-butyl peroxide.

Production of methane at the walls may make some contribution to the curvature in Fig. 1, though this becomes less likely at higher temperatures. The reaction [3]

$$CH_3 + CHO \rightarrow CH_4 + CO \qquad [3]$$

is, however, an important alternative to the primary rearrangement as an explanation of the curvature. The values given to k_0' are thus upper limits. The occurrence of reaction [3] might be tested by high intensity flash experiments with mixtures of $CH_3.CHO$ and $CD_3.CDO$: under conditions where only radical–radical reactions occur the presence of CH_3D and of CD_3H in the products would confirm reaction [3].

The confirmation of a low value of E_1 (and, consequently, of a more reasonable frequency factor, A_1) in experiments on the photolysis of acetaldehyde itself makes it certain that the photolysis mechanism is complex. Since at high temperatures reaction [1] is nevertheless the principal methane-producing reaction the complications probably lie in other reactions which affect the relationship between the methyl radical concentration and the light intensity.

ACKNOWLEDGMENT

I am greatly indebted to Dr. E. W. R. Steacie, for his continual help and encouragement during my tenure of a National Research Council Post-

doctorate Fellowship; to Dr. P. Ausloos for valuable discussion and correspondence; to them both for allowing me to see their manuscript (2) before publication; and to King's College in the University of Durham for leave of absence.

THE HYDROLYSIS OF PHOSPHATE DIESTERS WITH BARIUM HYDROXIDE[1]

By C. W. Helleiner[2] and G. C. Butler

ABSTRACT

The rate of alkaline hydrolysis of diphenyl phosphate has been found to be increased by the presence of barium. Similarly, desoxyribonucleate (DNA), which is not hydrolyzed rapidly by hot sodium hydroxide, is hydrolyzed by barium hydroxide. Only a very small proportion of the total phosphorus of either diphenyl phosphate or DNA is converted to inorganic phosphate during this hydrolysis. In addition to hydrolysis of the phosphate ester bonds of DNA, hot alkali also causes the deamination of desoxycytidylic acid residues and probably of the amino-purine nucleotides as well.

INTRODUCTION

For the study of nucleotide sequences in desoxyribonucleate (DNA) it seemed desirable to use a nonspecific hydrolytic agent to bring about partial degradation of the polymer to fragments whose identity could be established. Statements by Bredereck and Müller led us to believe that in hot alkaline solution, DNA would be degraded to tetranucleotides. Preliminary experiments showed that such degradation did not occur, but the work of Cherbuliez and Leber (9, 10) suggested that the reaction might proceed more readily if barium hydroxide were used instead of sodium hydroxide. It was found that barium hydroxide did apparently catalyze the hydrolysis of phosphate esters, and a more detailed study of the reaction with a model compound was undertaken.

EXPERIMENTAL

Materials and Methods

DNA was prepared from calf thymus glands by the method of Hammarsten (12).

Diphenyl phosphoric acid was prepared by hydrolysis of diphenyl phosphoryl chloride, which was kindly supplied by Dr. E. Baer. The product was recrystallized by dissolving it in hot water, acidifying the solution, and chilling.

Desoxycytidylic acid was prepared by the method described by Hurst, Marko, and Butler (14).

Desoxyuridylic acid was kindly given to us by Mr. I. G. Walker, who made it by deaminating desoxycytidylic acid with nitrous acid.

Determinations of phenol were done by the method of Folin and Ciocalteu (11) as modified by Kunkel and Tiselius (16).

Determinations of total phosphorus and inorganic phosphate were done by the method of King (15).

Hydrolysis of Diphenyl Phosphate

The hydrolysis of diphenyl phosphate was studied because this compound resembles DNA in containing a doubly-esterified phosphate group. The rate

[1]*Manuscript received November 26, 1954.*
Contribution from the Department of Biochemistry, University of Toronto, Toronto, Ontario.
[2]*National Research Council Fellow.*

of appearance of phenol and inorganic phosphate was determined in a solution containing 0.025% diphenyl phosphoric acid, sodium hydroxide, and barium chloride in the concentrations shown in Figs. 1 and 2. For each determination

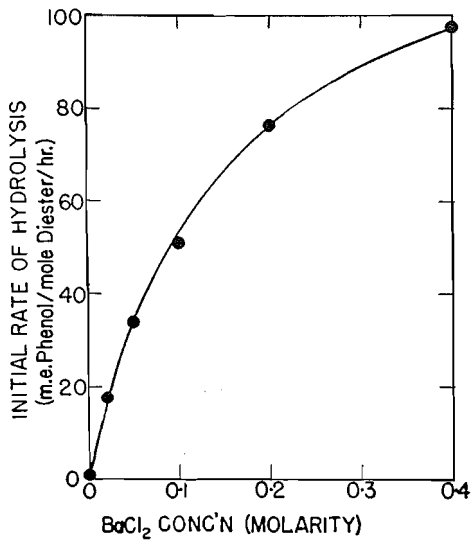

FIG. 1. Initial rate of release of phenol from diphenyl phosphate (0.025% solution) in the presence of 0.1 *N* sodium hydroxide and various concentrations of barium chloride.

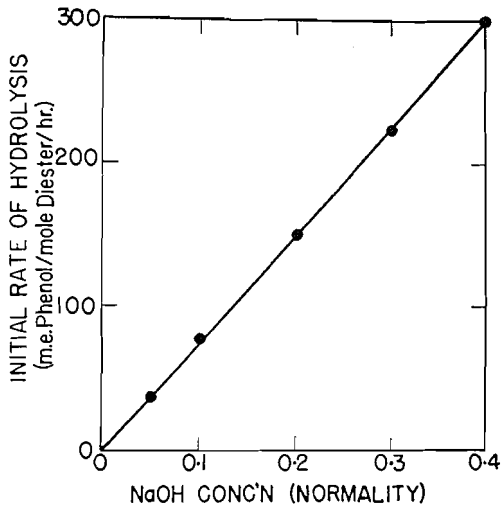

FIG. 2. Initial rate of release of phenol from diphenyl phosphate (0.025% solution) in the presence of 0.2 *M* barium chloride and various concentrations of sodium hydroxide.

a 3 ml. sample was cooled, acidified with 10% hydrochloric acid, and the barium precipitated by adding 0.5 ml. of saturated sodium sulphate solution. The barium sulphate was removed by centrifugation and total phosphorus, inorganic phosphate, and phenol were measured in the supernatant liquid. Most experiments were carried out in a boiling water bath; for the experiment

to investigate the effect of temperature on the reaction, the reaction mixture was sealed into glass tubes, which were heated in an oil bath.

The release of inorganic phosphate was in every case very slow compared to the release of phenol. The inorganic phosphate in various experiments amounted to from 0.1 to 0.4% of the total phosphorus after five hours' heating. Phenol, on the other hand, was released rapidly. Fig. 1 shows the effect of varying the concentration of barium chloride in the reaction mixture on the initial rate of appearance of free phenol. It can be seen that only very slow hydrolysis took place in the absence of barium chloride; as more barium was added to the digest, the rate of hydrolysis became greater. Fig. 2 shows the effect of varying the concentration of sodium hydroxide in the reaction mixture. The initial rate of appearance of free phenol was found to be directly proportional to the concentration of sodium hydroxide for concentrations up to 0.4 *N*. Evidently diphenyl phosphate was hydrolyzed to phenol and monophenyl phosphate, but very little hydrolysis of the resulting monophenyl phosphate occurred.

TABLE I

EXTENT OF HYDROLYSIS OF DIPHENYL PHOSPHORIC ACID (FINAL CONCENTRATION 0.025%) BY VARIOUS HYDROLYTIC AGENTS AFTER FIVE HOURS AT 100°

Hydrolytic agent	Extent of hydrolysis	
	Moles free phenol per mole diester	Moles inorganic phosphate per mole diester
0.01 *N* NaOH, plus:		
0.1 *M* Na_3AlO_3	0.176	0.004
0.43 *M* NH_4OH	0.006	—
approx. 0.01 *M* $Ca(OH)_2$ (saturated)	0.039	—
approx. 0.007 *M* $Mg(OH)_2$ (saturated)	0.012	—
0.1 *M* $BaCl_2$	0.260	0.003
no addition	0.0103	0.008

TABLE II

EXTENT OF HYDROLYSIS OF DIPHENYL PHOSPHORIC ACID (FINAL CONCENTRATION 0.025%) BY 0.1 *N* SODIUM HYDROXIDE, 0.2 *M* BARIUM CHLORIDE AFTER ONE HOUR AT VARIOUS TEMPERATURES

Temperature, (degrees C.)	Moles free phenol (per mole diester) released
90	0.039
100	0.102
110	0.224
120	0.446

Table I shows the effect of other di- and tri-valent cations on the hydrolysis of diphenyl phosphate. None of these was found to be as effective as barium in accelerating the reaction. The effect of temperature on the reaction, shown in Table II, conforms to the relation of Arrhenius.

Hydrolysis of DNA

The progress of the hydrolysis of DNA was followed by measuring the rate of increase in solubility in 10% trichloroacetic acid of the phosphorus-containing compounds of the mixture (17). Solutions containing 5 mgm. per ml. of DNA and the concentrations of sodium hydroxide and barium hydroxide shown in Table III were heated on a boiling water bath. Samples were treated as described for diphenyl phosphate to remove the barium, with precautions to avoid precipitation of DNA. To the solution from which the barium had been removed was added an equal volume of ice-cold 20% trichloroacetic acid. After filtration, the phosphorus contents of the original solution and of the filtrate were determined. This gave a measure of the solubility of the alkali-treated material in 10% trichloroacetic acid. Inorganic phosphate was also determined on the filtrate.

Table III shows that the hydrolysis of DNA apparently proceeds in accordance with expectations based on the findings with diphenyl phosphate. DNA is degraded to acid-soluble fragments with the production of only a little inorganic phosphate, and the reaction is accelerated by increasing the concentration of either barium or hydroxide. It was also found that the reaction could be speeded up by conducting it at 110°C. in a sealed reaction vessel.

TABLE III

0.2		10	1.5
0.1		9	0.6

Deamination of Desoxycytidylic Acid

It seemed probable that the drastic conditions employed for hydrolyzing DNA would not only cleave phosphodiester linkages but would also deaminate the purine and pyrimidine bases. This possibility was investigated by subjecting desoxycytidylic acid to the same conditions as those required to hydrolyze

DNA, and measuring the rate of deamination of this compound to desoxyuridylic acid.

Shugar and Fox (18) showed that uracil has an isosbestic point at 235 mμ, i.e., changes in pH of solutions of uracil from values of about 1 to 7 do not affect the extinction at this wavelength. Cytosine, on the other hand, exhibits a large change in the extinction at 235 mμ when the pH of the solution is changed from 1 to 7. Therefore any difference in the extinction at 235 mμ between pH 1 and 7 of a solution containing only desoxycytidylic and desoxyuridylic acids should be proportional to the quantity of desoxycytidylic acid present, and independent of that of desoxyuridylic acid. This relationship was verified experimentally by adjusting the pH of solutions containing varying proportions of desoxycytidylic and desoxyuridylic acids to 1.0 and 7.0 using a Beckman model G pH meter. The optical densities of the solutions were read at 235 mμ on a Beckman model DU spectrophotometer. It was found that

$$58.8\ \Delta\epsilon = \mu\text{gm. of desoxycytidylic acid per ml.}$$

where $\Delta\epsilon$ is the difference in optical density of two solutions containing the same quantity of desoxycytidylic and desoxyuridylic acids, adjusted to pH 1 and 7 respectively. $\Delta\epsilon$ is independent of the concentration of desoxyuridylic acid.

The extent of deamination of desoxycytidylic acid (final concentration 0.05%) under various conditions, as measured by this method, is shown in Table IV. It is evident that under no conditions could DNA be hydrolyzed by

TABLE IV

DESTRUCTION OF DESOXYCYTIDYLIC ACID (FINAL CONCENTRATION 0.05%) UNDER VARIOUS CONDITIONS

60 min.	110	0.1 *N* NaOH	0.4	67

alkali without considerable deamination of desoxycytidylic acid, and probably of the other nucleotides as well. This finding is in keeping with that of Hurst (13), who found that all the nucleotides are readily deaminated in hot alkaline solution. It was thought that speeding up the hydrolytic reaction by raising the temperature, or adding a large amount of ammonium hydroxide to the reaction mixture might reduce the amount of deamination, but neither of these measures brought about any appreciable reduction.

DISCUSSION

The catalysis of hydrolysis of phosphate esters, as well as anhydrides of phosphoric acid by di- and tri-valent cations in alkaline solution, has been reported by several groups of investigators. Bamann *et al.* (1–7) have noted this type of effect with hydroxides of lanthanum and other rare earths; their

results are difficult to assess, however, since the insolubility of these hydroxides makes it impossible to state their concentration in the system. These workers have interpreted their findings as "phosphatase models". They have compared the specificities and pH optima of various rare earth hydroxides in hydrolyzing a large number of esters and anhydrides of phosphoric acid.

Cherbuliez and Leber (10) studied the effect of calcium hydroxide on the hydrolysis of esters of phosphoric acid, though without quantitative analysis of the products of the reaction. They observed a catalytic effect with calcium, but not with barium hydroxide.

The statement of Bredereck and Müller (8) concerning the lability of DNA to sodium hydroxide has been shown to be misleading. Weygand, Wacker, and Dellweg (19) have reported the hydrolysis of DNA by lead hydroxide; these workers isolated desoxyribosides from the hydrolyzate in yields ranging from 1–6%.

Although we have demonstrated that increasing the concentration of barium hydroxide leads to more rapid hydrolysis of phosphate esters, we have not found any explanation for the phenomenon. We see no virtue in making analogies with the equally poorly understood phenomenon of enzymic catalysis. Cherbuliez and Leber (10) propose a mechanism which involves the formation of phosphonium ions, but if it were valid, monovalent cations should also catalyze the hydrolysis of phosphate esters, and we have demonstrated that they do not.

The fact that an increase of sodium hydroxide concentration in the absence of barium does not appear to lead to any acceleration of the hydrolysis, while an increase of either barium or sodium hydroxides when both are present does lead to such an acceleration, suggests that the true catalytic agent may be undissociated barium hydroxide. In order to be certain of this it would be necessary to have measurements of the degree of dissociation of barium hydroxide at high temperatures and hydroxyl ion concentrations.

SYNTHESIS AND CHARACTERIZATION OF D-XYLOFURANOSE-5-PHOSPHATE[1]

By J. L. Barnwell, W. A. Saunders, and R. W. Watson

ABSTRACT

Phosphorylation of 1,2-*O*-isopropylidene-D-xylose with diphenylphosphorochloridate yielded crystalline 1,2-*O*-isopropylidene-D-xylofuranose-5-diphenylphosphate. Subsequent hydrogenolysis in glacial acetic acid over Adams' catalyst quantitatively removed phenyl groups as shown by infrared analysis. Mild hydrolysis in acetic acid for two hours at 80°C. removed the isopropylidene grouping, and D-xylose-5-phosphate was isolated as an amorphous barium salt. A yield of 81% of theoretical was obtained from 1,2-*O*-isopropylidene-D-xylose, or an over-all yield of 72% from xylose. The product was characterized through its amorphous barium, disodium, and dipotassium salts, and its crystalline dibrucine and distrychnine salts.

One of the earliest observations on phosphoryl group migration in sugar phosphates was that of Levene and Raymond (10). In attempts to prepare xylose-3-phosphoric acid (8, 9, 10, 11) as a basis for testing Robinson's suggestion that xylose was the pentose component of nucleic acid (13), 5-acetyl-, 5-benzoyl-, and 5-benzyloxycarbonyl-1,2-*O*-isopropylidene-D-xylose were separately phosphorylated with phosphorus oxychloride (10, 11). After removal of the acyl and isopropylidene groups by hydrolysis, the only product obtained was D-xylose-5-phosphate. Migration of the phosphoryl group from carbon-3 to carbon-5 at some stage of the synthesis was explained by postulating the formation of a cyclic intermediate (11). The possible significance of this exchange reaction in biological systems, as well as fundamental interest in the mechanism, have indicated the need for more complete investigation. In the present communication a revised synthesis for the preparation of D-xylose-5-phosphate is reported.

The only previously reported synthesis of D-xylose-5-phosphate was that of Levene and Raymond (10, 11). Phosphorylation of 1,2-*O*-isopropylidene-D-xylose (20 gm.) with phosphorus oxychloride in dry pyridine at −30°C., followed by drastic hydrolysis in 2 *N* sulphuric acid at 80°C. for two hours yielded 5.5 gm. of barium D-xylose-5-phosphate. This represented 14.3% of the theoretical yield from 1,2-*O*-isopropylidene-D-xylose, or approximately 12% from xylose. In the present study substitution of diphenylphosphorochloridate as the phosphorylating agent in dry 2,6-lutidine followed by hydrogenolysis and mild hydrolysis in acetic acid has increased the yield from 1,2-*O*-isopropylidene-D-xylose to 81%. The over-all yield of barium-D-xylose-5-phosphate from xylose in a typical synthesis was 72%.

The phosphorylation product, 1,2-*O*-isopropylidene-D-xylose-5-diphenylphosphate, may be obtained pure by recrystallization from carbon tetrachloride. Its elementary analysis conforms to the theoretical, and it has an extremely sharp melting point (within 0.2°). Infrared analysis of finely ground crystals

[1]*Manuscript received January 4, 1955.*
Contribution from the Division of Applied Biology, National Research Laboratories, Ottawa, Canada. Issued as N.R.C. No. 3547.

in a nujol mull shows characteristic phenyl absorption bands and a strong hydroxyl peak. The sharp melting point suggests the absence of isomeric phosphates and the greater reactivity of the primary hydroxyl indicates preferential phosphorylation in the 5-position. The assumption that phenyl groups would prevent double phosphorylation through hindrance is borne out by the elementary and infrared analyses.

If the phosphorylated product is homogeneous, acid conditions during hydrogenolysis and hydrolysis would favor retention of the phosphoryl group in position 5. The final product in the form of its barium salt has no inorganic or acid-labile phosphate, and it consumes 3.0 moles of oxidant when reacted with sodium periodate at pH 4.7. Barium, phosphorus, and pentose are close to theoretical for a monophosphorylated compound. However, when subjected to periodate oxidation either in 0.05 *N* sulphuric acid or at pH 4.7, samples prepared by different methods release from 3 to 7% of formaldehyde. The amount of formaldehyde released may be correlated with the pH during acetic acid hydrolysis. No exact estimate of the purity of the product may be made at present, although the samples used for characterization probably contain 97% D-xylose-5-phosphate.

Crystalline derivatives of D-xylose-5-phosphate have not previously been reported. Levene and Raymond (10) performed an elementary analysis on the barium salt and determined specific rotations for the barium and disodium salts. In the present study attempts to prepare crystalline metal salts were unsuccessful. Dilithium, disodium, dipotassium, as well as the barium salts precipitated from water and ethanol in amorphous form. In order to place identification on a crystalline basis the dibrucine and distrychnine salts were prepared and their constants determined.

EXPERIMENTAL

*Preparation of 1,2-O-Isopropylidene-*D*-xylose and Diphenylphosphorochloridate*

Pure 1,2;3,5-di-*O*-isopropylidene-D-xylose (115 gm.) was prepared from pure xylose in 87% yield (6). Hydrolysis of this product gave 1,2-*O*-isopropylidene-D-xylose in 99% yield (12). By molecular distillation this compound was obtained as colorless crystals with $[\alpha]_D^{26} = -19.3$ ($c = 5.70$ in water) (14). Diphenylphosphorochloridate in essentially pure form (212 gm.) was prepared from 1.1 moles of freshly distilled phosphorus oxychloride and 2 moles of redistilled phenol (79% yield) (3, 4).

*Phosphorylation of 1,2-O-Isopropylidene-*D*-xylose*

Crystalline 1,2-*O*-isopropylidene-D-xylose (5.25 gm.) was mixed with reagent benzene and the benzene distilled to remove traces of water. After removal of the benzene freshly distilled anhydrous 2,6-lutidine (60 gm.) (2) was added, the mixture shaken until solution was complete, and cooled to −20°C. with dry ice. Dry diphenylphosphorochloridate (15 gm.) was added dropwise over a period of 10 min. from a separatory funnel fitted with a drying tube. After standing for two days at 5°C. the reaction mixture was filtered, and the crystalline 2,6-lutidine–hydrochloride washed several times with cold 2,6-lutidine. After evaporation of the filtrate to a thick sirup water was added

and the distillation to dryness repeated to remove 2,6-lutidine. The resulting sirupy residue was dissolved in 100 ml. of chloroform, washed nine times with 100-ml. portions of water, and the washings discarded. The chloroform solution was evaporated to a sirup *in vacuo* at 35°C., the last traces of chloroform being removed by azeotropic distillation after addition of ethanol. Colorless needles were obtained by crystallization from ether. (Yield 10.8 gm., 93% of theoretical.) After it was recrystallized from carbon tetrachloride, washed with petroleum ether, and dried *in vacuo* at 50°C., the pure 1,2-*O*-isopropylidene-D-xylose-5-diphenylphosphate had m.p. 102.2°–102.4°: $[\alpha]_D^{20} = +10.8$ ($c = 2.21$ in chloroform). (Found: C, 56.10; H, 5.38. Calc. for $C_{20}H_{23}O_8P$: C, 56.84; H, 5.49.) The compound was soluble in chloroform and acetone, slightly soluble in ether, ethanol, and carbon tetrachloride, and insoluble in water and petroleum ether.

*Hydrogenolysis and Hydrolysis of 1,2-O-Isopropylidene-*D*-xylose-5-diphenylphosphate*

Low pressure hydrogenation of the crystalline phosphorylation product (2.0 gm.) over 0.20 gm. of Adams' catalyst (1) in 60 ml. of glacial acetic acid was complete in 115 min. The solution was filtered and the filtrate, after adjustment to pH 1.5 ± 0.2 with water, was hydrolyzed at 80 ± 2°C. for two hours. Acetic acid was removed by vacuum distillation, the sirup dissolved in 90 ml. of water, and 0.3 *N* barium hydroxide added until the pH reached 8.5. Removal of inorganic phosphate was effected by centrifuging the slightly turbid aqueous solution before the addition of four volumes of ethanol. After standing at 5°C. for two hours the colorless barium salts were separated by centrifugation and washed with 75% ethanol and ether before drying *in vacuo* over anhydrone. (Yield, 1.33 gm.) Concentration of the supernatant liquid to 20 ml. on a Craig evaporator at 30°C., readjustment of the pH to 8.5 with saturated aqueous barium hydroxide, and reprecipitation with four volumes of ethanol recovered 0.245 gm. for a total yield of 1.575 gm. (90% of theoretical).

Characterization of D-*Xylose-5-phosphate*

Data obtained by analysis of the barium salt isolated from the reaction mixture agreed with theoretical values calculated for a monophosphorylated pentose. (Found: Ba, 37.51; P, 8.54; pentose 40.2. Calc. for $C_5H_9O_8PBa$: Ba, 37.59; P, 8.58; pentose 41.0.) Pentose was estimated by the modified method of Cohn and Volkin (5). A series of analyses at different time intervals showed maximum color development with D-xylose-5-phosphate in 15 min. so that the heating period was reduced from 20 min. to 15 min.

Free xylose-5-phosphoric acid had $[\alpha]_D^{20} = +25.0$ ($c = 2.00$ in water) and the specific rotation remained unchanged for two days. The disodium salt, prepared by addition of a stoichiometric quantity of dilute sodium carbonate solution to the barium salt, had an initial $[\alpha]_D^{20}$ of +10.0 ($c = 2.00$ in water, pH 7.2) which changed with time in a levorotatory direction to +7.0°, +4.4°, +1.9°, 0.0°, and −1.0° after one two, three, four, and five days respectively. The dipotassium salt had $[\alpha]_D^{20} = +13.4$ ($c = 2.09$ in water, pH 8.9). In

half-saturated sodium tetraborate solution the specific rotation of the disodium salt increased gradually in a dextrorotatory direction. After two, three, four, and five days the initial rotation of $[\alpha]_D^{20} = +5.5$ ($c = 2.00$ in water) had changed to +6.8°, +8.5°, +10.1°, and +10.6° respectively. Several attempts were made to prepare crystalline metal salts of xylose-5-phosphoric acid. Under the conditions explored, the dilithium, disodium, dipotassium, and barium salts were always obtained in amorphous form from either water or ethanol.

Acid-labile phosphate, measurable by King's method (7), was not released by hydrolysis of the barium salt for seven minutes in *N* hydrochloric acid at 100°C. Oxidation with 0.1 *M* sodium periodate at pH 4.7 consumed 3.0 moles of oxidant in 58 hr. However oxidation of various samples of the barium salt either with 0.1 *M* periodic acid in 0.05 *N* sulphuric acid or with an equivalent concentration of sodium periodate at pH 4.7 released from 3 to 7% formaldehyde, measured colorimetrically using chromotropic acid.

To identify D-xylose-5-phosphate on a crystalline basis, dibrucine and distrychnine salts were prepared and their constants determined. The former was prepared by adding a stoichiometric amount of brucine sulphate heptahydrate in 15 ml. of water to 100 mgm. of barium xylose-5-phosphate dissolved in water. Barium sulphate was removed by filtration and the filtrate evaporated to dryness *in vacuo* at 35°C. The crude dibrucine salt weighed 262.8 mgm. (90% yield). When recrystallized from ethanol by rapid evaporation, it formed long colorless needles of a hydrate from which water of crystallization was completely removed by heating for two hours *in vacuo* at 50°C. The degree of hydration of the dibrucine salt varied with the conditions during its formation. On standing in room air overnight the anhydrous salt took up water exactly equivalent to an octahydrate. When equilibrated over a water – sulphuric acid solution (sp. gr. 1.420, relative humidity = 35) in a closed vessel, it combined with 6.5 moles of water. Recrystallization from absolute ethanol gave a hydrate with 3.5 H_2O. Analyses were therefore performed on the anhydrous salt. (Found: P, 3.06; pentose 14.02. Calc. for $C_{51}H_{63}N_4O_{16}P$: P, 3.04; pentose 14.72.) Pentose was determined by the modified Cohn–Volkin procedure (5) after titration of the dibrucine salt in water to pH 10 with *N*/10 sodium hydroxide. The anhydrous salt had $[\alpha]_D^{20} = -37.8$ ($c = 2.02$ in chloroform) and it decomposed without melting above 150°C.

The distrychnine salt was prepared by the same procedure followed for the dibrucine salt. Recrystallized from ethanol and ether it formed a tetrahydrate on standing in room air. (Found: P, 3.07; pentose 15.15. Calc. for $C_{47}H_{55}N_4O_{12}P.4H_2O$: P, 3.20; pentose 15.46.) The pure compound had $[\alpha]_D^{20} = -33.2$ ($c = 1.02$ in water) and like the dibrucine salt it decomposed above 150°C. without melting.

ACKNOWLEDGMENT

The authors wish to thank Dr. Morris Kates for his kindly interest and advice, and acknowledge their indebtedness to Mr. F. Rollin for preparing the infrared spectrograms.

GLYCERIDE SYNTHESIS

I. SYNTHESIS OF SYMMETRICAL DIGLYCERIDES FROM DIHYDROXY ACETONE AND ALLYL ALCOHOL[1]

By P. J. Barry[2] and B. M. Craig

ABSTRACT

1,3-Distearoxy acetone and 1,3-dipalmitoxy acetone were prepared by interesterification of the methyl esters of the fatty acids with 1,3-dipropionoxy acetone diethyl mercaptal. The 1,3-diglycerides were obtained by hydrogenation of the ketone group. Allyl tetrahydropyranyl ether was oxidized to 1-tetrahydropyranyl glycerol which was acetylated and interesterified with methyl esters of fatty acids to produce 1,3-diglycerides.

