In view of the difficulties encountered previously with a solid catalyst a colloidal solution of platinum was used this time. It allows a better control of the reaction rate, especially at the beginning, and complete decomposition is more easily achieved. Any dilution effect of the platinum sol must be entirely negligible in the present conditions. The colloidal suspension was prepared after the classical method of Bredig (1) in which an electric arc is struck between platinum wires immersed in distilled water. The circuit comprised a 150-volt battery in series with a 90-ohm shunt and a 22-henry inductance. Because the latter was too low for stable performance the arc lasted only 15–20 sec. at a time. The brownish suspension of platinum was filtered to remove all coarse particles and diluted to a suitable concentration. Then it was placed in a small pipette closed by a stopcock and protected by a tiny glass tube over the tip to prevent drops of the catalyst from falling prematurely in the peroxide solution. The latter was contained in a small test tube in the central well of the calorimeter. Once thermal equilibrium was reached the pipette was taken out of the protective tube and the colloidal solution was added dropwise, very slowly at first, to secure a reasonable reaction rate. Analysis of the residue confirmed that in all cases decomposition was complete. In between runs it was necessary to clean the test tube with aqua regia as otherwise the sample of peroxide decomposed spontaneously owing to traces of platinum adsorbed on the glass.

The results of seven determinations (by experimenter M.) are compared in Table VII with values calculated from the heat of mixing and the heat of

decomposition of the pure peroxide averaged from extrapolations of each experimental result (in the fourth column). The latter quantities agree among themselves to within ±20 cal. except for that at 74.2% H_2O_2 for which the rate of reaction was too fast. When the present results are compared with those of previous authors (5, 12, 13) the only serious discrepancies arise from some of the preliminary measurements of Foley and Giguère considered doubtful at the time. As was done for the other calorimetric properties smoothed values of the heat of the chemical reaction

$$[N_p\ H_2O_2 + N_w\ H_2O](l) \rightarrow H_2O(l) + \tfrac{1}{2}N_p\ O_2(g)$$

were calculated for 0° and 25° C. by means of the equations

[5] $$\Delta H_{dec}(T°\ C.) = \Delta H_{dec}(26.9°\ C.) - \theta C_p\ .\ \Delta T$$

and

[6] $$\Delta_m H_{dec}(T°\ C.) = \Delta_m H_{dec}(26.9°\ C.) - \theta_m C_p\ .\ \Delta T;$$

these values are shown in Table VIII. The quantities thus found for 0° were deemed more reliable that any obtainable from direct determinations with the

ice calorimeter. As has been remarked before (6) the heat of decomposition of pure hydrogen peroxide in the liquid state is practically temperature-independent.

THE SYSTEM $D_2O - D_2O_2$

The same general pattern was followed in measuring the thermochemical properties of the deuterium compounds except that no determinations of the heat of decomposition were carried out because the amount of isotopic material needed would have been prohibitive. Instead, this quantity was calculated from the corresponding one for hydrogen peroxide and the zero-point energy difference of the two molecules (11). This method (details to be published later) leads, no doubt, to more reliable results than could be achieved experimentally at present. On the whole the calorimetric measurements for the deuterium system of compounds were fewer and less accurate than for the hydrogen compounds because of the difficulty and cost of preparation of deuterium peroxide. In fact this compound has been available in convenient quantities only since the application of the electrodeless discharge method (8).

Heat Capacity

Three solutions only were measured (Table IX) as the highest concentration of deuterium peroxide available at the time was about 75%. Two determinations with liquid heavy water (99.6% D_2O) gave a value within 1% of that extrapolated from the most recent data (2). As could be expected the experimental points fall on a curve nearly parallel to that for the hydrogen compounds (Fig. 1). This property was relied upon to extrapolate the curve to 100% D_2O_2. A set of smoothed values of C_p (Table X) were obtained from a large-scale plot. The mean heat capacity of heavy water vapor was taken as 8.13 (9), and that of deuterium peroxide vapor, as 11 cal./deg. mole (11).

Heat of Mixing

The second of the above-described methods was followed for measuring the heat of mixing of deuterium peroxide and heavy water at 26.9° C. As shown in Table XI and Fig. 5 the data are quite extensive, covering the composition range from 98.3% D_2O_2 (the highest concentration ever obtained) for the initial solution, to 7.1% for the most dilute solution. Smoothed values of the heat of

mixing were calculated as in the case of the hydrogen peroxide – water system; obviously, the uncertainty of these quantities (Table XII) is greater than for the hydrogen compounds. It is interesting to note that the heat of mixing of the $D_2O - D_2O_2$ system is smaller than that of the $H_2O - H_2O_2$ system contrary to the other calorimetric properties. The difference is particularly marked for the $\Delta_m H_{mix}$ function (Fig. 6). The significance of this situation will be considered later in the light of other associative properties of the two binary systems.

calculating the smoothed values at 0° and 25° (Table XIV) from the heat of mixing and the heat of vaporization of pure deuterium peroxide found by extrapolation. As in the case of water, isotopic substitution by deuterium raises the heat of vaporization of hydrogen peroxide, the effect (170 cal./mole) being about half of that for water (330 cal./mole).

CONCLUSIONS

The present thermochemical data for hydrogen peroxide and its mixtures with water are recommended as superseding previous values because they are based on extensive series of calorimetric measurements closely intercorrelated. The heat of decomposition and heat of vaporization were determined directly on very concentrated solutions in order to arrive at accurate values of these quantities for the pure peroxide. Numerous determinations of the heat of mixing enabled interpolation over the whole concentration range. Finally, from the heat capacities of the mixtures it is possible to recalculate the various properties with fair accuracy over a moderate temperature interval. Although, in general, the calorimetric measurements were executed in such a way as to yield the maximum of internal consistency, it must be remembered, in using the new data, that they are not all known to the same degree of accuracy.

As for the system D_2O–D_2O_2, the above measurements provide us not only with the thermodynamic properties of the pure peroxide, but also with comprehensive data on an isotopic system of compounds, the only one, no doubt, thus investigated so far. In a following paper of this series we intend to present a discussion of these two binary systems from the point of view of the existing theories of solutions of non-electrolytes, together with recalculated values of the excess functions and other associative properties.

ACKNOWLEDGMENT

The authors are grateful to the National Research Council for financial assistance and to Mr. R. L. Wentworth of the Massachusetts Institute of Technology for helpful suggestions.

RÉSUMÉ

On a mesuré à 0° C. dans un calorimètre à glace, et à 26.9° dans un calorimètre à oxyde de phényle les propriétés thermochimiques suivantes de mélanges de peroxyde d'hydrogène et d'eau à différentes concentrations: chaleur spécifique, chaleur de vaporisation, et chaleur de mélange. Des mesures semblables ont ensuite été effectuées sur les composés isotopiques, peroxyde de deutérium et eau lourde. La chaleur de décomposition du peroxyde d'hydrogène catalysée par le platine colloïdal a été déterminée de nouveau avec précision. Par corrélation interne de ces données on est arrivé à un système de fonctions et d'équations permettant de calculer les quantités thermochimiques à toute concentration et sur un intervalle de température modéré.

Outre leur intérêt pratique les nouveaux résultats sont importants du point de vue de la théorie des solutions de liquides associés.

COMBINATION AND DISPROPORTIONATION OF ETHYL RADICALS: INFLUENCE OF THE REACTION $H+C_2H_5 = C_2H_6$[1]

By Moyra J. Smith,[2] Patricia M. Beatty,[3] J. A. Pinder, and D. J. Le Roy

ABSTRACT

The mercury ($^3P_1$) photosensitized hydrogenation of ethylene has been studied at room temperature as a function of ethylene concentration, mercury concentration, and light intensity. In addition to combination and disproportionation, ethyl radicals have been shown to take part in the reaction

$$H+C_2H_5 = C_2H_6.$$

The conditions favoring this reaction have been established and anomalous values previously found for the ratio of ethane to butane have been explained. The value obtained for the ratio of the rate constants for the disproportionation and combination of ethyl radicals, $0.15\pm.01$, is in excellent agreement with the values obtained by other methods. Hexane formation is of some importance at low light intensities and high ethylene concentrations, and is adequately accounted for by the reactions

$$C_2H_5+C_2H_4 = C_4H_9$$
$$C_4H_9+C_2H_5 = C_6H_{14}.$$

INTRODUCTION

It is now generally agreed that in systems containing ethyl radicals both combination and disproportionation will take place. From the variety of data discussed by Steacie (13) it is clear that in some instances it is not justifiable to equate the ratio of the rate constants for disproportionation and combination, k_4/k_3, to $(C_2H_6)/(C_4H_{10})$, $(C_2H_4)/(C_4H_{10})$, or to $\frac{1}{2}((C_2H_6)+(C_2H_4))/(C_4H_{10})$ because of the occurrence of secondary reactions which consume ethylene or because the products may be formed in some other way. When these factors are taken into account both reactions appear to have small or negligible activation energies and steric factors not greatly different from unity (6). Nevertheless, in the case of the mercury photosensitized hydrogenation of ethylene there are differences in the apparent value of k_4/k_3 at room temperature which are greater than the experimental errors.

There is little doubt that the basic mechanism of the reaction at room temperature is the following:

$$Hg^*+H_2 = 2H+Hg \quad [1]$$
$$H+C_2H_4 = C_2H_5 \quad [2]$$
$$2C_2H_5 = C_4H_{10} \quad [3]$$
$$2C_2H_5 = C_2H_6+C_2H_4. \quad [4]$$

However, from the amounts of ethane and butane formed Moore and Taylor (11) found k_4/k_3 to be 0.17, while Le Roy and Kahn (9) found values ranging from 0.22 to 0.61. In their recent study of the mercury photosensitized hydrogenation of acetylene Cashion and Le Roy (4) found evidence for reactions [3] and [4], although the ratio $(C_2H_6)/(C_4H_{10})$ varied from 0.77 to 1.25.

[1]*Manuscript received January 27, 1955.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.
[2]*Present address: Somerville College, Oxford.*
[3]*Present address: Division of Applied Chemistry, National Research Council, Ottawa, Ontario.*

The latter authors suggested that in systems containing atomic hydrogen, as well as ethyl radicals, "high" values of the ratio might be obtained because of the following reactions:

$$H+C_2H_5 = C_2H_6^* \quad [5]$$
$$C_2H_6^* = 2CH_3 \quad [6]$$
$$C_2H_6^*+M = C_2H_6+M. \quad [7]$$

This set of reactions was first postulated by Darwent and Steacie (5) in order to explain their results on the mercury photosensitized decomposition of ethane. The over-all reaction

$$H+C_2H_5 = C_2H_6 \quad [8]$$

would be more likely to occur at high pressures, while the over-all reaction

$$H+C_2H_5 = 2CH_3 \quad [9]$$

would be more likely to occur at low pressures. Nevertheless, even at the low pressures (*ca.* 0.5 mm.) used in the Wood-Bonhoeffer discharge method there is some evidence that D atoms will add to ethyl radicals by the analogue of reaction [8] (14, 15). Berlie and Le Roy (2) studied the reaction of H atoms with ethane in a manner which made it possible to detect the occurrence of reaction [8], and their results indicate that it takes place to some extent at pressures as low as 5 mm.

In the present investigation we have been able to show that reaction [8] is of considerable importance in the mercury photosensitized hydrogenation of ethylene at room temperature and that when it is taken into account a value of k_4/k_3 may be obtained which is in good agreement with the most reliable values obtained by other methods.

The following *local* rate equations are obtained for the mechanism consisting of reactions [1], [2], [3], and [4]:

$$d(C_2H_6)/dt = k_4I_a/(k_3+k_4) \quad [i]$$
$$d(C_4H_{10})/dt = k_3I_a/(k_3+k_4). \quad [ii]$$

It follows that the ratio of the final concentrations, $(C_2H_6)_f/(C_4H_{10})_f$, should be independent of light intensity and the concentrations and equal to k_4/k_3.

If reactions [5], [6], and [7] are included in the mechanism the *local* rate equations cannot be solved explicitly unless certain approximations are made. Most of the present experiments were carried out with total pressures of the order of 220 mm., and the carbon balances indicated that reaction [6] was of no importance. The net effect of reactions [5] and [7] will be the consumption of H atoms and ethyl radicals by reaction [8]. Two limiting conditions then arise: (*A*) the rate of reaction [8] is sufficiently small that the relative concentrations of H atoms and ethyl radicals are not appreciably affected by its occurrence, and (*B*) the rate of [8] is sufficiently large that it controls the ethyl radical concentration.

For the limiting condition (*A*) it can be shown that

$$\frac{d(C_2H_6)/dt}{d(C_4H_{10})/dt} = \frac{k_4}{k_3}+\frac{2k_8(k_3+k_4)^{\frac{1}{2}}I_a^{\frac{1}{2}}}{k_2k_3(C_2H_4)}. \quad [iii]$$

This equation applies to *local* rates and cannot be integrated rigorously without a knowledge of the spatial distribution of I_a and of the radical concentrations. It is possible to calculate I_a as a function of the distance from the front window of the cell from a knowledge of the mercury concentration and the extinction coefficients for the absorption of 2537 Å radiation (which vary across the width of the absorption line), but the calculation can only be carried out for an assumed form for the emission line from the lamp. The rates of diffusion of the various species would also have to be taken into account. The spatial integration of [iii] is therefore fraught with a considerable amount of difficulty. Nevertheless, if a number of experiments are carried out with the same lamp, and using the same mercury concentration, the spatial distribution of I_a will remain constant, and under these conditions it will probably be justifiable to integrate [iii] with respect to time, viz.,

$$\frac{(C_2H_6)_f}{(C_4H_{10})_f} = \frac{k_4}{k_3} + \frac{4.606\ k_8(k_3+k_4)^{\frac{1}{2}} I_e^{\frac{1}{2}}}{-\Delta(C_2H_4)\ k_2k_3} \log\frac{(C_2H_4)_0}{(C_2H_4)_f}. \qquad [iv]$$

The quantity I_e in this expression will be the effective average value of I_a.

The expression analogous to [iv] for the limiting condition (B) is

$$\frac{(C_2H_6)_f}{(C_4H_{10})_f} = \frac{3\ k_8{}^2 I_e}{k_2{}^2 k_3} \cdot \frac{-\Delta(C_2H_4)}{(C_2H_4)_0{}^3 - (C_2H_4)_f{}^3}. \qquad [v]$$

If we set $(C_2H_4)_0/(-\Delta(C_2H_4)) = \sigma$, equation [v] may be written in the more convenient form,

$$\frac{(C_2H_6)_f}{(C_4H_{10})_f} = \frac{k_8{}^2 I_e}{k_2{}^2 k_3} \cdot \frac{1}{-\Delta(C_2H_4)\ .\ (C_2H_4)_0(\sigma - 1 + 1/3\sigma)}. \qquad [vi]$$

For example, if a constant conversion of 50% is used in each experiment $(\sigma - 1 + 1/3\sigma)$ will be equal to 7/6.

EXPERIMENTAL

A number of exploratory experiments showed that $(C_2H_6)_f/(C_4H_{10})_f$ decreased when either the incident light intensity or the concentration of mercury in the cell was reduced. In both cases this would amount to a reduction of I_a which, in its rigorous definition, is the number of quanta absorbed per unit volume per unit time at a point in the reaction vessel. It was also found that the ratio of ethane to butane increased when the ethylene concentration was decreased at constant hydrogen pressure. Previous work had shown that below 200°C. the ratio was not sensitive to hydrogen pressure over the range from approximately 100 to 300 mm. (9).

Since the preliminary experiments appeared to bear out the predictions of the theory outlined above, a number of experiments were carried out to study in detail the effect of incident light intensity, mercury concentration, and ethylene pressure. In addition, some experiments were performed using a cell with an optical path length of approximately two millimeters. With such a cell the amount of surface exposed to H atoms and ethyl radicals would be

approximately doubled and surface reactions, if they occurred, would be enhanced.

All of the experiments were carried out at room temperature and all pressures were corrected to 25°C. Products were fractionated by low temperature distillation (8) and the C_2 fraction was analyzed for ethylene and ethane by the method of Pyke, Kahn, and Le Roy (12). For the experiments reported here the lamps were of the low pressure type with rare gas carrier; for such lamps the half-width of the emission line is somewhat greater than for a true resonance lamp (10) and the effective reaction zone will penetrate farther into the cell.

EFFECT OF INCIDENT LIGHT INTENSITY

These experiments were carried out in a static system using a 1 liter spherical cell with a plane Vicor window. Initial hydrogen pressures were approximately 180 mm., initial ethylene pressures were approximately 20.5 mm., and the average pressure drop was 10.7 mm. The incident light intensity was varied simply by changing the distance between the lamp and the cell; in this way the rate of pressure drop was varied from 1.42×10^{-3} to 163×10^{-3} mm. min^{-1}.

The values of I_e were unknown and hence the results could only be expressed in relative terms. The inverse square law would not be valid for a finite source and thus the distances from lamp to cell could not be used to obtain relative values of I_e. However, since all of the products are saturated $-\Delta(C_2H_4)$ will be equal to $-\Delta P$, and the rate of pressure drop will be equal to the rate of consumption of ethylene. The latter is equal to $(1+k_3/(k_3+k_4))I_e$ for the limiting condition (A), and to I_e for the limiting condition (B).

In Fig. 1 a plot of $(C_2H_6)_f/(C_4H_{10})_f$ against $[(-\Delta P)^{\frac{1}{2}}t^{\frac{1}{2}}]^{-1}\log[(C_2H_4)_0/(C_2H_4)_f]$ is shown; this corresponds to the use of equation [iv], i.e. to the limiting condition (A). It is seen that as I_e approaches zero $(C_2H_6)_f/(C_4H_{10})_f$ becomes linear in $I_e^{\frac{1}{2}}$. The intercept at $I_e = 0$ is 0.14_5, in good agreement with the values

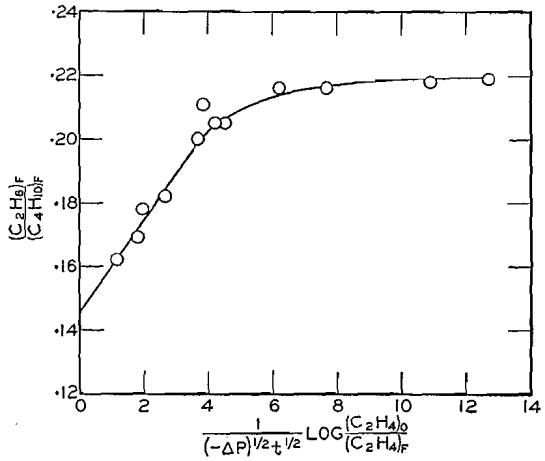

FIG. 1. Test of equation [iv] for variations in incident light intensity.

of k_4/k_3 obtained at room temperature by other methods (*vide* Table I). The decrease in slope which sets in at high light intensities (large values of the abscissa) is not predicted by the present mechanism; the curvature in Fig. 1 is opposite to that predicted on the assumption that the limiting condition (*B*) obtains at high light intensities. Because of the assumptions involved in the spatial integration of I_a this is not surprising. However, regardless of detailed mechanisms, it is obvious that reaction [8] should become negligible at low light intensities and that under these conditions $(C_2H_6)_f/(C_4H_{10})_f$ should approach k_4/k_3.

EFFECT OF MERCURY CONCENTRATION

Even though we do not know the spatial distribution of I_a it is clear that a reduction in the mercury concentration in the cell will cause a decrease in the number of quanta absorbed in unit time in any unit volume. According to the present mechanism this should cause a decrease in $(C_2H_6)_f/(C_4H_{10})_f$. A number of experiments were performed with a circulating system in which the gases were passed through a trap containing mercury at temperatures ranging from 27°C. to −12°C. before entering the cell. In each case hydrogen pressures of approximately 220 mm. and ethylene pressures of approximately 17.5 mm. were used. The pressure decreases were not kept as close to 50% of the initial ethylene pressure as in the other experiments and ranged from 5.7 to 14 mm. The incident light intensity was kept constant by fixing the position of the lamp with respect to the cell window. As shown in Fig. 2, the ratio

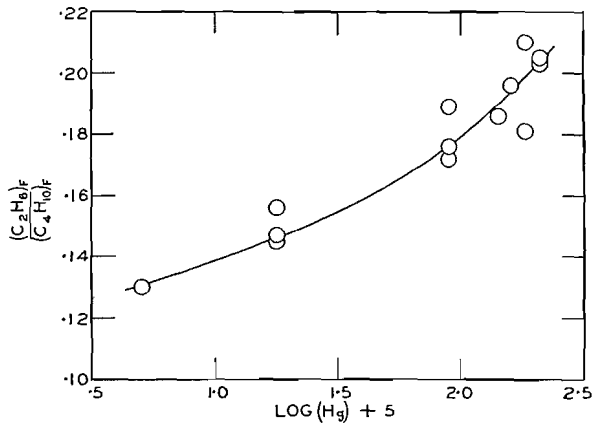

FIG. 2. Influence of the mercury concentration in the cell on the ethane/butane ratio.

$(C_2H_6)_f/(C_4H_{10})_f$ decreases as the mercury concentration is lowered, in agreement with the predictions of the present mechanism. It would be expected, of course, to approach a constant value, k_4/k_3, as I_e tends toward zero.

EFFECT OF OPTICAL PATH LENGTH

Since, in a mercury photosensitization experiment, most of the light is absorbed very close to the entrance window, an increase in the ratio of the surface to the effective volume of the reaction zone can best be accomplished

by using a cell with a short optical path. The cell was constructed by blowing a bulb in the middle of a piece of quartz tubing and then heating and sucking in one side to form a concave cell with more or less parallel sides approximately two millimeters apart. The side arms of the cell were painted black.

A series of three experiments using this cell and four with a cell having an optical path length of about 10 cm. were made using a circulating system. The same distance between lamp and cell was used in each case. Initial hydrogen pressures were approximately 205 mm.; initial ethylene pressures were approximately 17.5 mm. With the small cell $(C_2H_6)_f/(C_4H_{10})_f$ was $0.22_9 \pm .00_6$; with the large cell it was $0.22_7 \pm .00_7$. It would therefore appear that surface reactions, if they do occur, have no influence on this ratio.

EFFECT OF ETHYLENE CONCENTRATION

A series of experiments was performed in which the initial ethylene pressure was varied from 0.75 mm. to 17.9 mm. using a constant hydrogen pressure of approximately 218 mm. To provide sufficient products for analysis at the lower ethylene pressures a circulating system containing a buffer volume was used. The average fraction of ethylene consumed in any experiment was $0.52 \pm .05$. The results are plotted in Fig. 3 according to equation [iv]. The

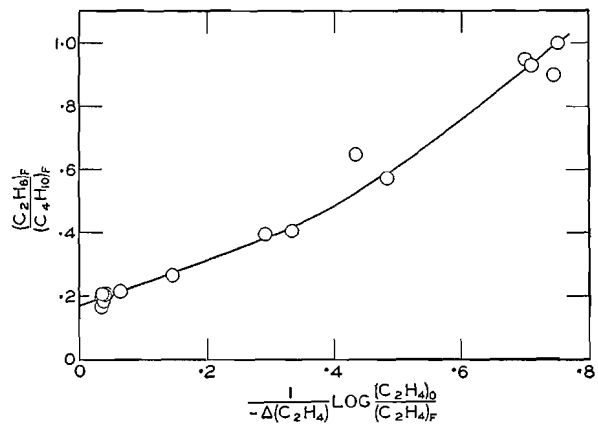

FIG. 3. Influence of ethylene concentration on the ethane/butane ratio. Since approximately 50% of the initial ethylene was used in each experiment, the abscissae are, roughly, $0.6/(C_2H_4)_0$.

value of I_e should be constant for the series, at least to a first approximation, since both the position of the lamp and the mercury concentration in the cell were fixed. The range of values of $(C_2H_6)_f/(C_4H_{10})_f$ shown in this figure is greater than any obtained previously by the method of mercury photosensitization and illustrates the important effect of ethylene concentration.

The value of k_4/k_3 obtained from the intercept of Fig. 3 is approximately 0.16. Accepting this value, it follows that for initial ethylene pressures of the order of 1 mm., and with the light intensities used in these experiments, approximately four times as much ethane is produced by reaction [8] as by reaction [4].

Fig. 3 shows an appreciable curvature upwards at low ethylene pressures (large values of the abscissa). Such a curvature would be expected if the limiting condition (B) were to come into play. However, it is believed that at least part of this curvature is due to the fact that the rate of circulation of the gases becomes important at low ethylene concentrations.

The circulating pump used had a displacement of 30 cm.^{3} min^{-1}. At high ethylene pressures this would be sufficient to ensure that the partial pressure of ethylene in the gas leaving the cell would not be much less than in the gas entering the cell. But at low ethylene pressures most of the ethylene entering the cell would be consumed. Because these experiments were of short duration much of the gas never left the buffer volume and as a result, although only approximately 50% of the total ethylene was consumed a considerably larger figure would apply to the gas which actually passed through the cell. If this effect could be allowed for the points for low ethylene pressures in Fig. 3 would be moved to the right, thus prolonging the range of linearity of the curve.

HEXANE FORMATION

At low light intensities, particularly at the higher ethylene concentrations, low temperature distillation indicated a product having a vapor pressure in the hexane range. Under the most favorable conditions for its formation it amounted to only 2.1% of the saturated products. Its vapor pressure was determined in the range $-52°$ to $-72°$ using the low temperature still (8) and the values agreed within a range of approximately 5°C. with those calculated for n-hexane from the data of International Critical Tables; the thermocouple used had not been calibrated. The vapor pressure at 27°C., determined as the condensation pressure in a McLeod gauge, was 155 mm., compared to 163 mm. calculated for n-hexane.

The most probable method of formation of n-hexane is by the sequence

$$C_2H_5+C_2H_4 = C_4H_9 \qquad [10]$$
$$C_4H_9+C_2H_5 = C_6H_{14}. \qquad [11]$$

The conditions which were found to be the most favorable for the formation of hexane are the least favorable for the occurrence of reaction [8] and hence it is unlikely that any hexane would be formed by the addition of H atoms to hexyl radicals.

For the limiting condition (A),

$$\frac{d(C_6H_{14})/dt}{d(C_4H_{10})/dt} = \frac{k_{10}(k_3+k_4)^{\frac{1}{2}}(C_2H_4)}{k_3 I_a^{\frac{1}{2}}}. \qquad [vii]$$

It was pointed out previously that the rate of pressure drop should be proportional to the effective average value of I_a, and hence, to a first approximation, $(C_6H_{14})_f/(C_4H_{10})_f$ should be directly proportional to $(C_2H_4)_0/(-\Delta P/\Delta t)^{\frac{1}{2}}$. The data plotted in Fig. 4 show that this is approximately true. Because of the small amounts involved, hexane could not be measured with very great accuracy.

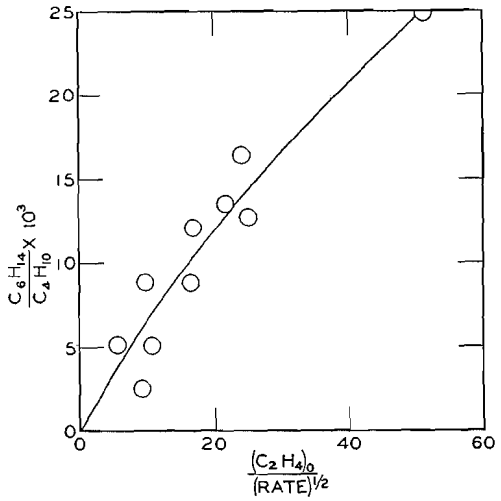

FIG. 4. Correlation of hexane formation with equation [vii]. The effective average value of I_a is assumed to be proportional to the rate of pressure drop.

DISCUSSION

From the present data the most probable value of k_4/k_3 is 0.15±.01. This is in good agreement with most of the recent work based on other methods, as shown in Table I.

TABLE I

VALUES OF k_4/k_3 OBTAINED BY DIFFERENT METHODS
(Room temperature)

Method	k_4/k_3	Ref.
Photolysis of diethyl mercury	0.35	(6)
Photolysis of propionaldehyde	0.1	(3)
Photolysis of diethyl ketone	0.12 ± .02	(7)
Photolysis of 2,2′,4,4′ tetradeuterodiethyl ketone	0.1	(16)
Photolysis of azoethane	0.13 ± .02	(1)
This research	0.15 ± .01	

The discrepancies among the values of the ratio $(C_2H_6)_f/(C_4H_{10})_f$ obtained by the method of mercury photosensitization can now be understood. Moore and Taylor (11) used an initial ethylene pressure of 40 mm. and their value of 0.17 would therefore be expected to be only slightly larger than k_4/k_3. Le Roy and Kahn (9), using the full intensity of the lamp and an initial ethylene pressure of 13.3 mm., obtained 0.61 and 0.44 for the ratio; from the pressure drops they observed the final pressures of ethylene would be approximately 1.0 and 1.3 mm., respectively. Using a lower light intensity, initial ethylene pressures of 15.7 mm., and final ethylene pressures of 5.3 and 5.9 mm., they obtained 0.22 and 0.28 for the ratio. Their results are therefore not out of line with those obtained in the present investigation.

Cashion and Le Roy (4) found ethane and butane to be important products in the mercury photosensitized hydrogenation of acetylene and attributed their origin to ethyl radicals produced in the reactions

$$C_2H_3+H_2 = C_2H_5 \quad [12]$$
$$H+C_2H_4 = C_2H_5. \quad [2]$$

However, since they found the ethane/butane ratio to be in the range 0.77 to 1.25 they concluded that ethane must be formed in some reaction in addition to [4], namely [8]. An examination of their results shows that for conditions in which [12] would be negligible compared to [2] (i.e. $(H_2) \rightarrow 0$, their Fig. 2) the ethane/butane ratio would be approximately 1.4. The ethylene concentration in this case would have been zero at the beginning of the experiment and about 0.2 mm. at the end. The large values of the ratio obtained by them can be adequately explained in terms of the present mechanism. They were reluctant to attribute ethane/butane ratios of almost ten times the accepted value of k_4/k_3 solely to the influence of reaction [8] and suggested the additional reaction

$$C_2H_5+C_2H_3 = C_2H_6+C_2H_2. \quad [13]$$

It is clear, however, that the last postulate is unnecessary.

THE RELATIVE ABUNDANCES OF NEODYMIUM AND SAMARIUM ISOTOPES IN THE THERMAL NEUTRON FISSION OF U^{235} AND U^{233} [1]

By E. A. Melaika, M. J. Parker, J. A. Petruska,[2] and R. H. Tomlinson

ABSTRACT

The relative fission yields of neodymium and samarium isotopes have been measured with a mass spectrometer for samples of natural uranium and U^{233} that had been irradiated with moderated neutrons. The cross sections for neutron capture by Sm^{149} and Sm^{151} have been determined to be $66{,}200 \pm 2500$ barns and 12,000 barns respectively, relative to the cross section of a B^{10} monitor. The half-lives of Pm^{147} and Sm^{151} have been evaluated to be 2.52 ± 0.08 yr. and $\sim$93 yr., respectively, from samarium fission yield data for samples differing in age by seven years.

INTRODUCTION

Inghram, Hayden, and Hess (5) have reported a mass spectrometric determination of the relative abundances of rare earth isotopes separated from fission products in uranium fuel rods. The values obtained were considered to represent relative fission yields of U^{235}, although the previously accepted mass–yield curve (9) for the thermal neutron fission of U^{235} was considerably different in this mass region. Inghram *et al.* pointed out, however, that the mass spectrometric values represent yields for the neutron energy distribution found in thick uranium slugs and do not necessarily correspond to those for the thermal neutron fission of U^{235}. Likewise, the various pile neutron capture cross sections reported by Inghram *et al.* need not be applicable for a thermal neutron energy distribution.

This paper reports the mass spectrometric determination of the relative yields of neodymium and samarium isotopes for the thermal neutron fission of U^{235} and U^{233}. The amount of neutron capture by Sm^{149} and Sm^{151} was large in a sample of uranium for which the integrated neutron flux was monitored with BF_3. From the observed ratios of the samarium isotopes in this sample, the measured fission yields of samarium isotopes, and the change in the B^{10}/B^{11} ratio for the BF_3, the neutron capture cross sections of Sm^{149} and Sm^{151} relative to that of B^{10} were obtained. Since the relative abundances of the samarium isotopes were measured at different times after irradiation for the various samples, it was possible to evaluate the half-lives of Sm^{151} and Pm^{147}.

EXPERIMENTAL

For the study of the fission yields for U^{235}, four samples of normal uranium metal were irradiated in the NRX reactor at Chalk River and one at Oak Ridge. A 50 mgm. sample of UO_3, in which the uranium content was 14.4 atom % U^{233}, 0.6 atom % U^{235}, and 85.0 atom % U^{238}, was irradiated in the

**Time of irradiation.*

†Time from beginning of irradiation until time of chemical separation and analysis by mass spectrometer.

NRX reactor for the study of U^{233} fission. The irradiation data are summarized in Table I. In no case was the integrated flux greater than 2×10^{19} neutrons/cm.^{2}, and hence Pu^{239} did not contribute more than 0.1% to the fission products of either U^{235} or U^{233}. In sample *D*, the contribution from fast neutron fission of U^{238} was estimated from pile data to be 2.5%; it was probably comparable in samples *B* and *C*. Sample *A*, which was irradiated in a thermal column, had essentially no U^{238} fission. Unfortunately, in the case of sample *A*, the time of irradiation was divided into three periods so that the time between periods could not be neglected. Since several determinations of fission yields were made for sample *A* at widely different times, and since there are three corresponding values of t_2 for each of these determinations, the value of t_2 tabulated for sample *A* is only an approximate average.

The uranium, after dissolution in nitric acid, was separated from the fission products either by ion exchange or by precipitation from solution at pH 7 with hydrogen peroxide. The ion exchange method permitted a separation of the neodymium from the samarium and other fission products, whereas the peroxide precipitation method did not. It was found, however, that separation of the rare earths prior to mass spectrometric analysis was not necessary. The peroxide precipitation method was preferred since a much higher chemical yield of neodymium and samarium could be obtained.

The mass spectrometer that was used was a 90° sector instrument with magnetic scanning and a hot filament ion source (2). When a platinum-plated tungsten filament was used, neodymium and samarium samples of 0.01 μgm. were adequate. The neodymium yields were measured from the NdO^+ ion spectrum at a relatively low filament temperature; the samarium was measured from the Sm^+ ion spectrum which occurred only at a higher filament temperature. The SmO^+ ions also appeared at this higher temperature and were used for the determination of the Sm^{152}/Sm^{154} ratio since a LaO^+ peak at mass 155 tended to interfere with the Sm^{154} metal ion peak when the fission products were not separated from each other. Since, in each case, only mass spectra of

the expected fission isotopes were observed, and since no changes in the ratios were observed with time, it was assumed that no other elements contributed to the mass spectrum of either the samarium or the neodymium.

RESULTS

The relative abundances of the samarium isotopes obtained from the thermal neutron fission in four samples of normal uranium and one sample of uranium containing 14.4% U^{233} are given in Table II. The fission samarium

abundances reported as the observed values have been corrected for contamination by natural samarium. The contamination corrections, which were about two to three per cent of the total samarium present, were based on the natural abundances of the samarium isotopes and the measurement of the Sm^{148} which is not formed in fission. In order to obtain the relative cumulative fission yields shown in Table II, it was necessary to take into account several known nuclear processes which occur in the various fission chains which form samarium isotopes. The equations relating the observed ratios to the cumulative fission yields of the samarium isotopes have been given by Inghram *et al.* (5).

Since beta decay in the mass 150 chain from fission terminates at Nd^{150}, the observed Sm^{150} is the result of neutron capture by Sm^{149}. The total relative yield for the mass 149 chain was obtained by direct addition of the Sm^{149} and Sm^{150} abundances. The ratio of the observed Sm^{149} to Sm^{150} is given by equation [1].

$$[1] \qquad \frac{N_{149}}{N_{150}} = \frac{1-\exp(-{}_{62}\sigma^{149}\phi t_1)}{{}_{62}\sigma^{149}\phi t_1 - 1 + \exp(-{}_{62}\sigma^{149}\phi t_1)}$$

where N_{149}/N_{150} = the observed ratio of Sm^{149} to Sm^{150},
${}_{62}\sigma^{149}$ = the neutron capture cross section for Sm^{149},
ϕ = the neutron flux,
t_1 = the time of irradiation.

For samples *A* and *C*, the amount of Sm^{149} capture was small and the flux could be estimated only from pile operation data. For sample *D*, however, there was a large amount of Sm^{150} formed, and the flux was accurately determined from the change in the B^{10}/B^{11} ratio in a sample of BF_3 that was irradiated simultaneously. The ratio of the B^{10}/B^{11} ratio before irradiation to the B^{10}/B^{11} ratio after irradiation was found to be 1.029 ± 0.001. The value of ${}_5\sigma^{10}\phi t_1$, where ${}_5\sigma^{10}$ is the neutron absorption cross section for B^{10}, was calculated to be 0.0286 ± 0.0010 assuming that all of the change in the ratio of the boron isotopes was due to the $B^{10}(n, \alpha)Li^7$ reaction. From the observed ratio N_{149}/N_{150} for sample *D*, a value of 0.472 ± 0.007 was calculated with equation [1] for ${}_{62}\sigma^{149}\phi t_1$. Thus, the ratio ${}_{62}\sigma^{149}/{}_5\sigma^{10}$ is 16.5 ± 0.6 at an estimated neutron temperature of 57°C. This ratio corresponds to a neutron capture cross section of $66{,}200 \pm 2500$ barns if a value of 755 barns (1) is used for the neutron capture cross section of natural boron and 18.83% (4) is used for the natural abundance of B^{10}.

The fission yield of Sm^{151} relative to that of Sm^{149} is given by equation [2] as a function of the observed samarium ratios and the time.

$$[2] \qquad \frac{N_{151}}{(N_{149}+N_{150})} = \frac{f_{151}[1-\exp(-{}_{62}\lambda^{151}t_1 - {}_{62}\sigma^{151}\phi t_1)][\exp(-{}_{62}\lambda^{151}t_2 + {}_{62}\lambda^{151}t_1)]}{f_{149}({}_{62}\lambda^{151} + {}_{62}\sigma^{151}\phi)t_1}$$

where $N_{151}/(N_{149}+N_{150})$ = the ratio of Sm^{151} to Sm^{149} plus Sm^{150} observed at time t_2,
f_{151}/f_{149} = the ratio of the cumulative yields of mass chains 151 and 149,

$_{62}\lambda^{151}$ = the decay constant of Sm^{151},
$_{62}\sigma^{151}$ = the neutron capture cross section for Sm^{151},
ϕ = the neutron flux,
t_1 = the time of irradiation,
t_2 = the time from the beginning of irradiation until the time of chemical separation and isotopic analysis.

If the time of irradiation is short compared to the time of the analysis, and if t_1 is small compared to the half-life of Sm^{151}, equation [2] reduces to equation [3].

$$[3] \qquad \frac{N_{151}}{(N_{149}+N_{150})}=\frac{f_{151}\exp(-{}_{62}\lambda^{151}t_2)[1-\exp(-{}_{62}\sigma^{151}\phi t_1)]}{f_{149}\,{}_{62}\sigma^{151}\phi t_1}.$$

In the case of samples A and C, the contribution to mass 150 resulting from neutron capture by Sm^{149} is only 1 to 2%, and, therefore, neutron capture by Sm^{151} will be negligible provided its cross section is less than that of Sm^{149}. Thus, for samples A and C, equation [3] reduces to equation [4].

$$[4] \qquad \frac{N_{151}}{(N_{149}+N_{150})}=\frac{f_{151}\exp(-{}_{62}\lambda^{151}t_2)}{f_{149}}.$$

The observed relative yield at mass 152 is given by equation [5], and its simplified forms, comparable to equations [3] and [4], are given by equations [6] and [7].

$$[5] \qquad \frac{N_{152}}{(N_{149}+N_{150})}=\frac{f_{152}}{f_{149}}+\frac{f_{151}\,{}_{62}\sigma^{151}\phi t_1}{f_{149}({}_{62}\lambda^{151}+{}_{62}\sigma^{151}\phi)^2t_1^2}$$
$$\times[({}_{62}\lambda^{151}+{}_{62}\sigma^{151}\phi)t_2-1+\exp(-{}_{62}\lambda^{151}t_1-{}_{62}\sigma^{151}\phi t_1)]$$

$$[6] \qquad \frac{N_{152}}{(N_{149}+N_{150})}=\frac{f_{152}}{f_{149}}+\frac{f_{151}}{f_{149}\,{}_{62}\sigma^{151}\phi t_1}[{}_{62}\sigma^{151}\phi t_1-1+\exp(-{}_{62}\sigma^{151}\phi t_1)]$$

$$[7] \qquad \frac{N_{152}}{(N_{149}+N_{150})}=\frac{f_{152}}{f_{149}}.$$

Thus, for samples A and C, the observed Sm^{152} ratios are the actual relative fission yields as shown by equation [7]. The yield of Sm^{151} for these samples, however, is dependent on the half-life of Sm^{151} as shown by equation [4]. From the observed ratios for these two samples, it was possible to solve this equation for both f_{151}/f_{149} and $_{62}\lambda^{151}$. For sample A, the uncertainty of the value of t_2 in this calculation is not significant. The value obtained for f_{151}/f_{149} is 0.398 and for $_{62}\lambda^{151}$ is 0.00747 $yr.^{-1}$ which corresponds to a half-life of 93 yr.

The yields of Sm^{151} and Sm^{152} for sample D have been set equal to the values obtained from samples A and C. For sample D, $_{62}\sigma^{151}\phi t_1$ may then be calculated from either the observed ratio $Sm^{151}/(Sm^{149}+Sm^{150})$ and equation [3], or the observed ratio $Sm^{152}/(Sm^{149}+Sm^{150})$ and equation [6]. These equations give values of 0.090 and 0.080, respectively, for $_{62}\sigma^{151}\phi t_1$. From the value of $_5\sigma^{10}\phi t_1$, the cross section of natural boron, and the natural abundance of B^{10} given

above, values of 12,500 and 11,200 barns are obtained for the neutron capture cross section of Sm^{151}.

The amount of Sm^{147} relative to the amount of Sm^{149} plus Sm^{150} is given by equation [8].

$$[8] \quad \frac{N_{147}}{(N_{149}+N_{150})} = \frac{f_{147}[{}_{61}\lambda^{147}t_1 - \exp(-{}_{61}\lambda^{147}t_2 + {}_{61}\lambda^{147}t_1) + \exp(-{}_{61}\lambda^{147}t_2)]}{f_{149}\ {}_{61}\lambda^{147}t_1}$$

where ${}_{62}\lambda^{147}$ = the decay constant of Pm^{147}.

In equation [8], there are two unknowns, ${}_{61}\lambda^{147}$ and f_{147}/f_{149}, and these can be evaluated using the observed data from samples *C* and *D* if it is assumed that f_{147}/f_{149} is the same for both samples. A value of 0.275 ± 0.007 yr.$^{-1}$ was obtained for ${}_{61}\lambda^{147}$ which corresponds to a half-life of 2.52 ± 0.08 yr. The ratio, f_{147}/f_{149}, was found to be 2.10 ± 0.04. The limits of error assigned to the above values are obtained only from the standard deviations of the mass spectrometric results for samples *C* and *D*. Data for sample *A* were not used for this calculation because of the uncertainty introduced by the three-period irradiation.

Since the samarium yields were determined for only one set of irradiation conditions with U^{233}, the relative fission yields could not be obtained in the same manner as above for U^{235}. In this case, it was necessary to assume a smooth fission mass–yield curve, which gave 0.422 for the ratio f_{151}/f_{149} and 0.278 for the ratio f_{152}/f_{149}.

For this U^{233} sample, neutron capture by Sm^{149} was considerable, and equation [1] was used to solve for ${}_{62}\sigma^{149}\phi t_1$. A value of 2.19 ± 0.09 was obtained. Also, equation [3] may be used to solve for ${}_{62}\sigma^{151}\phi t_1$ if the value of 0.422, interpolated from a smooth yield–mass curve, is taken for the relative yield of mass chain 151 to 149. A value of 0.229 is obtained for ${}_{62}\sigma^{151}/{}_{62}\sigma^{149}$. If a value of 66,200 barns is taken for the value of ${}_{62}\sigma^{149}$, then a value of 15,200 barns is is obtained for ${}_{62}\sigma^{151}$.

The results for the relative abundances of the neodymium isotopes in the fission of U^{235} and U^{233} have been given in Table II. The abundances reported as the observed values have already been corrected for contamination by a small amount of natural neodymium. The contamination corrections, which were about 0.5% of the total neodymium present, were based on the natural abundances of the neodymium isotopes and the measurement of Nd^{142}, which is not formed in fission. The relative fission yields take into account the amount of 282-day Ce^{144} which had not decayed to Nd^{144} at the time of analysis. The Ce^{144} correction for sample *C* was negligible.

DISCUSSION

Table II shows that the relative fission yields of the neodymium and samarium isotopes resulting from the thermal neutron fission of U^{235} decrease more rapidly with increasing mass than the yields obtained by Inghram *et al.* (5). The difference (e.g. 11% at mass 150) appears to be real since the precision of either set of data is better than one per cent. This may be the result of different neutron energy distributions, since the fission products analyzed by Inghram *et al.* were obtained from a fuel rod where a large fraction of the

neutrons would have energies of several Mev., whereas in the present work neutron energies were essentially thermal. When fission is induced by particles of very high energy, it is well known that the fission yield curve tends to become more symmetrical. Some evidence of this change has been shown to occur even with fast (fission) neutrons. For example, in the case of Pu^{239}, the relative yield of masses 153/140 was found to be 0.074 for thermal neutrons, whereas the same relative yield was 0.096 for fast (fission) neutrons (12). Whereas the neutron energy may account for the greater part of the difference between the relative yields reported by Inghram *et al.* and those obtained in this work, it is also necessary to consider that fission products contributed by the fast neutron fission of U^{238} and to a smaller extent from the thermal neutron fission of Pu^{239} may have influenced the values obtained by Inghram *et al.*

Apart from the general increase in the slope of the mass–yield curve, the present results indicate that the yield of mass 144 is about 7% greater than the value obtained by Inghram *et al.* and hence could not fall on a smooth curve such as Inghram *et al.* have drawn. The apparently high yield at mass 144 may be taken as evidence for the fine structure predicted for this mass by Pappas (8).

Table II also shows the relative fission yields of the neodymium and samarium isotopes resulting from the thermal neutron fission of U^{233}. These relative yields are probably accurate to within one per cent except at mass 154 where a combination of a low yield and a comparable contamination correction make this particular yield uncertain.

A further correction must be made for the contribution to the fission products from the 0.6 atom % U^{235} present in the sample. The largest correction would occur at Nd^{150} where the relative yield would be reduced by about one per cent if it is assumed that the cross section for the formation of the neodymium isotopes is approximately the same for U^{233} and U^{235} fission. Comparison of the relative yields of neodymium and samarium for U^{233} with those for U^{235} show that the former decrease more rapidly with increase in mass of the fission product. By radiochemical methods, Steinberg *et al.* (13) have obtained yields at masses 144 (3.4%) and 153 (0.078%) while Grummitt and Wilkinson (3) have obtained yields at masses 144 (2.2%) and 147 (0.6%) for thermal neutron fission in U^{233}. Although the agreement between these groups at mass 144 is poor, the relative values obtained by each group confirm the steeper slope of the U^{233} mass–yield curve when compared to the U^{235} mass–yield curve given by Coryell and Sugarman (10).

The value of the half-life of Pm^{147} found in this work is 2.52 ± 0.08 yr. which is longer than the value of 2.26 yr. obtained by Inghram *et al.* (5). The 2.52 yr. value, however, is based on relative abundances measured at different times rather than an assumed yield as was used by Inghram *et al.* The value of 2.52 ± 0.08 yr. compares favorably with the value of 2.6 ± 0.2 yr. obtained by a counting-rate decay method (11).

The half-life of Sm^{151} based on changes in the relative abundances of Sm^{151} in fission products differing in age by about seven years is found to be 93 yr.

Whereas no limit has been set on the accuracy of this value it is considered in reasonable agreement with a value of 73^{+25}_{-14} yr. found by Karraker *et al.* (6) from the change in Sm^{151} abundances over a 3.8 yr. period.

The 66,200±2500 barn value obtained for the neutron capture cross section of Sm^{149} is based on a 755 barn cross section for natural boron. Nuclear Data (7) have reported a value of 65,000 barns for the cross section of Sm^{149} averaged for a maxwellian distribution of neutron energies at a temperature of 20.4°C. A value of 47,000 barns for pile neutrons has been reported by Inghram *et al.* (5). This value, however, is not strictly comparable to the other values without more specific information about the neutron energies. A cross section of 12,000 barns has been found for Sm^{151} relative to a 755 barn cross section for natural boron. It is difficult to set a limit of accuracy on this value since the observed changes in the isotopic abundances from which this value was calculated were small. The value of 15,200 barns obtained from the U^{233} data is based on assumed fission yields and hence has unknown reliability. Inghram *et al.* (5) have obtained a cross section of 7200 barns for the pile neutron cross section of Sm^{151} based on assumed fission yields for U^{235}.

Absolute fission yields may be obtained from the relative thermal neutron fission yields of the U^{235} and U^{233} when suitable normalization values are obtained either by radiochemical or isotope dilution methods.

ACKNOWLEDGMENTS

We wish to thank Atomic Energy of Canada Limited for supplying the U^{233} and uranium metal and arranging for the irradiation of samples. The financial support of the National Research Council of Canada and Atomic Energy of Canada Limited is gratefully acknowledged. The authors are indebted to Dr. H. G. Thode and Dr. W. H. Fleming for helpful discussions and the isotopic analysis of the BF_3.

CATALYSIS ON FILMS OF ARSENIC, ANTIMONY, AND GERMANIUM[1]

By Sir Hugh Taylor

ABSTRACT

Arsenic, antimony, and germanium films laid down on glass surfaces by decomposition of the hydrides have been studied from the standpoint of reaction kinetics in three sets of reactions: the decomposition of hydrides and deuterides, the interaction of hydrides and molecular deuterium, and the exchange reaction of hydrogen and deuterium. Only in the first of these have the surfaces marked catalytic activity. The orders of reaction and the activation energies have been determined. The accelerated catalytic influence of foreign elements, notably antimony in arsine decomposition, has been established. The results obtained contrast strikingly with the properties of clean filaments and evaporated films among the transition elements. The results emphasize the basic importance of chemical factors and de-emphasize the importance of surface cleanliness as a controlling factor in problems of chemisorption and surface catalysis.

It is a pleasant opportunity to outline, in tribute to a lifetime devoted to academic teaching and research by Professor Otto Maass in physical chemistry, some results in an area of physical chemical investigation which, while remote from the area which Professor Maass has so diligently and successfully cultivated, nevertheless has been contemporaneous with that work and has brought to the writer a large measure of the same satisfactions which research and the educational effort bring.

It is proposed to present a summary of some results recently obtained in the Princeton laboratories by a group of postdoctoral students and concerned with the catalytic properties of arsenic, antimony, and germanium films laid down on glass surfaces by the decomposition of the corresponding hydrides at appropriate temperatures. The deposited films act catalytically in the decomposition of the hydrides. Comparative experiments can also be performed on the decomposition of the deuterides. It has also been possible to study the interactions of the hydrides and deuterides among themselves and with molecular hydrogen and deuterium. The exchange reaction between hydrogen and deuterium on the several surfaces has also been examined. The results have a definite bearing on the properties of evaporated metal films which have been intensively studied in recent years in elucidation of the catalytic properties of technical metal catalysts.

Researches by Roberts (3) on the chemisorption of gases on clean flashed tungsten filaments and by Beeck (1) on the adsorption of gases on clean evaporated films of a variety of metals including nickel, iron, tungsten, rhodium, and platinum had emphasized that the activation energy of chemisorption of hydrogen on such clean surfaces was negligible, since it was demonstrably occurring at temperatures in the neighborhood of liquid hydrogen. Such observations gave rise to a very prevalent generalization that if

[1]*Manuscript received January 26, 1955.*
Contribution from the Frick Chemical Laboratory, Princeton University, Princeton, New Jersey, U.S.A.

the metal surfaces were clean the chemisorption of gases might occur without any activation energy. The determination of activation energies of chemisorption of hydrogen on a variety of technical catalysts led to the view that the cause of the activation energy might lie in the impurities present on the surfaces of all technical catalysts.

Such a point of view tended to obscure an obvious fact in the science of catalysis, namely, the very specific activity of particular elements in bringing about catalytic change. The examples of such specificity which could be quoted are legion. It may suffice, however, to recall that whereas iron and osmium surfaces are excellent catalysts in the synthesis of ammonia, nickel, and platinum are obviously inferior. Since all of these metals readily chemisorb hydrogen even down to quite low temperatures, the differences between them in respect to ammonia synthesis would seem to lie in the capacity of these surfaces to chemisorb nitrogen.

Quite recently Trapnell (5) published some comparative data on the interaction of nitrogen, hydrogen, carbon monoxide, ethylene, acetylene, and oxygen with clean evaporated films of some twenty metals between 0 and −183°C. Oxygen chemisorption is universal among the metals studied save in the case of gold. Chemisorption of both nitrogen and hydrogen is limited to transition metals, W, Ta, Mo, Ti, Zr, Fe, and alkaline earth metals such as Ca and Ba. The metals Ni, Pd, Rh, Pt, Cu, Al, K, Zn, Cd, In, Sn, Pb, Ag, and Au do not chemisorb nitrogen in this temperature range but Ni, Pd, Rh, and Pt chemisorb hydrogen. Chemisorption of carbon monoxide, ethylene, and acetylene occurs on the metals which chemisorb both nitrogen and hydrogen and in addition to these Al, Cu, and Au. The metals Zn, Cd, In, Sn, Pb, and Ag do not chemisorb carbon monoxide, ethylene, and acetylene. It is the particular virtue of this study with clean evaporated films that it emphasizes the necessity for activation energy of chemisorption even on clean surfaces.

Dr. M. Boudart in Princeton pointed out that it was possible to expand the area of our knowledge of the chemisorption of hydrogen by a study of the production of films of arsenic, antimony, and germanium by decomposition of the respective hydrides and that the nature of the isotopic hydrogen produced by decomposition of mixtures of hydrides and deuterides of these elements would give clues with respect to the interaction between hydrogen and such surfaces. Further, the constant deposition of fresh elemental product of the reaction, As, Sb, or Ge, on the surface ensured a continuous cleanliness of the surface provided the purity of the original hydrides was secured. A series of researches dealing with these topics is now in process of publication. The present occasion permits a summary survey of the results obtained.

Antimony Surfaces

Dr. K. Tamaru has studied the decomposition of stibine by a static method in the temperature range of 10 to 45°C. The rate is dependent only on the stibine pressure and independent of the hydrogen pressure. The order of reaction in stibine is unity at 45°C. and decreases with decreasing temperature

reaching 0.75 at 10°C. At 40 cm.-Hg stibine pressure the activation energy of the reaction is 8.8 kcal./mole, with lower values at lower pressures. The rate of decomposition of deuterostibine is slightly lower than that for stibine under similar conditions.

A feature common to all three surfaces can now be indicated. Stibine decomposition in presence of deuterium at 25°C. did not produce any hydrogen deuteride which shows that no exchange reaction between hydrogen and deuterium occurs at that temperature on the antimony surface. Decomposition of a mixture of stibine and deuterostibine produced a large proportion of hydrogen deuteride.

Stibine decomposes very slowly on the glass surface of a clean vessel but as antimony is deposited on the glass the rate accelerates until after 200 cm.-Hg of stibine have been decomposed the rate becomes reproducible. When a small amount of oxygen is introduced into the stibine there is a small acceleration in reaction rate but very considerably less than that to be noted subsequently in the decomposition of germane.

The evidence indicates that at the higher temperature limit of 45°C. in the measurements the chemisorption of stibine on the surface determines the rate of reaction. As the temperature is lowered the desorption of hydrogen, resulting from the decomposition of the stibine, from the antimony surface becomes slow enough to be comparable with the chemisorption process. The order of the reaction decreases and at sufficiently low temperatures where desorption of hydrogen became determinant the order would be zero. The data indicate a transition over the temperature range employed between the two kinds of rate process.

Arsenic Surfaces

The decomposition of arsine can be studied only in a much higher temperature range, between 218 and 278°C. Dr. Tamaru overcame a difficulty which had prevented good kinetic measurements by van't Hoff and Kooj (2) and by Stock and co-workers (4). This difficulty lay in the inability to form a coherent arsenic film on the surface of glass. Tamaru solved this problem by first laying down on the glass surface a coherent film of antimony on which by subsequent decomposition of arsine a coherent film of arsenic was formed. These experiments demonstrated that arsine decomposes slowly on glass even at 350°C. but decomposes more rapidly on antimony surfaces than it does on arsenic surfaces. On the antimony surface the original rate of arsine decomposition is relatively rapid, the rate decreasing as the antimony becomes covered with arsenic, constant rates of decomposition being secured after some ten experiments, this rate being assumed to be characteristic of a coherent arsenic film. In such a manner the kinetics and the activation energy of arsine decomposition on such arsenic films have been successfully obtained. We hope to be able to characterize the surfaces by electron diffraction studies.

The reaction is first order with respect to arsine and independent of hydrogen concentration. The apparent activation energy on arsenic surfaces is 23.2 kcal./mole. In the decomposition of a mixture of arsine and deuteroarsine at

255°C. intermolecular exchange occurs as revealed by infrared spectroscopy. The decomposition product contains a high percentage of hydrogen deuteride. When arsine is decomposed with molecular deuterium at this temperature no hydrogen deuteride is found, indicating no exchange between hydrogen and deuterium on the arsenic surface. Analysis of the experimental data indicates that the chemisorption of arsine is the rate determining step on arsenic surfaces.

Germanium Surfaces

Dr. P. J. Fensham who initiated this whole experimental program found that the decomposition of germane and deuterogermane on germanium films did not differ significantly in velocity. He demonstrated that the product from the decomposition of mixtures of germane and deuterogermane contained considerable amounts of hydrogen deuteride in the product hydrogen. On the other hand, germane–deuterium mixtures and molecular hydrogen – deuterium mixtures contained minimal amounts of hydrogen deuteride after reaction.

Dr. Tamaru examined the kinetics of the decomposition in greater detail and succeeded in showing that a zero order surface-catalyzed decomposition of germane occurs simultaneously with a first-order homogeneous decomposition in the gas phase in the temperature range 230 to 330°C. The kinetic expression in cylindrical vessels with surface to volume ratios from 1 to 7.5 cm.$^{-1}$ was expressible by an equation

$$v = k_0 + k_1 p$$

where v is the observed velocity, k_0 and k_1 the zero and first order constants respectively. For the two reactions the activation energies were 41.2 and 51.4 kcal./mole respectively. By filling the reaction vessel with glass wool and thus enhancing the zero order reaction some 30-fold the surface zero order reaction became dominant and the first order reaction negligible. Even in the unpacked cylindrical vessels the ratios of k_0 to $k_1 p$ were such that below 10 cm. working pressure of germane the reaction was kinetically closely zero order.

The surface reaction evidently occurs on a surface practically covered with chemisorbed GeH_x radicals and adsorbed hydrogen atoms, the evaporation of which in the steady state determines the rate of the surface reaction. That Fensham did not observe marked hydrogen deuteride formation in his experiments with germane–deuterium mixtures means either that his surface reaction was dominant in his experimental conditions over the homogeneous reaction or that this latter, if it were occurring, proceeds via GeH_2+H_2 rather than via GeH_3+H. The presence of H atoms in the latter type of decomposition would ensure considerable formation of hydrogen deuteride via the homogeneous chain-reaction exchange process $H+D_2 = HD+D$, followed by $D+H_2 = HD+H$.

Some interesting added facts emerged from the kinetic measurements. Arsine decomposes very slowly on germanium surfaces at 302°C., much more slowly than on antimony and arsenic surfaces. Nevertheless, in presence of minor amounts of arsine the rate of decomposition of germane is measurably

accelerated. Apparently, the deposition of As atoms in the germanium surface enhances the catalytic activity for germane decomposition.

Much more striking effects resulted from the introduction of small amounts of oxygen into the germane. Rapid reaction between the two gases occurs. The decomposition of residual germane on the oxygen-contaminated germane surface was markedly greater than on a pure germanium surface. Further, the accelerating influence persists through successive runs with pure germane. This indicates that the oxygen impurity retains its position and effect in the germanium *surface* in spite of further deposition of germanium in the decomposition process. The accelerating action of oxygen contamination in the germanium surface contrasts strikingly with the pronounced inhibitory effects of oxygen contamination on iron-synthetic ammonia catalysts.

DISCUSSION

The obvious conclusion from these researches is that while clean arsenic, antimony, and germanium surfaces activate the X—H bond in the several hydrides they none have any marked activation efficiency with respect to the H—H bonds in the temperature range 10 to 330°C. It follows that chemistry is involved in the process of chemisorption and that cleanliness of the elemental surface cannot substitute for the chemical factors involved. The influence of arsenic and oxygen impurities in the hydride decomposition processes on these surfaces is additional evidence in the same direction. It is expected that further studies, now in progress, will correlate these catalytic data with the growing body of data on the solid state physics of germanium.

The experience gained in the present studies makes it possible to approach the general problem of chemisorption of gases on these surfaces. Such work is in progress and will permit a correlation with the data that are being accumulated on the adsorption of gases on single crystals, notably of germanium, of such importance in the modern use of transistors.

ACKNOWLEDGMENTS

My thanks are due to Drs. Boudart, Fensham, and Tamaru for permission to make use of the data that are in process of detailed publication elsewhere. These postdoctoral workers have been assisted either by the fellowship provided to Princeton University by the Shell Fellowship Committee of the Shell Companies Foundation, Inc., of New York City, or by a research project sponsored by the Office of Naval Research, N6onr-27018 on Solid State Properties and Catalytic Activity. To both these sources of support I wish to express the indebtedness of Princeton University for their generous assistance.

PRELIMINARY STUDY OF PHOTOCHEMICAL BEHAVIOR IN THE SYSTEM NITROGEN DIOXIDE – ETHANE[1]

By T. M. Rohr[2] and W. Albert Noyes, Jr.

ABSTRACT

The addition of ethane to nitrogen dioxide either during exposure to radiation transmitted by pyrex, or afterwards, reduces the amount of oxygen formed. At room temperature this is apparently due to the effectiveness of ethane in promoting the reverse reaction of nitric oxide and oxygen to form nitrogen dioxide. At temperatures over 100° there is a reaction which uses oxygen atoms produced in the primary process. Nitroethane (or nitrosoethane) is formed along with carbon monoxide, carbon dioxide, and some methane. The results suggest that acetaldehyde is an intermediate, but acetaldehyde could not be detected because it would react thermally with nitrogen dioxide. It is not possible to give a complete explanation of the results, but suggestions can be made which might form the basis for later work.

The photochemical reaction between nitrogen dioxide and methane has been studied, but no evidence for reaction found (4). The oxygen atoms almost certainly produced in the primary process might react either with nitrogen dioxide or with methane, and the rate of the former reaction seemed to be sufficiently great to obscure the latter. Harteck and Kopsch (5) showed that oxygen atoms produced in a discharge tube react with ethane with an estimated activation energy of 7 kcal.

It was hoped in starting this investigation to obtain information both about the reactions of oxygen atoms with ethane and possibly also about the reactions of hydroxyl radicals. As so often happens, the course of the reaction is complex, and only suggestions can be made about some of the steps. A few semiquantitative estimates of relative rates can be made.

EXPERIMENTAL

Nitrogen dioxide was prepared by heating lead nitrate in a stream of oxygen, condensation by dry ice – acetone, and fractional distillation. The middle third was retained and stored at the temperature of liquid nitrogen. Stopcocks were lubricated with Myvacene-S (Dow-Corning) which proved not to be attacked by nitrogen dioxide as far as could be ascertained.

Ethane (Phillips Petroleum Company, Research Grade) appeared upon hydrogenation to contain traces of ethylene. It was mixed with nitrogen dioxide at 160° to remove ethylene and the ethane was distilled from a trap at −150°.

Mercury vapor was mostly kept out of the reaction cell by a trap immersed in dry ice – acetone. Final traces were eliminated by admission of nitrogen dioxide and evacuation just before a run. Initial pressures of reactants were measured by a Bourdon gauge.

A Hanovia Alpine burner Type S-100 was used, and the radiation (except in the first series of runs) passed through Corning Filter No. 7740 to remove radiation below 3000 Å. The beam was collimated by a quartz lens and completely filled the cell which was 2.5 cm. in diameter and 20 cm. in length. A magnetically driven glass stirrer largely prevented the development of local concentration gradients.

Owing to the nature of the products the complete analysis proved to be difficult, and not all products have been completely identified.

The gases were condensed immediately after reaction to eliminate the reverse reaction

$$2NO+O_2 = 2NO_2. \qquad [1]$$

The products not condensed by supercooled liquid nitrogen at −210° were removed by a Toepler pump. These would consist of oxygen, nitrogen (if any), carbon monoxide, methane, and possibly traces of nitric oxide. The latter would, however, mainly be held back by formation of nitrogen trioxide with nitrogen dioxide. In a few runs when the nitrogen dioxide was nearly used up, nitric oxide might appear in this fraction.

Oxygen, carbon monoxide, and methane were determined by methods previously described (8).

The separation of condensable products proved to be difficult. Carbon dioxide could not be separated from the large amount of ethane present. After removal of the ethane at −155°, the residue was condensed in a cold finger subsequently filled with mercury. After a few hours' standing nitrogen dioxide was reduced to nitric oxide which could be pumped off at −150°. The remaining products were volatilized and burned to carbon dioxide over a copper oxide furnace at 650° and the pressure of carbon dioxide measured. Blank runs showed that nitroethane could be quantitatively determined in this way.

RESULTS

Blank runs showed no thermal reaction between nitrogen dioxide and ethane to occur at temperatures up to 160°, the highest temperature used in these experiments.

The results may be summarized briefly as follows:

(*a*) The addition of carbon dioxide (120 mm.) to nitrogen dioxide (5 mm.) did not affect the rate of production of gas uncondensed at −210°. Ratio of amounts with carbon dioxide to blanks at 108°: 1.03, 1.00.

(*b*) The addition of ethane (100 mm.) to nitrogen dioxide (5 mm.) reduces the amount of gas uncondensed at −210° (mainly oxygen) by the following ratios: 25° (1.09); 108° (0.54, 0.59); 160° (0.57).

In a series of experiments at 25° the oxygen yield was about the same whether or not ethane was added, and it was not influenced by variation in ethane pressure. The formation of condensable products in these experiments is probably due to impurities in the ethane, because with each successive run the amount diminished and it became zero after the sixth run.

In experiments at 108° and at 160° the decrease of the oxygen yield in the presence of ethane, compared to that either without ethane or merely with addition of carbon dioxide, cannot be explained by postulating that the missing oxygen is used for the oxidation of ethane even if one assumes the formation of products which escape detection by analysis. The presence of ethane favors the reaction of oxygen with nitric oxide as the following experiments showed.

If after radiation of 5 mm. of nitrogen dioxide at 160° for four hours the products were condensed immediately after turning off the light, one obtained 4.88×10^{-6} moles of oxygen. If the gases were condensed 30 min. after turning off the light, one obtained only 4.39×10^{-6} moles of oxygen. One tenth of the oxygen therefore was used by reacting with nitric oxide during this period of time. Addition of 50 mm. of ethane, immediately after radiation, greatly accelerated this reverse reaction since only 2.46×10^{-6} moles of oxygen were left after 30 min. Thus 50% was used in the same period.

(*c*) Nitroethane shows continuous absorption below about 3000 Å (2, 13), but no observable products were formed when the gas was irradiated under the conditions of the present experiments. Moreover there was no observable thermal reaction between nitroethane and nitrogen dioxide at temperatures up to 160°.

(*d*) When mixtures of nitrogen dioxide (5 mm.) and nitroethane (0.04 mm.) were irradiated, the rate of production of gas not condensed at −210° was unaffected by the presence of the nitroethane. When nitroethane was present at pressures of 27–35 mm., the yield of non-condensables was reduced to about half that in the blank runs. The non-condensables were oxygen and carbon monoxide. Products not volatile at −150° would not have been detected.

(*e*) When mixtures of ethane (usually 100 mm.) and of nitrogen dioxide (5 mm.) were irradiated at 160°, the gas uncondensed at −150° (measured as carbon dioxide, see above) was formed at a constant rate. In four runs of 4,

			4.59	>9.0[b]
0[d]	0.22	0	>7.2	3.1
0	0.47	0	4.1	>9.0
[e]	0.89	0	0	>9.0
0[c]	0.20	0		

[a] *Blank with no nitrogen dioxide.*
[b] *Thermal reaction.*
[c] *100 mm. ethane also present.*
[d] P_{NO_2} = *2.5 mm.*
[e] P_{NO_2} = *10 mm.*

It is evident that there is a thermal reaction between nitrogen dioxide and acetaldehyde even at room temperature but that this reaction does not lead to methane formation.

DISCUSSION

The absorption characteristics of the system nitrogen dioxide – nitrogen peroxide have been carefully studied by Hall and Blacet (3). Since this mixture had a total pressure of 5 mm. in the present work, it can be shown from the data of Giauque and Kemp (1) that the pressure of nitrogen peroxide at 25° would be 0.17 mm. At wave lengths of 3130 and 3650 Å the absorption will be almost exclusively by nitrogen dioxide and not by nitrogen peroxide even at room temperature, and absorption by the latter will be entirely negligible at the higher temperatures used (1, 3).

The photochemistry of nitrogen dioxide has been carefully studied (7, 10). The primary process is undoubtedly

$$NO_2 = NO + O \qquad [2]$$

and this is followed by

$$O + NO_2 = O_2 + NO. \qquad [3]$$

The yield of the primary process must be high, and in the absence of foreign gases Equation [3] must occur nearly quantitatively. When foreign gases are added, Equation [3] will compete with other reactions of oxygen atoms. The latter, under conditions of the present experiments, are almost certainly

formed in the normal (^3P) state. Kinetic energies of the oxygen atoms after primary dissociation might be equivalent to 4 kcal. at 3650 Å and 8 kcal. at 3130 Å provided dissociation proceeds immediately before vibrational energy can be lost by collision. Unless steric factors are high for hot oxygen atom reactions, one would not expect to find noticeable "hot atom" effects.

If ethane is added to nitrogen dioxide, the first reaction of oxygen atoms should be

$$O+C_2H_6 = C_2H_5+OH. \quad [4]$$

The data show this reaction to be negligible at 25° compared to Equation [3] since (*a*) the amount of oxygen formed is almost the same in the presence and in the absence of ethane; (*b*) products condensed at −150° but not at −210° are negligible if the ethane has been previously exposed to radiation in the presence of nitrogen dioxide. Apparent reaction is due therefore to impurities in the ethane at this temperature.

The rate of the reaction

$$OH+C_2H_6 = C_2H_5+H_2O \quad [5]$$

is not known with precision but may have a low activation energy (12). The first reaction of ethyl radicals formed from either Equation [4] or Equation [5] should be

$$C_2H_5+NO_2 = C_2H_5NO_2 \quad [6]$$

where $C_2H_5NO_2$ is probably nitroethane but might be ethyl nitrite. Mass spectrographic analysis tends to favor the latter.

It is not possible to obtain a precise estimate of the activation energy of Equation [4]. From the results at 160° $E_4-E_3 \sim 3$ kcal. if Equation [3] and Equation [4] have the same steric factors. This result is probably low since with such a low activation energy and similar steric factors reaction [4] should compete more successfully than it does with reaction [3] at 25°. On the other hand if one takes 'condensables at −150°' divided by 'non-condensables at −210°' as a measure of the ratio of rate of Equation [4] to rate of Equation [3], one obtains from the results at 108° and at 160° a value of 8 kcal. This is based on results with considerable scatter and is not a reliable figure. One may merely say that probably the activation energy of Equation [4] is less than 10 kcal. in agreement with the work of Harteck and Kopsch (5). An activation energy of 5 kcal. or more is compatible with the results at 25°.

Oxygen atoms evidently do react with nitroethane but at a somewhat slower rate than with ethane. Hirschlaff and Norrish (6) suggest a reaction of oxygen atoms with nitroethane to give ethylene and the latter in the present system would give dinitroethane and would escape analysis by the procedure used. The probable formation of small amounts of methane and of larger amounts of carbon monoxide suggests that acetaldehyde is an intermediate. This could be formed easily from ethyl nitrite (11). This would disappear rapidly either by thermal reaction with nitrogen dioxide or by a reaction with radicals or excited molecules.

One of the striking points is the formation of oxygen during the early stages of the reaction and its subsequent disappearance. This would indicate that as

reaction proceeds, some radical or atom is produced which reacts much more rapidly with oxygen than with nitrogen dioxide and other molecules present. Not over 20% of the nitrogen dioxide would have disappeared during even the longest run. Thus this radical or atom must have a rate of reaction with oxygen of the order of magnitude of 10 to 100 times as fast as with nitrogen dioxide. Alkyl radicals may fulfill this requirement and so might possibly oxygen atoms.

The amount of carbon monoxide produced was not affected markedly by varying (*a*) the ethane pressure; (*b*) the nitrogen dioxide pressure; (*c*) the time. Blank runs showed that this lack of variation with conditions is not due to impurities.

Oxygen atoms react much less readily with carbon monoxide than with oxygen (9), but carbon monoxide may react with ozone or with peroxy radicals in the system. A detailed study of the reason why carbon monoxide apparently reaches a steady state might prove of interest.

ACKNOWLEDGMENT

This work was supported in part by contract with the Office of Naval Research, United States Navy. We wish to thank Mr. R. C. Wilkerson, Celanese Corporation of America, Clarkwood, Texas, for mass spectrographic analyses.

FURTHER DEGRADATION REACTIONS OF ANNOTININE[1]

By F. A. L. Anet[2] and Léo Marion

ABSTRACT

Both the hydroxylactone obtained by the action of chromous chloride on annotinine chlorohydrin, and the unsaturated lactone B prepared by the action of the same reagent on the hydroxylactone, contain a secondary nitrogen and a vinyl group. The unsaturated lactone A which accompanies the hydroxylactone is a cyclic allylamine which on oxidation with potassium permanganate yields an amino acid $C_{14}H_{19}O_4N$. These facts make it possible to explain the reaction of chromous chloride with annotinine chlorohydrin. The amino acid can be dehydrogenated to an acid containing a free carboxyl and a lactamic grouping ($C_{14}H_{15}O_3N$) but no longer containing a lactone ring. The lactamic acid which seems to contain a benzene ring is readily decarboxylated to a neutral substance $C_{13}H_{15}ON$, showing color reactions and ultraviolet absorption similar to those of strychnine.

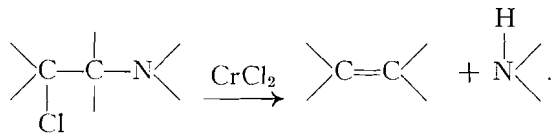
Annotinine, $C_{16}H_{21}O_3N$, was found (9) to react with hydrochloric acid to form annotinine chlorohydrin, $C_{16}H_{22}O_3NCl$, which was reduced (10) with chromous chloride to a mixture of "unsaturated lactone A", $C_{16}H_{21}O_2N$, and "hydroxylactone", $C_{16}H_{23}O_3N$. The latter compound on more vigorous treatment (10) with chromous chloride in strongly acidic solution gave "unsaturated lactone B", $C_{16}H_{21(23)}O_2N$. The two unsaturated lactones each contained a readily reducible double bond and gave two different dihydro-derivatives (10). The relationship of these compounds has now been clarified and affords supporting evidence for MacLean and Prime's suggestion (8) of the presence of the system  in annotinine and also for the modification of this scheme to  suggested by Wiesner *et al.* (6).

Following MacLean and Prime we can write  as a grouping in annotine chlorohydrin instead of  , although the evidence adduced by these authors for the former arrangement is meager. It does allow, however, of a simple interpretation for the chromous chloride reduction products, which is not possible with the alternate cleavage of the oxide ring of annotine (see below).

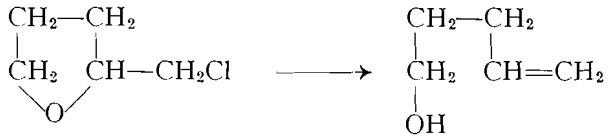
Chromous chloride is known to reduce various chlorinated derivatives of the senecio alkaloids, e.g., chloroisoheliotridene (i) by replacement of the halogen by hydrogen. Julian *et al.* (7) found that chromous chloride reduced

[1]*Manuscript received January 25, 1955.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3570.
[2]*National Research Council of Canada Postdoctorate Fellow. Present address: Department of Chemistry, University of Ottawa, Ottawa.*

steroid *vic*-dihalides to the corresponding unsaturated compounds. In both of these reductions, chromous chloride behaves in much the same way as does zinc in neutral or acidic conditions. Fieser and Ettore (5) found that zinc and acetic acid converted certain steroid *vic*-chlorohydrins to the olefins and therefore it would be anticipated that chromous chloride could effect the same reaction. Furthermore, it is only a simple extension to consider β-chloroamines which could react as below (see also Fig. 1)



That this extension is not unjustified is shown by the work of Paul (11) who showed that the reduction by metallic sodium of cyclic ethers of *vic*-chlorohydrin and of β-chloro*tert*.amine proceeds analogously, e.g., in the case of tetrahydrofurfuryl chloride and β-chloroethyldiethylamine,



$$(C_2H_5)_2N{-}CH_2{-}CH_2Cl \rightarrow (C_2H_5)_2NH + CH_2{=}CH_2\,.$$

It was found in the present work that the hydroxylactone was unsaturated and yielded a dihydro-derivative on hydrogenation and formaldehyde on ozonolysis. Although the action of acetyl chloride failed to give the expected product (10), treatment of the hydroxylactone with acetic anhydride produced a neutral O,N-diacetyl derivative (infrared bands 1740 and 1678 $cm.^{-1}$ in Nujol). The hydroxylactone was obviously not formed by simple replacement of the chlorine of annotinine chlorohydrin by hydrogen, but its formation could be readily explained by analogy to the reactions outlined above.

The unsaturated lactone A would be expected to be the olefin VIII (Fig. 1) corresponding to annotinine chlorohydrin, and this was substantiated by the reactions of the unsaturated lactone A which behaved as a cyclic allylamine. Its pK_a was 7.06 whereas that of its dihydro-derivative was 8.48 (cf. Ref. 14), and it gave a methosulphate which was smoothly hydrogenolized in the presence of Adams' catalyst with the uptake of two moles of hydrogen and the formation of a tertiary base X ($C_{17}H_{27}O_2N$). Oxidation of the unsaturated lactone A with potassium permanganate yielded an amino acid XV isolated as the sulphate, $C_{14}H_{19}O_4N \cdot \frac{1}{2}H_2SO_4$, which was identical with the oxidation

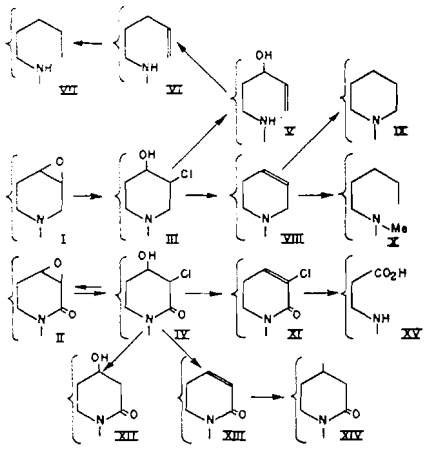


FIG. 1. Partial formulae of degradation products.

product obtained as described by Wiesner *et al.* (6) from the anhydro derivative of annotinine lactam chlorohydrin XI (8).

The relation of the unsaturated lactone B to the other products was obscured by the fact that its infrared spectrum showed no NH band although that of its dihydro-derivative did contain such a band. Yet it formed a neutral N-acetyl derivative (infrared band at 1762 cm.$^{-1}$) which yielded formaldehyde on ozonolysis. The easy reduction of the unsaturated lactone B to its dihydro-derivative, and the low intensity of its ultraviolet absorption at short wave lengths also indicated the presence of a terminal methylene group. The dihydrolactone B also gave a N-acetyl derivative (infrared band at 1755 cm.$^{-1}$).

The infrared spectra in carbon disulphide of the unsaturated lactone B and its dihydro-derivative were very similar and were consistent with the presence of a vinyl group in the former. We therefore assign the partial formulae VI and VII to these compounds respectively. This is also consistent with a re-investigation of the empirical formulae of this series which showed that the unsaturated lactone B was definitely $C_{16}H_{23}O_2N$ and not $C_{16}H_{21}O_2N$.

Annotinine lactam chlorohydrin (IV) which can be prepared either by oxidation (10) of annotinine chlorohydrin, or by treatment (8, 10) of annotinine lactam with hydrochloric acid gave two main products on chromous chloride reduction. These were identical with the compounds $C_{16}H_{21}O_4N$ and $C_{16}H_{19}O_3N$ prepared previously (8) by MacLean and Prime. Since the compound $C_{16}H_{21}O_4N$ was dehydrated (8) with phosphorus oxychloride to the second compound $C_{16}H_{19}O_3N$, the two products may be allotted the partial structures XII and XIII respectively. It may be noted that XIII is produced in the chromous chloride reduction under conditions that are not sufficient to dehydrate XII, which agrees with the mechanism proposed above. MacLean and Prime (8) found that catalytic or Clemmensen reduction of annotinine lactam chlorohydrin gave XII and XIV (Fig. 1). It is most probable that XII and XIII are the primary reduction products and that XIII is further reduced

to XIV. Indeed, as expected, XII could not be hydrogenated (8). The action of phosphorus oxychloride, or prolonged treatment with boiling hydrochloric acid convert (8) annotinine lactam chlorohydrin to a compound $C_{16}H_{18}O_3NCl$ which may be represented by XI (Fig. 1). Confirmation of the structures of XI and XIII is given by their ultraviolet spectra shown in Fig. 2 with those of

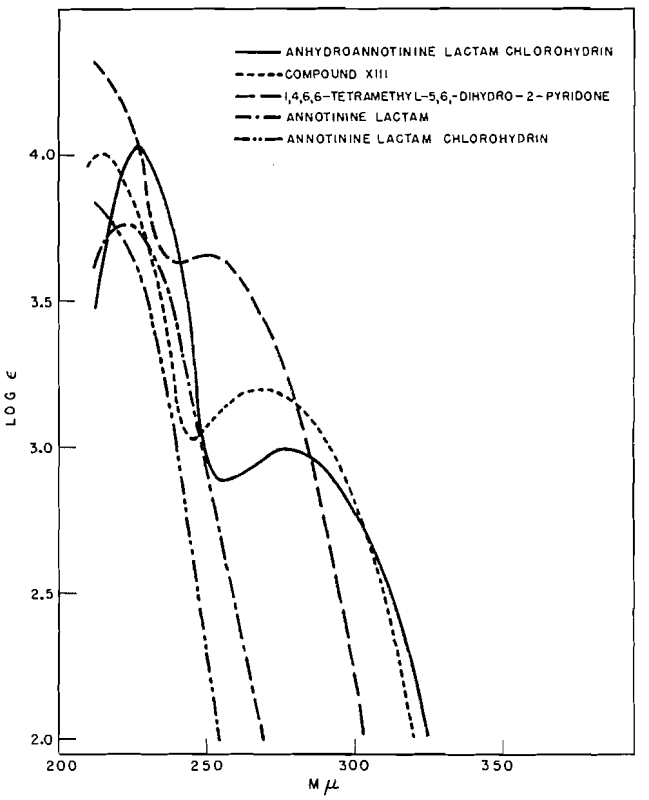

FIG. 2. Ultraviolet spectra in alcohol.

1,4,6,6-tetramethyl-5,6-dihydro-2-pyridone (12), annotinine lactam, and annotinine lactam chlorohydrin. The absorption bands of XI and XIII are at a longer wave length than would be expected when compared with the model compound, but there seems to be no doubt that a conjugated system is present. An $\alpha\beta$-unsaturated lactam system is also indicated by the infrared absorption spectra of XI and XII which contain two bands in the carbonyl region whereas the spectra of the saturated lactams contain only one band (cf. Edwards and Singh (4)). The spectra of all the compounds in Fig. 1 had a band at about 1780 cm.$^{-1}$ indicative of a γ-lactone group.

The amino acid XV, $C_{14}H_{19}O_4N$, was dehydrogenated in the presence of palladium on barium sulphate at 200–250° to an acid XVI, $C_{14}H_{13}O_3N$. The new acid no longer showed the γ-lactone band in its infrared spectrum but showed bands at 1715, 1620, and 1575 cm.$^{-1}$ in Nujol (curve 1, Fig. 4) and at

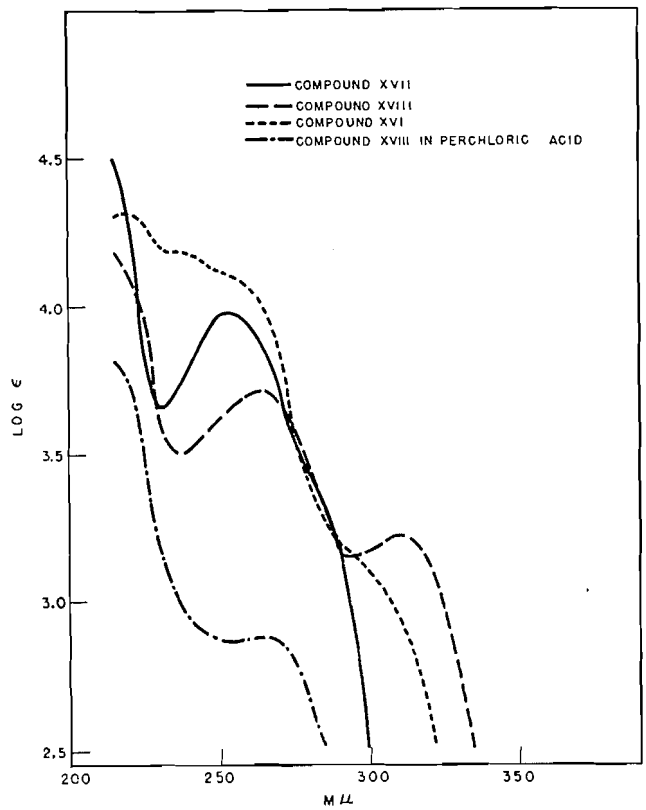

FIG. 3. Ultraviolet spectra.

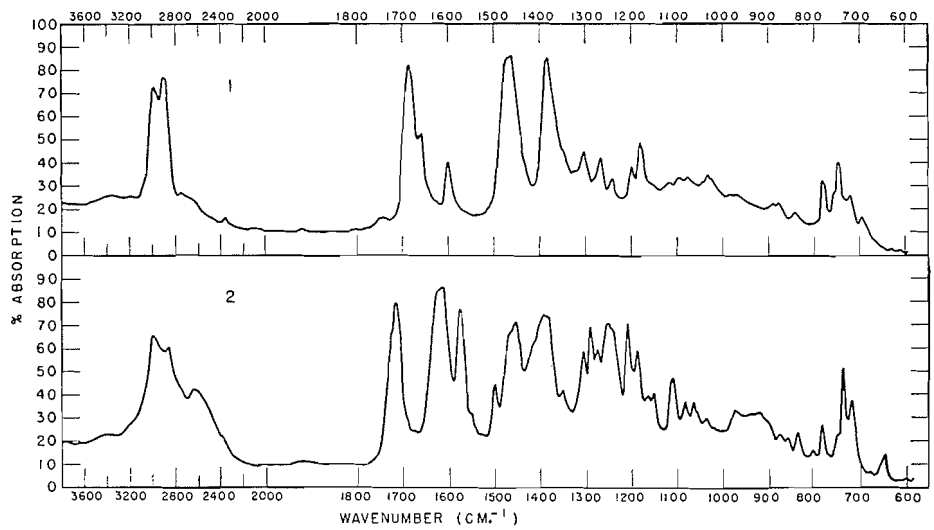

FIG. 4. Infrared absorption spectra: curve 1, compound XVI; curve 2, compound XVII.

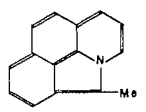
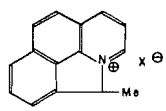
1692, 1665, 1610, and 1575 cm.$^{-1}$ in chloroform solution which are consistent with the presence of a carboxyl, an amide group, and a benzene ring. The ultraviolet spectrum is shown in Fig. 3. The dehydrogenated acid was decarboxylated by heating with copper powder to a neutral compound XVII, $C_{13}H_{15}ON$ (m.p. 70°). The ultraviolet spectrum of XVII is shown in Fig. 3 and the difference from that of the acid indicates that the carboxyl group is directly attached to the chromophoric system in the acid. The infrared spectrum in Nujol contained no bands in the NH region, but bands at 1685 and 1660 cm.$^{-1}$ (weak) assigned to an amide group and at 1600 cm.$^{-1}$ (benzene ring) (curve 2, Fig. 4). The bands were shifted in chloroform solution to 1655 and 1600 cm.$^{-1}$. Although the compound appears not to contain an NH band it is probable that an NH group is present, for if a benzene ring is present, as is almost certain (see also below) the dehydrogenated acid must contain one less ring than the acid XV. A carbon–nitrogen fission seems more likely than a carbon–carbon fission, and would result in the formation of a NH group. The ultraviolet spectrum of XVII is very similar to that of strychnine (13) and like this alkaloid, XVII gave an intense violet color with 80% sulphuric acid and a trace of chromic acid (Otto reaction).

Unfortunately, we have not been able to secure more than very small amounts of XVII. Reduction of XVII with lithium aluminum hydride in ether solution gave a weak base, which formed a crystalline picrate, m.p. 172° (decomp.). The base XVIII gave an intense red color with nitric acid or with ferric chloride and its ultraviolet spectrum, shown in Fig. 3, is roughly similar to that of strychnidine (13). In strong acid the spectrum changed to that of an isolated benzene ring.

More drastic dehydrogenation of annotinine itself at 300° over palladium gave a small amount of 7-methylquinoline, isolated as the picrate. Wiesner *et al.* (3) have recently studied the selenium dehydrogenation of annotinine and have isolated 8-*n*-propylquinoline as well as another base and a neutral nitrogen-containing substance. The formation of both 7-methyl-and 8-*n*-propylquinoline in the dehydrogenation of annotinine under different conditions is puzzling. With reference to the neutral nitrogen containing substance obtained in the selenium dehydrogenation, it may be stated that the structure XIX suggested by Wiesner *et al.* (3) for this substance seems highly unlikely



XIX



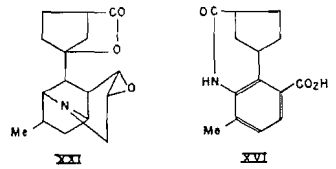
XX

as it is the anhydro base of XX and, therefore, would be expected to revert to the quaternary salt XX in the presence of acid.

On the other hand, the structure XXI that we suggested for annotinine in our preliminary note (2) does not explain the formation of 8-*n*-propylquinoline by dehydrogenation. According to the views of Wiesner *et al.* (6) on the relactonization of various annotinine derivatives to compounds containing a new γ-lactone, the acid XV should contain the grouping

O—C(=O)—C—C—CO_2H. Hence, the dehydrogenation of XV should give an *o*-phthalic acid derivative, because one of the carboxyl groups has been shown to be attached to a benzene ring. This is not so, however, for the other carboxyl group becomes involved in amide formation with the nitrogen atom that is attached to the benzene ring. Thus, the relactonization theory, although attractive, presents difficulties which can only be surmounted by assuming either a change in the carbon skeleton in the formation of XVI, or that the lactone ring in some of the derivatives of annotinine is larger than five-membered in spite of the infrared evidence.

It appears plausible that one of the rings in annotinine may be larger than six-membered and that the formation of quinoline derivatives in the dehydrogenations involves a rearrangement. However, formula XXI which we have tentatively suggested earlier (2) to represent annotinine possesses the merit



XXI XVI

that it permits the representation of the dehydrogenated acid XVI by a structure which is consistent with its ultraviolet absorption and its color reactions.

EXPERIMENTAL

Optical rotations were determined in a 1 dcm. tube. Ultraviolet absorption spectra were determined on a Beckmann spectrophotometer, Model D.U. Infrared absorption spectra were measured on a Perkin-Elmer double beam instrument, Model 21. Values of pK_a were determined in 50% methanol–water with a Beckmann pH meter (Model G) fitted with a glass and a calomel electrode; 0.1 *N* hydrochloric acid used for the titration was delivered from a microburette.

Unsaturated Lactone B

The compound prepared as described earlier (10) was twice crystallized from *n*-hexane from which it was obtained as colorless glistening prisms, m.p. 135–136°. Calc. for $C_{16}H_{23}O_2N$: C, 73.53; H, 8.87; 1 act. H, 0.386%. Found: C, 73.82; H, 8.86; (on sample sublimed at 10^{-4} mm.) C, 73.70, 73.79; H, 8.93, 8.82; act. H (at room temp.) 0.00%, (at 100°), 0.448%. $pK_a = 8.44$.

Dihydro Lactone B

The compound prepared as described before (10) was recrystallized from *n*-hexane and dried *in vacuo* at room temperature. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.57. Found: C, 73.12; H, 9.34%. $pK_a = 8.44$.

Acetyl Unsaturated Lactone B

Unsaturated lactone B (25 mgm.) in acetic anhydride (5 ml.) was heated on a steam bath for half an hour. The mixture was poured into water and after

hydrolysis of the excess acetic anhydride, made alkaline with sodium hydroxide and extracted with ether. The ether extract was washed with acid and then with water, dried, and evaporated. The residue, after recrystallization from *n*-hexane, had m.p. 137–138°, depressed to 125° by the starting product. Calc. for $C_{18}H_{25}O_3N$: C, 71.25; H, 8.31. Found: C, 70.96; H, 8.17.

Acetyl Dihydro Lactone B

This compound was prepared as described above for the unsaturated analogue and after recrystallization from *n*-hexane it formed fine needles, m.p. 141–142°. Calc. for $C_{18}H_{27}O_3N$: C, 70.79; H, 8.91. Found: C, 71.11, 71.44; H, 8.92, 8.86.

Unsaturated Lactone A

The compound (10) after sublimation *in vacuo* had m.p. 130–132°; pK_a, 7.06; $[\alpha]_D^{24} = -70°$ (*c*, 2.6 in ethanol).

Dihydro Lactone A

The compound (10) after sublimation *in vacuo* had m.p. 110°; pK_a, 8.48; $[\alpha]_D^{24} = -35°$ (*c*, 1.4 in ethanol).

Hydroxylactone

A sample of hydroxylactone (10) was sublimed *in vacuo* after which it had m.p. 174°; pK_a, 8.21; $[\alpha]_D^{22}$ −30° (*c*, 1.42 in ethanol).

Dihydro Hydroxylactone

Hydroxylactone (0.25 gm.) in methanol (15 ml.) was hydrogenated in the presence of Adams' catalyst (20 mgm.). Absorption of 23.4 ml. of hydrogen (*ca.* 1 mole) was complete after 2.5 minutes. The platinum was filtered off and the filtrate evaporated to dryness. Recrystallization of the residue from *n*-hexane gave long brittle needles, m.p. 141–142°. For analysis the compound was sublimed *in vacuo*. Calc. for $C_{16}H_{25}O_3N$: C, 68.78; H, 9.02. Found: C, 68.97; H, 9.26%. pK_a, 8.00; $[\alpha]_D^{22}$ −65° (*c*, 1.47 in ethanol). The dihydroxylactone was unaffected by prolonged boiling with chromous chloride in concentrated hydrochloric acid.

Ozonolysis of Hydroxylactone

Hydroxylactone (80 mgm.) in pure carbon tetrachloride (15 ml.) was ozonized at −10° for about two minutes. Water (10 ml.) and hydrochloric acid (1 ml.) were added, followed by a hot saturated solution of 2,4-dinitrophenylhydrazine in 15% hydrochloric acid (5 ml.). The mixture was refluxed for 15 min., cooled, and extracted with benzene (twice). The dried extract was evaporated to 20 ml. and the yellow solution passed through a short column of neutral alumina (activity II–III), which was then washed with a little benzene. The eluate was evaporated to dryness *in vacuo* and the residue crystallized from hexane. Yellow needles (14.6 mgm. 24%), m.p. 162–163°, were obtained. There was no depression of melting point with authentic formaldehyde 2,4-dinitrophenylhydrazone of m.p. 163–164°, and the infrared absorption spectra of the two compounds were identical.

Ozonolysis of Acetyl Unsaturated Lactone B

The lactone (63 mgm.) was ozonized in carbon tetrachloride solution (10 ml.) at 0° until ozone appeared from the guard tube containing water (10 ml.). The combined water and carbon tetrachloride solution was boiled for half an hour and then mixed with a solution of 2,4-dinitrophenylhydrazine in hydrochloric acid. The cooled mixture was extracted three times with benzene, and the combined dried extract passed through a column of alumina which was then washed with benzene. The benzene eluate gave on evaporation formaldehyde 2,4-dinitrophenylhydrazone (3.5 mgm.), m.p. 160–161°, undepressed by the authentic compound. Elution of the column with benzene containing methanol (3%) gave a fraction which, after two crystallizations from methanol, was obtained as yellow needles, m.p. 218–219°, and was not further investigated.

Unsaturated Lactone A Methosulphate

Unsaturated lactone A (200 mgm.) was dissolved in benzene (5 ml.) and allowed to stand 40 hr. with freshly distilled dimethyl sulphate (0.2 gm.). The faintly yellow prisms which separated were collected and recrystallized from methanol–ether. The methosulphate formed colorless prisms, m.p. 234–235°. Calc. for $C_{16}H_{21}O_2N\cdot(CH_3)_2SO_4$: C, 56.09; H, 7.06. Found: C, 56.28; H, 7.23.

Reduction of Unsaturated Lactone A Methosulphate

Unsaturated lactone A methosulphate (72 mgm.) was hydrogenated in water (10 ml.) in the presence of Adams' catalyst (7 mgm.). Absorption of 2 moles of hydrogen took 15 min. The filtered solution was made alkaline with ammonia and the glistening needles which separated were collected. The base was recrystallized from *n*-pentane and for analysis was sublimed *in vacuo*, m.p. 90–91°. Calc. for $C_{17}H_{27}O_2N$: C, 73.60; H, 9.81. Found: C, 73.67; H, 9.89%.

O,N-diacetyl Hydroxy Lactone

Hydroxylactone (60 mgm.) was heated at 100° with acetic anhydride (4 ml.) for three hours and the mixture then diluted with water (10 ml.) and kept for two hours. The mixture was extracted three times with ether and the combined extracts were washed with aqueous sodium carbonate and then with water. The residue obtained after evaporation of the ether from the dried extract crystallized from hexane in prisms, m.p. 124–126°. After several crystallizations the melting point was raised to 132–133°. Calc. for $C_{20}H_{27}O_5N$: C, 66.46; H, 7.53. Found: C, 66.62; H, 7.85%.

Chromous Chloride Reduction of Annotinine Lactam Chlorohydrin

Annotinine lactam (1.69 gm.) was boiled with concentrated hydrochloric acid (40 ml.) for 40 min. To the mixture was added, in an atmosphere of nitrogen, a filtered solution of chromous chloride, prepared from chromic chloride (30 gm.), concentrated hydrochloric acid (40 ml.), water (60 ml.), and amalgamated zinc (25 gm.). The mixture was refluxed under nitrogen for

2.5 hr., diluted with water (500 ml.), and the cold solution extracted with chloroform four times (total volume: 200 ml.). The dried extract was evaporated to dryness *in vacuo*. The residue (0.84 gm.) was triturated with benzene, filtered, and crystallized from aqueous ethanol from which it separated as prisms, m.p. 300° (decomp.), undepressed by the compound $C_{16}H_{21}O_4N$ prepared as described by MacLean and Prime (8). The benzene solution was chromatographed on alumina (activity II–III). Elution with benzene gave a small amount of low melting product, followed by a main fraction (0.4 gm.), m.p. 174–175° after crystallization from acetone–pentane. It was identical (mixed m.p.) with the compound $C_{16}H_{19}O_3N$ prepared as described by MacLean and Prime (8). Hydrogenation of this compound (0.1 gm.) with Adams' catalyst (20 mgm.) in ethanol (20 ml.) resulted in the uptake of 1 mole of hydrogen and the substance isolated had m.p. 176–177° identical with the compound $C_{16}H_{21}O_3N$ of MacLean and Prime.

Oxidation of Unsaturated Lactone A

The unsaturated lactone A (1 gm.) was dissolved in acetone (100 ml.) and treated with powdered potassium permanganate until the pink color was unchanged for five minutes. The filtered manganese dioxide was suspended in water and brought into solution by passing sulphur dioxide through the solution. Continuous ether extraction of the mixture gave after evaporation of the ether a viscous liquid containing some crystals. The product was crystallized from methanol–ether to yield colorless prisms (0.25 gm.), m.p. 232° (decomp.); $[\alpha]_D^{25}$ −31° (*c*, 1.7 in water) of the sulphate of XV. Calc. for $C_{14}H_{19}O_4N \cdot \frac{1}{2}H_2SO_4$: C, 53.48; H, 6.41. Found: C, 53.67; H, 6.64%. The compound was identical as shown by infrared spectra and mixed melting point with the amino acid sulphate prepared as described by Wiesner *et al.* (6) (see below). The compound showed only end absorption in the ultraviolet (log ϵ, 2.58 at 210 mμ).

Oxidation of Anhydro Annotinine Lactam Chlorohydrin (XI)

Annotinine lactam chlorohydrin (10) (1.83 gm.) was dissolved in dry pyridine (80 ml.) and mixed with phosphorus oxychloride (3 ml.). The mixture became warm and was kept for five hours at room temperature. It was poured into water, the pyridine neutralized with hydrochloric acid, and the mixture extracted with chloroform (four times). The combined extract was dried and evaporated to dryness. The residue was crystallized from methanol giving a total of 1.53 gm. of product, m.p. 186–187°. This modification gave a much better yield of XI than MacLean and Prime's method (8). Anhydro annotinine lactam chlorohydrin (0.95 gm.) in acetone (200 ml.) was oxidized with potassium permanganate (1.35 gm.). The mixture was worked up as described above and gave 0.3 gm. of the sulphate of XV, m.p. 232° (decomp.).

Dehydrogenation of $C_{14}H_{19}O_4N$ (XV)

The above amino-acid sulphate (0.13 gm.), barium carbonate (0.04 gm.), and 5% palladium – barium sulphate (0.5 gm.) were mixed and stirred with water (0.5 ml.). The dried mixture was heated in an atmosphere of nitrogen at 200° for one hour and the temperature was gradually raised to 250° during the

course of three hours. The product was extracted with ether several times, and the ether extract washed with acid. The ether was then extracted with 5% sodium carbonate solution. The ether solution generally contained a small amount of XVII formed by decarboxylation of XVI. The aqueous extract was acidified with hydrochloric acid and extracted with ether. Evaporation of the dried extract left a residue, crystallizing from benzene–pentane in colorless needles (0.018 gm.), m.p. 250° (decomp.); $[\alpha]_D^{25}$ +47° (*c*, 0.9 in ethanol). Calc. for $C_{14}H_{15}O_3N$: C, 68.55; H, 6.16; N, 5.71; equiv. wt. 245.3. Found: C, 68.90, 68.71; H, 6.35, 6.19; N, 5.87; equiv. wt. 250.

Decarboxylation of the Acid $C_{14}H_{15}O_3N$ (XVI)

The acid $C_{14}H_{15}O_3N$ (10 mgm.) was mixed with copper powder (20 mgm.) in a tube. The mixture was heated with a free flame, when a colorless oil distilled on the cooled parts of the tube. The oil crystallized on cooling and was purified by repeated sublimation *in vacuo*. The colorless prisms then had m.p. 70° and gave an intense violet color when a trace of the compound in 80% sulphuric acid was treated with a few drops of dilute chromic acid. Calc. for $C_{13}H_{15}ON$: C, 77.58; H, 7.51. Found: C, 77.40; H, 7.45%.

Lithium Aluminum Hydride Reduction of $C_{13}H_{15}ON$ (XVII)

The neutral compound $C_{13}H_{15}ON$ (10 mgm.) in dry ether was refluxed with a large excess of lithium aluminum hydride in ether for three hours. The mixture was decomposed with water and sodium hydroxide, and the ether layer separated and mixed with ethereal picric acid. The precipitate was recrystallized from methanol–ether when it was obtained as yellow prisms, m.p. 172° (decomp.). The regenerated base was obtained as an oil which gave an intense red color with ferric chloride solution and with concentrated nitric acid. There was insufficient pure material for elementary analysis.

Dehydrogenation of Annotinine

Annotinine (1.2 gm.) was mixed with 5% palladium – barium sulphate (1 gm.) and heated to 310° during the course of two hours. The cooled mixture and distillate was extracted twice with ether (10 ml. in all). The ether solution was extracted three times with dilute hydrochloric acid and the combined extract made strongly alkaline with sodium hydroxide. The mixture was distilled until 10 ml. of distillate had collected. The distillate was extracted with ether, and the ether evaporated. The residue was mixed with picric acid in methanol (3 ml.), and the crystals, which formed gradually, were collected by centrifugation. Three more crystallizations from methanol gave long yellow needles, m.p. 238–240°, and in admixture with 7-methylquinoline picrate of m.p. 240–241°, 239–241°. The infrared spectra of the two samples were virtually identical. The original ether extract containing the neutral products from the dehydrogenation gave a strong Ehrlich reaction in the cold and possibly contained indole derivatives, but no crystalline picrate was obtained.

ACKNOWLEDGMENT

The authors wish to express their gratitude to Dr. R. Norman Jones and Mr. R. Lauzon of these laboratories for taking the infrared absorption spectra.

FREE RADICALS BY MASS SPECTROMETRY

VII. THE IONIZATION POTENTIALS OF ETHYL, ISOPROPYL, AND PROPARGYL RADICALS AND THE APPEARANCE POTENTIALS OF THE RADICAL IONS IN SOME DERIVATIVES[1]

By J. B. Farmer[2] and F. P. Lossing

ABSTRACT

The ionization potentials of ethyl, isopropyl, and propargyl radicals have been measured by electron impact on radicals produced by thermal decomposition of appropriate compounds. The values are: ethyl 8.78±0.05 ev., isopropyl 7.90±0.05 ev., and propargyl 8.25±0.08 ev. From the appearance potentials of these ions in various compounds, the following values of bond dissociation energies were obtained:

$D(C_2H_5—H) = 98.5\pm2.3$, $D(s\text{-}C_3H_7—H) = 86.7\pm2.3$,
$D(s\text{-}C_3H_7—I) = 42.4\pm2.3$, $D(s\text{-}C_3H_7—Br) = 58.8\pm2.3$,
$D(s\text{-}C_3H_7—Cl) = 73.3\pm2.3$, $D(CH{:}C.CH_2—I) = 45.7\pm3.2$,
$D(CH{:}C.CH_2—Br) = 57.9\pm3.2$ kcal./mole, assuming no kinetic energy of the products.

INTRODUCTION

The ionization potential of the ethyl radical was measured by Fraser and Jewitt (5) by directing a beam of ethyl radicals and other products from the decomposition of lead tetraethyl into an ionization gauge detector. They found $I(C_2H_5) = 10.6\pm0.8$ ev., a value which was undoubtedly too high because of the presence of reaction products such as ethylene. Hipple and Stevenson (7) measured the ionization potential of the ethyl radical by electron impact on radicals produced by the thermal decomposition of lead tetraethyl in a quartz capillary furnace opening into the ionization chamber of a mass spectrometer. By this means they found $I(C_2H_5) = 8.67\pm0.1$ ev., a value which, taken in conjunction with the appearance potential of $C_2H_5^+$ in the mass spectrum of ethane, 12.92±0.1 ev. (23), led to a dissociation energy of the C_2H_5—H bond of 4.25±0.2 ev. or 98.0±4.6 kcal./mole. This is in good agreement with the average electron impact value of 4.20±0.04 ev. (96.9±1 kcal./mole) recently quoted by Stevenson (21) and the value of 98±2 kcal./mole obtained by photobromination (1).

The ionization potential of the isopropyl radical has not previously been measured directly, but a value of 7.45±0.1 ev. has been derived from the appearance potentials of $C_3H_7^+$ in the mass spectra of isobutane, isopentane, and 2,3-dimethyl butane, the heats of formation of these compounds, and the bond dissociation energies of CH_3—H and C_2H_5—H (20). This value, together with the appearance potential of the $C_3H_7^+$ ion in the mass spectrum of propane, 11.67±0.1 ev. (24), leads to a dissociation energy for the s-C_3H_7—H bond of 4.22±0.2 ev. (97.3±4.6 kcal./mole). This appears to be high by comparison with Stevenson's electron impact average of 4.09±0.09 ev.

(94.3±2 kcal./mole) and with the Butler and Polanyi pyrolysis value of ~89 kcal./mole (19).

As far as the authors are aware, no published measurements or predictions of the ionization potential of the propargyl radical ($CH{:}C.CH_2$) have been made. The radical does not appear to have been identified previously, although it has been suggested that its thermal stability might be high (27).

EXPERIMENTAL

Production of the Radicals

The fact that ethyl and isopropyl radicals are much less stable thermally than methyl, allyl, or benzyl radicals, whose ionization potentials were reported in an earlier paper (13), required a modification of the reactor used previously. In a reactor of the type described in earlier papers (14, 15) the residence time was sufficiently long to allow the disappearance of an appreciable fraction of the radicals at the temperature (~660°C.) at which mercury diethyl or azoisopropane decomposed. Although these radicals were found in considerable abundance under these conditions (12), the presence of appreciable amounts of the decomposition, disproportionation, and combination products caused serious interference at the parent peak of the radical. In order to reduce this interference a furnace was constructed in which the residence time would be shorter. This furnace was similar in design to that used by Hipple and Stevenson (7) and consisted of a quartz tube of 1.5 mm. internal diameter surrounded at the end by a heater, 2 cm. in length, cut from tantalum sheet in the shape previously described (15). The heater was enclosed in a quartz sheath sealed to the end of the quartz tube. A cylindrical radiation shield of Nichrome V surrounded the sheath. The furnace was mounted coaxially with the hole in the top plate of the ionization chamber, at a distance of about 1 mm. The compound was admitted to the reactor through a molecular-flow leak without the use of helium as a carrier. With this arrangement the pressure in the reactor was very low (~10^{-3} mm.) and second-order products were considerably reduced. The dissociation products of the radicals were still present but in reduced amounts.

(*a*) *Ethyl Radicals*

The decomposition of mercury diethyl at about 800°C. gave rise to ethyl radicals, butane, ethane, ethylene, and hydrogen. A small amount of undecomposed mercury diethyl was also present. Out of a combined peak height of 497 cm. at mass 29 using 50 ev. electrons, a net peak height of 249 cm. for the ethyl radical was obtained after subtraction of the contributions from ethane, butane, $C^{12}C^{13}H_4$, and mercury diethyl. The ratio of ethane to butane at 800°C. was 0.36:1. This ratio of disproportionation (k_1) to combination (k_2) (0.36) is not greatly different from that found ($k_1/k_2 = 0.1$ to 0.3) at lower temperatures (2, 10). If significant, this result would suggest that

$$E_{\text{combination}} \simeq E_{\text{disproportionation}}.$$

However, at the very low pressures involved (~10^{-3} mm.) it is questionable whether the ethane and butane arise from homogeneous disproportionation

and combination reactions rather than from surface reactions. Some butane may also be formed directly from mercury diethyl under these conditions.

(*b*) *Isopropyl Radicals*

As in the case of ethyl, the production of a high concentration of isopropyl radicals presented experimental difficulties owing to the thermal instability of the radicals. In the high pressure reactor, the decomposition of azoisopropane in a stream of helium at 6.5 mm. was almost complete at 665°C. The increase in the mass 43 peak at low electron energies showed the isopropyl radical to be present. At this temperature some isopropyl radicals were decomposing, the products being propylene and hydrogen almost exclusively (12). By the use of a retractable furnace (9) in the high pressure reactor, the product of dimerization of the radicals was found to be mainly 2,3-dimethyl butane with a small amount of another hexane, possibly 2-methyl pentane, showing that the radicals were indeed isopropyl radicals. In the low pressure reactor, azoisopropane was 90% decomposed at 655°C. At this temperature the mass 43 peak height was 1030 cm. After subtracting the contributions from 2,3-dimethyl butane, propane, and undecomposed azoisopropane, a peak height of 329 cm. for the isopropyl radical remained.

(*c*) *n-Propyl Radicals*

Attempts to produce the *n*-propyl radical in quantities sufficient for ionization potential measurements were unsuccessful. The decomposition of azo-*n*-propane at 665°C. in the high pressure reactor resulted in the formation of methyl radicals and ethylene in approximately equal amounts, together with nitrogen, *n*-hexane, propane, propylene, and some ethane formed from the combination of the methyl radicals (12). The mode of decomposition of *n*-propyl appears to be almost entirely by

$$n\text{-}C_3H_7 \rightarrow CH_3 + C_2H_4$$

and not by

$$n\text{-}C_3H_7 \rightarrow C_3H_6 + H.$$

This is in agreement with conclusions drawn from kinetic studies (19).

(*d*) *Propargyl Radicals*

The decomposition of propargyl iodide at 1000–1100°C. in either the high-pressure or the low-pressure reactor resulted in a good yield of propargyl radicals. The dimer, 1,5-hexadiyne, was also formed.

Measurement of the Ionization Potentials

The method of calibrating the voltage scale using a number of standards was the same as that used previously (13). In this case the calibration line was found to have a slope of unity within the precision of measurement. Krypton was added to the gas stream as a reference standard, and the difference between the appearance potential of the radical peak and the appearance potential of the krypton mass 84 peak was determined by the method of extrapolated voltage differences (28). The net peak height for the radical ion at 50 ev. was determined by subtracting the contributions from dimers and other prod-

ucts as described above. Ionization efficiency curves for the radical ions from these products were measured to ensure that no contributions to the peaks could occur at the low electron energies at which the voltage difference measurements were made. The only correction of this kind found to be necessary was a small correction to the krypton mass 84 peak as a result of the 2,3-dimethyl butane formed from isopropyl radicals. This correction was evaluated from measurements of the mass 84 peak in the absence of krypton, other conditions being the same.

Measurement of the Appearance Potentials

As found by Stevenson and Hipple (23) a significant correction to the mass 29 peak was required in the measurement of $A(C_2H_5^+)$ from ethane. The appearance potential of $C_2H_4^+$ from ethane is appreciably lower than that of $C_2H_5^+$ (23). Consequently the mass 28 peak is many times as high as the mass 29 peak at electron energies a few volts above $A(C_2H_5^+)$. The isotopic $C^{12}C^{13}H_4^+$ peak from $C_2H_4^+$ was found to account for almost one-third of the mass 29 peak under these conditions. The correction to mass 29 was calculated from the natural abundance of C^{13} assuming that no difference in the ionization efficiency curves of $C^{12}C^{12}H_4^+$ and $C^{12}C^{13}H_4^+$ or in the ratio of formation of the ions would occur as a result of isotopic factors. This correction raised the observed value of $A(C_2H_5^+)$ by about 0.2 ev. as was found by Stevenson and Hipple (23).

The ionization efficiency curves for $A(C_2H_5^+)$ from the halides showed curved δV vs. I plots and the extrapolated values being apparently low by 0.4 to 0.6 ev. are not reported here. The cause of this discrepancy is not obvious. I^- ions from the iodide were found, but only to the extent of about one part in 6000 of the $C_2H_5^+$ ion. This amount should not appreciably lower the appearance potential, and in any case the ion may arise by a secondary process. The formation of ethyl radicals by pyrolysis on the filament followed by diffusion back into the ionization chamber would lower the observed appearance potential. However, it is difficult to see, in view of the thermal instability of ethyl, why this effect should be larger than for the more stable methyl or allyl radicals.

The appearance potential of the mass 39 ion from propyne was not measured since this ion may arise by two different processes

$$CH{:}C.CH_3 + e \rightarrow CH{:}C.CH_2^+ + H + 2e \quad [1]$$
$$CH{:}C.CH_3 + e \rightarrow C{:}C.CH_3^+ + H + 2e \quad [2]$$

depending on which hydrogen atom is lost. In order to find out the extent to which process [2] occurs, the mass spectrum of a sample of $CH{:}C.CD_3$, kindly prepared by Dr. L. C. Leitch, was examined. The isotopic purity of the sample was determined from the mass spectrum obtained with electrons of energy sufficient to form the molecular ion but insufficient to form dissociation products (25). As shown in Table I, the sample was about 80% $CH{:}C.CD_3$.* In the 50-volt spectrum, after the parent ions have been subtracted in the

**The improbable rearrangement product $CD{:}C.CD_2H$ was assumed to be absent.*

ratio of their abundance, the fragment ion at mass 42 can arise only by

$$CH{:}C.CD_3 + e \rightarrow C{:}C.CD_3^+ + H + 2e \quad [3]$$

and that at mass 41 mainly by

$$CH{:}C.CD_3 + e \rightarrow CH{:}C.CD_2^+ + D + 2e \quad [4]$$

with a small contribution from the impurity

$$CH{:}C.CD_2H + e \rightarrow CH{:}C.CD_2^+ + H + 2e. \quad [5]$$

TABLE I

MASS SPECTRA OF TRIDEUTEROPROPYNE

Mass No.	Peak height at low energy	Mole %	Peak height at 50 ev.	Parent ions	Fragment ions
44	0.2	1.1	—	—	—
43	15.0	79.4	2015	2015	—
42	2.8	14.8	798	376	422
41	0.5	2.7	1482	69	1413
40	0.35	2.0	—	—	—

If the contribution from process [5] is ignored, the ratio H loss/D loss from $CH{:}C.CD_3$ is then 422/1413 = 0.30. It is possible, however, to correct for process [5] on the assumption that its probability is one half the sum of the probabilities of process [1] and process [2]. The contribution of process [5] to the mass 41 peak is then $376 \times \frac{1}{2} \times$ ratio mass 39/mass 40 in propyne (0.859). The fragment peak at mass 41 resulting from process [4] is then $1413 - (376 \times \frac{1}{2} \times 0.859) = 1252$, and the corrected ratio of H loss/D loss is 422/1252 or 0.337. This is almost exactly $\frac{1}{3}$, suggesting that after a propyne molecule has been struck by a 50-volt electron, the four hydrogens in the excited ion are equivalent and the loss of a hydrogen atom from either end occurs on a statistical basis. Unfortunately the isotopic purity of the sample was not sufficiently high to give appearance potentials for processes [3] and [4] free from interference.

The same inherent ambiguity exists in the mass 43 peak from propane. It has, however, been reported that this ion is mainly $s\text{-}C_3H_7^+$ (18, 26). In addition, it is possible to say that the process

$$C_3H_8 + e \rightarrow s\text{-}C_3H_7^+ + H + 2e \quad [6]$$

will have a lower appearance potential than the process

$$C_3H_8 + e \rightarrow n\text{-}C_3H_7^+ + H + 2e \quad [7]$$

since (21) $I(n\text{-}C_3H_7) > I(s\text{-}C_3H_7)$ and $D(n\text{-}C_3H_7\text{—}H) > D(s\text{-}C_3H_7\text{—}H)$. In view of these considerations it is very probable that $A(C_3H_7^+)$ corresponds to process [6] and that the derived dissociation energy can be assigned to the $s\text{-}C_3H_7\text{—}H$ bond.

RESULTS AND DISCUSSION

The individual and average values obtained for the ionization potentials of the three radicals are given in Table II, together with some measured and calculated values from the literature. The appearance potentials of the radical ions from the derivatives are given in Table III. The dissociation energies for the radical–atom bonds, derived on the assumption that no kinetic energy term is involved, are also given in Table III for comparison with values from the literature. The limits of error shown should be regarded as limits of precision and not of absolute error.

TABLE II

IONIZATION POTENTIALS OF THE FREE RADICALS ETHYL, ISOPROPYL, AND PROPARGYL

		Ionization potential (ev.)				
Radical	Source	Individual values	Average	Literature value	Method	
Ethyl	Mercury diethyl	8.80 8.79 8.76 8.78	8.78±0.05	8.67±0.1	Direct electron impact (7)	
Isopropyl	Azoisopropane	7.91 7.93 7.88 7.90	7.90±0.05	7.43±0.1 7.73 7.81	$A(s\text{-}C_3H_7^+)$ from isoalkanes Calculated Calculated	(20) (4) (22)
Propargyl	Propargyl iodide	8.23 8.23 8.28	8.25±0.08			

Ethyl

The average value for the ionization potential of the ethyl radical, 8.78 ±0.05 ev., agrees with that of 8.67±0.1 ev., measured by Hipple and Stevenson, within the combined limits of error. The appearance potential of $C_2H_5^+$ from ethane, 13.05±0.05 ev., lies within the estimated limits of error of the three previous measurements. Using the present data for $I(C_2H_5)$ and $A(C_2H_5^+)$, $D(C_2H_5—H)$ = 4.27±0.10 ev. (98.5±2.3 kcal./mole). This result is perhaps just significantly higher than the average value from electron impact data (21), and within the limits set by the photobromination data (1).

As described above, the appearance potentials of the ethyl ion from the halides were anomalously low, and no reliable values for the dissociation energies of the ethyl–halide bonds could be obtained. It would be interesting to study the ionization efficiency curves for the ethyl ion from these compounds using some means of detecting fine structure (3, 17).

Isopropyl

The measured ionization potential of the isopropyl radical, 7.90±0.05 ev., is considerably higher than the 7.43±0.1 ev. derived from the appearance potentials of $s\text{-}C_3H_7^+$ in the mass spectra of isoalkanes and from the relevant heats of formation (20). It is, in fact, very close to the 7.94±0.1 ev. derived in the same way for the *n*-propyl radical (21). As discussed in a previous section, there appeared to be no doubt of the identity of the isopropyl radical on the basis of the dimer formed. Even if some *n*-propyl radicals were initially

TABLE III

APPEARANCE POTENTIALS AND BOND DISSOCIATION ENERGIES

		Appearance potential (ev.)			Bond dissociation energy (kcal./mole)		
Substance	Ion	This work	Literature	Reference	This work	Literature	Reference
Ethane	Ethyl	13.05±0.05	12.92±0.1 12.81±0.2 12.71±0.4	(23) (11) (16)	98.5±2.3	98±2 96.9±1	(1) (21)
Propane	Isopropyl	11.66±0.05	11.67±0.1 11.5 ±0.3 11.76±0.1	(24) (11) (16)	86.7±2.3	∽89 94.3±2	(19) (21)
Isopropyl iodide	Isopropyl	9.74±0.05	—	—	42.4±2.3	46	(19)
Isopropyl bromide	Isopropyl	10.45±0.05	—	—	58.8±2.3	—	—
Isopropyl chloride	Isopropyl	11.08±0.05	—	—	73.3±2.3	—	—
Propargyl iodide	Propargyl	10.23±0.06	—	—	45.7±3.2	—	—
Propargyl bromide	Propargyl	10.76±0.06	—	—	57.9±3.2	—	—

formed, they would decompose very rapidly at the temperature of the reactor as was found in the attempt to produce the *n*-propyl radical. With the present method of plotting the ionization efficiency curves, the measured ionization potential would be high if some contribution to the 50 ev. peak at mass 43 had been neglected in calculating the net radical peak height at 50 ev. A decrease of 10% in the net 50 ev. peak height would lower the ionization potential by only 0.05 ev. The four individual values for $I(s\text{-}C_3H_7)$ given in Table III were obtained in two separate experiments separated by an interval of a few days.

The appearance potential of mass 43 from propane (11.66±0.05 ev.) is in good agreement with previously measured values (11, 16, 24). However the value of $D(s\text{-}C_3H_7\text{—}H)$ from the present data

$$A(s\text{-}C_3H_7^+) - I(s\text{-}C_3H_7) = 11.66 - 7.90 = 3.76 \pm 0.10 \text{ ev.},$$

or 86.7±2.3 kcal./mole, would appear to be considerably too low by comparison with the electron impact average of 94.3±2 kcal. The derived dissociation energies for the isopropyl–halide bonds also appear to be low, although the absence of reliable kinetic data for these bonds makes comparison difficult. The appearance potential data for the isopropyl ion would suggest that the measured ionization potential is too high by about 0.3 ev. It is interesting to note that two values of the ionization potential calculated by Franklin and Field (4) (7.73 ev.) and by Stevenson (22) (7.81 ev.) on the basis of a simplified molecular orbital method, both lie between the presently measured value and the average electron impact value. The calculated value of Franklin and Field, 7.73 ev., was based on $I(CH_3) = 10.07$ ev. and $I(C_2H_5) = 8.67$ ev., that of Stevenson on the later value for methyl $I(CH_3) = 9.96$ ev. and $I(C_2H_5) = 8.67$ ev. Using $I(CH_3) = 9.96$ and $I(C_2H_5) = 8.78$ as measured in this work, the same calculation of the ionization potential of the isopropyl radical gives 7.97 ev. In view of the assumptions and simplifications necessary in such a calculation, it is doubtful whether this result can be considered as support for the high value for $I(s\text{-}C_3H_7)$ found here. It would appear that further work is necessary to resolve the discrepancy.

Propargyl

The ionization potential of the propargyl radical, 8.25±0.08 ev., is only slightly higher than the 8.16±0.03 ev. found for the allyl radical (13). This difference is considerably smaller than that between the ionization potentials of propyne (10.43±0.1 ev.) (6) and propylene (9.84 ev.) (8).

The dissociation energies of the propargyl–halide bonds are not known from other sources for comparison purposes, but the derived values seem rather low in view of the high temperature required to dissociate propargyl iodide.

THE HYDRATION OF PLASTER OF PARIS[1]

By Fraser W. Birss[2] and T. Thorvaldson

ABSTRACT

The hemihydrate of calcium sulphate labelled with calcium-45 or sulphur-35 was hydrated in a supersaturated solution of calcium sulphate at 21°C. The distribution of the radioactive isotope between the solution and the solid phases and the concentration of the solution throughout the period of hydration were measured. The exchange of calcium ions between crystalline gypsum and its solution was also studied. The experimental results are discussed from the viewpoint of the mechanism involved. They are found to be in agreement with a mechanism which postulates a single passage of the structural units of the solid hemihydrate through the solution and not consistent with one of direct hydration without temporary independent existence of the products in the liquid phase.

INTRODUCTION

The availability of radioactive isotopes provides a new method for the study of reactions between slightly soluble substances and aqueous solutions. A paper by Graham, Spinks, and Thorvaldson (1) on the hydrolysis and hydration of tricalcium silicate and β-dicalcium silicate illustrates some of the possibilities of the method. The experimental results obtained by these workers are readily interpreted on the basis of the theory of Le Chatelier, that the anhydrous silicates pass into solution and react to form less soluble hydrated silicates, which then separate out of the supersaturated solution. They are not so readily interpreted on the basis of the direct hydration of the silicate in the solid state, with only calcium hydroxide splitting off to enter the hydrating liquid.

As the study of the hydration of these silicates is complicated by the variable lime–silica ratio and the gel-like nature of the hydrated silicates, it was considered desirable to apply the method to a simpler system. The hydration of plaster of Paris was selected because of its historical and scientific interest in relation to the chemistry of cements.

There are several points of difference between the hydration of tricalcium silicate and of plaster of Paris. In the case of the silicate labelled with calcium-45 two methods are available for following the progress of the reaction, i.e. the determination of (i) the alkalinity and (ii) the activity[3] of the liquid phase, while in the case of plaster of Paris labelled with calcium-45 or sulphur-35 only the second method is available. The solubility of the hydrated silicate in solutions of calcium hydroxide is extremely small while the solubility of gypsum in water is much higher and supersaturation of the order of fourfold with respect to the hydration product may be obtained during hydration of the hemi-

hydrate. The ratio of lime to silica in the silicate changes during the hydration and this ratio in the product varies with the concentration of lime in the solution, while the corresponding stoichiometric ratio of the calcium sulphate remains unchanged. Furthermore, the hydrolysis of the silicate is a comparatively long process, starting off fairly rapidly with the rate tapering off with time, while the hydration of the hemihydrate of calcium sulphate begins very slowly and continues at a steadily accelerating rate.

Assuming a "through-solution" mechanism for the conversion of the hemihydrate to the dihydrate, a mathematical expression for the progressive change in the activity of the liquid phase may readily be developed in a similar manner to that used in the case of the hydration of tricalcium silicate (1). Two complicating factors may enter: (i) substantial changes in the concentration of the hydrating liquid due to the formation of supersaturated solutions with subsequent precipitation of gypsum, and (ii) exchange of Ca^{45} or $S^{35}O_4$ ions between the solution and the hydration product after precipitation. These must be considered in applying the theoretical equation to the experimental data.

EXPERIMENTAL

Materials

Calcium sulphate dihydrate was prepared from reprecipitated "alkali-free" calcium carbonate. The latter was dissolved in hot dilute hydrochloric acid, calcium sulphate precipitated slowly with ammonium sulphate, washed, and dried over plaster of Paris. The radioactive samples were prepared by addition of a suitable amount of $Ca^{45}Cl_2$ or $H_2S^{35}O_4$, obtained from Atomic Energy of Canada, to the solution before the precipitation. The sample of gypsum labelled with calcium-45 was completely crystalline, composed mainly of thin prisms varying in thickness from 0.002 to 0.01 mm. with an occasional crystal as much as 0.025 mm. thick. The loss on dehydration agreed well with the theoretical value for the dihydrate.

The gypsum was dehydrated in an oven at 85–87°C. in a slow current of air. The time required to reduce the moisture content to that of the hemihydrate was about eight hours when further dehydration almost stopped. The Ca^{45}-labelled sample used for the hydration appeared to be mainly in the form of elongated fibrous plates, composed of aggregates of small crystals. The sample labelled with $S^{35}O_4$ ions was composed of smaller particles. The water content of the samples was close to the theoretical value for the hemihydrate.

Determination of the Activity of the Solutions

The activity of the solutions was determined on 0.500-ml. portions, at least in triplicate, after precipitation of the calcium as oxalate and evaporation to dryness, using an end window Geiger–Mueller tube (window thickness 1.7 mgm. per sq. cm.; scale of 64 scaler) and an electric timer. The geometry was kept constant and enough counts were made to reduce the probable error to less than 2%. Corrections were made for background, for self-absorption when necessary, and for the resolving time error of the tube-scaler assembly above counting rates of 25 registers per min.

Exchange of Calcium Between Gypsum Crystals and Solution

Freshly precipitated gypsum crystals were digested for a long period of time, first at 38°C. and then at 21°C., and after filtration were dried over plaster of Paris. The sample was composed of long prisms of fairly uniform thickness of from 0.004 to 0.007 mm. with an occasional crystal measuring 0.003 mm. In the exchange experiments 0.05-gm. samples were shaken in pyrex centrifuge tubes with 9 ml. water at 21°C. for four weeks, 1 ml. of a saturated solution of calcium sulphate labelled with calcium-45 was then added, the shaking was continued, and individual tubes were removed from time to time for counting the solution. The ratio of solid to dissolved calcium sulphate in the system was about 1:1. The room was thermostatted at 21°C.

The calculated activity at time of mixing, assuming no exchange, was 15.16 registers per min. for 0.5 ml. of solution. Counts were made on separate tubes at 30 sec.; 20, 40, and 60 min.; two, four, and six hours after adding the calcium-45 activity. The values obtained were (reg./min./0.5 ml.) 15.08, 15.12, 15.22, 15.21, 15.13, 15.07, and 15.03, respectively. For the conditions and duration of these experiments it appears that exchange of calcium ions between the solid and solution does not significantly affect the activity within the accuracy of counting.

In our hydration experiments with plaster of Paris one might expect greater exchange owing to smaller crystals and higher specific surface. A second series of experiments was therefore made to attempt to determine exchange rates with very small crystals. These were prepared by shaking together in pyrex centrifuge tubes weighed quantities of precipitated calcium carbonate and equivalent amounts of 0.1 molar sulphuric acid. Within two minutes the calcium carbonate had completely dissolved, followed by the formation of a voluminous precipitate of hydrated calcium sulphate. After rapid centrifuging, samples of the clear supersaturated liquid were removed for analysis to determine the concentration of the solution and the weight of solid (by difference). A standard solution of calcium sulphate labelled with calcium-45 was immediately added to each tube and the tubes shaken to allow exchange to take place. The total time required for these manipulations up to the beginning of the exchange shaking was approximately six minutes. From time to time tubes were centrifuged and the solution counted. The concentration of the solution was determined in each case and corrections applied to the count for self-absorption on the basis of previously determined values for the concentrations found.

The crystals formed by the action of the acid on the carbonate, separated from the mother liquor by rapid filtration two minutes after mixing, were fine prisms mostly less than 0.0015 mm. in diameter. At this stage the mother liquor was highly supersaturated with respect to gypsum, containing as much as five times the saturation value. The concentration after dilution with the active solution was still three to four times the saturation value. After an additional period of shaking with the mother liquor for 12 min. (i.e. the period required for complete hydration in the experiments described below) the crystals had grown considerably; many of them were more than 0.002 mm. in diameter and the solution was approaching saturation.

The experimental conditions were in some ways similar to those of the hydrations described below. The total weight of calcium sulphate in the system and the volume used were the same. The concentrations of the solutions at the beginning of the exchange shaking were of the same order as those at the beginning of the hydration runs. On the other hand in the exchange experiments the activity of the solution and the specific activity of the solute were at the maximum at the beginning when the size of the crystals was at a minimum while in the hydration runs the total and specific activities of the solute were at a minimum at the beginning when the crystals of gypsum were of minimum size. Thus the conditions were more favorable to high exchange in the present experiments than in the hydration runs.

The per cent exchange of calcium was calculated, correction being made for the activity removed from the solution by precipitation. This correction, which was based on the mean specific activity of the solute during the exchange period, is probably too small, since most of the precipitation occurred during the first half of the time interval when the specific activity is near the maximum, thus making the value attributed to exchange too large. The average value obtained for exchange was 2.2% in 10 min. and 4.8% in 20 min. This amounts to about 3% for a 12-min. period, the time required for the hydration runs. The great increase in the size of the crystals during this period suggests that the exchange is mainly due to recrystallization of the original inactive finely divided precipitate. As long as there are a large number of small crystals present subject to recrystallization, the rate of this process probably increases as the concentration of the solution falls giving proportionally greater exchange during the longer periods. While we were mainly interested in what happened during the first 12 min., the experiments were continued up to 24 hr. The approximate values obtained for the per cent exchange for the longer periods indicated that the rate of exchange increased up to a maximum in about one hour, then fell slowly, and that 100% exchange was approached in 24 hr. The question of exchange in the hydration experiments will be discussed later.

The Hydration of Plaster of Paris Labelled With Calcium-45

If one brings the active solid hemihydrate into contact with a saturated solution of gypsum it dissolves, producing, before any precipitation occurs, an active solution which is highly supersaturated with respect to the dihydrate. To reduce such dissolution of the active sulphate it is necessary to prepare an inactive supersaturated solution and to use this as the hydrating liquid.

The hydrating solution was prepared by adding successive portions of the inactive hemihydrate to freshly boiled and cooled redistilled water until apparently no further solution occurred on vigorous shaking. Five-milliliter portions of the centrifuged solution were placed in a number of 15-ml. centrifuge tubes each containing 44.0 mgm. of the radioactive plaster of Paris. These were immediately stoppered with serum bottle caps and shaken vigorously for a definite period of time. After centrifuging, three 0.500-ml. samples of the solution were withdrawn for determination of concentration (evaporation and weighing on a microbalance) and three samples for counting. Three

series of runs were made. The experimental values for the initial concentration of the hydrating liquid of the three series of runs were 4.42, 4.40, and 4.41 mgm. (expressed as the hemihydrate) per 0.5 ml. The average value 4.41 mgm./0.5 ml. was used in all the calculations. The maximum activity in the solution was, in each case, recorded at 11.7 min. The data for one of the series of runs are recorded in Table I. All the determinations of the activity for the three runs and the corresponding values for the concentration of the hydrating liquid are plotted in Fig. 1.

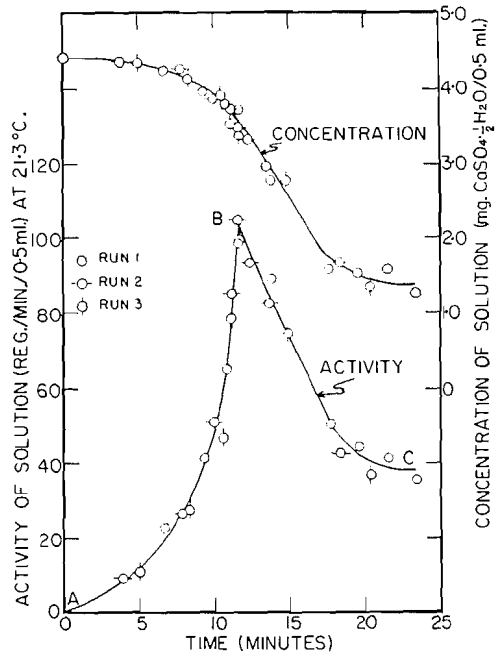

FIG. 1. The liberation of activity to the solution and the changes in concentration when 44 mgm. of the hemihydrate of calcium sulphate, labelled with calcium-45 (specific activity 43.1 reg./min./mgm.), were hydrated in 5 ml. of inactive calcium sulphate solution.

†Expressed as milligrams of plaster of Paris per 0.5 ml. of solution.

‡Corrected for background, self-absorption, and resolving time but not for changes in concentration of the solution.

The Hydration of Plaster of Paris Labelled with Sulphur-35

Three similar runs were made with the sample of plaster of Paris labelled with sulphur-35. The same types of curves were obtained both for the development of activity in the hydrating liquid and for changes in concentration. The maximum activity in the liquid was attained in a shorter time (approximately nine minutes) possibly owing to the smaller particles of the sample or to presence of more gypsum nuclei. There was somewhat greater variability in the experimental results. Otherwise there was no essential difference between the curves obtained for the hydration of the two samples of hemihydrate labelled with calcium-45 and sulphur-35.

DISCUSSION

Derivation of the Theoretical Expression for the Activity of the Solution

An expression for the relation between the extent of hydration and the activity of the hydrating solution may be derived on the basis of a through-solution mechanism. The derivation given below assumes:

(i) Constant concentration of the solution, i.e. that the rate of precipitation of gypsum is at all times equivalent to the rate of solution of the hemihydrate.

(ii) No exchange of the active ion between the solution and the hydrate after precipitation.

(iii) Rapid enough shaking so that the dissolved radioactive isotope is at all times essentially uniformly distributed throughout the solution.

Let a = moles of inactive $CaSO_4$ in the original solution,
m = moles of labelled solid hemihydrate placed in the system,
b = the specific activity per mole of the hemihydrate,
x = moles of labelled hemihydrate which have passed into the solution,
$f(x)$ = the specific activity of the calcium sulphate in the liquid phase.

Consider the hydration of dx moles of active plaster of Paris, releasing an activity bdx to give a solution of specific activity $f(x)$. The sulphate precipitates as gypsum carrying down an activity $f(x)dx$ from the solution. The net activity liberated to the solution during the process is $bdx-f(x)dx$. When x moles of the plaster of Paris have thus passed through the solution the activity in the solution becomes

$$\int_0^x (bdx-f(x)\,dx) = bx-\int_0^x f(x)\,dx.$$

One can evaluate $f(x)$ in terms of a, b, and x and integrate this expression by a method similar to that used by Graham, Spinks, and Thorvaldson (1), thus obtaining the expression for the activity in solution $= ab(1-e^{-x/a})$. Dividing by mb the total activity in the system and multiplying by 100 one obtains the percentage of total activity in the solution $= (100a/m)(1-e^{-x/a})$.

In place of "moles $CaSO_4$" one may use the weight of $CaSO_4$, $CaSO_4 \cdot \frac{1}{2}H_2O$, or $CaSO_4 \cdot 2H_2O$ in the system, or weight of any of these per unit volume of solution provided the basis of reference is the same for all quantities. In the discussion of the hydration experiments in this paper the concentration of

calcium sulphate in solution is always expressed in terms of milligrams of the hemihydrate per 0.5 ml. of solution.

The End Point of the Hydration

In each series of the hydration runs with the Ca^{45}-labelled sample, the maximum activity of the hydrating liquid was attained in 11.7 min. The question presents itself: was the hydration complete at this point or was an increase in activity due to subsequent hydration masked by a lowering due to precipitation? This question is answered by consideration of the specific activity of the calcium sulphate in the solution after the 11.7-min. point (Fig. 1, curve BC). If the specific activity of the solute remains constant, then precipitation is the only process taking place.[4] Calculation of the specific activity at points between 11.7 and 20.0 min. gave a constant value, i.e.,

$$[\text{activity (reg./min./0.5 ml.)}]/[\text{concentration (mgm./0.5 ml.)}] = 29.$$

This indicates that after the 11.7-min. point the only factor affecting the activity of the solution was precipitation and that the hydration was therefore essentially complete at this point.

The Correction for Changes in Concentration of the Hydrating Liquid

Before comparing the experimental values for the activity of the hydrating liquid during the period of hydration (Fig. 1, curve AB) with those calculated by use of the theoretical equation, correction must be made for changes in concentration. The gradual decrease in the concentration of the solution indicated in Fig. 1 corresponds to the removal of continually increasing amounts of activity. For the ascending portion (AB) of the hydration curve the change in concentration is comparatively small while after the end point of the hydration it is much more rapid until the solution approaches saturation with respect to gypsum.

An approximate value for the lowering of the activity of the solution due to the decrease in concentration during any small time-interval is given by the expression

$$(w_i - w_f)[\tfrac{1}{2}(a_i/w_i + a_f/w_f)]$$

where w_i and w_f are the concentrations at the beginning and end, respectively, of the interval, and a_i and a_f are the corresponding activities of the solution. The expressions a_i/w_i and a_f/w_f represent the specific activities of the calcium sulphate in the hydrating liquid at the beginning and end, respectively, of the time interval.

The calculated corrections for the period of hydration, using nine time-intervals, are given in Table II. Doubling the number of intervals does not change the corrected final a_f value materially.

The corrected experimental value for the activity of the solution at the end of the hydration period (i.e. at 11.7 min.) is 116 reg./min./0.5 ml. or 61% of the total activity of the system. The corresponding value for complete hydration calculated from the theoretical equation is 63% of the total activity.[5]

[4]*An exception to this statement would be the unlikely case where two or more compensating processes in addition to precipitation occur in the system.*

[5]*For total exchange the calculated value for the activity of the solution at the end point of the hydration, for our experimental conditions, is 76 reg./min./0.5 ml., or 40% of the total activity of the system.*

TABLE II

HYDRATION OF PLASTER OF PARIS
Correction of experimental activities for changes in concentration

Time interval (min.)	0–5	5–7	7–8	8–9	9–10	10–10.5	10.5–11	11–11.5	11.5–11.7
Activity* at beginning of interval (a)	0	11.8	20.5	28.5	38.2	50.5	57.5	73	95

a_f correction for change in conc. of soln.	11.9	21.0	29.3	39.8	53.8	61.9	79.3	105	116
Per cent of total activity in soln.	6.3	11.1	15.5	21.0	28.3	32.6	41.8	55	61

**All activities are expressed as registers per minute per 0.5 ml.*
†All concentrations are expressed as milligrams plaster of Paris per 0.5 ml.

These values may be considered to be in good agreement as any lack of thorough mixing of the solution during the hydration would tend to cause precipitation of gypsum in regions of high activity and thus lower unduly the activity of the solution. There is likely to be some lowering of activity due to this cause near the end of the hydration when the rate of reaction is very high and the diffusion of the calcium ions through a film adhering to the solid may become the limiting factor. Furthermore, the experimental values obtained at the 11.7-min. point are likely to be below the true maximum, as a slight displacement along the time axis, either way, from the true end point (which is not necessarily exactly 11.7 min.) would give lower values for the activity. For these reasons the maximum experimental value at 11.7 min. was used in the calculation of the final corrected maximum instead of the average for the three series of runs. The close reproducibility of the three series of experimental runs is an indication of the clock-like regularity of the hydration process under given conditions.

The Question of Exchange

The theoretical equation gives a measure of the exchange of the radioactive isotope between the solid and the solution, resulting from the dissolution of the active hemihydrate and the essentially simultaneous precipitation of an equivalent amount of an active dihydrate. Exchange of calcium occurring during the hydration period but after separation of the solid hydration product would reduce the experimental value for the activity of the solution below those values calculated by the equation. Recrystallization during the period of hydration through the solution of very small crystals with redeposition on larger ones, which means a second passage of the calcium sulphate through the solution, would also lower unduly the activity of the solution.

There is considerable evidence indicating that the effect of these processes on the experimental values for the activity of the hydrating liquid is small. The experiments described above indicate that the rate of exchange of the calcium ion between gypsum and its saturated solution, after the system has attained equilibrium, is negligible for the time of exposure involved in our experiments. During the hydration the surfaces of the growing crystals are continually in radioactive exchange equilibrium with the calcium sulphate in the solution. For further exchange the radioactive ion must pass from the surface to the zone of lower radioactivity inside the crystal. The very low rate of diffusion of the calcium ion in the crystalline solid therefore determines the rate of exchange.

The gypsum prisms formed in the hydration runs were of fairly uniform size, mainly 0.003 to 0.004 mm. in diameter, with very few less than 0.002 mm. This suggests a regular growth of the crystals during the hydration period and indicates that near the end of the hydration there were very few crystals small enough to take part in a recrystallization process. Such recrystallization would also be inhibited by the very high supersaturation of the solution right up to the end of the hydration period.

During the early part of the hydration period when both exchange through diffusion, due to the high specific surface, and exchange through recrystalliza-

tion, due to the small size of the crystals of gypsum, would be at a maximum, both the rate of hydration and the activity of the solution are very low. Less than 5% of the plaster of Paris is hydrated during the first third and less than 10% during the first half of the hydration period (see Fig. 3) thus favoring the growth of the gypsum nuclei present in the solution to a size where the tendency for recrystallization is reduced or eliminated. Even if there were considerable exchange during this early period the over-all effect for the hydration of the whole sample would be small.

The constancy of the specific activity of the dissolved solid in the post-hydration period is perhaps the strongest evidence for the absence of appreciable exchange effects through diffusion or recrystallization during the period of hydration, for such processes, if operating, would be expected to carry beyond the end point.

The experimental findings are therefore in agreement with the assumption that the structural units of crystalline plaster of Paris pass through the solution during the hydration and that the theoretical equation is applicable to the process.

The Rate of Hydration

From the corrected experimental values for the per cent of total activity found in the solution (Table II) one may calculate, by means of the theoretical equation, the percentage of the plaster of Paris hydrated (i.e. $100x/m$) corresponding to any given activity or the end of any time interval. Fig. 2 gives the calculated per cent hydration vs. the corrected activity of the solution and Fig. 3 the rate curve for the hydration at 21.3°C. under the conditions of our experiments.

Another approximation of the extent of hydration may be derived directly from the experimental data if the through-solution mechanism is assumed. In any interval, x_i moles of labelled hemihydrate pass into solution releasing an activity bx_i to the solution. If no concurrent precipitation took place the activity of the solution would become a_i+bx_i and the concentration w_i+x_i. Upon precipitation the solution assumes an activity a_f which is directly proportional to the final concentration attained, w_f.

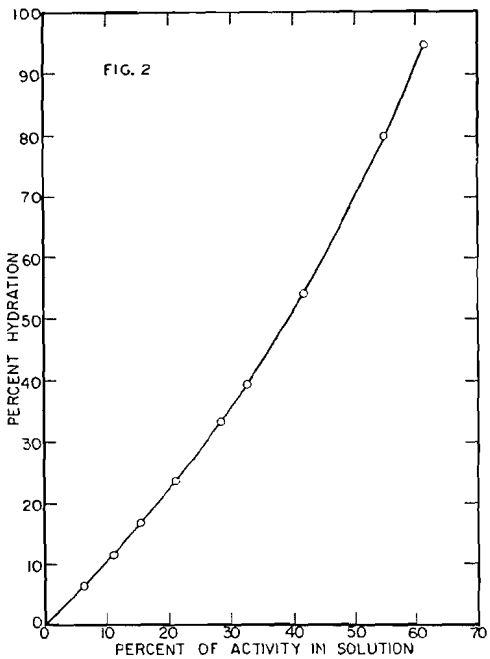
$$a_f = [w_f/(w_i+x_i)](a_i+bx_i)$$

and

$$x_i = (a_i w_f - a_f w_i)/(w_f b - a_f).$$

Calculations based on this approximation yield results in good agreement with those given in Figs. 2 and 3 if the intervals are sufficiently small.

It is of interest to note that the shape of our rate curve, which was obtained with a very low ratio of the hemihydrate to solution, is in general agreement with the thermal curve obtained by Weiser and Moreland (2) with a very high ratio of plaster to water (50 gm. to 30 ml.). The period of slow hydration at the beginning ("inhibition period") is attributed by these authors to dearth of crystal nuclei of the hydration product and was found to be shortened or eliminated by the addition of small amounts of finely crystalline gypsum to the plaster.



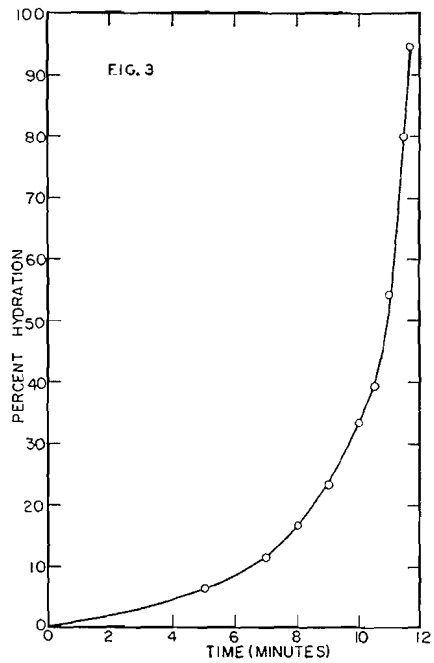


FIG. 2. The relation between the per cent of active plaster of Paris hydrated and the per cent of the total activity found in the hydrating liquid.
FIG. 3. The rate curve for the hydration of plaster of Paris at 21.3°C.

The Hydration of Plaster of Paris Labelled with Sulphur-35

The above discussion also applies to the data obtained with the sample of plaster of Paris labelled with S^{35}. The final value for the activity corrected for the effect of precipitation was 62% of the total activity in the system as compared to 64%, the value required by the theory for hydration by a through-solution mechanism under our experimental conditions.

GENERAL CONCLUSION

The experimental results for the hydration of plaster of Paris are in agreement with those calculated for a through-solution mechanism, while they are not consistent with the assumption of any mechanism of direct hydration without the solid passing into solution. Direct hydration alone would not give rise to activity in the solution. If one assumes that the first step of the process is a surface reaction between the crystals of the hemihydrate and water one would have to postulate that the dihydrate formed passes into solution and maintains the high supersaturation of the solution with respect to gypsum crystals during the period of hydration.

THE MECHANISM OF THE HYDRATION OF CALCIUM OXIDE[1]

By Fraser W. Birss[2] and T. Thorvaldson

ABSTRACT

Three samples of calcium oxide, designated as A, B, and C, were prepared from calcium carbonate labelled with calcium-45. A was heated to constant weight at 700°C.; B was heated an additional three hours at 1400 to 1550°C.; and C was heated six hours at the same temperature. The samples were hydrated in a supersaturated lime solution at 21°C., the development of activity and the changes in concentration of the solution being determined. The activity entering the solution accounted, according to theory, for the following percentages of the samples passing through the solution during the hydration: A, 27%; B, 57%; C, 94%. These results indicate that sample C ("dead-burnt" lime) hydrated by a "through-solution" mechanism, but that A and B either hydrated partly according to some other mechanism, such as a vapor phase process in the pores of the particles of lime, or the calcium ions failed to reach the bulk of the hydrating liquid before precipitation as calcium hydroxide.

INTRODUCTION

Three cases of hydration, namely of tricalcium silicate, β-dicalcium silicate, and the hemihydrate of calcium sulphate, have been studied by the newly developed method of using radioactive elements as tracers (1, 2). The experimental evidence available on the mechanism of the hydration of the two silicates has in the past been rather inconclusive. However, it is generally considered that when plaster of Paris is brought into contact with a large excess of water, the solid passes into solution and then crystallizes out as gypsum. The results of the experiments with the hemihydrate of calcium sulphate labelled with calcium-45 or sulphur-35 (1) were found to be compatible with such a "through-solution" mechanism, thus giving, when combined with the previous findings (2), indirect support to the theory of a similar mechanism for hydration of the silicates.

Calcium oxide was selected for similar experiments because of the violence of its reaction with water. It was thought that the tracer method applied to this reaction might give support to the alternative theory that some solids react directly with water, hydrating without passing through the solution in the process. It is well known that when calcium oxide is brought into contact with water, solutions highly supersaturated with respect to crystalline calcium hydroxide are formed, and that these solutions shed the excess hydroxide rather slowly. Thus it is evident that, at least in part, the solid passes through the solution. However, if the predominant reaction is a direct one between water and solid lime without the latter passing into solution, then the tracer method should disclose this and might show that the hydration goes completely by this path if a highly supersaturated solution of lime is used as the hydrating liquid.

EXPERIMENTAL

The experimental procedures were very similar to those described in the preceding paper (1) by Birss and Thorvaldson on the hydration of plaster of Paris. The methods and the precautions used to ensure accuracy of the measurements of radioactivity were the same. The work was done in a room thermostatted at 21±0.1°C.

Three samples of calcium oxide, A, B, and C, were prepared from calcium carbonate of high purity, labelled with calcium-45, by the various heat treatments indicated in Table I.

Supersaturated solutions containing from 1.26 to 1.35 gm. of inactive[3] calcium oxide per liter were used as the hydrating liquids so as to reduce, as far as possible, further increase in concentration through solution of active lime during the hydration. Fifty-milliliter aliquots of the supersaturated calcium hydroxide solution were shaken with freshly ignited 0.05-gm. samples (±1%) of active calcium oxide in sealed 100-ml. gold or silver lined steel tubes. At intervals tubes were centrifuged, 25 ml. of the clear liquid titrated with 0.06 *N* hydrochloric acid, and five 0.500-ml. samples counted. Duplicate series of hydrations were run with each sample of calcium oxide.

RESULTS

The three samples of lime showed considerable differences in their behavior on hydration. In each case the concentration of the supersaturated hydrating liquid increased; with samples B and C to a much greater extent than with sample A. Sample C, which gave the highest supersaturation, required the longest time for complete hydration. Some observations on the hydrations follow.

Sample A.—The concentration of the hydrating liquid rose rapidly from an initial 1.26 to 1.33 gm. CaO/liter (10 min.), then more slowly to 1.35 gm./liter (30 min.). The same value was obtained at 60 min., with a slight decrease during the next 60 min. The activity of the solution reached a maximum in 30 to 50 min. The duplicate series were not in close agreement.

Sample B.—The concentration rose from 1.29 to 1.44 gm. CaO/liter in five minutes, reached 1.46 to 1.47 gm./liter at 20 min., then remained almost constant until the two-hour test. The activity of the solution reached a maximum in 60 min., and showed very slight decrease at the two-hour test.

Sample C.—The concentration rose from the initial of 1.34 gm. CaO/liter to as high as 1.52 gm./liter in 5 to 10 min., then fell rapidly, reaching 1.30 gm./liter at four hours and 1.28 gm./liter at eight hours. The activity of the solution increased rapidly during the first 10 min., then slowly up to the four-hour test, and then fell slightly during the next four hours. The duplicate determinations of the two series with this sample were in fairly good agreement.

The apparent times required for complete hydration were:

Sample A, 30–50 min.; Sample B, one hour; Sample C, four hours.

[3]*The terms "inactive", "active", and "activity" will be used to refer to radioactivity and not to the chemical activity of the materials under discussion. The* Ca^{45} *was supplied by Atomic Energy of Canada.*

"Through-solution" Hydration of Lime

A theoretical expression for the liberation of radioactivity by a labelled sample of the hemihydrate of calcium sulphate when hydrated in a solution of inactive calcium sulphate has been developed in the preceding paper (1). The expression holds also for the case of the through-solution hydration of lime labelled with Ca^{45} in a solution of inactive calcium hydroxide, namely:

Per cent of total activity in the solution $= (100a/m)(1-e^{x/a})$

where a = moles of inactive lime in the original solution,

m = moles of labelled calcium oxide placed in the system,

x = moles of labelled calcium oxide which have passed into solution during the hydration.

The limitations in the application of the expression to the experimental data have been discussed in the preceding paper (1).

The experimental results obtained with sample C will be considered first. Fig. 1 gives the plot for the changes in the activity of the hydrating liquid with time, and the corresponding changes in the concentration of the solution. It also gives the plot of the experimental values of the activity in the solution corrected for the changes in the concentration, by the method described in the preceding paper (1). The corrected experimental activity at the maximum is 67.4% of the total activity of the system as compared with 70.5%, the theoretical value for complete hydration by a through-solution mechanism. This may be considered to be reasonable agreement because of probable errors which would tend to lower the experimental activity. Assuming complete radioactive exchange equilibrium between the lime in the solid and solution at the end of the hydration would give only 55% of the activity in the solution.