Numerous references may be found in the literature for the synthesis of symmetrical and unsymmetrical diglycerides (11). The methods used involve blocking a primary hydroxyl group as an acetal or ether, i.e. trityl, reacting the glycerol derivative with 2 moles of the particular fatty acid chloride, and subsequent hydrolysis or hydrogenolysis to yield the desired diglyceride. Clocker and other workers (2, 1, 7) have synthesized simple triglycerides readily and in good yield by the interesterification of triacetin and the methyl ester of the fatty acid with sodium methoxide as a catalyst. The advantages of interesterification are (*a*) the mild conditions for the reaction and (*b*) the use of the methyl ester directly which is the usual derivative by which the fatty acids are purified through fractional distillation and fractional crystallization. A side reaction has been found in the interesterification of triacetin and methyl esters but the product has not been identified. The present work describes the preparation of symmetrical diglycerides by interesterification using dihydroxy acetone or allyl alcohol as starting materials.

Schlenk, Lamp, and DeHaas (12) have synthesized a number of fatty acid mono- and di-esters of dihydroxy acetone using glycolic acid chloride as a starting material. The diglycerides were produced from these products by hydrogenation over Raney nickel. Dihydroxy acetone (3) and mono fatty-acid derivatives of dihydroxy acetone (12) will undergo monomer–dimer interconversions.

In the present work the ketone group was protected as a mercaptal to eliminate this difficulty. The series of reactions at the top of page 717 outline the synthesis of diglycerides from dihydroxy acetone.

The yield of 1,3-dipropionoxy acetone diethyl mercaptal was much higher than the diethyl ketal. The 1,3-distearoxy acetone diethyl mercaptal was easily separated from the interesterification and the yields were almost quantitative in the remaining steps to the diglyceride. The method represents a direct preparation of 1,3-diglycerides without a β–α shift which is usually encountered due to an initial blocking of a primary hydroxyl group in the glycerol. Dipalmitin was also prepared in the same manner. The preparation

[1]*Manuscript received December 16, 1954.*

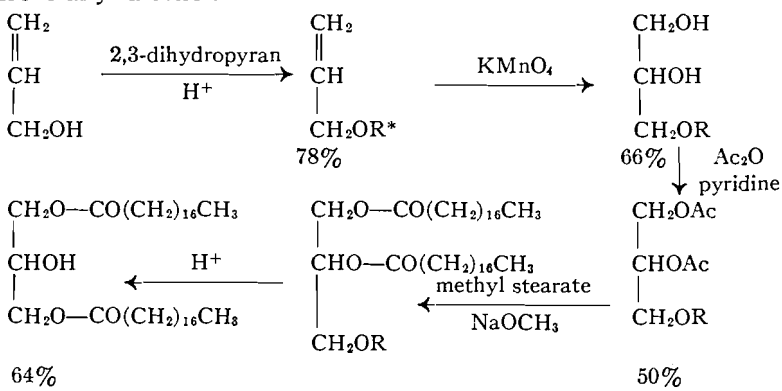
of unsaturated diglycerides would require a different procedure for reduction of the ketone group to an alcohol.

The synthesis of diglycerides from allyl alcohol required the formation of an acetal of allyl alcohol. The use of 2,3-dihydropyran for the preparation of acetals of alcohols has been investigated by Paul (10), Ott *et al.* (8), and Parham and Anderson (9). The reaction proceeds smoothly and in good yield and the acetal is readily cleaved by a mineral acid. Parham and Anderson (9) found it difficult to obtain the monoacetal of ethylene glycol. Preliminary work in this laboratory showed that it was difficult to obtain a monoacetal of glycerol. However allyl alcohol readily forms an acetal with 2,3-dihydropyran and oxidation of the ethylenic bond would yield the required monoacetal of glycerol.

The following series of reactions were followed for the synthesis of diglycerides from allyl alcohol.



Dipalmitin, 64%.

R*, tetrahydropyranyl group.

The oxidation of the allyl tetrahydropyranyl ether by $KMnO_4$ in aqueous solution at 5°C. proceeded smoothly and in fair yield. Acetylation of the 1-tetrahydropyranyl glycerol gave a low yield which may have been due to the conditions of isolation of the diacetyl derivative. The interesterification with methyl stearate produced a gel which is likely responsible for the relatively low yield of distearin. This series of reactions for the synthesis of symmetrical diglycerides merits further study, since the number of steps involved is considerably reduced as compared to conventional procedures.

EXPERIMENTAL

I. *Preparation from Dihydroxy Acetone*

(*a*) *1,3-Dipropionoxy Acetone*

1,3-Dipropionoxy acetone was prepared according to the method given by Fischer and Mildbrand (3). Five grams of (0.55 mole) dihydroxy acetone* was added to a solution of 100 ml. of dry pyridine and 120 gm. (0.923 M.) propionic anhydride, then shaken for 15 min., and allowed to stand at room temperature for two days. The solution was poured into ice water and extracted with ethyl ether. The ethereal solution was washed successively with dilute hydrochloric acid, 5% sodium bicarbonate, and water and was dried over anhydrous sodium sulphate. The ether was removed and the 1,3-dipropionoxy acetone was crystallized from petroleum ether (Skellysolve "F"). Yield, 54%; m.p., 60–60.5°C. Analysis for $C_9H_{14}O_5$: C, 53.67%; H, 6.909%. Calc.: C, 53.46%; H, 6.978%.

(*b*) *1,3-Dipropionoxy Acetone Diethyl Ketal*

The procedure used by Hurd and Pollack (4) was followed for the preparation of the diethyl ketal. Four grams of dipropionoxy acetone, 3.9 gm. of ethyl orthoformate, 5.8 gm. of ethyl alcohol, and 60 mgm. of *p*-toluene sulphonic acid were refluxed for eight hours and allowed to stand for 24 hr. The solution was neutralized with sodium ethoxide and made up to 40 ml. with water. Extraction of the aqueous solution with petroleum ether (Skellysolve "F") yielded 1.2 gm. of a yellow oil (yield 22%) which was distilled *in vacuo* to give a colorless oil, n_D^{25} 1.4296.

(*c*) *1,3-Dipropionoxy Acetone Diethyl Mercaptal*

Five grams of dipropionoxy acetone was dissolved in 50 ml. ethyl mercaptan followed by the addition of 2.5 gm. anhydrous zinc chloride. The mixture stood in a salt–ice bath for 24 hr. and was poured into a saturated aqueous solution of sodium bicarbonate. The aqueous solution was filtered and extracted with ethyl ether. The ethereal solution was dried and distilled. A colorless liquid, b.p. 157–158 at 6 mm., was obtained in 91% yield. The product was purified by distillation to yield 5.7 gm. of 1,3-dipropionoxy acetone diethyl mercaptal, n_D^{25} 1.4966. Analysis for S: found, 20.58%; calc., 20.75%.

(*d*) *1,3-Distearoxy Acetone Diethyl Mercaptal*

Three grams of dipropionoxy acetone diethyl mercaptal, 6 gm. of methyl stearate, and 0.3 ml. of a saturated solution of $NaOCH_3$ in methanol were

Supplied by Dr. A. C. Neish, Prairie Regional Laboratory, National Research Council, Saskatoon, Sask.

placed in a flask and heated on a rotary evaporator in a steam bath under vacuum. The mixture was extracted with ethyl ether and crystallized to yield 5.6 gm. (77%) of 1,3-distearoxy acetone diethyl mercaptal, m.p. 49.1–49.4°C. Analysis for S: found, 8.74%; calc., 8.79%.

(*e*) *1,3-Dipalmitoxy Acetone Diethyl Mercaptal*

Two grams of dipropionoxy acetone diethyl mercaptal, 3.55 gm. of methyl palmitate, and 0.2 ml. of a saturated $NaOCH_3$ in methanol solution were treated as in (*d*). The 1,3-dipalmitoxy acetone diethyl mercaptal was crystallized from acetone. Yield, 3.53 gm. (81%); m.p., 39.5–40.0°C. Analysis for S: 9.48%; calc., 9.52%.

(*f*) *1,3-Distearoxy Acetone*

One gram of distearoxy acetone diethyl mercaptal was dissolved in 9.5 ml. of hot acetone and 0.5 ml. of water was added. Then 2.5 gm. of $HgCl_2$ in 10 ml. of acetone was added and the mixture was refluxed for four hours. A further 25 ml. of acetone was added and the mixture was refluxed for 20 min. and filtered while hot. The residue was washed carefully with hot acetone and the 1,3-distearoxy acetone was crystallized from the acetone. Yield, 97%; m.p., 87–87.5°C.

(*g*) 1,3-Dipalmitoxy acetone was prepared in the same manner in a 97% yield with a m.p. 82–82.5°C. (reported m.p. 77–78°C. (12)).

(*h*) *1,3-Distearin and 1,3-Dipalmitin*

1,3-Distearoxy acetone, 0.67 gm., was dissolved in 75 ml. of tetrahydrofuran and was hydrogenated over Raney nickel at 50 p.s.i. for three hours at room temperature. The 1,3-distearin was recrystallized from acetone. Yield, 0.65 gm.; m.p., 78.5–79°C. (reported m.p. 79.5°C. (6)).

1,3-Dipalmitin was prepared in the same manner in a similar yield, m.p. 72.0°C. (reported m.p. 72.5 (6)). Analysis for $C_{35}H_{68}O_5$: C, 74.07%; H, 12.17%. Calc.: C, 73.89%; H, 12.04%.

II. *Preparation from Allyl Alcohol*

(*a*) *Allyl Tetrahydropyranyl Ether*

Allyl alcohol, 11.5 gm., 2,3-dihydropyran, 17 gm., and one drop of concentrated HCl were mixed at room temperature. The reaction mixture was shaken in a wrist action shaker for three hours at room temperature and was then neutralized with $NaHCO_3$. The product was distilled over $NaHCO_3$ at b.p. 165–167°C. in 78% yield, n_D^{25} 1.4421.

(*b*) *1-Tetrahydropyranyl Glyceryl Ether*

Allyl tetrahydropyranyl ether, 106.5 gm., was suspended in 450 ml. water and cooled to 5°C. in an acetone – dry ice bath. One hundred and twenty grams of $KMnO_4$ in 2550 ml. of water was added with stirring at a rate that maintained the temperature of the mixture at 5°C. ±1°C. After the addition was completed the mixture was allowed to stand in the cooling bath for two hours and was then heated for one hour on a steam bath. The solution was filtered, cooled to room temperature, and saturated with K_2CO_3. The oil was separated from the aqueous mixture, dried, and dissolved in ethyl ether.

The ethereal solution was dried over K_2CO_3 and the ether was removed to yield 102 gm. (66.5% yield) of crude product. The product distilled at 146–149°C. at 4 mm. pressure, n_D^{25} 1.4736. Oxidation of 1-tetrahydropyranyl glycerol ether with periodic acid (5) was quantitative showing a monoether of glycerol.

(*c*) *2,3-Diacetoxy-1-tetrahydropyranyl Glycerol*

Twenty five grams of tetrahydroglyceryl ether was added to a solution of 150 ml. of pyridine and 80 ml. acetic anhydride and shaken for one hour at room temperature. The mixture was allowed to stand at room temperature for two days, poured into ice water, and allowed to stand for two hours. The aqueous solution was extracted twice with ethyl ether and the ethereal solution was washed successively with water, 10% HCl, water, 5% $NaHCO_3$ solution, and water. After the solution was dried over anhydrous Na_2SO_4, the ether was removed and the product was distilled. The 2,3-diacetoxy-1-tetrahydropyranyl ether was obtained in 50% yield, n_D^{25} 1.4456, saponification value 426.5, calculated 430.7.

(*d*) *1,3-Distearin by Acyl Chlorides*

Tetrahydropyranyl glyceryl ether, 4.6 gm., was dissolved in 10 ml. of dry pyridine and 25 ml. of dry $CHCl_3$ and 10 gm. of stearyl chloride (2) dissolved in 10 ml. of dry $CHCl_3$ was added slowly to the reaction vessel. The mixture was allowed to stand at room temperature for one hour and was then refluxed for 12 hr. The product was extracted with petroleum ether (Skellysolve "F") which was washed with water, dilute hydrochloric acid, and water and was dried over anhydrous sodium sulphate. Dry HCl gas was bubbled into the petroleum ether solution for one-half hour. The solution was allowed to stand at room temperature for one hour and filtered. The 1,3-distearin was recrystallized from acetone, yield 12.6 gm. (72% of theoretical), with a m.p. 78.5–79°C. (reported m.p. 79.5 (3)). Analysis for $C_{39}H_{76}O_5$: C, 73.56%; H, 12.06%. Calc.: C, 73.55%; H, 12.10%.

(*e*) *1,3-Distearin by Interesterification*

2,3-Diacetoxy-1-tetrahydropyranyl glyceryl ether, 2.6 gm., was reacted with 6.0 gm. methyl stearate and 0.2 ml. of saturated solution of $NaOCH_3$ in methanol under vacuum at 90–95°C. Petroleum ether (Skellysolve "F") was added to the mixture and the soaps were removed by filtration. The solution was dried over anhydrous Na_2SO_4 and the salt was then removed by filtration. Dry HCl gas was passed into the solution for one-half hour and allowed to stand for one hour at room temperature. The precipitate was filtered and crystallized from acetone to yield 3.95 gm. (64% yield) of 1,3-distearin, m.p. 78–79°C. (reported 79.5°C.). Analysis for $C_{39}H_{76}O_5$: C, 73.41%; H, 12.07%. Calc. for C, 73.55%; H, 12.10%.

(*f*) 1,3-Dipalmitin, m.p. 72.5–73.5°C. (reported m.p. 72.5°C. (6)), was prepared in a similar manner in 63% yield.

NOTES

TETRAETHYL PYROPHOSPHATE LABELED WITH PHOSPHORUS-32

By J. R. Robinson

A supply of P^{32}-labeled tetraethyl pyrophosphate (TEPP) was required for research at this laboratory and, as no details of its synthesis[1] were found in the literature, the method described here was developed. The specific activity of the product was low, 65 microcuries per gram, but this could be increased by altering the ratio of active to inactive phosphorus and no major modification of the technique would be required.

EXPERIMENTAL

Labeled phosphoric acid,[2] suitably diluted with inactive orthophosphoric acid, was converted *via* silver phosphate to triethyl phosphate using reactions reported by Baldwin and Higgins (1).

$$PO_4^{\equiv} + 3Ag^+ \xrightarrow{\text{pH 7}} Ag_3PO_4$$

$$Ag_3PO_4 + 3C_2H_5Br \xrightarrow{\text{Heat}} (C_2H_5)_3PO_4 + 3AgBr$$

The final step of the synthesis utilized a reaction reported by Bell (2).

$$2(C_2H_5)_3PO_4 + SOCl_2 \xrightarrow{\text{Heat}} (C_2H_5)_4P_2O_7 + 2C_2H_5Cl + SO_2$$

Since the experimental technique is novel the details are reported in full.

Tetraethyl Pyrophosphate

Labeled triethyl phosphate (13.29 gm., 72.4 millimoles, 47 μc. per gm.) was placed in a Hickman vacuum still[3] and treated with 4 ml. (6.6 gm., 55.6 millimoles) of thionyl chloride. The still was fitted with a receiver and a calcium chloride tube. The system was suspended about one-half inch above a small hot plate and a thermometer was fixed in a horizontal position with its bulb touching the center point of the bottom of the still. Heating was adjusted until the thermometer was steady at 70–75° and this temperature was maintained for 24 hr. The temperature was then raised to 140° for half an hour to ensure completion of the reaction. During the total reaction time 1.5 ml. of excess thionyl chloride collected in the receiver while the sulphur dioxide and ethyl chloride passed off through the calcium chloride tube. The still was allowed to cool and then was fitted to a vacuum manifold. With the pressure at 10 mm. and the thermometer indicating 120° the last traces of reactants

[1]*The use of radioactive TEPP has been reported (3, 4, 5, 6, 7). References (3) and (4) were concerned with labeled hexaethyl tetraphosphate (HETP) which probably contained TEPP as the active principle.*

and by-products were removed. After one-half hour the pressure was lowered to 0.002 mm. and the tetraethyl pyrophosphate was distilled into weighed receivers. A forerun of 1.5 ml. (optimum quantity determined by inactive runs) was discarded and 6.4 gm. (61%) of TEPP was collected, b.p. 95–100°/ 0.002 mm., n_D^{25} 1.4174. (The boiling point and refractive index were determined on inactive samples produced in the same manner.) The corrected specific activity was 65 μc. per gm., representing a recovery of 41% of the initial radioactivity. The over-all chemical yield, also based on phosphoric acid, was 49%.

IDENTIFICATION OF DIHYDROCONIFERYL ALCOHOL

BY E. A. KVASNICKA, R. R. MCLAUGHLIN, AND S. REID

Dihydroconiferyl alcohol (3-(3-methoxy-4-hydroxyphenyl)-1-propanol) (7) is an important degradation product of lignin. It has been found not only in hydrogenolysis reaction mixtures (3, 9) but also after degrading naturally occurring related products (5).

Recently, this compound was found to be present in spruce sulphite liquor (6). At the same time, dihydroconiferyl alcohol was also found in the oxidized sulphite liquors (8).

During these investigations, extensive use has been made of the available methods of identification which are described in these papers. However, an important fact is reported here because of its special interest for those working at present in this field.

The UV spectra of dihydroconiferyl alcohol and similar compounds were reported by Schuerch (9), who found an absorption maximum of 265 mμ (determined in butanol). This value appeared to be in disagreement with the known rule that hydroxy groups in the γ-position in the side chain cause only negligible shifts of the UV absorption curve of the parent hydrocarbon (2). The UV absorption maximum of this hydrocarbon, coerulignol, is 281 mμ (1, 4).

and by-products were removed. After one-half hour the pressure was lowered to 0.002 mm. and the tetraethyl pyrophosphate was distilled into weighed receivers. A forerun of 1.5 ml. IDENTIFICATION OF DIHYDROCONIFERYL ALCOHOL

BY E. A. KVASNICKA, R. R. MCLAUGHLIN, AND S. REID

Dihydroconiferyl alcohol (3-(3-methoxy-4-hydroxyphenyl)-1-propanol) (7) is an important degradation product of lignin. It has been found not only in hydrogenolysis reaction mixtures (3, 9) but also after degrading naturally occurring related products (5).

Recently, this compound was found to be present in spruce sulphite liquor (6). At the same time, dihydroconiferyl alcohol was also found in the oxidized sulphite liquors (8).

During these investigations, extensive use has been made of the available methods of identification which are described in these papers. However, an important fact is reported here because of its special interest for those working at present in this field.

The UV spectra of dihydroconiferyl alcohol and similar compounds were reported by Schuerch (9), who found an absorption maximum of 265 mμ (determined in butanol). This value appeared to be in disagreement with the known rule that hydroxy groups in the γ-position in the side chain cause only negligible shifts of the UV absorption curve of the parent hydrocarbon (2). The UV absorption maximum of this hydrocarbon, coerulignol, is 281 mμ (1, 4).

In view of this discrepancy, we re-examined the spectrum of dihydroconiferyl alcohol. A sample was synthesized according to the procedure of Schuerch (9) and characterized by the refractive index and the preparation of the known derivatives (5).

We found absorption maxima of 281.6 mμ (solvent: 95% ethanol) and 281.8 mμ (solvent: *n*-butanol).

Therefore, dihydroconiferyl alcohol cannot be regarded as an exception to the above-mentioned rule.

EXPERIMENTAL PART

The sample of dihydroconiferyl alcohol was prepared by reduction of ethyl hydroferulate with lithium aluminum hydride according to the literature (9). The compound was characterized by the preparation of the benzoate and *p*-nitrobenzoate and the purity was checked by the refractive index and paper chromatography (6).

The spectra were determined with a Beckman model DU spectrophotometer, and the resulting data appear in Table I.

IX. THE SYNTHESIS OF PAPAVERINE AND PAPAVERALDINE BY THE POMERANZ-FRITSCH METHOD[1]

BY DONALD A. GUTHRIE,[2] ARLEN W. FRANK,[3] AND C. B. PURVES

ABSTRACT

Fritsch's cyclization of N-(α-veratrylveratrylidene)-aminoacetal in sulphuric acid was shown to give 1.1% of papaverine and 23% of an isomer, m.p. 164.5–165.5°C.; hydrochloride, m.p. 212°C. decomp., which was supposed to be 4,5-bis(3,4-dimethoxyphenyl)-2*H*-pyrrolenine, produced by an internal condensation of the acetal or the corresponding aldehyde with the reactive methylene group. A similar structure was proposed for another unidentified isomer prepared by Schlittler and Müller. Hydrogenation of Fritsch's acetal gave N-(α-veratryl-veratryl)-aminoacetal, m.p. 69.5–70°C., which was cyclized to a base, m.p. 155.5–156°C.; N-acetyl derivative, m.p. 203.5–204°C., formulated as 2,3-bis(3,4-dimethoxyphenyl)-3-pyrroline. Substances presumed to be the intermediate aldehyde and aldol were isolated as colorless oils. Condensation of the diketone veratril with aminoacetal, followed by cyclization of the crude product, constituted a new two-step synthesis of papaveraldine in 8% yield, and the reduction of the latter to papaverine was known.

Other crystalline compounds prepared incidentally and thought to be new were veratril monoanil, m.p. 172–173°C.; α,α′-biveratrylideneaminoacetal, m.p. 101–102°C.; a compound formulated as 2,3-bis(3,4-dimethoxyphenyl)-4-ethylmercaptopyrrolidine hydrochloride, m.p. 184–185°C.; from this an unidentified mercury complex, m.p. 109°C. decomp.; 4,4′dibenzyloxy-3,3′-dimethoxydesoxybenzoin, m.p. 141–142°C.; and its oxime, m.p. 137.5°C.

INTRODUCTION

The opium alkaloid papaverine is now produced in about 15% yield from vanillin by the Bischler-Napieralski isoquinoline synthesis (3, 4), but the possible application of the less familiar Pomeranz-Fritsch synthesis is still of interest because the product would in theory be obtained in fewer steps. Pomeranz (15) was the first to plan this application, but the attempts of Allen and Buck (1), Fritsch (8), and Schlittler and Müller (17) to put it into effect gave disappointing results. The present article reveals some of the factors that caused these attempts to fail, and describes modifications that lead to syntheses of papaverine and papaveraldine. Manske (14) reviewed the general methods available for the synthesis of isoquinolines.

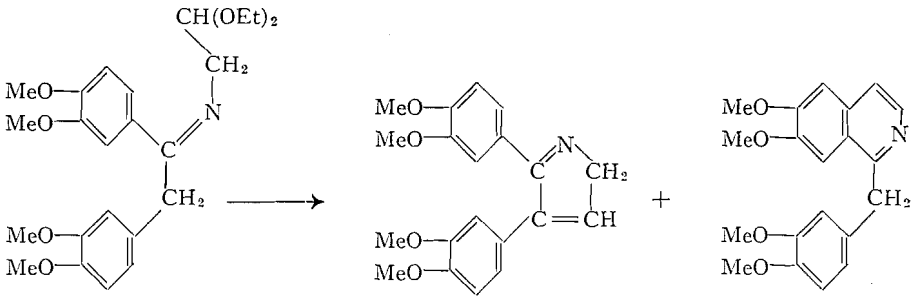
Fritsch (8) reported in 1903 that N-(α-veratrylveratrylidene)-aminoacetal (I), prepared by condensing desoxyveratroin with aminoacetal, was cyclized with 75% sulphuric acid at room temperature to give a 13% yield (based on desoxyveratroin) of a yellow compound melting at 162°C., or 15°C. higher than papaverine (III). Found: C, 70.7; H, 6.4; N, 4.8%. Calc. for papaverine, $C_{20}H_{21}O_4N$: C, 70.7; H, 6.2; N, 4.1%. Like papaverine, the yellow compound was soluble in acetone and sparingly soluble in ethanol and ether. On the basis of these results, Fritsch claimed that the compound was isomeric with papaverine, but he did not attempt to establish its structure.

As a preliminary to repeating Fritsch's synthesis, it was noted that one mole of water was expelled and one mole of aminoacetal was retained when benzoin was boiled with an excess of the acetal, and formation of the Schiff base was presumably complete. A new compound, the desoxybenzoin from O-benzylvanillin, was incidentally prepared in crystalline form. Desoxyveratroin was then condensed with aminoacetal by distilling a mixture of the two substances at atmospheric pressure and up to 245°C. until the water and the excess of aminoacetal were removed. Several attempts to carry out the condensation under milder conditions failed. The product, the Schiff base (I),



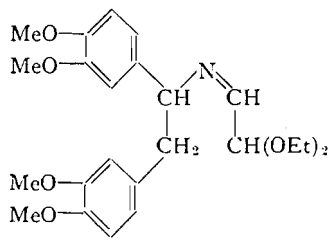
I II III

was an uncrystallized, viscous yellow oil, just as described by Fritsch (8). Cyclization of the Schiff base in 83% sulphuric acid gave an 18–23% yield of yellow needles melting at 164.5–165.5°C., whose composition confirmed the supposition that the compound was an isomer of papaverine. A small amount of papaverine (1.1%) was isolated from the mother liquor by chromatography on an alumina column.

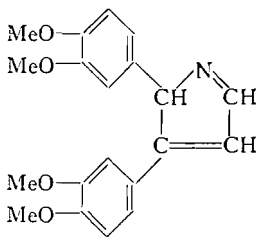
One possible isomer, 5,6-dimethoxy-1-veratrylisoquinoline, which might have arisen by cyclization at position 2 rather than position 6 in the veratryl nucleus, could be dismissed immediately, since this isomer had been prepared unambiguously by the Bischler-Napieralski method as a white crystalline solid, m.p. 89–91°C. (13). Another possibility was the isomer 4,5-bis(3,4-dimethoxyphenyl)-2*H*-pyrrolenine (II), formed by an internal aldol condensation of the acetal, or of the aldehyde produced by hydrolysis, with the reactive methylene group in (I). A mass of evidence was assembled in support of this structure. The absence of active hydrogen (Zerewitinoff) and an inability to prepare an acetyl or benzoyl derivative indicated the absence of the N—H

group. The base formed no methiodide, but a solution in hydrochloric acid and acetone deposited an orange-colored crystalline hydrochloride which was somewhat unstable to hot solvents and was sparingly soluble in water. Further support for structure (II) was gained from the infrared absorption spectrum of the base. The presence of two very close bands at 805–810 cm.$^{-1}$, corresponding to two unsymmetrical triply-substituted benzene rings, excluded the isoquinoline ring structure (papaverine has only one band in this region). A C=N band at 1566 cm.$^{-1}$ and the absence of the N—H band showed that, if a pyrrole ring were present, the hydrogen atoms would have to be distributed around the ring in an abnormal manner.

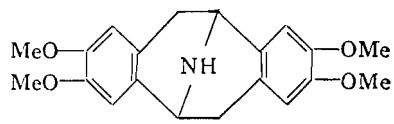
In accord with structure (II), we would like to propose a structure for another unidentified isomer of papaverine, obtained by Schlittler and Müller in 1948 (17). The Schiff base N-(α-veratrylveratryl)-iminoacetal (IV), prepared by condensing 1,2-bis(3,4-dimethoxyphenyl)-ethylamine with glyoxal semiacetal, was cyclized with 75% sulphuric acid in 10% yield to a white crystalline compound melting at 222–223°C. and with the carbon and hydrogen content required for $C_{20}H_{21}O_4N$. The product was probably 2,3-bis(3,4-



IV



V



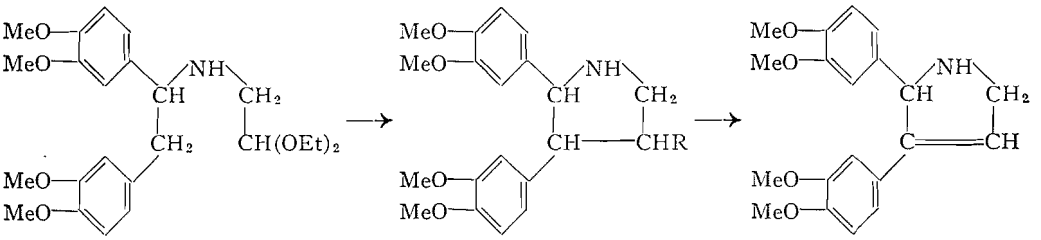
VI

dimethoxyphenyl)-2*H*-pyrrolenine (V), differing from (II) only in the position of the C=N bond.

An attempt was made by Allen and Buck (1) in 1930 to synthesize papaverine by the Fischer-Rügheimer modification of the Pomeranz-Fritsch synthesis. This modification, which was the subject of a recent paper (7), consisted of cyclizing N-benzylaminoacetals with sulphuric acid in the presence of an oxidizing agent such as arsenic pentoxide. Allen and Buck found that condensation of 1,2-bis(3,4-dimethoxyphenyl)-ethylamine with bromoacetal at 150°C. yielded a red oil, presumably N-(α-veratrylveratryl)-aminoacetal (VII), which could not be crystallized and which gave no crystalline derivatives. When the oil was treated with arsenic pentoxide in sulphuric acid solutions of various strengths, nothing but black amorphous material was obtained. In the present work, attempts were made to condense the amine with excess chloroacetal in boiling xylene, or with a slight excess of bromoacetal in cold benzene, but the first experiment yielded a black gum, and the second a white amorphous solid containing almost no nitrogen. In both cases much of the original amine could not be recovered. Allen and Buck (1) apparently employed the dimethyl acetal of bromoacetaldehyde instead of the more common

diethyl acetal used in the above experiments, and a direct comparison with their results was not possible.

It was then discovered that the desired secondary amine, N-(α-veratryl-veratryl)-aminoacetal (VII), could be prepared in good yield as a white crystalline solid by hydrogenation of the Schiff base (I) over Raney nickel. Cyclization of this crystalline amine (VII) under the conditions of the Rügheimer synthesis gave a white crystalline solid, m.p. 155.5–156°C., in yields of up to 56%. The product had the composition of dihydropapaverine, $C_{20}H_{23}O_4N$, but differed from the known substances 3,4-dihydropapaverine, m.p. 97–98°C., and pavine (VI), m.p. 201–202°C. (2, 18). Analogy with the cyclization of the Schiff base (I) suggested that the new substance was either the hitherto unknown 1,2-dihydropapaverine, or 2,3-bis(3,4-dimethoxyphenyl)-3-pyrroline (IX), formed by an internal aldol condensation of the acetal (or aldehyde) with the reactive methylene group. The former, however, was shown to be an unstable intermediate in the reduction of papaverine with tin and hydrochloric acid, cyclizing spontaneously in the acid solution to pavine (VI) (18). The absence of pavine in the acidic reaction mixture from the cyclization of (VII) was, therefore, an indication that no 1,2-dihydropapaverine was produced.



VII VIII, R = OH or SC_2H_5 IX

The over-all pattern of the infrared spectrum of the new base favored a structure similar to the pyrrolenine (II). A double band at 799–808 $cm.^{-1}$ indicated, as in the pyrrolenine, the presence of two unsymmetrical triply-substituted benzene rings. The presence of an N—H group was established by the presence of the N—H stretching frequency and by the preparation of a crystalline acetyl derivative. The base was, however, completely destroyed when attempts were made at dehydrogenation to the pyrrolenine with selenium at 250°C., with palladium-on-charcoal at 190°C., or with palladium black in boiling decalin.

Other experiments on the cyclization of the secondary amine (VII) at 20°C. showed that sulphuric acid of 20 to 65% strength was capable of hydrolyzing the acetal, but was unable to convert the product (aldehyde or aldol; see below) to the pyrroline (IX). At an acid strength of 75 or 83%, fair yields of the pyrroline were obtained, with or without arsenic pentoxide, but the duration of the reaction was critical (Fig. 1) because the product was unstable toward the condensing agent. When samples of the crystalline pyrroline were

dissolved in 83% sulphuric acid at room temperature and worked up in the usual manner after 2 and 18 hr., the recovery of the pyrroline was only 48% and 18%, respectively. The fact that the conditions of cyclization were so narrowly defined constituted another reason why Allen and Buck (1) failed to isolate the pyrroline.

The hydrolysis of N-(α-veratrylveratryl)-aminoacetal (VII) to the free aldehyde was studied in the hope that this procedure would reduce the time required for the subsequent cyclization. When the hydrolysis was carried out with 2 *N* hydrochloric acid for seven hours at 100°C. there was obtained, as anticipated, a product exhibiting a very strong positive dinitrophenylhydrazine test for the carbonyl function, and 92% of the theoretical amount of ethanol was recovered. The crude, gummy product was cyclized in 83% sulphuric acid over a four-hour period to the pyrroline (IX) in 32% yield (based on the acetal). When the acetal was hydrolyzed with concentrated hydrochloric acid at 20°C. for 0.5, 3, 6, 24, and 51 hr., the ethanol recovered amounted to 14, 71, 98, 100, and 99%, respectively, of the theoretical amount. Even after six hours, when the hydrolysis was complete, the colorless gum which formed the product gave a negative dinitrophenylhydrazine test for the carbonyl function. This product was probably the intermediate aldol, 2,3-bis(3,4-dimethoxyphenyl)-4-pyrrolidinol (VIII, R = OH). Concentrated hydrochloric acid, then, was presumably capable of cyclizing the acetal or aldehyde to the aldol, but not of dehydrating the aldol to the pyrroline.

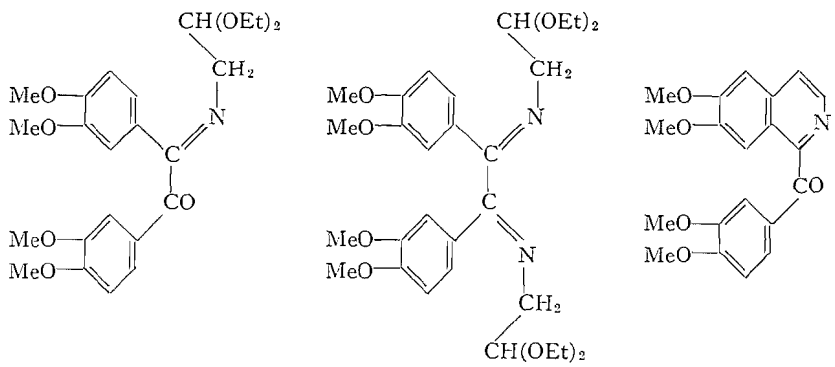
Support for this argument was unintentionally provided by the results of an attempt to prepare the free aldehyde, N-(α-veratrylveratryl)-aminoacetaldehyde, by conversion of the acetal (VII) to the thioacetal, followed by cleavage of the thioacetal with mercuric chloride and cadmium carbonate (22). Instead of the expected thioacetal, the crystalline product, isolated from the reaction of the acetal with ethyl mercaptan in concentrated hydrochloric acid, had the composition of the sulphide, 2,3-bis(3,4-dimethoxyphenyl)-4-ethylmercaptopyrrolidine hydrochloride (VIII, R = SC_2H_5). The concentrated hydrochloric acid had effected, at some stage in the reaction, an aldol condensation.

Treatment of the sulphide with mercuric chloride and cadmium carbonate, under the conditions normally employed for the hydrolysis of a thioacetal to the corresponding aldehyde (22), gave a brilliant yellow mercury complex, m.p. 109°C. decomp., which contained nitrogen atoms, methoxyl groups, and mercury atoms in the ratio 2:8:1. When the complex was decomposed with hydrogen sulphide a colorless oil resulted, which was probably the aldol (VIII, R = OH), since tests for halogen and carbonyl groups were negative, and the oil yielded up to 34% of the pyrroline (IX) when aliquots were treated with 83% sulphuric acid.

In retrospect, it appeared that a major obstacle to the completion of the synthesis of papaverine by the Pomeranz-Fritsch method was the reactivity of the methylene group in N-(α-veratrylveratrylidene)-aminoacetal (I), and that this obstacle might be removed by replacing the group with, for example, a hydroxyl or keto group. Veratroin was not a suitable starting material,

because it was difficult to purify (12), and would probably not withstand the drastic conditions required for condensation with aminoacetal. On the other hand, the diketone veratril was a stable, crystalline compound, readily prepared by mild oxidation of veratroin (10, 12), or by methylation of vanillil, a substance now isolated from oxidized waste sulphite liquor and of potential commercial importance. It was found advantageous to methylate the vanillil in the form of its bright yellow crystalline disodium salt.

Many attempts were made to prepare the desired mono-Schiff base, N-(α-veratroylveratrylidene)-aminoacetal (X), by condensing veratril with various proportions of boiling aminoacetal. The conditions finally employed were slightly milder than those for the similar condensation of desoxyveratroin, but efforts to employ a lower temperature resulted only in the quantitative recovery of the veratril. After isolation, the product soon deposited a substantial quantity of the disubstituted compound, α,α'-biveratrylideneaminoacetal (XI), as white crystals. Since this compound yielded veratril on hydrolysis with dilute acid, no further internal condensation, such as formation of an imidazole (11), had occurred. The remainder of the product was a yellow oil which resisted attempts at purification by chromatography on Magnesol or cellulose columns. A paper chromatogram of the oil, developed with petroleum ether saturated with water, and sprayed with acid 2,4-dinitrophenyl-



X XI XII

hydrazine, showed a yellow spot at R_f 0.79 and a red spot at R_f 0.68. Reference chromatograms with veratril and the crystalline di-Schiff base showed yellow spots at the base line and at R_f 0.79, respectively. The oil therefore contained some of the di-Schiff base and also a carbonyl compound which was assumed to be the sought-for mono-Schiff base (X). The oil, however, could not be crystallized, and repeated attempts to isolate the mono-Schiff base ended in failure. Attempts to reach the same goal by partial hydrolysis of the di-Schiff base were also fruitless. These failures were unexpected, because a preliminary condensation of veratril with boiling aniline readily gave the pale yellow crystalline monoanil in good yield.

An attempt was also made to isolate the secondary amine corresponding to the mono-Schiff base (X). The Schiff base mixture, or the pure di-Schiff base

alone, consumed no hydrogen when shaken with Adams' platinum oxide catalyst and 30–40 p.s.i. of hydrogen for 25 hr. at room temperature. Hydrogenation of the Schiff base mixture over freshly prepared Raney nickel at 1500 p.s.i. for three hours at 80–90°C. gave an oil which slowly deposited 2% of the unchanged di-Schiff base, but none of the desired secondary amine. Only 7% of veratril was recovered after hydrolysis of the residual oil with dilute hydrochloric acid, and neutralization of the acidic mother liquor caused the separation of a red ether-soluble oil (83% of the original veratril) which was not examined in detail.

In default of the pure mono-Schiff base (X), the experiments on cyclization were carried out on the original crude mixture. No papaveraldine (XII) was isolated from attempted cyclizations in 83% sulphuric acid for 20 hr. at room temperature, or in concentrated sulphuric acid for three minutes at 150°C., but an 8% yield, based on veratril, resulted from a cyclization carried out with 72% acid at room temperature or less. This result amounted to a new synthesis of papaverine (III), for papaveraldine was known to be reduced to papaverine with zinc dust and acetic anhydride (5, 19), as well as in a less direct way (5).

EXPERIMENTAL

Melting points were not corrected. The infrared spectra were obtained from Nujol mulls.

Materials

Veratroin was prepared from veratraldehyde by the benzoin condensation, and was reduced to desoxyveratroin substantially as described by Kubiczek (12). After the observation of Fritsch (8) that desoxyveratroin could not be separated from traces of veratril by crystallization had been confirmed, the crude product, 11.3 gm., was boiled for two hours under reflux with 100 ml. of anhydrous ethanol, 10 ml. of glacial acetic acid, and 6.7 gm. of Girard's "T" reagent for carbonyl compounds (the hydrochloride of N-trimethylaminoacethydrazide) (9). When cool, the solution was poured into 300 gm. of ice and water containing 21.5 gm. of potassium carbonate and was extracted with benzene until the extracts were colorless. The adduct was decomposed by acidifying the aqueous residue to pH 1 with hydrochloric acid, and an hour later the precipitated desoxyveratroin, 4.6 gm., was collected. The best overall yield was 18%, and m.p. 103.5–104.5°C., the recorded values being 106°C. (12, 21) or 107°C. (1).

Desoxyveratroin oxime, melting correctly at 128.5–129°C. (1, 12), was obtained in 99% yield by stirring a slurry of desoxyveratroin, hydroxylamine hydrochloride, and sodium acetate in aqueous ethanol for three days at room temperature. A yield of only 67% was obtained when the hydrochloride was used in pyridine solution (1). This oxime was reduced to 1,2-bis(3,4-dimethoxyphenyl)-ethylamine in 78% yield by sodium amalgam (1, 10), and in 69% yield by hydrogenation for 50 min. at 80–100°C. and 1300 p.s.i. over a Raney nickel catalyst. This catalyst was apparently more suitable than palladium-on-charcoal, which recently failed to give the expected result (21).

To prepare veratril, a mixture of 30.2 gm. (0.1 mole) of vanillil, m.p. 233–233.5°C. (diacetate, m.p. 139–140°C.), 24 gm. of sodium hydroxide, and 200 ml. of water was shaken rapidly until solution was complete. In a few minutes the red solution began to deposit in practically quantitative yield the bright yellow needles of the disodium salt of vanillil, which was washed with ethanol and dried *in vacuo* over solid potassium hydroxide. This salt melted above 265°C., was insoluble in all common organic liquids, but dissolved readily in water to give a yellow solution. A mixture of the dry, powdered salt with 28 ml. of dimethyl sulphate and 500 ml. of toluene was heated for five hours under reflux, and was then cooled. The next day the solid product, 55 gm., was freed from sodium salts by being ground in a mortar with 10% sodium carbonate, and the residue of almost pure veratril weighed 26.6 gm. (80.5%). One recrystallization from glacial acetic acid raised the melting point to 224–225°C., the recorded value being 223°C. (12). Veratril was also obtained by methylating vanillil with dimethyl sulphate and aqueous sodium carbonate or methanolic sodium hydroxide, but the yields were only 31% and 66%, respectively. Oxidation of the crude veratroin described above with copper sulphate in pyridine (10), or by air and alkali (12), gave veratril in over-all yields of 10% or less from veratraldehyde.

Aminoacetaldehyde diethyl acetal was prepared in 35% yield from chloroacetal as described by Richmond and Wright (16); the colorless product had the right composition, boiled correctly at 160–165°C., and yielded a picrate melting correctly at 142–143°C. When the chloroacetal was replaced by bromoacetal the yield of aminoacetal decreased to 14% or less; none was obtained from chloroacetal and sodamide suspended in boiling liquid ammonia, ether, or toluene.

4,4′-Dibenzyloxy-3,3′-dimethoxydesoxybenzoin

In accord with Kubiczek's general procedure (12), a solution of 35 gm. of O-benzylvanillin, m.p. 61°C., and 5.2 gm. of potassium cyanide in 100 ml. of ethanol was boiled under reflux for four and one-half hours in an atmosphere of hydrogen. The gum which precipitated when the solution was poured into 400 ml. of cold water was dissolved in 400 ml. of ether, and the ethereal solution was washed with dilute sodium carbonate, dilute sodium bisulphite, and finally with water. After the solution had been dried, evaporation of the ether left the benzoin as a crude oil, which was then dissolved in a boiling mixture of methanol, 300 ml., acetic acid, 150 ml., and water, 75 ml., and reduced by the gradual addition of 39 gm. of zinc dust during one and one-half hours. The white solid that separated when the solution cooled was extracted with acetone from excess zinc dust, and the extract was poured into water. The long white needles that separated weighed 9.5 gm. (28%) and their melting point of 141–142°C. was not changed by recrystallization from ethanol. Found: OCH_3, 13.0, 13.2%. Calc. for $C_{30}H_{28}O_5$: OCH_3, 13.2%. The oxime could not be prepared by stirring the desoxybenzoin with hydroxylamine hydrochloride and sodium acetate in 80% ethanol, but an 85% yield resulted when the substance was boiled for five and one-half hours with a solution of

the hydrochloride in pyridine. After three recrystallizations from ethanol, the melting point of the oxime was 137–137.5°C., depressed to 124–133°C. by admixture with the original desoxybenzoin.

Cyclization of N-(α-Veratrylveratrylidene)-aminoacetal (I)

A 125 ml. distillation assembly containing 25 gm. (0.079 mole) of desoxyveratroin and 30 gm. (0.225 mole) of aminoacetal was swept out with nitrogen and the heating was adjusted from time to time to give slow, uniform distillation of the excess aminoacetal. The temperature of the liquid rose steadily over the course of one hour from 165°C. to 245°C., as the last traces of the excess aminoacetal were carried over. The light yellow still residue of crude Schiff base (I) weighed 29.8 gm. (calc. 34.1 gm.).

Part of this oil (15.0 gm.) was dissolved in 160 ml. of chilled 83% sulphuric acid, the crimson solution was stirred for 20 hr. at room temperature, and was then mixed with 500 gm. of chopped ice. The slurry was made alkaline with aqueous sodium hydroxide and extracted with benzene. Extraction of the benzene solution with 0.1 *N* hydrochloric acid and addition of excess aqueous sodium hydroxide to the aqueous extract gave a slightly brown solid, which was then taken up in hot ethanol, decolorized with charcoal, and filtered. On cooling, there separated 2.89 gm. (21.5% based on desoxyveratroin) of yellow needles melting at 164–165°C. The melting point was raised slightly to 164.5–165.5°C. by recrystallization from ethanol. Found: C, 70.5, 70.8; H, 6.3, 6.2; N, 4.01, 4.02; OCH_3, 35.9, 36.1%; mol. wt., determined cryoscopically in benzene, 354, 336. Calc. for $C_{20}H_{21}O_4N$: C, 70.7; H, 6.2; N, 4.13; OCH_3, 36.6%; mol. wt., 339. Determinations made in anisole by the Zerewitinoff method showed the presence of only 0.12, 0.07 gm. of active hydrogen per mole. The compound was very soluble in chloroform, pyridine, glacial and aqueous acetic acid, sparingly soluble in acetone, methanol, and ethanol, and insoluble in water and ether.

The hydrochloride, prepared by adding a little concentrated hydrochloric acid to an acetone solution of the base, melted with decomposition at 212°C. Found: Cl, 9.36, 9.33%. Calc. for $C_{20}H_{22}O_4NCl$: Cl, 9.46%. This orange-colored substance was only sparingly soluble in water, and was rather unstable to recrystallization from hot solvents.

The brown ethanol filtrate, from which the yellow base had been removed, was evaporated to dryness and the residue digested exhaustively with boiling petroleum ether. Filtration and evaporation of the extract left 0.39 gm. of a pale yellow solid melting over the range 134–138°C. This solid was dissolved in dry benzene and chromatographed on an alumina column; the yellow base, $C_{20}H_{21}O_4N$, washed through the column weighed 0.17 gm. (1.3%) and melted at 164–165°C. The column was then extruded and all but the upper 0.5 cm., which was deep brown in color, was extracted with 5% pyridine in methanol. This extract yielded, on filtration and evaporation, 0.15 gm. (1.1%) of papaverine, m.p. 146.5–147.5°C. The base was converted to its hydrochloride, m.p. 221–222°C. The melting points of the base and its hydrochloride were identical with those of authentic papaverine and its hydrochloride, respectively, and no depression in the melting points was observed on admixture.

N-(α-Veratrylveratryl)-aminoacetal (VII)

The crude Schiff base (I), obtained as a pale yellow oil from a condensation of 20.0 gm. of desoxyveratroin with 33.7 gm. of aminoacetal, was dissolved in 100 ml. of ethanol and hydrogenated with 2 gm. of Raney nickel in a 300 ml. steel bomb at 1300 p.s.i. and 80–100°C. for 80 min. The yellow oil remaining after filtration and evaporation of the bomb contents was dissolved in 150 ml. of *N* hydrochloric acid and the solution was extracted several times with ether. A small amount (1.8 gm.; 9%) of desoxyveratroin was recovered from the ether extract. Neutralization of the acidic aqueous solution with sodium hydroxide caused the deposition of a mass of white crystals, which after washing and drying weighed 16.5 gm. (61% based on desoxyveratroin) and melted at 66–68°C. Repeated crystallization from methanol gave fine white felted needles and raised the melting point to 69.5–70°C. Found: C, 66.5, 66.5; H, 8.3, 8.3; N, 3.25, 3.29; OCH_3, 42.6, 42.2%. Calc. for $C_{24}H_{35}O_6N$: C, 66.5; H, 8.2; N, 3.24; OCH_3 (OC_2H_5 calc. as OCH_3), 43.0%. The product was very soluble in dilute mineral acids, ether, ethyl acetate, chloroform, and benzene, was only slightly less soluble in ethanol and methanol, and was insoluble in water.

In subsequent preparations under apparently identical conditions the yield of N-(α-veratrylveratryl)-aminoacetal (VII) was only 20–25% of the desoxyveratroin used.

2,3-Bis(3,4-dimethoxyphenyl)-3-pyrroline (IX) (Fig. 1)

The following experiment was typical of the series. A solution of 1.0 gm. of the acetal (VII) in 11 ml. of chilled 83% sulphuric acid was allowed to stand for seven hours at room temperature, and was then poured into ice water. After extraction with benzene, the acid solution was made alkaline and

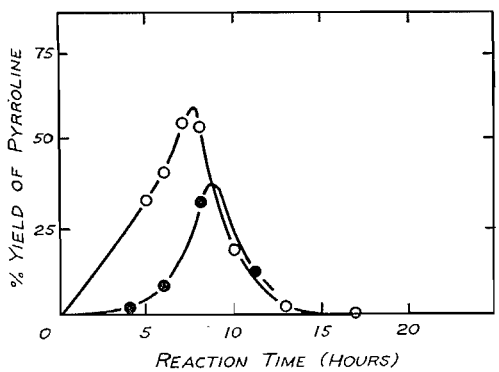


FIG. 1. Per cent yield of 2,3-bis(3,4-dimethoxyphenyl)-3-pyrroline (IX) from cyclization of N-(α-veratrylveratryl)-aminoacetal (VII) in sulphuric acid at 20°C. for various times; ○ in 83% acid, ● in 75% acid.

filtered. The acid-soluble white precipitate weighed 0.44 gm. (56%) and melted at 150–154°C. The melting point was raised to 155.5–156°C. by successive precipitation from hydrochloric acid solution with alkali. Found:

C, 70.3, 70.2; H, 6.9, 6.8; N, 4.05, 4.11, 4.02; OCH_3, 35.7, 35.5%. Calc. for $C_{20}H_{23}O_4N$: C, 70.3; H, 6.8; N, 4.10; OCH_3, 36.4%.

Treatment of the base with acetic anhydride in pyridine for three days at room temperature gave a 94% yield of the N-acetyl derivative melting at 203.5–204°C. Found: N, 3.56, 3.60; OCH_3, 32.1, 32.2%. Calc. for $C_{22}H_{25}O_5N$: N, 3.66; OCH_3, 32.4%.

2,3-Bis(3,4-dimethoxyphenyl)-4-ethylmercaptopyrrolidine Hydrochloride (VIII, R = SC_2H_5)

The acetal (VII), 3.65 gm. (0.0084 mole), was added to a stirred suspension of 15 ml. (0.20 mole) of ethyl mercaptan in 100 ml. of concentrated hydrochloric acid. After 24 hr., the mixture was poured into 100 ml. of water and the solution was washed with benzene. The solution was made alkaline with aqueous sodium hydroxide and again extracted with benzene. The benzene extract, on drying over anhydrous sodium sulphate and evaporating, yielded 1.98 gm. of a colorless oil. This oil was dissolved in acetone and converted to the hydrochloride by treatment with a few drops of the concentrated acid; the gum left on evaporation of the solution slowly crystallized when heated at 60°C. *in vacuo* for two hours. The product, washed with dry acetone and dry ether and then dissolved in a little methanol, was precipitated into dry ether. Weight, 1.38 gm. (37.5%), and m.p. 184–185°C. Found: C, 60.0; H, 5.9; N, 3.08, 2.99; S, 6.90, 7.08; OCH_3, 28.0, 27.9%. Calc. for $C_{22}H_{30}O_4NSCl$: C, 60.0; H, 6.9; N, 3.18; S, 7.28; OCH_3, 28.2%. The base, prepared from the hydrochloride by treatment with alkali, was an oil which appeared to decompose.

A solution of 1.29 gm. (0.003 mole) of the crystalline hydrochloride in water was made alkaline and extracted with benzene. The colorless oil left after evaporation of the dried extract was dissolved in 70 ml. of acetone to which had been added 3.75 gm. of mercuric chloride, 4.8 gm. of cadmium carbonate, and 1.0 ml. of water. The mixture was stirred for 24 hr. at room temperature, and was then filtered. The residue left after evaporation of the filtrate was dissolved in a large volume of chloroform and was washed with dilute aqueous potassium iodide followed by water. Evaporation of the dried chloroform solution left 1.17 gm. of a brilliant yellow solid melting with decomposition at 85°C. The melting point was raised to 109°C. by repeated solution in acetone and precipitation with ether. Found: N, 1.88, 1.90; OCH_3, 16.9, 17.2; Hg, 13.8%. These figures were in the ratio 1.96 N: 8.0 OCH_3: 1.0 Hg.

A solution of 0.800 gm. of this mercury complex in aqueous acetone containing a few drops of acetic acid was treated with hydrogen sulphide until no further precipitation of black mercuric sulphide occurred. This precipitate was dried and weighed to yield the analytical figure for mercury quoted above. The acetone solution was diluted with water, made alkaline, and extracted with benzene. Evaporation of the dried extract left 0.468 gm. of a colorless oil which was negative to tests for halogen and carbonyl groups; yield as the aldol (VIII, R = OH) based on the sulphide (VIII, R = SC_2H_5), 65%.

This oil was treated with 5 ml. of 83% sulphuric acid at room temperature. Aliquots were removed at various intervals and the pyrroline (IX) was

isolated as outlined previously. After 1.5, 3, 5, 7, and 15 hr. the yields of *IX* (based on the oil) were 22, 30, 34, 19, and 2% respectively. The authenticity of these products was established by mixed melting point with samples of the pyrroline (IX).