Discussion of Errors

The errors affecting the experimental results have been discussed at length in the preceding paper, and will therefore be considered only briefly here. The rapid reaction at the beginning of the hydration may result in incomplete mixing and consequent precipitation of the hydrated lime in regions of high

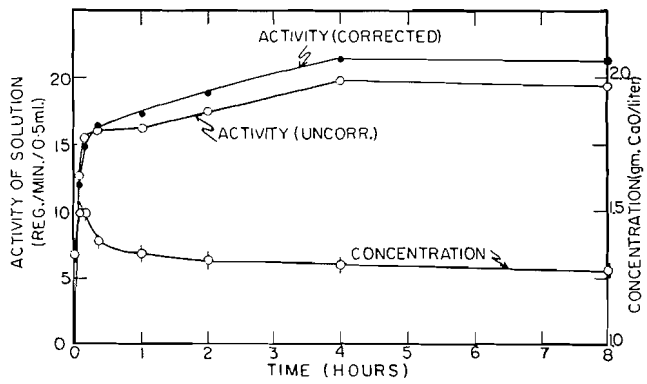

FIG. 1. The liberation of activity to the solution and the changes in concentration when 0.05-gm. samples of calcium oxide (heated six hours at 1400–1550°C.) labelled with calcium-45 (specific activity 63.2 reg./min./mgm.) were hydrated in 50 ml. of inactive lime solution 1.34 gm. CaO/liter).

activity. This would lower the observed activity in the liquid. In the hydration of plaster of Paris a similar danger was present near the end of the hydration period. The experimental measurement of activity at the four-hour point (Sample C, Fig. 1), which was taken as the maximum value, is not necessarily the true peak, thus possibly giving too low a maximum. However, as the slope of the curve at this point is small, the error is probably not large.

Exchange of calcium ions between the liquid and solid after the precipitation of the calcium hydroxide would lower the activity but the error is probably not large since the drop in activity, after correction for precipitation, from the four-hour to the eight-hour value is within the probable experimental error of counting. Direct determination of exchange by shaking inactive calcium hydroxide crystals with a solution of labelled calcium hydroxide (ratio of solid to dissolved calcium hydroxide six to one) gave a marked drop in the activity of the solution on mixing, probably owing to exchange of calcium ions between the liquid and the large area of surface of the thin calcium hydroxide plates. This was followed by a slow decrease in the activity of the solution. Surface exchange does not affect the results in the hydration experiments as the surface of the crystals is at all times in exchange equilibrium with the solution. When the initial drop in activity observed in the exchange experiments is eliminated and correction is made for the ratio of calcium hydroxide in the solid and liquid phase (0.8 to 1 in the hydration runs), the direct experiments give an estimated drop in activity of about 0.1% per hour for the conditions of the hydration experiments. This is of the order of the drop observed between four and eight hours in the hydration of sample C.

During the very rapid hydration of sample C in the first 10 min. when, by calculation, about 60% of the sample was hydrated, very small crystals of calcium hydroxide were probably formed. These would be subject to recrystallization, thus depressing the activity of the solution. During the 10–60 min. period (Fig. 1) the activity (lower curve) is depressed by the drop in the concentration of the solution. This correction has been made in the upper curve. However, the apparently low values for the one and two hour points on the "corrected" curve are probably due to recrystallization and the low experimental value for activity of 67.4 instead of the theoretical 70.5% may be mainly due to this factor.

Thus one must conclude that in the case of sample C there is no evidence of direct hydration of the solid calcium oxide without passage of the solid into solution during the over-all hydration process.

Comparison of the Hydration of Samples A, B, and C

The activity values obtained for the hydration liquids were corrected for changes in concentration (1). From the figures obtained the proportion of the calcium oxide apparently hydrated by a through-solution mechanism was calculated by means of the theoretical equation. The results are given in Fig. 2 and in Table I.

The marked difference in the behavior of the three samples is apparently due to the heat treatments. The sample of calcium carbonate was composed

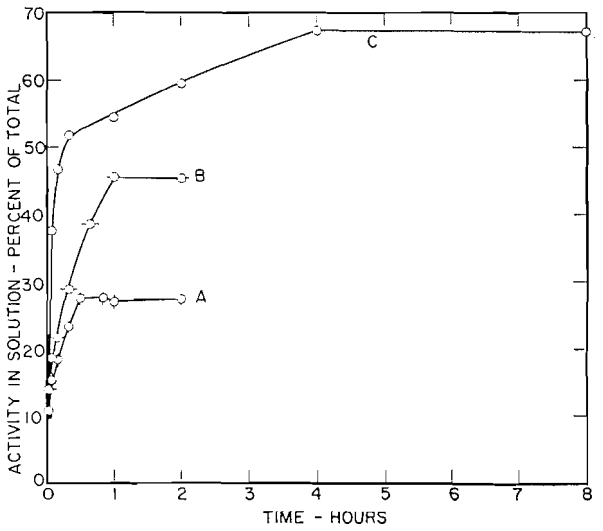

FIG. 2. Comparison of the activity liberated to the solution on hydration of three samples of calcium oxide labelled with calcium-45 (see Table I).

of crystals mainly 0.022 to 0.04 mm. in diameter. Sample A retained the shape of the original crystals and microscopic measurements indicated only slight shrinkage. The particles of samples B and C had to a great extent lost their original shape, were smaller, and some sintering had occurred.

Hedin and Thorén (3) have made a very thorough study of volume changes during the ignition of calcium carbonate at various temperatures. They have concluded that ignition at low temperatures produces particles of oxide of extremely loose structure composed of very small crystals of calcium oxide and having a large amount of internal pore space, but that progressive heating at higher temperatures gives closer packing and finally a compact crystalline material. They consider that the high rate of slaking of soft burnt lime is due to a large area of internal surface at which slaking can take place, while dead-burnt lime slakes only at the external surface of the particles. Hedin and

Thorén have further concluded from their studies on the hydration of calcium oxide that the first step of slaking is merely the dissolution of the oxide and that this solution presumably occurs by direct formation of ions. However, they do not exclude the possible formation of hydroxide in the solid but consider that the supersaturation is due to the direct dissolution of calcium oxide.

The results obtained with sample A could be explained on the assumption that the particles possess a large amount of internal surface and that a large proportion of the hydration of the oxide and precipitation of the hydroxide occurs in the capillaries and pores of the particles. This would, in part, prevent the radioactive ions of calcium from entering the bulk of the hydrating liquid. The average activity developed in the solution by this sample corresponded to a 32% hydration, through-solution. One would then assume that internal hydration occurs to a much lesser extent in sample B, which gave a calculated 57% through-solution hydration, while it is absent in sample C, where the normal through-solution mechanism becomes evident with sufficient time lag between solution and precipitation for approaching complete uniformity of concentration in the hydrating liquid.

On the basis of the above one might perhaps assume that essentially the mechanism of the hydration of the three samples is the same. There is, however, the question of the mechanism of the "internal" hydration. Does water, as liquid, enter the pore space, in which case the hydration might occur in liquid films, or does only water vapor pass into the capillaries giving a vapor phase reaction with the solid? Our experiments do not answer these questions but they indicate that sample C, which probably corresponds to "dead-burnt" lime, hydrates by a "through-solution" mechanism. While the "ionic" solution of the calcium oxide seems probable, the possibility that calcium hydroxide is first formed and then dissolves is not excluded.

THE ELECTRICAL CONDUCTANCE OF STRONG ELECTROLYTES: A TEST OF STOKES' EQUATION[1]

By A. N. Campbell and E. M. Kartzmark

ABSTRACT

The equation recently put forward by Wishaw and Stokes, purporting to reproduce the equivalent conductance of concentrated solutions of strong electrolytes, has been tested by applying it to the experimental data of Campbell, Kartzmark *et alii*. The agreement between the calculated and observed values of Λ is astonishingly good, in the case of lithium nitrate up to a concentration of 7 molar. The deviations found for silver nitrate and ammonium nitrate are attributed to ion-pair formation and a dissociation "constant" deduced (for silver nitrate) which does show approximate constancy; a similar calculation by Stokes for ammonium nitrate shows even better constancy. Since the Stokes' equation is fully theoretical and contains only quantities to which physical meaning can be attached, it is to be preferred to any empirical, or semiempirical, equation. The Stokes' equation, being merely an extension of the Debye–Hückel–Onsager concept, cannot be expected to apply to concentrations greater than, say, 5 N. Attention is again drawn to the empirical observation that in the region of very high concentration the plot of Λ versus log C is a true straight line.

For a number of years, the present authors in collaboration with others (1) have been determining the equivalent conductances of concentrated solutions of strong electrolytes, at various temperatures and at concentrations up to that of the molten salt (at sufficiently high temperature). This they have done in a purely experimental manner, since they lacked any theoretical equation which could be tested by their results, and there was no picture of the mechanism of conduction in strong solutions. The Debye–Hückel–Onsager equation, which requires a straight line relation between Λ and $\sqrt{C}$, is only valid in the extremely dilute region, say up to 0.01 N; at high concentrations it even gives negative values for Λ. It is unnecessary here to go into detail, since the situation is summarized by Harned and Owen in their well-known book (4, pp. 144–158). Suffice it to say that attempts have been made to extend the Debye–Hückel–Onsager equation by the addition of further terms to the $\sqrt{C}$ term. The best known of these are the equations of Onsager and Fuoss (7) and of Shedlovsky (8); the latter, however, is purely empirical. At best, these equations represent the variation of equivalent conductance with concentration only up to, say, 1.0 N.

Quite recently, Wishaw and Stokes (9) have produced an equation which is an extension of Onsager's equation, taking into account the effect of finite ionic size[2] (and Falkenhagen's evaluation of the relaxation effect (3)). The Wishaw–Stokes equation is

$$\Lambda = \left(\Lambda^\circ - \frac{B_2\sqrt{C}}{1+B\mathring{a}\sqrt{C}}\right)\left(1 - \frac{B_1\sqrt{C}.F}{1+B\mathring{a}\sqrt{C}}\right)\frac{\eta^\circ}{\eta}.$$

[2]"*The term* å *[distance of closest approach of the ions] is not the sum of the crystallographic radii of the appropriate ions (probably owing to the increase in effective radius of the ions due to their solvation sheaths), and must therefore be determined empirically.*" *Kortüm-Bockris (5).*

The symbols have the following meaning:

Λ = equivalent conductance at concentration C,
Λ° = limiting equivalent conductance,
$B_1 = 8.20\times10^5/(\epsilon T)^{3/2}$, where ϵ = dielectric constant of solvent,
$B_2 = 82.5/\eta^\circ(\epsilon T)^{\frac{1}{2}}$, where η° = viscosity of solvent,
$B = 50.29/(\epsilon T)^{\frac{1}{2}}$,
η = viscosity of solution,
å = mean distance of closest approach of ions, (Å),

$F = \dfrac{(e^{0.2929Ka}-1)}{0.2929Ka}$ where K = quantity in Debye–Hückel theory given by $K^2 = \left[\dfrac{4\pi Ne^2}{1000\epsilon kT}\right] C(\nu_1 z_1^2+\nu_2 z_2^2)$ and a = mean distance of closest approach (cm.).

Other symbols have their usual meanings.

Wishaw and Stokes have tested their equation using their own data for ammonium chloride and for ammonium nitrate (the latter data are identical with our own). For ammonium chloride they find good agreement up to 5 N ($\pm$1 mho), while the discrepancies observed with the ammonium nitrate results are attributed to ion-pair formation, and a dissociation constant is evaluated which is reasonably constant up to 6 N.

As our results are more extensive than those of Wishaw and Stokes and apply at different temperatures, it seems appropriate to test their very interesting equation using our results. Before doing so, however, some comment is necessary. In a letter from Dr. Stokes he makes use of the following words: "I am rather sorry that your extensive conductivity measurements refer to nitrates; the behaviour of these is less simple and respectful towards the theory than that of chlorides, etc. . . . I believe the ion-pair formation in nitrates is genuine—it ties up with the thermodynamic data and the diffusion fairly convincingly. . . For silver nitrate I should suggest an å something between 3.5 and 4 Å; not the crystallographic value. According to Bjerrum, one should really take å = 3.57 for the ionized part of a one: one electrolyte which forms ion-pairs, but this parameter is fairly elastic. The greatest difficulty in applying the theory to ammonium nitrate or silver nitrate at temperatures other than 25° is that we have no activity coefficient data to use in calculating the ion-pair dissociation-constant K. However, the theory may still be used to estimate α, the degree of dissociation of the ion-pairs, and to compare it at different temperatures. It is quite possible that α will be nearer to unity at your higher temperatures; the behaviour of the function $e^2/\epsilon kT$ ought to correlate with the amount of ion-pair formation at a given concentration at various temperatures. This function has the values 7.135 at 25°; 7.225 at 35°; 7.935 at 95°; all $\times$ 10^8."

We have applied the Stokes equation to our data for silver nitrate and ammonium nitrate, at 25°, 35°, and 95°, and to potassium chloride (6) at 25°, and to lithium nitrate at 25° (unpublished data by Dr. G. Debus, working in this laboratory).

In using Stokes' equation, the quantities which may require arbitrary selection are å and Λ°; F is not such a quantity. Λ° is well known or can be found from the ionic conductances, for all common electrolytes at 25°, but at other temperatures it becomes a matter of guesswork (in the absence of further experimental work). å is occasionally known (at 25°) but usually again only a probable value can be assigned. According to Bjerrum, å should have a fixed value of 3.57 for the ionized part of a 1:1 electrolyte which forms ion-pairs. This value, however, can be altered within reasonable limits and still retain its physical meaning but it must not vary with temperature. In other words, such a value of å is chosen (varying, say, between 3 and 4 Å) as fits the data for 25° (Λ° is known without ambiguity for this temperature) and this value of å is used for calculations at other temperatures.

There remains what Stokes calls "the vexed question" of a viscosity correction. While admitting that a viscosity correction is necessary, and that this correction is not given by the ordinary bulk viscosity, he is nevertheless forced to use this bulk viscosity. Stokes thinks there is "some justification" for this. The particular substances investigated by him, ammonium chloride and ammonium nitrate, exhibit anomalous viscosity, that is, up to quite high concentrations, the viscosity is somewhat less than that of water and never, even at the highest concentrations, much greater. Silver nitrate and lithium nitrate, which are used in our calculations, form very viscous solutions at high concentrations. It is fair to point out that some of the deviation observed may be due to the use of a viscosity correction which may be only approximate.

CALCULATIONS

Our calculations are contained in Tables I to IV. It should be emphasized once again that the choice of å and Λ° (except at 25°) is only guesswork but this does not detract from the value of Stokes' equation; it merely requires further experimental work. Ion-pair formation has been assumed with silver nitrate and a dissociation constant calculated using the activity coefficients given in Harned and Owen (4). The calculation was not carried beyond the point at which $\alpha(=\Lambda_{exp}/\Lambda_{calc})$ appeared to increase with further concentration. A similar calculation has already been made for ammonium nitrate by Wishaw and Stokes (10). The results for Λ_{exp} and Λ_{calc} are graphed in Figs. 1 to 5.

DISCUSSION

Obviously, the values of Λ obtained are dependent on the values of å chosen (and of Λ° if this is not known) but the general behavior is the same, whatever value of å is chosen. For example, a value of å may be chosen (e.g. 2.30 for silver nitrate) which may reproduce rather well the observed results over the initial range (up to 3 N for silver nitrate) and then give systematically decreasing values of Λ up to the limit of saturation. If it is objected that the value of 2.30 is too low to have physical significance and the more reasonable value of 4.35 assumed, then the initial calculated values are somewhat too high and later values finally become too low. In other words, the behavior is qualitatively the same. We have used a number of alternative å values in the case

of lithium nitrate, to demonstrate this. In view of Dr. Stokes' remark that nitrates are liable to ion-pair formation, in general we have preferred those values of å which give a calculated Λ greater than that we have observed, and from the α-value thus obtained we have calculated a dissociation constant; for silver nitrate it is reasonably constant. The agreement between Λ_{exp} and Λ_{calc} for lithium nitrate, using an å value of 4.5 Å, is so close, i.e. $\alpha \sim 1$, that we prefer these results and therefore we have not attempted to calculate a dissociation constant. This means that we believe there is no ion-pair formation in lithium nitrate solutions up to at least 7 N. Such deviations as do occur may be due to the viscosity correction being uncertain (*vide supra*, p. 889). This leaves the problem of explaining why lithium nitrate should not form ion-pairs, while other nitrates do, but a ready explanation offers itself in the well-known fact, or supposition, that the lithium ion is highly hydrated, in comparison with other univalent ions.

The equation of Stokes seems to us to constitute a major advance, in that it carries the Debye–Hückel–Onsager concepts up to a concentration of from 3 to 5 N. It is of course true that the figures obtained are far from exhibiting that close correspondence with the experimental results which an empirical equation might give but this is not the point. A similar objection might be made to van der Waals' equation of state, as contrasted with other empirical and semiempirical equations, but van der Waals' equation is still the best for teaching and theoretical purposes, because of the clear and relatively simple picture it gives of the structure of a compressed gas. The same may be said of Stokes' equation; it supplies a mechanism of conductance up to a region of truly high concentration.

The essential virtue of Stokes' equation is that it is entirely free from empiricism, every quantity contained in it having a clear physical meaning. It may be objected that å, the distance of closest approach of the ions, is really only an empirical constant, but against this there are the strong objections that

it is always of the order of magnitude that would be expected and, above all, is independent of temperature. We note that, in agreement with Stokes' suggestion, the α-values are larger at the higher temperatures (using of course the same å values), that is, ion-pair formation is less. As would be expected, the calculated results, measured in terms of so-called α-values, become meaningless above a concentration of about 5 N.

For solutions of the highest concentration and for anhydrous melts it may be that an entirely new theory is called for. In this connection, we cannot help referring again to an observation made by Mr. John Herron (2), when working with us, viz. that from the region of, say, 5 N (where the Stokes' equation begins to break down) the plot of Λ against log C is a rigorously straight line. This has recently been confirmed by Debus' observations on lithium nitrate (up to 9N). To say that any quantity plotted against log C would be a straight line or that the curve is merely approaching a straight line is incorrect; the curve is absolutely straight by any test with which we are acquainted. The observation is quite empirical but, if it is accepted, any proposed theory will have to account for this.

STUDIES ON CARRAGEENIN: THE EFFECT OF SHEAR RATE ON VISCOSITY[1]

By C. R. Masson and D. A. I. Goring

ABSTRACT

The viscosity of aqueous solutions of carrageenin of high molecular weight was markedly dependent on the rate of shear. The shear-dependence increased with decrease in the concentration of added electrolyte. Because of curvature, extrapolation of $[\eta]$ to zero rate of shear was not possible. The Huggins interaction coefficient, k', increased with decrease in rate of shear; k' also increased with increase in concentration of added electrolyte. In water, maxima of η_{sp}/c were observed at concentrations of carrageenin equivalent to the ionic impurities in the distilled water used. At higher concentrations the data fitted the Fuoss equation at rates of shear of 200 and 100 sec.$^{-1}$ but not below 100 sec.$^{-1}$ The constants A and D both increased with decrease in rate of shear.

INTRODUCTION

The polysaccharide carrageenin, a water-soluble extract of the red alga *Chondrus crispus*, is of interest as a naturally occurring polyelectrolyte of high molecular weight. Solutions of carrageenin show a wide range in viscosity (2, 6, 8, 9) depending on the method of preparation and treatment of the extract. The intrinsic viscosity, $[\eta]$, is important as a means of characterizing any given sample.

It has been shown previously (8) that the viscosity of solutions of carrageenin of relatively low molecular weight is similar to that of other polyelectrolytes, while for extracts of higher molecular weight the viscosity becomes shear-dependent. The present work is part of an attempt to establish some general measurement of viscosity independent of rate of shear or intermolecular interaction. This paper describes the effect of shear rate on the viscosity of aqueous solutions of carrageenin, both in the presence and absence of added salts.

EXPERIMENTAL

Preparation of Extract

Carrageenin was extracted with water at 80°C. from the residue of a preliminary extraction at 30°C.–40°C. In order to obtain a product of high molecular weight care was taken to avoid undue degradation or bacterial contamination.

The extract was filtered through a No. 10 "Selas" porcelain filter and precipitated in four volumes of 95% ethanol. The white fibrous material was washed in absolute ethanol and ether, dried *in vacuo*, ground to pass a 20-mesh screen, and stored at −13°C. This extract is referred to in this and subsequent work as "Extract G". A preliminary osmometric determination of its molecular weight gave a value of 2,500,000.

Recent work (6, 12, 13) has shown that carrageenin contains at least two components, distinguishable mainly by their gelling tendencies. Although no

[1]*Manuscript received January 17, 1955.*
Contribution from the Maritime Regional Laboratory, National Research Council, Halifax, Nova Scotia. Issued as N.R.C. No. 3569.

attempt was made in the present investigation to separate these components, recent results (6) indicated that a hot extract prepared in the above manner consists largely of the gelling fraction.

Preparation of Solutions

Solutions were made up as required by tumbling at room temperature. The sodium salt of the polyelectrolyte was used in all experiments. This was prepared by passing a solution of concentration 0.1 to 0.2 gm. dl.$^{-1}$ down a column of Amberlite IR 100 ion exchange resin. Final clarification was achieved with a No. 02 Selas filter element.

Buffering salts were added by mixing known volumes of the carrageenin with a stronger salt solution. The three ionic conditions studied were (1) distilled water, (2) $M/30$ sodium phosphate at pH 7.0 (referred to as $M/30$ phosphate), (3) $M/30$ sodium phosphate plus $M/20$ sodium chloride at pH 7.0 (referred to as $M/12$ phosphate/NaCl).

Viscosity Measurements

Capillary viscometers, each equipped with a series of bulbs to provide different hydrostatic heads, were employed. Various designs were tried in order to cover as wide a range of shear gradients as possible.

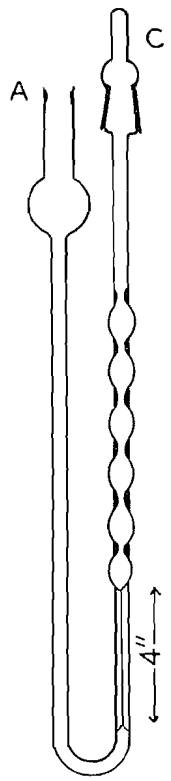

FIG. 1. Viscometer for checking on the possibility of drainage errors.

Three of the viscometers were similar to the one described by Schurz and Immergut (11). By using various lengths of capillary tubing a range of shear gradients for water between 221 and 2135 sec.$^{-1}$ was obtained. Where measurements were taken with different viscometers over the same range of shear gradients, the difference between the results was less than two per cent.

The design of a fourth viscometer, shown in Fig. 1, was such as to allow the liquid to flow into the dry bulbs, thus providing a check on the possibility of drainage errors. The viscometer was filled through A with cap C closed. Sufficient time was allowed for temperature equilibrium to be established, cap C was then removed, and the time required to fill each bulb in turn was noted. The range of shear gradients covered was 607 to 2061 sec.$^{-1}$ Results obtained with this instrument for a highly viscous aqueous solution agreed within experimental error with data from one of the other viscometers. Thus drainage errors were inappreciable.

Measurements were made at 25°C. in thermostats controlled to ±0.05°C. or better. Kinetic energy corrections were applied to all the results. Viscometers were calibrated by measuring the flow times of glycerol–water mixtures of known density and viscosity. Kinetic energy corrections were calculated for each bulb by the usual method. In one viscometer the correction for water in the bulb with the highest shear was 6% of the flow time and the correction decreased with increasing time of flow. All other corrections were lower than this and in several viscometers were negligible. The intrinsic viscosity, $[\eta]$, was obtained from the specific viscosity, η_{sp}, by the usual relationship

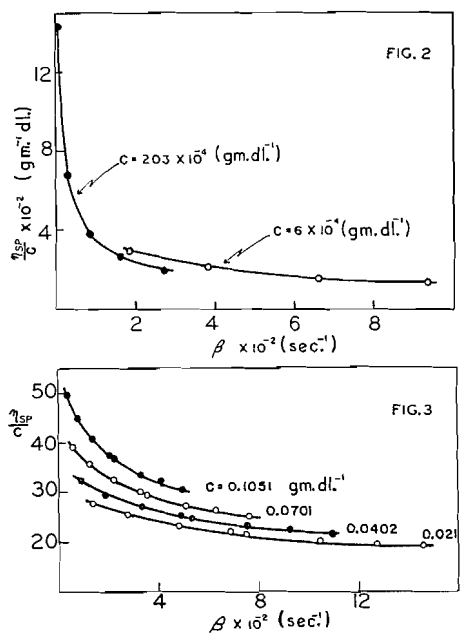

FIG. 2. η_{sp}/c vs. β for Extract G in water.
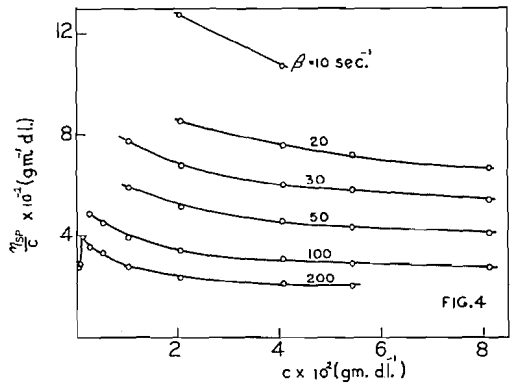
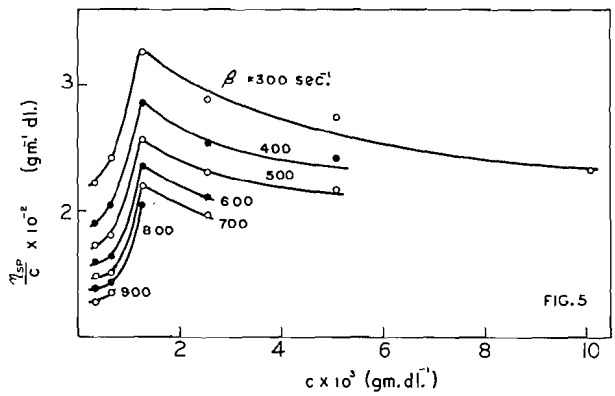
FIG. 3. η_{sp}/c vs. β for Extract G in $M/12$ phosphate/NaCl.





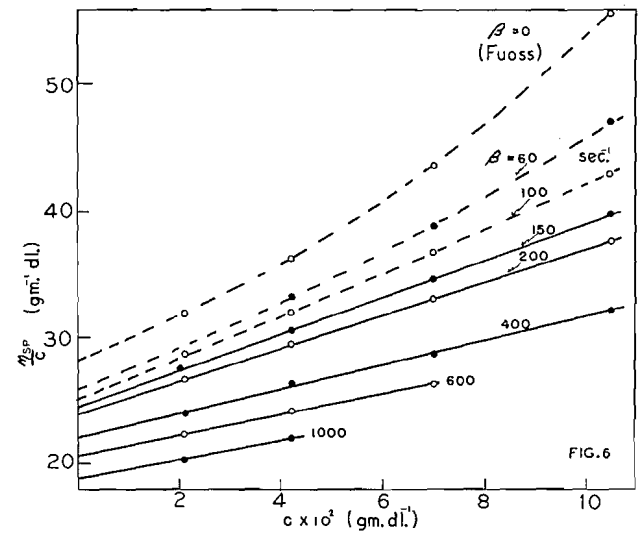


FIG. 4. Isoshear graphs of η_{sp}/c vs. c for Extract G in water. Values of β are from 10–200 sec.$^{-1}$

FIG. 5. Isoshear graphs of η_{sp}/c vs. c for Extract G in water. Values of β are from 300–900 sec.$^{-1}$

FIG. 6. Isoshear graphs of η_{sp}/c. vs. c for Extract G in $M/12$ phosphate/NaCl.

[1] $$[\eta] = (\eta_{sp}/c)_{c\to 0}$$

The average shear gradient, β, was calculated from

[2] $$\beta = 8V/3\pi r^3 t$$

where V is the volume of bulb, r is the radius of capillary, and t is the time of flow.

RESULTS

Experimental curves of η_{sp}/c vs. β for various concentrations of Extract G in water and $M/12$ phosphate/NaCl are given in Figs. 2 and 3. From such curves, values of η_{sp}/c at constant shear were derived and isoshear graphs of η_{sp}/c vs. c (Figs. 4, 5, and 6) were drawn. In $M/12$ phosphate/NaCl, as shown in Fig. 6, η_{sp}/c varied linearly with c except for the slight curvature at $\beta = 60$ sec.$^{-1}$ Extrapolation to $c = 0$ gave values of $[\eta]$ corresponding to definite shear rates. Similar results were obtained with $M/30$ phosphate; $[\eta]$ is plotted against β in Fig. 7 for both sets of measurements.

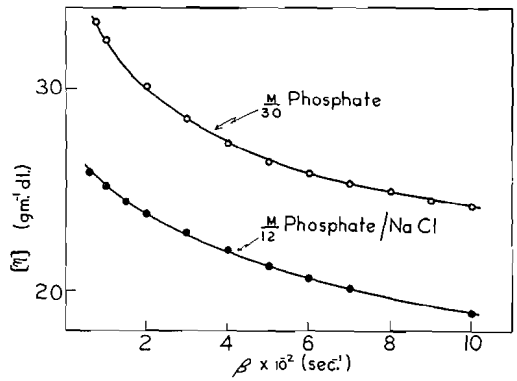

FIG. 7. Intrinsic viscosity vs. shear rate for Extract G in $M/30$ phosphate and $M/12$ phosphate/NaCl.

The isoshear graphs for Extract G in water did not permit extrapolation to zero concentration. At low shear rates (Fig. 4) the plots were curved upwards; at higher shear rates, where measurements could be carried to very low concentrations, distinct maxima in the plots were observed (Fig. 5).

DISCUSSION

The results fit the general pattern of polyelectrolyte behavior. Solutions containing added electrolyte behave like those of uncharged polymers, with the exception that curvature is noted in the plots of η_{sp}/c against c at low rates of shear (Fig. 6). This makes it difficult to obtain accurate values of $[\eta]$ at low shear rates. In addition, since the plot of $[\eta]$ vs. β (Fig. 7) is also curved, the value of $[\eta]$ at zero rate of shear can not be determined by extrapolation with any degree of accuracy.

An interesting feature of these measurements concerns the magnitude of the Huggins (7) interaction coefficient, k'. As shown in Table I, k' increases with

TABLE I

VALUES OF k' AT VARIOUS SHEAR GRADIENTS FOR EXTRACT G IN $M/30$ PHOSPHATE AND $M/12$ PHOSPHATE/NaCl

100		281

decreasing shear rate. Solutions of high molecular weight carrageenin have been shown to have a yield point which increases at higher concentration (8). Thus an increase in the concentration dependence of η_{sp}/c at low rates of shear might be expected. A similar dependence of k' on shear gradient has recently been noted (10) for solutions of cellulose and cellulose nitrate.

It is also of interest that the values of k' are higher with $M/12$ phosphate/NaCl than with $M/30$ phosphate, when comparison is made at the same rate of shear or the same intrinsic viscosity. This is the opposite behavior to that anticipated if the effect of adding salt is to cause a further coiling of the molecule in solution. A possible explanation is that neutralization of the charges on the polymer chain by the addition of electrolyte results in a decrease in electrostatic repulsion between neighboring chains thereby allowing an increase in some structure-forming tendency. In the case of carrageenin, the latter effect may predominate under the conditions studied. This interpretation is consistent with the gelling tendency of solutions of certain fractions of carrageenin (6) on the addition of electrolytes. A detailed interpretation of this anomaly must await the development of an adequate theory of polyelectrolyte solutions.

Regarding the measurements in the absence of added salts (Figs. 4 and 5), the occurrence of maxima similar to those observed here has been noted by Conway and Butler (1) for dilute solutions of thymus nucleic acid. Fuoss and Cathers (4) have shown that for solutions containing traces of added salt, such maxima are to be expected when the concentration of ions from the polyelectrolyte and salt are roughly equivalent. The specific conductance of the distilled water was approximately 2×10^{-6} mho cm.$^{-1}$ This could be attributed to sodium chloride in a concentration of 2×10^{-5} M. The maxima in the curves occur at a carrageenin concentration of 0.0012 gm. dl.$^{-1}$ The sulphate content (as OSO_3^-) of carrageenin is approximately 25% giving a value of 384 for the equivalent weight. The "molar" concentration of carrageenin was therefore 3×10^{-5} M. The occurrence of maxima in the viscosity curves in this region is thus probably due to the suppression of ionization by foreign cations in roughly equivalent concentration. Such effects have been

predicted by Flory and Osterheld (3) but can only be observed with polyelectrolytes of high molecular weight where viscosity measurements are still practicable at very low concentrations.

The curves shown in Fig. 4 have been plotted according to the equation of Fuoss and Cathers (4)

$$[3] \qquad z = \eta_{sp}/c = \frac{A}{1+Bc^{\frac{1}{2}}} + D.$$

Previous work (8) has shown that this equation adequately fits the viscosity–concentration relationship for carrageenin of low molecular weight. In the present work, the occurrence of maxima at $c = 0.0012$ gm. dl.$^{-1}$ makes the shape of the curves of η_{sp}/c vs. c uncertain at low concentrations. It was assumed, however, that this would not influence η_{sp}/c at concentrations above 0.01 gm. dl.$^{-1}$

From the linear plots of η_{sp}/c vs. $c^{-\frac{1}{2}}$, values of D were obtained at various shear rates. As shown in Fig. 8, D is markedly shear-dependent, increasing rapidly at low values of β. Since D represents the reduced specific viscosity at $c = \infty$, this means that even in concentrated solutions the molecule is rod-shaped. Values of D are higher than the corresponding intrinsic viscosities in salt solutions indicating that the coiling effect of a high concentration of polyelectrolyte is not as great as that of small quantities of added salt.

In Fig. 9, plots of $1/(z-D)$ vs. $c^{\frac{1}{2}}$ at various shear rates are shown. The plots are linear for shear rates of 200 and 100 sec.$^{-1}$ but become curved at lower shear. For $\beta = 200$ and 100 sec.$^{-1}$, A was respectively 800 and 1240 gm.$^{-1}$ dl. also

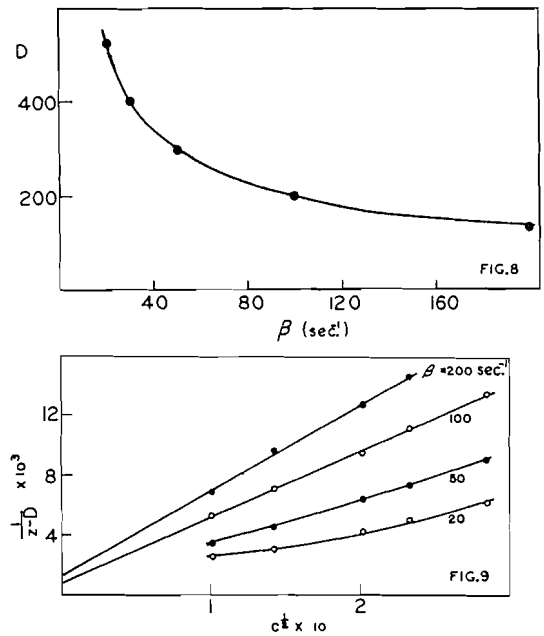

FIG. 8. Variation of D with rate of shear for Extract G in water.
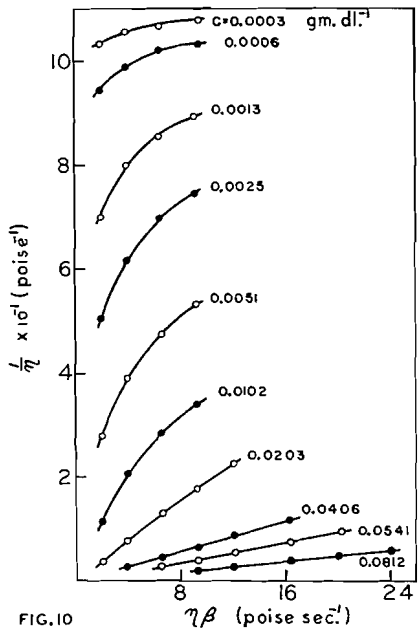
FIG. 9. Graph of $1/(z-D)$ vs. $c^{\frac{1}{2}}$ for Extract G in water.

showing marked shear-dependence. Values of 46 (±5) and 55 (±8) were obtained for the constant B at 200 and 100 sec.$^{-1}$ respectively. These values are similar to those obtained previously with a low molecular weight sample (8).

The data have also been analyzed by the method of Goldberg and Fuoss (5), in which $1/\eta$ is plotted against $\eta\beta$. For Extract G in water (Fig. 10) the results are similar to those obtained by these authors for aqueous solutions of poly-*n*-N-butyl-4-vinylpyridine. At high concentrations the relationship is linear, but extrapolation yields apparently negative values of $1/\eta$, indicating curvature near the origin. At lower concentrations the relationship is non-linear and extrapolation is uncertain.



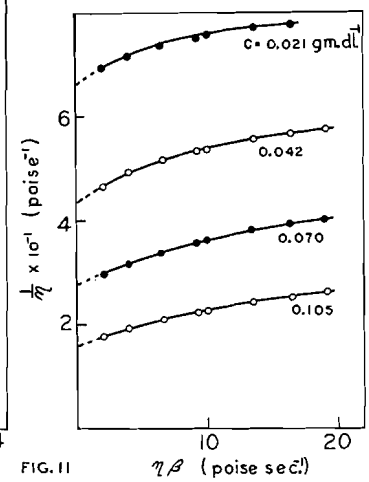


FIG. 10. Graph of $1/\eta$ vs. $\eta\beta$ for Extract G in water.
FIG. 11. Graph of $1/\eta$ vs. $\eta\beta$ for Extract G in $M/12$ phosphate/NaCl.

For the results in $M/12$ phosphate/NaCl, the curvature in these plots was not so pronounced (Fig. 11), and the method was applied to obtain a rough estimate of the value of $[\eta]$ at zero rate of shear. The curve of η_{sp}/c vs. c at zero rate of shear which is obtained in this way is included in Fig. 6.

Other empirical methods which have been described in the literature have been applied to the above results in attempts to extrapolate to zero rate of shear. All methods tried were unsuccessful; for characterization of the polyelectrolyte it appears best at present to use the value of $[\eta]$ at some arbitrary shear rate above 100 sec.$^{-1}$

THE HEAT OF WETTING OF SILK FIBROIN BY WATER[1]

By H. Brian Dunford[2] and John L. Morrison[3]

ABSTRACT

The heats of wetting by water of silk fibroin initially containing various amounts of adsorbed and desorbed water have been measured. These measurements along with the water vapor adsorption isotherm of Hutton and Gartside have been used to calculate the integral and differential heats, free energies, and entropies of adsorption. In contrast with cellulose, silk containing desorbed water evolves less heat than that containing adsorbed water. This fact suggests that any contribution by a heat of swelling term is very small for silk fibroin, so that the calculated thermodynamic properties probably can be assigned almost entirely to the adsorption process. The changes in the heats and entropies of adsorption appear to parallel the sequence of changes in film formation as revealed by surface area calculations.

Bull (2) determined the water vapor adsorption isotherms of a large number of proteins including silk fibroin at 25° and 40°C. Dole and McLaren (4) and Davis and McLaren (3) corrected and extended Bull's thermodynamic calculations of the water–protein systems. In these calculations, isosteric heats of adsorption were obtained by applying the Clausius–Clapeyron equation to the adsorption isotherms at the two different temperatures. Much uncertainty in this method of determining heats of adsorption occurs in the low and high water vapor pressure regions, yet it is these regions that are very important in understanding the nature of the adsorption process.

Direct measurement of the heats of wetting of water by silk fibroin over the whole range of vapor pressures are reported here. With these data and the adsorption isotherm of Hutton and Gartside (11), the thermodynamic functions have been calculated. The only reported similar measurements that have come to our attention were made at four initial water contents by Hedges (8).

EXPERIMENTAL

Rotating Adiabatic Calorimeter

A rotating adiabatic calorimeter as originally designed by Lipsett, Johnson, and Maass (13, 14) was used with some small modifications (1, 5).

The heat capacity of the calorimeter was obtained by the method used for the original apparatus (13). This consisted of measuring the heat of solution of sodium chloride in water, using sets of two determinations with the same salt–water ratios but differing absolute amounts of reactants. The average heat capacity for seven sets of determinations was within 0.08 calories of the calculated value of 13.09 calories. Although this is an error of 0.6% for the metal container, it is only 0.1% for the total heat capacity when the 50 ml. of accurately weighed water used for all heat of wetting measurements is included.

Evacuated Glass Calorimeter

The heat of wetting measurements were carried out in air. To determine the magnitude of the heat effect arising from the desorption of the air by water, some heat of wetting measurements were made in a simple vacuum calorimeter.

The glass reaction cell of the calorimeter was similar to that of Howard and Culbertson (10) and consisted of two compartments, one of about 20 ml. volume to hold the evacuated silk sample, and the other of about 50 ml. to hold the water. Upon breaking the hook-shaped thin glass partition between the two compartments, the water came in contact with the silk. The whole assembly, including glass cell, Beckmann thermometer, 50 ohm resistance wire, and glass stirring rod, was immersed in xylene (low heat capacity liquid) contained in a Dewar flask (inside dimensions: 6.7 cm. diameter by 28 cm. height). The top was sealed as completely as possible by a waxed cork. The glass cell was discarded after an experiment.

The temperature rise of the wetting process was simulated electrically so that it was unnecessary to determine the heat capacity of the calorimeter.

Silk Fibroin

Japanese raw silk was kindly supplied by Belding-Corticelli Ltd., Montreal. It was degummed by the method of Sookne and Harris (19).

Drying and Moistening Procedures

Most samples were dried by a procedure similar to that of Hedges (8). A stream of compressed air was passed successively through absorbent cotton, sulphuric acid scrubbers, sodium hydroxide pellets, and magnesium perchlorate towers. The dry air entered a copper coil and desiccator inside an oven at $105\pm1°C$. After it was dried for two hours in the oven desiccator, the sample was placed in a specially designed desiccator (16) over phosphorus pentoxide for 30 min. to cool.

If the sample was being used to determine the heat of wetting at the above dryness, the container for drying the sample was the inner box of the calorimeter. If, however, the sample was being prepared for heats of wetting measurements at finite initial moisture contents, the drying container was a weighing bottle. After the dry weight of the silk was obtained, the weighing bottle was placed over an aqueous sulphuric acid solution of concentration necessary to give the required initial moisture content. Then, after at least three days, the sample was transferred as rapidly as possible to the inner box of the calorimeter, covered by the weighed greased lid, and reweighed to determine the moisture content.

Some heat of wetting measurements were made on samples from which water had been partially desorbed. First, the samples were placed over distilled water, and then over various aqueous sulphuric acid solutions.

Bull's data as well as the present measurements are on a vacuum-dry basis. Three samples which had been previously dried by the above method were dried for two hours in an Aberhalden vacuum drying apparatus which uses boiling water as a heat source. These determinations showed that the oven-

dried samples contained 0.20% moisture on the vacuum-dry basis. The heat of wetting of one of these samples was determined.

Finally, for the heat of wetting measurements of evacuated samples, the silk was dried *in vacuo* at 105°C. by an electric furnace.

RESULTS AND CALCULATIONS

Net Heat of Adsorption

The heats of wetting of silk fibroin at 25°C. and equilibrated with various amounts of water, both adsorbed and desorbed, are given in Table I and Fig. 1. For comparison, Hedges' four determinations (8) are included in Fig. 1. A comparison of the degree of precision of our calorimetry with that of Hedges may be shown by the fact that, in our case, the mean deviation of three determinations at 0.20% moisture content is ± 0.03 cal. gm.$^{-1}$, while the mean deviation of Hedges' four values for the heat of wetting of dry wool is ± 0.4 cal. gm.$^{-1}$.

The measurements of the heat of wetting of seven evacuated samples in the Dewar calorimeter gave an average of 15.94 ± 0.11 cal. gm.$^{-1}$. Since these values agree with the result obtained in the presence of air, the air has no measurable effect. Also, the value of the initial, vacuum-dried sample (15.93) was confirmed by a different type of calorimeter.

The integral net heats of adsorption, ΔH, in calories per 100 gm. silk fibroin (above the heat of condensation of water vapor to liquid) have been calculated from the heats of wetting by the method of Dole and McLaren (4) (See also Wahba (21)).

In our case, the *heat of wetting*, q_0, of 100 gm. dry protein is evolved by Process 1.

(1) Protein (dry at $p = 0$) + excess liq. H_2O (at p_0) $\rightarrow$ Protein (with excess liq. H_2O at p_0), in which p_0 is the vapor pressure of pure water at 25°C.

Note on units: n, moles per 100 gm. fibroin; ΔH and ΔF, calories per 100 gm. fibroin; $\overline{\Delta H}$ and $\overline{\Delta F}$, calories per mole of water; ΔS, entropy units per 100 gm. fibroin; $\overline{\Delta S}$, entropy units per mole of water.

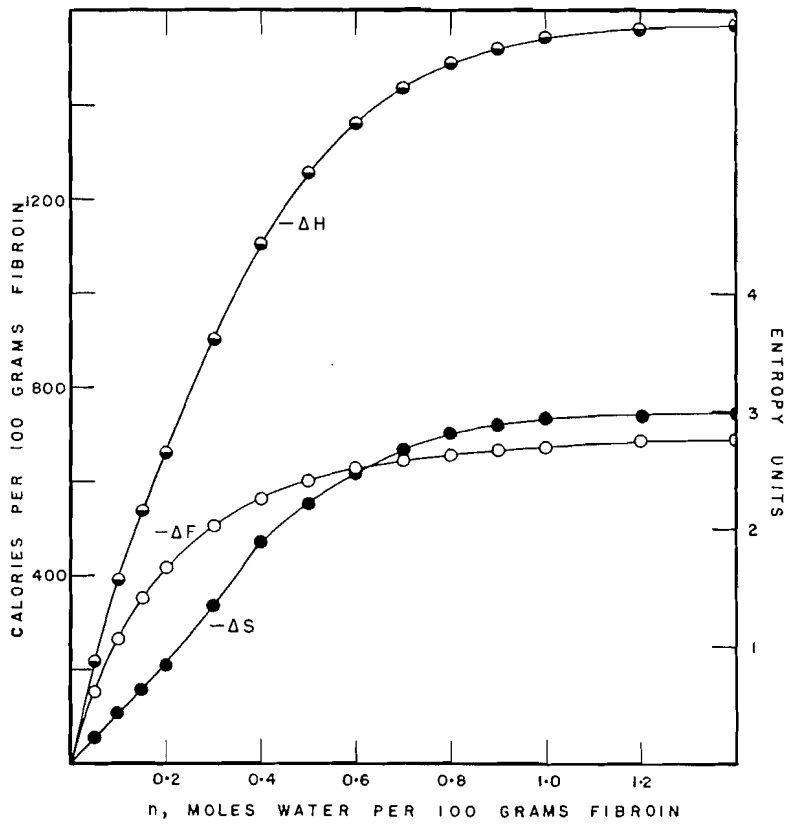

FIG. 2. The integral heat, free energy, and entropy of adsorption of water by silk fibroin.

Subtraction of Process 2 from Process 1 gives Process 3:

(3) Protein (dry at $p = 0$)$+n$ H_2O (at p_0) $\rightarrow$ Protein (with n H_2O at p), with the evolution of (q_0-q) calories/100 gm. dry protein, or ΔH, the integral net heat of adsorption.

Our Process 3 is the same as Dole and McLaren's Process (4). Values of ΔH are given in Table II and Fig. 2.

The differential net heats of adsorption, $\overline{\Delta H}$, given in Table II and Fig. 3, were obtained by careful graphical differentiation of the plot of ΔH vs. n, the number of moles of water adsorbed per 100 gm. fibroin.

Free Energy of Adsorption

The integral and differential free energies of adsorption of water on a protein are obtained from the vapor adsorption isotherm. Following Dole and McLaren (4), the differential free energy, $\overline{\Delta F}$, is given by

$$\overline{\Delta F} = RT \ln (P/P_0)$$

and the integral free energy, ΔF, of *our* Process 3 is given by

$$\Delta F = -RT \int_0^1 n d \ln(P/P_0) + nRT \ln(P/P_0).$$

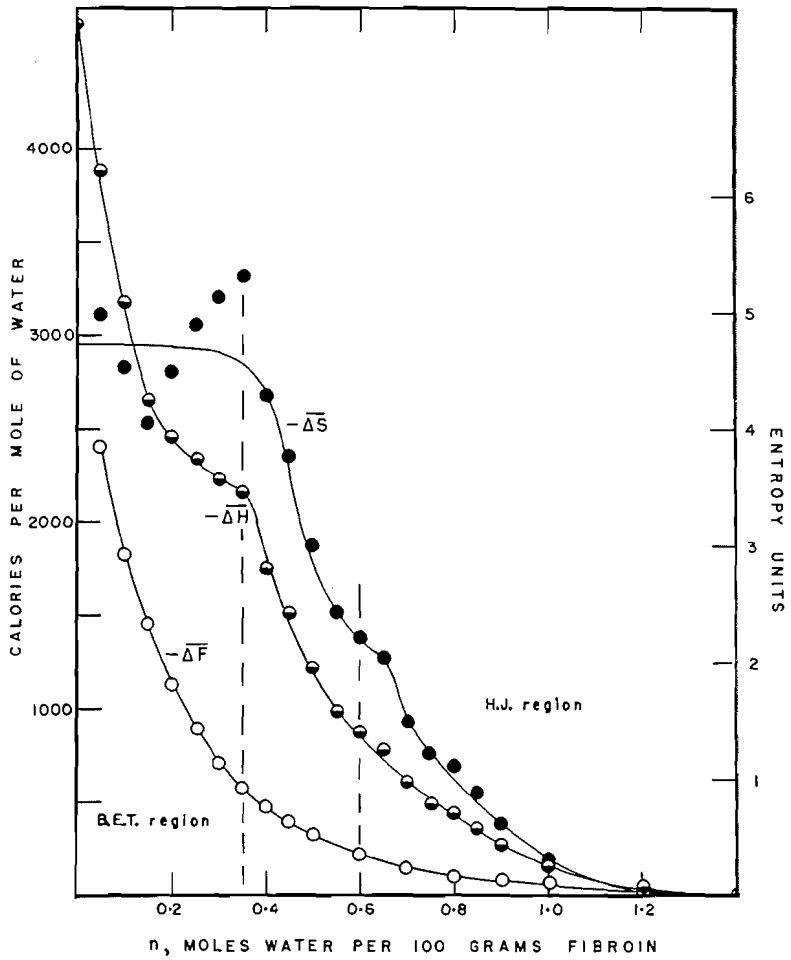

FIG. 3. The differential heat, free energy, and entropy of adsorption of water by silk fibroin.

A number of attempts were made to obtain a reproducible adsorption isotherm with a vacuum apparatus like that used by Wiig and Juhola (22) for charcoal. Although the middle and upper pressure parts of the adsorption branch matched the corresponding parts of the isotherm of Hutton and Gartside (11), the amount adsorbed in the low pressure region was lower than that obtained by them and others (2, 18). It was realized that the determination of the correct isotherm is a major project in itself.

Fortunately, Hutton and Gartside (11) have carried out an exhaustive study of the water isotherm on silk at 25°C. They found that degummed silks of Japanese, Chinese, and Italian origins gave practically the same isotherm, and by both the vacuum and the desiccator methods.

Dunford and Morrison (6) have shown that the Brunauer, Emmett, and Teller equation and the Harkins–Jura equation, although applying to the opposite extremes of Bull's water–protein systems, gave the same monolayer

adsorption for each protein. Liang's method (12) was used to correlate the two equations. These equations were applied to the isotherm of Hutton and Gartside. The B.E.T. plot gave a straight line over the relative pressure range 0.07 to 0.35, with a monolayer content, X_m, of 4.49 gm. water per 100 gm. silk fibroin. The H.J. plot gave a straight line over the relative pressure range 0.60 to 0.97 (and probably to 1.00), with $X_m = 4.46$ gm. It is considered that this coincidence of X_m values further validates the isotherm. The same test applied to our isotherm failed to produce a straight line for the B.E.T. plot, while it gave a value of $X_m = 4.48$ gm. for the H.J. plot.

Thus, the water vapor adsorption isotherm of Hutton and Gartside was used to calculate ΔF and $\overline{\Delta F}$, the results of which are given in Table II and Figs. 2 and 3.

Entropy of Adsorption

The integral and differential net entropies of adsorption, calculated by the well known equations

$$\Delta S = (\Delta H - \Delta F)/T$$
$$\text{and} \quad \overline{\Delta S} = (\overline{\Delta H} - \overline{\Delta F})/T,$$

are given in Table II and Figs. 2 and 3.

DISCUSSION

Comparison with Calculations of Davis and McLaren

The results shown in Figs. 2 and 3 may be compared with the corresponding calculations of Davis and McLaren (3), based on Bull's data (2). In contrast with their results, the present integral heats and entropies in Fig. 2 reach higher values and approach maximum values as saturation vapor pressure is reached.

The differential heats and entropies in Fig. 3 show similar general features to those of Davis and McLaren except at the extremes of the vapor pressure range. In the low pressure range, a mean value of about -4.7 e.u. is suggested for $\overline{\Delta S}$, the differential entropy change. Entropy values of this order of magnitude are maintained until appreciably above a B.E.T. monolayer film content. The value of -4.7 e.u., which is much less than the value of nearly -8 obtained by Davis and McLaren, is still sufficient to suggest chemisorption of water as proposed by Pauling (17). The fact that the entropy does not fall off until a film content 40% above the monolayer is reached suggests that some water in the second layer is very tightly held.

In the region of high vapor pressure, the upswing in the negative differential heats and entropies calculated by Davis and McLaren are not found in the present calculations; instead, $-\overline{\Delta H}$ and $-\overline{\Delta S}$ decrease regularly to those of liquid water. However, Davis and McLaren doubt the reality of their upswings.

Heat of Wetting Hysteresis

In interpreting thermodynamic calculations of adsorption systems, the question of how much of the changes arise from the adsorbate and the adsorbent respectively must be determined. This is particularly true of protein–water systems, in which swelling phenomena and even solution may occur.

The silk fibroin – water system appears to be a relatively simple one, so that the thermodynamic changes can be fairly definitely identified with purely adsorption phenomena. The fact that fibroin is very accessible to water, independently of its structure, so that its water vapor adsorption isotherm is unaffected by solution and reprecipitation (15) does not in itself eliminate the possibility of swelling phenomena. Wool, which shows swelling properties, behaves similarly to silk in that its adsorption isotherm is largely unaffected by the destruction of its structure. However, while the *amounts* adsorbed may be unaffected, the energy relations may be profoundly affected.

No comparison of silk with wool is possible because Hedges (8) who measured the heats of wetting of wool by water did not make measurements on "desorbed" samples. However, Argue and Maass (1) made measurements for cellulose and found that the heats of wetting on the 'desorbed' samples were significantly *higher* than for the corresponding 'adsorbed' samples. This is generally explained by including a heat of swelling term in the net heat of wetting on an 'adsorbed' sample, part of which would not be included in the heat of wetting of a 'desorbed' sample. In our case, if there is any heat of swelling, it is probably very small because the desorption heats of wetting are *below* the adsorption heats.

It must be remembered that both silk fibroin and cellulose give the same type of sorption isotherm hysteresis. At equal moisture contents, water is more tightly held on the desorption branch. Therefore we would expect the heat of wetting to be *less* for the desorption side if there are no phenomena occurring other than pure adsorption.

Adsorption Areas

Adsorption area measurements assist in the interpretation of the thermodynamic properties of adsorption systems. In the case of the silk fibroin – water system, it was shown (6) in common with all Bull's data that the B.E.T. and H.J. area equations when applied to the two parts of the adsorption isotherm gave coincident monolayer values (X_m = 4.48 gm. H_2O per 100 gm. fibroin). This confirms the observation of Mellon, Korn, and Hoover (15) that swelling phenomena do not appear to affect the accessibility of water molecules to the molecular chains of fibrous proteins. The coincidence of monolayer areas has been interpreted by Dunford and Morrison (6) to indicate that the upper part of the isotherm involves the formation of a condensed film above the monolayer laid down in the first part of the isotherm. This interpretation confirms the observations of Hoover and Mellon (9) who, by applying a polarization theory to protein–water sorption isotherms, showed "that sorption on active sites occurs at low vapor pressures and that sorption at higher vapor pressure is due to this prior sorption".

Finally, let us consider what happens when vapor saturated silk fibroin is immersed in liquid water. An attempt was made to measure the area of the protein by the absolute method of Harkins and Jura (7). A sample was kept above pure water for three days attaining 25.2% moisture content before being immersed in the calorimeter. The heat of wetting was 0.19 cal. gm.$^{-1}$. However,

the saturation moisture content of silk fibroin is 36% (11) and extrapolation to this water content gave a value of less than 0.10 cal. (Wahba (20) found 0.30 cal. gm.$^{-1}$ for cellulose under the same conditions). Assuming that the heat of immersion of the vapor saturated fibroin does not include swelling energy, the Harkins and Jura 'absolute' area is less than 3.5 sq. meters gm.$^{-1}$, compared with the isotherm area of 158 sq. meters gm.$^{-1}$. This suggests that near the relative vapor pressure of unity, the spaces between the molecular protein chains are completely filled with water and that the area 3.5 sq. meters gm. may correspond to the external area of the fibrils.

Conclusion

The area and thermal measurements and calculations of the silk fibroin – water system are consistent; in Fig. 3, the differential heat and entropy curves indicate a transition from monolayer and multilayer formation to a condensed film, which in turn becomes indistinguishable from liquid water. If swelling occurs, its effect is not reflected in either the amounts or energies of adsorption.

THE ADSORPTION OF NITROGEN, OXYGEN, AND ARGON BY GRAPHITE[1]

By H. L. McDermot and J. C. Arnell

ABSTRACT

The adsorption of nitrogen, oxygen, and argon by three Acheson graphites has been measured at liquid nitrogen and liquid oxygen temperatures. The isotherms were Type II in the B.E.T. classification and displayed two kinds of hysteresis. The first kind was attributed to the presence of pores in the graphite and the second kind to intercrystalline swelling.

INTRODUCTION

This paper describes an investigation of three artificial graphites manufactured by the Acheson Colloids Corporation. Very little detailed adsorption work has been done with graphites of this type with a view to elucidating their structure. Barrer (2) has measured the adsorption of nitrogen, argon, and hydrogen by an Acheson graphite over a considerable temperature range and has calculated isosteric heats from the isotherms. He found that the graphite was energetically heterogeneous to all three gases and that the heats in the case of nitrogen were unaffected by the addition of chemisorbed oxygen to the surface of the graphite. He concluded therefore that the heterogeneity was a property of the carbon structure. In the opinion of the authors, the weakness of this work lies in the fact that very few adsorption points were measured at each temperature and no desorption points at all were determined. Bartell and Dodd (4) measured the adsorption of nitrogen at liquid nitrogen temperatures by a number of carbons which included two Acheson graphites. The purpose of the work was to measure the surface area of the carbons so that only a small number of points were determined and only in the case of the diamond powder were desorption points taken. It is stated that no desorption points were measured for the graphite because reversibility for nitrogen adsorption had been established at liquid oxygen temperatures. Bartell and Dodd do not indicate to what pressures these measurements were carried, but it will be shown in the present paper that reversibility of the nitrogen isotherm at 90°K. is by no means a criterion for reversibility unless pressure measurements are extended to well over an atmosphere. Because of the lack of data on these graphites, it was decided to undertake a detailed study of three typical artificial graphites. The first step was to measure isotherms at low temperatures using as adsorbates nitrogen, oxygen, and argon. Unusual hysteresis effects were encountered and therefore a detailed study was made on one graphite using nitrogen as the adsorbate. For comparative purposes the nitrogen isotherm of a nonporous carbon black was also determined.

EXPERIMENTAL AND RESULTS

Samples of three graphites of surface areas up to 100 $m.^2/gm.$ were supplied by the Acheson Colloid Corporation. They were designated as Lot 6226, Lot 6131, and No. 39. For the purpose of this paper they have been designated as G-1, G-2, and G-3, respectively.

Nitrogen was supplied by the Canadian Liquid Air Co. It was stated to be 99.5% nitrogen and was used without further purification.

Oxygen was also supplied by the Canadian Liquid Air Co. and specified as 99.9% oxygen.

The argon used was Matheson Research Grade and was rated as 99.9% pure.

The adsorption isotherms were measured by means of a standard volumetric adsorption apparatus. For the isotherms at 77.5°K. and 90.0°K., open baths of liquid nitrogen and liquid oxygen were used. The maximum variation in the temperature of these baths was ±0.2°. For the isotherm at 70.6°K., a cryostat was used the temperature of which was controlled and measured by a nitrogen thermometer. The temperature of the cryostat was regulated to better than ±0.02°. Before commencing adsorption measurements the samples of graphite were outgassed by evacuation at 120°C. for at least 12 hr.

The isotherm for the adsorption of nitrogen by G-1 is shown in Fig. 1. The isotherm is Type II in the B.E.T. classification and displays a normal hysteresis loop from saturation down to a relative pressure of 0.45. Several scanning curves are also shown illustrating the effect of desorption from pressures below saturation. Below a relative pressure of 0.45, an unusual desorption curve

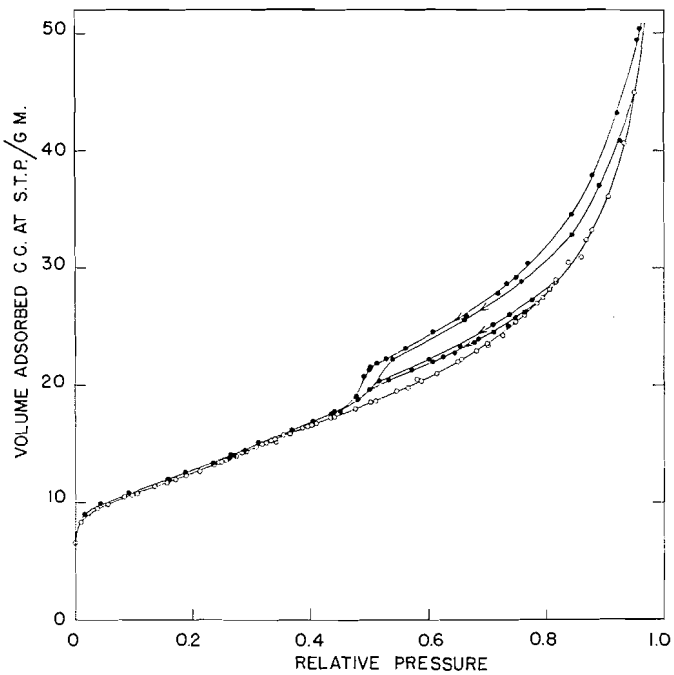

FIG. 1. Isotherm of nitrogen sorbed by G-1 at 77.5°K.

approximately parallel to the adsorption curve and slightly above it was found. The separation of the curves at this part of the isotherm is small, but is nevertheless believed to be real. Over ten separate adsorption–desorption cycles were carried out with this system and in every case the desorption points were observed to lie slightly above the adsorption points despite the fact that desorption was begun from a variety of relative pressures (all above the inception of the hysteresis loop). If for example a cumulative error existed, a different separation would be anticipated for each relative pressure chosen for the commencement of desorption. This was not found to be the case. However when desorption was carried out at pressures below the inception of the hysteresis loop then no hysteresis at all was observed. This point is illustrated by Fig. 2, which shows the isotherm of nitrogen adsorbed by G-1 at

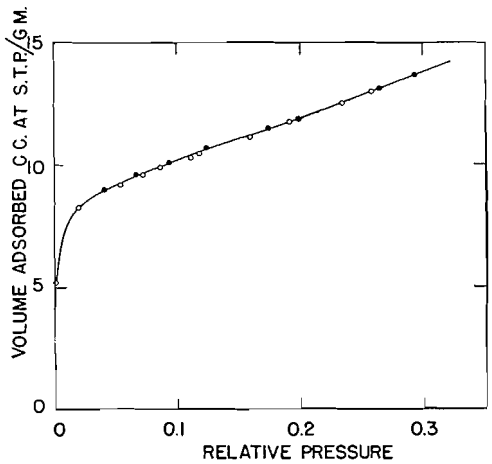

FIG. 2. Isotherm of nitrogen sorbed by G-1 at 90.0°K.

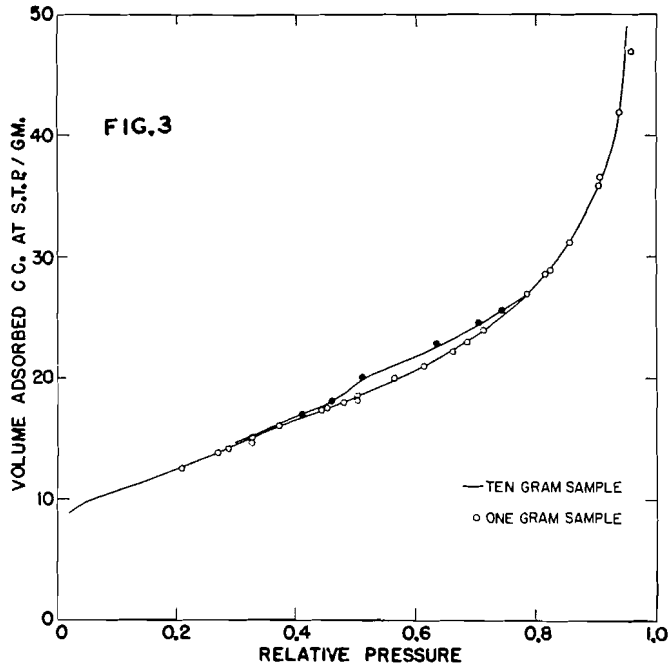
90.0°K. The characteristics outlined for the adsorption isotherm of nitrogen on G-1 were found to be typical of the nitrogen isotherms of all these graphites.

As the initial measurements with G-1 revealed the unusual hysteresis effects referred to above, experiments were conducted to discover if these effects stemmed from the packing of the powder in the adsorption cell. In the first of these experiments, the nitrogen isotherm was remeasured using 1 gm. of graphite instead of 10 gm. The results are plotted in Fig. 3 along with the original isotherm. There is no discernible difference between the two sets of data. In a second experiment, a 1 gm. sample was spread out (approximately 1 mm. in depth) on circular trays arranged on a vertical rod and separated from each other by washers. Before filling with graphite, the trays were washed with organic solvents to remove machining compounds and were thoroughly dried. The adsorption of nitrogen was then measured. The isotherm is shown in Fig. 4 along with that determined for a 1 gm. sample in bulk. Although the adsorption is somewhat greater for the sample on trays at high relative pressures, the hysteresis effects remained substantially unchanged. It was concluded therefore that the unusual hysteresis effects were real. No explana-



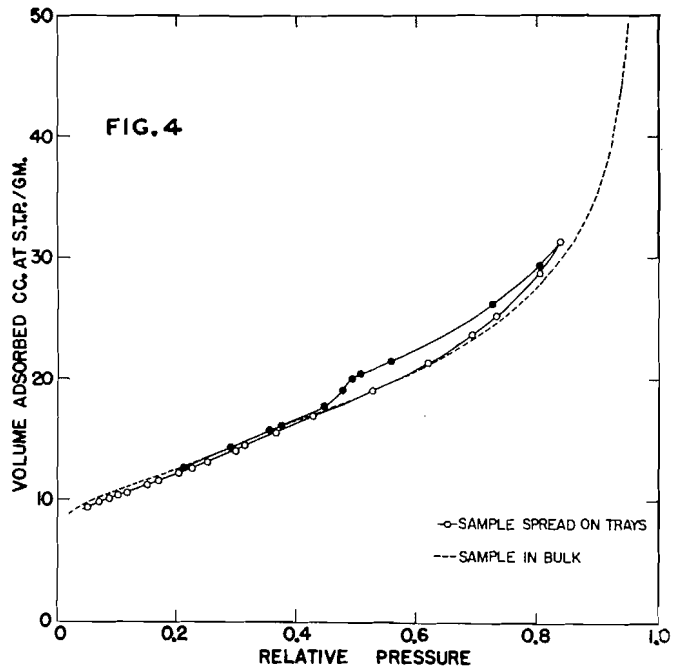


FIG. 3. Sorption isotherms of nitrogen by G-1 at 77.5°K. showing the effect of variations in sample size.

FIG. 4. Sorption isotherms of nitrogen by G-1 at 77.5°K. showing the effect of sample dispersion.

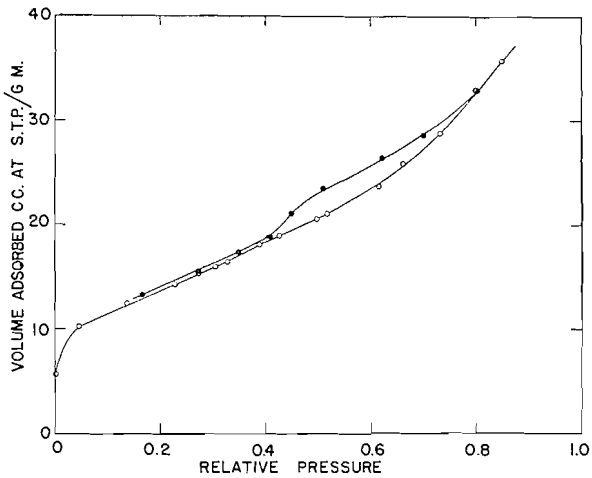

FIG. 5. Isotherm of oxygen sorbed by G-1 at 90.0°K.

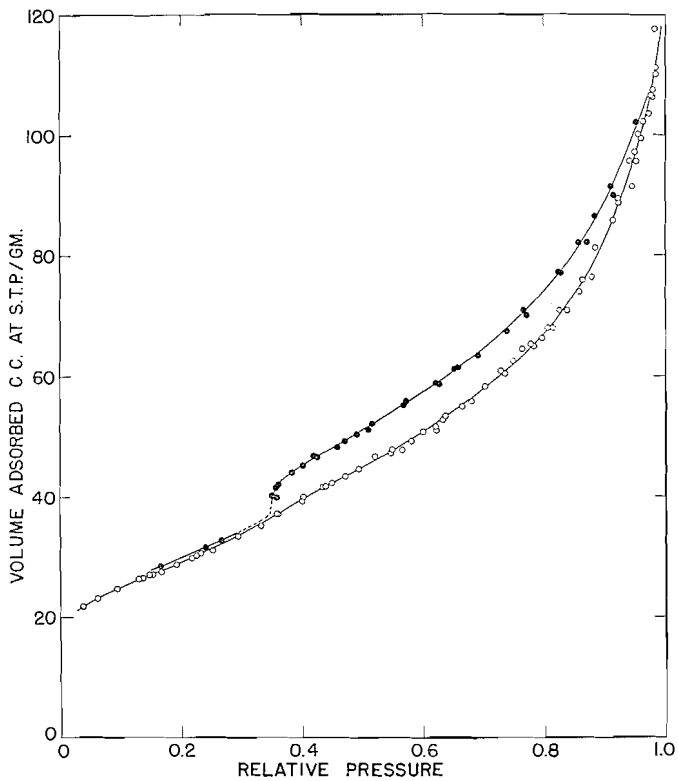

FIG. 6. Isotherm of argon sorbed by G-2 at 77.5°K.

tion has been found for the difference between the isotherms of the "bulk" sample and the "dispersed" sample. The reproducibility of the measurements indicates that the effect is real and not due to experimental error. An obvious speculation is that some packing is occurring in the "bulk" sample which hinders adsorption at higher relative pressures.

It was then suspected that the hysteresis phenomena observed in the adsorption isotherms of nitrogen by these graphites were due to the graphite structure. To confirm this suspicion, measurements were made with two other gases, oxygen and argon. Fig. 5 shows the adsorption isotherm of oxygen on G-1 at 90.0°K. and Fig. 6 the isotherm of argon on G-2 at 77.5°K. These isotherms clearly display the features previously described for the nitrogen isotherms.

Finally, a closer investigation of these phenomena was made utilizing the G-3 nitrogen system. This system was chosen because the separation of the lower part of the desorption curve from the adsorption curve was found to be greater for G-3 than for the other graphites. The isotherms for the adsorption

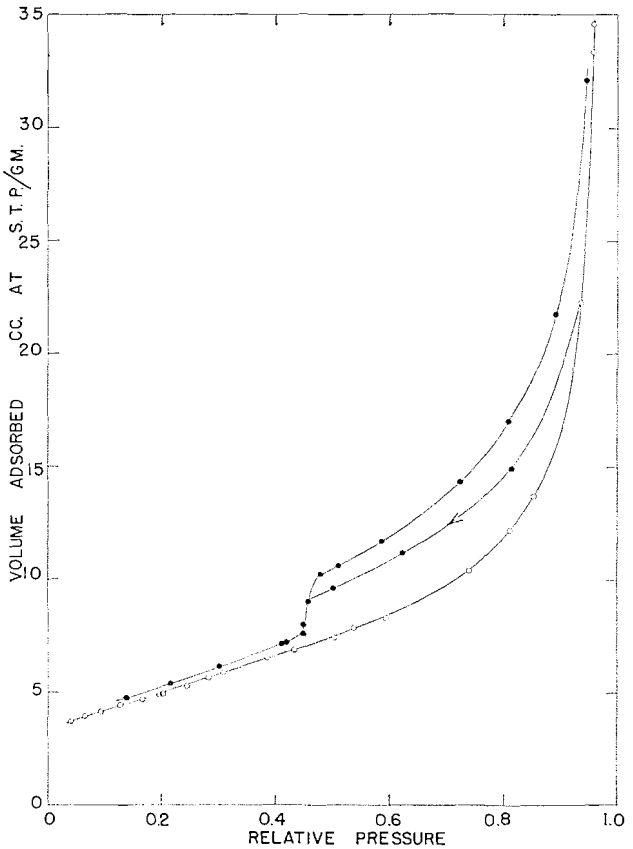

FIG. 7. Isotherm of nitrogen sorbed by G-3 at 77.5°K.

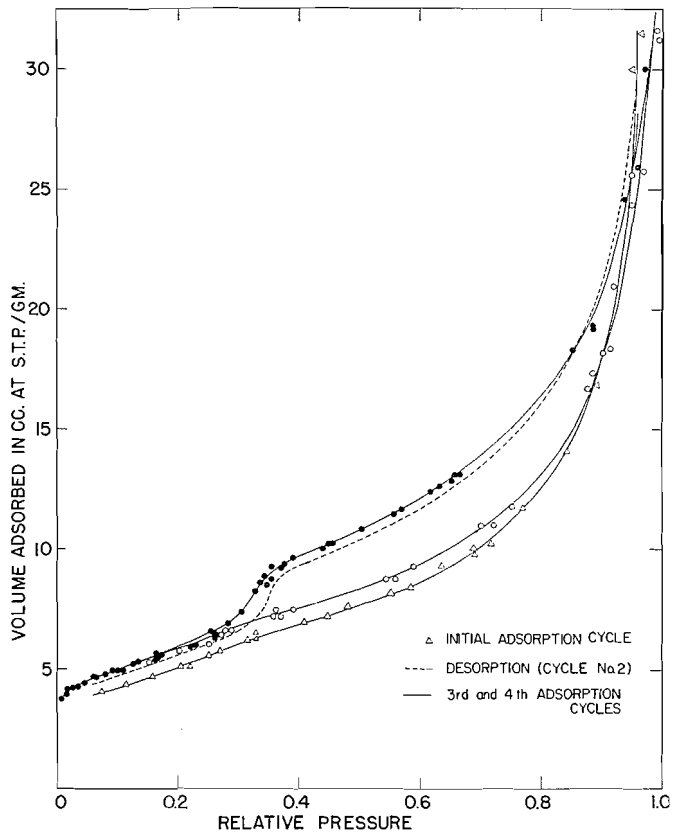

FIG. 8. Isotherm of nitrogen sorbed by G-3 at 70.6°K.

of nitrogen by G-3 at 77.5°K. and at 70.6°K. are shown in Figs. 7 and 8 respectively. It will be observed that the form of the isotherm at 77.5°K. is qualitatively similar to that for G-1 which is depicted in Fig. 1.

The data plotted in Fig. 8 are taken from these series of runs, with up to four successive adsorption cycles for a series. Except for the first cycle of a series, a typical adsorption cycle was begun by readsorption from the lowest desorption point of the previous cycle, without altering the bath temperature. Between each series the graphite was given the standard outgassing treatment. The initial adsorption curve is seen to be considerably below the subsequent ones. After the second adsorption cycle, the hysteresis loop closes completely and a reversible section of the isotherm is observed below the beginning of the loop. The dotted line and the points just below the upper of the two adsorption curves represent data from the second adsorption cycle, which appears to be a transition cycle between the first and final adsorption cycles. It can be seen from Figs. 7 and 8 that the separation of the adsorption curves is greater at 70.6°K. than it is at 77.5°K. This is partly the effect of the extra cycling at 70.6°K. and partly the effect of the lower temperature.

DISCUSSION

The foregoing results have shown that the low temperature isotherms of the three graphites considered are Type II with hysteresis.

The adsorption curves obey the B.E.T. equation from $p/p_0 = 0.08$ to $p/p_0 = 0.30$. The values of V_m derived from the B.E.T. plots and the surface areas calculated from them are given in the following table. In every case the data used were taken from the initial adsorption isotherm.

Graphite	Adsorbate	Temperature, °K.	V_m, cc. at S.T.P.	Area, m.²/gm.
G-1	Nitrogen	77.5	10.35	45.3
G-1	Nitrogen	90.0	9.86	41.6
G-1	Oxygen	90.0	11.49	43.4
G-2	Nitrogen	77.5	21.97	96.2
G-2	Argon	77.5	23.92	82.0
G-3	Nitrogen	77.5	4.21	18.4
G-3	Nitrogen	70.6	4.44	17.3

Closer examination has revealed two distinct types of hysteresis. The first type is represented by a wide loop extending from saturation down to a relative pressure of approximately 0.45. It is illustrated by a closed loop in Fig. 8. The second hysteresis effect is a much smaller one which takes the form of a slight elevation of the desorption curve above the adsorption curve at relative pressures below the beginning of the main hysteresis loop. This effect is most clearly shown in Fig. 8, which also shows that readsorption without evacuation follows the desorption branch until the main hysteresis loop is reached after which a new path is taken.

The first type of hysteresis is believed to be evidence that these graphites are porous. Moreover in agreement with the ideas of Wheeler (7) and of Barrett, Joyner, and Halenda (3) on the mechanism of the sorption of vapors in pores, it is believed that the loops are a result of the presence of pores greater than four to six molecular diameters. These arguments have been previously advanced by McDermot and Arnell (6) to explain the presence of hysteresis loops in the isotherms of wide-pored charcoals and their absence in narrow-pored charcoals. Thus the hysteresis loops are thought to be similar for the charcoals and for the graphites though the similarity may be masked by the widely different surface areas and porosities. The postulated mechanism of adsorption and desorption is briefly as follows: layer adsorption occurs on the walls of the pores until the layers build up to a point where they coalesce to form a meniscus after which capillary condensation may occur in that pore. Thus capillary condensation is occurring in the small pores while layer adsorption is taking place in larger pores which have not yet formed a meniscus. Hysteresis arises because adsorption takes place by a mixture of layer adsorption and capillary condensation, whereas desorption occurs by evaporation from pores that are initially full of liquid. An adsorbed layer is left on the walls as capillary evaporation proceeds, but the process is not the reverse of the adsorption process owing to delay in meniscus formation on the adsorption branch. This mechanism does not of course exclude any contributions to hys-

teresis that may be made by pore constrictions, but these are only important when an attempt is made to evaluate pore distributions. Further support for these ideas is offered by Carman (5), who has measured the isotherm of CF_2Cl_2 on Linde silica powder and on the same powder compressed into a plug of known porosity. A hysteresis loop was obtained for sorption by the plug and a reversible isotherm for the powder. More vapor was sorbed on the adsorption branch of the isotherm by the plug than by the powder until the plug was filled with liquid at which point sorption ceased. This behavior is in accord with the postulated hypothesis, because at a given relative pressure layer adsorption would be greater on a curved surface than on a plane one. In order to demonstrate that the hysteresis loops discussed here are characteristic of sorption by a porous material, an experiment similar to Carman's was performed using as a porous carbon a sample of G-2 and as a nonporous carbon a sample of Spheron 9 supplied by the Godfrey L. Cabot Co. Arnell and Henneberry (1) calculated the surface area of this carbon black from adsorption, permeability, and electron microscope data and found approximate agreement by all three methods. This is taken to be good evidence that Spheron 9 is nonporous. The adsorption of nitrogen at 77.5°K. by G-2 and by Spheron 9 is compared in Fig. 9. As Spheron 9 has a slightly larger surface area than G-2 the data are plotted as V/V_m versus p/p_0 rather than directly on the basis of volumes adsorbed. It will be observed that although the curves coincide initially the adsorption curve for the graphite rises above that of the carbon black. These results are qualitatively similar to those of Carman (5), and are considered sufficient proof that G-2 is porous.

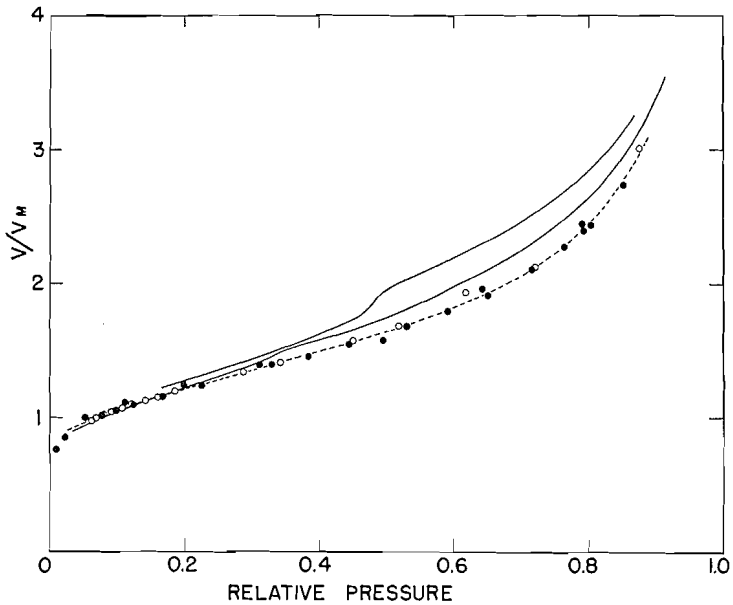

FIG. 9. Comparison between the sorption of nitrogen by G-2 and Spheron 9 at 77.5°K. Solid line represents the isotherm of G-2 and the dashed line that of Spheron 9.

The second hysteresis effect is most clearly observed in the adsorption isotherm of nitrogen on G-3 at 70.6°K. which is plotted in Fig. 8. It has been found that if one proceeds along the lower adsorption curve to a pressure at which the two curves are still well separated and then desorbs a reversible isotherm is obtained. If however adsorption is taken to a point where the two adsorption curves merge, then on desorption the upper curve is attained on completion of the main hysteresis loop. Moreover readsorption then takes place along the upper curve. Once the upper curve has been reached, it is only possible to regain the lower curve by warming the sample to the point where virtually all the nitrogen is desorbed. To sum up, the transition to the upper curve is only possible after the sorption of a considerable quantity of nitrogen, but once it has occurred it cannot be reversed. This type of behavior is characteristic of a sorption system which swells, and indeed the upper and lower adsorption branches in Fig. 8 are very similar in form to the isotherm of water sorbed by cellulose. It will be instructive to review the cellulose–water system and show that the resemblance noted above is not merely superficial. In the cellulose–water system swelling takes place along the adsorption branch and is only complete at saturation when the water has completely penetrated the structure. On desorption the path followed lies above the adsorption path because water which was able to enter the structure when it was swollen is trapped and can only be removed by completely drying the cellulose. Thus the initial adsorption curve can only be retraversed by completely drying the cellulose or in part by adding enough water to reswell the cellulose. By analogy it is believed that when sufficient gas is adsorbed by the graphite, the crystallites swell because of intercrystalline penetration. Once this penetration has occurred, some molecules are trapped and can only be removed by warming the graphite and desorbing all the gas. The analogy is not perfect because it is possible to scan the loop of the cellulose–water isotherm, but not the two adsorption curves of Fig. 8. The explanation is believed to be the following: on the sorption of water, cellulose swells gradually and continuously over the whole course of the adsorption loop and similarly on desorption water is lost gradually from the interior of the fiber. Hence the fiber can be reswollen from the partially dried state or dried from the partially swollen state, the amount of trapped water depending on the degree of swelling. In contradistinction, the graphite swells only when a critical quantity of nitrogen is sorbed and the process is sudden and irreversible. Once swelling has occurred, the quantity of trapped nitrogen is fixed and the lower curve cannot be attained without complete desorption.

THE MANNICH CONDENSATION OF COMPOUNDS CONTAINING ACIDIC IMINO GROUPS[1]

By Caurino Cesar Bombardieri[2] and Alfred Taurins

ABSTRACT

The synthesis of several new Mannich bases was accomplished by the condensation of secondary amines and formaldehyde with the following compounds: (1) 2-pyrrolidone, (2) 2,4-thiazolidinedione, (3) hydantoin, (4) 5,5-dimethylhydantoin, (5) uracil, (6) ethylnitramine, and (7) *n*-butylnitramine.

INTRODUCTION

While much work has been done on the Mannich condensation of compounds containing acidic hydrogen on carbon, considerably fewer data are available on the Mannich reaction of substances possessing active hydrogens on nitrogen, as it can be seen from this historical introduction.

Feldman and Wagner (6) prepared piperidinomethyl derivatives of succinimide, phthalimide, and carbazole. In their study of morpholinomethyl derivatives of urea and substituted ureas, Weaver, Simons, and Baldwin (13) condensed morpholinomethanol with phthalimide and succinimide. N-(Morpholinomethyl)- and N-(piperidinomethyl)-phthalimide were also synthesized by Moore and Rapala (12). The condensation of benzothiazole-2-thione and related compounds with formaldehyde and secondary amines was described in the German patent 575,114 in 1933. The purpose of the latter work was to prepare methylenediamine derivatives for use in the rubber industry.

Bachman and Heisey (1) condensed benzimidazole and benzotriazole with formaldehyde and secondary amines. Baker, Querry, Kadish, and Williams (2) prepared two Mannich bases of 4-quinazolone in reactions with formaldehyde, piperidine, and morpholine respectively. The Mannich condensation of pyrazole was studied by Huttel and Jochum (9). Butenandt and Hellmann (3) studied the reaction of hydantoin with formaldehyde and piperidine. However, they did not investigate the reaction product further. The most recent work on the synthesis of N-Mannich bases has been published by Hellmann and Löschmann (8). They describe the condensation of isatin, phthalimide, succinimide, and carbazole and give a few references on the previous publications of other authors.

That the alkylnitramines undergo a condensation with piperidinomethanol was observed by Franchimont (7) as early as 1910. However, he did not give any data on analysis and properties of the reaction product.

The objective of this work was to investigate the Mannich condensation of the cyclic imino compounds containing one or two imino groups in addition to the carbonyl groups as the hydrogen activators. We also studied the condensation of alkylnitramines in which the nitro group activates the hydrogen atom of the imino group.

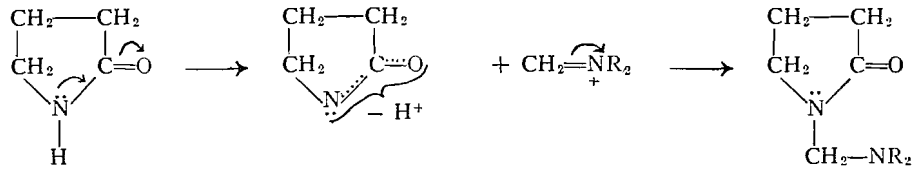
DISCUSSION

We consider the replaceability of a hydrogen of the imino group by halogens or by metals, or by both, as the guiding principle enabling us to indicate the compounds possessing the ability to react in the Mannich condensation. On the bases of a similar behavior of ketones and imides in the reactions of halogenation and salt formation via enolization, we can assume that the Mannich condensation in both groups of compounds must follow the same course. Lieberman and Wagner (11) postulated the formation of a carbanion from a C—H acid compound as a necessary step in this reaction. It is reasonable to assume that the N—H acidic substance undergoes an analogous change to give a mesomeric anion in which the negative charge is located in the group N—C=O. The formation of the Mannich base may be visualized as the addition of the intermediate methylene-ammonium cation or the protonated dialkylaminomethanol at the mesomeric anion, as in the example of the reaction of 2-pyrrolidone.



Most of the condensations of imino carbonyl compounds were carried out using free secondary bases, but not their salts because of the sensitivity of the N—CH_2—N bond towards acids. However, in a few cases the condensation was successful using even secondary amino hydrochlorides. Thus 2-pyrrolidone [2-pyrrolidinone] was successfully condensed with morpholine and piperidine bases, and dimethylamine hydrochloride as well.

2,4-Thiazolidinedione (4, 14) possesses acidic properties and forms alkali and silver salts. It reacted very easily at 0° with morpholine, piperidine, and dimethylamine. Even methylamine reacted with two molecules of the 2,4-thiazolinedione to give (VII). Both hydantoin [2,4-imidazolidinedione] and 5,5-dimethylhydantoin [5,5-dimethyl-2,4-imidazolidinedione] demonstrated their ability to react in the Mannich condensation with two molecules of formaldehyde and two molecules of morpholine. No reaction products were obtained in the attempted condensations of both hydantoins with piperidine and dialkylamines respectively.

We found that uracil [2,4-(1H, 3H)-pyrimidinedione] reacted with morpholine and formaldehyde to give 1-(morpholinomethyl)uracil. Despite the close resemblance to uracil, dihydrouracil did not react in the Mannich reaction.

In this work, alkylnitramines were prepared by the procedure of Curry and Mason (5). The attempted condensations of alkylnitramines with formaldehyde and secondary amines under reflux gave no desired products. However, the condensation succeeded when the reaction mixture was kept at 0° for 12 hr. It was found that dimethylamine and diethylamine did not undergo the Mannich condensation with *n*-butyl- and ethyl-nitramine. All attempts to form Mannich bases using methylnitramine were unsuccessful.

For the purpose of identification, the ultraviolet spectra of alkylnitramines and their derivatives were determined in absolute alcohol (DU Beckman spectrophotometer).

Compound	λ_{max}, $m\mu$	ϵ_{max}
Methylnitramine	230	14010
Ethylnitramine	227–232	28230
n-Butylnitramine	231–233	9727
N-(Morpholinomethyl)-ethylnitramine	232	6603
N-(Morpholinomethyl)-*n*-butylnitramine	234	2931

Although the observed values of λ_{max} are in agreement with the reported absorption spectra (10), the values of the molecular extinction coefficients are considerably higher than those given for methyl- and *n*-butyl-nitramine.

EXPERIMENTAL

1-(Morpholinomethyl)-2-pyrrolidone (I)

In a 50 ml. three-necked flask, a solution containing 2.55 gm. (0.03*M*) of 2-pyrrolidone in 20 ml. of water and 2.8 gm. (0.03*M*) of morpholine was placed. The mixture was stirred and 2.7 ml. (0.03*M*) of 35% formaldehyde was added slowly. The reaction mixture was refluxed at 100° for one hour. Upon cooling, the solution was extracted with chloroform and the extract was concentrated by distillation on a water bath. To this residue, 25 ml. of ethanol was added and the solution was concentrated by further distillation. After 12 hr., solid white crystals of I appeared which, after several crystallizations, melted at 68.5–69.5°. The total yield was 1.5 gm. (27.2%). The yield of I was increased to 2.1 gm. (37.8%) when the reaction time was extended to two hours.

Anal. Calc. for $C_9H_{16}N_2O_2$: N, 15.26%. Found: N, 15.12%.

1-(Piperidinomethyl)-2-pyrrolidone (II)

The compound II was prepared by refluxing the mixture of 2.55 gm. of 2-pyrrolidone, 2.7 ml. of 35% formaldehyde, 2.7 ml. of piperidine, and 20 ml. of water at 100° for one-half hour in the same manner as described for the above experiment. A precipitate was crystallized from ethanol and yielded 1.5 gm. (27.4%) of white crystals which melted at 47.5–49°.

Anal. Calc. for $C_{10}H_8N_2O$: N, 15.37%. Found: N, 15.25%.

1-(Dimethylaminomethyl)-2-pyrrolidone (III)

The reaction mixture of equimolar amounts (0.03*M*) of 2-pyrrolidone, 35% formaldehyde, dimethylamine hydrochloride, and 20 ml. of water was heated at 68° for one-half hour with constant stirring. The solution was cooled, made alkaline with 20% solution of potassium carbonate, and extracted with chloroform. The extract was evaporated and fractionally distilled to yield 1.5 gm. (37.4%) of a liquid product (III), b.p. 64–67° at 1 mm. pressure.

Anal. Calc. for $C_7H_{14}N_2O$: N, 19.7%. Found: N, 19.72%.

3-(Piperidinomethyl)-2,4-thiazolidinedione (IV)

To the solution of 3.5 gm. of 2,4-thiazolidinedione in 15 ml. of ethanol, an equimolar amount of formaldehyde and piperidine was added at 0°. In short time, crystals of IV appeared. After crystallization from absolute ethanol 6.17 gm. (95.9%) of white crystals, m.p. 76–77°, was obtained.

Anal. Calc. for $C_9H_{14}N_2O_2S$: C, 50.44; H, 658; N, 13.02%.
Found: C, 50.69; H, 6.55; N, 13.04%.

3-(Morpholinomethyl)-2,4-thiazolidinedione (V)

This substance was formed with great ease by the interaction of 2,4-thiazolidinedione, formaldehyde, and morpholine and was obtained as white crystals, m.p. 147°, in 99.9% yield.

Anal. Calc. for $C_8H_{12}N_2O_3S$: N, 12.95%. Found: 13.05%.

3-(Dimethylaminomethyl)-2,4-thiazolidinedione (VI)

The condensation product VI was obtained by a similar procedure in a yield

of 71.5%. It gave white crystals which after crystallization from absolute alcohol melted at 82°.

Anal. Calc. for $C_6H_{10}N_2O_2S$: C, 41.36; H, 5.79; N, 16.08%.

Found: C, 41.60; H, 5.92; N, 16.05%.

N-Methyl-N,N-bis(2,4-thiazolidinedionomethyl)amine (VII)

A mixture of 3.5 gm. of 2,4-thiazolidinedione dissolved in 15 ml. of ethanol and 2.7 ml. of 35% formaldehyde was cooled to 0° and 4.85 ml. of 25% methylamine solution was added dropwise. The reaction product was crystallized from absolute ethanol to yield 4.34 gm. (50%) of soft white crystals, m.p. 144–145°.

Anal. Calc. for $C_9H_{11}N_3O_4S_2$: N, 14.52%. Found: N, 14.59%.

The above experiment was repeated using a 2:2:1 mole ratio of 2,4-thiazolidinedione, formaldehyde, and methylamine respectively. The yield was increased to 7.1 gm. (83%).

1,3-Di(morpholinomethyl)hydantoin (VIII)

To the heated solution of 3 gm. (0.03*M*) of hydantoin in 20 ml. of water, 5.6 ml. of morpholine was added and 5.4 ml. of 35% formaldehyde was introduced dropwise. The mixture was stirred and heated at 85° for 15 min. The reaction product was extracted from the cold solution with chloroform. After recrystallization from ethanol VIII yielded 2 gm. (22%) of white crystals, m.p. 144–145.5°.

Anal. Calc. for $C_{13}H_{22}N_4O_4$: N, 18.84%. Found: 18.76%.

Acid Hydrolysis of VIII

Dry hydrogen chloride gas was bubbled through the solution of 0.3 gm. of VIII in 25 ml. of absolute ethanol. A white precipitate of hydantoin, m.p. 218°, separated (lit. m.p. 220°).

1,3-Di(morpholinomethyl)-5,5-dimethylhydantoin (IX)

The condensation of 5,5-dimethylhydantoin with morpholine and formaldehyde in molar ratio 1:2:2 respectively, was carried out at 90° for 30 min. The product was recrystallized from ethanol to yield 3.9 gm. (39.8%) of white crystals, m.p. 134–134.5°.

Anal. Calc. for $C_{15}H_{26}N_4O_4$: N, 17.1%. Found: N, 17.02%.

1-(Morpholinomethyl)uracil (X)

Uracil (3.4 gm.) dissolved in 40 ml. of water and morpholine (2.8 ml.) were cooled to 0° and 2.7 ml. of 35% formaldehyde was slowly added. A precipitate was formed which after crystallization from alcohol yielded 2.16 gm. (56%) of white crystals, m.p. 208–209°.

Anal. Calc. for $C_9H_{13}N_3O_2$: N, 19.89. Found: N, 19.92%.

N-(Morpholinomethyl)ethylnitramine (XI)

The reaction mixture of ethylnitramine, morpholine, and formaldehyde in molar ratio 1:1:1 respectively, was allowed to stand for 12 hr. at 4°. The product XI was crystallized from petroleum ether (b.p. 65–110°). The yield

of white plates, m.p. 86–87°, of XI was 92%.

Anal. Calc. for $C_7H_{15}N_3O_3$: C, 44.43; H, 7.99; N, 22.2%.

Found: C, 44.61; H, 8.0; N, 21.97%.

N-(Piperidinomethyl)-n-butylnitramine (XII)

A solution of 7.1 gm. of *n*-butylnitramine in 20 ml. of alcohol was cooled to 0° and 5.4 ml. of 35% formaldehyde was added dropwise. To this mixture, 5.4 ml. of piperidine was slowly introduced and the flask was kept at 0° for 12 hr. The alcohol was evaporated and the residue fractionally distilled. The total yield of XII was 4.6 gm. (35.7%; b.p. 97–100°) at 1 mm.

Anal. Calc. for $C_{10}H_{21}N_3O_2$: C, 55.78; H, 9.83; N, 19.52%. Found: C, 55.34; H, 10.08; N, 18.79%.

N-(Morpholinomethyl)-n-butylnitramine (XIII)

The substance XIII was prepared by the method described as above, with the exception that the reaction product was crystalline and it separated from the solution. It was crystallized from petroleum ether (b.p. 30–60°) and obtained as white crystals, m.p. 53–53.5°, in 97.6% yield.

Anal. Calc. for $C_9H_{19}N_3O_3$: N, 19.34%. Found: N, 19.62%.

DISINTEGRATION-RATE DETERMINATION BY 4π-COUNTING

PART II. SOURCE-MOUNT ABSORPTION CORRECTION[1]

By B. D. Pate[2] and L. Yaffe

ABSTRACT

The various methods in use for determining the correction for absorption due to the source mount used in a 4π-counter are discussed, and experiments conducted to test the validity of the correction, arising from these methods, for β emitters of varying end-point energies. The methods all give erroneous corrections for low energy β emitters and possible reasons for the errors introduced by the 'sandwich method' are discussed. An 'absorption curve' type method is proposed which is shown to give more accurate correction factors.

A. INTRODUCTION

In a previous publication (8), we have discussed the principles of 4π-counting and described the design of counting chamber used in this laboratory. We also discussed the errors to which the final disintegration-rate value is subject and the conditions under which the first of these—departure from unit counter response probability—is minimized. In the present paper, we shall discuss corrections for the second of the sources of error, namely absorption of radiation in the mounting film on which the source is deposited.

For determinations involving nuclides emitting monoenergetic radiation, such as α radiation and conversion electrons, of such an energy that the range of the particle in the source-mount material is greater than its path length in the film used, no source-mount absorption correction is necessary. As long as a sufficient number of ion pairs are produced by the ionizing particle to trigger the counting circuit, each disintegration will be recorded. The majority of determinations for which a 4π proportional counter will be employed, however, involve β radiation with a continuous distribution of particle energies; in this case a fraction of the emitted particles will always be absorbed by the film, the fraction being larger the smaller the end point of the beta spectrum.

We have already (7) described techniques developed in this laboratory for the production of films, for use in 4π-counters, of a superficial density of 5–10 μgm./cm^2. For disintegration-rate determinations of moderate precision with β radiation of moderate or high energy, the use of films of this thickness allows absorption of radiation in the source mount to be neglected. For work of the greatest precision, however, and particularly that with the weaker β emitters, the absorption loss must be accurately evaluated and a correction made. The use of very thin films is nevertheless still of considerable advantage, since the magnitude of the correction is reduced, and the final disintegration-rate value less sensitive to errors in the correction.

[2]*Holder of a National Research Council Studentship.*

Three methods of determining the absorption correction have been described in the literature: the so-called "sandwich" procedure, calculation from 2π and 4π counting rates, and the use of absorption curves.

(i) The "sandwich" procedure has been described by Hawkings *et al.* (3). The counting rate given by a source mounted on a known thickness of mounting film is determined, and then a second determination made with an identical film superimposed over the first so as to sandwich the source. The observed reduction of counting rate was applied as a correction to the single film value to arrive at the source disintegration rate, and the validity of this procedure was taken to be apparent "from a consideration of the contribution to the counting rate from each hemisphere". However, Smith (11) found that applying the sandwich procedure to similar sources of, for instance, S^{35} using sets of films of differing superficial density lead to results for the disintegration rate differing by as much as seven per cent. The results should of course be independent of the thickness of films used.

(ii) Seliger and co-workers (5, 9) have attempted to develop mathematical relationships which would allow calculation of the source disintegration rate from measured 2π- and 4π-, single and sandwiched film counting rates. The resulting formulae as quoted in the second and more rigorous of the two papers (5) were:

$$(a) \qquad (N_t - N_b)/(N_T - N_b) = 2\beta_f + \tau \approx \tau$$

where N_t and N_b are the counting rates observed in the top and bottom half-counters respectively, N_T is the counting rate observed from both halves combined, β_f is the fractional back-scattering factor, and τ the fractional absorption factor for the film used as source mount.

$$(b) \qquad (N_T - N_S)/(2N_T - N_S) = \tau/2$$

where N_S is the counting rate obtained with the source sandwiched between two similar films. The value of τ obtained from these equations was then to be substituted into

$$N_0 = N_T/(1 - \tau/2)$$

to obtain N_0, the true disintegration rate of a source where no self-absorption corrections have to be made.

As is common with calculations of this sort (11), the combination of a continuous distribution of beta energies with energy-dependent scattering and absorption coefficients and a complex geometrical arrangement make the problem analytically very difficult without the adoption of several simplifications. For example: Among those employed by Seliger *et al.* were the supposition that the absorption and scattering characteristics of β radiation were unaffected by the scattering process (e.g. degradation of the energy spectrum was neglected) and, in several places in the derivation, the assumption that β_f and τ were small compared to unity.

The latter may be true in the region of beta energies and film thicknesses where the absorption correction is in any case insignificant, but with lower beta energies where an accurate correction is required, both coefficients are

by no means negligible, and vary rapidly with changing beta energy. In particular, the back-scattering effect observed in a 4π geometry is found to be considerably larger than in conventional counter systems. The 4π-counter will respond to particles having undergone scattering at low angles to the source mount, and low angle scattering is evidently important even with thin films made from a material of low average atomic number. Using a 4π-counter, Meyer-Schützmeister and Vincent (6) have reported an 8% back-scattering for S^{35} β particles from 30–40 μgm./cm.^{2} cellulose films, Houtermans *et al.* (4) reported similar results for P^{32}, and Borkowski (1) found 5% back-scattering of Na^{24} β radiation from 50 μgm./cm.^{2} of Formvar.

Thus the over-all 2% accuracy claimed by Mann and Seliger (5) for their absorption correction is probably over-rated when one is using β emitters of low energy (e.g. Ni^{63}, C^{14}, S^{35}, etc.).

(iii) The 'absorption curve method' used to correct the results obtained from end-window counters for the absorption of radiation suggests itself as a corrective technique applicable to this case. A procedure of this sort was used by the workers at Göttingen (4, 6). They made a series of counting-rate measurements with a source mounted on a film, and with increasing thicknesses of aluminum foil placed *over* the source, and used the curves obtained to correct the original counting rate. However, such a procedure would appear to be open to the same objections as the ordinary sandwich procedure.

A study of the variation of counting rate as a function of the actual mount thickness was first carried out by Smith (11). He commenced with a source mounted on aluminum of 260 μgm./cm.^{2} and took measurements of the counting rates obtained with the source backed by increasing thicknesses of this material. The curve obtained on plotting the results was observed to be approximately linear, and Smith assumed that the value obtained by extrapolating back to zero mount thickness represented the source disintegration rate. However, this value was found to be low compared with the counting rate observed with a similar source mounted on 30 μgm./cm.^{2} of cellulose acetate, by 3% in the case of S^{35}, and 1.5% in the case of Co^{60}. The discrepancy probably arose from a change of slope in the absorption curve below 260 μgm./cm.^{2} superficial density, such as was observed by Suzor and Charpak in another connection (12). Provided sufficiently thin films and a suitable technique were used, this type of procedure would be expected to produce the most accurate means of correcting for mount absorption, the results being independent of any assumptions regarding counter mechanisms and so on. The anomalous back-scattering effects observed by Yaffe and Justus (13) and Glendenin and co-workers (2) would not be expected to cause any disturbing effects.

B. EXPERIMENTAL PROCEDURE AND RESULTS

For the following experiments, we have used the chamber and ancillary equipment described in the previous publication (8), operating under the conditions found to give unit response probability. We have performed two sets of experiments:

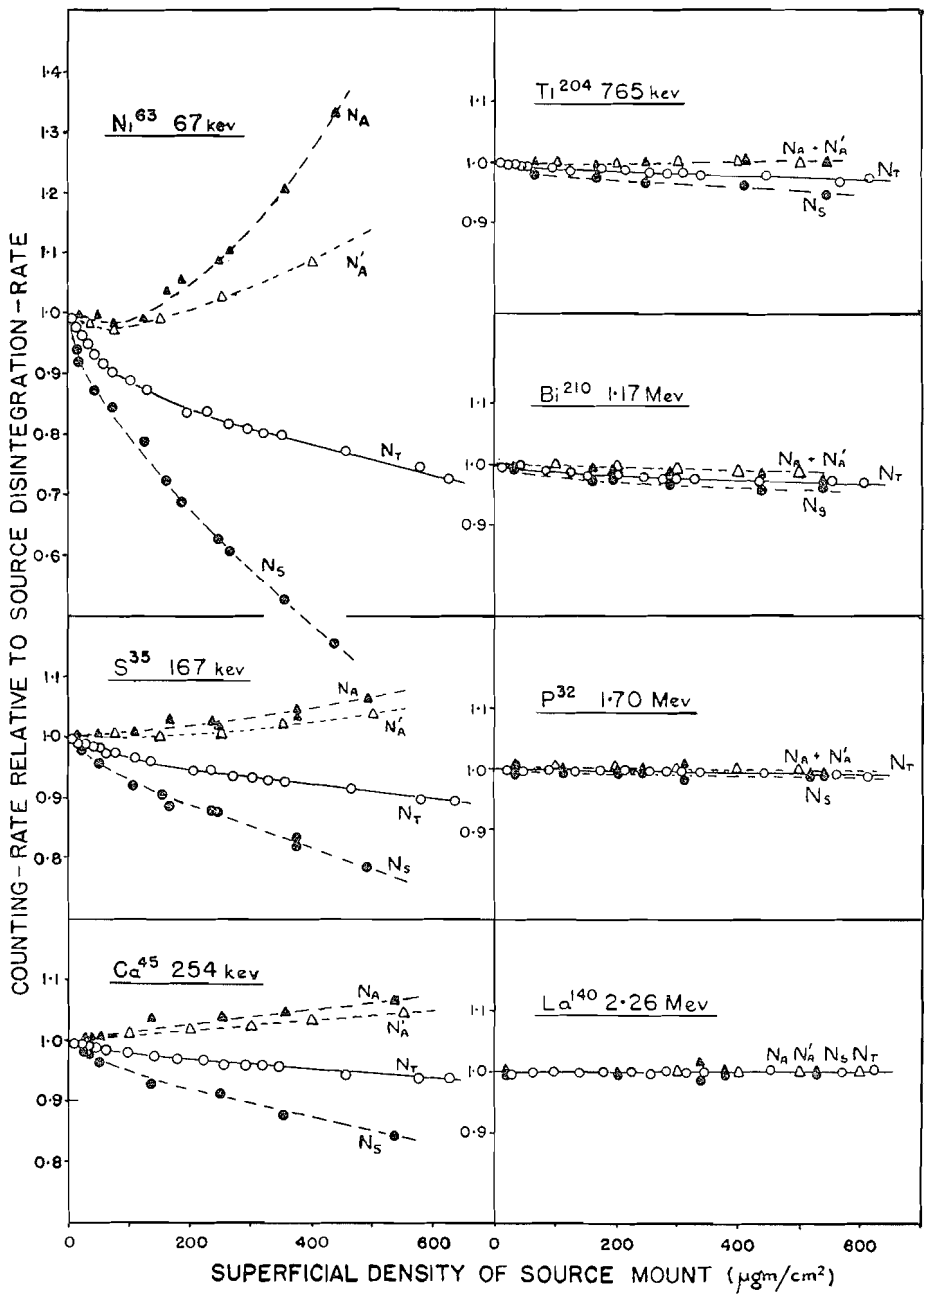

FIG. 1. Source-mount absorption characteristics for a series of beta emitters.

(i) *Single Film Source-mount Absorption Characteristics*

A series of counting-rate measurements was taken for each nuclide of the series of seven β emitters of increasing end-point energy, and four emitters of differing forms of radiation, whose nuclear characteristics were described earlier (8). For each of a series of increasing source-mount superficial densities, we have measured the total counter counting rate (N_T) with the anodes connected in parallel to the amplifying system. The source mounts used were of gold-coated VYNS film (7) mounted on a 1 mm. aluminum diaphragm of aperture 2.5 cm. in diameter. The thinnest films employed were of 5 to 10 μgm./cm.^{2} superficial density, and increasing thickness was obtained:

(*a*) up to about 70 μgm./cm.^{2} by allowing a series of films of known superficial density to adhere to the back of the initial mount;

(*b*) above 70 μgm./cm.^{2} by temporarily placing in contact with the back surface of the mount, in position in the chamber, each of a series of standardized films of increasing superficial density.

The results of these experiments are shown plotted in Figs. 1 and 2. Data as shown are for "weight-less" sources. Experiments with Ni^{63} have shown that identical results are obtained even for source thicknesses where self-absorption of the order of 80 to 90% occurs.

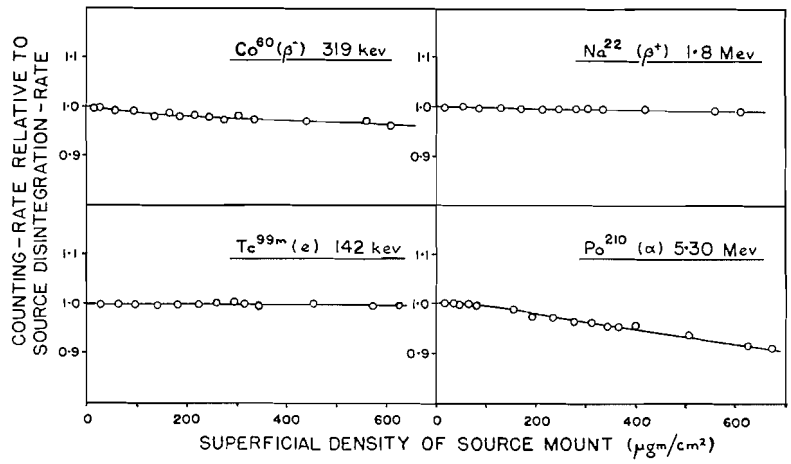

FIG. 2. Source-mount absorption characteristics for emitters of other forms of radiation.

(ii) *Sandwich Characteristics*

A second series of measurements was taken using the series of seven β emitters described above as shown in Fig. 1. In this case sources of each nuclide were prepared on a series of films of increasing superficial density and the following quantities measured: the total counting rate with the anodes in parallel with a single mount (N_T), and the total counting rate with a second identical sandwiching film added (N_S). From these values the expected disintegration rate of the sources used has been calculated by the procedure of Hawkings *et al.* (N_A) and by the more rigorous of the procedures of Seliger and co-workers (N_A'). The results are shown plotted as a function of source-mount

superficial density in Fig. 1, with the true source disintegration rates normalized to a common value for each nuclide using the curves for N_T obtained in the first series of experiments.

C. DISCUSSION

(*a*) *The Sandwich Procedure*

The results shown in Fig. 1 give a fairly complete picture of the accuracy of the sandwich procedure as a function of mount thickness and β end-point energy, whether applied by the method of Hawkings *et al.* (3) or by the NBS method (5, 9, 10), and are in accord with those found by Smith (11). Though the procedure may be said to work fairly well at higher particle energies, where the mount absorption is small in any case, at lower energies, where accurate information is desirable, it becomes progressively less and less useful. The fact that the calculation of the disintegration rate leads to results that vary considerably (for example in the case of Ni^{63}) with source mount thickness would indicate that the mathematical treatment was oversimplified.

(*b*) *The Absorption Curve Procedure*

The anomalous results obtained by this method by Smith (11) using mounts with a superficial density in excess of 260 μgm./cm.^{2} are readily understood on

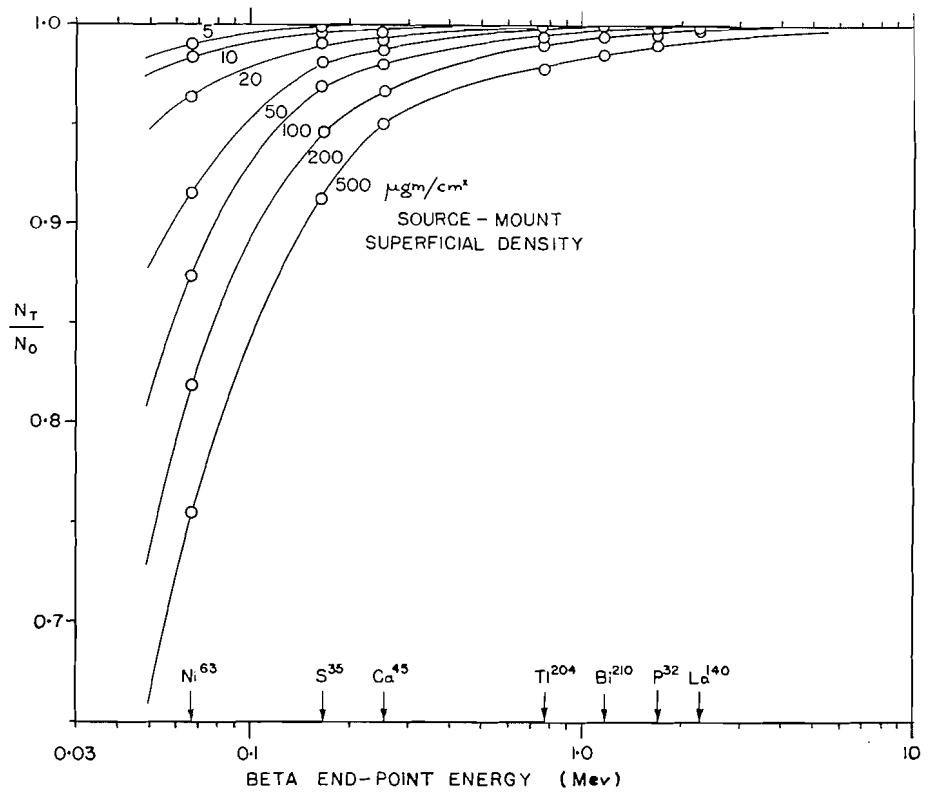

FIG. 3. Absorption parameter (N_T/N_0) as a function of beta end-point energy, for a series of film thicknesses.

a basis of the curves for N_T shown in Fig. 1. Extrapolation of the approximately linear portion of the curves obtained at higher mount thicknesses would take no account of the initial fall in counting rate, particularly pronounced at low β end-point energies, due to progressive absorption by the source mount of the softest radiation in the beta energy spectrum.

For work of moderate precision the data in Fig. 1 may be used directly to correct observed single-film results for source-mount absorption. In order to allow interpolation to intermediate β energies, the data are replotted in Fig. 3 with the absorption parameter (N_T/N_0) as a function of beta end-point energy for a series of film thicknesses. Clearly several approximations are introduced by use of the data in this way, including a neglect of variation in the form of the beta energy spectrum with nature of the beta transition (degree of forbiddenness etc.) and of the additional complication of nuclear gamma emission when this is present. Also, obviously the transition must be recognized as a beta transition and the end-point energy known.

For work of maximum precision, the procedure adopted to obtain our experimental results is recommended. In this case, the source material is mounted on the thinnest film available, and the counting rate N_T measured as a function of increasing mount thickness as outlined above. The disintegration rate is obtained by extrapolating to zero mount thickness.

The accuracy of the disintegration-rate value, arrived at in this way, can also be judged from Fig. 1. It is limited by the statistical deviation of the counting rates measured, and by the accuracy with which the superficial density values are known (7). No error of significance should be introduced by the technique of allowing additional films to adhere to the original mount, and we estimate that the error in the final disintegration-rate value can be reduced to about $\pm 0.2\%$ in the case of the weakest beta radiation studied, and probably to less than this at higher particle energies. We find this method satisfactory in routine use, the necessary measurements and manipulations taking very little more time than those required for the conventional sandwich procedure.

In the case of a beta emitter of unknown energy, once the disintegration rate is known from the absorption curve procedure, Fig. 3 may be used to derive from the observed value of N_T/N_0 a crude but nevertheless useful estimate of the end-point energy of the spectrum. This technique replaces those commonly used with end-window counters, which are inapplicable in a 4π steradian-geometry.

It is of interest to consider why the value of source disintegration rate predicted by the sandwich procedure should vary with increasing source-mount thickness, and in general differ (widely at low beta energies) from the figure unequivocally indicated by the absorption curve method. The reasons for variations in the separate counting rates of the hemispheres above and below the source mount, and in the rate of coincidences between the two half-counters, are various and will be discussed in the fourth paper of this series. However, the change in total counting rate (N_T) can only be due to increased absorption of radiation in the mounting film or reduction of particle energy to below that

required to trigger the counter. It has been shown in paper one of this series (8) that, under the adopted operating conditions, substantially all particles entering the counter gas produce the necessary minimum ionization and trigger the counter.

It is proposed to leave the quantitative analysis of the relative contribution of the various scattering and absorption processes to paper four of this series, in which a more complete set of data for the half-counter counting rates and coincidence rates observed with different forms and energy of radiation under different conditions will be presented.

One should, however, perhaps consider the data for N_T for Po^{210} shown in Fig. 2. Po^{210} is an α emitter of 5.30 Mev. energy which has a range of $\sim$5.1 mgm./cm.^{2} in air, and therefore using known atomic stopping powers one can compute the range in the film to be 4.9 mgm./cm.^{2} Hence, with film superficial densities of up to at least 600 μgm./cm.^{2} no fall in N_T with increasing d might be expected, whereas an approximately linear decrease is observed. One observes in this case (α emission) that the rate of coincidences between the two half-counters is very small ($<0.1\%$ of N_0) and that N_T is substantially the sum of the counting rates of the upper hemisphere (which is constant with increasing d) and of the lower hemisphere (which decreases linearly with increasing d). Thus, the observed effect is due solely to absorption of α particles in the film, which at the film thicknesses used should be small in view of the monoenergetic nature of the emission.

However, if the film thickness is again d and the range of the radiation in film material is R, as in Fig. 4, then of those α particles emitted in the 2π steradian angle towards the film, only those inside the cone of half-angle

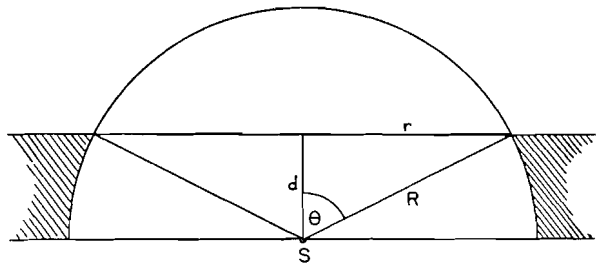

FIG. 4. Film absorption of α radiation (schematic).

subtended by the radius r will emerge into the gas volume and register. The proportion of the total radiation emitted outside this cone and totally absorbed in the film can be shown to be $(2\pi rd)/4\pi R^2$ for large values of θ

$$= rd/2R^2$$
$$\simeq d/2R$$

in agreement with the observed linearity with d. In a film thickness corresponding to 600 μgm./cm.^{2}, the loss by absorption is found to be 6.5% compared to an observed value of 7.5%. The agreement is fair considering the assumptions made regarding the range of Po^{210} α particles in the film material.

The absence of apparent decrease of N_T with d in the case of the (monoenergetic) conversion electrons from Tc^{99m} (Fig. 2) is presumably due to their longer range (26 mgm./cm.^{2}) and the influence of back-scattering.

ACKNOWLEDGMENTS

SIMULTANEOUS SURFACE EXCHANGE STUDIES USING BOTH CATION AND ANION[1]

By R. M. Stow[2] and J. W. T. Spinks

ABSTRACT

Labelled Sr^{++} and $SO_4^{=}$ have been used simultaneously to measure the apparent surface area of a $SrSO_4$ precipitate by the direct radioactive method. The values found differ by about 90%. By contrast, when labelled Pb^{++} and $SO_4^{=}$ are used to measure the apparent surface area of $PbSO_4$, the values found are in close agreement. The results are discussed with reference to the kinetics of surface exchange reactions.

INTRODUCTION

The heterogeneous exchange between the ions on the surface of a solid and the ions in a solution has been widely used as the basis for the radioactive method for determining the "active" surface area of a solid. The method was introduced by Paneth and Vorwerk (4), and has been the subject of numerous investigations (for recent summaries, see (3, 8)). There appears to be a very rapid primary exchange, involving only the surface layer of the solid, followed by a much slower secondary exchange which may involve penetration of ions into the crystal. In the primary exchange, equilibrium is reached in a few minutes. According to Paneth, at equilibrium $N_S^1/N_S = N_L^1/N_L$ where N_S^1 = number of tracer atoms (or ions) on the surface, N_S = total number of this species of atoms (or ions) on the surface, N_L^1 = number of tracer atoms (or ions) in the bulk of the solution, and N_L = total number of this species of atoms (or ions) in the bulk of the solution. N_S is readily calculated knowing N_S^1, N_L^1, and N_L, and from this the surface area, $S = N_S l^2$, can be calculated. l^2 is the effective area of the tagged atom (or ion) on the surface and is given by $l^2 = (\text{M.W.}/aNd)^{2/3}$ where M.W. = the formula weight of the solid, a = number of gram atoms (or gram ions) of the tagged species of atoms per formula weight of solid, N = Avogadro's number, and d = density.

Using Paneth's method, tracers isotopic with either cation or anion of the precipitate should, on the basis of simple theory, yield the same surface area. However, Imre (1, 2) has suggested that surface exchange may not be quite so simple as Paneth suggests. He suggests rather that for the surface exchange equilibrium $(N_S^1/N_S)(N_L/N_L^1) = K$, where $K = K_0\, e^{-E/RT}$ and is not necessarily unity. K_0 is a symmetry factor which is equal to unity for self-adsorption systems (e.g. Pb^{++} on $PbSO_4$). For self-adsorption, $K = e^{-E/RT}$, K being called the 'activation' factor and E the 'activation energy'. This terminology is perhaps unfortunate since it seems to imply that we are dealing with kinetics of exchange reactions whereas in fact we are dealing with measurements of exchange equilibrium. Imre states that different K values result for the exchange of Pb^{++} and $CrO_4^{=}$ on $PbCrO_4$ but suggests that the K values will

[1]*Manuscript received January 10, 1955.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan, with financial assistance from the National Research Council of Canada.
[2]*Died while a student in Cambridge, England, 1951.*

be the same for the exchange of Pb^{++} and $SO_4^{=}$ on $PbSO_4$. The availability of S^{35}, Sr^{90}, and Pb^{212} has made it possible to test this hypothesis with precipitates of $SrSO_4$ (7) and $PbSO_4$. In some experiments surface exchange was carried out with either cation or anion labelled; in other experiments, both cation and anion were labelled in the same experiment.

EXPERIMENTAL

Radioactive Materials

S^{35} was obtained from Chalk River in the form of an aqueous solution of sulphuric acid. Tests showed that all the S^{35} was in the form of $SO_4^{=}$ and that the half life and absorption half thickness were in agreement with published values (6). Sr^{90}, obtained from Chalk River as $SrCO_3$[3], was converted to the acetate to form a stock solution (5). Immediately prior to a surface exchange experiment, the Y^{90} daughter was separated from the Sr^{90} by adding yttrium holdback carrier and precipitating Sr as the sulphate. The precipitated $SrSO_4$ was washed with a small amount of saturated $SrSO_4$ solution.

Pb^{212} was obtained from the emanation from thorium hydroxide (5). No attempt was made to remove the 60.5-min. half life daughter, Bi^{212}.

Strontium Sulphate

The strontium sulphate used was that prepared in 1946 by Singleton (5) and kept in contact with strontium sulphate solution since that time.

Lead Sulphate, Suspension S (Precipitate Prepared Using Excess Sulphate)

The first precipitate was prepared using 5% excess sulphate. A solution of 250 gm. reagent grade lead nitrate in 650 ml. distilled water was added with stirring to 300 ml. of a sulphuric acid solution. The addition took place over a period of one hour. When the addition was complete, a test of the filtrate showed it to contain excess sulphate ion. The precipitate was washed, with accompanying stirring, with 15 1-liter portions of distilled water over a period of one month.

Lead Sulphate, Suspension L (Precipitate Prepared Using Excess Lead)

This precipitate was prepared in a manner similar to that described for Suspension S except that the chemicals were added in the reverse order, and a 5% excess of lead, instead of sulphate, was used. A test of the filtrate, after the mixing of the chemicals, showed an excess of lead ion.

The washing scheme for this precipitate was identical to that for Suspension S.

Saturated Solutions of the Precipitates in Water

The individual washings of a precipitate were accomplished by agitating the precipitate for 24 hr., with 1-liter portions of distilled water, by means of an electrically driven stirrer. When the last agitation of a precipitate in any particular set of washings had been completed, the suspension was allowed to settle and some of the solution decanted, filtered, and saved. The solution

[3]*The more convenient Sr^{89} was not readily available at that time (1949–50).*

obtained was thus a saturated solution of the precipitate compound in water at room temperature, as given by the precipitate at that stage of washing.

Solutions Containing Sr^{90}

A small amount of highly active strontium sulphate precipitate, freed from yttrium, was stirred with a quantity of saturated inactive strontium sulphate solution. As exchange between the precipitate and solution occurred, activity entered the solution. After approximately one hour, when the solution had attained a sufficient degree of activity,[4] the mixture was allowed to settle and the solution decanted and filtered. Solutions containing Sr^{90} were thus obtained without introducing additional strontium or foreign ions.

Solutions Containing $S^{35}O_4^{=}$

One-tenth of a milliliter of the stock solution of $S^{35}O_4^{=}$ obtained from Chalk River was diluted to 1 ml. with distilled water. To approximately 400 ml. of saturated inactive strontium or lead sulphate solution a sufficient quantity (0.15 ml.) of the diluted stock solution was added to give an activity of 80 counts per sec. per 5 ml.

Solutions Containing ThB

After the platinum foil in the emanation apparatus had been collecting activity for two days, the foil was removed and rinsed in a quantity of saturated inactive lead sulphate solution. After 15 min. the platinum foil was removed and the solution was ready for use.

Measurement of Radioactivity

Counting equipment consisted of an Atomic Instrument Company Scale of 64 scaler and an end-window Geiger tube. The usual corrections for resolving time and background were made. Backscattering corrections were avoided by always using identical 1 ml. Pt dishes, diameter 2.2 cm., for counting. Statistical counting errors were reduced to about 1% by recording 10,000 counts. Self-absorption corrections were eliminated by preparing all samples containing a given radionuclide in such a way that they contained the same weight of absorbing agent. Thus, samples from experiments with the strontium sulphate precipitate were all counted with the residue left upon evaporation of 5 ml. of saturated strontium sulphate solution. This residue weighs approximately 0.62 mgm., equivalent to 0.2 mgm. per sq. cm. when evaporated on dishes of 2.2 cm. diameter. Similarly, samples from experiments with the lead sulphate precipitates have been counted with the residue, weighing approximately 0.20 mgm., from 5 ml. of saturated lead sulphate solution.

Miscellaneous Equipment

A mechanical shaker was used to keep samples agitated during the absorption experiments.

Thirty-milliliter glass stoppered flint glass bottles were used as shaking bottles, the same as in previous experiments (5).

Suspensions were stirred with an electrically driven stirrer.

[4]*Radioactivity.*

Experimental Procedure

The procedure was essentially the same as that used in the previous work on strontium sulphate (5, 6). After the precipitate suspension had been agitated by a mechanical stirrer for at least five minutes, an aliquot of the suspension, usually 5 ml., was withdrawn by pipette and placed in a shaking bottle. An aliquot, usually 15 ml., of the appropriate active solution was then pipetted into the bottle and shaking on the mechanical stirrer was begun immediately. The temperature was room temperature, approximately 20°C. Shaking time was measured from the time the solution had completely drained into the shaking bottle. When shaking was complete the bottle was removed and centrifuged for approximately one minute. Five milliliters of the supernatant liquid was then withdrawn by pipette and evaporated in successive portions in a 1-ml. platinum dish on a semimicro water bath.

The radioactivity of the sample in the Pt dish was then measured under an end-window Geiger tube.

It is necessary to know the starting activity of the active solution before admixture with the precipitate, as well as the activity after mixing, if the amount adsorbed by the precipitate in an exchange experiment is to be obtained by difference. The procedure used in measuring the starting activity of an aliquot of active solution was such that the starting activity samples went through all experimental operations except the actual addition of the precipitate. The effects of adsorption, if any, of tracer ions on equipment were thus made to cancel out. The starting activity samples were made by transferring an aliquot of inactive solution to a shaking bottle and adding the same volume of active solution as used in the exchange experiment. The solution was shaken for a time, then a portion was withdrawn and evaporated on a sample dish. The aliquot of inactive solution to which active solution was added was equal in volume to the volume occupied by liquid in an aliquot of the precipitate suspension. For example, the volume occupied by liquid in a 5 ml. aliquot of strontium sulphate suspension was $(5-0.24) = 4.76$ ml., the volume of the solid precipitate being 0.24 ml.

The amount of precipitate suspension and the amount of active solution used in each experiment were so chosen that roughly 50% adsorption or exchange of activity would occur. At 50% adsorption the accuracy of the experiment is at a maximum.

The weight of precipitate in an aliquot of suspension was determined by transferring a number of aliquots to a Gooch filter crucible, filtering, drying in an oven (105°C.) overnight, and weighing.

Corrections for the Growth of Y^{90} from Sr^{90}

The sample was measured first without an absorbing screen and then with an absorbing screen of thickness 231 mgm./sq. cm. between it and the Geiger tube. This reduced the Sr^{90} count to less than 0.2% but transmitted 39% of the Y^{90} count. Multiplying the second count by 100/39 and subtracting this from the first count gave the count due to Sr^{90}.

Counting of S^{35} in the Presence of Sr^{90} Plus Y^{90}

By counting the sample through a screen of 17.4 mgm./sq. cm. thickness all the S^{35} radiations were cut out. Combining this count with a knowledge of the fraction of the Sr–Y radiations transmitted by this screen and a measurement of the amount transmitted by a 231 mgm./sq. cm. screen allowed the calculation of both S^{35} and Sr^{90} activities in a given sample.

Counting of S^{35} in the Presence of ThB

The ThB was measured by counting the sample behind a 17.4 mgm./sq. cm. screen which absorbed the S^{35} radiations. The S^{35} was measured six days later when all the ThB had decayed.

Method of Calculation

The starting activity and the activity of the exchange samples belonging to a particular set of experiments were first corrected for background. They were then brought to the same basis by taking into account any dilution that had occurred as a result of the experimental procedure.

When dealing with Sr^{90} the next step in the calculations was the correction for growth of daughter activity.

After applying these corrections the quantity of activity adsorbed by the precipitate was obtained by difference. Substitution was then made in the ratio on the left side of the fundamental equation:

$$\frac{\text{No. tracer anions or cations in soln.}}{\text{No. tracer anions or cations in surf.}} = \frac{\text{No. of anions or cations in soln.}}{\text{No. of anions or cations in surf.}}.$$

The quantity "number of anions or cations in solution" is calculated from the solubility of the precipitate in water. For strontium sulphate, formula weight 183.7 and solubility in water 0.1233 gm. per liter (7), the number of strontium or sulphate ions per milliliter of saturated solution is

$$0.1233\times6.02\times10^{23}/1000\times183.7 = 4.04\times10^{17} \text{ ions per ml.}$$

For lead sulphate, formula weight 303.3 and solubility in water 2.56×10^{-4} moles per liter at 20°C., the corresponding figure is 1.54×10^{17} ions per ml. Using the formula given in the Introduction, the area per molecule is, for strontium sulphate (density 3.96 gm. per ml.), $(183.7/3.96\times6.02\times10^{23})^{2/3} = 1.81\times10^{-15}$ sq. cm. The corresponding area for lead sulphate (density 6.2 gm. per ml.) is 1.88×10^{-15} sq. cm.

Typical Calculations

(*a*) *Exchange of Sr^{90} at the Surface of a Strontium Sulphate Precipitate*

Five milliliters of a suspension of strontium sulphate was added to 15 ml. of saturated strontium sulphate solution containing Sr^{90}. The mixture was shaken for 10 min. and then centrifuged. Five milliliters of the centrifugate was evaporated and counted. After correcting for yttrium, the activity was 23.65 registers/min. (1 reg. = 64 counts). Five milliliters of the original solution gave 52.9 reg./min. Thus, the percentage activity adsorbed or exchanged $= (1-23.65/52.9)\ 100 = 55.3\%$. The weight of $SrSO_4$ in the suspension was

1.1315 gm. and the total volume of solution was 19.76 ml. Thus, the number of ions in the surface per gram of precipitate equals

$$\frac{55.3}{44.7} \times \frac{19.76 \times 4.04 \times 10^{17}}{1.1315} = 8.55 \times 10^{18}.$$

The surface area per gram, corresponding to 8.55×10^{18} ions in the surface, is equal to $8.55 \times 10^{18} \times 1.81 \times 10^{-15} = 15{,}500$ sq. cm.

(*b*) *Combined Sr^{90} and $S^{35}O_4^{=}$ Experiment*

An experiment was conducted in which 5 ml. of a suspension of strontium sulphate were shaken with 15 ml. saturated strontium sulphate solution containing approximately equal activities of Sr^{90} and $S^{35}O_4^{=}$. Shaking time was 10 min. The results are recorded in Table I.

TABLE I

EXCHANGE EXPERIMENT USING BOTH S^{35} AND Sr^{90}

	Activity, registers/min., corrected for background	
	Starting activity sample	Exchange sample
1. No screen	61.7	33.4
2. 17.4 mgm./sq. cm. screen	20.1	9.56
3. 231 mgm./sq. cm. screen	0.53	0.50
4. Calculated Sr^{90} activity passing 231 mgm./sq. cm. screen	0.04	0.02
5. Y through 231 mgm./sq. cm. screen ((3)−(4))	0.49	0.48
6. Y, no screen ((5).100/39)	1.25	1.23
7. Y through 17.4 mgm./sq. cm. screen (0.95(6))	1.19	1.17
8. Sr^{90} through 17.4 mgm./sq. cm. screen ((2)−(7))	18.91	8.39
9. Sr^{90}, no screen ((6)/0.56)	33.8	14.95
10. S^{35}, no screen ((1)−(9)−(6))	26.7	17.2

% Sr adsorbed = [(33.8−14.95)/33.8]100 =55.8 ;
% S^{35} adsorbed = [(26.7−17.2)/26.7]100 = 35.5.
These figures correspond to areas of 16,200 and 7050 sq. cm. per gram of precipitate, respectively.

RESULTS

$SrSO_4$

The effect of time of shaking on percentage adsorption of $S^{35}O_4^{=}$ on $SrSO_4$ is shown in Fig. 1, together with the corresponding figures for the exchange of Sr^{++} by the same precipitate (see Ref. (5)) in experiments done two years earlier. As before, there is a very rapid primary exchange followed by a much slower secondary exchange. The primary exchange is essentially complete in about ten minutes, and as a consequence this time of shaking has been rather arbitrarily chosen as the point at which to calculate surface area in most experiments.

Shaking time, 10 min.

(*a*) Using Sr^{90} only, average area per gm. = 15,000 sq. cm. (cf. Singleton, 12,800 sq. cm., in 1947).

(*b*) Using Sr^{90} and S^{35} simultaneously; based on Sr^{90}, area per gm. = 16,200 sq. cm.; based on $S^{35}O_4^{=}$, area per gm. = 7050 sq. cm.

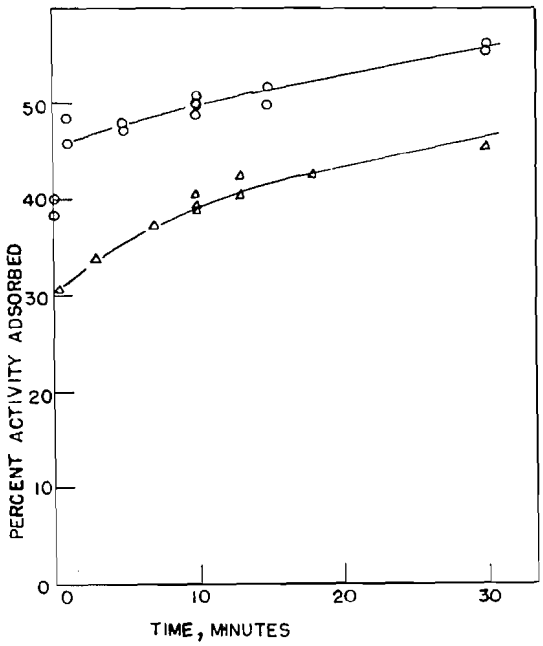

FIG. 1. Variation of percentage adsorption of ions on a strontium sulphate precipitate, with time of shaking; ○, Sr^{90} (Singleton 1947), △, $S^{35}O_4^{=}$ (Stow 1949).

The precipitate was then washed with six 1-liter portions of distilled water and the exchange experiments repeated with the following results:
Based on $S^{35}O_4^{=}$, average area per gm. = 7830 sq. cm.
Based on Sr^{90}, average area per gm. = 14,400 sq. cm.
Washing the precipitate thus had very little effect on the apparent surface area.

Celestine

A single, well-formed crystal of celestine[5] was reduced to a fine powder using an agate mortar and pestle. The powder was washed by stirring with 10 successive 300-ml. portions of water over a period of 40 hr. and then used in exchange experiments with labelled Sr^{++} and $SO_4^{=}$. Shaking 8.5 gm. powdered celestine with 8.5 ml. saturated $SrSO_4$ solution for 20 min. resulted in 65.5% adsorption of $SO_4^{=}$ and 75% adsorption of Sr^{++}. The relative surface areas as measured by Sr^{++} and $SO_4^{=}$ were thus in the ratio (75/25)(34.5/65.5) = 1.58 (cf. 1.9 for $SrSO_4$ prepared in the laboratory). The surface area per gram as measured by Sr^{++} was 2140 sq. cm.

$PbSO_4$; Suspensions S and L

Results for time of shaking experiments with $PbSO_4$ suspensions are recorded in Figs. 2 and 3.

In four of the experiments both $SO_4^{=}$ and Pb^{++} were labelled; in the remainder, one ion only was labelled. For Suspension S the percentage adsorptions of $SO_4^{=}$ and Pb^{++} were not significantly different and the difference was only

[5]*Obtained from Ward's Natural Science Establishment.*

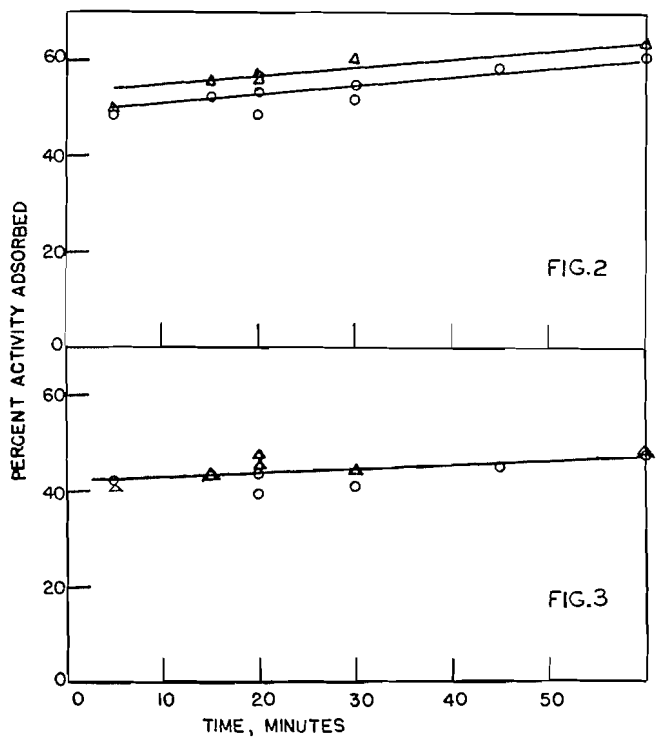

FIG. 2. Variation of percentage adsorption of ions on a lead sulphate precipitate, Suspension L, with time of shaking; ○, ThB; △, $S^{35}O_4^{=}$.

FIG. 3. Variation of percentage adsorption of ions on a lead sulphate precipitate, Suspension S, with time of shaking; ○, ThB; △, $S^{35}O_4^{=}$.

slight for Suspension L. The mean surfaces per gram of precipitate (20 min. shaking) are 2160 and 3650 sq. cm. for S and L, respectively.

The precipitate was then washed with six 1-liter portions of distilled water and the exchange experiment repeated. Again the percentage adsorptions for a given suspension were not significantly changed by the washing for either ThB or $S^{35}O_4^{=}$. Thus washing the precipitate had little effect on the surface area.

DISCUSSION

The foregoing experiments, in which two labelled ions have been used simultaneously to measure the degree of exchange at a surface consisting of the two ions, indicate that the degree of exchange is not necessarily the same for the two ions. The statistical mechanical approach of Imre has indicated that factors other than those considered by Paneth may sometimes be involved. It is of particular interest that his prediction that the degrees of exchange for Pb^{++} and $SO_4^{=}$ on $PbSO_4$ would be the same is borne out by the present experiments. It is also of some interest that the degrees of exchange for Sr^{++} and $SO_4^{=}$ on $SrSO_4$ differ markedly from one another, both for artificially prepared $SrSO_4$ and for the naturally occurring celestine. While altogether too few experiments have been done to warrant any speculation concerning the origin of the differ-

ence, it might possibly be due to differing hydration energies of the Sr^{++} and $SO_4^{=}$ ions. However the present experiments do indicate that this method, and possible extensions of it, does provide a powerful tool for investigating the behavior of ions at surfaces. Further experiments have been planned.

INTERFACIAL POTENTIALS[1]

By J. T. Davies and Sir Eric Rideal

ABSTRACT

A new relation between interfacial distribution potentials and interfacial surface (contact) potentials is presented. By a suitable choice of experimental system either distribution potentials or surface potentials may be measured separately; results are in good agreement with theory. Surface potentials are shown to be made up of several independent components. The rates of decay of surface potentials are also discussed.

The origin of interfacial potentials between oil and water, important as biological analogies, has long been a matter of some controversy. Many of the early experiments were conducted with salicylaldehyde or *o*-toluidine as the oil phase, and the potential differences measured when different organic salts were added changed slowly with time during the experiments. Beutner (4, 5) believed that the potential differences arise from the free charge at the interface due to an unequal distribution of the various cations and anions across the interface. The distribution potential difference caused by this process may be termed after Lange the ψ or outer potential. Baur (3) on the other hand believed the changes were due to selective ionic adsorption at the oil–water interface. Such surface or interfacial potentials may be represented by ΔV or by $\delta\chi$ in Lange's nomenclature.

After much controversy Baur accepted Beutner's explanation as to their origin. Some years later Dean, Gatty, and Rideal (15) showed theoretically that if one or more types of ions can dissolve in both oil and water no *stable* interfacial potential ΔV can be measured.

Whether the older potential differences were distribution or surface potentials has been summed up by Adam (1):

> "It seems quite likely, however, that both (Beutner and Baur) were right, according to circumstances; although the final potential when thermodynamic equilibrium is attained is not an adsorption potential, the establishment of this equilibrium probably takes a very long time".

Indeed, since the paper of Dean, Gatty, and Rideal (15), it has become clear that the time for decay of the surface potential ΔV determines whether we measure $\Delta\psi$ or ΔV when different organic salts are added. In this paper we shall estimate such times, and confirm that with polar oils at equilibrium only $\Delta\psi$ is measured. Although ψ may take a considerable time to reach equilibrium, owing to the slow diffusion of the salts, and although a diffusion potential (6) may also be measured while this occurs, the surface potential ΔV must decay to zero extremely rapidly in the systems of Beutner and Baur.

Further, by a suitable choice of oils, it has now become possible to measure potential changes ascribable wholly to ψ or to V.

(*a*) DISTRIBUTION POTENTIALS

According to Nernst's theory of distribution potentials, these are measured when the salt has an appreciable solubility in the oil and they arise from the different solubilities of the positive and negative ions in the two phases. We can express this in the following manner:

$$B_+ = \exp[({}_w\mu_+^0 - {}_o\mu_+^0)/RT] \text{ or } RT \ln B_+ = {}_w\mu_+^0 - {}_o\mu_+^0,$$

$$B_- = \exp[({}_w\mu_-^0 - {}_o\mu_-^0)/RT] \text{ or } RT \ln B_- = {}_w\mu_-^0 - {}_o\mu_-^0,$$

where $B_\pm$ refers to the ionic distribution coefficients, and μ^0 the standard chemical potential. Subscripts o and w refer to the oil and water phases respectively.

These different solubilities of the two ions cause a potential between the two phases, as shown in Fig. 1.

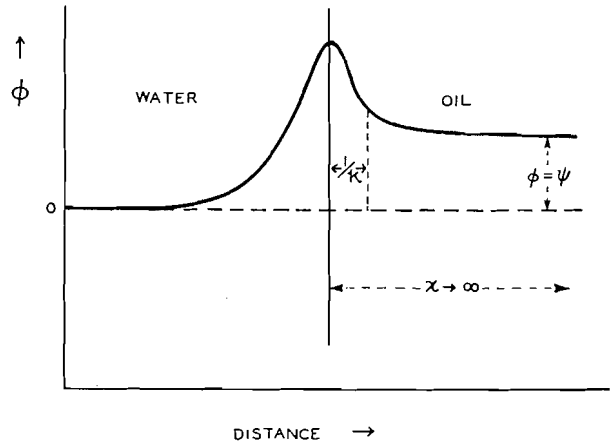

FIG. 1. Variation of ϕ (relative to the interior of the water phase) near an oil–water interface. The oil is assumed polar. The distance from the interface is represented by x, and measurements are made where $x \longrightarrow \infty$ compared with the ionic double layer thickness $1/\kappa$.

The water phase is generally assigned zero potential, while the oil phase has a potential in Lange's notation ϕ (sometimes termed the inner or Galvani potential). If positive ions (e.g. tetramethylammonium) dissolve preferentially in the oil phase, while (say) chloride ions tend to remain in the water, ϕ is positive. The potential ϕ includes both ψ and V thus: $\phi = \psi + V$, or in Lange's notation, $\phi = \psi + \chi$.

We now relate ϕ to B_+ and B_- by means of their electrochemical potentials, $\bar{\mu}$. The Faraday unit is written F.

[1] $${}_w\bar{\mu}_+ = {}_w\mu_+^0 + RT \ln {}_wc_+$$

[2] $${}_o\bar{\mu}_+ = {}_o\mu_+^0 + RT \ln {}_oc_+ + \phi F$$

[3] $${}_w\bar{\mu}_- = {}_w\mu_-^0 + RT \ln {}_wc_-$$

[4] $${}_o\bar{\mu}_- = {}_o\mu_-^0 + RT \ln {}_oc_- - \phi F$$

At equilibrium:

[5] $$ {}_w\bar{\mu}_+ = {}_o\bar{\mu}_+ $$

and

[6] $$ {}_w\bar{\mu}_- = {}_o\bar{\mu}_- . $$

Further, each phase must be electrically neutral, therefore

[7] $$ {}_wc_+ = {}_wc_- $$

and

[8] $$ {}_oc_+ = {}_oc_- . $$

By substitution of equations [1] to [4] into equations [5] and [6], we find:

$$ {}_w\mu_+^0 + RT \ln {}_wc_+ = {}_o\mu_+^0 + RT \ln {}_oc_+ + \phi F $$

and

$$ {}_w\mu_-^0 + RT \ln {}_wc_- = {}_o\mu_-^0 + RT \ln {}_oc_- - \phi F . $$

If we subtract, remembering equations [7] and [8], we obtain:

$$ ({}_w\mu_+^0 - {}_o\mu_+^0) - ({}_w\mu_-^0 - {}_o\mu_-^0) = +2\phi F $$

or

$$ RT \ln B_+ - RT \ln B_- = 2\phi F $$

or

[9] $$ \phi = \phi_{x=\infty} = (RT/2F)\ln(B_+/B_-) . $$

Here $\phi_{x=\infty}$ is defined as in Fig. 1, ϕ being measured far from the interface when x is great compared with the Debye–Hückel term $1/\kappa$. Equation [9] is the required relation between ϕ, B_+, and B_-. If B_+ is large compared with B_-, ϕ is positive.

It can easily be shown that if S is the ratio (conc. salt in oil)/(conc. salt in water),

[10] $$ S = (B_+ . B_-)^{\frac{1}{2}} . $$

Hence, from equations [9] and [10],

$$ \phi = (RT/2F)\ln(S^2/B_-^2) . $$

Although the absolute potentials ϕ are not measurable, we can determine differences in ϕ for (say) NaI and KI. Then B_- is constant, and

$$ \Delta\phi = (RT/F)\ln(S_{NaI}/S_{KI}) . $$

Since ΔV should theoretically not contribute to $\Delta\phi$ in such systems (15), and since $\Delta\phi = \Delta\psi + \Delta V$, if x tends to infinity,

[11] $$ \Delta\phi = \Delta\psi = (RT/F)\ln(S_{NaI}/S_{KI}) . $$

Further, as we may see from inspection of equation [9], $\Delta\phi$ is independent of the common ion. Thus $\Delta\phi$ or $\Delta\psi$ is the same if chlorides are considered instead of iodides in equation [11], since

[12] $$ \Delta\phi = (RT/2F)\ln(B_{Na^+}/B_{K^+}) . $$

Karpfen and Randles (18) have recently set up the cell shown in Fig. 2. They found good agreement between theory, as given by equation [11], and experiment.

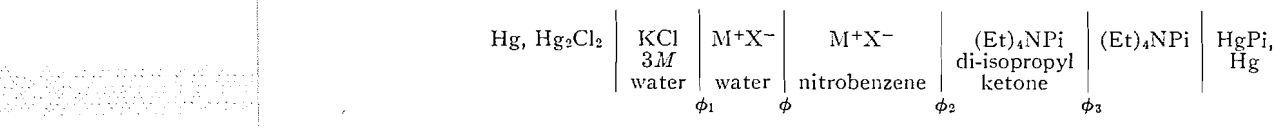

FIG. 2. Cell for measuring $\Delta\phi$ at interface of water and a polar oil such as nitrobenzene (18). Salt bridges are chosen so that when the salt MX is changed, the measured potential change is $\Delta\phi$, i.e. ϕ_1, ϕ_2, and ϕ_3 remain constant. In such an experiment $\Delta\phi$ is measured across thicknesses of solvent great compared with the thickness of the interfacial electrical double layers. Pi is picrate.

Results are shown in Table I, the distribution coefficients for simple salts in nitrobenzene having been found by Davies (7). The agreement is strong support for the validity of equation [11] if the oil is polar. Similar evidence in favor of equation [11] has recently been forthcoming from Göttingen, where Dr. Strehlow and his colleagues have been working along similar lines.

TABLE I

System (see Fig. 2)	$\Delta\phi$ calculated from distribution experiments (7), using equations [11] and [12]. Quoted from (18)	$\Delta\phi$ (observed) (18)
K^+ replaced by $(Et)_4N^+$	−124 mv.	−126 mv.
K^+ replaced by Na^+	− 50 mv.	− 53 mv.
Cl^- replaced by I^-	+ 95 mv.	+102 mv.

(*b*) SURFACE POTENTIALS IN RELATION TO DISTRIBUTION POTENTIALS

If now an oil is chosen in which practically no salt can dissolve (e.g. a paraffinic oil such as decane), an ionic double layer cannot build up completely in the thickness of oil (e.g. 1 mm.) available. Hence equation [8] does not apply to measurements with this oil, although, since the system is by definition at equilibrium in that the free energy is minimal for this thickness of oil, equations [1] to [7] still hold.

Dividing the potential at the oil side of the interface into V (due either to a dipole array formed by spreading or by adsorption or to a charged film) and $\psi_{x=\infty}$ (see Fig. 3) we shall show that if the oil solubilities of the interfacial film and of the salt present are very small, only ΔV contributes to the measured change in ϕ when a film is spread.

From the above equations, if equation [8] is no longer true, equation [9] is extended to:

$$[13] \qquad \phi = \frac{RT}{2F}\ln\left(\frac{B_+}{B_-}\right) - \frac{RT}{2F}\ln\left(\frac{{}_oc_+}{{}_oc_-}\right)$$

in which ${}_oc_+$ and ${}_oc_-$ refer to ionic concentrations in the oil at the point where

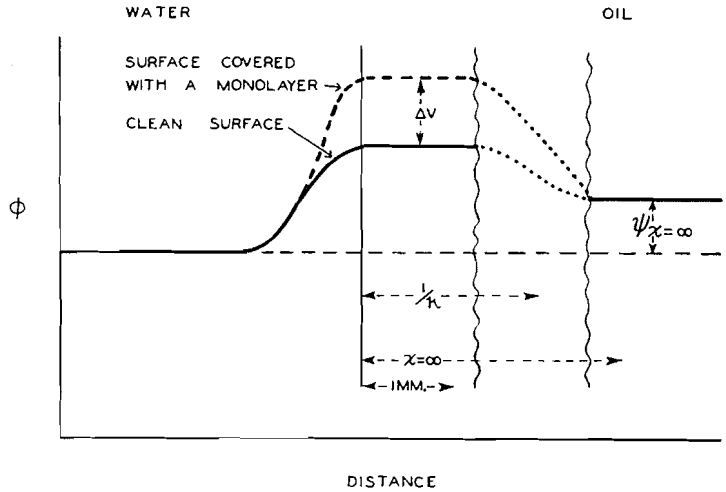

FIG. 3. Variation of ϕ (relative to the interior of the water phase) at the interface with a paraffinic oil. Measurements are made with $x(\sim 1$ mm.) less than $1/\kappa$.

ϕ is measured. To express these concentrations in terms of measurable quantities, we apply the equations of Boltzmann in the form:

[14] $$ {}_oc_+ = ({}_oc_+)_{x=\infty} \times \exp[-e(V - \psi_{x=\infty})/kT] $$

and

[15] $$ {}_oc_- = ({}_oc_-)_{x=\infty} \times \exp[+e(V - \psi_{x=\infty})/kT] $$

and, in the hypothetical region of oil at $x = \infty$, where the electrical double layer is complete,

[16] $$ ({}_oc_+)_{x=\infty} = ({}_oc_-)_{x=\infty}. $$

Hence equation [13] becomes:

$$ \phi = \frac{RT}{2F} \ln\left(\frac{B_+}{B_-}\right) - \frac{RT}{2F} \ln \exp[-2e(V - \psi_{x=\infty})/kT]. $$

The double layer is complete at $x = \infty$, so $\phi_{x=\infty} = \psi_{x=\infty}$ and hence, according to equation [9],

$$ \psi_{x=\infty} = \frac{RT}{2F} \ln\left(\frac{B_+}{B_-}\right). $$

Therefore

$$ \phi = \psi_{x=\infty} + \frac{2RTe}{2kTF}(V - \psi_{x=\infty}) $$

or

$$ \phi = \psi_{x=\infty} + (V - \psi_{x=\infty}) $$

or

$$ \phi = V. $$

Here ϕ is independent of B_+ and B_-, and

[17] $$ \Delta\phi = \Delta V (= \delta\chi, \text{ Lange nomenclature}). $$

From the above considerations we note that with a polar oil in a cell of the type shown in Fig. 2, we can make measurements with direct current (18) to test equation [11]:

[11] $$\Delta\phi = \Delta\psi = (RT/F)\ln(S_{NaI}/S_{KI}) .$$

With a non-conducting oil, the vibrating plate method (8, 9) must be employed. This is a capacity method, and depends upon alternating current, since no measurable direct current can pass through a non-conducting oil, in which salts are effectively insoluble. To such potentials, equation [17] applies:

[17] $$\Delta\phi = \Delta V.$$

To test the theories we thus require different oils: if the oil is polar, $\Delta\phi$ should depend only on the distribution coefficients, and not on ΔV; but if the oil is paraffinic, $\Delta\phi$ should depend on ΔV and not on S, the distribution coefficient.