Condensation of Veratril with Aminoacetal

A mixture of 16.5 gm. (0.05 mole) of veratril and 25.0 gm. (0.17 mole) of aminoacetal was boiled gently under reflux in a nitrogen atmosphere until all of the veratril was dissolved. After cooling, the viscous red product was dissolved in ether and the solution was filtered to remove the unchanged veratril, which in this run weighed only 0.1 gm. The ethereal solution was extracted several times with water to remove the excess aminoacetal, then was dried over anhydrous potassium carbonate and evaporated. On rubbing with a little ethanol, the residue partly crystallized in well-formed white hexagonal plates, which weighed 3.3 gm. (12%) and melted at 98.5–100°C. after one recrystallization from ethanol–water. Two more recrystallizations from ethanol–water raised the melting point to 101–102°C., unchanged by recrystallization from ligroin. Found: C, 64.3, 63.8; H, 7.8, 7.7; N, 4.82, 4.84, 4.89, 4.84; OCH_3, 43.3, 43.4%. Calc. for α,α'-biveratrylideneaminoacetal (XI), $C_{30}H_{44}O_8N_2$: C, 64.3; H, 7.9; N, 5.00; OCH_3 (OC_2H_5 calc. as OCH_3), 44.3%. Another 1.2 gm. of this di-Schiff base was recovered from the eluates of the experiments on column chromatography, bringing the total yield up to 16%. The product was very soluble in methanol, ethanol, ether, chloroform, and benzene, less soluble in hot ligroin, and insoluble in water.

A solution of 47.6 mgm. of the di-Schiff base, 2 ml. of ethanol, and 10 ml. of *N* hydrochloric acid was kept for 10 hr. at room temperature and then filtered. The veratril weighed 6.5 mgm. (23%) and melted at 223.5–224°C. (mixed m.p. undepressed). The recovery of veratril was increased to 42% when the reaction was carried out on the steam bath for six hours under reflux.

Papaveraldine (XII)

Condensation of 3.30 gm. of veratril with 5.0 gm. of aminoacetal as described above gave 6.6 gm. of a partly crystalline red oil, and 0.33 gm. of veratril was recovered. Part of this mixture of Schiff bases, 4.7 gm., was dissolved cautiously in 50 ml. of 72% sulphuric acid and kept for two days at 5°C. and for another three days at room temperature. The dark red solution was poured onto 50 gm. of chopped ice, filtered, and extracted twice with ether. When the aqueous portion was neutralized with 10% sodium carbonate an amorphous buff-colored solid separated, together with much black gummy material. A solution of the solid in benzene was combined with a benzene extract of the filtrate, and applied to a 6 in. alumina column. The black material remained at the top of the column. The benzene eluates were separately evaporated, the residues taken up in dilute hydrochloric acid, and the solutions distilled to dryness under reduced pressure. Some of the fractions yielded a crystalline hydrochloride, m.p. 189–192°C. These fractions were combined, taken up in hot water, and neutralized with concentrated ammonia. The

base which separated, when collected on a filter and washed thoroughly with water, weighed 0.177 gm. (8%) and melted at 205–207°C. One recrystallization from methyl ethyl ketone gave 0.135 gm. of papaveraldine melting at 208–209°C., not depressed on admixture with an authentic sample, m.p. 208–209°C., prepared by oxidation of papaverine with selenium dioxide as described by Taylor (20).

The hydrochloride, prepared by covering the base with 10% hydrochloric acid, heating the mixture on a steam bath, and adding water dropwise until solution was complete, crystallized on cooling in fine yellow needles, m.p. 198–199°C., undepressed on admixture with a sample similarly prepared from authentic papaveraldine. Papaveraldine was reported to melt at 210°C. corr., and its hydrochloride at 200°C. corr. (6, 20).

Veratril Monoanil

A mixture of 3.30 gm. (0.01 mole) of veratril and 4.65 gm. (0.05 mole) of freshly distilled aniline was heated under nitrogen for three hours with steady reflux (bath temp. 230°C.). The mixture partly crystallized on cooling. After being triturated with ether in a mortar, the mixture left a residue of 1.75 gm. which was identified as veratril (52% recovery).

The ethereal mother liquor was evaporated to dryness and the residual oil was mixed with 5 ml. of ethanol. A crop of yellow crystals, 0.757 gm., slowly separated. Further dilution with ethanol yielded two more crops of 0.826 gm. and 0.476 gm. Recrystallization of the middle crop from ethanol gave a product, m.p. 172–173°C. with strong sintering at 159°C., which appeared to be a mixture of two crystalline substances, one pale yellow and the other golden yellow. Recrystallization from ethyl acetate removed the golden yellow impurity, and the veratril monoanil then melted at 172–173°C. Found: C, 70.8, 70.7; H, 5.7, 5.8; N, 3.33, 3.36; OCH_3, 30.5, 30.5%. Calc. for $C_{24}H_{23}O_5N$: C, 71.1; H, 5.7; N, 3.45; OCH_3, 30.6%. The anil was very soluble in chloroform, soluble in benzene, ether, and hot ethyl acetate, slightly soluble in ethanol, and insoluble in water and hexane.

A solution of 30.2 mgm. of veratril monoanil, 2 ml. of ethanol, and 5 ml. of *N* hydrochloric acid was heated on the steam bath for six hours under reflux. After cooling, the mixture was poured into water, allowed to stand undisturbed for several hours, and filtered. The veratril weighed 22.8 mgm. (93%) and melted at 223.5–224°C. (mixed m.p. undepressed).

ACKNOWLEDGMENTS

We wish to thank Mr. A. W. Pross of Canadian Industries (1954) Limited, McMasterville, Que. for determining and interpreting the infrared spectra, and Dr. C. A. Sankey of the Ontario Paper Company, Thorold, Ont. for a generous gift of vanillil. Two of us are grateful for assistance in the form of scholarships from Canadian Industries Limited (D.A.G.), from the Spruce Falls Power and Paper Company (A.W.F.), from the Pulp and Paper Research Institute of Canada (A.W.F.), and from the National Research Council of Canada (D.A.G. and A.W.F.).

THE VAPOR PHASE PHOTOLYSIS OF HEXAFLUOROACETONE IN THE PRESENCE OF METHANE AND ETHANE[1]

By P. B. Ayscough,[2] J. C. Polanyi,[3] and E. W. R. Steacie

ABSTRACT

The photolytic decomposition of hexafluoroacetone by light of wavelength 3130 Å has been used to produce trifluoromethyl radicals for a study of their reactions with methane and ethane. It has been shown that these radicals abstract hydrogen with greater facility than do methyl radicals. The activation energies for the two reactions

$$CF_3 + CH_4 \rightarrow CF_3H + CH_3$$

and

$$CF_3 + C_2H_6 \rightarrow CF_3H + C_2H_5$$

are found to be 10.3 ± 0.5 kcal./mole and 7.5 ± 0.5 kcal./mole respectively, if one can assume zero activation energy for the recombination of trifluoromethyl radicals.

INTRODUCTION

Relatively few kinetic studies have been made on the reactions of fluoroalkyl radicals and most of those so far reported have not yielded very precise data about the elementary reactions of these radicals. In part this is the result of analytical difficulties in handling the mixtures of fluorinated compounds in the reaction products. Further difficulties have arisen because of low quantum yields (as in the photolysis of trifluoromethyl iodide (2, 4, 6)), side reactions caused by the necessity of using high temperatures for pyrolyses (as in the pyrolysis of tristrifluoromethyl arsine (1)), or the production of more than one type of radical in the primary breakdown (as in the photolysis of trifluoroacetone (12)). Some exploratory work on the photolysis of hexafluorodimethyl mercury (11) showed that trifluoromethyl radicals were produced by straightforward fission of the mercury–carbon bonds but the total yield was small on account of the low volatility of the substrate.

During a preliminary study of the photolysis of hexafluoroacetone it was found that this compound fulfills most of the requirements of a source of trifluoromethyl radicals and that a simple analytical procedure can be devised for estimating the products. It was therefore decided to begin a study of the elementary reactions of these radicals with an investigation of their reactions with the simpler hydrocarbons, using the photolysis of hexafluoroacetone as the source of the radicals.

Between 80° and 300°C. hexafluoroacetone yields on photolysis only hexafluoroethane and carbon monoxide, in the stoichiometric proportions. The quantum yield is independent of light intensity and is only slightly affected by pressure in the range used (20–100 mm.). In the presence of hydrocarbons fluoroform is found in the products and under certain conditions replaces the hexafluoroethane almost completely. For instance when 25 mm. hexafluoroacetone is photolyzed at 120°C. in the presence of an equal amount of isobutane

[1]*Manuscript received November 30, 1954.*

over 99% of the fluorine appears in the products as fluoroform. It therefore seems that above 80°C. the primary decomposition is a simple split into radicals

$$CF_3COCF_3 \rightarrow 2\ CF_3 + CO$$

and that these radials can abstract hydrogen or dimerize according to the composition of the reaction mixture. Above 300°C. some attack on the walls of the vessel takes place with the formation of silicon tetrafluoride and carbon dioxide, though the rate of this reaction can be considerably reduced by placing on the inside of the vessel a thin coating of calcium fluoride. No carbon tetrafluoride was found even at the highest temperatures used (about 350°C.) so it appears that the activation energy for reactions such as

$$CF_3 + CF_3COCF_3 \rightarrow CF_4 + CF_3COCF_2$$

is quite high.

A more detailed report on the photolysis of hexafluoroacetone will be presented elsewhere. The present paper describes experiments in which this compound was photolyzed in the presence of methane and ethane.

EXPERIMENTAL

Apparatus

The apparatus was essentially the same as that used in experiments on the photolysis of acetone described in earlier papers from this laboratory. The light source was a B.T.H. high pressure mercury lamp (type ME/D, 250 watts) operated on 220 v. d-c. This lamp gives a concentrated beam of light which was easily collimated by a single quartz lens and a stop. The quartz reaction vessel (10 cm. long, 5 cm. diam.) had a volume of about 190 ml. It was found desirable to use a beam of light of smaller diameter than the vessel in order to reduce attack on the walls by fluorinated radicals at high temperatures, so the illuminated volume was only 62 ml. A layer of calcium fluoride a few wavelengths in thickness was sputtered on to the inside of the vessel to further prevent access of the radicals to the quartz. (It should be stated that there is no proof that these precautions are necessary at the lower temperatures used in studying hydrogen-abstraction reactions such as those reported here. The vessel and optical system were designed for experiments at high temperatures at which this form of attack is troublesome.) The reaction cell was heated in an aluminum block furnace, the temperature of which could be controlled to within 1°C.

All the runs described in this paper were carried out using a combination of 5 cm. nickel sulphate (200 gm./l.), 1 cm. potassium chromate (0.2 gm./l.), 1 cm. potassium hydrogen phthalate (5 gm./l.), and a 3 mm. C.S. 7–54 (9863) filter to isolate the 3130 Å line.

Materials

Two samples of hexafluoroacetone were presented by the Minnesota Mining and Manufacturing Co., to whom we are greatly indebted. Further samples were prepared in collaboration with Dr. L. C. Leitch and Mr. A. T. Morse by the permanganate oxidation of perfluoroisobutene (3, 10). The final sample

after drying over P_2O_5 was distilled in a Podbielniak column and a small middle cut taken for use. This material had a b.p. of −27.8°C. at 754 mm. pressure, and when analyzed on the mass spectrometer showed a spectrum which could be completely identified with that expected from CF_3COCF_3. It was stored in a blackened bulb at liquid air temperature because some decomposition was observed at room temperature. The methane and ethane were Phillips Research Grade and were found by mass spectrometric analysis to contain less than one per cent impurity (mainly higher hydrocarbons).

Procedure

Hexafluoroacetone was admitted to the heated reaction vessel and its pressure measured on a mercury manometer. When methane was to be added the hexafluoroacetone was condensed in a cold finger close to the cell at −180°C. while the methane was admitted. After allowing the hexafluoroacetone to warm up to cell temperature the total pressure was measured. From this the pressure of methane could be obtained. After the reactants were mixed for at least five minutes by means of a Toepler type pump the reaction vessel was isolated by closing a cutoff valve and the light switched on. When ethane was used the two reactants were condensed separately into the cold finger and then mixed as before. The photolyses were allowed to proceed until the amount of decomposition was about five per cent. No correction for pyrolysis was necessary in the experiments described.

Analytical Methods

The products were analyzed by means of two LeRoy stills in conjunction with a mercury diffusion pump and a combined Toepler and gas burette. The bulk of the hexafluoroacetone was condensed in the first still at −145°C. while the second still was maintained at −210°C. to retain all the products except CO (and CH_4 in reactions with this gas). Mixtures of CO and CH_4 were estimated mass spectrometrically. The second still was then raised to −155°C. to collect the C_2F_6, CF_3H, C_2H_6, and SiF_4 and CO_2 if present. Two methods were used to analyze this fraction; the mass spectrometer was used when an approximate estimate of all the components was needed, but in most of the experiments described here C_2F_6 and CF_3H accounted for at least 95% of this fraction and it was found more convenient and probably more accurate to use the infrared absorption of these compounds for the estimation. Both have very strong and sharp bands in the region 1300 cm.$^{-1}$ to 1100 cm.$^{-1}$ and there is very little overlapping. In the presence of a large excess of ethane correction must be made for the pressure broadening of the CF_3H band. When mass spectrometric and infrared analyses were made on the same mixtures the agreement was excellent. The hexafluoroacetone remaining was examined mass spectrometrically for the presence of other products such as CF_3CH_3 and $CF_3CH_2CH_3$, but quantitative analysis for such substances is very uncertain.

RESULTS

In Table I are presented the results of experiments in which hexafluoroacetone was photolyzed in the presence of methane or ethane, together with a

few runs without hydrocarbon. The runs were carried out in several series with different light intensities to show that the value of the ratio $R_{CF_3H}/R^{\frac{1}{2}}_{C_2F_6}$ (CH_4) is not affected by changes in intensity. This method of grouping the results also had the effect of showing that there was none of the progressive change in rate constants due to surface effects that had been a feature of previous investigations (1).

Hexafluoroethane and fluoroform are major products at all temperatures and these clearly result from dimerization and hydrogen-abstraction reactions of trifluoromethyl radicals. The following reaction scheme will account for these products.

$$CF_3COCF_3 \rightarrow 2\ CF_3 + CO \qquad [1]$$

$$2\ CF_3 \rightarrow C_2F_6 \qquad [2]$$

$$CF_3 + CH_4 \rightarrow CF_3H + CH_3 \qquad [3]$$

$$CF_3+C_2H_6 \rightarrow CF_3H+C_2H_5. \quad [3']$$

Since CF_3CH_3 and C_2H_6 were found in appreciable amounts in the products from experiments with methane as substrate it is reasonable to assume that the methyl radicals produced in reaction [3] disappear by reactions such as

$$CH_3+CF_3 \rightarrow CF_3CH_3 \quad [4]$$

and

$$2\ CH_3 \rightarrow C_2H_6. \quad [5]$$

The disappearance of the ethyl radicals produced in reaction [3'] can be accounted for by the analogous reactions

$$C_2H_5+CF_3 \rightarrow CF_3C_2H_5 \quad [4']$$

and

$$2\ C_2H_5 \rightarrow C_4H_{10}. \quad [5']$$

The amount of CF_3CH_3 and C_2H_6 increases markedly with temperature as would be expected from this mechanism. Further support for this reaction scheme can be provided by evaluating the functions

$$R_1 = [2(C_2F_6)+(CF_3H)+(CF_3CH_3)]/CO \text{ and } R_2 = [2(C_2H_6)+(CF_3CH_3)]/CO$$

which should both be equal to unity if all the radicals can be accounted for in this way. For three runs in which complete analyses were made the values were, for R_1, 0.97, 0.95, 0.97 and for R_2, 0.85, 0.90, 1.05. This is considered satisfactory in view of the difficulty of estimating small quantities of CF_3CH_3 in the presence of excess hexafluoroacetone.

If the reaction mechanism suggested is substantially correct, the rate of formation of C_2F_6 can be expressed by

$$R_{C_2F_6} = k_2[CF_3]^2$$

and the rate of formation of CF_3H by

$$R_{CF_3H} = k_3[CF_3][CH_4]$$

or

$$k_3'[CF_3][C_2H_6].$$

From these equations it follows that

$$k_3/k_2^{\frac{1}{2}} = R_{CF_3H}/R_{C_2F_6}^{\frac{1}{2}}[CH_4] = A_3/A_2^{\frac{1}{2}}.e^{-(E_3-\frac{1}{2}E_2)/RT}$$

and

$$k_3'/k_2^{\frac{1}{2}} = R_{CF_3H}/R_{C_2F_6}^{\frac{1}{2}}[C_2H_6] = A_3'/A^{\frac{1}{2}}.e^{-(E_3'-\frac{1}{2}E_2)/RT}.$$

Reference to Fig. 1 will show that the Arrhenius plots for both reactions are straight lines within the experimental error, in the temperature range used. The values obtained by the method of least squares for the differences in activation energy are

$$E_3-\tfrac{1}{2}E_2 = 10.3 \text{ kcal./mole}$$
$$E_3'-\tfrac{1}{2}E_2 = 7.5 \text{ kcal./mole.}$$

Assuming an effective cell volume of 62 ml., the ratios of rate constants at 182°C. (455°K.) are

$$k_3/k_2^{\frac{1}{2}} = 1.52 \times 10^{-12} \text{ (molecule/cc.)}^{-\frac{1}{2}}\text{sec.}^{-\frac{1}{2}}$$
$$k_3'/k_2^{\frac{1}{2}} = 3.18 \times 10^{-11} \text{ (molecule/cc.)}^{-\frac{1}{2}}\text{sec.}^{-\frac{1}{2}}$$

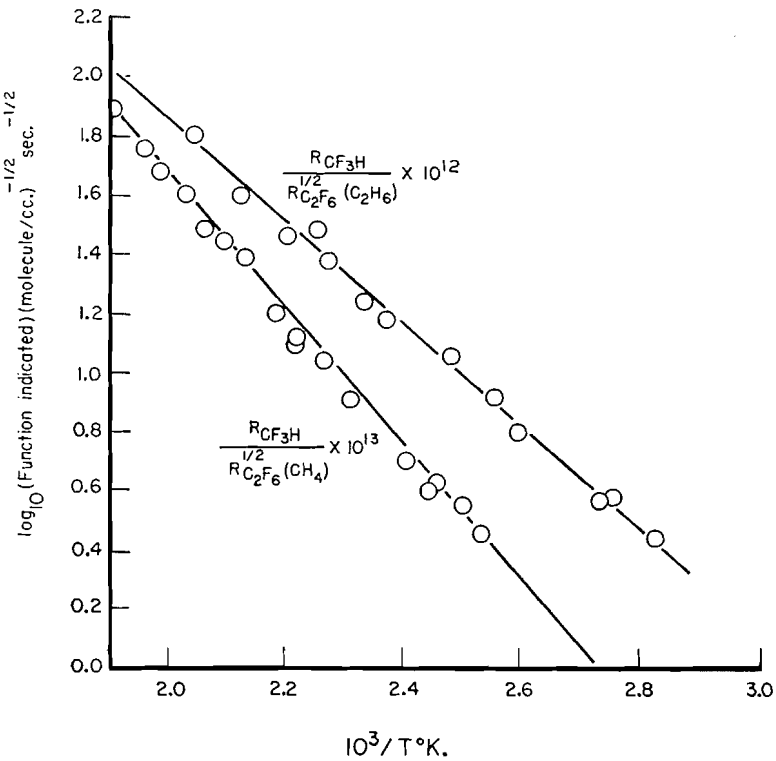

FIG. 1. Arrhenius plots for the photolysis of hexafluoroacetone.

and the ratio of steric factors

$$P_3/P_2^{\frac{1}{2}} = 5 \times 10^{-3}$$
$$P_3'/P_2^{\frac{1}{2}} = 3 \times 10^{-3}.$$

For these calculations the collision diameters assumed were as follows: CH_3, 3.5 Å; CH_4, 3.5 Å; C_2H_6, 4.5 Å; CF_3, 4.0 Å. The mean square deviation of the values of the activation energies is 0.22 kcal./mole in each case, but the systematic errors in the analyses are probably greater and the error is more likely to be about 0.5 kcal./mole.

DISCUSSION

It has been shown that hexafluoroacetone is a convenient source of trifluoromethyl radicals and that the technique used for studies of the reactions of methyl radicals may be applied in a very similar manner to these radicals. At the moment lack of sufficient quantitative data makes a close comparison between methyl and trifluoromethyl radicals rather speculative. In order to use the available data it is necessary to make certain assumptions about the steric factors and activation energies for the dimerization reactions of methyl and trifluoromethyl radicals. It is now reasonably certain that the steric factor for the recombination of methyl radicals is about unity and the activa-

tion energy zero or very nearly so (5, 7, 8), and there seems to be no reason to suppose that the steric factor is markedly different for the dimerization of trifluoromethyl radicals. This suggestion is supported by the fact that the steric factors obtained in this study are "normal" (compare the value 6×10^{-4} obtained by Trotman-Dickenson, Birchard, and Steacie (13) for the reaction $CH_3+C_2H_6 \rightarrow CH_4+C_2H_5$). However, it does not appear to be entirely justifiable to assume zero activation energy for the dimerization of trifluoromethyl radicals. Sieger and Calvert (12) have mentioned this possibility, basing their suggestion on configurational differences between methyl and trifluoromethyl radicals. It seems to us that even if there is no important difference in configuration the marked polarity of the carbon–fluorine bonds will result in dipole–dipole interaction at some stage of the reaction which may cause an energy barrier of significant proportions. However, it is extremely unlikely that it would be as high as 5–6 kcal. which would be necessary to bring the values of E_3 and E_3' into line with the currently accepted values for the analogous reactions $CH_3+CH_4 \rightarrow CH_4+CH_3$ (13–14 kcal.) (14, 9), and $CH_3+C_2H_6 \rightarrow CH_4+C_2H_5$ (about 10.4 kcal.) (13). Thus there is little doubt that trifluoromethyl radicals do abstract hydrogen with greater facility than do methyl radicals, though it would not be wise to suggest that the observed differences in activation energies for abstraction by methyl and trifluoromethyl radicals have any great quantitative significance. On the basis of present information the difference appears to be about 3 kcal./mole, assuming for the moment zero activation energy for the reaction $2\ CF_3 \rightarrow C_2F_6$. Sieger and Calvert give a value of 2.3 kcal./mole for this difference in the case of abstraction of hydrogen from trifluoroacetone (12). It is, however, clearly desirable to determine the rate constants of the dimerization reaction with sufficient accuracy to evaluate the activation energy and pre-exponential factors before discussing this question further.

ACKNOWLEDGMENT

We are indebted to Mr. R. Lauzon for assistance in the infrared analyses and to Miss F. Gauthier and Miss J. Fuller for the mass spectrometric analyses.

FREE RADICAL RECOMBINATION IN THE PHOTOLYSIS OF ACETONE[1]

By S. N. Naldrett[2]

ABSTRACT

$(CH_3CO)_2$-1-C^{14} (I) was prepared by irradiating $(CH_3)_2CO$ in the presence of CH_3I-C^{14}. Acetone was then irradiated at room temperature with light of 2537 Å in the presence of (I). Radioactivity was found in all products which contained methyl groups but not in any carbon monoxide product. The amount of carbon-14 ultimately found in acetone confirms that the quantum efficiency of the primary photolytic process is nearly unity and that extensive recombination of methyl and acetyl radicals to form acetone is responsible for the low over-all quantum efficiency of decomposition.

INTRODUCTION

The photolysis of acetone has been exhaustively investigated. (For reviews see Dorfman and Noyes (2) and Steacie (7).) One important feature of the mechanism is the explanation of the low quantum yield at low temperatures by the recombination reaction:

$$CH_3 + CH_3CO \rightarrow CH_3COCH_3.$$

It seemed of value to make a direct check of this reaction by the use of radioactive carbon.

EXPERIMENTAL

The Photolysis System

Irradiations were carried out in a cylindrical quartz vessel 45 mm. in diameter and 108 mm. long with polished plane parallel windows. Illumination was supplied by a neon-mercury resonance lamp in a quartz envelope with a filter of chlorine gas so that the light was mostly 2537 Å. Three different lamps were used in the course of the experiments. All irradiations were carried out at room temperature.

Measurement of Radioactivity

All samples were counted in Geiger-Mueller tubes as gases, so that no counts were lost because of self-absorption or window absorption and only a geometry correction was necessary. The counting efficiency of each gas mixture was checked by the response given to an external radioactive standard. Usually no external quench was required, but if necessary a Neher-Harper type of electronic quenching circuit was used. Sufficient counts were observed so that the uncertainty in the count rate recorded was less than other errors such as measurement of sample size, loss by adsorption, or in stopcock grease, etc.

Preparation of Biacetyl-1-C^{14}

Active $(CH_3CO)_2$ was prepared by irradiating a mixture of CH_3COCH_3 and CH_3I-C^{14} in the vapor phase. In the first attempt a mixture of 2.7×10^{-3}

[1]*Manuscript received October 22, 1954.*

[2]*Present address: Royal Military College, Kingston, Canada.*

moles acetone and 8.6×10^{-5} moles of active methyl iodide with an activity of 1.9×10^{7} disintegrations per minute was irradiated for 110 hr. with a current of 30 ma. through the lamp in the irradiation system described. Less than 0.5% of the activity was recovered as $(CH_3CO)_2$-C^{14} and since the amount was not sufficient, the preparation was repeated. For the second preparation a mixture of 5.6×10^{-3} moles of acetone and 2.3×10^{-5} moles of CH_3I-C^{14} with an activity of 8.5×10^{7} d.p.m. was irradiated for 690 hr. with a lamp current of 100 ma. The light absorbed in the cell was of the order of 10^{19} quanta/hour. A tubulation which had been added to the irradiation cell was kept at 0°C. and served to reduce the amount of biacetyl vapor in the light beam, so that reaction to carbon monoxide and ethane was reduced. The 3.8×10^{-4} moles of biacetyl recovered had an activity of 7.4×10^{6} d.p.m. This amounts to 9.1% of the total methyl groups and 8.7% of the total activity in the reaction cell. Although neither of these figures is very reliable, the similarity between them seems to indicate that there has been a very high degree of exchange of methyl radicals amongst the molecules CH_3I, CH_3COCH_3, and $(CH_3CO)_2$.

Purification of Biacetyl-1-C^{14}

Radioactive tracers and also mass spectrometer analysis showed that biacetyl and acetone were not separated by low pressure fractionation in a Ward type still to the extent expected from their relative vapor pressures. However, for the purpose of this project the presence of acetone in the biacetyl was not a disadvantage, provided that the acetone was not radioactive. To ensure this, bulk amounts of inactive biacetyl (about 0.75 gm.) and of inactive acetone (about 0.3 gm.) were added to the micro amount of active biacetyl product, and the acetone fraction was then separated in the Ward type still. Further additions of inactive acetone and fractionations were made until the process had been repeated seven times. No further changes in the specific radioactivities of either the biacetyl or acetone fractions were observed in the last three fractionations, indicating that the removal of radioactive acetone was complete. Mass spectrometer analysis showed that there was about 14% inactive acetone in the active biacetyl sample.

Analysis of the Products

After the irradiation the products were separated into fractions by means of a Ward-Savelli still (5). The temperatures of the four condensers were set at −183°; −140°; −78°; −60° respectively, and the fractions as separated consisted largely of (1) CH_4 and CO; (2) C_2H_6; (3) $(CH_3)_2CO$, and (4) $(CH_3CO)_2$. The carbon monoxide was removed from the methane fraction by oxidation over hot copper oxide and absorption in Ascarite. No measurable amount of hydrogen was found in preliminary runs and attempts to estimate it separately from the carbon monoxide were discontinued. The volumes of the fractions were measured and the quantities are shown in Table I as moles $\times 10^{5}$. The analysis of the products of Photolyses Nos. 6 and 7 was made by means of a mass spectrometer.

The radioactivity of each of the fractions was measured directly in Experiments 1, 3, and 5. In the other experiments each fraction was further treated after the volume was measured, by addition of carriers and hold-back carriers and refractionated until radiochemical purity was attained. For example, after the volume of the acetone product had been measured, there was added to it convenient amounts of ethane, acetone, and biacetyl, and the acetone fraction was again recovered by fractionation in the Ward-Savelli still. The process was repeated, usually three times, until it was assured that the radioactivity was definitely associated with the substance being determined and not with a contaminant. Some of the product was sacrificed to the more volatile and to the less volatile carriers at each fractionation, and in the end the total radioactivity recovered in all of the products was only about one half the total activity of the reactants.

OBSERVATIONS AND DISCUSSIONS

The results of some typical experiments are listed in Table I. Experiment No. 2 shows results which are typical of the behavior of pure acetone when irradiated in this system; the results are quite similar to what has been reported by others. Experiment No. 1 shows typical behavior of pure biacetyl; these observations also are similar to what has been reported by others (1). The remainder of the table indicates what was observed when mixtures of radioactive biacetyl and inactive acetone were irradiated. The products obtained in these experiments are not far different from the composite which would result from the separate irradiation of the biacetyl and the acetone. The addition of biacetyl therefore does not seem to have any particular effect on the decomposition of acetone and the conclusions can probably be applied to the photolysis of pure acetone.

The most significant feature of the observations is that after irradiation, radioactivity is present in every substance which contains methyl radicals, but no radioactivity was found in the carbon monoxide fraction in any experiment. This confirms the fact that free radicals play a major role in the photolysis reactions and that recombination of free radicals to acetone occurs.

The next to the last column in the table shows an estimate of the degree of exchange of radicals amongst acetone and the other substances. This figure is simply the ratio of the specific activity of the methyl groups in acetone to the average specific activity of all methyl groups recovered. However, for some experiments only about half of the original radioactivity was recovered, and in using this figure as a measure of the extent of exchange, it is assumed that the fraction of active acetone lost between the first measurement of volume and the counting after purification is the same as the average loss of the other active compounds. Of course this assumption may be in error; the only justification for it is that it gives results which are consistent with those obtained in experiments in which nearly all of the radioactivity was recovered, and in which this assumption does not enter. It would appear that exchange was from one fifth to three fifths completed by the irradiation given in these experiments.

The results indicate that the exchange increased with irradiation, although a precise measurement of the number of quanta absorbed was not made. The dimensions and the intensity of the light beam in these experiments were not carefully controlled since the irradiations extended over several days and had to be left unattended. However, an estimate of limited value can be made from the yield of carbon monoxide. The quantum efficiency for the production of carbon monoxide in the photolysis of acetone at room temperature by light of 2537 Å was determined by Herr and Noyes (3) to be 0.22 for somewhat similar light intensities and pressures of acetone. The validity of this figure for the conditions of the experiments described here was established by determining the amount of hydrolysis of a solution of monochloroacetic acid (6) under the same experimental conditions before and after Photolysis No. 6. The light absorbed by the cell from Lamp C during Photolysis No. 6 was thereby determined to be 2.8×10^{18} quanta per hour, and the quantum efficiency of carbon monoxide production from these data is 0.20. This figure was used to calculate the total quanta absorbed, and the quanta per molecule for each photolysis as shown in the table. The differences in the absorption coefficients of biacetyl and acetone for the radiation involved is certainly less than 10% (4) and therefore equal absorption has been assumed in making the calculations.

On the simplest assumption that one quantum per molecule will produce free radicals and permit exchange, it would be expected that the figure for degree of exchange would be similar to the figure for quanta absorbed per molecule. These figures are reasonably similar except for Photolysis No. 8, and for this experiment the estimate of quanta absorbed from carbon monoxide production seems too low by comparison with Photolysis No. 3 in which the same lamp was used for a shorter irradiation. These observations are confirmatory evidence that the quantum efficiency is close to unity for the primary process: $CH_3COCH_3+h\nu = CH_3+CH_3CO$ and that the recombination of radicals to reform acetone accounts for the low over-all quantum efficiency of decomposition of acetone.

The behavior of $C^{12}H_3$ and $C^{12}H_3CO$ will, of course, not be quite the same as that of the C^{14} compounds. The isotope effect will, however, be negligible as far as our present purpose is concerned.

ACKNOWLEDGMENT

The author is grateful to Dr. F. P. Lossing for the mass-spectrometer analyses, and to Dr. E. W. R. Steacie for generous assistance with the photochemical technique, and many helpful discussions.

THE DETERMINATION OF MOLECULAR WEIGHT[1]

By A. F. Sirianni and I. E. Puddington

ABSTRACT

The molecular weights of organic compounds of known constitution have been determined with satisfactory accuracy, using milligram quantities of materials, by a static measurement of the vapor pressure difference between pure solvents and solutions of the compounds. The method may be used over a considerable temperature range. The suitability of solvents is governed by their chemical stability and vapor pressure. Results obtained using compounds in the molecular weight range of 600–1000 are reported.

INTRODUCTION

A previous publication (4) indicated some success in using static measurements of the difference in vapor pressure between pure solvents and solutions to estimate the molecular weights of non-ionizing solutes. The procedure utilized a mercury micromanometer that was relatively insensitive to the vibration normally encountered in laboratories. In the previous work compounds having molecular weights below about 350 were used and the measurements were all made at 20°C., using solvents to which a hydrocarbon base stopcock lubricant was substantially inert.

Since the method appeared to be applicable to the measurement of the molecular weights of polymers with relatively low degrees of polymerization, it seemed desirable to extend the temperature range of the instrument and to increase the number of usable solvents, by eliminating the possible contamination from stopcock grease. As this has involved considerable modification in the construction and operation of the apparatus, the present communication is intended to record some of the more essential refinements that have been suggested as the result of several years of use and to indicate results that have been obtained. Compounds of molecular weight up to about 1000 that had known constitutions, with a variety of solvents, concentrations, and temperatures, have now been used successfully.

APPARATUS AND EXPERIMENTAL

The apparatus that was eventually adopted is shown in Fig. 1. Part *A* was built in such a way that it could be enclosed by a thermostat constructed of "aluminum foil backed masonite" and "ten test", equipped with heaters, fans, and thermoregulators to give temperatures that varied not more than ±1°C. in various locations within the box and ±0.1°C. in any one location, over the range 30° to 100°.

Continuous resistance heaters controlled by variacs were located on the side walls of the thermostat and a low power intermittent heater controlled by the thermoregulator was located in the slip stream of a 10 in. fan. The manometer and burette were enclosed in a secondary ten-test box, open at

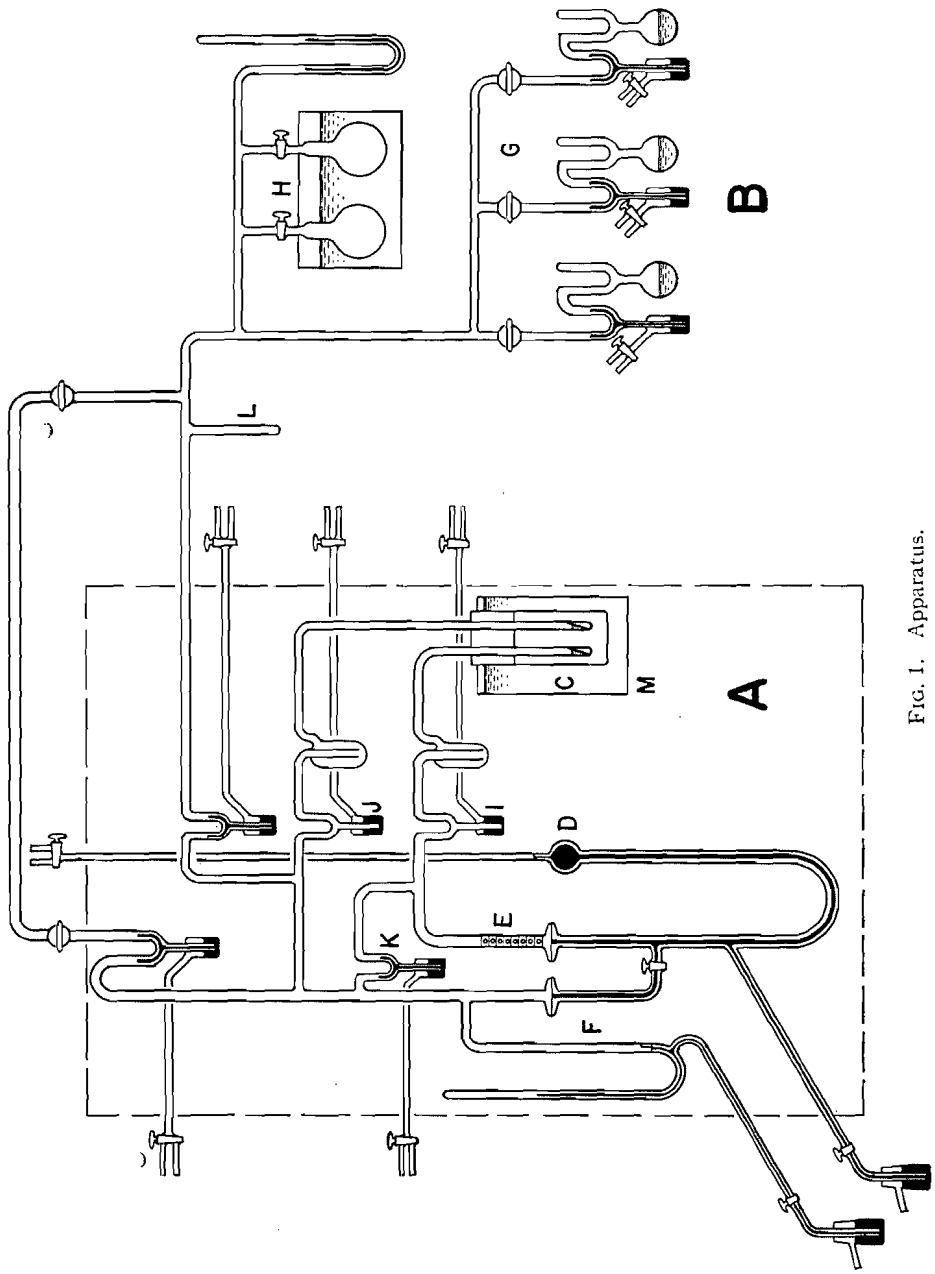

FIG. 1. Apparatus.

the top and containing an 8 in. fan blowing outward, located in one side near the bottom, to give a continuous downward flow of air through the box. The temperature within this box did not vary by more than 0.2°C. Thermostat "*C*" contained the solution and solvent holders enclosed in a copper block, the details of which are shown in Fig. 2. This thermostat consisted of a

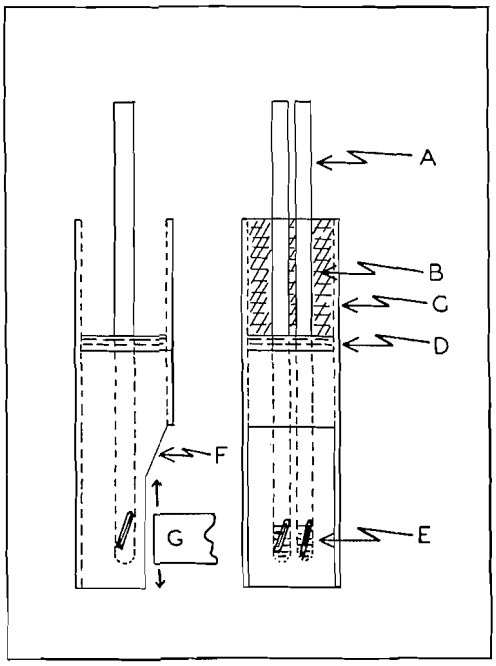

FIG. 2. Enlarged view of copper block. *A*, sample holders; *B*, glass wool insulation; *C*, cellulose acetate sleeve; *D*, mercury film; *E*, stirrers; *F*, recessed portion of copper block; *G*, magnet.

2 liter, wide mouth, dewar flask. It was maintained at 10–30° below the air thermostat to prevent solvent condensation in the connecting tubing. The temperature of the oil contained in the thermostat was controlled to ±0.0005°C. Good thermal contact was maintained between the sample holders and the copper block with a film of mercury and the copper block itself was partially insulated from the bath with a piece of cellulose acetate tubing and a heavy coat of shellac. Both solution and solvent were stirred with glass sheathed bars of iron, actuated by an alnico magnet that oscillated in a vertical direction with a frequency of about 20–25 cycles per minute.

As suggested in the earlier paper, etching of the inside of the two bulbs forming the arms of the U tube was found desirable to give reproducible contact angles at the mercury–glass–vapor interface. This is important since the operation of the manometer assumes that the volume of mercury transferred between the arms of the U tube is proportional to the pressure change. Experiments have indicated that the contact angle is quite sensitive to temperature changes, changes in the type of vapor contained in the bulb, and probably to large differences in the pressure of any one vapor. No pair of

bulbs yet used seems to behave in an identical fashion and while the zero point of the instrument has remained constant to ± 0.001 mm. for periods up to 10 days, if conditions are kept reasonably constant, it may change substantially if, for example, alcohol vapor is substituted for benzene or the vapor pressure of the solvent is raised by several centimeters with mercury cutoff K open. These effects obviously become more important as the magnification factor of the instrument is increased. The behavior of the manometer was invariably good if the contact angle was sufficiently diffuse that no sharp line of contact was visible at the mercury–glass interface. It could frequently be improved by contaminating the mercury surface with about 10^{-7} to 10^{-9} gm. of lithium stearate added in distilled methanol. Contact angles rarely gave any trouble, however, at temperatures above about 30°C.

The most convenient method found for etching the bulbs to the desired degree consists in placing a few grams of 200–325 mesh carborundum in the bulbs along with a few cubic centimeters of water and sections of flattened lead shot. The bulbs are then rotated for 16–24 hr. at a speed just below that required to carry the pieces of lead around with the rotating bulb. This must be followed by a thorough cleaning and steaming before the bulbs are fixed into the rest of the apparatus. Final traces of grinding residues were sometimes removed by reducing the pressure suddenly when the glass surface was wet with methanol.

All of the stopcocks within the thermostat in contact with the solvent vapor were replaced with short arm mercury cutoffs equipped with glass check valves. The cutoffs could be controlled by two way stopcocks located outside the thermostat. The stopcock separating the two arms of the U tube was lubricated with a film of dried aquadag* plus a very thin film of heavy lithium stearate grease. This tap was operated by a felt lined stirrup attached to an iron rod extending through the top of the thermostat. It did not have to be relubricated more frequently than once in two years. It was exposed to temperatures up to 90°C. A mercury sealed 4 mm. pyrex stopcock similar to Corning 7500 was found quite satisfactory for this valve. The large bulbs and the stopcock were set in plaster of Paris to ensure rigidity.

In order to increase the range of the manometer, a series of small bulbs about equal to the measuring capillary in volume were located in the short piece of capillary (E) above the right hand arm of the U tube. These bulbs were marked volumetrically with etches. If, during a measurement, the tail end of the mercury thread was off scale when the advancing end reached the first etch, it was merely pushed on to the etch that allowed a reading to be made on the measuring capillary. In the present case three bulbs were used to give a total range of about two millimeters pressure difference, with a magnification of approximately 2000. The diameters of the bulbs that formed the arms of the U tubes were about 5 cm.

A change in manometer design was examined wherein the essential difference was the reversal of the positions of the measuring capillary and bulb D.

**A dispersion of graphite in water prepared by the Acheson Colloids Corp., Port Huron, Michigan, U.S.A.*

The expansions in capillary *E* were then placed below the bulb forming the right hand arm of the U tube. In this model the volume of mercury in the right hand arm was measured by withdrawing it into the empty bulb *D* and again noting the location of the mercury thread in the measuring capillary when the tail end of the mercury was at a convenient etch. While this design offered the advantages at high magnifications of using much less mercury and of a considerable saving of time, during readings, owing to the fact that only a small thread of mercury rather than a large volume had to pass through the measuring capillary, the older model was quite satisfactory for most work.

In making a molecular weight determination, the solute in amounts varying from 0.1 to about 2 mgm. was weighed into a 3 to 4 mm. i.d. pyrex tube. After placing the stirrer within the tube, it was sealed to the apparatus and the pressure reduced to about 10^{-5} mm. Pure solvents, previously deaired by refluxing *in vacuo* until a sample of the vapor could be condensed into a 1 mm. capillary to give a thread of liquid containing no bubbles, were stored in the bulbs *B* outside of the air thermostat.

A cold finger containing dry ice made a satisfactory reflux condenser for the deairing procedure. Although slightly different methods were used with the various solvents, the Reagent Grade compounds were usually passed through a chromatographic column packed with silica gel and alumina, and dried with calcium hydride (1, 2) wherever practicable, prior to degassing. The amount of solvent to be used was measured in the vapor state in the calibrated volumes *H* contained in a thermostat. After the solvent vapor in the connecting tubing was condensed into the reservoir, the vapor in one of the bulbs "*H*" was quantitatively condensed on the solute sample. The requirement on the solvent side could then be supplied from the other bulb, and the solvent and solution connected to their respective sides of the manometer. If the determination was the first after the interior of the apparatus had been exposed to the air, it was flushed with solvent vapor, to displace residual air or water vapor adsorbed on the glass walls, and re-evacuated.

In the early operation of the apparatus it was learned that the manometer provided a sensitive means of testing the purity of the solvent. If pure solvent was condensed in about the same volume in both the solvent and solution holders, no vapor pressure difference should be detectable after successive portions were removed from one of the containers. Solvents of this purity are not infrequently difficult to obtain, however, and in order to reduce any fractionation of solvent that might occur to a minimum during a determination, two closely similar volumes were used at *H*. The dead space on either side of the U tube was made the same, the final adjustment being made by selection of the position in *F* to which the mercury was adjusted to read the vapor pressure of the pure solvent. Small compensating adjustments in volume required by the use of different size sample holders could be made by changing slightly the position of the mercury level in the necks of cutoffs *I* and *J* before a vapor pressure difference was measured. Since the apparatus was contained in a thermostat, thermal expansion of the mercury was not a problem. The zero point of the manometer needed to be checked only in-

frequently, usually after a series of readings for one concentration. The null point not infrequently varied from run to run but this appeared to be due to the distillation of mercury within the system when no solvent vapor was present. There was no indication of a zero point change during a run.

As observed by Frazer and his associates (3) the attainment of vapor pressure equilibrium required only about 30 min. provided the solvent was air free; a trace of air increased this time considerably, however. When high vapor pressures were used, it was necessary to know the dead space on the solution side of the manometer accurately since the concentration of the solution was determined by making the appropriate dead space correction on the amount of solvent measured in *H*.

By condensing the solvent in side arm *L* after a determination was completed, the solvent could be used over again to prepare a slightly more concentrated solution for a second determination. It was thus possible to measure the vapor pressure difference on a rather wide range of solution concentration on a single solute sample and with a minimum expenditure of pure solvent. A usual solution contained between 15 and 90 mgm. of solvent.

Consecutive readings of vapor pressure lowering on the same sample normally did not vary by more than one per cent.

RESULTS

The results of the determination of molecular weight of sucrose octaacetate (mol. wt. = 678), raffinose hendecaacetate* (mol. wt. = 967), and three samples of bitumen† in various solvents and at a number of temperatures are shown in the accompanying graphs. Variations from the mean are normally

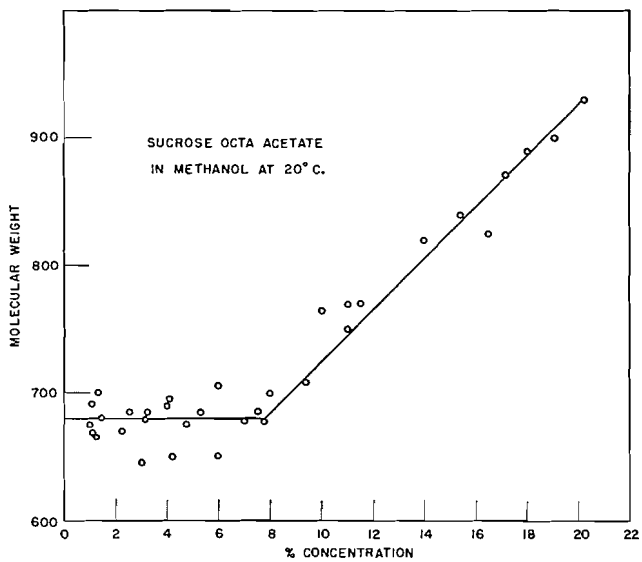

FIG. 3. Variation in molecular weight of sucrose octaacetate with concentration in methanol at 20°C.

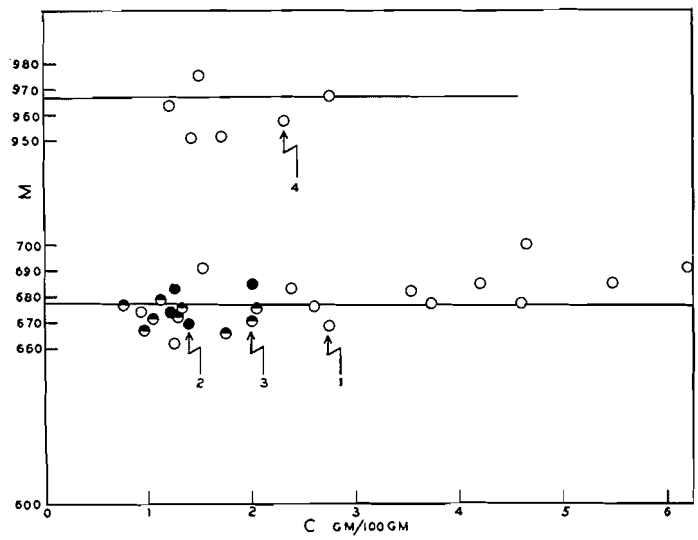

FIG. 4. Molecular weight of sucrose octaacetate and raffinose hendecaacetate in benzene at various temperatures: (1) sucrose octaacetate at 30°C., (2) sucrose octaacetate at 50°C., (3) sucrose octaacetate at 55°C., (4) raffinose hendecaacetate at 55°C. Solid lines in each case represent theoretical molecular weight.

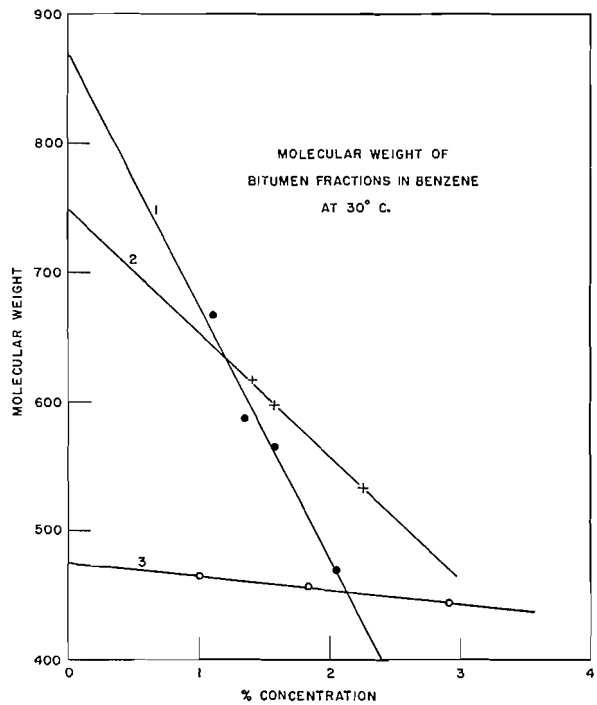

FIG. 5. Molecular weight vs. concentration for three samples of bitumen in benzene at 30°C.

not more than two per cent. With the crystalline materials dependence of molecular weight on concentration over the range examined was noted only with sucrose octaacetate in methanol at 20°C. and in concentrations in excess of 8% by weight. This is probably due to association of the solute. The bitumen samples on the other hand behaved like polymers. The weight of solute used in all cases was between 0.3 and 1.1 mgm. The method has been used successfully to determine the molecular weights of polymers up to about 20,000. The results of this work will be presented in a future publication.

PARTICLE MOTIONS IN SHEARED SUSPENSIONS

III. FURTHER OBSERVATIONS ON COLLISIONS OF SPHERES[1]

By R. St. J. Manley[2] and S. G. Mason

ABSTRACT

Two-body interactions between glass spheres of diameters a_1 and a_2 caused by velocity gradients vary with a_1/a_2. When $1 < a_1/a_2 < 2$, well-defined collisions similar to those previously reported for spheres of equal size can be observed. Fair agreement is found between the experimentally observed and calculated collision frequencies over a range of particle concentrations and velocity gradients. When $a_1/a_2 > 2$ the particles are separated at all times and the phenomena of interaction are more complex. Single air bubbles rotate at the same angular velocity as rigid spheres. When two air bubbles of equal size are brought into collision a doublet is formed; instead of the mirror-image separation observed with neutral rigid spheres, the doublet continues to rotate for as many as 60 rotations before coalescence occurs. Less frequently a doublet with distinct particle separation is observed. Periods of rotation of both types of doublet and certain details of the rotational orbit of a doublet of touching air bubbles have been measured and compared with values predicted from Jeffery's theoretical equations for rigid ellipsoids. Apart from their intrinsic interest, the phenomena described are of importance in theories of viscosity and coagulation of suspensions and colloidal dispersions.

INTRODUCTION

In an earlier paper (5), the two-body collisions of rigid neutral spheres of equal size suspended in a liquid subjected to a velocity gradient were described in some detail. It was shown experimentally that in a simple field of fluid shear described by

$$u = Gy, \qquad v, w = 0 \tag{1}$$

where u, v, and w are the respective velocities along the X-, Y-, and Z-axes and G is the rate of shear, two spheres can approach one another along an undisturbed rectilinear path parallel to the X-axis until they come into apparent collision at the rate

$$f = 4a^3nG/3 \tag{2}$$

$$= 8cG/\pi\,. \tag{3}$$

Here, f denotes the number of collisions per particle per unit time, a the particle diameter, n the number of particles per unit volume of suspension, and c the volume of particles in the suspension.

The doublet formed by two colliding spheres rotates about the Z-axis at a constant angular velocity

$$\omega = G/2 \tag{4}$$

until it reaches the mirror image through the Y–Z plane of the initial position of contact; the two particles then separate.

The measured values of the mean and maximum doublet lives and the distribution function of doublet lives were shown to be in good agreement with values calculated from the experimentally established mechanism of doublet behavior. Most of the experimental evidence suggested that the contact between the spheres of the doublet is real, resulting from a force which is generated by distortion of the local field of fluid motion and which operates to push the particles together. In one set of experiments, however, in which the motion was interrupted by a period of quiescence, the behavior of the doublets suggested that the particles do not come into true contact (5).

Equations [2] and [3] are readily derived (5, 8) by calculating the number of particle centers which are carried in unit time along rectilinear paths parallel to the X-axis, at the translational velocities given by equation [1], into a "collision sphere" of radius a drawn about the center of a reference sphere. For simplicity the reference sphere is placed at the origin of the coordinate system. If two spheres of different diameters a_1 and a_2 approach one another in a similar manner until they collide, the binary collision frequency is obtained by substituting $(a_1+a_2)/2$ for a in equation [2], i.e.