If the non-aqueous phase is so non-polar that ions cannot appreciably dissolve in it, the interfacial potential will alter only if an interfacial film is formed—the partition coefficients being assumed to be unaltered by the interfacial monolayer. Ions are unstable in air near a water surface, and no double layer can therefore form above a water surface; thus the measurement (23) of film potentials at the air–water surface is rendered possible and equation [17] can be tested, where ΔV is the difference of potential between the clean water surface and one on which a film has been spread, as shown in Fig. 3. Such potential changes are perfectly stable with time, no decrease ever having been observed with insoluble films. Exactly similar results are obtained, though the experimental technique is different (8, 9, 12), with paraffinic oils, as shown in Fig. 4. The petrol-ether used in this experiment is made up of decane and near homologues.

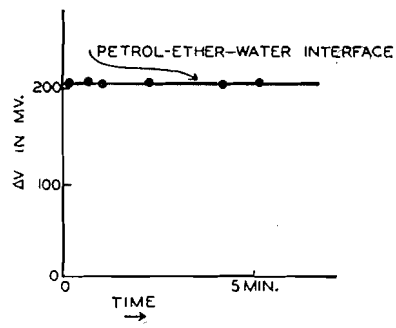

FIG. 4. Surface potential for monolayer of $C_{18}H_{37}N(CH_3)_3^+$ spread to 92 Å² per chain between petrol-ether and water. The latter contained 1.0 *N* NaCl. The potential does not change with time (12).

Again, if the paraffinic oil be replaced by a fairly polar oil there should, by equation [11] which is now applicable, be no change in potential between the system with a clean interface and one with a monolayer at the interface. Only if the distribution coefficient is changed will the potential alter. This is in full accord with experiment.

If, however, we study a very slightly polar oil, spreading a film and measuring the potential difference $\Delta\phi$ (equation [17]), this should now slowly decrease to zero, since, if the oil is slightly polar, ions from the water will redistribute themselves and set up a new double-layer in the oil. During this process of ionic redistribution (Fig. 5) we pass from the region of applicability

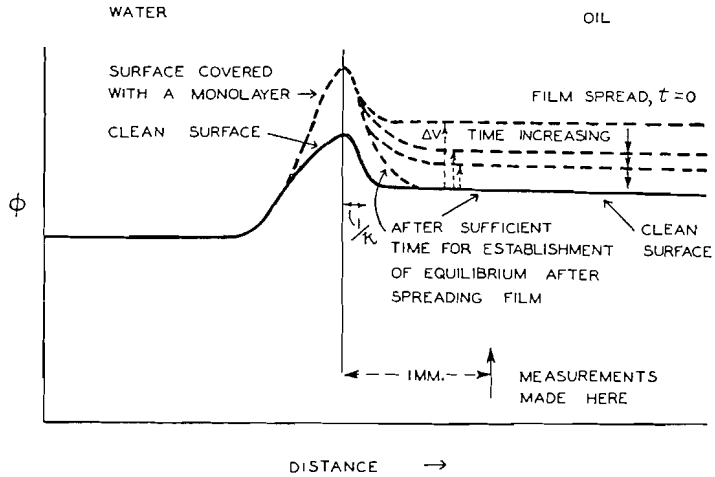

FIG. 5. Potential redistribution on oil side of interface after spreading a film if the oil is slightly polar. The (negatively charged) ionic atmosphere slowly builds up in the oil till ΔV has decreased to zero, provided that the thickness of oil used is sufficient to dissolve the necessary ions.

of equation [17] to that of equation [11]. The latter predicts $\Delta\phi$ should be zero, since a monolayer will not appreciably affect the distribution coefficients. Thus the potential difference $\Delta\phi$ due to the spread film should decrease with time and, if a complete double layer can form in the oil, will eventually become zero. This is borne out by experiment (Fig. 6).

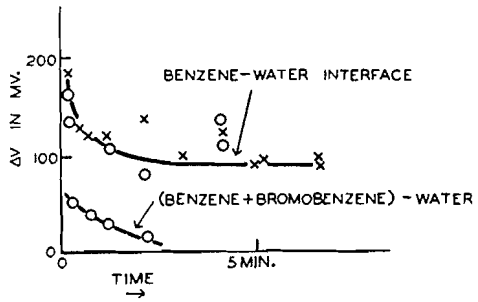

FIG. 6. Interfacial potentials of film of $C_{18}H_{37}N(CH_3)_3^+$ spread to 92 Å^2 per chain between water and slightly polar oils. The decrease in ΔV with time reflects the change from the region of applicability of equation [17] to that of equation [11]. Crosses denote potentials measured with the vibrating plate apparatus (8, 9) and circles those found with the radioactive source method (2).

We can now proceed further and observe that if the times for the potential to decay to one half its initial value are found, a rough correlation with the

TABLE II

Non-aqueous phase	Calculated concentration of Cl^- in non-aqueous phase	Depth of ionic atmosphere, i.e. $1/\kappa$	Time calculated for Cl^- to reach equilibrium positions after film was spread	Observed time of decay of ΔV to $1/e$ of original value
Air	$10^{-65}N$	10^{24} cm.	10^{54} sec.	∞
Petrol-ether (decane)	$10^{-33}N$	10^{8} cm.	10^{21} sec.	∞
Benzene	$10^{-11}N$	5×10^{-3} cm.	$\sim$1 sec.	60 sec.
Benzene + bromobenzene	$10^{-8}N$	5×10^{-4} cm.	$\sim$0.01 sec.	$\sim$1 sec.

rates of diffusion of the counter-ions from the water into the oil (to build up the new double layer) might be expected. In Table II this is shown, the calculated times (12) being functions of the polarity of the oil, i.e. of the equilibrium concentration of chloride ions immediately on the oil side of the interface. From here the ions must diffuse through the oil to a mean distance of $1/\kappa$ (the Debye–Hückel function) away from the interface. Although benzene is only slightly more polar than paraffins, it dissolves more water, so that ions in benzene can be at least partly hydrated and in consequence more ions can dissolve in benzene than in petrol-ether. Thus interfacial potentials at the benzene–water interface decrease with time, although those at the paraffin–water interface are stable.

(c) COMPONENTS OF ΔV, THE SURFACE POTENTIAL

Throughout this paper the orientation of the dipoles at the water surfaces has been neglected, and by definition $\phi_{H_2O} = 0$. If ψ, the free charge, is zero in the water, the absolute potential ϕ_{H_2O} is V or χ, the potential of the water dipoles. Although questions of absolute potentials have been avoided in the present work, it is interesting to note that V has been estimated for the air–water surface. The figures range, however, from -0.5 volts to $+0.4$ volts (21).

If, however, a monolayer is spread on a clean water surface, the water dipoles will be reoriented about the film-forming molecules, because of the new dipoles introduced into the surface. This change, for each molecule spread

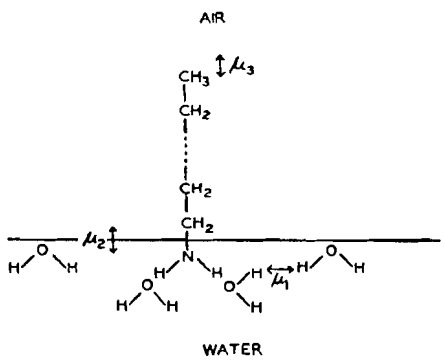

FIG. 7. Components μ_1, μ_2, and μ_3 of the surface potential ΔV for an electrically neutral monolayer.

in the monolayer, will be denoted μ_1. The dipoles of the film-forming molecules (e.g. C—NH_2 in a long-chain amine) will also contribute to ΔV by an amount depending on the dipole moment μ_2. A third component of ΔV for electrically neutral films spread at the air–water surface is μ_3, the moment of the bond (e.g. C—H) at the upper limit of the monolayer (Fig. 7). If we apply the Helmoltz formula for an array of n dipoles per cm.^{2}, and if they are all vectorially additive in the vertical direction (Eucken), we obtain:

$$[18] \qquad \Delta V = 4\pi n\mu = 4\pi n\mu_1 + 4\pi n\mu_2 + 4\pi n\mu_3$$

where μ is an over-all dipole moment including all components.

Unfortunately μ_1 cannot be measured, so it is usual to combine this term with μ_2, especially since the reorientation of the water dipoles, given by μ_1, probably depends on μ_2, as in Fig. 7.

The term μ_3 is normally constant since paraffinic chains are usual in surface active molecules, so that then equation [18] becomes for an electrically neutral film:

$$[19] \qquad \Delta V = 4\pi n\mu = 4\pi n\mu_D$$

where $\mu_D = \mu_1 + \mu_2 + \mu_3$, characteristic of the dipole of the head-group (e.g. C═O, C—NH_2) of the molecules in the monolayer.

In recent years there has been added interest in substituted hydrocarbon chains, and to investigate these we use [18] in the form:

$$[20] \qquad \Delta(\Delta V) = 4\pi n(\Delta\mu_3) \ .$$

Thus by comparing films with the same numbers of molecules per cm.^{2}, spread at the same interface, and having the same polar head groups, we measure the difference in potential due to substitution of the —CH_3 group at the upper

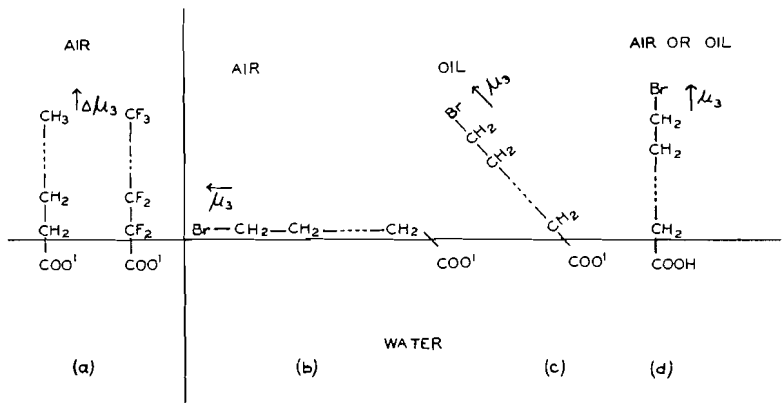

FIG. 8. (*a*) Anions of an aliphatic acid and of a perfluoro acid spread at the air–water interface. The difference in ΔV is due to the change in μ_3, the vertical dipole moment of the uppermost bond (19).

(*b*) Anion of ω-bromohexadecanoic acid at air–water interface. The vertical component of μ_3 is zero (13).

(*c*) Anions of ω-bromohexadecanoic acid at decane–water interface. Vertical component of μ_3 now appreciable, as the ω-bromo group is easily lifted into the oil (13).

(*d*) Molecule of ω-bromohexadecanoic acid in close-packed film at pH 4 at air–water surface. The dipole μ_3 is now relatively large (17).

limit of the film by (say) —CH_2Br or —CF_3, as shown in Fig. 8. Some results are shown in Table III. That $\Delta\mu_3$ is less than the dipole of the carbon–halogen link suggests that there is mutual polarization of the dipoles in condensed films (first and last examples in Table III). Further, the dipoles of such ω-halogen links are unlikely to be oriented vertically, but rather at half the tetrahedral angle (17).

TABLE III

VARIATIONS IN μ_3 FOR DIFFERENT FILMS AT THE AIR–WATER AND OIL–WATER INTERFACES

Film	ΔV	$\Delta(\Delta V)$	$\Delta\mu_3$ (vertical component of dipole differences in ω-bonds)	Difference in μ for ω-bond and C—H bond from bulk measurements
Myristic acid with carboxyl group ionized (25 Å², air–water)	−50 mv.	−900 mv. (19)	−600 mD. (see Fig. 8*a*)	−1800 mD.
Perfluorodecanoic acid with carboxyl group ionized (25 Å², air–water	−950 mv.			
Hexadecanoic acid on 1 *N* NaOH at 66 Å², air–water	−28 mv.	0 (13)	0 (see Fig. 8*b*)	−1900 mD.
ω-Bromohexadecanoic acid on 1 *N* NaOH at 66 Å², air–water	−28 mv.	−132 mv. (13)	−230 mD. (see Fig. 8*c*)	−1900 mD.
ω-Bromohexadecanoic acid on 1 *N* NaOH at 66 Å², oil–water	−160 mv.			
Hexadecanoic acid pH4 air–water (20 Å²)	+390 mv.	−1260 mv. (17)	−660 mD. (see Fig. 8*d*)	−1900 mD.
ω-Bromohexadecanoic acid, pH4, air–water (20 Å²)	−870 mv.			

If now we consider a charged film of $C_{18}H_{37}N(CH_3)_3^+$ ions, an additional term ψ_0 for the electrostatic potential of the interface relative to the subjacent layers of liquid is necessary. Thus equations [18] and [19] become:

$$[21] \qquad \Delta V = 4\pi n\mu = 4\pi n\mu_1 + 4\pi n\mu_2 + 4\pi n\mu_3 + \psi_0,$$

$$[22] \qquad \Delta V = 4\pi n\mu = 4\pi n\mu_D + \psi_0,$$

or

$$[23] \qquad \mu = \mu_D + \mu_0$$

where μ_0 is the dipole contribution of the electrical double layer.

At low surface coverages, ψ_0 may be expected to contribute to μ a dipole moment (Fig. 9) given by the product of the mean thickness of the ionic double layer (the Debye–Hückel term $1/\kappa$) and the charge thus separated per molecule, i.e. one electron. Both these quantities are large (e.g. $1/\kappa$ may be

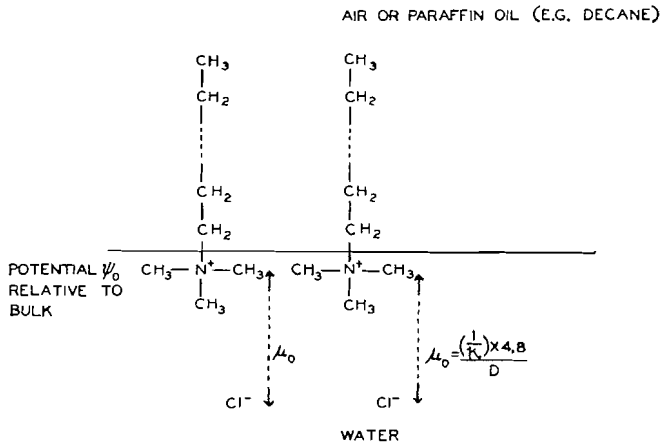

FIG. 9. A monolayer of $C_{18}H_{37}N(CH_3)_3^+$ at air–water or decane–water interface. The mean depth of the Cl^- counter-ions is $1/\kappa$, and this makes possible very large dipole contributions if the ionic strength is low (Table IV). The electrostatic potential at the interface is ψ_0 relative to the bulk of the aqueous phase.

several hundred Angstrom units), so very large dipole moments may be expected. To treat the double layer as an array of dipoles in this manner we have assumed that the dielectric constant D of the water is always 80 in the electrical double layer, and that the charges are far enough apart in the surface for their mutual interactions to be neglected. Thus:

[24] $$\underset{n\to 0}{\mu_0} = \frac{(1/\kappa) \times 4.8}{D}$$

and hence, by [23],

[25] $$\underset{n\to 0}{\mu} = \mu_D + \frac{(1/\kappa) \times 4.8}{D}.$$

Comparison of μ thus calculated with the experimental results at different ionic strengths (8) is made in Table IV. The value of μ_D is 400 mD. throughout (11). Although the dipole moments, especially on 10^{-4} N solution ($1/\kappa$ = 300 Å), are very high, the potentials at 1000 Å (Table IV) are not very great. However, since n is then only 10^{13}, μ is large by equation [22]. At greater surface concentrations (n increasing), ΔV increases only slightly, and μ falls steeply owing to mutual interaction of the electrical charges (8).

Equation [22] can also be tested (10) using the Gouy equations for ψ_0:

[26] $$\psi_0 = \frac{2kT}{e} \sinh^{-1}\left(\frac{134 \times 10^{-16} \times n}{\sqrt{c}}\right).$$

Comparison with experiment is made in Table V, combining equations [22] and [26]:

[27] $$\Delta V = 4\pi n\mu_D + \frac{2kT}{e} \sinh^{-1}\left(\frac{134 \times 10^{-16} \times n}{\sqrt{c}}\right).$$

These considerations all apply to the air–water or decane–water interface. If, however, a polar oil is used, ΔV for charged films is found (see above) to

TABLE IV

CALCULATED AND MEASURED DIPOLE MOMENTS μ FOR COMPLETELY IONIZED FILMS OF $C_{18}H_{37}N(CH_3)_3^+$ AT THE AIR–WATER OR DECANE–WATER INTERFACES. THE DISTANCE $1/\kappa$ IS GIVEN BY $3/\sqrt{c}$ Å, WHERE c IS THE SALT CONCENTRATION

TEST OF EQUATION [27]. DATA FOR $C_{18}H_{37}N(CH_3)_3^+$ (11, 10). AS BEFORE, μ_D = 400 MD.

Function of ΔV	Calculated	Experimental
$\left(\frac{\partial(\Delta V)}{\partial \log c}\right)_n$	-59 mv. $= \frac{2.303kT}{e}$ if c not too high	-57 mv. to -62 mv.
$\left(\frac{\partial(\Delta V - 4\pi n \times 400)}{\partial \log n}\right)_c$	$+118$ mv. $= \frac{2 \times 2.303kT}{e}$ if n not too low	$+110$ mv.
$\Delta V - 4\pi n \times 400 = \psi_0$ ($n = 3.33 \times 10^{13}$)	$+108$ mv.	$+112$ mv.
$\Delta V - 4\pi n \times 400 = \psi_0$ ($n = 6.67 \times 10^{13}$)	$+142$ mv.	$+145$ mv.

be zero at equilibrium, in agreement with the theory of Dean, Gatty, and Rideal (15). They pointed out that a compensative electrical double layer must also be set up in a polar oil (whether or not ψ_0 is zero), and this, represented here as ψ_{oil}, must at equilibrium be given by:

$$\Delta V = 4\pi n\mu_D + \psi_0 + \psi_{oil} = 0. \quad [28]$$

GENERAL DISCUSSION

That the Gouy equations, based on the assumption of a uniformly charged and impenetrable film in contact with counter-ions which are point charges, predict so accurately ψ_0 up to high ionic strengths had been interpreted (14) in terms of compensation of the effects of the finite sizes of the counter-ions with the penetration of some of the counter-ions between the charged groups

constituting the film. This conclusion has been supported by studying the surface viscosity and interfacial reaction kinetics as ψ_0 changes.

In the last few years various authors have measured interfacial potentials with cells of the type shown in Fig. 2. Thus McMullen (20) found that the introduction of cetyltrimethylammonium bromide into an octyl alcohol – water system caused a potential $\Delta\phi$ of about 130 mv. although this decayed rapidly. Similar results were found with amyl-acetate. On the other hand Dupeyrat and Guastalla (16), using nitrobenzene as oil, found $\Delta\phi$ to be constant at 400 mv. when a myristyl-trimethylammonium salt was added. We consider that distribution potentials ($\Delta\psi$ of equation [11]) and diffusion potentials are responsible for all these results, the very thin layers of oil used by McMullen eventually making possible distribution potentials at *both* oil–water interfaces ($\Delta\phi_2 \sim \Delta\phi$ in Fig. 2, owing to diffusion). The potential of Dupeyrat and Guastalla is certainly a stable $\Delta\psi$, though rather higher than found by Powell and Alexander (22), whose measurements are more difficult to interpret. They used the contact potential method, ionizing the air gap above the oil layer (and possibly the oil itself) with a mesothorium source. Interfacial potentials due to cetyltrimethylammonium bromide added to the water were usually constant after the first few minutes, and then it was found that $\Delta\phi$ varied in the order:

$$\Delta\phi(\text{air}) \gg \Delta\phi(\text{amyl acetate}) > \Delta\phi(\text{octyl alcohol}) .$$

This sequence is in the reverse order of the dielectric constants. Powell and Alexander interpret these $\Delta\phi$ measurements as ΔV potentials, though by comparison with the results of Fig. 6 and Table II this seems unlikely, especially as they claim that the equilibrium postulated by Dean, Gatty, and Rideal (15) must be very slow in attainment since their potentials are stable with time after a few minutes. We consider that Powell and Alexander's oil–water results are probably distribution potentials or may sometimes be due to diffusion to and adsorption at the upper (oil–air) interface. Distribution potentials would be expected to decrease with increasing dielectric constant of the oil, since B_+ depends on ${}_o\mu_+^0$.

Our considerations concerning the adsorption and ion partition potential differences which may develop at liquid–liquid interfaces and the effects of an added electrolyte on their magnitude can evidently be extended to the case in which, for example, a lipoid-like membrane is inserted between two aqueous phases. The best known method of estimating the various components of a membrane potential into phase boundary and diffusion potentials has been laid on a sure foundation by the investigations of Kurt Meyer and T. Teorell.

CONCLUSION

In general $\Delta\phi = \Delta\psi + \Delta V$, but by choosing polar and paraffinic oils, we can separate $\Delta\psi$ and ΔV thus:

$$\Delta\phi \begin{cases} \Delta\psi = f(B_+, B_-) & \text{polar oil,} \\ \Delta V = f(n, \mu) & \text{paraffinic oil.} \end{cases}$$

From our results we conclude that Beutner was indeed correct—Baur's adsorption potentials (surface potentials) either cannot be detected or are very transient for polar oils. Only with recent techniques for investigating interfacial potentials between water and pure paraffinic oils can stable oil–water interfacial potentials (ΔV or $\delta\chi$) be measured (8, 9). This lends strong support to the theory of Dean, Gatty, and Rideal (15).

Surface potentials have been analyzed into components from the dipoles of the polar "head groups" of film-forming molecules, from the dipoles at the upper end of the carbon chain, and from ionic redistributions if the film is electrically charged.

CYSTINE AS AN ADDITION AGENT IN THE ELECTRODEPOSITION OF COPPER[1]

By A. J. Sukava[2] and C. A. Winkler

ABSTRACT

The steady state polarization of 100 mv. in acid copper sulphate electrolyte, at 2 amp./dm.^{2}, appears to consist of 45 to 50 mv. activation overpotential to deposit aquo–copper complexes, 20 to 25 mv. concentration polarization, and about 30 mv. polarization due to hydrogen ion interference. The presence of cystine in the electrolyte gave rise to polarization–time curves similar to those observed previously with gelatine. The increase of polarization caused by cystine appears to be due to an obstructive effect of adsorbed cystine (or its copper complex), together with an increase of concentration polarization. Cystine alone probably does not affect the activation overpotential. Addition of sufficient chloride virtually eliminated the polarization due to obstruction by cystine, possibly by acting as an electron bridge or by forming more readily dischargeable chloro–cystine–copper complexes. Chloride also eliminated the increment in concentration polarization caused by cystine. Attainment of a minimum total steady state polarization of about 40 mv. in the presence of cystine and chloride appeared to reflect an increase of surface, hence a decrease of true current density with time of deposition. The addition agent behavior of methionine was, in most respects, similar to that of cystine. The behavior of thiourea at low concentrations appeared to be complicated, but the effects of chloride were similar to those observed with gelatine.

INTRODUCTION

Since gelatine is probably the most commonly used addition agent in the electrodeposition of copper, much work has been done in this laboratory and elsewhere to study its behavior in this capacity. An understanding of its action is clouded, however, by the complex structure of the gelatine molecule, and it has seemed desirable to find, if possible, a simple amino acid with which the addition agent effect of gelatine might be closely simulated. A previous study with glutamic acid (1) indicated that this substance was not a satisfactory substitute for gelatine. The present paper recounts similar studies with some simple thioamino acids.

EXPERIMENTAL

Polarization measurements were made with the equipment and procedure outlined in earlier papers (1, 10). All chemicals were reagent grade, and water was twice distilled from alkali. The standard electrolyte contained 125 gm./liter $CuSO_4.5H_2O$ and 100 gm./liter H_2SO_4. The composition of other electrolytes used in the study will be specified as required. The Haring cell contained 150 ml. of electrolyte in all experiments, and measurements were made at 24.5° C. throughout the study.

Each cathode surface was brought to a standard condition by electrodeposition from standard electrolyte at 24.5° C. at 3 amp./dm.^{2} for 30 min.,

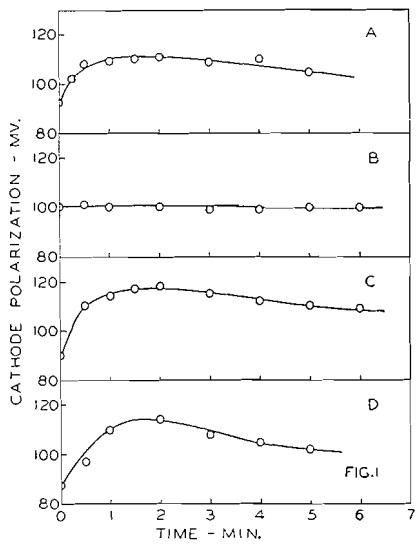
followed by deposition at 2 amp./dm.^{2} until steady state polarization (100 $\pm$ 5 mv.) was attained (4).

RESULTS

Initial Cathode Polarization in Absence of Addition Agent

In an earlier study (10) it was observed that, at 2 amp./dm.^{2}, the polarization rose almost instantaneously to about 100 mv. in the standard electrolyte, and then increased slowly to a slightly higher steady state value. A more detailed study of the behavior with the cathode ray oscilloscope or the Brush recorder has shown that a zero time* polarization of 85 to 90 mv. was followed by an increase to about 115 mv. after one to two minutes, and a subsequent decrease during about 30 min. to the steady state value. Typical results are shown in Fig. 1. Transition from the behavior represented in Fig. 1B to that of Fig. 1C was essentially complete after interruption of the current for one to two minutes. This indicates that the time for dissipation of the cathode film is about the same as that for attainment of the initial maximum polarization and for formation of the cathode film (2).



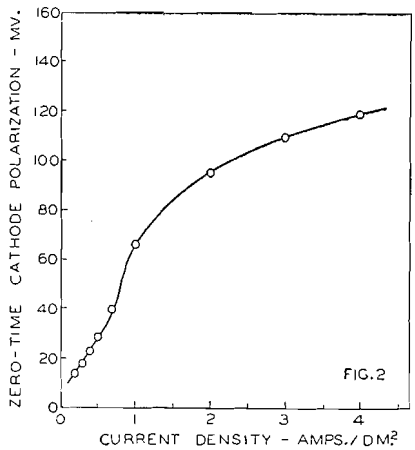


FIG. 1. Initial cathode polarization–time relation for standard electrolyte and standard cathode surface.
A. Cathode film absent at zero time (new standard electrolyte).
B. Cathode film present at zero time (current switched off and immediately re-established).
C. Cathode film absent at zero time (current switched off and cell left undisturbed for four hours).
D. Cathode film absent at zero time (current switched off and solution stirred for one minute).
FIG. 2. Zero-time cathode polarization – current density relation with standard electrolyte and standard cathode surface.

The concentration polarization at the steady state was found to range from 20 to 25 mv. Hence the true zero time polarization presumably should have been 75–80 mv. It is probable that the higher value recorded includes

Zero time is taken as the time at which a first polarization value could be identified.

some initial build-up of concentration polarization before the first reading was obtained on the C.R.O. or Brush recorder.

The effect of current density on the zero time polarization (Brush recorder) in the absence of cathode film is shown in Fig. 2. The linear relation at low current densities is similar to that observed for other polarization values under different conditions (3, 11, 12); at current densities above 0.6 amp./dm.^{2} the polarization was, within experimental error, linear with the logarithm of the current density.

Cathode Polarization in the Presence of Cystine

The initial polarization pattern observed when cystine was added to the standard electrolyte resembled that previously observed with gelatine (10). The presence of cystine caused the polarization to pass through an early maximum, P_{max} (after a fraction of a second), then through a minimum, P_{min} (after about two seconds), followed by a gradual rise to the steady state value, P_s. As with gelatine, the values of P_{max} and P_{min} increased with immersion time, i.e. the time the electrode was in contact with the electrolyte before electrolysis was begun. The following data were obtained with 50 mgm./liter cystine and 2 amp./dm.^{2}:

Immersion time (min.)	Initial polarization (mv.) (maximum at 0–0.05 sec.)	(minimum at 1–2 sec.)
1	150	120
5	177	122
10	205	125
15	235	145
30	270	155
50	275	155
85	292	157

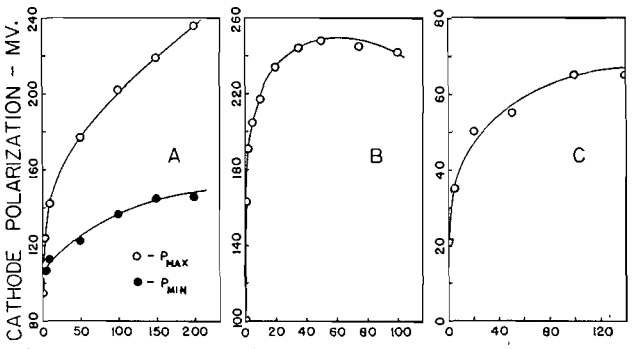
The time to attain P_{max} showed no definite dependence on immersion time. A constant immersion time of five minutes was adopted for routine purposes, and is applicable to the remainder of the discussion.

The value of P_{max}, and to a lesser extent that of P_{min}, was found to increase steadily with increased cystine concentration (Fig. 3A). The times to P_{max} and to P_{min} decreased with increased concentration of cystine. Both P_{max} and P_{min} always exceeded the lowest zero-time polarization (80 mv.) measured in the absence of addition agent.

The steady state polarization was found to be related to cystine concentration as shown in Fig. 3B. The values for concentrations of cystine below about 10 mgm./liter are approximate only, since there was a continued slight decrease of polarization even after five to seven hours electrolysis. The concentration polarization at the steady state, obtained with the C.R.O. (13), also showed a definite, though somewhat erratic, increase with increased cystine concentration (Fig. 3C).

Effect of Chloride on the Polarization in the Presence of Cystine

Addition of various amounts of chloride ion to standard electrolyte containing 20 mgm./liter cystine showed that the depolarizing effect of chloride



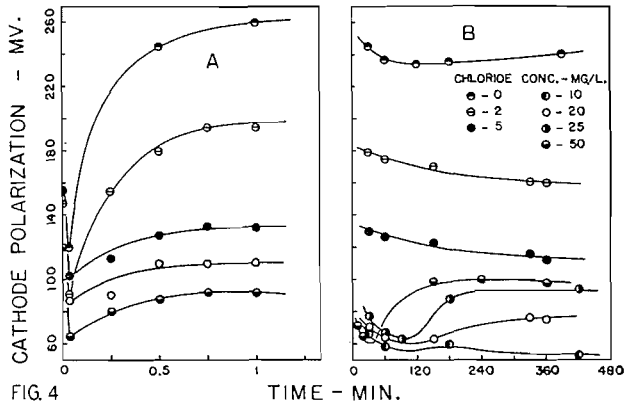


FIG. 3. Cathode polarization – cystine concentration relations.

B. Polarization–time pattern after prolonged electrolysis.

was immediate (Fig. 4A). Concentrations of chloride higher than about 15 mgm./liter eliminated the influence of cystine to give a behavior, during the first minute, almost identical with that observed in the absence of addition agent. Much higher chloride concentrations (50 to 100 mgm./liter) reduced the initial polarization further by 15 to 20 mv. Following upon the immediate depolarization due to chloride were the slower changes shown in Fig. 4B. These were not due to chemical changes other than electrode processes, since aging the solutions prior to electrolysis had no effect.

The steady state polarization as a function of chloride concentration is shown in Fig. 5A. The minimum polarization (about 50 mv. at 12 mgm./liter chloride) was always accompanied by a coarse, irregular deposit.

The effect of cystine concentration on the position of the minimum in the steady state polarization – chloride concentration curve is shown in Fig. 5B.

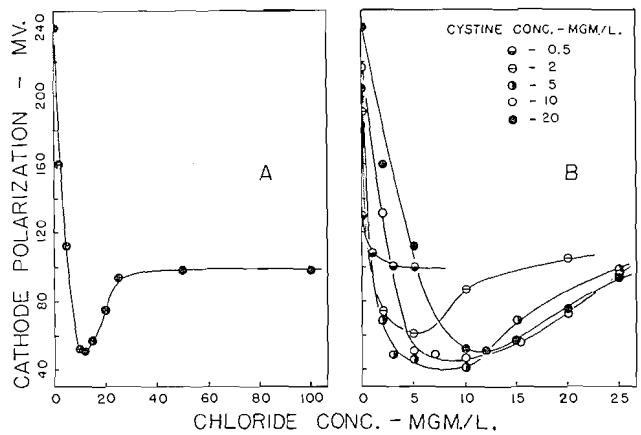

FIG. 5. Steady state cathode polarization – chloride concentration relations for different concentrations of cystine.
A. Effect of wide range of chloride concentrations with 20 mgm./liter cystine.
B. Effects of low chloride concentrations with different amounts of cystine.

It would seem that approximately 40 mv. represents the lower limit to which the polarization may be reduced by chloride in the presence of cystine for the conditions of electrolysis used.

The initial polarization in the presence of cystine and chloride is determined largely by the surface condition of the electrode. This was shown by the following experiment: A solution containing 5 mgm./liter cystine and 10 mgm./liter chloride was electrolyzed (starting with a standard surface electrode), at 2 amp./dm.^{2}, to the steady state polarization of 40 mv. The solution was removed from the cell and the cell thoroughly rinsed with water and standard electrolyte to remove as much adsorbed cystine and chloride as possible. Electrolysis was then resumed with fresh electrolyte of the same composition as in the first electrolysis. During the first electrolysis with a standard surface cathode a sharp decrease in polarization from 92 mv. to a minimum at 65 mv. occurred after two seconds. This was followed by an increase during the next half minute to 110 mv. and a subsequent decrease to the steady state value after about three hours. The second electrolysis showed a small decrease in polarization (55 mv. to 50 mv.) during the first two seconds, which was succeeded by an increase to 70 mv. after 1.5 min., and thereafter by a decrease to the steady state value in about the same time as the first electrolysis. Repetition of the experiment with a steady state surface obtained at a polarization of 105 mv. in electrolyte containing 2 mgm./liter cystine and 20 mgm./liter chloride gave initial polarization values in the second electrolysis that were within 5 mv. of those in the first electrolysis. Evidently, the steady state and standard electrode surfaces were essentially identical in this last experiment.

Concentration polarization at 2 amp./dm.^{2} in the presence of different concentrations of cystine and chloride had the following values:

Cystine conc. (mgm./liter)	Chloride conc. (mgm./liter)	Concentration polarization (mv.)
0.5	1	20
2	20	20
5	5	20
5	10	20
10	50	20
20	0	50
20	1	35
20	10	25
20	12	25
20	20	20
20	50	20
20	100	20

It would appear that the presence of amounts of chloride above the concentrations corresponding to the minima in the steady state polarization – chloride concentration curves reduced the concentration polarization effectively to the value observed in the absence of addition agent.

The effect of acid concentration of the electrolyte on the initial polarization maximum was determined in the absence and presence of cystine, at 2 amp./dm.^{2}, with a standard cathode surface. Not only was the initial maximum polarization a linear function of acid concentration in both systems, but the increase of polarization in the presence of cystine over that in its absence was virtually constant at the different acid concentrations, thus:

Cystine conc. (mgm./liter)	Acid conc. (gm./liter)	Polarization (mv.)		
		Initial max.	Steady state	Concentration
0	25	60	—	
0	50	70	64	25
0	75	77	87	25
0	100	85	99	25
0	150		107	25
20	50	128	203	50
20	75	137	233	50
20	100	146	234	50
20	150	—	235	50

While the steady state polarizations indicate roughly parallel behavior with acid concentration in the presence and absence of addition agent, changes in surface characteristics at the cathode undoubtedly influence these values somewhat. For example, the surface corresponding to the steady state polarization with 50 gm./liter acid, in the absence of cystine, showed microscopically a rough, irregular structure, in contrast to the smoother texture of the initial standard surface.

If the relation between initial maximum polarization and acid concentration is assumed to be linear down to zero acid concentration, the contribution made by acid of a given concentration to the total polarization may be estimated by extrapolating to zero acid concentration and noting the difference between the polarization for zero acid and that at the given acid concentration. This treatment of the data yields a value of about 30 mv. for the contribution by acid to the polarization at a standard cathode surface in electrolyte containing 100 gm./liter acid.

Cathode Polarization in the Presence of Methionine

With methionine alone as addition agent, the initial polarization–time relations, the variation of initial polarization maximum with methionine concentration, and the relations of steady state total and concentration polarization values with methionine concentration, were all quite similar to the corresponding relations when cystine was the addition agent.

When chloride was added in conjunction with methionine, the depolarizing action was immediate, as it was with cystine. However, prolonged electrolysis revealed some differences in the behavior of the two addition agents. In particular, with higher chloride concentrations (5 to 25 mgm./liter) there were no minima in the polarization–time curves with methionine, while at all chloride concentrations the change of polarization to the steady state was slower. The steady state polarization showed the same type of relation with chloride ion concentration as that observed with cystine. The only difference appeared to be that the minimum polarization (again, about 40 mv.) was obtained with 5 mgm./liter, instead of 12 mgm./liter, chloride ion concentration, when the concentrations of the addition agents were 20 mgm./liter.

Cathode Polarization in the Presence of Thiourea

The cathode polarizations obtained with concentrations of thiourea of 3 mgm./liter and lower, though not those with higher concentrations, were found to be very irreproducible. Moreover, they were found to vary considerably with age of the stock solution of electrolyte containing the addition agent, possibly as a result of oxidation by cupric ion. After about 10 days, the solution contained a yellowish precipitate, apparently free sulphur.

Regardless of the age of the electrolyte and with concentrations of thiourea up to 3 mgm./liter, the polarization–time curves consisted of an early low polarization stage (70–90 mv.) followed by an increase, perhaps due to an anodic oxidation product, to a higher value (200–220 mv.) after about one hour electrolysis. The polarization during the initial stage increased at first with age of solution, then decreased to a limiting low value of about 70 mv. after eight days. The higher second stage value was practically eliminated by such aging when the thiourea concentration was 2 mgm./liter or less. When the electrolyte containing 3 mgm./liter thiourea was treated with hydrogen peroxide at room temp, then warmed to decompose excess peroxide, the resulting solution decreased the polarization to a steady state value of 70 mv., unaltered by further electrolysis.

Addition of chloride to freshly prepared electrolyte containing 10 mgm./liter thiourea gave steady state polarization values with a minimum at about 160 mv., corresponding to a chloride concentration of about 2 mgm./liter. (The polarization with 10 mgm./liter thiourea alone was about 240 mv.) With higher chloride concentrations, the deposits had a very rough and nodular structure. The behavior, including the high value of the minimum polarization, is reminiscent of the previous observations with gelatine as the addition agent.

DISCUSSION

The increase in initial polarization maximum, P_{max}, with increased immersion time in the presence of cystine is strong evidence for the prior adsorption of cystine on the copper cathode. The time required to attain a steady state in respect of adsorption is probably increased by simultaneous corrosion at the copper surface. Adsorption prior to electrolysis should, of itself, result in an increase of zero time polarization values with increase of cystine concentration in accordance with an adsorption isotherm type of relation. On the other hand, P_{max} might be expected to include additional polarization due to cataphoretic migration to the cathode of positively charged cystine (or cysteine) when electrolysis is begun. (It may be assumed that cysteine is formed by cathodic reduction.) This, too, should increase with increase of cystine concentration. Hence, the sustained increase of P_{max} in Fig. 3A appears to be reasonable. On the other hand, a maximum in P_{max} with immersion time might be expected, since in these experiments a constant addition agent concentration was used, and the contribution due to cataphoresis should be substantially constant.

The presence of subsequent minimum and steady state polarizations as electrolysis is continued may be explained in the manner suggested previously for the similar behavior with gelatine (10).

The rapid increase of steady state polarization as the cystine concentration is increased might be attributed to adsorption of cystine, with consequent decrease of active area and increase of true current density. Alternatively, it might be due to adsorption of copper–cystine complexes from which copper is discharged with difficulty or not at all. For standard electrolyte and a standard surface, the activation overpotential of 45 to 50 mv.* presumably corresponds to discharge of the aquo-complex. Only by consideration of the effect of chloride does it seem possible to suggest a reason for the increase of polarization in the presence of cystine over that observed in its absence.

From the data presented, it is evident that all but 40 to 50 mv. of the total steady state polarization in the presence of cystine can be overcome by addition of an appropriate amount of chloride. It seems reasonable to assume that this residual polarization is due mainly to concentration polarization plus an overpotential caused by hydrogen ions, acting perhaps as a barrier to approach of the copper ions to the cathode.† Values of these polarizations somewhat less than the 20 mv. and 30 mv. respectively estimated for the standard surface might be expected if the rougher surfaces laid down in the presence of cystine are of larger active area and the true current density therefore less. In this event, there would remain some (probably small) activation polarization at the steady state.

The amount of chloride necessary to give the 40–50 mv. minimum steady state polarization in the presence of cystine reduced the *initial* (one to two

**Determined as the difference between the total polarization (100 mv.) and the sum of the concentration polarization (20 to 25 mv.) and that due to hydrogen ion (30 mv.).*

†Since the increase of polarization due to increased acid concentration was essentially the same in the absence and presence of cystine, it seems doubtful that adsorption of hydrogen ions on the copper surface is responsible for the contribution to polarization made by hydrogen ions.

minutes) polarization to approximately the level (100 mv.) obtained in the absence of addition agent. Since the concentration and hydrogen ion contributions to the 100 mv. polarization are essentially the same (20 mv. and 30 mv. respectively) in the standard electrolyte and in the presence of cystine, the remaining 50 mv. in both cases probably also represents the same activation overpotential for discharge of aquo-complexes. It seems significant that the levels of the initial polarizations, with amounts of chloride capable of yielding minimum steady state polarizations, were but little influenced by the amount of cystine present. This would indicate that the activation overpotential involved is independent of cystine, and this would be true if it involved the aquo-complex.

With a chloride concentration much larger than that necessary to give a minimum steady state polarization (50 mgm./liter chloride with 20 mgm./liter cystine) the *initial* polarization (i.e. after one to two minutes) was some 15 mv. lower than the value for standard electrolyte. This lowering presumably represents a decrease in activation overpotential to about 30–35 mv. This cannot correspond to facilitated deposition from a chloro–aquo-complex since chloride ion (5 to 10 mgm./liter) in the absence of other addition agents increases the steady state polarization by about 15 mv. for the conditions of the present experiments (9). It might, however, represent discharge of a chloro–cystine–copper complex.

On the basis of the data and analysis presented above, the steady state polarization *in excess of about 100 mv.*, due to cystine alone, might reasonably be attributed to an increment (about 30 mv.) in concentration polarization, plus a component of the polarization arising from the obstructive influence of adsorbed cystine or cystine–copper complexes. Virtual elimination of this component of the polarization by chloride might be explained by facilitated electron transfer through an electron bridge, in the manner suggested by Heyrovsky (5), or by the formation of more readily dischargeable chloro–cystine–copper complexes, in accordance with Lyons' views (6, 7). The tendency for the initial activation overpotential in the cystine–chloride system to attain, with excess chloride, a lower value than that corresponding to discharge of the aquo-complex, as discussed previously, gives some support, perhaps, to the second suggestion.

The increment in concentration polarization caused by cystine may be explained if the cystine–copper complex is less readily discharged than the aquo-complex. A reaction of the type

$$\mathrm{Cu(Cystine)}_m^{+2} + 4\ \mathrm{H_2O} = \mathrm{Cu(H_2O)_4^{+2}} + m\ \mathrm{Cystine}$$

would then proceed to the right under kinetic conditions of current flow and be restored to equilibrium when the current is stopped only by further hydrolysis of the cystine complex, corresponding to the observed increment in concentration polarization. Rapid formation of directly dischargeable chloro–cystine complexes on addition of chloride would render formation of aquo-complexes by the above reaction less significant as a factor in maintaining current flow, hence in determining the magnitude of the concentration polar-

ization. With sufficient chloride, the limiting concentration polarization of 20 mv. probably reflects diffusion and convection effects only.

The increase in polarization caused by increasing the chloride concentration above the point of minimum polarization with cystine and methionine may be attributed to accumulation and adsorption of colloidal cuprous chloride on the cathode, as discussed previously for gelatine (8). The delay of about one hour, after electrolysis is begun, before the rise in polarization is noted suggests that the cuprous chloride originates at the anode (1). The magnitude of the overpotential caused by adsorption of cuprous chloride may be estimated by taking advantage of the observation that the surface laid down at 100 mv. *steady state* overpotential in the presence of cystine plus excess chloride was microscopically similar to that obtained at 100 mv. steady state overvoltage in standard electrolyte. If this be taken to indicate that the true current densities were approximately equal in the two systems, a hydrogen ion contribution of about 30 mv. may be ascribed to both polarizations. Also, the activation overpotential for discharge of chloro-cystine complexes at the 100 mv. steady state polarization should have about the same value as that estimated previously (30–35 mv.) for these complexes at a standard surface in the absence of adsorbed cuprous chloride, i.e. from the initial polarization values. These polarization values, together with 20 mv. concentration polarization give, by subtraction from the 100 mv. total steady state polarization, a value of 15–20 mv. for the overpotential due to adsorption of cuprous chloride at the steady state. A similar value is obtained from McConnell's value of 115 mv. for the effect of chloride alone (9), by introducing the hydrogen ion and concentration polarization values given above, together with the previously estimated activation overpotential of 45–50 mv. for discharge of aquo-complexes.

MICROCALORIMETRIC DETERMINATION OF THE CRITICAL CONCENTRATION AND THE MOLECULAR DIMENSIONS OF POLYVINYL ACETATE IN SOLUTION[1]

By Michel Parent[2] and Marcel Rinfret

ABSTRACT

Heats of mixing of polyvinyl acetate fractions with *s*-tetrachloroethane and methanol have been determined for the low concentration region. At the lowest concentrations the graphs of ΔH vs. volume fraction are linear as predicted by the van Laar, Scatchard, and Hildebrand theory. As the concentration increases, an inflection point appears, the enthalpy increment being smaller for a short concentration interval and then resuming its former value up to the limit of the range studied. The position of the critical interval depends on the solvent employed and on the molecular weight of the fraction. An equation, based on Flory's theory, has been developed for predicting the critical concentration from intrinsic viscosity. Assuming that, at the critical concentration, the molecules are just coming into contact, it is possible to calculate the diameter of the sphere equivalent to a molecule. Comparison of the dimensions obtained from the critical concentration and the root-mean-square end-to-end distance of the molecule calculated by the Flory equation leads to agreement within 10%.

INTRODUCTION

The existence in high polymer solutions of a critical concentration, above which the macromolecules are entangled, was first postulated by Staudinger (9). More recently, Boyer and Spencer (1) have made a survey of the literature on the subject and Streeter and Boyer (10) have demonstrated its existence by viscosity measurements on highly dilute solutions of polystyrene. Further microcalorimetric studies of heats of mixing by Daoust and Rinfret (2) and determinations of partial molal volumes by Horth and Rinfret (5) give results in accord with the findings of Boyer and co-workers. The purpose of this paper is to show the dependence of the critical concentration on the nature of the solvent and the molecular weight of the solute. Moreover it will be shown that it is possible to deduce the dimensions of the macromolecule in solution from the critical concentration.

Most high polymers are amorphous and are often considered as very viscous liquids. The enthalpy change in mixing with a solvent is therefore given by the van Laar, Scatchard, and Hildebrand theory (4),

$$[1] \qquad \Delta H_M \doteq \Delta E_M = V_M B \Phi (1 - \Phi) ,$$

V_M being the total volume of mixture, and Φ the volume fraction of the solute. B is a parameter characterizing the net heat of interaction between solute and solvent. According to Scatchard (8),

$$[2] \qquad B = C_{11} + C_{22} - 2C_{12}$$

where C_{11}, C_{22}, and C_{12} are the interaction energies per milliliter (also called

cohesive energy densities) between similar and dissimilar molecules. It can be shown that for similar molecules, the cohesive energy density per milliliter is given by:

[3] $$C_{11} = (\Delta E_v/V)_1 \quad \text{and} \quad C_{22} = (\Delta E_v/V)_2$$

where ΔE_v is the energy of vaporization per mole and V, the molar volume of species 1 and 2 respectively. It has not been possible to calculate C_{12} for dissimilar molecules, and it has been postulated by Scatchard that:

[4] $$C_{12} = (C_{11} \cdot C_{22})^{\frac{1}{2}}.$$

Using [2], [3], and [4] equation [1] can be rewritten:

[5] $$\Delta H_M = V_M\left[\left(\frac{\Delta E}{V}\right)_1^{\frac{1}{2}} - \left(\frac{\Delta E}{V}\right)_2^{\frac{1}{2}}\right]^2 \Phi(1-\Phi).$$

Equation [5] indicates that all heats of mixing are positive. That many mixtures are accompanied by a negative heat evolution shows that the Scatchard postulate [4] is only valid for limiting cases. Where C_{12} is much different from the value given in [4] because of specific interaction between solute and solvent, B can take negative as well as positive values but is still a measure of the net heat of solute–solvent interaction.

Since polymer–solvent interactions take place between a molecule of solvent and an adjacent short segment of polymeric chain, the net energy of interaction should be independent of chain length. This will be shown to be true by the constancy of parameter B over a large range of molecular weights for a given polymer–solvent pair.

EXPERIMENTAL

A polyvinyl acetate fraction of molecular weight 29,000 was available from a previous investigation (2). A sample of Gelva-15, from Canadian Resins and Chemicals Co., of average molecular weight 60,000 was dissolved in 2% acetone solution and precipitated by water into seven main fractions using a method derived from Flory (3). Fractions were kept under vacuum over phosphoric anhydride.

The *s*-tetrachloroethane was of Eastman grade, stored over "Drierite", and distilled before use. Methanol was an acetone-free sample from Brickman Co. and was distilled, at high reflux ratio, in a 35 theoretical plates fractionating column. The microcalorimetric technique was essentially the same as already described (2). An improvement over the results obtained previously was effected by an even greater elimination of evaporation losses and the metallization of the Pyrex calorimeter cells to promote better heat conduction to the thermocouples. These cells were first chemically silvered and then a thin coat of copper was deposited by electrolysis. Intrinsic viscosities were determined with modified Ubbelohde viscometers as described elsewhere (2).

RESULTS

Table I together with Figs. 1–3 shows the heats of mixing of polyvinyl acetate fractions of various molecular weights in methanol and *s*-tetrachloro-

ethane. The values of B given in the table are derived from equation [1] below the critical concentration and from the following equation above the inflection point:

$$[6] \qquad \Delta H_M/V_M = B\Phi(1 - \Phi) + C$$

where C is the parallel displacement of the curve before and after the inflection point, along the $\Delta H_M/V_M$ axis.

The molecular weights of the fractions M_v were calculated from an equation given by Wagner (11) for polyvinyl acetate in solution in acetone at 25° C.:

$$[7] \qquad \log M_v = 1.47 \log[\eta] + 5.519.$$

Table II gives the intrinsic viscosities, at 25° C., of the various fractions of polymer in the two solvents used in this study.

TABLE II

INTRINSIC VISCOSITIES OF POLYVINYL ACETATE FRACTIONS IN METHANOL AND *s*-TETRACHLOROETHANE AT 25° C.

M_v	$[\eta]$ in methanol	$[\eta]$ in *s*-tetrachloroethane
536,000	0.79	2.10
255,000	0.62	1.54
191,000	—	1.00
29,000	0.25	0.42

DISCUSSION

When the results given here are compared with those of Daoust and Rinfret (2) a great improvement is noticed. This must be ascribed to a more elaborate experimental technique, as described above, and to a greater care in reducing impurities in polymer and solvent such as elimination of all trace of moisture. A relatively slight increase in accuracy has shown that the curves of $\Delta H_M/V_M$ vs. Φ such as that of Fig. 4 (of Reference 2, above) were actually straight lines. With this knowledge it was possible to make a better choice of concentrations to be investigated and to reject spurious results due to losses by evaporation and other causes.

Figs. 4 and 5 show the displacement of the inflection point with molecular weight for a poor solvent, methanol, and a very good solvent, *s*-tetrachloroethane. The values of the parameters B and C together with the critical concentration are given in Table III. The accuracy of positioning of the inflection point for the low molecular weight fraction (Fig. 3) is lower than that of the other fractions, but the experimental results (Table I) show that the inflection points are real even if their final position is subject to slight revision. A remarkable feature is that after the inflection point the slope of the curves, B, resumes its former value. Parameter B is also quite constant over the range of molecular weight; any slight change with molecular weight might be ascribed to previous history of the polymer fraction. Similar remarks can be made about C, although here there may be a real effect in the higher value found in both solvents with the 536,000 molecular weight fraction.

TABLE III

PARAMETERS B AND C AND THE CRITICAL CONCENTRATION FOR VARIOUS FRACTIONS IN METHANOL AND *s*-TETRACHLOROETHANE

Solvent	Fraction mol. wt.	Critical volume fraction $\times 10^2$	B, cal. per ml.	C, cal. per ml. $\times 10^2$
Methanol	536,000	0.86	+ 6.9	−0.9
	255,000	1.2_1	+ 7.0	-0.7_5
	29,000	1.9_2	+ 7.2	−0.6
s-Tetrachloroethane	536,000	0.22	−20.9	+0.7
	255,000	0.24	−21.1	+0.4
	191,000	0.35	−20.7	$+0.3_5$
	29,000	1.05	−21.6	$+0.4_5$

As stated in the introduction, parameter B measures the net heat of interaction per contact of polymer segment – solvent molecule times the number of such contacts per segment. Although the total number of contacts between polymer and solvent increases with concentration, B will be essentially constant at low concentrations. At the moment of critical concentration Weissberg, Simha, and Rothman (12) have shown that the random polymer coils would be compressed because of the tendency of a polymer molecule to exclude all others from the space it occupies. Since this phenomenon occurs at only one concentration, it appears as a parallel displacement of the curves and parameter C is not affected by concentration. This effectively amounts to a new spatial distribution of polymer and solvent in the solution. An interesting property of the critical concentration lies in its use in the calculation of the dimension of the polymer molecule in solution. By making the assumption

that at this point each molecule occupies a sphere that has a diameter equal to the end-to-end distance of the chain, this dimension can be calculated. Given A the side of a cube occupied by N_s spheres of diameter D one finds for closed-packed spheres:

$$N_s = 1.41\ A^3/D^3. \quad [8]$$

If $A = 10$ cm. the number of spheres becomes the number per liter. This number N_S is also given by:

$$N_S = (m_c \times N)/M \quad [9]$$

where N is Avogadro's number, m_c, the critical concentration in grams per liter, and M, the molecular weight of the polymer. From [8] and [9], it is found that:

$$D = 13.3(M/m_c)^{\frac{1}{3}}\ \text{Å}. \quad [10]$$

The dimensions obtained from equation [10] are given in Table IV where they are compared with the value of $(\overline{r^2})^{\frac{1}{2}}$, the root-mean-square separation of

TABLE IV

MOLECULAR DIMENSIONS OF POLYVINYL ACETATE IN SOLUTION AT 25° C.

Solvent	Fraction mol. wt.	D in Å equation [10]	$(\overline{r^2})^{\frac{1}{2}}$ in Å equation [11]
Methanol	536,000	500	580
	255,000	350	420
	29,000	140	150
s-Tetrachloroethane	536,000	790	810
	255,000	600	570
	191,000	480	450
	29,000	180	180

polymer chain ends from Flory's equation:

$$(\overline{r^2})^{\frac{1}{2}} = (M[\eta]/\phi)^{\frac{1}{3}}\ \text{cm}. \quad [11]$$

where ϕ is a universal constant derived by Kirkwood and Riseman (6), who found the value 3.6×10^{21}, and recently determined experimentally by Newman, Krigbaum, Laugier, and Flory (7). Their best value is given as 2.5×10^{21}.

Concordance of the two methods in Table IV for calculating molecular dimensions is good enough to suggest equating D and $(\overline{r^2})^{\frac{1}{2}}$ to give:

$$13.3(M/m_c)^{\frac{1}{3}} = (M[\eta]/\phi)^{\frac{1}{3}} \times 10^8 \quad [12]$$

and therefore:

$$m_c = 5.9/[\eta] \quad \text{and} \quad [13]$$

$$\Phi_c = 5.9 \times 10^{-3}/(d_p \times [\eta]) \quad [14]$$

where Φ_c is the critical volume fraction and d_p the density of the polymer.

Because of the differences between D and $(\overline{r^2})^{\frac{1}{2}}$ in Table IV, this equation should be taken as a semiquantitative guide to the value of the critical concentration, until further investigation.

SOME THERMODYNAMIC CONSIDERATIONS OF SURFACE REGIONS

SURFACE TENSION, ADSORPTION, AND ADSORPTION HYSTERESIS[1]

By E. A. Flood

ABSTRACT

Thermodynamic conditions for equilibrium between bodies which exert forces upon one another are discussed. The two bodies are treated as assemblies of infinitesimal volumes of pure components and the influence of the mutual potential fields examined. The results provide a thermodynamic description of surface tension and certain types of adsorption phenomena, as well as throwing considerable light on adsorption hysteresis.

INTRODUCTION[2]

In general where any two bodies are in contact with one another, they exert forces upon each other, usually only the very short range forces being of importance thermodynamically. As a consequence of these short range forces, when considering equilibria within the interfacial region, we cannot "regard as immaterial the position . . . of the various homogeneous parts of which . . ." each body is composed, as done by Gibbs (7) in deducing the phase rule. In general, these short range forces give rise to potentials of position.

The influence of these potentials on the thermodynamic conditions for equilibrium may be treated formally, in much the same way as the influence of the gravitational potential is treated. However, in the case of the gravitational potential, the force function of the field is treated as though it is independent of the state of the substance, while in the case of the interaction between two bodies, the "potential" is almost certainly influenced by the state

[1]*Manuscript received January 21, 1955.*

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3581. An Abstract of this paper was presented at the Symposium on Problems Relating to Adsorption of Gases by Solids at Kingston, Ontario, September 10–11, 1954. The text of the paper presented at the Symposium appears in the special issue of the Canadian Journal of Chemistry covering the Symposium (5).

[2]*A primary object of this enquiry is to obtain some insight into the physical factors which control rates of flow of fluids through porous adsorbents. The author is greatly indebted to Dr. Otto Maass of McGill University for encouragement and assistance in the pursuit of this problem.*

In the case of adsorption of condensable gases, liquid–vapor interfaces as well as solid–vapor interfaces are to be expected. Accordingly, it is necessary to know something of the natures of these surface regions in order to discuss "surface" flow mechanisms.

Evidence has been presented previously that where adsorbates are contained within pores which are fairly large compared with molecular dimension (10^{-7} to 10^{-5} cm.) adsorbates may be regarded as Polanyi compressed films, and that flow mechanisms of such films are essentially those of classical laminar flow, but flow rates are controlled by density and pressure gradients (both normal and parallel to the direction of flow) that are functions of the surface forces. These adsorbate gradients are very different from the directly observable or applied "gradients" of the gas outside the range of the surface forces. Generally adsorbate gradients are not directly observable and must be measured indirectly or inferred from measurements of adsorbate densities, surface tensions, surface energies, or other measurable average properties. Where we can determine adsorbate density gradients and can assume that the adsorbate behaves as a single substance, we can calculate corresponding pressure gradients, and make considerable progress in relating net flow rates to the physical structure of these fine grained porous adsorbents; while where the adsorbate cannot be regarded as a single component fluid the problem of correlating the permeability with the structure of an adsorbent, if at all possible in any literal sense, is much more complex.

of the bodies in contact (i.e., the potential of position may be a function of the density, pressure, and temperature as well as of the mass).

When two bodies of different kinds of matter are in contact with one another, the different kinds of material will eventually diffuse into one another to a greater or lesser degree, and the whole system everywhere must be regarded ultimately as a two component system. However, there are many cases where these diffusive processes are so slow, or where the equilibrium states are such, that the two bodies, including the interfacial regions, may be regarded as two distinct volumes each consisting of a single component. Evidently we must assume in such cases that the surface "potential" is such that, as the "boundary" of one of these volumes of pure component is approached, very strong repulsive forces are called into play ultimately limiting the density of this component to vanishing values (i.e. preventing interpenetration). When the two bodies in contact are more or less rigid solids, the short range surface forces acting between the bodies will give rise to states of stress in the interfacial regions which differ from those prevailing throughout the bulk phases. These states of stress will be accompanied by deformations, or states of strain, in the interfacial region which will result in small over-all deformations of the two bodies as they are brought into contact. If, however, one of the bodies is a highly compressible fluid, the density of the fluid in the interfacial region will be very materially influenced by the surface forces, resulting in comparatively large changes in volume of the compressible fluid as a result of its being brought into contact with the solid, i.e., adsorption will occur.

Thus we may consider the whole of the volume of the compressible fluid (or gas) as constituting a single component system bounded by regions of complex potential fields which are functions of the pressure, temperature, and natures of the gas and solid.

We confine our interest to cases where all the material of the compressible component in the interfacial region is fluid, and we shall inquire into the thermodynamic conditions for equilibrium which must prevail in such complex single component fluid systems. While the thermodynamic conditions for equilibrium in constant potential fields are discussed in standard texts, the thermodynamics of the more general case where the force function of the field may depend on the density, pressure, and temperature of the fluid has been largely ignored.

In Part I of what follows, we present some general thermodynamic considerations of the equilibrium conditions which must prevail in complex single component fluid systems; in Part II, these ideas are applied to surface tension problems; and in Part III, they are applied to gas adsorption problems.[3]

It is shown that these ideas lead to a plausible detailed thermodynamic description of surface tension phenomena, and that in the case of adsorption phenomena, they predict results capable of experimental verification.

[3]*When applied to adsorption theory, the thermodynamic considerations lead to what is essentially a Polanyi (14) adsorption potential theory, but where the "potential" of the surface is variable, i.e., is a function of the equilibrium pressure of the gas, the density of the adsorbate, etc., thus providing for so-called "co-operative effects".*

I. SINGLE COMPONENT COMPLEX FLUIDS

Thermodynamics is, strictly, a science of observable quantities and hence is a science dealing with the properties of matter in bulk. Accordingly, the validity of the assigning of thermodynamic properties to elementary volumes of material is open to question.

Tolman (19) in his theory of surface tension treats elementary laminar volumes as thermodynamic systems and discusses the validity of such treatments. When we consider the pressure gradients, energy gradients, etc. of a gas in a gravitation field, we assume that such gradients are continuous. Thus we tacitly assume that laminae of infinitesimal dimensions have thermodynamic properties. It is evident that when we deal with helium we may take as the thickness of a lamina a dimension considerably less than that of the diameter of the spherical molecule, only those molecules whose centers of mass lie within the lamina being considered as "contained" within the elementary laminar volume. In this way it is quite possible to construct statistical model fluids that are very accurate descriptions of real gases, and which are equally applicable to infinitesimal volumes and to large finite volumes, equally applicable to volumes small or large compared with molecular dimensions. If the fluid molecules are dipoles and may be subject to orientation in a field, the situation is somewhat more complex and it might seem that we must consider adjacent laminae as consisting of different "kinds of material" as would be the case in an ionic crystal. In the latter case the long range order is a permanent condition, a state of the system, and even after very long periods of time, neighboring elementary laminar volumes cannot be regarded as consisting of the same substance, i.e., they are not reversibly convertible into one another by any ordinary sort of thermodynamic process (e.g., layers containing almost wholly chloride ions and layers containing sodium ions are not thermodynamically interconvertible). If, however, any orientation forces can be resolved into forces and couples acting on and about molecular mass centers, a statistical model fluid can be constructed such that elementary volumes regardless of size can be regarded as elementary thermodynamic systems containing the same component as the whole assembly of elementary volumes. Without looking more closely into statistical details of such problems, we shall define a single component fluid complex as follows: an assembly of elementary fluid volumes, where every elementary volume is thermodynamically identical with an equal elementary volume of a single fluid in some bulk state, the bulk state being in reversible equilibrium with externally applied forces no matter how bizarre these forces may be. Thus the state of each elementary volume corresponds exactly to a bulk state of a single substance under specific external forces. All the elementary volumes are thus inherently capable of reversible thermodynamic conversion into another. Since we will be mainly concerned with fluids, we shall assume that pressures of elementary volumes are equal in all directions and that all pressure, energy, density gradients, etc. are continuous. The forces transmitted across boundaries of adjacent elementary volumes are necessarily equal.

Thermodynamic Equilibria in Single Component Complexes

When two bodies exert forces upon one another, the energy associated with separating them is not strictly a property of either body alone. However, we may arbitrarily fix the energy of one of these bodies and consider it as being in a reference state and accordingly assign the energy of separation to the second body. This is the normal procedure when considering equilibrium in a force field. Since in the usual derivations of the conditions for equilibrium in force fields the force field is assumed independent of the state of the body, it is necessary to re-examine the equilibrium when the potential of position of unit mass may be a function of the volume of the mass.

The condition that changes in thermodynamic states of a system under the action of external forces shall be reversible is that the heat received by the system during such changes shall be equal to the change in the energy of the system plus the maximum work which the system can do against the external forces if such a maximum exists. When no potential of position is involved and the only work is associated with a change in volume, this condition for reversibility is expressed by the well-known equation

$$dE_0 = TdS - pdv + \mu_0 dm$$

where E_0 is the intrinsic energy, T the temperature, S the entropy, p the pressure, v the volume, μ the intrinsic thermodynamic potential, and m the mass.

When a "potential" of position is involved we can write
where

$$[1] \quad dE = dE_0 + d\omega = TdS - pdv + \mu_0 dm + d\omega$$
$$= TdS - pdv + \mu_0 dm + \Omega dm$$
$$= TdS - pdv + \mu_0 dm + \frac{\partial}{\partial m}\int_{x_0}^{x} f(x)\, dx \,.\, dm$$
$$= TdS - pdv + \mu dm$$

where
$$d\omega = \Omega dm = \frac{\partial}{\partial m}\int_{x_0}^{x} f(x)\, dx \,.\, dm,$$

and $(\partial/\partial m)\int_{x_0}^{x} f(x)dx$ represents the maximum or reversible work associated with moving unit mass at constant S and v from the initial position x_0 to the final position x. This work is assumed dependent only on the initial and final positions in the potential field. Such fields are sometimes referred to as scalar fields. It is implied that in the reference state corresponding to x_0, $f(x)$ is zero. Other relations expressed by the equations are self-explanatory.

By definition of the single component complex, Equation [1] is applicable to every element of volume of the assembly, and accordingly an equation of similar form is applicable to assemblies of these volumes. The conditions for equilibrium between these volumes will depend upon the physical conditions assumed applicable within the complex, or between elements of the complex and a reference volume. Since the complex is essentially a fluid mass, heat and

matter may be assumed to be in a state of flux between the various parts. Accordingly we assume the following physical conditions: (*a*) increments of heat-energy and mass, independently, may flow in to or out of any of the volumes concerned, (*b*) no work is involved in the transport of entropy through finite distances, (*c*) the transport of mass through finite distances involves performance of work against the force function of the field. With these conditions, following exactly the method of Gibbs, it can readily be shown that the necessary and sufficient conditions for equilibrium throughout the complex are: (*a*) uniformity of temperature, (*b*) uniformity of total potential per unit mass, μ or $\mu_0+\Omega$. Evidently the existence of potentials of position that may be functions of the volume as well as of the mass of the substance concerned does not change the basic equilibrium conditions applicable to systems in constant potential fields.

Equation [1] may be written in the form

$$\begin{aligned} dF &= -SdT+vdp+\mu_0 dm+\frac{\partial}{\partial m}\int_{x_i}^{x} f(x)\,dx\,.\,dm \\ &= -SdT+vdp+\mu dm \end{aligned}$$

where $F = E-TS+pv$ and $\mu = \partial F/\partial m = \partial E/\partial m$, etc.

Assuming that $F(T, p = 0, x, m = 0) = 0$ and that $\int_{x_0}^{x} f(x)dx = 0$ when $m = 0$, we can write for the potential F of any mass m of fluid at any position x under any pressure p,

$$F = \int_{p=0,m=0}^{p,m} (vdp+\mu dm),$$

the path of integration corresponding to increasing the mass of material at some position x while v, p, and μ take particular values for various values of m.

We suppose that the complex is in equilibrium with a bulk reference fluid of uniform properties, and that the complex remains in reversible equilibrium with the bulk reference fluid throughout a path where the density and pressure of the reference fluid vary from zero to specified values.

Assigning the value x_0 to the bulk reference state and the value x_{ai} to the ith element of the complex, we can write for equal masses of material at x_0 and x_{ai}

$$F_0(p_1, m_i, x_0) = \int_{p=0,m=0}^{p=p_1,m=m_i} (vdp+\mu_0 dm),$$

$$F_{ai}(p_{ai}, m_i, x_{ai}) = \int_{p=0,m=0}^{p=p_{ai},m=m_i} (vdp+\mu_{ai}dm),$$

and $F_0 = F_{ai}$ and $\mu_0 = \mu_{ai}$ throughout the path of integration. Also we may write

$$F_{ai} = \int_{p=0,m=0}^{p=p_1,m=m_i} (vdp+\mu_0 dm)+\int_{p_1,x_0}^{p_{ai},x_0} vdp+\int_{x_0,p_{ai}}^{x_{ai},p_{ai}} f(x)\,dx$$

where

$$\int_{p_1,x_0}^{p_{ai},x_0} vdp + \int_{x_0,p_{ai}}^{x_{ai},p_{ai}} f(x)\,dx = \int_{p_1,x_{ai}}^{p_{ai},x_{ai}} vdp + \int_{x_0,p_1}^{x_{ai},p_1} f(x)\,dx.$$

It will be noted that $\int_{p_1,x_0}^{p_{ai},x_0} vdp$ is not necessarily equal to $\int_{p_1,x_{ai}}^{p_{ai},x_{ai}} vdp$. When they are equal, the equation of state (v of p, T constant) is independent of the field. When the integrals are not equal, the force function of the field is a function of v.

We may suppose the uniform reference fluid broken up into elementary volumes δv_i of mass δm_i equal to the mass of each elementary volume of the complex δv_{ai} at x_{ai}. For the equilibrium between these elementary volumes, the x coordinates remaining constant while δm_i and the pressures vary, we have

$$\delta v_{1i} \cdot \delta p_1 + \mu_0 dm_i = \delta v_{ai} \cdot \delta p_{ai} + \mu_{ai} dm_i,$$

and since $\mu_0 = \mu_{ai}$,

$$\sum_i \delta v_{ai} \cdot \delta p_{ai} = \delta p_1 \cdot \sum_i \delta v_{1i} = \frac{\delta p_1}{\rho_1} \sum_i \delta v_{ai} \cdot \rho_{ai}.$$

Therefore

$$v_a \delta \bar{p}_a^{\,v} = v_a \bar{\rho}_a \cdot \frac{\delta p_1}{\rho_1}$$

where the density of the uniform reference fluid is ρ_1, and $\rho_1 = \delta m_i/\delta v_{1i}$. Hence

$$[2] \qquad \bar{p}_a^{\,v} = \int_{p=0,m=0}^{p=p_1,m=m} \bar{\rho}_a/\bar{\rho}_1 \cdot dp_1.$$

Thus the volumetric mean pressure $\bar{p}_a^{\,v}$ can be determined if the volumetric mean density $\bar{\rho}_a$ is known as a function of p_1, i.e., if m and v_a are known functions of the pressure, p_1, of the reference gas along a path of thermodynamic reversibility where the equilibrium pressures vary from zero to p_1 while m varies from 0 to m.

It will be noted that since $\bar{\rho}_a$ and ρ_1 are positive, $\bar{p}_a^{\,v}$ is necessarily positive for any path of thermodynamic reversibility where the equilibrium pressure increases from zero to p_1. If, however, other paths of thermodynamic reversibility intersect this path at points below p_1, say at p_1', so that if the pressure of reference fluid is raised from zero to p_1 and then reduced to p_1'' below p_1', the system may follow the second path from p_1' to p_1'' and

$$\bar{p}_a^{\,v} = \int_0^{p_1} \frac{\bar{\rho}_a}{\rho_1} \cdot dp_1 + \int_{p_1}^{p_1'} \frac{\bar{\rho}_a}{\rho_1} dp_1 + \int_{p_1'}^{p_1''} \frac{\bar{\rho}_a'}{\rho_1} dp_1$$

$$= \int_0^{p_1'} \frac{\bar{\rho}_a}{\rho_1} \cdot dp_1 - \int_{p_1''}^{p_1'} \frac{\bar{\rho}_a'}{\rho_1} \cdot dp_1.$$

If the second integral is larger than the first, $\bar{p}_a^{\,v}$ may be negative.

When $\bar{\rho}_a > \rho_1$, $\bar{p}_a^{\,v} > p_1$ and the potential of position of the reference fluid is greater than the average potential per unit mass of the complex.

The mean "potential" difference between the complex and the reference fluid may be expressed by

$$\sum_i \frac{p_{ai}-p_1}{\overline{\rho_{ai}}|_{p_1-p_{ai}}} \cdot \rho_{ai} \cdot \delta v_{ai} = -\omega$$

where $\overline{\rho_{ai}}|_{p_1-p_{ai}}$ is the mean density of the reference fluid over the pressure interval p_1 to p_{ai}. Thus

$$\omega = cv_a(p_1-\bar{p}_a{}^v)$$

where c is a dimensionless positive quantity. If $\bar{p}_a{}^v > p_1$, $c \geqslant 1$. If the material is incompressible in all of the ranges p_1 to p_{ai}, $c = 1$. In general ω will be dependent on the distribution function, $v(\omega)$, of the complex and upon the equation of state of the reference fluid. It will be noted that $\Omega(x_{ai}-x_0, p_1)$ is not necessarily the same as $\Omega(x_{ai}-x_0, p_{ai})$. Thus in general we cannot determine ω when $\bar{p}_a{}^v$ can be determined unless the fluid is incompressible in the various pressure intervals p_1 to p_{ai}. If the reference fluid is a condensable gas and p_1 is above the saturation pressure, that is p_1 is the pressure of the reference liquid, then if the liquid is practically incompressible, we can obtain a measure of ω, i.e., $\omega = v_a(p_1-\bar{p}_a{}^v)$.

Phase Rule Considerations

We have assumed that each elementary volume or lamina is thermodynamically identical with equal elementary volumes of the fluid in some bulk state. Accordingly elementary volumes having the same p, T, and μ but different densities are to be regarded as different phases in the sense of the phase rule. However, the fundamental thermodynamic equation has in addition to S, v, and m one more variable, namely, that measuring the force function of the field, $f(x)$. When v of p (T and m constant) is not influenced by $f(x)$, if the potential of position $\Omega(x-x_0, p_1)$ vanishes at three values of x in the surface region, and the corresponding laminae have three different densities for given values of T, p, and μ, the system will be invariant in the sense of the phase rule. But if the relation between v and p is influenced by $f(x)$, then where $f(x)$ is not zero, the density of a fluid lamina for given values of p may differ from the density where $f(x)$ is zero. Since $\Omega(x-x_0, p_1)$ may vanish for some value of x for which $f(x)$ does not vanish, we may have $\Omega(x-x_0, p_1)$ zero for three values of x, while $f(x)$ is zero for only two of these values. Under these circumstances, we may have two density states corresponding, say, to normal liquid and vapor, and a third density state where $f(x)$ is large, while the system is still monovariant in the phase rule sense.

We cannot, in general, suppose a fluid divided into laminae and treat the "spreading pressure" of each layer as an independent variable in order to calculate the phase "variance". However, when a force field is involved p_{at} will in general differ from p_1 and may be regarded as constituting a measure of the potential of the field and of $f(x)$ (cf. Rowley and Innes (16)).

In Part II of this paper the interface between a liquid and vapor of a single substance will be treated as a single component complex and in Part III the boundary of a fluid or gas in contact with a solid of a different kind of substance will be similarly treated. While both cases are essentially similar, in the former

case both bulk phases consist of a single component while in the latter case the two bulk phases are different components. In both cases surface forces are assumed to be classical.[4]

II. SURFACE TENSION

The Liquid–Vapor Interface, A Single Component Complex Fluid

Consider a liquid separated from its vapor by a flat interface. Far from the interface the net hydrostatic pressures of the liquid and of the vapor are the same and are, of course, positive. The interfacial region, however, exhibits a tension, and accordingly negative pressures or negative stress intensities are to be expected in this region. If following Tolman (19) we think of the interface as made up of very thin laminae parallel with the surface and if we suppose the material constituting these laminae to be fluid so that stress intensities acting on elementary volumes (i.e., laminae) are equal in all directions, we must suppose a sharp pressure gradient to exist along the normal to the surface, the gradient vanishing within the body of the liquid and within the vapor.

Let $p(x)$ be the pressure of the fluid as a function of x, where x is the distance along a normal to the surface, measured from liquid to gas. If h is the thickness of the interface, the thickness of the region wherein $p(x)$ varies with x, then $\int_x^{x+h} p(x)\,dx \equiv \bar{p}(x)\cdot h$ is the net parallel surface force exerted by unit area of the surface region, and $\bar{p}(x)$ is the mean value of the stress intensities exerted by the various laminae parallel with the surface. If $\bar{p}(x)$ is negative, $-\bar{p}(x)\cdot h$ is literally a positive "surface tension". The work done by the surface system when the surface of area σ is increased by $d\sigma$, the thickness remaining constant, is, of course, $\bar{p}(x)\cdot h\cdot d\sigma$. Hence the corresponding Helmholtz free energy change is given by $(\partial A/\partial\sigma)_{T,h} = -\bar{p}(x)\cdot h = \gamma$. Thus, this "surface tension", γ, is unambiguously the Helmholtz free energy per unit surface.

It may be remarked that considerable confusion (18) exists in the literature dealing with the relations between "surface tension" and "surface free energy". This confusion arises partly from following Lewis and Randal (11) and equating the change in Gibbs free energy, F (where $F = E - TS + pv$), of the surface to the work of stretching the film, i.e., in writing $dF_T = \gamma d\sigma$ instead of

[4]*If the energy states of molecules of the fluid with respect to the surface force field are continuous and the distribution of these states largely classical in character, the detailed structure of all of the energy states at a given temperature will be largely characteristic of the fluid in some bulk state. Accordingly, fluid laminae under the influence of such fields will behave as a single substance in the sense that laminae of the bulk states of fluid can exist in equilibrium with external forces in states that are thermodynamically practically identical with corresponding laminae in the force field. However, when the energy states of the molecules in the surface layers are quantized and the surface forces large, the detailed structure of the energy states at any given temperature may be quite different from those of any bulk state of the pure fluid. Accordingly, laminae under the influence of such potential fields will not behave as the same substance, thermodynamically, as the bulk fluid, and the assembly of surface laminae cannot be treated as an assembly of volumes of a single component.*

A pure component of a chemical compound or of a solution is, in general, capable of reversible transformation with the same substance in the compound or solution. For such a process $\Delta F = 0$, but ΔA, ΔE, $\Delta S \neq 0$. For the special case of an ideal gas solution where each gas behaves as a vacuum to each other gas ΔF, ΔA, ΔE, $\Delta S = 0$ but $\Delta v \neq 0$, $\Delta\bar{p}^v \neq 0$. When ΔF, ΔA, ΔE, ΔS, Δv, $\Delta\bar{p}^v$, etc. $= 0$ the forces of interaction between the bodies in the combined system take the place of the external forces of the pure components. The latter case may be called "mechanical" or "physical" interaction, as distinct from the first case of "chemical" interaction and from the second case of pure "solution".

equating the Helmholtz free energy to this work, i.e., instead of writing $dA_T = \gamma d\sigma$.[5] However, these difficulties are due mainly to the fact that some authors treat the surface as an isolated thermodynamic system distinct from the material lying on either side of it, while others define surface tension by $(\partial A/\partial\sigma)_{T,v} = \gamma$ where the operation $(\partial A/\partial\sigma)_{T,v}$ is applied to systems containing surfaces and bulk material. Thus in the latter case, a distortion of a solid at constant volume would yield a "surface free energy" or "surface tension" quite different from the "surface tension" that would be obtained if the process $(\partial A/\partial\sigma)_{T,v}$ corresponded to increasing the number of crystals while decreasing their size, their shapes remaining constant. In the case of liquids with flat surfaces, if $(\partial A/\partial\sigma)_{T,v}$ corresponds to the process of changing the shape of the container of a liquid–gas system so that the surface area of the interface is increased while the volume remains constant,

$$(\partial A/\partial\sigma)_{T,v} = [\bar{p}(x) - p_0]\, h$$

where p_0 is the vapor pressure of the liquid. Evidently the operation $(\partial A/\partial\sigma)_{T,v}$ applied to a system containing surfaces and bulk material does not in general constitute a measure of a definite quantity, the operation being capable of yielding a variety of "surface tensions" depending upon further particulars not specified by the operation.

In the case of a liquid the actual net force of the surface tension is one of its most striking characteristics and is directly measurable. In most cases the methods of measurement of the surface tension of a liquid correspond closely to the operation $(\partial A/\partial\sigma)_T$ applied to the surface layer only. Accordingly, in what follows we shall consider that surface tension is the net parallel mechanical force actually exerted by the surface. Thus we put $-\bar{p}(x) \cdot h = \gamma$.[6]

In general, if a surface has an energy per unit surface area, under equilibrium conditions the surface energy will be a minimum consistent with its entropy. Thus the flat surface will not be quite smooth, but will have a somewhat greater area than the flat surface, the excess area corresponding to the thermal energy of motion of the surface as a whole. In the absence of gravitational and other external fields, changes in position of the interface will have no effect on the equilibrium within the systems. If we suppose the surface region divided into geometrically flat elementary laminae parallel with the mean position of the surface region and of area equal to the apparent area of the "flat" interface separating a liquid from its vapor, the assembly of laminar

[5] *Replacing pv by $\bar{p}(x).h.\sigma$ then for the surface system only, $dw = \bar{p}(x).h.d\sigma$, $dA_T = -\bar{p}(x).hd\sigma$, $dF_T = h.\sigma.d\bar{p}(x)$, and if $\bar{p}(x)$ is constant, $dF_T = 0$. Thus increasing the area of a flat surface is, formally, exactly equivalent to increasing the volume of a phase in equilibrium with other phases. If a system consists of bulk phases and surface phases so that the potential per unit mass is given by $\mu = E - TS + pv - \gamma\sigma$, etc., we should write $dF = -SdT + vdp - \sigma d\gamma$, and when T, p, and γ are constant, $dF = 0$ irrespective of any work done when stretching the surface or when increasing the volume.*

[6] *Some writers regard the "surface tension" as a fiction but regard the surface free energy as real. This is much like regarding the pressure of a gas as a fiction but its thermodynamic potential as real (1). In the case of ionic substances "surface free energy" phenomena might be exhibited by very marked gradients in electrical charge density and corresponding gradients in mass density. In this case mechanical stress gradients in the surface regions might be quite negligible and the actual "surface tension" practically zero.*

volumes will constitute, thermodynamically, a single component complex as defined in Section I above. Evidently all of the thermodynamic relations applicable to the single component fluid complex are applicable to liquid–vapor systems including the interfacial regions when these interfacial regions are fluid throughout.

It will be noted that, in general, the mean pressure of laminae within the interfacial region will be negative if the surface tension is positive. If we regard the vapor as the reference fluid and the interfacial region as the complex, the interfacial region cannot be formed reversibly along a constant temperature path of increasing pressure of the reference gas. Thus if we fill a fixed volume with vapor of a condensable substance and increase the pressure until a liquid–vapor interface is formed, if the interface is of finite dimensions and has a positive surface tension, some irreversibility is involved in the process (cf. p. 984). However, we may suppose the volume filled with vapor above the critical temperature and then cooled reversibly so that the meniscus can form reversibly. Along this path $\bar{p}_a{}^v$ and $\bar{p}(x)$ can become negative reversibly. To form a strictly flat interface by such a process in the absence of other sources of potential, it would appear necessary that the fixed volume be of infinite size. Accordingly, in the absence of condensing surfaces the formation of the flat meniscus by a strictly reversible process would appear to be experimentally unattainable. However, a spherical drop could be formed by such a process at constant volume. Of course, as pointed out by Gibbs (7) curved surfaces of tension cannot be in, strictly, stable reversible equilibrium with any source of constant pressure, in the absence of condensing surfaces or other sources of potential.

Thermodynamic Description of a Fluid Liquid–Vapor Interface

Writing $\Omega(x)$ as the potential of position as a function of the distance x along the normal to the surface, we may take $\Omega(x)$ as zero within the body of the liquid far from the interface. Evidently $\Omega(x)$ must become positive in regions of negative pressure and finally vanish in the interior of the vapor. Accordingly, $\Omega(x)$ must have at least one maximum. Since

$$\frac{dF}{dx} = v\frac{dp}{dx} + \frac{d\Omega}{dx} = 0,$$

$$v\frac{dp}{dx} = -\frac{d\Omega}{dx} = f(x)$$

everywhere along the normal to the surface. When $\Omega(x)$ is a maximum or a minimum $f(x)$ and dp/dx are necessarily zero. Further, as before, taking h as the thickness of the surface region, i.e., the region where $\Omega(x)$ may differ from zero,

$$\int_0^h \frac{dp}{dx}\,dx = \overline{\frac{dp}{dx}} \cdot h = 0$$

for flat surfaces, and also

$$\int_0^h f(x)\,dx = \int_0^h v\frac{dp}{dx}\,dx \equiv \overline{v \cdot \frac{dp}{dx}} \cdot h = 0.$$

The latter two necessary conditions impose a considerable constraint on possible forms of $\Omega(x)$, $p(x)$, and $v(x)$. Thus, if $\Omega(x)$ has only one extreme value and that a maximum at x_m, $0 < x_m < h$. Then since the specific volume $v(x)$ increases by large factors as the vapor is approached from the liquid and the mean value of $v(x)$ on the liquid side of x_m (i.e., in the range 0 to x_m) is less than that on the vapor side of x_m, it follows that the specific volume on the liquid side of x_m must rise to greater values than on the vapor side. Hence, the rapid increase in volume must occur mainly on the liquid side of x_m. The point x_m is the point at which $\Omega(x)$ is a maximum and $p(x)$ a minimum; accordingly in this case the minimum pressure must occur in the region where $v(x)$ is large, i.e., in regions where densities are comparable with vapor densities. The relations are illustrated in Fig. 1. From physical considerations dilute gases cannot exert negative pressures. Accordingly, the relations illustrated in Fig. 1 could only apply to systems where gas densities were relatively high and/or surface tensions small or negative. (If $\bar{p}(x)$ is less than p_0, the system will exhibit "surface tension" behavior, but if $\bar{p}(x)$ is positive the surface tension is negative.) Evidently, in cases where surface tensions are high and vapor densities much less than liquid densities $\Omega(x)$ cannot have the simple form indicated in Fig. 1. In the case of the flat interface where the bulk liquid and vapor have equal pressures, if $\Omega(x)$ has more than one extreme value in the interval $0 < x < h$, there must be at least three equal values of $p(x)$ in this interval. Thus, there must be at least three laminae having different densities but equal values of T, p, and μ. Accordingly, $(\partial F/\partial p)_x$ must be a function of x; i.e. the "equation state" must be influenced by the force field. Otherwise the system would be invariant in the sense of the phase rule (cf. I, p. 985). In Fig. 2*A* the relations between the various functions are shown, assuming $\Omega(x)$ to have the simplest form consistent with a positive surface tension, and $v(x)$ to have a plausible maximum and minimum.

It will be noted that whatever the shape of the curve $\Omega(x)$, if $f(x)$ is positive for any value of x in the interfacial region it must also have negative values. Thus, if material is attracted toward the liquid on the liquid side of the x_{m_1}, it must be repelled from the liquid somewhere in the region $x_{m_1} \leqslant x \leqslant h$. Some authors treat the surface forces as though a net thermodynamic potential difference existed between the liquid and its vapor.

The relations indicated in Fig. 2*A* correspond physically with a case where the "interface" adsorbs its own vapor, i.e., both the density and pressure rise as the interface is entered from the vapor. These relations are consistent with some statistical mechanical descriptions of an interface (20). It is not, of course, necessary from thermodynamic considerations alone that $v(x)$ have a maximum and a minimum.

The $v(x)$ curve as drawn is intended to suggest that in order for molecules to enter the more or less close packed liquid structure some selection is involved resulting in a reduction in density of the "transition" laminae. In the case of very dense liquids this "surface" might behave very much like a solid surface and allow only limited penetration, i.e., a comparatively large percentage of the molecules "striking the surface" would be reflected.

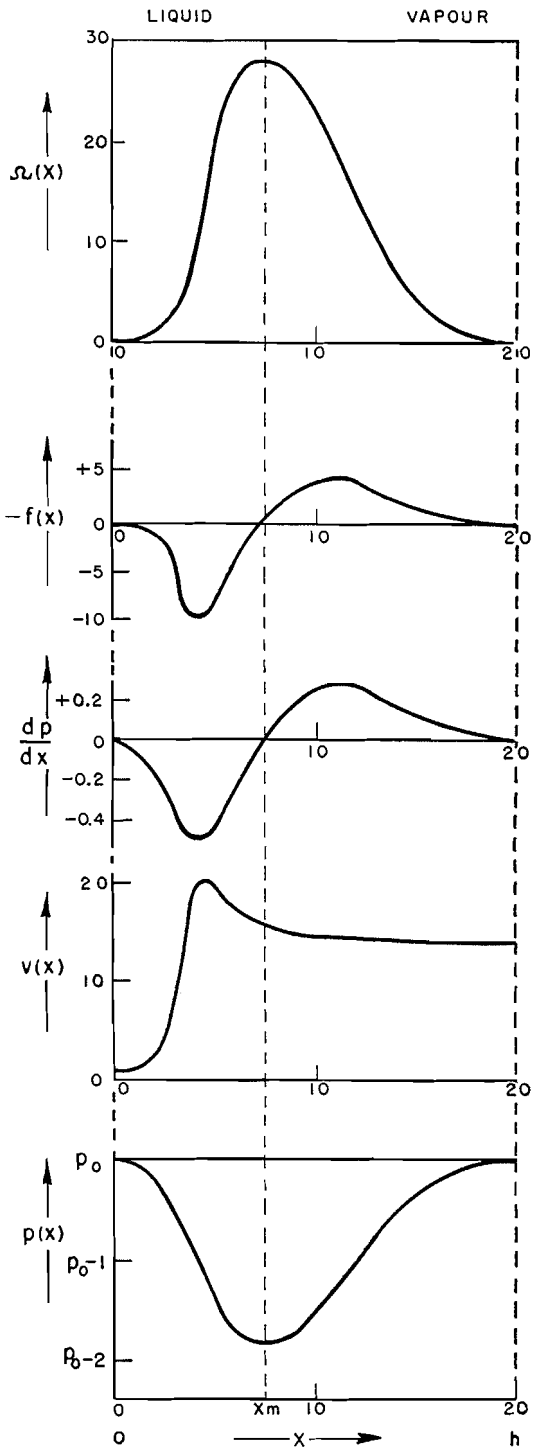

FIG. 1.

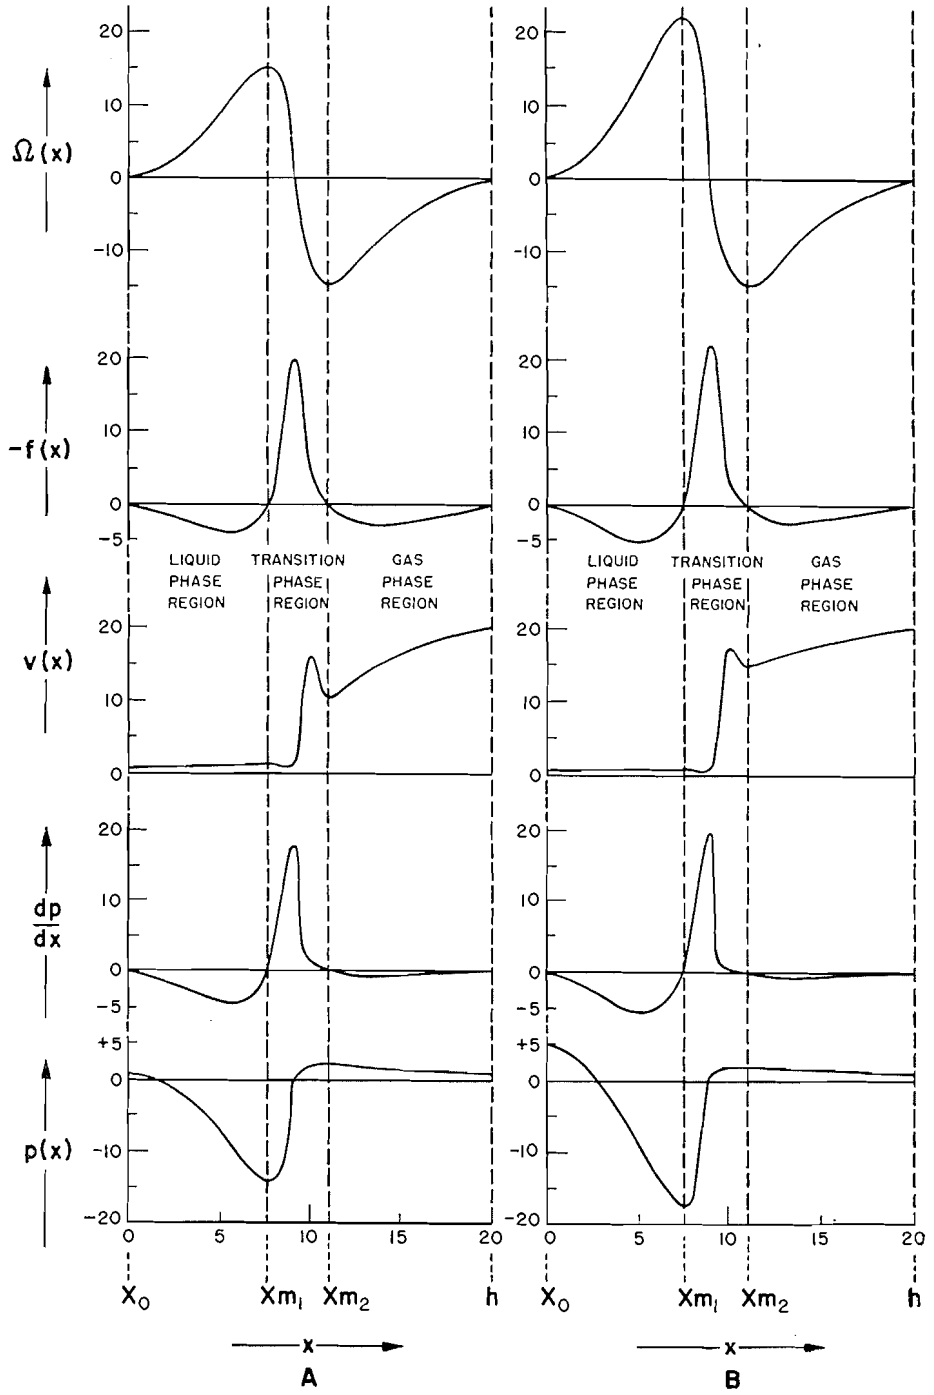

FIG. 2.

Referring to Fig. 2*A*, at the maximum of $\Omega(x)$, $f(x) = 0$ and $v(x)$ must be that corresponding to normal bulk liquid under the corresponding negative stress. Thus in the region $0 \leqslant x \leqslant x_{m_1}$, we regard the fluid as being essentially normal liquid under negative hydrostatic stress; in the region $x_{m_2} \leqslant x \leqslant h$ the fluid is normal gas; while in the intermediate region the equation of state v of p is materially influenced by the force field. Thus in the region where $\Omega(x) \rightarrow 0$ but $f(x)$ approaches a maximum, the fluid is neither normal liquid nor normal gas but is in a transition state.

Capillary Rise and Depression

As a variation of the "flat" interface illustrated by Fig. 2*A* we may suppose the whole system raised or lowered in a potential field independent of surface potential fields. If we impose the condition $dF = 0$ for this variation the conditions are analogous to capillary rise or depression.

In order that $dF = 0$, the relative changes in liquid and gas pressures will be more or less proportional to densities. Accordingly, the $p(x)$ curve must be distorted so that $\int_0^h (dp/dx)\, dx \neq 0$. However, for small rises or depressions $\bar{p}(x)$ and $\bar{\Omega}(x)$ will not be changed appreciably, since the magnitudes of $\bar{p}(x)$, $p(x_m)$, etc. are large compared with the pressure changes introduced by the rise or depression. For large depressions, analogous to the effect of curvature on very small droplets, the pressure changes may be comparable with $\bar{p}(x)$. In such cases to retain constancy of surface tension either $\Omega(x)$ must change or the surface thickness, h, or both must change. A natural assumption is that the tendency of the surface to adsorb its own vapor becomes less on surfaces concave toward the dense phase and hence that $\Omega(x)$ is changed. Fig. 2*B* illustrates a "capillary depression" of the hypothetical system illustrated by Fig. 2*A*, the values of $\bar{p}(x)$ and h being unchanged, but $v(x)$, $p(x)$, and $\bar{\Omega}(x)$ distorted so that there is a net pressure difference between liquid and vapor. The surface tensions and the surface thicknesses are the same for the two cases, but $\Omega(x)$ is greater for the depressed curved surface. Rice (17) has pointed out that γ might be expected to increase with increasing pressure, in view of the Lewis (11) relation,

$$(\partial\gamma/\partial p)_{\sigma,T} = (\partial v/\partial\sigma)_{p,T}.$$

Since γ is essentially a mean volumetric stress intensity, the interpretation of this equation, if valid at all, is obscure. In general one would expect $\Omega(x)$ to be due largely to the density gradient in the surface region and consequently that changes in the vapor–liquid equilibrium conditions which tended to make the density and compressibility differences vanish would also tend to make $\Omega(x)$ vanish. Both large increases or decreases in vapor pressures would tend toward reducing density and compressibility differences between liquid and vapor. Accordingly, we should expect $\Omega(x)$ to be a maximum for nearly flat surfaces. Thus for exceedingly minute gas bubbles or drops γ should be materially less than that corresponding to the flat surface and the pressure differences across small spheres reach a maximum and finally practically vanish as the radius diminishes.

Thickness of the Interface

For convenience of illustration the difference between the specific volumes of liquid and vapor has been taken much less than is the case with liquid–vapor systems such as water. The magnitudes of the negative pressures are also much smaller with respect to vapor pressures than is the case in ordinary systems of appreciable surface tension.

In the case of the water interface $-\bar{p}(x) \cdot h \simeq 70$ dynes cm.$^{-1}$ at room temperature. If the thickness of the interface, h, lies between 10 and 1 Å, the mean negative pressure or mean stress intensity must lie between 7 and 70 hundred atmospheres. Evidently such large tensile stresses cannot be sustained in the more dilute regions of the fluid interface and hence practically the whole contribution to $\bar{p}(x)$ must come from the region where the fluid has high tensile strengths, high densities, and low compressibilities, i.e., from the liquid region of the interface. The maximum tensile stress in this region will exceed the mean tensile stress by factors depending on the relative thicknesses of these regions, the factors being the greater, the smaller the ratio of the thickness of the dense region to the thickness of the whole interface. In the case illustrated in Fig. 2*A* this factor is about five and correspondingly, the maximum tensile stress is between 35 and 3.5 thousand atmospheres for total film thicknesses between 1 and 10 Å. The film thickness as measured by the Rayleigh method will be the region of rapid change of refractive index and thus will be the region of rapid increase in specific volume. The thickness of the water interface as measured by Raman and Ramdas (15) using the Rayleigh method is about 1 Å. If the relative thicknesses of the various regions are as illustrated, the total film thickness is somewhat less than 10 Å and the maximum tensile stress of the order of 4×10^3 atmospheres. It seems very improbable that this figure can be much too low since it is comparable with the measured tensile strength of some metals.

The Laplace (10) method of calculating the tensile strength of liquids, neglecting the quite appreciable heat of "evaporation" of monomolecular layers, leads to values of the order of 25×10^3 atmospheres which are almost certainly too high. Further, owing to relaxation effects, it seems unlikely that the maximum negative stress sustained in the surface layers of a free surface will be as large as the tensile strength of the bulk liquid.

Thus it would appear that the maximum tensile stress in the surface region of liquid water is of the order of 10^3 atmospheres or less and hence that the thickness is of the order of 10 Å or more.

Surface Potential

Finally a word may be said concerning the factors giving rise to the surface potential $\Omega(x)$. The energy of a vapor is, of course, in general much greater than the energy of the corresponding liquid. The heat energy or TS energy change from liquid to vapor is somewhat greater than the internal energy change (i.e., by $p_0 \Delta v$). In order that a positive potential of position exist $\Delta(E+p_0v)/\Delta x$, p_0 constant, must exceed $T\Delta S/\Delta x$. We may ascribe the positive potential of position as being, in the main, due to an increase in energy without

a compensating increase in entropy. In the dense part of the interface where the fluid compressibility is small, any increase in volume, i.e., a small increase in mean distance of nearest neighbors, will give a large energy increase with little change in entropy. Proceeding further toward the gas the region is reached where fluid extensibility is large and the rapid increase in volume is accompanied by a large increase in entropy. In the case indicated in Fig. 2*A* the negative potential of position corresponds to a condition where the entropy of the nearly gaseous layers is larger with respect to their energy than prevails in the body of the gas. Ultimately these laminae correspond to states of "supersaturation" of the vapor. While laminae near the liquid or vapor side may be expected to have the normal equation of state of bulk liquid or gas, in the intermediate regions the relations between p, T, and μ or E, S, and v (per unit mass) will depend upon $f(x)$.

We may express the total potential of the surface, ω, as follows (cf. p. 985):

$$\omega = -\sum_{\delta v_{ai}} \frac{p_{ai}-p_0}{\overline{\rho_{ai}}|_{p_0-p_{ai}}} \cdot \rho_{ai} \cdot \delta v_{ai},$$

and since in this case $\delta v_{ai} = \sigma \delta x_i$ and $p_{ai} = p(x)$, we may write

$$\omega = \sigma \int_0^h \frac{[p_0-p(x)]}{\overline{\rho(x)}|_{p_0-p(x)}} \cdot \rho(x)\, \delta x$$

$$= c\sigma[p_0-\bar{p}(x)] \cdot h = c\sigma[poh+\gamma]$$

where $c \geqslant 1$. Since in cases where the surface tension is large, by far the greater mass of material lies in the regions where fluid compressibilities are small (i.e., where $c = 1$) and the pressures are of large negative magnitudes, ω is very nearly equal to $\gamma\sigma$. Thus γ is practically energy per unit surface. Where compressibilities are high throughout the surface region (near the critical temperature) ω will be greater than $\gamma\sigma$. Further, we should expect ω to consist partially in a decrease in entropy as well as an increase in energy. Thus near the critical region γ will not constitute a measure of surface energy.

III. ADSORPTION AND ADSORPTION HYSTERESIS

If in adsorption processes adsorbates and adsorbents retain their own individual properties, adsorbates at suitable temperatures and equilibrium pressures may be regarded as single component complex fluids as defined in Part I of this paper. In such cases all of the thermodynamic relations applicable to the single component complex are applicable to the adsorbates. Thus we have at once a method of calculating the mean volumetric pressures of the adsorbates from isotherm data, provided that the relevant isotherms represent paths of thermodynamic reversibility.

From Part 1, the mean volumetric adsorbate pressure will be given by

$$\bar{p}_a{}^v = \int_0^t \frac{\bar{p}_a}{\rho_1}\, dp_1 = \alpha p_1$$

and α can be calculated from isotherm data (6). The corresponding change in

reversible (elastic) volumetric mean state of stress of the solid can be shown to be related to the adsorbate stress by the following equation,

$$[3] \qquad v_a \cdot \bar{p}_a{}^v + v_c \bar{p}_c{}^v = (v_a + v_c) p_1$$

where v_a and v_c are the volumes of adsorbate and solid; v_a+v_c is the total volume of the porous body; $\bar{p}_a{}^v$ and $\bar{p}_c{}^v$ are the changes in volumetric mean states of stress of the void volume v_a and solid volume v_c, respectively, while p_1 is the change in hydrostatic state of stress of the whole porous body.

From Equation [3] we get at once

$$\bar{p}_c{}^v = (1+\phi-\phi\alpha)p_1$$

where $\phi = v_a/v_c$, $\bar{p}_a{}^v = \alpha p_1$, and $\bar{p}_c{}^v$ refers to the actual change in elastic state of stress of the adsorbent as a result of the adsorption reaction.[7]

If we are interested in comparing changes in linear dimensions of an adsorbent due to adsorption of gas, we can expect a correlation between these dimensional changes and its change in state of stress. The change in linear dimension per unit length will be a function of the change in linear average state of stress. If $\bar{p}_c{}^v$, the mean volumetric change of stress, were a measure of a change of hydrostatic stress (as would be the case if $\bar{p}_a{}^v$ were a uniform hydrostatic pressure equal to p_1), $\bar{p}_c{}^v$ would be the same as the change in linear average stress, $\bar{p}_c{}^l$. If in a given direction the solid were perfectly uniform in cross section and its surface field uniform in this direction, then $\bar{p}_c{}^v$ and $\bar{p}_c{}^l$ would be the same. However, in general, these quantities are not equal. Let us write

$$\bar{p}_c{}^v = p_1 + (\bar{p}_c{}^v)',$$
$$\bar{p}_c{}^l = p_1 + (\bar{p}_c{}^l)',$$

where $\bar{p}_c{}^v$ is considered as consisting of the hydrostatic stress p_1 due to the gas pressure and the additional stress $(\bar{p}_c{}^v)'$ due to interaction with the gas, i.e., due to its surface field. Similarly, $(\bar{p}_c{}^l)'$ is the additional linear stress due to interaction. While in the general case $(\bar{p}_c{}^l)'$ may be greater or less than $(\bar{p}_c{}^v)'$, if the surface forces are more or less uniform but the cross section variable, the ratio $(\bar{p}_c{}^l)'/(\bar{p}_c{}^v)'$ will be greater than unity and the ratio will be a constant descriptive of the structure of the adsorbent. Putting $(\bar{p}_c{}^l)' = K(\bar{p}_c{}^v)'$ we get $\bar{p}_c{}^l = (1+K\phi-K\phi\alpha)p_1$. Hence for isotropic solids which obey Hooke's law we can write

[7] *Following Gibbs (7) we can write for a solid or for an assembly of solid systems*

$$[A] \qquad dE = TdS = \sum\sum'[X_x' \, \delta(dx/dx') \, dxdydz$$
$$= TdS - \bar{p}_c{}^v.dv$$

where $\sum\sum'[X_x' \, \delta(dx/dx')]$ *and* $-\bar{p}_c{}^v$ *represent the generalized state of stress of the element of volume dxdydz. Thus* $-\bar{p}_c{}^v$ *represents the volumetric mean adiabatic strain energy per unit volumetric strain. The variation in Gibbs free energy corresponding to a variation in reversible state of strain, all other independent variables remaining constant, may be written* $dF = v_c d\bar{p}_c{}^v$ *where* v_c *is the total volume of the assembly of solid volumes. It is important to note that these relations imply that release of the stress (i.e. putting* $\bar{p}_c{}^v = 0$*) will be accompanied by the spontaneous release of the strain, the elements dxdydz becoming identical with the reference elements dx'dy'dz'. Thus Equation [A] cannot be used to describe strains beyond the elastic limit or irreversible strains. In the case of a so-called self-strained body, the state of strain of the body as a whole is to be taken as zero when the matter comprising the body is everywhere statistically at rest and no external forces are operative.*

[4] $$\delta l/l = -\tfrac{1}{3}\beta(1+K\phi-K\phi\alpha)p_1,$$

where l is the length of the sample and β[8] its compressibility. Where the dilation (or contraction) is isotropic we do not need to introduce the Poisson ratio. If the adsorbent is not isotropic both "β" and K will differ in different directions. In very extreme cases where K is very different in different directions, corrections of the Poisson contraction type will be necessary, and must be known or inferred for accurate correlation of experimental results.

It has been shown (6) that Equation [4] can be used to describe experimental data fairly well.[9] Accordingly the view that the adsorbate may be regarded as a single component complex appears to have considerable validity. The factor K in so far as it is determined by the solid structure will be a constant and thus have the same value for different gases at various temperatures. However, if the mechanism of adsorption changes, the value of K will change. Thus as we have shown (6) K will have different values for a given solid structure when the void volume is filled with liquid under a uniform pressure (e.g. extreme cases of capillary condensation) as compared with the case where the adsorbate is condensed in layers upon the surface.

Adsorption and Adsorption Hysteresis

In general when considerable adsorption occurs, the apparent potential of the surface is modified by molecular interactions of the adsorbate, i.e., the "potential" is a function of the equation of state of the gas. If the gas is condensable, liquid–gas interfaces will form and these interfaces introduce additional "potentials" of position which must be combined with the surface potentials. However, as long as the isotherm represents a path of thermodynamic reversibility, the mean volumetric pressure of the adsorbate will be given by Equation [2] of Part I.

The formation of adsorbate liquid–gas interfaces may lead to irreversible adsorption. The adsorption mechanism commonly referred to as "capillary condensation" is inherently a thermodynamically irreversible process. While the thermodynamics of hysteresis and reversible and irreversible adsorption have been treated by Hill (8) and others using statistical mechanical models, there are a number of inferences that can be drawn from purely thermodynamic considerations which are important and quite independent of any models.

The usual method of measuring adsorption isotherms is to expose the initially evacuated adsorbent to sources of constant gas pressure. When equilibrium is attained at each pressure, the thermodynamic potentials of the gas and adsorbate are the same, thus $\partial F/\partial m_1$, the partial molar free energy or thermodynamic potential of the adsorbate, equals dF/dm_1, the thermodynamic potential of the gas, and in each case,

$$\Delta F = \int_{m_1=0,m_2}^{m_1,m_2} \frac{\partial F}{\partial m_1}\,dm_1 = \int_{m_1=0}^{m_1} \frac{dF}{dm_1}\,.\,dm_1$$

[8]*This assumes that the compressibility of the solid is uniform and not changed by the adsorption. Even where the fundamental equations are strictly applicable, i.e., where the adsorbent changes* only *in state of stress, if the accompanying change in volume is large, β will be neither uniform nor constant.*

[9]*The validity of Equation [4] may be considered as a criterion for judging the validity of the potential theory of adsorption. If Equation [4] is valid the surface forces behave as a "potential".*

and in the case of the gas,

$$\Delta F = \int_0^{p_1} v_1 dp_1.$$

If the adsorbate behaves as a single component complex so that the volume of the adsorbate has a physical meaning,

$$\Delta F = \int_{\bar{p}_0{}^v=0}^{\bar{p}_0{}^v} v_a d\bar{p}_0{}^v.$$

However, all of these relations assume that v_1 or m_1 (the mass adsorbed) and hence that F and μ are known as functions of p_1 or that p_1 is known as a function of m_1. If the equilibrium gas pressure is anywhere a decreasing function of m_1, say at m_1', the system would be mechanically unstable when containing the mass m_1' and would spontaneously fill irreversibly to some value m_1''. The equilibrium pressures and hence the potentials corresponding with the filling would not be observable in this case under ordinary experimental conditions. Such mechanisms as the "Cohan" (3) or any other "capillary condensation" mechanism would lead to such results.

Suppose, for example, that the equilibrium gas pressure as a function of the mass adsorbed has the form shown in Fig. 3.[10] The line CF is the only line[11]

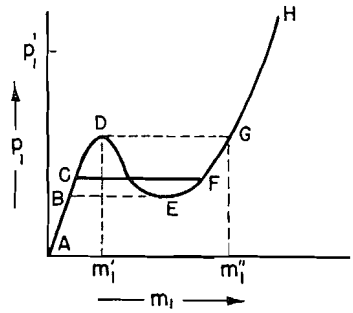

FIG. 3.

along which the mass may increase at constant pressure and give the correct value of ΔF. If the filling is premature, i.e., occurs at lower pressures along the line BE, the apparent observed value of ΔF from $p_1 = 0$ to some point $p_1 = p_1'$ will be too large, while if the filling occurs at higher pressures, e.g. along DG, the apparent value of ΔF will be too small.

If $p_1(m_1)$ has the form shown above, and the adsorbate behaves as a single component complex regardless of mechanism of adsorption, $\bar{p}_a{}^v$, the adsorbate pressure, will be a function of p_1 having the form shown in Fig. 4.[12] The point C of Fig. 4 corresponds with the line CF of Fig. 3. If the adsorption actually

[10] *$p_1(m_1)$ is assumed as measured in a small constant volume apparatus. $p_1(m_1)$ cannot, of course, have any such form when exposed to sources of m_1 at constant pressure.*

[11] *The position of CF is obtained from a plot of v_1 against p_1 using Maxwell's rule of equal areas (cf. Hill (8)).*

[12] *Assuming suitable relative magnitudes of corresponding gas and adsorbate densities.*

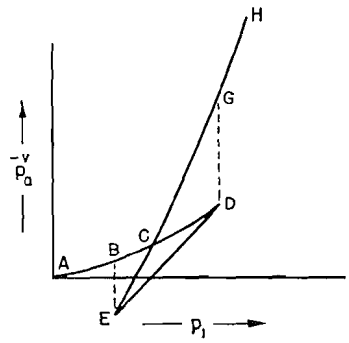

FIG. 4.

followed the curve of Fig. 3 the corresponding adsorbate pressures would follow the curves *AD*, *DE*, *EH* in Fig. 4. If the adsorption follows the path *ABEH* of Fig. 3 the corresponding path in Fig. 4 will be *ABEH*. If the adsorption follows *ADGH* of Fig. 3 the adsorbate pressure will follow *ADGH* of Fig. 4. In the former of the irreversible cases the adsorbate pressures will become negative, while in the latter case they will be positive throughout.

It is to be emphasized that $\bar{p}_a{}^v$, the adsorbate pressure, can only become negative on *adsorption* if the filling occurs at equilibrium pressures below the line *CF*. If the filling occurs along *CF* or at pressures above *CF*, $\bar{p}_a{}^v$ will be positive. In order that the adsorbent, if reasonably isotropic, contract on adsorption, i.e., on increasing the equilibrium pressures, the net adsorbate pressure must become negative and this can only occur if the filling occurs irreversibly along a path lying below *CF*. The fact that in some cases quite appreciable contractions are observed in the lower pressure regions of increasing pressure indicates that $p_1(m_1)$ is a decreasing function of m_1 in these lower pressure regions. This may be construed as evidence of the existence of "capillary condensation" or of some equivalent mechanism such as the "two-dimensional condensation" of Pierce (13).

When the filling of the adsorbate volume is irreversible whether above or below the line *CF* the observed "ΔF" (i.e. $\int_0^{p_1} v_1\, dp_1$) is not an accurate measure of the actual ΔF of the adsorbate and the application of thermodynamic relations based on such values of ΔF will be in error. Such errors are to be expected when liquid–vapor surface tensions are high.

While as pointed out by Hill (8) we would normally expect that irreversible transitions would be delayed (i.e. occur above *CF* of Fig. 3) the fact that contractions are observed on increasing pressure paths indicates that these transitions are premature (i.e., occur below *CF*). The absence of appreciable hysteresis in these regions together with the fact that contractions on desorption and adsorption are of much the same magnitude indicates that on *desorption* the transition is *delayed*. This apparently anomalous behavior may be due to the difference in sign of the temperature effect of adsorption and

desorption. Thus if the hypothetical constant pressure (p_s') line at the higher temperature lies below that at the lower temperature (e.g. if $\partial p_s'/\partial t$ is negative in these regions (cf. Coolidge (4)) the transition may occur, as expected, above the line corresponding to the actual temperature of the adsorbent, the adsorbate pressures being positive at the adsorbent temperature but becoming negative on cooling to the isothermal bath temperature. The reverse temperature effect would be expected on desorption and thus tend to equalize the adsorption and desorption states actually obtained.

In general, if the actual quantity of material per "site" "area" or "pore" for which $p_1(m_1)$ has the form of Fig. 3 is very small, filling of these sites irreversibly may be controlled by minor differences in experimental procedures. In addition there may be little apparent difference between adsorption and desorption isotherms, depending on the distribution of pressures corresponding to CF lines for the various sites. If, however, the quantity of material is large so that there are large differences in mass m_1 per site as CF is traversed, filling of these sites will in general occur at pressures above CF and the emptying (desorption) occur below CF. This will, in general, lead to marked hysteresis. In the extreme case of the filling of large void volumes, such volumes will fill with liquid only at pressures above saturation but the liquid will persist considerably below saturation if separated from the equilibrium gas by small pores. If appreciable areas of liquid–vapor surfaces having appreciable positive tensions are formed along paths of increasing pressures some irreversibility must be involved. Where a considerable mass of adsorbate is under a net negative pressure due, say, to capillary condensation and where this condition is reached along a path of increasing gas equilibrium pressures, the irreversibility will be large and ΔF quite different from the observed value of $\int_0^{p_1} v_1\, dp_1$. Under these circumstances $\bar{p}_0^v$ as measured by the observed value of αp_1 will be seriously in error and is apt to be of the wrong sign. The mean adsorbate pressure, in some cases, may be estimated by adding "Kelvin" adsorption and "reversible" adsorption, but in general these pressures are not additive quantities.

It is quite possible for the adsorption isotherm to represent a path of almost perfect thermodynamic reversibility from zero gas pressures up to saturation, and that a considerable part of the desorption branch also represents such a path even when the hysteresis is large, so that the two thermodynamically reversible branches are widely different. In this case ΔF and $\bar{p}_a^v$ can be correctly calculated from the observed data along the two reversible branches. Of course, the desorption curve must eventually meet the adsorption curve at lower relative pressures and hence involve considerable irreversibility in these regions of the desorption branch.

In general where the theoretically reversible continuous curve p_1 (m_1) has negative values of $\partial p_1/\partial m_1$, observed reversible isotherms will be stepwise.

Finally if p_1 (m_1) is nowhere for any site (area or pore) a decreasing function of m_1, ΔF will be given accurately by $\int_0^{p_1} v_1\, dp_1$ applied to the equilibrium gas

and $\bar{p}_a{}^v$ by $\int_0^{p_1} \bar{\rho}_a/\rho_1 \cdot dp_1$, or αp_1, quite regardless of whether liquid–vapor interfaces of any form are present or not. In such cases the "tension" of any liquid–vapor interfaces must be negative, i.e., pressures in these surfaces must be positive.

Adsorption Isotherm

The validity of the Polanyi (14) potential theory of adsorption is commonly based on the ability to calculate adsorption isotherms of a variety of gases at various temperatures from the characteristic curve for one representative gas. This, of course, involves the assumptions that the "potential" of the surface is the same for each gas and is independent of the temperature. It assumes that the equations of state of the gases concerned are known reasonably well. Although there are many exceptions, it is indeed surprising to what an extent these rather violent assumptions have been confirmed. Without any reservations concerning the nature of the potential field, if Equation [4] above is valid it constitutes strong evidence of the essential validity of the Polanyi theory. Thus our previously reported experimental results may be taken as confirmation of Polanyi's compressed film hypothesis. McBain's (12) "disproof" of the potential theory was based on considerations of adsorbate pressures. Some of the fallacies in McBain's "disproof" have been pointed out by Brunauer (2). Our results indicate that such considerations instead of contributing to a "disproof" of the compressed film hypothesis" lend very considerable support to it. Adsorption equilibrium is, of course, thermodynamic equilibrium. Accordingly, in its broadest sense, the "potential" theory is necessarily correct. We usually limit the "potential" theory of adsorption to processes where the adsorbate may be regarded as a single substance and thus distinguish "physical adsorption" from chemical reaction, and from solution. In its most restricted sense the "potential theory" is limited further to those cases where the "surface potential" is constant. The principal weakness of the potential theory of adsorption lies in its generality, since even in its most restricted form almost any type of adsorption isotherm can be consistent with it, as has been shown by many authors. Even if we assume that a condensable gas obeys the ideal gas law exactly, below the saturation pressure, and that above saturation it is an incompressible liquid of density unity, ignoring liquid–vapor interfaces a great variety of isotherm shapes can be generated depending on the form of the volumetric distribution of the "potential" of the surface region as well as upon the magnitude of the mean potential with respect to RT.[13]

[13]*Let $V(\Omega)\,d\Omega$ be the volume of the surface region having a potential lying between Ω and $d\Omega$, and let*

$$V(\Omega) = v_a/h)\ \Omega\, e^{-h\Omega}, \qquad 0 \leqslant \Omega \leqslant \infty.$$

Taking v_a as ½ cc. per gram of adsorbent and neglecting the concentration of vapor, one gets

$$x/m = \tfrac{1}{2}(p/p_s)^a[1 - \log(p/p_s)^a]$$

where $a = 2RT/\mu\bar{\Omega}$. Fig. 5 shows a plot of this equation for various values of a. Evidently to determine whether or not experimental points fall on such curves or on, say, a Freundlich curve, we must be very sure of the experimental data and resort to rather elaborate mathematical analysis of these data (cf. Honig (9)).

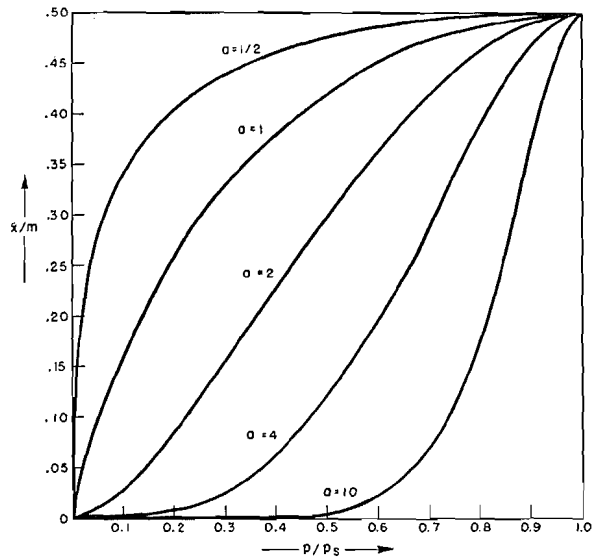

FIG. 5.

Since we cannot deduce an equation of state of a single homogeneous substance from purely thermodynamic considerations, it is evident that we cannot deduce an adsorption isotherm from such considerations. All so-called "thermodynamic" derivations of adsorption isotherms are based either directly or indirectly on assumed equations of state of both the equilibrium gas and the corresponding adsorbed material.

OXIDATION OF ALKENES BY MERCURIC SALTS[1]

By D. A. Shearer and George F Wright

ABSTRACT

The α-oxymercurials of cyclohexene, 2-methyl-1-phenylpropene-1, and the geoisomers of stilbene have been shown to be the intermediates in the oxidation of these alkenes by mercuric nitrate and other salts, usually in methanol. These intermediates are stable in the oxidation environment and their alkoxy groups appear intact in the oxidation product; indeed organomercurials without vicinal alkoxy groups are likewise oxidized. The reaction products from alkenes in methanol are 1,2-dimethoxyethanes, 1,1-dimethoxyethanes, and (with mercuric nitrate) 1-methoxy-2-nitroxyethanes, formation of the latter being most rapid. The oxidation is stereospecific, each geoisomer yielding its characteristic diastereomeric products. It is catalyzed by acids such as nitric acid but not by nitrate ion, though neither affect the ratio of products. This over-all second-order reaction, first-order in organomercurial and first-order in mercuric salt, becomes over-all first-order with mercuric acetate when it is catalyzed by boron fluoride. Combination of the catalyst with the organomercurial must be rate-controlling. The similarity of the oxidation and the acid decomposition reactions of organomercurials is discussed.

The oxidation of alkenes by mercuric salts is not a new reaction (3, 2, 25) but interest has recently been revived because of its application to sterol dehydrogenation (4, 5, 38, 39). A mechanism for the sterol dehydrogenation has been proposed involving a "mercurinium ion" (33) but it seems to be inconsistent with the observed formation of mercurous salts rather than metallic mercury. On the other hand, another mechanism has been suggested (11) for the oxidation of cycloalkene by mercuric salts (20, 36, 37) which does not take into account the equilibration: $2HgOAc \rightleftarrows Hg + Hg(OAc)_2$. Neither mechanism is consistent with the earlier observations that two equivalents of mercuric salt are involved in the oxidation of an alkene to an alkadiene or an alkenyl ester as well as to a glycol derivative (7) or rearrangement product (10, 30).

The consumption of two equivalents of mercuric salt per equivalent of alkene was confirmed by Brook and Wright (10) who also proposed a mechanism for the conversion of cyclohexene to formylcyclopentane not involving the intermediacy of an oxymercurial. These workers thought that an oxymercurial could not be involved because "hydroxymercuration with mercuric nitrate is not a significant reaction in water". We have now found this statement to be incorrect.

The error of Brook and Wright lay in dilution of their reaction aliquots with excess aqueous sodium chloride. The hydrochloric acid generated in this way decomposed the mercurial. Alternatively if cyclohexene is mixed with an equivalent each of mercuric nitrate and nitric acid (1 molar) and diluted after 10 min. into *one equivalent* of cold aqueous sodium chloride a maximal 80% yield of 2-hydroxy-1-chloromercuricyclohexane may be isolated. The equilibrium is shifted to afford a 63% yield when the system is 2 molar in nitric acid.

[1]*Manuscript received January 21, 1955.*
Contribution from the Chemical Laboratory, University of Toronto, Toronto, Ontario.

Kinetic studies* show that the oxidation of cyclohexene by two equivalents of aqueous mercuric nitrate proceeds through the intermediate mercurial, and that the over-all second-order kinetics are first-order in respect of mercurial and of mercuric nitrate, *i.e.* the oxymercuration of the alkene is so fast that the subsequent oxidation is rate-controlling. Table I shows, by comparison of Expt. 1 with Expts. 2, 3, and 4, that the rate is enhanced by addition of nitric acid, but the effectiveness does not increase in direct proportion to the concentration. Expt. 5 has been carried out with an excess of mercuric nitrate and the rate has been calculated by the expression

$$kt = [2.303/(a-b)] \log [b(a-x)/\{a(b-x)\}], \qquad [i]$$

where a is the concentration of mercuric salt *after mercuration is assumed to have occurred*, and b is the concentration of mercurial assumed to form instantly at zero time while $a-x$ and $b-x$ are corresponding values after certain time

TABLE I

REACTION OF CYCLOHEXENE WITH AQUEOUS MERCURIC NITRATE AT 25.0±0.1°C.

1	.50	.25	—	.25	.25	0.25	.0259±.0008	71.8
2	.50	.25	1.0	.25	.25	1.25	.0473±.0041	60.6
							.0476±.0017	57.7
							.0489±.0036	60.1
3	.50	.25	1.5	.25	.25	1.75	.0505±.0014	62.0
4	.50	.25	2.0	.25	.25	2.25	.0520±.0043	69.8
5	.50	.125	1.0	.375	.125	1.125	.0447±.0043	75.0

intervals. Agreement of this rate constant with that obtained from systems containing a comparable amount of nitric acid (Expt. 2) shows that the rates are independent of cyclohexene concentration because the alkene is very rapidly converted to the mercurial. These results are valid for about 60% of the reaction, after which the rate falls off markedly. The deviation from simple second-order kinetics is not unexpected since the isolable yield of product, formylcyclopentane, has never exceeded 45% of theoretical.

This oxidation of cyclohexene is not limited to use of aqueous mercuric nitrate alone. The reaction proceeds in methanolic mercuric nitrate solution (two equivalents with one equivalent of both cyclohexene and nitric acid, each 0.25 molar) but 41 hr. are required for 65% of oxidation, in contrast to two hours for 60% of oxidation in the aqueous system. It may be significant that the intermediate methoxymercurial is a more stable compound than the hydroxymercurial which is intermediate in the aqueous system. The product from the methanolic system seems to be the dimethylacetal of formylcyclo-

**A referee has adversely but correctly questioned the value of kinetic data based on this complex reaction which is not in stoichiometric balance, and in which the limited analytical precision precludes wide variation in reagent concentration. Indeed the kinetic studies only have value in so far as the same conclusions can be drawn from experiments using four different alkenes.*

pentane according to the sluggish reaction with 2,4-dinitrophenylhydrazine. The same product is obtained when 2-methoxycyclohexylmercuric nitrate is treated with mercuric nitrate in methanol.

The conversion of cyclohexene to formylcyclopentane is not limited to use of the nitrate salt. A 45% combined yield of the aldehyde and cyclopentanecarboxylic acid is obtained with mercuric sulphate and molar sulphuric acid; the reaction is comparable in rate with that of the nitrate salt, but is difficult to follow kinetically because mercurous sulphate precipitates during the reaction. The reaction is much slower in aqueous mercuric benzenesulphonate containing benzenesulphonic acid, but the same products are obtained. Thus the anion can be varied within limitations (chloride is ineffective and acetate is unduly slow). But the mercury is necessary. Nitrate salts of barium, cadmium, copper II, iron III, lead, zinc, and bismuth are ineffective in the oxidation either of cyclohexene or of its oxymercurials.

The oxidation study has been extended to 2-methyl-1-phenylpropene-1 (I). This compound has previously been methoxymercurated. The 2-methoxy-2-methyl-1-phenylethylmercuric salt thus obtained has been converted by means of iodine or bromine to substances which essentially are oxidation products of the alkene (6). The action of methanolic mercuric nitrate on 2-methyl-1-phenylpropene-1 or 2-methoxy-2-methyl-1-phenylethylmercuric nitrate (VI) does not produce two of these products (3-phenylbutanone-2 and 2-methyl-2-phenylpropanal) but the third, 1,2-dimethoxy-1-methyl-2-phenylpropane (II), is obtained in fair yield. Additionally the mercuric nitrate oxidation yields a higher boiling compound, seemingly 2-methoxy-2-methyl-1-phenylpropyl nitrate (III), since it gives a positive diphenylamine test for nitrate and is reduced by zinc and acetic acid to a 71% yield of 2-methoxy-2-methyl-1-phenylpropanol-1 (IV, characterized as its *p*-nitrobenzoate). Although previously reported (35) this alcohol actually was unknown (6). However it has

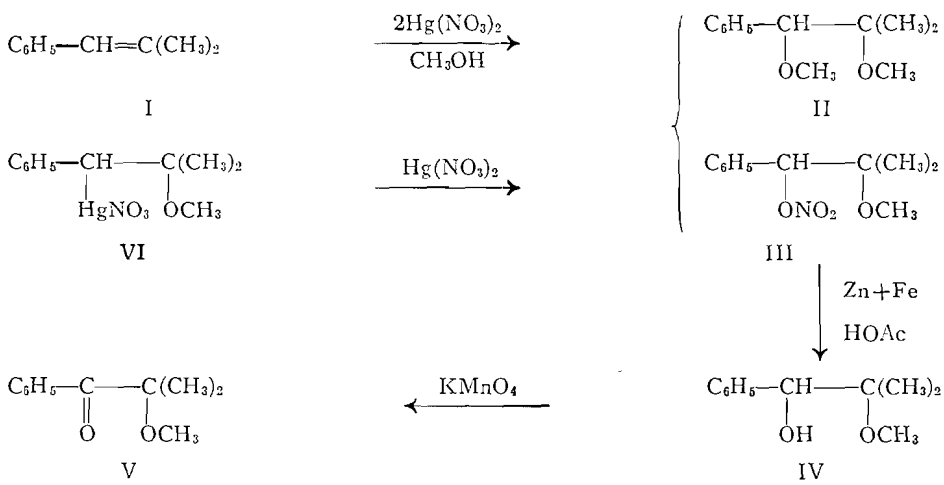

TABLE II

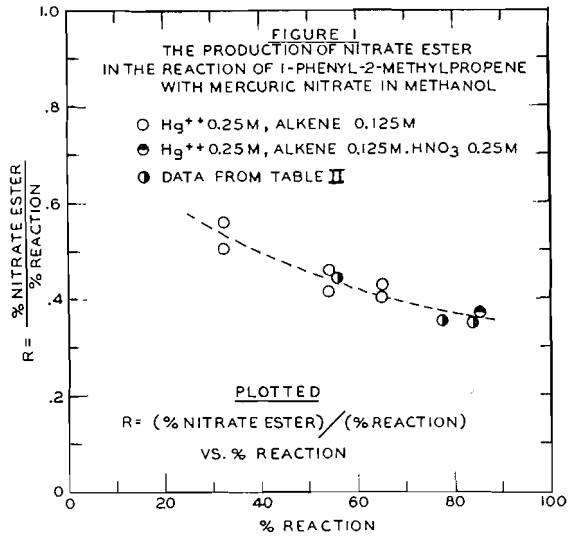
REACTION OF 1-PHENYL-2-METHYLPROPENE AND OF 1-PHENYL-2-METHOXY-2-METHYL-PROPYLMERCURIC NITRATE WITH MERCURIC NITRATE IN METHANOL

Expt. No.	Initial molarities				Time (hr.)	Yields, %			Ratio, nitrate ester: total yield
	Alkene	Mercurial	$Hg(NO_3)_2$	70% HNO_3		Dimethyl ether	Nitrate ester	Total	
1	.25	—	.52	.5	0.5	31	25	56	.45
2	.25	—	.52	—	20	50	28	78	.36
3	—	.25	.26	—	48	54	30	84	.36

now been identified by oxidation to the known 2-methoxy-2-methyl-1-phenyl-propanone (V).

The relative yields of II and III from either the alkene I or its mercurial VI are shown in Table II. The apparent augmentation of III is due to incompleteness of Expt. 1 and not to presence of nitric acid. It is shown clearly in Fig. 1 that the ratio of II to II+III is related to duration of reaction; i.e. nitroxylation is faster than methoxylation. Although nitric acid is ineffective in changing



the ratio of nitrate ester to ether, it does increase the rate of reaction. This effect is shown by the first four experiments in Table III in which the rates have been calculated on the assumption that formation of the oxymercurial VI is virtually complete at the onset of oxidation. Then if b is the initial concentration of this mercurial VI and a is the initial concentration of mercuric

nitrate after mercuration, the rate may be calculated according to equation [i] where x is extent of oxidation at time t. The comparable rates of Expts. 3 and 4 indicate that this assumption is approximately true; further the data show that the oxidation is first-order in mercurial and first-order in mercuric nitrate. The effectiveness of nitric acid may be due to its acidity since the over-all second-order rate is enhanced markedly by addition of water to the system

TABLE III

REACTION OF 1-PHENYL-2-METHYLPROPENE WITH MERCURIC NITRATE IN METHANOL AT 25°C.

Expt. No.	Initial molarities			Molarities after mercuration			Molarity of other reagents	Second-order specific rate k (l. moles^{-1} min.$^{-1}$)	% Investigated

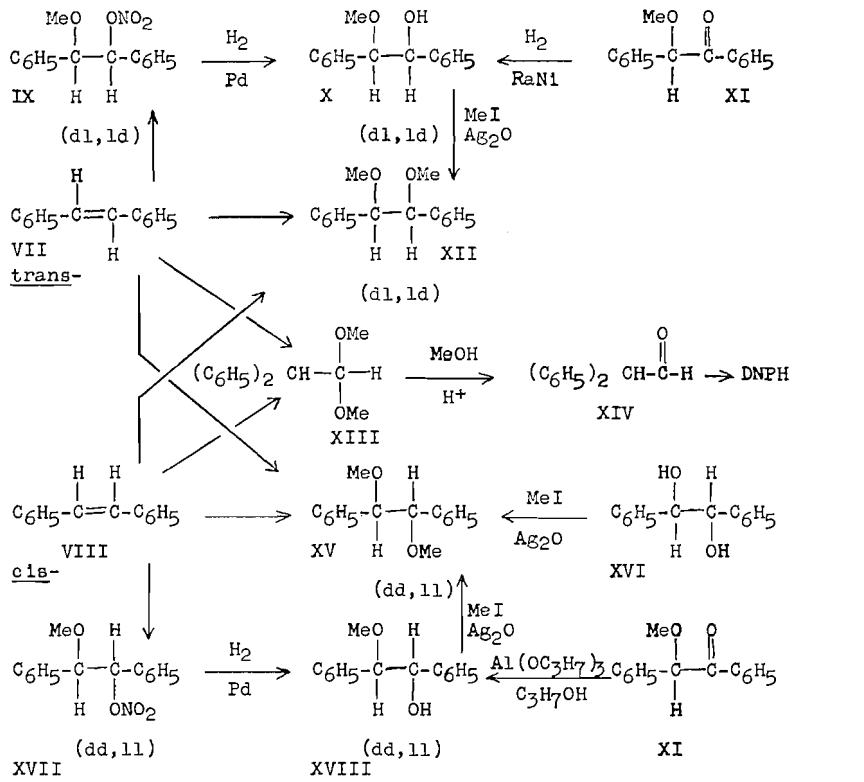
(Expt. 5). It may be noted (Expt. 6) that nitric oxide is ineffective in alteration of the rate.

The complexity of the reaction is indicated by oxidation of 2-methyl-1-phenylpropene-1 with two equivalents of other mercuric salts. Aqueous mercuric sulphate in two days gives a 70% yield of 2-methyl-1-phenylpropanediol-1,2 and no sulphate ester although aqueous mercuric nitrate seems to yield a compound not the diol (to be reported in detail in the future). Methanolic mercuric trifluoroacetate in two days gives 50% of 1,2-dimethoxy-1-phenyl-2-methylpropane contaminated with a trace of 3-phenylbutanone-2. Methanolic mercuric acetate does not react appreciably with 2-methyl-1-phenylpropene-1 until 0.5 equivalent of boron trifluoride etherate is added. After the rapid oxymercuration is complete the subsequent formation of 1,2-dimethoxy-1-phenyl-2-methylpropane is first-order over-all ($k = 1.16 \times 10^{-3}$ min.$^{-1}$), as if co-ordination with the boron fluoride were the rate-determining step.

Some years ago the oxidation of the 2-methoxy-1,2-diphenylethylmercuric chlorides was reported (7) and these studies have now been elaborated by use of pure *cis*- and *trans*-stilbenes* as well as their oxymercurials. Each of the geoisomeric alkenes yields, besides the original alkene, three characteristic crystalline products as well as a common oil, 1,1-dimethoxy-2,2-diphenylethane (XIII), when each is treated with two equivalents of methanolic mercuric nitrate.

**The question of cis-stilbene purity has always been vexing. Although this geoisomer has usually been thought to melt below 0°, Brackman and Plesch recently (8) reported the melting point to be 5–6°, decreasing to 0.62° with age. Many years ago material of high melting point was available in our laboratory but subsequently could not be obtained. Now we have found that pure (40) cis-stilbene (which is best obtained without distillation of the mercurial decomposition product) is dimorphic. The form most readily obtained melts at −24 to −23° (uncorr.) but when this melt is seeded with cis-stilbene, m.p. 1.5–3.0° (uncorr.), it resolidifies and then melts entirely at the higher temperature.*



These products are listed below in the order that they are separated by elution from an alumina column by frontal displacement:

From *cis*-stilbene			From *trans*-stilbene
(VIII)	*cis*	(1) stilbene	*trans* (VII)
(XVII)	*dd,ll*	(2) 2-methoxy-1,2-diphenylethyl nitrate	*dl,ld* (IX)
(XII)	*dl,ld*	(3) 1,2-dimethoxy-1,2-diphenylethane	*dl,ld* (XII)
(XIII)		(4) diphenylacetaldehyde dimethylacetal	(XIII)
(XV)	*dd,ll*	(5) 1,2-dimethoxy-1,2-diphenylethane	*dd,ll* (XV)

The *cis*-stilbene is conveniently identified by methoxymercuration with mercuric acetate while *trans*-stilbene is identified by mixture melting point. The two diastereomeric nitrate esters, only one of which is obtained from each geoisomeric stilbene, were hitherto unknown. They have been identified by analysis and by catalytic hydrogenation with palladium-on-charcoal (24) to the diastereomeric 2-methoxy-1,2-diphenylethanols which in turn have been configurationally characterized. The (*dl,ld*)-methoxydiphenylethanol (X) (19), which also is obtained almost quantitatively by Raney nickel reduction of benzoin methyl ether (XI), is converted by Purdie methylation to the configurationally-known (*dl,ld*)-1,2-dimethoxy-1,2-diphenylethane (XII) (19). The (*dd,ll*)-methoxydiphenylethanol (XVIII), which may also be obtained by

fractional crystallization of the diastereomeric mixture from aluminum isopropoxide reduction of benzoin methyl ether (XI), is likewise related by methyl iodide – silver oxide methylation to the known (*dd,ll*)-1,2-dimethoxy-1,2-diphenylethane (XV) (13). Finally the 1,1-dimethoxy-2,2-diphenylethane (XIII), which obviously arises by 1,2-rearrangement in these systems, is identified by analysis and by conversion to the 2,4-dinitrophenylhydrazone of 2,2-diphenylethanal (XIV).

TABLE IV

A COMPARISON OF THE REACTIONS OF *cis*- AND *trans*- STILBENES WITH MERCURIC NITRATE IN METHANOL

Alkene	Time (hr.)	Per cent yields of products					Recovered alkene, %	Fraction of total products			
		dl,ld Ether	*dd,ll* Ether	Nitrate ester	Acetal	Total		*dl,ld* Ether	*dd,ll* Ether	Nitrate ester	Acetal
				(*dd,ll*)							
cis-	48	2.5	16.7	37.8	39.0	96.0	1.2	.025	.17	.39	.41
	11	1.0	19.1	34.2	34.6	88.9	3.7	.011	.21	.38	.39
				(*dl,ld*)							
trans-	40	21.8	2.3	33.6	20.6	78.3	10.9	.28	.029	.43	.26
	41	22.4	1.0	35.3	24.4	83.1	14.7	.27	.012	.42	.29

The yields of these oxidation products from *cis*- and *trans*-stilbenes are shown in Table IV. The stereospecificity which completely gives *dd,ll*-2-methoxy-1,2-diphenylethyl nitrate (XVII) from *cis*-stilbene and the *dl,ld* diastereomer (IX) from *trans*-stilbene is also preponderant for the 1,2-dimethoxy-1,2-diphenylethanes although a yield of 2–3% of the *dl,ld* diether (XII) arises from VIII. Also 1–2% of *dd,ll* diether (XV) arises from *trans*-stilbene. Both render stereospecificity incomplete. However in large part these oxidation products are characteristic of over-all apex–base (*trans*) addition to the geoisomers.

Recovery of alkene as shown in Table IV is much greater when *trans*-stilbene is oxidized, by contrast to the *cis* geoisomer. But this might be expected if the methoxymercurials are intermediates in these oxidations since the oxymercuration of *trans*-stilbene has been shown (40) to be less complete than that of *cis*-stilbene. Finally one may note in Table IV that the ratio (0.68) of acetal yields for *trans*- versus *cis*- stilbene is roughly inversely proportional to the ratio (0.72) of the diether yields from *cis*- versus *trans*- stilbene. By contrast the ratio of nitrate ester yields is 0.9. This contrast may be due to the more rapid formation of nitrate ester versus diether if methoxylation must compete with relatively slow 1,2-rearrangement.

Addition of nitric acid to the system comprising methanolic mercuric nitrate and each of the stilbenes accelerates reaction with the *cis* geoisomer and retards it with the *trans* form although, as is shown in Table V, the ratios of product yield are essentially unchanged. It is probable then that nitric acid exerts a dual effect by accelerating the oxidation of the intermediate oxymercurial but also by decreasing the equilibrium concentration of the oxymercurial. The favorable equilibrium of the *cis*-stilbene system favors the first effect, while the adverse equilibrium in the *trans*-stilbene system is accentuated owing to the latter effect.

TABLE V

ADDITION OF NITRIC ACID TO METHANOLIC SYSTEMS 0.26 MOLAR IN MERCURIC NITRATE AND 0.125 MOLAR IN STILBENES

Geo-isomer	Molarity HNO_3	Time, hr.	% Yield of products				Recovered stilbene, %	% of total product		
			Ether	Ester	Acetal*	Total		Ether	Ester	Acetal

.39	.125	48	24	33	21	78	2	31	42	27

The data of Table VI show that the ratios of products are practically unaffected by fourfold variation in the concentrations of *trans*-stilbene and mercuric nitrate in methanol. Likewise the augmentation of ionic strength by inclusion of lithium nitrate (Table VII) does not affect the yield of *dl,ld*-2-methoxy-1,2-diphenylethyl nitrate (IX) until the concentration is very large, but it does alter markedly the ratio of diether (XII) to acetal (XIII). This effect is not unexpected when a 1,2-rearrangement is involved, and the relatively slow methoxylation ought to be affected more than the rapid nitroxylation. The effect of added lithium nitrate does seem to show that methoxylation and, especially, nitroxylation are not directly dependent on the ionic species.

TABLE VII

REACTION OF 0.625 MOLAR *trans*-STILBENE AND 0.13 MOLAR MERCURIC NITRATE IN METHANOL WITH ADDED LITHIUM NITRATE

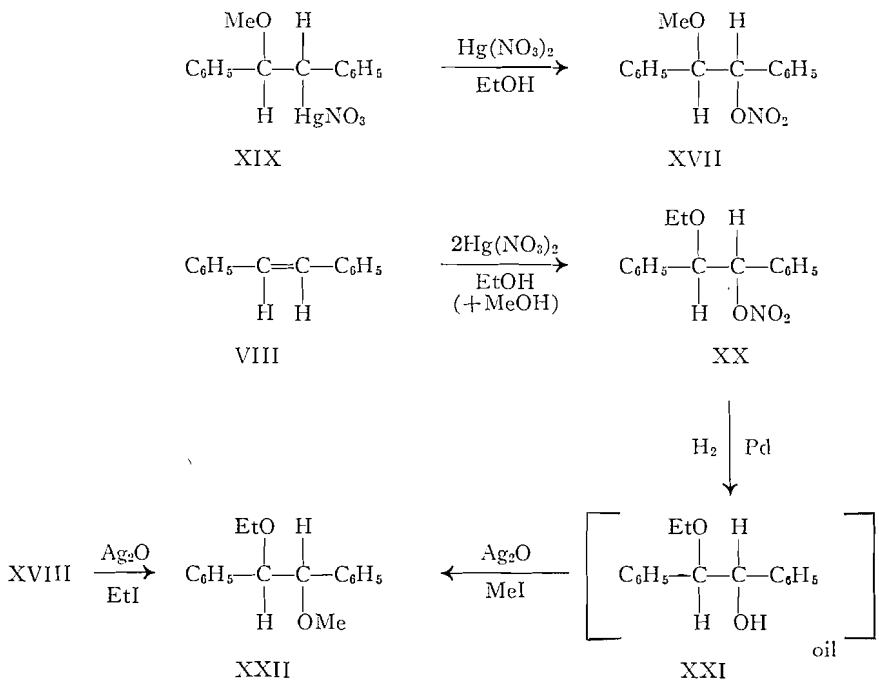
3.50	46	13	28	38	79	8	16	36	48

Before kinetic studies of the stilbene oxidation are considered it seems advisable to establish unequivocally that the oxymercurials are intermediate in the reaction. This has been done in three different ways of which the first is a

demonstration that organomercurials in general are oxidized by mercuric salts of oxy acids. When benzylmercuric nitrate in methanol is shaken with an equivalent of mercuric nitrate for 40 hr. the products are mercurous nitrate, a 46% yield of benzyl methyl ether, and a 15% yield of benzyl nitrate. Toluene in this environment is unaffected, so the reaction does not involve hydrolytic decomposition of the mercurial. Actually hydrolysis may be deleterious to the oxidation since the less stable *sec*-butylmercuric nitrate gives only a 5% yield of *sec*-butyl nitrate and no other product.

Secondly it can be shown that the oxymercurial is formed rapidly under the conditions of oxidation. When *cis*-stilbene is treated with two equivalents of a 0.125 molar methanolic solution of mercuric nitrate for 10 min. and then drowned in cold dilute aqueous sodium chloride the mercurous salt which is formed indicates that 8–9% of oxidation already has occurred, but the remainder of the precipitate (washed with hexane to remove stilbene) is 2-methoxy-1,2-diphenylethylmercuric chloride in 78% yield. It is believed that this yield represents an equilibrium concentration since it is depressed to 74% and to 73% by inclusion into the reaction system of two or four equivalents of nitric acid; these additions only increase the amount of oxidation to 10%.

Thirdly we have demonstrated that the oxymercurial rather than the alkene is the species which undergoes oxidation. When α-2-methoxy-1,2-diphenylethylmercuric nitrate (XIX) is treated with mercuric nitrate in ethanol a 39% yield of (*dd*,*ll*)-2-methoxy-1,2-diphenylethyl nitrate (XVII) is obtained, as compared with the 35% yield of this diastereomer obtained by oxidation of *cis*-stilbene from which the α mercurial is derived. If oxidation of the mercurial



had involved appreciable reversion to the alkene the product would have been the ethoxy nitrate (XX). The proof is valid unless the single equivalent of methanol which would be formed by decomposition of the methoxymercurial to the alkene were to be selected for the oxidation process from a large excess of ethanol. This doubt has been dispelled by treatment of *cis*-stilbene with two equivalents of mercuric nitrate in ethanol containing one equivalent of methanol. The product in 25% yield is evidently (*dd,ll*)-2-ethoxy-1,2-diphenylethyl nitrate (XX) since it is reduced by palladium-on-charcoal to ammonia and an oil. This oil must be (*dd,ll*)-2-ethoxy-1,2-diphenylethanol (XXI) since treatment with methyl iodide and silver oxide produces (*dd,ll*)-1-ethoxy-2-methoxy-1,2-diphenylethane (XXII), identical according to mixture melting point with that prepared by ethylation with silver oxide and ethyl iodide of (*dd,ll*)-2-methoxy-1,2-diphenylethanol (XVIII). Therefore it seems to be definite that the alkene reacts with two equivalents of mercuric nitrate, first to form the oxymercurial, the carbon–metal linkage of which is replaced by nitroxylation (and presumably by alkoxylation) without involvement of the vicinal oxy linkage.

Thus for kinetic study the oxidation of *cis*-stilbene by alcoholic mercuric nitrate may be described by two equations:

$$\underset{\text{VIII}}{\text{Alkene}} + \underset{A}{\text{Hg(NO}_3)_2} + \text{ROH} \underset{k_1}{\overset{k_2}{\rightleftharpoons}} \underset{\text{XIX}}{\text{mercurial}} + \text{HNO}_3 \qquad \text{[ii]}$$

$$\text{XIX} + \underset{A'}{\text{Hg(NO}_3)_2} + \text{ROH} \xrightarrow{k} \underset{B}{\text{Hg}_2\text{(NO}_3)_2} + (\gamma)\text{HNO}_3 + \begin{pmatrix}\text{XIII}\\ \text{XV}\\ \text{XVII}\end{pmatrix} \qquad \text{[iii]}$$

where γ is the fraction of nitrate ester (XVII) to total products. No general integrated equation has been devised (29) to express the kinetic behavior of such a reacting system, especially in consideration of the observed catalytic effect of nitric acid. However the knowedge that $k_1 \gg k_2 \gg k$ in the reaction with *cis*-stilbene makes this system amenable to study if the effect of nitric acid is neglected by examination of the early stages of reaction. This expedient is probably workable because the catalytic effect of nitric acid opposes its equilibrium-depressant effect in the first reaction. Then the kinetics may be described in terms of [iii] and if a is the initial concentration of A' and b is the concentration of XIX (or A) the second-order relationship of equation [i] is applicable.

However since k_1 is not infinitely larger than k_2 it is apparent that analytically it is better to follow the appearance of mercurous salt rather than the disappearance of mercuric salt. This preference is exemplified in Fig. 2 (see also Table XIII) wherein the combined rate of oxymercuration (reaction [ii]) and oxidation (reaction [iii]) is not apparent as a second-order relationship in $1/M$ but may be so interpreted in $1/P$. But this expedient is ineffective in the oxidation of *trans*-stilbene in methanol for several reasons. Firstly the system is not initially homogeneous. Secondly it is probable that k_2 actually is larger than k_1 and both are comparable with k. Nevertheless a roughly determined rate constant (0.017 l. moles^{-1} min.$^{-1}$) has been calculated showing

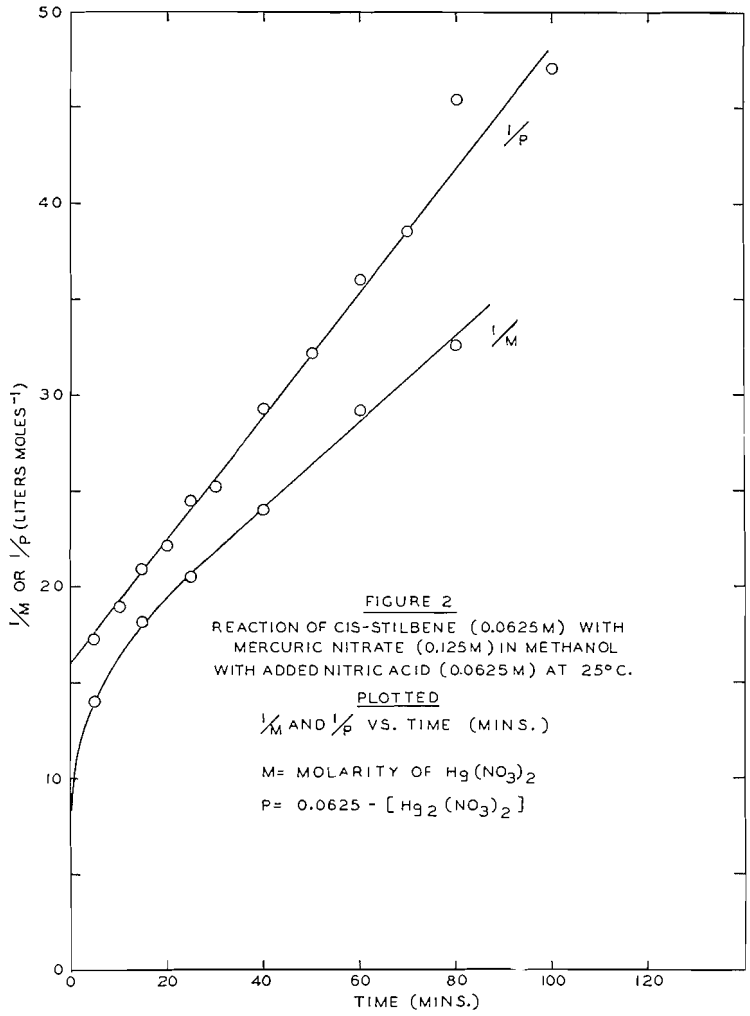


FIGURE 2
REACTION OF CIS-STILBENE (0.0625 M) WITH MERCURIC NITRATE (0.125 M) IN METHANOL WITH ADDED NITRIC ACID (0.0625 M) AT 25°C.

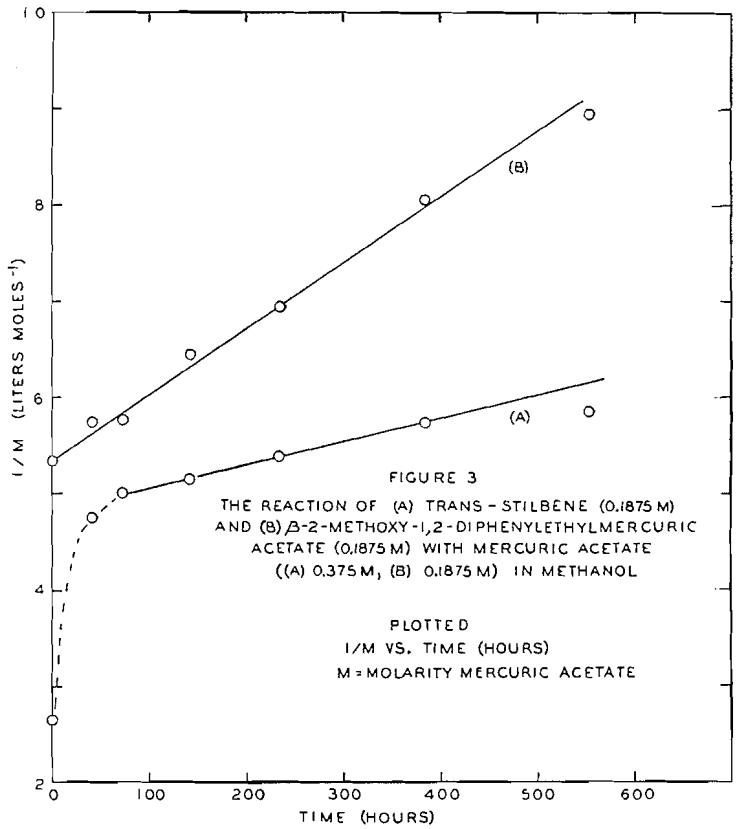
P= 0.0625 - $[Hg_2(NO_3)_2]$

at least that the over-all oxidation of the *trans*-isomer is slower than that of the *cis* form. Since mercurials easily decomposed according to reaction [ii] are usually oxidized more easily according to reaction [iii] it would seem that the slow rate of *trans*-stilbene oxidation is due to an especially unfavorable equilibrium in reaction [ii].