[5] $$f_{12} = (a_1+a_2)^3 n_2 G/6$$

where f_{12} is the number of collisions per unit time suffered by a type-1 sphere with type-2 spheres, and n_2 is the number concentration of the latter. If c_2 is the volume fraction of type-2 spheres in the suspension, $\pi a_2^3 n_2/6 = c_2$, whence by substitution in equation [5]

[6] $$f_{12} = \frac{(a_1+a_2)^3}{a_2^3} c_2 G.$$

The present paper deals with an experimental study of interactions in binary suspensions of rigid spheres of different diameter ratios and in suspensions of air bubbles of approximately equal size. These experiments were carried out to extend the earlier observations (5), to test equation [6], and to attempt to resolve the question of whether or not the two spheres of a doublet come into true physical contact. Although the question of contact remains incompletely answered, a number of interesting and, it is believed, significant observations were made which have application to theories of viscosity and coagulation of suspensions and colloidal dispersions.

EXPERIMENTAL PART

The experiments were conducted in the concentric cylinder apparatus previously described (9). Single particles and doublets were observed at the origin of a field of motion as defined by equation [1], through a microscope directed along the Y-axis of the coordinate system so that the particles were viewed as their projections on the X–Z plane (Fig. 1). The velocity gradient G could be calculated with a precision of 0.1% from the measured speeds of rotation and could be varied continuously from 0 to 2.5 sec^{-1}.

Binary suspensions of rigid spheres were prepared by suspending glass spheres ranging from 5μ to 180μ in diameter in corn sirup having a viscosity of about 50 poises and a density of 1.3 gm./cc. The experimental methods for

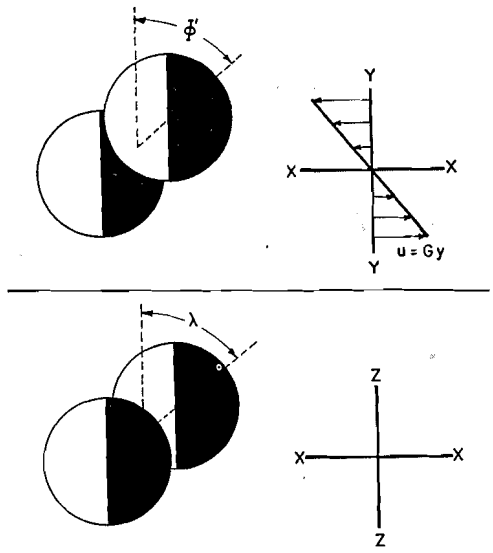

FIG. 1. Coordinate system for describing velocity gradients and motions of spherical doublets. Experimental observations are made along Y-axis so that particles are viewed as projections on the X–Z plane. ϕ' is the azimuthal angle referred to Z as the polar axis, and λ the azimuthal angle referred to Y as polar axis. The angular velocity $\omega = -d\phi'/dt$.

uniform dispersion and deaeration previously employed with monodisperse systems were used (5). For measurements of the collision frequency f_{12}, a supply of two sizes of glass spheres having a narrow size distribution was prepared by screen fractionation of bulk samples. The size spectra are given in Table I. Suspensions of volume concentration c_2 from 0.4 to 1.6% were prepared; each of these suspensions contained about 0.02 volume per cent of type-1 spheres which were used as reference particles.

TABLE I

SIZE DISTRIBUTION OF SPHERES

Diameter a_1, μ	% of diameter $< a_1$	Diameter a_2, μ	% of diameter $< a_2$
160	0.91	107	2.5
165	17.3	112	28.6
175	49.0	117	74.0
185	91.0	122	95.0
190	100.0	127	100.0
Number average diameter = 179μ		Number average diameter = 117μ	
Standard deviation = 9.0μ		Standard deviation = 4.4μ	

Attempts to produce suitable uniform dispersions of fluid drops were only partly successful. However, dilute "foams" of air bubbles of unknown and variable concentration were prepared by vigorous mechanical stirring of viscous liquids such as corn sirup and glycerine. After agitation, the systems were allowed to stand so that larger bubbles rose to the surface leaving behind bubbles of fairly uniform diameter of about 150μ.

RESULTS

1. *Glass Spheres*

General

The type of interaction between two spheres of diameters a_1 and a_2 (where $a_1 > a_2$) was found to depend upon the ratio a_1/a_2. In systems in which $a_1/a_2 < 2$ approx., collisions were easily recognizable and, indeed, were similar to those of equal-sized spheres (5). The doublet formed by the two colliding particles appeared to rotate as a rigid dumbbell until a position was reached which was a mirror image about the Y–Z plane of the point of initial contact; separation then occurred and each sphere was restored to the same y-coordinate existing before the onset of collision.

When $a_1/a_2 > 2$, the interactions were much more complex and the particles could be seen to be separated at all times. One striking type which was repeatedly observed was as follows: upon approaching a large sphere, a small sphere began to describe the type of planetary motion around the large one as illustrated in Fig. 2, moving in a gradually widening spiral path past the

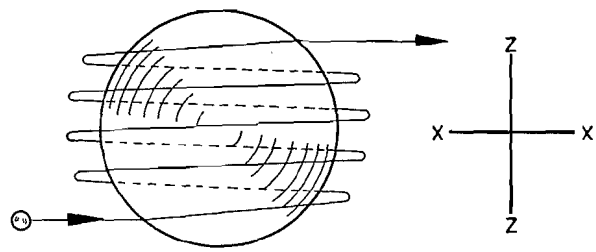

FIG. 2. Planetary motion of a sphere moving in an upward spiral path around a larger reference sphere (schematic).

equatorial plane until it attained a latitude roughly equivalent to that at which it started. It then separated from the large sphere at a velocity which appeared to be equal to that with which it approached. Upon reversal of the field of fluid motion (by reversing the directions of rotation of the two concentric cylinders), it was found that the smaller sphere continued to move upwards. In a number of instances, a "zig-zag" motion of the small sphere upwards in a roughly constant X–Z plane was also observed.

Collision Frequency

These measurements were made using spheres having the dimensions given in Table I. The collision frequency f_{12} was determined over a range of values of c_2 and G in the same manner as for monodisperse spheres (5). The results together with the values calculated from equation [6] are summarized in Table II. For a total of 857 observed collisions the ratio $f_{obs}/f_{calc} = 1.08$; since the standard deviation of this ratio is estimated to be 16% from the spreads in particle diameters given in Table I and 3% from the random sampling error of 900 collisions, the agreement may be considered satisfactory.

TABLE II

COMPARISON OF OBSERVED AND CALCULATED COLLISION FREQUENCIES

**Number of collisions counted.*

2. *Air Bubbles*

General

Single air bubbles were not visibly deformed up to the highest velocity gradients attempted (2.5 sec.$^{-1}$) and were found to spin about the Z-axis in the same manner as rigid spheres (9). Two bubbles, upon approaching one another, formed a doublet which rotated about the Z-axis; however, instead of rotating through the angle 2ϕ, where ϕ ($< \pi/2$) is the azimuthal angle corresponding to the point of initial contact (Fig. 1), and then separating at the mirror image of the initial position of contact ($-\phi$) as was observed with equal-sized glass spheres (5), the doublet continued to rotate for as many as 60 complete rotations over a period as long as one-half hour, *until the pair suddenly coalesced into a single bubble.* During the interval between initial contact and coalescence, the doublet rotated about the Z-axis in a manner qualitatively similar to that of a rigid cylindrical particle, i.e. somewhat like

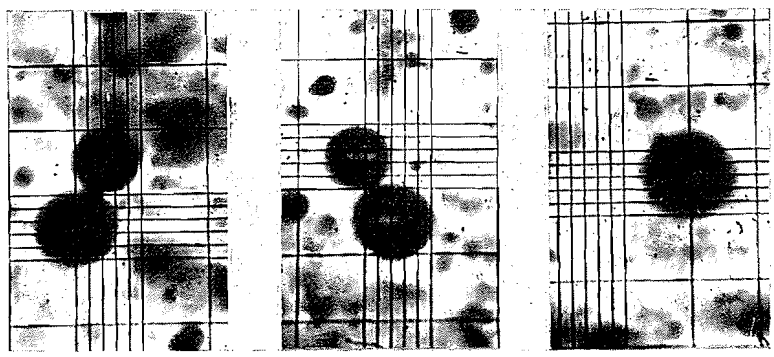

FIG. 3. Photomicrographs of a doublet of air bubbles (of different diameters) at $\lambda > 0$ (No. 1), $\lambda < 0$ (No. 2), and after coalescence to a single sphere (No. 3).

a precessing gyroscope (9). A doublet in two positions before and one position after coalescence to a single sphere is shown in the photomicrographs in Fig. 3.

Practically all of the interactions observed were as described above, i.e. the bubbles came into apparent contact and after a time coalesced. In many instances, a doublet of bubbles in contact collided with a singlet to form a triplet of which a pair eventually coalesced, thus forming a doublet which eventually coalesced into a singlet. In a number of cases doublets were formed in which the bubbles were clearly separated, but which executed a number of complete rotations as a pair and then separated.

Rotation of Single Bubbles

It has been shown theoretically (4, 11) and confirmed experimentally (9) that a single rigid sphere spins about the Z-axis at the angular velocity given by equation [4], i.e. with a period

$$[7] \qquad T_1 = 4\pi/G.$$

It was considered to be of interest to see how closely equation [7] was followed by air bubbles.

Although the bubbles were opaque in the directly illuminated microscope field, their rotational motion could be followed by observing particles of carbon 2μ to 5μ in diameter which were dispersed in the liquid medium and became lodged at the air/liquid interface during the agitation process. One of these particles suitably chosen could be used as a convenient reference point. The time required by the particle to make two successive crossings of the X–Z plane (Fig. 1) was taken to be the half-period of rotation. The precision of these measurements was not as high as with glass spheres (5, 9); the latter were transparent in the microscope field and reference marks on the surface or inside of the particle could be seen throughout the rotation.

Table III contains the observed periods of rotation of an air bubble over a range of velocity gradients. For purposes of comparison the periods calculated from equation [7] are also given. The agreement is seen to be reasonably good considering the difficulty in making accurate measurements.

TABLE III

PERIODS OF ROTATION OF SINGLE AIR BUBBLES

G, sec.$^{-1}$	T_1, sec. Observed	Mean observed	Calculated	Observed / Calculated
0.625	22.4, 23.6, 19.2, 22.8	22.0	20.1	1.09
0.737	18.6, 17.4, 18.0, 18.0	18.0	17.1	1.05
0.985	12.0, 11.8, 12.4, 12.4	12.1	12.8	0.94
1.34	8.4, 8.2, 9.0, 8.8	8.6	9.4	0.91
2.33	4.8, 6.2, 7.0, 7.2, 5.0	6.0	5.4	1.11
				Mean 1.02

These results show that over the range of velocity gradients studied here, the air bubbles rotate like rigid spheres. This observation accords with Garner's

observation that at low Reynolds numbers sedimenting fluid spheres behave as though they were solid, i.e. they fall at the Stokes velocity without the expected circulation of fluid inside the drop (3).

Periods of Rotation of Air Doublets

A series of measurements of the periods of rotation T_2 about the Z-axis of the doublet formed by two colliding spheres which ultimately coalesced was made over a range of shear rates. The experimental method was similar to that previously described for cylindrical particles (9). In these experiments care was taken to select doublets having bubbles of equal size. Table IV shows

TABLE IV

PERIODS OF ROTATION OF DOUBLETS FORMED BY THE COLLISION OF FLUID SPHERES

G, sec.$^{-1}$	Mean T_2, sec.	$T_2G/2\pi$
Doublet No. 1		
0.581	40.4	3.74
0.846	27.6	3.72
1.12	20.8	3.72
1.44	16.0	3.68
1.87	11.9	3.55
Doublet No. 2		
0.566	41.0	3.70
0.733	32.2	3.76
1.07	21.6	3.68
1.41	16.4	3.69
2.17	10.4	3.60
	Mean	3.68

typical results for two doublets over a range of shear rates. It will be noted from values shown in the last column that T_2 varies inversely with the velocity gradient.

Periods of rotation of two doublets of separated and hence non-coalescing bubbles were also measured; these are given in Table V.

TABLE V

PERIODS OF ROTATION OF AIR DOUBLETS WITHOUT BUBBLE CONTACT

G, sec.$^{-1}$	Mean T_2, sec.	$T_2G/2\pi$
1.776	16.4	4.64
2.020	22.4	7.20

According to Jeffery (4), the period of rotation about the Z-axis of a rigid prolate spheroid of axis ratio r is given by

$$T_2 = 2\pi[r+(1/r)]/G \qquad [8]$$

which for $r = 2$ yields a value $T_2G/2\pi = 5/2$. It is seen from Table IV that

the period of rotation of a doublet of contacting spheres is greater than that of a spheroid of corresponding axis ratio. The "equivalent ellipsoidal axis ratio" r_e may be calculated from equation [8] by inserting the *measured* value of $T_2G/2\pi$. This yields a value of $r_e/r = 1.69$ for contacting bubbles; this is considerably higher than the corresponding values of 0.5 for a doublet of neutral rigid spheres (equation [4]), and 0.6 to 0.7 for rigid cylindrical particles having r's ranging from 130 to 20 (9).

Details of Orbit

It has been previously shown (9) that the spherical elliptical orbit of a prolate spheroid predicted by Jeffery (4) may be transformed to the form

$$\tan \lambda = \tan \lambda_{max} \cdot \sin 2\pi t/T \qquad [9]$$

where t is time, λ is the angle between the Z-axis and the X–Z projection of the major axis of the particle (Fig. 1), and λ_{max} is the maximum value of λ achieved in a particular orbit. Equation [9], which describes the rocking to and fro between the angles $\pm\lambda_{max}$ of the X–Z projection of the particle, has been confirmed experimentally for rigid cylindrical particles (9).

The variation of λ with time of a doublet of touching air bubbles was measured using a goniometric ocular on the microscope in the same manner as with cylindrical particles (9). The results, which are shown plotted over a half-rotation in Fig. 4, show excellent agreement with equation [9].

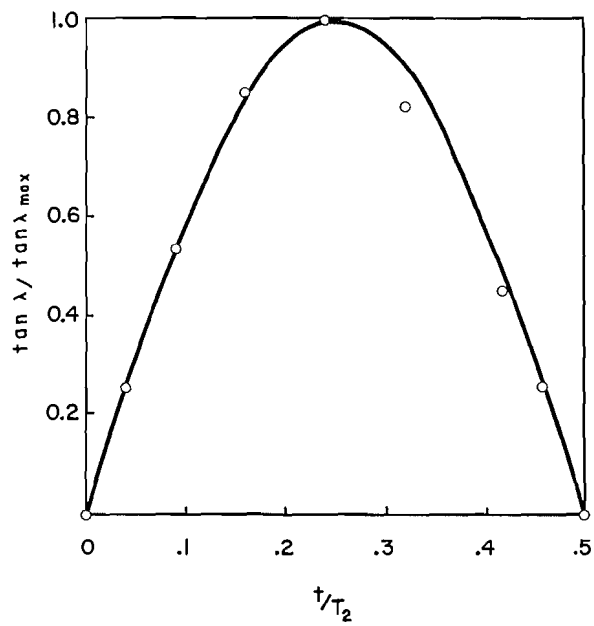

FIG. 4. Variation of the azimuthal angle λ (Fig. 1) with time for a semirotation of a doublet formed by the collision of two air bubbles of equal size. The points are calculated from measured values of λ and T_2 and the curve from Jeffery's equation for a rigid ellipsoid in the form of equation [9].

DISCUSSION

General

Except when $a_1/a_2 > 2$, when the particles can be seen to be separated at all times, the evidence of true contact between glass spheres from these experiments and from the more detailed experiments reported and discussed previously (5) is inconclusive.

The planetary motion observed when $a_1/a_2 > 2$, and which became more marked as the ratio was increased, is complex in nature but may be a manifestation of streamlines around the larger of the two spheres; circular streamlines in the X–Y plane around an isolated rigid sphere may be expected, but the details have not yet been worked out from theory. No explanation can be offered for the "zig-zag" motion. The upward motion of the smaller sphere relative to the larger, which has been shown to occur independent of the direction of rotation of the spheres, is most probably due to differential sedimentation, since a downward sedimentation of the glass spheres in the less dense liquid medium is to be expected.

The coalescence of the air bubbles, while not positive proof of contact, suggests an initial approach of the two spheres close enough so that they adhere with sufficient force to prevent separation in the mirror-image position observed with glass spheres. Owing to the uncertain nature of the long range London – van der Waal's attraction forces, and of the electrostatic repulsion and electroviscous effects existing in thin liquid films which are revealed in the experiments of Derjaguin (1), Elton (2), and others, caution must be exercised in interpreting the significance of the observations on coalescence until additional experiments are carried out.

The formation of air bubble doublets with complete separation cannot be explained although it is possible that it may be related to the planetary motion observed in the binary systems of glass spheres.

Steady State Concentration of Doublets

The persistence of a doublet of neutral rigid spheres for a finite period between collision and separation causes a steady state concentration of doublets to be built up when the suspension is stirred, caused to flow, or otherwise subjected to a velocity gradient. At statistical equilibrium, the number formed per unit time equals the number which die by separation. Thus if F is the total number of doublets formed in unit volume per unit time, and $\bar{\tau}$ is the mean doublet life, then the steady state number of doublets n' per unit volume is given by

$$n' = \bar{\tau}F. \qquad [10]$$

For equal-sized spheres, $F = fn/2$ and $\bar{\tau} = \pi/G$ (5). It readily follows that the volume fraction of doublets (c') in the steady state becomes

$$c' = 8c^2 \qquad [11]$$

where c is the total volume concentration of singlets. Equation [11] can be valid only at low concentrations since the depletion of the system of singlets and the formation of triplets, etc., have been ignored. Several values from

equation [11] are shown in Table VI where it is seen that even at low concentrations an appreciable fraction of neutral spheres can exist in doublet form.

TABLE VI

STEADY STATE CONCENTRATION OF DOUBLETS IN A SUSPENSION OF NEUTRAL SPHERES

c, volume %	c', volume %	100 c'/c
2	0.3	15
4	1.3	32
8	5.1	64

We wish next to consider the doublet concentration in a binary system where $a_1/a_2 < 2$. Equation [6] gives the collision frequency per particle; the collision frequency per unit volume F_{12} is given by $f_{12}n_1$. Thus for collisions between k different species uniformly dispersed, the total number of two-body collisions of all types in unit time and unit volume is given by

$$F = \tfrac{1}{2}\sum_{j=1}^{k}\sum_{j=1}^{k} f_{ij}n_i, \qquad [12]$$

the factor $\frac{1}{2}$ appearing since each collision has been counted twice under the summation sign. This reduces to

$$F = \frac{G}{12}\sum\sum (a_i+a_j)^3 n_i n_j. \qquad [13]$$

For a binary system, i.e. $k = 2$, this yields

$$F = \frac{24G}{\pi^2}\left[\frac{c_1^2}{a_1^3}+\frac{c_2^2}{a_2^3}+\frac{(a_1+a_2)^3}{4a_1^3a_2^3}\right]c_1c_2, \qquad [14]$$

the first two terms corresponding to 1–1 and 2–2 collisions respectively, and the third to 1–2 collisions. Assuming that the doublet life for unequal spheres is the same as that for equal spheres, it follows that the steady state concentration of doublets is given by

$$c' = 8c_1^2+8c_2^2+(1+a_1/a_2)^3(1+a_2^3/a_1^3)c_1c_2. \qquad [15]$$

It is readily shown that c' is a minimum when $a_1 = a_2$; it follows therefore that polydispersity may increase the steady concentration of doublets.

Recently we have shown (6) how doublet formation as described above in monodisperse and polydisperse suspensions may be used to modify a theoretical equation due to Vand (11); this modification gives good agreement with measured values of the relative viscosity of rigid spheres at concentrations up to 18% by volume.

The interaction phenomena are of interest in connection with the well-known increase in rate of coagulation of hydrosols and aerosols caused by stirring, turbulent flow, etc. The theory of this effect, which is based upon the increase in collision frequency due to velocity gradients (orthokinetic collisions)

over the normal Brownian (perikinetic) collisions, was first developed by Smoluchowski (8) and has since been extended by Tuorilla (10), Muller (7), and others.

ACKNOWLEDGMENT

We are indebted to A. P. Arlov for the preparation of the photomicrographs shown in Fig. 3.

THE RECIPROCAL SALT-PAIR SYSTEM: SODIUM CHLORIDE – AMMONIUM SULPHITE – SODIUM SULPHITE – AMMONIUM CHLORIDE – WATER AT 20°C. AND 60°C.

PART I. TERNARY SYSTEMS[1]

By J. A. Labash[2] and G. R. Lusby

ABSTRACT

Solubility data have been obtained at 20°C. and 60°C. for the following ternary systems:

(1) $NaCl–NH_4Cl–H_2O$ (2) $NH_4Cl–(NH_4)_2SO_3–H_2O$
(3) $Na_2SO_3–(NH_4)_2SO_3–H_2O$ (4) $NaCl–Na_2SO_3–H_2O$

No evidence of the formation of double salts or of solid solutions in the first three systems was obtained. Ammonium sulphite monohydrate does not appear to dehydrate at 60°C. in solutions saturated with sodium sulphite or ammonium chloride. In the study of the $NaCl–NH_4Cl–H_2O$ system, the data agree with average values obtained from the literature and some discrepancies in the published data have been noted. In the $NaCl–Na_2SO_3–H_2O$ system some anomalous results can be explained on the basis of the existence of solid solutions of the hydrated and anhydrous forms of sodium sulphite and sodium sulphate.

INTRODUCTION

The work described in the present paper and in a following paper was carried out for the purpose of obtaining data necessary for the development of a process for making sodium sulphite and ammonium chloride directly from sodium chloride, sulphur dioxide, and ammonia. The carrying out of such a process industrially requires careful control of liquor compositions in order that products of high purity may be obtained. Because the solubility data in the literature were insufficient for such control of the proposed process, a phase rule study was made of the reciprocal salt-pair system: $NaCl–(NH_4)_2SO_3–Na_2SO_3–NH_4Cl–H_2O$, at 20°C. and 60°C., and of the four associated ternary systems.

EXPERIMENTAL

(1) *Chemicals*

Analytical reagent (A.R.) ammonium sulphite was found to contain a relatively high percentage of sulphate and its use was abandoned after a series of preliminary experiments. Ammonia and sulphur dioxide gases were added in place of solid ammonium sulphite wherever possible. When the solid [$(NH_4)_2SO_3.H_2O$] was needed, it was freshly prepared from the constituent gases; the solid, thus prepared, was found to contain much less sulphate than the reagent chemical. Ammonium sulphite was used in some cases in the form of a thick slurry, in order to avoid the oxidation which occurs during filtering and drying operations.

Sodium sulphite heptahydrate for the 20°C. work was freshly prepared by cooling a saturated solution of anhydrous sodium sulphite. It, also, was used in the form of a slurry when it was possible to do so.

[1]*Manuscript received January 17, 1955.*
Contribution from Central Research Laboratory, Canadian Industries (1954) Limited, McMasterville, Quebec.
[2]*Present address*: *Canadian Industries (1954) Limited, Hamilton, Ontario.*

The ammonium chloride, sodium chloride, and anhydrous sodium sulphite were of A.R. grade. The latter contained about 1% of sodium sulphate.

(2) *Procedure*

A constant temperature bath was used, of which the temperature was controlled to ±0.1°C. For most of the work, solutions were stirred in three-necked flasks using glass propeller-type stirrers. In earlier work it was found that the sulphate content of the solution increased considerably over a period of a few days, particularly at 60°C. In most of the present work therefore the air was displaced with nitrogen in order to keep oxidation at a minimum. It was also found that ammonia has quite an appreciable vapor pressure over these solutions. Loss of ammonia therefore occurred and this resulted in the formation of bisulphite ion. Solutions were analyzed frequently for bisulphite, which was then neutralized by the addition of ammonia gas.

A solution was sampled by allowing salts to settle and then quickly drawing a sample up into a pipette. A short length of glass tubing containing a wad of absorbent cotton was attached by a rubber tube to the lower end of the pipette to prevent any salts being drawn up into the pipette. In the case of solutions above room temperature the pipette and filter tube were heated. The sample was run into a weighing bottle which was then stoppered and weighed. The sample was diluted in a volumetric flask and suitable aliquots were taken for analysis.

The procedure used in studying the ternary systems consisted in preparing a saturated solution of a single salt, to which portions of the second salt were then added, and the solution was stirred in the presence of an excess of the first salt. After time was allowed for equilibrium to be reached, the solution was analyzed. Additions of the second salt were continued until the composition of the solution became constant. When it was desired to determine the composition of the solid phase, the "rest" method of Schreinemakers was followed. Use was also made of the microscope for identification of solids.

Duplicate analyses were not usually carried out on solutions representing points on lines of ternary (or quaternary) systems. The data for solutions at points of intersections of lines (univariant points), however, are averages of two or more analyses.

(3) *Analytical Methods*

(*a*) *Bisulphite*

Owing to the buffering action of the sulphites, these solutions could not be analyzed accurately for bisulphite or free ammonia by a direct titration with standard alkali or acid respectively. The sulphite was therefore oxidized to sulphate and bisulphite to bisulphate by the addition of neutral hydrogen peroxide (A.R.). This oxidation was carried out at room temperature because the hydrogen peroxide contained a stabilizer which developed acidity in a hot solution. The oxidized solution was then titrated with standard alkali in the presence of methyl red to determine bisulphite, now in the form of bisulphate. Excess ammonia, when present, was titrated with standard acid in the presence of phenolphthalein, after oxidation of the sulphite.

(*b*) *Sulphite*

In order to minimize oxidation an aliquot was taken immediately after dilution of the sample and was added to $N/10$ iodine solution, the excess of which was then titrated with $N/10$ thiosulphate solution using starch indicator. The sulphite concentration was calculated in the usual way and a correction was made when bisulphite was present.

(*c*) *Sulphate*

An aliquot was oxidized with bromine water and the total sulphate was determined gravimetrically as barium sulphate. The actual sulphate content of the solution was then determined by subtracting from the total sulphate, the sulphate equivalent to the sulphite and bisulphite in the liquor.

(*d*) *Chloride*

A fourth aliquot was analyzed for chloride by the standard volumetric method using $N/10$ silver nitrate in excess and back-titrating with $N/10$ ammonium thiocyanate, using ferric alum indicator.

(*e*) *Ammonium*

Ammonium was determined by the method of Ronchèse (11), which is based on the fact that formaldehyde reacts with the ammonia contained in ammonium salts to form hexamethylene tetramine. The liberated acid can then be titrated to give a measure of the combined ammonia. Because formaldehyde reacts with sulphites, however, the solution used for the ammonium determination was that in which the sulphite had already been oxidized with iodine as described above (*b*). Methyl red was added to this solution at the end of the thiosulphate back-titration and the acid was exactly neutralized with sodium hydroxide solution. An excess of neutral 20% formaldehyde solution was added and the solution was heated to about 50°C. for a few minutes. The acid liberated by the reaction between ammonia in the ammonium salts and the formaldehyde was then titrated with standard sodium hydroxide solution using phenolphthalein indicator. The sodium hydroxide was standardized by the same procedure using dried A.R. ammonium chloride.

The neutralization of 20% formaldehyde solution was done by taking a measured quantity, diluting it with water to about the same extent as in a regular analysis, and then titrating it with sodium hydroxide, using phenolphthalein indicator. From the volume of sodium hydroxide used in this titration was calculated the amount to be added to the bottle containing the 20% formaldehyde. Alternatively, an electrometric titration was also found to be useful in exactly neutralizing the acidity of the 20% formaldehyde solution, which otherwise is difficult because of buffering action.