Probably because the reaction becomes more quickly homogeneous, and possesses a more favorable equilibrium in the mercuration step (like reaction [ii]), the kinetics of the oxidation of *trans*-stilbene by mercuric acetate in methanol (7) are more amenable for study than oxidation with mercuric nitrate though both mercurous nitrate and acetate are separable from mercuric salt. Titration of unchanged mercuric acetate after chloroform extraction of mercurial (41) provides concentration values of A' (reaction [iii]) from which reciprocals are plotted versus time (Curve A, Fig. 3). Despite the marked initial curvature characterizing the slow attainment of a steady-



state concentration of β-2-methoxy-1,2-diphenylethylmercuric acetate the remainder of the curve is sufficiently linear for calculation of 0.39×10^{-4} l. moles^{-1} min.$^{-1}$ as a second-order specific rate constant. However a better evaluation is possible since it is realized that the mercurial is an intermediate in the oxidation. Direct reaction of β-2-methoxy-1,2-diphenylethylmercuric acetate (from the chloromercurial and silver acetate) with one equivalent of methanolic mercuric acetate occurs according to Curve *B*, Fig. 3, the slope of which gives a realistic second-order rate constant of 1.2×10^{-4} l. moles^{-1} min^{-1}.

The products of the reactions of *cis*- and *trans*-stilbenes, as well as their characteristic oxymercurials, with methanolic mercuric acetate (containing boron fluoride etherate) are shown in Table VIII. The results, obtained by chromatographic separation, resemble those obtained with mercuric nitrate since *trans*-stilbene (VII) yields chiefly (*dl*,*ld*)-1,2-dimethoxy-1,2-diphenylethane (XII) together with a small amount of the (*dd*,*ll*)-diastereomer (XV), while the converse distribution of diastereomeric diethers is obtained from *cis*-stilbene. However it is notable that the ratio (*ca.* 4 : 1) of (*dd*,*ll*) to (*dl*,*ld*) diastereomer obtained from *cis*-stilbene is somewhat smaller than the ratio (*dl*,*ld*) to (*dd*,*ll*) (*ca.* 21 : 1) of these diastereomers obtained from *trans*-stilbene and methanolic mercuric acetate. Similar but lesser differences (diastereo-

meric ratios of *ca.* 7 : 1 for *cis*-stilbene and *ca.* 15 : 1 for *trans*-stilbene) are found (Table IV) for reactions of comparable duration with methanolic mercuric nitrate. Since the reactions with mercuric acetate are slower than those

TABLE VIII

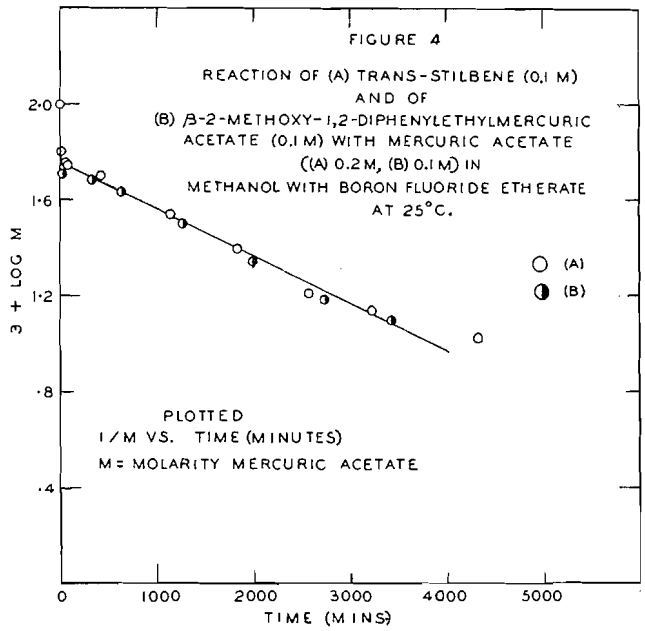
utilizing mercuric nitrate, and (as will be explained below) when the highly acidic methoxytrifluoboric acid is present, the systems described in Table VIII will suffer *cis–trans* isomerism (9). Although the exact position of the *cis–trans* equilibrium between the stilbenes is still in doubt (12) it is at least 95% *trans*. It might then be expected that, despite the faster rate of *cis*-stilbene mercuration, the preponderance of *trans*-stilbene following small extents of geoisomerization would tend to accentuate the diastereomeric ratio of (*dl*,*ld*) to (*dd*,*ll*). Evidence for some geoisomerization during the oxidation is provided by the observation that *cis*-stilbene recovered from the oxidations contains some *trans*-isomer. In consequence of these observations it is conceivable that the oxidation reaction is entirely stereospecific, and the nonstereospecific product is a consequence of side-reaction during experiments of long duration. Significant to this argument are the yields of 1,1-dimethoxy-2,2-diphenylethane (Table VIII) which are about the same for *cis*- and *trans*-stilbenes in these slow reactions with mercuric acetate, although they are quite different for the more rapid reactions with mercuric nitrate (Table IV).

It has been noted that the experiments described in Table VIII include boron trifluoride etherate (the methylate behaves identically) which has been shown previously (7) to accelerate oxidation of alkenes and their mercurials by mercuric acetate. The type, if not ratios, of products is the same if the catalyst is not used, but of course the yields are meager and are contaminated with products of side-reactions caused, for example, by the slow oxidation of methanol by mercuric acetate which takes place in absence of alkenes. However we have necessarily assumed, because of experimental difficulties of isolation, that the kinetic results of the uncatalyzed reaction of stilbenes with mercuric acetate give about the same amounts of products as those which have been isolated from reactions which are catalyzed with boron fluoride.

The kinetic behavior of the boron-fluoride-catalyzed reaction is quite different from that of the uncatalyzed reaction. In presence of the catalyst the reaction is first-order over-all up to at least 70% of completion. This behavior



is evident in Fig. 4 where the logarithm of mercuric acetate concentration has been plotted against time of reaction with *trans*-stilbene (Curve *A*) and its mercurial (Curve *B*) in presence of boron fluoride. The linearity is that expected of a first-order reaction although the initial stages indicate that oxymercuration, though rapid, does not go to completion; conversely the oxymercurial when used initially seems to decompose reversibly so as to regenerate mercuric acetate. This behavior is shown more clearly in Fig. 5, describing reaction of β-2-methoxy-1,2-diphenylethylmercuric acetate in methanol with boron fluoride alone. Disappearance of mercuric and appearance of mercurous salt have been determined simultaneously. At first there is a rapid appearance of mercuric acetate which then remains relatively constant at a ratio of 2 $Hg(OAc)_2$: 8 oxymercurial until, after about five hours, it begins to increase. The increase undoubtedly is due to shifting equilibrium caused by acetic acid generated by the oxidation which, according to the generation of mercurous salt, is proceeding continually.

The significance of the catalyst in respect of the first-order kinetics is shown in Table IX, where the rate is found to be directly proportional to the boron fluoride concentration. Also significant is the fact that the first-order oxidation rate of either *cis*-stilbene or its derivative, α-2-methoxy-1,2-diphenylethylmercuric acetate, is approximatey the same as that of *trans*-stilbene or the β-methoxymercurial. This similarity is shown by comparison of Expts. 1 and 2, Table X, with the rate constant (5.56×10^{-4}) for the comparable experiment with β-2-methoxy-1,2-diphenylethylmercuric acetate in Table IX. Expts. 3 and 4, Table X, also are comparable, although the recorded rate constants are different because Expts. 3–7 were analyzed for mercurous salt

while mercuric acetate was determined in the first two experiments. The rate constants are more accurate when calculated from mercurous salt analyses.

Inspection of Expt. 7, Table X, shows that first-order kinetics no longer are valid when the molar ratio of mercuric acetate to *cis*-stilbene becomes large. The same type of deviation is observed when the ratio of mercuric acetate to β-2-methoxy-1,2-diphenylethylmercuric acetate is 2 : 1 rather than 1 : 1 (k = 5.35 versus 4.9×10^{-4} min.$^{-1}$). Additionally the apparent rate seems to increase as the reactions with excess of mercuric acetate proceed. These behaviors are exemplified by comparison of the detailed kinetic data of Expt. 4 (and Expts. 6 and 7 are similar) with Expt. 7 in Table X. The comparison is delineated in Table XI in terms of calculated first- and second-order rate constants. No satisfactory integral order can be defined for Expt. 7, in contrast to the first-order kinetic agreement for Expt. 4.

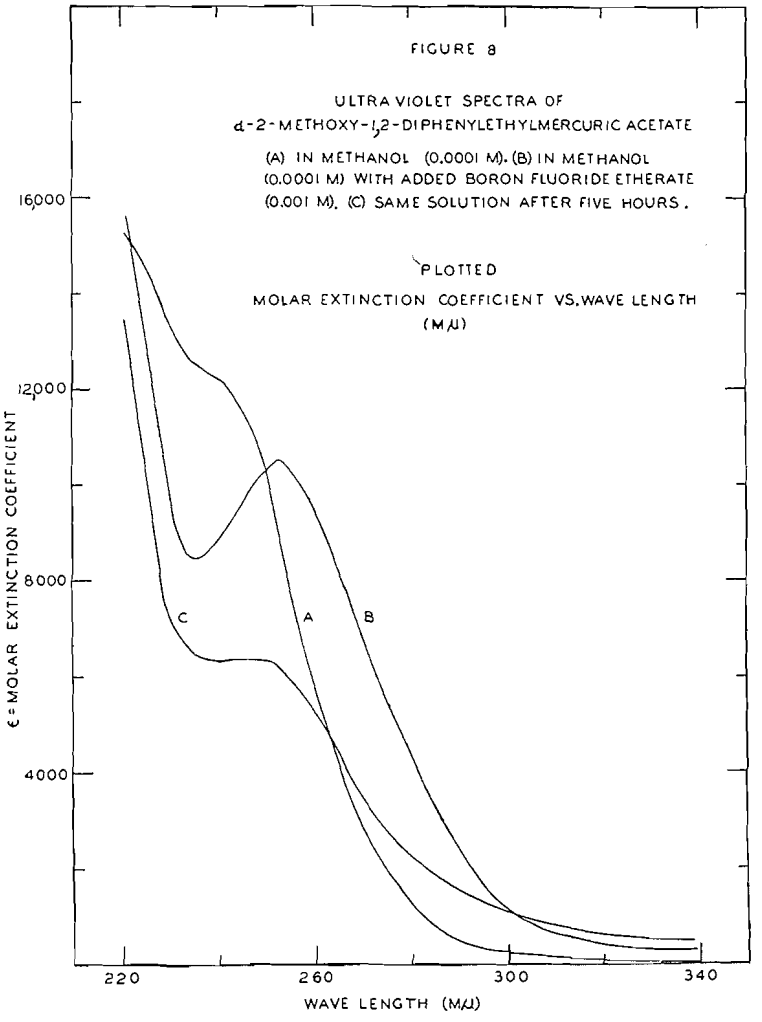
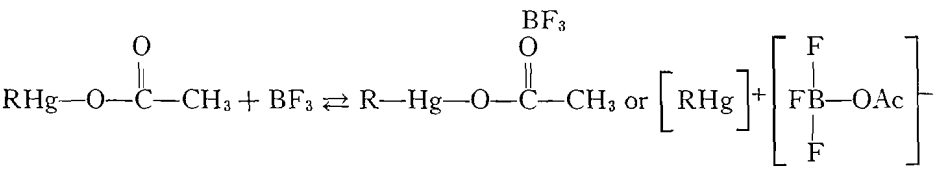
In order to evaluate these results the ultraviolet spectra of some of these systems have been examined. It may be seen in Fig. 6 that aqueous mercuric acetate (0.00023 *M*) is as transparent as water at wavelengths longer than 255 mμ but methanolic mercuric acetate (0.0005 *M*) begins to absorb at 300 mμ and is completely opaque at 220 mμ. The addition of boron fluoride etherate (0.0005 *M*) to this latter solution does not change its absorption. On the other hand it is seen in Fig. 7 that methanolic β-2-methoxy-1,2-diphenylethylmercuric acetate (0.0001 *M*) begins to absorb at about 340 mμ and the absorption rises steadily until a single inflection is found (E_{molar} = 11,000) at 240 mμ. Addition of boron fluoride etherate (0.001 *M*) to this solution has a profound effect. The absorption rises more steeply from 340 mμ to a peak at 253 mμ (E_{molar} = 9500) and then dips to a trough of transmission (E_{molar} = 7000) at 235 mμ. The α-2-methoxy-1,2-diphenylethylmercuric acetate in methanol shows essentially the same behavior (Fig. 8). However its solution containing



10 equivalents of boron fluoride has been examined further, with respect to time. After five hours it is found that the peak has almost disappeared, as if a complex were decomposing to give substances of greater transparency than those contained in the original system. These substances cannot include appreciable amounts of the stilbenes since the *cis*-isomer absorbs strongly at 270 mμ while the *trans* form absorbs at 300 mμ.

It would seem from these data that the combination of boron fluoride with acetate involves the rate-controlling step, which should then be first-order. Furthermore, since the ease of oxidation of alkenes (and of course the intermediate oxymercurial) is greater with salts of strong acids rather than weak ones, the boron fluoride must be creating a salt of a strong acid. The creation of an u.v. absorption region when boron fluoride is added to the oxymercurial, and the disappearance of this band at a rate commensurate with that of oxidation, indicates the reaction:



but the deviation from first-order kinetics with consequent acceleration when mercuric acetate is in large excess ought to involve the reaction:

$$AcOHgOAc + BF_3 \rightleftarrows [AcOHg]^+ [BF_3OAc]^-.$$

Thus the rate of oxidation by mercuric salts seems to depend on the acid involved with the mercury and, especially, with the intermediate organomercurial. However it is doubtful that the acid is functioning in an ionic form. The effectiveness of acids (HNO_3, H_2SO_4 > $HClO_4$ > $C_6H_5SO_3H$, CF_3COOH) does not correspond with the dissociation of these acids in water. Certainly in media such as ethanol, nitric acid is largely non-dissociated (15, 16, 21, 28). The ion concentration would have to be very low, but in this circumstance the reaction would have to be very sensitive to added ions. It has been shown (Table VII) that the oxidation as such is unaffected by addition of lithium nitrate. From these considerations it would seem that the acid and its salts were not active in the oxidation as free ions.

The effect of acid in the oxidation has an additional significance. It is known, and has further been demonstrated in the present report, that acids cause decomposition of oxymercurials, which then revert to the parent alkene. But those oxymercurials which are most stable toward acid decomposition are also most difficult to oxidize. For example, hydroxyethylmercuric nitrate and 2,2′-dinitratomercuridiethyl ether (which actually can be prepared from ethylene in acid solutions of mercuric salts) are recovered unchanged after treatment with mercuric nitrate in methanol.

Of course the hydrolytic decomposition and the oxidation of oxymercurials have other characteristic resemblances. Both seem to be stereospecific in the

sense that diastereomeric oxymercurials tend to revert by acid decomposition to the geoisomer from which they were originally derived, while oxidation gives derivatives characteristic of this geoisomer. This would seem to preclude the postulation of a carbonium ion intermediate in either reaction. The demonstration in the present report that the vicinal alkoxy group is not involved directly in the oxidation renders improbable the participation of an epoxonium ion. It would seem likely that molecular species are operative in both reactions either by ion-pair exchange (giving HgX^+ and X^- in the acid decomposition versus HgX^- in the oxidation) or by homopolar exchange giving HgX radicals from which mercuric or mercurous salts could be formed.

EXPERIMENTAL*

Acidic Hydroxymercuration of Cyclohexene

A solution 0.5 molar in mercuric nitrate and 1.0 molar in nitric acid was treated with cyclohexene equivalent to the mercuric salt. After 10 min. the system was poured into 0.1 molar aqueous sodium chloride equivalent to the cyclohexene. The yield of α-2-hydroxycyclohexylmercuric chloride, m.p. 145–147°, was 79%. A 20-min. experiment gave the identical yield. When the reaction system was 1.0 molar in mercuric nitrate and 2.0 molar in nitric acid the otherwise identical experiment gave a 63% yield.

Formylcyclopentane and Its Derivatives

(*a*) *From Mercuric Nitrate – Cyclohexene*

To a solution of 68.6 gm. (0.2 mole) of mercuric nitrate monohydrate in 400 ml. of water containing 12.6 ml. (0.2 mole) of 70% nitric acid was added with vigorous stirring 10.1 ml. (0.1 mole) of cyclohexene. After 84 hr. the system (which contained 0.8 gm. of free mercury) was extracted with four 50-ml. portions of chloroform. Distillation yielded 2.22 gm. (23%) of formylcyclopentane, b.p. 40–50° (8 mm.), n_D^{20} 1.4460, and 1.54 gm. (14%) of cyclopentanecarboxylic acid, b.p. 94° (8 mm.) n_D^{20} 1.4597. The residue, separated from 0.11 gm. of mercurous salt, was crystallized from 95% ethanol, 1.20 gm. (12%) of 2,4,6-tricyclopentyl-1,3,5-trioxane, m.p. 123–125°, identified by mixture melting point.

(*b*) *From Mercuric Nitrate and 2-Hydroxycyclohexylmercuric Nitrate*

When 8.38 gm. (0.025 mole) of 2-hydroxycyclohexylmercuric chloride was shaken with 50 ml. of water containing 4.25 gm. (0.025 mole) of silver nitrate and 5 ml. of methanol for 70 min. the precipitate of silver chloride weighed 3.71 gm. (92%). To the filtrate was added 8.54 gm. (0.026 mole) of mercuric nitrate in 50 ml. of water. The system was azeotropically distilled at 8 mm. and 35° for two hours. No cyclohexene was found in the ice-cooled or dry-ice-cooled receivers but 0.93 gm. (38%) of formylcyclopentane, b.p. 75–85° (94 mm.), was obtained by distillation of the ether extract. No cyclopentanecarboxylic acid was found.

**Melting points have been corrected against reliable standards. X-ray diffraction patterns were determined using Cu K_α (Ni filtered) radiation at relative intensities I/I_1 and d spacings in Angstrom units.*

(*c*) *From Methanolic Mercuric Nitrate – Cyclohexene*

A system containing 6.86 gm. (0.02 mole) of mercuric nitrate, 0.63 ml. (0.01 mole) of 70% nitric acid, and 1.01 ml. (0.01 mole) of cyclohexene in 40 ml. of methanol was studied kinetically by removal of 10-ml. aliquots into 40 ml. of 5% aqueous sodium chloride. After 17.5, 41.5, and 114 hr. the mercurous chloride weighed 0.28, 0.77, and 0.89 gm. respectively, representing oxidation to the extent of 24, 65, and 76%. The filtrate from the third aliquot on treatment with a solution of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid yielded 0.12 gm. of formylcyclopentane dinitrophenylhydrazone (17% based on cyclohexene), m.p. 148–152°, with X-ray diffraction pattern [10] 4.05; [6] 5.12; [5] 7.48; [4] 3.20; [1] 3.40; [0.5] 3.05, 2.44, 2.03, identical with an authentic specimen.

(*d*) *From Mercuric Nitrate and 2-Methoxycyclohexylmercuric Nitrate*

A quantitative yield of silver chloride was obtained when 3.49 gm. (0.01 mole) of α-2-methoxycyclohexylmercuric chloride was treated with 1.70 gm. (0.01 mole) of silver nitrate. The remainder of the system after three days with 3.25 gm. (0.01 mole) of mercuric nitrate was diluted with 100 ml. of water and extracted with 125 ml. of ether in four portions. This extract, washed with alkali and with water and dried with magnesium sulphate, was distilled to yield only 0.54 gm. (55%) of formylcyclopentane, n_D^{20} 1.4495, identified as the dinitrophenylhydrazone. The extracted aqueous dilution liquor yielded mercurous chloride quantitatively upon treatment with aqueous sodium chloride.

(*e*) *From Cyclohexene and Mercuric Sulphate*

After 11 hr. a system comprising 43.4 gm. (0.2 mole) of mercuric oxide in 50 ml. of 6 molar sulphuric acid (0.3 mole), 340 ml. of water, and 10.1 ml. (0.1 mole) of cyclohexene gave a negative test for mercuric salt. The suspension was flash-distilled at 10–12 mm. into receivers at −15° and −80°. Extraction of the distillate yielded 3.5 gm. (37%) of formylcyclopentane, b.p. 65–68° (75–76 mm.), identified as the dinitrophenylhydrazone. Extraction of the 96% yield of mercurous sulphate with chloroform gave an oil which, combined with the residue from distillation of the aldehyde, yielded about 0.8 gm. (7%) of cyclopentanecarboxylic acid, b.p. 80–90° (9 mm.).

(*f*) *From Cyclohexene and Other Mercuric Salts*

After five days a system comprising 9.48 gm. (0.06 mole) of benzenesulphonic acid, 4.34 gm. (0.02 mole) of mercuric oxide, and 1.01 ml. (0.01 mole) of cyclohexene was filtered to remove 0.12 gm. (3%) of free mercury. Treatment of the filtrate with sodium chloride followed by extraction with ether gave successively 3.65 gm. (77%) of mercurous chloride and 0.39 gm. of oil which gave the dinitrophenylhydrazone of formalcyclopentane. By contrast no trace of the aldehyde was obtained from mercuric phosphate.

2-Methyl-1-phenylpropene (I) Purification

The preparation according to Tiffeneau and Orékoff (35) gave a product in 90% yield, b.p. 75–86° (15–17 mm.), redistilled for 75% over-all yield, b.p. 75–79° (12–14 mm.), n_D^{20} 1.5376, d_4^{20} 0.903, m.p. −66 to −63°. After conversion

to 2-methoxy-2-methyl-1-phenylethylmercuric chloride (6), m.p. 78.5–80°, which was crystallized, the alkene was recovered by decomposition of the mercurial with 1 : 1 methanol – concentrated hydrochloric acid, aqueous dilution, and petroleum ether extraction. The distilled product boiled at 65.5–66° (12 mm.) or 75–77° (18 mm.), n_D^{20} 1.5405, and seemed to exist in polymorphic forms. Crystallization by rapid cooling gave a melting point of about −56°; if maintained at this temperature the sample resolidified, then melted at −50° to −48°.

2-*Methyl*-1-*phenylpropene with Mercuric Salts*

(*a*) *With Mercuric Nitrate in Methanol*

The addition of 17.0 gm. (0.052 mole) of mercuric nitrate to 100 ml. of methanol produced a yellow precipitate, principally mercuric oxide, but it redissolved within two minutes when 3.65 ml. (0.025 mole) of 2-methyl-1-phenylpropene was added. After 20 hr. the system was filtered from 4.74 gm. of mercurous nitrate. The filtrate, diluted with 200 ml. of water and thrice extracted with a total of 200 ml. of ether, was then treated with sodium chloride to precipitate mercurous chloride. Since the remaining liquor with hydrogen sulphide gave 0.6 gm. of mercuric sulphide, the total recovery of mercury is 98%.

The ether solution, washed with water, 5% alkali, and water, then dried with magnesium sulphate, contained 4.66 gm. of oil which was distilled (8 mm.) to yield two lots of impure (40%) 1,2-dimethoxy-2-methyl-1-phenylpropane (II), b.p. 94–100° (n_D^{20} 1.4966), m.p. 0–6°, and b.p. 100–106° (n_D^{20} 1.4980), finally purified by fractional freezing of the 2.11 gm. total, m.p. 8–11.5°, identified by mixture melting point (6). After an intermediate fraction, b.p. 106–122°, 0.57 gm. (n_D^{20} 1.5027), there distilled 1.30 gm. (23%) at 124–126° (n_D^{20} 1.5083) 2-methoxy-2-methyl-1-phenylpropyl nitrate (III). Anal.: Calc. for $C_{11}H_{15}O_4N$: N, 6.22. Found: N, 5.96. The intermediate and final fractions were contaminated with small amounts of benzaldehyde or its acetal, identified by preparation of its dinitrophenylhydrazone, m.p. 237–238°, with unchanged mixture melting point. The amount of benzaldehyde was enhanced by addition of nitric acid to the original system. Essentially the same yields of principal products were obtained (according to refractive indices) when 2-methoxy-2-methyl-1-phenylpropylmercuric nitrate replaced the 2-methyl-1-phenylpropene in the original system, although contamination with benzaldehyde was diminished.

In order to demonstrate that the nitrate ester is formed more rapidly than the 1,2-dimethoxy-2-methyl-1-phenylpropane a system comprising 2.029 gm. (0.00625 mole) of finely ground mercuric nitrate and 0.459 ml. (0.00313 mole) of 2-methyl-1-phenylpropene made up to 25 ml. with methanol was maintained at 25°. One series of 1-ml. aliquots was withdrawn periodically and analyzed according to kinetic methods outlined below. Another set of 5-ml. aliquots was periodically diluted with 10 ml. of 0.1 *N* nitric acid. The ether extract (40 ml.) of this diluate was extracted with two 10-ml. portions of 5% sodium sulphate, then diluted to exactly 50 ml. with ether. Two 10-ml. aliquots

of this solution were evaporated, treated with *m*-xylenol and sulphuric acid (42), and examined through a blue filter in the Klett Summerson colorimeter using potassium nitrate as a standard. A second experiment was performed with inclusion of 0.262 ml. (0.00625 mole) and at 29°. A single analysis was performed after 130 min. Results are outlined in Table XII.

TABLE XII

RATE OF NITRATE ESTER FORMATION IN REACTION OF MERCURIC NITRATE WITH 2-METHYL-1-PHENYLPROPENE

Expt.	Time, min.	% Reaction (*Y*)	% Nitrate ester (*X*)	Ratio *X*/*Y*
1	30	32	17	0.53
1	70	54	24	0.44
1	120	66	27	0.42
2	130	86	30	0.35

(*b*) *With Mercuric Trifluoroacetate in Methanol*

Mercuric trifluoroacetate was prepared by solution of 10.83 gm. (0.05 mole) of mercuric oxide in 10 ml. (0.147 mole) of trifluoroacetic acid. After the initial evolution of heat a further 5-ml. portion of trifluoroacetic acid was added, and the whole was heated on the steam bath until solution was almost complete. The hot suspension was filtered through sintered glass and chilled to 0°. The white crystals were filtered off and vacuum dried, 10.9 gm. (53%), m.p. 164–168° with softening at 158°. The X-ray diffraction pattern was: [20] 10.00; [18] 10.64; [16] 15.49, 13.71; [14] 4.90; [12] 7.82, 4.18; [10] 4.07, 3.40, 3.15; [8] 4.48, 3.53; [6] 5.27, 3.91, 2.98, 2.66, 2.28; [4] 6.91, 3.76, 2.93, 2.36, 2.23, 2.03; [2] 6.44, 5.49, 4.76, 3.33, 2.77, 2.00, 1.96, 1.93; [1] 7.49, 5.71, 2.59, 2.48. Anal.: Calc. for $Hg(CF_3COO)_2$: Hg, 47.0. Found: Hg, 46.7.

To a solution of 4.27 gm. (0.01 mole) of mercuric trifluoroacetate in 20 ml. of methanol was added 0.73 ml. (0.005 mole) of 2-methyl-1-phenylpropene. Dilution with 25 ml. of water after two days and extraction with 20 ml. of chloroform gave a solution which, washed with water, 2 *N* hydrochloric acid, 5% aqueous alkali and water, then dried, was distilled at 16 mm. giving 0.45 gm., b.p. 106–111°, n_D^{20} 1.4999, and 0.17 gm., b.p. 110–120, $_D^{20}$ 1.5080, and 0.21 gm. of residue. The first fraction (m.p. −16 to −6°) was converted in part to 3-phenylbutanone-2 dinitrophenylhydrazone with the methanolic hydrochloride reagent and was identified by mixture melting point. According to the 1.98 gm. of mercurous chloride obtained from the diluted reaction liquor by hydrochloric acid treatment the oxidation reaction was 84% complete.

(*c*) *With Mercuric Sulphate in Water*

To the bright yellow precipitate obtained when 21.7 gm. (0.1 mole) of mercuric oxide was shaken with 200 ml. (0.2 mole) of molar sulphuric acid was added 7.31 ml. (0.05 mole) of 2-methyl-1-phenylpropene. After shaking for two days 23.5 gm. (95%) of mercurous sulphate was filtered off and washed with methanol and ether. The filtrate was extracted with this ether and with three more 25-ml. portions of ether and three 50-ml. portions of chloroform.

Evaporation of the combined, dried extract left 5.80 gm. (70%) of 2-methyl-1-phenylpropanediol-1,2 which crystallized slowly, m.p. 47–62°. Crystallization from diethyl ether and petroleum ether (b.p. 40–50°) gave 4 gm., m.p. 63–63.5°, identified by mixture melting point with an authentic sample.

2-Methoxy-2-methyl-1-phenylpropanol-1 (IV)

A solution of 0.78 gm. (0.0035 mole) of 2-methoxy-2-methyl-1-phenylpropyl nitrate in 7 ml. of acetic acid was warmed gently while small amounts of zinc dust and iron powder were added until a test sample no longer gave a blue color with diphenylamine and sulphuric acid. The dark-brown mixture was filtered into 30 ml. of water containing 15 gm. of potassium carbonate (pH 8). A triple extraction with 40 ml. total of ether removed an oil, b.p. 118–124° (12 mm.), 0.44 gm. (70%), n_D^{20} 1.5177, m.p. 17–23° (actual yield probably only half this apparent 70%). A repeated partial freezing raised this melting point to 36–39°. This alcohol, still impure, was identified by preparation of derivatives.

After oxidation of 0.08 gm. of the impure alcohol with one equivalent of alkaline permanganate at 0° the mixture was extracted with ether and the extract evaporated. The oil was dissolved in methanol and the dried solution was treated with 2,4-dinitrophenylhydrazine to yield 0.03 gm. of α-methoxyisobutyrophenone dinitrophenylhydrazone, m.p. 124–127°, which, crystallized from methanol and from 20 : 1 petroleum ether – benzene, melted at 139–140° (0.01 gm.). The X-ray powder diagram was: [10] 10.97, 3.54; [9] 3.09; [7] 9.25, 4.13; [6] 6.21, 3.97; [5] 6.75, 5.53, 3.23; [4] 4.87; [3] 4.31, 2.82; [2] 2.97. Comparison with this powder diagram and by mixture melting point showed that this derivative was identical with that obtainable from the known ketone (1).

trans-Stilbene with Methanolic Mercuric Nitrate

A clear solution was obtained after one hour from 0.90 gm. (0.005 mole) of *trans*-stilbene and 3.41 gm. (0.0105 mole) of mercuric nitrate in 40 ml. of methanol. Dilution with 100 ml. of water after 38 hr. gave a mixture which was thrice extracted with a total of 70 ml. of ether. Treatment of the aqueous layer with 10 ml. of saturated sodium chloride precipitated 2.28 gm. (92%) of mercurous chloride.

The etherous extract, washed with 5% alkali and water, then dried with sodium sulphate, was evaporated leaving 1.19 gm. of semisolid, of which a benzene solution of 339 mgm. was chromatographed on non-activated 80–200 mesh Alcoa alumina in a column 29 × 1.6 cm. Elution with benzene gave 10 fractions: 1, 10 ml. (29 mgm.), m.p. 110–119°; 2, 11 ml. (131 mgm.), m.p. 85–89°; 3, 10 ml. (42 mgm.), m.p. 120–135°; 4, 10 ml. (27 mgm.), m.p. 139.5–140.5°; 5, 10.5 ml. (11 mgm.), oily solid; 6, 10 ml. (32 mgm.), oil; 7, 11 ml. (21 mgm.), oil; 8, 16 ml. (12 mgm.), oil; 9, 15.5 ml. (1 mgm.); 10, 40 ml. (9 mgm.), m.p. 89–91°.

Fraction 1, crystallized from ethanol, was *trans*-stilbene (VII), m.p. 121–123°, identified by mixture melting point. Fraction 2 was crystallized four times from methanol, m.p. 91.4–92.0°, and this (*dl,ld*)-2-methoxy-1,2-diphenylethyl nitrate (IX) gave a positive test with diphenylamine and sulphuric acid.

Anal.: Calc. for $C_{15}H_{15}O_4N$: C, 65.9; H, 5.50; N, 5.13. Found: C, 66.2; H, 5.69; N, 5.09. X-Ray diffraction pattern: [10] 3.79; [7] 9.25, 3.39; [5] 5.65, 5.50, 5.18; [4] 7.62, 6.13, 3.97; [3] 4.29, 4.16; [2] 3.26, 3.02; [1] 4.79, 2.90, 2.79. Fraction 3 is an impure specimen of fraction 4, which is almost-pure (*dl,ld*)-1,2-dimethoxy-1,2-diphenylethane (XII) as was authenticated by mixture melting point and by X-ray diffraction pattern: [10] 5.21; [9] 4.98; [8] 4.76, 3.50; [7] 5.96; [6] 4.01; [4] 9.45, 4.53, 4.44; [3] 6.91, 6.53, 3.37, 3.28; [2] 3.21; [1] 3.13, 3.03, 2.99, 2.81, 2.76. Disregarding fraction 5, the next three, 6, 7, and 8, were combined (n_D^{20} 1.5280) and evidently comprised in large part diphenylacetaldehyde dimethyl acetal (XIII) since it gave no active hydrogen and no carbonyl addition in the Grignard machine, yet slowly yielded the 2,4-dinitrophenylhydrazone of diphenylacetaldehyde (m.p. 143–146°) when it was treated with the methanolic hydrochloride reagent. Two crystallizations from ethanol or chloroform–petroleum ether (b.p. 60–70°) or from methanol–ethyl acetate raised this melting point to 150.2–150.5°. Anal.: Calc. for $C_{20}H_{14}O_4N_4$: C, 63.8; H, 4.29; N, 14.9. Found: C, 63.7; H, 4.24; N, 14.6. The X-ray diffraction pattern was: [10] 15.6; [8] 5.20, 3.65, 3.18; [7] 4.60, 3.94; [6] 6.93; [5] 7.73; [4] 5.64, 5.40. When this derivative was prepared from authentic diphenylacetaldehyde, b.p. 165–166° (12 mm.), n_D^{20} 1.5878, d_4^{20} 1.09, it was found to be identical with the analyzed sample. Fraction 10 was shown by mixture melting point to be (*dd,ll*)-1,2-dimethoxy-1,2-diphenylethane. Its X-ray diffraction pattern was: [10] 6.30, 3.55; [9] 5.01, 4.95; [6] 7.28; [5] 8.58, 4.26, 4.13; [4] 3.32; [3] 5.43, 4.74; [2] 5.88, 3.76; [1] 3.96, 3.06, 2.90.

(*dl,ld*)-2-*Methoxy*-1,2-*diphenylethanol* (*X*)

(*a*) *From Benzoin Methyl Ether*

The procedure of Irvine and Weir (19) was altered by reduction with Raney nickel in ethanol at 27° and 1–2 atmospheres. The product (97%) melted at 100–102°, X-ray diffraction pattern: [10] 5.14; [9] 3.63, 3.42; [7] 8.66, 3.90; [6] 4.66; [4] 12.7, 6.39, 5.64, 4.27, 3.98; [3] 4.88, 3.82, 3.74; [1] 3.34. The configuration was demonstrated by treatment of 1.14 gm. (0.005 mole) with 7.10 gm. (0.05 mole) of methyl iodide and 4.35 gm. (0.016 mole) of fresh gradually-added silver oxide under reflux for five hours. The product (83%) m.p. 140–142° after crystallization was identical (mixture melting point) with that obtained by methylation of hydrobenzoin.

(*b*) *From* (*dl,ld*)-2-*Methoxy*-1,2-*diphenylethyl Nitrate* (*IX*)

A solution of the nitrate ester (27 mgm., 0.0001 mole) in 4 ml. of 1 : 1 dioxane–ethanol was hydrogenated at atmospheric pressure over 0.1 gm. of palladium-on-charcoal (17). The system, containing ammonia, was filtered and evaporated, 19 mgm. (83%), m.p. 97.5–100°. Crystallization from ethanol–water raised the melting point to 100.5–101.8°. The compound was identical with that obtained by procedure (*a*).

(*c*) *From Stilbene Oxide and Methyl Nitrate – Nitric Acid*

When 0.196 gm. (0.001 mole) of stilbene oxide (34) (m.p. 68–69°) in 10 ml. of methanol was treated with 0.154 gm. (0.002 mole) of methyl nitrate (b.p.

65–66°, n_D^{20} 1.3754, d_4^{20} 1.192) at 27° for 29 hr. it was recovered unchanged. However when 0.105 ml. (0.0025 mole) of absolute nitric acid was added the system upon vacuum evaporation after 42 hr. yielded 0.226 gm. of yellow solid, m.p. 40–90°. Chromatography on alumina did not yield any methoxy nitrate ester or dimethoxy compound but 97 mgm., m.p. 91–96°, was obtained, from which (*dl,ld*)-2-methoxy-1,2-diphenylethanol, m.p. 99.5–100.5°, was identified (after crystallization from petroleum ether (b.p. 60–70°) and ethanol–water) by mixture melting point. Both (*dl,ld*)-1,2-dimethoxy-1,2-diphenylethane and (*dl,ld*)-2-methoxy-1,2-diphenylethyl nitrate were found to be stable in the reaction system.

cis-Stilbene with Methanolic Mercuric Nitrate

A shaken suspension of 3.41 gm. (0.0105 mole) of mercuric nitrate and 0.43 gm. (0.0024 mole) of *cis*-stilbene (40) in 40 ml. of methanol was clear after five minutes. After 48 hr. the system was diluted into 80 ml. of water. The diluate, extracted with three 10-ml. portions of chloroform, was then treated with 10 ml. of saturated aqueous sodium chloride to precipitate 1.33 gm. (0.0055 mole) of mercurous chloride. Addition of ammonia to the filtrate then precipitated 1.09 gm. (0.0043 mole) of aminomercuric chloride to give a total of 93% of the original mercury.

The chloroform extract, washed with 5% alkali and with water and dried over sodium sulphate, was evaporated to leave 0.703 gm., semicrystalline, of which 0.242 gm. in benzene was chromatographed as was described for the oxidation of *trans*-stilbene. Fraction 1, 3 mgm., was *cis*-stilbene; 2, 94 mgm., m.p. 87–93°; 3, 6 mgm., m.p. 115–138°; 4, 81 mgm., oil; 5, 31 mgm., m.p. 85–91°. Fraction 2 was twice crystallized from methanol and once from ethanol, m.p. 93.6–93.9°. The X-ray diffraction pattern of this (*dd,ll*)-2-methoxy-1,2-diphenylethyl nitrate (XVII, which gave a blue color with diphenylamine and sulphuric acid) was measured: [10] 10.77, 10.39, 4.08, 4.04; [9] 6.94, 6.73; [8] 7.43, 7.25; [7] 5.18, 5.09, 2.78; [5] 3.64, 3.36; [4] 3.19; [3] 8.07, 7.79, 6.15, 5.30, 4.98. A mixture melting point with the (*dl,ld*)-diastereomer was depressed. Anal.: Calc. for $C_{15}H_{14}NO_4$: C, 65.9; H, 5.50; N, 5.13. Found: C, 65.9; H, 5.80; N, 5.02. Fraction 3, when crystallized from methanol, melted at 138–140°, identified as (*dl,ld*)-1,2-dimethoxy-1,2-diphenylethane by mixture melting point and X-ray diffraction pattern. Fraction 4 was converted to diphenylacetaldehyde 2,4-dinitrophenylhydrazone, m.p. 145–146°, with the methanolic hydrochloride reagent. After crystallization (m.p. 150°) it was authenticated by mixture melting point. Fraction 5 was identified by mixture melting point and X-ray diffraction pattern as (*dd,ll*)-1,2-dimethoxy-1,2-diphenylethane (XV).

(*dd,ll*)-2-*Methoxy*-1,2-*diphenylethanol* (*XVIII*)

(*a*) *From Benzoin Methyl Ether and Aluminum Isopropoxide*

A mixture of 2.12 gm. (0.01 mole) of benzoin methyl ether, 4.0 gm. (0.02 mole) of aluminum isopropoxide, and 35 ml. of isopropyl alcohol in a Hahn apparatus (14) was slowly distilled (28 ml.) until acetone (dinitrophenylhydrazine test) no longer was produced. The cooled residue, diluted with 35 ml.

of 7% hydrochloric acid, was twice extracted with ether. The extract (washed with 5% alkali and water, and sodium-sulphate-dried) was evaporated, 1.88 gm., m.p. 55–59°. By fractional crystallization from petroleum ether (b.p. 60–70°) the more soluble component was separated, m.p. 54.5–55.5°; X-ray diffraction pattern: [10] 5.21; [7] 8.66, 5.71; [6] 4.77; [5] 6.65; [3] 5.01; [2] 4.35, 4.07, 4.00, 3.85, 3.74, 3.49; [1] 13.4, 3.69. Anal.: Calc. for $C_{15}H_{16}O_2$: C, 78.9; H, 7.07. Found: C, 78.4; H, 7.16. The configuration was confirmed by methyl iodide – silver oxide methylation; 0.094 gm. (99%), m.p. 80–88°, was crystallized from 0.5 ml. of methanol, m.p. 92–93°. This (*dd,ll*)-1,2-dimethoxy-1,2-diphenylethane (XV), identical with that obtained by methylation of isohydrobenzoin, was compared by mixture melting point and X-ray diffraction pattern.

(*b*) *By Reduction of* (*dd,ll*)-2-*Methoxy*-1,2-*diphenylethyl Nitrate* (*XVII*)

The procedure used for the (*dl,ld*)-diastereomer gave a 75% yield, m.p. 50–52°. After crystallization from petroleum ether (b.p. 60–70°) this (*dd,ll*) isomer, m.p. 54.3–55.5°, was identified by mixture melting point and X-ray diffraction pattern.

α-2-*Methoxy*-1,2-*diphenylethylmercuric Chloride*

After about four minutes a strongly shaken mixture of 1.07 gm. (0.0033 mole) of mercuric nitrate and 0.281 gm. (0.0016 mole) of *cis*-stilbene in 25 ml. of methanol at 25° was clear. After 10 min. of reaction time the system was added to 25 ml. of cold 0.4 *N* aqueous sodium chloride. The precipitate, 0.737 gm., was extracted with chloroform, then with methanol to remove mercuric chloride, leaving 0.129 gm. (17%) of mercurous chloride.

The evaporated chloroform solution (0.584 gm.) was washed with 1 ml. of petroleum ether (b.p. 60–70°) to leave 0.548 gm., m.p. 132–139°. After crystallization from ethanol the product (m.p. 141–143°) was identified by mixture melting point.

α-2-*Methoxy*-1,2-*diphenylethylmercuric Nitrate* (*XIX*) *with Ethanolic Mercuric Nitrate*

After 1.118 gm. (0.0025 mole) of α-2-methoxy-1,2-diphenylethylmercuric chloride and 0.425 gm. (0.0025 mole) of silver nitrate in 10 ml. of anhydrous ethanol was shaken for 35 min. and the silver chloride (0.354 gm. or 0.0025 mole) was filtered and washed with 10 ml. of anhydrous ethanol, the combined filtrate and washings were shaken with 0.845 gm. (0.0026 mole) of mercuric nitrate for 72 hr. Filtration removed 1.047 gm. (0.004 mole) of mercurous nitrate; the filtrate, diluted with an equal volume of water, was thrice extracted with 5-ml. portions of chloroform and was treated then with dilute hydrochloric acid. The precipitated mercurous chloride weighed 0.31 gm. (0.001 mole).

The water-washed chloroform extract was dried and evaporated, leaving 0.633 gm. This product was partially chromatographed, as outlined above, to yield two fractions. The first was crystallized from petroleum ether (b.p. 60–70°), 0.237 gm. (39%), identified as (*dd,ll*)-2-methoxy-1,2-diphenylethyl

nitrate, m.p. 93.5–94°, by mixture melting point. The second fraction, which was oily and weighed 0.290 gm., was treated with hot methanolic 2,4-dinitrophenylhydrazine hydrochloride reagent, yielding the derivative, m.p. 133–138°. After crystallization from ethyl acetate – methanol, m.p. 150–151°, this diphenylacetaldehyde dinitrophenylhydrazone was identified by mixture melting point. If the oil is the diethyl acetal the yield is 43% of theoretical.

(dd,ll)-2-Ethoxy-1,2-diphenylethyl Nitrate

To a mixture of 1.69 gm. (0.0052 mole) of mercuric nitrate in 20 ml. of anhydrous ethanol containing 0.080 gm. (0.0025 mole) of methanol (shaken until the solid had disintegrated) was added 0.4506 gm. (0.0025 mole) of *cis*-stilbene and the mixture was shaken vigorously for 48 hr. After dilution with water the system was thrice extracted with a total of 20 ml. of chloroform. The aqueous layer yielded 0.0049 mole of mercurous chloride when it was treated with aqueous sodium chloride.

The water-washed chloroform extract was dried and evaporated to leave 0.658 gm. of an oil. Chromatography of 258 mgm. of this oil by the method outlined above yielded 29 mgm., m.p. 48–68°, and 80 mgm., m.p. 67–73°, as well as 117 mgm. of an oil. The 80 mgm. portion was crystallized from petroleum ether (b.p. 60–70°), 52 mgm., m.p. 74–75°. Recrystallization raised this melting point to 74.8–75.5°; X-ray diffraction pattern: [10] 3.88; [5] 10.04, 4.82; [4] 4.58, 4.13; [3] 2.94. Anal.: Calc. for $C_{16}H_{17}NO_4$: C, 66.9; H, 5.97; N, 4.88. Found: C, 67.3; H, 6.14; N, 4.68. The residue from the evaporated crystallization liquors melted at 57–69°, 27 mgm.

(dd,ll)-1-Ethoxy-2-methoxy-1,2-diphenylethane (XXII)

(a) From (dd,ll)-2-Methoxy-1,2-diphenylethanol (XVIII)

Gradual addition of 0.46 gm. (0.002 mole) of fresh silver oxide to 83 mgm. (0.0036 mole) of the alcohol in 2.0 ml. (0.0025 mole) of boiling ethyl iodide during four hours gave a mixture which was filtered and evaporated; 89 mgm. slowly crystallized, m.p. 51–54°. A benzene solution, passed through 10 gm. of Alcoa alumina in a column, gave a fraction (79 mgm.), m.p. 54–55°, which was crystallized from 0.3 ml. of petroleum ether (b.p. 40–50°), m.p. 55.2–55.5°, with X-ray diffraction pattern: [10] 6.48; [9] 5.24; [5] 9.16, 7.13, 4.20; [4] 3.81, 3.57, 3.44. Anal.: Calc. for $C_{17}H_{20}O_2$: C, 79.7; H, 7.86. Found: C, 79.7; H, 7.97.

(b) From (dd,ll)-2-Ethoxy-1,2-diphenylethyl Nitrate (XX)

Hydrogenation of 36 mgm. (0.00125 mole) of the nitrate ester with palladium-on-charcoal as outlined earlier yielded 30 mgm. of oil which was methylated with silver oxide and methyl iodide. The crude product in benzene was passed through 2 gm. of Alcoa alumina in a column and the main fraction upon evaporation slowly crystallized, m.p. 53–54.5°. A mixture melting point with product prepared by procedure (*a*) was not lowered.

β-2-Methoxy-1,2-diphenylethylmercuric Acetate

After shaking 5.0 gm. (0.0112 mole) of β-2-methoxy-1,2-diphenylethylmercuric chloride and 1.87 gm. (0.012 mole) of silver acetate in 40 ml. of

methanol for one hour in the dark the mixture was filtered from silver chloride (100%). Vacuum evaporation of the filtrate left 5.35 gm. (100%), m.p. 100–104°. Solution in 15 ml. of methanol followed by dilution with 8 ml. of water gave 4.22 gm., m.p. 103.5–105°. After crystallization from 95% ethanol the X-ray diffraction pattern of the compound, m.p. 104.5–105.5°, was determined: [10] 11.04; [9] 4.16; [8] 3.43; [6] 4.38; [5] 5.79, 4.58; [3] 3.73; [1] 7.59, 5.27, 4.95. Anal.: Calc. for $C_{17}H_{18}HgO_3$: Hg, 42.6. Found: Hg, 42.4. The product was identified by reconversion to the chloromercurial by treatment of a methanolic solution with aqueous sodium chloride.

cis- or trans-Stilbene or the Corresponding Methoxymercurials with Methanolic Mercuric Acetate and Boron Fluoride Etherate at 25°

The reaction with *trans*-stilbene is typical. A solution of 0.90 gm. (0.005 mole) of *trans*-stilbene, 3.19 gm. (0.01 mole) of mercuric acetate (crystallized from acetic acid), and 0.28 gm. (0.002 mole) of boron fluoride etherate was made up to 100 ml. with dry methanol. The reaction was followed by titration of 2-ml. aliquots with thiocyanate solution after they had been diluted with water and extracted with chloroform. After five days the system was filtered to remove 1.70 gm. (65%) of mercurous acetate. The filtrate, evaporated and diluted with water, was thrice extracted with chloroform. The extract, washed with 5% alkali, water, and then dried and evaporated, yielded 1.055 gm. of semisolid. Chromatography of 277 mgm. as described before yielded 26 mgm. of stilbene, 130 mgm. of impure (*dl,ld*)-1,2-dimethoxy-1,2-diphenylethane, m.p. 137–139° (mixture melting point at 140–141.5° after crystallization from ethanol), 40 mgm. of diphenylacetaldehyde acetal, converted to its 2,4-dinitrophenylhydrazone, m.p. 145–147°, purified 149–150°, m.m.p., and finally 6 mgm. of impure (*dd,ll*)-1,2-dimethoxy-1,2-diphenylethane, crystallized from methanol to melt at 90–91°, m.m.p.

Benzylmercuric Nitrate and Methanolic Mercuric Nitrate

A mixture of 6.54 gm. (0.02 mole) of benzylmercuric chloride (22), m.p. 105–105.5°, and 3.40 gm. (0.02 mole) of finely-ground silver nitrate in 20 ml. of methanol was vigorously shaken for several hours, then filtered to remove 2.75 gm. (0.019 mole) of methanol-washed silver chloride. Then 6.83 gm. (0.021 mole) of mercuric nitrate was added and the system was shaken nine hours and let stand 30 hr. After filtration to remove 0.17 gm., infusible, the system was diluted with an equal volume of water and four times extracted with 50 ml. total of chloroform. The extract, washed with cold 5% aqueous sodium hydroxide and water, then dried over sodium sulphate, was distilled, yielding two discreet fractions. The first one (0.90 gm., 46%) was benzyl methyl ether, b.p. 62–70° (15 mm.), n_D^{20} 1.5042; redistilled at 168–171° (750 mm.), n_D^{20} 1.5040, m.p. −61 to −56°, it was identified by mixture melting point with an authentic sample, b.p. 170.5°, n_D^{20} 1.5034, m.p. −56 to −54° (31).

The second fraction, b.p. 65–75° (1.5 mm.), n_D^{20} 1.5212 (0.47 gm., 15%), was redistilled at 66–72° (1–2 mm.), n_D^{20} 1.5204, m.p. −21 to −19°, and then frozen fractionally, m.p. −19.5 to −15°. Anal.: Calc. for $C_7H_7NO_3$: NO_3, 40.5. Found: NO_3, 40.0. This benzyl nitrate was identified by mixture melting point

with an authentic sample (26), b.p. 99–100° (16 mm.), n_D^{20} 1.5211, m.p. −17 to −15° (uncorr.). When toluene was subjected to the same reaction conditions used for the mercurial neither of the products was detected and no mercurous salt was formed.

sec-Butyl Nitrate

A mixture of 5.86 gm. (0.02 mole) of *sec*-butylmercuric chloride (27), m.p. 128.5–129.3°, and 3.40 gm. (0.02 mole) of finely-ground silver nitrate in 25 ml. of methanol was shaken for 30 min. After filtration from 2.93 gm. of silver chloride the filtrate with 20 ml. of methanolic washings was shaken with 6.83 gm. (0.021 mole) of mercuric nitrate for 10 hr., then filtered to remove 3.33 gm. (30%) of mercurous nitrate. The filtrate diluted with water was ether extracted and the extract, water and alkali washed, was dried and distilled to yield a fraction, b.p. 120–123° (750 mm.), 0.12 gm. (5%), n_D^{20} 1.4006. This product was identified as *sec*-butyl nitrate by its physical constants (23), by a positive test with diphenylamine – sulphuric acid, and by uptake of hydrogen over palladium-on-charcoal to the extent of 96% of that expected for *sec*-butyl nitrate with consequent formation of ammonia.

2,2′-Dinitratomercuridiethyl Ether with Methanolic Mercuric Nitrate

Both this compound and hydroxyethylmercuric nitrate were prepared by the method of Hoffmann and Sand (18) and both were stable toward 10% nitric acid although they were decomposed by hydrochloric acid. When a methanolic solution of dinitratomercuridiethyl ether was shaken for five days with mercuric nitrate there was no evidence for mercurous salt formation, even when some water was added to the system.

Methods of Analysis for Kinetic Studies

When analysis for mercuric salts in absence of chlorides was possible the method of thiocyanate titration following chloroform extraction (41) was used. However the interference by mercurous salt frequently made this method unusable and the procedure of Personne (32) was refined for our purpose. By this refinement a 1 or 2 ml. aliquot (which might be about 0.5 molar in total inorganic mercury I and II) was added to 10 ml. of water in a separatory funnel and 1 ml. of 1 *N* nitric acid was added to prevent hydrolysis of the inorganic mercury salts. Three extractions with 5-ml. portions of chloroform were made for removal of organomercurial, then the aqueous layer was rinsed into 10 ml. of 2 *N* hydrochloric acid. The resulting precipitate of mercurous chloride was filtered off after 20 or 30 min. with celite as filter-aid, and washed at least four times. Filtrate and washings were combined and treated with 10 ml. of 0.19 *N* potassium iodide solution. The clear solution was diluted to a volume of about 80 ml. and was titrated with standardized (against red mercuric oxide in nitric acid) 0.1 *N* mercuric nitrate solution to the first appearance of a permanent red color due to mercuric iodide. Best results are obtained using a dark background and side-lighting. The titer value was subtracted from a blank carried out similarly on the potassium iodide solution. It is important that the final volume of each analyzed solution be nearly the same.

$$\text{Molarity of } Hg^{++} = \frac{\text{normality}}{2} \cdot \frac{\text{(vol. of blank titer} - \text{vol. of sample titer)}}{\text{volume of aliquot}}$$

Since 2-hydroxycyclohexylmercuric salts cannot be extracted quantitatively by chloroform the kinetic study of cyclohexene oxidation by aqueous mercuric nitrate does not include the extraction step and the aliquot is added directly to dilute hydrochloric acid which decomposes the hydroxymercurial and precipitates the mercurous salt at the same time. In this event the rate must be calculated on the assumption that the oxymercuration has gone rapidly to completion (see equation [i]).

The determination of mercurous salt above, or of both mercurous and mercuric salt, is obviously better suited to a kinetic study of oxidation by mercuric salt than is a determination of the mercuric salt alone, especially since the organomercurial is involved as an intermediate. Two methods have been employed.

In the first method, after extraction of the organomercurial the mercurous salt is precipitated but then filtered and washed by suction on a micro filtering crucible from which it is dissolved and oxidized by warming with 2 ml. of *aqua regia* until solution is complete. This solution is diluted, treated with potassium iodide, and titrated as described before,

$$Hg_2^{++} = \frac{\text{normality}}{4} \cdot \frac{\text{blank titer} - \text{sample titer}}{\text{volume of aliquot}},$$

while the mercuric salt is determined as before.

The second method is iodometric. After extraction of the organomercurial the aqueous layer is rinsed into a solution of 0.5 gm. of potassium iodide in 10 ml. of 2 *N* hydrochloric acid plus 5 ml. of 0.1 *N* standard iodine solution. Titration is then carried out with 0.1 *N* standard thiosulphate using a starch endpoint because of a tendency for the final solution to be slightly yellow.

Kinetic studies based on this determination of mercurous salt are shown in Table XIII, depicting the reaction of *cis*-stilbene with mercuric nitrate in methanol at 25°. Rates calculated from data corresponding to the $1/P$ curve, Fig. 2, show (Expts. 1 and 2, 3 and 4, 5 and 6) a satisfactory second-order relationship dependent on the concentration of nitric acid, which exerts an accelerating effect.

THE PHOTOINITIATED ADDITION OF MERCAPTANS TO OLEFINS

II. THE KINETICS OF THE ADDITION OF *n*-BUTYL MERCAPTAN TO 1-PENTENE[1,2]

By M. Onyszchuk[3] and C. Sivertz[4]

ABSTRACT

The detailed kinetics involved in the photoinitiated addition of *n*-butyl mercaptan to 1-pentene is presented. It has been shown that side reactions such as propagation and α-dehydrogenation are relatively negligible and the principal mechanism comprises attack by thiyl radical followed by transfer with mercaptan by the alkyl radical. The velocity constant of the attack step is estimated to be 7×10^6 and that of the transfer step 1.4×10^6 liters/mole-sec. These values together with approximate termination velocity constants are shown to explain the kinetics over a wide range of concentration.

INTRODUCTION

In the first study (2) rates were observed for only *equal* concentrations of mercaptan and olefin. This preliminary work emphasized the need for a more general formulation of the kinetics and the inadmissability of simplifying assumptions with regard to terminations. The mechanism previously proposed (2) involved an attack step followed by a transfer step but the isolation of each of these was not accomplished. It was therefore the principal object of this work to vary the concentrations of reagents over a wide range and test the proposed reaction scheme in terms of a more general kinetic description, and if possible to measure both the attack and transfer velocity coefficients.

BASIC REACTIONS: UNCONJUGATED VINYLS

The basic reactions and consequent steady state equations are presented in considerable detail in this paper to form a foundation of symbolism and theory for subsequent papers. Some estimates of incidental velocity coefficients at 30°C. are included to help in forming a judgment of the reactions which need to be considered.

In this paper we discuss only the photoinitiated addition of *n*-butyl mercaptan to unconjugated vinyls, and proceed to break the over-all process up into the various steps involved. Velocity constants are in liters moles^{-1} sec^{-1}.

Origin of Radicals

As in previous work (2) the origin of radicals is through the photolysis of 2,2′-azo-bis-isobutyronitrile designated Q_2, using a filter system which forbids activation of reactants:

(1) $\quad Q_2 + h\nu = 2\dot{Q} \qquad\qquad k(I)$

where $k(I)$ is the rate of origin of kinetic chains (moles/liter-sec.). In the

[3]*Graduate student 1952. Present address—University of Cambridge, Cambridge, England.*
[4]*Associate Professor of Chemistry, University of Western Ontario, London, Ontario.*

present treatment we will assume that $\dot{Q}$ radicals have negligible concentration compared to all others and that they disappear by transfer with mercaptan:

(2) $\dot{Q}+RSH = QH+R\dot{S}$ k_3^0

Initiation

The thiyl radical attacks monomer to produce an unconjugated radical designated $\dot{X}$, e.g. $RSCH_2\dot{C}HCH_2CH_2CH_3$ results from an attack on 1-pentene. That the addition was counter Markovnikov was proved by product analysis.

(3) $R\dot{S}+M = \dot{X}_1$ k_1 2.5×10^6 (2)

Propagation

Nothing much is known of the propagation of $\dot{X}$ radicals into monolefins in the liquid phase. If we extrapolate James and Steacie's (5) values to 30° for the gas phase propagation of C_2H_5 radicals into 1-heptene and also their dehydrogenation constant, it may be shown that the kinetic chain would be of the order of unity, owing to degradative transfer, even in the absence of mercaptan. Consequently we can neglect propagation.

(4) $\dot{X}_1+M = \dot{X}_2$ $k_2 = 0$

Chain Transfer

In the presence of sufficient mercaptan the principal transfer reaction is

(5) $\dot{X}+RSH = P+R\dot{S}$ k_{3X} 2.5×10^6(2)

where P is addition product.

At low mercaptan concentrations we have reason to believe that there may be significant α-hydrogen transfer with the production of the strongly stabilized allylic radical designated $\dot{A}$.

(6) $\dot{X}+M = P+\dot{A}$ $k_{3\alpha}$ 150 (5)

This value for $k_{3\alpha}$ is that for the dehydrogenation of 1-heptene in the gas phase determined by James and Steacie (5).

(7) $R\dot{S}+M = RSH+\dot{A}$ $k_{3\alpha}'$

Finally reaction (7) is reversible, hence

(8) $\dot{A}+RSH = M+R\dot{S}$ k_{3A} 100

Since $k_{3\alpha}'/k_{3A} = K$, the equilibrium constant for (7), we can estimate K through bond energies to be somewhat less than unity. The value of $k_{3A} = 100$ is about the transfer constant of isoprenyl radical previously reported (2).

Termination

(9)	$2R\dot{S} = RSSR$	k_4'	6×10^{11}	(2)*
(10)	$R\dot{S}+\dot{X} = RSX$	k_5		
(11)	$2\dot{X} = X_2$	k_6'	10^{11}	(2)*
(12)	$\dot{X}+\dot{A} = X\dot{A}$	k_7		
(13)	$2\dot{A} = A_2$	k_8'	10^9	
(14)	$R\dot{S}+\dot{A} = RSA$	k_9		

In the light of the experimental results to be reported we have found it expedient to deal with the system:

**Recent work in this laboratory indicates that the value 6×10^{11} previously reported is an average for $R\dot{S}$ and $\dot{X}$ with $k_4' > k_6'$.*

(1) assuming the geometric mean for the crossed terminations and including the α-dehydrogenation,

(2) neglecting α-dehydrogenation and making no simplifying assumption with regard to cross terminations.

Total Radical Termination

With the assumption of the geometric mean for crossed termination two added constants suffice to express all termination constants in terms of one. Let $k_4 = u^2k_6$, $k_8 = \sigma^2k_6$, then all terminations may be expressed as $k_6(u\dot{RS}+\sigma\dot{A}+\dot{X})^2$.

Here we write $k_4 = 2k_4'$, $k_6 = 2k_6'$, $k_8 = 2k_8'$, and $k_5 = 2\sqrt{k_4'k_6'} = \sqrt{k_4k_6}$. Such a definition of the crossed termination k_5 is suggested by elementary collision theory since the collision number for unlike species is twice that for single. With this convention the expression $k_6[u\dot{RS}+\sigma\dot{A}+\dot{X}]^2$ is equal to the rate of disappearance of *all* radicals. We may note that in terms of the approximate values of k_4, k_6, and k_8 given above $u \div 2$, $\sigma \div 0.1$.

STEADY STATE EQUATIONS

The radical whose steady state is described is shown on the left. Since all terminations except those for $\dot{Q}$ radicals are included, the rate detail for terminations is implied by the letters T. For example

$T_{II} = k_4(\dot{RS})^2+k_5(\dot{RS})(\dot{X})+k_9(\dot{RS})(\dot{A})$.

I	$\dot{Q}$	$k(I) = k_3^0(RSH)(\dot{Q})$
II	$\dot{RS}$	$k_3^0(RSH)(\dot{Q})+k_{3A}(RSH)(\dot{A})+k_{3X})RSH)(\dot{X}) = k_1(\dot{RS})(M)+k_{3\alpha}'(\dot{RS})(M)+T_{II}$
III	$\dot{A}$	$k_{3\alpha}'(RS)(M)+k_{3\alpha}(\dot{X})(M) = k_{3A}(RSH)(\dot{A})+T_{III}$
IV	$\dot{X}$	$k_1(\dot{RS})(M) = k_{3X}(RSH)(X)+k_{3\alpha}(M)(\dot{X})+T_{IV}$.

Summation to infinity yields

$$[1] \qquad k(I) = \Sigma T = k_6[u\dot{RS}+\sigma\dot{A}+\dot{X}]^2.$$

The reaction rate measured dilatometrically is

$$[2] \qquad R = k_1(\dot{RS})(M) = k_{3X}(RSH)(\dot{X})$$

providing we neglect T_{IV} and $k_{3\alpha}(M)$ compared to $k_{3X}(RSH)$. The former is not permissible, as $RSH \neq 0$. For *long* kinetic chains we can express $(\dot{RS})$ and $(\dot{A})$ in terms of $(\dot{X})$ through IV and III. This value of $(\dot{X})$ substituted in [2] yields

$$[3] \qquad R = k_{3X}(RSH)\omega_6 \Big/ \left[1+u\frac{k_{3X}(RSH)}{k_1(M)}+\sigma\frac{k_{3\alpha}(M)}{k_{3A}(RSH)}\right]$$

after elimination of insignificant terms. In [3], $\omega_6 = \sqrt{k(I)/k_6}$. Owing to the last term in the denominator of [3] this equation predicts *lower* rates at *low mercaptan* than would be the case if $k_{3\alpha} = 0$. If α-dehydrogenation is neglected equation [3] can take a linear form, viz.,

$$[4] \qquad \frac{1}{R} = \frac{1}{k_{3X}(RSH)\omega_6}+\frac{u}{k_1(M)\omega_6},$$

from which on varying RSH at constant (M_0)

[5] $$u\,k_{3X}/k_1 = \text{Intercept}(M_0)/\text{slope}.$$

By the same procedure the rate may be expressed in terms of the RṠ radical (equation [2]).

[6] $$R = k_1(M)\omega_6/[u+k_1(M)/k_{3X}(RSH)\{1+k_{3\alpha}(M)/k_{3A}(RSH)\}].$$

No sigmoidal form of R vs. M such as that implied in [3] for R vs. RSH is now apparent, but the rate should fall at high M values owing to $k_{3\alpha}$. Again if $k_{3\alpha} = 0$ [6] can be written in a similar form to [4]

[7] $$R = k_1(M)\omega_6/u[1+k_1(M)uk_{3X}(RSH)]$$

which in linear form yields

[8] $$uk_{3X}/k_1 = \text{slope/intercept}(RSH_0).$$

Cross Termination

If the cross termination is not given by the geometric mean we can represent it quite generally thus: $k_5 = \phi\sqrt{k_4k_6}$ in which ϕ may have any value from 0 upwards. When this is included in the solution for the steady states it readily follows that equation [3] neglecting α-hydrogen reactions now becomes:

[9] $$R_1 = k_{3X}(RSH)\omega_6/[1+2\phi br+b^2r^2]^{\frac{1}{2}}$$

where $b = uk_{3X}/k_1$ and $r = (RSH)/(M)$. Similarly [7] becomes

[10] $$R_2 = k_1(M)\omega_6 br/u[1+2\phi br+b^2r^2]^{\frac{1}{2}}.$$

As rates R_1 are measured, varying RSH at constant M_0 a limiting value of [9] is implied at $(r \div \infty)$ $R_1^\infty = k_1(M_0)\omega_6/u$. Similarly $R_2^\infty = k_{3X}(RSH_0)\omega_6$ $(r \div 0)$. Consequently we can write [9] and [10] in terms of the two constants b and ϕ, and the limiting rates R_1^∞ and R_2^∞ viz.,

[11] $$R_1 = R_2^\infty r/[1+2\phi br+b^2r^2]^{\frac{1}{2}},$$

[12] $$R_2 = R_1^\infty b/[1+2\phi br+b^2r^2]^{\frac{1}{2}}.$$

METHODS

In general the methods employed were those described in the first paper (2) except that a new apparatus was constructed employing a series of four quartz lenses to collimate and focus the mercury arc light in a manner similar to that of Bartlett *et al.* (3).

The ultraviolet light source was a Hanovia A H-8, 85-watt lamp. The *photosensitizer* was again 2,2-azo-isobutyronitrile (AIN) employed in such concentration as to absorb not more than 20% of the light in the cell. Corning *filters* 9863 and 5840 were used to isolate radiation capable of photolyzing the AIN alone. Dilatometer technique was identical with that previously described (2).

EXPERIMENTAL

1-*Pentene*—Phillips Petroleum Research Grade was used without further purification.

Normal butyl mercaptan—Eastman Kodak's white label was distilled under an atmosphere of nitrogen through a 40-plate Todd column. The middle cut retained had the following properties: b.p. 98.0°C. at 750 mm., $n_D^{26} = 1.4410$. *Benzene*—Merck's Reagent Grade Thiophene-free was used without further purification.

Azo-isobutyronitrile was prepared by the method of Overberger *et al.* (7); m.p. 102.5–103.5°C.

The following series of experiments were carried out. All concentrations are expressed in moles/liter. *n*-Butyl mercaptan is represented as BuSH. Temperature was constant at 25°C.

TABLE I

	(AIN)10^3	(1-Pentene)	(*n*-BuSH)	$10^7k(I)$
Series I	3.15	1.59	1.61	1.1
Series II	3.15	4.8	0.803(const.)	1.1
Series III	3.15	0.797(const.)	4.8	1.1

k(I) values were determined by the method of Reference (1).

RESULTS AND DISCUSSION

Series I was designed to show the reproducibility of rate measurements, which is shown in Fig. 1. The measured rates are 0.159, 0.161, 0.161, and 0.16 mm./sec.

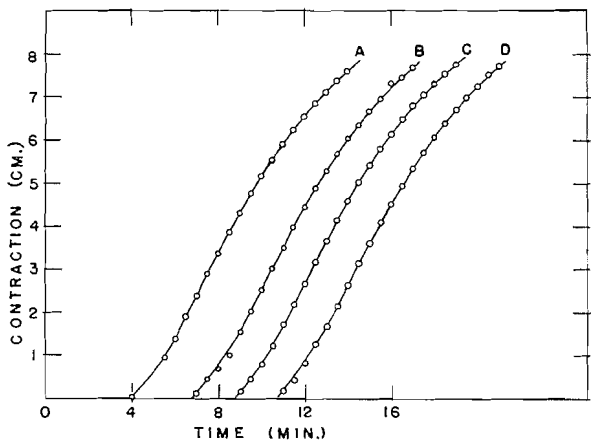

FIG. 1. Dilatometric measurement of the rate of addition of *n*-butyl mercaptan to 1-pentene, showing reproducibility of rate measurements. Series I.

Butyl Mercaptan and 1-Pentene

Series II—Analysis of the data plotted in Fig. 2, in the light of the theory, proceeded by attempting first to fit equation [6]. This suggested that the last term in the denominator was so small that it could not be distinguished from possible effects due to the considerable changes in environment as the composition was altered. In general the shape of the curve in Fig. 2 is that anticipated

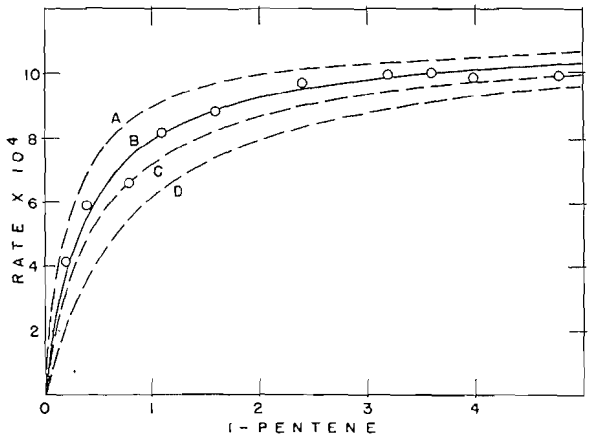

FIG. 2. Rate of addition of mercaptan as a function of 1-pentene at constant mercaptan (0.803 moles/liter). Series II. Curve A: $b = 0.3$, $\phi = 1$; Curve B: $b = 0.5$, $\phi = 1$; Curve C: $b = 0.5$, $\phi = 1.5$; Curve D: $b = 1.0$, $\phi = 1$.

by equation [7] or [12]. We could then proceed to apply equation [7] which assumes the geometric mean or equation [12] which does not. The result of the first alternative in terms of the linear form of equation [7], Fig. 3, yields an intercept $1/k_{3X}(\mathrm{RSH})_0\,\omega_6 = 900$ liter sec./mole, and a slope $u/k_1\omega_6 = 360$ sec., and hence a value of $u\,k_{3X}/k_1 = b \div 0.5$. The application of equation [12] is discussed below.

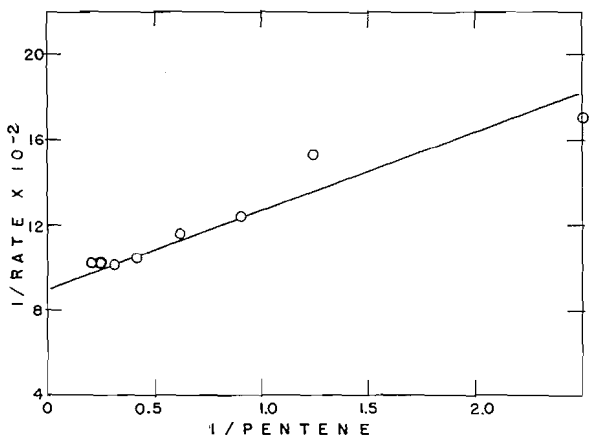

FIG. 3. Plot of data in Fig. 2 according to linear form of equation [7]. Intercept = 900 liter-sec./mole, slope = 360 sec.

Series III—The data are plotted in Fig. 4. From Series II we have values for $k_{3X}\omega_6$ and $u\,k_{3X}/k_1$, and hence "calculated" rates neglecting α-dehydrogenation can be determined. These are shown in Fig. 2*B* and 4*B*. A glance at the latter shows that the rates are lower than calculated in both low and high mercaptan regions. It is hence obvious that the linear form [4] cannot apply to

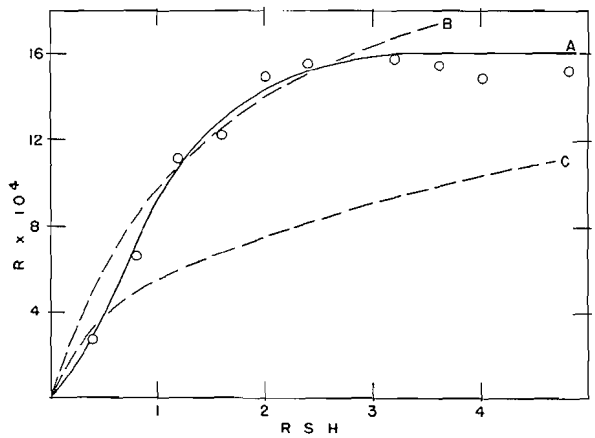

FIG. 4. Rate of addition of mercaptan as a function of mercaptan, 1-pentene constant (0.797 moles/liter). Series III. Curve A: smoothed experimental curve. Curve B: $b = 0.5$, $\phi = 1$; Curve C: $b = 0.5$, $\phi = 6$.

all values of mercaptan. Nevertheless the *general form* is that anticipated by [3] or [11] proceeding from a region where rates are dependent on mercaptan through a *transition* region to one in which rate is independent of mercaptan. Moreover the relative value of constants, viz., $u\ k_{3X}/k_1 = 0.5$ determined from Series II, does locate the position of the transition region. The deviation at low mercaptan may be partly imputed to some α-dehydrogenation (equation [3]). Another obvious reason for low rates could be the neglect of termination by Q radicals (basic reaction (2)) which cannot be valid at low mercaptan concentrations. There is nothing in the kinetics which anticipates the sharp levelling off of rates at *high* mercaptan and we can only surmise that this is due to the considerable changes in environment. Also shown are curves A and D, Fig. 2, which indicate the sensitivity to $b = u\ k_{3X}/k_1$ values when $\phi = 1$. Fig. 4 shows in curve C the effect of $\phi = 6$, $b = 0.5$.

Application of Equations [11] *and* [12]: *Non-geometric Termination*

Considering that α-dehydrogenation appears to be close to negligible we may with more confidence apply equations [11] and [12]. It should be noted that only unique values of ϕ and b will satisfy both equations. It was found that when $b = 0.5$ and $\phi = 0.5$ a reasonably good fit of the data is again obtained (Fig. 5). However the data can hardly discriminate between this interpretation and that of the geometric mean. Our main conclusions are (*a*) the cross termination is close to the geometric mean, (*b*) the value of $u\ k_{3X}/k_1$ appears to be quite closely given as 0.5 at 25°C., (*c*) deviations from the anticipated rate curves at high mercaptan values are probably due to environmental effects on the mechanism, but the general form is that predicted by the basic reactions given.

Estimation of Absolute Velocity Constants

While it was not the object of this work to determine the velocity coefficients and no half-life measurements were made, we may estimate these by taking

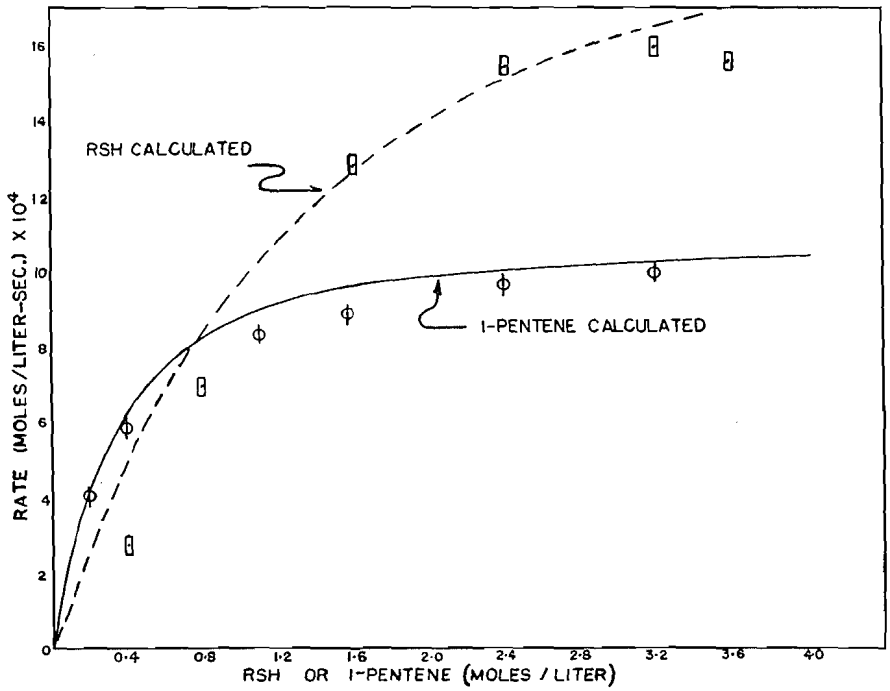

FIG. 5. Plot of equations [11] and [12] with $b = 0.5$, $\phi = 0.5$, showing agreement with measured rates.

$k_6 = 10^{11}$ which corresponds to 5×10^{10} for k_6', the recombination constant of $\dot{X}$ radicals. This value is somewhat lower than that previously reported (2) and higher than Ivin and Steacie (4) report for C_2H_5 radicals in the gas phase, viz., 1.56×10^{10}. This value for k_6 together with the $k(I)$ (Table I) for the series yields $\omega_6 \div 10^{-9}$. From Fig. 3 we found $1/k_{3X}(RSH_0)\omega_6 = 900$ or alternatively that $R_2^{\infty} = k_{3X}(RSH_0)\omega_6$ (Fig. 2) $= 1.1 \times 10^{-3}$. Therefore since $(RSH_0) = 0.8$, $k_{3X} = 1.1 \times 10^{-3}/0.8 \times 10^{-9} = 1.4 \times 10^6$ liter/mole-sec. If we take k_4 for the $R\dot{S}$ radical as 6×10^{11} (2), then $u = 2.45$ and hence $k_1 = 7 \times 10^6$. This happens also to yield for $u\,k_{3X}/k_1$ the value $2.45 \times 1.4 \times 10^6/7 \times 10^6 = 0.52$, which is hence consistent with the direct experimental value.

GENERAL CONCLUSIONS

(1) The "calculated" curves shown in Fig. 5 are seen to be in substantial agreement with the experimental results except for high mercaptan concentrations. In consequence we can presume that the mechanism of the photoinitiated addition of mercaptan to 1-pentene does in fact take place in two independent steps: an attack step ($k_1 = 7 \times 10^6$) and a mercaptan transfer step ($k_{3X} = 1.4 \times 10^6$).

(2) With regard to equation [7] it should be noted that the last term in the denominator $k_1(M)/uk_{3X}(RSH)$ is equal to $(\dot{X})/u(R\dot{S})$ and hence measures the relative abundance of these radicals. On the plateau of Fig. 2 we may

hence presume that $(\dot{X}) > (R\dot{S})$, and a half life in this region may be assigned to the $\dot{X}$ radical. In a similar manner we might isolate the $R\dot{S}$ radical. Melville, Robb, and Tutton (6) were the first to point out that when such measurements of half lives are combined with one made in a region of obvious cross-termination the cross-termination velocity constant k_5 could be measured. It is concluded here that such a procedure is valid only (*a*) if it has been shown that such side reactions as α-dehydrogenation are negligible, (*b*) if no propagation occurs, (*c*) provided the regions where radicals may be taken as isolated have been defined experimentally such as shown in this paper.

SEDIMENTATION AND VISCOSITY STUDIES OF BOVINE SERUM ALBUMIN IN UREA SOLUTION[1]

BY P. A. CHARLWOOD

ABSTRACT

Sedimentation and viscosity measurements were made on bovine serum albumin during denaturation at pH 9.9 in 8.0 *M* urea in the presence of sodium-*p*-chloromercuribenzoate. The results suggested that the urea caused a rapid initial increase in the axial ratio and equivalent volume of the protein molecule. A subsequent slower increase in asymmetry was attributed to the effect of the mercury compound.

INTRODUCTION

The action of strong urea solutions on proteins is an example of "denaturation", a subject recently reviewed by Putnam (34). For many proteins the primary change in denaturation is believed to be a rearrangement of the secondary-bonded structure (21, 34). At this stage molecular weight is unaltered (5, 35), but changes in molecular shape will occur. The present work was undertaken to study the gross changes which occur in the shape of the bovine serum albumin molecule in the presence of urea.

The dynamic characteristics of a protein will reflect changes of molecular shape, but there are many difficulties involved in establishing the precise relation (13). To avoid some of these difficulties Scheraga and Mandelkern (39) related the observed characteristics of the protein molecule to a hypothetical "hydrodynamically equivalent ellipsoid", through a function, β, which depends only on the axial ratio of the (prolate or oblate) ellipsoid.

For the calculation of β, accurate measurements of several quantities should be made (in the same solvent, under the same conditions) and extrapolated to infinite dilution of protein. One combination consists of the sedimentation constant, s, intrinsic viscosity, $[\eta]$ (10), partial specific volume, $\bar{v}$, and molecular weight, M. From these characteristics $\beta = Ns[\eta]^{1/3}\eta_0 / M^{2/3}(1-\bar{v}\rho_0)$, where η_0 and ρ_0 are respectively the viscosity and density of the solvent, and N is Avogadro's number. Recently Champagne (6) applied a similar method of Sadron (36). However, Sadron (36) attempted to attribute a portion of the equivalent volume to hydration expressed in terms of $\bar{v}$, a procedure which Scheraga and Mandelkern (39) deprecate.

Measurements of s and $[\eta]$ made here have been used to follow the changes in β which occur when urea acts on bovine serum albumin in aqueous solution.

Contribution from the Division of Applied Biology, National Research Laboratories, Ottawa, Canada. Issued as N.R.C. No. 3557.

Viscosity measurements under different conditions were made to obtain information about the intramolecular changes responsible for the alterations in β.

EXPERIMENTAL

Stock solutions of bovine serum albumin (Armour, batch 66706) were made up, and their concentrations determined by diluting samples for measurements in the differential refractometer (4). A specific refractive increment of 0.00186 (32) was assumed at the wavelength used (5890 Å).

Chemicals were reagent grade. Further purification of the urea was considered unnecessary (42). It was, however, dried by heating *in vacuo* for six hours at 55°C. (16). The solvent used for the main group of experiments contained urea (8.0 *M*), sodium borate (borax) (0.05 *M*), and sodium *p*-chloromercuribenzoate* (0.005 *M*), the last constituent being added to prevent aggregation (15). The pH, measured on a Beckman model G pH meter, was about 9.9, varying slightly (±0.03) from batch to batch and with time for a given protein solution. In some experiments phosphate buffers (pH 7.0 and 8.3, ionic strength 0.2) were used.

In the main group of experiments series of measurements were made at each of six protein concentrations in the range 0.25–1.5%. The stock solutions of protein and solvent were respectively 11 and 1.1 times the concentrations required in the mixture. Coarse sintered glass filters were used to eliminate dust. At the start of each series, the stock solutions were mixed. At intervals, samples were removed from the mixture for ultracentrifuge runs. In each series seven runs were made, extending to about six days after mixing. A standard schedule was followed so that, in corresponding runs at different protein concentrations, photographs were taken at the same time after mixing. Replicate mixtures were used to avoid the necessity of doing runs during the night. Concurrently with the ultracentrifuge runs, viscosity measurements were made every 30–60 min. in triplicate, extending to about 27 hr. after mixing. Different viscosimeters contained the various replicate mixtures, so that each relative viscosity – time graph was composite, providing information on reproducibility.

A slight opalescence developed in the mixtures at pH 9.9 after 24 hr., more particularly at the higher protein concentrations. One solution (1% protein) was left standing for a week. Some gross particles were removed by passage through a coarse sintered glass filter, and part of the filtrate was centrifuged in the preparative ultracentrifuge. Comparative viscosity measurements were made on the solution which was centrifuged and that which was not. Some of the centrifuged solution was dialyzed exhaustively against 0.2 ionic strength phosphate buffer (pH 7.0), and examined in the analytical ultracentrifuge.

A solution of about 1% bovine serum albumin, 8.0 *M* urea, 0.2 ionic strength phosphate buffer (pH 8.3), and 0.00015 *M* PCMB, after three days at 25°C., was redialyzed against phosphate buffer (pH 7.0, ionic strength 0.2) containing 0.00015 *M* PCMB. Sedimentation and viscosity measurements were made using this protein solution and several dilutions of it (in the same buffer). Similar measurements were made on albumin not exposed to urea.

**This will be referred to subsequently as PCMB.*

Various viscosity experiments were done in urea at several PCMB concentrations, at a lower pH (8.3), and in the presence of silver nitrate. Additional measurements were made in 0.005 *M* PCMB at pH 9.65 in the absence of urea.

Sedimentation constants were measured at 59,780 r.p.m. in the Spinco ultracentrifuge in the usual way (7). The 3-mm. cell was employed for protein concentrations above 0.9%, the 12-mm. cell for the rest. Eight photographs were taken at 16-min. intervals during each run. Because of the slow separation of the peak from the meniscus, the first exposure could not be made until the rotor had been at top speed for about an hour. Since even a slight leak would introduce a large relative error in the distance moved by the peak, the position of the meniscus was determined with particular care during measurement of the photographs. The rotor temperature immediately prior to each run was adjusted so that the rise of about 2°C. during the run ensured a mean temperature of approximately 25°C. The temperature at the middle of the time interval between first and last exposures was estimated in the manner of Kegeles and Gutter (22), taking into account the 1°C. correction indicated by Waugh and Yphantis (44) and Biancheria and Kegeles (3). Sedimentation constants were corrected to water at 20°. The viscosity of solvent, rather than solution, was used (20, 24). Solvent density, determined from weighings of the volumetric flask used, agreed closely with that expected from the data of Gucker, Gage, and Moser (17). As urea solutions have no exceptional compressibility (33), no correction was applied for this.

Viscosity determinations were made in Ostwald-Fenske type viscosimeters (ASTM No. 100), giving a flow time of 70–120 sec. at the temperature of the thermostat (25.1°C.). In experiments not involving urea, ASTM No. 50 viscosimeters were used to keep the flow times sufficiently long. The ratio of flow times for protein solution and solvent was taken as the relative viscosity (10). However, for measurements in the absence of urea, when the relative viscosity was low, the effect of the protein on the solution density was taken into account.

RESULTS

In the main group of sedimentation measurements, values at finite concentrations decreased with time (Table I). The concentration dependence (Table I) was several times greater than for the original albumin (22). Regression lines were calculated at each time, the intercepts giving the extrapolated values shown in Table II. The mean deviation of points from these lines amounted to about 1.7%, and about 15% of the points showed deviations of over 3%. These unusually large errors were probably due to the small distances moved by the boundaries in the rather viscous and dense solvent. For two reasons, the points were not weighted in the calculation of the regression lines. Firstly, the greater sharpness of the maxima of peaks at the higher concentrations was less pronounced when the short cell was used. Secondly, the boundaries moved more rapidly at lower concentrations.

Viscosity measurements in the main group were plotted as reduced viscosity (10), η_{red}, against time at each protein concentration. The derived curves,

which resembled those obtained at 30°C. by Frensdorff, Watson, and Kauzmann (15), were of the same type as obtained in the presence of silver (Fig. 4, upper curves). A few points fell so far off the curves as to indicate errors of ±0.3 sec., but usually the deviations were much smaller.

From the viscosity curves values of η_{red} were read at times corresponding to the middle of the ultracentrifuge runs. These figures were plotted as η_{red} against protein concentration at six different times (Fig. 1). Regression was linear within experimental error, the deviations of points at the lowest concentration corresponding to a systematic difference of only 0.1 sec. Extrapolation to zero protein concentration showed the intrinsic viscosity increasing with time (Fig. 1 and Table II). The slopes of the lines also increased steadily with time, indicating increased intermolecular influences. In the fitting of the regression lines shown, weights were assigned to the points, based approximately on the relative errors in η_{red} produced at different concentrations by

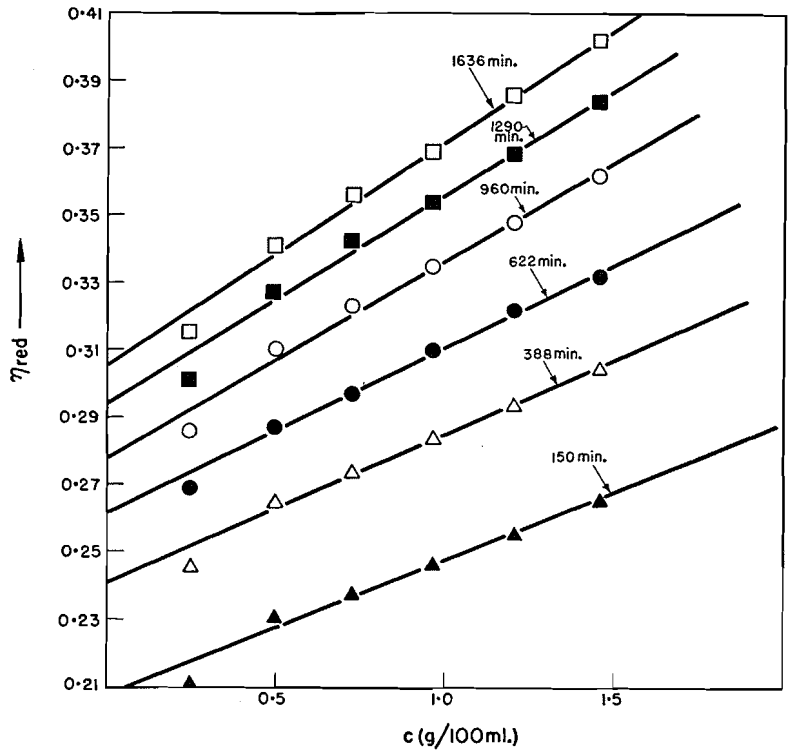

FIG. 1. Reduced viscosity of bovine serum albumin after various times at pH 9.9 in 8.0 M urea, 0.05 M borax, 0.005 M PCMB.

the same absolute error in timing. Experiments in which the head was varied confirmed that flow was Newtonian.

In the calculations of β from $s^0_{20,w}$ and $[\eta]$, $\bar{v}$ was taken as 0.734 (12) and M as 66,000 (see Discussion). In urea solution, β increased with time (Table II). Since the first six values of $s^0_{20,w}$ in urea solution did not show a statistically significant trend, this increase was due to the rise in intrinsic viscosity. However, when the value at 8798 min. was included, the whole series showed time dependence ($p \sim 0.02$).

In each series of ultracentrifuge runs (except the one at the highest concentration) the areas under the peaks showed no measurable decrease. The peaks showed no obviously abnormal degree of spreading, although no quantitative measurements of the spread were attempted. There was only a very slight difference in viscosity between the sample from the preparative ultracentrifuge and that which was not centrifuged. This evidence indicates that the material responsible for the opalescence is rendered insoluble without prior formation of soluble aggregates.

Removal of urea by dialysis against pH 7.0 phosphate buffer caused extensive aggregation. There was some precipitation, and the ultracentrifuge revealed an asymmetric peak which moved several times faster than normal, and spread quickly. In the absence of PCMB, urea caused s to increase with

time and the boundary spread rather rapidly (cf. 34). The material recovered from solution in 8.0 *M* urea, 0.00015 *M* PCMB at pH 8.3 gave a clear solution on redialysis. In pH 7.0 phosphate buffer in the ultracentrifuge it gave one peak moving only slightly faster than normal (Table II). There was a trace of a heavier component, but no more than in the untreated albumin.

Under all conditions 8.0 *M* urea caused a rapid initial increase in the viscosity of bovine serum albumin. Subsequent behavior depended on the composition of the solution. At pH 9.9 (in 0.05 *M* borax) there was always a slow secondary increase. At the protein concentration used, the minimum secondary effect occurred at about 0.0005 *M* PCMB (Fig. 2). At pH 8.3 (0.2 ionic strength

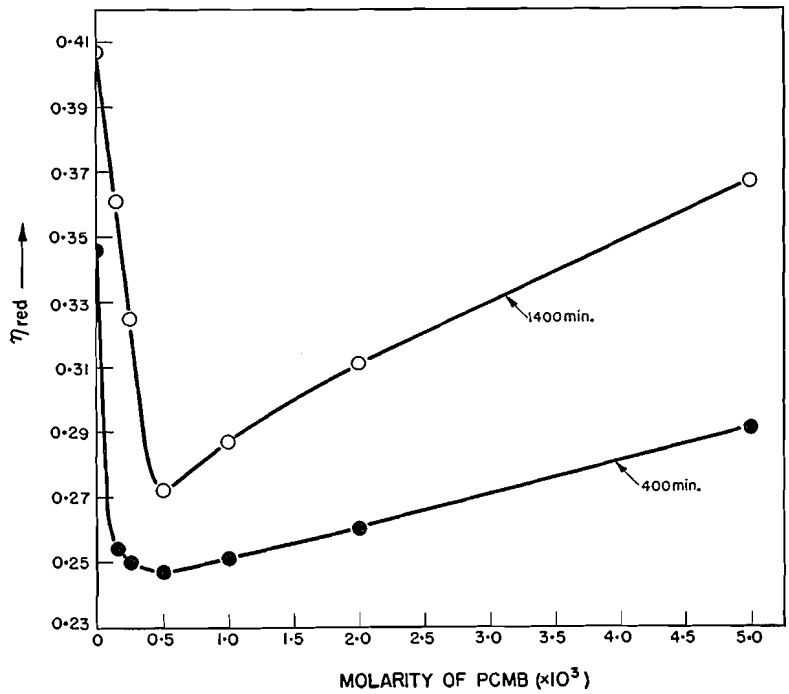

FIG. 2. Effect of PCMB concentration on the reduced viscosity of bovine serum albumin at pH 9.9 in 8.0 *M* urea, 0.05 *M* borax. Protein concentration 0.97%.

phosphate) in 0.00015 *M* PCMB (about one mole per mole of protein), the viscosity remained constant for a day after the initial increase (Fig. 3). At higher concentrations of PCMB there was a detectable secondary increase, illustrated in Fig. 3 by the behavior at 0.005 *M*.

At pH 8.3 (phosphate buffer) one mole of silver nitrate per mole of protein prevented a secondary increase in viscosity. This increase reappeared in the presence of 0.005 *M* PCMB (Fig. 4). At pH 9.9 (borate buffer) silver nitrate failed to eliminate the secondary effect, either in the absence, or in the presence, of PCMB (Fig. 4).

At pH 9.65 (borate buffer), in the absence of urea, 0.005 *M* PCMB caused no detectable variation in the viscosity of the protein solution over the course of 48 hr.

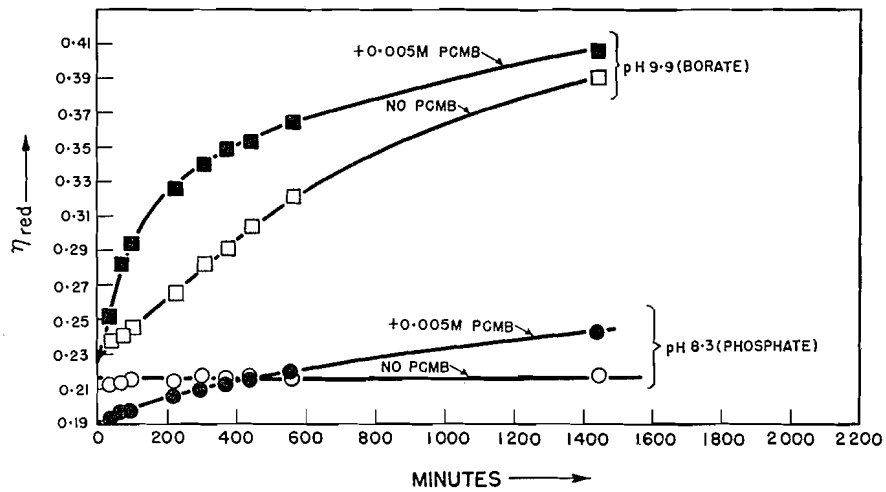

FIG. 4. Reduced viscosity of bovine serum albumin in 8.0 *M* urea with one equivalent of silver nitrate added. Protein concentration 0.97%.

DISCUSSION

As Scheraga and Mandelkern (39) emphasized, quite high experimental accuracy must be attained for successful application of their method, as axial ratio is critically dependent on β. It is evident, from the discrepancies between measurements on the same protein by different workers, that such accuracy is uncommon in available data. It was hoped to circumvent this problem by choice of suitable conditions, and by the use of a series of comparative measurements.

The solvent used was chosen because the work of Frensdorff, Watson, and Kauzmann (15) showed that η_{red} would be reasonably high, and would give measurable variations with time.

Although it is known that crystalline bovine serum albumin contains impurities of higher molecular weight (1), similar or other important objections could be raised to the use of alternative proteins. Moreover, as this albumin has been widely studied, it presented some advantages. Recent determinations of M by independent methods have given 65,400 (11), 66,100 (26), and about 66,000 (18) and for human albumin 65,600 (25). If the 1°C. temperature correction is applied to the sedimentation measurements of Creeth (11), and the most recent value of $\bar{v}$ (12) substituted for that he used, the value of M is increased, but only slightly. In the calculations in the present paper M was taken as 66,000.

Since no method presented itself for following possible changes in molecular weight, conditions were chosen under which there is believed to be little alteration (5). Incorporation of PCMB in the solution should not only prevent much aggregation (15), but also help to prevent autoxidation, which might otherwise occur at pH 9.9 (27). At a concentration of 0.005 M, this reagent is equivalent to albumin present at about 1.1%, even if all the sulphur in the protein were to exist in the form of —SH groups.

Although enhanced intermolecular influences were evident from the magnitude of the concentration dependence of s (Table I; cf. 22 for native albumin), any aggregation must have been slight in extent, as there was no curvature of the η_{red} regression lines (Fig. 1; cf. 15). Extrapolation to zero concentration should eliminate complications introduced by intermolecular effects, including any aggregation. The values of β should, therefore, not contain errors due to these causes.

According to Frensdorff, Watson, and Kauzmann (14), the ionic strength of the borax is high enough to suppress anomalies in viscosity measurements. There is no curvature of the sedimentation regression lines to suggest that the ionic strength was not sufficiently high for these experiments. In any case, extrapolation should eliminate any small anomalies which persist.

Since s, when measured at finite concentrations, decreases with time (Table I), the usual method of computation is not strictly accurate. Analogous problems have been recently discussed. Schwert (40) has considered the effect of increasing temperature, and Alberty (2) the effect of variations in s due to concentration changes in the ultracentrifuge cell. A treatment similar to that of Alberty (2), based on a Taylor expansion, showed that the errors involved in using the ordinary method of calculation were negligible. This conclusion was not surprising, because the total variation of s during a run (from all causes) was never more than double the error of a determination, and there was no significant curvature of the $\log x$ vs. t lines.

Several points relating to ultracentrifuge measurements were discussed earlier (7, 8). One very important factor, which influences the values of β, is the density factor, $\bar{v}\rho$. This has been discussed by Longsworth (24) and by Schachman and Lauffer (37). The magnitude of β in urea solution (Table II)

is consistent with the assumption that $\bar{v}$ in these solutions is not greatly different from normal (29). The trend of β would be the same even if $\bar{v}$ were different. Only a decrease of $\bar{v}$ with time in urea solution might invalidate the conclusions.

In so far as the bovine serum albumin molecule may be identified with the equivalent ellipsoid, the results suggest that initial exposure to the urea solution increases both the axial ratio and the volume of the protein molecule. Subsequently the axial ratio continues to increase with time, but the volume may decrease. This secondary change may be due to the PCMB. Frensdorff, Watson, and Kauzmann (15) have suggested that under alkaline conditions intramolecular —S—S— bridges undergo some hydrolysis, liberating —SH groups. Reaction of these with PCMB would accentuate the splitting and produce a more extended molecule.

The secondary increase which occurs in the viscosity of bovine serum albumin in urea solution (in the absence of inhibitors) was ascribed by Hospelhorn, Cross, and Jensen (19) to aggregation resulting from a chain reaction. Ultracentrifuge experiments under these conditions also strongly suggested aggregation (see Results). The chain reaction was believed to be initiated by the free —SH group of the albumin molecule. At pH 8.0 (phosphate buffer) Hospelhorn, Cross, and Jensen (19) found that incorporation of one or two equivalents of silver nitrate in the urea solution eliminated the secondary increase in viscosity. This they ascribed to the blockage of the free —SH group.

The effects of one equivalent of silver nitrate and one of PCMB were similar at pH 8.3 in phosphate buffer (Figs. 3, 4). Probably, therefore, the PCMB under these conditions merely blocks the free —SH group. Much higher concentrations of PCMB restored the secondary increase (Figs. 3, 4), presumably by splitting the —S—S— bridges, as discussed above.

The failure of silver nitrate at pH 9.9 (borate buffer) to prevent the secondary effect (Fig. 4) might be accounted for by some hydrolysis, either of the silver derivative or of the —S—S— bridges. Both processes would liberate —SH groups capable of starting aggregation. The further increase in viscosity at pH 9.9 when PCMB was also incorporated (Fig. 4) could be due to its effect on the splitting of the —S—S— bridges.

To account for the shape of the curves in Fig. 2 it may be assumed that at very low molarities there is insufficient PCMB to block all —SH groups, and aggregation can occur. As the concentration increases, there is enough to react with the —SH groups, and to promote the splitting of —S—S— links, causing an increase in viscosity. The minima in the curves of Fig. 2 will occur when aggregation has been largely suppressed, but the concentration of PCMB is not yet great enough to exert much influence on the hydrolysis of the intramolecular —S—S— links. The lack of effect of PCMB in the absence of urea seems to indicate that it can act only after a preliminary opening up of the protein molecule. All the phenomena are thus explicable in terms of the complementary propositions of Frensdorff, Watson, and Kauzmann (15) and Hospelhorn, Cross, and Jensen (19).

The basis of the concept of Scheraga and Mandelkern (39) has been challenged (43) on the grounds that the sedimentation constant and intrinsic viscosity of an actual protein (bovine serum albumin being quoted as a possible example) might lead to a value of β less than 2.12 ($\times 10^6$), which is inconsistent with the theory. The sedimentation constant used by Tanford and Buzzell (43) does not include the 1°C. correction. Careful determination of the intrinsic viscosity (Table II) gave 0.042, in agreement with 0.042 obtained by Oncley, Scatchard, and Brown (31) and 0.041_3 by Koening and Perrings (23). Using 0.042 for $[\eta]$ and increasing s to 4.4 units in the data used for computing β gives 2.15 from sedimentation and viscosity, or 2.13 from diffusion and viscosity. The example given by Tanford and Buzzell (43) does not, therefore, provide unequivocal verification of their general hypothesis. Nevertheless, a quantitative theoretical investigation of their ideas is highly desirable.

Scheraga and Mandelkern (39) applied their theory to measurements by Neurath and Saum (29) of the viscosity and diffusion of horse serum albumin in the presence of urea (pH 5.2). They remarked that β values obtained, 1.98–2.07, were within experimental error of 2.12, but that a value of 2.23 for the native protein was not. These conclusions seem inconsistent. Moreover, it has been suggested (35) that an empirical correction factor should be applied to diffusion measurements made in solutions of high viscosity. Recently Scheraga *et al.* (38), using diffusion and viscosity data, calculated $\beta = 2.15$ (± 0.10) and 2.35 (± 0.07) for untreated and urea-denatured fibrinogen respectively. They did not regard these figures as differing significantly, in view of the probable errors shown in brackets, and were of the opinion that their results did not provide evidence of any gross unfolding on denaturation.

Ogston (30) and Shulman (41) have compared the method of Scheraga and Mandelkern (39) with earlier, more conventional ones. Agreement in some instances was poor. Generally, lower axial ratios (and higher equivalent volumes) were given by the newer theory. This is only to be expected, because the older methods are based on assumptions which may sometimes be far from correct (39).

It has been suggested (21) that the molecules of bovine serum albumin denatured in urea may approximate to random coils rather than to rigid ellipsoids. For flexible chain molecules forming a random coil, Mandelkern and Flory (28) gave a treatment similar to, but not identical with, that of Scheraga and Mandelkern (39). They deduced that a function $\Phi^{1/3}P^{-1}$, which is formally the same as β, should be constant. The value they found experimentally for this constant was about 2.5 ($\times 10^6$). Although β (Table II) does not become as large as this, it is increasing, and might well attain 2.5 at later times. Thus, although the results quoted are consistent with the ellipsoidal model, it is possible that at later times a random coil might be a better approximation. If that is so, the actual shape of the molecule will probably combine some characteristics of both types, the relative importance altering with time.

It appears from the viscosity experiments that the first, rapid change in the protein is due to the urea, but the secondary change is brought about by the combined action of the urea and PCMB. The recovered albumin had been submitted to conditions in which only the first type of change occurred. The figures (Table II) show that the molecule returned to a more symmetrical shape, but was less symmetrical than untreated material.

The general conclusion from this work is that the Scheraga–Mandelkern (39) theory gives a very reasonable account of the changes observed. Chernyak and Pasynsky (9), using figures for the adsorption of urea by horse serum albumin as a measure of solvation, attempted to evaluate the relative contributions of volume and shape changes to the observed viscosities of the protein in urea solutions. Their method is based essentially on the older type of treatment. Moreover, since they used a different albumin under different conditions, no comparison can be made with the present results.

INTERNAL ROTATION

VIII. THE INFRARED AND RAMAN SPECTRA OF FURFURAL[1]

By G. Allen[2] and H. J. Bernstein

ABSTRACT

The Raman spectrum of furfural has been obtained photoelectrically in the liquid over a temperature range of 50° and in solution. The infrared spectrum has been obtained for the solid, the liquid (over a temperature range of 90°), and in dilute solution over a 50° temperature range. The vibrational spectrum is interpreted in terms of an equilibrium mixture of two rotational isomers with planar configuration. The isomer with higher electric moment is the more stable form in the liquid and in the solid.

Mirone (5) has summarized the observed Raman and infrared data for furfural in a recent article and reported intense doublets at 2800, 1670, 1420, and 1370 cm^{-1}. Further, for solutions of furfural in organic solvents the distribution of intensity in the doublets at 1670 $cm.^{-1}$ and 1470 $cm.^{-1}$ is a function of concentration and is also dependent on the particular solvent used (5). This indicates that the doublets arise in one of three ways. A doublet arising from a Fermi type of resonance interaction might behave in this manner, on the other hand these observations could be interpreted in terms of the existence of two rotational isomers. Another alternative is that the doublets might occur because of the high degree of association usually encountered in this type of compound. We have established that there are at least four doublets in the infrared and Raman spectra of furfural which behave in a similar manner for temperature and environmental changes and find that the spectrum can best be explained in terms of the existence of two rotational isomers  and  . Conjugation of the carbonyl group with the furane ring will exclude nonplanar configurations.

EXPERIMENTAL

Purification of Furfural

Furfural was purified by distillation through a Stedman column to give a colorless oily liquid (b.p. 160° C.). The pure compound oxidizes to a yellow liquid when in contact with air. In the 30 min. required to obtain a Raman spectrum no appreciable change in color was observed, but if the furfural was irradiated over a period of an hour the liquid became amber in color. The $NaNO_2$ filter used in obtaining the Raman spectra retarded the discolorization. Pure furfural could be kept in vacuo for a period of days before becoming colored.

[1]*Manuscript received January 11, 1955.*

The Raman spectra were recorded photoelectrically (cf. Fig. 1) using a White spectrometer (8). Depolarization ratios (ρ) were obtained by the method of Edsall and Wilson (3) and corrected for convergence by the method

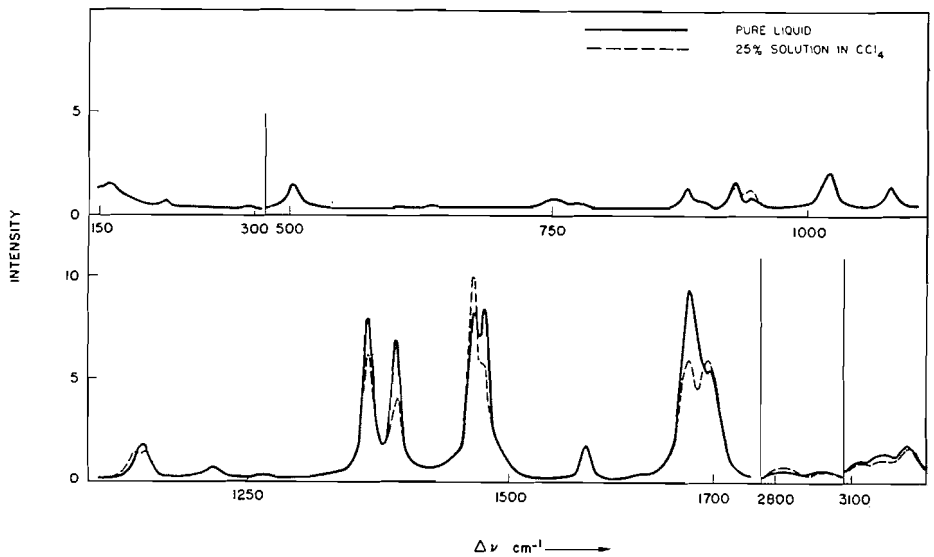

FIG. 1. Raman spectrum of furfural.

of Rank and Kagarise (7). These data are recorded in Table I. Scattering coefficients ($\tilde{S}$) referred to the 458 cm.$^{-1}$ band in CCl_4 and corrected for convergence error, viz.:—

$$\tilde{S} = I/I_{458} \cdot \sigma_{\Delta\nu}/\sigma_{458} \times [(1+\rho_{458})/(1+\rho_{obs})],$$

have been obtained for the Raman bands in the mixture of the two isomers of furfural. In the expression (1) for $\tilde{S}$, I is the integrated intensity and $\sigma_{\Delta\nu}$ is the spectral sensitivity of the photomultiplier tube at the wavelength corresponding to a Raman shift $\Delta\nu$. Standard Raman intensities per molecule could not be obtained since it was not possible to obtain a Raman spectrum of a pure sample of one isomer. The temperature dependence of the Raman spectrum has been studied over a range of 10–60° C. for the pure liquid. The Raman spectra of 25, 50, and 75% solutions of furfural in CCl_4 were also obtained to determine the effect of the dielectric constant of the medium on the relative concentration of the two isomers (cf. Fig. 1).

The infrared spectra were obtained with a Perkin-Elmer Model 12C spectrometer. The infrared spectrum of the pure liquid at 20° C. and of the solid at $\sim -70°$ C. were investigated in the region 3000–700 cm.$^{-1}$ using LiF, CaF_2, and NaCl optics. The results are shown in Fig. 2 and Table I. The temperature dependence of the intensity of the infrared doublet at 2800 cm.$^{-1}$ was studied over a range of 20–70° C. for a 0.001 M solution of furfural in CCl_4 and over a range of 20–110° C. for a thin film of the pure liquid (cf. Fig. 3). The temperature dependence of other doublets could not be studied accurately

TABLE I

INFRARED AND RAMAN SPECTRUM OF FURFURAL

because they were not well resolved and because of strong water vapor absorption in the region where the most intense doublets occur.

The infrared spectrum of solid furfural (Fig. 2) was obtained by condensing the vapor onto a transparent NaCl window which was suspended in vacuum and cooled externally. If the vapor at room temperature was condensed rapidly to a solid (No. 1) deposit then an infrared spectrum could be obtained which was similar to the spectrum of the liquid at room temperature. However if this solid No. 1 is allowed to melt the resulting liquid has a different spectrum

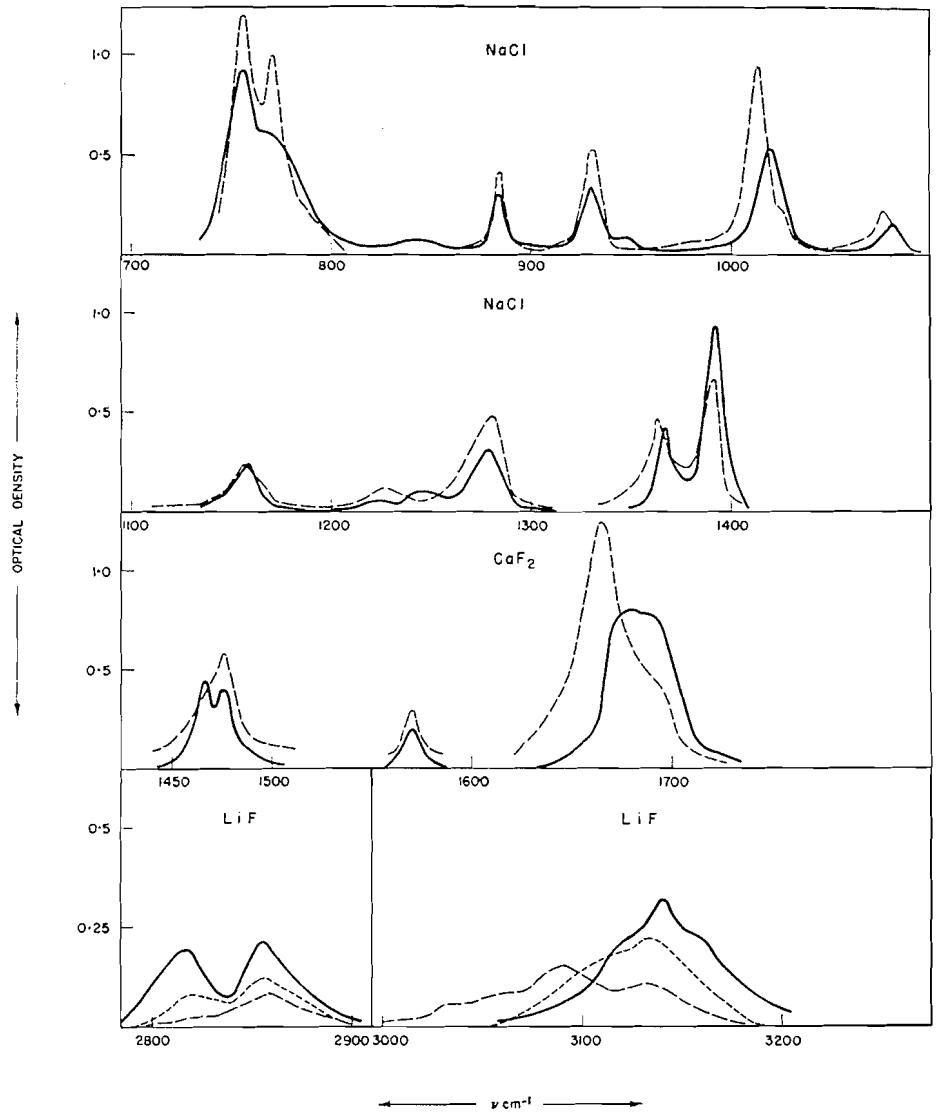

FIG. 2. Infrared spectrum of furfural.
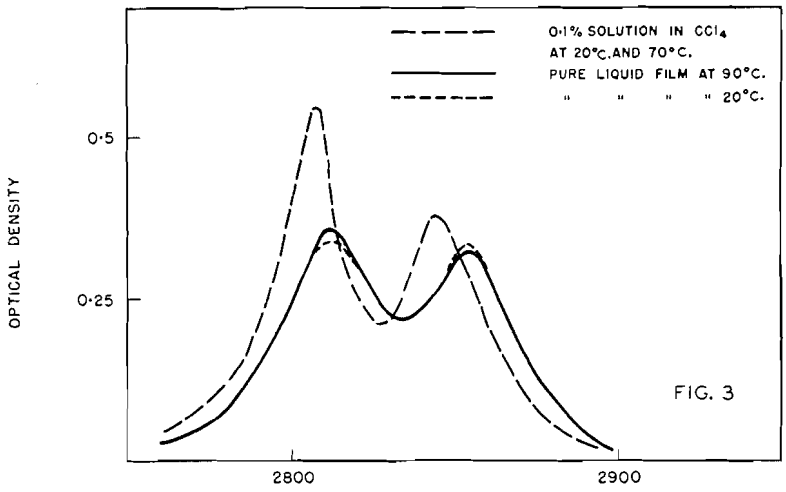
——— liquid at 20° C. - - -liquid at −37° C.
— — — solid at −70° C.

and the most noticeable changes occur in the intensity distribution within the doublets previously discussed. Fig. 4 shows these changes for the doublet at 2800 cm^{-1}. If the liquid is then cooled slowly a crystalline modification (solid No. 2) is obtained in which one component of the 2800 $cm.^{-1}$ doublet almost disappears (Fig. 4). The infrared spectrum of solid No. 2 is shown in Fig. 2 and it is readily seen that other bands at 1690, 1466, 1244, 947 $cm.^{-1}$ disappear on solidification and the contours of the bands at 3100, 1369, 1160, and 770 $cm.^{-1}$ undergo an appreciable change.



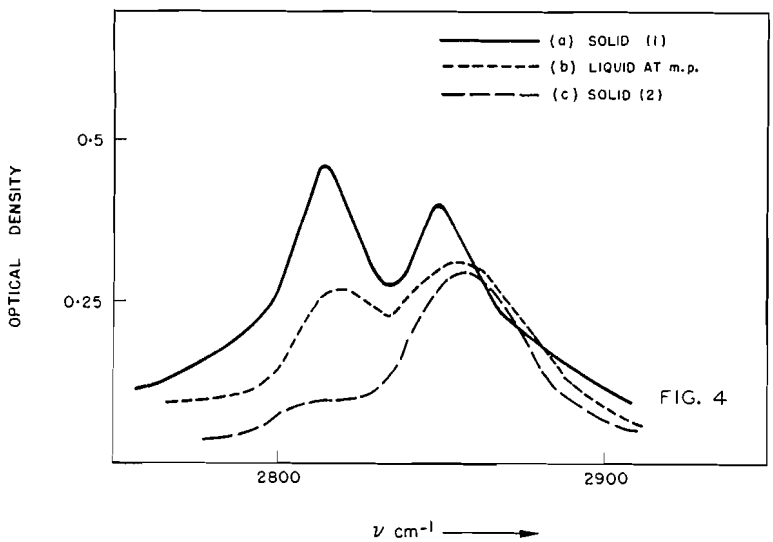


FIG. 3. Temperature dependence of the 2800 cm.$^{-1}$ doublet in the infrared spectrum of furfural. Optical density scale for the pure liquid is twice that for the solution.

FIG. 4. Infrared spectrum of furfural in the 2800 cm.$^{-1}$ region.
(*a*) Solid No. 1 obtained by rapidly freezing the vapor.
(*b*) Liquid obtained from melting solid No. 1.
(*c*) Solid No. 2 obtained by slow cooling of liquid (*b*).

DISCUSSION OF RESULTS

Fermi resonance can be ruled out as a possible explanation for the doublets in the furfural spectrum since it is extremely unlikely that there would be so many (~6), and furthermore the intensity distributions in the doublets would not all have the same dependence on environmental changes (see for example the effect of dilution, Fig. 1, and solidification, Fig. 2). On the other

hand the type of behavior observed on solidification of furfural is well known for solids containing rotational isomers (2, 4). Further a mixture of rotational isomers could also account for the intensity changes observed on dilution.

The spectra shown in Figs. 1 and 2 might also be explained in terms of molecular association. To exclude this possibility the temperature dependence of the doublet at 2800 cm.$^{-1}$ was investigated for a dilute solution ($\sim$0.001 M) of furfural in CCl_4. The doublet has exactly the same contour at 20° and 70° C. and is shown in Fig. 3. The fact that both components of the doublet are intense at very high dilution and also the absence of any temperature dependence of intensity renders unlikely an explanation of the doublet in terms of molecular association. Molecular association would however be expected to broaden some bands which arise from vibrations in associating groups.

The gross features of the Raman and infrared spectra can now be interpreted in terms of two rotational isomers (A and B) of furfural. From Fig. 2 the change in the infrared spectra on solidification indicates that the bands at 2854, 1675, 1476, 1225, and 930 cm.$^{-1}$ belong to one isomer (A) and the bands at 2815, 1690, 1466, 1244, 947 cm.$^{-1}$ belong to the other isomer (B). Configurations can be assigned to isomers A and B from a comparison of the Raman spectrum of the pure liquid with the Raman spectrum of a solution of furfural in CCl_4 (Fig. 1). The pure liquid has a dielectric constant of $\sim$45 whereas the dielectric constant of a 25% solution in CCl_4 is in the region of 5–10, consequently the isomer with the larger dipole will be more stable in the pure liquid than in the solution (6). From Fig. 1 it will be seen that pronounced changes in the spectrum do occur when furfural is diluted with CCl_4. The bands which do not disappear on solidification (isomer A) decrease in intensity and those which disappear on solidification (isomer B) increase in intensity. Hence isomer A is identified with the configuration having the higher dipole moment, viz.:—  and the configuration of isomer B is then  .

The intensities of the 2853 and 2815 cm.$^{-1}$ infrared bands were studied over a range of temperature in an attempt to measure the energy difference between the rotational isomers. No temperature dependence was observed for the vapor (10–110° C.), or for the 0.1% solution in CCl_4, indicating that the isomeric energy difference is small. A small temperature dependence was observed in the pure liquid for these bands over the range −37° to 110° C. corresponding to an energy of isomerization of the order of one kcal. This was confirmed in a qualitative manner for other doublets at 1680 and 1470 cm.$^{-1}$ in the Raman spectrum of the pure liquid.

Some of the bands in the spectrum of furfural may now be assigned to the isomers A and B (last column of Table I) and the approximate character of the mode of vibration has been tentatively assigned in some cases. The identification of the doublet at 1380 cm.$^{-1}$ is uncertain. From Fig. 2, the bands at 1393 cm.$^{-1}$ and 1363 cm.$^{-1}$ in the solid may be assigned to the A isomer. The shift to 1369 cm.$^{-1}$ in the liquid suggests that this band is a superposition of a band from A and one from B. This would account also for the change in

relative intensity of the bands at 1371 cm.$^{-1}$ and 1397 cm.$^{-1}$ in the Raman spectrum of the CCl_4 solution (Fig. 1). A similar doubt exists for the doublet at 760 cm.$^{-1}$; the intensity change on solidification is not very pronounced but it appears that the 770 cm.$^{-1}$ band belongs to the isomer *A*. The doublet observed in both the infrared and Raman spectrum at 1160 cm.$^{-1}$ could be the ν C—CHO mode since this would not be expected to be very different for the two isomers. In the ν CH region of the spectrum, the strong band observed at ~3140 cm.$^{-1}$ in the infrared spectrum of the liquid is associated with a ν CH ring vibration in isomer *B*, the corresponding mode probably occurs at ~3090 cm.$^{-1}$ in isomer *A* since this band increases in intensity on solidification. A shift in frequency is to be expected for the hydrogen stretching mode (of the ring) nearest to the aldehyde group.

Finally it will be noticed that there is a small shift (~5 cm.$^{-1}$) for some bands in the spectrum of solid furfural. A tentative explanation for this is that the bands are unresolved doublets in which the positions change as the relative intensities of the bands change on solidification.

THE PHOTOLYSIS OF METHYL ETHYL KETONE[1]

By P. Ausloos[2] and E. W. R. Steacie

ABSTRACT

Methyl ethyl ketone has been photolyzed at temperatures between 25° and 240°C., at varying pressures and intensities. Azomethane has also been photolyzed in the presence of methyl ethyl ketone. It is concluded that the ratio of disproportionation to recombination for a methyl and an ethyl radical is of the order of 0.04. The activation energy for the abstraction of hydrogen from the ketone by methyl is 7.4 ± 0.1 kcal., and by ethyl it is 8.0 ± 0.1 kcal.

INTRODUCTION

The purpose of the present work was to make a study of a system in which both methyl and ethyl radicals were present. Methyl ethyl ketone has therefore been photolyzed over a range of temperature. In addition, the photolysis of azomethane has been used to produce methyl radicals in the presence of methyl ethyl ketone. Because of the complexity of the system the results are not as clean cut as might have been hoped. The results do, however, furnish some interesting information on certain elementary processes.

Several workers (11, 13) have investigated the photolysis of methyl ethyl ketone in the presence of iodine in order to determine the ratio of the two primary steps:

$$CH_3COC_2H_5 + h\nu \rightarrow CH_3CO + C_2H_5 \qquad (A)$$
$$CH_3COC_2H_5 + h\nu \rightarrow C_2H_5CO + CH_3. \qquad (B)$$

A gradual increase in the ratio A/B has been observed with decrease in wave length. At 3130 Å the ratio is over 10, so that process (B) is not of much importance. After the primary step the CH_3CO and C_2H_5CO radicals may further decompose, either spontaneously by energy carried over from the primary step or by normal thermal decomposition.

On the basis of previous work the following secondary reactions may be proposed to account for the noncondensable reaction products:

$$CH_3 + CH_3COC_2H_5 \rightarrow CH_4 + CH_3COC_2H_4 \qquad [1]$$
$$C_2H_5 + CH_3COC_2H_5 \rightarrow C_2H_6 + CH_3COC_2H_4 \qquad [2]$$
$$CH_3 + CH_3 \rightarrow C_2H_6 \qquad [3]$$
$$C_2H_5 + C_2H_5 \rightarrow C_2H_6 + C_2H_4 \qquad [4]$$
$$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \qquad [5]$$
$$CH_3 + C_2H_5 \rightarrow CH_4 + C_2H_4 \qquad [6]$$
$$CH_3 + C_2H_5 \rightarrow C_3H_8. \qquad [7]$$

It may be assumed that it is mainly secondary hydrogen atoms in the ketone which are abstracted by methyl or ethyl. Although the fate of the $CH_3COC_2H_4$ radical has not been investigated, it can safely be assumed by

analogy with $C_2H_5COC_2H_4$ that it may undergo one of the following reactions:

$$CH_3COC_2H_4+CH_3 \rightarrow CH_3COC_3H_7 \quad [8]$$
$$CH_3COC_2H_4+C_2H_5 \rightarrow CH_3COC_4H_9 \quad [9]$$
$$2\,CH_3COC_2H_4 \rightarrow (CH_3COC_2H_4)_2 \quad [10]$$
$$CH_3COC_2H_4 \rightarrow CH_3+CH_3CH{=}CO \quad [11]$$
$$CH_3COC_2H_4 \rightarrow CH_3CO+C_2H_4. \quad [12]$$

At low temperatures other products may be formed from acetyl and propionyl radicals.

EXPERIMENTAL

The apparatus has been previously described (5). The light source was a Hanovia S-500 medium pressure mercury arc. For the photolysis of azomethane in the presence of methyl ethyl ketone a Corning filter No. 7380 was used to cut off radiation below 3400 Å. For the photolysis of methyl ethyl ketone itself the full arc was used.

The analysis of the products was done as described previously (5), both a mass spectrometer and a LeRoy–Ward still being used.

RESULTS

If methane, ethane, ethylene, propane, and butane are formed only by reactions [1] to [7], the following relationships exist:

$$R_M = k_6[CH_3][C_2H_5]+k_1[CH_3][K]$$
$$R_E = k_3[CH_3]^2+k_4[C_2H_5]^2+k_2[C_2H_5][K]$$

or

$$R_M = \frac{k_6}{k_7}\cdot R_P+\frac{k_1k_5^{\frac{1}{2}}}{k_7}\cdot\frac{R_P}{R_B^{\frac{1}{2}}}[K] \quad [I]$$

$$R_E = \frac{k_4}{k_5}R_B+\frac{k_3k_5}{k_7^2}\cdot\frac{R_P^2}{R_B}+\frac{k_2}{k_5^{\frac{1}{2}}}\cdot R_B^{\frac{1}{2}}[K] \quad [II]$$

where R_M, R_E, R_P, and R_B represent the rates of formation of methane, ethane, propane, and butane, and $[K]$ represents the concentration of methyl ethyl ketone.

The Disproportionation and Recombination of Methyl and Ethyl

Recent work on the photolysis of diethyl ketone (7, 9, 10) gives accurate information on the relative rates of reactions [4] and [5], i.e. $k_4/k_5 = 0.125$. Whence, assuming reaction [12] to be negligible,

$$k_6/k_7 = (R_{C_2H_4}-0.125\,R_B)/R_P. \quad [III]$$

This relationship may be expected to be valid only at lower temperatures and higher intensities where reaction [12] is unimportant.

The values calculated from equation [III] are given in the last column of Table I. The values of k_6/k_7 increase at high temperatures, because of the occurrence of reaction [12]. They also increase at low temperatures. The low temperature increase is probably due to the occurrence of the reaction

$$C_2H_5+CH_3CO \rightarrow C_2H_4+CH_3CHO. \quad [13]$$

There is much evidence (2, 3, 4) for the analogous reactions

$$CH_3+CH_3CO \rightarrow CH_4+CH_2{=}CO$$

and

$$CH_3CO+CH_3CO \rightarrow CH_3CHO+CH_2{=}CO.$$

The analogous reaction

$$C_2H_5+C_2H_5CO \rightarrow C_2H_6+C_2H_4CO$$

will be of less importance since $[CH_3CO] \gg [C_2H_5CO]$.

In the range from 78° to 130°C. the ratio k_6/k_7 remains approximately constant with a mean value of about 0.04. This value also is consistent with other aspects of the kinetics. It appears reasonably safe, therefore, to assume that k_6/k_7 is equal to 0.04 ± 0.02.

Wijnen (14) has recently investigated the photolysis of mixtures of CD_3COCD_3 and $C_2H_5COC_2H_5$. For CD_3 and C_2H_5 radicals he arrives roughly at the value $k_6/k_7 < 0.08$ in agreement with the present results.

The Abstraction Reaction $CH_3+CH_3COC_2H_5 \rightarrow CH_4+CH_3COC_2H_4$

If the ratio k_6/k_7 is known, it is possible to calculate $k_1k_5^{\frac{1}{2}}/k_7$, and thus obtain some information about the abstraction reaction [1]. A value of 0.04 has been used for k_6/k_7. As discussed above, there is some uncertainty in this value. However, except at high intensities and low temperatures, the methane formed by reaction [6] is negligible, and hence k_6/k_7 does not have to be known accurately. The only experiments in which this is not so are 2, 3, and 4. Since the results for these agree well with 1, further support is furnished for the value $k_6/k_7 = 0.04$.

In Fig. 1, $\log k_1 k_5^{\frac{1}{2}}/k_7$ is plotted against $1/T$. A good straight line is obtained. There are some indications of a deviation from linearity at room temperature. The results are not accurate enough, however, to establish this with certainty. From the slope of the Arrhenius plot in Fig. 1 a value of 7.4 ± 0.1 kcal. is obtained for $E_1+\frac{1}{2}E_5-E_7$. E_5 and E_7 are almost certainly zero since they apply to radical combination reactions. Hence $E_1 = 7.4 \pm 0.1$ kcal.

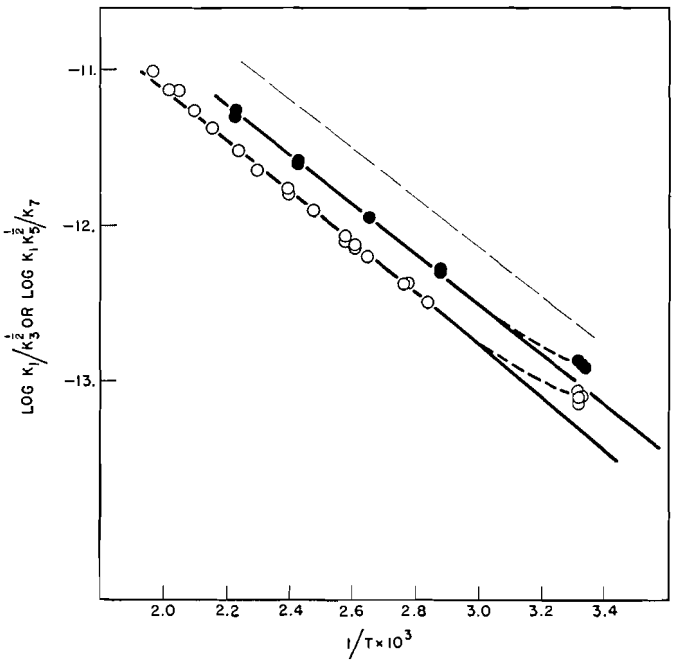

FIG. 1. The reaction of methyl radicals with methyl ethyl ketone.
○ Photolysis of methyl ethyl ketone.
● Photolysis of azomethane – methyl ethyl ketone mixtures.

As a check on this value, azomethane was photolyzed in the presence of methyl ethyl ketone, using light of wave length greater than 3400 Å. Under these conditions methane is also produced by

$$CH_3 + CH_3N_2CH_3 \rightarrow CH_4 + CH_3N_2CH_2 \qquad [14]$$

so that

$$\frac{k_1}{k_3^{\frac{1}{2}}} = \frac{R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}} - k_{14}/k_3^{\frac{1}{2}}[CH_3N_2CH_3]}{[CH_3COC_2H_5]}.$$

The values of $k_{14}/k_3^{\frac{1}{2}}$ have been taken from an experimental plot for azomethane alone (1). The results for $k_1/k_3^{\frac{1}{2}}$ are given in the last column of Table II, and an Arrhenius plot is given in Fig. 1. The slope of the line corresponds to an activation energy of 7.4 ± 0.1 kcal. Hence $E_1 = 7.4$ kcal., in exact agreement with the value obtained from the direct photolysis of methyl ethyl ketone. Some curvature is present in the plot at low temperatures, as is the

case in the photolysis of methyl ethyl ketone alone. Analogous curvature has been found in the case of acetone, and has been ascribed (2) to wall reactions.

In principle it should be possible to estimate $k_7/k_3^{\frac{1}{2}}k_5^{\frac{1}{2}}$ from the displacement of the two curves in Fig. 1. In this way a value of about 1.8 was obtained. This is rather rough. However, it is of interest that a similar value (1.84), also rather rough, has recently been obtained (14) from the photolysis of mixtures of CD_3COCD_3 and $C_2H_5COC_2H_5$.

For comparison Fig. 1 also gives the results obtained in a previous investigation for the reaction

$$CH_3+C_2H_5COC_2H_5 \rightarrow CH_4+C_2H_4COC_2H_5.$$

It will be seen that the curves are nearly parallel. Abstraction is, however, approximately twice as fast from diethyl ketone which contains two ethyl groups.

The Abstraction Reaction $C_2H_5+CH_3COC_2H_5 \rightarrow C_2H_6+CH_3COC_2H_4$

It can be seen from equation [II] that it is possible to calculate $k_2/k_5^{\frac{1}{2}}$ if k_4/k_5 and k_7^2/k_3k_5 are known. It is probable that k_4/k_5 is known with sufficient accuracy. The calculation is quite sensitive to the value of k_7^2/k_3k_5 especially at low temperatures, and this is only known approximately. It can therefore be expected that the values of $k_2/k_5^{\frac{1}{2}}$ will be reliable at high temperatures, but uncertain at low temperatures. If the value of 1.84 is used for $k_7/k_3^{\frac{1}{2}}k_5^{\frac{1}{2}}$, an Arrhenius plot of $k_2/k_5^{\frac{1}{2}}$ gives a reasonably good straight line at higher temperatures, but shows a downward break at low temperatures. A value of 2.0 gives a good straight line over most of the temperature range. Results calculated in this way are given in Table I, and are plotted in Fig. 2. The curve leads to a value of $E_2-\frac{1}{2}E_5 = E_2 = 8.0 \pm 0.1$ kcal. The uncertainty is, of course, somewhat greater than the stated precision because of the approximate nature of the calculation.

In Fig. 2, results for mixtures of azoethane and diethyl ketone are also given for comparison. These apply to the reaction

$$C_2H_5+C_2H_5COC_2H_5 \rightarrow C_2H_6+C_2H_4COC_2H_5. \qquad [15]$$

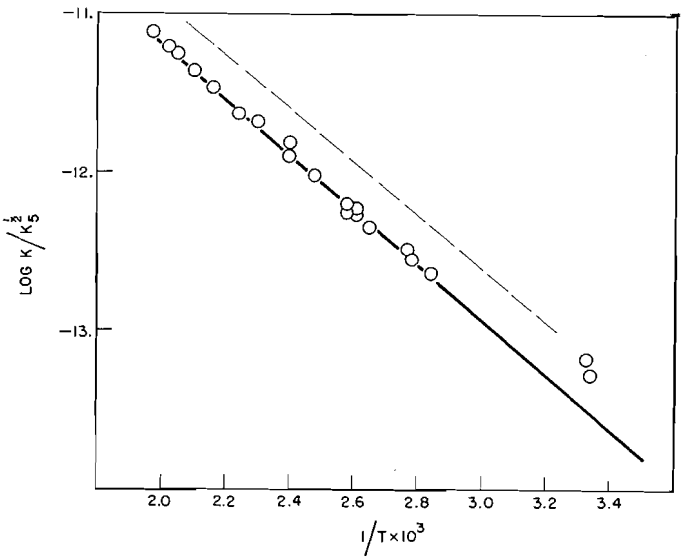

FIG. 2. The reaction of ethyl radicals with methyl ethyl ketone.

The activation energies of [5] and [15] are about the same but the steric factor appears to be twice as great for [15], as might be expected.

DISCUSSION

The above results clearly indicate that the ratio of the rate of disproportionation to that of combination for a methyl and an ethyl radical is considerably smaller than the ratio for two ethyls, i.e.

$$k_6/k_7 \sim 0.04$$
$$k_4/k_5 = 0.125 \pm 0.01.$$

All the reactions probably have activation energies of zero, so that the degree of exothermicity is not the rate determining factor. This is confirmed by the above results where the most exothermic disproportionation reaction gives the smallest ratio.

There are a number of other cases, which are similar in that the more exothermic disproportionation reaction appears to occur to the smaller extent. Thus for the reactions (2)

$$CH_3CO+CH_3CO \rightarrow CH_3CHO+CH_2CO \quad [16]$$
$$CH_3CO+CH_3CO \rightarrow CH_3COCOCH_3 \quad [17]$$
$$CH_3+CH_3CO \rightarrow CH_4+CH_2CO \quad [18]$$
$$CH_3+CH_3CO \rightarrow CH_3COCH_3 \quad [19]$$

the ratio k_{18}/k_{19} is apparently considerably less than k_{16}/k_{17}, although reaction [18] is considerably more exothermic than [16].

Similarly for the reactions

$$CH_3CH_2CH_2+CH_3CH_2CH_2 \rightarrow CH_3CH_2CH_3+CH_3CH{=}CH_2 \quad [20]$$

$$CH_3CH_2CH_2+CH_3CH_2CH_2 \rightarrow C_6H_{14} \quad [21]$$

$$CH_3CHCH_3+CH_3CHCH_3 \rightarrow CH_3CH_2CH_3+CH_3CH{=}CH_2 \quad [22]$$

$$CH_3CHCH_3+CH_3CHCH_3 \rightarrow C_6H_{14} \quad [23]$$

k_{20}/k_{21} has been found to be in the range 0.1 to 0.17 (6, 12) while k_{22}/k_{23} is about 0.5 (6, 8) although [20] is more exothermic than [22].

It is possible to explain all these cases on purely steric grounds if it is assumed that the rates of the recombination reactions are not greatly different. There is definite evidence (7) that the rates of recombination of methyl and of ethyl radicals are not greatly different. Also, it can be shown from the present data at 114°C., where acetyl will be almost completely decomposed, that after correction for C_2H_6 formed by abstraction, the relative amounts of ethane, propane, and butane are very nearly in the ratio 1:2:1 as would be the case if the rate constants for all three recombination reactions were equal.

We will therefore assume that the differences in the ratio of disproportionation to recombination are mainly to be ascribed to the disproportionation reactions. In reaction [6] there are three primary hydrogens in the ethyl radical which may be abstracted in the disproportionation reaction, while in reaction [4] there are six. On this basis [4] may be expected to be of the order of twice as fast as [6]. Similarly one would expect [16] to be faster than [18] in the ratio 6/3, and [22] to be faster than [20] in the ratio 12/4. While this is all very rough and somewhat naive it does explain rather puzzling results in all three cases.

The difference in activation energy between the abstraction reactions [1] and [2] amounts to 0.6 ± 0.2 kcal. This is the same as the difference previously found for the corresponding reactions of diethyl ketone.

THE STRUCTURE AND PROPERTIES OF DL-1,2-*O*-CYCLOHEXYLIDENEGLYCEROL[1]

By A. J. E. Porck[2] and B. M. Craig

ABSTRACT

DL-1,2-*O*-Cyclohexylideneglycerol was prepared by reacting cyclohexanone and glycerol in the presence of sulphuric acid. It is miscible with all common organic solvents and is slightly soluble in water. It is not affected by hydrogenolysis at 25°C. over palladous oxide at 50 p.s.i. for 24 hr. The DL-1,2-*O*-cyclohexylidene-3-*O*-*p*-nitrobenzoylglycerol is readily cleaved by mineral acids to yield 3-*O*-*p*-nitrobenzoylglycerol. Proof of the 1,2 ketal structure was obtained by (*a*) preparation of the monomethyl derivative, acid hydrolysis, and periodic acid oxidation of the resultant 1-monomethyl ether of glycerol and (*b*) treatment of the tosyl derivative with sodium iodide which gave a 93% yield of sodium *p*-toluenesulphonate.

O-Cyclohexylideneglycerol was first prepared by Kühn (3) in 1940 but the structure was not established. The compound was most likely a 1,2 ketal similar to DL-1,2-*O*-isopropylideneglycerol. Since *O*-cyclohexylideneglycerol can be prepared readily in large quantities it seemed desirable to investigate the structure and the chemical properties to evaluate the compound as a possible starting material for the synthesis of glycerides.

O-Cyclohexylideneglycerol was prepared in 58% yield by reacting glycerol with cyclohexanone in the presence of sulphuric acid. It is miscible with all common organic solvents, slightly soluble in water, and is not affected by catalytic hydrogenolysis at 25°C. over palladous oxide at 50 p.s.i. for 24 hr. It is readily cleaved by mineral acids.

Evidence of the 1,2 cycloketal structure was obtained by preparation of the monomethyl derivative and subsequent acid hydrolysis. Periodic acid oxidation of the resultant monomethylglycerol showed consumption of 1 mole of oxidant. The DL-1,2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulphonylglycerol was prepared and reacted with sodium iodide in acetic anhydride at 100°C. Sodium *p*-toluenesulphonate was obtained in 93% yield and constituted proof that the tosyl group was at a terminal position in the glycerol. DL-1,2-*O*-Cyclohexylidene-3-*O*-*p*-nitrobenzoylglycerol was prepared and the ketal was cleaved with dilute sulphuric and dilute hydrochloric acids to give 1-*O*-*p*-nitrobenzoylglycerol in yields of 70 and 73% respectively.

The DL-1,2-*O*-cyclohexylideneglycerol appears to be similar to DL-1,2-*O*-isopropylideneglycerol and could be used in glyceride synthesis. It offers an advantage in the ease of preparation.

EXPERIMENTAL

(1) DL-*1,2-O-Cyclohexylideneglycerol*

A mixture of 665 gm. (700 ml.) of anhydrous cyclohexanone, 330 gm. (262 ml.) of anhydrous glycerol, and 46 ml. of concentrated sulphuric acid

[1]*Manuscript received January 4, 1955.*
Contribution from the Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan. Issued as Paper No. 186 on the Uses of Plant Products and as N.R.C. No. 3591.
[2]*National Research Council of Canada Postdoctorate Fellow 1954.*

was shaken at room temperature for 20 min. Anhydrous $CuSO_4$ (160 gm.) was added and shaking was continued for 30 min., whereupon the mixture was filtered by suction. The filtrate was dissolved in 400 ml. of ethyl ether and was stirred vigorously with a solution of 200 gm. K_2CO_3 in 3000 ml. of water for 30 min. The ethereal layer was separated, washed once with water, and dried over anhydrous K_2CO_3. After evaporation of the ether the product was distilled in a Podbielniak Heligrid distillation column to yield 360 gm. (58% of the theoretical amount) of analytically pure ketal, b.p. 137° at 17 mm., 252° at 714 mm., $n_D^{25} = 1.47645$, reported b.p. 133–135° at 15 mm. (3).

The DL-1,2-*O*-cyclohexylideneglycerol is miscible with all common organic solvents. It is soluble in water at 26°C. to the extent of 6.5% and the solubility of water in the cyclohexylideneglycerol at 26°C. is 30%.

The ketal is stable to hydrogenolysis by catalytic hydrogenation at 25°C. over palladous oxide at 50 p.s.i. for 24 hr. with methanol as a solvent.

(2) DL-*1,2-O-Cyclohexylidene-3-O-p-nitrobenzoylglycerol*

p-Nitrobenzoyl chloride, 43.2 gm., was added to a solution of 40 gm. of DL-1,2-*O*-cyclohexylideneglycerol in 200 ml. of anhydrous pyridine. The mixture was shaken at room temperature for 18 hr., poured into 1000 ml. of ice water, and stirred. The crystals were filtered off, dried in a desiccator, and recrystallized once from *n*-butanol. Yield, 50 gm. (67% of the theoretical amount). Further recrystallizations from ethanol, Skellysolve "B", and methanol gave the pure compound, m.p. 49.5–50.0°C. (stout prisms with a slightly yellow color). Analysis for $C_{16}H_{19}O_6N$: C, 59.92%; H, 5.99%; N, 4.35%. Calc. for C, 59.80%; H, 5.96%; and N, 4.36%.

The compound is very soluble in acetone and chloroform, soluble in methanol, benzene, ethanol, and carbon tetrachloride, slightly soluble in ethyl ether, and nearly insoluble in water.

(3) DL-*1,2-O-Cyclohexylidene-3-O-methylglycerol*

Acetone, 1500 ml., and DL-1,2-*O*-cyclohexylideneglycerol, 200 gm., were placed in a 3 liter flask equipped with a stirrer, reflux condenser, and two dropping funnels. The solution was heated to 50°C., 370 gm. (278 ml.) of dimethyl sulphate and a 50% aqueous solution of NaOH (272 gm.) in the dropping funnels were added simultaneously at a rate sufficient to maintain reflux and an alkaline medium. After the addition of the alkylating agents was completed, the bulk of the acetone was distilled off with continuous stirring. The remaining liquid was stirred with 400 ml. of 30% NaOH solution at 100°C. for three hours. The nonaqueous layer was separated and distilled on the Podbielniak distillation column. Yield, 184 gm. (85% of the theoretical amount), b.p. 106° at 12 mm., 226° at 714 mm., n_D^{25} 1.4539. Analysis for $C_{10}H_{18}O_3$: C, 64.03%; H, 9.70%. Calc. for C, 64.48%; H, 9.74%.

The compound is miscible with common organic solvents, and is insoluble in water and glycerol.

(4) *Hydrolysis of* DL-*1,2-O-Cyclohexylidene-3-O-methylglycerol*

Sixty milliliters of DL-1,2-*O*-cyclohexylidene-3-*O*-methylglycerol and 60 ml. of 10% sulphuric acid were refluxed for four hours. The aqueous layer

was neutralized with sodium carbonate solution, separated from the cyclohexanone and distilled. A second distillation of the product yielded 30 gm. of 1-*O*-methylglycerol, b.p. 135° at 40 mm. (reported b.p. 135.5–136°C. at 40 mm.) (2). The product was oxidized with periodic acid in aqueous solution at room temperature. Periodic acid, 0.99 moles, was consumed after one hour and no change was observed after an additional 20 hr.

(5) DL-*1,2-O-Cyclohexylidene-3-O-p-toluenesulphonylglycerol*

p-Toluenesulphonyl chloride, 4.5 gm., was added to a solution of 4 gm. of DL-1,2-*O*-cyclohexylideneglycerol in 20 ml. of anhydrous pyridine cooled in an ice-water mixture. The mixture was allowed to stand at room temperature for 48 hr. and was then poured into 110 ml. of ice water and stirred. The DL-1,2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulphonylglycerol, which crystallized, was filtered and dried. Yield of crude material, 6.5 gm. (86% of the theoretical amount), m.p. 49°. Several recrystallizations from Skellysolve "B" – amyl alcohol (1: 1) gave the analytically pure compound in the form of prisms, m.p. 48.5–49.0°C. Analysis for $C_{16}H_{22}O_5S$: C, 59.05%; H, 6.76%; S, 9.88%. Calc. for C, 58.87%; H, 6.79%; and S, 9.82%.

The compound is very soluble in acetone, chloroform, benzene, ethyl acetate, and ethyl ether, soluble in methanol, ethanol, and carbon tetrachloride, slightly soluble in Skellysolve "F", and almost insoluble in water.

(6) *Reaction of* DL-*1,2-O-Cyclohexylidene-3-O-p-toluenesulphonylglycerol with Sodium Iodide*

One gram of the tosyl derivative and 1.2 gm. of anhydrous sodium iodide were dissolved in 15 ml. of acetic anhydride and the solution was heated at 100°C. on a steam bath. Precipitation of sodium *p*-toluenesulphonate began after 15 min. and heating was continued for five hours. The precipitate was collected, dried, and weighed. Yield, 0.55 gm. (93% of the theoretical amount).

(7) *Acid Hydrolysis of* DL-*1,2-O-Cyclohexylidene-3-O-p-nitrobenzoylglycerol with Mineral Acids*

(*a*) *Sulphuric Acid*

Two grams of the compound was added to a solution of 38 ml. of acetone and 5 ml. of 1.0 *N* H_2SO_4 and the mixture was refluxed for four hours. The solution was diluted with an equal volume of water, neutralized by passing through a column of Amberlite IR-4B, and evaporated to a volume of 25 ml. The oil which separated was taken up in 60 ml. of hot chloroform; the chloroform layer was separated and evaporated to a volume of 15 ml. The 1-*O*-*p*-nitrobenzoylglycerol was crystallized from this solution. Yield, 1.05 gm. (70% of the theoretical amount), m.p. 107° (reported m.p. 107°) (1).

(*b*) *Hydrochloric Acid*

Acid hydrolysis was carried out in the same manner with 1.0 *N* hydrochloric acid. Silver oxide was used to neutralize the acid after hydrolysis. Yield, 1.1 gm. (73% of the theoretical amount), m.p. 107°.

ACKNOWLEDGMENT

The microanalyses were made by J. A. Baignee of the Prairie Regional Laboratory.

OLIGOSACCHARIDES OF XYLOSE FROM WHEAT STRAW HEMICELLULOSE[1]

By C. T. Bishop

ABSTRACT

A series of oligosaccharides were prepared by autoclaving wheat straw hemicellulose at 120°C. in distilled water. The di- to the hepta-saccharide inclusive were shown to be members of the (1 → 4)-β-D-xylopyranose series. The octasaccharide was shown to be doubly branched. Certain aspects of the structure of wheat straw hemicellulose are discussed on the basis of these results.

The structure of a polysaccharide is usually determined by identifying and estimating hydrolysis products of the methylated polysaccharide. This procedure gives a picture of the gross structure of the polysaccharide, but, because of uncertainty of complete methylation or difficulty in separating the hydrolysis products, finer details may be missed. With the advent of chromatographic methods (9, 11) it is now possible to isolate oligosaccharides produced by partial hydrolysis of unsubstituted polysaccharides. Finer details in the structure of the parent polysaccharide are often revealed by characterization of oligosaccharides. A large number of these compounds have already been investigated (12).

A previous report (3) described the preparation of a crystalline xylan and a mixture of mono- and oligo-saccharides from wheat straw hemicellulose. The purpose of the present investigation was to characterize the oligosaccharides and relate the results to the gross structures previously proposed for wheat straw hemicellulose (1, 2).

Individual components in the mixture of mono- and oligo-saccharides obtained by the autoclaving of wheat straw hemicellulose were isolated by successive displacement from charcoal columns (11) and by repeated chromatography on large paper sheets. The monosaccharides consisted of D-xylose and L-arabinose. The oligosaccharides were separated into seven, chromatographically-pure components which appeared to constitute a polymeric homologous series. Table I records the yields and properties of these components. Molecular weights of the compounds corresponded to the calculated values for a series of pentose oligosaccharides ranging from a di- to an octasaccharide. Hydrolysis of each oligosaccharide released only D-xylose. These results suggested that the compounds were members of the (1 → 4)-β-D-xylopyranose series first isolated, up to the heptasaccharide, by Whistler and Tu (13, 14, 15) from corncob xylan. The di- and tri-saccharides were crystallized and identified as xylobiose and xylotriose by their physical properties and those of their crystalline acetates (Table II). The tetra-, penta-, and hexasaccharides could not be crystallized but yielded crystalline acetates (Table

II) having physical constants identical with those reported (14) for the acetates of xylotetraose, xylopentaose, and xylohexaose. The hepta- and octa-saccharides could not be crystallized, nor did they yield crystalline acetates. Characterizations of these two compounds were therefore based on optical rotations and oxidations with periodate.

In a polymeric homologous series, if the linkages are identical, $[M]_{n/n}$ plotted against $(n-1)/n$ yields a straight line where $[M]_n$ is the molecular rotation (specific rotation × molecular weight/100) and n is the degree of polymerization (7, 14). When molecular rotations of the acetates of the present series of oligosaccharides were plotted in this way a linear relationship was found to exist from the di- to the hepta-saccharide inclusive (Fig. 1). These results indicated that the heptasaccharide was most likely xyloheptaose, a member of the (1 → 4)-β-D-xylopyranose series, the lower members of which were positively identified. The octasaccharide, however, must have contained some linkages different from the (1 → 4)-β-D-type.

Some structural details of carbohydrates can often be revealed by periodate oxidation. Members of the present series of oligosaccharides were oxidized by periodate using the micromethod developed by Perlin (10), in which the oxidation can be followed by continuous measurement of the formic acid

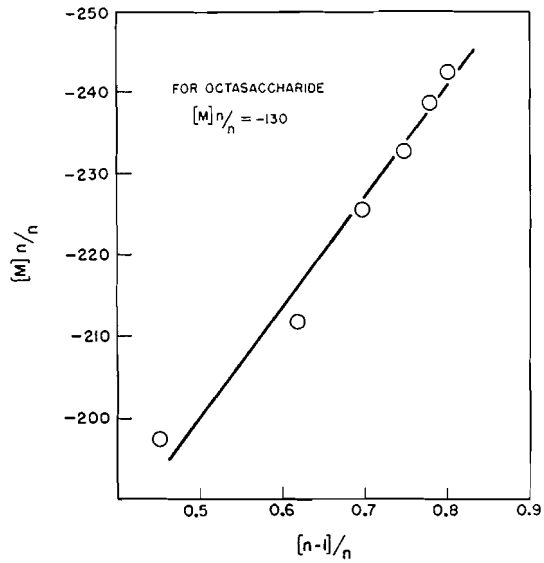

FIG. 1. Relation between molecular rotations and degrees of polymerization of oligosaccharide acetates.

produced, without stopping the reaction. Theoretically, each member of a (1 → 4)-β-D-xylopyranose oligosaccharide series should consume $n+2$ moles of periodate with the production of three moles of formic acid. Results of the oxidations are shown in Fig. 2. All members of the present series consumed the theoretical $n+2$ moles of periodate and all except the octasaccharide produced 3 moles of formic acid. The octasaccharide produced almost five (4.82) moles of formic acid indicating that it was doubly branched, i.e. it possessed one reducing and three non-reducing xylopyranose units. In such an octasaccharide two of the eight xylopyranose units would be protected, by

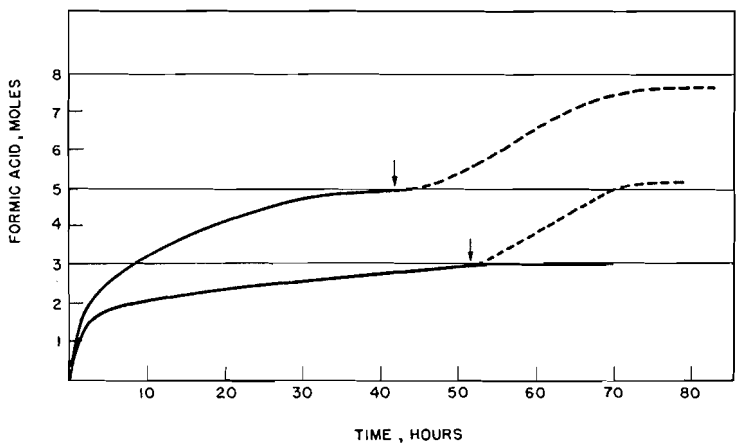

FIG. 2. Periodate oxidation of oligosaccharide series. Upper curve, octasaccharide. Lower curve, tri-, tetra,- penta-, hexa-, and hepta-saccharides. Broken lines, overoxidations of octa- and hepta-saccharides.

the branching, from oxidation by periodate. The oxidized octasaccharide was therefore hydrolyzed and recovery of 2 moles of xylose confirmed the presence of the doubly branched structure. It should be mentioned that following the initial oxidations of the hepta- and octa-saccharides there was a time lag in the reactions after which overoxidation occurred (Fig. 2, broken lines). No difficulty was experienced in distinguishing between the two phases of oxidation.

The results presented here are in reasonable agreement with those of previous investigations on wheat straw hemicellulose (1, 2, 3) in which the same predominance of $(1 \rightarrow 4)$-β-D-xylopyranose linkages were found. However, isolation of the doubly branched octasaccharide showed that at least 1.56% of the xylose units in the polysaccharide were joined by another type of linkage. Detection of this branching illustrates the advantage of examining oligosaccharides formed by partial hydrolyses of polysaccharides. It should also be mentioned that D-xylose, autoclaved under the same conditions, showed no evidence of syntheses. Investigations of the gross structure of wheat straw hemicellulose by methylation techniques have been reported by Adams (1) and by Aspinall and Mahomed (2). Adams (1) found that all of the 2-*O*-methyl-D-xylopyranose could be accounted for by 2,3,5-tri-*O*-methyl-L-arabofuranose, thus obviating any possibility of branching in the xylan chain. However, it is doubtful whether the analytical methods available are sensitive enough to estimate differences in the quantities of these two sugars to account for a small amount of branching. Aspinall and Mahomed (2) obtained 3.4% of 2-*O*-methyl-D-xylopyranose which was attributed to incomplete methylation and demethylation during hydrolysis. In the light of our present work it seems probable that part of this 2-*O*-methyl-D-xylopyranose was due to branching in the xylan chain. The work reported here shows that some of the xylan chains in wheat straw hemicellulose have a structure similar to that of esparto (4) and pear cell-wall (5) xylans, in which single branch points were found every 75 and 115 units respectively.

EXPERIMENTAL

The following solvents (v/v) were used to separate sugars on paper chromatograms: (*A*) pyridine: ethyl acetate: water—1: 2: 2; (*B*) butanol: pyridine: water—6: 4: 3; (*C*) butanol: pyridine: water—5: 5: 3. Specific rotations were measured in a 1 dm. tube and are equilibrium values. Evaporations were done at 35°C. or less and molecular weights were estimated by the alkaline iodine method (15). All melting points are corrected.

Formation of Oligosaccharides

Wheat straw hemicellulose (32 gm.) was autoclaved in distilled water at 120°C. and the resulting mixture of soluble sugars was isolated as previously described (3). This mixture, dried to constant weight over phosphoric anhydride at 0.03 mm., was a yellow, friable solid (24.3 gm., 76% of the hemicellulose). D-Xylose autoclaved under the same conditions yielded no oligosaccharides.

Separation on Charcoal Columns

One-third (8.09 gm.) of the sugar mixture, dissolved in water (100 ml.), was adsorbed on a column (170 × 34 mm.) consisting of a mixture of equal parts by weight of Darco G-60 and Celite 535 (11). The mixture of adsorbed sugars was resolved into four fractions by successive displacement with water (900 ml.), 5% ethanol (1100 ml.), 15% ethanol (800 ml.), and 30% ethanol (900 ml.). The course of desorption was followed by anthrone spot tests. The remaining two-thirds of the mixture was fractionated in the same way and the corresponding eluates were combined. Examination of the four fractions by paper strip chromatography (solvent *A*) showed that they could be designated as the monosaccharide, disaccharide, trisaccharide, and higher oligosaccharide fractions, respectively.

Monosaccharide Fraction

The water eluates were evaporated to dryness leaving a sirup (6.5 gm., 20% of the hemicellulose), part of which was redissolved in water and chromatographed on large sheets of Whatman 3MM paper (solvent *A*). Extraction of appropriate portions of the chromatograms yielded D-xylose, m.p. and mixed m.p. 144–145°C., $[\alpha]_D^{25} = +19.5$ ($c = 3.2$ in water), and L-arabinose, identified by formation of its crystalline benzoylhydrazone, m.p. and mixed m.p. 185–186°C.

Purification of Oligosaccharides

The 5%, 15%, and 30% ethanol eluates from the charcoal columns were evaporated separately and the residues were purified by chromatography on Whatman 3MM paper (solvent *B* for the 5% and 15% ethanol fractions, solvent *C* for the 30% ethanol fractions). Extraction of appropriate portions of the papers yielded a disaccharide from the 5% ethanol eluate, a trisaccharide from the 15% ethanol eluate and tetra-, penta-, hexa-, hepta-, and octa-saccharides from the 30% ethanol eluate. The last five oligosaccharides were purified by rechromatography in the same way. Table I gives yields, molecular weights, and physical properties of all the oligosaccharides together with the corresponding reported or calculated values for the (1 → 4)-β-D-xylopyranose series. The di-, and tri-saccharides were crystallized from methanol and 85% ethanol respectively. Attempts to crystallize the other oligosaccharides were unsuccessful.

The oligosaccharides were acetylated by the sodium acetate – acetic anhydride method so that all anomeric hydroxyl groups were in the β-D-configuration. Table II lists the physical properties of these acetates and the corresponding values reported for acetates of the (1 → 4)-β-D-xylopyranose oligosaccharide series.

Hydrolysis of Oligosaccharides

A portion (10 mgm.) of each oligosaccharide was heated at 97°C. for five hours with *N* hydrochloric acid (0.5 ml.). At one hour intervals samples were removed from each hydrolysis and chromatographed on Whatman No. 1

paper in solvent *A*. The developed chromatograms showed that all hydrolyses were completed in the first hour and that xylose was the only sugar produced.

Periodate Oxidations

Each oligosaccharide except xylobiose was oxidized by periodate in the Warburg respirometer by the method of Perlin (10) which permitted the use of small samples (2—4 mgm.). Fig. 2 gives the results of the oxidations which were done in duplicate at 20°C. and pH 5.7. When production of formic acid first reached a constant value, one set of samples was removed for estimation of periodate (arrows in Fig. 2). Periodate consumption by the tri-, tetra-, penta-, hexa-, hepta-, and octa-saccharides were respectively 4.9, 6.0, 6.86, 7.91, 8.96, and 9.88 moles.

For oxidation of the octasaccharide 2.73 mgm. samples were taken. If the octasaccharide was double-branched then the oxidized samples should release 0.756 mgm. of xylose when hydrolyzed. The two octasaccharide oxidations (after estimation of periodate), together with two blanks to which 0.76 mgm. of D-xylose had been added, were deionized with Amberlite IR 120 and Dowex-2 (carbonate form). The deionized solutions were evaporated to 1 ml. and were boiled under reflux for two and one-half hours with 12% hydrochloric acid (0.25 ml.). The hydrolyzates were neutralized with Dowex-2 (carbonate form) and the xylose present in each of them was estimated by quantitative (6) paper chromatography (solvent *A*). Average recoveries of xylose were 0.544 mgm. from the blanks, 0.579 mgm. from the oxidized octasaccharides.

ACKNOWLEDGMENTS

The author wishes to thank Dr. A. S. Perlin, Prairie Regional Laboratory, National Research Council, Saskatoon, for assistance with the periodate oxidations. The careful technical assistance of R. W. Rowsome is gratefully acknowledged.

FREQUENCY SPECTRA OF FREE LATTICES AND PARTICLE SIZE EFFECTS ON THE HEAT CAPACITY OF SOLIDS[1]

By D. Patterson[2]

ABSTRACT

The effect of particle size on the heat capacity of solids has been investigated using lattices with free boundaries as models. A monatomic lattice shows a low temperature effect associated with the acoustic modes. This can be compared with results obtained from a continuum model. With a diatomic lattice, however, an effect is also associated with the optical modes and is apparent at higher temperatures. The possibility that this latter effect can explain some recent experimental results is examined.

The continuum model of the solid has been used to predict an effect of particle size on the specific heat which would be observable at low temperatures (4, 12, 17); such an effect has recently been found with NaCl (14). However, an effect at higher temperatures which had not been predicted has also been found using TiO_2 in the rutile form (5), and a theoretical explanation is required. The frequency spectrum of rutile contains both acoustic and optical modes, as is shown by the fact that the specific heat is fitted with a combination of Einstein and Debye functions (16). The continuum (Debye) model must therefore be inadequate in this case and it seemed worth while to investigate the particle size effect using simple lattice models. These have the advantage of giving a more adequate picture of the acoustical modes and of also being able to show the optical (Einstein) modes when the lattice contains atoms of differing mass. Although a simple model of nearest neighbor interactions only is employed in the three-dimensional case, the essential features of the effect are displayed and an extension to more elaborate models may be made when warranted by the sensitivity of the experiments. The effect of particle size on the specific heat of a monatomic lattice is treated in Part I and thus only the acoustic modes are considered there. It is shown that at low enough temperatures the continuum model gives the same results as the lattice model, as might be expected.

Part II goes on to consider lattices containing atoms of differing mass. It is shown that particle size effects are associated with the optical modes as well as the acoustic modes and should be observable at high temperatures. A calculation assuming a simple cubic structure for TiO_2 gives about one-fifth of the effect actually observed at higher temperatures. Although a calculation for the actual TiO_2 lattice should produce a larger result, it is thus possible that some other effect occurs.

While the only thermodynamic property dealt with explicitly is the specific heat, it is apparent that once the effect of particle size on the frequency spectrum is known the corresponding effects on the other thermodynamic proper-

ties may be obtained by the conventional methods of statistical thermodynamics.

I. EFFECT OF PARTICLE SIZE ON SPECIFIC HEAT (MONATOMIC LATTICES)

The frequencies of vibration of free chains and free lattices have already been discussed to some extent, the former particularly in connection with long chain molecules (10, 15). Born (3) remarks that the frequencies of the free monatomic chain should be given by

$$[1] \qquad \pi\nu = \sqrt{\frac{a}{m}} \sin \phi_l; \quad \phi_l = \pi l/2N, \qquad l = 0, 1, \ldots (N-1).$$

Here a is the Hooke's Law constant for the interatomic interactions, m the mass of the atoms, and N the number of atoms in the linear chain. This is to be compared with the case of a chain where consideration of the boundary has been obviated by the adoption of periodic boundary conditions. Then

$$[2] \qquad \phi_l = \pi l/N, \qquad l = 0, 1, \ldots (N-1).$$

Halford (7) has obtained [1] for the free chain and has generalized it to a three-dimensional lattice, taking into account nearest neighbor interactions only. For vibrations parallel to the x direction

$$[3] \qquad \pi^2\nu^2 = \frac{a}{m}\sin^2\phi_x + \frac{b}{m}\sin^2\phi_y + \frac{b}{m}\sin^2\phi_z,$$
$$\phi_x = \pi l/2N_x, \quad \phi_y = \pi m/2N_y, \quad \phi_z = \pi n/2N_z;$$

$l = 0, 1, \ldots (N_x-1)$, $m = 0, 1, \ldots (N_y-1)$, $n = 0, 1, \ldots (N_z-1)$ where N_x, N_y, N_z are the numbers of atoms in the linear dimensions of the particle and a and b are the Hooke's Law interactions in the direction of vibration and perpendicular to it. The spectrum of frequencies in the other two directions is obtained by interchanging x, y, z so that the total number of modes is $3N_xN_yN_z$. For the case of periodic boundary conditions

$$\phi_x = \pi l/N_x, \qquad \phi_y = \pi m/N_y, \qquad \phi_z = \pi n/N_z.$$

The validity of the model has already been discussed to some extent (7). It may be shown further that at low temperatures the model becomes equivalent to a consideration of nearest neighbor interactions as well, provided this interaction is small, as is usually the case. When these conditions are fulfilled, the spectrum with next nearest neighbors is given by Blackman (2) to be

$$[4] \qquad 4\pi^2\nu^2 = \frac{(\alpha+4\gamma)}{m}\phi_x^2 + \frac{2\gamma}{m}\phi_y^2 + \frac{2\gamma}{m}\phi_z^2$$

where α and γ are the constants for nearest and next nearest interactions. [4] may be compared with [3], putting

$$[5] \qquad (\alpha+4\gamma) = a,$$
$$2\gamma = b.$$

The specific heat associated with the lattice vibrations may be obtained as the sum of Einstein terms over the frequency spectrum, i.e.

$$[6] \qquad C = \sum_{\nu} E(\nu) = \sum_{\nu} k \frac{(h\nu/2kT)^2}{\sinh^2(h\nu/2kT)}.$$

The specific heat of the linear chain will first be considered. According to [1] ν may be taken as a function of ϕ evaluated at equal intervals between ϕ_0 and ϕ_{N-1}. The summation [6] may therefore be replaced by an integration through the use of the Euler–Maclaurin series (R. B. Dingle, private communication). Thus if

$$h = \phi_1 - \phi_0 = \phi_2 - \phi_1 = \ldots = \phi_{l+1} - \phi_l,$$

$$[7] \qquad h \sum_{\phi=\phi_0}^{\phi=\phi_{N-1}} E(\phi) = h \sum_{\phi=\phi_0}^{\phi=\phi_N} E(\phi) - E(\phi_N)$$
$$= \int_{\phi_0}^{\phi_N} E(\phi)\, d\phi + \tfrac{1}{2}\{E(\phi_0) - E(\phi_N)\}$$
$$+ h \sum_{m=0}^{N-1} \int_{m}^{m+1} (\phi - m - \tfrac{1}{2}) \frac{dE}{d\phi} d\phi$$

(see Jeffreys and Jeffreys (8), for instance). The error in replacing the summation by the integral is given by the last term of [7] which is quite negligible if

$$h\nu_0/2kT \ll 2N/\pi \quad \text{where } 2\pi\,\nu_0 = (4\alpha/m)^{\frac{1}{2}},$$

the maximum frequency of the spectrum. For the chain with free boundary conditions, then

$$h = \pi/2N, \quad \phi_0 = 0, \quad \phi_N = \tfrac{1}{2}\pi, \quad \text{and}$$

$$[8] \qquad C = (2N/\pi) \int_0^{\frac{1}{2}\pi} E(\phi)\, d\phi + \tfrac{1}{2}\{E(0) - E(\tfrac{1}{2}\pi)\}$$
$$= (2N/\pi) \int_0^{\frac{1}{2}\pi} E(\phi)\, d\phi + \tfrac{1}{2}\{k - E(\tfrac{1}{2}\pi)\}.$$

Thus C contains a term proportional to N, the number of atoms in the chain, plus a constant term due to an "end effect" on the frequencies. At low temperatures $\sin\phi \sim \phi$ and $E(\frac{1}{2}\pi) \sim 0$. [7] may be integrated to give

$$C = \tfrac{1}{2}k + \frac{2N}{\pi}\left(\frac{2kT}{h\nu_0}\right) \int_0^{\infty} \frac{u^2 du}{\sinh^2 u}$$

of the form

$$[9] \qquad C = \tfrac{1}{2}k + AT.$$

Such a constant contribution does not arise when periodic boundary conditions are assumed, i.e. the frequencies are given by [2] and $\phi_0 = 0$, $\phi_N = \pi$. The constant term then becomes $\frac{1}{2}\{E(0) - E(\pi)\}$, which is zero since $E(0) = E(\pi) = 0$. Thus, although [1] and [2] show the frequency density of modes to be the same whether or not the free boundary is considered, the frequencies associated with ϕ_N are different, producing a particle size effect in one case and not in the other. As will be seen, the same holds for a diatomic chain and

in the three-dimensional case. Born (3) shows that in the former case the density of modes is the same whether free or periodic boundary conditions are chosen. For the three-dimensional case Ledermann (11) has proved quite generally that the difference in the density of modes due to considering the boundary is one which tends to zero with increasing size of the solid. However, in these cases a particle size effect exists for a particular model at least and arises from the behavior of the frequency spectrum when $\phi \sim 0$.

The specific heat of the three-dimensional lattice may be dealt with in a manner analogous to the one-dimensional case, the summation [6] over the frequency spectrum [4] being evaluated by means of the Euler–Maclaurin approximation applied three successive times. There are then contributions to the specific heat which may be associated with the volume, surface, and edges of the lattice, and finally with the translation of the lattice. Of these, the first two are most important, whence

$$C = k\left(\frac{2}{\pi}\right)^3 N_x N_y N_z \int_0^{\frac{1}{2}\pi}\int_0^{\frac{1}{2}\pi}\int_0^{\frac{1}{2}\pi} E(\phi_x, \phi_y, \phi_z)\, d\phi_x\, d\phi_y\, d\phi_z$$
$$+k\left(\frac{2}{\pi}\right)^2 (N_xN_y+N_yN_z+N_zN_x) \int_0^{\frac{1}{2}\pi}\int_0^{\frac{1}{2}\pi} \tfrac{1}{2}\{E(\phi_x, \phi_y, 0)-E(\phi_x, \phi_y, \tfrac{1}{2}\pi)\}\, d\phi_x d\phi_y \qquad [10]$$

plus corresponding terms for the vibrations in the other two directions. In the case of periodic boundary conditions, the integrand of the surface contribution is

$$\tfrac{1}{2}\{E(\phi_x, \phi_y, 0)-E(\phi_x, \phi_y, \pi)\}$$

and vanishes.

It may be noted that in both the one- and three-dimensional cases the Euler–Maclaurin approximation requires correction through the final term of [7] when $h\nu_0/2kT \sim 2N/\pi$, where N is the linear dimension of the lattice. In the one-dimensional case as $T \rightarrow 0$ the correction term $\rightarrow \frac{1}{2}k$, so that $C \rightarrow k$ instead of $\frac{1}{2}k$ as would be expected from [8]. In the three-dimensional case the contribution of particle size to the specific heat ceases to be extensive in the surface area as in [10]. It has been suggested (9) that the excess specific heat be considered as a surface thermodynamic quantity. It is seen, however, that the particle size and the temperature must be of sufficient magnitude for these surface thermodynamics properties to be extensive.

At high temperatures the full integration of [10] would be difficult. At low temperatures, however, the approximation becomes valid. Blackman (2) has shown that in this case the specific heat follows a T^3 law and an analogous treatment of the surface contribution in [10] shows that it follows a T^2 law. In fact [10] reduces to

$$C = 464(T/\theta)^3+B(T/\theta)^2 \text{ cal./deg.-mole where}$$
$$B = \frac{(36\pi)^{\frac{1}{3}}}{2}\frac{N_s}{N_v}\frac{a^{\frac{1}{2}}+b^{\frac{1}{2}}}{a^{\frac{1}{2}}b}\int_0^\infty \frac{u^3 du}{\sinh^2 u} \qquad [11]$$

with N_s/N_v as the proportion of atoms on the surface of the solid. There is an exact correspondence between [11] and the low temperature form of the

expression given by Montroll (12) for the specific heat of small particles, provided the factor $(a^{\frac{1}{2}}+2b^{\frac{1}{2}})/a^{\frac{1}{2}}b$ of the lattice model compares with $3^{2/3}c_3^{2/3}/c_2$ in the Montroll continuum model.

II. EFFECT OF PARTICLE SIZE ON THE SPECIFIC HEAT (OPTICAL MODES)

If now alternate atoms of a free chain of $2N$ atoms are of differing masses m_1 and m_2 there are $2N$ equations of motion whose compatibility is assured by the following secular equation

$$[12] \qquad \begin{vmatrix} \frac{a}{m_1}-4\pi^2\nu^2 & \frac{a}{m_1} & & & \\ \frac{a}{m_2} & \frac{2a}{m_2}-4\pi^2\nu^2 & \frac{a}{m_2} & & \\ & \cdot & & & \\ & & \cdot & & \\ & & & \frac{a}{m_1} & \frac{2a}{m_1}-4\pi^2\nu^2 \quad \frac{a}{m_1} \\ & & & \frac{a}{m_2} & \frac{a}{m_2}-4\pi^2\nu^2 \end{vmatrix} = 0.$$

By means of a diagonal expansion it may be shown that the determinant

$$[13] \qquad C = \begin{vmatrix} \frac{a}{m_1}-4\pi^2\nu^2 & \frac{a}{m_1} \\ \frac{a}{m_2} & \frac{a}{m_2}-4\pi^2\nu^2 \end{vmatrix}$$

is a factor. Thus, two of the frequencies of the chain are given by the secular equation for a free pair of atoms, $C = 0$, leading to a translation of zero frequency and the vibration

$$[14] \qquad 4\pi^2\nu^2 = a\left(\frac{m_1+m_2}{m_1m_2}\right).$$

The remaining modes are those of a chain of $(N-1)$ pairs of atoms given by

$$[15] \qquad 4\pi^2\nu^2 = \frac{a(m_1+m_2) \pm a\sqrt{m_1^2+m_2^2+2m_1m_2\cos 2\phi_l}}{m_1m_2}$$

$$\phi_l = \frac{\pi l}{2N}, \quad l = 1, 2, \ldots (N-1).$$

The frequencies may be compared with those found for a chain with periodic boundary conditions in which the $2N$ frequencies are given by [15] but with $\phi_l = \pi l/N$ and $l = 0, 1, \ldots (N-1)$. In the free case the modes lie along two branches but that corresponding to $l = 0$ of the optical branch has been displaced downwards, as shown in Fig. 1. The significance of the position of this mode becomes apparent if $m_1 \ll m_2$. In this case, the $(N-1)$ frequencies

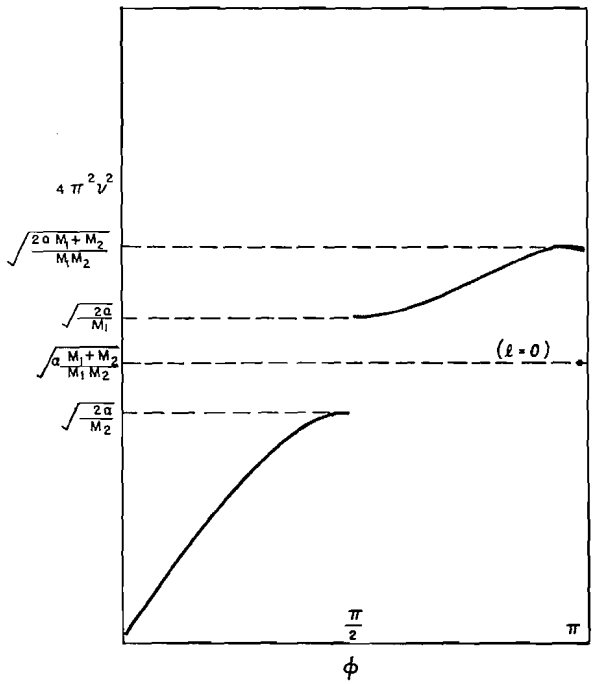

FIG. 1. Acoustic and optical modes for a free diatomic chain.

of the optical branch given by [15] may be approximated by the single Einstein frequency $4\pi^2\nu^2 = 2a/m_1$ and the remaining mode is of frequency $4\pi^2\nu^2 = a/m_1$. In the case of periodic boundary conditions, all N optical modes would have $4\pi^2\nu^2 = 2a/m_1$. Here each atom is identical in interacting with two neighbors, while in the free boundary case the end atoms have only one neighbor. This result may be obtained directly from [12]. As $m_2 \rightarrow \infty$, $a/m_2 \rightarrow 0$, so that in [12] the off-diagonal elements in alternate rows reduce to 0 and the diagonal elements each become $-4\pi^2\nu^2$. The determinant is then easily expanded to give

$$[16] \qquad (-4\pi^2\nu^2)^N\left(\frac{2a}{m_1}-4\pi^2\nu^2\right)^{N-1}\left(\frac{a}{m_1}-4\pi^2\nu^2\right)$$

or the product of the diagonal elements. Thus the frequency spectrum comprises an N-fold root at 0 (the acoustic modes), $(N-1)$ roots at $2a/m_1$, and a root at a/m_1. In the periodic case the N optical modes fall at $2a/m_1$.

The integration of [6] is now performed separately over the acoustic $(-)$ and optical $(+)$ modes in order to obtain the specific heat. In the periodic case

$$[17] \qquad C = \frac{N}{\pi}\int_0^{\pi} E_+(\phi)\,d\phi + \tfrac{1}{2}\{E_+(0)-E_+(\pi)\} + \frac{N}{\pi}\int_0^{\pi} E_-(\phi)\,d\phi + \tfrac{1}{2}\{E_-(0)-E_-(\pi)\}.$$

Now $E_+(0) = E_+(\pi) = E_-(0) = E_-(\pi) = 0$, whence

$$C = \frac{N}{\pi}\int_0^{\pi} E_+(\phi)\,d\phi + \frac{N}{\pi}\int_0^{\pi} E_-(\phi)\,d\phi.$$

In the case of the free boundary the frequency of the optical mode at $l = 0$ has been replaced by half the value in the periodic case or the term $E_+(0)$ must be replaced by $\mathscr{E}_+(0)$. The specific heat then becomes

$$\begin{aligned} C &= \frac{2N}{\pi}\int_0^{\frac{1}{2}\pi} E_+(\phi)\,d\phi - \tfrac{1}{2}\{E_+(0)+E_+(\tfrac{1}{2}\pi)\} + \mathscr{E}_+(0) \\ &\quad + \frac{2N}{\pi}\int_0^{\frac{1}{2}\pi} E_-(\phi)\,d\phi + \tfrac{1}{2}\{E_-(0)-E_-(\tfrac{1}{2}\pi)\} \\ &= \frac{N}{\pi}\int_0^{\pi} E_+(\phi)\,d\phi - \tfrac{1}{2}\{E_+(0)+E_+(\tfrac{1}{2}\pi)\} + \mathscr{E}_+(0) \\ &\quad + \frac{N}{\pi}\int_0^{\pi} E_-(\phi)\,d\phi + \tfrac{1}{2}\{E_-(0)-E_-(\tfrac{1}{2}\pi)\} \end{aligned} \qquad [18]$$

and the effect of free ends is to add the bracketed terms to the specific heat. It may be noted that when $m_1 = m_2$ the second bracket is zero and the contribution reduces to

$$\tfrac{1}{2}\{k - E_+(0)\}.$$

Since enumeration of the optical modes starts with $l = 0$ corresponding to the highest frequency, $E_+(0)$ is the same as $E(\frac{1}{2}\pi)$ for the chain of equal masses. Thus [18] reduces to [8] when the masses are equal.

The contribution to the specific heat given by [18] is plotted in Fig. 2 as a function of $2kT/h\nu_0$ for mass ratios $m_1/m_2 = 1, 9, 16$. Thus if the masses are

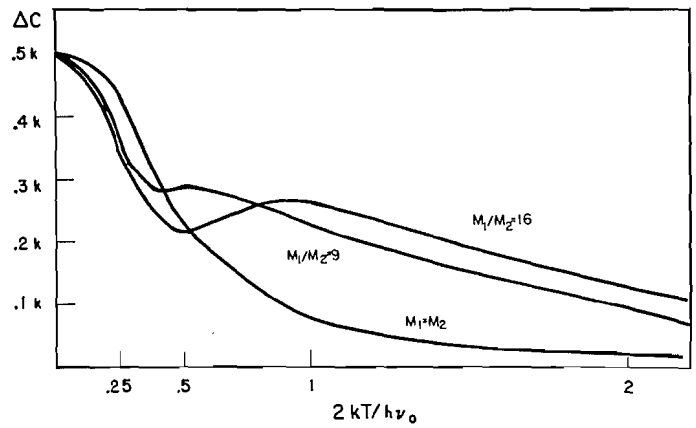

FIG. 2. Contribution of "end effect" to specific heat of a free diatomic chain.

quite different and there is a gap between the acoustic and optical modes, the effect associated with the acoustic modes may die away before that associated with the optical modes becomes prominent.

In the three-dimensional case the effect of the free boundary is easily evaluated when one of the masses is much greater than the other, say as

$m_2 \rightarrow 0$. The secular determinant corresponding to [12] may then be expanded as the product of its diagonal elements, from which the roots are found immediately. If the lattice is of dimensions $2N_x \times 2N_y \times 2N_z$ atoms the roots fall into groups associated with the acoustic ($\nu^2 \sim 0$) and the optical modes which are further subdivided into groups associated with atoms in the bulk of the material, on the surface, along the edges, and finally at the corners. Of these, the most important are the bulk and surface groups. There are $4(N_x-1)(N_y-1)(N_z-1)$ of the former with $4\pi^2\nu^2 = 2(a+2b)/m_1$ and $4(N_x-1)(N_y-1)$ of the latter with $4\pi^2\nu^2 = 2(a+b) = 2(a+b)+b/m_1$, and similarly modes found by interchanging $x, y; y, z; z, x$.

Since the modes associated with the surface atoms have a lower frequency of vibration than those associated with the bulk, a higher contribution to the specific heat will result. The excess specific heat due to the surface modes may be found by taking the Einstein functions of the frequencies involved. In most cases $\gamma/\alpha \sim 0.1$ or, using [5], $b/a \sim 0.14$ so that the frequencies of vibration of surface atoms perpendicular to the surface are considerably different from the frequency of an interior atom, while vibrations in the plane of the surface are not greatly different. With $\gamma/\alpha = 0.1$ the mode of vibration perpendicular to the surface has 0.78 of the frequency of an interior atom and at a temperature one-half of the characteristic Einstein temperature the contribution to the specific heat of the modes is 25% higher than from an interior atom. Thus with small particles which may have 10% of their atoms on the surface it should be quite feasible to observe the effect.

Obviously it cannot be correct to apply these considerations to the complex rutile structure since a simple cubic lattice is assumed. Nevertheless, the order of magnitude of the particle size effect may be obtained. It appears that only about one-fifth of the observed specific heat difference between the small particles and the bulk crystal (3% at 270°K.) can be accounted for in this way. It should be noted, however, that the predominant rutile surface ({110}) is covered with chains of relatively exposed oxygen atoms producing a rougher surface than the predominant {100} of the simple cubic structure, and hence a larger surface effect.

SUMMARY

The lowered frequency spectrum of a monatomic lattice with free boundaries results in an increased specific heat as shown by equation [10]. At low temperatures the expression [11] results which compares with the result found using a continuum model. If atoms of differing mass are present in the lattice, a particle size effect is associated with the optical modes and appears at high temperatures. It is evident that although the model chosen is a simple one, refinements such as the introduction of next nearest neighbors and lattice defects may be introduced into the lattice model in order to give a better picture of the particle size effect.

ACKNOWLEDGMENT

I should like to thank Dr. J. A. Morrison and Dr. J. S. Dugdale for their assistance through much invaluable discussion.

THE DEGRADATION OF CARRAGEENIN

II. INFLUENCE OF FURTHER VARIABLES[1]

By C. R. Masson, D. Santry, and G. W. Caines

ABSTRACT

A further study has been made of the degradation of carrageenin in aqueous solution. An 80°C. extract of *Chondrus crispus* degraded more rapidly than a preparation from which a 30°C. extract had been first removed. The latter preparation could be degraded to a lower limiting intrinsic viscosity under suitable conditions. Degradation was mainly random, but a more rapid initial degradation was observed under all conditions studied. The presence of dissolved oxygen accelerated the reaction above 60°C. Maximum stability was observed in an inert atmosphere at pH 9 in the presence of salts. Hydroxymethylfurfural and formic acid were identified as products, the yield of the former being higher than from D-galactose alone. The results have been discussed in the light of recent work on the constitution of the polysaccharide.

INTRODUCTION

In Part I (8) the kinetics of degradation of carrageenin of low molecular weight were described. It is of interest to observe if similar kinetics are obtained with an extract of high molecular weight, and to examine the effect of other variables, such as concentration, pH, and atmospheric oxygen, on the reaction. It is also important to establish the nature of the products. These aspects are investigated in the present work.

EXPERIMENTAL

Materials

The carrageenin used for the kinetic experiments was an 80°C. extract of dried Irish moss which had been previously extracted at 30°C. The significant details are given elsewhere (9). It had a number average molecular weight, determined osmometrically, of approximately 2.5×10^6. It is referred to as extract G.

In the experiments designed to identify the products of degradation, an 80° extract was employed, no attempt being made to remove the 30° extract separately. This extract is designated H. Both extracts were stored at −13°C.

Solutions were prepared as described previously (8). For all experiments with extract G the sodium salt was used.

Oxygen-free nitrogen was prepared by passing gas from a cylinder through heated copper turnings.

Measurements

Experiments in the presence of air were carried out exactly as described previously (8). For experiments in the absence of oxygen, two techniques were employed. In the first, carrageenin solutions were contained in sealed

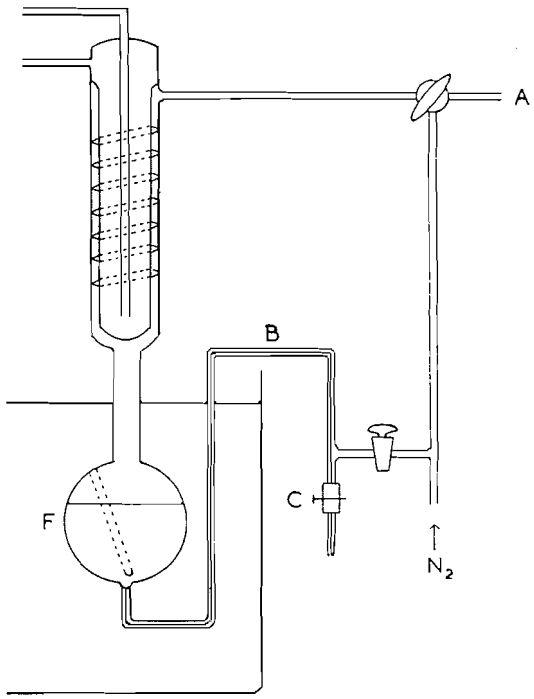

FIG. 1. Apparatus for studying degradation in nitrogen.

pyrex tubes which had been either flushed thoroughly with nitrogen or degassed by repeated freezing and thawing of the contents *in vacuo*. Tubes were immersed simultaneously in a bath at the appropriate temperature and removed at various intervals. This method was later discontinued and the apparatus shown in Fig. 1 was constructed for studying the degradation in an atmosphere of nitrogen. The solution was introduced into flask F *via* clip C, by applying suction at A. During an experiment, nitrogen was passed through the solution *via* capillary B. By suitable manipulation of the stopcocks a pressure of nitrogen could be applied to the surface of the solution and samples removed *via* C without the introduction of air.

It has recently been shown (9) that the viscosity of solutions of carrageenin of high molecular weight is markedly dependent on the rate of shear. For each sample, therefore, the viscosity was measured at various rates of shear as well as at various concentrations. Capillary viscosimeters similar to those described elsewhere (9) were employed. The shear-dependence decreased, as expected, during an experiment and became negligible when the intrinsic viscosities had fallen to 5.5 gm.$^{-1}$ 100 cm.^{3} Lower viscosities were therefore measured in a simple Ostwald viscosimeter, with a flow time for water of 179.2 sec.

Polarograms were obtained with a Sargent-Heyrovsky No. XII instrument. Aqueous 0.1 *N* KCl, with or without buffer, was used as supporting electrolyte, and gelatin in 0.01% concentration was used to suppress undesired maxima.

RESULTS

Degradation in Air at pH 7.0

A 0.1314% solution of extract G in $M/30$ sodium phosphate buffer (pH 7.0) was heated at 90°C. in the presence of air, and samples were withdrawn at various times for viscosity measurements. Inspection of the results showed that all measurements could be referred to a common shear rate of 700 sec.$^{-1}$. Linear plots of η_{sp}/c against c at this shear rate were extrapolated to yield values of $[\eta]_{S=700}$ for various times during the run. The results are presented in Table I.

TABLE I

DEGRADATION OF EXTRACT G IN AIR AT pH 7.0

Comparison of Results for Extracts F and G

For comparison with previous work, the results are plotted as $1/[\eta]_t - 1/[\eta]_0$ against t, where $[\eta]_0$ and $[\eta]_t$ are the intrinsic viscosities at zero time and time t respectively. This plot is chosen as no relationship between $[\eta]$ and M is at present available at high molecular weights. Trial shows, however, that the nature of the above plot is not greatly influenced by the value of the exponent

Insert (same ordinates), showing early stages of degradation.

α in the equation $[\eta] = KM^{\alpha}$, so that the main features of the degradation are adequately depicted in this way.

Fig. 2 shows this plot for the present results and for the degradation of the low-molecular-weight extract F studied previously (8). Three features are observed: (*a*) Extract G is degraded more slowly than extract F under the same conditions. (*b*) Both extracts show an initial sharp decrease in viscosity, followed by random degradation. The initial change is slight for extract G, and is complete in about two hours as compared with five hours for extract F. (*c*) With extract G, the rate of random degradation eventually decreases until, after 300 hr., a lower limiting viscosity of $[\eta] = 2.15$ is reached. This value of $[\eta]$ is only slightly lower than the initial intrinsic viscosity of extract F.

Effect of Oxygen

Initial experiments (extract G) showed that, at temperatures below 55°C., the rate of fall in viscosity was unaffected by passing oxygen, nitrogen, or air through the solutions.

At higher temperatures, however, the rate is slower *in vacuo* or in nitrogen than in the presence of air. Fig. 3 shows the results of experiments in sealed tubes at 90°C. and pH 7.0. The experiments were performed at various

◒ $c = 0.0468\%$ *in nitrogen*.

concentrations to check that the reaction is truly first-order. The scatter in the points is due to the difficulty of determining the true initial viscosity for each sample, as the viscosity of the blank solution dropped appreciably during the time required for degassing the solutions. The effect of oxygen is, however, obvious. The slopes of the lines indicate that the rate of random degradation in air is approximately 4.6 times that *in vacuo* or in nitrogen.

In unbuffered solution, as noted previously (8), the degradation of carrageenin in the presence of air is accompanied by a decrease in pH. In one experiment the pH decreased from 6.15 to 2.88 on heating for 102 hr. at 90°C. In the presence of nitrogen, however, the decrease in pH is less pronounced, although the viscosity of the solution still drops markedly. The pH of an unbuffered solution of extract G, for example, decreased only from 6.50 to 6.10 on heating for 265 hr. at 90°C. The specific conductance of this solution remained constant at 1.740±.04, while the value of $(\eta_{sp})_{\beta=200}$ at c = 0.052 gm./100 ml. fell from 9.27 to 0.03.

This result shows also that the rate of degradation is considerably retarded by the presence of salts. Thus the intrinsic viscosity of a buffered solution of extract G, after heating for 265 hr. in nitrogen, is $[\eta]_{\beta=700}$ = 6.05. This may be compared with the value of (η_{sp}/c) = 0.58 obtained for the unbuffered solution above. The difference in salt concentration and shear rate in the two sets of measurements would, if taken into account, further accentuate this difference. It is evident also that, in the absence of salts, the viscosity falls well below the limiting value attained in buffered solution in the presence of air.

Effect of $[H^+]$

Experiments were done to determine the pH for optimum stability of carrageenin in the presence of nitrogen. Portions of a 0.396% solution of extract G in 0.05 *M* sodium chloride were brought to different pH values by the addition of a few drops of 1 *N* NaOH or 1 *N* HCl. The solutions were then heated at 90°C. for four hours in nitrogen, quenched in ice water, and the viscosities measured. A shear rate of 100 sec.$^{-1}$ was common to the measurements. The specific viscosities of the heated solutions, at this rate of shear, are plotted against pH in Fig. 4. $(\eta_{sp})_{\beta=100}$ for the unheated blank was 18.65. Maximum stability is observed around pH 9, although even at this pH a significant decrease in viscosity has occurred.

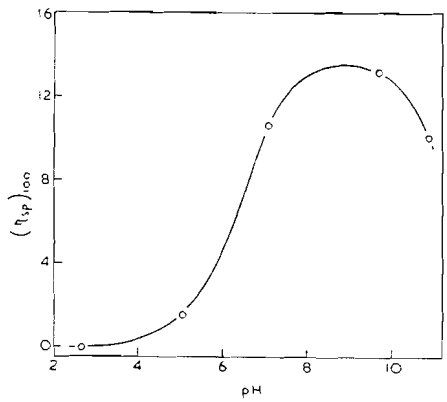

FIG. 4. Effect of $[H^+]$.

The course of the degradation at pH 10 in 0.5 *M* sodium carbonate – bicarbonate buffer was studied at 90°C. in nitrogen. The results could be compared

over a range of shear rates. Measurements at three shear rates are given in Table II. The plot of $1/[\eta]_t - 1/[\eta]_0$ against t was found to be independent of the rate of shear and showed the initial rapid degradation illustrated previously.

126.0	6.45	6.4	6.4

Products of Degradation

Attempts were made to identify some of the products of degradation using polarographic and spectrophotometric methods. The only products conclusively identified were 5-hydroxymethyl-2-furaldehyde (HMF) and formic acid. The presence of the former was established by comparison of its ultraviolet absorption spectrum and polarograms with those of an authentic sample, and of the latter by chemical tests supplemented by its polarographic behavior.

Three hundred milliliters of a 1% solution of extract H in water was autoclaved for three hours at 127°C. and 21 lb. The resulting light brown solution (pH 5) was extracted with ethyl acetate. The absorption spectrum of the extract (λ_{max} = 2750 Å) was not identified. The solution, after extraction, was boiled under reflux for a further 36 hr. The pH dropped to 2 and the solution darkened further in color. This solution was extracted continuously with ether for eight hours. The ether extract, which was light brown in color and highly acidic, had a strong penetrating odor resembling that of formic or acetic acid. On distilling off the ether under reduced pressure and allowing the vapors to pass through an ice trap, a few milliliters of a colorless liquid were collected. This gave the usual tests for formic acid. Polarograms in dilute buffered and unbuffered solution were exactly similar to those obtained using dilute formic acid. In unbuffered solution, well-defined waves having half-wave potentials $E_{\frac{1}{2}}$ of −1.61 v. and −1.57 v. (vs. S.C.E.) were obtained at pH 3.6 and 2.9 respectively. In buffered solution (pH 6.3) the waves were less clearly defined and had $E_{\frac{1}{2}}$ = −1.80 v. From the magnitude of the diffusion currents the yield of formic acid was estimated to be approximately 3% of the weight of carrageenin.

The brown residue remaining after removal of the ether dissolved only partly in water. The absorption spectrum of the dilute filtered solution was identical with that of HMF prepared by the method of Haworth and Jones (6). In addition, polarograms of this solution and of HMF showed identical half-wave potentials under the same conditions. This solution also gave positive tests with Fehling's solution, α-naphthol – sulphuric acid and resorcinol–HCl reagents, indicating that this compound is most probably

responsible for the positive ketose tests so often reported for carrageenin (3, 4, 5, 12, 14).

After extracting with ether, the solution of degraded carrageenin was still brown in color and still acidic. Attempts to isolate further low-molecular-weight products, however, were unsuccessful. A sensitive photometric test (1) for furfural was applied to further extracts of degraded carrageenin with negative results. Control tests showed that furfural could have been detected in 0.002% concentration. Tests for reductic acid, using sodium-2,6-dichlorobenzenoneindophenol (2) on several acid fractions, were also negative.

Origin of HMF

The yield of HMF from carrageenin was found to be 31 times larger than from D-galactose under the same conditions. A 10% gel of carrageenin and a 10% solution of D-galactose each in 1% HCl were heated on a steam bath for one and one-half hours. After neutralizing the solutions with NaOH, buffering with phosphate, and diluting, the absorption spectra were compared. The ratio of the peak heights at λ 2825 Å gave the relative yields of HMF.

That HMF did not originate from the liberation of ketose residues or from 2-keto gluconic acid was indicated by heating solutions of inulin and calcium-2-ketogluconate under the same conditions as carrageenin and comparing the absorption spectra. This was further verified by the absence of spots due to these compounds on paper chromatograms of various solutions of degraded carrageenin (11).

Yield of HMF from Extract G

(*a*) *In Air*

A 0.0856% aqueous solution of extract G was heated at 90°C. in air for 102 hr. The pH dropped from 6.18 to 2.88. The solution was titrated potentiometrically with 0.005 *N* NaOH. Found: pK = 3.79. Alkali, 15.8 ml., neutralized 20 ml. solution. The absorption spectrum of the neutral solution was similar to HMF and had an optical density of 1.13 at λ 2825 Å. A test for free sulphate was positive.

To calculate the total yield of HMF, it was first assumed that all the sulphate groups in the polymer had been hydrolyzed. Taking a value of 25% for the sulphate content (as SO_4) of the polymer, the acidity due to this cause was calculated. The remaining acidity may then be attributed to organic acids. On the basis that these consisted of formic and levulinic acids arising from the decomposition of HMF, the yield of HMF required to account for this was calculated to be 0.01083 gm./100 ml. From its extinction coefficient (7) at λ 2825 Å, the yield of free HMF was found to be 0.00152 gm./100 ml. The total HMF calculated in this way represents a maximum yield of 14.4% of the weight of carrageenin.

(*b*) *In Nitrogen*

A 0.104% aqueous solution of extract G was heated in nitrogen at 90°C. Examination of the absorption spectrum at various times showed that HMF was formed considerably more slowly than in air. Slight absorption (λ_{max}

2600 Å, $D = 0.23$; λ_{min} 2420 Å, $D = 0.195$) appeared after 164 hr., but the spectrum of HMF was not observed until later. The yield of HMF after 264.5 hr. was only 1.05%, the rate of formation being approximately 1/35 of that in the presence of air.

DISCUSSION

It is apparent that the decrease in viscosity which occurs on mild hydrolysis of carrageenin is associated with the liberation of HMF, and that this does not arise from the galactan portion of the molecule nor from ketose residues in the chain. The negative furfural test indicated that the degradation was not due to the liberation of pentose sugars.

Recent work (13) has revealed the presence in carrageenin of two distinct components, the relative amounts of which vary in different preparations according to the method of extraction. It has also been found (10) that 3,6-anhydro-D-galactose is a constituent of the so-called κ-, or gelling, component. Several features of the present results may be interpreted in the light of these observations.

O'Neill has pointed out (10) that 3,6-anhydro-D-galactose would be expected to yield HMF readily on heating, particularly in acid solution, and the formation of this compound is thus accounted for. The yield of HMF is high in unbuffered solution in air on account of the drop in pH, which catalyzes its formation. The value of 14.4% found for the yield from extract G may be compared with the value of 18.7% for the pure κ fraction (10). This indicates a high percentage of κ-carrageenin in this extract.

The random degradation may thus be attributed to the splitting out of 3,6-anhydro-D-galactose residues from the polysaccharide. The difference in rate observed for extracts F and G may be due to a higher proportion of these residues in the former extract. If the degradation is attributed to the instability of the κ fraction, the result indicates a higher percentage of this fraction in extract F. This is in accord with the results of Smith and Cook (13) who showed that a 60°C. extract contained a greater proportion of the κ fraction than an extract of the residue at higher temperatures.

Previous results (8) indicated the absence in extract F of long chains of 1–3 linked D-galactose residues, as this extract could be degraded randomly to very low viscosities. For extract G, however, the limiting viscosity reached on degradation at pH 7.0 (Fig. 2) may correspond to the presence of such residues. Whether this is an actual portion of the molecule or a separate component is not at present known.

The rate of random degradation of extract G will, of course, be lower than that of extract F by virtue of the presence of this stable residue. Allowance has therefore been made for this by plotting the quantity $[1/([\eta]_t - 2.15)] - [1/([\eta]_0 - 2.15)]$ against time for the early stages of random degradation of extract G, and comparing the rate curve with that obtained for extract F. The correction is, however, insufficient to account for the difference in rates for the two extracts. This indicates that the component responsible for random degradation in extract G is not identical with that in extract F. Further

studies, using separate fractions of carrageenin, are obviously necessary to explain this difference in rate.

From a practical aspect, the results indicate that for extraction of carrageenin with minimum of degradation, best results are to be obtained at pH 9 in the presence of salts, and with the exclusion of dissolved oxygen if the temperature exceeds 60°C.

ACKNOWLEDGMENTS

Our thanks are due to Dr. E. Gordon Young for his interest in this work and for helpful suggestions concerning the manuscript. We wish also to thank our colleagues in these laboratories for useful discussions.

SULPHATED DERIVATIVES OF LAMINARIN[1,2]

By A. N. O'Neill

ABSTRACT

The polysaccharide, laminarin, was prepared from the marine alga, *Laminaria digitata*, and was sulphated with chlorosulphonic acid in pyridine and in liquid sulphur dioxide at temperatures below 0°. Derivatives containing both O-sulphate and N-sulphate groups were prepared by sulphating β-aminoethyl ethers of laminarin obtained by the reaction of laminarin with ethylenimine. These derivatives were found to act as anticoagulants for blood *in vitro*. The preparations with highest sulphate were most active, and for equivalent sulphate that with both O-sulphate and N-sulphate groups was more active than the one containing only the former.

INTRODUCTION

A naturally occurring blood anticoagulant was isolated in 1916 by McLean (15) from liver and bovine heart. It was named heparin by Howell and Holt (9). Structural studies (25, 6, 12) have shown that it is a polysaccharide composed of D-glucuronic acid and D-glucosamine residues (1:1). Extensive work has indicated that the anticoagulant activity of heparin is dependent largely upon the degree of sulphation (11.3% S). Recently it has been shown (13, 17, 24, 26) that the amino groups in the molecule are sulphated and that these are readily removed by mild hydrolysis resulting in essentially complete inactivation. The molecular weight of heparin has been reported to be 15,000–20,000 (16, 26).

In 1935 Bergström (2) discovered that polysaccharides which contained sulphate groups had anticoagulant activity while similar derivatives of mono- and di-saccharides were inactive. Since that time a number of synthetic anticoagulants have been prepared by sulphating such polysaccharides as chondroitin sulphuric acid (2, 14), cellulose (14, 5, 1), inulin (10), starch (1), chitin (14, 1), alginic acid (19), and dextran (21). These sulphated derivatives had the disadvantage of possessing a much lower anticoagulant activity and a much higher toxicity than heparin. In view of recent work (26, 27, 7) the low activity can be attributed to their lack of sulphamic acid groups and the toxicity to their high molecular weights.

Laminarin, a water-soluble polysaccharide composed of D-glucopyranose units joined through C_1 and C_3 by β-glucosidic linkages, is found in some brown marine algae. It occurs in greatest amount in the fronds of *Laminaria*, and comprises 30–50% of the dry plant. The molecular weight of laminarin has been reported (20) to be about 4000–8000, and hence this polysaccharide should be suitable for the preparation of anticoagulants without recourse to partial hydrolysis and fractionation as has been found necessary for other polysaccharides.

RESULTS AND DISCUSSION

Since it was desirable that sulphation be accomplished without serious degradation of the polysaccharide, attempts were made to carry out the reaction of laminarin with chlorosulphonic acid in pyridine at -5 to $-15°$. This, however, was not completely satisfactory since the maximum sulphate content obtained was only 35% or about one sulphate half-ester group per glucose unit. The degree of sulphation below this value could be varied by changing the proportion of chlorosulphonic acid in the reaction mixtures. By increasing the temperature to 65–70° preparations could be obtained with higher sulphate but these were severely degraded as noted from their color and reducing properties.

The derivatives with highest sulphate were prepared by treating laminarin with a solution of chlorosulphonic acid in liquid sulphur dioxide at $-20°$. By this procedure preparations were obtained containing 1.7 sulphate groups per glucose unit. These were white in color and nonreducing and showed no noticeable degradation. Liquid sulphur dioxide is an excellent solvent for chlorosulphonic acid and it may be readily removed by simple evaporation. The reaction is heterogeneous since the polysaccharide is not soluble in this solvent. The use of sulphur dioxide as a solvent was proposed previously for preparing arylsulphonic acids (4, 22), and was used by Meyer (18) for the sulphation of chondroitin sulphuric acid with sulphur trioxide.

Derivatives of laminarin containing primary amino groups which could be sulphated to the corresponding sulphamic acid residues at first proved difficult to prepare. All attempts to replace tosyl groups by amino in a derivative in which the primary alcohol groups had been tosylated were not successful. However the introduction of such groups was readily accomplished with ethylenimine, whereby a β-aminoethyl ether derivative was obtained. This is a general reaction for polysaccharides and was carried out in a closed flask in the presence of an emulsifying agent at 80–90°. The degree of substitution was controlled by varying the proportion of ethylenimine in the reaction and preparations containing from 0.5 to 1.0 β-aminoethyl residues per monosaccharide unit were obtained. Several side reactions may occur such as the formation of a polyethylenimine ether and a hydroxyethylimine of laminarin. However agreement between the nitrogen analyses by the Kjeldahl and Van Slyke methods indicated that essentially all of the nitrogen was in the form of primary amino groups and hence the derivatives were the β-aminoethyl ethers. These derivatives formed very basic and highly viscous solutions in warm water. They were sulphated with chlorosulphonic acid in liquid sulphur dioxide to give products containing both sulphamic acid and half-ester sulphate groups.

The neutral sodium salts of all these derivatives were tested for their anticoagulant activities in comparison with a standard heparin by the method of Howell as modified by Charles and Scott and described by Jaques and Charles (11). The only modification was that freshly drawn human venous blood was used instead of that from the cannulated carotid artery of a cat.

TABLE I

COMPARISON OF THE ANTICOAGULANT ACTIVITIES OF SULPHATED DERIVATIVES OF LAMINARIN WITH THAT OF A STANDARD HEPARIN BY *in vitro* ASSAY

Preparation	Description of material	Sulphate, %	Activity, I.U. per mgm.
Heparin	Standard from Connaught Medical Research Laboratories		100
1	Laminarin sulphated at −20° with chlorosulphonic acid in liquid sulphur dioxide	46.5	25
2	β-aminoethyl ether of laminarin (7.28% N) sulphated at −20° with chlorosulphonic acid in liquid sulphur dioxide	46.2	40
3	β-aminoethyl ether of laminarin (3.2% N) sulphated at −20° with fluorosulphonic acid in liquid sulphur dioxide	43.8	20
4	Laminarin sulphated at −10° with chlorosulphonic acid in pyridine	32.8	6
5	Laminarin sulphated at −5° with chlorosulphonic acid in pyridine	35.0	6
6	Laminarin sulphated at −15° with chlorosulphonic acid in pyridine	29.6	6
7	β-aminoethyl ether of laminarin (7.28% N) sulphated at 90° with chlorosulphonic acid in pyridine. Highly degraded	39.1	6

The apparent potency of the sulphated laminarins, assuming the standard heparin to contain 100 I.U. per mgm., is shown in Table I. In general, preparations with highest sulphate groups per glucose residue had an anticoagulant activity of 25–30% that of a standard heparin. The material prepared by sulphating a β-aminoethyl ether of laminarin, which contained 7.28% nitrogen, had an activity of 35–40% that of heparin. This derivative contained both sulphamic acid and half-ester sulphate groups.

These results have been confirmed by *in vivo* studies in rats and dogs and are to be reported elsewhere (8).

EXPERIMENTAL

Preparation of Laminarin

The soluble form of laminarin was prepared from local *Laminaria digitata* (3). The yield from 500 gm. of dried plant was 85 gm.; $[\alpha]_D^{24} -12.2°$ (*c* 3.0, water), ash 0.8%.

Sulphation of Laminarin

(*a*) *With chlorosulphonic acid in pyridine.*—Dried, finely powdered laminarin (5.0 gm.) was dissolved in 50 ml. of pyridine and 20 ml. of formamide and the solution cooled to −5°. The pyridine had been freshly distilled over phosphorus pentoxide. Freshly distilled chlorosulphonic acid (6.0 ml.) was dissolved in dry chloroform (25 ml.) and added dropwise over a period of 30 min. to the solution of laminarin. The mixture was rapidly stirred at −5° for three hours and then allowed to stand at this temperature overnight. Sufficient ice and water were added to dissolve the precipitated derivative followed by sodium bicarbonate until the evolution of carbon dioxide ceased.

The solution was exhaustively extracted with ether, and the resulting aqueous solution neutralized to phenolphthalein with dilute sodium hydroxide and dialyzed until free from sulphate. The sulphated derivative was precipitated by the addition of ethyl alcohol and a little sodium chloride. It was washed with absolute ethanol and ether and finally dried to a white powder. Yield, 8.6 gm.; sulphate, 35.0%.

(*b*) *With chlorosulphonic acid in liquid sulphur dioxide.*—Commercial gaseous sulphur dioxide from a cylinder was dried by passage through three drying towers containing respectively silica gel, sulphuric acid, and phosphorus pentoxide. It was condensed in a flask which was protected from atmospheric moisture and was immersed in a bath of dry ice and acetone. The liquid sulphur dioxide (120 ml.) was cooled in an ice–salt bath to −20°. Freshly distilled chlorosulphonic acid (3 ml.) was added followed by 2.0 gm. of dry laminarin. The mixture was continuously stirred at −20° for six hours and then the sulphur dioxide was allowed to evaporate. On completion of the evaporation 100 ml. of *N* sodium hydroxide at −5° were added to dissolve the solid residue. The solution was neutralized with sodium hydroxide. It was dialyzed against running water for two days and against distilled water for one day. The dialyzed solution was concentrated *in vacuo* to 200 ml. and the sulphated laminarin precipitated by pouring the solution into 1000 ml. of 95% ethanol containing a small amount of sodium chloride. The precipitate was centrifuged, washed with absolute ethyl alcohol, with ether, and dried. Yield, 4.0 gm.; sulphate, 46.5%.

Preparation of Ethylenimine

Ethylenimine was prepared from β-aminoethyl sulphuric acid by heating with sodium hydroxide (23). It was purified by distilling over potassium hydroxide through a 15 in. Widmer column and collecting the fraction boiling between 56° and 58°. It was stored in the refrigerator over solid sodium hydroxide.

Reaction of Laminarin with Ethylenimine

Air-dried laminarin (5.0 gm.) and 0.5 ml. of a 1% solution of emulsifier BRIJ 35 (Atlas Powder Co.—polyoxyethylene lauryl alcohol) were mixed to a paste and 4.8 ml. (4.0 gm.) of ethylenimine were added. The mixture was stirred in a closed reaction flask at 80–90° for four hours. The resulting material was dissolved with some difficulty in 200 ml. of warm water. After cooling, the viscous solution was filtered through a sintered glass funnel of medium porosity and poured with stirring into 1000 ml. of ethyl alcohol. The precipitate was recovered by centrifugation, washed with aqueous methyl alcohol acidified with hydrochloric acid, absolute ethanol, and finally with ether. It was dried *in vacuo*. Yield, 7.7 gm.; N (Kjeldahl) 7.28%, (Van Slyke) 6.9%.

Sulphation of the β-Aminoethyl Ether

An amount of 1.6 gm. of the above material was sulphated in 100 ml. of liquid sulphur dioxide with 2.6 ml. of chlorosulphonic acid in the same manner as described for laminarin. Yield, 2.5 gm.; sulphate, 46.2%.

CARBOHYDRATE THIOETHERS

I. 6-DEOXY-6-THIOETHYL-D-GALACTOSE[1]

By Samuel B. Baker

ABSTRACT

A thioalkyl derivative has been synthesized by two distinct methods. One of these methods left no doubt as to the structural configuration. It is suggested that the other method of synthesis yields first an epoxy anhydro derivative which on further reaction leads to the thioalkyl carbohydrate, namely, 6-deoxy-6-thioethyl-D-galactose.

Thioalkyl substituted carbohydrates in which the sulphur atoms were not linked to the glycosidic carbon atoms were first obtained by Raymond (6) and by Brigl and Schinle (1).

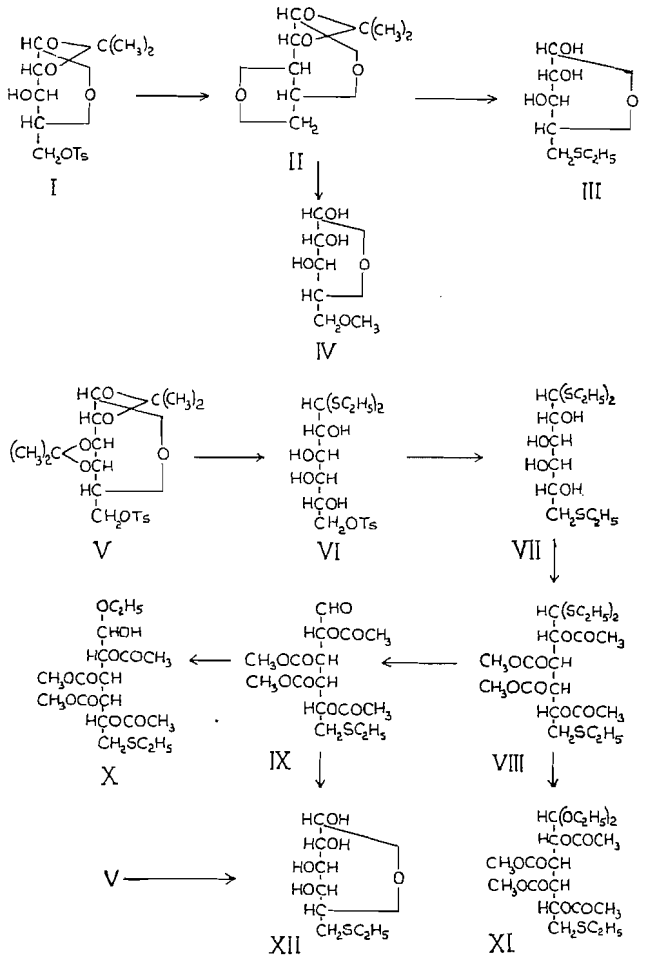
Levene and Raymond (4) synthesized 3,5-anhydro-1,2-isopropylidene-D-xylofuranose (II) and, unequivocally, determined the structure of this substance. Hot methanolic sodium methylate led to the formation of a monomethyl pentose, after removal of the isopropylidene group. This methyl pentose, being different from the known 3-methyl-D-xylose, was assumed to be 5-methyl-D-xylofuranose (IV).

Raymond (6) then synthesized a substance which he considered to be 5-deoxy-5-thioethyl-D-xylose (III) by treating 1,2-isopropylidene-5-*O*-*p*-tolylsulphonyl-D-xylofuranose (I) with two molecular equivalents of dry potassium ethanethiolate followed by hydrolysis of the isopropylidene group. Owing to the fact that the C-3 position had an hydroxyl group, it is probable that under the conditions of the experiment anhydridization would occur and the anhydro derivative (II) would cleave in the presence of the second molecular equivalent of potassium ethanethiolate (3) to yield the product 1,2-isopropylidene-5-deoxy-5-thioethyl-D-xylofuranose.

In similar manner, this worker (6) obtained 6-deoxy-6-thiomethyl-D-glucose from 1,2-isopropylidene-6-*O*-*p*-tolylsulphonyl-D-glucofuranose and two molecular equivalents of dry potassium methanethiolate. The intermediate 5,6-anhydro-1,2-isopropylidene-D-glucofuranose would be formed and this would then cleave to yield the glucose thioether.

The present publication pertains to a third ω-thioalkyl aldose, namely 6-deoxy-6-thioethyl-D-galactose (XII) that was obtained by two methods, one of which left no doubt as to the configuration. In the first method, 1,2-3,4-diisopropylidene-6-*O*-*p*-tolylsulphonyl-D-galactose (V) was treated with concentrated hydrochloric acid and ethanethiol. The isopropylidene groups were cleaved and the tolylsulphonyl aldose reacted with the ethanethiol to yield 6-*O*-*p*-tolylsulphonyl-D-galactose diethyl thioacetal (VI). This product was then treated with two molecular equivalents of dry sodium ethanethiolate to give the substance VII, 6-deoxy-6-thioethyl-D-galactose diethyl thioacetal. In addition, when VI was treated with one molecular equivalent of sodium

[1]*Manuscript received November 19, 1954.*
Contribution from the Research Institute, Montreal General Hospital, Montreal, Quebec.



methylate and the reaction product acetylated, a sirup was obtained. Treating the sirup with one molecular equivalent of sodium ethanethiolate yielded VII.

The second method of preparation of 6-deoxy-6-thioethyl-D-galactose (XII) left no doubt about its structural configuration. One molecular equivalent of 1,2-3,4-diisopropylidene-6-*O*-*p*-tolylsulphonyl-D-galactose (V) was heated in a suitable solvent with one molecular equivalent of sodium ethanethiolate. The sirupy product, after hydrolysis to remove the two isopropylidene groups, yielded XII. Possibly the tolylsulphonyloxy group was cleaved to yield a carbonium ion and since there were no free or potential hydroxyl groups under the reaction conditions employed, anhydro ring formation could not occur. The nucleophilic thioethyl group reacted with the electrophilic carbonium center.

Acetylation of VII, 6-deoxy-6-thioethyl-D-galactose diethyl thioacetal, yielded the tetraacetate VIII. This latter substance (VIII) formed *aldehydo-*

2,3,4,5-tetraacetyl-6-deoxy-6-thioethyl-D-galactose (IX) on reaction with mercuric chloride and cadmium carbonate in methanol-free acetone. The *aldehydo* derivative (IX) reacted directly with ethanol to yield the hemiacetal (X). This phenomenon appears to be general for *aldehydo* acetyl sugars (2, 8). Mercuric chloride and cadmium carbonate, on reaction with VIII, in the presence of absolute methanol and absolute ethanol yielded the dimethyl and diethyl acetals, respectively, of 2,3,4,5-tetraacetyl-6-deoxy-6-thioethyl-D-galactose.

EXPERIMENTAL

1,2-3,4-*Diisopropylidene*-6-*deoxy*-6-*thioethyl*-D-*galactose*

1,2-3,4-Diisoproylidene-6-*O*-*p*-tolylsulphonyl-D-galactose (7) (V) (60 gm.) and freshly prepared dry sodium ethanethiolate (16 gm.) were dissolved in N,N-dimethylformamide (275 cc.). The reaction mixture was heated at 100° for two hours and after cooling to room temperature it was poured into cold water (2000 cc.). A sirup separated, and after it had been left to stand for two hours at 5°, it was taken up in ether. The ethereal solution was dried over sodium sulphate, filtered, and the filtrate concentrated *in vacuo*. The resulting viscous sirup weighing 39 gm. (89%) did not crystallize from any solvent and it was distilled at 123–126°/0.12 mm. yielding 33.4 gm. (76%). A portion was redistilled at 124–126°/0.12 mm. yielding a colorless viscous sirup which was insoluble in water but soluble in all common solvents including petroleum ether. The refractive index was $\eta_D^{24°}$ 1.4795 and $[\alpha]_D^{22°}-85.7°$ ($CHCl_3$; *c*, 6.5052). Anal.: Calc. for $C_{14}H_{24}SO_5$: C, 54.28; H, 7.89; S, 10.52. Found: C, 54.06; H, 7.96; S, 10.6.

6-*Deoxy*-6-*thioethyl*-D-*galactose* (*XII*)

The sirupy 1,2-3,4-diisopropylidene-6-deoxy-6-thioethyl-D-galactose (30 gm.) was dissolved in 95% ethanol (250 cc.). Water (100 cc.) containing sulphuric acid (5 cc.) was added and the solution was heated for two hours at 70°. The hot solution was then diluted with hot water (350 cc.) and neutralized with an excess of barium carbonate. The barium salts were removed by centrifugation and the clear supernatant was concentrated *in vacuo* at 40°. Traces of water were removed by three codistillations with absolute ethanol and the dry, somewhat turbid, sirup was dissolved in absolute ethanol (125 cc.) and the solution was treated with charcoal to remove the turbidity and a trace of color. Ether was added to the colorless solution until it became slightly turbid, and crystallization occurred on extended cooling at −20°. The product was recrystallized from a small volume of absolute ethanol and the yield was 14.7 gm. (67%), m.p. 98–100°, and $[\alpha]_D^{22°}+73.8°$ equil. (water; *c*, 1.3536). Anal.: Calc. for $C_8H_{16}SO_5$: C, 42.85; H, 7.14; S, 14.28. Found: C, 42.78; H. 7.21; S, 14.19.

6-*O*-*p*-*Tolylsulphonyl*-D-*galactose Diethyl Thioacetal* (*VI*)

1,2-3,4-Diisopropylidene-6-*O*-*p*-tolylsulphonyl-D-galactose (V) (25 gm.) was dissolved in ethanethiol (30 cc.). Concentrated hydrochloric acid (25 cc.) was added and the mixture was agitated on the shaking machine for one hour.

The colorless reaction mixture became milky with the partial separation of reaction product and after cooling to 5° the mixture was cautiously neutralized with cold ammonium hydroxide. Petroleum ether (30–60°) was added and the heterogeneous mixture stirred well and allowed to stand at 5° for about one hour. The mixture was filtered and the reaction product washed with cold water and finally with petroleum ether (30–60°). The yield was 15 gm. (64%) and, after one recrystallization from hot acetone, the melting point was 114–115° and $[\alpha]_D^{21°}+7.5°$ (pyridine; *c*, 8.6314). Further recrystallization did not alter these constants. The literature (5) reports m.p. 115° and $[\alpha]_D^{20°}+7.66°$ (pyridine).

6-*Deoxy*-6-*thioethyl*-D-*galactose Diethyl Thioacetal* (*VIII*)

(1) 6-*O*-*p*-Tolylsulphonyl-D-galactose diethyl thioacetal (VI) (3.5 gm.) and sodium ethanethiolate (1.4 gm., 2 mol. equiv.) were dissolved in anhydrous N,N-dimethylformamide (40 cc.). The mixture warmed spontaneously and it was then heated at 100° for two hours, cooled to 15°, and the sodium *p*-toluenesulphonate was removed by filtration. The filtrate was added to cold water and the separated feathery mass was filtered, washed with a small volume of cold water, and then air-dried. It was recrystallized from acetone and an additional crop was obtained from the mother liquor. The combined yield was 2.2 gm. (90%), the melting point was 157–158°, and the optical rotation $[\alpha]_D^{24°}-6.2°$ (pyridine; *c*, 4.0292). Anal.: Calc. for $C_{12}H_{26}S_3O_4$: C, 43.63; H, 7.87; S, 29.1. Found: C, 43.6; H, 7.94; S, 29.1.

(2) 6-*O*-*p*-Tolylsulphonyl-D-galactose diethyl thioacetal (VI) (4 gm.) was suspended in anhydrous methanol (50 cc.). A solution (10 cc.) of sodium methylate, containing 0.2 gm. (1 mol. equiv.) of sodium, was added. Solution occurred rapidly and, after the reaction mixture had been allowed to stand for six hours at 22°, carbon dioxide was passed into it to destroy any unreacted sodium methylate. The reaction mixture was then concentrated *in vacuo* at 40° and the dry residue containing sodium *p*-toluenesulphonate was acetylated with pyridine and acetic anhydride. The reaction mixture was poured into cold water and after it had stood for 24 hr. at 22° the sirup did not crystallize. The sirup was taken up in ether and the ethereal solution was dried over sodium sulphate and the solvent removed *in vacuo*. The resulting sirup, probably 5,6-anhydro-D-galactose diethyl thioacetal triacetate, was dissolved in N,N-dimethylformamide (50 cc.) and dry sodium ethanethiolate (0.8 gm.) was added. The solution was allowed to stand overnight at 5°, heated one hour at 100°, cooled to room temperature, and then added to cold water (150 cc.). The product that separated was air-dried and recrystallized from acetone. The yield was 2 gm. (66%) and the melting point, 157–158°, was not depressed when a sample was admixed with 6-deoxy-6-thioethyl-D-galactose diethyl thioacetal.

(3) 6-Deoxy-6-thioethyl-galactose and 1,2-3,4-diisopropylidene-6-deoxy-6-thioethyl-D-galactose were each mercaptalated by the usual hydrochloric acid – ethanethiol method and the products that were isolated in each case were recrystallized from acetone and melted at 157–158°. Mixed melting point

determinations with authentic samples of 6-deoxy-6-thioethyl-D-galactose diethyl thioacetal showed identity.

2,3,4,5-*Tetrabenzoyl*-6-*deoxy*-6-*thioethyl*-D-*galactose Diethyl Thioacetal*

6-Deoxy-6-thioethyl-D-galactose diethyl thioacetal (VII) (7.8 gm.) was dissolved in anhydrous pyridine (50 cc.). The solution was cooled to $-10°$ and benzoyl chloride (14.8 gm.) was added dropwise with stirring. The reaction mixture was then allowed to stand overnight at room temperature and finally poured into water. Solid potassium bicarbonate was added to dissolve benzoic acid that arose from the excess benzoyl chloride used. The sirupy product did not crystallize and it was extracted with chloroform. The chloroform solution was dried over anhydrous sodium sulphate, filtered, and then concentrated *in vacuo*. The light yellow sirup was dissolved in 99% ethanol and petroleum ether (30–60°) was added until the solution became slightly turbid. The solution was cooled to $-20°$ and an oil separated. More 99% ethanol was added so that the oil was just redissolved and further cooling caused the deposition of a crystalline product. The material was again recrystallized from a small volume of absolute ethanol. The yield was 11.7 gm. (71%) and the substance melted at 90–91°. The substance rotated $[\alpha]_D^{23°}+5.8°$ ($CHCl_3$; *c*, 5.5592). Anal.: Calc. for $C_{40}H_{42}S_3O_8$: C, 64.34; H, 5.63; S, 12.87; C_6H_5CO, 56.3. Found: C, 64.28; H, 5.71; S, 12.9; C_6H_5CO, 56.1.

2,3,4,5-*Tetraacetyl*-6-*deoxy*-6-*thioethyl*-D-*galactose Diethyl Thioacetal* (*VIII*)

6-Deoxy-6-thioethyl-D-galactose diethyl thioacetal (VII) (23 gm.) was suspended in anhydrous pyridine (75 cc.) and acetic anhydride (50 cc.). The reaction mixture was allowed to stand overnight at room temperature and the colorless solution was poured into a large volume of cold water. A sirup separated and it solidified within 30 min. The solid was broken up, filtered, and washed to remove pyridine. The substance was dissolved in ether and the solution dried over anhydrous sodium sulphate and then filtered. The filtrate was concentrated to about 50 cc. and petroleum ether (30–60°) was added until the solution became turbid. The turbidity was cleared with several drops of ether and after cooling for 48 hr. at $-20°$ large colorless hexagonal crystals separated. The product melted at 77.5–78° and rotated $[\alpha]_D^{22°}-4.9°$ ($CHCl_3$; *c*, 7.6792). The yield was 30.5 gm. (88%). Anal.: Calc. for $C_{20}H_{34}S_3O_8$: C, 48.19; H, 6.82; S, 19.27; CH_3CO, 34.54. Found: C, 48.06; H, 7.02; S, 19.2; CH_3CO, 34.4.

Aldehydo-2,3,4,5-*tetraacetyl*-6-*deoxy*-6-*thioethyl*-D-*galactose* (*IX*)

2,3,4,5-Tetraacetyl-6-deoxy-6-thioethyl-D-galactose diethyl thioacetal (VIII) (5 gm.) was dissolved in methanol-free acetone (100 cc.) and cadmium carbonate (20 gm.) was added, followed by mercuric chloride (11 gm.). The mixture was heated under reflux for five hours, filtered hot into fresh cadmium carbonate, and the filter washed twice with hot methanol-free acetone. The combined filtrates were concentrated to dryness in the presence of cadmium carbonate. The residue was refluxed with three portions of absolute reagent

diethyl ether (containing not more than 0.01% ethanol) and the combined ether solutions were washed with 10% aqueous potassium iodide solution to remove the mercury compounds. The washed ether solution was dried over anhydrous sodium sulphate, filtered, and then concentrated to about 20 cc. Cooling at −15° caused precipitation of the product and after filtration it was washed once with pure absolute diethyl ether (5 cc.) at −15°. The yield was 3.2 gm. (82%) and the substance melted at 102–103° and rotated $[\alpha]_D^{26°} -28.7°$ ($CHCl_3$—ethanol free; *c*, 1.772). Mutarotation occurred in USP chloroform probably owing to the direct combination with the ethanol found in USP chloroform to form the hemiacetal (X). Anal.: Calc. for $C_{16}H_{24}SO_9$: C, 48.98; H, 6.12; S, 8.16; CH_3CO, 43.8. Found: C, 48.91; H, 6.41; S, 8.2; CH_3CO, 43.6.

2,3,4,5-*Tetraacetyl*-6-*deoxy*-6-*thioethyl*-D-*galactose Ethyl Hemiacetal* (*X*)

A sample of the aldehydo derivative (IX) (2 gm.) above was dissolved in hot absolute ethanol (5 cc.). The solution was allowed to stand overnight at room temperature when crystallization occurred. The product was recrystallized from toluene, m.p. 129.5–130° and $[\alpha]_D^{24°} -3.05°$ ($CHCl_3$; *c*, 5.0728). Anal.: Calc. for $C_{18}H_{30}SO_{10}$: C, 49.31; H, 6.82; S, 7.3. Found: C, 49.24; H, 6.98; S, 7.3. The semicarbazones were made from IX and from the hemiacetal (X) by the usual method of water and potassium acetate and after recrystallization from hot water the melting points and mixed melting points were 202–204°. Anal.: Calc. for $C_{17}H_{27}SN_3O_9$: N, 9.35; S, 7.12. Found: N, 9.28; S, 7.1.

2,3,4,5-*Tetraacetyl*-6-*deoxy*-6-*thioethyl*-D-*galactose Dimethyl Acetal*

2,3,4,5-Tetraacetyl-6-deoxy-6-thioethyl-D-galactose diethyl thioacetal (VIII) (11.2 gm.) was dissolved in anhydrous methanol (150 cc.). Powdered cadmium carbonate (50 gm.) and mercuric chloride (26 gm.) were added and the mixture was refluxed vigorously for four hours. The reaction mixture was allowed to stand overnight at room temperature. Additional quantities of cadmium carbonate (30 gm.) and anhydrous methanol (150 cc.) were added and the mixture refluxed for three hours. The hot mixture was filtered into some cadmium carbonate in a distilling flask and the filtrate was concentrated to dryness *in vacuo* at 40°. Chloroform (200 cc.) was added, the solution filtered, and the filtrate extracted twice with 10% potassium iodide solution to remove soluble mercury compounds. The chloroform solution was dried over anhydrous sodium sulphate, the mixture filtered, and the filtrate concentrated to dryness *in vacuo* at 40°. The resulting sirup was dissolved in a small volume of ether, and petroleum ether (30–60°) was added to turbidity. Cooling at −15° caused precipitation. The product was recrystallized twice from ether – petroleum ether and once from a large volume of hot petroleum ether (65–110°). The yield was 6.8 gm. (69%) and the melting point 89–90° and rotation $[\alpha]_D^{23°} +6.1°$ ($CHCl_3$; *c*, 4.0592). Anal.: Calc. for $C_{18}H_{30}SO_{10}$: C, 49.31; H, 6.82; S, 7.3; CH_3CO, 40.1. Found: C, 49.11; H, 6.88; S, 7.3; CH_3CO, 39.8.

2,3,4,5-*Tetraacetyl*-6-*deoxy*-6-*thioethyl*-D-*galactose Diethyl Acetal* (*XI*)

2,3,4,5-Tetraacetyl-6-deoxy-6-thioethyl-D-galactose diethyl thioacetal (XIII) (5 gm.) was dissolved in absolute ethanol (100 cc.). Cadmium carbonate (25 gm.) was added followed by mercuric chloride (11 gm.). The mixture was refluxed for two hours, filtered into fresh cadmium carbonate, then concentrated to dryness. The residue was extracted with three portions (50 cc.) of hot chloroform and after filtration, the chloroform solution was washed twice with 10% potassium iodide solution to remove soluble mercury compounds. The solution was dried over sodium sulphate, filtered, and concentrated *in vacuo* to a thick sirup, which crystallized on standing. The solid mass of crystals was recrystallized twice from 60% ethanol and it did not reduce Fehling's solution prior to acid hydrolysis. The yield was 3.6 gm. (76%) and the melting point was 94.5–95.5° and it rotated $[\alpha]_D^{20°}+4.1°$ ($CHCl_3$; *c*, 4.8468). Anal.: Calc. for $C_{20}H_{34}SO_{10}$: C, 51.50; H, 7.29; S, 6.86; CH_3CO, 39.05. Found: C, 51.42; H, 7.31; S, 6.9; CH_3CO, 38.8.

6-*Deoxy*-6-*thioethyl*-D-*galactose Diethyl Acetal*

The solution, above, from the optical rotation determination (1.2117 gm.) was cooled to −15° and sodium methylate solution (0.5 cc. of 0.3 *N*) was added. The clear solution was allowed to stand at room temperature and within two hours a thin gel formed. The reaction mixture, after it had been left to stand 24 hr. at room temperature, was added to anhydrous ether (100 cc.) and the crystalline product washed with a small volume of anhydrous ether. The crude product was twice recrystallized from a small volume of hot water and it melted at 143.5–144° and rotated $[\alpha]_D^{19°}+11.1$ (pyridine; *c*, 2.464). The yield was 0.6 gm. (80%). Anal.: Calc. for $C_{12}H_{26}SO_6$: C, 48.32; H, 8.72; S, 10.73. Found: C, 48.2; H, 8.91; S, 10.69.

The above substance (0.5 gm.) was acetylated with pyridine and acetic anhydride and after isolation and one recrystallization from 60% ethanol, the product, weighing 0.58 gm. (75%), had a melting point of 94–95°. The melting point of a sample mixed with 2,3,4,5-tetraacetyl-6-deoxy-6-thioethyl-D-galactose diethyl acetal, obtained previously, was 94–95°.

GEOMETRICAL CORRECTIONS TO THE BRAGG-GRAY RELATION APPLIED TO ABSOLUTE CHEMICAL DOSIMETRY[1]

By P. J. Dyne

ABSTRACT

The γ-ray irradiation conditions for the valid application of the Bragg-Gray relation, which relates the energy deposition in a solid to the ionization in an air-filled cavity, are examined with particular reference to some published experiments on the yield of the radiation-induced oxidation of ferrous sulphate. It is pointed out that experiments in which divergent radiation is used will give a higher oxidation yield than the relation indicates. A quantitative treatment is advanced which accounts for the discrepancies between certain experimental results.

White, Marinelli, and Failla (10) have shown that the Bragg-Gray relation will give erroneous results if applied to ion chambers which are irradiated by divergent radiation and have given a method for estimating the error. Weiss, Bernstein, and Kuper (9) suggested that this was the reason for some of the discrepant results reported by different experimenters on the G value (No. of ions oxidized per 100 ev. absorbed) for the radiation-induced oxidation of ferrous sulphate. Earlier work in which the energy absorption was obtained from ion chamber measurements, using the Bragg-Gray relation, gave a G of about 20 which is considerably higher than the now well-established value of about 16 (3, 5, 7, 9). This paper will describe explicitly the reason for the failure of the Bragg-Gray relation in these earlier experiments and will show that the treatment given by White, Marinelli, and Failla can be extended to give a semiquantitative explanation of the anomalous high G values.

For this purpose we shall discuss a set of experiments in which the energy deposition in a solution was obtained from the ionization in an identical volume of air. All these experiments were carried out with polystyrene vessels using hard γ or X rays and differ only in the geometrical arrangement of source and solution. "Edge" effects, which arise because the solution near the polystyrene wall is being irradiated by secondary electrons generated in the wall, can be shown, from the relative stopping powers and electron densities of polystyrene and 0.8 N H_2SO_4, to be negligible.

The chosen set comprises the experiments of Miller (6), Hardwick (2), Hochanadel and Ghormley (3), and Weiss, Bernstein, and Kuper (9). The G values which they reported are shown in column A of Table I. As different values were used in their calculations for the energy per ion pair and the ratio of the stopping powers of air and polystyrene we have recalculated their results using the values used by Weiss, Bernstein, and Kuper. These are shown in column B. It can be seen that there is a discrepancy of about 15% between the first two experiments and the last two.

The Bragg-Gray relation (1, 8) states that the rate of energy deposition per unit volume, E, in a mass of solid material is given by $E = JW\rho$ where J

TABLE I

G VALUES FOR THE OXIDATION OF FERROUS SULPHATE

	A	B
Miller	20.3	18.5
Hardwick	20.7	18.5
Hochanadel and Ghormley	16.7	15.5
Weiss, Bernstein, and Kuper	15.9	15.9

is the rate of formation of ion pairs per unit volume in an air-filled cavity in the solid, W is the energy per ion pair for air, and $\rho = n_S S_S / n_A S_A$ where n_S and n_A are the electron densities in the solid and air respectively and S_S, S_A are the stopping powers of the solid and air respectively. For this relation to hold it is required that the dimensions of the cavity be small compared with the range of the secondary (Compton recoil) electrons in air. Apart from this restriction, the relation is independent of the geometry of the cavity, provided that the radiation field is strictly uniform over the whole volume of the chamber. This is demonstrated most clearly in the treatment given by Laurence (4).

This requirement of uniform irradiation may be fulfilled experimentally either by a uniform parallel beam of gamma or X rays or by isotropic irradiation which could be realized, for example, by placing the sample at the center of a spherical shell of material which emitted gamma rays. The former configuration was used by Weiss, Bernstein, and Kuper, the latter was approached by Hochanadel and Ghormley whose irradiation cell was placed on the axis of a cylindrical source of Co^{60}. Both of these values may be taken to be in agreement with $G \simeq 16$.

The irradiation apparatus used by Miller and by Hardwick is shown diagrammatically in Fig. 1. The radioactive source (*S*) is placed on the axis

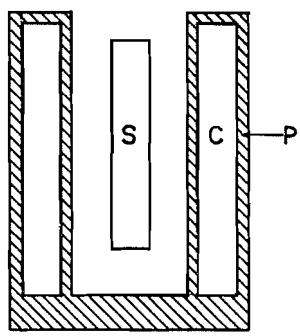

FIG. 1. Cylindrical ion chamber as used by Miller and by Hardwick. *S*, source; *C*, cavity; *P*, polystyrene wall.

of a cylindrical shell (*C*) of solution or air which is enclosed by polystyrene walls (*P*). The experimental volume is being irradiated by a divergent, nonuniform field and we cannot apply the Bragg-Gray relation to the ion current to obtain the energy deposition in the liquid.

The energy deposition in the liquid can be calculated for divergent radiation by a modification of the method of White (11) and White, Marinelli, and Failla (10). These workers discussed the case of a cavity between two concentric spherical shells with a point source of radiation at the center. In Fig. 2

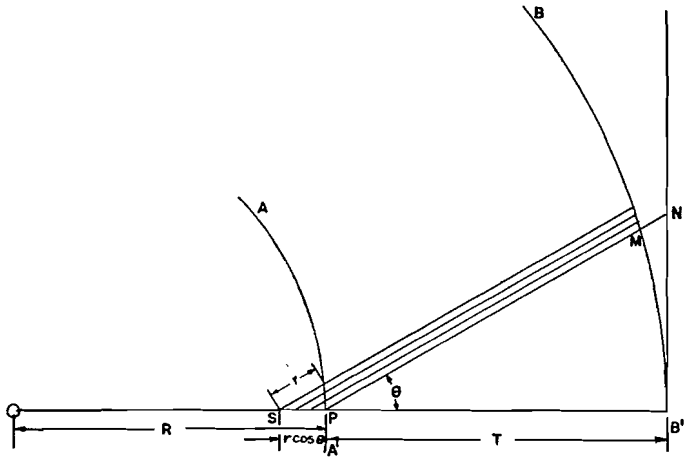

FIG. 2. Paths of secondary electrons crossing a spherical shell.

we show the paths of secondary electrons generated by γ rays originating from the point O crossing the walls of the spherical chamber, AA', BB'. Let the γ rays generate n secondary electrons per cm. having a range r cm. in the solid, which are scattered through an angle θ from the direction of the incident γ ray. Since the range of the secondaries in air is very much greater than that in the wall, secondaries which are formed up to a distance $r \cos \theta$ inside the wall will be able to cross the air cavity. The number of secondaries crossing the air cavity is, therefore, $nr \cos \theta$. Since $r \ll T$, the thickness of the air cavity, these secondaries have path lengths which are all effectively equal to PM. We put $PM = PN/\lambda = T/\lambda \cos \theta$. If these secondary electrons produce τ ions per cm. in air, losing W ev. per ion pair, the total energy deposition in the gas is $E_G = nr \cos \theta$. $(T/\lambda \cos \theta)\tau W = (nrT\tau W)/\lambda = JW$, where J is the ion current.

When the air cavity is filled with liquid (or any condensed medium) the energy deposition is due entirely to secondaries generated in the liquid. The γ rays cross T cm. of liquid and will produce nT secondaries of range r cm. if the wall and liquid are equivalent. Each secondary will deposit $r\tau\rho W$ ev. where $\rho = n_L S_L / n_A S_A$ as before, the subscripts referring to the liquid and air respectively. The energy deposition in the liquid is $E_L = nrT\tau\rho W$ ev. Combining the equations for E_L and E_G and noting that $E_G = JW$ we find

$$E_L = E_G \rho \lambda = JW\rho\lambda, \qquad [1]$$

which is a form of the Bragg-Gray relation modified by the introduction of the geometric factor λ. It can be seen from Fig. 1 that λ is appreciably greater than unity. Application of the unmodified Bragg-Gray relation will, therefore,

underestimate E_L and consequently will overestimate the G value for a radiation-induced reaction.

White, Marinelli, and Failla showed that for a cavity in the shape of a spherical shell

$$\lambda = T/\{[(R\cos\theta)^2+2RT+T^2]^{\frac{1}{2}}\cos\theta - R\cos^2\theta\}.$$

This formula was applied to measurements on a set of ion chambers of different dimensions. For $\theta \simeq 60°$ a satisfactory agreement was obtained between their measurements and earlier independent measurements on the specific gamma ray output from radium. It should be noted that θ is an empirical parameter.

The calculation of the energy deposition in a cylindrical cavity follows precisely the same steps. The paths of secondary electrons crossing the cavity are shown in Fig. 3. The lines MQ and OQ are in the YOZ plane. The source

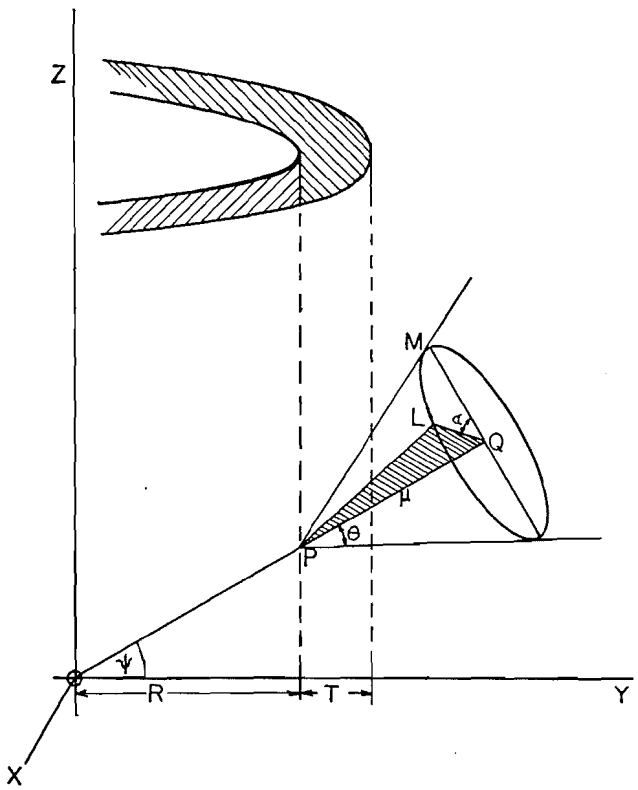

FIG. 3. Paths of secondary electrons crossing a cylindrical cavity.

is at the origin, halfway along the length of the cylindrical cavity. A γ ray follows the path OPQ making an angle ψ with the Y axis and generates secondary electrons which emerge, in effect, at the point P at the edge of the inner wall. The paths of all the secondaries crossing the air cavity, scattered through an angle θ, generate a cone, semiangle θ with an axis OPQ, vertex at P.

The coordinates (x, y, z) of the point L shown in the diagram are

$$[2] \qquad x = \mu \tan\theta \sin\alpha,$$
$$[3] \qquad y = R+\mu(\cos\psi-\tan\theta\cos\alpha\sin\psi),$$
$$[4] \qquad z = R\tan\psi+\mu(\sin\psi+\tan\theta\cos\alpha\cos\psi).$$

These may be taken as the parametric equations of the line LP which is the path of an individual secondary electron specified by the angles ψ, θ, and α.

For the cylindrical ion chamber the equation of the outer cylinder which terminates the paths of the secondary electrons is

$$[5] \qquad x^2+y^2 = (R+T)^2.$$

The path length D of the secondary electron crossing the cylindrical cell is $\mu/\cos\theta$ when, from equations [1], [2], and [5],

$$\mu^2[\tan^2\theta\sin^2\alpha+(\cos\psi-\tan\theta\cos\alpha\sin\psi)^2] +2\mu R(\cos\psi-\tan\theta\cos\alpha\sin\psi)+R^2-(R+T)^2 = 0;$$

whence

$$[6] \qquad D = \frac{+R\beta+\sqrt{(R+T)^2(\tan^2\theta\sin^2\alpha+\beta^2)-R^2\tan^2\theta\sin^2\alpha}}{\cos\theta(\tan^2\theta\sin^2\alpha+\beta^2)}$$

where $\beta = (\tan\theta\cos\alpha\sin\psi-\cos\psi)$.

A secondary electron whose path is defined by ψ, θ, and α has the path length $D(\alpha)$ and will deposit $D(\alpha)\tau W$ ev. in the cavity. To obtain the total energy deposition for gamma rays having the direction ψ we first multiply this energy by the number of secondary electrons having this path and then integrate over all values of α. The paths of secondary electrons inside the wall, near the edge of the cavity, are shown in Fig. 4. The points P and S correspond to the points

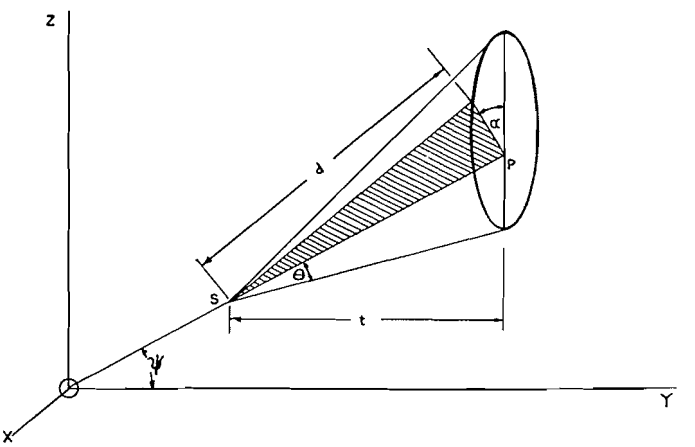

FIG. 4. Paths of secondary electrons inside the wall, at the edge of the cavity.

P and S in Figs. 2 and 3. The paths of secondary electrons in the wall are terminated by a vertical *plane* (since $r \ll R$). It can be shown using equations

[2], [3], and [4] above that a secondary of path length d is generated a distance t inside the wall where $t = d(\cos\theta - \tan\theta \sin\psi \cos\alpha)\cos\theta = -d\beta\cos\theta$. All secondaries generated along the path $SP = t/\cos\psi$ when $d = r$ will cross the cavity. Using our previous notation the number of secondary electrons $N(\alpha)$ specified by the direction α which cross the cavity is given by

$$N(\alpha) = -nr\beta\cos\theta/\cos\psi.$$

The total energy deposition from secondaries generated by γ rays having the direction ψ is E_G where

$$[7] \qquad E_G = \int_0^{2\pi} N(\alpha)D(\alpha)\tau W d\alpha \Big/ \int_0^{2\pi} d\alpha.$$

When the cavity is filled with liquid the γ rays cross $T/\cos\psi$ cm. of this medium and consequently the energy deposition in the liquid E_L is given by

$$[8] \qquad E_L = nTr\tau\rho W/\cos\psi,$$

whence we find

$$[9] \qquad E_L = -E_G\rho T \int_0^{2\pi} (1/\beta\, D(\alpha))d\alpha \Big/ \cos\theta \int_0^{2\pi} d\alpha,$$

which we may rewrite, noting that $E_G = JW$, as $E_L = JW\rho\eta$. This is similar to equation [1], the factor η corresponding to the factor λ defined for spherical cavities. The quantity η may be evaluated numerically.

Since η is a function of ψ the factor required to correct the experimental results is the value of η, weighted for the distribution of γ rays as a function of ψ averaged over ψ. Since in the experiment which we are discussing the source of γ rays was a cylinder of length and diameter comparable with those of the cell itself (not a point source by any means) we do not know this distribution function. All we shall do is to discuss the values which η make take for chosen values of ψ.

In our calculations we used a value of $\theta = 60°$ as found experimentally by White, Marinelli, and Failla. This describes the average path of electrons generated by a gamma ray whose path is normal to a spherical wall. For small angles of ψ we would expect θ to be unchanged for the cylindrical wall since the radius of curvature of the wall is large compared with the path length of the secondaries in the wall. For $R = 10$ mm., $T = 4$ mm., dimensions corresponding to the Miller and the Hardwick cell, and for $\psi = 0°$, $10°$, and $15°$, η has the values of 1.16, 1.18, and 1.19 respectively. The G values, as they were originally calculated, would be about 18% higher than the true value if the averaged value of η was of this magnitude.

When $\psi > 15°$ we cannot use equation [7] for, with the experimental cells, some of the secondary electrons crossing the air cavity are not terminated by the cylindrical wall but by the plane end of the cell. The geometrical correction will therefore be greater than the value of η given by equation [9]. The calculation is further complicated when $\psi > 30°$ for, with $\theta = 60°$, only part of the cone of secondary electrons cross the air cavity at all. The value

of η is still however appreciably greater than unity. For small values of ψ, η is in the range 1.15–1.20.

These calculations are based on an idealized model and too much weight should not be placed on the numerical values we have quoted. In addition to the fact that the angular distribution of gamma rays is not known, we have assumed a single value of θ. The value chosen was that found experimentally for electrons generated by a gamma ray whose path is normal to the edge of the cavity. When the incident γ ray intersects the cavity obliquely we should not expect the average scattering angle to be quite the same. This will not alter the conclusion of the last paragraph, namely that the correction is always appreciably greater than unity, but the possible range of values for the correction should be extended.

We can say, in conclusion, that the Bragg-Gray relation applied to cylindrical ion chambers as used by Miller and by Hardwick will give energy depositions in a condensed medium which are low by 10–20%. This observation is offered as an explanation of the high G values obtained by these experimenters compared with those obtained by Hochanadel and Ghormley and by Weiss, Bernstein, and Kuper.

ACKNOWLEDGMENTS

I should like to acknowledge many helpful discussions with Dr. R. W. Attree; in particular the generous help and guidance I received from him on the mathematical derivations in this paper. I should also like to acknowledge helpful correspondence with Dr. N. Miller and Dr. T. N. White.

A SYNTHESIS OF D-TAGATOSE FROM D-GALACTURONIC ACID[1]

By P. A. J. Gorin,[2] J. K. N. Jones,[2] and W. W. Reid[3]

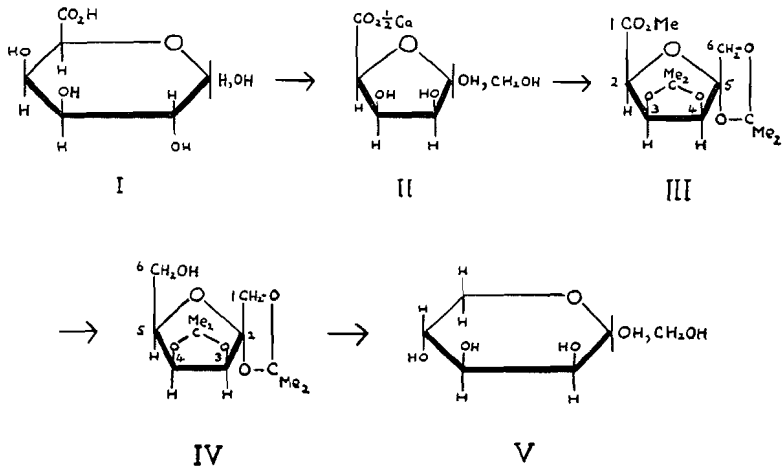
ABSTRACT

D-Tagatose has been synthesized by a series of reactions from D-galacturonic acid.

INTRODUCTION

D-Tagatose is generally prepared by the isomerization of D-galactose with very dilute alkali (1) or hot pyridine (4). However, the yields from these reactions are small and the isolation of the product tedious. D-Tagatose has also been prepared by the biochemical oxidation of the rare sugar derivative D-talitol using *Acetobacter suboxydans* (5).

We now describe a preparation of D-tagatose from D-galacturonic acid. This material is readily prepared by the enzymic hydrolysis of pectic acid (3). Isomerization of D-galacturonic acid (I) with lime water gave the calcium salt of 5-keto-L-galactonic acid (II; 2) which on treatment with an acetone–sulphuric acid mixture followed by esterification with ethereal diazomethane



yielded 3,4;5,6-di-*O*-*iso*propylidene-5-keto-L-galactofuronic acid methyl ester (III). An ethereal solution of this material was reduced with lithium aluminum hydride to 1,2;3,4-di-*O*-*iso*propylidene-D-tagatose (IV) which was identical with an authentic specimen prepared from D-tagatose. Acid hydrolysis of (IV) gave a material indistinguishable from D-tagatose (V) in 25% over-all yield from the calcium salt of 5-keto-L-galactonic acid.

EXPERIMENTAL

Evaporations were carried out under reduced pressure. Optical rotations were measured at 16±2°C. Melting points are uncorrected.

3,4;5,6-*Di-O-isopropylidene*-5-*keto*-L-*galactofuronic Acid Methyl Ester* (III)

The calcium salt of 5-keto-L-galactonic acid (II; 620 mgm.), prepared by the isomerization of D-galacturonic acid (I) by alkali, was shaken in dry acetone (12 ml.) containing sulphuric acid (0.5 ml.) for four hours. The solution, which contained a suspension of calcium sulphate, was neutralized by rapid addition to aqueous lime. The alkaline solution was then neutralized with carbon dioxide, filtered, and the filtrate evaporated to a white solid (the calcium salt of 3,4;5,6-di-*O-iso*propylidene-5-keto-L-galactofuronic acid). The free acid was obtained from the salt by the addition of dilute sulphuric acid to an emulsion of ether and a solution of the calcium salt in ice-cold water. The ethereal extract was washed with water (four times), dried (sodium sulphate), filtered, and esterified by addition of an excess of ethereal diazomethane. After 30 min. the solution was evaporated to a sirup which crystallized. Two recrystallizations from ethanol gave white needles (353 mgm.) with m.p. 60°C. and $[\alpha]_D$ +22° (*c*, 1.0 in chloroform). Found: C, 54.4; H, 7.0%. Calc. for $C_{13}H_{20}O_7$: C, 54.2; H, 6.9%.

1,2;3,4-*Di-O-isopropylidene*-D-*tagatose* (*IV*)

3,4;5,6-Di-*O-iso*propylidene-5-keto-L-galactofuronic acid methyl ester (III; 848 mgm.) was added with stirring to an excess of lithium aluminum hydride (500 mgm.) in ether (20 ml.). After five hours, excess of reagent was destroyed by addition of ethyl acetate. Water (50 ml.) was added and organic solvents evaporated. The solution was neutralized with acetic acid, filtered, and the filtrate extracted with an equal volume of chloroform. The extract was washed once with water, dried (sodium sulphate), filtered, and evaporated to a sirup (674 mgm.) which crystallized. Two recrystallizations from light petroleum (b.p. 30–60°C.) gave white needles which had m.p. 63–64°C. not depressed on admixture with an authentic specimen of 1,2;3,4-di-*O-iso*propylidene-D-tagatose which had been prepared from D-tagatose and $[\alpha]_D$ +64° (*c*, 0.80 in chloroform). Found: C, 55.1; H, 7.5%. Calc. for $C_{12}H_{20}O_6$: C, 55.4; H, 7.6%.

D-*Tagatose* (*V*)

1,2;3,4-Di-*O-iso*propylidene-D-tagatose (IV; 173 mgm.) was hydrolyzed by heating in 0.05 *N* sulphuric acid (5 ml.) at 100° for one hour. The reaction mixture was neutralized (aqueous barium hydroxide, then barium carbonate), filtered, and evaporated to a sirup (115 mgm.). The product was crystallized twice from ethanol to give white crystals (71 mgm.) which had m.p. 131–132°C. undepressed on admixture with authentic D-tagatose prepared by isomerization of D-galactose and $[\alpha]_D$ +2° (2 min.) → −3° (30 min.; constant value) (*c*, 1.0 in water). Found: C, 40.3; H, 7.0%. Calc. for $C_6H_{12}O_6$: C, 40.0; H, 6.7%.

THE SYNTHESIS OF D,L-SERINE BY SELECTIVE REDUCTION OF N-SUBSTITUTED AMINOMALONIC AND CYANOACETIC ESTERS[1,2]

By Louis Berlinguet[3]

RÉSUMÉ

L'étude de la réduction sélective de l'amino malonate d'éthyle libre ou substitué sur l'azote par des radicaux acylés et de l'acétamido cyano acétate d'éthyle, par les hydrures $LiAlH_4$, NaH_4B, KH_4B, et $LiBH_4$ dans différents solvants et différentes conditions expérimentales a été faite. Une nouvelle synthèse de la D,L-sérine, à la fois rapide et facile, a ainsi été effectuée. Par réduction sélective des esters N-substitués des acides amino malonique et amino cyanoacétique, au moyen de l'hydrure de sodium et de bore dans l'eau et l'éthanol, suivie d'hydrolyse acide, on obtient la D,L-sérine avec de bons rendements.

INTRODUCTION

Serine is an important amino acid. One of its derivatives, azaserine, has been used with success in cancer research. However, most of the general methods for the synthesis of D,L-serine are not convenient. The starting materials for some of them are difficult, laborious, or expensive to prepare, and the over-all conversion to serine is not particularly good by any of them.

The best method published so far is by King (9) who condensed quantitatively formaldehyde with ethyl acetamidomalonate (I). However, acid hydrolysis of the intermediate gave no serine but ammonium chloride and pyruvic acid. Owing to the instability of the condensation product in acid, it had to be first monosaponified with one equivalent of normal alkali, acidified, decarboxylated, and then hydrolyzed to D,L-serine, with an over-all yield of 65%. With the condensation product of formaldehyde and ethyl acetamidocyanoacetate (II), no serine could be obtained either by acid or by alkaline hydrolysis.

Both ethyl acetamidomalonate (I) and ethyl acetamidocyanoacetate (II) contain the three-carbon skeleton of serine and are easily available. It was felt that a better synthesis of serine could be worked out from these starting materials if the condensation with formaldehyde and the subsequent hydrolysis were avoided.

The availability of powerful reducing agents such as the hydrides and their recent use in the synthesis of 2-amino alcohols (1) have prompted us to study the selective reduction of N-substituted aminomalonic esters, and ethyl acetamidocyanoacetate, products easily available in large quantities. Three possibilities were to be expected in the reduction of ethyl acetamidomalonate (I): (1) No reduction, in which case, the unchanged starting material would yield glycine (III) by acid hydrolysis. (2) Reduction at both ester groups to

[1]*Manuscript received in original form September 13, 1954, and, as revised, January 21, 1955. Contribution from the Department of Biochemistry, Faculty of Medicine, Laval University, Quebec, P.Q.*

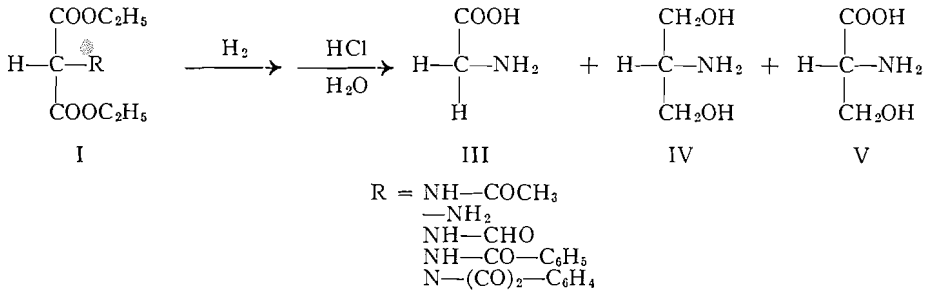
[3]*Holder of a Fellowship of the National Cancer Institute of Canada.*

give after hydrolysis 2-amino-1,3-propanediol (IV). (3) Selective reduction at one ester group which would form ethyl N-acetyl serine ester, from which D,L-serine (V) would be obtained by hydrolysis.

REDUCTION OF N-SUBSTITUTED AMINOMALONIC ESTER

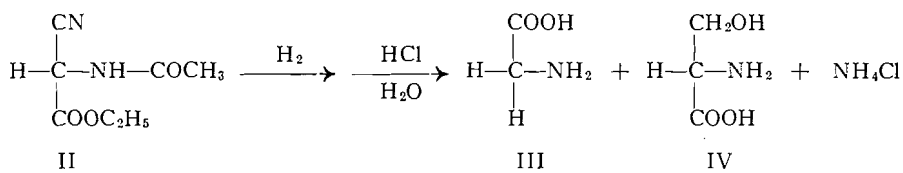


It was highly improbable that the amide group would be reduced to the secondary amine since Bory and Mentzer (3) had shown that this reduction required very drastic reducing conditions, which were not found in our experiment.

It was hoped that suitable conditions would be found in which possibilities (1) and (2) would be absent or reduced to a minimum, with the reduction proceeding only on one ester group to give D,L-serine.

In the reduction of ethyl acetamidocyanoacetate only two products were possible. In fact, no reduction was to be expected at the nitrile or at the amide groups since the reducing conditions were not drastic enough. Hence, only glycine and serine could be produced.

REDUCTION OF ETHYL ACETAMIDOCYANOACETATE



Several N-acyl derivatives of ethyl aminomalonate were reduced and subsequently were hydrolyzed to give serine, some glycine, and a trace of amino alcohol (Table I). No significant differences were found between N-acetamido, N-formamido, N-phthalimido, and N-benzamido ethyl malonates, except a slight decreasing yield in serine, probably due to the lower solubilities of the latter esters. In the case of N-unsubstituted ethyl aminomalonate, practically no serine and no glycine were found but free ammonia was abundant, apparently produced by the decomposition of the ester molecule.

As expected the reduction of ethyl cyanoacetate gave serine, no amino alcohol, but here again glycine was produced, though in a small yield.

Experimental conditions used during these reductions were studied in order to minimize the yield of glycine and 2-aminopropanediol.

Effect of Solvent (Table I)

When the ester to be reduced is water soluble, an aqueous medium gives the highest yield in serine. If the reduction is carried out in alcohol, a more complete reduction takes place at both ester groups with a subsequent greater formation of propanediol at the expense of serine and glycine.

Ethyl acetamidocyanoacetate does not give propanediol and, therefore, reduction in alcohol gives a slightly better yield of serine on account of the better solubility of this ester in alcohol than in water.

Nature of the Hydride (Table I)

Sodium borohydride gives the best yield in D,L-serine. Potassium borohydride also gives serine but is of slightly inferior reducing power. Lithium borohydride does not improve the yield. Lithium aluminum hydride in ether or in tetrahydrofuran at different temperatures does not reduce selectively any of the esters. In all cases no serine could be detected on paper chromatograms.

It is significant to note that it has been claimed previously that sodium and potassium borohydrides could not reduce esters, especially in water.

The concentration of the hydride, the order of addition, the pH of the medium, and the surface of contact between the hydride and the ester have no effect on the yield of the reduction. An increase of temperature, however, decreases the yield of serine (Table II).

From these studies, a new direct synthesis of serine has been worked out by reduction of ethyl acetamidomalonate or by reduction of ethyl acetamidocyanoacetate with sodium borohydride in aqueous medium.

EXPERIMENTAL PART

Compounds

Sodium borohydride, potassium borohydride, and lithium aluminum hydride were obtained from Metal Hydrides Inc., Beverly, Mass., and were used without purification.

Ethyl isonitrosomalonate was prepared according to Cerchez (4). The oxime has been described as an oil. However, when it was dissolved in benzene, a crystalline product was obtained in the cold. Melting point: 87°C.* Calc. for $C_7H_{11}O_5N$: N, 7.41%. Found: N, 6.87%. Subsequent recrystallizations from benzene did not raise the nitrogen content. This solid product, which seemed to be the oxime, was transformed into ethyl acetamidomalonate with the same yield as the ordinary oil.

Ethyl aminomalonate was obtained by reducing diethyl isonitrosomalonate with aluminum amalgam, according to Cerchez (5). The product was obtained as an oil. From this oil, the hydrochloride, m.p. 162°C., and the oxalate, m.p. 138°C., were prepared, as described by Cerchez (5), in yields of 45% and 55% respectively, calculated from the diethyl isonitrosomalonate. Calc. for $C_7H_{14}O_4NCl$: N, 6.56%. Found: N, 6.45%. Calc. for $C_9H_{15}O_8N$: N, 5.28%. Found: N, 5.20%.

**Melting points are not corrected.*

Some oximes have been reduced to amines with $LiAlH_4$ (18) but we have tried unsuccessfully to reduce diethyl isonitrosomalonate with $LiAlH_4$ and NaH_4B. No positive test to ninhydrin was obtained and free ammonia was present.

Ethyl formylaminomalonate was prepared according to Galat (7). Yield: 50%. Melting point 47°C. Calc. for $C_8H_{13}O_5N$: N, 6.90%. Found: N, 6.78%.

Ethyl phthalimidomalonate was obtained by reaction of ethyl bromomalonate with potassium phthalimide as described in *Organic Syntheses* (12). Melting point: 73°C. Yield: 70%. Calc. for $C_{15}H_{15}O_6N$: N, 4.59%. Found: N, 4.55%.

Ethyl benzamidomalonate was prepared according to Redeman and Dunn (15) by reacting benzoyl chloride and diethyl aminomalonate in pyridine. Melting point: 55°C. (from benzene and ligroin). Yield: 80%. Calc. for $C_{14}H_{17}O_5N$: N, 5.02%. Found: N, 5.10%.

Ethyl acetamidomalonate was prepared from isonitrosomalonic ester which was hydrogenated and acetylated with zinc dust in acetic anhydride and acetic acid. Melting point: 96°C. (from ether or ethyl acetate). Yield: 71%. Calc. for $C_9H_{15}O_5N$: N, 6.45%. Found: N, 6.52%.

Ethyl acetamidocyanoacetate was prepared by reducing isonitroso ethyl cyanoacetate with sodium hydrosulphite in acetic anhydride (19). Melting point: 129°C. (from acetic acid). Yield: 65%. Calc. for $C_7H_{10}O_3N_2$: N, 16.48%. Found: 16.58%.

Analytical Procedures

In order to study the relative yields of glycine and serine in the reduction experiments, methods of analysis for these products had to be found.

Paper Chromatography

Paper chromatography has been widely used for the analysis of amino acids and amino alcohols. However, glycine and serine, having very similar R_f values in most solvents, are difficult to separate. In our case pyridine and water (80:20) have been used with great success. In this system, the R_f values for glycine and serine are respectively 0.19 and 0.30. 2-Amino-1,3-propanediol has a much higher value at 0.75.

Glycine and serine were determined quantitatively with standard methods of paper chromatography. The simplified procedure used was as follows: Weighed drops of the calibrated solution obtained after reduction were placed on a paper chromatogram. The ascending chromatograms were run in pyridine and water (80:20) and were dried at room temperature. They were sprayed with 0.5% ninhydrin in acetone and were dried in the oven at 110°C. for 10 min. When allowed to dry at room temperature, serine appeared first, giving a bright bluish color, with glycine appearing later with a reddish color. The color due to aminopropanediol is rather slow to appear and is always weak. The two spots of serine and glycine were cut, placed in a test tube, triturated with 4 ml. of warm water, and filtered on a fritted disk. The filter paper was further washed with 1 ml. of warm water and the optical density of the clear filtrate was read at 540 mμ in a Beckman spectrophotometer.

Standard molar solutions of serine, glycine, and serine plus glycine were analyzed as above. As expected, equivalent molecular quantities of serine and glycine gave the same intensity when sprayed with 0.1% ninhydrin in butanol. However with 0.5% ninhydrin in acetone, serine gave a much deeper color than glycine.

The relative yields of serine and glycine were of primary importance in this study. For this reason, the amounts of serine and glycine in the reaction mixtures were determined colorimetrically from the ninhydrin color developed and eluted after chromatography. The "comparative" yield of serine was expressed as the number of moles of serine in 100 moles of amino acids (serine and glycine) in the reaction mixture. Since in most cases the amounts of aminopropanediol and other secondary products were negligible, the "comparative yield" approximated the true yield.

To reveal serine and the amino alcohol, a useful identification test has been used. The chromatogram was dipped in a watch glass containing a 10% solution of periodic acid. Then, it was dipped in Nessler reagent. Ten to twenty seconds later, a yellow spot developed which rapidly turned brown, then black. If this yellow color develops in Nessler reagent without having first dipped the paper in periodic acid, ammonia is present. The R_f values obtained in pyridine–water (80:20) with this test were respectively: 0.30 for serine, 0.52 for ammonium chloride, and 0.75 for aminopropanediol.

This test for serine was first described by Consden, Martin, and Gordon (6). We have found that it can be very useful in detecting 2-amino alcohols on paper chromatograms.

Periodate Estimation

When no amino alcohol was present, as in the reduction of ethyl acetamidocyanoacetate, for instance, the direct estimation of D,L-serine could be made by the method of Rees (16). In this method the amino acid is oxidized with periodic acid and the formaldehyde produced is titrated with bisulphite. Glycine was found by difference.

This procedure measures serine, threonine, glycols, and 2-amino alcohols. Thus if it is to be used to determine serine in presence of aminopropanediol, care must be taken to remove the latter before carrying out the oxidation.

Methods of Isolating Serine

The isolation of serine can be carried out by different procedures.

(1) Owing to the much higher solubility of glycine as compared to serine, the two amino acids can be separated by two or three recrystallizations from water–alcohol mixtures, serine crystals separating first. The hydrochloric acid used during hydrolysis can be removed from the amino acid by one of the following: (*a*) silver carbonate, (*b*) deacidite column, or (*c*) neutralization with an equivalent of lithium hydroxide forming LiCl which is soluble in alcohol.

(2) When small quantities are involved, the ideal separation would appear to be the chromatographic procedure used by Moore and Stein (8, 11) on Dowex-50 columns. An excellent method of isolation of serine by adsorption

on Zeo-Karb has been described by Partridge (13). Another chromatographic procedure has been used with success. When the amino acids are adsorbed on Permutit S-1 and eluted with 0.1 *N* acetic acid, glycine appears first, followed by a mixture of serine and glycine. Then serine alone is eluted.

(3) For larger batches of serine, the selective removal of glycine is made using classical methods (2), such as distillation of the ethyl ester of glycine or selective precipitation of glycine with 5-nitronaphthalene-sulphonic acid (17).

Separation of Glycine and Serine on Permutit S-1

A solution of D,L-serine (1.0 gm.) and glycine (1.0 gm.) was slowly passed through a column of Permutit S-1 (35 × 180 mm.). The amino acids were retained on the column. Elution was made with 0.1 *N* acetic acid. Aliquots from each 25 ml. of the eluate were analyzed with paper chromatography.

The first 250 ml. contained no amino acid. In the next 150 ml. only glycine was present. The solution was evaporated and the residue recrystallized from ethanol and water. Yield of pure glycine: 0.4 gm. (40%). Calc. for $C_2H_5O_2N$: N, 18.66%. Found: N, 18.50%.

The following 225 ml. contained a mixture of glycine and serine. When evaporated, the total weight of the residue was 0.6 gm.

Aliquots from the next 200 ml. gave only the serine spot on paper chromatograms. The solution was evaporated to dryness and the residue was recrystallized from aqueous ethanol. Yield of D,L-serine: 0.8 gm. (80%). Calc. for $C_3H_7O_3N$: N, 13.32%. Found: N, 13.55%.

Conditions Used During the Reductions

Different experimental conditions were used in the reductions of different esters in order to find out the best synthesis of serine. Results are summarized in Tables I and II.

The standard conditions used for the reductions were as follows: One gram of the ester was dissolved in the selected solvent system, water, methanol, ethanol, tetrahydrofuran, ether, or mixtures of them. Two grams of the hydride in solution or in solid form were then added at a chosen rate, with vigorous agitation. After one or two hours, the mixture was first acidified with dilute hydrochloric acid to pH 1.0 and then hydrolyzed by boiling for four to six hours for substituted aminomalonates and 12 to 17 hr. for acetamidocyanoacetate.

After hydrolysis, the solution was evaporated to dryness and the residue was dissolved in distilled water to a calibrated volume of 100 ml. Aliquots were analyzed for their glycine and serine contents as described.

Some of the reductions were carried out in the refrigerator, some in boiling water. When the surface of contact was studied, the above standard procedure for the reduction was carried out in a column (300 mm. × 20 mm.) packed with glass beads.

When lithium aluminum hydride was used, drops of water were carefully added to the reduction mixture at the end of the reaction to decompose any unreacted hydride.

In order to obtain lithium borohydride, equivalent quantities of potassium borohydride and lithium chloride were mixed in ethanol prior to the addition of the ester (10, 14).

TABLE I

YIELDS OF SERINE AS COMPARED TO THE TOTAL YIELD OF SERINE AND GLYCINE

Reductions of Ethyl Aminomalonates

Reduction of Ethyl Aminomalonate

With LiH_4Al, no ninhydrin test was obtained after hydrolysis. Free ammonia was formed, indicating decomposition of the aminomalonate.

With NaH_4B, and KH_4B, slight traces of glycine, serine, ammonia, and aminopropanediol were detected on paper chromatograms.

These reductions were carried out on the free amino ester. When the oxalate or the hydrochloride were reduced, the yields of 2-aminopropanediol and serine seemed to increase a little.

Reduction of Ethyl Phthalimidomalonate

As was to be expected, reduction with $LiAlH_4$ gave no serine but a mixture of glycine, free ammonia, and several unknown products.

When NaH_4B was used, serine was produced in good or poor yields, depending on the solvent used. In water, the ester is too insoluble to react with the hydride; hence, glycine is produced by acid hydrolysis. With ethanol and water, paper chromatography has shown that serine and glycine are produced in relative yields of 60% and 40%.

Reduction with KBH_4 gave about the same results as with $NaBH_4$.

Reduction of Ethyl Benzamidomalonate

In a mixture of water and ethanol, the reduction with NaH_4B gave "comparative" yields of 60% serine and 40% glycine.

Reduction of Ethyl Formamidomalonate

In this case, the reduction with $LiAlH_4$ in tetrahydrofuran gave in low yield some serine, with glycine, ammonia, and unknown products.

Ethyl formamidomalonate (5.0 gm.), treated with 3.0 gm. NaH_4B in aqueous methanol or ethanol, gave after hydrolysis 1.29 gm. (50%) of D,L-serine. Silver carbonate was used to liberate the amino acid from hydrochloric acid. After recrystallization from aqueous alcohol, transparent platelets, characteristic of D,L-serine, were obtained. Calc. for $C_3H_7O_3N$: N, 13.32%. Found: N, 13.37%. No glycine was found on paper chromatograms from this isolated serine.

In the reductions with KBH_4, equal quantities of serine and glycine were found on paper chromatograms.

Reduction of Ethyl Acetamidomalonate

Reductions in different experimental conditions were studied. The results are presented in Tables I and II.

In tetrahydrofuran or ether, the reduction with $LiAlH_4$ gave no serine but glycine and free ammonia.

When ethyl acetamidomalonate was monosaponified with an equivalent of sodium hydroxide before reduction with $NaBH_4$, the yield of serine was only about 30%.

With KBH_4, the reduction gave about the same yield in glycine and serine as with $NaBH_4$.

TABLE II

YIELDS OF SERINE AS COMPARED TO THE TOTAL YIELD OF SERINE AND GLYCINE

Reduction of ethyl acetamidomalonate in water with NaH_4B; at room temperature, except where specified

Conditions used	Yields, %
Hydride into ester	67
Ester into hydride	71
Temperature: 0°C.	74
Temperature: 100°C.	44
Surface (glass beads)	67
pH (Dowex 50)	50

Reduction of Ethyl Acetamidocyanoacetate

After reduction with $LiAlH_4$ and hydrolysis, the residue gave on a paper chromatogram a spot at 0.17 (glycine), a very weak spot at 0.48 (NH_4Cl), and a very strong blue spot at 0.68 (unknown product). No serine was present.

When $NaBH_4$ was used to reduce the ester, the yields in D,L-serine obtained from the periodate analysis were around 70%, irrespective either of the solvent or of the acid used during the hydrolysis (Table III).

With KBH_4, the yields in serine were much lower (35%).

TABLE III

PERIODATE ANALYSIS OF THE REDUCTION PRODUCTS OF ETHYL ACETAMIDOCYANOACETATE

Solvent	Hydride used	Hydrolysis with	Mgm. of serine		% yield	"Comparative" yield
			Found	Calc.		
Blank (no reduction)	—	HCl	0	0	—	—

Typical Synthesis of Serine

From Ethyl Acetamidomalonate

From these studies, a new direct synthesis of serine has been worked out.

The best conditions found for ethyl acetamidomalonate are to reduce it with an excess of $NaBH_4$ in water or water–alcohol (80: 20) solution in the cold, with a subsequent two-hour hydrolysis with dilute acid. In this case, propanediol is produced in a negligible quantity and glycine is reduced to a minimum. Paper chromatograms indicated a proportion of serine over glycine of 4 to 1. Depending on the various methods used in the isolation of serine, D,L-serine was obtained in yields ranging from 40% to 60%.

To a solution of 43.4 gm. of ethyl acetamidomalonate (0.2 mole) in 200 ml. of methanol and water (1: 1) were added, over a period of an hour with vigorous stirring and cooling, 12.0 gm. of solid sodium borohydride. The mixture was stirred for an additional hour, 200 ml. of concentrated HCl were added, and the mixture was boiled for three hours.

The solution was evaporated to dryness *in vacuo*, and the residue was leached with boiling ethanol. The insoluble inorganic salts were removed by filtration and the filtrate was evaporated. The residue was dissolved in water and divided in four equal portions.

(*a*) The first solution was neutralized to pH 6.0 with lithium hydroxide and concentrated to a small volume (25 ml.). Warm ethanol (500 ml.) was slowly added and D,L-serine crystallized. It was recrystallized from aqueous ethanol and dried. Yield: 3.1 gm. (59%).

(*b*) The second portion was neutralized with ammonium hydroxide to pH 6.5 and concentrated to a small volume. Methanol was added and after cooling, the crystalline amino acid was filtered, recrystallized, and dried. Yield: 2.8 gm. (53%).

(*c*) The third solution was treated with an excess of silver carbonate, filtered, saturated with hydrogen sulphide, and filtered again. After treatment with charcoal, warm ethanol was added to the clear filtrate. D,L-Serine crystallized in the cold. The amino acid was recrystallized and dried. Yield: 2.6 gm. (49.5%).

(*d*) Finally, the last portion was passed through a column of Permutit S-1. The amino acids were retained and eluted with 10% acetic acid. The eluate was evaporated to dryness and the residue was recrystallized from ethanol and water. Yield: 2.4 gm. (46%).

The four samples of D,L-serine thus obtained were mixed, recrystallized, and analyzed. At the microscope, the crystals appeared as transparent platelets which had a melting point of 244°C. (decomp.) on the Fisher-Johns block. No sublimate was observed on the upper glass slide, whereas commercial glycine has been found to give such a sublimate. When a paper chromatogram of the sample was run in pyridine-water, no glycine was present. Chloride was absent. Calc. for $C_3H_7O_3N$: N, 13.32%. Found: N, 13.30%.

D,L-Serine ethyl ester hydrochloride.—Dry HCl was bubbled through a suspension of 4.05 gm. of the above D,L-serine in ethanol. The ester hydrochloride was recrystallized from methanol–ether. Yield: 5.15 gm. (86%). Melting point: 133°C. Lit.: 134°C. (9). Calc. for $C_4H_9O_3N$. HCl: N, 9.01%, Cl, 22.8%. Found: N, 9.00%. Cl, 22.7%.

From Ethyl Acetamidocyanoacetate

Similar and even better is the synthesis of serine from the reduction of ethyl acetamidocyanoacetate with NaH_4B in ethanol at room temperature, followed by hydrolysis for six hours with concentrated HCl. No propanediol was produced and the yield of serine was around 70%, as shown by both quantitative analysis and paper chromatography.

A solution of ethyl acetamidocyanoacetate containing 10.0 gm. of the ester in 25 ml. ethanol was reduced by adding slowly 6.0 gm. of sodium borohydride, while vigorous agitation was maintained. After the addition, the solution was further mixed for an hour, 200 ml. of concentrated HCl were added, and the mixture was boiled for eight hours.

The amino acid hydrochlorides were treated with silver carbonate and D,L-serine was isolated as described for ethyl acetamidomalonate. Yield: 3.6 gm. (58%). Calc. for $C_3H_7O_3N$: N, 13.32%. Found: N, 13.10%.

No glycine was detected on paper chromatograms obtained from this serine.

CONCLUSIONS

D,L-Serine can be prepared directly by reducing ethyl acetamidocyanoacetate or ethyl acetamidomalonate with sodium borohydride.

Sodium and potassium borohydrides are capable of reducing certain esters even in water.

ACKNOWLEDGMENTS

To the National Cancer Institute of Canada, the author expresses his gratitude for a Fellowship. He is also grateful to the Permutit Company for a sample of Permutit S-1. His thanks are also due to Mr. Bertin Girard for technical assistance.

BENZYL 2-CHLOROETHYL ETHERS[1]

By Marshall Kulka and F. G. Van Stryk

ABSTRACT

The solvolysis reaction between benzyl chlorides and ethylene chlorohydrin has been employed for the synthesis of a series of benzyl 2-chloroethyl ethers (III) required in insecticide screening tests. This method is limited to the synthesis of III which possesses a partially deactivated nucleus. Several new benzyl chlorides are recorded.

Several classes of compounds including derivatives of chlorobenzenesulphonic acid (8, 10), 2-hydroxybenzophenones (9), and phenoxymethyl 2-chloroethyl ethers (11) have been synthesized in this laboratory and screened for insecticidal value by Musgrave and Kukovica (14) at the Ontario Agricultural College. In continuation of the joint program of insecticide research this report deals with a class of compounds possessing the grouping $-CH_2OCH_2CH_2Cl$.

Genzer, Huttrer, and van Wessem (5) developed a method for the synthesis of benzyl 2-chloroethyl ether (III) and its *ortho* chloro-derivative which comprises treatment of benzyl chloride (I) with the monosodium salt of ethylene glycol (IV) followed by conversion of the resulting benzyl 2-hydroxyethyl ether (V) to III (Method B). Although this method was satisfactory in many cases, a more direct method was sought. The solvolysis reaction between benzyl halides (I) and ethylene chlorohydrin (II) to form III and hydrogen

$$\underset{\text{I}}{X{-}C_6H_4CH_2Cl} + \underset{\text{II}}{HOCH_2CH_2Cl} \rightarrow \underset{\text{III}}{X{-}C_6H_4CH_2OCH_2CH_2Cl} \qquad \text{(A)}$$

$$\underset{\text{I}}{X{-}C_6H_4CH_2Cl} + \underset{\text{IV}}{NaOCH_2CH_2OH} \xrightarrow{SOCl_2,\ C_6H_5N(CH_3)_2} \underset{\text{V}}{X{-}C_6H_4CH_2OCH_2CH_2OH} \qquad \text{(B)}$$

chloride under the influence of heat (Method A) was found to be of preparative value though of limited scope. The failure of Method A in some cases can be attributed to the fact that benzyl halides are susceptible to polymerization under the influence of heat and acid catalyst and the extent of this side reaction is governed by the reactivity of the benzene nucleus. The following benzyl halides (I) gave polymers almost exclusively when heated with II: 2,4-dimethyl- (7), 2,4-dimethyl-5-chloromethyl (7), 3,4-dimethoxy- (12), 3-bromo-4-methoxy- (15), 2-nitro-4,5-dimethoxy-, 2-(2-chloroethoxy)-5-chloro-, 2,4-bis(chloromethyl)- (7), and *p*-nitrophenoxy- (17) benzyl chlorides

Contribution from the Dominion Rubber Company Limited Research Laboratories, Guelph, Ontario.

as well as 6-chloro-8-chloromethyl-1,3-benzodioxane (1) and 1-chloromethylnaphthalene (2). The nuclei of the majority of these compounds are activated by alkyl or alkoxyl substituents. Benzyl halides (I) possessing nuclear deactivating substituents such as chloro or nitro polymerized to a lesser extent when heated with ethylene chlorohydrin and formed the benzyl 2-chloroethyl ethers (III) (Table I). The reaction between I and II to form III was complete after heating under reflux for 24 to 48 hr. except in one case. Much of *p*-nitrobenzyl chloride remained unchanged after heating with II for four days.

The benzyl chlorides required for this investigation were prepared by chloromethylation of the appropriate aromatic compounds. It is interesting to note that 2-nitro-4,5-dimethoxybenzyl chloride, which was obtained from 3,4-dimethoxybenzyl chloride (12) by nitration, unlike the parent compound, is stable at room temperature. However it decomposes rapidly when warmed with alcoholic solutions of alkali or potassium cyanide to form resinous materials. Heating with ethanolic thiourea produced stable 2-nitro-4,5-dimethoxybenzyl isothiuronium chloride.

The benzyl 2-chloroethyl ethers (III) suffer degradation in the presence of acidic reagents. An attempt to chloromethylate benzyl 2-chloroethyl ether (III, X = H) resulted only in low-boiling materials. Similar results were obtained in attempts to chlorinate and nitrate III. The alkyl chlorine of III is far less reactive than the chlorine in bis(2-chloroethyl) sulphide (mustard gas), but like bis(2-chloroethyl) ether will react with alcoholic potassium thiocyanate after prolonged heating.

**In the preparation of this compound it was necessary to heat the reaction mixture for 18 hr. instead of 2 hr.*

EXPERIMENTAL

2-*Nitro*-4,5-*dimethoxybenzyl Chloride*

To a solution of 3,4-dimethoxybenzyl chloride (12) (46 gm.) in acetic acid (120 ml.) kept at 8–10° was added dropwise with stirring concentrated nitric acid (d = 1.42) (37 gm.) over one-half hour. After the reaction mixture was stirred at 8–10° for two hours it was poured into cold water. The yellow precipitate was filtered, washed, and crystallized from methanol. The yellow prisms weighed 26 gm. (50%) and melted at 87–88°. Anal. calc. for $C_9H_{10}NO_4Cl$: C, 46.65; H, 4.32; N, 6.05. Found: C, 47.08, 46.86; H, 4.43, 4.42; N, 6.23. Heating with thiourea in methanol under reflux produced *S*-2-*nitro*-4,5-*dimethoxybenzyl isothiuronium chloride* in 90% yield. The light-yellow needles melted at 215–216° with decomposition. Anal. calc. for $C_{10}H_{14}N_3O_4ClS$: C, 39.03; H, 4.55. Found: C, 38.64; H, 4.82.

3-*Nitro*-4-*n*-*butoxybenzyl Chloride*

This is essentially the method previously used for the preparation of 3-nitro-4-methoxybenzyl chloride (4). Into a suspension of trioxymethylene (16 gm.), zinc chloride (25 gm.), and acetic acid (350 ml.) dry hydrogen chloride was passed until saturated. Then *o*-nitro-*n*-butoxybenzene (100 gm.) was added and the resulting solution was heated at 75–80° for 72 hr. The

solution was added to water, extracted with benzene, and the benzene extract washed with water, with aqueous sodium bicarbonate, and with water. Removal of the solvent and distillation of the residue yielded a yellow oil (80 gm. or 64%) boiling at 140° (0.3 mm.) or 200° (12 mm.), $n_D^{20} = 1.5450$. Anal. calc. for $C_{11}H_{14}NO_3Cl$: C, 54.21; H, 5.75. Found: C, 54.66; H, 5.70.

3-*Nitro*-4-(*β-bromoethoxy*)*benzyl Chloride*

This was prepared in 54% yield by the same method as was 3-nitro-4-*n*-butoxybenzyl chloride above from *o*-nitro-*β*-bromoethoxybenzene which was obtained from *o*-nitrophenol and ethylene dibromide. The product distilled at 150–170° (0.3 mm.) and crystallized from methanol as white needles melting at 78–79°. Anal. calc. for $C_9H_9NO_3ClBr$: C, 36.67; H, 3.06. Found: C, 36.57; H, 3.09.

3-*Nitro*-4-*n-dodecyloxybenzyl Chloride*

This was prepared in 56% yield by the same method as was 3-nitro-4-*n*-butoxybenzyl chloride above from *o*-nitrododecyloxybenzene. It crystallized as white needles from methanol and from ethyl acetate and melted at 55–56°. Anal. calc. for $C_{19}H_{30}NO_3Cl$: C, 64.13; H, 8.44. Found: C, 64.01; H, 8.58.

3-*Chloro*-6-(*β-chloroethoxy*)*benzyl Chloride*

This was prepared in 65% yield by the method used for the preparation of 3-nitro-4-*n*-butoxybenzyl chloride above from *β*-chloroethyl *p*-chlorophenyl ether (3). In this case it was not necessary to heat for 72 hr.; 20 hr. was sufficient and the amount of zinc chloride should be reduced by 30%. The product distilled at 165–175° (12 mm.), crystallized as white prisms from methanol, and melted at 34–35°. Anal. calc. for $C_9H_9Cl_3O$: C, 45.09; H, 3.76. Found: C, 45.25, 45.26; H, 3.79, 3.85.

p-(*β-Chloroethyl*)*benzyl Chloride*

Into a stirred reaction mixture of *β*-chloroethylbenzene (50 gm.), ethylene dichloride (100 ml.), paraformaldehyde (10 gm.), and zinc chloride (10 gm.) hydrogen chloride was passed for three hours. The temperature was maintained at 40° by cooling at first and warming later. After standing overnight, the reaction mixture was washed with water, with aqueous sodium bicarbonate, and with water. The solvent was removed and the residue was distilled and the fraction (32 gm.) boiling at 140° (12 mm.), $n_D^{20} = 1.5550$, was collected. Anal. calc. for $C_9H_{10}Cl_2$: C, 57.14; H, 5.29. Found: C, 57.39, 57.14; H, 5.39, 5.14.

3-*Nitro*-4-*methylbenzyl Chloride*

This was prepared by a method similar to that of Matsukawa and Shirakawa (13). To stirred 20% oleum (475 gm.) was added dropwise a solution of *o*-nitrotoluene (137 gm.) and crude methyl chloromethyl ether (100 gm.) over one and a half hours, the temperature being kept at 5–10° by cooling. After it was stirred for an additional two hours at 5–10° the dark reaction mixture was poured onto cracked ice. The precipitated oil was extracted with benzene, the extract washed with water, and the solvent removed. The residue was

distilled and the fraction (39 gm.) boiling at 140–150° (12 mm.) was collected. This solidified on standing and was crystallized from methanol, m.p. 44–45°; literature (18) m.p. 45°.

2,5-Dichlorobenzyl Chloride and 2,5-Dichloro-p-xylylene Dichloride

To stirred 20% oleum (500 gm.) kept at 0–5° by cooling was added dropwise a solution of *p*-dichlorobenzene (74 gm.) in 150 gm. of crude methyl chloromethyl ether over one hour. The reaction mixture was stirred at 0–5° for two hours, let stand overnight at 8–10°, and then poured on cracked ice. The reaction mixture was extracted with chloroform, the extract was washed with water, and the solvent was then removed. The residue was fractionally distilled and two main fractions were collected. The first fraction, a colorless liquid (14 gm.) which was *2,5-dichlorobenzyl chloride*, boiled at 122–124° (15 mm.), $n_D^{20} = 1.5750$. Anal. calc. for $C_7H_5Cl_3$: C, 42.97; H, 2.56. Found: C, 42.29; H, 2.61.

The second fraction boiled at 165–180° (15 mm.) and the distillate (16 gm.) which solidified was crystallized from ethanol. The colorless rhombohedrans of *2,5-dichloro-p-xylylene dichloride* (13 gm.) melted at 98–99°. Anal. calc. for $C_8H_6Cl_4$: C, 39.35; H, 2.46. Found: C, 39.68; H, 2.48.

The *S,S'-2,5-dichloro-p-xylylene bis-isothiuronium chloride* was prepared by boiling the 2,5-dichloro-*p*-xylylene dichloride with thiourea in ethanol. It melted at 289–292° (with decomposition) after crystallization from water. Anal. calc. for $C_{10}H_{14}N_4Cl_4S_2$: C, 30.30; H, 3.54. Found: C, 30.02; H, 3.72.

Preparation of Benzyl 2-Chloroethyl Ethers by Method A

Some of the benzyl 2-chloroethyl ethers listed in Table I were prepared by a method used for the preparation of *p-xylylene bis-2-chloroethyl ether* which follows: A solution of *p*-xylylene dichloride (7) (20 gm.) in dry ethylene chlorohydrin (100 ml.) was heated under reflux for 24 hr. The hydrogen chloride gas was allowed to escape through a condenser kept at about 60°. The excess ethylene chlorohydrin was removed and the residue distilled. The colorless liquid boiled at 200–203° (12 mm.), $n_D^{20} = 1.5260$. The yield was 26 gm. or 85%. Anal. calc. for $C_{12}H_{16}O_2Cl_2$: C, 54.75; H, 6.08. Found: C, 55.12, 55.13; H, 5.97, 5.99.

o-Xylylene bis-2-chloroethyl ether.—This was prepared in 68% yield by Method A from *o*-xylylene dichloride (7). The colorless liquid boiled at 190–195 (14 mm.). Anal. calc. for $C_{12}H_{16}O_2Cl_2$: C, 54.75; H, 6.08. Found: C, 54.44, 54.49; H, 5.53, 5.60.

Preparation of Benzyl 2-Chloroethyl Ethers by Method B

Some of the benzyl 2-chloroethyl ethers listed in Table I were prepared by Method B. This method, which was used by Genzer *et al.* (5), is further exemplified by the preparation of *2,5-dichloro-p-xylylene bis-2-chloroethyl ether.*

(*a*) *2,5-Dichloro-p-xylylene bis-2-hydroxyethyl ether.*—To a solution of dry ethylene glycol (50 ml.), xylene (25 ml.), and sodium (2.5 gm.) was added a solution of 2,5-dichloro-*p*-xylylene dichloride (12 gm.) in xylene (25 ml.).

The reaction mixture was heated under reflux for two hours, most of the xylene and glycol were removed *in vacuo*, and the residue was treated with water. The white solid was filtered and crystallized from methanol. The white crystals (12 gm.) melted at 120–121°. Anal. calc. for $C_{12}H_{16}O_4Cl_2$: C, 48.82; H, 5.42. Found: C, 49.32; H, 5.47.

(*b*) 2,5-*Dichloro-p-xylylene bis*-2-*chloroethyl ether*.—To a stirred suspension of 2,5-dichloro-*p*-xylylene bis-2-hydroxyethyl ether (10 gm.), dimethylaniline (10 ml.), and dry chloroform (25 ml.) was added dropwise with cooling a solution of thionyl chloride (6 ml.) in chloroform (10 ml.), the temperature being kept at 20–30°. The dark reaction mixture was heated under reflux for one-half hour and then poured into cold dilute hydrochloric acid. This was extracted with chloroform, the extract was washed with dilute hydrochloric acid and with water, and the solvent was removed. The residue was crystallized from methanol and from petroleum ether (30–60°) yielding 9 gm. (80%) of white needles which melted at 70–71°. Anal. calc. for $C_{12}H_{14}O_2Cl_4$: C, 43.38; H, 4.22. Found: C, 43.81, 43.77; H, 4.33, 4.32.

p,p′-Dichlorobenzhydryl 2-*Chloroethyl Ether*

A method simpler than A or B which was employed by Kato *et al.* (6) was followed in this case.

To a hot solution of *p,p′*-dichlorobenzhydrol (16) (10 gm.) in ethylene chlorohydrin (40 ml.) was added a solution of concentrated sulphuric acid (2 ml.) in water (10 ml.) and the resulting solution was heated at 80° for six hours. The reaction mixture containing a precipitated oil was poured into water, extracted with benzene, the benzene extract washed with water, and the solvent removed. The residue distilled at 167–170° (0.2 mm.) giving a colorless liquid (15 gm.), $n_D^{20} = 1.5830$. Anal. calc. for $C_{15}H_{13}OCl_3$: C, 57.06; H, 4.12. Found: C, 57.00; H, 4.14.

o,p′-Dichlorobenzhydryl 2-*Chloroethyl Ether*

This was prepared in 90% yield as above from *o,p′*-dichlorobenzhydrol. The colorless liquid distilled at 155–160° (0.2 mm.), $n_D^{20} = 1.5835$. Anal. calc. for $C_{15}H_{13}OCl_3$: C, 57.06; H, 4.12. Found: C, 57.52; H, 4.25.

3-*Nitro*-4-*methoxybenzyl* 2-*Thiocyanatoethyl Ether*

A solution of 3-nitro-4-methoxybenzyl 2-chloroethyl ether (13 gm.) in ethanol (150 ml.) and potassium thiocyanate (6 gm.) was heated under reflux for 40 hr. The precipitated potassium chloride was filtered and the ethanol was distilled off from the filtrate. The residue was dissolved in benzene and washed with water. The solvent was removed and the residue distilled yielding a malodorous yellow liquid (8 gm.), b.p. = 165–170 (1 mm.). Anal. calc. for $C_{11}H_{12}N_2O_4S$: C, 49.25; H, 4.48. Found: C, 48.82, 48.78; H, 4.81, 4.74.

p-Chlorobenzyl 2-*Thiocyanatoethyl Ether*

This was prepared in 65% yield as above. It boiled at 187–192° (12 mm.), $n_D^{20} = 1.5358$. Anal. calc. for $C_{10}H_{10}NOClS$: C, 52.75; H, 4.39. Found: C, 52.45; H, 4.83.

ACKNOWLEDGMENT

The analyses of all compounds were provided by Gisela von Stritzky.

INTENSITY IN THE RAMAN EFFECT

III. THE EFFECT OF DEUTERIUM SUBSTITUTION ON THE INTENSITY OF RAMAN BANDS OF BENZENE[1]

By G. Allen[2] and H. J. Bernstein

ABSTRACT

Standard intensities of the Raman bands of C_6H_6, 1,3,5,-$C_6H_3D_3$, and C_6D_6 have been obtained photoelectrically. An ambiguity in the vibrational assignment for 1,3,5,-$C_6D_3H_3$ has been removed, and the assumption of the invariance of the polarizability and anisotropy derivatives upon isotopic substitution has been tested. A sum rule for depolarization ratios of Raman bands in isotopic homologues has been derived subject to the same assumptions used for obtaining the intensity sum rules.

The Raman shifts and normal mode assignments are well known (1, 6, 7) both for C_6H_6 and C_6D_6 and the relative intensities of the Raman bands have been obtained photographically (1). Rank (10) has reported integrated intensities for C_6H_6 obtained with an electronically recording spectrometer but there are no corresponding data for C_6D_6. The Raman intensities are of interest because Lord and Teller (8) have calculated the intensities of the a_{1g} modes in C_6D_6 in terms of the intensities of the a_{1g} modes in C_6H_6 and Crawford (3) has derived a sum rule for intensities in isotopically substituted molecules which applies to the a_{1g} and the e_{2g} modes in these molecules.

1,3,5-Trideuterobenzene has been studied by Langseth and Lord (7) and also by Ingold *et al.* (1). There is disagreement on the assignment of the e'-type fundamentals which are associated with the C—H and C—D stretching modes. The two reports also disagree in the assignment of one of the e''-type modes. Langseth and Lord have calculated the intensities of the a'_1-type vibrations in 1,3,5-$C_6H_3D_3$ relative to the intensities of the a_1'-type vibrations in C_6H_6.

We have obtained standard intensities with a photoelectric spectrometer for the three benzene molecules in the liquid phase and have cleared up the ambiguity in the assignment for $C_6H_3D_3$, and have tested the assumption of the invariance of the polarizability derivatives for isotopic substitution.

EXPERIMENTAL

The Raman spectra and depolarization ratios were obtained at 27°C. using a White Raman spectrometer (12). Standard intensities of scattering per molecule referred to the 458 cm.$^{-1}$ band of CCl_4 were obtained by a method previously described (2). The expression used to obtain the standard intensities is (2):

$$[1]\quad S = \frac{I}{I_{458}} \cdot \frac{1+\rho_{458}}{1+\rho} \cdot \frac{n^2}{n^2_{CCl_4}} \cdot \frac{\sigma}{\sigma_{458}} \cdot \frac{R(n)}{R(n)_{CCl_4}} \times \frac{M}{d}\left(\frac{d}{M}\right)_{CCl_4} \cdot \frac{\Delta\nu}{458}\left(\frac{\nu-458}{\nu-\Delta\nu}\right)^4 \cdot \frac{1-e^{-1.44\Delta\nu/T}}{1-e^{-1.44\times 458/T}} = \frac{45(\alpha')^2+7(\gamma')^2}{[45(\alpha')^2+7(\gamma')^2]_{458}}$$

Reflection loss = 1.04.

corrected for convergence to ρ_{true} by the method of Rank and Kagarisse (11). In order to obtain

$$\frac{45(\alpha')^2+13(\gamma')^2}{[45(\alpha')^2+13(\gamma')^2]_{458}},$$

the theoretical quantity given for transverse scattering, S should be multiplied by $(1+\rho_{obs})$.

Two samples of C_6D_6 were investigated. The intensities reported in Table I were obtained from a sample loaned by Professor Langseth. The second sample was prepared by Dr. Leitch and good agreement for the intensities of all bands except 867 and 661 cm.$^{-1}$ was obtained. In the sample obtained from Dr. Leitch the two anomalous bands had "shoulders" which were due to an impurity and which prevented an accurate estimation of the integrated intensities of these bands.

The sample of 1,3,5,-$C_6H_3D_3$ was obtained from Professor Langseth. In this case the estimation of standard intensities was complicated by the presence of about 17.5% of 1,3-$C_6H_4D_2$ in the sample. 1,3-$C_6H_4D_2$ has bands which

overlap all the fundamentals in 1,3,5-$C_6H_3D_3$ with the exception of 955 cm.$^{-1}$. In order to estimate the amount (17.5%) of 1,3-$C_6H_4D_2$ in the sample (and hence to correct the observed intensities to correspond to pure 1,3,5-$C_6H_3D_3$) we assume:

(*a*) the 955 cm.$^{-1}$ band in $C_6H_3D_3$ and the 968 cm.$^{-1}$ band in $C_6H_4D_2$ have the same standard intensity,

(*b*) where bands from each molecule overlap then the observed intensity is equal to the intensity in pure 1,3,5-$C_6H_3D_3$.

The first assumption is not unreasonable because the standard intensities of the corresponding bands in C_6H_6 and C_6D_6 differ only by $\backsim$10%. The second assumption means that the maximum error in the intensities is 17.5%. In Table II, therefore, the intensities of the 955 cm.$^{-1}$ and 1576 cm.$^{-1}$ bands

are accurate within the limits of the first approximation, since these bands could be obtained without overlap. The intensities of the remaining bands are subject to the validity of the second assumption.

The intensities obtained photographically by Ingold *et al.* (1) should be compared with the intensities listed under $\bar{S}$.

DISCUSSION

A comparison of our results for C_6H_6 and C_6D_6 shows the same general features as the photographic intensities. For the a_{1g} and the e_{2g} modes there is a slight decrease in intensity on deuteration. For the e_{1g} mode however both investigations show that there is an increase in intensity on deuteration. This anomaly has been successfully explained by Lord and Teller (8).

Lord and Teller have also calculated the relative intensities of the a_{1g} modes in C_6H_6 and C_6D_6 assuming that the polarizability and anisotropy derivatives with respect to internal coordinates do not change on deuterium substitution. The intensities of the a_{1g} vibrations in C_6D_6 (a'^{CC}_{1g} and a^{CD}_{1g})

are expressed as linear superpositions of the a_{1g} vibrations in C_6H_6, viz.:

$$a'^{CC}_{1g} = \xi_1 a^{CH}_{1g} + \eta_1 a^{CC}_{1g}; \qquad a^{CD}_{1g} = \xi_2 a^{CH}_{1g} + \eta_2 a^{CC}_{1g}.$$

The coefficients ξ and η have been evaluated by Lord and Teller from the amplitudes of vibration obtained from the equations of motion using a complete quadratic potential function. Since our standard intensity S is defined in terms of the normal coordinate Q, it cannot be substituted directly into these equations. It must be transformed as shown below into S', viz.:

$$[2] \qquad S' = S \cdot \frac{458}{\Delta\nu} = \frac{[45(\alpha')^2 + 7(\gamma')^2]}{[45(\alpha')^2 + 7(\gamma')^2]_{458}} \cdot \frac{Q^2_{\Delta\nu}}{Q^2_{458}}.$$

The experimental values for S' are given in Table III. Using our data for S' and ρ we have followed through the calculations of Lord and Teller. The results of the calculations are also given in Table III. This represents a more satisfactory test of Lord and Teller's treatment than the one given in their original paper.

TABLE III

CALCULATED RAMAN INTENSITIES

	$\Delta\nu$, cm.$^{-1}$	Observed		Calculated	
		S'	ρ_{true}	S'	ρ_{true}
C_6H_6	992	2.034	0.11

[a] *The errors arise from the experimental errors in the observed S' for the C_6H_6 bands.*

If the coefficients ξ and η derived for a simple valence force potential function by Lord and Langseth (7) are used to calculate the intensities of the a_1' modes in $C_6H_3D_3$ from the experimental data for C_6H_6, the results given in the lower field of Table III are obtained. The calculation for the intensity of the band at 955 cm.$^{-1}$ is satisfactory but the disagreements between the calculated and observed intensities for the bands at 1004 cm.$^{-1}$ and 2283 cm.$^{-1}$ are well outside the experimental error. The observed and calculated intensities for the Raman band at 3054 cm.$^{-1}$ cannot be compared directly. There is some doubt about the assignment of this band. Langseth and Lord assign the band as a superposition of the a_1' and e' νCH modes. Ingold *et al.* observe the e'-type νCH mode at 3082 cm.$^{-1}$ in the infrared spectrum of $C_6H_3D_3$ vapor and they conclude that the Raman band observed at 3054 cm.$^{-1}$ in the spectrum of the liquid arises solely from the a_1'-type mode. We have investigated the infrared spectrum of liquid $C_6H_3D_3$ using LiF optics, and find bands at 3055 and 2273 cm.$^{-1}$; these bands are assigned to the

e'-type νCH and νCD modes respectively. It appears then that the assignment given by Lord and Langseth is correct for the spectrum of liquid $C_6H_3D_3$. This is supported by the fact that the depolarization ratio for this band is higher than that for the other a_1-type bands in the Raman spectra of $C_6H_3D_3$, C_6H_6, and C_6D_6. All the other a_1-type νCH or νCD modes reported in this paper have depolarization ratios in the region of 0.22, but the depolarization ratio for the 3054 cm.$^{-1}$ band is 0.36. The observed intensity (S') of the a_1-type band at 3054 cm.$^{-1}$, is therefore <1.16, and the calculated value is too high.

This over-all poor agreement between observed and calculated intensities for the totally symmetrical modes of 1,3,5-$C_6H_3D_3$ may be due to the fact that only a simple valence force potential function (7) has been used to evaluate the ξ's and η's and the calculation of intensities is very sensitive to the values of force constants employed.