(*f*) *Sodium*

Sodium was determined by the standard method of converting all sodium salts to the sulphate, evaporating the solution to dryness, and heating the residue to constant weight.

The accuracy of the analytical methods was such that duplicate analyses checked within 2 parts per 1000 in the case of the sulphite, ammonium, and

chloride determinations, and within 4 parts per 1000 for sodium and total sulphate determinations.

EXPERIMENTAL RESULTS AND DISCUSSION

(1) *NH_4Cl–$NaCl$–H_2O System*

The data obtained in the present work at 20°C. and 60°C. are presented in Tables I and II.

**Not used in averaging the data, and plotted separately in Fig. 1.*

It was noted that there were quite large differences between the present data and those in the literature, for solutions saturated with both sodium and ammonium chlorides at 60°C. Consideration of these differences led to a survey of all the available literature data on the mutual solubilities of these two salts. The original papers, the International Critical Tables and the handbooks of Seidell and Landolt-Bornstein, were consulted. The data thus found are summarized in Table II and plotted in Fig. 1. In those cases where two or more sets of data were available at a given temperature, the average values were plotted. However, data differing considerably from the average were not included in the average but were plotted separately. In addition to these larger discrepancies which are shown in Fig. 1, several smaller ones are apparent from a study of the data in Table II.

An explanation of some of these discrepancies may be that sufficient time of agitation was not allowed for equilibrium to be reached. In some cases, the explanation may be the occurrence of typographical errors. For example, Yarlikov (14) gives the same value for NaCl at 35°C. and 50°C. The 50°C. value is evidently a typographical error as it can be calculated from other data which he gives in Table II of his paper that the value at 50°C. should be 22.8 instead of 23.9 gm. NaCl/100 gm. of H_2O. The 50°C. value of Yarlikov (14.48%), given in Table II of the present paper was calculated using the value of 22.8 gm./100 gm. of H_2O.

Data obtained in the present work at 20°C. and 60°C. for solutions saturated with both salts appear to be in quite good agreement with curves representing average values of the published data, as indicated in Fig. 1.

(2) *NH_4Cl–$(NH_4)_2SO_3$–H_2O System*

(*a*) *20°C. Data*

The data are given in Table III and Fig. 2.

Ishikawa and Murooka (3) showed that ammonium sulphate does not form solid solutions with ammonium sulphite and there is no evidence in the

R	0	37.34	0.49	—	—	—	$(NH_4)_2SO_3.H_2O$

literature for the existence of solid solutions of ammonium chloride and ammonium sulphate. The sulphate content of a given rest could therefore only be due to ammonium sulphate in the adhering mother liquor and to oxidation of the sulphite by air during filtration. Because the sulphate content of the rest was usually much higher than that which could be accounted for by the adhering mother liquor, a correction was made by converting the ammonium sulphate in the rest to ammonium sulphite and adding this value to the $(NH_4)_2SO_3$ value before the rest composition was plotted in Fig. 2.

The data in Table III and Fig. 2 show no evidence of double salt or solid solution formation between ammonium chloride and ammonium sulphite at 20°C.

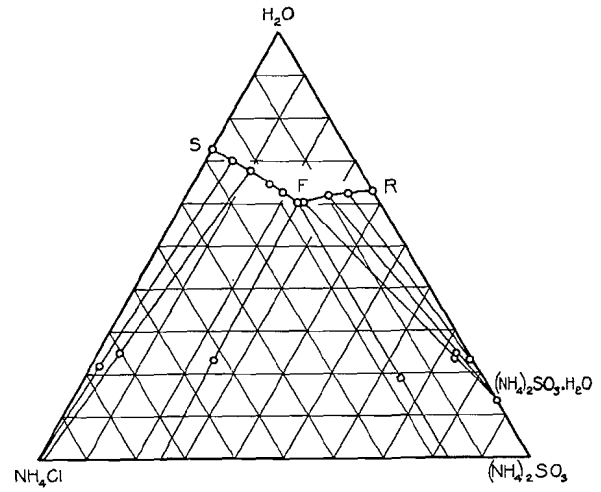

FIG. 2. Ammonium chloride – ammonium sulphite – water system at 20°C.

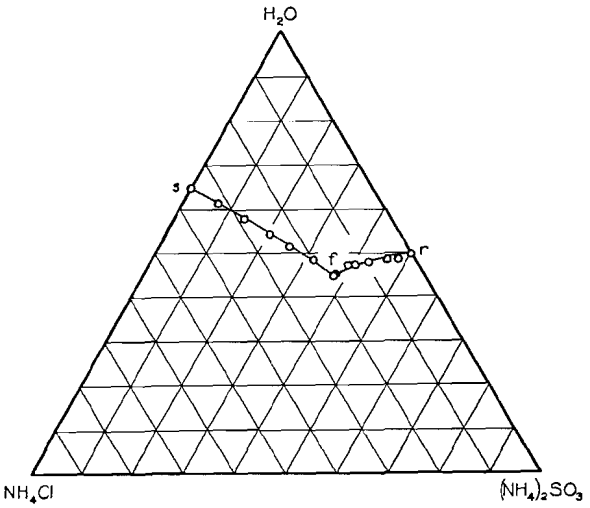

FIG. 3. Ammonium chloride – ammonium sulphite – water system at 60°C.

(b) 60°C. Data

The data in Table IV and in Fig. 3 show no evidence of the formation of a double salt or of solid solutions of ammonium chloride and ammonium sulphite at 60°C. The results also indicate that ammonium sulphite monohydrate does not dehydrate at 60°C. in solutions containing ammonium chloride, although no rest analyses were made to confirm this point.

The composition of the solution saturated with both salts is considerably different from that found by Zil'berman and Ivanov (15).

(3) *Na_2SO_3–$(NH_4)_2SO_3$–H_2O System*

(a) 20°C. Data

When portions of each salt were added to a saturated solution of the other salt, it was found that the two final compositions at 20°C. were not the same (Table V and Fig. 4). This result indicates the formation of a new solid phase between *G* and *H*, but sufficient work was not done to establish its nature.

**Zil'berman and Ivanov (15).*

were obtained by starting with solutions saturated with sodium sulphite and with ammonium sulphite respectively, and adding portions of the other salt until the compositions became constant. It is seen from Table VI that these compositions are practically identical, but these data do not show whether there is formation of a double salt or a solid solution at 60°C. or if dehydration of ammonium sulphite monohydrate occurs. The data obtained, however, are

in fair agreement with those of Zil'berman and Ivanov (15) for a solution saturated with respect to $(NH_4)_2OS_3.H_2O$ and Na_2SO_3.

(4) *NaCl–Na_2SO_3–H_2O System*

(*a*) *20°C. Data*

The data obtained are given in Table VII and are shown plotted in Fig. 5. Between *P* and *C*, the solid phase is NaCl, and between *Q* and *L* it is $Na_2SO_3.7H_2O$. The space between *L* and *C* indicates the existence of an undetermined solid phase.

**Zil'berman and Ivanov (15).*

(*b*) *60°C. Data*

Sodium chloride was added to a solution saturated with sodium sulphite (*q*) until a constant composition was reached at *l* (Table VII and Fig. 6). Similarly, when sodium sulphite was added to a solution saturated with sodium chloride the point *c* was obtained. The experiment was repeated several times with the same result being obtained each time. That is, the compositions of the two solutions stopped at *l* and *c* respectively, solid sodium chloride at *l*, and solid sodium sulphite at *c* having little effect on the compositions even after several days' stirring. Thus, there appeared to be an undetermined solid phase present in this system at 60°C. as well as at 20°C.

The following attempts were made to obtain solutions between *c* and *l*, since analysis of the rests from such solutions should give the identity of the solid phase in the region between *c* and *l*. Portions of a filtered solution at *l* were added to three bottles of 150 ml. capacity. To each bottle were added 0.1 gm. of sodium sulphite and 1.0 gm. of sodium chloride. Similarly, a solution

at c was filtered and portions of it were placed in three bottles. To these were added 0.1 gm. of sodium chloride and 1, 2, and 3 gm. of sodium sulphite respectively. These bottles were closed with glass stoppers (greased) and rotated, so that the solids fell from top to bottom of each bottle and vice versa, during a revolution, for seven weeks in a constant temperature bath. At the end of that time the bottles were removed, and analyses were made on the solutions and rests.

The data obtained are given in Table VIII. It will be noted that the sulphate content in solutions c_3 is very low and is evidently in error. The sodium sulphite content in solutions c, c_1, c_2, and c_3 shows comparatively little change except

Calc. by diff.

in the case of solution c_3 but even in this case it is still considerably below the value for the solution at l. Two grams of sodium sulphite would have been sufficient, had it all dissolved, to move the composition of the solution from c to l. In the case of the experiments in which sodium chloride and a small proportion of sodium sulphite were added to solutions at l (Table VIII), there was no significant decrease in the sulphite content nor increase in the chloride content during seven weeks, for the first and third solutions (l_1 and l_3). In the case of solution l_2, the decrease in the contents of both sodium chloride and sodium sulphite and the fact that there was insufficient rest for and analysis indicate that water leaked into this bottle.

Because a series of solutions with compositions lying between l and c was not obtained, the results of these experiments do not indicate the nature of the unknown solid phase. A possible explanation of the results may be the formation of solid solutions of sodium sulphate in sodium sulphite, as several such solid solutions are known. It might be, for example, that sodium chloride is in equilibrium with one solid solution of sodium sulphate in sodium sulphite

at *c* (60°C. diagram) and with a different solid solution at *l*. In a second paper dealing with the quaternary system the nature of the solid phase between *L* and *C* (20°C. data) and between *l* and *c* (60°C. data) will be discussed further.

THE RECIPROCAL SALT-PAIR SYSTEM: SODIUM CHLORIDE – AMMONIUM SULPHITE – SODIUM SULPHITE – AMMONIUM CHLORIDE – WATER AT 20°C. AND 60°C.

PART II: THE QUATERNARY SYSTEM[1]

By J. A. Labash[2] and G. R. Lusby

ABSTRACT

In the above quaternary system at 60°C., besides those representing the four salts at the corners of the Janecke diagram two other saturation areas were found. At 20°C. there are three, and possibly more than three additional areas. In the course of the present work it was not possible to establish the nature of the solid phases in these additional areas of the quaternary system. However, the data of Lewis and Rivett suggest that at least some of these unknown areas may indicate the presence of different solid solutions of sodium sulphate in sodium sulphite. This quaternary system appears to be a rather complex one and much further work remains to be done in order to complete the knowledge of it at 60°C. and 20°C., particularly at the latter temperature.

INTRODUCTION

Zil'berman and Ivanov (6) made a study of the reciprocal salt-pair system: $NaCl$–$(NH_4)_2SO_3$–Na_2SO_3–NH_4Cl–H_2O at 60°C. and 85°C., and of the system: $NaCl$–NH_4HSO_3–$NaHSO_3$–NH_4Cl–H_2O at 25°C. and 60°C. The ultimate purpose of their work was the same as that of the present work, namely, the industrial preparation of sodium sulphite and ammonium chloride from sodium chloride, sulphur dioxide, and ammonia.

The process as developed in this laboratory and used in the plant at Hamilton, Ont. (1), consists essentially in adding sulphur dioxide and ammonia gases to a mother liquor containing sodium chloride in suspension, and centrifuging off the precipitated sodium sulphite at 60°C. The mother liquor is cooled to 20°C., the ammonium chloride which crystallizes out is centrifuged off, and the mother liquor is used for the next cycle.

Such a cyclic process as outlined above is the subject of several German patents dating from 1887. Zil'berman and Ivanov point out that these patents are very vague in regard to the details of the process and that they found it necessary to carry out solubility studies in order to define more precisely the operating conditions. It was for the same reason that the present work was undertaken.

In the previous paper (2) data were given on the four ternary systems associated with the reciprocal salt-pair system: $NaCl$–$(NH_4)_2SO_3$–Na_2SO_3–NH_4Cl–H_2O at 20°C. and 60°C. The present paper contains data on the quaternary system.

The experimental methods were essentially the same as those used for the ternary systems.

EXPERIMENTAL

The presence of sulphate ion as an impurity presents a difficulty in the accurate plotting of the data according to the method of Janecke for reciprocal salt-pairs. Because it was usually not known how the sulphate was distributed between the ammonium and sodium ions, the ionic ratios of these two ions were based on the total sodium and ammonium values.

(1) *60°C. Data*

In Fig. 1 it will be noted that there are two saturation areas where the solid phase has not been identified, namely, (*a*) the area between the lines *cb* and *le*, and (*b*) the area between the lines *ej* and *do*.

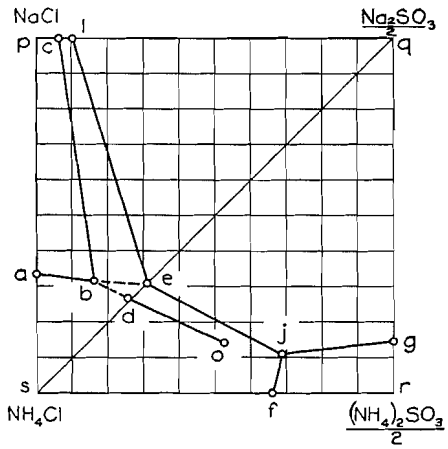

FIG. 1. Sodium chloride – ammonium sulphite – sodium sulphite – ammonium chloride – water system at 60°C.

(*a*) Area between *cb* and *le* at 60°C.

The points *c* and *l* at the top of this area have already been discussed under the $NaCl–Na_2SO_3–H_2O$ system (2). Ammonium chloride was added in portions to a solution at *c*, in the presence of excess sodium chloride and sodium sulphite, and the solution was analyzed after each addition. In this way several points were obtained along the line *cb*. At *b* the solids were filtered off and each of the three salts sodium chloride, ammonium chloride, and sodium sulphite was added singly, to the filtered solution, which was stirred for several hours in each case. No change in composition occurred and it thus seemed that the solution at *b* was saturated with these three salts. Points along *cb* were also obtained by adding sodium sulphite to solutions plotting to the left of *cb*.

To a solution at *a*, in the presence of excess sodium and ammonium chlorides, sodium sulphite was added and points were obtained along *ab*. The composition became constant at *b*, and was practically the same as that obtained by starting from *c* (Table I).

The point *e* was obtained by adding ammonium chloride to a saturated solution of sodium sulphite and then, after the composition had become

constant, adding sodium chloride. No change in composition occurred when the latter salt was added so the solution at *e* was also apparently saturated with the three salts, sodium chloride, ammonium chloride, and sodium sulphite. Points along the line *le* were obtained by adding sodium chloride to solutions which plotted to the right of this line. In some cases the composition did not stop at this line, but moved into the *cbel* area. The addition of ammonium chloride to a solution on the lower part of the line *le* always caused the composition to move towards the corner *s* of the diagram until the line *be* was reached.

Points on *be* were also obtained by adding sodium chloride to solutions plotting below *be*. Once the composition reached a point on *be*, however, the presence of an excess of solid sodium chloride did not cause the composition to move towards *b*. Also, no noticeable change in composition occurred in a few hours on adding the three salts sodium chloride, ammonium chloride, and sodium sulphite separately to solutions represented by points on the line *be*. There was no difficulty, however, in moving the composition from *b* to *e* by adding ammonium sulphite to a filtered solution at *b*.

(*b*) Area between *ej* and *do* at 60°C.

When ammonium chloride was added to a saturated sodium sulphite solution, the composition moved along the diagonal from *q* to *e*, where the composition became constant. Similarly, when sodium sulphite was added to a saturated ammonium chloride solution, the composition moved from *s* to *d*. The existence of the two points *d* and *e* indicates the presence of another solid phase, which could be a double salt or a solid solution. Points *d* and *e* were also obtained when these experiments were repeated using solutions which were slightly ammoniacal. This was done because the only known double salt containing sodium and ammonium sulphites has the formula $2Na_2SO_3.(NH_4)_2S_2O_5.10H_2O$ (4). This double salt was encountered in the present work in certain solutions containing bisulphite ion, but it dissolved readily when the solution was neutralized with ammonia. The possibility of its formation was therefore assumed to have been eliminated by avoiding acidic conditions in the above experiments at the points *d* and *e*, and the existence of the area between *d* and *e* is presumably not due to formation of this double salt.

Chemical analysis and microscopic examination of the rests indicated the presence of sodium chloride, ammonium chloride, and sodium sulphite at *e* and ammonium chloride and sodium sulphite at *d*. The microscopic technique, however, would not have revealed the presence of solid solutions if these had differed only slightly in optical properties from the pure salts. It was decided to investigate the nature of the unknown solid phase by attempting to obtain points between *d* and *e* in the pseudoternary system: NH_4Cl–Na_2SO_3–H_2O in the following manner.

All solids were filtered from a solution at *e*, which was then divided into five portions. To each portion (about 150 gm.) was added 0.1 gm. of sodium sulphite and 1.0 to 2.5 gm. of ammonium chloride, the latter quantity being more than sufficient to move the composition to *d* if it dissolved. Similarly, to each of five portions of filtered liquor at *d* were added 0.2 gm. of ammonium

chloride and 2 to 6 gm. of sodium sulphite. These solutions and their respective solids were placed in bottles and rotated in the constant temperature bath at 60°C. for six to seven weeks. At the end of that time the solutions and rests were analyzed. In all cases except two (d_1 and d_4), the solution compositions were found not to have changed appreciably and the rests, as indicated by analysis, were mostly ammonium chloride at *e* and mostly sodium sulphite at *d* (Table II). Because points were not obtained between *d* and *e*, these experiments did not result in the identification of the solid phase between the lines *ej* and *do*.

The areas between *b* and *d*, and between *o* and *j* were not explored; *d* and *o* do not represent univariant points but simply the last points determined along the line *do*. The line *do* was explored by adding ammonium sulphite to a liquor at *d*. It was noticed that the composition had a tendency to move across the area between *ej* and *do*, so that when one analysis showed the composition to be on *do*, the analysis after another addition of ammonium sulphite frequently showed the composition to be on *ej*. To avoid this difficulty, solutions were made up whose compositions were represented by points below *do*. On addition of anhydrous sodium sulphite in excess, the compositions moved to points on *do*.

It is interesting to note that the composition found by Zil'berman and Ivanov (6) for the solution saturated with sodium chloride, ammonium chloride, and sodium sulphite corresponds with the composition of the solution at *d*, which in the present work was found to be not saturated with sodium chloride (Table I and Fig. 1). This difference may be due to a difference in the sulphate content of the two solutions.

When sodium sulphite was added to a solution at *f*, points were obtained along *fj*, and the composition became constant at *j*. Ammonium chloride was added to a solution at *g* and the composition was followed along *gj* until *j* was again reached, as indicated in Table I. Analysis of the rest indicated the presence of anhydrous sodium sulphite, ammonium chloride, and ammonium sulphite, but it was not determined whether the latter was in the form of the hydrate or not.

When ammonium sulphite hydrate was added to a solution at *e*, along with excesses of sodium sulphite and ammonium chloride, points were obtained along *ej* until the solution reached a constant composition. It will be seen that the final composition *j* in this case is somewhat different from the other two compositions, particularly in respect to the ammonium chloride value (Table I). This difference may be due to the higher content of sodium sulphate in this particular solution. The difference between the composition of the solution at *j*, obtained by Zil'berman and Ivanov, and the present values may also be due to differences in the sulphate contents.

(2) *20°C. Data*

The 20°C. data are given in Table I and Fig. 2.

The points *C* and *L* have already been mentioned in connection with the ternary system $NaCl$–Na_2SO_3–H_2O at 20°C. (2). To a solution at *C* in the

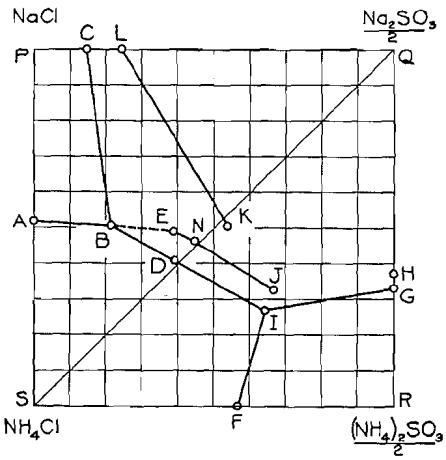

FIG. 2. Sodium chloride – ammonium sulphite – sodium sulphite – ammonium chloride – water system at 20°C.

presence of excess sodium chloride and sodium sulphite, portions of ammonium chloride were added. Analyses gave solution compositions which plotted along the line *CB*. Finally the point *B* was reached where the solid phases appeared to be sodium chloride, anhydrous sodium sulphite, and ammonium chloride. Several points on *CB* were also obtained by adding anhydrous sodium sulphite to solutions to the left of *CB* in the sodium chloride area. Similarly, by adding sodium sulphite to a solution at *A*, the composition followed the line *AB* until it became constant at *B*. The two compositions thus obtained agree quite well (Table I).

Points were obtained along *LK* by adding sodium chloride to solutions in the sodium sulphite heptahydrate area to the right of *LK*. Such solutions were analyzed after each addition of sodium chloride until their compositions became constant and remained so for several days. The apparent solid phases were sodium chloride and sodium sulphite heptahydrate.

Several solutions were obtained, which plotted along a line between *CB* and *LK*, and which appeared to be in equilibrium with sodium chloride and anhydrous sodium sulphite but sufficient work was not done to establish definitely the position of this line.

The point *K* was obtained by adding ammonium chloride in portions to a solution saturated with sodium sulphite heptahydrate (*Q*). The composition of the solution moved along the diagonal *QS* until it approached *K*, when it left the diagonal and became constant at *K*, where the solid phases appeared to be sodium sulphite heptahydrate, anhydrous sodium sulphite, and sodium chloride. After further portions of ammonium chloride had been added, the composition returned to the diagonal and moved to the point *N*, where the solid phases were apparently ammonium chloride and anhydrous sodium sulphite.

Several solutions were obtained which were apparently in equilibrium with sodium sulphite heptahydrate and anhydrous sodium sulphite in the region

between K and H but this area was not studied sufficiently to establish the boundary line between the hydrated and anhydrous forms of sodium sulphite. The procedure followed in these experiments was to add ammonium chloride to solutions in contact with excess sodium sulphite heptahydrate. The results were inconsistent, possibly because of metastable states of equilibria. No data are given therefore.

The point I was obtained by adding anhydrous sodium sulphite to a liquor at F in equilibrium with solid ammonium chloride and ammonium sulphite hydrate. The composition became constant at I where the solid phases were apparently ammonium chloride, anhydrous sodium sulphite, and ammonium sulphite monohydrate. Points on the line IG were obtained by adding anhydrous sodium sulphite to solutions whose compositions plotted below IG.

The point I was apparently reached also by adding ammonium sulphite monohydrate to a solution at D and following the line DI. The difference in composition between the two solutions at I (Table I) is possibly due to the difference in sulphate content. Several points along BI were obtained by adding anhydrous sodium sulphite to solutions below this line. Solutions plotting between B and D usually moved slowly towards BE in the presence of an excess of anhydrous sodium sulphite. In some cases the compositions changed quite quickly on the addition of sodium sulphite, to points between D and E. On the other hand solutions along DI showed little tendency to change even after a week's stirring.

The addition of sodium chloride to solutions along the line BD caused the compositions to move immediately to points on BE. For example, on taking a solution at D in contact with excess ammonium chloride and anhydrous sodium sulphite and adding sodium chloride to it, the new composition corresponded to E. The solids were filtered off and the clear solution was stirred separately with each of the three salts. No significant change in composition was observed, which indicated that the solution at E was apparently saturated with ammonium chloride, sodium chloride, and anhydrous sodium sulphite.

Solutions along BE behaved similarly to those along be in the 60°C. diagram. That is, the addition of sodium chloride to a solution on BE in the presence of excess ammonium chloride and anhydrous sodium sulphite did not have any noticeable effect on its composition. On the other hand, ammonium sulphite added to solutions along BE caused their compositions to move along BE to E.

By adding ammonium sulphite (in the form of ammonia and sulphur dioxide gases) to a solution on NJ, a constant liquor composition was reached at J. The filtered solution was tested singly with the three salts—anhydrous sodium sulphite, ammonium chloride, and ammonium sulphite (added in the form of the two gases), but no appreciable change in the liquor composition was noted in any case.

The present data at 20°C. as plotted in Fig. 2 indicate that there are at least three unknown saturation areas one of which, within the region of the points K, H, G, I, and J may represent solutions in equilibrium with anhydrous

sodium sulphite. A possible explanation of the presence of these unknown saturation areas is discussed below.

GENERAL DISCUSSION

In the 60°C. diagram (Fig. 1), the existence of unknown saturation areas could indicate the presence of double salts or solid solutions of either sodium chloride and sodium sulphite or ammonium chloride and sodium sulphite. It would seem more reasonable, however, to base an explanation of the results on the formation of solid solutions of sodium sulphite and sodium sulphate. (Sulphate was an impurity in the present work.) Such solid solutions are well known as a result of the work of Lewis and Rivett (3, 5). Thus, the line *cb* may represent solutions in equilibrium with sodium chloride and one solid solution of sodium sulphate in sodium sulphite, while in the case of the line *le* the solids may be sodium chloride and a different solid solution. The area between the lines *cb* and *le* (and similarly the area between *bdo* and *ej*) would then be due to the overlapping of two areas which represent solutions saturated with respect to two different solid solutions of sodium sulphate in sodium sulphite. In a similar manner may be explained the existence of unknown saturation areas in the 20°C. diagram. The tendency of sodium sulphate and sodium sulphite to form metastable solid solutions may explain some apparently metastable states of equilibrium encountered in the present study.

The quaternary system is obviously more complicated at 60°C. than the results of Zil'berman and Ivanov indicate, and it is still more complex at 20°C. It is not the intention of the present authors to continue the study of this system of salts but it is hoped that the information presented in these two papers will be of assistance to others in future studies. Much work remains to be done on the quaternary system at 20°C. and 60°C. particularly on the identification of the solid phases, and X-ray diffraction techniques should be very useful in such studies. Literature data on the three ternary systems containing sulphites are also rather scanty, so that salt systems containing sulphites present a large field for phase rule investigations.

ON THE INTERMOLECULAR FORCE FIELD OF NITRILES[1]

By F. E. Murray[2] and W. G. Schneider

ABSTRACT

The nature of the intermolecular force field of the nitriles is considered on the basis of the electron orbital structure and charge distribution of the nitrile group. The directional nature of the force field is due to a well-directed lone pair orbital on the N atom, which may be expected to exhibit strong donor properties, and two π-orbitals which may exhibit weak donor properties. Accordingly with good acceptor molecules such as chloroform and hydrogen chloride, simple 1:1 molecular addition compounds should occur. The existence of molecular complexes of this type was confirmed with the aid of binary freezing-point diagrams which were determined for aceto-, propio-, butyro-, and benzo-nitrile with chloroform and hydrogen chloride. The 1:1 association complex was absent, however, in the system acetonitrile–chloroform. This is accounted for by the stronger association occurring in acetonitrile itself, the nature of which is discussed. The structure of the 1:1 molecular complexes is considered. Additional molecular complexes with lower nitrile mole ratios are indicated in the freezing-point diagrams. Of particular interest are the well-defined compounds appearing in the nitrile – hydrogen chloride systems with the composition RCN.5HCl. The possibility that the π-orbitals of the nitrile group may function as donors in these compounds is discussed, and a tentative structure is suggested.