SUM RULES FOR RAMAN INTENSITY

Recently Crawford (3) derived intensity sum rules for Raman bands in isotopic molecules. The intensity of the a^{th} fundamental of Raman shift $\Delta\nu_{1a}$ in the gas phase is given by the following expression according to Placzeck (9):

$$[3] \qquad I_{1a} = \frac{K_{1a}N}{\Delta\nu_{1a}} \cdot [P_\alpha(\bar{a}_{1a})^2 + P_\beta(\bar{\beta}^2_{1aa})].$$

In this expression a universal constant is included in I, N is the number of scattering molecules, $K_{1a} = (\nu - \Delta\nu_{1a})^4(1 - e^{-1.44\Delta\nu_{1a}/T})^{-1}$, where ν is the frequency of the exciting line and T is the absolute temperature. The notation in the square bracket is that used by Crawford. Here P_α and P_β are constants depending only on the conditions of observation. Equation [3] is used for the intensity in the liquid phase also, since whatever changes occur in passing from gas to liquid might be expected to be very nearly the same for isotopic homologues. The temperature dependent term is included in the intensity expression since it is very nearly independent of phase and indeed has been shown to give the correct Stokes/anti-Stokes intensity ratio in liquid CCl_4 (2). Following Crawford we write his Σ^F rule in the form

$$[4] \qquad \sum_a \frac{I_{1a}}{K_{1a}\Delta\nu_{1a}} = \sum_a \frac{[P_\alpha(\bar{a}_{1a})^2 + P_\beta(\bar{\beta}^2_{1aa})]}{\Delta\nu^2_{1a}} = (F^{-1})^{kj}[P_\alpha(\bar{a}_{1k})(\bar{a}_{1j}) + P_\beta(\bar{\beta}^2_{1kj})]$$

and his Σ^G rule* in the form

$$[5] \qquad \sum_a \frac{I_{1a}\Delta\nu_{1a}}{K_{1a}} = (G_1)^{kj}[P_\alpha(\bar{a}_{1k})(\bar{a}_{1j}) + P_\beta(\bar{\beta}^2_{1kj})].$$

In these equations K_{1a} has been included in the summation and not considered to be constant (3) and the number of molecules N has been assumed constant since the same volume of the isotopic homologues is used to obtain the Raman spectra.

**There is a misprint in equation (26) in Crawford's paper. The L.H.S. should read $\Sigma_a I_{1a}{}^R\omega_{1a}$ instead of $\Sigma_a I_{1a}{}^R/\omega_{1a}$. Prof. Crawford (private communication, Feb. 11, 1955) suggested that this might be a suitable way in which to record this correction.*

									13.73
			L.H.S. of equation [6] = 10.78, R.H.S. = 9.70						
			L.H.S. of equation [11] = 6.24, R.H.S. = 6.00						
			L.H.S. of equation [12] = 32.54, R.H.S. = 2 × 13.73 = 27.46						
606 (e_{2g})	1.33		0.49	577 (e_{2g})	1.10		0.44		
1178 (e_{2g})	1.12		0.42	867 (e_{2g})	1.03		0.41		
1584, 1606 (e_{2g})	1.15		0.43	1560 (e_{2g})	1.02		0.40		
[a]3045 (e_{2g})	1.33		0.50	[b]2264 (e_{2g})	1.22		0.48		
	4.93		1.84		4.37		1.73		
			L.H.S. of equation [6] = 4.93, R.H.S. = 4.37						
			L.H.S. of equation [11] = 1.84, R.H.S. = 1.73						

[a,b] *These bands are doublets which were only partially resolved. The experimental error in determining their intensity is about* $\pm 10\%$.

The R.H.S. of equation [4] is invariant with isotopic substitution when (i) the force constants of the most general quadratic potential function do not change with isotopic substitution, (ii) the polarizability and anisotropy derivatives with respect to internal coordinates do not change with isotopic substitution, (iii) anharmonicity effects may be neglected. Assumption (ii) is valid only for symmetry types for which there is no molecular rotation which changes the equilibrium polarizability.

As long as the conditions of irradiation and observation are the same for the isotopic molecules, integrated intensities observed with any experimental arrangement may be used to verify equation [4] in the form

$$[6] \qquad \sum_a \frac{I_{1a}}{K_{1a}\Delta\nu_{1a}} = \sum_a \frac{I_{2a}}{K_{2a}\Delta\nu_{2a}}.$$

Here subscripts $_1$ and $_2$ refer to the two isotopic species. In Table IV, $\bar{S}$, the integrated intensity of the Raman bands of the a_{1g} and e_{2g} symmetry species of C_6H_6 and C_6D_6, referred to the intensity of the 458 cm.$^{-1}$ band in CCl_4 and corrected for the sensitivity of the photomultiplier tube, has been used to form the sums of equation [6]. The disagreement between the L.H.S. and R.H.S. of this equation is within the experimental error because of the difficulty in measuring accurately the intensity of the components of the partially resolved doublets at 3050 cm.$^{-1}$ and 2280 cm.$^{-1}$ in C_6H_6 and C_6D_6 respectively.

For parallel transverse irradiation $P_\alpha = 45$ and $P_\beta = 13$ in equations [3], [4], and [5]. The depolarization ratio under these experimental conditions is given by

$$[7] \qquad \rho_{1a} = \frac{6(\bar{\beta}^2_{1aa})}{45(\bar{\alpha}_{1a})^2 + 7(\bar{\beta}^2_{1aa})}.$$

Substituting from equation [7] in equation [3], the following expressions may be derived in the same manner as given by Crawford for equations [4] and [5]:

$$[8] \qquad \sum_a \frac{I_{1a}}{K_{1a}\Delta\nu_{1a}(1+\rho_{1a})} = (F^{-1})^{kj}[45(\bar{\alpha}_{1k})(\bar{\alpha}_{1j}) + 7(\bar{\beta}^2_{1kj})],$$

$$[9] \qquad \sum_a \frac{I_{1a}\Delta\nu_{1a}}{K_{1a}(1+\rho_{1a})} = (G_1)^{kj}[45(\bar{\alpha}_{1k})(\bar{\alpha}_{1j}) + 7(\bar{\beta}^2_{1kj})].$$

Equation [8] gives the intensity sum rule

$$[10] \qquad \sum_a \frac{I_{1a}}{K_{1a}\Delta\nu_{1a}(1+\rho_{1a})} = \sum_a \frac{I_{2a}}{K_{2a}\Delta\nu_{2a}(1+\rho_{2a})}$$

in which the intensities to be used in forming the sum are those observed under conditions of parallel transverse irradiation. Equation [10] then is a sum rule for depolarization ratios on isotopic substitution. In the simple case when there is only one vibration in the symmetry species (e.g. H_2, the a_{1g} mode in CH_4) it is apparent from equations [6] and [10] that the depolarization ratio is unchanged for complete isotopic substitution. If there are several modes of vibration in the symmetry species, the depolarization ratios of corresponding bands may still be the same but are not required to be so.

It has been shown (2) that the ratio $I/(1+\rho)$ is independent of experimental conditions provided that under the usual conditions of irradiation the incident beam may be considered to make an average angle with the direction of observation. Since this assumption has been shown to be valid (2) within the experimental error equation [10] may be written in terms of the standard intensity defined in equation [1], viz.:

$$[11] \qquad \sum_a \frac{S_{1a}}{\Delta\nu_{1a}^2} = \sum_a \frac{S_{2a}}{\Delta\nu_{2a}^2}.$$

A satisfactory experimental verification of this equation is shown for the a_{1g} and e_{2g} modes of C_6H_6 and C_6D_6 in Table IV.

Similarly one may write $\Sigma_a S_{1a}$ instead of the L.H.S. in equation [9].

Decius (4) has shown that the same relations are valid upon isotopic substitution for the L.H.S. of equation [9] and $\Sigma_a \Delta\nu_a{}^2$. Thus for example for the a_{1g} and b_{1u} modes of C_6H_6 and C_6D_6, and the a_1' modes of 1,3,5-$C_6H_3D_3$, one should have

$$[12] \qquad \sum S_{(C_6H_6)} + \sum S_{(C_6D_6)} = 2\sum S_{(1,3,5\text{-}C_6H_3D_3)}.$$

Since the b_{1u} modes for C_6H_6 and C_6D_6 are inactive in the Raman effect their contribution to the sums is zero. In Table IV the experimental data for verification of equation [12] are given. Again within the experimental error the rule has been verified.

It is readily seen from application of equations [8] and [9] to the molecules H_2, HD, and D_2 that the depolarization ratio is constant.

LIGHT ABSORPTION STUDIES

PART I. ULTRAVIOLET ABSORPTION SPECTRA OF SUBSTITUTED ACETOPHENONES[1]

By W. F. Forbes and W. A. Mueller

ABSTRACT

The steric hindrance postulated by Arnold and co-workers to account for anomalous reaction rates of some substituted acetophenones has been verified by means of ultraviolet light absorption data. The spectra of a number of other substituted acetophenones have been discussed in terms of the electronic and steric effects of substituents.

INTRODUCTION

Acetophone exhibits an intense band near 240 mμ, $\epsilon \sim 10$–15,000, which also appears in benzaldehyde, propiophenone, and butyrophenone (see Table I). This band, which is typical of $\pi-\pi$ conjugation, is ascribed to an N $\rightarrow$ V transition, and is found in a variety of phenyl derivatives containing unsaturated side-chains (styrenes, aromatic amines, benzoic acids, benzamidines, etc.), as also in biphenyls and cyclohexene derivatives. In acetophenone, therefore, the allowed transition from a state having a non-ionic wave function to one having an ionic wave function can be represented by Ph—C=O $\rightarrow$ Ph^+ =C—O^-. As has previously been pointed out elsewhere (6), whilst in benzaldehyde, *m*- and *p*-methyl groups cause a small increase in ϵ, and *o*-methyl groups produce a small decrease, in the acetophenones, *m*- and *p*-methyl groups also cause small increases in ϵ, but *o*-methyl groups produce very marked decreases in ϵ. A similar effect is observed for *o*- and *p*-methyl substituted propiophenones (see Table I). This effect is ascribed to steric overlap between the *o*-methyl groups and the keto-methyl or keto-ethyl group setting up appreciable interference and thus preventing the attaining of a uniplanar configuration. Steric inhibition of electronic interaction thus raises the energy level of the ground state, but since the phenyl-carbon link in the postulated polar excited state contains a larger amount of double bond character, and since the energy required to twist a double bond is considerably in excess of that required to twist a single bond, and further since the interplanar angle cannot from theoretical considerations (Franck–Condon principle) change during a transition, therefore the energy-level of the excited state will be raised even more than that of the ground state. Thus the transition energy is increased, which results in a hypsochromic shift of the band, and also in a reduced transition probability, which results in a loss of absorption intensity (ϵ).

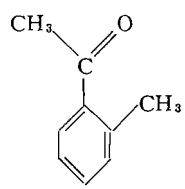
ULTRAVIOLET ABSORPTION SPECTRA

Propiophenone itself, compared to acetophenone, gives rise to a slight steric effect of the type referred to above, presumably because the replacement of a

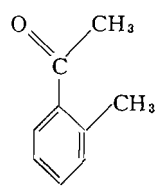
[1]*Manuscript received January 20, 1955.*
Contribution from the Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland.

hydrogen atom by a methyl group gives rise to further steric overlap between the additional hydrogen atoms and the carbonyl group and/or the ortho-positioned hydrogen atom of the benzene ring. *n*-Butyrophenone has an absorption spectrum almost entirely similar, which is as expected—from steric considerations alone—since the additional methyl group is too far removed to interfere effectively with the rest of the molecule. It is somewhat surprising though that the reported value of isobutyrophenone (9) does not indicate additional steric interference, since one would expect the additional methyl group to exert further steric overlap. One would expect the change from acetophenone, propiophenone, and isobutyrophenone, i.e. the successive replacement of two hydrogen atoms by two methyl groups, to be accompanied by first a slight, and then by a more pronounced steric effect, since in each case the molecule will assume the sterically most favorable position—there being no, or very little, restriction to the free rotation of the methyl group. Thus accommodation of the second methyl group—the molecule having attained the sterically most favorable position after the introduction of the first methyl group—would be at least equally, but probably more, difficult and hence involve more appreciable steric overlap. The spectra of propio- and isobutyrophenone, however, are reported to be the same (9); our own values indicate a slight, though definite, change of absorption intensity as expected from the above hypothesis (see Table I).

A further point of interest is that the change in spectral properties between 4-methylacetophenone and 2-methylacetophenone is almost identical with the change observed between 4-methylpropiophenone and 2-methylpropiophenone. For the first pair there is a bathochromic shift of 10 mμ and the ratio of the molar extinction coefficients is 0.57 (8500/15,000), whilst for the second pair the shift is 9 mμ, and the corresponding ratio is 0.57 (8000/14,000) (see Table I). This is reasonably conclusive evidence that the preferred planar configuration of 2-methylacetophenone and 2-methylpropiophenone is IA rather than IB, since if IB were correct, the replacement of the methyl group by the ethyl group in 2-methylpropiophenone would increase the steric overlap



IA

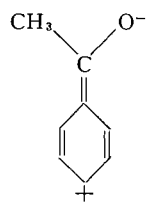


IB

already caused by the 2-methyl group (relative to 4-methylacetophenone), which would be in a position directly adjoining the more bulky ethyl group. This argument is verified by the absorption spectra of pairs of compounds, where the replacement of a methyl by an ethyl group normally causes additional steric effects (see, for example, Table I, for spectra of pentamethyl- and pentaethyl-acetophenones).

For 4-methylbenzaldehyde and 2-methylbenzaldehyde there is no bathochromic shift and the ratio of the molar extinction coefficients is 0.87 (13,000/15,000). Thus whilst in acetophenone and propiophenone the intensity of absorption is approximately halved by the introduction of a 2-methyl group, in benzaldehyde the intensity of absorption remains approximately constant. This type of steric effect has previously been discussed (5) and has been shown to be prevalent in conjugated systems which can exist in at least one unhindered or only weakly hindered uniplanar configuration, and has been ascribed to transitions involving non-planar ground states and planar excited states (6). Thus the fraction of molecules which are in a sufficiently planar ground state to be able to be raised to the postulated planar excited state governs the observed intensity of absorption. Therefore in 2-methylbenzaldehyde, the number of permitted near-planar vibrational states is only very slightly reduced, whilst in 2-methylacetophenone or in 2-methylpropiophenone it is approximately halved, indicating that structures of type IB can no longer contribute appreciably to the absorption band. This hypothesis is confirmed for 2,6-dimethylacetophenone where the absorption band has almost completely disappeared (see Table I).

The band under consideration is clearly sensitive to *para*-substituents and has on account of this previously been provisionally assigned to electronic transitions associated with *para*-resonance forms of type IC (7).



IC

Thus 4-methyl substituents will increase the *para*-resonance contributions to the hybrid of the ground—and even more so its contributions to the excited—states, giving rise to a bathochromic shift and an increased probability of absorption. An *ortho*-methyl group will likewise tend to exert a similar bathochromic shift accompanied by increased intensity of absorption, but in this instance, these effects are counterbalanced by the previously described steric effects. Hence the steric effect of the *ortho*-methyl group is larger than it appears to be, since it has to overcome the electronic effect associated with resonance forms of type IC. This is why it is necessary to compare the *ortho*-substituted compounds with the *para*-substituted analogues, rather than with the unsubstituted parent compounds. Also, it may be noted that this electronic effect of the *ortho*-methyl group becomes more evident in certain compounds, such as 2-methylbenzaldehyde and 4-acetylhydrindacene (II). In the latter, the second *ortho*-methylene group (which is comparable to a methyl group) gives rise to a bathochromic shift of about 10 mμ, which is similar to the

bathochromic shift observed between acetophenone and *p*-methylacetophenone.

In 2,6-dimethylacetophenone, the molecule can no longer take up a more favorable steric configuration (as is the case for 2-methylacetophenone, where the molecule takes up the more favorable configuration IA) and the interplanar angle is considerably increased resulting in an almost total loss of the conjugation band (see Table I).

Introduction of a third methyl group in the *para*-position gives rise to a slight bathochromic shift accompanied by increased transition probability, evidently due to the increased double bond character between the carbonyl group and the benzene ring caused by greater contributions of resonance forms of type IC. This decreases the interplanar angle and gives rise to the observed effect. It may further be noted that a similar difference is observed between 2,3,5,6-tetramethyl- and 2,3,4,5,6-pentamethyl-acetophenones (see Table I).

To account for the spectrum of 4-acetylhydrindacene (II) it must be noted that here both positions corresponding to structures IA and IB are equally possible. The observed maximal absorption at 252 mμ is approximately as expected for two *ortho*-alkyl substituents, but the intensity of absorption indicates a certain amount of steric hindrance of the type described above, i.e. corresponding to non-planar ground states and planar excited states. Since there is a decrease of intensity of absorption relative to acetophenone and an increase in intensity of absorption relative to 2,6-dimethylacetophenone, the

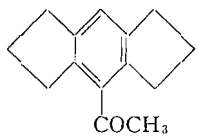
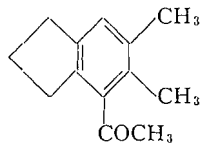
ortho-methylene group in the cyclopentyl ring offers steric resistance intermediate to that of an *ortho*-hydrogen atom and an *ortho*-methyl group, which is indeed as would be expected from an examination of scale models.

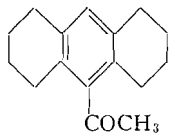
In 9-acetyloctahydroanthracene (IV), the steric effect due to the methylene group, as indicated by the location of maximal absorption, is considerably more pronounced, in agreement with the observation of Arnold and Craig (1), who found from reactivity measurements and in part from the values of carbonyl Raman frequencies that the steric hindrance around the carbonyl group decreases in the order V > IV > III > II. Thus the methylene group, held in a position where there is considerable interaction between the methyl group of the —$COCH_3$ group and the hydrogen atoms of the methylene group, increases the transition energy which results in the observed hypsochromic shift of the band. The observed intensity of absorption can be con-



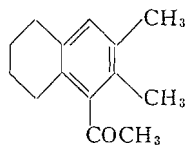
II



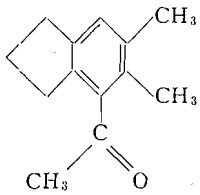
III



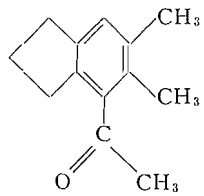
IV



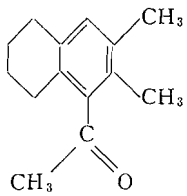
V



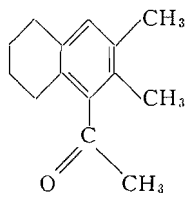
IIIA



IIIB



VA



VB

sidered to be largely due to the superposition of absorption due to the "tetramethylbenzene" band at 214 mμ.

For 4-acetyl-5,6-dimethylindane (III) two structures (IIIA) and (IIIB) are possible. The tendency for coplanarity between the carbonyl group and the rest of the molecule—which is due both to contributions of resonance forms to the ground-state hybrid and possibly to steric effects of the *ortho*-methylene group—will be opposed by the usual steric effect.

If structure IIIA predominates, the location and intensity of the absorption band should be similar to that of 2,6-dimethylacctophenone, although two secondary effects will be operating in opposite directions. Thus the molecule will be more hindered since the additional methyl group in the meta-position increases the steric effect (cf., for example, Table I, the spectra of 2,6-dimethyl- and 2,3,5,6-tetramethyl-acetophenones), but this effect will be opposed by the substitution of the cyclopentyl group for the second *ortho*-methyl group, which, as has been noted above, will reduce steric hindrance. If structure IIIB predominates, the location and intensity of the absorption band should again resemble that of 2,6-dimethylacetophenone, but having undergone further steric hindrance due to the "buttressing" effect of the methyl group in the *meta*-position. Since it has been shown that the pronounced steric effect in 2,6-dimethylacetophenone is due to the interference of the α- and *ortho*-methyl groups, the cyclopentyl group in IIIB would not be expected to affect the amount of steric hindrance obtained. Therefore, if structure IIIB were correct, a further steric effect relative to 2,6-dimethylacetophenone should occur. From Table I it is seen that only structure IIIA can fit the observed spectrum. This is also what would have been expected from scale models, since the C=O group has a smaller interference radius than the methyl group and would more readily be accommodated in the arrangement as represented by IIIA.

On applying a similar argument to the spectrum of 5-acetyl-6,7-dimethyltetralin (V), the data at first sight seem to point to a structure VB rather than to a structure VA, since the observed spectrum closely resembles the spectrum of 9-acetyloctahydroanthracene (IV), and also exhibits an absorption intensity more than twice as high as that of 4-acetyl-5,6-dimethylindane (IIIA); this is an argument that the two structures are probably dissimilar, since if they were similar, the absorption intensity of VA would be smaller than that of the corresponding five-membered ring compound IIIA. However, if the observed intensity of IV and V is almost wholly due to "tetramethylbenzene" absorption, as is indicated by the spectrum of tetramethyl benzene, the argument clearly becomes invalid and the question of the preferred configuration remains open. It should be remembered that for compounds IV and V, the interplanar angle approaches 90°, and since conjugation is hence almost completely inhibited, one would not expect to be able to draw conclusions about preferred configurations of these compounds, from a study of *this* particular band.

The spectrum of 2,3,5,6-tetramethylacetophenone (Table I) is of interest as it illustrates the "buttressing" effect of the *m*-methyl group, which may

be regarded as preventing bending away of the *o*-methyl group (5). That the pronounced effect in the spectrum is chiefly of a steric, rather than electronic, nature is indicated since in 4-acetylhydrindacene (II), no similar effect (i.e. a very pronounced hypsochromic shift) is observed, although in that compound both the *m*-positions are also occupied.

The secondary band, near 280 mμ, which may be regarded as derived from the low intensity band of benzene near 255 mμ and which is benzenoid in character (4), is not sensitive to the steric influences discussed in the present communication. The effect of substituents on this band, together with the effect of different solvent systems and temperature variations, will be the subject of a separate communication.

The absorption spectra of the 2,4-dinitrophenylhydrazones of some of the sterically hindered acetophenones, together with those of some reference compounds, are listed in Table II. The dinitrophenylhydrazones of acetophenones and propiophenones which absorb maximally at 372 and 374 mμ indicate interaction between the hydrazine group and the benzene ring, which is enhanced in *para*-substituted acetophenones as evidenced by a further bathochromic shift and increased intensity of absorption. In the dinitrophenylhydrazone of 2-methylpropiophenone this interaction is inhibited and the spectrum closely resembles that of the 2,4-dinitrophenylhydrazone of cyclohexanone, in which no cross-conjugation is possible, and must be ascribed to the $\rangle C{=}N{-}NH{-}R$ (R = 2,4-dinitrophenyl chromophore). The spectrum of the 2,4-dintrophenylhydrazone of isobutyrophenone is entirely similar and therefore indicates that in this instance, the change from propiophenone to isobutyrophenone brings about a change from a planar or near-planar to a non-planar configuration. The 2,4-dinitrophenylhydrazones of 4-acetylhydrindacene (II) and 4-acetyl-5,6-dimethylindane (III) absorb maximally at 366 mμ and 362 mμ respectively, indicating an increasing amount of steric inhibition of conjugation. 9-Acetyloctahydroanthracene (IV), 5-acetyl-6,7-dimethyltetralin (V), tetramethyl-, pentamethyl-, or pentaethyl-acetophenones do not form 2,4-dinitrophenylhydrazones, oximes, or semicarbazones under

TABLE II

ABSORPTION SPECTRA OF 2,4-DINITROPHENYLHYDRAZONES OF ACETOPHENONES AND RELATED COMPOUNDS IN CHLOROFORM

Wave-lengths and intensities of the main maxima

Carbonyl compound	λ_{max}, mμ	ϵ_{max}	Color
Benzaldehyde	372	29,000	Orange-red
Acetophenone	372	25,000	Red
Propiophenone	374	25,000	Red
4-Methylpropiophenone	380	25,500	Red
2-Methylpropiophenone	362	23,500	Red
Isobutyrophenone	362	23,500	Yellow
Cyclohexanone	362	23,500	Yellow

4-Acetyl-5,6-dimethylindane	362	22,000	Orange

the usual conditions. The amount of steric hindrance can also sometimes be estimated in the above-mentioned 2,4-dinitrophenylhydrazones by their color (see Table II).

EXPERIMENTAL PART

The ultraviolet spectra were determined by standard methods using a Unicam SP 500 spectrophotometer. ϵ represents the molecular extinction coefficient defined by $\epsilon = [\log_{10}(I_0/I)]/cl$, where I_0 and I = intensity of incident and of transmitted light, respectively, c = concentration in moles/liter, and l = cell thickness in centimeters.

Melting points are uncorrected; analyses were carried out in the microanalytical laboratory (Mr. F. H. Oliver) of the Department of Organic Chemistry, Imperial College, London, England.

Benzaldehyde, Acetophenone, Propiophenone, Isobutyrophenone

The commercially available compounds were redistilled to constant refractive index and intensity of absorption. Light absorption in ethanol: see Table I. The 2,4-dinitrophenylhydrazones of these, as well as of the other carbonyl compounds described below, were chromatographed on alumina from chloroform–benzene and crystallized, unless otherwise stated, from ethanol – ethyl acetate mixtures. Benzaldehyde 2,4-dinitrophenylhydrazone crystallized from glacial acetic acid as red needles, melting point 241–242° (Johnson (10) gives melting point 239–240°); acetophenone 2,4-dinitrophenylhydrazone crystallized from glacial acetic acid as red needles, melting point 250° (Johnson (10) gives melting point 247–248°); propiophenone 2,4-dinitrophenylhydrazone crystallized as red plates, melting point 196–197° (with decomposition) (Johnson (10) gives melting point 193–194°); isobutyrophenone 2,4-dinitrophenylhydrazone crystallized as yellow monoclinic prisms, melting point 165–166° (Johnson (10) gives melting point 161–162°). Light absorption in chloroform: see Table II.

4-Methylpropiophenone

Anhydrous aluminum chloride (9.1 gm.) was added to toluene (100 ml.), and propionyl chloride (6.3 gm.) was added dropwise with stirring at 0°C. After stirring for one hour, the mixture was hydrolyzed and isolated in the usual manner. The product distilled at 110°, 12 mm., yield 5.5 gm. (55%), $n_D^{22.5}$ 1.5264 (Birch *et al.* (3) give boiling point 135°, 30 mm.; n_D^{20} 1.5278). Light absorption in ethanol: see Table I. The 2,4 dinitrophenylhydrazone crystallized from ethyl acetate as red monoclinic prisms, melting point 209° with decomposition (Cullinane *et al.* (8) give melting point 201°). Light absorption in chloroform: see Table II.

2-Methylpropiophenone

2-Methylpropiophenone was prepared according to the method of Birch *et al.* (3), and was obtained as a colorless liquid, boiling point 100° at 18 mm., n_D^{22} 1.5243 (Birch *et al.* (3) give n_D^{20} 1.5250), yield 9.2 gm. (62%). Light absorption in ethanol: see Table I. The 2,4-dinitrophenylhydrazone crystallized from ethanol as red plates, melting point 115°. Anal.: Calc. for $C_{15}H_{14}O_4N_4$:

C, 57.3; H, 4.5; N, 17.8%. Found: C, 57.3; H, 4.5; N, 17.7%. Light absorption in chloroform: see Table II.

2,3,5,6-Tetramethylacetophenone

Durene (4 gm.), prepared from xylene by the method of Smith (13), was dissolved in carbon disulphide (40 ml.) at 0°. Aluminum chloride (4 gm.) was added to the stirred mixture in small portions followed by the dropwise addition of acetyl chloride (2.4 gm.) over a period of 10 min. Stirring was continued for three hours at 0°, and the mixture was then allowed to stand overnight at room temperature. It was then poured onto an ice – hydrochloric acid mixture and extracted with ether. After drying, removal of ether afforded the acetophenone in 55% yield, which crystallized from petroleum ether (boiling range 40–60°) as colorless plates, melting point 75° (Meyer (11) gives melting point 73°). No oxime, semicarbazone, or 2,4-dinitrophenylhydrazone could be obtained under the usual conditions. Light absorption in ethanol: see Table I.

2,3,4,5,6-Pentamethylacetophenone

Pentamethylbenzene (2 gm.), prepared by the method of Smith (13), was dissolved in carbon disulphide (50 ml.) and treated with aluminum chloride (1.8 gm.) and acetyl chloride (1.1 gm.) as described above. The product, which crystallized from methanol as colorless needles, melting point 87°, was obtained in 90% yield. Anal.: Calc. for $C_{13}H_{18}O$: C, 82.1; H, 9.5%. Found: C, 82.1; H, 9.7%. No oxime, semicarbazone, or 2,4-dinitrophenylhydrazone could be obtained under the usual conditions. Light absorption in ethanol: see Table I.

2,3,4,5,6-Pentaethylacetophenone

Pentaethylbenzene (5.1 gm., n_D^{25} 1.5130), prepared by the method of Smith and Guss (14), was treated with aluminum chloride (3.2 gm.) and acetyl chloride (2.7 gm.) as described above. The product which crystallized from 95% ethanol as colorless needles, melting point 143.5–144°, was obtained in 80% yield. Anal.: Calc. for $C_{18}H_{28}O$: C, 83.0; H, 10.9%. Found: C, 83.0; H, 11.0%. No oxime, semicarbazone, or 2,4-dinitrophenylhydrazone could be obtained under the usual conditions. Light absorption in ethanol: see Table I.

4-Acetyl-5,6-dimethylindane (III)

5,6-Dimethylindane (1.9 gm., $n_D^{26.5}$ 1.5318), prepared by the method of Arnold and Craig (1), in carbon disulphide (30 ml.) was treated with aluminum chloride (1.7 gm.) and acetyl chloride (1 gm.) as described above. Fractionation at 3 mm. afforded the indane as a pale yellow oil, which solidified on standing and crystallized from petroleum ether (boiling range 40–60°) as monoclinic prisms, melting point 42.5°. Arnold and Craig (1) report melting point 43° for this compound. Light absorption in ethanol: see Table I. The 2,4-dinitrophenylhydrazone crystallized from benzene as yellow plates, melting point 196–197°. Anal.: Calc. for $C_{19}H_{20}O_4N_4$: C, 61.9; H, 5.5; N, 15.2%. Found: C, 61.9; H, 5.5; N, 15.1%. Light absorption in chloroform: see Table II.

4-Acetylhydrindacene (II), 9-Acetyloctahydroanthracene (IV), and 5-Acetyl-6,7-dimethyltetralin (V)

These compounds were crystallized to constant melting point and constant intensity of absorption. Their preparation has previously been described (1, 2) and we are grateful to Professor R. T. Arnold for very kindly providing us with the required specimens. The last two compounds do not form any oximes, semicarbazones, or 2,4-dinitrophenylhydrazones. The 2,4-dinitrophenylhydrazone of 4-acetylhydrindacene crystallized from ethanol as orange needles, melting point 185°. Anal.: Calc. for $C_{20}H_{20}O_4N_4$: C, 63.15; H, 5.3; N, 14.7%. Found: C, 63.2; H, 5.3; N, 14.6%. Light absorption in chloroform: see Table II.

ACKNOWLEDGMENTS

The authors are greatly indebted to Dr. E. A. Braude for a number of invaluable discussions, and to the National Research Council of Canada for a research grant. They also wish to thank two students of the University for determining some of the absorption spectra (Mr. N. Coates) and for assisting in the preparation of the manuscript (Miss R. M. Gosine).

GROWTH RATES OF SINGLE CRYSTALS OF ETHYLENE DIAMINE TARTRATE[1]

By A. H. Booth[2] and H. E. Buckley[3]

ABSTRACT

Single crystals of ethylene diamine tartrate were grown under controlled conditions and the growth rate of the faces measured directly in the solution at short intervals by means of a travelling microscope. For the $(\bar{1}10)$ $(1\bar{1}0)$ pair of faces, the fastest growing form, steady growth at constant supersaturation was interrupted by occasional short periods of more rapid growth. Rejecting these erratic "spurts", reasonably reproducible values could be obtained, and the dependence upon supersaturation plotted. The equivalent faces at the opposite end of the polar axis of the crystal grew, at low supersaturation, with erratic starts and stops, so that reproducible growth-rate values could not be obtained. The results are discussed in relation to existing crystal growth theories.

INTRODUCTION

Plates cut from large crystals of ethylene diamine tartrate (EDT) have been used instead of quartz in the filter circuits needed for carrier telephone systems (9). Growing EDT crystals large enough for this purpose requires careful control (7). In order to study the influence of solution conditions on the growth of a single crystal it was desired, as a first step, to determine the growth rates of the various faces as a function of supersaturation. This paper describes an attempt to do this. A later paper reports the use made of the method in a search for possible growth "improvers".

At the outset it was not known whether reproducible growth-rate measurements could be obtained on single crystals. Rates of crystalline precipitation are usually reproducible, but they represent merely the mean growth rate of the large number of crystals involved. Corresponding studies have rarely been made on single crystals, and the little information available was confusing. It has been observed by many that visibly flawed crystals grow two or three times as fast as clear flawless ones, but it seems to have been rather generally assumed that crystals free from obvious flaws would grow at the same rate. However, no data to support this could be found in the literature. There is, in fact, some evidence against it. Berg (1) and others (2, 5) determined growth rates of the cube faces of sodium chlorate in a thin film of solution under the microscope, while measuring concentration gradients continuously by an optical interference method. They found that the growth rates of equivalent faces of the same crystal varied widely and that occasionally a face completely stopped growing for a while even though it was in contact with a strongly supersaturated solution.

The reason for this behavior is not clear. A possible explanation is that the faces studied were so minute that the nucleation centers at which growth

layers started were few or zero. Their distribution would then be of critical influence on the growth rate. It seemed possible that by working with moderate sized crystals more reproducible growth rates might be obtained. Diffusion effects would, of course, have to be eliminated or held constant. On this point Egli and Zerfoss (3) state that usually only moderate stirring is needed to eliminate diffusion as a rate controlling factor. Van Hook (6) found this to be so for sucrose and concluded that the reaction at the crystal face is a slower process than transport toward it.

EXPERIMENTAL

The apparatus is shown in Fig. 1. It consisted of a crystallizing chamber enclosed by a water jacket, both made of transparent plastic. The volume of the crystallizing cell was made large enough in relation to the crystal seed so that as the crystal grew, the supersaturation remained constant during the

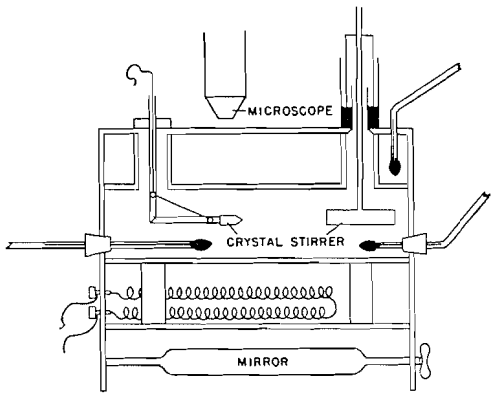

FIG. 1. Crystal growth-rate apparatus.

measuring period. The temperature could be held constant within 0.1°C. The shaft of the stirrer operated through a mercury seal to prevent evaporation. The crystal was viewed and measured with a low power travelling microscope, the transit of which read directly to 0.001 mm.

Solutions were prepared by dissolving recrystallized EDT-monohydrate in water. (The monohydrate is the stable form below 40.6°C.) The solutions were used only until they became slightly colored by decomposition products and then were discarded. The crystal seeds were about 4–12 mm.^{2} in cross section, and were free from visible flaws. They were cemented on a hinged plastic rod which was inserted in the cell and the hinged part then drawn up into position with a wire. Solutions saturated at the required temperature were prepared in a separate water bath; but after the cell was filled the saturation temperature was checked in the following way. The crystal was allowed to grow somewhat and then the temperature was raised very slowly until the first sign of rounding of the sharp edges was seen. This method was found to be accurate to within 0.2°C. The saturation temperature was checked frequently throughout the life of the solution to ensure that the supersaturation had not been lowered appreciably by the growth of the crystal.

Normally most rapid growth is on the wedge shaped $(\bar{1}\bar{1}0)$ $(1\bar{1}0)$ pair of faces which cap the negative end of the *y*-axis. Generally, the edge of the wedge was taken as the marker, and measurements were made of the growth along the axis. The recorded values therefore do not represent directly the growth rates of any real face, but if they are multiplied by cos 45° 30′ (one half the interfacial angle) they give the average for the two members of the pair. The two were always nearly equal unless one of the faces was visibly flawed. In such a case the flawed face grew more quickly so that its area decreased relative to the other, and the crystal became asymmetric.

The equivalent faces at the positive end of the *y*-axis, (110) $(\bar{1}10)$, are reportedly "non-growing" under the conditions in the industrial crystallizer. They are said to grow appreciably only when visibly flawed (7). Measurements at this end of the crystal were made in the same way. The top and side faces (001) and (100) were not studied in detail. Their growth behavior seemed similar to that of the (110) $(\bar{1}10)$ pair.

The settings of the microscope cross hairs against the crystal point were reproducible to about 0.003 mm. Growth rates were recorded for equal increments of added length, usually 0.02 mm. The average of at least 10 readings was taken in each case.

The effect of stirring speed was studied first. With quite moderate agitation a maximum growth rate was reached; then the stirring speed could be doubled without any further increase. All subsequent work was done with stirring speeds that were well over the necessary minimum. Unfortunately, with such agitation it was not possible to work at undercoolings of more than 4 or 5°C. (supersaturations of 1.5%) without great danger of spontaneous crystallization.

Growth rates covering the practical supersaturation range were measured. The reproducibility for different individual crystals and the dependence upon solution composition and temperature were then studied.

RESULTS

(*a*) *The Negative End of the y-Axis*

At constant supersaturation the measured value of the growth rate, when the crystal was growing with its normal habit faces and without visible flaws, was nearly constant. However, occasionally a sudden jump to a value erratically higher was noted. This was commonly about twice as great as the steady value, the deviation being quite outside the combined errors of temperature and length measurement. The rate usually dropped back to the steady value in a short time, often on the next reading. The irregularities seemed greater when the temperature was changing than when it was held nearly constant. It was found better to measure the growth rates at each supersaturation separately, holding the temperature constant for a time and dropping it stepwise, rather than by interpolating the values from a continuous cooling curve.

These erratic periods of more rapid growth left no visible mark in the crystal. However, sometimes when the supersaturation was high the enhanced rate of growth continued for a much longer time before dropping back to the

normal rate. Then a visible "veil" appeared. Veils were more frequent when the stirring was inefficient. They could be produced almost at will on a given face by orienting the face so that it was in the lee of the current. Presumably, dead spots in the circulation leading to irregularities in the supersaturation of the solution at various points along the face promoted the disordered growth.

Despite the complication caused by the erratic jumps, it was quite feasible to evaluate "normal" growth rates. The jumps were usually well-defined and not too close together, and so could be rejected unambiguously. The rate values quoted later always refer to these corrected values, not to the gross average rates.

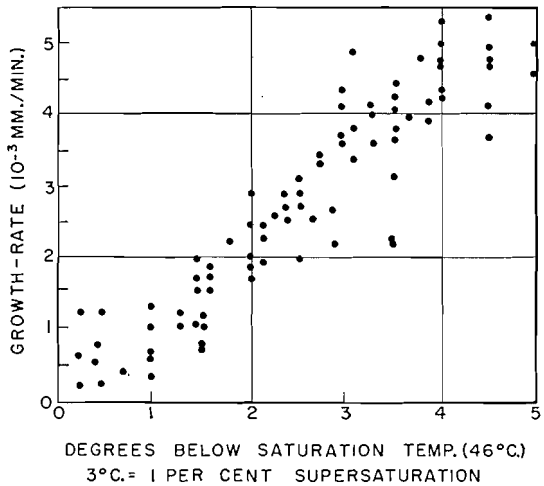

FIG. 2. Growth rates at negative end of y-axis.

Even with this limitation, some variation outside experimental error was found in measurements made under apparently identical conditions. First with the same crystal in position, measurements were taken up and down the supersaturation scale several times. Then four other crystals successively were treated in the same way in the same solution. Later in the work, four other crystals were measured at various times in similar solutions. The differences between the values obtained in different runs with the same crystal were just as great as those between different individual crystals. In Fig. 2 all the values obtained are shown without distinguishing separate cases. Although not good, the reproducibility was sufficient to allow study of some factors which might be presumed to affect the growth rate.

The effect of temperature was studied first. A series of curves for the same crystal over different temperature ranges was plotted. These were replotted by interpolation as rate curves at different fixed temperatures. It will be seen in Fig. 3 that the rates increase appreciably with increase in temperature. On the other hand, the rate was found to be not very sensitive to the presence of those substances which normally occur as impurities in EDT solutions. Variations

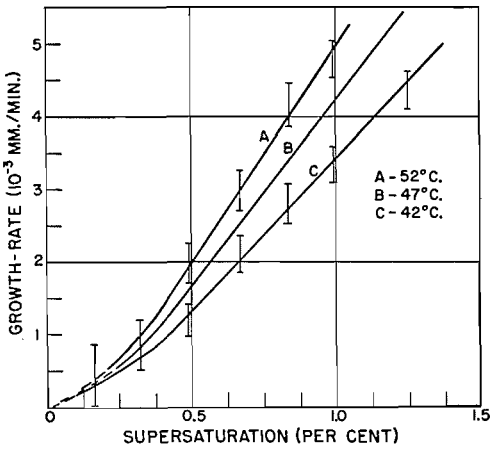

FIG. 3. Growth rates at various temperatures.

in pH over the range 5.0 to 8.0, due to excess of either tartaric acid or ethylene diamine, gave no change sufficiently large to be observable. The decomposition products* of EDT also had little effect, at least when in low concentration. Solutions aged at 40–55°C. for periods up to four months produced no detectable change in the growth curve. One very much older solution gave erratic values, but this effect was not studied further.

Variation of the size of the crystal from 1 to 10 mm.^{2} cross section did not affect the rate of growth. Moreover, the values obtained are of the same order of magnitude as those observed with the larger crystals (100 times greater facial area) which are grown industrially. Most likely the rate is independent of the size of the face.

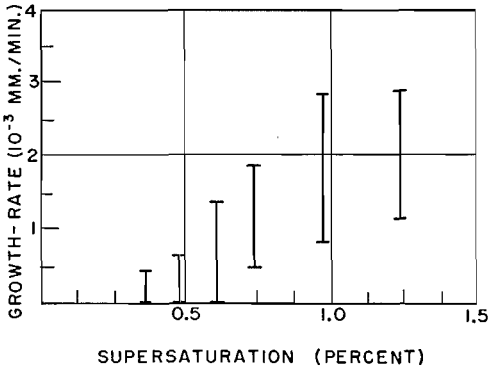

FIG. 4. Growth rates at positive end of y-axis.

*Walker (7) states that "heat and sunlight both cause brownish decomposition products", but it was found that the color is entirely a result of atmospheric oxidation, heat accelerating the reaction. The solutions remained colorless when under an inert atmosphere or when sodium sulphite was added.

(b) The Positive End of the y-Axis

Growth at the positive end of the y-axis of the crystal was quite different from that at the negative end discussed above. It proceeded discontinuously except when the supersaturation was high. There were long pauses, during which no growth at all occurred, intermingled with periods of activity. This is represented diagrammatically in Fig. 4 where the markers delimit the highest and lowest values observed in a series of tests.

DISCUSSION

The marked difference between the growth at the positive and negative ends of the crystal makes it necessary to discuss the two separately.

(a) The Negative End

It is well established that crystals grow by the spreading out of thin layers which start from growth centers on the faces. The irreproducibility of the growth-rate determinations under apparently identical conditions must be caused by differences in the surface structure, leading to differences in the pattern of developing layers. The nature of the growth centers is still under discussion. In the Frank dislocation theory (4) they are the points where screw dislocation lines emerge at the surface. Growth is controlled by a few of the most active ones. Variations in the growth rate would then be caused by the shifting of dominant screw dislocations under the influence of slight stresses.

However the erratic "spurts" may be associated with grosser changes in the surface structure caused by the interference of slightly disoriented layer systems with each other— an idea rather similar to that suggested by Yamamoto (10) to explain skeletal growth. Disoriented junctions between layer systems would serve as strong growth centers and lead to more rapid growth. Probably there are then two opposing tendencies. One is for a group of active centers to become dominant, bridge over gaps, and heal the surface. The other is for the disordered structure to spread, and to become less amenable to healing; for the gaps between disoriented layers will become larger as growth proceeds outward. Consequently, the surface either heals quickly or not at all. In the latter event a visible veil appears. It is interesting that a veil usually covers a face completely but does not spread to adjacent faces. No doubt, this follows from the observed fact that spreading layers usually end at the edge of the face on which they start. That veils can frequently be induced to heal at low supersaturation may be evidence of the ability of the most active growth center to dominate the others.

(b) The Positive End

The peculiar growth behavior of the (110) ($\bar{1}$10) faces is similar to that described for the cube faces of microscopic sodium chlorate crystals (1). This raises the possibility that the phenomenon may be a rather common one and the smoother increase with supersaturation shown by the ($\bar{1}\bar{1}$0) (1$\bar{1}$0) faces exceptional. Since data for other crystals are lacking, this remains speculation.

The complete stopping and sporadic restarting of growth is difficult to explain. Blockage of nucleation centers by adsorption of impurities is a possibility. More probably, however, the solvent itself interacts with these crystal faces in such a way as to inhibit growth. The likelihood of this can be seen by considering an experiment of Wells (8). He found that resorcinol grown from benzene solution grows equally well at the two ends of the polar axis but from water solution most of the growth takes place at one end. He was able to explain this convincingly as caused by the interaction of water molecules with the non-growing end, the structure of which exposes hydroxylic groups at the surface. It will be of interest to determine whether a similar correlation can be made in the case of EDT when its structure is fully determined.

THE EFFECT OF BORIC ACID ON THE GROWTH OF ETHYLENE DIAMINE TARTRATE CRYSTALS[1]

By A. H. Booth[2] and H. E. Buckley[3]

ABSTRACT

When present in ethylene diamine tartrate (EDT) solutions in small concentration boric acid produces many crystallographic phenomena associated with specific adsorption on crystal faces; especially habit modification and growth inhibition. These effects are typical of those given, incidentally, by "growth improvers", and it is concluded that boric acid would be a logical choice for intensive testing as a flaw suppressor in the solutions from which large single crystals of EDT are grown.

INTRODUCTION

To be useful in fabricating channel filters for carrier telephone systems crystals of ethylene diamine tartrate must be free from flaws, at least from those of visible size. The most common type of flaw is a "veil", an opaque region in the otherwise clear crystal caused by disordered growth (also called skeletal, disoriented, porous, or rotten growth). To prevent the appearance of such veils the crystal must be grown very slowly and uniformly. In industrial practice a growing period of several months is required to obtain the desired size, which is about one pound in weight. In the present work methods for speeding up the growth of flawless crystals were sought.

It appears to be a general principle of crystal growth, first established by Yamamoto (4), that for any crystal there is a critical growth rate which, if exceeded, results in skeletal rather than clear compact growth. The critical rate depends greatly on the size of the face, being lower for large than for small faces, and this makes it all the more difficult to grow perfect crystals of large size. The critical rate can, however, be greatly raised by the presence in the solution of specific impurities, often in very small amount. Such additives have been used successfully in several cases for improving the growth of large crystals (1, 2), and the principles involved in selecting a suitable additive are becoming clear. Presumably they owe their effect to selective adsorption on the crystal faces, which restrains the initiation of new layers. This limits the number of layer series existing contemporaneously and so prevents them from interfering with one another.

The adsorption is usually revealed by a number of other crystallographic effects. The most important of these are a change of crystal habit, a slowing down of the growth rate, and an increase in the supersaturation range in which spontaneous crystallization does not occur. A *decrease* in growth rate compared with a pure solution of equal supersaturation is thus connected with an *increase* in the critical rate (the maximum rate for clear growth). To evaluate the worth

[3]*Present address: University of Manchester, Manchester, England.*

of an "improver" directly is a difficult and time consuming problem, so that an attempt was made to make a preliminary selection of likely substances by a study of these associated effects.

EXPERIMENTAL

Habit modification effects were studied by crystallizing single crystals in test tubes, or in a cell under the microscope. Growth inhibition was studied in the apparatus described in the preceding paper. In addition a few tests were made in an apparatus similar to that used in industrial practice, as described by Walker (3). The crystallizing vessel was a 5 liter beaker. Large seeds about 2 in. wide were mounted on a "spider" which rotated in the solution with a reciprocating motion, the direction of stirring being reversed every 30 sec.

RESULTS

The crystals were for the most part quite unaffected by the presence of small amounts of foreign substances introduced into the solution. This applies to common inorganic ions, surface active agents, and some arbitrarily chosen organic compounds. However, a very powerful and striking effect was found with small quantities of boric acid.

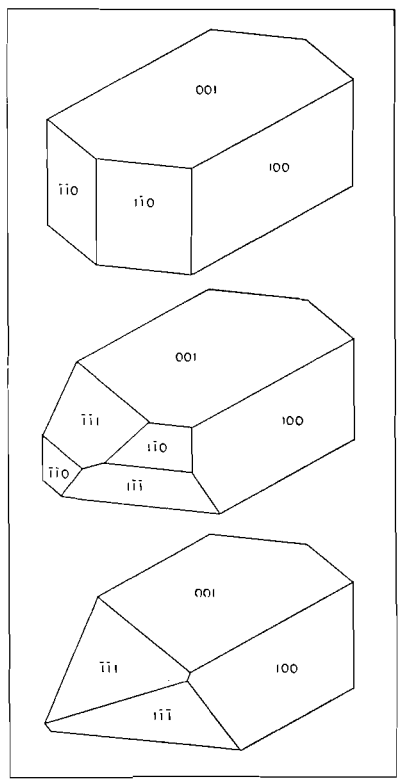

FIG. 1. Crystal habits of EDT: (top) normal; (center and bottom) modified by presence of boric acid in the solution.

(*a*) *Habit Modification*

Quite small amounts of boric acid suppress the development of the $(\bar{1}\bar{1}0)$ $(1\bar{1}0)$ faces. The $(\bar{1}\bar{1}1)$ $(1\bar{1}\bar{1})$ pair, not normally present, appears in their stead. It has no such effect at the positive end of the *y*-axis. The actual concentration required depends on the rate of growth. At very slow rates maintained for long times, as in the industrial type crystallizer, concentrations over 0.04 gm. per liter invariably produced an appreciable development of the $(\bar{1}\bar{1}1)$ $(1\bar{1}\bar{1})$ faces, and at concentrations over 0.1 gm. per liter they completely replaced the $(\bar{1}\bar{1}0)$ $(1\bar{1}0)$ pair. If both pairs were coexisting and the growth rate was then increased the $(\bar{1}\bar{1}1)$ $(1\bar{1}\bar{1})$ faces became smaller and finally disappeared. In the growth rate measurement apparatus the crystals were mostly growing at somewhat higher rates than in the larger crystallizer, so that appreciable development of the $(\bar{1}\bar{1}1)$ $(1\bar{1}\bar{1})$ faces was not observed below concentrations of about 0.5 gm. per liter, with complete replacement of the other pair at about 1.0 gm. per liter. The normal and modified forms are shown in Fig. 1.

(*b*) *Growth Inhibition*

The rate curves for several concentrations of boric acid are shown in Fig. 2. Below 0.2 gm. per liter there was no detectable change. From 0.2 to 0.6 gm. per liter there was a progressive slowing down of the rate. This was accompanied by an apparent decrease in the number of the sudden erratic "spurts" discussed in the preceding paper. The tendency toward spontaneous crystallization was also lessened. The temperature could be lowered several degrees below that at which "snow-storm" crystallization usually occurs.

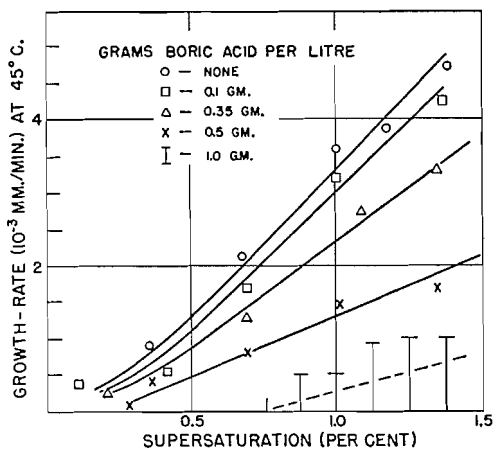

FIG. 2. Growth rates with boric acid additive.

At concentrations of about 1.0 gm. per liter a rounded (partially dissolved) seed grew out to form plane faces and then stopped growing completely. This was with a supersaturation of 1.0%. The temperature was then lowered, but growth did not start again until the supersaturation was about 2.0%. The crystal then grew slowly for a short time but soon stopped growing again and remained completely stopped for several hours.

The behavior with even larger amounts of boric acid in the solution is interesting. The crystals will grow only at high supersaturations and the faces appear warped or rounded. Above about 10 gm. per liter a rounded seed does not grow out to form plane faces. Instead, a mass of extremely small crystals form over the surface. These crystals drift off into the solution and start a dense microcrystalline precipitation. Apparently under these conditions it is easier for new crystals to form than for growth to proceed on existing ones. At yet higher concentrations nuclei formation is so inhibited that the solution can be evaporated to a sirup which sets to a glass on cooling.

This behavior appears to be similar to that observed with substances that have been used as growth improvers in other cases. For instance, Egli and Zerfoss (1), speaking generally, say that "if concentrations beyond the optimum are used habit is modified, flaws are induced and spontaneous nuclei occur more readily than from pure solution".

On the evidence of these effects, then, which point to an adsorption of the desired kind, boric acid would appear to be a logical choice for intensive testing as a flaw suppressor in EDT crystallizer solutions. The optimum concentration would probably be below that needed for habit modification.

ACKNOWLEDGMENTS

The encouragement given by Mr. C. E. Richards of the Post Office Research Department of Great Britain is gratefully acknowledged. One of us (A.H.B.) is indebted to the National Research Council of Canada for a grant and special leave.

STEROIDS

III. THE EPIMERIC N-ACETYL-3-AMINOCHOLEST-4- AND -5-ENES[1]

By R. A. B. Bannard and A. F. McKay[2]

ABSTRACT

Lithium aluminum hydride reduction of the oximes of 3-ketocholest-4- and -5-enes gave mixtures of amines. These amines on acetylation and separation gave respectively N-acetyl-3(α)-aminocholest-5-ene, N-acetyl-3(β) aminocholest-5-ene, N-acetyl-3(α)-aminocholest-4-ene, and N-acetyl-3(β)-aminocholest-4-ene. The N-acetyl-3(α)-aminocholest-5-ene (m.p. 184.5°C.) was shown to be identical with the cholesterylacetamide obtained by the acetylation of the degradation product from N-benzyl-3(α)-aminocholest-5-ene (m.p. 90–91°C.).

It was previously (6) shown that benzylamine and 3(β)-chlorocholest-5-ene heated together at 180°C. gave a mixture of 3(β)-benzylaminocholest-5-ene (m.p. 116.5–117.5°C., $[\alpha]_D^{25}$ −23°) and 3(α)-benzylaminocholest-5-ene (m.p. 90–91°C., $[\alpha]_D^{25}$ −9°). Julian *et al.* (5) had degraded the 3(β)-benzylaminocholest-5-ene to 3(β)-aminocholest-5-ene which they converted into 3(β)-acetylaminocholest-5-ene (m.p. 243°C.). The same 3-cholesterylacetamide (m.p. 243°C.) was prepared by Windaus and Adamla (7) by heating 3(β)-chlorocholest-5-ene with ammonia solution in a sealed tube and by reduction of cholest-4-ene-3-one oxime with sodium in alcohol. Two other isomeric cholesterylacetamides melting at 190°C. and 216°C. were isolated also from the latter reaction. When 3(α)-benzylaminocholest-5-ene was degraded (6) to the corresponding amine and converted to 3(α)-acetamidocholest-5-ene (m.p. 184.5°C.[3]), it was thought that this cholesterylacetamide might correspond to the one melting at 190°C. isolated by Windaus and Adamla (7). However since there was no way of confirming this by direct comparison of the cholesterylacetamides from the two different reactions, the four epimeric N-acetyl-3-aminocholest-4- and -5-enes were synthesized.

Cholest-5-ene-3-one oxime (m.p. 184.5–186.5°C.) on reduction with lithium aluminum hydride gave a mixture of epimeric 3-aminocholest-5-enes. The free amines on conversion to their acetyl derivatives and chromatographic separation gave a 46.6% yield of pure N-acetyl-3(β)-aminocholest-5-ene (m.p. 243°C.; $[\alpha]_D^{24.8}$ −44.9°) and a 23% yield of pure N-acetyl-3(α)-aminocholest-5-ene (m.p. 184.5°C.; $[\alpha]_D^{24.8}$ −59.4°). The identity of this N-acetyl-3(α)-aminocholest-5-ene with the cholesterylacetamide (m.p. 184.5°C.) obtained from the degradation of 3(α)-benzylaminocholest-5-ene (6) was established by a mixed melting point determination.

The configurations of the epimeric 3-benzylaminocholest-5-enes were deduced (6) from their rotations in agreement with the rule that the 3(α) form of a steroid will have a higher positive rotation than the 3(β) form (1). If this

[1]*Manuscript received March 7, 1955.*
Contribution from Defence Research Chemical Laboratories, Ottawa, Ontario. Issued as D.R.C.L. Report No. 172.
[2]*Present address: Monsanto Canada Limited, Ville LaSalle, Quebec.*
[3]*This melting point was previously (6) reported as 189°C. but the substance melted at 184.5°C. in the Hershberg melting point apparatus used in these studies.*

rule applies to the N-acetyl-3-aminocholest-5-enes then the higher melting compound (243°) having the more positive rotation will have to be assigned a 3(α) configuration. This would reverse the assignments given above for these cholesterylacetamides. Thus one must conclude that degradation of the 3-benzylaminocholest-5-enes is accompanied by an unexpected (6) Walden inversion at the C_3—N bond or the above rotation rule does not apply to the N-acetyl-3-aminocholest-5-enes. The purity and rotations of the epimeric N-acetyl-3-aminocholest-5-enes were checked repeatedly to confirm the given rotations.

The reduction of cholest-4-ene-3-one oxime (m.p. 158°C.) with lithium aluminum hydride gave a mixture of epimeric 3-aminocholest-4-enes. This mixture was acetylated and the acetamides were separated by chromatography. This procedure gave a 27% yield of pure N-acetyl-3(β)-aminocholest-4-ene (m.p. 223.5°C.; $[\alpha]_D^{24.8}$ +6.2°) and a 28% yield of pure N-acetyl-3(α)-aminocholest-4-ene (m.p. 163–164°C.; $[\alpha]_D^{24.8}$ +105.5°). This is the first time that the latter acetamide (m.p. 164°C.) has been described. The rotations of the epimeric N-acetyl-3-aminocholest-4-enes agree with the rule that the 3(α) epimer should possess the higher positive rotation.

This work confirms the structure originally (6) assigned to the new N-benzyl-3(α)-aminocholest-5-ene (m.p. 90–91°C.).

EXPERIMENTAL[4,5]

Cholest-5-ene-3-one

Cholest-5-ene-3-one (m.p. 122–124°C.) was prepared in 54% yield from cholesterol via cholesterol dibromide and 5(α), 6(β)-dibromocholestan-3-one following the procedure of Fieser (4).

Cholest-5-ene-3-one Oxime

Cholest-5-ene-3-one (2.96 gm.; 0.0077 mole), hydroxylamine hydrochloride (0.71 gm.; 0.01 mole), and fused sodium acetate (0.83 gm.; 0.01 mole) in 95% ethanol (90 cc.) were heated under reflux for six hours. After the reaction mixture had cooled to room temperature, the resultant crystalline slurry was poured slowly into 300 cc. of water with stirring and the colorless crystalline precipitate (m.p. 165–169°C.) was removed by filtration and dried, yield 3.04 gm. (98.6%). Three recrystallizations from methanol raised the melting point to 184.5–186.5°C. with decomposition, yield 1.79 gm. (58.1%). Butenandt and Schmidt-Thomé (2) report the melting point of cholest-5-ene-3-one oxime as 188°C. with decomposition.

Reduction of Cholest-5-ene-3-one Oxime with Lithium Aluminum Hydride

Cholest-5-ene-3-one oxime (1.00 gm.; 0.0025 mole) was placed in a glass extraction thimble consisting of a glass tube with a sealed-in fritted-glass disk. For hot extraction the thimble was placed in a tube which was attached to the center neck of a three-neck 300-cc. round-bottom flask equipped with an

[4]*All melting points are uncorrected and were observed in a Hershberg melting-point apparatus using a temperature rise of 2°C. per minute.*

[5]*Microanalyses by Micro-Tech Laboratories, Skokie, Illinois.*

Allihn condenser set for reflux and protected from entry of moisture with a calcium chloride guard tube. A second neck of the flask was fitted with a dropping funnel, and the third neck was closed by means of a glass stopper. The flask was equipped with a "glascol" heating mantle and a magnetic stirrer. The entire apparatus was swept with "oxygen-free" dry nitrogen as for a Grignard reaction. Lithium aluminum hydride (0.862 gm.; 0.023 mole), which was weighed in a nitrogen-swept dry-box, was added to the reaction flask along with 75 cc. of anhydrous ether. The mixture was heated under reflux with stirring until the oxime had all been extracted from the thimble (one hour). After the solution had been refluxed for a further period of six hours, it was allowed to cool and stand overnight at room temperature. During this time the reaction mixture was maintained under an atmosphere of nitrogen. The stirred suspension was hydrolyzed after addition of a further 100 cc. of anhydrous ether by dropwise addition of water until evolution of hydrogen ceased and the precipitate became colorless and granular (5 cc.). Stirring was continued for a further hour after which the precipitate was collected by filtration and washed with anhydrous ether (6 × 25 cc.). The combined ethereal solutions were concentrated to a volume of 125 cc. and dried over anhydrous sodium sulphate (15 gm.). The dry ether solution was evaporated to dryness first at atmospheric pressure and then *in vacuo* at 60°C. The resultant colorless, porous, solid residue weighed 0.975 gm.

No attempt was made to separate this mixture of cholesterylamines but the residue was heated with 5 cc. of acetic anhydride at 70°C. for 10 min., cooled, treated with 20 cc. of anhydrous ether, and heated under reflux for one hour in an apparatus protected from entry of moisture. The mixture was poured into 100 cc. of water with stirring and a colorless precipitate separated at the ether–water interface. Stirring was continued for 30 min. to complete the hydrolysis after which the colorless solid (m.p. 233–236°C.) was removed by filtration and dried, yield 250 mgm. The residual aqueous phase was neutralized to pH 6 by addition of 10% sodium hydroxide solution followed by 5% sodium bicarbonate solution, extracted with "peroxide-free" ether (6 × 50 cc.), and the combined ethereal solutions evaporated to a volume of 200 cc. and dried over anhydrous sodium sulphate (15 gm.). The dried solution was decanted and evaporated to a volume of 25 cc. on the steam-bath, whereupon colorless platelets (m.p. 234–237°C.) separated, yield 202 mgm. The ether solution failed to yield more of this substance so was evaporated to dryness. The residual pale yellow oil was heated *in vacuo* at 60°C. in the presence of potassium hydroxide to remove a trace of acetic acid, whereupon the oil slowly crystallized, yield 675 mgm. The latter material, on boiling with 30–60° petroleum ether, partially dissolved, leaving behind 42 mgm. of insoluble substance melting at 222–232°C. The filtrate was evaporated to dryness, the residue (578 mgm.) dissolved in 25 cc. of anhydrous 56–67° petroleum ether and transferred to a column for chromatographic analysis (diam. 20 mm.) packed with alumina (neutralized, reactivated, activity II, 17 gm.). The column was eluted with 50-cc. portions of solvent. The benzene–ether (1 : 1) eluates furnished two crops of crystalline material, the first and larger amount of which

on recrystallization from methanol yielded 248 mgm. (23.2%) of fine colorless needles, $[\alpha]_D^{24.8}$ −59.4° (103.1 mgm. substance dissolved in chloroform, 10 cc., 1 dm. tube); m.p. 183–184.5°C. alone and in admixture with an authentic specimen of N-acetyl-3(α)-aminocholest-5-ene of m.p. 184.5°C. previously (6) prepared.

The smaller quantity of crystalline material, m.p. 235°C., (60 mgm.) from the chromatogram proved to be identical with the higher melting crops (250 mgm., 202 mgm., and 46 mgm. respectively) previously obtained at various stages in the purification of the mixture of N-acetylcholesterylamines. This substance on recrystallization from acetone furnished 498 mgm. (46.6%) of N-acetyl-3(β)-aminocholest-5-ene as colorless platelets, m.p. 242–243°C.; $[\alpha]_D^{24.8}$ −44.9° (104.2 mgm. substance dissolved in chloroform, 10 cc., 1 dm. tube). Anal.: Calc. for $C_{29}H_{49}NO$: C, 81.45; H, 11.54; N, 3.27%. Found: C, 81.49; H, 11.59; N, 3.71%. This substance is undoubtedly the N-acetylcholesterylamine of m.p. 244°C. and 238–240°C. reported by Windaus and Adamla (7) and by Julian *et al.* (5) respectively.

Cholest-4-ene-3-one

Cholest-4-ene-3-one of m.p. 81–82°C. was prepared in 94% yield from cholest-5-ene-3-one by Fieser's (4) procedure.

Cholest-4-ene-3-one Oxime

Cholest-4-ene-3-one (10.0 gm.; 0.0260 mole) was heated under reflux for six hours with hydroxylamine hydrochloride (2.80 gm.; 0.0403 mole) and anhydrous sodium acetate (3.20 gm.; 0.0390 mole) in 350 cc. of 95% ethanol, allowed to stand overnight, and poured slowly into 2500 cc. of water with stirring. The colorless flocculent precipitate which separated was collected by suction filtration and dried to constant weight in a vacuum desiccator in the presence of phosphorus pentoxide. The crude cholest-4-ene-3-one oxime weighed 10.3 gm. and exhibited a double melting point of 88–90°C. and 149–151°C. This substance was dissolved in boiling ethyl acetate (75 cc.) and the filtered solution allowed to stand in a desiccator in the presence of phosphorus pentoxide. Slow adsorption of the solvent by the desiccant caused long clusters of colorless needles (m.p. 157–158°C.) to separate. In this manner, over a period of four weeks, four crops of crystals of the above melting point were obtained, yield 8.90 gm. (85.6%). Diels and Abderhalden (3) report the melting point of cholest-4-ene-3-one oxime as 152°C.

Reduction of Cholest-4-ene-3-one Oxime with Lithium Aluminum Hydride

The apparatus and procedure were the same as described for the reduction of cholest-5-ene-3-one oxime except that 2.00 gm. (0.005 mole) of cholest-4-ene-3-one oxime, 1.70 gm. (0.045 mole) of lithium aluminum hydride, and 150 cc. of anhydrous ether were used. The crude mixture of cholesterylamines (1.81 gm.) which resulted from hydrolysis of the complex followed by ether extraction was acetylated with acetic anhydride (10 cc.) by the same procedure as described for the mixture of cholesterylamines resulting from reduction of cholesten-5-one-3 oxime.

The cholesterylacetamides proved to be entirely ether extractable. The ether extract on evaporation to dryness *in vacuo* furnished 2.00 gm. of pale yellow solid. This material was refluxed with 58–64° petroleum ether (25 cc.), the suspension filtered, and the solid residue (m.p. 221.5–223°C.) on the filter washed with 2 × 10 cc. of boiling petroleum ether, yield 262 mgm. This substance proved to be identical with a second crop of material (m.p. 221–223°C.) which separated from the petroleum ether solution on cooling, yield 298 mgm. The petroleum ether solution failed to yield any further crystalline substance on slow evaporation and was consequently evaporated to dryness *in vacuo* and brought to constant weight. The resultant pale yellow oily solid (1.45 gm.) was dissolved in 58–64° petroleum ether and transferred to a column (diam. 24 mm.) packed with alumina (neutralized, reactivated, activity II, 46 gm.) for chromatographic analysis. The column was eluted with 100-cc. portions of solvent.

Elution with benzene–ether (1 : 1) gave 143 mgm. of crystalline substance which, after recrystallization from methanol, gave 71 mgm. of flat colorless needles which proved to be identical with the substance of m.p. 221–223°C. previously obtained. The three crops of this substance (262 mgm., 298 mgm., and 71 mgm. respectively) were combined and recrystallized from methanol (35 cc.) yielding 592 mgm. (27.7%) of N-acetyl-3(β)-aminocholest-4-ene, m.p. 222.5–223.5°C., $[\alpha]_D^{24.8}$ +6.2° (104.2 mgm. substance dissolved in chloroform, 10 cc., 1 dm. tube), as long flat needles. Calc. for $C_{29}H_{49}NO$: C, 81.45; H, 11.54; N, 3.27%. Found: C, 81.22; H, 11.71; N, 3.27%.

Elution with ether containing 0.5% methanol gave 801 mgm. of colorless crystalline substance, which on recrystallization from *n*-pentane (35 cc.) yielded 615 mgm. (28.8%) of colorless feathery needles melting at 160–161°C. Two more recrystallizations from the same solvent raised the melting point to 163–164°C., $[\alpha]_D^{24.8}$ +105.5° (103.1 mgm. substance dissolved in chloroform, 10 cc., 1 dm. tube). Anal.: Calc. for $C_{29}H_{49}NO$: C, 81.45; H, 11.54; N, 3.27%. Found: C, 81.16; H, 11.30; N, 3.64%. The latter substance is the hitherto unreported N-acetyl-3(α)-aminocholest-4-ene.

ACKNOWLEDGMENTS

The authors wish to thank Mr. R. O. Braun for assistance with some of the chromatography.

THE INFRARED AND RAMAN SPECTRA OF *cis* AND *trans* DIBROMOETHYLENE, TRIBROMOETHYLENE, AND AN APPLICATION OF THE FREQUENCY SUM RULE[1]

By J. C. Evans[2] and H. J. Bernstein

ABSTRACT

Complete vibrational assignments have been obtained for tribromoethylene and *cis* dibromoethylene and thermodynamic functions calculated. Ten of the twelve fundamentals of *trans* dibromoethylene have been assigned and the approximate frequency of the missing pair evaluated by application of the frequency sum rule. The heat capacity of *trans* dibromoethylene has been calculated.

Satisfactory spectroscopic data exist for vinyl bromide (6) and 1,1-dibromoethylene (9), while the infrared active fundamentals of tetrabromoethylene below 300 cm.$^{-1}$ remain to be observed (11). Previous investigations did not enable complete vibrational assignments to be made for tribromoethylene, or for *cis* and *trans* dibromoethylene. The Raman spectrum of tribromoethylene has been obtained (15), but in the absence of values for the depolarization ratios only a very limited assignment was attempted. More extensive work has been done on the *cis* and *trans* dibromoethylenes (8, 10, 17), but for both molecules the assignments are incomplete.

In this investigation, the Raman spectra of the liquids with depolarization ratios and the infrared spectra of the liquids and their vapors were obtained for tribromoethylene and *cis* and *trans* dibromoethylene. Complete assignments for tribromoethylene and *cis* dibromoethylene, and an assignment of all but two modes (Raman inactive, infrared active lying below 250 cm.$^{-1}$) for the *trans* molecule, have been made.

EXPERIMENTAL

The sample of C_2HBr_3 (Eastman Kodak) was fractionally distilled under reduced pressure. A mixture of *cis* and *trans* $C_2H_2Br_2$ (Eastman Kodak) was redistilled and a partial separation of the isomers was achieved by fractional distillation with absolute alcohol (18).

A White photoelectric recording grating spectrometer (20) and a Perkin Elmer Model 12C double pass infrared spectrometer (LiF, CaF, NaCl, KBr, and CsBr optics) were used to obtain the spectra. Depolarization ratios were measured (7) and corrected for convergence error (16). The Raman spectra of liquid mixtures of *cis* and *trans* dibromoethylene were obtained at several temperatures between 0° and 85°C., the temperature variation of the *cis* $\rightleftharpoons$ *trans* equilibrium being sufficient over this range to enable the identification of the Raman bands of the *cis* and the *trans* species to be made. The spectra of the *cis*-enriched and the *trans*-enriched samples at room temperature made the identification unequivocal.

Under conditions of optimum resolution with the NaCl prism it was possible to resolve only partially the rotational structure of the perpendicular a_u band of *trans* dibromoethylene at 899 cm^{-1}. Complications from hot bands may account for this.

Figs. 1, 2, and 3, respectively, illustrate the Raman spectrum of the liquid, the infrared spectra of the liquid and solution, and the infrared spectrum of the

DISCUSSION

cis and trans Dibromoethylene

The assignments are consistent with the selection rules, the depolarization ratios, the vapor band contours,* and with the assignments for the corresponding chloroethylenes (5). The missing *trans* fundamentals, ν_7 and ν_{12}, lie beyond the CsBr prism limit but a rough estimate of their sum may be made from the vapor phase equilibrium data obtained by Noyes and Dickenson (14). For the equilibrium *cis* $\rightleftharpoons$ *trans*, these authors determined the heat of isomerization to be -130 ± 300 cal./mole. Assuming $\Delta E_0^\circ \approx 0\pm300$ cal./mole, and using the moments of inertia quoted in the footnote and the equilibrium constant at 158°C. of 0.98, it is found by a calculation analogous to that described for the chloroethylenes (5) that $\nu_7+\nu_{12} = 340\pm90$ cm^{-1}.

Another estimate of each missing frequency will be described below.

Tribromoethylene

The 12 fundamental modes are distributed between the symmetry species a' and a'' as $9a'+3a''$. The three depolarized Raman bands are assigned to the $3a''$ modes and, in the case of the highest and strongest ν_{10}, the infrared vapor band contour provides confirmation. The nine polarized a' modes fall readily into the approximate descriptions given in Table V.

**Assuming bond lengths for both cis and trans molecules: C=C = 1.34Å, C—Br = 1.84Å, C—H = 1.07Å, and all angles 120°, the following moments of inertia were determined: trans $I_A = 9.3$, $I_B = 1344$, $I_C = 1353$ gm. cm.$^2 \times 10^{-40}$ (approximates to a symmetric top); cis $I_A = 106$, $I_B = 679$, $I_C = 785$ gm. cm.$^2 \times 10^{-40}$; $S = -0.95$, $\rho = 5.6$ for the cis molecule(1).*

The Frequency Sum Rule

It has been shown that the frequency sum rule is applicable to the chloroethylenes (4) and that the five parameters of Table VI describe the relations between the sums adequately. Here n is the number of substituted halogen atoms in the series $C_2H_{4-n}H_n$. To apply the sum rule to the bromoethylenes

TABLE VI

n	Molecule	$\Sigma\nu$
0	C_2H_4	a
1	C_2H_3X	$a+b$
2	1 : 1—$C_2H_2X_2$	$a+2b+c$
2	*cis* $C_2H_2X_2$	$a+2b+d$
2	*trans* $C_2H_2X_2$	$a+2b+e$
3	C_2HX_3	$a+3b+c+d+e$
4	C_2X_4	$a+4b+2(c+d+e)$

the data given in Table VII have been used. Just as for the chloroethylenes the sum rule should apply to the in-plane modes and out-of-plane modes as well as for all the modes. In Table VIII the sums for *trans* dibromoethylene and C_2Br_4 have been calculated from the experimental sums for ethylene, vinyl bromide, *cis*- and *asym*-dibromoethylene and tribromoethylene. In this

		$+\nu_{10}+\nu_{12}$				

[a,b,c,d,e] *Same footnotes as in Table VII.*
[f] *From parametric equations.*
[g] *From linear plots.*

The frequency sum rule may be applied in a graphical manner and possibly less uncertain values may be obtained. From Table VI it is readily seen that the values of $\sum\nu$ for $n = 0$, 1, the average for $n = 2$, $n = 3$, and 4 lie on a parabola. The sums then for two homologous series such as the chloroethylenes $C_2H_{4-n}Cl_n$ and bromoethylenes $C_2H_{4-n}Br_n$ are given by two quadratic equations, viz.:

$$\sum\nu C_2H_{4-n}Cl_n = a+n\left(b-\frac{c+d+e}{6}\right)+n^2\left(\frac{c+d+e}{6}\right)$$

and

$$\sum\nu C_2H_{4-n}Br_n = a+n\left(b'-\frac{c'+d'+e'}{6}\right)+n_2\left(\frac{c'+d'+e'}{6}\right).$$

In general there will be a relation between $\sum\nu\ C_2H_{4-n}Cl_n$ and $\sum\nu\ C_2H_{4-n}Br_n$ of the type

$$\sum\nu\ C_2H_{4-n}Cl_n = A+B(\sum\nu\ C_2H_{4-n}Br_n)+C(\sum\nu\ C_2H_{4-n}Br_n)^2.$$

However, this will be linear if C, which is proportional to

$$[(c'+d'+e')/b']-[(c+d+e)/b],$$

is very small.

In the case of the above-mentioned series the three points corresponding to $n = 0$, 1, and 3 plotted for the sums of the chloro- and bromo-ethylenes lie within the experimental uncertainty on a straight line (Fig. 6). Similarly, straight lines are obtained from the plots of the in-plane and out-of-plane sums. Interpolation from the known value of the average of the sums of the three disubstituted chloroethylenes gives a value for the average of the three disubstituted bromoethylenes and extrapolation to the value for C_2Cl_4 allows the corresponding values for C_2Br_4 to be estimated.

In Table VIII the calculated sums for *trans* dibromoethylene and C_2Br_4 obtained from linear plots of corresponding sums are also shown. In Table IX

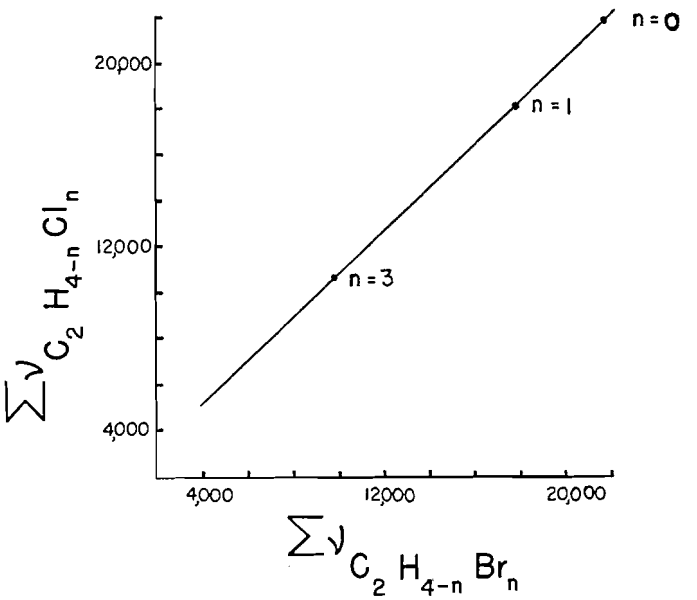

FIG. 6. Frequency sums (cm.$^{-1}$) of the chloro- and the bromo-ethylenes.

the calculated values for missing frequencies in these molecules have been collected. The usefulness of the sum rule for estimating low lying frequencies may be judged from the uncertainties for these values given in Table IX.

TABLE IX

CALCULATED MISSING FREQUENCIES

		From linear plots	From relations of Table VI	From equilibrium data	Mean value
trans $C_2H_2Br_2$	ν_7	154±30	194±63		164±50

[a] *Using the assignment for C_2Cl_4 given by Mann, Acquista, and Plyler (12). Somewhat different values are obtained if the assignment of Bernstein (2) is used.*

Thermodynamic Functions

The vibrational contributions were computed from tables by Miller, West, and Bernstein (13), while the formulae given by Rossini *et al.* (19) were used to determine the rotational and vibrational contributions. The moments of inertia of the dibromoethylenes have been quoted earlier. Using the same values for bond lengths and angles, the product of the moments of tribromoethylene was determined as $I_A I_B I_C = 1.210 \times 10^{-111}$ gm.^{3} cm^6.

TABLE X

CALCULATED THERMODYNAMIC FUNCTIONS

300	16.53	75.80	64.07
400	19.17	80.93	67.65
500	21.17	85.43	70.77
600	22.71	89.44	73.55
trans dibromoethylene as an ideal gas			
300	17.00		
400	19.40		
500	21.30		
600	22.80		

The thermodynamic functions have been given for a few temperatures only since liquid data have been used for many of the vibrational frequencies. Furthermore, only C°_p was calculated for *trans* dibromoethylene since large uncertainties arise in calculating the other thermodynamic functions from the uncertainties in the values for ν_7 and ν_{12}. It may be shown numerically that for two modes ν_a and ν_b, the contribution to the vibrational heat capacity from ν_a plus the contribution from ν_b is very nearly equal to twice the contribution from $(\nu_a+\nu_b)/2$ (at the same temperature). The best estimate for $\nu_7+\nu_{12}$, 320 cm.$^{-1}$, was used in the computation, and the error in C°_p is determined by the error in estimating $\nu_7+\nu_{12}$.

The results for the three molecules are given in Table X.

The authors have appreciated helpful correspondence with Professor M. de Hemptinne who has been investigating the vibrational spectra of *cis* and *trans* dibromoethylene and their deuterated analogues at the same time as the present work was done.

NOTES

THE SYNTHESIS OF ETHANOLAMINE-1-C^{14}

By D. E. Douglas and Anna Mary Burditt

Pilgeram *et al.* (4) have reported a synthesis of uniformly labelled ethanolamine-C^{14} from barium carbonate-C^{14} via acetylene and ethylene oxide, yielding di- and tri-ethanolamine as by-products.

We have synthesized ethanolamine-1-C^{14} from radiocyanide through the formation of (C^{14}-cyano)methyl benzoate (1, 3) and its subsequent reduction with lithium aluminum hydride to ethanolamine in 30% over-all yield. This method involves only two stages and yields solely primary amine. The reactions are as follows:

$$H_2O+HCHO+NaC^{14}N \rightleftarrows HOCH_2C^{14}N+NaOH$$

$$NaOH+HOCH_2C^{14}N+C_6H_5COCl \rightarrow C_6H_5COOCH_2C^{14}N+NaCl$$

$$C_6H_5COOCH_2C^{14}N \xrightarrow{LiAlH_4} C_6H_5CH_2OH+HOCH_2C^{14}H_2NH_2.$$

EXPERIMENTAL

(C^{14}-Cyano)methyl benzoate was prepared by the method of Aloy and Rabaut (1) on a semimicro scale as follows: To 0.154 gm. (2.9 mM.) of sodium cyanide-C^{14} (3.28×10^7 counts/min. total activity) in 0.5 ml. of water cooled in an ice-bath and stirred with a magnetic stirrer was added 0.24 ml. of 37% formalin (2.7 mM. of formaldehyde). After one hour, 0.30 ml. (2.6 mM.) of benzoyl chloride was added, and stirring at 0° C. continued three hours longer. After the addition of 3 ml. of 5% sodium bicarbonate, the reaction mixture was extracted continuously with ether for two to three hours. The ether extract was dried thoroughly, first over calcium chloride, then over Drierite.

The cyanomethyl benzoate was reduced without isolation by the gradual addition of the dried ether solution to 3.5 ml. of an ethereal solution of lithium aluminum hydride (approximately 2.6 mM. per ml.). The complex was decomposed by stirring with 30 ml. of water, added slowly, the ether was removed by evaporation, and the aqueous phase was saturated with carbon dioxide. The aluminum hydroxide was centrifuged off and washed thoroughly with several portions of hot water. The supernatant and washings were combined, 1 ml. of ethylene glycol monobutyl ether (2) and 5 ml. of 0.5 *N* sodium hydroxide added, and the ethanolamine and water removed by lyophilization and condensed into a trap cooled with dry ice – isopropyl alcohol. The residue remaining was taken up in water, 1 ml. of ethylene glycol monobutyl ether added, and lyophilization repeated. This process was carried out four times altogether. The ethanolamine was recovered as hydrochloride by evaporation

of the combined condensates from the cold trap with excess hydrochloric acid, and the salt recrystallized from isopropyl alcohol – ether. Yield: 0.0946 gm. (30.9%, based on sodium cyanide). The material was recrystallized for activity and melting point determinations. Specific activity: 132,000 counts per min. per mgm. Melting point: 79.8–82° C. Mixed melting point with authentic ethanolamine hydrochloride: 79.8–83° C.

Thirty-seven per cent of the initially added radiocyanide activity was found in the aqueous phase after ether extraction of the cyanomethyl benzoate.

To check the radiopurity, ethanolamine hydrochloride prepared by the above procedure was chromatographed on paper, with water-saturated phenol as the developing solvent. Radioautography indicated that the material was essentially free from radioactive contaminants. The R_f was 0.76.

A SELF PUMPING DROPPING MERCURY ELECTRODE FOR USE WITH STIRRED SOLUTIONS[1]

BY D. M. MILLER

The theory of polarography assumes the formation of a polarized layer around one electrode in an electrolysis cell. If through agitation of the solution this layer is disturbed the current passing through the cell is no longer diffusion dependent and the Ilkovic equation does not apply. Wilson and Smith (12) studied the effect of increasing flow rate of solution on the dropping mercury electrode (DME) and found first of all a deviation from diffusion controlled current and finally a complete disruption of the regular drop formation. By employing a slow rate of flow in a horizontal direction they were able to monitor continuously sulphur dioxide in industrial solutions by a polarographic method (13). This principle has been used by a number of workers (1, 11) while others have employed baffles (4, 5, 6, 7, 14) and some have even abandoned the ordinary DME in favor of the vibrating DME (2), or solid electrodes (3, 9, 10).

This paper describes a cell in which the DME is situated in a side arm and the solution is circulated past the electrode by the pumping action of the detached drops descending through a capillary. Basically the cell consists of a Lingane-Laitinen H cell (8) to which a side arm has been attached

A SELF PUMPING DROPPING MERCURY ELECTRODE FOR USE WITH STIRRED SOLUTIONS[1]

BY D. M. MILLER

The theory of polarography assumes the formation of a polarized layer around one electrode in an electrolysis cell. If through agitation of the solution this layer is disturbed the current passing through the cell is no longer diffusion dependent and the Ilkovic equation does not apply. Wilson and Smith (12) studied the effect of increasing flow rate of solution on the dropping mercury electrode (DME) and found first of all a deviation from diffusion controlled current and finally a complete disruption of the regular drop formation. By employing a slow rate of flow in a horizontal direction they were able to monitor continuously sulphur dioxide in industrial solutions by a polarographic method (13). This principle has been used by a number of workers (1, 11) while others have employed baffles (4, 5, 6, 7, 14) and some have even abandoned the ordinary DME in favor of the vibrating DME (2), or solid electrodes (3, 9, 10).

This paper describes a cell in which the DME is situated in a side arm and the solution is circulated past the electrode by the pumping action of the detached drops descending through a capillary. Basically the cell consists of a Lingane-Laitinen H cell (8) to which a side arm has been attached

[1]*Contribution No. 45, Science Service Laboratory, London, Ontario.*

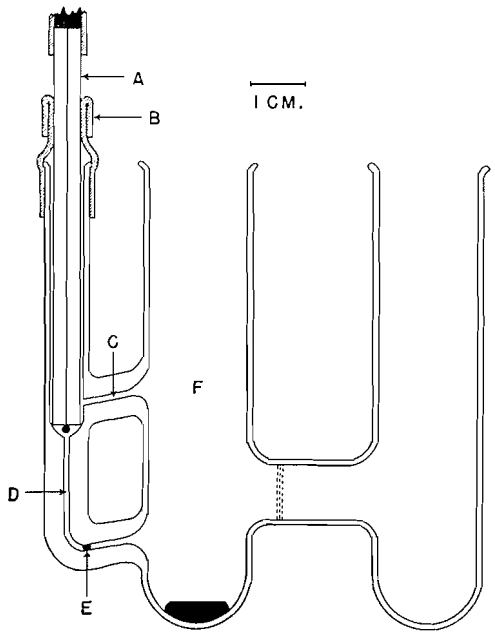

FIG. 1. Polarographic cell assembly.

as shown in Fig. 1. The DME capillary *A* is inserted through rubber tubing *B* into the top part of the side arm, the mercury drops falling into capillary *D*. The diameter of *D* is slightly smaller than that of the detached mercury drops (approximately one millimeter) so that the drop seals the capillary and forces the solution downward as it falls. This draws fresh solution into the side arm through *C* and because of the small volume of liquid in the side arm the solution is completely changed with every two or three drops. Each drop comes to rest at *E*, the lowest point in *D*, where it remains until forced out by the succeeding drop and thus temporarily seals the side arm against disturbances in the main body of the solution *F*. Since the drop descends to *E* in less than a second, the solution is in motion for only a short time at the beginning of each drop formation, and for drop times of four seconds or greater the effect on the polarogram is negligible.

To test the response of the DME to changes in solution composition, 10 ml. of a 0.1 *N* KCl solution saturated with air were placed in the cell and the polarogram recorded by a Sargent Model XXI Visible Recording Polarograph. The applied e.m.f. was constant at −0.75 v. vs. S.C.E., the sensitivity set at 0.030 μamp./mm., the damping switch in the off position, and the drop time 4.55 sec. The polarogram obtained under these and the following conditions is shown in Fig. 2. For the first minute the diffusion current due to oxygen is recorded. At point *L* a fritted glass gas dispersion tube was plunged into *F* and nitrogen bubbled through the solution at about 100 ml./min. The rapid drop in the oxygen concentration is indicated by the fall in the current between one and three minutes. Two drops of cadmium sulphate

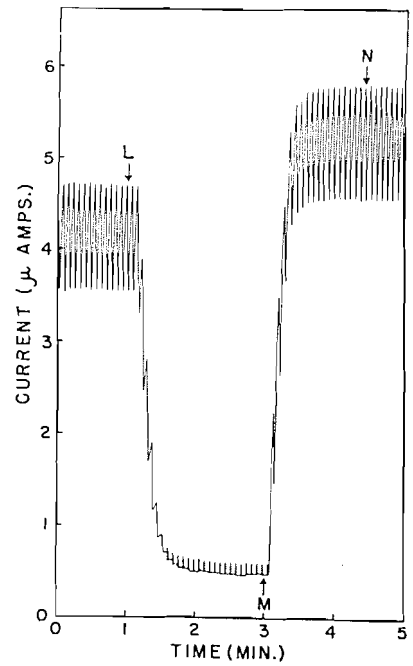

FIG. 2. Response of polarograph cell:
L—nitrogen bubbled through cell.
M—cadmium sulphate solution added.
N—bubbler withdrawn.

solution were introduced at *M* and the subsequent rise in current demonstrates a 98% response in 30 sec. following a change in concentration in *F*. At point *N* the dispersion tube was withdrawn with no visible effect on the polarogram.

The cell as depicted in Fig. 1 has proved very useful for general polarographic work. If clamped into a water bath and cleaned by suction it provides the added advantage that the position of the DME is fixed and reproducible. Certain precautions must be observed however in the building of this cell or design of other assemblies based on the same principle. The length of *C* must not be too great because of its high resistance (this was 1200 ohms in the cell used by the author with 0.1 *N* KCl as ground electrolyte). Further, the agitation in *F* must not be violent enough to cause vibration of the DME or to dislodge the mercury drop prematurely from its position at *E*. Actually, stirring by the means described here is preferable since it is thorough, smooth, and rapidly deoxygenates any added reagents. The DME is undisturbed by the gas flow, even to the point at which the solution foams over the top of the cell.

THE NATURE OF THE INTERACTION FORCES BETWEEN PARTICLES IN SUSPENSIONS OF GLASS SPHERES IN ORGANIC LIQUID MEDIA[1]

BY P. G. HOWE,[2] D. P. BENTON,[2] AND I. E. PUDDINGTON

ABSTRACT

Electrostatic agglomeration can be induced in suspensions of glass beads in organic liquid media. The stability of the agglomerates is markedly dependent on temperature. The influence of surface roughness and the presence of small quantities of water on the interparticle interaction is discussed. Assuming a simple model the observed relationship between yield value and particle size for systems containing the same concentration of solid phase is derived.

INTRODUCTION

The behavior of suspensions of solids in liquid media is of considerable importance owing to the numerous practical applications of systems of this type which exhibit non-Newtonian behavior. Basically, the behavior of such a system is determined by the interparticle interaction, which is, in turn, determined by the nature and composition of the supporting medium. Suspensions of inert solids in organic liquids have been investigated by a number of workers (5, 12) and the presence of small amounts of water as an immiscible liquid has recently been shown to be of profound importance (9, 10).

Eggleton and Puddington (4) investigated the effect of temperature on suspensions of glass beads in toluene containing various amounts of water. Although the suspensions containing large amounts of water behaved as expected, showing a minimum yield value below the freezing point of water, the anhydrous suspension and that containing 0.1% water showed an unexpected and steady increase in sedimentation volume and yield value as the temperature was lowered to $-60°$ C. This work is concerned with a further investigation of this phenomenon and a consideration of other factors involved in systems of this type.

EXPERIMENTAL

Glass beads, -275 mesh, were supplied by the Flexolite Manufacturing Corporation. The beads were fractionated dry in a current of air by means of an Aminco Roller Particle Size Analyzer. A fraction of average diameter 41 μ

was used in all experiments. Fig. 1 shows the distribution of bead sizes. This fraction was selected to conform with that of 43 μ obtained by Eggleton and Puddington by wet fractionation. The main impurity in the beads was a ferromagnetic dust, the bulk of which was removed by flowing the aqueous

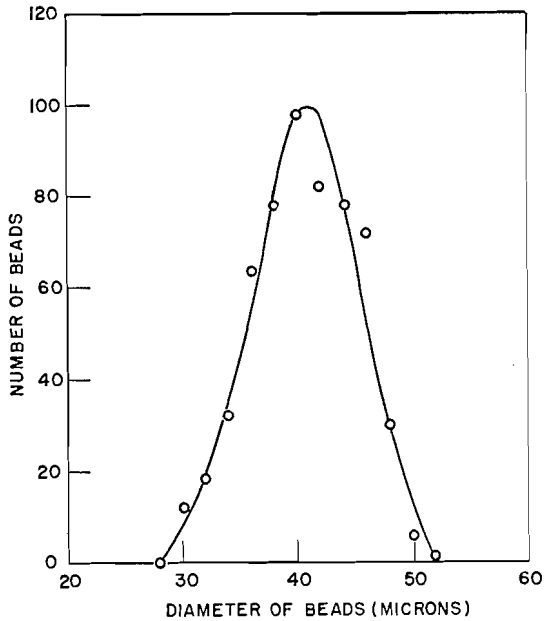

FIG. 1. Size distribution of glass beads.

suspension of beads through a glass tube placed between the poles of a powerful magnet. The beads were then cleaned in aqua regia and extracted with hot distilled water by decantation to remove acid. End washings were strongly alkaline and analysis of the supernatant liquor for Na and Ca showed considerable solution of the soft glass. It is possible that the glass beads used in similar work (4, 13) were considerably etched by solution of the glass. The beads were finally oven-dried before use.

The reagent grade organic liquids were purified as follows. Toluene was dried over calcium hydride and refluxed *in vacuo*. Chloroform was washed several times with distilled water, dried over silica gel, and refluxed *in vacuo*. Methyl alcohol was partially dried over calcium oxide, was distilled into a vacuum reservoir containing magnesium turnings, and after solution of the magnesium was degassed by refluxing *in vacuo*. The required amount of beads was weighed into a calibrated 12 mm. tube attached to the vacuum line. The glass beads were then baked out *in vacuo* at 350° C. until a stick vacuum in the McLeod gauge was obtained, and were allowed to cool. The required organic liquid was then further degassed by repeated distillation between two traps and finally distilled into the tube containing the beads. The tube was then immersed in liquid nitrogen and sealed off at a preformed constriction. A similar tube containing beads with no supporting liquid was also prepared.

Copper spheres, 100–200 mesh, were substituted for the glass spheres in one tube. These were reduced at 350° C. in an atmosphere of hydrogen and the water reaction product was frozen out in a liquid nitrogen trap. The system was then degassed at 350° C. and filled with toluene as described above.

RESULTS AND DISCUSSION

(*a*) *The Behavior of Glass and Copper Spheres in Anhydrous Media*

It was found that the sedimentation volume of the glass beads in toluene was a minimum (the same as for the beads *in vacuo*) and virtually independent of temperature, as long as the suspension was not subjected to too vigorous or sustained agitation. Observations were carried out in an air thermostat capable of regulation to 0.3° C. between room temperature and −60° C. Gentle agitation by inversion of the tube would eventually cause agglomeration and the time required was shortened to a few seconds by vigorous shaking. The maximum sedimentation volume so obtained (about 2 ml./gm. compared with about 0.67 ml./gm. minimum) also appeared to be independent of the temperature, but at room temperature the subsequent collapse of the settled agglomerate to the minimum volume was very rapid, whereas at lower temperatures the agglomerate appeared to be very stable and showed no tendency to collapse over periods of some six hours. Similar behavior was observed for the beads in chloroform but in methyl alcohol no increase in sedimentation volume was observed.

Gallay and Puddington (6) have shown that an attractive force between particles causes an increase in the sedimentation volume by preventing the close packing of the particles. It is apparent from the above observations that the agglomeration observed in the anhydrous toluene and chloroform is caused by the build-up of electrostatic charges which exert a strong attraction between the beads. The formation of the charges is probably owing to the collisions which take place between the beads during agitation or to the relative motion of the glass beads and the supporting liquid. The formation of electrostatic charges by the relative motion of two dielectrics is a well-known phenomenon. It appears that the presence of the liquid phase is important in that it allows for relative motion of the beads with respect to each other or to the liquid medium. The agitation of the glass beads *in vacuo* did not give any agglomeration since there is no resistance to flow.

The reduced copper spheres in anhydrous toluene showed no agglomeration at all from room temperature to −60° C. The resistance of the settled beads measured between two sealed-in tungsten electrodes about 1 cm. apart was less than 1 ohm. This value was obtained immediately after settling and did not alter with time of standing. An adsorbed layer of toluene would be expected to give an appreciably higher resistance since the resistance of the original oxide coated beads was of the order of 5 megohms.

The agglomeration of the glass beads in anhydrous toluene and chloroform and the absence of any such aggregation in anhydrous methanol can be considered in the light of the electrical conductivities of these liquids. Both toluene and chloroform are good dielectrics; toluene has a volume resistivity

of about 10^{-14} ohm-cm. whereas that of methanol is about 10^{-6}. No appreciable adsorption of toluene on glass would be expected but methanol should be chemisorbed and give a suitably conducting surface, thus preventing the formation of localized charge centers during agitation. At room temperature the surface conductance of the glass in toluene is apparently sufficient to cause a rapid collapse of the charged agglomerate.

It is surprising that the agglomerates are so stable at lower temperatures. At contact points the behavior of the liquid can be compared to that of a liquid in a capillary of molecular dimensions. The temperature coefficients of surface resistivity and of liquid viscosity in such a system are not known but are possibly of an order which will explain the observed properties. There is little doubt that adsorption energies and electroviscous forces in such a system are very high compared with normal bulk properties.

The copper beads in toluene showed no agglomeration, and in this case no *localized* charges are capable of existing on the surface of the bead. It should be noted that if the glass beads all possessed a uniform surface charge of the same sign, no agglomeration would be expected since the existence of a uniform surface potential would tend to stabilize a suspension by repulsion between the particles in the same way as an electrical double layer stabilizes aqueous suspensions. The glass beads may, however, possess *localized* surface charges all of the same sign, and agglomerate by electrostatic induction. Alternatively, the beads may possess both positive and negative localized surface charges which would cause the observed flocculation. The existence of a stable charge mosaic on the surface of glass has been suggested elsewhere (3).

The actual mechanism of the electrostatic agglomeration is important in connection with the stabilization of suspensions of inert materials in organic liquid media. Garner and co-workers (7) have shown that an electrical charge is present at the surface of particles of carbon black dispersed in organic liquids and that the particles may be either positive or negative according to the nature of the supporting medium. Toluene was found to give a negatively charged suspension and chloroform a positively charged one. It is possible that this phenomenon and that of the electrostatic agglomeration of the glass beads are related and the same basic phenomenon may cause both stabilization and agglomeration of a suspension according to the nature of the suspended material. When this is sufficiently conductive the charge will distribute itself over the whole surface and stabilization of the suspension will result. The stability of a double layer on a conducting particle of this type may be owing to the seat of the charge not being confined to the periphery of the solid but being smeared out throughout the whole particle. In the case of the glass suspensions, charges may be localized at points on the surface and the adsorption of oppositely charged solvent molecules could take place at other surface locations.

The electrostatic agglomeration of the beads is not affected by small amounts of water although this is more apparent below 0° C., when the water is frozen out on the beads. However, the indication is that the electrostatic behavior is inherent in such suspensions and is not owing to the presence of ionic im-

purities. Suspensions of various materials in organic and aqueous solutions in which the particles are capable of hydrogen bonding with the liquid medium are generally stabilized against flocculation (8). Thus, suspensions of copper sulphide in water and ether are stabilized by the addition of hydrogen sulphide which allows for such bonding to occur. Such bonding would also be expected in suspensions of glass beads in methanol and water and, in fact, these suspensions do not flocculate. However, it might also be expected that in such systems stabilization is brought about by the formation of a continuous double layer on the surface owing to the adsorption of one of the ionic dissociation products of the stabilizing medium.

(*b*) *Minimum Sedimentation Volumes*

The settled volumes of the glass spheres in various liquids are shown in Table I. The minimum volumes are the same in methanol, toluene, water, and

TABLE I

MINIMUM SEDIMENTATION VOLUMES OF GLASS SPHERES IN DIFFERENT LIQUIDS

Supporting medium	Sedimentation volume, ml./gm.		
	Settled under gravity	Tapped down while settling	Centrifuged
Water	0.67	0.67	0.67
Methanol	0.66	0.66	—
Vacuum	—	0.68	—
Toluene	0.67	0.67	—
Chloroform*	0.70	0.70	—

**Higher values in chloroform may be due to small amounts of decomposition products of the chloroform.*

in vacuo indicating that electrostatic agglomeration is absent. In all these cases it is to be noted that the minimum volume is well above that expected for a closest packing of the spheres and since the spheres cover a small but definite fraction range it would be expected that the close packed volume would be still smaller. Table II shows the void fraction for various theoretical types of packing (2) of uniform spheres.

Taking a density of 2.32 for soft glass and 0.67 ml./gm. as the minimum sedimentation volume observed, the calculated porosity is about 0.36. This lies between the orthorhombic and tetragonal-sphenoidal porosities and

TABLE II

THEORETICAL CLOSE PACKING OF PERFECT SPHERES (2)

Packing orientation	Porosity*	Contacts per sphere
Cubic	0.476	6
Orthorhombic	0.395	8
Tetragonal-sphenoidal	0.302	10
Rhombohedral	0.260	12

**Porosity = volume of void space per total volume.*

corresponds to about 9 contacts per sphere compared with the theoretical maximum of 12 contacts per sphere. This may well be the closest packing which can be obtained experimentally but no dilatancy is apparent and there is some evidence that all these suspensions possess a small residual yield value, which would prevent closer packing owing to the force of interaction between the beads. This might be due to a small London – van der Waals interaction between the beads.

(*c*) *The Influence of Water and Surface Roughness*

For suspensions of glass beads in toluene the results of Eggleton and Puddington show that the influence of the electrostatic effect is still apparent in the presence of small amounts of water below a certain concentration. The behavior of the beads with 0.1% water is the same as in the anhydrous suspensions between −60° C. and +30° C., but with 0.28% water only weak electrostatic forces are apparent below 0° C. This is probably owing to the surface roughness of the beads. Preferential adsorption of water would be expected in the surface depressions leaving the surface peaks exposed. Localized charge build-ups would then be able to take place at these peaks. This is in keeping with general electrostatic phenomena.

With 0.28% water the surface depressions will be filled leaving only a few high points exposed. Below 0° C. only weak electrostatic forces are present and the yield value is low. Above 0° C. enough of the surface is covered with water to allow some water necks to form between some of the beads, which causes the yield value to increase sharply. However, the yield value falls off quickly as the temperature is raised owing to the increasing solubility of water in the toluene. The small apparent residual yield value obtained with larger amounts of water below 0° C. might be attributed to a small residual electrostatic effect on a better conducting ice surface or, since surface discontinuities will have been smoothed out by filling the depressions with water, it might also be attributed to increased London – van der Waals forces.

The B.E.T. area of the water-etched beads was shown by Thompson (13) to be as much as 21 times the value for unetched beads. This corresponds to a monolayer coverage by about 0.04% water. At 0.28% water, where coverage is practically complete, about seven monolayers would appear to be sufficient to fill up the surface depressions. Assuming that the volume of the depressions is equal to the volume of the peaks, an approximate mean height of the surface peaks can be estimated as being equal to the thickness of a film of water composed of 14 monolayers, i.e., *ca.* 50 Å. This is probably a low estimate but indicates that the maximum surface irregularities may be of the order of 100 Å.

(*d*) *Yield Value of Suspensions Containing Water*

The high maximum yield value and the large sedimentation volumes of inert suspensions containing water immiscible with the organic liquid medium are owing to the formation of water "necks" between the particles. Bloomquist and Shutt (1) related the sedimentation volumes of glass spheres in various organic liquids to their interfacial tension against water. Those with the largest values gave the largest sedimentation volumes. Kruyt and van Selms (9,

10) found that the yield value of starch and quartz suspensions in organic liquids depended on the care taken in drying the materials and the amount of water subsequently added.

McFarlane and Tabor (11) have shown that the force between a bead and a plate owing to the neck of liquid between them is given by the expression

$$F = 4\pi R\gamma \cos\alpha \quad [1]$$

where F is the force in dynes, R the radius of the bead, γ the interfacial tension, and α the contact angle. The equation applies strictly only for small amounts of water and when the contact angle is very small, but, essentially, for small amounts of water the adhesion is independent of the amount of water in the neck. It has been observed by the present authors that as the water in the neck is increased to large amounts, the adhesion decreases somewhat.

For the adhesion between two spheres the same equation will hold where γ is the interfacial tension between water and the organic liquid. For quartz suspensions Kruyt and van Selms (9, 10) have shown that the yield value is constant over the range 2–12% water and then begins to fall off until the point is reached where the quartz and water separate out as a second phase. This behavior is consistent with that expected for the adhesion between the beads. Below 2% water, where the sigmoid characteristic of the yield value versus water content appears, several factors probably account for the shape of the curve. This could be influenced, for example, by the solubility of water in the organic liquid, the extent of adsorption of water from the organic liquid when below saturation, or the filling of surface discontinuities by water and the consequent continuous increase in neck formation up to the maximum possible.

Kruyt and van Selms also showed that for the same concentration of solid phase the maximum yield value is inversely proportional to the radius of the spheres. They arrived at a relationship between the yield value and the water content of the suspension by calculating the *work* required to separate a pair of glass beads with a known quantity of water in the neck joining them. Eggleton and Puddington noted that the yield value has the dimensions of a force, rather than of work, and that the adhesion between the beads is the important factor.

The observed proportionality between particle size and yield value can be derived by considering the following simple model. Systems in which the interparticle interaction is strong will form a continuous network in the supporting medium composed of chains of particles. The force required to break down this network and cause flow is the yield value of the suspension. Consider an ideal system of uniform spheres which interact strongly when supported in a liquid medium. Let a unit volume of the system contain x chains, each of which is composed of n spheres of radius r. For two such systems containing the same weight of solid but with spheres of radius r_1 and r_2, then the ratio of the total numbers of spheres in the two systems is given by

$$n_1x_1/n_2x_2 = r_2^3/r_1^3. \quad [2]$$

The ratio of the chain lengths is given by

[3] $$n_1 r_1 = n_2 r_2.$$

Combining equations [2] and [3] gives the ratio of the number of chains

[4] $$x_1/x_2 = r_2^2/r_1^2.$$

For any plane of the same area intersecting the volume element the number of chains cutting the plane will be Px where P is some constant allowing for the random orientation of the chains. Therefore, the ratio of the number of chains intersecting such a plane is given by

[5] $$Px_1/Px_2 = r_2^2/r_1^2.$$

The yield value θ is assumed to be proportional to the force across the plane, i.e., the force required to break all the chains intersecting the plane. The force F required to break any one chain will be the force between any two beads in the chain. From equation [1] it is seen that the maximum force between two beads of radius r with a connecting water neck is given by $F = 4\pi r\gamma \cos\alpha$, i.e., $F \propto r$. It follows therefore that

[6] $$\theta_1/\theta_2 = F_1 Px_1/F_2 Px_2 = r_2/r_1.$$

Thus for the same concentration of solid phase, the yield value is inversely proportional to the radius of the spheres, which is the experimentally observed proportionality.

THE REACTION OF NITRAMINES WITH HYDROCHLORIC ACID[1]

By A. F. McKay, W. G. Hatton, and M. Skulski

ABSTRACT

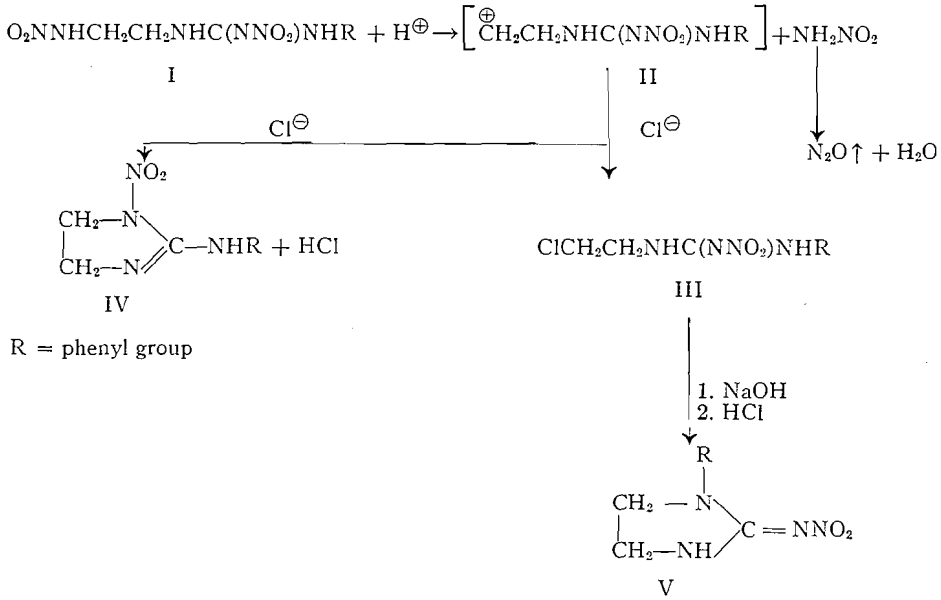
A facile process for the conversion of N-(β-nitraminoethyl)-N′-substituted-N″-nitroguanidines into the reactive N-(β-chloroethyl)-N′-substituted-N″-nitroguanidines has been developed. N-(β-Nitraminoethyl)-N′-phenyl-N″-nitroguanidine on standing in concentrated hydrochloric acid solution gives a mixture of N-(β-chloroethyl)-N′-phenyl-N″-nitroguanidine and 1-nitro-2-phenylamino-2-imidazoline. N-(β-Chloroethyl)-N′-diethyl-N″-nitroguanidine, which is prepared in a similar manner, is unstable at room temperature and it slowly cyclizes to give 1-nitro-2-diethylamino-2-imidazoline. Some new nitroguanidine derivatives formed from the reaction of amines with methylnitrosonitroguanidine also are described.

It was previously (2) shown that alkyl nitramines in dilute acid solutions decomposed to give alkyl cations. Thus methylnitramine in dilute hydrochloric acid solution gave a 50% yield of methyl chloride from the reaction of the intermediate methyl cation with the chloride ion. The mechanism of this reaction indicated the possibility of substituting the chloro group for a nitramino group in good yield by treating an aliphatic nitramine with an excess of concentrated hydrochloric acid. This assumption was realized (8) with N-β-nitraminoethyl-N′-nitroguanidine on treatment with concentrated hydrochloric acid when a 92.6% yield of the expected N-β-chloroethyl-N′-nitroguanidine was obtained. Since this reaction provided a simple method of obtaining the reactive and highly substituted N-β-chloroethyl-N′-nitroguanidines, it was investigated further.

N-(β-Nitraminoethyl)-N′-phenyl-N″-nitroguanidine (I) in concentrated hydrochloric acid solution gave a 74.2% yield of N-(β-chloroethyl)-N′-phenyl-N″-nitroguanidine (III). The filtrate after neutralization in the cold with sodium hydroxide solution gave a 20.4% yield of 1-nitro-2-phenylamino-2-imidazoline (or the tautomeric 1-nitro-2-phenyliminoimidazolidine) (IV). These products are easily explained on the basis of the formation of an intermediate alkyl cation II as shown below. The similarity of the reactions depicted here to those previously outlined for the reaction of acetyl chloride with N-(β-nitraminoethyl)-N′-substituted-N″-nitroguanidines (4, 7, 9, 10) will be apparent. As stressed before (7) the main reason for the complexity ascribed to some of the acetyl chloride – nitramine reactions was the variety of products isolated. Some of these products undoubtedly arose from secondary reactions during the involved isolation procedures. The products from the reaction of the N-(β-nitraminoethyl)-N′-substituted-N″-nitroguanidine with concentrated hydrochloric acid solution can be separated with ease, which eliminates this difficulty.

The structure of N-(β-chloroethyl)-N′-phenyl-N″-nitroguanidine (III) was

[1]*Manuscript received March 21, 1955.*
Contribution from Defence Research Chemical Laboratories, Ottawa, Ontario, and L. G. Ryan Research Laboratory of Monsanto Canada Limited, Ville LaSalle, Quebec. Issued as D.R.C.L. Report No. 140.



confirmed by its infrared spectrum and by its conversion to the known 1-phenyl-2-nitriminoimidazolidine (V) (12). 1-Phenyl-2-nitriminoimidazolidine was previously (12) referred to as the tautomeric 1-phenyl-2-nitramino-2-imidazoline. The reason for this change in nomenclature has been discussed recently (13).

A more highly substituted compound N-(β-nitraminoethyl)-N′-diethyl-N″-nitroguanidine also was allowed to stand at room temperature in hydrochloric acid solution. The product from this reaction melted at 96–97° C. and it was identified as N-(β-chloroethyl)-N′-diethyl-N″-nitroguanidine by analysis and by its chemical properties. When N-(β-chloroethyl)-N′-diethyl-N″-nitroguanidine was heated with water it cyclized to 1-nitro-2-diethylamino-2-imidazoline. The latter compound was isolated as its picrate. On standing in a vial the crystalline N-(β-chloroethyl)-N′-diethyl-N″-nitroguanidine changed into a viscous oil with entrained gas bubbles. This oil was dissolved in water and then treated with a saturated solution of picric acid. A 69% yield of 1-nitro-2-diethylamino-2-imidazolinium picrate was obtained. Thus the original crystalline N-(β-chloroethyl)-N′-diethyl-N″-nitroguanidine cyclized on standing at room temperature. The presence of gas bubbles in the viscous oil suggests that some decomposition also occurred.

Some new nitroguanidine derivatives have been prepared by the reaction of amines with methylnitrosonitroguanidine (6, 14). These are described in the Experimental section.

EXPERIMENTAL[2]

N-Methyl-N-nitroso-N′-nitroguanidine

This compound (m.p. 118° C. with decomp.) was prepared as previously described (11).

[2]*All melting points were taken on a Kofler block. Microanalyses by Micro-Tech Laboratories, Skokie, Illinois.*

N-Acetyl Ethylenediamine

N-Acetyl ethylenediamine was prepared by the method of Hill and Aspinall (1, 5). Ninety-five per cent ethylenediamine (570 gm., 9.0 moles) was mixed with 264 gm. (3.0 moles) of ethyl acetate and left at room temperature for eight days. The ethyl alcohol and excess amine were removed by distillation *in vacuo*. The residue on distillation *in vacuo* gave 233.3 gm. (69.9%) of N-acetyl ethylenediamine, b.p. 99–103° C. (0.5 mm.). This distillate soon solidified after which it melted at 49.5° C. The melting point given in the literature (5) is 51° C. The residual solid (62.6 gm.) in the distillation flask melted sharply at 173–174.5° C. after one crystallization from 95% ethanol (2.4 cc./gm.). A melting point of 175° C. is given in the literature (5) for N,N′-diacetyl ethylenediamine.

N-(β-Acetylaminoethyl)-N′-nitroguanidine

To 32.7 gm. (0.032 mole) of monoacetylethylenediamine in 35 cc. of water was added portionwise 15.7 gm. (0.0107 mole) of methylnitrosonitroguanidine over a period of 25 min. During the addition period the temperature was held at 22–27° C. A creamy-white solid separated which was removed by filtration and washed with water, yield 11.24 gm. (56.2%). One crystallization from 95% ethanol (9 cc./gm.) raised the melting point from 134° C. to 150.5–151.5° C. Calc. for $C_5H_{11}N_5O_3$: C, 31.75; H, 5.82; N, 37.03%. Found: C, 31.54; H, 5.87; N, 37.28%.

Monocarbethoxyethylenediamine

Monocarbethoxyethylenediamine (b.p. 135–137°C. (23 mm.); ($n_D^{24.8}$ 1.455; $d_4^{24.8}$ 1.029) was prepared in 40% yield by the method of Moore *et al.* (15).

N-(N-Carbethoxy-β-aminoethyl)-N′-nitroguanidine

To 7.5 gm. (0.0568 mole) of monocarbethoxyethylenediamine in 30 cc. of water was added gradually with stirring 2.79 gm. (0.019 mole) of methylnitrosonitroguanidine over a period of 32 min. During the addition period and an additional half hour of stirring, the temperature was held at 30–35° C. The white solid (m.p. 165.0° C.) was removed by filtration and washed with water, yield 3.34 gm. (80.2%). One crystallization from absolute ethanol (44.3 cc./gm.) raised the melting point to 165.5° C. Calc. for $C_6H_{13}N_5O_4$: C, 32.88; H, 5.93; N, 31.96%. Found: C, 33.05; H, 6.22; N, 32.22%.

N-(β-Nitraminoethyl)-N′-diethyl-N″-nitroguanidine

Five grams (0.029 mole) of 1-nitro-2-nitriminoimidazolidine were covered with 20 cc. of diethylamine and then allowed to stand at room temperature for three days. This reaction mixture was acidified and then placed in the refrigerator for two days. The crystals were removed by filtration and washed with ether and ethanol, yield 3.05 gm. (43.1%). Two crystallizations from 95% ethanol raised the melting point from 133–135° C. with decomposition to 152.5° C. with decomposition. The Franchimont test using dimethylaniline was negative. Calc. for $C_7H_{16}N_6O_4$: C, 33.85; H, 6.45; N, 33.85%. Found: C, 33.86; H, 6.48; N, 33.81%.

N-(β-Nitraminoethyl)-N'-phenyl-N''-nitroguanidine

N-(β-Nitraminoethyl)-N'-phenyl-N''-nitroguanidine (m.p. 139.5–140.5° C.) was prepared in 96% yield as previously described (10).

Reaction of N-(β-Nitraminoethyl)-N'-phenyl-N''-nitroguanidine with Hydrochloric Acid Solution

N-(β-Nitraminoethyl)-N'-phenyl-N''-nitroguanidine (4.97 gm., 0.018 mole) was suspended in 10 cc. of concentrated hydrochloric acid solution and left at room temperature for 48 hr. After the reaction mixture was diluted with 10 cc. of water, it was placed in the refrigerator for 12 hr. The crystals (m.p. 101–102° C., resolidified at 112° C. and then decomposed at 160–163° C.) were removed by filtration and washed with water, yield 3.245 gm. (74.2%). Two crystallizations from methanol at room temperature by the addition of water increased the melting point to 112–113° C. with resolidification at 117–118° C. and decomposition at 160–163° C. Calc. for $C_9H_{11}Cl\,N_4O_2$: C, 44.54; H, 4.56; Cl, 14.62; N, 23.09%. Found: C, 44.75; H, 4.65; Cl, 14.92; N, 22.80%. This product possessing a double melting point was further identified as N-(β-chloroethyl)-N'-phenyl-N''-nitroguanidine by cyclization to the known 1-phenyl-2-nitriminoimidazolidine (12). N-(β-Chloroethyl)-N'-phenyl-N''-nitroguanidine (500 mgm., 0.002 mole) was refluxed for one minute with 117 mgm. (0.0027 mole) of potassium hydroxide in 2 cc. of 95% methanol. On cooling, colorless crystals (m.p. 164–168° C.) separated, yield 394 mgm. (92.7%). One crystallization from 95% methanol raised the melting point to 168–168.5° C. The melting point was unchanged on admixture with an authentic sample of 1-phenyl-2-nitriminoimidazolidine (m.p. 168–169° C.).

The mother liquor from the N-(β-chloroethyl)-N'-phenyl-N''-nitroguanidine gave 140 mgm. of the original N-(β-nitraminoethyl)-N'-phenyl-N''-nitroguanidine (m.p. 138–139° C.). The latter compound was identified by a mixed melting point determination with an authentic sample of N-(β-nitraminoethyl)-N'-phenyl-N''-nitroguanidine (m.p. 139.5–140.5° C.).

The original filtrate from the first crop of crystals on neutralization with 10% sodium hydroxide solution gave 602 mgm. (20.45%) of crystals (m.p. 129–130° C.). One crystallization from ethanol raised the melting point to 138–139° C. (m.p. 132.5–133.5° C. by the capillary method). This compound gave a deep green color with dimethylaniline in the Franchimont test (3). Calc. for $C_9H_{10}N_4O_2$: C, 52.42; H, 4.89; N, 27.17%. Found: C, 52.49; H, 4.99; N, 27.00%. This compound gave a picrate (m.p. 146–147° C.) when treated in the usual manner, yield 80.5%. This picrate was identified as 1-nitro-2-phenylamino-2-imidazolinium picrate by a mixed melting point determination with an authentic sample (10).

Reaction of N-(β-Nitraminoethyl)-N'-diethyl-N''-nitroguanidine with Hydrochloric Acid Solution

N-(β-Nitraminoethyl)-N'-diethyl-N''-nitroguanidine (5.0 mgm., 0.020 mole) was covered with 15 cc. of concentrated hydrochloric acid solution and left at room temperature for 19 hr. The clear solution was diluted with one volume of water and then placed in the refrigerator for several hours. During neutral-

ization of the cold solution with 10% sodium hydroxide solution, colorless crystals separated, yield 2.53 gm. (53.51%). Another 534 mgm. (total yield 66.39%) of crystalline material was obtained from the mother liquor on evaporation. The melting point (96–97° C.) of the crude material was not changed by crystallization from absolute methanol. Calc. for $C_7H_{15}ClN_4O_2$: C, 37.76; H, 6.74; Cl, 15.94; N, 25.18%. Found: C, 38.02; H, 6.66; Cl, 16.15; N, 25.00%.

A sample (377 mgm., 0.0015 mole) of this N-(β-chloroethyl)-N′-diethyl-N″-nitroguanidine was converted to 1-nitro-2-diethylamino-2-imidazoline by refluxing for 15 min. with 10 cc. of water. The aqueous solution on addition of a saturated aqueous picric acid solution gave a yellow picrate, yield 337 mgm. (47.9%). The picrate melted at 128.5° C. Calc. for $C_{13}H_{17}N_7O_9$: C, 37.58; H, 4.12; N, 23.60%. Found: C, 37.43; H, 4.01; N, 23.20%.

The crystalline N-(β-chloroethyl)-N′-diethyl-N″-nitroguanidine changed into a viscous liquid containing gas bubbles on standing for a few weeks at room temperature. A sample (207 mgm., 0.0009 mole) of this oil gave a 69.9% yield of the picrate melting at 128.5° C. on treatment with an alcoholic solution of picric acid. This picrate did not depress the melting point of the above-described picrate of 1-nitro-2-diethylamino-2-imidazoline.

THE STRUCTURE OF MONO-*O*-METHYLENE- AND DI-*O*-METHYLENE-D-GLUCOSE[1]

By W. P. Shyluk, John Honeyman, and T. E. Timell

ABSTRACT

The structure of 1,2-*O*-methylene-α-D-glucofuranose has been proved by preparing the 3,5,6-trimethanesulphonate and the 3,5,6-tri-*p*-toluenesulphonate derivatives of this compound from the corresponding derivatives of 1,2-*O*-isopropylidene-α-D-glucofuranose. The results also constitute an additional proof for the recently established structure of the 1,2;3,5-di-*O*-methylene-α-D-glucofuranose.

Brownell (1), who was interested in proving the structure of di-*O*-methylene-D-glucose, obtained by its partial hydrolysis a crystalline, non-reducing mono-*O*-methylene-D-glucose. Before his work was completed, however, Schmidt, Distelmaier, and Reinhard (5) established the constitution of the di-*O*-methylene derivative. The present study of the structure of mono-*O*-methylene-D-glucose also confirmed that for the di-*O*-methylene derivative deduced by Schmidt *et al.*

The presence of a furanose ring and the location of the methylene group in the 1,2-position in mono-*O*-methylene-D-glucose were shown by the following reaction sequence. Treatment of 1,2-*O*-isopropylidene-α-D-glucofuranose[2] (I) with methanesulphonyl chloride gave the trimethanesulphonate (II), which had previously been prepared by Helferich and Gnüchtel (2). The isopropylidene group was replaced by a methylene group giving 1,2-*O*-methylene-α-D-glucofuranose 3,5,6-trimethanesulphonate (III), identical with the compound obtained by esterification of mono-*O*-methylene-α-D-glucofuranose (IV). Similarly, 1,2-*O*-isopropylidene-α-D-glucofuranose was converted into 1,2-*O*-methylene-α-D-glucofuranose 3,5,6-tri-*p*-toluenesulphonate, also obtained directly from mono-*O*-methylene-D-glucose.

The above results also prove the structure of the di-*O*-methylene-D-glucose. Hough, Jones, and Magson (3) have shown that the hydroxyl group on C_6 is free. Since one methylene group is in the 1,2-position and there is a furanose ring, the second methylene group must be in the 3,5-position.

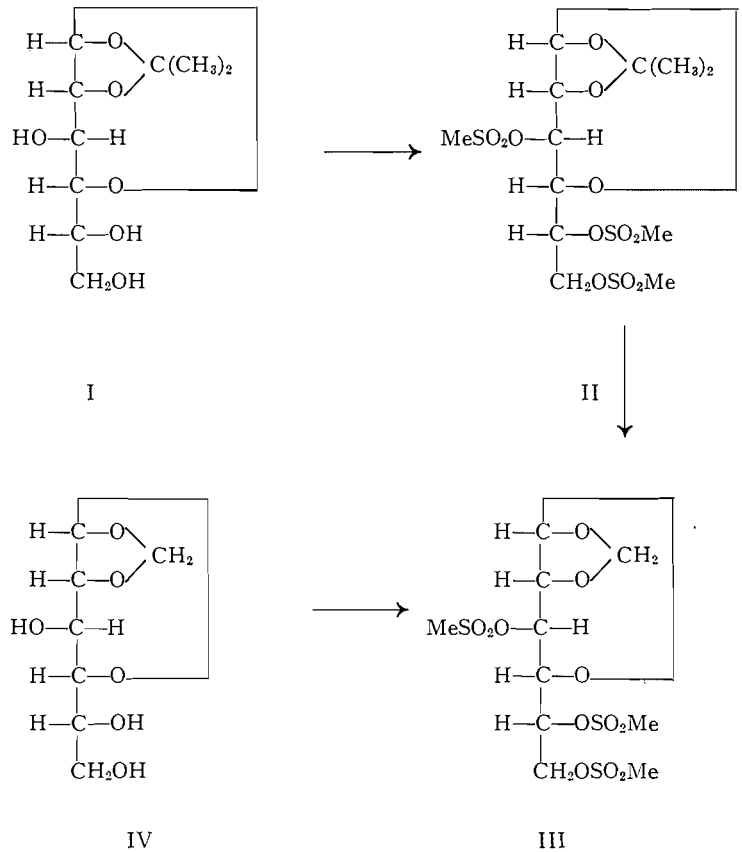
Ohle and Wilcke (4) prepared the 3,5,6-tri-*p*-toluenesulphonate from 1,2-*O*-isopropylidene-α-D-glucofuranose and from its 3-*p*-toluenesulphonate in 15 and 30% yields, respectively. In the present study, preparation of the tri-*p*-toluenesulphonate has been found to present no inherent difficulty, since direct esterification of 1,2-*O*-isopropylidene-α-D-glucofuranose gave the triester in a yield of 82% after one recrystallization from ethanol.

EXPERIMENTAL

1,2;3,5-Di-O-methylene-α-D-glucofuranose

Di-*O*-methylene-D-glucose was obtained by deacetylation with barium methylate in methanol of the di-*O*-methylene-D-glucose 6-acetate, which was

[1]*Manuscript received March 25, 1955.*
Contribution from the Division of Industrial and Cellulose Chemistry, McGill University, and the Wood Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Quebec.
[2]*The more likely α configuration is assumed throughout.*



prepared according to the method of Hough *et al.* (3). The sirup was crystallized and its melting point and specific rotation were identical with those reported by Schmidt *et al.* (5).

1,2-O-Methylene-α-D-glucofuranose

A solution of 1,2;3,5-di-*O*-methylene-α-D-glucofuranose, 13.0 gm., in 2.0% aqueous hydrochloric acid, 175 ml., was kept at 100° C. for one hour, then deacidified by passage through a column of anion exchange resin (Amberlite IR-4B) and evaporated *in vacuo* to 42 ml. The neutral solution was extracted eight times with 70-ml. portions of ethyl acetate and evaporated *in vacuo* to a sirup, 2.73 gm. Glucose was removed by fermentation of its aqueous solution with baker's yeast for 36 hr. at 30° C., after which Super-Cel was added and the mixture was filtered. The clear filtrate was deionized with Amberlite IR-4B and Amberlite IR-120 exchange resins and concentrated *in vacuo* to a sirup, 1.95 gm., which partly crystallized on standing. The crystalline material weighed 0.24 gm. and melted at 145–146° C. Recrystallization from 1.5 ml. of ethanol gave pure 1,2-*O*-methylene-α-D-glucofuranose, m.p. 147–148° C., $[\alpha]_D^{22}$ −6.2° (*c*, 1.2 in water). Calc. for $C_7H_{12}O_6$: C, 43.8; H, 6.30%. Found:

C, 43.7; H, 6.21%. The material was non-reducing to the copper reagent of Shaffer and Somogyi (6).

Crude di-*O*-methylene-D-glucose, 6.8 gm., was recovered by evaporation of the first four ethyl acetate extracts. The other four extracts were evaporated *in vacuo* to a sirup, 3.6 gm., which was dissolved in 10 ml. of water and extracted twice with 10-ml. portions of ethyl acetate. The glucose was removed by fermentation and the solution evaporated to a sirup, which was dissolved in a small amount of ethanol and seeded with pure 1,2-*O*-methylene-α-D-glucofuranose, crystallization occurring slowly at room temperature. The crude material was recrystallized from ethanol to yield 0.09 gm. of 1,2-*O*-methylene-α-D-glucofuranose, m.p. 147–148° C. The total yield of the mono-*O*-methylene-D-glucose was 0.34 gm. or 5.8% of theory.

1,2-O-Isopropylidene-α-D-glucofuranose 3,5,6-Trimethanesulphonate

Monoacetone glucose, 4.4 gm., was dissolved in 9 ml. of pyridine with slight heating, after which methanesulphonyl chloride, 5.5 ml., was added and the mixture cooled while shaking. After 42 hr. at room temperature a few drops of water were added to the reaction mixture followed after 15 min. by a few more drops. An additional amount of water, 30 ml., was added after some time, at which point the sirup crystallized while the mixture was being stirred. The crude product amounted to 8.0 gm., corresponding to a yield of 90.5%. The material was recrystallized twice from chloroform and *n*-pentane at room temperature to give 6.3 gm. of 1,2-*O*-isopropylidene-α-D-glucofuranose 3,5,6-trimethanesulphonate, m.p. 162.5–163.5° C., $[\alpha]_D^{22}$ −20.4° (*c*, 1.8 in pyridine). Helferich and Gnüchtel report m.p. 165° C., $[\alpha]_D$ −24.2° in pyridine for this compound.

1,2-O-Isopropylidene-α-D-glucofuranose 3,5,6-Tri-p-toluenesulphonate

Monoacetone glucose, 4.4 gm., was dissolved in 10 ml. of pyridine and 16 gm. of *p*-toluenesulphonyl chloride was added gradually while cooling, after which the mixture was kept at room temperature for four days. Water was added dropwise with cooling and stirring; the thick sirup crystallized while being ground in a mortar with more water. The crystals were collected and washed with water. The crude product weighed 14.1 gm., m.p. 118–123° C. Recrystallization from ethanol at room temperature gave 1,2-*O*-isopropylidene-α-D-glucofuranose 3,5,6-tri-*p*-toluenesulphonate, 11.1 gm., in 81.6% yield, m.p. 129–130° C., $[\alpha]_D^{22}$ −4.3° (*c*, 1.4 in chloroform). Ohle and Wilcke (4) report m.p. 129° C., $[\alpha]_D$ −5.4° in chloroform for this compound.

Conversion of 1,2-O-Isopropylidene-α-D-glucofuranose 3,5,6-Trimethanesulphonate into the Methylene Analogue

Paraformaldehyde, 2.75 gm., and 1,2-*O*-isopropylidene-α-D-glucofuranose trimethanesulphonate, 2.5 gm., were dissolved in 10 ml. of glacial acetic acid by heating on a steam bath. Concentrated sulphuric acid, 0.75 ml., was slowly added and the reaction mixture kept on a steam bath for 80 min. Water, 20 ml., was added to the cooled reaction mixture, which was subsequently extracted twice with 20-ml. portions of chloroform. The combined chloroform solut-

ions were washed with 20 ml. of water, then another 20-ml. portion of water, to which solid sodium bicarbonate was added until no more reaction was evident. After further washing with two 20-ml. portions of saturated aqueous sodium bicarbonate and three 20-ml. portions of water, the chloroform solution was dried over anhydrous sodium sulphate and concentrated *in vacuo* at 50°C. to a partially crystallized sirup. Crystallization from chloroform and *n*-pentane gave 1,2-*O*-methylene-α-D-glucofuranose 3,5,6-trimethanesulphonate, 1.4 gm. in 60% yield, m.p. 92.5–100° C. Two more recrystallizations from the same solvents yielded 0.8 gm. of a pure product, m.p. 104.5–105.5° C., $[\alpha]_D^{22}$ −13.4° (*c*, 1.4 in pyridine). Calc. for $C_{10}H_{18}O_{12}S_3$: C, 28.3; H, 4.24%. Found: C, 27.8; H, 4.18%.

Conversion of 1,2-O-Isopropylidene-α-D-glucofuranose 3,5,6-Tri-p-toluenesulphonate into the Methylene Analogue

Paraformaldehyde, 2.75 gm., and 1,2-*O*-isopropylidene-α-D-glucofuranose 3,5,6-tri-*p*-toluenesulphonate, 2.5 gm., were suspended in 10 ml. of glacial acetic acid and the mixture cooled in an ice-bath. Concentrated sulphuric acid, 0.75 ml., was slowly added and the mixture was kept on a steam bath for 80 min. The product was isolated as described for the trimethanesulphonate and amounted to 2.1 gm. in 84% yield, m.p. 120–128° C. after one recrystallization from chloroform and *n*-pentane at room temperature. Two more recrystallizations from the same solvents gave 0.8 gm. of 1,2-*O*-methylene-α-D-glucofuranose 3,5,6-tri-*p*-toluenesulphonate, m.p. 134.5–135° C., $[\alpha]_D^{22}$ +9.8° (*c*, 1.2 in chloroform). Calc. for $C_{28}H_{30}O_{12}S_3$: C, 51.4; H, 4.59%. Found: C, 51.3; H, 4.47%.

1,2-O-Methylene-α-D-glucofuranose 3,5,6-Trimethanesulphonate

Methanesulphonyl chloride, 0.2 ml., was added to a solution of 0.152 gm. of 1,2-*O*-methylene-α-D-glucofuranose in 0.32 ml. of pyridine and the mixture was kept at room temperature for 40 hr. Excess mesyl chloride was decomposed by addition of a few drops of water. After the addition of 2 ml. of water, the sirup crystallized while being stirred; the solid, after washing with two 2-ml. portions of water, amounted to 0.32 gm. Two recrystallizations from chloroform and *n*-pentane at room temperature gave 1,2-*O*-methylene-α-D-glucofuranose 3,5,6-trimethanesulphonate, 0.16 gm., m.p. 106–107° C., $[\alpha]_D^{22}$ −12.8° (*c*, 1.3 in pyridine). No depression of melting point was detected when this material was mixed with the product from the replacement of the isopropylidene by a methylene group in 1,2-*O*-isopropylidene-α-D-glucofuranose 3,5,6-trimethanesulphonate.

1,2-O-Methylene-α-D-glucofuranose 3,5,6-Tri-p-toluenesulphonate

p-Toluenesulphonyl chloride, 0.55 gm., was slowly added to a solution of 1,2-*O*-methylene-α-D-glucofuranose, 0.15 gm., in 0.35 ml. of pyridine. The solution was allowed to stand at room temperature for three days, after which a few drops of water were added to decompose the excess tosyl chloride. The sirup was stirred with 2.5 ml. of water and the crystals formed were separated and again treated with 2.5 ml. of water. The crude product, 0.50 gm., was recrystallized twice from chloroform and *n*-pentane to yield 0.18 gm. of

1,2-*O*-methylene-α-D-glucofuranose 3,5,6-tri-*p*-toluenesulphonate, m.p. 135.5–136° C., $[\alpha]_D^{22}$ +10.0° (*c*, 1.4 in chloroform). No depression of the melting point was noted when this material was mixed with the product from the replacement of the isopropylidene group by a methylene group in 1,2-*O*-isopropylidene-α-D-glucofuranose 3,5,6-tri-*p*-toluenesulphonate.

ACKNOWLEDGMENT

The authors wish to express their gratitude to Professor C. B. Purves, Head of this Division, for his kind interest in the present study.

REACTIONS OF ARYLSULPHONIC ESTERS

II. THE ALKYL GROUP[1]

By P. M. Laughton[2] and R. E. Robertson

ABSTRACT

As part of the project outlined in Paper I of this series, we report kinetic data, including Arrhenius parameters, for the solvolysis of a number of alkyl benzene- and toluene-sulphonates in ethanol and in water. The alkyl groups include the α- and β-methylation series: methyl, ethyl, isopropyl, *n*-propyl, isobutyl, and neopentyl; the straight chain series *n*-butyl and *n*-amyl; and a small group of oxygen-containing chains. The observed rates for the α-methylation series parallel those for the bromides and nitrates, and for the β-methylation, those for the bromides. However, it is evident that current interpretations of rate differences observed in the straight chain and oxygenated series cannot be applied with confidence to the benzenesulphonates since the changes in the Arrhenius parameters are larger than the observed differences in the rate.

In connection with our survey of the behavior of alkyl arylsulphonates in solvolysis, we have examined the effect of changing the structure of the alkyl group. Since this work was undertaken, Winstein's laboratory has reported data on many alkyl groups, mostly in acetic acid and in formic acid and from the point of view of rearrangements. Our work is chiefly concerned with nucleophilic solvents—water and alcohols—and with less complicated alkyl groups.

In particular we hope to be able to characterize the system

$$ROH + ArSO_3R' \rightarrow R{-}O{-}R' + ArSO_3H$$

sufficiently comprehensively that our data may be used in an attack on the problem of the detailed picture of solvent participation in this apparently very simple reaction.

The analysis of the mechanism of displacement reactions has reached a point where most of the large rate-controlling effects have yielded to a semi-quantitative treatment. Hammett's (17) free energy relationship, $\log k/k^\circ = \rho\sigma$, where σ is a measure of the relative effect of substituents in rigid molecules, has recently been extended by Swain (33) to some nucleophilic displacement reactions in the aliphatic series, $\log k/k^\circ = sn$, where s is a measure of the sensitivity of substrate to the nucleophility of the attacking agent. Swain also points out that this equation and that of Winstein, Grunwald, and Jones (39) $\log k/k^\circ = Ym$ (where Y = "solvent ionizing power") may both be special cases of the more general case, $\log k/k^\circ = sn + s'e$, where s' is a measure of substrate sensitivity to electrophilicity in a generalized termolecular displacement. Even the very difficult problem of steric effects seems to be approaching quantitative treatment (cf. Dostrovsky, Hughes, and Ingold (10); Newman (26); Brown (4); Taft (35), among many others).

This leaves as a major unknown variable the problem of the detailed participation of the medium. While an approach to this problem can be made by considering the solvent as a bulk dielectric, this can only be a first approximation. Taft (34) and Evans and Hamann (13) have interpreted relative rates using the concept of interference with solvation by groups about the reaction site. Yet, as Swain (33) comments, few precise kinetic data are available for treating the effect of different solvents on relative rates of substrates. A further complication is that most of the data available, for solubility reasons, are in a variety of mixed solvent systems. Also, much of the work has been reported at single temperatures because, in the words of Ingold (19, pp. 255–56), as "kinetic effects become smaller, the first quantity to show unintelligible irregularities is the Arrhenius energy of activation".

While we are by no means certain what lines of attack will solve the problem of solvent participation, we hope that our consistent body of kinetic data may provide information useful in this respect. We are certainly going to exercise due caution about attaching any simple significance to small differences in activation energy (19); however, we are sanguine enough to provide temperature coefficients in the hope that what we cannot ourselves interpret may prove useful to others.

RESULTS AND DISCUSSION

α-Methylation Series

The survey reported here covers a number of alkyl groups of recurring interest in other systems. Since this work was undertaken, two communications from Tommila's laboratory have appeared, dealing with some of these systems (37, 38). Table I shows relative rates and Arrhenius parameters ($k = pZ\,e^{-E_A/RT}$) for the series of increasing α-methylation in ethanol and water. (We also (11, 37) have found *t*-butyl sulphonates too unstable for isolation.) This series shows the minimum at the ethyl compound to be expected (19, pp. 317–18) for a shift in mechanistic category from S_N2 toward S_N1. It is noteworthy that the increased rate for the isopropyl derivative in both solvents is due to a more favorable entropy term which outweighs an increase in activation energy. One factor which should result in a more positive entropy for isopropyl is the probability that the solvent is more highly ordered about the initial state, in which ionic contributions to the structure are favored. This increase would, however, have to be larger than any corresponding change in ordering about the more nearly ionized transition state.

In water the anticipated shift towards S_N1 is apparent, the ethyl compound drawing up to the methyl, and isopropyl greatly increasing.[3] These relationships are dealt with in detail in the previous paper in this series (28) in which the benzenesulphonates are compared with the bromides and the nitrates.

β-Methylation Series

The second series of wide interest is that of β-methylation. Table II records

[3]*That the solvolysis of the primary esters must be stereochemically S_N2 is, however, established by the elegant work of Streitwieser on active butanol-1-d p-Br benzenesulphonate (J. Am. Chem. Soc. 77: 1117. 1955).*

our data in ethanol and water for the series ethyl, *n*-propyl, isobutyl, and neopentyl.

**The "errors" reported for the Arrhenius energies of activation may be partially attributed to the ΔC_p of activation for these systems, which is of the order of 30 cal./mole degree in water (29). For example, such a C_p would be equivalent to a curvature of ±0.4 kcal./mole for a 25° range. Known or estimated ΔC_p's are capable of accounting for most of the small discrepancies between our work and the Arrhenius parameters recently reported by Tommila et al. (37, 38).*

**Tosylate.* ***Extrapolated.*

In alcohol we see again the slight jump of about 1 kcal./mole in activation energy for the isobutyl derivative, followed by the large jump of 7 kcal./mole for the neopentyl compound, as noted before in the case of the bromides (10).

Winstein (40, 41) shows that changing the solvent from ethanol through acetic acid to formic acid steadily increases the rate of neopentyl tosylate, indicating a cationic intermediate in all three. He also presents evidence for some anchimeric participation by the β-methyls. This probable difference in mechanism together with the possibility that solvent may assist the ionization by an attack on the β-carbon discourages detailed speculation about the rise in the entropy factor. The possible explanation for the similar increase with isopropyl, based on a more polar initial state, is not available for this compound.

The neopentyl tosylate was prepared in order to check the data of Winstein (40, 41) but the benzenesulphonate was used for the work in water because of solubility difficulties. Winstein's value for the solvolysis of neopentyl tosylate in alcohol touches our two-temperature Arrhenius plot, although his extrapolated value at 75° implies a somewhat different activation energy.

The relative rates for our series in water at 60° (Me: Et: *i*Bu: NeoPen: :10: 9.6: 2.2: 1.0) are similar to the corresponding series for the tosylates in acetic acid (10: 9.1: 2.8: 1) although there is a difference in rate between the two series of more than three powers of ten. Since there is also a difference in the range of activation energies (9 kcal./mole in acetic acid and $4\frac{1}{2}$ kcal./mole in water) one must recognize that the similarity in relative rate sequences here results from fortuitous choice of temperatures for comparison.

Straight-chain Series

Because of the appearance, among the more usual monotonously decreasing rate series (13; 19, p. 319), of the occasional report of straight-chain anomalies in the butyl–pentyl region, we have also examined the series: methyl, ethyl, propyl, butyl, and pentyl in both ethanol and water. Data are recorded in Tables III and IV. Adsorption effects, which begin to become important at very low solubilities (*ca.* 0.0002 *M* for the pentyl compound), have impeded an extension of the series in water. *n*-Hexyl benzenesulphonate in water, on the basis of less precise data, (judging from scatter in the Guggenheim rate plots) solvolyzes more slowly than *n*-pentyl.

There is a minimum rate at propyl in water, but the differences both in rates and in activation parameters are very small. We have no explanation for this minimum which could be generalized for other cases, some of which show peculiar fluctuations.

For example, the following orders of reactivity may be found in the literature for primary amines: Me > Et < Pr < Bu < Pen (5); Me < Et > Pr < Bu < Pen (5); Me > Et > Pr < Bu > Pen (1, 22). Brown (5) has suggested that a break in the series should occur for the first member for which the free rotation of the end of the chain is reduced or increased by changes at the reaction site in the product or transition state. This concept by itself implies

a vertical displacement at the critical chain length in an otherwise monotonously increasing or decreasing series, an effect which seems intuitively reasonable although its order of magnitude is difficult to evaluate, especially in a condensed phase. However, this cannot be the whole story where the series passes through a minimum as it does in the case of Table IV, or where the curve has a zig-zag character (13).

Anomalies similar to our own have been reported for displacements by ions. Segaller's (31) results for the displacement of alcoholic phenoxide on alkyl iodides show a dip at pentyl. Crowell's (9) work on the attack of alcoholic thiocyanate on alkyl bromides shows a rise to octyl from a minimum at butyl. McKay (23) also found a minimum at butyl for the iodide exchange reaction, pentyl being slightly faster than propyl. On the other hand, the data of Conant and Hussey (6) for iodide displacement on chlorides in acetone show upward displacements in a decreasing curve at pentyl and octyl.

Oxygen-containing Alkyl Groups

Because of the peculiarity reported by Rabinovitch and Schramm (27) for the alkaline hydrolysis in aqueous acetone of β-ethoxyethyl acetate (k_2 twice that for ethyl acetate, but E_A 15.4 kcal./mole versus 11.7 for the ethyl ester), we examined several β- and γ-substituted derivatives in alcohol.[4] All three compounds, β-ethoxyethyl, γ-ethoxypropyl, and β-carbethoxyethyl *p*-toluenesulphonate were an order of magnitude *less* reactive than the simple alkyl esters. (The β-chloroethyl and β-cyanoethyl compounds also reacted very slowly, but the second functional group in each reacted at comparable rates.) However, the activation energies are slightly lower than others in the series, the drop in rate arising from the entropy factor.

This decrease in rate corresponds to that noted for solvolysis of β-ethoxyethyl chloride in aqueous dioxane versus butyl (2), and the very slow solvolysis of β-ethoxyethyl iodide in water (21) as compared with ethyl iodide. In this latter note (21) and in an earlier paper from the same laboratory (8), the suggestion made by Hinshelwood, Laidler, and Timm (18) is used to relate the polar effect of substituents on the heat of activation in displacement reactions. Although this relation should hold only for ΔH_A^0, not for ΔH_A^T, these authors base their discussion on a value of E_A for methyl iodide in water, a reaction which has the large ΔC_p of -67 cal./mole degree (15), and one for ethyl iodide which is in doubt because of a side reaction (25). Further, they assume that the only changes in E_A that are significant arise from polar effects of the substituents, although whatever changes in the ordering of solvent are responsible for the large changes in $\Delta S^{\ddagger}$ must surely make substantial concomitant contributions to E_A.

Although both electron-releasing (12, 14) and electron-withdrawing (3) substituents may facilitate S_N2 displacements by anions, evidently those involving neutral molecules are hindered by electron-withdrawing groups. One might expect the electrophilicity of the carbon undergoing substitution to be more important for the weaker nucleophilics.

EXPERIMENTAL

Materials

Properties of the esters are given in Table V. Methyl and ethyl benzenesulphonate were purified as used by fractional freezing of Eastman Kodak

[4]*We later became aware of the paper by Salmi and Leimu (30) reporting data for the acetates and a number of other esters in pure water and aqueous dioxane. In both solvents the rate of the Cellosolve esters is again roughly twice that of the ethyl esters, but activation energies calculated from their rates are only about 1 kcal./mole higher for the β-ethoxyethyl esters.*

white label material. β-Cyanoethyl and β-ethoxycarbonylethyl *p*-toluenesulphonate were prepared according to the published methods (32). The remaining esters were synthesized by the Tipson method (36) using the appropriate alcohols. Of the alcohols, propyl, isopropyl, butyl, isobutyl, methoxyethyl, ethoxyethyl, β-cyanoethyl, and β-chloroethyl were refractionated from the best available commercial products. All liquid esters were repurified before each series of runs by redistillation from a molecular still, giving colorless products.

γ-Ethoxypropyl alcohol was prepared by reduction of refractionated Eastman Kodak β-ethoxypropionaldehyde with either lithium aluminum hydride or hydrogen and Raney nickel catalyst. After fractionation under reduced pressure its properties correspond to those given by Karvonen (20). The alkoxyalkanols were redistilled just before use because of peroxide formation.

Since analytical grade *n*-pentyl alcohol proved to be a mixture on fractionation, both it and neopentyl alcohol were prepared by Grignard reactions with formaldehyde (7), using *n*-butyl bromide and *t*-butyl chloride respectively.

n-Hexyl alcohol, d_{20}^{20} 0.8178, n_D^{20} 1.4159, was purified from Eastman Kodak practical grade by repeated recrystallization of the *p*-hydroxybenzoate, m.p. 52.0–2.8°, (from petroleum ether) followed by saponification and fractionation.[5]

Ethanol was purified by distillation from sodium and diethyl phthalate (24). Conductance water was prepared by passing distilled water through an Amberlite MB-1 mixed bed resin.

Methods

The work in alcohol as a solvent was done as described in Paper I (28).

In water, rates were followed by conductance methods to be described in Paper III of this series. The Guggenheim method of treatment of data was

[5]*This purification was carried out by Mr. A. Rayner of Carleton College.*

used (16). Precisions recorded in the tables are within runs for the work in ethanol and between runs for the work in water.

For the work in alcohol, temperature was controlled to ±0.01–0.02 C.° using tenth degree thermometers calibrated by the Heat Section of the Division of Physics. For the conductance work, temperature was controlled to ±0.001–0.003 C.°, measured by a platinum resistance thermometer and a Leeds and Northrup G-1 Mueller bridge.

We were initially disturbed by the fact that ethyl benzenesulphonate in water gave a consistently higher value by conductance than by titration according to Tommila's procedure (38). However, there appeared to be appreciable hydrolysis of the ester during the titration. Accordingly, we carried out a titration run in an early model of a continuous titration device. This result confirmed that obtained by conductance. Except for the least soluble esters, adsorption did not appear to interfere with the conductance measurements, since results were indistinguishable for the variety of sizes and shapes of cells which were used in many of the runs. For the *n*-butyl and the pentyl esters, cells with small surface to volume ratios had to be used.

ACKNOWLEDGMENT

Thanks are due to Mr. P. Tymchuck and to Mr. A. Relf for careful technical assistance in the course of this investigation.

A NEW METHOD FOR THE PREPARATION OF D-ERYTHROSE AND OF L-GLYCERALDEHYDE[1]

By A. S. Perlin and Carol Brice

ABSTRACT

D-Glucose is degraded selectively to di-*O*-formyl-D-erythrose by oxidation with two moles of lead tetraacetate. The ester groups are easily hydrolyzed, giving D-erythrose in an over-all yield of at least 80% of theory. In like manner oxidation of L-arabinose, followed by hydrolysis, affords L-glyceraldehyde. It is suggested that D-erythrose can readily associate intermolecularly, a property previously ascribed among sugars only to the trioses.

INTRODUCTION

Among monosaccharides the tetroses constitute probably the most poorly characterized group. Only one preparation of a crystalline tetrose, that of D-threose, has been reported (6), but subsequent investigations by Hockett (9, 10) and Hockett *et al.* (11) have cast serious doubt on the identity of this preparation. The current importance of the tetroses is illustrated by the use of D-erythrose as a starting point for synthesis of 2-deoxy-D-ribose (20, 29) and of ribose-1-C^{14} (7, 18).

At least seven methods for preparing D-erythrose are recorded in the literature. Five of these have been evaluated by Overend, Stacey, and Wiggins (20), who recommended the Ruff procedure (26) as modified by Hockett and Hudson (12), and two additional methods have since been reported (30, 25, 16, 14). All of these procedures involve degradation of an appropriate sugar derivative—the acid, glucal, acetal, or mercaptal—which, however, is itself sometimes not obtained readily or in good yield. This communication now reports a convenient preparation of D-erythrose in high yield directly from D-glucose.

When aldohexoses are treated with lead tetraacetate they rapidly consume two moles of oxidant, after which the reaction becomes very slow (13, 24). Applied to D-glucose it is found that the initial rapid stage of the reaction corresponds to virtually complete conversion of the hexose to D-erythrose. With one mole of oxidant, D-arabinose as well as D-erythrose is obtained (23). The oxidation is carried out in acetic acid solution by the addition of two moles of the powdered oxidant per mole of glucose. Removal of the divalent lead and distillation of the solvent affords a clear, colorless sirup, in 90 to 95% yield, which exhibits the properties of a diformate ester of D-erythrose (24). The ester groups are easily hydrolyzed by heating in water or dilute acid, giving a product which has an equilibrium specific rotation of about $-30°$ and which is uncontaminated by hexose or pentose sugars (paper chromatogram). The infrared absorption spectrum of the free sugar, using the potassium bromide

[1]*Manuscript received March 28, 1955.*

window technique (27), is identical with that of D-erythrose prepared from 4,6-*O*-ethylidene-D-glucose (25), and gives no indication of the presence of other compounds. The compound has been further characterized as D-erythrose by hydrogenation to erythritol, by oxidation with bromine to D-erythrono-γ-lactone, and by preparation of the crystalline 2,5-dichlorophenylhydrazone.

On paper chromatograms the new preparation of D-erythrose and the sample prepared from ethylidene glucose behave in identical fashion but show complex properties. For example, each gives a single equally-fast-travelling spot when the solvent is ethyl acetate/acetic acid/water (3/1/3) (15), but in butanol/ethanol/water (4/1/5) (2) much streaking from the origin almost to the solvent front is observed. When an aqueous solution of either preparation is frozen, then thawed, and examined on the chromatogram with the use of methyl ethyl ketone/water (4), at least two spots are found, the major component having an R_f of 0.22 and the other remaining close to the origin. The proportion of slow-moving component is, however, less if the solution is first heated on the boiling-water bath before chromatographing. This behavior may be related to gross changes in optical rotation which have been observed when a solution of the sugar is frozen and thawed. Thus, a solution of D-erythrose having an equilibrium specific rotation of $-31°$, after freezing for 18 hr. and thawing, had a specific rotation of about $-6°$, reverting to the original value during a period of four hours at room temperature. The specific rotation changed to $+2°$ when the solution was stored in the frozen state for 48 hr. These results suggest that D-erythrose in solution readily enters into loose intermolecular association possibly with formation of a dimer or other complex. Such behavior has long been recognized with glyceraldehyde (35), but appears not to have been reported for tetroses. The observed mutarotation changes might therefore correspond to a polymer ↔ monomerfuranose interconversion together with attainment of an α,β-anomer equilibrium for the latter. Perhaps this complexity in part accounts for the wide variation in specific rotations reported for erythrose, such as $-14.5°$ for the D-isomer and $+32.7°$ for the L-isomer (33). Further, the tendency of D-erythrose to associate or dimerize may explain why attempts to crystallize the compound have been unsuccessful.

Pentoses also quickly consume two moles of lead tetraacetate and it was therefore to be expected, by analogy with hexoses, that the degradation should yield the corresponding triose. D-Glyceraldehyde, first prepared by Wohl and Momber (34), is readily obtainable through the elegant method of Fischer and Baer (5), which involves periodate or lead tetraacetate oxidation of 1,2;5,6-di-*O*-isopropylidene-D-mannitol, and, more directly, through the procedure recently reported by Schöpf and Wild (28) in which D-glucose is oxidized with three moles of periodate. By contrast, L-glyceraldehyde is not as easily obtained since the methods just noted require the corresponding but rare L-sugars. Thus Baer and Fischer (2) prepare L-glyceraldehyde from 1,2;5,6-di-*O*-isopropylidene-L-mannitol which is first synthesized from L-arabinose *via* the cyanohydrin reaction and reduction. With lead tetraacetate oxidation, however, L-arabinose is degraded directly to L-glyceraldehyde in high yield. As with D-erythrose the product is recovered from the reaction as

a sirupy formate ester (24), which yields the free glyceraldehyde upon hydrolysis in water or dilute acid. The compound gives an elongated spot on the chromatogram (ethyl acetate/acetic acid/water solvent) with a rate of travel slightly smaller than D-erythrose, possibly due to its existence as a dimer. Traces of arabinose and erythrose were detected in some preparations. The butanol solvent causes much streaking of material on the chromatogram and several spots are discernible, but these are attributed at present to the various modifications possible for glyceraldehyde (2). It will be remembered that erythrose also behaved atypically with this solvent. The equilibrium specific rotation of the compound in water, $[\alpha]_D^{25}$ $-7°$, is close to the value of $+9°$ reported for a freshly-prepared solution of the D-isomer (3). The relatively high purity of the preparation is indicated by the fact that it gave a 73% yield of the L-glyceraldehyde dimedon, which agreed well with the yield of 75% obtained by Baer and Fischer from pure L-glyceraldehyde (2). The product was characterized further as the crystalline 2,4-dinitrophenylhydrazone.

Since oxidation of other aldohexoses and aldopentoses by lead tetraacetate parallels the foregoing oxidations, it is seen, for example, that D-threose may readily be prepared directly from D-galactose and D-glyceraldehyde from D-xylose. A description of their preparation is included in another communication (24), which considers the mechanism of the lead tetraacetate oxidation of reducing sugars.

EXPERIMENTAL

Lead tetraacetate was prepared according to the procedure of Vogel (31). A commercial sample (Matheson Co., Inc.) was also used. All other chemicals were reagent grade.

Spray reagents used for chromatography were triphenyltetrazolium chloride (32), silver nitrate (21), and aniline (22).

Solutions were concentrated *in vacuo* at 35° C.

*Di-O-formyl-*D*-erythrose*

D-Glucose (1.50 gm., 8.3 mM.) dissolved in 3 ml. of water was taken up in 150 ml. of glacial acetic acid. Lead tetraacetate[2] (7.7 gm., 17.4 mM.) was added over a period of three to four minutes to the rapidly stirred solution. Within five minutes' reaction time the lead tetraacetate had dissolved and the solution gave a faint potassium iodide – starch test. Oxalic acid dihydrate (1.9 gm.), dissolved in glacial acetic acid, was added,[3] and the suspension was stirred for an additional 30 min. The precipitate was filtered and washed with acetic acid and the filtrate was concentrated to a volume of a few milliliters. Ethyl acetate was added and the precipitate which formed was triturated with several portions of ethyl acetate. The extracts were combined, filtered, and concentrated to a sirup which was further purified twice by extraction with ethyl acetate. The product was a clear, pale yellow oil. Weight, 1.30 gm. This

[2]*If the compound was dark it was recrystallized before use from acetic acid. Or, it was dissolved in glacial acetic acid and the solution was filtered and added to the glucose solution.*

[3]*Excess lead tetraacetate was thereby decomposed and the divalent lead precipitated.*

compound, which is described in greater detail elsewhere (24), is found to contain two formate ester groups.

D-*Erythrose*

Di-*O*-formyl-D-erythrose (0.201 gm.) was dissolved in 20 ml. of 0.05 *N* hydrochloric acid (a slight turbidity was removed by filtering) and the solution was heated at 50° C., the hydrolysis being followed polarimetrically: $[\alpha]_D$ +0.55° (initial) → −0.40° (two hours, constant). The reducing power of the hydrolyzate, measured by hypoiodite oxidation (8), was equivalent to 0.122 gm. of tetrose (91%); $[\alpha]_D^{27}$ −32.7°. Acid was removed by use of a column (1 cm. × 10 cm.) of Amberlite IR4B resin with some loss of reducing power. The calculated weight of D-erythrose was 0.114 gm., an over-all yield from D-glucose of 80% of theory. $[\alpha]_D^{27}$ −30.0° (equilibrium) (*c*, 0.64).

Erythritol

Di-*O*-formyl-D-erythrose (1.0 gm.) was dissolved in absolute alcohol (40 ml.) and was hydrogenated at ambient temperature and pressure using reduced platinum oxide catalyst (1). Fifty milliliters of hydrogen was taken up, corresponding approximately to one mole per mole of erythrose, and the solution was then only faintly reducing to Fehling's solution. The catalyst was filtered and the filtrate concentrated to a colorless sirup which quickly crystallized. After washing with alcohol and drying the product weighed 0.25 gm. (73%); m.p. 114–116° C. Recrystallization from alcohol raised the melting point to 118° C.; the mixed melting point with an authentic specimen of erythritol (m.p. 118.5° C.) was 118–118.5° C. The X-ray diffraction pattern was identical with that of erythritol.

D-*Erythrono-γ-lactone*

Barium carbonate (10 gm.) was suspended in an aqueous solution of D-erythrose (2.0 gm. in 30 ml.), and bromine (3.4 ml.) was added dropwise with stirring. After three hours' reaction time excess bromine was removed by aeration, and there were added in succession silver carbonate to remove bromide, hydrogen sulphide gas to remove excess silver, and dilute sulphuric acid to precipitate excess barium. The final colorless solution was concentrated, giving a sirup which solidified when dried in high vacuum at 60° C. Weight, 1.3 gm. (65%). After one recrystallization from alcohol, m.p. 103–104° C., $[\alpha]_D^{27}$ −72.1° (*c*, 1, water); (m.p. 103° C., $[\alpha]_D$ −73.3° (26)).

D-*Erythrose 2,5-Dichlorophenylhydrazone*

D-Erythrose sirup (0.44 gm.), prepared by concentrating an aliquot of the neutral solution described above, was taken up in 20 ml. of methanol in an evaporating dish. 2,5-Dichlorophenylhydrazine (0.65 gm.) was added and the methanol was rapidly distilled on the steam bath (procedure of Mandl and Neuberg (17)). The product was dissolved in ether, filtered, and the ether was distilled. The residue was dissolved in ethyl acetate, treated with charcoal, and an equal volume of benzene was added. Crystallization was rapid in the cold. Weight, 0.68 gm. (68%), m.p. 101–105° C. Recrystallized twice from

ethyl acetate – benzene (1: 1), m.p. 110–112° C., $[\alpha]_D^{27}$ −12.5° (*c*, 1, methanol). (m.p. 110° C. (19)). Calc. for $C_{10}H_{12}O_3N_2Cl_2$: N, 10.04%; found: N, 10.06%.

By using an excess of the hydrazine reagent (1.6 moles per mole) and distilling off three successive additions of methanol containing a few drops of acetic acid, an osazone was obtained. Melting point after recrystallization from ethyl acetate – benzene (1: 1), 219–220° C. Calc. for $C_{16}H_{14}O_2N_4Cl_4$: N, 12.81%; found: N, 12.85%.

L-*Glyceraldehyde*

The method for preparation of the L-glyceraldehyde formate ester was the same as for di-*O*-formyl-D-erythrose differing only in the quantities of oxidant and oxalic acid used. L-Arabinose (1.5 gm.) was oxidized with 9.0 gm. of lead tetraacetate and most of the lead was removed by the addition of 2.5 gm. of oxalic acid dihydrate dissolved in acetic acid. The product obtained by ethyl acetate extraction was a clear, pale yellow oil. Weight, 1.2 gm. This compound, which is described in greater detail elsewhere (24), is found to contain about 1.5 formate ester groups.

The ester (0.201 gm.) was hydrolyzed to constant rotation in 10% acetic acid at 50° C. (7.5 hr.), and the acid was removed by distillation. The quantity of sugar estimated by hypoiodite oxidation was 0.102 gm., corresponding to a yield of L-glyceraldehyde from the ester of 83% $[\alpha]_D^{27}$ −7.15° (equilibrium) (*c*, 2).

Dimedon-L-*glyceraldehyde*

L-Glyceraldehyde formate ester (1.02 gm.) in 100 ml. of phosphate buffer (containing 10 ml. of 1 *M* monopotassium phosphate and 5.9 ml. of 1 *N* sodium hydroxide) was treated with 2.0 gm. of dimedon at room temperature. After 18 hr. reaction time the solution was concentrated and the crystalline product was recovered by filtration. Weight, 1.73 gm. (73%), m.p. 191–200° C. Two recrystallizations from 50% alcohol raised the melting point to 196.5–198.5° C.; $[\alpha]_D^{27}$ −208° (*c*, 0.5, ethanol), (m.p. 198° C., $[\alpha]_D$ −198° (2)). Calc. for $C_{19}H_{26}O_5$: C, 68.24%; H, 7.84%; found: C, 67.97%; H, 7.86%.

L-*Glyceraldehyde-2,4-dinitrophenylhydrazone*

To a solution of L-glyceraldehyde (0.71 gm.) in 25 ml. of water, cooled in an ice-bath, was added a slightly warm solution of 2,4-dinitrophenylhydrazine (1.6 gm.) in 2 *N* hydrochloric acid (90 ml.) over a period of 30 min. The reaction mixture was maintained at 0° C. for an additional 30 min. A copious yellow precipitate which formed was filtered, then washed with dilute hydrochloric acid and water, and dried. Weight, 0.97 gm., m.p. 120–140° C. Recrystallized three times from 50% alcohol, m.p. 146–148° (m.p. 147–148° (2)). Calc. for $C_9H_{10}O_6N_4$: C, 40.00%; H, 3.73%; found: C, 40.09%; H, 3.83%.

ACKNOWLEDGMENT

The technical assistance of Mr. J. Giroux is gratefully acknowledged. The authors express their gratitude to Dr. A. C. Neish for the gift of a sample of D-erythrose, to Mr. J. Baignee for analyses, to Miss A. Epp for preparation of infrared spectra, and to Dr. W. H. Barnes for X-ray diffraction analyses.

MECHANISM FOR THE FORMATION OF GUANIDINE FROM UREA AND AMMONIUM SULPHAMATE[1]

By Jean L. Boivin and A. L. Lovecy

ABSTRACT

The over-all mechanism of the formation of guanidine from urea and ammonium sulphamate is briefly discussed. Experimental results are presented, indicating that primary formation of the ammonium salt of ureasulphonic acid and subsequent dissociation into cyanamide and ammonium sulphate, which further react to form guanidine in the known manner, constitute the main steps in the process.

The essential process of conversion of urea to guanidine may be described as the ammonolysis of urea:

[1] $$\begin{matrix} NH_2 \\ | \\ C{=}O \\ | \\ NH_2 \end{matrix} \rightleftharpoons \begin{matrix} NH \\ \| \\ C{-}OH \\ | \\ NH_2 \end{matrix} + NH_3 \rightleftharpoons \begin{matrix} NH \\ \| \\ C{-}NH_2 \\ | \\ NH_2 \end{matrix} + H_2O\,.$$

Although this equilibrium reaction has been stated to occur in liquid ammonia, there is no reliable evidence that an acceptable yield is obtainable. Blair (2) obtained a 23% yield; Sander (6) using aluminum, aluminum chloride, or phosphorus pentoxide to remove the water formed reported yields of 90%.

In considering possible dehydrating agents to remove the water formed and so assist the completion of the equilibrium reaction (Eq. [1]), sulphur trioxide or its reaction products with ammonia are attractive (5) from the viewpoint of economy and availability:

[2] $$H_2N{-}SO_3NH_4 + H_2O \rightarrow (NH_4)_2SO_4.$$

Combining equation [2] with [1] gives the following over-all equation:

[3] $$\begin{matrix} NH_2 \\ | \\ C{=}O \\ | \\ NH_2 \end{matrix} + H_2N{-}SO_3NH_4 \rightarrow \begin{matrix} NH_2 \\ | \\ C{=}NH\,. \\ | \\ NH_3.NH_4SO_4 \end{matrix}$$

Whilst in fact urea does react with sulphamic acid to produce guanidine the reaction is not adequately described by the simple dehydration process indicated above (Eq. [3]), since the following facts must be explained: The fusion of equimolar quantities of urea and sulphamic acid yields traces of guanidine; substitution of ammonium sulphamate gives a pronounced increase in yield mainly when an excess of the former is used (5). Ammonium sulphamate does not in fact react readily with water (3).

In view of these facts, there is no evidence that the reaction-sequence involves an initial dehydration of urea (Eq. [1]) with subsequent or simultaneous interaction of ammonium sulphamate with the water formed (Eq. [2]).

[1]*Manuscript received March 2, 1955.*
Contribution from the Organic Section of Canadian Armament Research and Development Establishment, Valcartier, Quebec. Issued as C.A.R.D.E. Report No. 43, August 1950.

In seeking an alternative mechanism, it is reasonable to consider the elimination of ammonia rather than water as the primary step, particularly in view of the observation that ammonia is liberated at a temperature of 140° C.

There are two ways in which this might occur when urea and ammonium sulphamate are fused together:

[4] $$\begin{array}{l} NH_2 \\ | \\ C{=}O \\ | \\ NH_2 \end{array} + H_2N{-}SO_3NH_4 \rightarrow \begin{array}{l} NH_2 \\ | \\ C{=}O \\ | \\ NH_2.HO_3S{-}NH_2 \end{array} + NH_3,$$

[5] $$\begin{array}{l} NH_2 \\ | \\ C{=}O \\ | \\ NH_2 \end{array} + H_2N{-}SO_3NH_4 \rightarrow \begin{array}{l} NH_2 \\ | \\ C{=}O \\ | \\ NHSO_3NH_4 \end{array} + NH_3.$$

As regards equation [4], attempts to prepare a definite urea salt of sulphamic acid were unsuccessful. When an aqueous solution containing equimolar quantities of the base and acid was evaporated to dryness, and the solid obtained was extracted with alcohol, a solution of urea and a residue of sulphamic acid were obtained.

Attention was therefore turned to the second alternative (Eq. [5]), i.e. the formation of ammonium ureasulphonate. Ureasulphonic acid itself has been prepared by the sulphonation of urea with sulphur trioxide and is an intermediate in the formation of sulphamic acid as described by Baumgarten (1). It has now been prepared in 60% yield by treatment of urea with sulphuric acid and acetic anhydride at low temperature, whereby a viscous product separates, believed to be the urea salt of ureasulphonic acid. By dissolving this material in absolute ethanol and passing in gaseous ammonia a crystalline compound was obtained, m.p. 168–170° C.; this was the ammonium salt of ureasulphonic acid, described by Linhard (4).

By fusion of this salt alone at 240° C. a yield of guanidine equivalent to 43–45% of the theoretical was obtained (estimated as the picrate). Melamine was also shown to be present in 22% yield. This result indicates that ureasulphonic acid may be involved in the conversion of urea to guanidine. Heating under a pressure of ammonia was tried, the ammonia being introduced as liquid. At a pressure of 1500 p.s.i. and 295° C., the yield of guanidine obtained after one and one-quarter hours was 63%, and at a pressure of 200 p.s.i. and 300° C., the yield of guanidine was only 10% but melamine was formed in 77% yield.

A reaction based on the formation of cyanic acid from urea would also explain the mechanism:

[6] $$NH_2{-}CO{-}NH_2 \rightleftharpoons NH_4OCN \rightleftharpoons NH_3 + HOCN,$$

[7] $$HOCN + NH_2SO_3NH_4 \rightarrow NH_4SO_3{-}NH{-}CO{-}NH_2.$$

The formation of cyanic acid takes place at temperatures upwards of 140° C. and it seems that this active fragment reacts with sulphamic acid to form ureasulphonic acid. Actually, a 57% yield of the latter compound has been

isolated from a melt of urea with ammonium sulphamate, carried out at a temperature not exceeding 140° C. under reduced pressure.

Assuming the primary formation of ammonium ureasulphonate as probable, its subsequent conversion to guanidine is still by no means obvious. It is conceivable that a further dissociation and rearrangement is involved, particularly since a temperature in the region of 290° C. seems necessary in order to obtain a good yield.

By analogy with the fusion of amides with ammonium sulphamate or the intermediate product, ammonium N-alkylsulphamates, which are transformed into high yields of nitriles (3), it seems that ammonium ureasulphonate should produce the corresponding nitrile which is cyanamide (Eq. [8]).

[8] $$\begin{matrix} NH_2 \\ | \\ C{=}O \\ | \\ NHSO_3NH_4 \end{matrix} \rightarrow \begin{matrix} NH_2 \\ | \\ C{\equiv}N \end{matrix} + NH_4HSO_4$$

[9] $$\begin{matrix} NH_2 \\ | \\ C{\equiv}N \end{matrix} + (NH_4)_2SO_4 \rightarrow \begin{matrix} NH_2 \\ | \\ C{=}NH \\ | \\ NH_3.NH_4SO_4 \end{matrix}$$

It is well known that cyanamide in the presence of ammonium salt is quickly transformed into guanidine (Eq. [9]) or its trimer, melamine.

EXPERIMENTAL

Ammonium Ureasulphonate

To a cold solution (−20° C.) of acetic anhydride (250 ml.) and sulphuric acid (95%, 48 gm., 0.5 mole) was added a solid feed of finely powdered urea (60 gm., 1.0 mole). The temperature of the mixture was allowed to rise slowly to 15° C. with occasional stirring. Urea dissolved completely, and at 15–18° C. a viscous product was formed which was decanted. This oily material was dissolved in absolute ethanol (500 ml.) (methanol is not suitable). The solution was chilled to −30° C. and saturated with gaseous ammonia. A crystalline compound separated out. It was filtered, washed thoroughly with ether, and dried, m.p. 167.5–168° C. with decomposition. Yield, 47 gm. (60% from sulphuric acid). The urea in excess may be recovered by evaporation of the filtrate.

This ammonium ureasulphonate was hydrolyzed quantitatively with dilute nitric acid to urea nitrate and sulphuric acid. By treatment of this substance with concentrated sulphuric acid, sulphamic acid is obtained (1).

Guanidine from Ammonium Ureasulphonate

(*A*) This ammonium salt (5.1 gm.) was heated at 225–230° C. for one-half hour. The residue was dissolved in water and analyzed for guanidine and melamine. Guanidine: 0.8 gm. (42%); melamine: 22%.

(*B*) The same ammonium salt (5.3 gm., 0.03 mole) and liquid ammonia (20 ml.) were heated in a closed vessel at 295° C. for 75 min. at a pressure of 5100 p.s.i.g. Guanidine: 63%; melamine was absent.

(*C*) The same reaction was effected as above, but conditions were the following: temp.: 300° C.; heating time: 17 hr.; pressure: 200 p.s.i.; melamine: 77%; guanidine: 10%.

Preparation of Ammonium Ureasulphonate from Urea and Ammonium Sulphamate

Urea (6.0 gm., 0.1 mole) and ammonium sulphamate (11.7 gm., 0.1 mole) were heated at 135–140° C. under reduced pressure (15 mm.) in order to eliminate the ammonia formed in the reaction. The heating was effected during six hours. The reaction mixture was boiled with 85% ethanol. On cooling, a crystalline compound separated out. It was filtered and dried, m.p. 165–166° C. By working up the filtrate, it was possible to isolate 9.1 gm. of this material (57%). A portion of this solid was recrystallized from ethanol. It melted at 167–168° C. A mixed melting point with an authentic sample was not depressed.

INFRARED AND RAMAN SPECTRA OF 1-CHLOROPROPYNE AND 1-CHLOROPROPYNE-d_3[1]

By D. W. Davidson[2] and H. J. Bernstein

ABSTRACT

The infrared spectra of 1-chloropropyne and 1-chloropropyne-d_3 have been investigated in the vapor state, in solution, and, in part, in the liquid over the spectral region 3 to 35μ. Intensities of the infrared bands have been measured from the spectra of the solutions. The Raman spectra of the compounds in the liquid state, together with standard intensities and depolarization ratios of the Raman bands, were obtained. A complete assignment, based on a normal coordinate calculation of the fundamentals, has been made. Coriolis coupling coefficients of three of the perpendicular-type fundamentals of $CH_3C{\equiv}CCl$ were determined and those of the other two shown to be near unity. Two coupling coefficients for $CD_3C{\equiv}CCl$ were obtained. The potential function and isotope effects on Raman intensity and Raman displacement of the CCl stretching vibration are discussed.

INTRODUCTION

1-Chloropropyne (methylchloroacetylene: $CH_3C{\equiv}CCl$) has been investigated previously by Cleveland and Murray (5), who obtained the Raman spectrum of the liquid, as prepared by a Grignard reaction from methylacetylene. These Raman bands were tentatively assigned by Meister (14), with the aid of a normal coordinate treatment. Parts of the chloropropyne spectrum were obscured, however, by lines arising from the presence of ethyl bromide in considerable quantity in the sample. Morse and Leitch (15) have recently reported a more efficient synthesis and have provided us with a sample both of $CH_3C{\equiv}CCl$ and of the completely deuterated form $CD_3C{\equiv}CCl$ (1-chloropropyne-d_3). We have investigated the vibrational spectra of these molecules and confirm Meister's assignment of fundamentals for $CH_3C{\equiv}CCl$.

Methylchloroacetylene belongs to the C_{3v} symmetry point group and possesses five normal vibrations of symmetry type A_1 and five doubly degenerate E-type vibrations. With the exception of $\nu_{10}(e)$, all the fundamentals in both molecules have been observed. Assignments have been made for the combination bands, although in some cases it has not been possible to choose between alternative assignments. Sum and difference bands involving $\nu_{10}(e)$ have been used to fix approximately the frequency of this mode.

An attempt has been made to measure the intensities of prominent bands in both the infrared and Raman spectra and the depolarization ratios of the stronger Raman bands. The Coriolis coupling coefficients were determined for the fundamental bands of the perpendicular type, wherever these were resolved.

EXPERIMENTAL METHODS

The infrared data were obtained with a single beam double pass Perkin-Elmer spectrometer (Model 112) using LiF, CaF_2, NaCl, KBr, and CsBr

[1]*Manuscript received January 18, 1955.*

prisms. Window materials were KBr, except for the CsBr region where windows of KI-TlI were used. Except for a few strong bands, which were examined also at lower pressures, vapor spectra were obtained at the vapor pressure of the liquid at 22°C. For $CH_3C{\equiv}CCl$ and $CD_3C{\equiv}CCl$ these pressures were approximately 530 and 560 mm., respectively.[3] Band intensities were determined for spectra obtained in solutions in CS_2 or CCl_4. The solution spectra were useful also for resolving bands which overlap in the vapor spectra, and, together with the liquid spectra recorded at low frequencies, for detecting weak bands.

Raman spectra of $CH_3C{\equiv}CCl$ were recorded by two methods. In the first, as in previous work (2), a double-prism photographic instrument (f/3.5, dispersion 29 Å/mm. at 5000 Å) was used. The second instrument was a new photoelectric-recording grating spectrometer (21), constructed by the White Development Corporation, Stamford, Connecticut. The photoelectric instrument has the advantage of speed and simplicity in the determination of relative intensities and depolarization ratios. The method of Edsall and Wilson (8) was used to measure depolarization ratios. The Raman spectrum of $CD_3C{\equiv}CCl$ was obtained with the photoelectric instrument only. Both liquids turned yellowish under mercury radiation, although the effect was considerably reduced when a filter consisting of a saturated aqueous solution of $NaNO_2$ was placed between the mercury source and the Raman tube. This filter also practically eliminated excitation by the Hg > 4047 line.

RESULTS

The infrared spectra are shown in Figs. 1 and 2 and the observed bands listed in Tables I and II. The photoelectrically-recorded Raman spectra are reproduced in Fig. 3 and the data given in Tables III and IV.

Most of the observed infrared and Raman bands could be satisfactorily ascribed to $CH_3C{\equiv}CCl$ or $CD_3C{\equiv}CCl$. Near 800 cm.$^{-1}$, however, absorption occurred in solution spectra of both molecules, although it was absent in the vapor spectra. It was greatly reduced by distillation and is attributed to traces of grease.

The results of Cleveland and Murray (5) are included in Table III. The band observed by them at 184 cm.$^{-1}$ was not observed directly in the present work, probably because of its weakness and interference from grating ghosts in this part of the spectrum. Nor was the corresponding band in the spectrum of $CD_3C{\equiv}CCl$ observed.

INTENSITIES OF INFRARED BANDS

Integrated extinction coefficients (ϵ) for the solution bands (Tables I and II) were calculated from the maximum optical density ($d_{max.} = \log_{10} I_0/I$) and the band width ($\Delta\nu_{\frac{1}{2}}$) at half-maximum intensity, assuming the Lorentz band shape. The small correction for finite spectral slit width (s) was incorporated in ϵ by multiplying $d_{max.} \cdot \Delta\nu_{\frac{1}{2}}/c.l$ by the factor K, usually not quite $\pi/2$, as tabulated by Ramsay (16). The concentration c has been expressed in moles

[3]*These values were derived by an extrapolation of the vapor pressure vs. temperature curves of Morse and Leitch (15).*

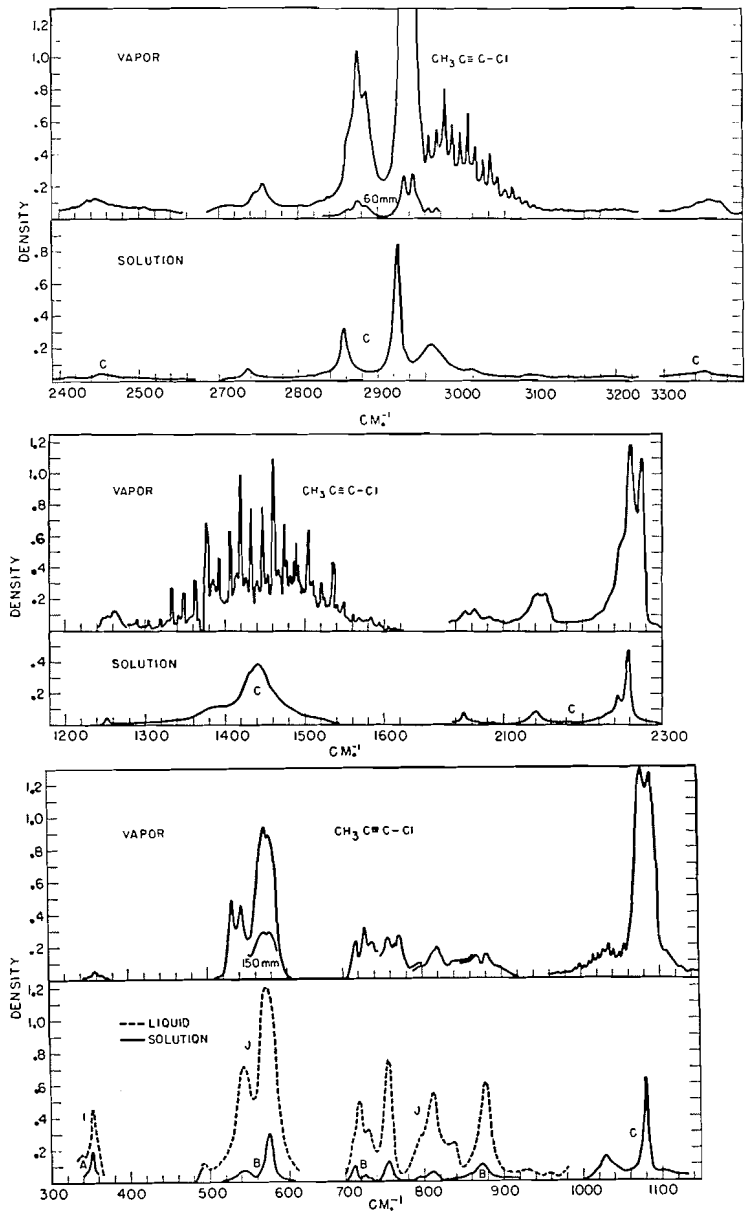

FIG. 1. Infrared spectra of $CH_3C\equiv C—Cl$.

per liter and the cell thickness l in centimeters. The value of s was taken to be half the spectral slit width for single pass optics.

DEPOLARIZATION RATIOS AND INTENSITIES OF RAMAN BANDS

Because of the convergence of light from the source on the Raman tube, the observed depolarization ratio ρ has been corrected to give the true value

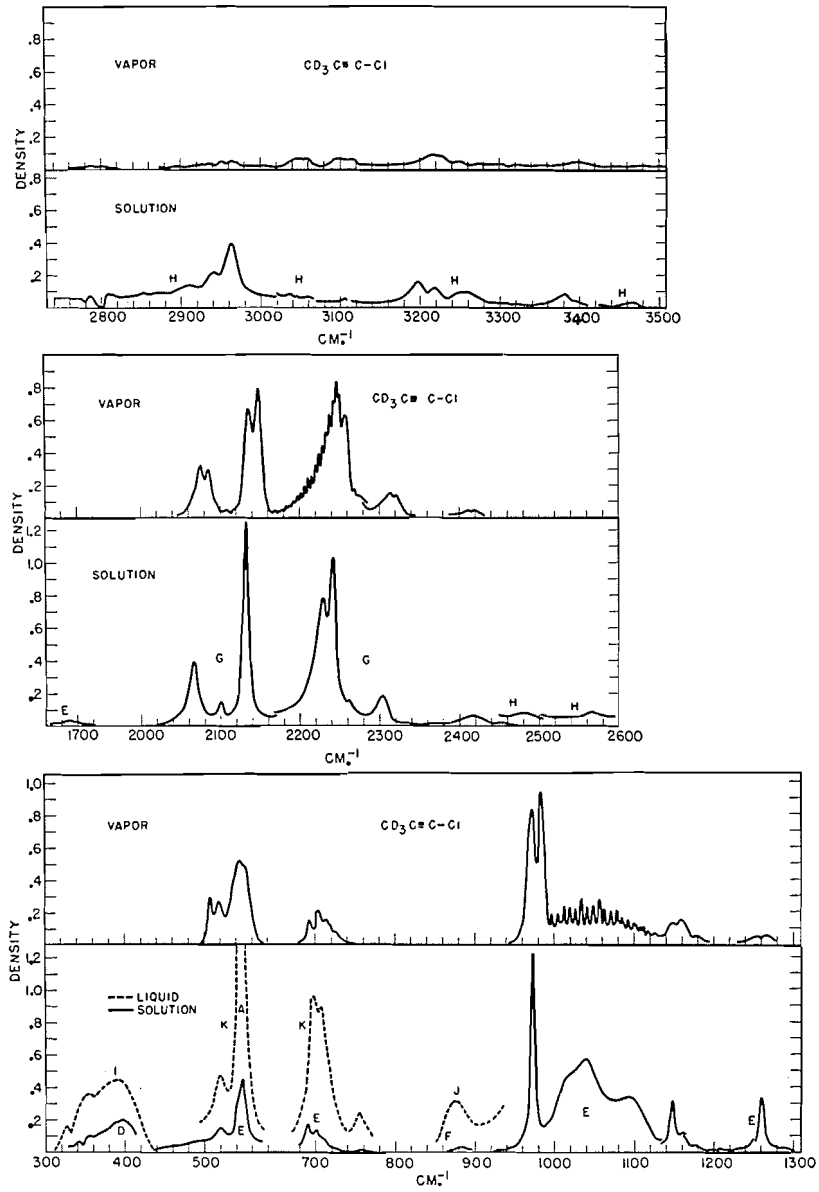

FIG. 2. Infrared spectra of $CD_3C{\equiv}C{-}Cl$.

ρ_t essentially according to the method of Rank and Kagarise (17). Values of ρ and ρ_t are given in Tables III and IV.

These tables include also the peak intensity (i) relative to that of the $\nu_1(a_1)$ band (taken as $i = 100$) which includes the correction for the spectral sensitivity of the IP21 photomultiplier. The observed half-band widths ($\Delta\nu_{\frac{1}{2}}$) and spectral slit width s are also given and the standard intensity S referred to the 458 cm.$^{-1}$ band in CCl_4 for each band obtained from the equation (1).

[1] $$S = \frac{I}{I_{458}} \frac{1+\rho_{458}}{1+\rho} \frac{n^2}{n^2_{CCl_4}} \frac{\sigma_{\Delta\nu}}{\sigma_{458}} \frac{R(n)}{R_{CCl_4}} \frac{M}{d} \left(\frac{d}{M}\right)_{CCl_4} \times \frac{\Delta\nu}{458} \left(\frac{\nu-458}{\nu-\Delta\nu}\right)^4 \frac{1-e^{-1.44\Delta\nu/T}}{1-e^{-1.44\times458/T}}.$$

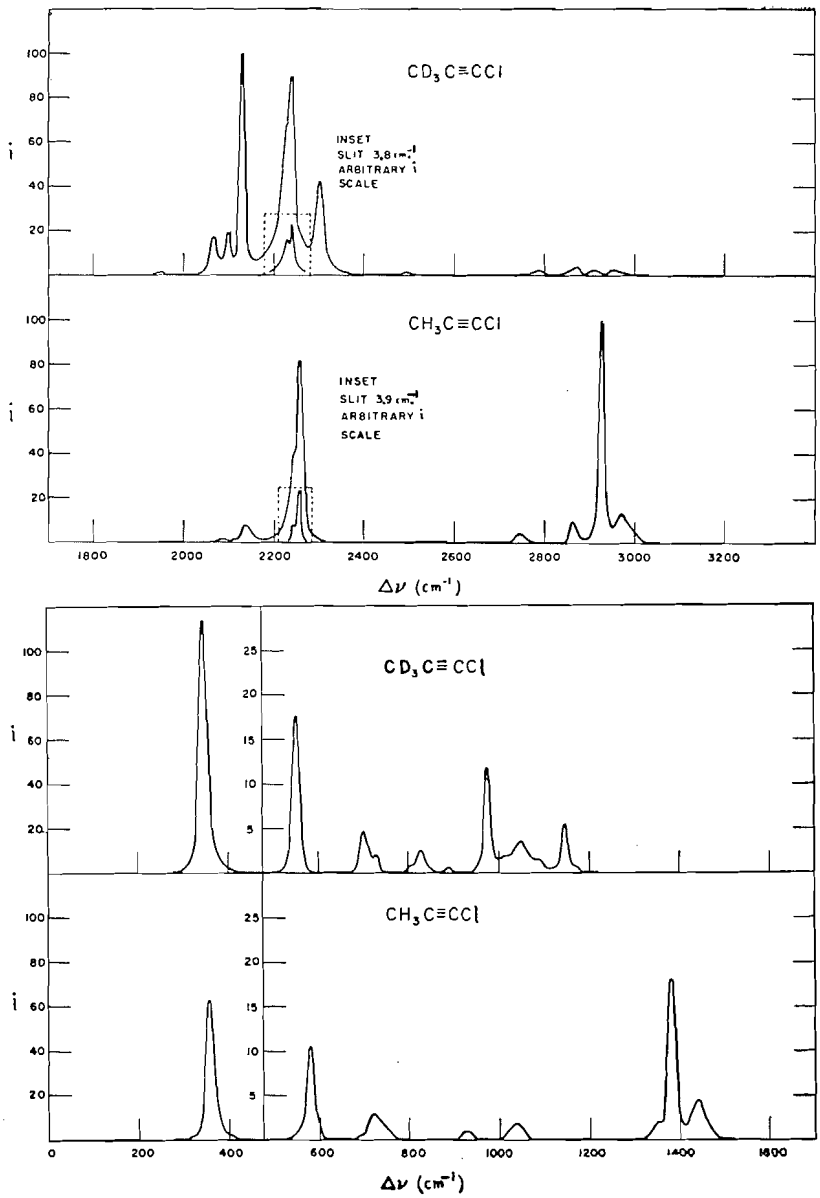

FIG. 3. Raman spectra of liquid $CH_3C{\equiv}C{-}Cl$ and $CD_3C{\equiv}C{-}Cl$.

[b]*See footnote c, Table III.*

Here I is the integrated intensity of the band in question,
ρ is the observed depolarization ratio,
n is the refractive index of the material,
$\sigma_{\Delta\nu}$ is the spectral sensitivity of the IP21 tube at the wavelength corresponding to $\Delta\nu$,
$R(n)$ is the reflection loss,
M is the molecular weight and d the density of the material,
$\Delta\nu$ is the wave number of the Raman band,
ν is the wave number of the exciting radiation,
and T is the absolute temperature.

The subscript CCl_4 indicates the corresponding quantities for the reference substance CCl_4, and the subscript 458 refers to the band at 458 cm.$^{-1}$ in CCl_4. In Reference (1) it has been shown that

$$S = \frac{[45(\partial\alpha/\partial Q)^2+7(\partial\gamma/\partial Q)^2]_{\Delta\nu}}{[45(\partial\alpha/\partial Q)^2+7(\partial\gamma/\partial Q)^2]_{458}}$$

where α and γ are the average polarizability and anisotropy respectively and Q is the normal coordinate for the band whose Raman shift is $\Delta\nu$. In obtaining a standard intensity from this formula the integrated intensity has been obtained by using the product of the peak intensity and the observed half-band width and then correcting for the effect of the finite slit width by means of the curves calculated by Bernstein and Allen (1) to give the true integrated intensity. In the above equation the observed intensity has been corrected also for convergence of the incident beam, spectral sensitivity of the detector, the amount of light the spectrometer sees, the amount of light incident on the sample tube; and then expressed as scattering intensity per molecule. The intensities determined in this way are probably accurate to $\pm 10\%$ for the strong isolated bands at 343 cm.$^{-1}$ and 551 cm.$^{-1}$ in $CD_3C{\equiv}CCl$ and at 355 cm.$^{-1}$ and 579 cm.$^{-1}$ in $CH_3C{\equiv}CCl$. Because of overlapping in the region 2000–2400 cm.$^{-1}$ the standard intensities are considerably less accurate.

For $CH_3C{\equiv}CCl$ and $CD_3C{\equiv}CCl$ values of n are given by Morse and Leitch (15). A rough determination of the density gave 1.008 for $CH_3C{\equiv}CCl$ at 25°C. The molecular volume of $CD_3C{\equiv}CCl$ was assumed to be the same as that for $CH_3C{\equiv}CCl$.

CALCULATION OF THE FREQUENCIES

Meister (14) has calculated the fundamental frequencies of methylacetylene-type molecules, $CH_3C{\equiv}C{-}X$, from a potential energy function which includes all eight bond-stretching and -bending force constants and five interaction constants. In our treatment, we have adopted the same potential function and the same symbols for the force constants and the molecular dimensions.

Some of the E elements in the G matrix used by Meister are in error.[4] For the symmetry coordinate R_{1a}, R_{1b}, R_{2a}, . . . R_{5b} chosen by Meister, the values of G_{14}, G_{24}, G_{25}, and G_{34} are to be multiplied by -2. The changes in

[4]*These corrections were pointed out by A. V. Golton in correspondence with A. G. Meister, who has kindly communicated them to us.*

these elements arise from the necessity of choosing $\mathbf{S}^t_{4a}$ and $\mathbf{S}^t_{5a}$ for all t to lie in the same plane through the symmetry axis as the other $\mathbf{S}^t_{ja}$ (the Wilson $\mathbf{S}$ vectors for the atom t and the symmetry coordinate R_{ja}) and the new values are readily verified. The F matrix elements and the remaining G matrix elements are unchanged.

Following Meister, we have transferred most of the force constants from methylacetylene to methylchloroacetylene. Golton [5] has recalculated the force constants of methylacetylene, taking into account the G matrix changes mentioned above. The potential constants that appear in the F matrix for the A_1 vibration are the same as those of Meister. Of the remainder, k_α, k_β, and $k_{\alpha\beta}$ are not greatly altered, but the change in the value of k_ϕ is considerable. Both sets of values are listed in Table V, together with the set we have adopted for use in the present calculations.

TABLE V

FORCE CONSTANTS FOR METHYLCHLOROACETYLENE (10^5 DYNES/CM.)

	Meister's value	Golton's value	Adopted value
k_H	4.8384	Same	Same
k_c	5.1296	Same	Same
k_a	15.799	Same	Same
k_X	5.3008	Same	Same
k_{ca}	0.47059	Same	Same
$k_{c\gamma}$	−0.26186	Same	Same
k_{Xa}	0	0	0
k_α	0.45342	0.4515	0.4515
k_β	0.56207	0.5636	0.5636
$k_{\alpha\beta}$	0.01285	0.0108	0.0108
k_ϕ	0.12714	0.1524	0.1524
k_θ	0.09729		0.09624
$k_{\phi\theta}$	0.045303		0.05244

It is worth noting that all force constants except k_H, k_X, k_θ, and $k_{\phi\theta}$ have been taken over from methylacetylene. The value of k_H is that calculated by Meister from the frequencies of $\nu_6(e)$ in all three methylhaloacetylenes investigated in the Raman effect by Cleveland and Murray (5); Meister evaluated k_X from the observed frequency of $\nu_2(a_1)$. We have calculated k_θ and $k_{\phi\theta}$ by taking $\nu_9(e)$ = 353 cm.$^{-1}$ and $\nu_{10}(e)$ = 184 cm.$^{-1}$ for $CH_3C{\equiv}CCl$. No frequencies of $CD_3C{\equiv}CCl$ were used to evaluate force constants.

The atomic masses and molecular dimensions used in the calculation were the same as those employed by Meister. The calculated fundamental frequencies, shown in Table VI (second and last columns), are explicit solutions of the fifth power secular equations. Table VI also includes fundamental frequencies calculated by Meister (third column).

ASSIGNMENTS

Fundamentals

With the exception of $\nu_{10}(e)$ all fundamentals in each molecule were observed in either the infrared or Raman spectrum.

The A_1 fundamental bands in the infrared have the doublet structure

[5] *Private communication to the authors.*

[3] Assumed in order to calculate k_θ, $k_{\phi\theta}$.

characteristic of parallel-type bands of symmetric top molecules, with P–R peak separations approximately as predicted by the Gerhard–Dennison formula (9), viz., 11.2_3 cm.$^{-1}$ for $CH_3C{\equiv}CCl$ and 10.6_7 cm.$^{-1}$ for $CD_3C{\equiv}CCl$. The half widths of the corresponding solution bands are comparatively small ($\sim$8 to 12 cm.$^{-1}$). Likewise, the Raman bands are comparatively sharp, with half widths of the order of 15 cm^{-1}. The depolarization ratios are considerably less than 6/7, except for $\nu_3(a_1)$ in $CD_3C{\equiv}CCl$ which is not strong enough for accurate depolarization measurements.

The spacing between the sub-bands of the doubly degenerate perpendicular fundamental depends on the strength of the Coriolis coupling between degenerate modes. Sub-bands were resolved from one another in $\nu_6(e)$ and $\nu_7(e)$ for both molecules and in $\nu_8(e)$ for $CH_3C{\equiv}CCl$. The latter fundamental was not observed in the vapor spectrum of $CD_3C{\equiv}CCl$, even with a path length of 1 meter. In neither molecule was $\nu_9(e)$ strong enough in the vapor to stand out well among the water bands in the region near 350 cm.$^{-1}$, despite considerable reduction of the water vapor content of the spectrometer by flushing dry nitrogen through a specially constructed housing. In the solution spectra, the perpendicular fundamentals were broad bands with half widths usually greater than 20 cm^{-1}. The Raman bands are likewise comparatively broad with the exception of $\nu_9(e)$. The depolarization ratios which could be measured for the E-type fundamental were found to be 6/7 within experimental error.

It is worth noting that for these molecules the magnitude of the half-band width of the fundamentals appearing in the infrared and Raman spectra of the liquids and solutions provides a criterion for dividing the bands into A_1 and E types. This is true also for the bands in the infrared spectrum of liquid methyl iodide.[6]

The observation by Cleveland Murray (5) of $\nu_{10}(e)$ at 184 cm.$^{-1}$ in the light molecule was approximately confirmed by the frequencies of combination

[6] As may be seen by examination of the spectra recorded by Irving L. Mador and Ruth S. Quinn (J. Chem. Phys. 20: 1837. 1952).

bands in which $\nu_{10}(e)$ appears, as is also the calculated value 177 cm.$^{-1}$ for the frequency of this fundamental in the heavy molecule (see below).

The value of $\nu_{10}(e)$ in $CD_3C{\equiv}CCl$ may also be obtained from the Teller–Redlich product rule for the E-type fundamentals (11); viz.,

$$[2] \qquad \nu_{10}(e) = \frac{\prod_{i=6}^{10} \nu_i(e)}{\prod_{i=6}^{9} \nu_i'(e)} \cdot \left(\frac{m_H}{m_D}\right)^{3/2} \cdot \left(\frac{M'}{M}\,\frac{I'_B}{I}\right)^{1/2} = 171 \text{ cm}^{-1}.$$

This value is in good agreement with the values calculated in Table VI and estimated from combination tones. In equation [2] the primed quantities refer to $CD_3C{\equiv}CCl$ and the other symbols have their usual meanings.

The product rule for the fundamentals of the A_1 type is

$$[3] \qquad \prod_{i=1}^{5} \nu_i(a_1) \Big/ \prod_{i=1}^{5} \nu_i'(a_1) = \left(\frac{m_H}{m_D}\,\frac{M'}{M}\right)^{\frac{1}{2}}.$$

The theoretical ratio of the frequencies is 1.946, and the observed value of the left-hand side is 1.930.

COMBINATION AND DIFFERENCE BANDS

$CH_3C{\equiv}CCl$

The remaining bands in the spectra of $CH_3C{\equiv}CCl$ may be readily assigned, as indicated in Tables I and III, on the basis of binary sums or differences. Ternary combinations of the type $\nu_2(a_1)+n\nu_i(e)-n\nu_i(e)$, however, appear to account best for the series of infrared bands lying just below the C≡C stretching fundamental $\nu_2(a_1)$. Meister (14) has made the assignment $[\nu_2(a_1)+\nu_9(e)]-\nu_9(e)$ to the band that occurs on the low frequency side of $\nu_2(a_1)$ in the Raman spectra of 1-chloro, 1-bromo, and 1-iodo acetylene, with $\nu_1(a_1)-2\nu_9(e)$ an alternative assignment. In 1-chloropropyne, however, $\nu_1(a_1)-2\nu_9(e)$ ($=2223$ cm.$^{-1}$) appears to lie too low to account for any of the strong bands in this region. The band occurring at 2252 cm.$^{-1}$ in the infrared and at 2244 cm.$^{-1}$ in the Raman spectrum is probably $\nu_2(a_1)+\nu_{10}(e)-\nu_{10}(e)$. "Hot" transitions of the form $\nu_2(a_1)+n\nu_i(e)-n\nu_i(e)$ have previously been assigned to bands occurring on the low frequency side of the C≡C stretching fundamental (which corresponds to $\nu_2(a_1)$ in methylchloroacetylene) in the Raman (12) and infrared (4) spectra of methylacetylene.

Fermi resonance with $\nu_5(a_1)$ may account for the high intensity in the infrared spectrum of the band assigned as $\nu_9(e)+\nu_{10}(e)$ (A_1+A_2+E). The fundamental $\nu_7(e)$ gives rise to a very strong overtone (A_1+E) in the infrared, whose intensity is probably enhanced by Fermi interaction with $\nu_1(a_1)$. Similarly, in the Raman spectrum, the $2\nu_7$ band is stronger than the ν_7 band.

Since the strong band at 2749 cm.$^{-1}$ appears to be stronger than the $\nu_3(a_1)$ fundamental, it is more likely to arise from $\nu_1(a_1)-\nu_{10}(e)$ rather than $2\nu_3(a_1)$.

A value of 184 cm.$^{-1}$ for $\nu_{10}(e)$, as mentioned above, appears satisfactory, although examination of the frequencies of the combination and difference

bands in which $\nu_{10}(e)$ occurs suggests that a higher value (190 to 195 cm.$^{-1}$) is to be preferred, at least for the molecule in the vapor.

The assignment of the infrared band at 819 cm.$^{-1}$ is not completely satisfactory.

$CD_3C{\equiv}CCl$

In spite of the presence of strong atmospheric water and solvent absorption, the infrared spectrum of $CD_3C{\equiv}CCl$ appears to show at least three bands below 400 cm^{-1}. Besides $\nu_9(e)$, the binary combinations $[\nu_3(a_1)-\nu_8(e)]$ (E), $2\nu_{10}(e)$ (A_1+E), and $[\nu_5(a_1)-\nu_{10}(e)]$ (E) may occur in this region, and $2\nu_{10}$ has the correct symmetry for resonance with $\nu_9(e)$.

More than one assignment is possible for many of the weaker bands of $CD_3C{\equiv}CCl$. Some of these involve ternary combinations in which $\nu_9(e)$ or $\nu_{10}(e)$ occur. In general, wherever $\nu_9(e)$ occurs in a combination assignment (Table II), an alternative assignment in which $2\nu_{10}(e)$ replaces $\nu_9(e)$ may be made. There appears to be only one band, that at 2318 cm.$^{-1}$ in the infrared spectrum of the vapor, to which may be unequivocally assigned a transition involving $\nu_{10}(e)$. With due regard to anharmonicity the assignment $\nu_1(a_1)+\nu_{10}(e)$ to this band leads to a value of $\nu_{10}(e) > 176$ cm^{-1}. The infrared band at 513 cm.$^{-1}$ gives $\nu_{10}(e) > 170$ cm.$^{-1}$ if assigned to $\nu_9(e)+\nu_{10}(e)$, and $\nu_{10}(e) > 171$ cm.$^{-1}$ if assigned to $3\nu_{10}(e)$. The actual value of $\nu_{10}(e)$ therefore appears to be close to the calculated frequency of 177 cm^{-1}.

There is good evidence for the existence of strong Fermi interaction between $\nu_2(a_1)$ and the band that occurs with a Raman shift of 2302 cm.$^{-1}$ in the liquid and at 2318 cm.$^{-1}$ in the infrared spectrum of the vapor. This band has been assigned to $2\nu_3(a_1)$. In both the Raman and infrared spectra it has an intensity about equal to that of the $\nu_2(a_1)$ fundamental. In the second place, the Raman band is strongly polarized. Thirdly, the experimental value of the frequency of $\nu_2(a_1)$ is lower than would have been expected while that of $2\nu_3(a_1)$ is higher. If one compares, for the data of Table VI, the calculated value of $\delta\nu$, the change in frequency of a fundamental in going from $CH_3C{\equiv}CCl$ to $CD_3C{\equiv}CCl$, with the observed change, one finds that $\delta\nu_{\text{obs.}}-\delta\nu_{\text{calc.}}$ has values from $+1$ to $+15$ cm.$^{-1}$ for all fundamentals, with the exception of $\nu_2(a_1)$, for which this quantity is -18 cm^{-1}. It therefore seems likely that Fermi interaction has reduced the frequency of the $\nu_2(a_1)$ fundamental by about 20 cm.$^{-1}$, while raising that of $2\nu_3(a_1)$ to about the same extent (observed value of $2\nu_3(a_1)=$ 2318 cm.$^{-1}$ vs. $\nu_3(a_1) = 1151$ cm.$^{-1}$).

Band Contours

The contours of the combination bands in the infrared spectra of the vapors tend to resemble those of the parallel fundamentals, even when the symmetry class of the transition is A_1+E or, as in a few cases, solely E. Possibly a diffused E component would be expected to be less pronounced than an A_1 component of equal intensity, and E bands with large ζ values (see Rotational Structure of Perpendicular Bands, below) take on the appearance of parallel bands under conditions of low resolution. Large ζ_{ij}'s are expected for transitions $\nu_i(a_1)+\nu_j(e)$ in which ζ_j is itself large (3). For both molecules, ζ_9 and ζ_{10} are near

unity (see below). The $CH_3C{\equiv}CCl$ band at 765 cm.$^{-1}$ [$\nu_5(a_1)+\nu_{10}(e)$] shows the type of contour expected under these conditions. The sharpness (for a perpendicular band) of the corresponding band in the solution spectrum may perhaps also be attributed to a large ζ value.

ROTATIONAL STRUCTURE OF THE PERPENDICULAR BANDS

The rotational structure of several of the E-type fundamentals was resolved. The Q-branches of the sub-bands that arise from $\Delta K = +1$, $\Delta J = 0$ transitions are given by

$$[4] \quad \nu_0^{sub} = \nu_0 + A'(1-\zeta)^2 - B' \pm 2[A'(1-\zeta) - B']K + [(A'-B') - (A''-B'')]K^2$$

which is identical with the expression given by Herzberg (13) except for the factor $(1-\zeta)^2$ instead (4) of $(1-2\zeta)$ which shifts the band origin ν_0 for large ζ. To determine ζ from equation [4], dimensions of the chloropropyne molecule were assumed. Except for the C—Cl bond distance, the dimensions were taken to be the same as those obtained for 1-bromo- and 1-iodo-propyne by Sheridan and Gordy (19); $r_{CH} = 1.092$ Å, $r_{C{\equiv}C} = 1.207$ Å, $r_{C-C} = 1.459$ Å and $\measuredangle$ HCH = 109°8′. The value of the C—Cl distance was taken to be 1.632 Å, the same as that in chloroacetylene as determined from the microwave spectrum (20). Reciprocal moments are then $A'' = 5.281$, $B'' = 0.075$ cm.$^{-1}$ for $CH_3C{\equiv}CCl$ and 2.661 and 0.067 cm.$^{-1}$, respectively, for $CD_3C{\equiv}CCl$.

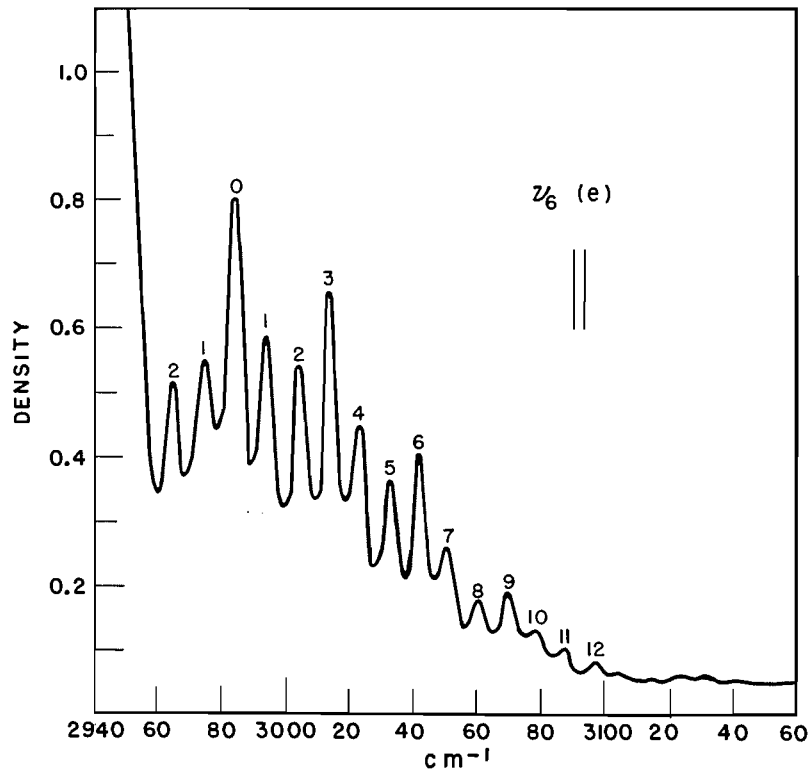

FIG. 4. $\nu_6(e)$ band of $CH_3C{\equiv}C{-}Cl$. The spectral slit width is shown.

In making the K assignments to the sub-bands, one is greatly assisted by the strong, weak, weak, strong, . . . intensity sequence imposed by the nuclear spin of the H (or D) atoms. The strongest peak corresponds to the transition in which K goes from 0 to 1.

The sub-band frequencies observed in $\nu_6(e)$ of $CH_3C{\equiv}CCl$ (Fig. 4) are given in Table VII. The ^PQ branch for large K's is obscured by $\nu_1(a_1)$. By least

TABLE VII

SUB-BAND FREQUENCIES IN $\nu_6(e)$ OF $CH_3C{\equiv}CCl$

$\nu_{vac.}$, cm.$^{-1}$	Value of K in ^PQ_K	$\nu_{vac.}$, cm.$^{-1}$	Value of K in ^RQ_K
2964.6	2	2984.6	0
2974.8	1	2994.5	1
		3004.3	2
		3014.0	3
		3023.5	4
		3033.2	5
		3042.4	6
		3051.4	7
		3060.7	8
		3070.1	9
		3079.0	10
		3087.5	11
		3096.9	12
		—

		(3123)	
		(3131)	

squares the observed peaks have been fitted to equation [4] (with an average deviation of ± 0.13 cm.$^{-1}$) to give

$$[5] \qquad \nu_0^{sub} = 2984.7_0 \pm 9.884\,K - 0.0460\,K^2.$$

Since $A'' \gg B''$, $(A'-B')-(A''-B'')$ can be set nearly equal to $A'-A''$, whence $A' = 5.235$ cm.$^{-1}$, $B' = B''$, $\nu_0 = 2979.9$ cm.$^{-1}$, and $\zeta_6 = 0.042$.

The intensity distribution among the sub-bands of $\nu_7(e)$ of $CH_3C{\equiv}CCl$ (Fig. 5) permits a choice of either 1419 or 1461 cm.$^{-1}$ for the 0–1 transition. That the latter is probably the correct assignment is shown by the occurrence of the solution peak at 1440 cm^{-1}. Besides the intensity distribution, many of the sub-band frequencies are apparently affected by the presence of overlapping and perturbing bands: $\nu_3(a_1)$ at *ca.* 1395 cm.$^{-1}$, $(\nu_3(e)-\nu_{10}(e))$ (A_1+E) at 1258 cm.$^{-1}$, at least one "hot" transition (see below), and probably a band at about 1510 cm.$^{-1}$ (most likely $(\nu_3(a_1)+\nu_{10}(e))$ (E). The ^RQ_K sub-bands for K greater than 2 appear to be perturbed, especially in the region between 1500 and 1580 cm^{-1}. The frequencies in Table VIII assigned to ^PQ_K and ^RQ_K transitions (the latter up to $K = 2$) may be fitted with a mean deviation of ± 0.3 cm.$^{-1}$ by

$$[6] \qquad \nu_0^{sub} = 1460.81 \pm 13.901\,K - 0.0276\,K^2.$$

Thus $A' = 5.253$ cm.$^{-1}$, $\nu_0 = 1453.78$ cm.$^{-1}$, and $\zeta_7 = -0.337$.

$\nu_8(e)$ (Fig. 6) is a comparatively weak band, with most of the ^RQ sub-bands obscured by $\nu_4(a_1)$ and some irregularity in the ^PQ spacings (see Table IX).

(Fig. 7) are obscured by $\nu_2(a_1)$. The intensity distribution in the rest of the band makes it uncertain whether $^RQ_0$ is 2224 or 2238 cm^{-1}. Since the solution frequency (here 2229 cm.$^{-1}$) is ordinarily lower than that of the vapor band center, $^RQ_0$ is probably 2238 cm^{-1}. By least squares (average deviation ± 0.4 cm.$^{-1}$),

$$[7] \qquad \nu_0^{sub} = 2237.41 \pm 4.619\,K + 0.01385\,K^2,$$

with the result that $A' = 2.675$ cm.$^{-1}$, $\zeta_6 = 0.112$, and $\nu_0 = 2235.3_7$ cm^{-1}.

Frequencies in the $\nu_7(e)$ band (Fig. 8) are shown in Table XI. Two spurious

[2]*Grisenthwaite–Thompson results.*

generally that the sum rule for the ζ's of C_{nv} molecules, when there are n equivalent atoms symmetrically disposed about the symmetry axis and only one degenerate symmetry class E, is

$$[9] \qquad \sum_i \zeta_i = (\text{no. of axial atoms}) - 2 + B/2A,$$

to a first order approximation. For $CH_3C{\equiv}CCl$

$$[10] \qquad \zeta_9 + \zeta_{10} = 1.90_2,$$

which places each of the individual ζ values between 0.90 and 1. The corresponding range in methylacetylene is 0.96 to 1. For $CD_3C{\equiv}CCl$, where only ζ_6 and ζ_7 have been determined:

$$[11] \qquad \zeta_8 + \zeta_9 + \zeta_{10} = 2.30_7,$$

which is consistent with a value of ζ_8 not far from 0.4 and ζ_9 and ζ_{10} again near unity. The signs and magnitudes of the ζ's for chloropropyne are similar to those observed for similar degenerate vibrations in other molecules.[7]

In addition to the strong features in the $\nu_7(e)$ band of $CH_3C{\equiv}CCl$, there appear a large number of weak subsidiary peaks interspersed between the $\nu_7(e)$ peaks. Although the presence of water absorption and the occurrence of the doublet contour of $\nu_3(a_1)$ around 1400 cm.$^{-1}$ introduce uncertainties into the values of the frequencies, an attempt has been made to fit them by equation [4]. Eighteen of the twenty-four subsidiary peaks listed in Table XIII and shown in Fig. 5 can be fitted with success; the remainder, in the region of 1500 cm.$^{-1}$, may arise from other "hot" bands or from the effects of water absorption. The $\nu_7(e)$ sub-bands at 1535 cm.$^{-1}$ show an irregular intensity, and it and other features in this region may be associated with the presence of a weak solution band near 1510 cm^{-1}. The equation resulting from the assignment shown in Table XIII, viz.,

[7]*A rough empirical correlation may be seen between ζ values and vibrational type, as shown, for example, by the similarity in ζ's for corresponding vibrations in methylacetylene and chloromethylacetylene (Table XII). For CH_3CN and CH_3NC, where there is only one low-lying perpendicular bending mode, the ζ's are 0.068, −0.45, 0.42, and 0.99, and 0.08, −0.33, 0.36, and 0.92 respectively (Thompson, H. W. and Williams, R. L. Trans. Faraday Soc. 48: 502. 1952). In $H_3BC{=}O$, $\zeta_1 = 0.13$ and $\zeta_3 = 0.56$ (Cowan, R. D. J. Chem. Phys. 18: 1101. 1950).*

[12] $$\nu_0^{sub} = 1440.0 \pm 14.06\,K + 0.015\,K^2,$$

gives $A' = 5.296$ cm.$^{-1}$, $\nu_0 = 1430.5$ cm.$^{-1}$, and $\zeta = -0.34$ with much less accuracy than before. The K assignment is uncertain, since the intensity alternation is not clear, and it may be that the band origin should be shifted by one or more peaks. The solution spectrum shows a weak shoulder located at about 1428 cm^{-1}. Although the ν_0 value is therefore doubtful, the value of ζ will not be greatly dependent upon the assignment. It is, within experimental limits, identical with the value of ζ for $\nu_7(e)$, as is to be expected for a transition of the type $\nu_7(e)+n\nu_i(e)-n\nu_i(e)$. Our resolving power was not great enough to make the presence of hot bands in conjunction with other strong perpendicular fundamentals observable.

With the exception of the "hot" bands mentioned above, no combination band showed sufficiently well-defined perpendicular structure to make possible an estimation of ζ.

DISCUSSION

There are two aspects of the isotope effect on the vibrational spectrum of these molecules which require emphasis. Firstly there is a shift in frequency of the $\nu_5(a_1)$ band of 28 cm.$^{-1}$ which seems too large to anticipate for a C—Cl valence vibration so far removed from the C atom where isotopic substitution took place.[8] Secondly, this band doubles in intensity in the Raman effect on deuterium substitution and the $\nu_9(e)$ band for example is enhanced in intensity by about a factor of 3 whereas smaller intensity changes are observed for these bands in the infrared spectra. It is readily noticed that there is no simple relation between the observed intensities of corresponding Raman bands of $CD_3C{\equiv}CCl$ and $CH_3C{\equiv}CCl$. Nor do the intensities of the corresponding infrared bands of $CD_3C{\equiv}CCl$ and $CH_3C{\equiv}CCl$ change in any simple manner. However, for isotopic substitution Crawford has developed a sum rule (7)

[8]*The isotopic shift of the C—Cl vibration in CH_3Cl and CD_3Cl is 87 cm.$^{-1}$, cf. Ref. (11), page 315.*

which is applicable to the sum of I/ν^2 for the infrared bands and the sum of $S/\Delta\nu^2$ for the Raman bands of the A_1 modes. Unfortunately the measurement of both the infrared and Raman intensities of these modes is complicated by the fact that several bands overlap, by contributions from bands in Fermi resonance, and by uncertainty in placing the background for the Raman bands at $\sim$2925 cm^{-1}. The experimental errors introduced by these difficulties make it impossible to test quantitatively the validity of the intensity sum rules for these molecules.

The large changes in Raman intensity of corresponding bands of these molecules are probably due to the fact that here the molecular polarizability varies in a complicated manner with the normal coordinate whereas in 1-chloropropane, the saturated analogue of 1-chloropropyne, the intensity of the C—Cl mode for example is given approximately by polarizability changes in the C—Cl bond.

The necessity of dealing with the molecular polarizability in $CH_3C{\equiv}CCl$ rather than bond polarizabilities is further indicated by the presence of the abnormally short CH_3—C and C—Cl bonds in this molecule showing that strong interactions exist between all pairs of bonds between axial atoms. The explanation for the short C—Cl bond in $HC{\equiv}C{-}Cl$ has been given (18) in terms of resonance with the doubly bonded form $H\bar{C}{=}C{=}\overset{+}{Cl}$, whereas hyperconjugation has been involved to account for the short C—C bond in $CH_3C{\equiv}CH$ (6). Thus a realistic potential function for this type of molecule should include non-negligible interaction constants between adjacent bonds. Meister's function (14) for 1-chloropropyne might be criticized on these grounds since the C≡C, CCl interaction constant (K_{Xa}) is taken as zero.[9] However since the agreement between observed and calculated frequencies for $CH_3C{\equiv}CCl$ is quite good it must mean that the K_{Xa} interaction has been taken up in the values for the other constants. In this connection it is instructive to inspect the sets of force constants that Meister has tested for $CH_3C{\equiv}CBr$ (14). They are all about equally good from the point of view of closeness of fit between calculated and observed frequencies, yet one set differs from the others essentially by having a fairly large (0.65×10^5 dynes per cm.) value for the C≡C, CBr interaction constant. The resulting adjustment necessary in the other constants is only to change $K_{C\equiv C}$ by about 4%, K_{CCl} by about 8%, with minor changes in two interaction constants.

ACKNOWLEDGMENT

We are indebted to Dr. D. J. Boyd for helpful discussions.

MESYL* DERIVATIVES OF HYDRAZINE[1]

By Alan G. Newcombe[2]

ABSTRACT

Monomesylhydrazide, 1-acetyl,2-mesylhydrazide, and *sym*-dimesylhydrazide were obtained by means of the Schotten–Baumann reaction. For comparison with these compounds the hydrazinium dimesylate, hydrazinium monomesylate, monomesylhydrazide mesylate, and monoacetylhydrazide mesylate were prepared. The preparation of dimesyldiimide by the action of metallic sodium on N,N-dichloromesylamide was attempted.

INTRODUCTION

Although numerous hydrazides of aromatic and aliphatic carboxylic acids have been prepared, very little is known of the hydrazides of sulphonic acids. The few sulphonic acid hydrazides which have been prepared were chiefly derivatives of aromatic sulphonic acids. It seemed, therefore, of interest to ascertain whether aliphatic sulphonic acid hydrazides could be prepared.† Because of the ready availability of mesyl chloride the hydrazine derivatives of methanesulphonic acid were investigated first.

It was found that few of the reactions available for the preparation of the hydrazides of carboxylic acids can be used for the synthesis of the hydrazides of aromatic or aliphatic sulphonic acids. Curtius and Lorenzen (4) found that by treating hydrazine with either the anhydride or the ethyl ester of benzenesulphonic acid the hydrazine disulphonate salt, and not the *sym*-dibenzenesulphonylhydrazide, was formed. Similar results were obtained in this laboratory using the corresponding aliphatic sulphonic acid derivative (mesyl anhydride (1) or ethyl mesylate (1)) in attempts to prepare the *sym*-dimesylhydrazide.

Raschig's (16) method for the preparation of hydrazodisulphonic acid (HO—SO_2—NH—NH—SO_2—OH) was also found to be unsuitable for the preparation of the *sym*-dimesylhydrazide when mesyl chloride was used as the sulphonating agent. Very small quantities of *sym*-dimesylhydrazide were obtained, however, by using the method of Diels and Paquin (8), substituting mesyl chloride for the chloromethyl carbonate.

Considerably better, although still low, yields of *sym*-dimesylhydrazide were obtained by means of the Schotten–Baumann reaction under the conditions reported by Helferich *et al.* (10, 12) for the preparation of dimesylimide.

**The use of the word mesyl, which was first suggested by Helferich and Gnüchtel (11), in place of methanesulphonyl is followed throughout this paper.*

†*G. H. Stempel, Can. Patent No. 511,584, April 5, 1955, reports the preparation of aliphatic monosulphonylhydrazides by the use of the Schotten–Baumann reaction utilizing alkyl sulphonyl halides having at least four carbon atoms.*

Several changes in the procedure were made in order to increase the yield, but were unsuccessful.

Analysis of the material produced by the Schotten–Baumann reaction gave figures that agreed well with those calculated for *sym*-dimesylhydrazide. It was realized, however, that the reaction product might have been hydrazinium dimesylate, hydrazinium monomesylate, monomesylhydrazide mesylate, hydrazinium dimethanesulphinate,‡ or 1,1-dimesylhydrazide, since these materials possess similar or identical analytical figures. The possibility of the Schotten–Baumann product being identical with one of the first three compounds named was ruled out by comparing it with hydrazinium dimesylate, hydrazinium monomesylate, and monomesylhydrazide mesylate prepared by reliable methods (2). Since the Schotten–Baumann product did not react with benzaldehyde under conditions which resulted in the immediate formation of benzalmesylhydrazone and benzalazine from monomesylhydrazide hydrochloride and hydrazinium dimesylate, respectively, it could not have been hydrazinium dimethanesulphinate or 1,1-dimesylhydrazide.

In a similar manner it was shown that the Schotten–Baumann reaction of acetylhydrazide with mesyl chloride yielded the 1-acetyl,2-mesylhydrazide and not acetylhydrazide mesylate, acetylhydrazide methanesulphinate, or 1-acetyl,1-mesylhydrazide.

In attempting to prepare a monosubstituted hydrazide, namely the monomesylhydrazide, the methods for the preparation of the monohydrazides of carboxylic acids were investigated first. Following the method of Curtius and Struve (5) by heating the methane sulphonamide with hydrazine hydrate or anhydrous hydrazine yielded only the unchanged starting material. Heating the ethyl or butyl (14) mesylate with hydrazine hydrate or anhydrous hydrazine following the method of Curtius and Hofmann (3) yielded in every case the undesired hydrazinium monomesylate. These results are in line with those obtained by Curtius and Lorenzen (4) in their attempts to prepare the monobenzenesulphonylhydrazide. The monomesylhydrazide was readily obtained, and in excellent yield, by means of the Schotten–Baumann reaction. The monomesylhydrazide, a viscous oil, gave a solid hydrochloride and on treatment with benzaldehyde immediately formed the benzalmesylhydrazone.

It was thought that the diacylhydrazides (*sym*-dimesylhydrazide and 1-acetyl,2-mesylhydrazide) might be useful starting materials in the preparation of dimesyldiimide and acetylmesyldiimide. The preparation of these substances by the oxidation of the hydrazides with fuming nitric acid according to Diels *et al.* (7, 8) proved unsuccessful. The method of Stollé (17) was found not to be feasible since the mercury salts of *sym*-dimesylhydrazide and 1-acetyl,2-mesylhydrazide decomposed too readily to permit their isolation. Attempts to prepare the diimide derivatives by oxidation of the disubstituted hydrazides by means of lead tetraacetate in glacial acetic acid were also unsuccessful. While no reaction occurred with 1-acetyl,2-mesylhydrazide at either 0°, 25°, or the boiling point of the solution, the *sym*-dimesylhydrazide

‡*Dann and Davies (6) have shown that the production of sulphinate salts from hydrazine and sulphonic acid chlorides occurs rather easily.*

reacted vigorously, even in the cold, with the evolution of a gas and complete decomposition of the hydrazide. The oxidation of the similar diacetylhydrazide (*sym*) with lead tetraacetate in glacial acetic acid gave a reddish colored oil in a yield of 33% which, like the "diacetyl diimide" of Stollé(17) and Inhoffen, Pommer, and Bohlman (13), decomposed too rapidly to permit analysis.

Finally the possibility of preparing the dimesyldiimide via the action of sodium metal on a N,N-dihalomesylamide was investigated. For this purpose the unknown N,N-dichloromesylamide was prepared by the action of sodium hypochlorite on an aqueous solution of mesylamide at 0°. The N,N-dichloromesylamide was obtained in a pure state and a high yield. While this investigation was in progress Mel'nikov, Sukhareva, and Kavenoki (15) reported the preparation of N,N-dichloromesylamide by the same procedure. The bromination of mesylamide with sodium hypobromite gave a product which lost bromine on washing with ether or other organic solvents.

When a suspension of N,N-dichloromesylamide in ether or benzene was treated with sodium wire and the solvent removed, an orange colored mixture was obtained from which, however, no dimesyldiimide could be isolated.

EXPERIMENTAL

sym-Dimesylhydrazide

To an ice-cold solution of 5.48 gm. (80 mM.) of hydrazine hydrochloride in 10 ml. of water, 20.9 gm. (182 mM.) of mesyl chloride and 60.5 ml. of 4.34 *N* sodium hydroxide solution were added dropwise and at such a rate that the pH of the solution was in the proximity of 8.0. During the addition, which in general required 30 min., the temperature of the solution was kept at 6°. The stirring of the mixture was continued for 15 min. after the addition was completed. At the end of this time hydrochloric acid was added and the solid was filtered off, washed with water, and dried *in vacuo*. The dimesylhydrazide was obtained in yields ranging from 8 to 12%; m.p. 168.5–170° (with decomposition). Calc. for $C_2H_8O_4N_2S_2$ (186.2): C, 12.8; H, 4.25; N, 14.9; S, 34.05%. Found: C, 12.8; H, 4.21; N, 15.2; S, 33.80%.

Variations.—Using, instead of the 4.34 *N* sodium hydroxide, 2 *N* sodium hydroxide, 2 *N* potassium hydroxide, saturated barium hydroxide, or sodium bicarbonate solution, or adding the mesyl chloride at a faster rate did not improve the yield of the *sym*-dimesylhydrazide.

Hydrazinium Dimesylate

A solution containing 9.61 gm. (100 mM.) of methanesulphonic acid, dissolved in 10 ml. of water, was prepared and cooled to 0°. The solution was then added slowly to 2.5 gm. (50 mM.) of hydrazine hydrate. The resultant solution, on standing overnight at 6°, produced a crystalline precipitate, which was filtered off and air dried. Concentrating the mother liquor *in vacuo* yielded more material. The total yield of hydrazinium dimesylate was 8.31 gm. (74%). The material, after drying *in vacuo* at 100° to constant weight, melted at 202–203°. *Analyses*: Calc. for $C_2H_{12}O_6S_2N_2$ (224.3): C, 10.71; H, 5.39; N, 12.50; S, 28.59%. Found: C, 10.97; H, 5.29; N, 12.48; S, 28.89%.

The hydrazinium dimesylate was recovered unchanged by recrystallization

from 99% ethanol. On recrystallization from 95% ethanol only hydrazinium monomesylate, melting at 143.0–143.5°, was obtained. The decomposition of a hydrazine di-salt to the corresponding mono-salt is not uncommon (9).

Hydrazinium Monomesylate

To an ice-cold mixture of 5.0 gm. (100 mM.) of hydrazine hydrate and 22 ml. of ether in a flask equipped with a reflux condenser, was added slowly 9.61 gm. (100 mM.) of methanesulphonic acid. After the exothermic reaction ceased the ether was distilled off, and the white residue was recrystallized from a small amount of ethanol. The material thus obtained melted from 139 to 144°. For further purification it was dissolved in a small volume of hot water and precipitated by the addition of 99% ethanol to the point of turbidity; m.p. 143.0–143.5°. Calc. for $CH_8O_3SN_2$ (128.2): C, 9.37; H, 6.29; N, 21.85%. Found: C, 9.42; H, 6.46; N, 21.74%.

Monomesylhydrazide

A solution of 5.0 gm. (100 mM.) of hydrazine hydrate in 15 ml. of water was placed in a three-necked flask immersed in a salt–ice bath. To the solution, 11.5 gm. (100 mM.) of mesyl chloride and 50 ml. of a 2 *N* sodium hydroxide solution were added dropwise and with stirring in such a manner that the temperature did not rise above 8°. After the addition had been completed the solution was concentrated *in vacuo* with the occasional removal of sodium chloride. To the concentrate was added 99% ethanol and the solution again was concentrated *in vacuo*. The residue was taken up in anhydrous ether, centrifuged, and the solvent removed *in vacuo*. The residue, a clear, colorless, viscous oil weighed 10.31 gm. (93.5%). The monomesylhydrazide is moderately soluble in alcohol or ether; but readily soluble in chloroform or carbon tetrachloride. *Analyses*: Calc. for $CH_6O_2N_2S$ (110.1): C, 10.9; H, 5.50; N, 25.4%. Found: C, 10.7; H, 5.25; N, 25.1%.

Monomesylhydrazide Hydrochloride

The mesylation of 5.0 gm. (100 mM.) of hydrazine hydrate was carried out as described above. To the reaction mixture was added 25 ml. of concentrated hydrochloric acid, and the *sym*-dimesylhydrazide which was formed in a small amount was filtered off. The filtrate was concentrated *in vacuo*. The white residue was recrystallized twice from boiling 99% ethanol. The crystals of monomesylhydrazide hydrochloride, after drying *in vacuo*, weighed 10.79 gm. (73.7%) and melted at 152–153°. *Analyses*: Calc. for $CH_7O_2N_2SCl$ (146.6): C, 8.20; H, 4.82; N, 19.14%. Found: C, 8.24; H, 5.20; N, 19.21%.

Monomesylhydrazide Mesylate

This salt of monomesylhydrazide was best prepared by the following method. A solution of 1.10 gm. (10 mM.) of monomesylhydrazide in 10 ml. of water was added to a solution of 0.96 gm. (10 mM.) of methanesulphonic acid in 30 ml. of water and the mixture was concentrated *in vacuo*. The oil was dissolved in 99% ethanol and the solution again concentrated *in vacuo*. This operation was repeated once more. The white crystalline substance was recrystallized, after solution in a warm mixture of 20 ml. of 99% ethanol and

2 ml. of chloroform, by the addition of anhydrous ether to the point of turbidity. The substance (m.p. 137–138°) was recrystallized once more using a warm mixture of chloroform: absolute ethanol (1:1 v/v) and anhydrous ether. In this manner 0.24 gm. (11.7%) of the monomesylhydrazide mesylate was obtained; m.p. 144–145°. *Analyses*: Calc. for $C_2H_{10}O_5N_2S_2$ (206.2): C, 11.63; H, 4.88; N, 13.59%. Found: C, 11.43; H, 5.08; N, 13.67%.

Benzal Mesylhydrazone

A solution of 1.10 gm. (10 mM.) of monomesylhydrazide in 16 ml. of water was added to a solution of 1.06 gm. (10 mM.) of benzaldehyde in 30 ml. of hot 95% ethanol. The mixture was heated to the boiling point and alcohol was added until the precipitate was dissolved. The yellow precipitate which formed on cooling was filtered off, redissolved in hot ethanol, and precipitated by the addition of water. The colorless crystals were once more recrystallized from warm ethanol and water. The benzal mesylhydrazone weighed 1.11 gm. (56%); m.p. 150–151°. *Analyses*: Calc. for $C_8H_{10}O_2N_2S$ (198.2): C, 48.5; H, 5.07; N, 14.13%. Found: C, 48.4; H, 5.10; N, 14.19%.

1-*Acetyl,2-mesylhydrazide*

Acetylhydrazide was obtained by the method of Curtius and Hofmann (3) and mesylated in the following manner.

To a cooled solution of 5.0 gm. (67.5 mM.) of acetylhydrazide in 10 ml. of water were added dropwise and with gentle stirring 7.75 gm. (67.5 mM.) of mesyl chloride and 34 ml. of 2 *N* sodium hydroxide at such a rate that the pH was kept below 8.0. The temperature of the mixture was not allowed to rise above 8°. Towards the end of the addition the 1-acetyl,2-mesylhydrazide, a fine white crystalline solid, precipitated. The solid was collected with suction on a Büchner funnel, washed with a small volume of water, and dried *in vacuo*. Yield: 2.27 gm. (22.2%); m.p. 197–199°. *Analyses*: Calc. for $C_3H_8O_3N_2S$ (152.2): C, 23.65; H, 5.29; N, 18.40%. Found: C, 23.59; H, 5.22; N, 18.28%.

Acetylhydrazide Mesylate

To a solution of 0.77 gm. (6.8 mM.) of 95% methanesulphonic acid in 30 ml. of water was added a solution of 0.50 gm. (6.8 mM.) of acetylhydrazide in 4 ml. of water, and the mixture was concentrated *in vacuo*. The sirupy residue was taken up in 99% ethanol and the solvent removed *in vacuo*. This process was repeated twice using anhydrous ether followed by 99% ethanol. The dry material was then recrystallized from warm 99% ethanol by the addition of anhydrous ether. The acetylhydrazide mesylate was thus obtained in a yield of 1.06 gm. (90%), m.p. 114–116°. *Analyses*: Calc. for $C_3H_{10}O_4N_2S$ (170.2): C, 21.20; H, 5.92; N, 16.47%. Found: C, 21.10; H, 6.09; N, 16.35%.

Reactivity of Hydrazine Derivatives with Benzaldehyde

Hydrazinium Salts

To a solution of 5 mM. of hydrazinium monomesylate or hydrazinium dimesylate and equivalent amounts of sodium acetate in 2.2 ml. of water was

added 10 mM. of freshly distilled benzaldehyde. In each case, the formation of the well-known benzalazine took place immediately.

Monoacylhydrazide Salts

To a solution of acetylhydrazide mesylate (0.447 gm., 2.63 mM.) and 0.292 gm. (3.56 mM.) of anhydrous sodium acetate in 5 ml. of water was added 0.279 gm. (2.63 mM.) of benzaldehyde and the mixture was well shaken. The known benzalacetylhydrazone was formed.

In a similar experiment with monomesylhydrazide hydrochloride (2.63 mM.), but using 80% acetic acid as solvent (10 ml.), the known benzalmesylhydrazone was obtained.

Diacylhydrazides

Neither the 1-acetyl, 2-mesylhydrazide nor the *sym*-dimesylhydrazide reacted with benzaldehyde under conditions similar to the one immediately above. Both hydrazides were recovered unchanged.

N,N-Dichloromesylamide

To a solution of 0.64 gm. (16 mM.) of sodium hydroxide in 3.5 ml. of water cooled in ice was added 0.76 gm. (8 mM.) of mesylamide, and chlorine gas was passed through the solution for a period of 15 min. The white precipitate which formed immediately was filtered off, washed with a small amount of water, and dried *in vacuo*. The N,N-dichloromesylamide was obtained in a yield of 1.09 gm. (83.2%); m.p. 84–86°. Carbon, hydrogen, and nitrogen analyses were attempted but the substance exploded in the combustion tube. Iodometric analysis indicated a positive chlorine content of 43.1%. Theory, 43.2%.

THE APPLICATION OF GAS–LIQUID PARTITION CHROMATOGRAPHY TO PROBLEMS IN CHEMICAL KINETICS[1]

By A. B. Callear[2] and R. J. Cvetanović

ABSTRACT

A gas–liquid partition chromatographic method for analysis of samples of the order of magnitude of a micromole is described. Examples of application are given.

INTRODUCTION

The analysis of 'liquid products', produced for example in photochemical reactions, has in the past been attempted by mass spectrometer analysis, by infrared analysis, and by specific tests for various functional groups. The liquid products are most frequently complex mixtures and in usual chemical kinetic investigations appear in quantities varying from a fraction to several micromoles. Their analysis has great significance for elucidating the mechanism of the process. Owing to the small size of the samples and their complexity, a complete mass spectrometric analysis can rarely be carried out. Other methods of analysis usually lead to an incomplete picture of the reaction products. The present paper describes the application of gas–liquid partition chromatography to these and some related problems.

Two types of gas chromatography have been considered in connection with the present problem: the displacement method (3, 7, 11) and the gas–liquid partition method (4, 5, 6). In the former, the mixture to be analyzed was first adsorbed on charcoal in a column, and was then displaced from the column by nitrogen containing a material such as bromobenzene or ethyl acetate. Separation occurred as a result of the difference in adsorption energies. In the latter method the stationary phase used was Celite 545 (kieselguhr) mixed with a liquid of low vapor pressure (silicones, liquid paraffin, glycerol, dinonyl phthalate, and others). The gases were eluted from the column with nitrogen, and separation occurred as a result of the different partition coefficients between the gas and liquid. This method was first used for the separation of organic acids (5) and amines (4, 6) and the analyzer was an automatic burette. Later Ray (12, 13) developed a more general method using thermal conductivity cells as the analyzer. He analyzed samples of about 10 mgm. and used a 6 ft. column containing 0.45 gm. dinonyl phthalate per gram of celite.

In the present work the partition method has been chosen for analysis of liquid products in preference to the displacement method because the same column can be used indefinitely and there is no contamination of the components with the displacing compound. There are also, in individual cases, the advantages of reversibility and greater selectivity. The method of Ray is

further developed in order to make it applicable to the extremely small quantities of material produced in chemical kinetic studies. The details of a gas–liquid partition chromatographic apparatus applicable to samples of the order of magnitude of a micromole are given with particular emphasis on a discussion of the factors of importance for its construction and use. Some examples of application are given. In some favorable cases as little as 2×10^{-9} moles of a gas can be detected. In general, the sensitivity is of the order of 1×10^{-8} moles and is, therefore, at least as good as that of a gas burette or of a mass spectrometer. Isolation of fractions from relatively large samples has been previously reported (7, 8). The possibility of the isolation of fractions from the extremely small samples used in the present work has been investigated and it has been found that chromatographic fractionation can be combined, with distinct advantage, with other analytical procedures. This is especially true in cases when the peaks overlap and some of the constituents cannot be isolated singly. The method has proved applicable both for quantitative analysis and for identification of components of unknown mixtures.

SENSITIVITY OF THE THERMAL CONDUCTIVITY MEASUREMENTS

The possibility of application of gas–liquid partition chromatography to the extremely small amounts of products encountered in kinetic studies depends on a high sensitivity of detection of these products in very large amounts of the eluent gas. Thermal conductivity measurements appear to be, at present, the most convenient means of achieving the necessary sensitivity, provided that a high sensitivity can be obtained while the general "noise" level is kept low. A number of factors affect both the sensitivity and the stability of thermal conductivity measuring devices.

In the present work two thermal conductivity cells, forming in the customary manner the adjacent arms of a Wheatstone bridge, were used. They were, however, both placed at the exit end of the column and separated from each other by a series of cold traps so that the substances eluted from the column affected only the first cell while pure eluent gas passed through the second cell. For the measurement of very small amounts of substances this arrangement was preferred to the usual one, with the "reference" cell preceding the column, because of the difficulty of completely eliminating fluctuations in the input pressure of the eluent gas. The bridge was balanced with the eluent gas alone in both cells. The temperature change of the platinum resistance wire in the conductivity cell due to the presence of an impurity is proportional to V^2, the square of the e.m.f. across the wire. A given resistance change of the wire produces an off-balance signal proportional to V. The sensitivity, i.e., the off-balance signal arising from the presence of a fixed percentage of an impurity, is, therefore, proportional to V^3. A very marked increase in sensitivity can, evidently, be achieved by increasing the e.m.f. across the resistance wire. However, it was found that if the wire temperature was increased to over 200°C., a permanent change in the zero position occurred at every peak, indicating either a physical change in the surface of the wire or a change of its position within the cell. The former would alter the tempera-

ture discontinuity (14) at the gas–solid interface and thus change the zero point. The platinum wires were actually maintained at about 100°C., as was established by observing resistance change with wattage dissipation. At the flow rates used, no appreciable difference in the wire temperature could be observed for stationary and flowing gas.

Platinum resistance wire of 10^{-3} in. diameter was used for the conductivity cells. Since the desired sensitivity was achieved, no experiments with different thicknesses of the wire were conducted. Thinner wires may offer some advantage in the greater response, but are more difficult to handle and in all probability would be more sensitive to pressure fluctuations because of greater temperature discontinuity.

The effect of an impurity on the thermal conductivity of a gas is given by Chapman and Cowling (1) for a special molecular model. If the impurity has a very high molecular weight compared to the bulk of the gas, this equation reduces to

$$\lambda(\text{impure mixture}) = \lambda - n_{21}\lambda^2(5-4B)/2F$$

where λ is the thermal conductivity of the pure gas, B is a constant and, under these conditions, F is inversely proportional to the molecular weight of the impurity. n_{21} is the ratio of the number of impurity molecules to the number of eluent gas molecules. Thus for this ideal case, the effect of a constant amount of impurity is proportional to the square of the thermal conductivity of the eluent gas and proportional to the first power of the molecular weight of the impurity. Though the practical case will only approximate to this relationship, it is clear that a gas of high thermal conductivity should be used. For this reason, hydrogen has been chosen for the eluent gas in preference to nitrogen. The use of hydrogen as eluent gas has recently been reported by Patton, Lewis, and Kaye (10).

A rough comparison of the performance of hydrogen and nitrogen gas eluents can be made. The thermal conductivity ratio is about 7 to 1. The changes in thermal conductivity of the gases on addition of the same percentage of a vapor of high molecular weight differ by at least a factor of 7 and possibly by a factor as high as 7^2. If the wire is to be at 100°C. for both gases, the ratio of the e.m.f.'s is $7^{1/2}$. It follows that the off-balance signal produced by the impurity in the nitrogen is between $7^{3/2}$ and $7^{5/2}$ times less than that for hydrogen. The small fluctuations in temperature between the two thermal conductivity cells would produce a "noise" $7^{1/2}$ times greater for hydrogen than for nitrogen, since the voltage is that much higher. Thus the ratios of signal to noise for the two cases would differ by a factor between 7 and 7^2 in favor of hydrogen. Apart from this fundamental difference in behavior, to obtain the same size "peak" for both gases on the recording chart, the amplification has to be very much higher for nitrogen, introducing further electrical noise and noise due to pressure variations, making stable working conditions more difficult to achieve.

Since each molecule of an impurity present in the eluent gas can be regarded as making its own contribution to the recorded peak and this contribution

is proportional to the time each molecule remains in the thermal conductivity cell, it can be expected that the area under the peaks should decrease with increasing rate of eluent gas flow. A marked variation in peak area with flow rate has been observed with the experimental arrangement used, though the flow rates were not known sufficiently accurately to establish a quantitative relationship.

GENERAL FEATURES OF THE APPARATUS AND THE PROCEDURE

The flow system is shown in Fig. 1. Hydrogen gas from a cylinder and reducing valves enters the apparatus at *A* at a pressure slightly greater than one atmosphere as regulated by the small buffer volume *B* (200 cc.) and the

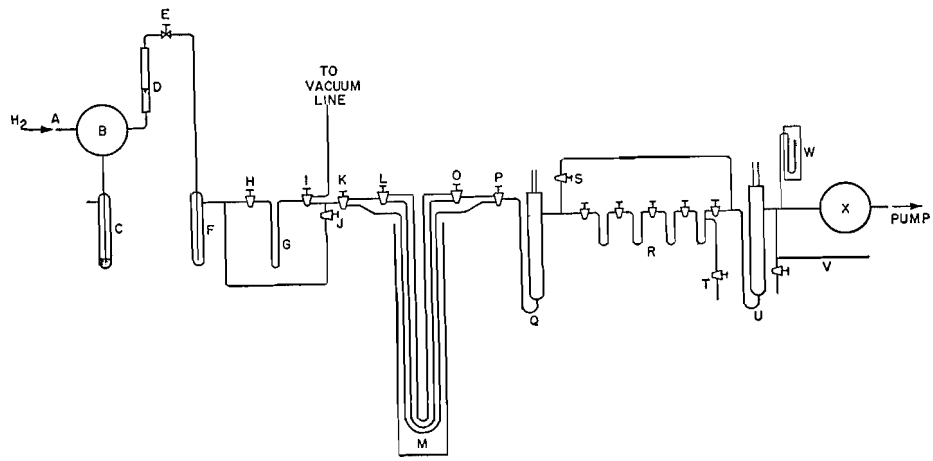

FIG. 1. General outlay of the apparatus.

bubbler *C* containing dibutyl phthalate. Through the latter, excess gas is allowed to bubble at a constant rate. The rotameter *D* gives an approximate value for the rate of flow and a polythene diaphragm valve *E* can be used to vary the pressure applied to the column. The liquid nitrogen trap *F* removes any condensable impurities from the hydrogen. The sampling trap *G* can be evacuated by closing the vacuum stopcock *H* and opening the two-way capillary vacuum stopcock *I* to the vacuum manifold. The sample is measured in a gas burette and is condensed in *G*, care being taken to raise finally the level of liquid nitrogen above the condensed sample. During introduction of sample, the hydrogen bypasses *G* by means of stopcock *J*. To introduce the sample to the column, *I* is closed and *H* is slowly opened to disturb the pressure as little as possible. With *G* full of hydrogen at one atmosphere, *I* is opened to the column and *J* is closed. It is usually necessary to pass hydrogen for a few minutes to restore stability of the analyzer. The sample is then evaporated into the gas stream by replacing the liquid nitrogen with hot water. The present apparatus incorporates three columns for different types of separation. The column is selected by operation of three-way capillary vacuum stopcocks *K*, *L*, *O*, and *P*. The sample passes through the column *M* which is contained

in a 6.5 cm. i.d. glass cylinder about 100 cm. long. A spiral of resistance wire placed inside the cylinder is used to heat the column to the desired temperature, as measured on a thermometer near the center of the cylinder. The 'dead space' between G and M is reduced as much as possible by using capillary tubing. After leaving M, the gas passes through about 20 cm. of 4 mm. i.d. thin-walled glass tubing, so that it is cooled to room temperature before entering the first thermal conductivity cell Q. After passing through Q, the sample can be removed from the hydrogen in a series of cold traps R, made of 4 mm. i.d. thin-walled glass tubing. The volume is kept as small as possible by using capillary stopcocks between the traps. The various components passing through the first thermal conductivity cell are recorded automatically in the form of peaks. They can usually be trapped out in successive liquid nitrogen traps R on the first run. In the case of an unknown mixture which gives overlapping peaks, it is sometimes necessary to observe the chromatographic spectrum on the first run and then send the sample through again, in order to effect the most favorable fractionation. The last trap is connected through stopcock T to the vacuum system so that the fractions can be successively removed and measured. While this is done the stream of hydrogen is bypassed through S. After the second thermal conductivity cell U the gas stream enters a 15 liter flask, serving as a buffer volume, and is then pumped out by a vacuum oil pump. The pressure is observed on the manometer W, and is maintained constant by bleeding in air through the $\frac{1}{2}$ mm. i.d. glass capillary tubing V. In some experiments the pressure was 40 mm. and in others 70 mm. Variations in pressure between these values had little effect on the separations. The flow rates were determined by observing the time taken for a small amount of air to pass between Q and U. The volume of the tubing and traps between Q and U was known. The flow rates in cc. (N.T.P.) per min. were

Column 1: 1.8; Column 2: 15.3; Column 3: 3.3.

CONSTRUCTION OF THE THERMAL CONDUCTIVITY CELLS

Fig. 2 shows one of the thermal conductivity cells. The gas enters the cell through the 4 mm. i.d. thin-walled glass tubing A. The platinum wire FG

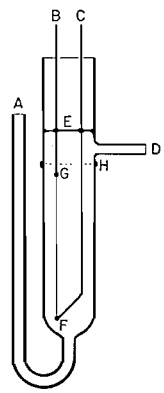

FIG. 2. Thermal conductivity cell.

(10^{-3} in. in diameter) is silver soldered to thick platinum crosspieces which, in turn, are silver soldered to tungsten rods *B* and *C*. Spot welded contacts used originally were found to be unsatisfactory. The tungsten leads are protected from the thermostatting water by extension of the 15 mm. i.d. glass tube of which the cell is made some 10 cm. above the seal *E*. The wire is mounted by breaking the cell at *H* and sealing back on when the wire has been attached. The gas exit is at *D*. The two cells are embedded side by side in paraffin wax contained in a glass cylinder 10 cm. in diameter. The whole is in a two liter beaker containing water which is stirred. The paraffin wax extends to *E* and the water level is about 5 cm. above this. A layer of oil is spread on the surface of the water to prevent evaporation. In early experiments, the inner cylinder contained mercury instead of paraffin wax. The performance was poor, becoming worse when the mercury was stirred. A gel was used successfully until, after a few weeks, it began to decompose and liquefy when it was replaced with paraffin wax.

The platinum wires formed two adjacent arms of a Wheatstone bridge network, the junction of the two wires being connected to the amplifier and the other ends of the wires to a 12 volt battery. A box of oil-immersed resistances formed the other arms of the bridge. In series with the battery was a 30 ohm resistance. All the connections in the bridge network were made with thick copper wire. The off-balance signal was amplified with a d-c. amplifier (Liston-Becker Model 14) and the output was fed to a pen recorder. Screening of the circuit was not necessary. The amplifier was not used on full gain and its "noise" level was far below that arising from temperature fluctuations between the two thermal conductivity cells. The resistance of the platinum wires was about 12 ohms at room temperature.

CONSTRUCTION AND EXPERIMENTS WITH DIFFERENT TYPES OF COLUMNS

A number of different columns were made and their performance with synthetic samples observed. In order to maintain the flow rates within suitable limits, columns of relatively small diameters were used. The dinonyl phthalate columns were $2\frac{1}{4}$ mm. i.d. glass capillary tubing, and the glycerol column was 4 mm. i.d. glass tubing. They were made in *U* shape, each arm of the *U* being 3 ft. They were filled by attaching small funnels to the open ends and the stationary phase was packed in by prolonged tapping of the curved portion on a solid floor. The packing was improved by heating the column to 100°C. during this operation, and seemed to result in a uniformly packed column. It was found that a certain amount of tailing was exhibited by the peaks as smaller and smaller samples were used. The following experiments were all carried out with a mixture of methyl and ethyl alcohol in order to test the separation and the tailing of the peaks with different column materials. (*a*) Since it has been suggested that the tailing occurs as a result of some adsorption on the solid (5), some columns were made containing celite which had been stirred in a solution of 10% dinonyl phthalate in methyl alcohol and acetone. The resulting solid was drained on a Büchner funnel and most of the alcohol and acetone was removed by drawing air through it. The resulting

column contained 4 gm. dinonyl phthalate to 10 gm. of celite. This treatment did not reduce the tailing of the peaks. (*b*) Varying amounts of sorbitol tristearate were added, in order to block the surface with strongly adsorbed polyfunctional groups. This had little effect. (*c*) Instead of celite some weaker adsorbents were tried as supporting materials. Oxidized copper spheres (200–325 mesh) proved unsatisfactory, as did powdered teflon. Glass spheres (passing 270 mesh) on the other hand proved to be advantageous from the point of view of tailing and the uniformity of column packing. Larger glass spheres were tried but were less successful. The glass spheres contained some iron oxide and attempts were made to remove this in aqua regia followed by washing with distilled water. Columns made from glass spheres prepared in this way gave very little separation of the two alcohols. The untreated glass spheres gave the most satisfactory columns. They were mixed with 4% dinonyl phthalate by weight in a beaker, and the resulting mixture packed uniformly and tightly into the glass tubing. As a result a suitable, relatively slow flow rate was obtained. Most of the work described below was carried out on columns constructed in this way. (*d*) It was found that addition of phosphoric acid to the columns reduced the tailing of organic acids (5). Addition of phosphoric acid to the dinonyl phthalate glass columns caused complete removal of alcohols, possibly through formation of non-volatile esters. This type of column might have use for some special problems, where small amounts of material are to be separated from an excess of alcohol. The three columns that were finally integrated into the apparatus were : (1) 1 part dinonyl phthalate and 25 parts glass spheres passing 270 mesh; (2) 20 parts of celite and 9 parts of dinonyl phthalate; (3) 1 part of glycerol and 100 parts glass spheres passing 270 mesh. Column 2 is used for the less volatile mixtures since it gives a higher flow rate. Column 3 has not yet been used to advantage since the separations have been successfully carried out on the dinonyl phthalate columns.

THE EFFECT OF TEMPERATURE ON SEPARATION

In a theoretical treatment of gas–liquid partition chromatography, James and Martin (5) have defined the retention volume of a substance as the product of the flow rate and the appearance time of the center of the peak. Both of these quantities are dependent on the pressures at the inlet and outlet of the column and if these pressures are varied, the retention volume changes. In the present work it was found more convenient to consider the appearance times rather than the less direct quantities, the retention volumes.

The results of James and Martin and later of Ray (12) showed that the appearance times of successive members of a homologous series are mutually related in a simple manner. Ray pointed out that separation of a mixture is impaired if the temperature of the column is too high. This was confirmed in the present work when it was shown that a sample of 10^{-6} mole of a mixture of methanol and ethanol gave overlapping peaks at 70°C. while a good separation was effected at room temperature. It was found to be of advantage in a number of cases to carry out separation of the more volatile components at

room temperature and to start heating the column part way through the experiment in order to avoid excessive appearance times for the less volatile components.

EXAMPLES OF APPLICATION

Liquid products formed by reaction of oxygen atoms with ethylene, reaction of oxygen atoms with acetaldehyde, and decomposition of ethylene oxide in the presence of ethylene have been analyzed by the present method in order to test its applicability. The details and kinetics of these reactions are given elsewhere (2). The detection of impurities in an ethylene cylinder was also carried out, since in some chemical reactions the ethylene gave rise to abnormal behavior.

Since aldehydes are important products in the reaction of oxygen atoms with ethylene, as well as in a large number of other reactions, experiments were carried out using synthetic mixtures of acetaldehyde, propionaldehyde, and butyraldehyde. Fig. 3*a* shows the separation obtained on column 1 at

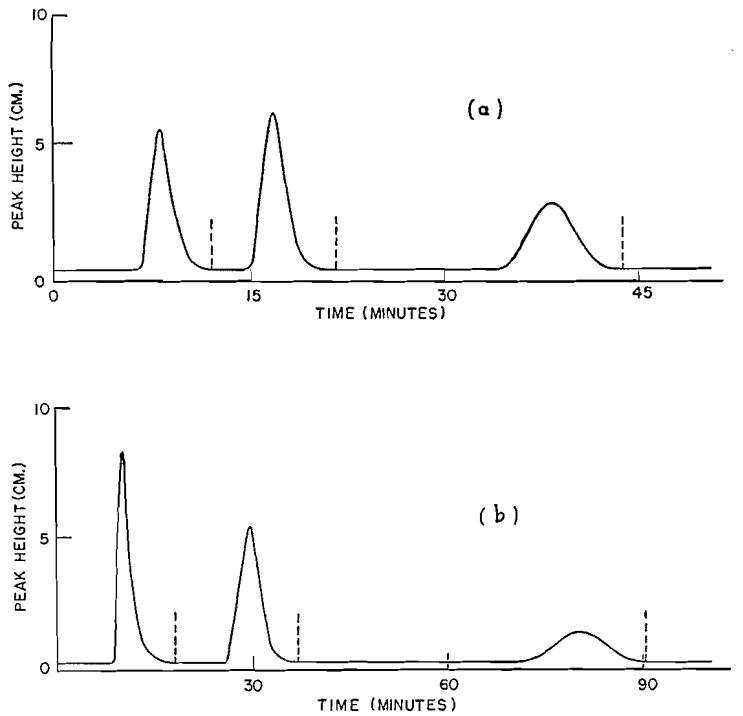

FIG. 3. (*a*) Chromatogram of a synthetic mixture of acetaldehyde, propionaldehyde, and butyraldehyde. (*b*) Chromatogram of −80°C. fraction from the reaction of O-atoms with ethylene.

50°C. The compounds were trapped out at points shown by the vertical dotted lines. Each component was measured before and after recovery with a gas burette, on a volume of 2.85 cc. Each burette reading on this quantity could be in error by 2%.

	Burette reading (pressure in mm. Hg)	
	Introduced	Recovered
Acetaldehyde	10.9	11.5
Propionaldehyde	13.6	13.7
Butyraldehyde	8.5	8.3

Fig. 4 shows the variation in peak height for acetone, with the size of the sample, demonstrating the linearity of the recording device, and the reproducibility of the method.

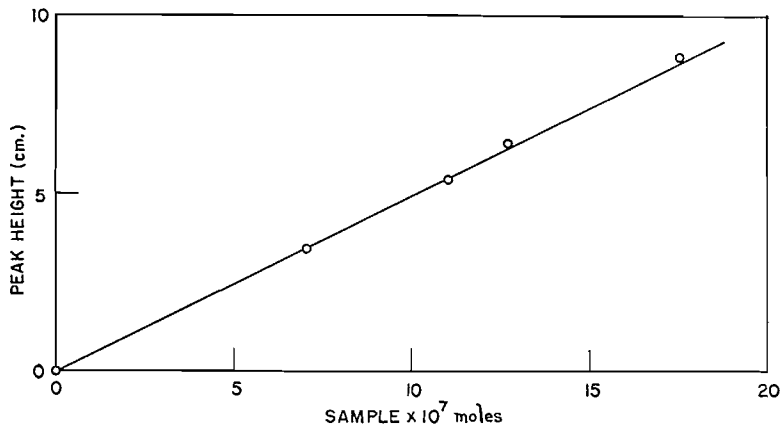

FIG. 4. Variation of peak height with varying amounts of acetone.

Fig. 3*b* shows the chromatogram obtained at 26°C. from the −80°C. Le Roy still (9) fraction from the oxygen atom and ethylene reaction. The peaks were trapped out and mass spectrometric analysis identified the first as acetaldehyde, the second as propionaldehyde, and the third as largely butyraldehyde. The rest of the third peak could have been accounted for as some compound isomeric with butyraldehyde. It was shown that under identical conditions methyl ethyl ketone separated only partially from the butyraldehyde. In another experiment, the third peak was split by trapping at the maximum point. The two halves had the same mass spectrum. With the column at 26°C. instead of 50°C. as used on the synthetic mixture of aldehydes, the ratio of the appearance times of the higher aldehydes to lower aldehydes has increased and the separation has considerably improved.

Fig. 5*a* shows the chromatogram obtained from the −80°C. fraction from the reaction of oxygen atoms and acetaldehyde carried out on column 1 at 26°C. The peaks were trapped out and identified by the mass spectrometer. The heater was switched on after 75 min. and the temperature of the column was 85°C. at the appearance of the third peak. The first peak is the excess acetaldehyde, the second peak is acetone, and the third is biacetyl. The acetone was present to the extent of 3% of the acetaldehyde. It is doubtful if it could have been identified by any conventional method since although the parent peak of the acetone would be observed in such a mixture on the mass spectrometer, the rest of the spectrum would be masked. As a check a

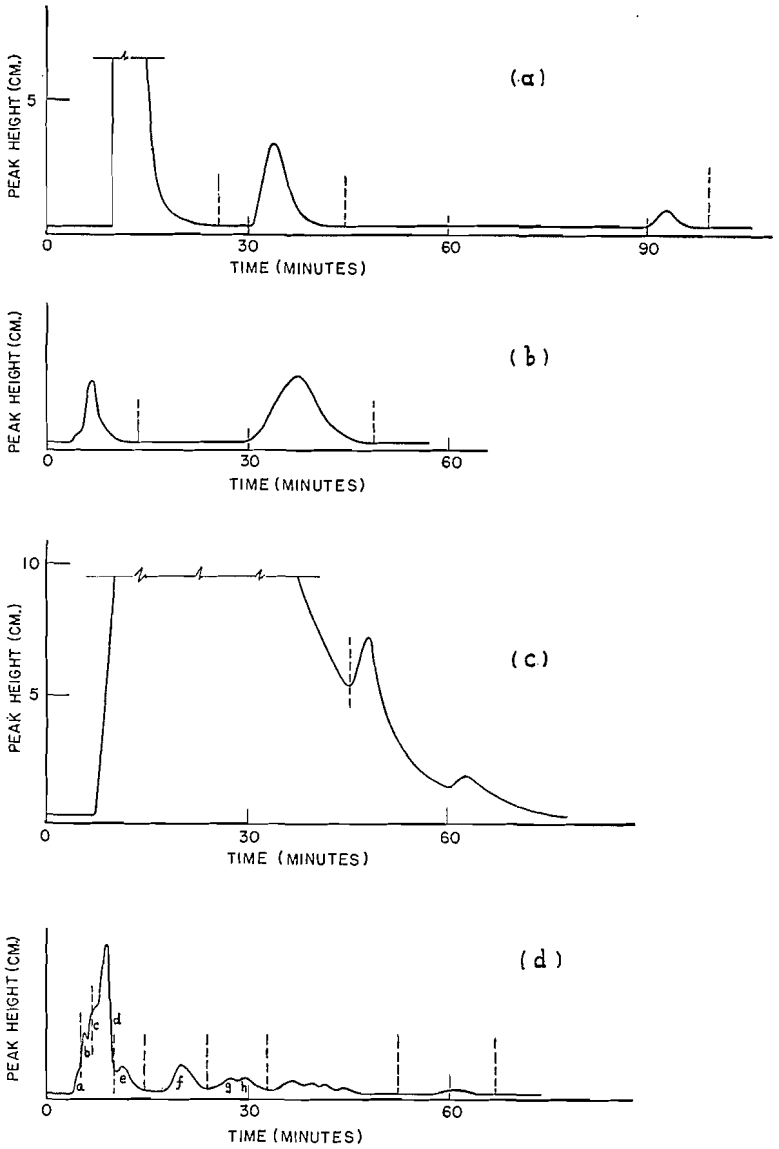

FIG. 5. (*a*) Chromatogram of −80°C. fraction from the reaction of O-atoms with acetaldehyde. (*b*) Chromatogram of room temperature fraction. (*c*) Chromatogram of −80°C. fraction from the mercury sensitized decomposition of ethylene oxide in the presence of small amounts of ethylene. (*d*) Chromatogram of the impurities in cylinder ethylene gas.

synthetic mixture of 30 parts of acetaldehyde and 1 part of acetone was run on the column and the same appearance times were observed. Fig. 5*b* shows the room temperature fraction from the same reaction separated on column 2 at 26°C. The peaks were trapped out and measured and analyzed as water and biacetyl. A sample of water was passed through the column and the position of the first peak was verified.

Fig. 5*c* shows the chromatogram of the −80°C. fraction obtained on column 1 at 26°C. for the decomposition of ethylene oxide in the presence of ethylene. The heater was switched on after 29 min. The sample was 1.5×10^{-3} moles consisting mainly of ethylene oxide which, in such a large quantity, appeared to saturate the column. The two small peaks on the tail of the ethylene oxide peak were trapped out as shown by the vertical line. At the appearance of the third peak the temperature was 102°C. The sample obtained from the tail of the ethylene oxide peak was rechromatographed and gave three separate peaks. The first was ethylene oxide, the second butyraldehyde, and the third pentaldehyde.

Fig. 5*d* shows the chromatogram obtained for the −60°C. fraction from a cylinder of ethylene prepared by dehydration of ethyl alcohol. Four hundred milliliters of impure ethylene at one atmosphere were condensed on a Le Roy still. The ethylene was removed at −175°C. and the −60°C. fraction yielded 1.04×10^{-5} moles of impurity. The chromatogram was started at 26°C. and the heater was switched on after 24 min. By trapping out according to the vertical lines, the impurities were identified by mass spectrometric analysis as (*a*) CO_2, (*b*) propylene, (*c*) isobutane, (*d*) butene-2, (*e*) isopentane, (*f*) diethyl ether and pentene-2, (*g*) hexane, (*h*) hexene (branched chain). The rest of the spectrum consisted of heptenes, heptanes, octenes, and octanes. No ethyl alcohol was detected.

The foregoing examples illustrate the applicability of the gas–liquid partition chromatography to the very small samples encountered, for example, in chemical kinetic and photochemical investigations. Good reversibility of the gas–liquid partition process is demonstrated by the observed quantitative recovery of the aldehydes. It should be mentioned at the same time that with the small samples used in the present work some compounds exhibit a partially irreversible adsorption. In some instances the reversibility is strongly temperature dependent. Thus, water and biacetyl show incomplete recoveries, especially at lower column temperatures. It is, therefore, necessary, when quantitative determinations are made, to establish the percentage recovery for each compound in the mixture at a particular column temperature.

ACKNOWLEDGMENT

Applicability of gas–liquid partition chromatography to chemical kinetic problems is being independently investigated in these laboratories by Dr. K. O. Kutschke and the authors are pleased to acknowledge some useful exchange of information and discussion. The authors are also thankful to Drs. J. E. Currah and R. R. Barefoot of Canadian Industries Ltd., McMasterville, P.Q., for some general information on the subject, to Dr. A. Tickner for mass spectrometer analysis, and to Mr. L. C. Doyle for valuable technical assistance.

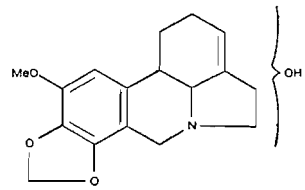
NOTES

A NOTE ON THE ALKALOIDS OF *BUPHANE DISTICHA*

By L. G. Humber and W. I. Taylor

In the course of work which has been discontinued we had occasion to examine the alkaloidal content of some bulbs of *Buphane disticha* Herb. (*Haemanthus toxicarius* Herb.) and our results differ somewhat from those recorded by Tutin (8) and Lewin (4). The crude alkaloids were chromatographed over activated alumina to furnish in low yield lycorine (previously isolated by Tutin) and a new base which does not appear to have been characterized previously. The base, m.p. 189°, analyzed for $C_{17}H_{19}O_4N$, had one methoxyl, no N-methyl, one active hydrogen, and one readily hydrogenatable double bond which from infrared data must be trisubstituted. The infrared spectra of the free base and its perchlorate showed that the double bond could not be $\alpha\beta$ to the nitrogen atom. It gave a positive test for a methylenedioxy group with Labat's reagent and the ultraviolet spectrum (λ_{max} 285 mμ, log ϵ 3.2) suggested the presence of the aromatic moiety shown in (I) since it closely resembled safrole (5). The double bond was not conjugated with the aromatic nucleus since the ultraviolet absorption spectrum of the dihydro-compound was identical to that of the original base. The active hydrogen was present in a hydroxyl group since the dihydro-base gave an O-acetate (ν_{CO} 1710 cm.$^{-1}$) rather than a N-acetyl derivative. The nature of the hydroxyl group has not been determined but it is unlikely to be tertiary since it acetylated readily; however in an attempted chromic acid oxidation of the dihydro-compound only the starting material could be isolated in 50% yield.

I



If this alkaloid resembles other members of this class of known constitution, e.g. lycorine (2, 7), homolycorine (3), and lycorenine (3), then the above results are compatible with the formula (I). The lack of material precludes further study at this time but we have shown by direct comparison and infrared spectra that our new base is not identical with crinamine, m.p. 193–194° (6), or haemanthamine, m.p. 200° (1), both of which have the formula $C_{17}H_{19}O_4N$ and contain a methylenedioxy and a methoxyl group.

EXPERIMENTAL[1]

Dried shredded bulbs of *Buphane disticha* (1500 gm.) were percolated with 95% alcohol (48 liters). The combined extracts were concentrated to dryness

[1]*All melting points are uncorrected and the infrared spectra are measured in potassium bromide mulls.*

and the residue triturated with dilute hydrochloric acid. The acid solution after several washings with chloroform was basified and the precipitated alkaloids taken up in chloroform. The dried extract on concentration afforded the crude bases (4.3 gm.) which were chromatographed over activated alumina (300 gm.). Most of the material was irreversibly adsorbed but a chloroform eluate (850 mgm.) and an ethanolic eluate (250 mgm.) were obtained.

Lycorine

In ethanol the ethanolic eluate slowly deposited needles (75 mgm.), m.p. 260°, which gave an undepressed melting point on admixture with an authentic sample of lycorine. Found: C, 66.9; H, 6.0. Calc. for $C_{16}H_{17}O_4N$: C, 66.9; H, 5.9%.

The Base

The chloroform eluate in ethanol slowly gave the base in large prisms (350 mgm.), m.p. 189°, unchanged on further crystallization. Found: C, 67.8; H, 6.4; N, 4.7; OMe, 10.6; act. H (Zerewitinow), 0.35. Calc. for $C_{17}H_{19}O_4N$: C, 67.7; H, 6.3; N, 4.7; OMe, 10.3; act. H, 0.33%. In microhydrogenation 4.6 mgm. took up 0.37 ml. (N.T.P.) and the theoretical for one double bond requires 0.35 ml. (N.T.P.). The ultraviolet absorption spectrum measured in 95% ethanol showed a maximum 285 mμ (log ε 3.17) and a minimum 260 mμ (log ε 2.59) and was unaltered in acidic or alkaline solution. The base gave a positive test for a methylenedioxy group with Labat's reagent.

Base Perchlorate

The salt was crystallized from water, m.p. 119°. Found: C, 47.6; H, 5.5. Calc. for $C_{17}H_{19}O_4N.HClO_4.1.5H_2O$: C, 47.5; H, 5.5%.

Dihydro-base

The base was hydrogenated in acetic acid using platinum oxide as a catalyst. The dihydro derivative had m.p. 200°, from acetone. Found: C, 67.3; H, 7.0. Calc. for $C_{17}H_{21}O_4N$: C, 67.3; H, 7.0%. The ultraviolet absorption spectrum showed a maximum at 285 mμ (log ε 3.2), and in the infrared the medium strength band present at 840 $cm.^{-1}$ in the original base had disappeared.

Monoacetyldihydro-base Perchlorate

The dihydro-base (50 mgm.) was acetylated in acetic anhydride (2 ml.) using a drop of perchloric acid as a catalyst. The free base after isolation could not be obtained crystalline and was converted into its perchlorate, which crystallized readily from water, m.p. 131–132°. Found on a sample dried at 60° for 12 hr. *in vacuo*: C, 45.8; H, 5.8. Calc. for $C_{19}H_{23}O_5N.HClO_4.3H_2O$: C, 45.6; H, 6.0%. The infrared showed ν_{CO} at 1710 cm^{-1}.

ACKNOWLEDGMENTS

We are indebted to the National Research Council of Canada for support and to Dr. S. Uyeo for a sample of crinamine and Dr. Hans-G. Boit for the haemanthamine. We thank Mr. W. Fulmor and Staff of Lederle Laboratories Division of American Cyanamid for the determination of the infrared spectra.

The *Buphane disticha* was obtained in the Belgian Congo through the facilities afforded by the Institut National pour L'Etude Agronomique at Keyburg.

THE VIBRATIONAL SPECTRUM OF THE SULPHITE ION IN SODIUM SULPHITE[1]

BY J. C. EVANS[2] AND H. J. BERNSTEIN

The Raman and infrared spectra of the sulphite ion in sodium sulphite have been reinvestigated. Hibben (3), on reviewing the work done prior to 1939, decided that the Raman spectrum of the sulphite ion required further examination. More recently, Siebert (7) has obtained the Raman spectra, without measuring the depolarization ratios, of aqueous solutions of three sulphites and has assigned the four bands observed in each spectrum to the four fundamental modes of the ion. In the infrared, Miller and Wilkins (4) included several sulphites in their study of the absorption spectra of solid salts, but confined their study to the region 3–16 μ. We have shown that measurement of the depolarization ratios of the Raman bands and an examination of the infrared spectrum between 3 and 33 μ confirm Siebert's assignment.

Two samples of sodium sulphite which gave identical spectra were examined. One was made available to us by Professor H. G. Thode and the other was C.P. grade (Fischer Scientific Company). The Raman spectrum of a saturated aqueous solution was obtained with a White photoelectric recording spectrometer (8), and depolarization ratios were measured (1) and corrected (5). A Perkin Elmer double-pass infrared spectrometer with LiF, NaCl, KBr, CsBr optics was used to obtain the infrared spectra of a saturated aqueous solution and of solid films of the sulphite. Nujol films and films obtained by evaporating aqueous solutions on AgCl were examined.

The results are tabulated in Table I. In some regions in the infrared, absorption by water or nujol made examination difficult or impossible.

X-Ray diffraction results (9) indicate that the sulphite ion is pyramidal (C_{3v}) with the sulphur atom at the apex. This model should have two sym-

metric modes of vibration ν_1 and ν_2 (a type) and two asymmetric doubly degenerate modes ν_3 and ν_4 (e type). All four modes are infrared and Raman active.

The observed Raman spectrum is immediately explained in terms of the four expected fundamental vibrations. The strong polarized Raman band at 967 cm.$^{-1}$ is assigned to ν_1, the symmetric stretching mode, while the other polarized weak band at 620 cm.$^{-1}$ is assigned to ν_2. The two depolarized bands of medium intensity at 933 and 469 cm.$^{-1}$ are assigned to ν_3 and ν_4 respectively. The remaining very weak band at 896 cm.$^{-1}$ may be 2 ν_4.

The infrared spectrum of the aqueous solution shows three bands which must be identified as ν_1, ν_2, and ν_3. ν_4 was not observed, the absorption of the water in this region being strong. The large discrepancies between the positions of the Raman and infrared bands must be ascribed to the strong intermolecular interaction, and, as is usually found in such cases, the infrared bands have higher frequencies (6).

The infrared spectrum of the solid shows several bands that are satisfactorily explained as combinations and overtones of the four fundamental modes.

Using the mean values of the Raman and infrared frequencies of the four modes in aqueous solution, the dimensions of the ion from X-ray data, and the equations derived from a four-constant potential function (2), the following values of the four constants were calculated: $K_1 = 5.49_6$, $K_1' = 0.64_3$, $K_\delta = 1.01_9$, and $K_\delta' = 0.31_0$ all in units of 10^5 dynes per cm. These constants were used to calculate the following frequencies of the fundamentals in the isotopic ion $S^{34}O_3^{16}$: $\nu_1 = 972$, $\nu_2 = 623$, $\nu_3 = 937$, and $\nu_4 = 457$, all in cm.$^{-1}$.

We wish to thank Professor H. G. Thode for suggesting this problem.

AN OSCILLOSCOPIC POLAROGRAPH

BY G. F. ATKINSON AND W. A. E. MCBRYDE

Polarographic half-wave potentials may be determined without the necessity of obtaining the whole polarographic wave by the use of several derivative techniques. Many of these are based on the introduction of a low-voltage alternating signal into the cell circuit, and observation of some change produced in this signal by its passage through the cell. We have extended the designs of Müller *et al.* (4) and Boeke and van Suchtelen (1) for an oscilloscopic polarograph (*i*) by the introduction of phase-shifting components so as to produce elliptical Lissajous patterns, and (*ii*) by the incorporation of an electronic switch in the oscilloscope's vertical input so as to provide a reference signal in addition to that observed for the polarographic cell. Since the apparatus was built we became aware of the circuit of Rodrequez and Sancho (5) which incorporates the first of the above features. As this type of determination requires the recognition of a distorted pattern on the oscilloscope screen, discrimination is made much easier by the presence of a second undistorted pattern at the same time, especially as the two images may be superimposed.

The circuit is shown in Fig. 1. The cell circuit proper, in which the polarizing direct current flows, is made up of the polarographic cell, the source of direct voltage, the coupling transformer to the detecting circuit, and the resistance across which the alternating signal is supplied. The source of alternating signal was a Heathkit Audio Oscillator, Model AO-1, which was operated to produce a sine wave at 200 c.p.s. The output of this was about 4.1 volts under normal load, and was fed directly to the horizontal input of the oscilloscope and through a resistor to the synchronizing terminal. The signal for the cell circuit was tapped from a 10,000-ohm linear carbon volume control across the oscillator output, and applied across one of a selection of small resistors in the cell circuit.

Direct voltage was supplied by a Fisher Elecdropode manual polarograph modified in two respects. In parallel with the 100-ohm "STD" control a 400-ohm control was added, with considerable gain in convenience in setting the slidewire span voltage. The main voltage divider was replaced by a 10-turn, 200-ohm Helipot potentiometer, Model A. The Model W Duodial used with this was marked to 1 mv., and could be read to 0.5 mv. without difficulty.

The alternating signal was detected by a filament transformer operated

AN OSCILLOSCOPIC POLAROGRAPH

BY G. F. ATKINSON AND W. A. E. MCBRYDE

Polarographic half-wave potentials may be determined without the necessity of obtaining the whole polarographic wave by the use of several derivative techniques. Many of these are based on the introduction of a low-voltage alternating signal into the cell circuit, and observation of some change produced in this signal by its passage through the cell. We have extended the designs of Müller *et al.* (4) and Boeke and van Suchtelen (1) for an oscilloscopic polarograph (*i*) by the introduction of phase-shifting components so as to produce elliptical Lissajous patterns, and (*ii*) by the incorporation of an electronic switch in the oscilloscope's vertical input so as to provide a reference signal in addition to that observed for the polarographic cell. Since the apparatus was built we became aware of the circuit of Rodrequez and Sancho (5) which incorporates the first of the above features. As this type of determination requires the recognition of a distorted pattern on the oscilloscope screen, discrimination is made much easier by the presence of a second undistorted pattern at the same time, especially as the two images may be superimposed.

The circuit is shown in Fig. 1. The cell circuit proper, in which the polarizing direct current flows, is made up of the polarographic cell, the source of direct voltage, the coupling transformer to the detecting circuit, and the resistance across which the alternating signal is supplied. The source of alternating signal was a Heathkit Audio Oscillator, Model AO-1, which was operated to produce a sine wave at 200 c.p.s. The output of this was about 4.1 volts under normal load, and was fed directly to the horizontal input of the oscilloscope and through a resistor to the synchronizing terminal. The signal for the cell circuit was tapped from a 10,000-ohm linear carbon volume control across the oscillator output, and applied across one of a selection of small resistors in the cell circuit.

Direct voltage was supplied by a Fisher Elecdropode manual polarograph modified in two respects. In parallel with the 100-ohm "STD" control a 400-ohm control was added, with considerable gain in convenience in setting the slidewire span voltage. The main voltage divider was replaced by a 10-turn, 200-ohm Helipot potentiometer, Model A. The Model W Duodial used with this was marked to 1 mv., and could be read to 0.5 mv. without difficulty.

The alternating signal was detected by a filament transformer operated

backward, and was fed to a 6-watt amplifier built in the Department of Physics, University of Toronto. A 500-ohm output was used, and, at full gain with bass boost on, the gain was 700 for a 200-cycle signal. The noise level was 0.2 mv. at full gain, and there was no distortion of a sine wave up to 135 v. output. The cell signal and a reference signal were presented to the oscilloscope through a DuMont Electronic Switch, Model 185. The signals were observed on a Heathkit 5-in. oscilloscope, Model O-7, operated on its 400-v. range at very low vertical gain, to produce a trace as free from noise and visible tran-

sients as possible. Many leads were shielded, as shown, to prevent pickup of stray signals.

To observe the summit potential phenomenon described by Delahay and Adams (2), a Hewlett-Packard A.C. Vacuum Tube Voltmeter was connected as shown, and operated on its 3-v. range.

The characteristics of the components used led to the choice of the following operating conditions: (*i*) a high switching speed, with the pattern appearing as a line, (*ii*) relatively high gain on the amplifier before the switch, (*iii*) lowest possible gain in the switch and oscilloscope, (*iv*) low intensity setting to minimize halo.

Method of operation.—With the cell operating, the oscilloscope, electronic switch, and signal generator were turned on. This gave a pattern shown in Fig. 2*a*. This was adjusted by means of the "A" gain of the switch and the

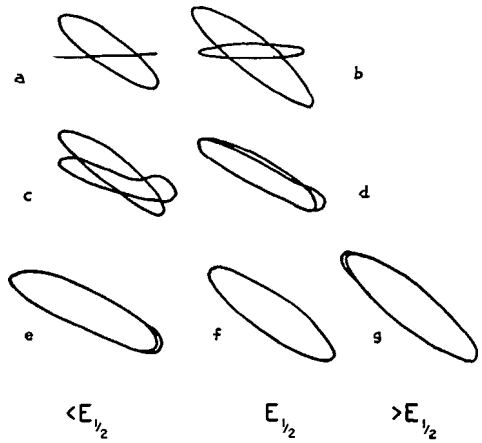

FIG. 2. Oscilloscopic traces.

horizontal gain of the oscilloscope to a suitable size, the phase-shifting resistance having first been set to tilt the figure at about 45°. Next, the amplifier and polarograph were turned on with the applied potential set at zero (Fig. 2*b*). The height of the cell signal was set by the "B" gain of the switch and the amplifier gain to a somewhat lower level. While observing the screen, the potential was increased until a point was reached at which the cell figure became elliptical (Fig. 2*c*). The phase-shifting circuit was used to place the reference signal at the same angle as the cell signal, and the balance and gain controls of the switch were used to superimpose the figures if desired (Fig. 2*d*). Then a short potential interval was investigated with the polarograph until the point of no deviation of the two ellipses was found. By using the sweep generator of the oscilloscope, two sine waves could be matched in the same way. It will be noted that the circuit provides for elimination of the electronic switch so that a single sine wave or ellipse can be projected if desired.

Measured half-wave potentials.—The following observations were made for solutions for which known half-wave potentials were available for comparison.

Solution	Supporting electrolyte	$E_{\frac{1}{2}}$ vs. N.C.E., volts Observed	Literature
0.001 *M* $CdSO_4$	0.1 *M* KCl	−0.661	−0.63 (3)
0.001 *M* $Cu(ClO_4)_2$	0.1 *M* KCl	−0.029	−0.03 (3)
0.001 *M* $Pb(NO_3)_2$	0.1 *M* KNO_3	−0.432	−0.46 (3)
			−0.43 (6)

In each case the reading was checked by resetting the potential dial several times. For cadmium there was found to be an interval of 4 mv. in which no distortion was visible, the middle of which could easily be located to 1 mv. For copper and lead the region of no distortion was about 10 mv. Bubbling with nitrogen for a period of two hours did not change the indication obtained for a fresh solution of cadmium ion.

We do not doubt that the details of this circuit could be improved; for instance, the use of a double-gun oscilloscope would obviate the electronic switch. The principal difficulty encountered was the elimination of stray noise, and it must be stressed that adequate shielding and grounding of the circuit are imperative for satisfactory operation.

We are greatly indebted to Professor J. M. Anderson of the Department of Physics, University of Toronto, for the loan of equipment and for much help with the design of the circuit. We also gratefully acknowledge financial assistance from the University's Advisory Committee on Scientific Research.

THE FORMATION OF MOLECULAR COMPLEXES BETWEEN SOLID UREA AND *n*-OCTANE VAPOR

By H. G. McAdie[1] and G. B. Frost

The formation of molecular complexes, called adducts, between urea and *n*-paraffins has been known for some time. Schlenk (3) has given a detailed account of their preparation from solution, and has reported an elucidation of their structure on the basis of X-ray evidence. He showed that when straight chain hydrocarbon molecules are added to a concentrated solution of urea, in a suitable solvent, crystallization of the urea occurs in such a way that each hydrocarbon molecule becomes imprisoned in a canal formed by a hexagonal arrangement of urea molecules, as contrasted with the normal closely packed

THE FORMATION OF MOLECULAR COMPLEXES BETWEEN SOLID UREA AND *n*-OCTANE VAPOR

By H. G. McAdie[1] and G. B. Frost

The formation of molecular complexes, called adducts, between urea and *n*-paraffins has been known for some time. Schlenk (3) has given a detailed account of their preparation from solution, and has reported an elucidation of their structure on the basis of X-ray evidence. He showed that when straight chain hydrocarbon molecules are added to a concentrated solution of urea, in a suitable solvent, crystallization of the urea occurs in such a way that each hydrocarbon molecule becomes imprisoned in a canal formed by a hexagonal arrangement of urea molecules, as contrasted with the normal closely packed

[1]*C.I.L. Fellow in Chemistry, 1954–55.*

tetragonal lattice of urea. The hexagonal structure has now been worked out in detail (4) and the whole subject of urea adducts has been reviewed elsewhere (1, 5).

Schlenk (3) has also reported the slow formation of urea adducts by the mere contact of finely divided tetragonal urea crystals with certain pure liquid *n*-paraffins, and has also suggested the possibility of forming such adducts by exposure of tetragonal urea to the vapor of the lower boiling *n*-paraffins. Redlich and co-workers (2) have reported measurements of equilibrium pressures for various systems consisting of adduct, solid urea, and a long chain molecule. These measurements imply a reversibility between the reactions involving adduct decomposition and formation.

The present work was undertaken in an attempt to throw light upon the mechanism of this reaction between tetragonal urea and pure *n*-paraffin vapors, which is an interesting one from the standpoint of the molecular forces involved. The following is a report of some preliminary experimental findings, and an indication of some of the experimental work in progress.

Reagent grade urea was recrystallized, dried, and screened, the "through 60 mesh on 80 mesh" portion being used. Small samples (40 mgm.) were contained in a basket of 100-mesh copper gauze and suspended on a quartz spiral balance. The balance case was connected with the usual vacuum system and means were provided for the exposure of the suspended sample to *n*-octane vapor at its saturation vapor pressure at 25° C. Provision was also made for the addition of other gases.

On exposure of urea samples, prepared in this way, to *n*-octane vapor, no evidence of adduct formation was observed after 24 hr. It was found, however, that adduct formation took place rapidly in the presence of water vapor, and that if the adducts so formed were decomposed under vacuum, addition of *n*-octane vapor then occurred rapidly in the absence of water vapor, and that cycles of decomposition and absorption of hydrocarbon could be carried out. Adduct formation in the presence of water vapor has been confirmed by X-ray diffraction, the line patterns being identical with those obtained for adducts of several normal hydrocarbons and alcohols prepared from saturated solutions of urea in methanol. The nature of the products formed by the addition of *n*-octane vapor after the evacuation of the adduct and in the absence of water vapor has not as yet been definitely established.

The results of a typical experiment are shown in Fig. 1 where the weight increase, as obtained by readings of spiral extension, is plotted against the square root of the time in minutes. In this experiment, the urea sample was evacuated at 10^{-4} mm. and 25° C. for 24 hr., in order to remove traces of water vapor. It was then exposed to *n*-octane vapor at its saturation vapor pressure at 25° C. for 24 hr. No significant change in weight was observed during this period. Water vapor at a pressure of approximately 11 mm. was then admitted. The sample started to increase in weight immediately, and a gradual swelling occurred. Zero time in Fig. 1 is taken as the time of admission of water vapor.

When the reaction appeared to be approaching completion, vacuum was applied and the weight of the sample decreased rapidly to its initial value.

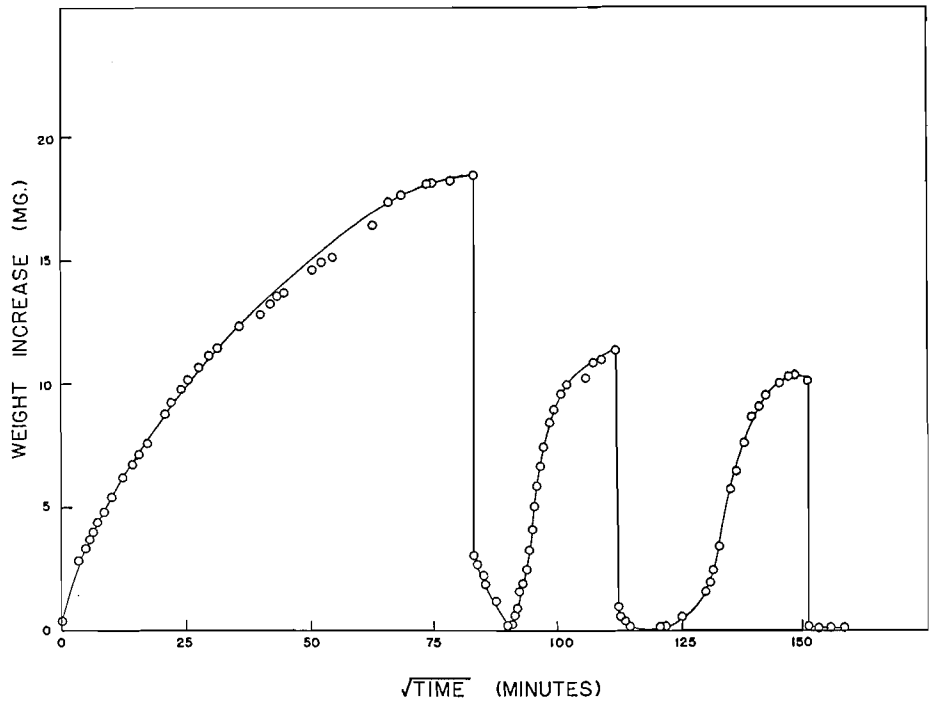

FIG. 1. Typical formation and decomposition curves for the urea–*n*-octane adduct.

Pure *n*-octane vapor at its saturation pressure was then admitted, but no water vapor. A rapid increase in weight occurred (the second rise shown in Fig. 1), the rate decreasing at a much lower uptake of the hydrocarbon. The reaction was allowed to proceed for a time and the cycle of operations repeated. Uptake of *n*-octane was again observed.

If adduct formation occurs during the second and third exposures, some stability of the hexagonal lattice after the withdrawal of the hydrocarbon chain may be indicated. It is also possible that the removal of the hydrocarbon at very low pressure may result in the collapse of the hexagonal lattice into an assembly of microcrystals of tetragonal urea, and that adduct formation takes place more readily on this material of high surface area. It is also possible that the observed uptake of *n*-octane in the absence of water vapor is due to adsorption. Experiments are being carried out with the purpose of deciding among these alternatives.

Adduct formation in the presence of water vapor was accompanied by a marked swelling of the sample. This is probably due to the increased volume of the hexagonal channel structure over the normal tetragonal crystals and has been reported by others (1). It is interesting to note that this swollen state persisted after the decomposition of the sample at low pressure.

While extensive quantitative results are not yet available, the rate of adduct formation appears to have a linear dependence on water vapor pressure over the range from 8 to 15 mm. There appears to be a lower limit of water vapor

pressure (approximately 7 mm.) below which adduct formation does not occur for crystals of the dimensions used in these experiments.

The reaction between urea crystals and *n*-octane vapor in the presence of water vapor was also observed by a photomicrographic technique. At water vapor pressures of 14 to 15 mm. the reaction was observed to proceed quite readily. This was shown by the loss of transparency of the urea crystal and the formation of a fuzzy, opaque, somewhat larger crystal.

Photomicrographic evidence appears to indicate that not all the urea crystals react at once. However, once initiation of reaction occurs on a given crystal, the reaction progresses rapidly through that crystal. When water vapor was present to the extent of 7 to 8 mm. no reaction occurred after 24 hr., indicating again the presence of a limiting water vapor pressure below which adduct formation does not occur.

The fact that water vapor promoted the adduct formation led to an investigation of other possible promoters. Methanol and ethanol, at pressures in the region of 10 to 15 mm., promoted the reaction after considerable time. There is some indication that nitromethane and ethylenediamine behave in a similar manner. The effect of other substances is being studied.

Work is being carried out on the adsorption of water vapor on urea, the determination of the change in surface area on removal of hydrocarbons at low pressure, and more extensive utilization is being made of X-ray techniques. The results will be reported in a subsequent paper.

1-ALKYL-2-IMIDAZOLIDINETHIONES[1]

BY G. D. THORN[2]

For the study in this laboratory of the fungicidal activity of compounds containing the thiocarbamoyl grouping, it became necessary to have a series of 1-alkyl-2-imidazolidinethiones. Except for a paper by Rich and Horsfall (10) in which is reported the fungitoxicity of *n*-octyl-, *t*-octyl-, and *n*-octadecylethylenethiourea (for which no physical characteristics are given), no reference to simple 1-alkyl-2-imidazolidinethiones is to be found in the literature.

1-ALKYL-2-IMIDAZOLIDINETHIONES[1]

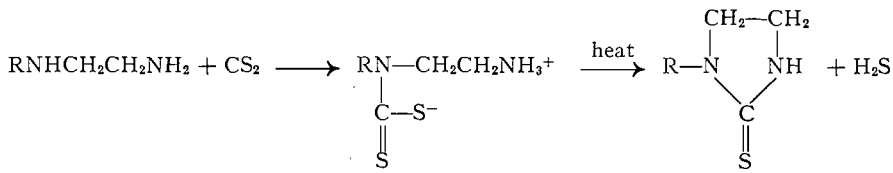
BY G. D. THORN[2]

For the study in this laboratory of the fungicidal activity of compounds containing the thiocarbamoyl grouping, it became necessary to have a series of 1-alkyl-2-imidazolidinethiones. Except for a paper by Rich and Horsfall (10) in which is reported the fungitoxicity of *n*-octyl-, *t*-octyl-, and *n*-octadecylethylenethiourea (for which no physical characteristics are given), no reference to simple 1-alkyl-2-imidazolidinethiones is to be found in the literature.

[1]*Contribution No. 51, Science Service Laboratory, London, Ontario.*
[2]*Senior Chemist.*

The reaction of equimolar amounts of ethylenediamine and carbon disulphide was shown by Hofmann (4) to yield N-(β-aminoethyl)dithiocarbamic acid (I, R = H). Thermal decomposition of this inner salt gave 2-imidazolidinethione (II, R = H). These reactions were later extended to various N- and N,N′-substituted 2-imidazolidinethiones by van Alphen (1), Baum (2), Donia, Shotton, Bentz, and Smith (3), Hurwitz and Auten (5), Lob (7), Newmann (8), Schmidt (11), Vaugh and Bean (12), and Zienty (13).

Following the classical procedures, a series of 1-alkyl-2-imidazolidinethiones has been prepared.



I II

EXPERIMENTAL[3]

The N-alkylethylenediamines were prepared either by reaction of the requisite alkylamine with 2-bromoethylamine (9) (R = ethyl through hexyl), or by reaction of an alkyl halide with 98% ethylenediamine (6) (R = heptyl through dodecyl).

The N-alkyl-2-imidazolidinethiones were prepared essentially according to the method given by Donia *et al.* (3). The reaction of the amine with carbon disulphide was carried out in ether to give a fine white precipitate of the dithiocarbamic acid inner salt. The use of acetone (3) as the reaction medium resulted in yellow gummy precipitates, which could however be triturated with ether to give more tractable material.

A typical preparation is described, in which the alkyl group is octyl: A solution of 10.1 gm. (0.059 mole) of N-octylethylenediamine in 80 ml. ether was cooled to 10° C. in an ice-bath, and stirred vigorously while 4.72 gm. (0.062 mole) of carbon disulphide in 30 ml. ether was added dropwise. Stirring was continued for 30 min. after addition was completed. The precipitate was removed by filtration, washed with ether, and air-dried. The yield was 14.3 gm. (98%). Found: N, 11.2%. Calc. for $C_{11}H_{24}N_2S_2$: N, 11.3%.

The inner salt was heated for two hours in a wide-mouthed Erlenmeyer flask immersed in an oil bath at 130° C. The dark residue was crystallized from hexane to give 9.7 gm. (77%) of 1-octyl-2-imidazolidinethione. The material was then recrystallized from hexane to constant melting point (Table I).

The yields given in Table I are calculated from the amount of material obtained after one crystallization of the crude imidazolidinethione. Hexane was the preferred solvent for recrystallization, except for the first three members of the series, where ether or hexane–acetone was used.

[3]*All melting points are uncorrected and were obtained on the Fisher-Johns block.*

PYROLYSIS OF ETHYL MERCAPTAN[1]

BY JEAN L. BOIVIN AND RODERICK MACDONALD

ABSTRACT

The decomposition of ethyl mercaptan to ethylene and hydrogen sulphide was studied at various temperatures, with and without a catalyst. Metal sulphides (copper, nickel, and cadmium) proved to be the most efficient catalysts for cracking ethyl mercaptan into unsaturated end products, the optimum temperature being 500–600° C. When no catalyst was used a 40–50% yield of ethylene and a nearly quantitative conversion to hydrogen sulphide was observed between 600 and 700° C. Other products identified in the exit gas were carbon disulphide, carbonyl sulphide, methane, hydrogen, ethane, thiophene, diethyl sulphide, and free sulphur. Identification of these products was aided by infrared and mass spectral analysis of the gas. A tentative mechanism for the reaction justifying the presence of the above by-products is outlined.

INTRODUCTION

Sabatier and Mailhe (4) report that diethyl sulphide and hydrogen sulphide are formed when dry ethyl mercaptan is passed over a cadmium sulphide catalyst at 330° C. and that upon heating to 380° C. ethylene and hydrogen sulphide are quantitatively formed:

$$2CH_3CH_2{-}SH \xrightarrow[CdS]{330^\circ\ C.} (CH_3CH_2)_2S + H_2S \qquad [1]$$

$$CH_3CH_2{-}SH \xrightarrow[CdS]{380^\circ\ C.} CH_2{=}CH_2 + H_2S. \qquad [2]$$

The conditions reported by Sabatier and Mailhe were reproduced but no reaction product was obtained. Hydrogen sulphide was absent, which proved that even diethyl sulphide was not formed (Eq. [1]) at this temperature. A study was then undertaken to determine the optimum conditions for the preparation of ethylene and hydrogen sulphide from ethyl mercaptan.

APPARATUS

The reaction chamber consisted of a Pyrex or silica tube 24 in. in length and 1 in. in diameter mounted vertically in a cylindrical furnace. The bottom of the tube was connected through a ground-glass joint to a two-necked flask which served as the vaporization vessel. To the second neck was attached a measuring dropping funnel for the introduction of ethyl mercaptan. The products of the reaction were allowed to escape through an opening at the

[1]*Manuscript received April 4, 1955.*
Contribution from the Organic Section of Canadian Armament Research and Development Establishment, Valcartier, Quebec. Issued as C.A.R.D.E. Report No. 115–55.

top of the reaction chamber and passed through an upright water-cooled condenser. The gaseous fraction was led from the top of the condenser to a series of scrubbers (for H_2S and unsaturated compounds) while condensable materials were retained in a flask attached to the bottom of the condenser. In operation the reaction tube was packed with alternate layers of glass wool and catalyst, or glass wool only. The inside temperature was recorded by means of a thermocouple. The vaporization flask was heated by a glas-col mantle.

GENERAL METHOD

In operation a weighed quantity of ethyl mercaptan was added from the dropping funnel at the rate of 1 gm. per min. to the vaporization flask which was held at 150°C. The volatilized mercaptan entered the reaction tube (held at a constant temperature) and emerged as a mixture of gases and some condensable products. The gases were bubbled first through water to remove free sulphur, then through 30% sodium hydroxide to remove hydrogen sulphide, and finally through bromine (under water) to remove unsaturated material.

When a total analysis of the reaction products was required a sample was taken directly from the top of the condenser. Using an Orsat apparatus, the sample (100 ml.) was measured at equalized pressure and sent through an absorption pipette containing 30% sodium hydroxide until the volume of remaining gas remained constant. The loss in volume was measured as hydrogen sulphide. Unsaturated materials were removed with fuming sulphuric acid (20%) or bromine. The remaining portion was passed through hot copper oxide several times to determine its hydrogen content, and then the remainder was burned in the presence of oxygen and the volumes of carbon dioxide and water formed were measured. The latter measurements enable one to determine the amount of methane and ethane in a sample of gas when only the two are present.

RESULTS

Since cadmium sulphide was reported as a good catalyst by Sabatier, it was studied over a wide range of temperatures. One mole of ethyl mercaptan was used and samples were taken five to ten minutes after the reaction had begun, to ensure the absence of air.

With this catalyst, formation of ethylene (Table I) started at 400° C. with a yield of only 5.7% of the total gases coming out of the reactor. Also much liquid condensed, which was identified as diethyl sulphide with minor quantities of ethyl mercaptan.

A maximum yield was attained at 600° C. with 24.1% of ethylene in the gas mixture. As can be noted, the ethylene formation passed through a maximum at 600° C. The hydrogen sulphide formation was very high at the start and then decreased steadily with increasing temperatures. Sulphur was also formed in small amounts.

Hydrogen formation increased with the temperature of pyrolysis. This is undoubtedly due to the cracking of hydrocarbon or hydrogen sulphide. Also the mixture of gas B after ethylene, hydrogen sulphide, and hydrogen have

B refers to gases that could not be analyzed by the Orsat apparatus.

been removed increased with the temperature. This mixture of gases when burned in the Orsat apparatus could not be calculated as methane and ethane.

Following these results a search for a more efficient catalyst was made. Other sulphides were studied.

With nickel sulphide catalyst (Table I) results were similar to cadmium sulphide except that the formation of ethylene took place at a higher temperature (450° C. instead of 400° C.).

Other sulphides were used, namely those of cobalt, copper, and iron, and gave similar results to nickel sulphide with minor differences.

Aluminosilicate behaved like sulphides, except that less hydrogen was formed. The yield of ethylene was about 30% at 500° C.

Without a catalyst (Table I), ethylene was produced at 500° C. and the composition of the gas remained nearly constant from 500 to 700° C.

IDENTIFICATION OF PRODUCTS

The condensate obtained from the reaction products was quite large at low reaction temperatures. This was shown by a boiling point determination to be diethyl sulphide with a small amount of unreacted ethyl mercaptan.

A white colloidal material was noticed in the water scrubber after the reaction had proceeded for 30 min. Extraction with carbon disulphide removed this material. Upon evaporation sulphur was obtained.

(*a*) *Infrared Spectra*

The gas coming out of the reactor was sampled in a gas cell with sodium chloride windows. Another sample was usually taken after hydrogen sulphide and ethylene were removed.

Ethylene was easily identified by its broad and very intense band at 949 cm.$^{-1}$ and a triplet at 1860, 1889, 1910 cm.$^{-1}$ (3). Other bands may be common to other products.

After removal of ethylene and hydrogen sulphide, the spectrum also showed the presence of methane with an absorption band at 1306 cm.$^{-1}$ (3) and of ethane at 820 cm.$^{-1}$ (3).

The mixture also contained carbon disulphide as shown by the band at 2183 cm.$^{-1}$ (3).

Carbonyl sulphide was detected by its very intense absorption at 2050 cm.$^{-1}$, which in many cases has a dual nature under dilution (1). Another band which might be characteristic of thiophene was present at 710 cm.$^{-1}$ (2). The spectrum of the unscrubbed and scrubbed gases is fully explained and all bands were assigned to known gases.

(*b*) *Mass Spectrometry*

In order to know the relative amount of product present in one of these mixtures of gases mass spectral analysis was used. Since the Orsat apparatus could give reasonable accuracy for the estimation of ethylene, hydrogen sulphide, and hydrogen, the samples used for mass spectral analysis were free of hydrogen sulphide and ethylene.

Results obtained when using cadmium sulphide catalyst at 500° C. showed an average composition of 41% of ethane, 8.4% of methane, and 47% of hydrogen, and traces of other materials such as carbon disulphide, carbonyl sulphide, and thiophene. Therefore the proportion of ethane in this gas mixture is high and that of methane, low. The composition of this fraction of gas indicates cracking of ethane or ethylene.

DISCUSSION

The pyrolysis of ethyl mercaptan under flow conditions is very slightly catalytic if at all. With the best catalysts used, such as sulphides of copper, nickel, cobalt, and cadmium, the lowest temperature at which ethylene is produced is 450° C. The yield is small, and the best temperature for the optimum formation of ethylene, with catalysts, is 500° C. Moreover, from 500 to 700° C. without a catalyst, the yield of ethylene is practically constant. It is considered that temperatures of 500–600° C. would be efficient using Pyrex or silica tubes packed with glass wool.

MECHANISM

The basic reaction in the pyrolysis of ethyl mercaptan is analogous to the dehydration of ethyl alcohol. This dehydration reaction is reversible under certain conditions. Also the pyrolysis of ethyl mercaptan, which can be termed as a desulphurization process, is a reversible reaction:

$$CH_3CH_2{-}OH \underset{H_2SO_4}{\overset{Al_2O_3}{\rightleftharpoons}} CH_2{=}CH_2+H_2O \qquad [3]$$

$$2EtOH \longrightarrow Et_2O+H_2O \qquad [4]$$

$$CH_3CH_3SH \rightleftharpoons CH_2{=}CH_2+H_2S\,. \qquad [5]$$

At lower temperatures, when the hydrogen sulphide formation is high, some liquid is formed, which was identified as diethyl sulphide (Eq. [1]).

Since elemental sulphur is formed in the pyrolysis, it should come from the decomposition of hydrogen sulphide which is said to start at 400° C. Even if the dissociation of hydrogen sulphide is small, the equilibrium is shifted to the right by removal of sulphur or hydrogen, which are both present in the reaction products.

Ethane is found at all the temperatures studied as evidenced by the infrared spectra obtained. It is likely to be formed by the reduction of ethylene with the hydrogen generated from hydrogen sulphide. At higher temperatures methane is produced in greater proportion and the hydrogen content of the gaseous products is higher indicating that another pyrolysis is taking place.

Carbon disulphide, carbonyl sulphide, and thiophene are also formed in traces. The occurrence of carbon disulphide indicates that methane has reacted with sulphur vapor (Eq. [6]). This reaction is the basis of a commercial process to make carbon disulphide:

$$CH_4+4S \longrightarrow CS_2+2H_2S\,. \qquad [6]$$

The presence of carbonyl sulphide is due to some oxygen in the system, probably some oxide impurity in the catalyst, and the presence of thiophene is due to the dehydrogenation of diethyl sulphide or to the condensation of ethylene with hydrogen sulphide followed by dehydrogenation.

THE PAPILIONACEOUS ALKALOIDS

XXI. THE ALKALOIDS OF *LUPINUS PILOSUS* WALT. AND THE STRUCTURE OF TETRALUPINE[1]

By A. F. Thomas,[2] H. J. Vipond,[2] and Léo Marion

ABSTRACT

The alkaloidal extract from *Lupinus pilosus* Walt. was found to contain two alkaloids, one widely occurring one, *d*-lupanine, and one which had already been reported to occur in this plant, i.e., *d-epi*lupinine, but no lupinine. The alkaloid tetralupine has been found by direct comparison of the bases and their corresponding salts and by their infrared absorption spectra to be identical with *dl-epi*lupinine. A study of the infrared absorption spectra of lupinine and *epi*lupinine leads to the same conclusion as the chemical evidence, i.e., that in the former the hydroxymethylene group occupies the axial position whereas in *epi*lupinine this group is in the equatorial position.

Although *Lupinus pilosus* has been mentioned as a source of *l*-lupinine (2), White (11) reported *d-epi*lupinine as the only identifiable alkaloid in the plant. Since there was available a crude alkaloidal extract of *Lupinus pilosus* Walt. (*Lupinus villosus* Willd.) prepared and given to us by Dr. James F. Couch, the alkaloids were reinvestigated. The crude extract consisted of a thick dark syrup. A quantity of the syrup was dissolved in benzene, chromatographed on a column of alumina, and eluted with a number of solvents taken in the order benzene–ether–chloroform–methanol, the proportions of each being gradually changed. A trace of non-alkaloidal material was eluted first. Solvents containing benzene (40%) and ether (60%) to ether (95%) and chloroform (5%) eluted a colorless oil which behaved chromatographically on buffered paper as *d*-lupanine. This base formed a crystalline perchlorate, the melting point of which was undepressed on mixing with *d*-lupanine perchlorate. The identity of this salt was further confirmed by comparison of its Debye-Scherrer powder diagram with that of authentic *d*-lupanine perchlorate. This fraction composed about 15% of the crude mixture.

Fractions eluted in the solvent range ether (60%) – chloroform (40%) to ether (40%) – chloroform (60%) gave crystals, m.p. 76–78°, representing 35% of the original crude mixture. This crystalline substance on a paper chromatogram behaved like lupinine, but mixing with the latter lowered the melting point to 43–47°. The crystalline base, after recrystallization, melted at 78–79° and had $[\alpha]_D$ +37.1° (12), which agreed with the properties reported for *d-epi*lupinine, and the melting point was undepressed in admixture with a sample of the latter prepared as described by Schöpf, Schmidt, and Braun (10). The infrared absorption spectra of the two were superimposable (Fig. 1, curve 1) but different from that of lupinine (Fig. 1, curve 2).

Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3649.
[2]*National Research Council of Canada Postdoctorate Fellow.*

NOTE ADDED IN PROOF: *After submission of the manuscript, a paper was published by W. D. Crow and N. V. Riggs (Australian J. Chem. 8: 136. 1955) reporting the occurrence of d-epilupinine and d-epilupinine-N-oxide in* Lupinus varius *L.*

In order to ascertain that *epi*lupinine did not arise on the column of alumina by epimerization of lupinine, some of the latter was chromatographed in the same way and eluted with ether containing increasing quantities (up to 10%) of chloroform. All the lupinine was recovered unchanged.