INTRODUCTION

Because of its highly directional character, the intermolecular force field of the nitrile group is of particular interest. Although the nitriles, as for example the alkyl nitriles, RCN, have high dipole moments, the strong molecular association of such molecules cannot in general be attributed primarily to dipole interaction. The charge distribution which gives rise to the strongly polar force field is made up of two π-orbitals which are directed at right angles to each other and centered mainly in the region between the C and N atoms, and of a lone pair orbital centered on the N atom. The latter can be represented approximately by a digonally hybridized *sp* orbital directed along the CN axis, and it is accordingly an excellent "donor" (7). Thus boron trifluoride, a typical vacant orbital acceptor, forms stable addition compounds with nitriles (4) and hydrogen cyanide associates into linear chains by hydrogen bonding (1). Because the lone pair orbital on the N atom is directed along the molecular axis, it is largely responsible for the high dipole moment of the nitrile group. Moreover, because of the greater electronegativity of the N atom relative to C, the π-orbitals will be displaced somewhat toward the N atom. Accordingly the over-all charge distribution will be such as to make the N atom considerably more negative than the C atom, which may be roughly represented as follows:

$$R—\overset{+}{C}\equiv\overset{-}{N}- - -$$

the dotted line indicating the direction of the lone pair orbital.

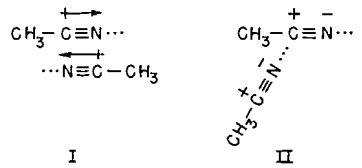
Molecular association in acetonitrile vapor has been studied by Lambert *et al.* (3). From measurements of the second virial coefficient as a function of temperature, it was concluded that dimerization occurs, with a heat of dimerization of approximately 5200 cal./mole. Dimerization was considered to be due to dipole interaction resulting from a parallel orientation of dipoles as shown in (I). This configuration would, however, appear to be extremely



I II

unlikely, since the mutual repulsions of the high charge densities in the region of the CN triple bond would make it unfavorable. The configuration shown in II in which the N lone pair orbital is directed at the C atom of the second molecule would appear to be a more probable one. This structure is closely related to the configuration observed in the crystal of the linear molecule dicyanoacetylene (2); instead of a parallel arrangement of the rod-shaped molecules, the structure is an open one in which the closest approach between neighboring molecules is between the N atom of one molecule and one of the innermost C atoms of the second molecule.

Apart from molecular interactions involving a "donor" action of the N lone pair orbital, there is also the possibility of a similar role by the two π-orbitals of the CN group. Such interaction to form the so-called π-complexes has been observed for the ethylenic and aromatic π-electrons. It is very probable, however, that the "donor" action of the π-electrons in the nitrile group is much weaker than that of the N lone pair orbital and may become significant only in the presence of very strong electron acceptors (acids).

The present work was undertaken in order to obtain a better understanding of the nature of the force field of the nitriles and their molecular associations. It was desired to investigate particularly those molecular associations of the nitriles which will lead to definite compound formation in the solid, the configuration of which can later be established by X-ray methods. Accordingly, the freezing-point diagrams of aceto-, propio-, butyro-, and benzo-nitrile with chloroform and with hydrochloric acid have been determined. Both chloroform and hydrochloric acid may be expected to function primarily only as acceptors, and hence if only the N lone pair orbital of the nitrile group interacts strongly with these reagents, simple 1:1 addition compounds may be expected to appear in the freezing-point diagram.

EXPERIMENTAL

A modified Beckmann freezing-point apparatus was used to obtain cooling curves. The inner glass cell, which contained the mixture being studied, was joined to a vacuum system. A glass stirrer into which was sealed a small iron slug was moved up and down by mechanically driven magnets. Cooling was effected by conduction to liquid nitrogen and the rate could be altered by

changing the pressure in the space between the inner cell and the outer glass tube.

A glass thermocouple well was sealed into the inner cell and temperatures were measured using two copper–constantan junctions. The thermocouple voltage (reference junctions in ice) was recorded continuously during cooling with a recording potentiometer. A platinum resistance thermometer was used to obtain a calibration of the thermocouple–recorder arrangement.

Compositions of the binary liquid mixture were changed by addition of one of the components, either from a pipette or by condensation from a weighing bulb attached to the vacuum system. Hydrogen chloride was added to the nitrile by condensing it into the cell with liquid nitrogen. The amount of gas condensed was obtained by measuring the pressure change in a calibrated volume. Reagent grade chemicals were used throughout without further purification. Interpretation of cooling curves was based on the analysis by Mair *et al.* (5). Temperature measurements were accurate within ±0.5° C.

RESULTS

The freezing-point diagrams for chloroform with each of the four nitriles studied are plotted in Fig. 1. In Fig. 2 the corresponding binary diagrams for hydrogen chloride with each of the three alkyl nitriles are shown. The melting points of the addition compounds appearing in these diagrams are collected in Table I.

DISCUSSION OF RESULTS

The occurrence of intermolecular complexes of both chloroform and hydrogen chloride with the nitriles in a 1:1 mole ratio had been anticipated. The considerations underlying this expectation have been outlined above and the results amply confirm the basic concepts of the nature of the molecular interaction put forward. However, the absence of the 1:1 complex in the chloroform–acetonitrile system was unexpected. The most probable explanation of this anomaly is that acetonitrile is capable of associating with itself more strongly than with chloroform. The nature of the mutual association of acetonitrile molecules has already been referred to; it does not appear likely that this is due to dipole association but results from the positive character of the C atom of the nitrile group. The latter accordingly acts as an acceptor to the donor lone pair orbital on the N atom of a neighboring molecule. In the higher nitriles the positive character of the nitrile C atom is less pronounced owing to the greater inductive effect of the larger alkyl groups. In these nitriles the C atom is now a weaker acceptor than the H atom of the chloroform molecule, with which they accordingly form the 1:1 compound.

If the above explanation for the absence of the 1:1 compound in the acetonitrile–chloroform system is correct, we may expect that with a much stronger acceptor (acid) than chloroform, such as HCl, the mutual association in acetonitrile would be disrupted in favor of the more stable addition compound $CH_3CN.HCl$. This is confirmed by the freezing-point diagram shown in Fig. 2.

Since the donor lone pair orbital on the N atom of the nitrile group is directed out along the C–N axis the 1:1 addition compounds of the nitriles with chloroform and hydrogen chloride can be assigned the following structures:

$$R—C{\equiv}N- - -H—CCl_3 \qquad R—C{\equiv}N- - -H—Cl$$

where the dotted line indicates the direction of the lone pair orbital. The latter forms a hydrogen bond with the H atom of chloroform and with that of hydrogen chloride. These structures presumably involve a completely linear configuration of nuclei* as follows: C—C≡N- - -H—C in the first com-

**This statement assumes a collinear configuration of the lone pair orbital direction and the H—X acceptor in the hydrogen bond (see Ref. (7)).*

pound, and C—C≡N- - -H—Cl in the second, where in each case the first C atom is part of the alkyl group. A determination of the crystal structure of these compounds, which may be expected to have a somewhat open structure, would therefore be of interest.

The 1:1 addition compounds of the nitriles with hydrogen chloride cannot be regarded as salts. The low melting point of these compounds is not compatible with such a structure. On the other hand there is some evidence that in the presence of moisture the addition compound may slowly change to the corresponding salt. Thus if acetonitrile is saturated with hydrogen chloride and allowed to stand at room temperature in the presence of water vapor, white crystals, presumably the salt, are observed to separate from the solution after several days. The transition from a molecular addition compound, in which the binding forces are primarily the electrostatic forces of a hydrogen bond, to that of the corresponding salt may be expected to be favored by the presence of a high dielectric medium such as water. Hydrolysis of the nitrile under these conditions (room temperature) to the corresponding carboxylic acid may however occur to some extent.

The fact that the nitriles do not readily form salts with hydrogen chloride, whereas the corresponding amines do, is of some interest in connection with the relative donor properties exhibited by the nitrogen lone pair orbital in these two classes of compounds. From considerations of the degree of *sp* hybridization occurring in the N lone pair orbital in amines (or ammonia) and in the nitriles, it was previously concluded (7) that the latter should exhibit stronger donor properties. This conclusion is, however, not confirmed by the present results. An alternative relative measure of donor strength of lone pair orbitals is the ionization potential since, for molecules of the type under consideration here, ionization involves removal of an electron from the lone pair orbital. Hence the lower the ionization potential the stronger should be the donor property of the lone pair electrons. The ionization potentials for acetonitrile and methylamine are 12.4 ev. and 9.4 ev. respectively (6), which thus appear to represent more nearly the relative donor strengths indicated by the present experiments.

Additional molecular compounds other than the 1:1 compounds also occur in some of the freezing-point diagrams at lower nitrile concentrations. A number of these have incongruent melting points. Thus butyronitrile forms an incongruent melting compound with chloroform having the probable composition $C_3H_7CN.3CHCl_3$. The three alkyl nitriles studied all form incongruent melting compounds with hydrogen chloride with the probable composition 2RCN:3HCl.

Of particular interest are the well-defined compounds occurring in the alkyl nitrile – HCl systems with the composition RCN:5HCl (a further compound with even lower nitrile concentration appears in the acetonitrile–HCl system). From the general shape of the freezing-point diagrams, these compounds are evidently much less stable than the corresponding 1:1 compounds. Since they appear in all three nitrile systems, the alkyl group, R, is not a determining factor, and hence the additional donor "centers" which

are evidently brought into play must be attributed to the nitrile group. Apart from the lone pair orbital on the N atom, the only other possible donor "centers" available are the two π-orbitals of the C–N triple bond. Since these orbitals are orthogonal to each other and are directed at right angles to the C–N axis, the configuration shown in Fig. 3 would appear to be the most

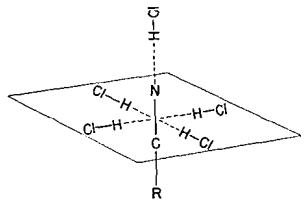

Fig. 3.

probable structure for the 1:5 compounds. One HCl molecule is bonded to the N lone pair, while four HCl molecules are accommodated in a plane at right angles to the molecular axis. It is assumed that each π-orbital can act as donor to two HCl molecules which are directed in the plane at an orientation of 180°. Little is known about the donor properties of π-orbitals, and particularly about those of the "triple" bond. However, if such donor action, even though it is weak, is possible at all, one might expect it to be manifest under the conditions of the present experiments, that is to say at low temperatures and in the presence of a strong small-molecule acceptor such as HCl. Moreover, if the above-postulated structure is correct one might expect analogous structures to occur with hydrogen chloride and acetylene or its derivatives. This possibility is now being investigated.

ACKNOWLEDGMENT

We wish to thank Mr. Yves Lupien for assistance in some of the experimental measurements.

HYDROGEN PEROXIDE AND ITS ANALOGUES

VII. CALORIMETRIC PROPERTIES OF THE SYSTEMS $H_2O - H_2O_2$ AND $D_2O - D_2O_2$[1]

By Paul A. Giguère, B. G. Morissette[2], A. W. Olmos[3], and O. Knop[4]

ABSTRACT

The heat of mixing of hydrogen peroxide and water and the heat of vaporization of the mixtures were measured over a wide concentration range at 0° C. with a Bunsen ice calorimeter and at 26.9° with a diphenyl ether calorimeter. The heat capacities of the solutions were determined between these two temperatures. Similar measurements were carried out on the corresponding deuterium compounds. The heat of decomposition of hydrogen peroxide catalyzed by colloidal platinum was also measured at 26.9° as a function of concentration. Correlation of all the results leads to the following recommended values for the thermochemical properties of the pure peroxides in the liquid state at 25° C.

		H_2O_2	D_2O_2
Heat of decomposition	(kcal./mole)	23.44 ± 0.02	23.41 ± 0.02
Heat of vaporization	(kcal./mole)	12.34 ± 0.03	12.51 ± 0.05
Heat of mixing	(cal./mole)	819 ± 2	807 ± 2
Heat capacity	(cal./deg. mole)	21.35 ± 0.05	22.9 ± 0.1

A number of related functions are given for convenience in recalculating these quantities to other temperatures. Apart from their practical value the new data are of interest in connection with molecular association and hydrogen bonds.

INTRODUCTION

A previous paper in this series (5) reported measurements of some thermal properties of hydrogen peroxide made at 0° C. in an ice calorimeter. Among these were preliminary results on the heat of decomposition of the liquid at various concentrations, which showed serious discrepancies with other published values. In view of the importance of such data in thermochemical equations involving hydrogen peroxide it was felt desirable to repeat the measurements using a more reliable technique. In order to minimize the importance of corrections to 25° C., the standard temperature, an isothermal calorimeter working with diphenyl ether (m.p. 26.9°) was used as described elsewhere (7). This calorimeter also has the advantages of greater sensitivity and easier operation than the ice calorimeter.

Calculation of the heat of formation of gaseous hydrogen peroxide from the heat of decomposition of the liquid requires knowledge of the heat of vaporization. Therefore, this quantity was also measured at the same temperature as a function of concentration. Comparison of the results with those previously found at 0° C. revealed a strong temperature dependence of the heat of mixing of hydrogen peroxide and water. As only scanty data on this property were available in the literature, the present measurements were extended to include

direct determinations of the heat of mixing at both 0° and 26.9° C. from 99% down to fairly low concentrations of peroxide.

The importance of these measurements is twofold. First, they make possible a more exact correlation between the various sets of thermochemical data and a more accurate extrapolation to arrive at the properties of pure hydrogen peroxide. Secondly, they provide much-needed experimental material for testing the validity of proposed theories of solutions of non-electrolytes. Indeed, the system hydrogen peroxide – water is of special interest in that connection as it is probably the simplest binary system with extensive hydrogen bonding. The only systematic investigation of sufficient accuracy to warrant calculation of the relevant thermodynamic functions dealt with vapor pressure of the mixtures (14). However, the results had to be extrapolated considerably beyond the temperature range of the measurements. Even if the present results are only of a modest degree of precision they are valuable in that they provide a direct source of information on the associative properties of the system hydrogen peroxide – water. In the meantime, the availability of mixtures of deuterium peroxide and heavy water was an incentive to extend the investigation to the isotopic system of compounds.

THE SYSTEM $H_2O - H_2O_2$

So far the heat of decomposition, the latent heat of vaporization, and the heat of mixing of mixtures of hydrogen peroxide and water have been investigated and reported in the literature (cf. (15) for a review). Of these quantities the last one is by far the smallest. It may be obtained indirectly from the other two but the calculations involve differences between two large quantities. To arrive at reasonably precise values the heats of decomposition or vaporization would have to be measured with much greater accuracy than has been done until now. Therefore, it seemed more logical to determine experimentally the heat of mixing of hydrogen peroxide and water and then to use the results to obtain accurate values of the heats of decomposition and vaporization from pertinent data for the pure components.

The temperature dependence of these quantities could be ascertained either directly, by measurements at two or more different temperatures, or indirectly through Kirchhoff's equation. For the latter method the heat capacities of the solutions are needed, and since no reliable data could be found in the literature for this quantity, it was determined at a number of concentrations.

Heat Capacity

The method and experimental details were essentially the same as used previously for measuring the heat capacity of pure liquid hydrogen peroxide (5), except that the initial temperature of the sample was 26.9° C. instead of 25°. The results listed in Table I give an idea of the precision of the measurements. In particular, the average of three determinations with pure water agrees to better than 0.1% with the accepted values of the mean specific heat c_p over the same temperature interval. Extrapolation leads to 0.628 cal./deg. gm. or 21.35 cal./deg. mole for pure H_2O_2, a value considered fairly accurate on account of the short extrapolation and the practically straight-line

relationship in that range. A slightly higher value, 0.632 cal./deg. gm., has been reported by Foley and Giguère; the discrepancy was traced to a small error in the calibration of the mercury thermometer used by these authors. For the present work a platinum resistance thermometer (Leeds and Northrup, certified at the National Bureau of Standards) was employed.

A plot of the molar enthalpy change of the solutions from 0° to 26.9° C. is shown in Fig. 1 as a function both of the weight fraction w_p and mole fraction N_p of hydrogen peroxide. From a large-scale graph smoothed values were obtained and from these various related properties were derived for convenience in calculating other thermochemical quantities of the peroxide–water mixtures as illustrated below. These derived functions are defined in Table II and their numerical values are given in concentration steps of $10w_p$. For these calculations the following constants were used: oxygen, $C_p = 6.97$; water vapor, $C_p = 7.98$; hydrogen peroxide vapor, $C_p = 10$ cal./deg. mole (11).

[d] $\theta_m C_p = C_p(H_2O, l) + \frac{1}{2} N_p C_p(O_2, g) - C_p(\text{solution}) = N_p \theta C_p$.
[e] $\theta C_p = (1+n) C_p(\text{solution}) - (1+n) C_p(H_2O, l) - \frac{1}{2} C_p(O_2, g)$.

Heat of Mixing

Previous measurements of this quantity reported in the open literature are, in chronological order, those of de Forcrand (3), of Roth, Grau, and Meichsner (13), of Evans and Uri (4), and of Kubaschewski and Weber (10). However they covered only a narrow concentration range and the experimental conditions were not always fully stated. For the present work two different experimental techniques were tried in succession. In the first one (experimenter M.) two small test tubes, one fitting inside the other, were used. The inner tube containing the peroxide solution had a very thin bottom so that it could easily be broken with a glass rod that also served as a stirrer. It was

noticed that the thermal leak was always slightly greater after the mixing owing to a slight decomposition of the peroxide by the glass fragments. However, the difference was small (of the order of 0.5 cal./hr.) and the correction was applied from the instant of mixing.

In the second method (experimenter K.), which was applied only to measurements in the diphenyl ether calorimeter, the water was added to the peroxide solution in a small test tube from a long pipette fitted with a rubber bulb. Care was taken that the tip of the pipette did not touch the inside walls of the test tube nor the peroxide solution. The tip of the pipette was formed into a thick-walled capillary and it was coated with a thin film of Halocarbon grease to reduce the size of the drops and prevent them from creeping up the outer wall of the pipette. The amount of water added was determined by difference weighing. To prevent drops of water from falling prematurely into the peroxide solution the pipette was warmed a little before it was filled with water and weighed. Stirring was achieved by means of a small glass-enclosed magnet (Alnico alloy) resting in the peroxide solution. A similar magnet was placed in the bottom of the calorimeter well and so oriented that it repelled the magnet in the test tube. Raising and lowering the latter provided sufficient

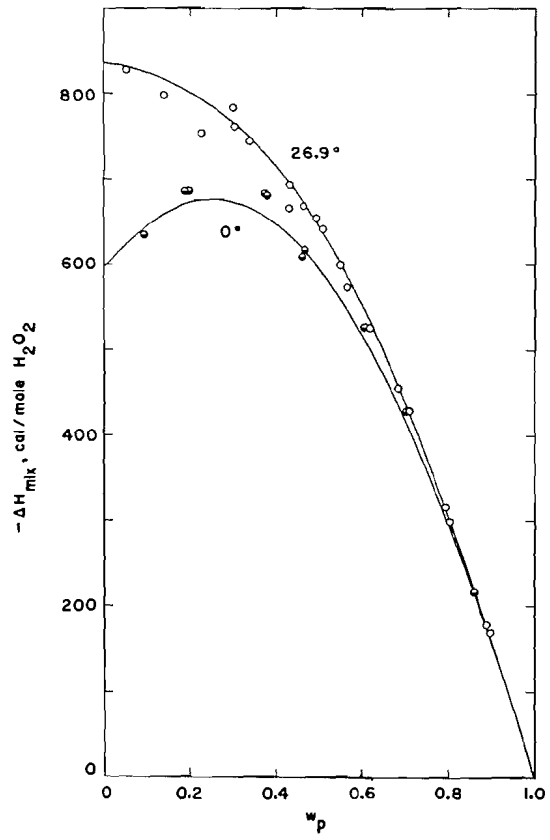

FIG. 2. Heat of mixing of hydrogen peroxide and water at 0° and 26.9° C.

stirring. The progress of the mixing operation could be followed visually to some extent by observing the "schlieren" in the solution but the only safe indication that the mixing was complete was the thermal leak of the calorimeter as shown by the movement of the mercury in the capillary (7).

A run lasted about two hours including the determination of the heat leak of the calorimeter after the reaction. The final concentration of the solution was checked by means of the refractive index; the agreement with the calculated composition was always good. The maximum amount of liquid that could be accommodated in the test tube was only 3 ml. For that reason most of the determinations were carried out with concentrated solutions of peroxide in order to have a good precision on the calorimetric measurements. This had the advantage of minimizing the importance of extrapolation to 100% hydrogen peroxide. On the other hand, it increased the uncertainty at low concentrations because the curve flattens out then (Fig. 2) and the differential heat effect becomes progressively smaller. On recalculating to one mole of peroxide the

experimental error is magnified gradually, so that it is quite large at zero concentration of peroxide.

The experimental results given in Table III refer to both one mole of peroxide, ΔH_{mix}, and one mole of solution, $\Delta_m H_{mix} = N_p \cdot \Delta H_{mix}$, as is customary. Graphical extrapolation led to 834 cal./mole for the heat of mixing of the pure peroxide to infinite dilution at 26.9° C. and from this, the correction to be applied to each determination was computed. The results at 26.9° were taken as the basis of the correlation for the following reasons. They are twice as numerous as those at 0° and they were obtained by two different experimenters using two different techniques in one of which, at least, errors due to decomposition of the peroxide were successfully eliminated. Then the measurements were made at a later stage when more experience had been gained. Finally the diphenyl ether calorimeter is more than three times as sensitive as the ice calorimeter and its performance has also been found to be somewhat more regular and reliable.

A set of smoothed values of the heat of mixing at 26.9° were obtained by interpolation and extrapolation from the composite aggregate. As may be seen in Fig. 2 the majority of experimental points fit very closely to the smoothed curve. By means of the equations

[1] $$\Delta H_{mix}(T° \text{ C.}) = \Delta H_{mix}(26.9° \text{ C.}) - \Delta C_p \cdot \Delta T$$

and

[2] $$\Delta_m H_{mix}(T° \text{ C.}) = \Delta_m H_{mix}(26.9° \text{ C.}) - \Delta_m C_p \cdot \Delta T,$$

where ΔT is the temperature interval from 26.9° and the terms ΔC_p and $\Delta_m C_p$ are taken from Table II, the smoothed values of the heat of mixing given in Table IV were obtained. It may be pointed out here that recalculation of the

data to 0° C. involves no great uncertainty since it does not require knowledge of the instantaneous values of the heat capacity of the solutions, the enthalpy changes having been measured directly between the two very same temperatures. The fit of experimental points to the calculated curve at 0° is not especially good (Fig. 2). In particular it is strange that the two points showing the

greatest discrepancy were duplicated closely. A similar situation occurred in previous measurements of the heat of decomposition (5) and must have originated in the performance of the ice calorimeter.

A plot of the heat of mixing per mole of solution shows that the curve for 26.9° is nearly symmetrical with respect to the axis $N = 0.5$ (Fig. 4). In fact a general second-degree equation derived from all the experimental results in Table III exhibited no significant departure from a symmetrical form. Considering the exceptional nature of the hydrogen peroxide – water mixtures this property is interesting. The dotted line in Figs. 3 and 4 refers to the equation derived by Scatchard, Kavanagh, and Ticknor (14) from their vapor pressure measurements. Their expression

$$[3] \qquad \Delta_m H_{mix} = N_p N_w[-1017+85(N_p-N_w)+13(N_p-N_w)^2]$$

leads to much too high values, especially for dilute peroxide solutions, but this is not surprising as the numerical coefficients were chosen in such a way as to give an equation independent of temperature. These authors felt that the accuracy of their measurements did not warrant calculation of the variation of the heat of mixing with temperature. They pointed out that their equation

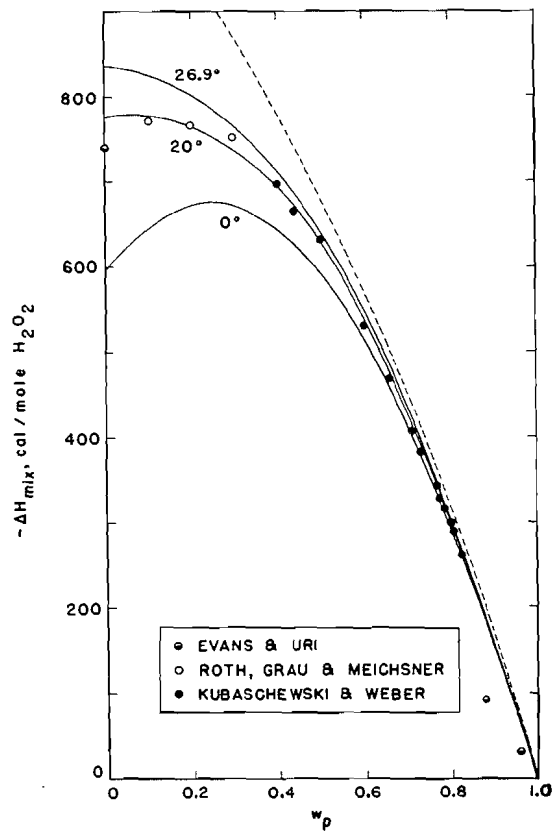

FIG. 3. Comparison of various published data for the heat of mixing of hydrogen peroxide and water with the present ones recalculated to 20° (solid curve).

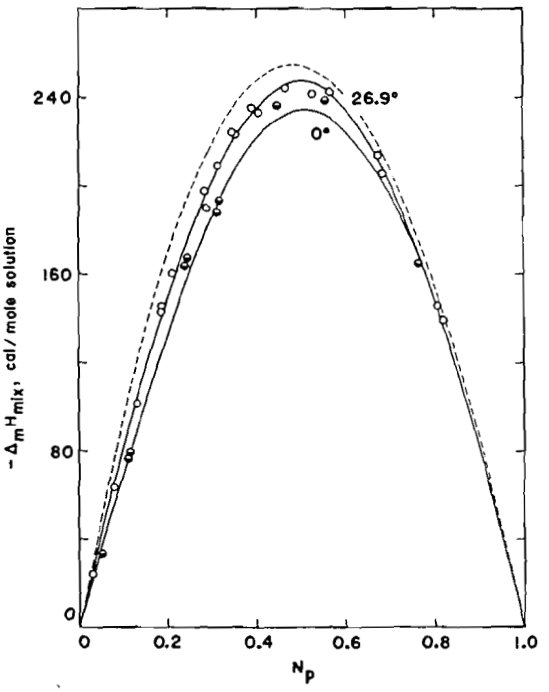

FIG. 4. Heat of mixing, per mole of solution, of hydrogen peroxide and water at 0° and 26.9° C.

should yield more correct values of the heat of mixing in the temperature range of their vapor pressure measurements, namely 60° to 90° C., and this is borne out by the trend of the curves in Fig. 3.

Heat of Vaporization

Measurements of the heat of vaporization at 26.9° were carried out as described before (5) and mostly with concentrated solutions in order to secure a reliable value for the pure peroxide. The quantity obtained by extrapolation, 12,315 cal./mole, was combined with the heat of mixing to obtain the heat of vaporization at various concentrations. Agreement with the experimental results (in Table V) is very good in all cases, the maximum deviation (at

74.2% H_2O_2) being less than 0.3%. From these data smoothed values were obtained for 0° and 25° by means of the equation

$$[4] \qquad \Delta_m H_{vap}(T°\ C.) = \Delta_m H_{vap}(26.9°\ C.) - D_m C_p \,.\, \Delta T.$$

Here again (Table VI) excellent agreement is found with the quantity previously reported for pure hydrogen peroxide at 0°, 12.59 kcal./mole (5).