The remaining fractions from the main chromatogram yielded a dark brown glass which resisted all attempts at crystallization, and failed to give either a

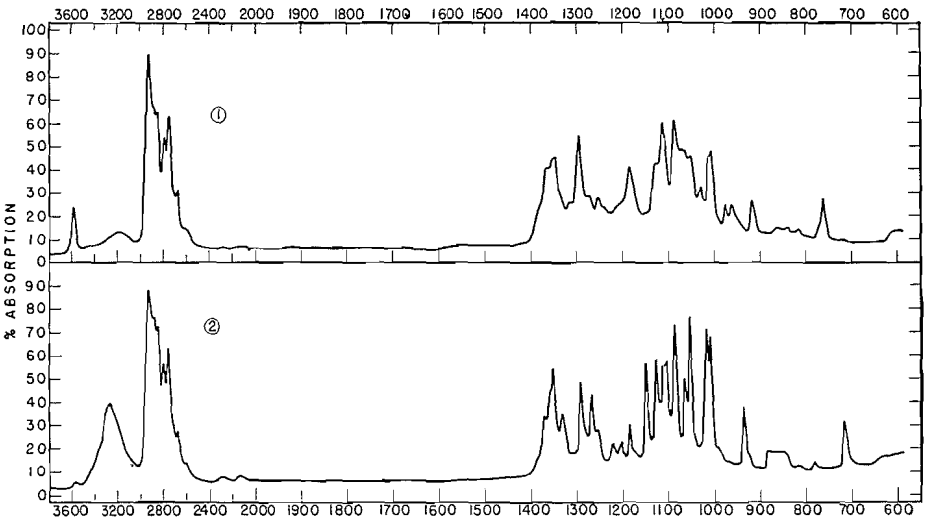

FIG. 1. Infrared absorption spectra taken in carbon disulphide solution on a Perkin-Elmer double beam spectrophotometer, model 21. Curve 1, *epi*lupinine; curve 2, lupinine.

crystalline picrate or perchlorate. When this glass was chromatographed on paper, it gave a number of indeterminate streaks. A paper chromatogram of the original crude alkaloidal extract had shown that there were only two major components which are, therefore, *d*-lupanine and *d-epi*lupinine.

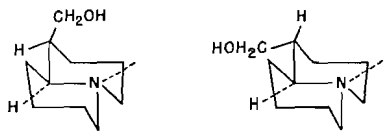
As previously recorded (10, 12) *d-epi*lupinine showed a depression in melting point when mixed with the isomeric alkaloid tetralupine discovered by Couch[3] in 1934 (4). A sample of tetralupine was dissolved in benzene, chromatographed on a column of alumina, eluted, sublimed *in vacuo*, and recrystallized from petroleum ether. It then melted at 83° and was optically inactive (Couch had reported $[\alpha]_D$ +4.63°). It formed a picrolonate, a picrate, and a methiodide which were all crystalline. Comparison of tetralupine and its salts by melting point and mixed melting point with authentic samples of *dl-epi*lupinine and its corresponding salts, kindly supplied by Professor G. R. Clemo, showed the identity of the two bases. The identity was confirmed by the infrared absorption spectrum of tetralupine which was exactly superimposable on those of *d-epi*lupinine and *dl-epi*lupinine. It can, therefore, be concluded unambiguously that tetralupine is identical with *dl-epi*lupinine.

An examination of the infrared absorption spectra of lupinine and *epi*-

[3]*Dr. James F. Couch, about a year before his death, had most generously given to the senior author his entire supply of tetralupine.*

lupinine in nujol mulls shows that both contain a broad bonded OH band at *ca.* 3160 cm.$^{-1}$, but that in carbon disulphide solution the hydroxyl band in the spectrum of *epi*lupinine becomes sharp and is shifted to 3580 cm.$^{-1}$, while in the spectrum of lupinine the hydroxyl band moves only to 3270 cm.$^{-1}$ and remains broad.

This observation is indicative that in lupinine the hydroxyl group is hydrogen bonded, as previously inferred by Cookson (3), whereas it is not in *epi*lupinine. It is also significant that lupinine is eluted from an alumina column before *epi*lupinine. Consequently, lupinine must be assigned a conformation with the hydroxymethylene group occupying a position in which it may easily form a hydrogen bond to the nitrogen atom. Such hydrogen bonding is possible in the axial position I, but is impossible in the equatorial position II. Hence formula I must be assigned to lupinine while formula II must represent *epi*lupinine.



I LUPININE II EPILUPININE

This assignment of conformations from the absorption characteristics of the hydroxyl group in the infrared spectra of the two bases is in agreement with the conformations assigned recently by Galinovsky and Nesvadba (6) to lupinine and *epi*lupinine from the interpretation of the rearrangement readily undergone by the tosyl ester of lupinine and the stability of the tosyl ester of *epi*lupinine. Lupinine can be degraded to 2-*n*-butyl-3-methylpiperidine (12) and by an unambiguous synthesis of the isomers of this substance Leonard and Ryder (7) have correlated the stereochemistry of the degradation product with that of lupinine. Recently, Ratuský, Reiser, and Šorm (9) by a study of the dipole moments of lupinine and *epi*lupinine as well as of the two forms of 3-hydroxymethylquinolizidine have reached the same conclusion as to the conformations of the two alkaloids. Consequently, all the evidence points to formula I for lupinine and formula II for *epi*lupinine.

Paper chromatography has been shown to be a useful preliminary tool to examine the constituents of a crude alkaloidal mixture in the lupine series. When using sodium phosphate – citric acid buffers and saturated aqueous *n*-butanol as the developing agent, the R_F values obtained for a group of lupine alkaloids show that they can be separated easily. The spots were detected with the Munier-Dragendorff reagent (8). The papers were buffered by dipping in a buffer solution of appropriate strength, blotting, and allowing to dry completely (contrast Brindle *et al.* (1)).

EXPERIMENTAL

d-Lupanine

A quantity (1.0 gm.) of the crude alkaloidal extract was dissolved in dry benzene (100 ml.), the solution filtered, and chromatographed on alumina.

The column was eluted with benzene, ether, chloroform, and methanol, 98 fractions of 60 ml. each being collected. The initial fractions contained non-basic material. From fractions 26–43 (60% ether – 40% benzene to 95% ether – 5% chloroform) a colorless oil was obtained (150 mgm.) which with 60% perchloric acid gave a perchlorate $[\alpha]_D^{19}$ +46° (*c*, 1.0 in water), m.p. 207–210°, and after two recrystallizations from methanol, m.p. 211°, either alone or in admixture with an authentic sample of *d*-lupanine perchlorate. The literature (5) gives $[\alpha]_D$ +46.8°. The identity of the perchlorate was further confirmed by comparison of its Debye-Scherrer powder diagram with that of authentic *d*-lupanine perchlorate. Each fraction had been shown by paper chromatography at pH 7 to be the same, and to behave in the same way as *d*-lupanine with varying pH.

d-Epilupinine

Fractions 53 (60% ether – 40% chloroform) to 70 (40% ether – 60% chloroform) of the chromatogram yielded a crystalline substance, 350 mgm., m.p. 76–78°, which after two recrystallizations from petroleum ether melted at 78–79° and had $[\alpha]_D^{19}$ +37.1° (*c*, 1.0 in ethanol). Found: C, 71.4; H, 11.1. Calc. for $C_{10}H_{19}ON$: C, 71.0; H, 11.3%. The melting point of this base was unaffected by mixture with *d-epi*lupinine, but depressed to 68–78° by admixture with tetralupine, and to 43–47° by admixture with lupinine. Comparison of the infrared absorption spectra confirmed the identity of the base with *d-epi*lupinine.

Chromatography of Lupinine

Lupinine (390 mgm.) was dissolved in ether and chromatographed on alumina. It was eluted at once by the same solvent, the last traces being removed with ether – 10% chloroform.

Tetralupine

A quantity of tetralupine was chromatographed on alumina and eluted exactly as described for *d-epi*lupinine. The substance was sublimed in a high vacuum and recrystallized from petroleum ether from which it separated in small colorless prisms, m.p. 83°, and in admixture with an authentic sample of *dl-epi*lupinine, m.p. 82–83°, $[\alpha]_D$ 0 in ethanol. The infrared absorption spectrum of tetralupine was superimposable on that of *dl-epi*lupinine. Tetralupine formed a picrolonate, m.p. 231–232°, undepressed by admixture with *dl-epi*lupinine picrolonate (m.p. 225°). Found: C, 55.41; H, 5.97. Calc. for $C_{10}H_{19}ON \cdot C_{10}H_{27}O_6N_5$: C, 55.41; H, 6.28%. The picrate consisted of yellow needles, m.p. 145.5–147°, either alone or in admixture with synthetic *dl-epi*lupinine picrate. Found: C, 48.18, 48.41; H, 6.09, 5.46. Calc. for $C_{10}H_{19}ON \cdot C_6H_3O_7N_3$: C, 48.24; H, 5.57%. Tetralupine also formed a methiodide, m.p. 251–253°, either alone or in admixture with *dl-epi*lupinine methiodide (m.p. 248°). Found: C, 42.92; H, 7.31. Calc. for $C_{11}H_{22}ONI$: C, 42.44; H, 7.13%.

ACKNOWLEDGMENT

We wish to express our thanks to Professor G. R. Clemo, University of Durham, for his kindness in supplying us with authentic samples of *dl-*

*epi*lupinine and its salts, and to Mr. R. Lauzon and Dr. R. N. Jones of these laboratories for taking the infrared absorption spectra.

THE SELECTIVE DEGRADATION OF WHEAT GLUTEN[1]

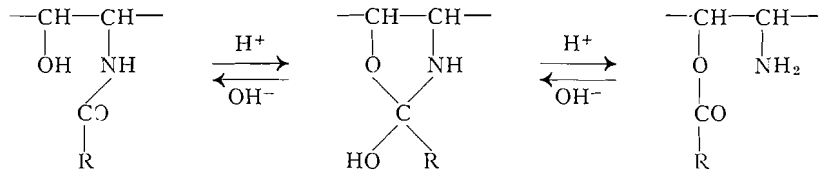
By L. Wiseblatt,[2] L. Wilson,[3] and W. B. McConnell

ABSTRACT

A method believed to hydrolyze peptide bonds of proteins selectively at the amino groups of serine was used to obtain polypeptides from wheat gluten. The procedure involved the use of strong acid and introduced appreciable amounts of sulphur into the products possibly as sulphonic acid groups. Most of the serine appeared at the amino termini of the peptides. The peptides displayed a striking electrophoretic homogeneity which may at least in part be accounted for by the acquired acid groups. Osmotic pressure measurements indicated an average molecular weight near 20,000 and terminal group estimates indicate that each molecule contained several N-terminal serine residues. There appeared to be strong association or chemical cross linking between peptide chains of the degraded gluten.

INTRODUCTION

In 1948 Desnuelle and Casal (8) showed that when proteins are hydrolyzed in 10 *N* hydrochloric acid at 30°C. the amino groups of the hydroxy amino acids, serine and threonine, are released much more rapidly than those of other amino acids. They suggested that the increased rate of rupture of these bonds involved a preliminary migration of the acyl part of the peptide bond from the amino group to the hydroxyl group of the hydroxy amino acid. The mechanism probably involves formation of an intermediate hydroxyoxazolidine structure as follows (1, 9):



More recently Desnuelle and Bonjour (7) observed that a more specific hydrolysis at hydroxy amino acids could be obtained by pretreating the protein with cold anhydrous sulphuric acid according to the method of Reitz, Ferrel, Fraenkel-Conrat, and Olcott (19). Subsequent hydrolysis in 6 *N* hydrochloric acid at 18°C. released the amino groups of the hydroxy amino acids many times more rapidly than those of all other amino acids.

Elliott (9) utilized the above observations in an ingenious manner. Silk fibroin was treated with cold concentrated sulphuric acid to produce the N-peptidyl → O-peptidyl shift. The product was then acetylated to block the newly freed amino groups. Subsequent treatment with cold dilute barium hydroxide saponified the ester links yielding N-acetyl peptides. About 60%

of the serine and no threonine was N-terminal. The absence of terminal threonine was not considered very significant because of the very low percentage of that amino acid in silk. In a subsequent degradation of lysozyme Elliott (11) found that nearly all the serine and about one-third of the threonine was terminal. The amino groups of serine and threonine accounted for all of the amino nitrogen in the degradation products of lysozyme (11) whereas a small amount of non-specific hydrolysis of silk fibroin occurred.

This communication is a report of results obtained when Elliott's degradation scheme was applied to wheat gluten. The method seemed particularly attractive because serious solubility problems are encountered in almost all chemical investigations of native gluten. Thus denaturation occurs irreversibly in dilute alkali, the only aqueous medium which gives apparently monodisperse solutions, and aqueous acetic acid, sodium salicylate, and urea do not give molecular dispersions of the protein. If gluten could be specifically degraded to soluble products, these difficulties would be partly overcome. Information from a study of degradation products might well help elucidate the constitution of gluten.

EXPERIMENTAL METHODS AND RESULTS

Sulphuric Acid Treatment of Gluten

Ten grams of wheat gluten prepared by the method of Lusena (15) was suspended in 200 ml. of anhydrous sulphuric acid (sulphuric acid containing 10% by volume of 20% oleum). After 24 hr. at −20°C. the mixture was allowed to warm slowly to room temperature and was left to stand with occasional shaking for another five days. The resulting viscous brown liquid was poured with vigorous stirring into 2 liters of anhydrous ether at −35°C. The precipitate was collected by centrifugation, washed three times with dry ether, and finally added to 600 gm. of crushed ice on which it formed a sticky yellow mass.

Degradation of Gluten Sulphate

The suspension obtained above was adjusted to pH 5 with solid sodium acetate and treated over a period of two hours with 100 ml. of acetic anhydride. The temperature was not allowed to exceed 5°C. Sodium acetate was added as required to maintain pH at 5. The reaction products were dialyzed against water until they reached a constant low acidity as measured by titration or until the washings were acetate free as indicated by the sensitive lanthanum nitrate spot test (7, 13). The dialysis washings were discarded after they had been shown to be nitrogen free. The contents of the dialysis bag were reduced to about 100 ml. in a stream of air and the gluten derivative, which settled out as a spongy mass, was collected and added to 100 ml. of 0.1 *N* barium hydroxide. After two hours at room temperature all material dissolved to yield a yellowish brown solution. This was saturated with carbon dioxide and the precipitated barium carbonate discarded after it had been shown to be free of nitrogen. The supernatant solution was freeze dried to yield about 9 gm. of acetyl peptide.

In an attempt to remove acetyl groups 1 gm. of acetyl peptide was shaken with a mixture of 100 ml. of dry methanol and 1 ml. of concentrated hydro-

chloric acid for three days at 5°C. (In a few later experiments a 1% solution of anhydrous hydrochloric acid in dry methanol was used to reduce unspecific peptide bond hydrolysis.) The solid residue was filtered off, washed with methanol, then dissolved in water and freeze dried yielding a pale brown methanol insoluble peptide (hereinafter called MIP). The filtrate was evaporated at room temperature *in vacuo*, the residue taken up in water and freeze dried to yield the methanol soluble peptide (MSP). Both MSP and MIP were readily soluble in water, yielding solutions which foamed readily and which gave precipitates with trichloroacetic, tannic, and metaphosphoric acids.

MSP gave a strong color reaction with ninhydrin but both the original acetyl peptide and MIP were ninhydrin negative. It appeared therefore that deacetylation was incomplete and that only MSP contained free amino groups. This suggestion was supported by the qualitative detection of acetyl groups in MIP but not in MSP. A modification of the method of Clark (6) was used for acetyl determinations but as might be expected with N-acetyl derivatives of comparatively long chain peptides quantitatively reliable data could not be obtained. It was further observed that MIP did not contain amino groups detectable by either the formal titration or the Van Slyke nitrous acid method of deamination.

Reitz *et al.* (19) have shown that the preferential reaction of sulphuric acid with proteins is the formation of sulphuric esters with aliphatic hydroxyl groups of hydroxy amino acids followed by sulphonation of the aromatic ring of tyrosine and conversion of cystine and cysteine to thiosulphates. Some sulphur determinations were, therefore, done on the degradation products by the method of Sundberg and Royer (21). All analyses showed that sulphuric acid treated gluten contained about three times as much sulphur as the original gluten. For example, a preparation of acetyl peptide contained 3.5% sulphur whereas the gluten from which it was derived contained 1.1% sulphur. This is approximately equal to the addition of one mole of sulphur for each 12–14 amino acid residues. This amount would be expected to contribute in an appreciable way to the properties of the peptides.

Terminal Group Determinations

Sanger's method (20) of detecting N-terminal amino acids by reaction with 1-fluoro-2,4-dinitrobenzene (DNFB) was applied to the methanol soluble peptides. Seventy-five milligrams MSP were dissolved in 5 ml. of water, and 100 ml. of sodium bicarbonate and 250 mgm. of DNFB in 10 ml. of ethanol were added. The mixture was shaken for three hours, evaporated to dryness, and extracted with ether until no more of the yellow reagent could be removed. The residue was hydrolyzed by boiling in 6 *N* hydrochloric acid for eight hours and after evaporating to dryness *in vacuo* it was extracted with ether to dissolve any dinitrophenyl (DNP) amino acids produced from N-terminal amino acids.

The ether extracts were chromatographed on No. 1 Whatman filter paper impregnated with pH 6 phthalate buffer and were developed by both ascending and descending flow. The following solvent systems were used: 30 : 70

propanol–cyclohexane; 10 : 90 ethanol – benzyl alcohol and tertiary amyl alcohol (2). DNP acids for comparison were prepared as described by Porter (18). Except for spots due to the reagent and to 2,4-dinitroaniline the chief spot on all chromatograms corresponded to DNP serine. The yellow spots were extracted from the paper with ether and hydrolyzed in a sealed tube at 100°C. for two hours with concentrated aqueous ammonia. When these hydrolyzates were chromatographed on paper using 75% aqueous phenol as solvent they all gave ninhydrin positive spots with the same R_f value as serine.

The above results strongly suggest that serine is a major N-terminal amino acid residue in degraded gluten. Quantitative estimates of N-terminal serine and threonine in MSP were attempted by a microdiffusion method employing periodate oxidation (23). No N-terminal threonine was found but ammonia corresponding to 5.7 gm. serine per 16 gm. MSP nitrogen was obtained. Since Wiseblatt and McConnell (23) found by the same method that gluten contains 5.7 gm. serine per 16 gm. gluten nitrogen, the result indicates complete liberation of serine amino groups by the Elliott degradation. The value for terminal serine in degraded gluten is high compared to Elliott's yields of about 60% for silk fibroin. An experimentally reproducible value for N-terminal serine (7.7 gm. serine per 16 gm. nitrogen) was obtained with a colorimetric method in which formaldehyde from periodate oxidation was collected by distillation (4). Since carbohydrates, some of which could also have given formaldehyde, were shown (17) to be present only in trace amounts no explanation for the high results can be offered. Although the results may not be quantitatively acceptable they do support the qualitative suggestion that the degradation scheme used was effective in liberating much of the serine nitrogen in gluten.

Preliminary experiments were attempted to identify C-terminal amino acids present in the peptides. Because appreciable N-terminal serine appeared to be liberated the C-terminal residues may be assumed to be largely those bound to serine in the original gluten. Samples of both the MIP and MSP were refluxed for eight hours with equal weights of lithium aluminum hydride in 100 volumes of tetrahydrofuran. The products were hydrolyzed and the amino alcohols isolated by the methods of Fromageot, Jutisz, Meyer, and Penasse (12). Paper chromatography of the ether extract of each hydrolyzate with the recommended solvent systems gave mainly one ninhydrin positive spot. (R_f corresponded most closely to that of phenylalaninol.) Other spots were present in smaller quantities. It is emphasized that the results are not sufficient to show that there is one major C-terminal amino acid, but they suggest that there may be a relatively simple pattern of C-terminal residues. More experiments are required on this phase of the work before definite statements regarding the liberation of C-terminal amino acids can be made.

Electrophoretic Properties

The apparatus and procedure described by Kunkel and Tiselius (14) was used for paper electrophoresis of some products of the gluten degradation. Fig. 1 shows "ionograms" obtained from acetyl peptides, MIP, and MSP in acetate buffer at pH 4.5 and ionic strength 0.1. With each sample a single,

fairly well defined peak was obtained. There was no indication of a multiplicity of peaks or of marked spreading as ordinarily obtained with a heterogeneous substance. Paper ionograms were made with a number of different preparations of the gluten degradation products and it is significant that single peaks were obtained (Fig. 1). The results served to distinguish sharply between the MSP

3. MIP	28 hr.	0.20 ma. per cm.

and MIP as derived from the deacetylation step and are in general accord with the earlier suggestion that the latter was not deacetylated.

A limited number of experiments were made with a moving boundary electrophoresis apparatus (Aminco Portable, American Instrument Co., Silver Springs, Maryland). MSP and MIP which had been kept in 0.1 *N* NaOH at 5°C. for 16 hr., freeze dried, taken up in the desired buffer, and filtered were used. Drawings of the patterns obtained with the treated MSP are given in Fig. 2. The alkali treatment had evidently changed the electrophoretic properties of MSP but, as with experiments on paper, the method failed to effect any separation of the material into fractions of different mobility. On the contrary, the sample displayed a striking electrophoretic homogeneity, and in buffers of pH 8.6, 6.0, and 4.5 it had mobilities of 2.08×10^{-4}, 1.91×10^{-4}, and 1.31×10^{-4} cm.^{2}/sec./volt, respectively. If acidic groups had been introduced perhaps during the sulphuric acid treatment, the movement toward the anode would have been expected. The MIP treated with sodium hydroxide as described above gave patterns of the same general character as shown in Fig. 2 for sodium hydroxide treated MSP.

The reason for the markedly different behavior of MSP before and after alkali treatment is not known. It is likely that many of the acidic groups on the dissolved material were converted to methyl esters during the treatment with methanolic hydrochloric acid and that before saponification at 5°C. deacetylated amino groups caused migration toward the cathode (Fig. 1). It would appear, therefore, that in the saponified peptides a preponderance of

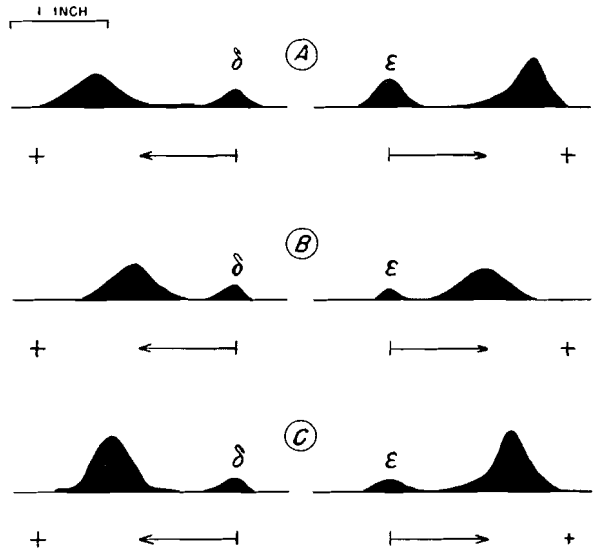

FIG. 2. Electrophoretic patterns of MSP obtained with Aminco Portable Electrophoresis Apparatus.

acidic groups was effective in masking charge differences arising from different degrees of deacetylation of amino groups. If, as is reasonable to suppose, the sulphur acquired by the peptides during the degradation occurs as ionizable acid groups, and if, after treatment with sodium hydroxide the acid groups are free, the peptides would be expected to behave as anions. The contribution of the acidic groups to electrical properties of the material might well be large compared to that from amino groups and may account for the observed electrophoretic homogeneity.

By contrast, gluten is known to be heterogeneous according to physical chemical criteria. It seems unlikely, therefore, that the degradation is sufficiently systematic and the array of amino acids in gluten sufficiently regular to yield peptides with the degree of homogeneity suggested by the electrophoretic results. Because the contribution of sulphonic acid groups to the electrical properties is not known it is difficult to determine whether the degradation product is more or less homogeneous than gluten.

The introduction of acid groups into the degradation products may also

explain results obtained in attempts to fractionate them by selective adsorption on ion exchange resins. Samples were applied to 100 cm. columns of either 12% or 2% cross linked Dowex 50 and eluted according to procedures described by Moore and Stein (16). The bulk of the peptide nitrogen was quickly eluted from the column in pH 3.5 buffer. No other nitrogenous material was detected by nesslerization in eluates obtained with buffers of increasing pH.

Molecular Size Estimates

From the value of 5.7 gm. N-terminal serine per 16 gm. of MSP nitrogen given above it was calculated that the average molecular weight of MSP would be not more than 1400 (assuming single unbranched chains). Such a peptide would have been expected to pass freely through a dialyzing membrane. Experiments were therefore done to determine directly the molecular weight of MSP in pH 4.5 acetate buffer of ionic strength 0.1. Osmotic pressure measurements were made according to the method of Bull (5) except that semipermeable membranes of cellophane transfusion tubing were used instead of collodion bags. The average molecular weight was estimated to be 20,500. The value, although much larger than originally indicated by terminal amino acid analysis, was consistent with the physical behavior of MSP solutions upon dialysis.

The osmotic pressure equilibrium tended to drift slowly downward over a period of several days but the change did not represent a large increase in the molecular weight of the peptide. Redetermination of the terminal serine residues on MSP dialyzed in cellophane bags showed that, although appreciable material had passed through the membrane, the weight equivalent to each remaining terminal residue was not more than 3000. The results could be most readily explained by assuming that the degradation products consisted of branched chain structures with an average molecular weight of about 20,000. The number of free serine amino groups suggested that there are several chains in each molecule but the data were not considered sufficiently precise for a quantitative statement of the degree of branching.

Although MSP may possess branched chains it cannot also be assumed that undegraded gluten also possesses branched chains. For example, Elliott (11) found that lysozyme, which diffuses at an appreciable rate through a dialysis membrane, became non-diffusible after treatment with sulphuric acid and formic – acetic anhydride. A high proportion of the nitrogen was non-diffusible after alkaline hydrolysis. Elliott suggested that, since indoles polymerize under the influence of acid, cross linkages may have been formed through tryptophan residues and supported his suggestion with the observation that tryptophan could not be detected in the preparation by the Ehrlich color reaction. Although gluten probably contains no more than 1.5% tryptophan (22) a similar phenomenon may occur in its degradation.

Ultracentrifuge studies at 250,000 gravities for a period of 80 min. at 27°C. showed that the peptides were of "low" molecular weight—the "peak" had not completely separated from the meniscus after an hour. Also there was

sufficient broadening or spreading of the peak to indicate considerable heterogeneity and to render attempts at quantitative determination useless.

Formylation of Gluten Sulphate

One of the objectives of this study was to derive from gluten a uniform water soluble product suitable for further study. Incomplete deacetylation with resultant division of the product into MIP and MSP was therefore undesirable.

No other method for removal of blocking acetyl groups was known which would not also lead to fission of peptide chains. Experiments were done to test an alternative procedure for protecting amino acids exposed by the N-peptidyl → O-peptidyl shift. Carbobenzoxylation seemed attractive except that a relatively high sulphur content in the peptides might interfere with catalytic hydrogenolysis. Recourse was taken therefore to a formylation method suggested by Elliott (10). Boissonnas and Preitner (3) have demonstrated that this group can be removed with methanolic hydrochloric acid without hydrolysis of peptide chains. In this investigation it was observed that ninhydrin positive groups of sulphuric acid treated gluten were completely "formylated" by treatment at pH 5 with sodium formate and anhydrous formic acid for 12 hr. at room temperature. As with acetylated materials degradation to soluble products occurred upon saponification with 0.1 *N* $Ba(OH)_2$. Treatment with 1.5 *M* hydrogen chloride in methanol at 20°C. for 24 hr. gave a 90–95% yield of a ninhydrin positive material soluble in methanol. A comparison of the material with MSP has not been made but formylation appears superior to acetylation in experiments where recovery of peptides with unprotected terminal amino groups is required. Work to be described in a later publication suggests that deamination with nitrous acid can be used to prevent reversal of the acyl migration from peptide nitrogen to β-hydroxy group. Although the terminal amino acid is destroyed the method may sometimes be used to replace the blocking methods.

In the present work it was hoped to obtain a soluble derivative suitable for further chemical studies on the nature of gluten. In general the results give promise of meeting these objectives. Water soluble products were obtained apparently with a high degree of specificity. These should be amenable to study with experimental techniques not formerly applicable to gluten itself. The indication, for example, of a fairly simple pattern of C-terminal amino acid residue suggests that gluten may possess systematic structural features. This is particularly true because although gluten contains about 25% glutamic acid there was no evidence of appreciable amounts of C-terminal glutamic acid in the peptides. Changes may occur however which limit the usefulness of the peptides for further study. An unknown amount of cross linking of peptide chains may have occurred. If this is so it is impossible to estimate the degree of cross linking in gluten from the amount of chain branching observed in the degraded fractions. Furthermore, introduction of sulphonic acid groups may markedly alter the electrical properties of the material. The striking electrophoretic homogeneity of the peptides and the difficulty in fractionating them on a Dowex column may have been caused by this modification.

ACKNOWLEDGMENT

These studies were made possible by a National Research Council Studentship held by one of us (L. Wiseblatt). The authors are indebted to Dr. L. R. Wetter for advice and assistance with the electrophoretic work and to Drs. W. H. Cook and J. R. Colvin of the National Research Laboratories in Ottawa for measurements made with the ultracentrifuge.

THE PHOTOLYSIS OF ACETONE IN THE LIQUID PHASE: THE GASEOUS PRODUCTS[1]

By R. Pieck[2] and E. W. R. Steacie

ABSTRACT

An investigation has been made of the photolysis of liquid acetone in the temperature range from 55° to −25°C. The quantum yields of all products are small, and decrease strongly with decreasing temperature. It is concluded that the low yields can be explained both on the basis of the 'cage effect', and by the deactivation of an excited molecule. At high temperatures and intensities the gaseous products can be accounted for on the assumption that radicals have escaped from the 'cage' and react analogously to the gas-phase mechanism. At low temperatures ethane formation in the 'cage' may be of importance.

INTRODUCTION

The photolysis of acetone in the gas phase has been extensively investigated. The photolysis in the liquid phase was investigated by Bowen and co-workers (1, 2, 3). They found practically no gaseous products with acetone alone, while tertiary alcohols were produced when they worked in hydrocarbon solvents. Frankenburg and Noyes (4) have also investigated the photolysis of the liquid systems acetone–oxygen and acetone–heptane–oxygen. Their work with pure acetone was confined to a rough determination of quantum yields.

It seemed of interest to investigate the photolysis of pure liquid acetone to obtain information about the behavior of radicals in the liquid phase, and to see how far the mechanism parallels that in the gas phase.

EXPERIMENTAL

Materials

Acetone (Merck) was dried over potassium carbonate and purified by a bulb-to-bulb distillation. Deutero-acetone was prepared for us by Dr. L. C. Leitch of these laboratories. *n*-Heptane was a "Phillips Pure Hydrocarbon" product. Special care was taken in degassing these reagents, in view of the sensitivity of the reaction to traces of oxygen.

Apparatus

The acetone was irradiated in a quartz cell of approximately 5 cm. diameter and 0.05 cm. thickness. The cell was provided with two outlets, one of which was sealed off after filling, while the other, closed by a break-seal, could be connected to the analytical system. Between experiments the cell was washed with acetone, attached to the filling system, heated *in vacuo* at 200°C. for two hours, and filled by distilling acetone into it.

Irradiation was carried out in a thermostat consisting of a brass cylinder with double walls, the space between the walls being evacuated. The cell was placed in an aluminum block which was located in the thermostat in such a

[1]*Manuscript received March 24, 1955.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1953–54.*

way that the cell was as close as possible to the innermost of two quartz windows through which the light beam entered the thermostat. The thermostat was filled with ethyl alcohol purified by the method of Leighton (7).

For experiments above room temperature the thermostat was heated electrically by an immersion heater. For low temperature experiments a copper coil was immersed in the alcohol. The coil was connected to a large container of alcohol which was cooled by a small refrigeration unit and kept automatically at the desired temperature. The temperature could be maintained constant to within ± 0.5°C.

Light Source

For most experiments the light source was a B.T.H. high pressure mercury lamp (type ME/D, 250 watts) operated on 220 v. d-c. The beam was roughly collimated by a quartz lens. A Corning filter (9-53) cut off wave lengths below 2800 Å. The beam thus consisted mainly of wave lengths around 3130 Å.

For experiments with light in the neighborhood of 2537 Å a Hanovia S500 lamp was used, together with a filter consisting of a quartz cell of 1 cm. thickness filled with a solution of diphenylbutadiene in ether (5).

The light intensity was reduced in some experiments by the use of quartz neutral density filters.

Analysis

A comparison of the infrared spectrum of pure acetone and that of a sample of irradiated acetone did not reveal the presence of any liquid products. However, in view of the large amount of acetone present, it is not surprising that small quantities of liquid products could not be detected. At temperatures below 0°C., however, a very small amount of liquid residue remained in the cell after acetone had been distilled off.

After an experiment the contents of the cell were distilled into a column, at the top of which was a "cold finger" maintained at -78°C. The acetone was refluxed continuously in the column to remove dissolved gases. The gaseous products were then fractionated by means of two modified Ward stills (8). The CO–CH_4 fraction was removed at -195°C., and the C_2H_6 fraction at -170°C. The amount of CO was determined by combustion of the CO–CH_4 fraction over hot copper oxide. In a number of cases check analyses were made with a mass spectrometer.

RESULTS

(A) Determination of the CO Quantum Yield

An estimate of the quantum yield of CO was made by comparing the photolysis in the liquid phase at 25°C. with the gas-phase photolysis at 164°C. A quantum yield of unity was assumed for the latter. Values obtained were:

$\lambda > 2800$ Å (mainly 3130 Å)	0.9×10^{-4}
$\lambda \sim 2537$ Å	2.3×10^{-4}.

The results are uncertain by a factor of about 2, and hence there is no certain

difference between the two wave lengths. The values are in agreement with the rough estimate of Frankenburg and Noyes (4).

(B) Variation of the Rate with Intensity

Table I gives the results of experiments at four different temperatures and at various light intensities. In view of the inhomogeneous nature of the light absorption, too much accuracy cannot be expected as far as kinetic constants are concerned, although the very short path length minimizes this effect. It is evident from the table that, although there is a decided drift in some of the constants, all products are formed at a rate proportional to the light intensity to within a factor of 3.

TABLE I

The last two columns give the ratios $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ and $R_{CH_4}/R_{C_2H_6}$. On the basis of the gas-phase mechanism methane arises by

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3$$

and ethane by

$$2CH_3 \rightarrow C_2H_6.$$

This leads to the constancy of the former ratio. It is evident that this is not so in the liquid phase. The ratio $R_{CH_4}/R_{C_2H_6}$ remains roughly constant (to within a factor of about 2) over the intensity range. The ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$, on the other hand, varies at 40°C. by a factor of about 12, and at all tem-

peratures shows a steady fall with decreasing intensity. However, there are definite indications that the ratio is approaching constancy at high intensities. (See Fig. 1).

(C) Variation of the Rate with Temperature

Table II gives the results of experiments at temperatures from 55°C. to −25°C. at constant intensity. To avoid side reactions the conversion was always kept below 5%.

A plot of log $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ against $1/T$ (Fig. 2) gives a good straight line and an apparent activation energy of 8 kcal. as compared with 9.7 kcal. for the gas phase. In plotting the results only those at higher intensities were used,

TABLE II

VARIATION OF RATE WITH TEMPERATURE

Temp., °C.	Time, min.	[Ac], molecules/cc. $\times 10^{-21}$	Products, molecules/cc./sec. $\times 10^{-13}$			$\frac{R_{CH_4}}{R^{\frac{1}{2}}_{C_2H_6}[Ac]} \times 10^{14}$
			CO	CH_4	C_2H_6	
55	120	7.77	24.3	740	6.9	11.5
55	100	7.77	20.7	565	9.5	7.47
40	120	7.96	16.3	360	5.5	6.81
40.5	100	7.95	14.6	340	4.2	6.61
41	100	7.92	18.2	387	5.1	6.10
33	214	8.05	9.6	229	3.6	4.75
33	210	8.05	13.2	213	3.5	4.46
33	260	8.05	12.0	181	3.2	3.97
15	245	8.26	6.4	84	2.1	2.24
6.5	350	8.37	4.5	38.8	1.44	1.21
6.0	320	8.38	5.2	41.1	1.40	1.31
0.5	200	8.44	4.2	26.2	1.00	0.98
0.5	240	8.44	4.4	26.1	2.00	0.69
−15	1385	8.60	1.8	5.66	0.32	0.37
−16	1215	8.60	1.95	5.46	0.37	0.33
−24	1395	8.65	0.98	2.59	0.21	0.21
−25	1580	8.67	1.57	2.54	0.19	0.21

since the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ falls off rapidly with decreasing intensity. Since in most cases the high intensity runs still do not give a quite constant ratio, the results are open to some uncertainty. In view of this the agreement with the gas-phase results is probably satisfactory.

If Arrhenius plots are made of R_{CH_4}, R_{CO}, or $R_{C_2H_6}$ reasonably good straight lines are obtained, from which *apparent activation energies* may be calculated, viz.

$$E_{CH_4} = 11.4 \text{ kcal.}$$
$$E_{CO} = 6 \text{ kcal.}$$
$$E_{C_2H_6} = 7 \text{ kcal.}$$

These have no simple meaning but indicate the order of magnitude of the variations in quantum yield with temperature.

Some experiments with a 1:1 mixture of CH_3COCH_3 and CD_3COCD_3 are shown in Table IIIA. The results agree well with those for light acetone. There is, however, one puzzling feature. In the gas phase it has been found

TABLE IIIA

RUNS WITH A MIXTURE $CH_3COCH_3+CD_3COCD_3$ IN RATIO 1/1

Temp., °C.	Molecules/cc./sec. $\times 10^{-13}$								$\frac{CH_4+CD_3H}{CD_4+CH_3D}$

**Runs with 2537* Å.

that there is a higher activation energy for the abstraction of D, as compared with H. On this basis the ratio

$$(CH_4+CD_3H)/(CD_4+CH_3D)$$

should have the values given in the second to last column of Table IIIA. The actual values of the ratio are given in the last column. It will be seen that the ratio falls rapidly at lower temperatures, which is the reverse of the predicted behavior.

The two experiments at 2537 Å give lower rates because of lower light intensity, but show the same trend.

A few experiments were also made with pure CD_3COCD_3, and the results are given in Table IIIB.

TABLE IIIB

RUNS WITH CD_3COCD_3

5	26.5	2.48	0.75
−19	7.35	0.8	0.24

(*D*) *Runs with 2537* Å

The results of a few experiments with λ2537 Å are given in Table IV, and plotted in Fig. 2. The results are rather scattered because of the relatively weaker intensity and therefore smaller amounts of products. In general, however, the trend appears to be very similar. As pointed out above, the quantum yield is not appreciably different at 2537 Å. The results for methane are more accurate than the others because of the larger amounts of products,

and it is possible that the apparent activation energy is a trifle smaller. However, the accuracy of the results is not sufficient to justify any definite conclusion. There thus appears to be no direct evidence for hot radical effects.

DISCUSSION

There are a number of very puzzling features about the results. It should be emphasized that in view of the high absorption, the distribution of absorbed intensity is very inhomogeneous. As a result the kinetic data can only be assumed to have semiquantitative significance. The discussion will, therefore, be confined to a somewhat qualitative consideration of the main features of the reaction.

The Quantum Yield

The major difference between the present results and those of the gas-phase photolysis is the low quantum yields. Thus ϕ_{CO} is about 10^{-4} at 25°C. and about 10^{-5} at −25°C. $\phi_{C_2H_6}$ is still smaller. The values of ϕ_{CH_4} are somewhat larger, falling from about 2×10^{-3} at 25°C. to 2×10^{-5} at −25°C. Also, the yield of all reaction products increases very strongly with temperature. Thus over the range −25°C. to 55°C. ϕ_{CH_4} increases by a factor of about 300.

There are two possible explanations of the low quantum yields. In the first place, if the primary step in the gas phase is

$$CH_3COCH_3 + h\nu \rightarrow CH_3COCH_3^* \qquad [1]$$

followed by the decomposition of the excited molecule, it is possible that ϕ will be cut down largely by deactivation in the liquid phase. If this explanation holds deactivation must be strongly temperature dependent. It seems certain that the results are to be explained, at least partially, on the basis of deactivation. There is no question that active molecules play some role in the gas-phase reaction, as indicated by fluorescence studies. There seem to be two types of excited molecule one of which has a life of about 10^{-4} sec. Since there is considerable self quenching which is temperature dependent there seems to be not only collisional deactivation, but also an activation energy for the dissociation of active molecules. The low yields and the effect of temperature on the quantum yields can therefore be attributed at least to some extent to excited molecule deactivation.

The other explanation of the low value of ϕ is recombination because of the cage effect, i.e.

$$CH_3COCH_3 + h\nu \rightarrow CH_3CO + CH_3 \qquad [2]$$

followed by

$$CH_3 + CH_3CO \rightarrow CH_3COCH_3, \qquad [3]$$

the rate of [3] being greatly enhanced by the cage effect. The increase in the quantum yield with temperature is then explained by the increase in the rate of diffusion. A similar explanation has been suggested by Lampe and Noyes (6, 9) to explain the variation of the quantum yield of iodine dissociation in inert solvents. It may be mentioned that reaction [3] may also occur out of the cage. In view of the low quantum yield of ethane formation, however, this must be of minor importance. As mentioned above the apparent activation energy for methane production at 3130 Å is 11.4 kcal. Since methane is by far the largest product, this is approximately the temperature coefficient of the

quantum yield of the over-all decomposition. It is presumably to be related to the temperature coefficient of the diffusion process.

Experiments with a 1:1 mixture of CD_3COCD_3 and CH_3COCH_3 and with pure CD_3COCD_3 give results in general agreement with those with CH_3COCH_3.

The Dissociation of Acetyl by Energy Carry-over

In the gas-phase photolysis it is postulated that, depending on wave length, between 0.07 and 0.22 of the acetyl radicals formed dissociate spontaneously,

$$CH_3CO^* \rightarrow CH_3+CO. \qquad [4]$$

If this were so in the present case ϕ_{CO} could not be nearly as low as it is. This suggests either that deactivation of an excited molecule is the main cause of the low quantum yield, or else that in the liquid phase most hot acetyls are deactivated and that [4] rarely occurs. This is supported by the fact that ϕ_{CO} has a considerable temperature coefficient.

Disproportionation

In the gas phase there is evidence that reaction [5]

$$CH_3+CH_3CO \rightarrow CH_4+CH_2{=}CO \qquad [5]$$

occurs about 1/10 to 1/100 as often as [3], and also has an activation energy of about zero. If this were true in the liquid phase it would be impossible to obtain a very low value of ϕ_{CH_4}, unless this were due to deactivation. Also, reaction [5] would lead to E_{CH_4} approaching zero at low temperatures which is far from the case. It seems probable that in the liquid phase where the excited complex $CH_3COCH_3^*$ formed by [3] or [5] will have a very short life, disproportionation may well become negligible compared with recombination. These conclusions are, however, incompatible with those of the following paragraphs concerning deuterium exchange. It is therefore possible that the low quantum yields are due to deactivation of an excited molecule rather than to primary recombination.

It is also possible that disproportionation may occur outside the cage between radicals which have been formed from different molecules. As a check on this a 1:1 mixture of CH_3COCH_3 and CD_3COCD_3 was photolyzed. If the gas-phase mechanism holds almost all methane formed will arise from the abstraction reactions

$$CH_3+CH_3COCH_3 \rightarrow CH_4+R \qquad [6]$$

$$CH_3+CD_3COCD_3 \rightarrow CH_3D+R' \qquad [7]$$

$$CD_3+CH_3COCH_3 \rightarrow CD_3H+R'' \qquad [8]$$

$$CD_3+CD_3COCD_3 \rightarrow CD_4+R'''. \qquad [9]$$

In the gas phase there is little difference between the rates of abstraction by CH_3 and CD_3, but there is considerable difference between the abstraction of an H- or a D-atom. The ratio $(CH_4+CD_3H)/(CD_4+CH_3D)$ can be calculated from known rate constants, and will increase slightly at low temperatures as shown by the calculated values in Table IIIA. Actually there is a strong decrease at low temperatures. It should be noted that the ratio is not affected

by uncertainties in the relative ease of splitting off CD_3 or CH_3 from an active molecule. It depends solely on the relative ease of abstracting an H- or a D-atom in the subsequent abstraction reactions.

If methane is also formed by disproportionation between CH_3 or CD_3 radicals and CH_3CO and CD_3CO, since all the disproportionations occur with zero activation energy, the ratio of methanes from disproportionation will be unity. Hence the above ratio will tend toward unity at low temperatures where abstraction is negligible, and will rise rapidly with temperature and approach the 'calculated' values in Table IIIA. The observed behavior thus indicates that disproportionation is becoming more and more important at low temperatures.

The Abstraction Reaction

In the gas-phase photolysis of acetone the methane and ethane formed are almost all accounted for by the reactions:

$$CH_3+CH_3COCH_3 \rightarrow CH_4+CH_2COCH_3 \qquad [6]$$

$$CH_3+CH_3 \rightarrow C_2H_6 \qquad [10]$$

from which

$$R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[\text{Acetone}] = k_6/k^{\frac{1}{2}}_{10}.$$

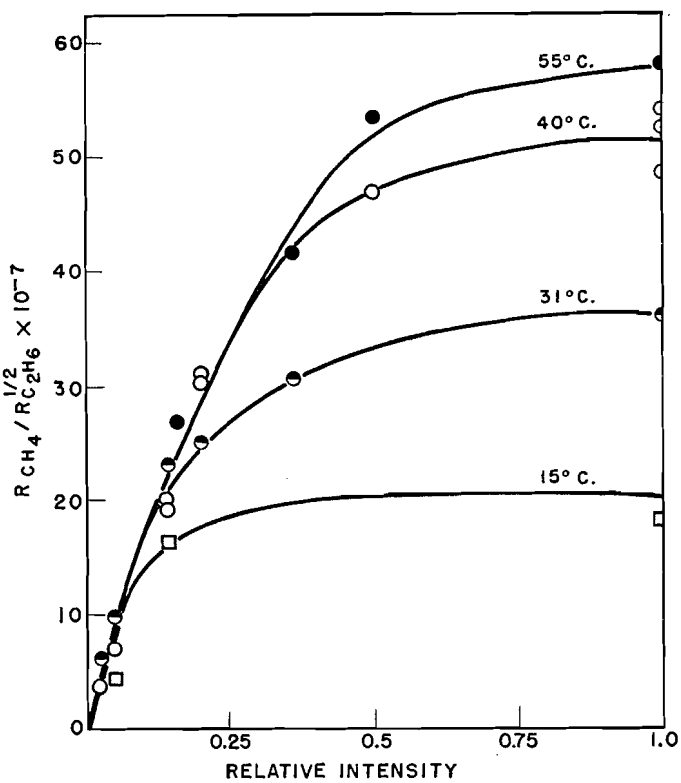

FIG. 1. The variation of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ with intensity.

If this relation holds in the liquid phase, $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ should be independent of the absorbed intensity. In Fig. 1 $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ has been plotted against the intensity for different temperatures. The figure shows that the ratio decreases sharply with intensity in the low intensity region, although it is tending towards constancy at high intensities. The results suggest that the formation of ethane at low intensity is mainly by some reaction dependent on the first power of the intensity, i.e. of the radical concentration. Possible explanations are formation of ethane to some extent in the cage, or by a direct intramolecular reaction.

The fact that $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ is nearly independent of intensity at high intensities indicates that under these conditions most methane and ethane is formed by reactions [6] and [10], and that at high intensity inter-cage effects predominate. The photolysis of CD_3COCD_3 furnishes further proof that some ethane is formed by inter-cage effects. In this case the higher strength of C—D bonds reduces the effect of abstraction, and C_2D_6 is greater than CO. This would be impossible if all ethane were formed in the cage.

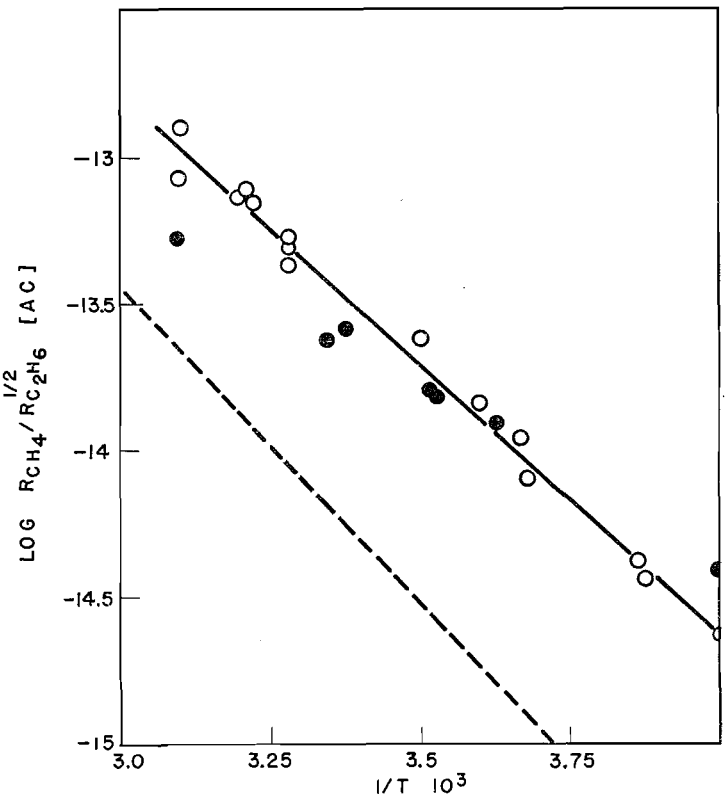

FIG. 2. Arrhenius plot of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ [Acetone] for liquid acetone.
○ wave length approximately 3130 Å.
● wave length approximately 2537 Å.
The dotted curve represents an extrapolation to low temperatures of results for gaseous acetone.

In Fig. 2 an Arrhenius plot is given of $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ [Acetone] for runs with CH_3COCH_3 at 3130 Å and high intensities (i.e. in the region where the ratio is essentially independent of intensity). A good straight line is obtained, from which $E_6 - \frac{1}{2}E_{10} \sim E_6 = 8$ kcal. This agrees satisfactorily with the gas-phase value of 9.7 kcal., since the result will be approximate because of errors due to diffusion effects, to inhomogeneity of absorption, and to the formation of methane by disproportionation of CH_3 and CH_3CO at low temperatures. While the slopes of the two lines agree reasonably, the gas-phase line lies considerably below that for the liquid phase, corresponding to a difference of a factor of about 7 in the ratio. This has little significance, however, in view of the uncertain meaning of concentration in the liquid phase.

The results obtained by photolyzing CD_3COCD_3 are no doubt affected to a much greater extent by the occurrence of reaction [5], because of the slower rate of abstraction of D from CD_3COCD_3 as compared with H from CH_3COCH_3. The results lead to an apparent activation energy about 2 kcal. lower than those for CH_3COCH_3, but this is presumably complex and has no simple significance.

The data at 2537 Å are not sufficiently extensive to warrant detailed discussion.

A few experiments were made with acetone–water and acetone–*n*-hexane solutions, and are given in Tables V and VI. The results indicate:

(*a*) With water, no change larger than the rather considerable experimental error occurs in the $R_{CH_4}/[Ac]$, or $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}$ [Ac] ratios. It is evident that water acts essentially as an inert solvent, as far as the production of gaseous products is concerned, and that the reaction

$$CH_3 + H_2O \rightarrow CH_4 + OH$$

does not occur to an appreciable extent. This is expected in view of the high H—OH bond dissociation energy (*ca.* 118 kcal.). Previous work (10) indicates that condensable products such as formaldehyde and acetic acid are formed.

(*b*) With acetone–hexane solutions there is a slight but significant drop in the ratio $R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[Ac]$. Since the activation energy of the reaction

$$CH_3 + n\text{-}C_6H_{14} \rightarrow CH_4 + C_6H_{15} \qquad [11]$$

is less than that of

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3 \qquad [12]$$

by 1.6 kcal. (11), while the steric factors are in the ratio $P_{11}/P_{12} = 0.3$, it would be expected that abstraction by [11] would be faster than by [12] by a factor of 3.3. A considerable increase in methane would therefore be expected. Actually there is a decrease. However, in view of the probable formation on irradiation of an addition compound between acetone and *n*-hexane (4) the situation is complex and further discussion is unwarranted.

It is apparent that many features of the results cannot be explained in detail. The above discussion at least points out the general problems involved.

It is hoped that further work on the more complex products, and on the reaction at still lower temperatures, may throw more light on the mechanism.

ACKNOWLEDGMENT

The authors are indebted to Dr. P. Ausloos for much advice and discussion.

SUR L'OXYDATION LENTE DE L'ÉTHER DIÉTHYLIQUE EN PHASE GAZEUSE[1]

PAR ANDRÉ LEMAY[2] ET CYRIAS OUELLET

RÉSUMÉ

La réaction de l'éther diéthylique avec l'oxygène a été étudiée dans un récipient en Pyrex, dans l'intervalle de température 160–175° C., voisin de la limite inférieure de flamme froide. L'oxygène est consommé durant la baisse initiale de pression suivant une réaction d'ordre zéro, affectée d'une énergie d'activation d'environ 50 kcal./mole, durant laquelle il apparaît de l'eau, des peroxydes, des acides, et autres produits. La hausse de pression qui survient plus tard correspond à des réactions postérieures à l'oxydation proprement dite; elle peut avoir lieu en l'absence d'oxygène. Les taux d'oxydation tirés de la vitesse maximum d'accroissement de la pression sont ainsi remis en question. On discute quelques processus susceptibles d'intervenir dans chacune de ces deux phases de la réaction.

INTRODUCTION

Divers phénomènes caractéristiques de la combustion—oxydation lente, flamme froide, et explosion—peuvent être étudiés dans des conditions particulièrement avantageuses dans l'oxydation de l'éther diéthylique. Ils y sont observables à des pressions basses de l'ordre de 10 à 100 mm. Hg et dans un intervalle de températures allant de 150 à 250° C., tandis que la plupart des hydrocarbures ne subissent ces réactions qu'à des pressions et températures beaucoup plus élevées. Plusieurs aspects de la flamme froide de l'éther ont été étudiés dans notre laboratoire (18) en particulier au moyen du spectromètre de masse à échantillonnage continu de Léger (10, 11). Dans le but de mieux comprendre en quoi consiste le passage de l'oxydation lente à la flamme froide, nous avons cherché dans le présent travail à obtenir de nouvelles données sur la cinétique de l'oxydation lente de l'éther dans l'intervalle de 160 à 175° C. situé immédiatement en dessous de la limite de flamme froide.

L'oxydation des éthers semble occuper une place intermédiaire entre celle des hydrocarbures (5, 12, 15, 21) et celle des aldéhydes (12, 13) mais est moins bien connue que ces dernières. Walsh et ses collaborateurs (4, 14) ont fait une étude détaillée des domaines d'inflammation des éthers, surtout de l'éther diéthylique; mais pour ce qui concerne l'oxydation lente, ces auteurs se sont attachés surtout à celle de l'éther diisopropylique. Eastwood et Hinshelwood (7) ont comparé les oxydations lentes de cinq éthers aliphatiques. Dans le cas de l'éther diéthylique, le plus facilement oxydable de la série étudiée, la réaction débute par une baisse de pression suivie d'un accroissement de pression analogue à celui qui succède à la période d'induction classique des hydrocarbures. En se basant sur cette ressemblance, ces auteurs ont pris comme mesure du taux d'oxydation la pente maximum de cette montée de pression. Ils ont constaté que les peroxydes formés au début de la réaction sont relative-

ment stables et survivent même au passage d'une flamme froide. Il se peut que cette propriété résulte uniquement du fait que la flamme froide de l'éther se produit à une température relativement basse, comparée, par exemple, à celle du butanone (1) durant laquelle les peroxydes accumulés disparaissent rapidement.

MÉTHODE EXPÉRIMENTALE

La réaction est étudiée en système statique en l'absence de vapeur de mercure. La chambre à réaction est un cylindre en Pyrex de 4.4 × 14 cm. et la pression est enregistrée électriquement.

Appareil

La figure 1 montre un dessin schématique de la chambre à réaction *C* et de ses principaux accessoires. Elle est enfermée dans un four en acier *F* chauffé

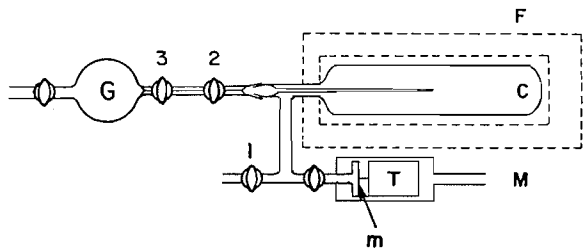

FIG. 1. Schéma montrant la chambre à réaction *C*, le manomètre à membrane *m*, et à transducer *T*, ainsi que le système *G*-3-2 pour l'injection de gaz étrangers.

électriquement et est entourée d'un manchon en laiton destiné à uniformiser la température. Un thermomètre pénètre dans le four et un couple thermo-électrique peut être déplacé sous le manchon, où le gradient de température ne dépasse pas 1° C. d'une extrémité à l'autre de la chambre à réaction. Un transformateur Sola à voltage constant et un Variac permettent de contrôler la température du four. Le robinet 1 sert à l'introduction des réactifs; il conduit d'une part au réservoir contenant le mélange de gaz et d'autre part à un piège à −80° C. suivi d'une pompe à diffusion utilisant de l'huile silicone et d'une pompe mécanique.

Les tubes qui vont de *C* aux premiers robinets sont chauffés à 100° C. pour empêcher une condensation qui se produit aux stages ultérieurs de la réaction et qui s'est manifestée dans plusieurs de nos expériences par une baisse considérable de la pression, vers la fin de la réaction.

L'injection, en plein centre de la chambre à réaction, de petites quantités dosées de gaz inhibiteurs, se fait au moyen du tube capillaire, précédé d'un petit volume calibré, inclus entre les robinets 2 et 3, et d'un réservoir *G*.

La pression est enregistrée au cours de la réaction au moyen d'un manomètre différentiel. Le déplacement d'une membrane *m* de duralumine de 0.07 mm. d'épaisseur, collée sur une capsule de verre, est transmis à un "transducer" *T* de type Statham G1-1.5-315, alimenté par une tension de 1.5 volt. Le signal de sortie est transmis à un enregistreur Brown qui trace la courbe de pression. La capsule manométrique et le transducer sont enfermés dans une boîte étanche

en laiton où règne la pression de référence mesurée sur le manomètre anéroide *M* de type Wallace & Tiernan. Dans la région de 100 mm. Hg qui nous intéresse, la valeur absolue de la pression est mesurée à 0.5 mm. près et les variations sont enregistrées à 0.1 mm. près avec une inertie de l'ordre d'une seconde.

Réactifs

L'éther diéthylique est distillé trois fois en contact avec une solution acide de permanganate, séché en présence de sodium, puis redistillé en rejetant les premières et les dernières fractions. On a aussi employé, avec des résultats identiques, la méthode de Dasler (6) suivant laquelle l'éther est libéré de peroxyde et d'eau par passage à travers une colonne d'alumine activée. Cet éther est conservé sous vide dans un ballon lié à l'appareil. Pour préparer un mélange, on en laisse évaporer une partie dans un ballon évacué, on ajoute la quantité d'oxygène requise, et on laisse reposer pendant quelques heures. Des mesures au spectromètre de masse ont révélé que l'oxygène, provenant directement d'un cylindre, contenait un peu d'azote, mais il a été vérifié que ce gaz n'affecte pas le cours de la réaction. Les robinets sont lubréfiés avec des graisses Apiezon T et L et silicone. Il a été vérifié par des mesures manométriques que ces graisses n'absorbent pas de quantité appréciable d'éther diéthylique, contrairement à ce qui se produit avec les éthers supérieurs.

Parmi les gaz injectés, le formaldéhyde est produit par chauffage de paraformaldéhyde, tandis que l'oxyde nitrique, le propylène, et l'acide bromhydrique sont de marque Mathieson; on les prélève directement des cylindres.

Analyses

On dose l'oxygène en mesurant sa pression partielle dans un analyseur magnétique de Pauling, modèle Beckman D. Au moment choisi, on aspire dans l'analyseur évacué un échantillon (environ 10 cc.) de gaz provenant de la chambre à réaction, après avoir balayé le gaz froid des canalisations en l'aspirant dans un récipient auxiliaire. La quantité de gaz ainsi prélevée est telle qu'il faut interrompre la réaction.

Pour doser les acides et les peroxydes, on évacue la chambre à réaction au moment choisi et on capte dans un piège les produits condensables à $-80°$ C. On extrait ces derniers au moyen de 20 cc. d'eau bidistillée. Les acides sont titrés immédiatement par la soude 0.01 *N* en présence de phénolphtaléine. Le dosage des peroxydes se fait dans une atmosphère d'azote en titrant par le thiosulfate, 0.01 *N* d'abord l'iode libéré en 15 min. en présence d'un excès d'iodure de potassium en milieu neutre et, ensuite, l'iode libéré en trois heures en milieu acide.

RÉSULTATS

Marche et produits de la réaction

La réaction est mesurable dans un intervalle de températures restreint; en dessous de 155° C., elle est trop lente, au-dessus de 175° C., elle est trop rapide et tend à dégénérer en flamme froide. La figure 2 montre l'allure générale des phénomènes pour une réaction produite dans des conditions moyennes. Les quantités d'acides et de peroxydes y sont représentées par les pressions

partielles que ces produits exerceraient dans les conditions de l'expérience. Les courbes de pression totale sont reproductibles à 3% près, sauf pour la première expérience d'une série.

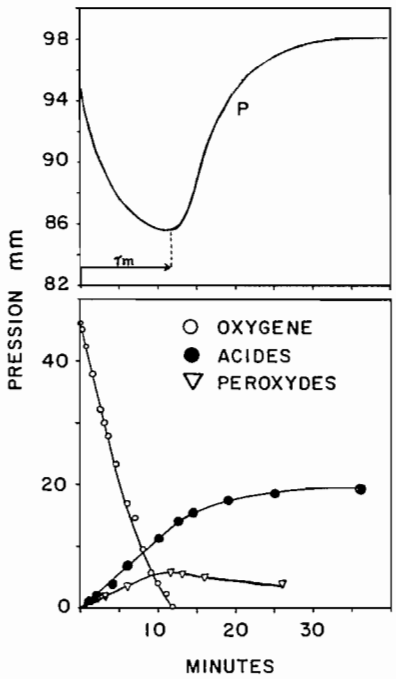

FIG. 2. Courbes de pression totale P et de pressions partielles au cours de la réaction à 168° C. d'un mélange équimoléculaire d'éther et d'oxygène.

Pour le cas typique représenté par la figure 2, la pression totale décroît au début jusqu'à un minimum atteint au bout d'environ 10 min. et se met ensuite à croître pour tendre vers un palier légèrement supérieur à la pression initiale. C'est durant la faible baisse initiale de la pression qu'a lieu la principale réaction d'oxydation, puisque l'oxygène est entièrement consommé durant cette période. Le taux de cette consommation est sensiblement d'ordre zéro. A mesure que l'oxygène disparaît, la pression partielle des produits acides croît linéairement à une vitesse égale à un quart de celle de la consommation de l'oxygène. La concentration des produits peroxydiques croît parallèlement à celle des acides, mais deux fois moins vite. Tout l'iode titrable est libéré rapidement en milieu neutre, ce qui est caractéristique du peroxyde d'hydrogène et des peracides. Après le minimum de pression, les acides augmentent lentement, à un taux sensiblement égal à celui de la diminution des peroxydes.

Des renseignements additionnels sur la variation de la composition du mélange au cours de la réaction ont été fournis par quelques expériences de M. L. P. Blanchard, qui a suivi cette oxydation au moyen d'un spectromètre de masse à échantillonnage continu (10). Les mesures faites avec des mélanges contenant 50 et 30% d'éther indiquent qu'il disparaît deux molécules d'oxygène

pour une d'éther. On observe aussi, dès le début, et jusqu'au moment où le minimum de pression est atteint, un accroissement d'abondance de la masse 18 attribuée à l'eau, et de la masse 43, attribuable à l'acide peracétique ou à l'acide acétique. Rien n'indique une accumulation appréciable de peroxyde d'hydrogène. Durant la montée de pression, on voit croître l'abondance de le masse 28 qui peut refléter, entre autres composés, l'oxyde de carbone. Les résultats de cette étude encore en cours seront publiés plus tard. Des courbes très différentes des précédentes ont été observées dans des expériences sur l'oxydation à 235° C. de l'éther diméthylique par une égale quantité d'oxygène; la réaction débute, sans période d'induction, par un faible accroissement de pression qui se poursuit linéairement jusqu'à un palier.

Influence de la température et de la composition du mélange

La figure 3 fait voir quelques familles de courbes de pression totale et de pression partielle d'oxygène obtenues avec des mélanges de trois compositions différentes, à diverses températures. On voit que le coefficient de température

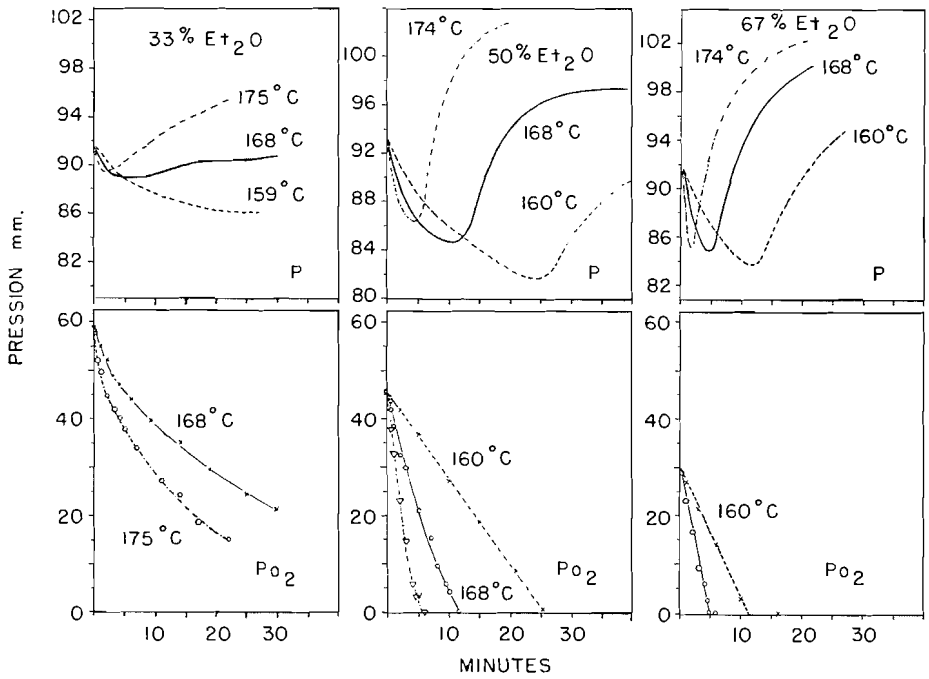

FIG. 3. Comparaisons de courbes de pression totale (haut) et de pression d'oxygène (bas) pour des mélanges contenant initialement 33%, 50%, et 67% d'éther en volume. (Les courbes de pression totale sont obtenues par enregistrement continu.)

est positif et grand à toutes ces compositions, tant par les taux de descente et de montée de la pression que pour celui de la consommation d'oxygène. Dans les mélanges contenant 50% d'éther ou plus, la consommation d'oxygène semble être d'ordre zéro et est complète au moment où la pression totale passe par le minimum. Les mélanges contenant, au départ, deux fois plus d'oxygène

que d'éther accusent deux particularités: la montée de pression est supprimée aux basses températures; à température plus élevée, la consommation d'oxygène, rapide et apparamment d'ordre zéro jusqu'au minimum, se poursuit ensuite plus lentement et suivant une loi du premier ordre. Cette loi est mise en évidence par la transposition à l'échelle logarithmique des deux courbes obtenues à 168° C. et 175° C.

Comme il n'est pas facile de mesurer sans ambiguité la pente initiale de pression, nous prenons, comme mesure de la vitesse de la première étape de la réaction, soit la pente de la courbe de l'oxygène, soit l'inverse du temps τ_m (figure 2) qui s'écoule entre l'instant initial et celui où le minimum de pression est atteint. La figure 4 montre les droites d'Arrhenius obtenues par ces deux

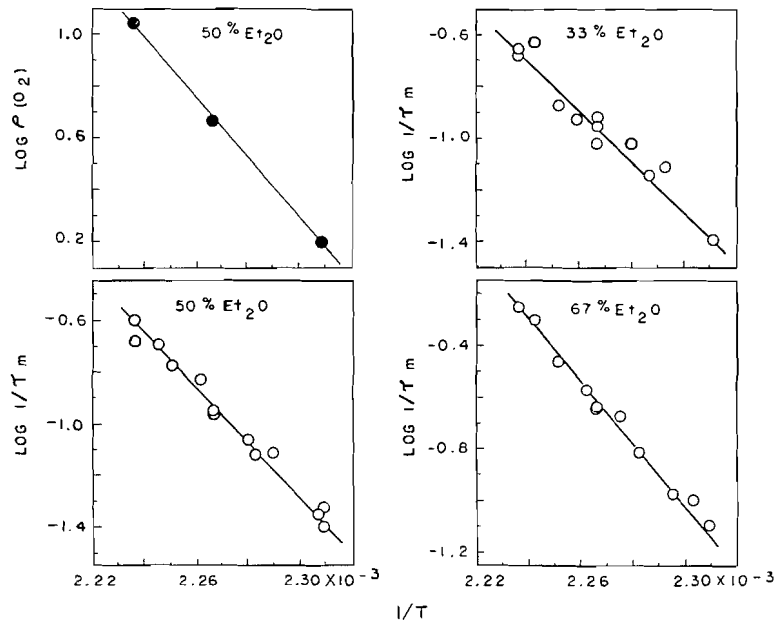

FIG. 4. Courbes de $1/T°$ K. contre les logarithmes de la vitesse initiale calculée d'après le taux de consommation d'oxygène (O_2) et d'après le temps τ_m écoulé au minimum de pression.

méthodes. On a pu vérifier, dans le cas du mélange à 50%, que le coefficient de température obtenu par les deux méthodes est le même, ce qui permet de considérer τ_m comme une grandeur significative. En prenant pour mesure de la vitesse de la seconde étape de la réaction la pente maximum ρ_m de la montée de pression, on obtient les droites d'Arrhenius de la figure 5.

Nos données permettent un calcul approximatif des énergies d'activation apparentes. Pour la phase initiale (figure 4), les valeurs obtenues pour 33%, 50%, 67%, et 90% d'éther sont de 44, 51, 55, et 48 kcal./mole respectivement. La valeur obtenue d'après le taux de consommation d'oxygène à 50% d'éther est 53 kcal./mole, en bon accord avec la valeur ci-dessus tirée de τ_m. Le taux maximum ρ_m d'accroissement de pression conduit à des valeurs de 32, 25, et 26 kcal./mole pour 50, 67, et 90% d'éther respectivement. Ces valeurs gros-

sières, obtenues sur un étroit intervalle de températures, peuvent néanmoins servir à caractériser le coefficient de température près de la limite de flamme froide.

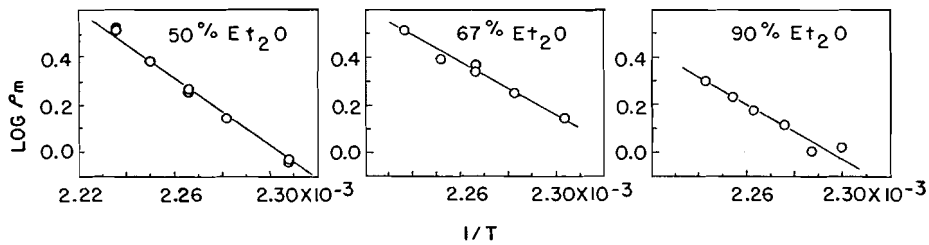

FIG. 5. Courbes de $1/T°$ K. contre le logarithme du taux maximum ρ_m de l'accroissement de pression.

L'influence de la proportion des réactifs sur les deux vitesses représentées par $1/\tau_m$ et ρ_m se voit dans la figure 6. On voit que ces grandeurs sont sensiblement indépendantes de la composition tant qu'il y a moins de 50% d'éther, mais qu'elles varient rapidement dans les mélanges pauvres en oxygène. On a aussi trouvé que, pour un mélange à 50% à 170° C., $1/\tau_m$ varie peu avec la pression totale entre 45 et 95 mm. Hg tandis que ρ_m est sensiblement proportionnel à cette pression. Des expériences effectuées dans le dessein de dégager l'influence de la pression partielle de chacun des réactifs ont abouti à des

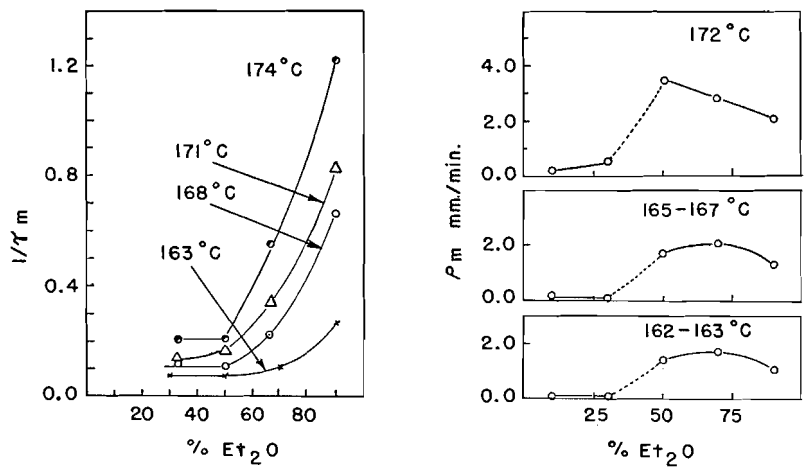

FIG. 6. Variations de la vitesse initiale $1/\tau_m$ min.$^{-1}$ et du taux maximum ρ_m de l'accroissement de pression, en fonction de la composition du mélange.

courbes présentant des maxima semblables à ceux de ρ_m dans la figure 6. Il semble donc que la proportion des réactifs soit le facteur le plus important. Dans l'ensemble, ces résultats concordent avec ceux de Eastwood et Hinshelwood (7) qui ont observé une inhibition considérable par l'oxygène; en effet, la figure 6 montre que la réaction est toujours plus lente aux fortes proportions d'oxygène.

Influence de la surface et de gaz étrangers

Un cylindre en quartz de mêmes dimensions que notre chambre à réaction en Pyrex a donné les mêmes courbes de pression et d'oxygène. Par contre, en traitant la paroi de Pyrex par une solution de chlorure de potassium, nous avons obtenu les courbes de la figure 7. Cet effet a déjà été observé par L. Ouellet et C. Ménard (17), qui nous ont suggéré ces expériences. On voit que, dans ces conditions, l'allure de la réaction ressemble à celle des oxydations d'hydrocarbures et de l'éther diisopropylique (4, 12, 14); une courte période d'induction est décelable sur la courbe de pression et sur celle de la consommation de l'oxygène, mais il n'y a plus de minimum de pression.

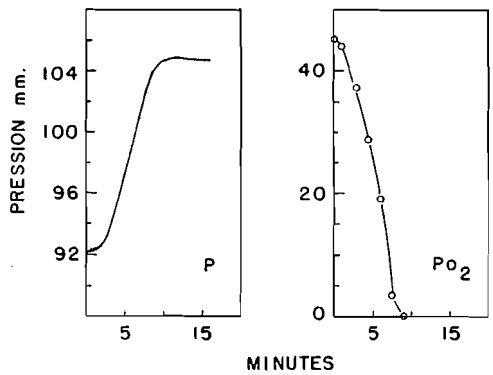

FIG. 7. Courbes de pression totale P et de pression d'oxygène P_{O_2} pour une réaction à 168° C. et 50% d'éther en volume, dans un récipient en Pyrex traité au chlorure de potassium.

L'injection de petites quantités d'oxyde nitrique à diverses époques avant ou durant la réaction inhibe dans tous les cas la consommation de l'oxygène et l'abaissement de la pression, mais n'agit pas toujours de la même façon sur l'accroissement de la pression. La vitesse est réduite d'environ 30 fois par 0.6% d'oxyde nitrique, ce qui donne une indication approximative de la longueur des chaînes. Ces effets et ceux qui résultent de l'addition de propylène, d'acide bromhydrique, et de formaldéhyde seront décrits dans une autre publication.

DISCUSSION

La réaction débute sans période d'induction appréciable, contrairement aux oxydations des hydrocarbures et de l'acétaldéhyde; les peroxydes formés n'exercent donc pas d'effet autocatalytique. On distingue deux phases assez nettement séparées dans le temps. La première phase correspond surtout à la consommation de l'oxygène et s'accompagne d'un abaissement de la pression. Sa forte inhibition par l'oxyde nitrique indique qu'il s'agit d'une réaction en chaînes longues. La seconde phase s'accompagne d'un accroissement de la pression; elle n'exige pas la présence d'oxygène libre. Cette seconde phase peut être accélérée, par traitement de la surface en chlorure de potassium, à tel point qu'elle n'est plus en retard sur la précédente; on retrouve alors la courbe de pression ascendante caractéristique des hydrocarbures (figure 7). La compa-

raison des figures 7 et 2 montre que le taux de la consommation de l'oxygène est peu affecté par ce changement de surface.

Cette séparation en deux phases semble constituer la principale différence entre l'oxydation de l'éther diéthylique et celle des hydrocarbures. On peut vraisemblablement l'attribuer à la température anormalement basse d'oxydation de l'éther, plutôt qu'à une différence essentielle de mécanisme; les réactions de la seconde phase seraient suffisamment lentes à cette température pour ne pas masquer la phase initiale d'oxydation. Si cette hypothèse est vraie, on devrait pouvoir reproduire cette séparation en oxydant un hydrocarbure sur une surface empoisonnée, ou la retrouver dans le cas d'hydrocarbures oxydables à température relativement basse. On sait (3) que certaines oléfines semblent se comporter comme l'éther aux basses températures et comme les paraffines aux températures élevées. Dans l'ensemble, l'oxydation lente de l'éther sur le Pyrex et le quartz ressemble beaucoup plus à celle de l'acétaldéhyde, qui débute aussi par une baisse de pression et a lieu dans le même domaine de températures (13), qu'à celle des hydrocarbures (5, 12). Remarquons que la coutume de prendre le taux maximum ρ_m de l'accroissement de pression comme mesure de la vitesse d'oxydation ne peut être suivie dans le cas de l'éther diéthylique; les comparaisons basées sur cette grandeur (7) réflètent plutôt les vitesses des réactions secondaires.

Bien que les faits connus actuellement ne permettent pas une analyse détaillée de la cinétique et du mécanisme de la réaction, il est utile de supposer que les processus en jeu dans chacune des phases sont de mêmes types que ceux qui ont été invoqués pour interpréter l'oxydation des hydrocarbures (2, 5, 12, 21). Appliquant la distinction développée systématiquement par Niclause, Combe, et Letort (15, 16), on peut penser qu'en gros l'abaissement de pression représente la partie de la réaction attribuable à l'oxydation proprement dite, et que la partie de l'oxygène consommé dont cet abaissement ne rend pas compte est engagée dans des dégradations oxydantes s'effectuant sans changement de pression. Enfin, l'accroissement de pression correspondrait à des pyrolyses induites par l'oxygène résiduel ou par la décomposition de peroxydes. L'importance relativement faible des variations de pression laisse supposer que la dégradation oxydante prédomine. L'ordre zéro par rapport à l'oxygène peut être considéré comme une manifestation de l'inhibition par un excès de ce réactif. Ce comportement, bien connu chez les réactions de ce type (2, 5, 7), a été attribué (2) à la prédominance d'un processus de rupture par recombinaison de radicaux peroxydiques.

Pour ce qui concerne la nature des produits intermédiaires au cours de la première phase, il faudra rendre compte de l'apparition hâtive de l'eau et d'un peracide. Il est peu probable que le peroxyde dihydroxyéthylique, produit connu (19) de l'oxydation de l'éther liquide à froid, joue un rôle à la température de notre réaction. Le mode d'initiation le plus vraisemblable est l'abstraction d'un hydrogène secondaire par l'oxygène et par les radicaux, en particulier les radicaux peroxydiques produits au cours de la chaîne.

$$C_2H_5OC_2H_5 + O_2 = CH_3\dot{C}HOC_2H_5 + HO_2^{\cdot} \qquad [1a]$$

$$C_2H_5OC_2H_5 + HO_2^{\cdot} = CH_3\dot{C}HOC_2H_5 + H_2O_2 \qquad [1b]$$

Ce gros radical peut capter une molécule d'oxygène pour former un radical peroxydique $CH_3CH(O\dot{O})OC_2H_5$ et éventuellement l'hydroperoxyde correspondant; il peut aussi se décomposer et donner lieu aux réactions suivantes:

$$CH_3\dot{C}HOC_2H_5 = CH_3CHO + C_2H_5^{\cdot} \qquad [2]$$

$$C_2H_5^{\cdot} + O_2 = C_2H_5OO^{\cdot} \qquad [3]$$

$$C_2H_5OO^{\cdot} = CH_3CHO + OH^{\cdot} \qquad [4a]$$

$$C_2H_5OO^{\cdot} = CH_3CO^{\cdot} + H_2O \qquad [4b]$$

$$CH_3CO^{\cdot} + O_2 = CH_3COOO^{\cdot} \qquad [5]$$

$$CH_3COOO^{\cdot} + RH = CH_3COOOH + R^{\cdot} \qquad [6]$$

où le rôle de RH sera joué au début par l'éther, mais de plus en plus par l'acétaldéhyde, dont l'hydrogène est plus facile à abstraire. Dans la mesure où [4*b*] est possible contre la concurrence de [4*a*] et de [7], on obtiendrait, dans les premiers temps de la réaction, le bilan

$$C_2H_5OC_2H_5 + 2O_2 = CH_3CHO + CH_3COOOH + H_2O \qquad [a]$$

qui correspond au rapport observé des taux de consommation de l'éther et de l'oxygène, mais ne comporte pas d'abaissement de pression. Par ailleurs, [4*a*] et [4*b*] seront vraisemblablement concurrencées par la réaction

$$C_2H_5OO^{\cdot} + RH = C_2H_5OOH + R^{\cdot}. \qquad [7]$$

On sait que l'hydroperoxyde d'éthyle se décompose sur la surface avec une demi-vie de l'ordre d'une minute, (9) vers 170° C., avec formation d'acétaldéhyde et d'eau

$$C_2H_5OOH \xrightarrow{S} CH_3CHO + H_2O \qquad [8]$$

et que cette décomposition est fortement catalysée par le chlorure de potassium. Par la voie [2-3-7-8], on obtiendrait deux molécules d'acétaldéhyde. Dans la région de 160 à 175° C., ce dernier s'oxyde, à une vitesse sensiblement égale (13) à celle de l'oxydation de l'éther, suivant:

$$CH_3CHO + O_2 = CH_3COOOH. \qquad [9]$$

Il est probable que le chlorure de potassium catalyse aussi la décomposition de l'acide peracétique. Ce dernier réagirait aussi dans une certaine mesure avec l'acétaldéhyde, suivant:

$$CH_3COOOH + CH_3CHO = 2CH_3COOH. \qquad [10]$$

Dans tous les cas envisagés, un fragment de la molécule d'éther donne immédiatement une molécule d'acétaldéhyde suivant (2). L'autre fragment peut être oxydé rapidement en acide peracétique par une seule chaîne [3-4*b*-5-6]. Ceci donnerait le bilan [*a*] ne comportant aucune variation de pression. Mais ce second fragment peut aussi donner d'abord une seconde molécule d'acétaldé-

hyde par l'une des voies [4*a*] ou [3-7-8] puis de l'acide peracétique par [9]. Le faible abaissement de pression réfléterait l'importance relative de la réaction [9]. Enfin, la réaction [10] expliquerait que la quantité d'acide dépasse nettement celle du peroxyde et s'accroît aux dépens de cette dernière.

Au début de la seconde phase, s'il reste beaucoup d'oxygène, la pression continue à décroître à cause de la réaction [9] si la température est assez basse (figure 3). Mais à température plus élevée ou dans un mélange pauvre en oxygène, les réactions de pyrolyse de l'acétaldéhyde (et autres produits) prédominent et la pression croît. Dans ces conditions, la réaction [5] cède le pas à la décomposition du radical acétyle, affectée d'une énergie d'activation de l'ordre de 15 kcal./mole (20):

$$CH_3CO^{\cdot} = CH_3^{\cdot} + CO.$$

Le radical méthyle pourra, en l'absence d'oxygène, former du méthane par abstraction et de l'éthane par recombinaison; en présence d'un peu d'oxygène, il sera surtout oxydé suivant l'un des schémas proposés par Grumer (8), avec formation d'oxyde de carbone, de méthanol, et d'eau.

Il est difficile de dire dans quelle mesure la décomposition d'un peroxyde contribue directement à l'accroissement de la pression. Il se peut qu'une telle décomposition gouverne la vitesse de la seconde phase, dont l'énergie d'activation globale est du bon ordre de grandeur, soit de 25 à 30 kcal./mole.

En somme, la première phase correspondrait dans l'ensemble à la dégradation en molécules à deux atomes de carbone, la seconde phase, à celle en molécules à un atome de carbone. En présence de chlorure de potassium (figure 7), la décomposition de l'acide peracétique et éventuellement de l'hydroperoxyde d'éthyle serait accélérée à tel point que la seconde phase ne serait plus en retard sur la première.

La comparaison du taux d'oxydation lente de l'éther à ceux d'autres substances est impossible du fait que la pente maximum ρ_m de la courbe d'accroissement de pression a été prise par plusieurs auteurs comme mesure des taux d'oxydation lente de diverses substances organiques. Or, dans le cas de l'éther et vraisemblablement dans plusieurs autres, cette grandeur n'a pas la signification qu'on lui avait prêtée.

REMERCIEMENTS

Nous adressons nos remerciements au Comité de Recherches pour la Défense pour un octroi (DRB-129) et au Conseil National de Recherches qui a accordé des bourses à l'un de nous (A.L.). Nous remercions aussi M. E. G. Léger de l'aide fréquente qu'il nous a prêtée au cours de ce travail, M. L. P. Blanchard qui nous a fourni les spectres de masses, ainsi que MM. P. Ausloos et L. Ouellet qui nous ont fait d'utiles suggestions.

SUMMARY

The reaction of diethyl ether and oxygen in a Pyrex vessel has been studied over the temperature range 160–175° C., below the lower limit of cool flame. During the initial pressure drop, oxygen is consumed in a zero order process with an activation energy of some 50 kcal./mole, giving rise to water, peroxides,

acids, and other products. The pressure rise which follows is secondary to the main oxidation reaction; it does not require the presence of oxygen. Oxidation rates derived from maximum rates of pressure rise are therefore questionable. A number of processes, which may account for these two reactions stages, are examined.

POLYMERIZATION OF 2-FLUOROBUTADIENE-1,3 AND PROPERTIES OF POLYMERS[1]

By R. J. Orr and H. Leverne Williams

ABSTRACT

Fluorobutadiene has been copolymerized with styrene in emulsion at 5°C. The rate of mercaptan consumption, rate of conversion, copolymer composition, and the intrinsic viscosity of the copolymer have been measured. Reactivity ratios and regulating indices were calculated for this temperature. Copolymerization reactions at 50°C. were studied in solution, and the reactivity ratios calculated. These were, for the following monomers as monomer 2: styrene at 5°C., $r_1 = 1.61 \pm 0.24$ and $r_2 = 0.16 \pm 0.08$; styrene at 50°C., $r_1 = 1.55 \pm 0.10$ and $r_2 = 0.50 \pm 0.10$; acrylonitrile at 50°C., $r_1 = 0.59 \pm 0.10$ and $r_2 = 0.07 \pm 0.03$; isoprene at 50°C., $r_1 = 2.05 \pm 0.19$ and $r_2 = 0.19 \pm 0.10$; α-methyl styrene at 50°C., $r_1 = 1.77 \pm 0.19$ and $r_2 = 0.38 \pm 0.11$; and methyl methacrylate at 50°C., $r_1 = 1.54 \pm 0.08$ and $r_2 = 0.64 \pm 0.08$. Polyfluorobutadiene has a cohesive energy density of 90–100 cal./cc., a second order transition point of −62.5°C., and some units formed by 1,2 or 3,4 addition.

INTRODUCTION

There are few data on the polymerization of 2-fluorobutadiene or on the physical properties of its polymers. The patent literature contains information on preparation of the polymers in emulsion and their properties (8, 9, 10, 16, 17, 18, 19, 24). Other papers have appeared summarizing the properties and preparations of the polymers (21, 33).

Fluorobutadiene lies between butadiene and chlorobutadiene in its properties. It polymerizes nearly as rapidly as chlorobutadiene, but unlike the latter copolymerizes with many monomers readily. Homopolymers have been found to be resistant to crystallization on stretching but require reinforcement for development of high tensile properties. Methods of synthesis of the monomer have been reported in a number of patents (2, 11, 12, 25, 26, 27, 28, 29).

EXPERIMENTAL RESULTS

Copolymerization Rates

The rate of conversion was measured as a function of monomer ratio for copolymerization with styrene at 5°C.; the results are given in Table I. The conversion rate is unaffected by the per cent diene in the charge. The time–conversion relation is quite linear, showing a rate of conversion considerably more rapid than during the polymerization of butadiene.

Chain Transfer Reactions

The intrinsic viscosities of the polymers prepared to different conversions, from various charge ratios and mercaptan contents, were measured in benzene and ethylene dichloride. The mercaptan used was a mixture of tertiary mercaptans of an average molecular weight 220. The data are in Table II. The disappearance of mercaptan (RSH) over the course of the polymerization was determined by amperometric titration. The results are in Table III.

Polymer Compositions from Emulsion and Solution Polymerizations

Polymers from polymerizations in emulsion and solution, at 5° and 50°C. respectively, were analyzed for per cent diene.

Styrene was the comonomer at 5°C. and the comonomers at 50°C. were styrene, acrylonitrile, isoprene, α-methyl styrene, and methyl methacrylate.

The emulsion polymers were obtained at varying conversions. The polymers prepared in solution were as low conversion as possible. The results of the analyses are in Table IV.

TABLE IV

POLYMER COMPOSITIONS FOR FLUOROBUTADIENE (M_1) COPOLYMERS

Effect of Solvents on Vulcanized Polyfluorobutadiene

The tendency of this polymer to swell in a series of solvents of varying cohesive energy densities was determined. The per cent swell was determined by soaking a strip of the rubber in the solvent and determining the weight increase. The equilibrium weight was used to determine the amount of swelling.

Some of the cohesive energy density values were taken from publications (14, 31). Those unavailable were calculated from the relation c.e.d. $= \Delta H_{vap} - RT$. In Table V are given the results.

TABLE V

SWELL BEHAVIOR OF VULCANIZED POLYFLUOROBUTADIENE

Solvent	c.e.d. (Ref.)	% Swell
Toluene	80 (14)	115
Benzene	82 (14)	110
Methyl ethyl ketone	86	93
Ethylene dichloride	96	219
Carbon disulphide	97	134
Acetone	100 (14)	110
Pyridine	100 (31)	203
Dioxane	100 (14)	199
Dimethyl formamide	140 (31)	100
Nitromethane	160 (31)	183

Second Order Transition Temperature

This was determined by a dilatometric method as being −62.5°C. There was no evidence of crystallization at this temperature.

Infrared Spectra of Polyfluorobutadiene

All infrared spectroscopic work had to be done on the solid films since the polymers were insoluble in carbon disulphide. No quantitative conclusions were possible but qualitative results could be obtained. In Fig. 1 are curves for polyfluoro- and polychloro-butadiene. These are compared with the spectra of polybromoprene (20). Since all spectra were determined in polyethylene, no data were obtained below 7.8 microns where polyethylene begins to interfere.

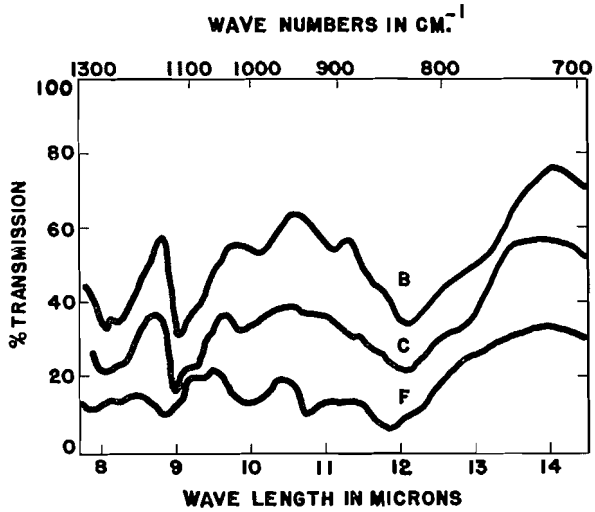

FIG. 1. Infrared spectra of polyfluorobutadiene (F), polychlorobutadiene (C), and polybromobutadiene (B).

DISCUSSION

Emulsion Polymerizations

Emulsion copolymerization rates are quite rapid compared to butadiene (3, 6) indicating either efficient utilization of initiating radicals or a high solubilization of monomers by soap. The independence of rate with per cent fluorobutadiene in the charge suggests polymerization rates similar to those of styrene. The low intrinsic viscosities of the polymers may be due to low molecular weight, a highly gelled polymer, or an improper choice of solvent. Since the values did not change markedly for measurements using two liquids of a different cohesive energy density, the choice of solvent could not have been responsible. There seems little possibility that the polymers were gelled since the intrinsic viscosity of polyfluorobutadiene prepared in the absence of mercaptan did not show the peak characteristic of gelation, even at very low conversion. The low intrinsic viscosities must be characteristic of low molecular weights due to chain transfer reactions. These cannot be due to mercaptan since the intrinsic viscosity is independent of the mercaptan content of the original charge. Either the fluorobutadiene itself, or some impurity difficult to remove, such as difluorobutene, must be responsible. The mercaptan does react during polymerization at a rate indicating the same reactivity toward the fluorobutadienyl radical as toward butadienyl (6). If this reaction is first order with respect to mercaptan over the first part of the reaction, the regulating indices would be 1.8 and 0.6 for 78/22 and 60/40 fluorobutadiene–styrene charge ratios respectively.

Structure of Polyfluorobutadiene

The dominant band in the spectra near 12 microns must be due to the C–H on the CH=CF group. This completely obscures that portion of the spectra which would give a measure of the proportion of *cis* 1,4 addition (by analogy with the spectrum of Hevea). Some 1,2 or 3,4 addition is indicated by the band at 10.75 microns. This is different from polychlorobutadiene which is 100% 1,4 (20).

Solubility of Polyfluorobutadiene

One method of determining the cohesive energy density (c.e.d.) of a polymer is to find the liquid in which the swelling of the vulcanized polymer is a maximum (31). From the data in Table V, the cohesive energy density of polyfluorobutadiene was estimated as 90–100 cal./cc. Acetone and nitromethane gave anomalous results. The cohesive energy density is of the order of that for polyvinyl chloride and is larger than the value for polychlorobutadiene and 75/25 butadiene–acrylonitrile copolymers. Fluorine changed the cohesive energy density of the polymer in the same direction but to a greater extent than did chlorine. This does not correlate well with the low values obtained with other fluorine containing polymers (31). The structure of the polymer chain may affect the part that fluorine plays in determining the cohesive energy density.

Reactivity Ratios of Fluorobutadiene in Copolymerization

The reacted monomer data from the emulsion polymerizations were extra-

polated to zero conversion. Solution polymerizations were stopped at low conversions and the polymer composition assumed to be identical with that formed at zero conversion. These values, with the corresponding charge ratio, were substituted in the copolymerization equation, the r_1–r_2 lines calculated, and the values of r_1 and r_2 determined. The error was estimated from the size of the triangle of intersection. A typical r_1–r_2 plot is shown in Fig. 2. In Table VI are the values which were determined.

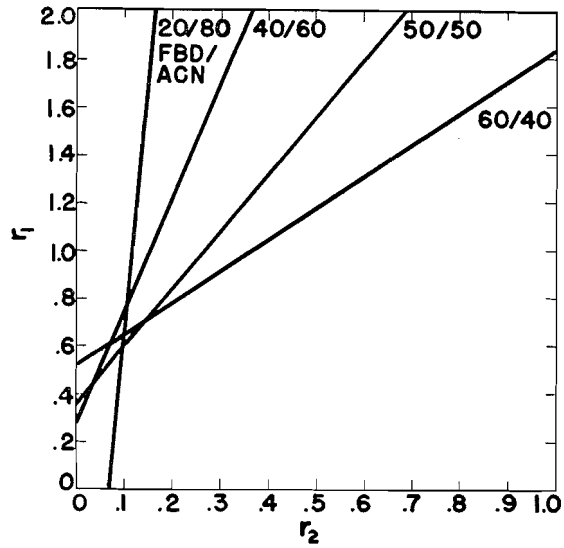

FIG. 2. r_1–r_2 lines for fluorobutadiene–acrylonitrile copolymerization at 50°C.

TABLE VI

REACTIVITY RATIOS OF FLUOROBUTADIENE WITH COMONOMERS

Comonomer (M_2)	T (°C.)	r_1	r_2	$r_1 \times r_2$
Styrene	5	1.61±0.24	0.16±0.08	0.26
Styrene	50	1.55±0.10	0.50±0.10	0.78
Acrylonitrile	50	0.59±0.10	0.07±0.03	0.04
Isoprene	50	2.05±0.19	0.19±0.10	0.39
Alpha methyl styrene	50	1.77±0.19	0.38±0.11	0.67
Methyl methacrylate	50	1.54±0.8	0.64±0.08	0.99

The influence of temperature on r_2 seems much more pronounced than on r_1. There is a strong tendency to alternate in the copolymers, reaching a maximum with acrylonitrile and a minimum with methyl methacrylate. The ratio of r_1 and r_2 indicates a general tendency to enter the copolymer more rapidly than the comonomer.

The Q and e Values of Fluorobutadiene

These values were calculated from the Alfrey-Price equation and are in Table VII. The values for fluorobutadiene were determined using styrene as the primary standard with $Q = 1.0$ and $e = -0.8$. Those for the other comonomers were determined using the fluorobutadiene as a secondary standard.

TABLE VII

Q AND e VALUES FOR FLUOROBUTADIENE AND THE COMONOMERS

Monomer	T (°C.)	Q	e
Fluorobutadiene	5	1.39	+0.36
Fluorobutadiene	50	1.32	−0.30
Methyl methacrylate	50	0.85	−0.30
Acrylonitrile	50	2.5	+1.5
Isoprene	50	0.86	−1.27
Alpha methyl styrene	50	0.98	−0.93

Agreement with the values reported previously (1) is within experimental error except for the e value of methyl methacrylate which was reported as 0.4. The Q and e values for isoprene at 50°C. were not previously reported but the deviation from butadiene at this temperature is in accord with that observed at −18°C. (22, 23).

It is of interest to compare the relative effects of chlorine and fluorine substitution on the polarity of the double bond and the resonance stabilization of the dienyl free radical. The reactivity ratios for chlorobutadiene have been reported as $r_1 = 3.41$, $r_2 = 0.59$ for butadiene and $r_1 = 3.65$, $r_2 = 0.133$ for isoprene (chlorobutadiene being monomer-1) at 50°C. (30). Using butadiene as a secondary standard with $Q = 1.33$ and $e = -0.8$, then Q and e for chlorobutadiene are 1.5 and −0.24 respectively. It may be seen that the change in Q and e caused by the substitution of the fluorine group is in the same direction, but not as pronounced as it was for the chlorine. Fluorobutadienyl radical is less resonance stabilized and the double bond of the monomer is poorer in electrons than that of the chlorobutadiene.

EXPERIMENTAL METHODS

The recipe was similar to one developed previously for butadiene copolymerization (6) and is:

Monomers	100 parts by weight, active material
Water	180
Potassium fatty acid soap flakes	5.0
Mixed tertiary mercaptans	Variable
Cumene hydroperoxide	0.10
Ferrous sulphate heptahydrate	0.14
Potassium pyrophosphate	0.177

An emulsion of ditertiary butyl hydroquinone was used as the stopping agent.

Fluorobutadiene was prepared by the Defence Research Chemical Laboratory through the courtesy of Dr. H. Sheffer. It was subjected to simple distillation before use. Other monomers were commercial materials which were fractionated, taking the center fraction. All polymerization chemicals were standard Commercial grade. Analytical reagents were C.P. grade.

The mercaptan in the latex was determined by amperometric titration (13). Intrinsic viscosities were measured at 30.0°C. by dissolving the latex directly in an 80:20 benzene–ethanol or ethylene dichloride – ethanol solution. Dilutions were made with pure benzene (or ethylene dichloride) so that intrinsic viscosities could be calculated (4, 7, 15).

The polyfluorobutadiene was synthesized at 5°C., coagulated in brine acid, stabilized with BLE, compounded in the test recipe, and vulcanized. Swelling indices were done on the vulcanized stock. Second order transition points were determined on uncured samples by a dilatometric technique. Polymers were purified for analysis by swelling in benzene and extracting in methanol.

A normal Parr bomb combustion using 50 mgm. polymer, 15 gm. sodium peroxide, and 0.5 gm. benzoic acid was used. The ignition was electrical and it was found that the position of the fuse wire in respect to the top of the combustion mixture was critical. Potassium perchlorate was omitted from the combustion mixture since it was found to have a deleterious effect in the subsequent colorimetric analysis for fluoride ion.

Fluoride was determined on aliquots of the solution containing the soluble combustion products by the extent of bleaching brought about by the addition of fluoride ions to a ferric thiocyanate solution (5, 32). The amount of bleaching is definite and reproducible but not a linear function of fluoride ion concentration. There is a slow but distinct decrease in the colorimeter reading with time and the color varies considerably with pH. The combustion mixture was brought to pH = 7.0 with nitric acid and further adjusted to 2.0 with hydrochloric acid. The method was standardized against sodium fluoride solution with readings taken on a Klett-Summerson colorimeter and a Beckman DU ultraviolet spectrophotometer set at 4900 Å wavelength. Analysis of polyfluorobutadiene indicated complete recovery and identification of organic fluorine.

ACKNOWLEDGMENT

Mr. G. Turner (Polymer Corporation Limited) measured and interpreted the infrared spectra. Dr. L. Breitman determined the second order transition temperature. Messrs. S. J. Butler and C. Freeman assisted with the work. The authors appreciate the permission to publish this paper extended by the Defence Research Board and Polymer Corporation Limited.

STUDIES ON THE HETEROGENEITY OF CARRAGEENIN[1]

By David B. Smith,[2] A. N. O'Neill,[3] and A. S. Perlin[2,4]

ABSTRACT

The carbohydrate residues in κ-carrageenin are 3,6-anhydro-D-galactose and D-galactose which are present in nearly equal amounts. Tests following fractional precipitation of κ-carrageenin indicate general chemical homogeneity but physical heterogeneity. κ-Carrageenin is not susceptible to oxidation with periodate. Fractional precipitation of λ-carrageenin separates a main fraction which contains only D-galactose and a trace of 3,6-anhydro-D-galactose. This polysaccharide is susceptible to periodate oxidation. It is polydisperse on a mass basis. Materials containing glucose, xylose, and L-galactose segregate into minor fractions of λ-carrageenin and hence cannot be integral parts of the principal polysaccharides of carrageenin. L-Galactose has been isolated from carrageenin by a simple procedure.

Carrageenin is the polysaccharide complex which is extracted with water from certain red seaweeds, in particular, *Chondrus crispus* and *Gigartina stellata* (26). D-Galactose comprises about two-thirds of the organic matter. The principal remaining organic constituent is 3,6-anhydro-D-galactose recently identified by O'Neill (17, 18). The presence of small amounts of glucose, pentose, and L-galactose has been established (2, 13). Carrageenin contains also about 30% of monoesterified sulphuric acid and consequently, in neutral solution, exists as a salt.

Chemical evidence (4, 13, 15) bearing on the structure of carrageenin has usually been interpreted on the basis of a monotypical substance though the possibility of greater complexity has been admitted (13). Differences in degree of gel formation and other properties among fractions obtained by extraction at successively higher temperatures (7, 9, 10, 20) have been taken to indicate different polysaccharides. However, the principal chemical difference reported in the earlier literature has been in cation ratios and it has been suggested that the polysaccharides are otherwise essentially identical (2).

The development of a new method of fractionation (23) based on the gelatinizing effect of potassium ions on carrageenin has opened a new approach to the structure of this material. This fractionation, provided it is performed on sufficiently dilute carrageenin solutions, permits a sharp separation into potassium-sensitive material which is precipitated by potassium ions and potassium-insensitive material which remains in solution (23, 24).

This paper describes some analytical and physical characterization of subfractions of these two materials. The suggestion made previously (24) that the potassium-sensitive fraction (κ-carrageenin) would be more chemically homogeneous than the potassium-insensitive material (λ-carrageenin) is confirmed.

MATERIALS AND METHODS

Preparation of Carrageenin and Its κ- and λ-Components

Dried *Chondrus crispus* was ground coarsely, washed briefly with cold water, and extracted in 1% suspension for one hour at 90°C. in water containing 0.2% NaCl and 0.1% Na_2CO_3. Insoluble material was filtered out and re-extracted for one hour at 90°C. using one-third the first volume of extractant. The combined extracts were dialyzed against several changes of 0.2 *M* NaCl to remove ions other than Na^+. The dialyzed solution was clarified by centrifugation at 2000 *g*. The carrageenin was precipitated from a portion of this solution with three volumes 95% ethanol and was washed and dried with ethanol and ether. This sample was designated CL3.

The remaining carrageenin solution was diluted with water to 0.24% solids. Solid KCl was added slowly with stirring to a concentration of 0.25 *M*. The crude κ-carrageenin precipitate was separated by centrifugation at 2000 *g*. The precipitate was dialyzed first against 0.1 *M* NaCl to remove potassium ions and then against water to remove NaCl. The κ-carrageenin dissolved and was diluted to about 0.2%. Potassium chloride was added to 0.25 *M* and the κ-carrageenin again separated by centrifugation. Dialysis with solution of the κ-carrageenin and its reprecipitation were repeated once more. The final κ-carrageenin precipitate was suspended in 0.5 *M* NaCl, dialyzed free of potassium ions, and precipitated with three volumes of ethanol. After the precipitate was washed free of chloride ion with 80% ethanol followed by absolute ethanol and ether, it was dried over $CaCl_2$. This sodium κ-carrageenate preparation was designated CL3 κ-1.

The supernatants from the foregoing centrifugations (with the exception of the last which contained a negligible amount of polysaccharide) were combined and evaporated at 35°C. to one-tenth the initial volume. The λ-carrageenin (CL3 λ-1) was precipitated from this solution, and washed and dried in the same manner as the previous preparations.

Fractionation of κ- and λ-Carrageenins

κ-Carrageenin (CL3 κ-1) was fractionated by precipitation from dilute solution (0.2% in 0.25 *M* NaCl) by the graded addition of ethanol at 20–25°C. The precipitate was removed after each addition of ethanol by centrifugation. The fractions were washed free of chloride ion and dried over $CaCl_2$ after absolute ethanol and ether washes. The ethanol concentration ranges used for fractionation and the yields obtained are shown in Table I. (Considerable loss of material, particularly of Fraction 2*a*, attended the first fractionation.)

The fractionation of λ-carrageenin (preparation C5 λ-2) has been described before (24). Particulars and yields are reproduced, for reference, in Table I.

Physical Measurements

Viscosity at 25°C. and sedimentation rates were measured in the manner already described (24). For extrapolation of the sedimentation results to zero concentration the method of Newman, Loeb, and Conrad (16) was used.

TABLE I

SUBFRACTIONATION OF CARRAGEENIN FRACTIONS

Fractionation No.	Fraction obtained	Ethanol concentration range, %	Yield (% of original sample)
1	CL3 κ-1 Fr. 1*a*	0–30	2
	Fr. 2*a*	30–45	35
	Fr. 3*a*	45–75	16

	Fr. 4	36–48	11
	Fr. 5	48–60	1.4

Analytical Methods

Sulphate was determined after refluxing for 24 hr. in 0.5 *N* HCl followed, after tenfold dilution, by precipitation as $BaSO_4$.

For chromatographic analyses, samples (1% in 0.5 *N* H_2SO_4) were hydrolyzed in sealed tubes for 10–15 hr. on a boiling water bath. After neutralization of the hydrolyzates with $BaCO_3$ and filtration, the filtrates were examined by descending paper chromatography (12, 19). For quantitative chromatographic analysis, the method of Flood *et al.* (5) was used. Isolation of galactose as the crystalline α-methyl-α-phenylhydrazone was also employed for galactose estimation.

L-Galactose was taken to be the galactose remaining after treatment of the neutral hydrolyzate with a suspension of a galactose fermenting yeast, *Saccharomyces cerevisae*, strain N.R.C. No. 824, (16 hr. culture from D-galactose agar) at 37°C. for 3.5 hr. The activity of the culture was simultaneously tested with a 1% solution of D-galactose. After incubation, the yeast, together with added charcoal, was separated by centrifugation and the supernatant liquor examined on the chromatogram. D-Galactose was completely fermented as was glucose, but xylose was unaffected.

3,6-Anhydro-D-galactose cannot be determined directly because of its instability during acid hydrolysis. The following procedure takes advantage of its degradation under such conditions to 5-hydroxymethyl-2-furaldehyde which can be determined spectrophotometrically. Samples (25 mgm.) were weighed into tubes containing 2 ml. 0.15 *N* H_2SO_4. After they were sealed, the tubes were placed in a bath at 100°C. At intervals tubes were removed, their contents neutralized with $BaCO_3$ and filtered quantitatively into 10 ml. volumetric flasks which were made to volume. The optical densities at 2850 Å (the characteristic absorption maximum for 5-hydroxymethyl-2-furaldehyde) were determined on suitable dilutions. Since 5-hydroxymethyl-2-furaldehyde undergoes a first order decomposition under the above conditions to formic and levulinic acids (25), the logarithms of the optical densities were plotted against time and the curves extrapolated to zero time (Fig. 1). From these extrapolated values and the molar extinction coefficient (16,500) of 5-hydroxymethyl-2-furaldehyde, the initial amounts of the latter were estimated and recalculated as 3,6-anhydro-D-galactose.

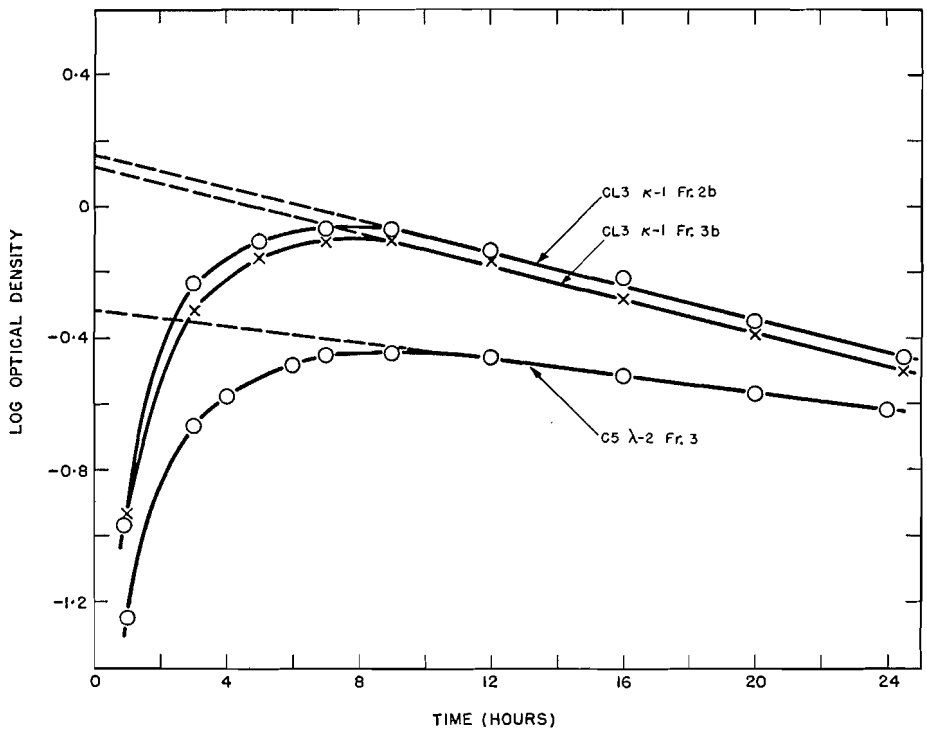

FIG. 1. Course of the formation and disappearance of 5-hydroxymethyl-2-furaldehyde.

Isolation and Identification of L-*Galactose*

Carrageenin (sample C5 (24), 8 gm.) was hydrolyzed in 800 ml. 0.3 N H_2SO_4 for four hours at 100°C. The hydrolyzate was neutralized with $BaCO_3$, decolorized with charcoal, and incubated at 37°C. for four hours with a suspension of *S. cerevisae* cells (strain N.R.C. No. 824) from a 16 hr. culture in D-galactose broth. After the cells were precipitated with charcoal and the solution concentrated, the sirup (1.3 gm.) was chromatographed on a cellulose column using *n*-butanol saturated with water as the developing solvent (11). Those portions of the eluate containing galactose were combined and dried *in vacuo* at 50°C. The residue (0.11 gm.) was extracted with water and the extract was incubated with yeast cells, as above. The product recovered from this second fermentation by extraction into alcohol readily crystallized in the cold. Amount obtained was 0.09 gm., m.p. 162–163°C. Two recrystallizations raised the melting point to 167°C. The X-ray powder diagram was identical with that of D-galactose, but the optical rotation was negative, $[\alpha]_D^{27}$ −96° (15 min.) → −76° (eqm.) (*c* 2.0, water). This product was, therefore, α-L-galactose.

Oxidation with Periodate

Samples (100 mgm.) of carrageenin fractions were dissolved in 25 ml. water (solution was neutral to methyl red) at 16.6°C. and 250 mgm. sodium metaperiodate was added. Formic acid was estimated on aliquots removed from

the reaction mixture at intervals by titration in the presence of potassium iodide with thiosulphate after the addition of excess ethylene glycol. Periodate consumption was measured iodometrically on similar aliquots after the addition of sodium bicarbonate, arsenite, and potassium iodide (8).

RESULTS AND DISCUSSION

Paper chromatograms of hydrolyzates of κ-carrageenin showed only two principal components, identified as galactose and 5-hydroxymethyl-2-furaldehyde. The latter has been shown to be a decomposition product of 3,6-anhydro-D-galactose which can be isolated from κ-carrageenin as the crystalline diethylmercaptal obtained after mercaptolysis of the polysaccharide (17, 18). A trace of xylose could also be detected.

Chromatography of hydrolyzates of λ-carrageenin revealed galactose as the main component, lesser amounts of glucose and xylose, and only a trace of 5-hydroxymethyl-2-furaldehyde. Examination of the fractions of λ-carrageenin indicated that Fraction 3 contained predominantly galactose with a trace of 5-hydroxymethyl-2-furaldehyde, that Fraction 4 contained mostly galactose but also glucose and xylose, and that Fraction 5 also contained these three sugars but that galactose had become a minor constituent. Fraction 5 gave a red color with iodine. These results suggest that xylose and glucose polymers are not integral components of carrageenin but represent small amounts of xylan and floridean starch coextracted by the isolation procedure. From this point of view, the trace of xylose found in κ-carrageenin could also be ascribed to contamination.

A small proportion of the galactose residues in carrageenin was reported by Johnson and Percival (13) to consist of L-galactose. In the present study, however, it became evident that the component containing L-galactose was separable by fractional precipitation from the D-galactose polymers which comprise the bulk of carrageenin. After fermentation with a yeast strain capable of utilizing D-galactose, a reference solution of D-galactose and a hydrolyzate of κ-carrageenin were found to contain no galactose, a hydrolyzate of C5 λ-2 Fraction 3 showed only a trace of galactose, but hydrolyzates of C5 λ-2 Fractions 4 and 5 gave strong tests for galactose. The "tail" fractions of λ-carrageenin thus account for most of the L-galactose. This sugar therefore is not associated with the polysaccharides which make up the greater part of carrageenin.

The validity of these fermentation tests was assessed by the isolation of L-galactose from the nonfermented residue of a large-scale fermentation. Although the yield of L-galactose was low (about 2% of the sugars present in carrageenin), the availability of the starting material and the ease of isolation of the L-galactose make carrageenin a ready source of this rare sugar. May and Weinland (14) have recently isolated L-galactose from snail galactogen by a similar procedure.

After 220 hr. reaction time, there was no detectable consumption of periodate by κ-carrageenin. This result conforms with the formulation of κ-carrageenin as consisting of D-galactose-4-sulphate residues glycosidically linked through

carbon atoms 1 and 3 (2) and with the presence of 3,6-anhydro-D-galactose residues (17, 18). The possibility of branching (1, 4, 13) is not precluded, but the terminal units of such branches must be 3,6-anhydro-D-galactose since end units of D-galactose-4-sulphate would consume periodate at the 2,3-glycol configuration. The lack of effect of periodate on κ-carrageenin is in agreement with the previous finding (23) that after treatment of whole carrageenin with sodium periodate, the κ-fraction could still be precipitated by potassium chloride.

In a parallel experiment, the main fraction of λ-carrageenin (C5 λ-2 Fr. 3) consumed, per mole of sugar residue, 0.30 moles of periodate in 165 hr. and 0.31 moles in 220 hr. At the same reaction times 0.12 and 0.13 moles respectively of formic acid were produced. Since, therefore, one unit in five must have at least one free diol group and one unit in eight, a free triol group, this fraction cannot consist only of a chain of 1,3-linked D-galactose-4-sulphate residues. A model involving branching could account for the periodate consumption with some residues unesterified. It would be necessary that some of the latter be end groups to yield formic acid. Johnson and Percival (13) and Dillon and O'Colla (4) have presented evidence of branching from methylation studies.

The reaction of C5 λ-2 Fraction 3 with periodate raises doubts about the use of this oxidant in the method whereby Dillon and O'Colla (4) "purified" carrageenin. These workers ascribed the consumption of periodate to oxidation of floridean starch and cellulose. Fraction 3 contained neither of these materials.

The results of analyses of some of these carrageenin preparations are given in Table II. Though the sum of the residues found totals only about 90% in

TABLE II

both the κ-carrageenin and the principal fraction of λ-carrageenin, this discrepancy is believed to represent the sum of determination errors since, with the exception of a trace of xylose in the κ-carrageenin preparation, no components other than those listed could be found. The content of 3,6-anhydro-D-galactose is much lower in the principal fraction of λ-carrageenin than in κ-carrageenin while the galactose content is higher. The slightly smaller amount of 3,6-anhydro-D-galactose found in unfractionated κ-carrageenin compared with the mean content of its two major subfractions suggests that the small first fraction may be low in the anhydro sugar. Unfortunately

insufficient amounts of the first fraction were available for analysis. The amount of sulphate nearly parallels the galactose content with molar ratios of galactose to sulphate of about unity with κ-carrageenin and about 0.9 with λ-carrageenin. The sulphate contents recorded in Table II confirm those reported earlier (23).

The results of viscosity and sedimentation rate measurements on carrageenin preparation CL3, its κ-component, and the fractions of the κ-carrageenin are shown in Table III. Also included are molecular weights computed using a random coil model by the Mandelkern–Flory equation and using an ellipsoid model by the Perrin and Simha equations (24).

If the fractionation of the κ-carrageenin had been based solely on size, $[\eta]$, S, and M should have decreased as the mean alcohol concentration required for the precipitation of the fractions increased. However, this simple pattern, adhered to in the subfractionation of C5 λ-2 Fraction 3 (24), was not found in the fractionation of κ-carrageenin. Hence the differences in solubility responsible for the fractionation must reflect (besides size differences) differences in structure, composition, or both. Since the analytical data (Table II) suggest general similarity of composition, it is likely that the solubility differences may be partly explained by structural differences (varying degrees and types of branching).

CONCLUSIONS

Previous physical investigations of carrageenin and carrageenin extracts obtained at different temperatures by viscosity, sedimentation, diffusion, osmotic, and electrophoretic methods (3, 6, 7, 20, 21) have provided evidence that these materials are heterogeneous on a mass basis. Some of this heterogeneity is due to the differences between κ- and λ-carrageenins. However, both of these components, particularly λ-carrageenin (24), have been shown to be polydisperse.

The differences between κ- and λ-carrageenin in response to potassium and similar ions, in sulphate content, optical rotation (23), effect on milk viscosity (22), shape, and size (24), have a chemical basis in the greatly differing D-galactose: 3,6-anhydro-D-galactose ratios. Bayley (1) has used these compositional data in conjunction with measurements of intramolecular spacings from

X-ray diffraction studies to put forward a tentative explanation of the potassium sensitivity of κ-carrageenin.

Probably many of the differences in behavior between carrageenin extracts obtained at different temperatures are due to differing contents of κ- and λ-carrageenins (23). Other factors must include the average size and nature of the mass polydispersity of these components within the extracts, the chemical heterogeneity, and the cation content.

At the present stage in the investigation of the structure of carrageenin, two major and several minor components can be discerned.

1. One of these major components contains D-galactose and 3,6-anhydro-D-galactose residues in a ratio of approximately 1.4 : 1 together with about 25% esterified sulphate. Since fractionation studies have provided evidence of both mass and structural polydispersity, it is not inconceivable that considerable variation in the relative amounts of these residues may be found if the material is fractionated more narrowly. The greater part (perhaps all) of this component is aggregated or gelled by the addition of potassium ions. Though nearly all the material that may be precipitated from dilute (0.1%) aqueous solutions by potassium chloride is precipitated at 0.15 *M*, a small additional amount is precipitated between 0.15 *M* and 0.25 *M* (24). It may be that small quantities of this component are not readily precipitated by potassium ions and would consequently be left in the supernatant after centrifugation. The small amount of 3,6-anhydro-D-galactose found in C5 λ-2 Fraction 3 (Table II) may have arisen in this way.

The extension of the original definition of κ-carrageenin (23, 24) from the material affected by potassium ions to include all of the component consisting of D-galactose, considerable amounts of 3,6-anhydro-D-galactose, and esterified sulphate is proposed.

2. In the second major component of carrageenin, D-galactose together with about 35% esterified sulphate greatly predominates over the small amount of 3,6-anhydro-D-galactose which may be an impurity. It is suggested that the term λ-carrageenin, hitherto (24) referring to all the material not precipitable by potassium, be restricted to this polysaccharide.

3. Minor amounts of various polysaccharides are found in carrageenin preparations and may be regarded as impurities. On hydrolysis, these give rise to glucose (possibly from floridean starch), xylose (possibly from a xylan), and L-galactose.

The similarities between the two principal types (κ- and λ-carrageenins) suggest that intergrading material may exist. However, in those samples of carrageenin so far tested, the sharp fractionation achieved indicates that the amount of such intermediate material must be small.

ACKNOWLEDGMENTS

The authors wish to thank Dr. W. H. Cook for his interest and encouragement. They are also grateful to Dr. W. H. Barnes for an X-ray diffraction diagram, to Miss M. T. Clement for supplying yeast cultures, and to Messrs. J. Giroux, J. Labelle, and D. R. Muirhead for technical assistance.

SOME NEW REACTIONS AND DERIVATIVES OF KOJIC ACID[1]

By Andrew Beélik[2] and C. B. Purves

ABSTRACT

The stability of the ring structure in kojic acid toward various reagents was investigated. Cleavage to an open-chain, dienol derivative in *N* sodium hydroxide at 25°, or fragmentation of the structure, was very slow. The benzoyl group in the fifth (phenolic) position of dibenzoylkojic acid was removed by hydroxylamine hydrochloride in pyridine so selectively that the method was of value in synthesizing certain new derivatives. Although catalytic hydrogenation readily reduced the pyrone ring in kojic acid to undefined substances, zinc dust in glacial acetic acid reduced the hydroxymethyl group in the dibenzoate to a methyl group and yielded benzoylallomaltol. The ring in dibenzoylkojic acid was apparently opened, with retention of both benzoyl groups, by semicarbazide hydrochloride and pyridine to yield two isomeric "disemicarbazones", $C_{22}H_{22}N_6O_7$, decomp., 215° and 172–173°, respectively. The higher-melting isomer when boiled with dilute acid gave a compound $C_{21}H_{15}N_3O_5$, m.p. 244°, which was apparently cyclic; the same isomer with nitrous acid yielded two isomeric, apparently open-chain "monosemicarbazones", $C_{21}H_{19}N_3O_7$, decomp., 215° and 178–179°, respectively. The structures of these five compounds were not determined. The following substances were thought to be new: sodium kojate, a white powder, and its crystalline tetrahydrate; 5-hydroxy-2-(methoxymethyl)-γ-pyrone, m.p. 75–76°, and its crystalline aluminum salt, decomp. 270–271°; molecular addition compound of dibenzoylkojic acid and benzoic acid, m.p. 120–121°; 2-(acetoxymethyl)-5-benzoxy-γ-pyrone, m.p. 144°; 2-(benzoxymethyl)--5-hydroxy-γ-pyrone, m.p. 180–181°; and 2-(benzoxymethyl)-5-methoxy-γ-pyrone, m.p. 110–111°. A more convenient synthesis was discovered for 5-benzoxy-2-(hydroxymethyl)-γ-pyrone, and the published melting point was revised from 136° to 143–144°; the melting point of 5-benzoxy-2-(triphenylmethoxymethyl)-γ-pyrone was revised from 206–208° to 213–214°.

INTRODUCTION

Kojic acid, (5-hydroxy-2-(hydroxymethyl)-γ-pyrone) (I), is a crystalline substance which can be produced in good yield by the action of many molds of the *Aspergillus* family on a wide range of carbohydrates. This biological synthesis has been studied extensively because it is the simplest example of the conversion of a sugar to a γ-pyrone. The possibility of utilizing industrial carbohydrate by-products by converting them to kojic acid has also stimulated interest in the chemical properties of this compound. Barham and Smits

(4) have summarized the earlier literature, and a new review is to appear elsewhere (6).

Practically all the known derivatives of kojic acid were formed by reactions involving the two hydroxyl groups, by nuclear substitutions at position 6, or by the replacement of the ring oxygen atom with the nitrogen of ammonia or amines to give γ-pyridones (6, 11, 12). A few γ-pyrones other than kojic acid, however, were cleaved at the ring oxygen atom by cold dilute aqueous alkalies to yield open-chain derivatives. With the possible exception of Haitinger and Lieben's "xanthochelidonic acid" (10), the dienolic compounds initially produced underwent further changes to more stable ketonic forms (19). Acidification (10), or heating with dilute acid (19), usually regenerated the original γ-pyrone. Willstätter and Pummerer (20) prepared stable derivatives of the dienolic cleavage product of γ-pyrone itself by methylation and benzoylation in the alkaline reaction mixture. The similar open-chain form (I*a*) was assumed as the final intermediate in the biosynthesis of kojic acid (6), but the only experimental evidence for its existence was the fact that kojic acid in warm dilute alkali resembled other α-carbonyl dienol structures in reducing Tillman's reagent (2,6-dichlorophenol-indophenol) (18). When the alkali was more concentrated, or was heated, the pyrone ring was fragmented; thus Yabuta (22, 23), and more recently Arnstein and Bentley (3), found that dimethylkojic acid was degraded to formic acid, methoxyacetic acid, and methoxyacetone by boiling aqueous barium hydroxide. The present research had the object of studying the action of bases on kojic acid under milder conditions, and of isolating open-chain derivatives in an unfragmented state.

One-gram samples of kojic acid were accordingly dissolved in approximately 1.2 *N* sodium hydroxide and the clear yellow solutions were acidified with 20% sulphuric acid after various times. Table I, column 4, records the amount

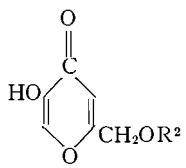
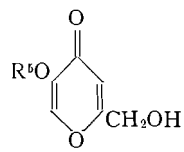
of kojic acid which crystallized when the acidified liquor was kept at −3°; in some experiments the mother liquors were concentrated to recover a second fraction, and in others 60% of the volume was distilled at atmospheric pressure in order to estimate any formic acid produced. Even after 32 hr. in an excess of the alkali, more than 80% of the kojic acid could be recovered as such,

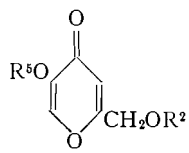
and only a few per cent had been decomposed to formic acid. Kojic acid was therefore either nearly stable in these conditions, or its hypothetical open-chain enolic form (I*a*) recyclized almost quantitatively when the solution was acidified.

In attempts to methylate or benzoylate any enolic compound formed, dimethyl sulphate or benzoyl chloride was added to solutions of kojic acid in aqueous alkali. The methylation was carried out with a molar ratio of 1:6:3.7 for kojic acid, potassium hydroxide, and dimethyl sulphate, respectively, but the only product, obtained in low yield, was a new, crystalline monomethyl ether of kojic acid itself. This ether imparted a deep wine color to ferric chloride solution and therefore contained a free phenolic hydroxyl group; methylation with diazomethane gave the known 5-methoxy-2-(methoxymethyl)-γ-pyrone. Hence the new monomethyl ether was 5-hydroxy-2-(methoxymethyl)-γ-pyrone (IV). In the process of purification, IV reacted with the alumina in a chromatograph column to give a pale yellow, crystalline derivative in which three moles were substituted by one atom of aluminum; that is, the derivative had the composition of the aluminum phenoxide. The isomeric monomethyl ether, 2-(hydroxymethyl)-5-methoxy-γ-pyrone (VIII), was obtained in a crude yield of 72% by Campbell and his co-workers (8) from kojic acid, potassium hydroxide, and dimethyl sulphate in a 1:1:1 molar ratio. Heyns and Vogelsang (11) prepared the dimethyl ether from the same reagents, using a molar ratio of 1:8:9.

Two methods were used for the benzoylations, differing mainly in the excess of sodium hydroxide present throughout the reaction. When this excess was considerable, the products were the known, crystalline dibenzoylkojic acid (5-benzoxy-2-(benzoxymethyl)-γ-pyrone) (22, 23) and a new, crystalline addition compound, m.p. 120–121°, between equimolecular amounts of this dibenzoate and benzoic acid. The infrared spectrum of a benzene solution of the adduct was identical with that given by an equimolecular mixture of its compon-







IV R^2 = methyl
V R^2 = benzoyl
VI R^2 = acetyl
VII R^2 = trityl

VIII R^5 = methyl
IX R^5 = benzoyl
X R^5 = sodium

XI R^2 = trityl; R^5 = benzoyl
XII R^2 = benzoyl; R^5 = methyl
XIII R^2 = acetyl; R^5 = benzoyl

ents, a Perkin-Elmer Model 21 spectrophotometer fitted with a rock salt prism being used for the determination. This addition compound could be recrystallized without change from hydrocarbon solvents, but dissociated into its constituents when dissolved in polar liquids. When the excess of alkali used in the benzoylation was small, the product consisted of the above adduct, together with a monobenzoyl derivative of kojic acid which melted at 142–143°. This melting point was 7° higher than a value reported by Yabuta for a mono-

benzoate prepared from kojic acid and benzoyl chloride in ether (22, 23), or from 5-benzoxy-2-(triphenylmethoxymethyl)-γ-pyrone (XI) by detritylation (25). The latter unequivocal synthesis was repeated, the proper melting point of the resulting 5-benzoxy-2-(hydroxymethyl)-γ-pyrone (IX) was found to be 142–143°, and identity with the monobenzoate under discussion was proved.

Other attempts to isolate a derivative of I*a* involved the complete evaporation of aqueous solutions of kojic acid containing one or two molecular equivalents of sodium hydroxide. The product was the new sodium kojate, which occurred either as a crystalline tetrahydrate or in the anhydrous condition. This "salt" was presumably the 5-sodio derivative (X). The tetrahydrate reacted with benzoyl chloride in dry benzene to give the 5-monobenzoate (IX); the yield of the latter rose to 79.5% when anhydrous sodium kojate was used. These observations, together with the results of the methylations and benzoylations, seemed to indicate the absence of an open-chain form like I*a* from solutions of kojic acid in dilute aqueous alkali.

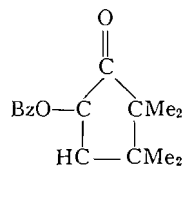
As was expected from the inert nature of the carbonyl group, no derivatives could be isolated when kojic acid was treated with hydroxylamine hydrochloride or with semicarbazide hydrochloride. The customary procedures for oximation, however, produced from dibenzoylkojic acid in up to 90% yield a crystalline substance which proved to be a new monobenzoate and not an oxime. Benzoylation in dry pyridine gave back the dibenzoate, and the presence of a free phenolic function in the monobenzoate was indicated by the wine color it produced with ferric chloride. Methylation with diazomethane yielded another new crystalline substance which was identified as 2-(benzoxymethyl)-5-methoxy-γ-pyrone (XII) by a synthesis from VIII and benzoyl chloride. The monobenzoate was therefore the 2-derivative (V).

The selective deacylation displayed by hydroxylamine in the above reaction was also illustrated by the smooth debenzoylation of the 5-benzoxy derivatives of 2-acetoxymethyl- (XIII) and 2-(triphenylmethoxymethyl)-γ-pyrone (XI), and of benzoylallomaltol to the corresponding 5-hydroxy derivatives (VI, VII, and II). The method should thus be useful for preparing derivatives of kojic acid monosubstituted in the generally less reactive 2-position, especially when a substituent such as acetyl or trityl offers but little resistance to conventional methods of hydrolysis. Although the cleavage of esters by hydroxylamine in the presence of a strong base is frequently used for the preparation of substituted hydroxamic acids (26), the method has not hitherto been employed for selective deacylations. Ingold and Shoppee (15), however, incidentally observed that their oximation of 2-benzoxy-4,4,5,5-tetramethyl-2-cyclopenten-1-one (XIV) was accompanied by debenzoylation, although the benzoyl group in the analogous saturated ketone was unaffected under identical conditions. The results support the view that enolic and phenolic ester groups adjacent to a carbonyl group are cleaved with particular ease by hydroxylamine. It therefore seems probable that the same method might prove useful in other compounds containing the same grouping; for example, in the selective deacylation of flavonols at position 3.

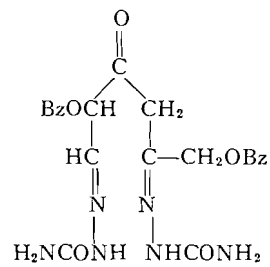
Another selective debenzoylation, this time involving the group in the

second instead of the fifth position of dibenzoylkojic acid, was brought about by reduction with zinc dust in glacial acetic acid. The products included nearly one mole of benzoic acid and a crystalline substance which was proved to be the benzoate of allomaltol (II) (5-benzoxy-2-methyl-γ-pyrone). This proof consisted of repeating Yabuta's reduction (24) of 2-(chloromethyl)-5-hydroxy-γ-pyrone (III) to the 2-methyl derivative (II) and benzoylating the latter. The primary alcohol unit in dibenzoylkojic acid thus resembled that in benzyl ethers in its tendency to undergo reductive fission. In accord with this inference, the dibenzoate yielded 0.6 mole of benzoic acid when hydrogenated at room temperature and atmospheric pressure over a platinum catalyst. This hydrogenation probably involved hydrogenolysis, since hydrolysis was not likely in the glacial acetic acid used as a solvent. The other product of the hydrogenation was a sirup which was not studied in detail because numerous earlier catalytic hydrogenations of kojic acid, its ethers and esters, gave sirups of indefinite composition (6). Ingold and Shoppee (15) observed that the enolic benzoyl group in (XIV) was unaffected by zinc or sodium amalgam in glacial acetic acid, while the double bond was readily reduced (with retention of the benzoyl group) by hydrogenation.

Dibenzoylkojic acid failed to form a benzoylhydrazone and a 2,4-dinitrophenylhydrazone, but condensation occurred with semicarbazide hydrochloride in boiling ethanol–pyridine. The product consisted of two white, neutral, microcrystalline isomers, but the one with the lower melting point was formed in too small yield to be examined in detail. The molecular formula of these isomers, $C_{22}H_{22}N_6O_7$, corresponded to disemicarbazones of an open-chain form of dibenzoylkojic acid, and structures such as XV were tentatively assigned to them. The higher-melting isomer was readily saponified by cold dilute alkali,



XIV



XV

but the only product identified was benzoic acid in nearly quantitative yield. These structures were unusual, for the initial open-chain products from other γ-pyrones and hydrazines invariably lost one additional molecule of water to give cyclic end products. Bedekar and co-workers (5) represented these end products as pyridones, but Ainsworth and Jones (1) recently found very good evidence in favor of pyrazole structures. No carboxylic acid derived from a pyridone or pyrazole, however, could be recovered when the higher-melting isomer was oxidized with potassium permanganate, only benzoic and benzoyl-

glycolic acids being identified. When the same isomer was boiled in 10% hydrochloric acid, the yellow-white, microcrystalline substance which formed in small yield had the molecular formula $C_{21}H_{15}N_3O_5$, which corresponded to the loss of one semicarbazide unit and two molecules of water. Cyclization probably occurred in this case, but the point could not be definitely proved owing to lack of material.

The higher-melting "disemicarbazone" lost one semicarbazide group on treatment with nitrous acid (9, 21), and two neutral, microcrystalline "monosemicarbazones" resulted. The lower-melting, or "β", form was the main product (69%), and the "α-isomer" was isolated only when a larger quantity of nitrous acid was employed. Since an excess of nitrous acid did not convert the β- to the "α-monosemicarbazone" the two were perhaps position isomers. To judge from the composition of these two products, $C_{21}H_{19}N_3O_7$, both were open-chain derivatives and no cyclization occurred during the treatment with nitrous acid. No carboxylic acids other than benzoic and benzoylglycolic could be isolated when the β-isomer was oxidized with aqueous potassium permanganate. An attempt to regenerate the "disemicarbazone" from the "β-monosemicarbazone" by treating the latter with semicarbazide hydrochloride and pyridine in boiling methanol failed, the starting material being recovered unchanged. Hydroxylamine hydrochloride likewise had no effect. These results were surprising, because the presence of a carbonyl group created by the fission of a semicarbazone unit could reasonably have been assumed (21); the negative outcome with hydroxylamine also suggested that neither of the two benzoyl groups was of the phenolic type present in dibenzoylkojic acid. At this point, attempts to elucidate the structures of the "monosemicarbazones" had to be abandoned.

The failure of *N* sodium hydroxide to open the ring of kojic acid stood in sharp contrast to the apparent cleavage of the ring in the dibenzoate by semicarbazide, a much weaker base. Cleavage of γ-pyrone rings was presumably initiated by a nucleophilic reagent at position 6, where the drift of electrons toward the carbonyl group would create an electrophilic center. This might happen in the case of dibenzoylkojic acid, as indicated in I, when semicarbazide was the attacking nucleophile (14). In sodium hydroxide, kojic acid would be present as the kojate anion (I*b*), and an important contribution to the resonance hybrid of this anion could be expected from the diketo form (I*c*) with the full negative charge located at position 6. This nucleophilic center would face the nucleophilic hydroxyl ion, and no cleavage would result. If this explanation was correct, the production of open-chain forms of kojic acid by basic cleavage required either the use of very weak bases or the blocking of the hydroxyl group in position 5 by a substituent stable to alkali.

EXPERIMENTAL

All melting points were corrected. All of the nitrogen analyses, and two carbon and hydrogen analyses marked by an asterisk, were by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A. Reactants were always weighed to the nearest 10 mgm.

5-Hydroxy-2-methoxymethyl-γ-pyrone (IV) and Its Aluminum "Salt"

Dimethyl sulphate, 47 gm. (0.373 mole), was slowly added over a period of three hours and at room temperature to a stirred solution of 15 gm. (0.106 mole) of kojic acid and 37.5 gm. (0.6 mole) of potassium hydroxide in 315 ml. of water. The mixture slowly warmed to 37°, but was then kept below 30°. The alkaline liquor, having been concentrated at 50° *in vacuo* to 250 ml., was extracted continuously with benzene to remove any dimethylkojic acid, but the yellow extract yielded only traces of an oil. The aqueous liquor was then acidified to pH 2 with 50% sulphuric acid and was re-extracted continuously with benzene for 21 hr. This dark red extract was treated with activated carbon, concentrated to small volume, and diluted with ligroin. The red oil which separated solidified on chilling to a yellow-brown substance, 6.85 gm. melting between 55° and 66°. Crystallization from ethyl acetate left 1.85 gm. (11.2%), m.p. 75–76°, unchanged by recrystallization from toluene–hexane. Found: C, 53.7, 53.8; H, 5.3, 5.2; OCH_3, 20.4, 20.4%. Calc. for $C_6H_5O_3(OCH_3)$: C, 53.9; H, 5.1; OCH_3, 19.9%.

The combined mother liquors from the above crystallizations were evaporated, and a concentrated solution of the residue in benzene was applied to a short column of alumina. Elution with benzene, evaporation of the eluates, and recrystallization of the orange products from ethanol gave 0.71 gm. (4%) of pale yellow crystals melting with decomposition at 270–271°. A qualitative test demonstrated the presence of aluminum. Found: Ash, 10.4; Al, 5.5; OCH_3, 18.6%. Calc. for Al $[C_6H_4O_3(OCH_3)]_3$: Ash, 10.4; Al, 5.5; OCH_3, 18.9%.

A solution of 0.15 gm. of these crystals in water was adjusted to pH 2 with dilute sulphuric acid and evaporated cautiously to a sirup. Extraction of this sirup with toluene yielded 0.09 gm. (63%) of 5-hydroxy-2-(methoxymethyl)-γ-pyrone with the proper melting point, undepressed by admixture with an authentic sample.

A 0.5 gm. sample of the monomethyl ether was kept dissolved in 20 ml. of dry benzene containing about 0.56 gm. of diazomethane (2) for 12 hr. at room temperature. Evaporation of this solution, and crystallization of the yellow residue from benzene–hexane, yielded 0.33 gm. (60.5%) of white needles melting at 89–90°, undepressed by admixture with an authentic sample of dimethylkojic acid (11).

Sodium Kojate and Its Crystalline Tetrahydrate

A solution of 3.0 gm. (21 mM.) of kojic acid and 0.88 gm. (21 mM.) of sodium hydroxide in 15 ml. of water was evaporated to dryness *in vacuo* at 40°. The residual solid was recrystallized twice from 5 ml. of hot water, and the white crystals were dried in air at 25°. Yield, 2.62 gm. or 53%. Found: Na, 10.3; loss of weight at 110°, 30.3, 30.2; at 25° over phosphorus pentoxide, 29.7%. Calc. for $C_6H_5O_4Na.4H_2O$: Na, 9.8; water, 30.5%.

The water of crystallization was determined by drying samples either for about six hours at 110° or for about 18 hr. *in vacuo* over phosphorus pentoxide at 25°. Anhydrous sodium kojate was a white powder when prepared by the latter method, and a tan powder by the former.

A New Synthesis of 5-Benzoxy-2-(hydroxymethyl)-γ-pyrone

Crude sodium kojate was prepared from 2 gm. (14 mM.) of kojic acid as just described, and was rendered anhydrous by drying *in vacuo* over phosphorus pentoxide. The product was shaken in the original tightly-stoppered flask with 50 ml. of dry benzene and 2.5 gm. (18 mM.) of benzoyl chloride at room temperature for 26 hr. It was necessary to interrupt the shaking to loosen solid material which adhered initially to the walls of the flask. After adding 30 ml. of benzene, the white suspension was heated to boiling and was filtered while hot. The residual solid was re-extracted with hot benzene, then with water, and again with benzene. The combined benzene solutions, when dried and evaporated, deposited 2.53 gm. of white needles melting at 143–144°, together with a second fraction which was recrystallized from aqueous acetone to give 0.22 gm. with the proper melting point. Total yield, 79.5%. A mixed melting point with authentic 5-benzoxy-2-(hydroxymethyl)-γ-pyrone (see below) was not depressed.

The authentic sample was prepared from 5-benzoxy-2-(triphenylmethoxymethyl)-γ-pyrone, (XI), which when recrystallized from aqueous dioxane melted at 213–214°, and not at 206–208° as recorded by Yabuta and Anno (25). The removal of the trityl group with boiling 80% acetic acid, followed by the separation of triphenylcarbinol, left a product which was crystallized from benzene. Yield, 55%, and melting point 140–141°. Further recrystallizations from benzene raised the melting point to 142–143°, the value quoted by Yabuta being 135–136°.

Dibenzoylkojic Acid – Benzoic Acid Addition Compound

(*a*) *Benzoylation in Sodium Hydroxide*

A solution of 5 gm. (35 mM.) of kojic acid and 7.3 gm. (177 mM.) of sodium hydroxide was prepared in 177 ml. of water. Benzoyl chloride, 19.7 gm. (140 mM.), was added slowly, with stirring and at room temperature, during two and three-quarter hours, and the granular solid which separated was recovered. A solution of 5.8 gm. (140 mM.) of sodium hydroxide in 50 ml. of water was added to the acidic filtrate, and the benzoylation was repeated with another 140 mM. of benzoyl chloride. After one hour more of stirring, a second crop of the solid was recovered from the liquor, which again had become acid. The two crops when combined and crystallized from dry benzene–hexane yielded 1.55 gm. (18%) of a less soluble fraction which consisted of white crystals with the composition and melting point, 142–143°, of 2-(hydroxymethyl)-5-benzoxy-γ-pyrone (IX). A mixed melting point with an authentic sample was not depressed.

The more soluble fraction was composed of 5.88 gm. (35.5%) of matted white needles melting at 117–118°, raised by further recrystallizations to m.p. 120–121°. Mixtures of this molecular addition compound with dibenzoylkojic acid and with benzoic acid showed depressions in melting point. Found: C, 68.8, 69.0; H, 4.4, 4.4%. Calc. for $C_{20}H_{14}O_6.C_7H_6O_2$: C, 68.6; H, 4.2%.

A solution of 0.50 gm. of the addition compound in 5 ml. of warm acetone was diluted with an equal volume of cold water; the mixture was cooled and the

white precipitate which had immediately formed was recovered. The precipitate melted correctly for dibenzoylkojic acid at 134–135°, a mixed melting point with an authentic sample was not depressed, and the yield of 0.37 gm. was 100% of theory. The clear filtrate when concentrated to half-volume deposited 0.12 gm. (92.5%) of benzoic acid melting at 117–119°, raised to the proper value of 122° by recrystallization from water. A mixed melting point was not depressed. Dibenzoylkojic acid also crystallized from solutions of the adduct in dioxane (on dilution with water), 95% ethanol, ethyl acetate, absolute methanol, and pyridine. The benzoic acid was extracted selectively by aqueous 5% sodium carbonate from a solution of the adduct in benzene. On the other hand, the adduct could be recrystallized substantially without change from benzene, benzene–hexane, toluene, and glacial acetic acid.

(*b*) *Benzoylation in Pyridine*

Five grams (36 mM.) of benzoyl chloride was added in several increments to a solution of 2 gm. (14 mM.) of kojic acid in dry pyridine. Next day the pyridine was evaporated in a current of dry air, with gentle heating, to leave a moist pulp. The product in this pulp was separated from the pyridine salts by extraction with hot benzene, and was recovered from the extract in several fractions. The less soluble fractions yielded 3.45 gm. (70%) of pure dibenzoylkojic acid, which was carefully identified as such. Recrystallization of the more soluble fractions from benzene–ligroin gave 0.66 gm. (10%) of white matted needles whose melting point of 120–121° was not depressed by admixture with the dibenzoylkojic acid – benzoic acid addition compound.

The product from a similar benzoylation was isolated in the customary way by pouring the mixture into chilled 5% aqueous sulphuric acid. A 98.5% yield of pure dibenzoylkojic acid was obtained.

2-(Benzoxymethyl)-5-hydroxy-γ-pyrone (*V*)

A solution of 0.30 gm. (0.86 mM.) of dibenzoylkojic acid and 0.12 gm. (1.7 mM.) of hydroxylamine hydrochloride in 4 ml. of pyridine was kept for 12 hr. at room temperature, then diluted with 20 ml. of cold water. After the suspension had been kept cold for a few hours, the white precipitate was recovered. Yield, 0.19 gm. (90%); m.p. 179–180°, increased to 180–181° by recrystallization from ethanol. Found: C, 63.5, 63.6; H, 4.1, 4.2; COC_6H_5, 41.7, 41.0%. Calc. for $C_6H_5O_4(COC_6H_5)$: C, 63.4; H, 4.1; COC_6H_5, 42.7%.

The same product was obtained in 83% yield by boiling dibenzoylkojic acid with three equivalents each of hydroxylamine hydrochloride and pyridine in 95% ethanol for 30 min.; also by replacing the pyridine with sodium acetate and using 80% ethanol. In the latter case the pure product crystallized in 74% yield when the solution cooled. Three equivalents of either sodium acetate or hydroxylamine hydrochloride alone had no appreciable effect on dibenzoylkojic acid in boiling ethanol.

A 15% excess of benzoyl chloride was slowly added to an ice-cold solution of the above monobenzoate in dry pyridine. An 89% yield of dibenzoylkojic acid was recovered, melting at 135°, after crystallization from aqueous acetone. A mixed melting point was undepressed.

2-(Benzoxymethyl)-5-methoxy-γ-pyrone (XII)

One gram (4.1 mM.) of finely powdered 2-(benzoxymethyl)-5-hydroxy-γ-pyrone was added to 18 ml. of benzene containing about 0.5 gm. of diazomethane (2). Practically all of the solid dissolved within six hours, and the product was isolated by concentrating and cooling the solution. The yield was 0.52 gm. (49%) of near-white crystals melting at 109–110°; the use of absorbent charcoal in ethanol, and recrystallization from benzene–ligroin, gave a snow-white product melting at 110–111°. Found: C, 64.7, 64.9; H, 4.6, 4.8; OCH_3, 12.0, 12.1%. Calc. for $C_{13}H_9O_4(OCH_3)$: C, 64.6; H, 4.6; OCH_3, 11.9%.

The same product was obtained when 2-(hydroxymethyl)-5-methoxy-γ-pyrone (VIII), prepared according to Campbell and co-workers (8), was esterified with benzoyl chloride in dry pyridine. A mixture of the two samples showed no depression in melting point.

2-(Acetoxymethyl)-5-benzoxy-γ-pyrone (XIII)

A solution of 2.8 gm. (11 mM.) of 5-benzoxy-2-(hydroxymethyl)-γ-pyrone (IX) in 24 ml. of dry pyridine was chilled, mixed with 4.1 gm. (40 mM.) of acetic anhydride, and kept overnight at room temperature. Precipitation of the solution into 200 ml. of cold water yielded 3.06 gm. (93%) of crystals melting at 143–144°. Recrystallizations from benzene and from aqueous acetone left the melting point of the white plates at 144°, and a mixed melting point with the starting material was depressed to 120–127°. Found: C, 62.8, 62.5; H, 4.3, 4.5%. Calc. for $C_{15}H_{12}O_6$: C, 62.5; H, 4.2%.

A solution of 0.96 gm. (3.3 mM.) of XIII and 0.46 gm. (6.6 mM.) of hydroxylamine hydrochloride in 13 ml. of pyridine was kept at room temperature for 12 hr. before being diluted with six volumes of cold water. After being extracted with benzene, the aqueous liquor was evaporated to dryness *in vacuo* at 50° and the solid, yellow residue was extracted with boiling benzene. The combined benzene extracts yielded a total of 0.47 gm. (77%) of white needles melting at 134–135°, plus a second fraction (6%) of slightly less pure material. 2-(Acetoxymethyl)-5-hydroxy-γ-pyrone (VI), whose published melting point was 133.5° (12) and 137° (17), gave a wine color with aqueous ferric chloride. When acetylated in the presence of sodium acetate (13), the substance yielded 5-acetoxy-2-(acetoxymethyl)-γ-pyrone which was carefully identified by comparison with an authentic sample.

Debenzoylation of 5-Benzoyl-2-(triphenylmethoxymethyl)-γ-pyrone (XI)

The debenzoylation was accomplished as just described, except that an 8.4 molar equivalent of hydroxylamine hydrochloride was used. After recrystallizations from benzene–ligroin, dioxane–water, and carbon tetrachloride – isopropyl ether, 66% of pure 5-hydroxy-2-(triphenylmethoxymethyl)-γ-pyrone (VII) remained, melting at 180–182° (25).

Benzoylallomaltol from Dibenzoylkojic Acid

Thirty grams of technical grade zinc dust was added to a hot solution of 5 gm. (14.3 mM.) of dibenzoylkojic acid in 125 ml. of glacial acetic acid; the mixture was vigorously stirred on the steam bath, and eight drops of concen-

trated sulphuric acid were added during five minutes. Stirring was stopped after one hour, the hot mixture filtered, the residual zinc rinsed with hot glacial acetic acid, and the combined liquors were evaporated completely *in vacuo*. The residual brown oil was treated with an excess of solid sodium carbonate, the resulting mixture was extracted with boiling benzene, and the benzene extract was washed with dilute aqueous sodium carbonate and with water. Pure benzoic acid, 1.31 gm. (75%), was recovered from the benzene-insoluble solid residue and the sodium carbonate washings. The golden brown benzene solution was completely evaporated and the residual tan solid was recrystallized twice from isopropyl ether, using a small amount of decolorizing charcoal. The yield was 1.48 gm. (45%) of benzoylallomaltol as off-white, flat needles melting at 125–126°. An analytical sample, recrystallized from the same solvent, melted at 126–127°, undepressed when mixed with an authentic sample (24). Found: C, 67.9*, 67.8; H, 4.8*, 4.8%. Calc. for $C_{13}H_{10}O_4$: C, 67.8; H, 4.4%.

A solution of 2.4 gm. (10 mM.) of benzoylallomaltol and 0.95 gm. (14 mM.) of hydroxylamine hydrochloride in 25 ml. of pyridine was kept at room temperature for 11 hr., and was then evaporated *in vacuo*. After being dried over solid potassium hydroxide in a vacuum desiccator, the residual brown oil was extracted several times with boiling benzene. The combined benzene extracts yielded a total of 1.05 gm. of crude allomaltol as white crystals melting at 143–149°; recrystallization from a mixture of isopropyl ether and ethyl acetate left 0.93 gm. (71%) melting at 150–151°. This substance was soluble in water and gave a wine color with ferric chloride. Benzoylation with benzoyl chloride in dry pyridine gave back benzoylallomaltol. An authentic sample of allomaltol prepared by Yabuta's method (24) also melted at 150–151°, not at 166° as reported, and a mixed melting point was undepressed. The present value confirmed that recently given by Looker and Okamoto (16).

Dibenzoylkojic Acid "Disemicarbazone"

(*a*) A mixture of 14 gm. (40 mM.) of dibenzoylkojic acid, 14 gm. (125 mM.) of semicarbazide hydrochloride, 14 ml. (174 mM.) of pyridine, 40 ml. of water, and 350 ml. of ethanol was boiled under reflux for 50 min. and then kept at room temperature for six days. The crop of yellow-white crystals deposited from the clear solution was extracted in succession with hot ethyl acetate, water, and dioxane, and the residual microcrystalline white solid, 6.04 gm., melted at 212° with decomposition. A second crop, recovered from the original mother liquor 15 days later, increased the yield to 7.96 gm. or to 41.5%. This "disemicarbazone" was sparingly soluble in glacial acetic acid but insoluble in all other liquids tried. The sample for analysis was dissolved in much glacial acetic acid by warming to not more than 70° and was reprecipitated by adding five volumes of cold water. The melting point was then 215° with decomposition. Found: C, 54.8, 54.8; H, 4.7, 4.8; N, 16.9%. Calc. for $C_{22}H_{22}N_6O_7$: C, 54.8; H, 4.6; N, 17.4%.

(*b*) The above condensation was repeated with 5 gm. of dibenzoylkojic acid, 3.2 gm. of semicarbazide hydrochloride, 5 ml. of pyridine, 10 ml. of water, and

60 ml. of ethanol, the molar ratio of the first three substances being about 1:2:4 instead of about 1:3:4. The yellow solution deposited a yellow-white solid decomposing at 179–181° when concentrated on the steam-bath, and a soft solid separated when the mother liquor was diluted with water and chilled. Extraction of the latter fraction with boiling ethyl acetate removed 0.33 gm. of a solid, m.p. 183–184°, which was combined with the previous fraction of similar melting point. These fractions were purified by extraction with hot ethyl acetate and water to yield 1.65 gm. (24%) of the "disemicarbazone" noted in (*a*) and melting at 213°.

On cooling overnight, the red ethyl acetate extract deposited 0.61 gm. of white crystals melting at 121° with decomposition. Recrystallizations from ethyl acetate and from ethanol–methanol left 0.4 gm. (6%) of this isomeric "disemicarbazone" and raised the melting point to 172–172.5° with decomposition. Found: C, 54.6, 54.5; H, 5.0, 4.9; N, 16.6%. Calc. for $C_{22}H_{22}N_6O_7$: C, 54.8; H, 4.6; N, 17.4%.

Experiments with the Higher Melting "Disemicarbazone"

(*a*) *Action of Dilute Alkali*

Two grams of the above "disemicarbazone" dissolved almost completely when stirred at room temperature for 30 min. with 20 ml. of 10% potassium hydroxide. The clear filtrate contained no substances that could be extracted by ether or chloroform. When acidified with hydrochloric acid, the filtrate deposited 0.95 gm. (95%) of benzoic acid with the correct melting point and mixed melting point.

(*b*) *Action of Dilute Acid*

A suspension of 1.5 gm. of the "disemicarbazone" in 25 ml. of 10% hydrochloric acid was boiled under reflux for three and one-half hours. The sticky brown residue was separated from the acidic filtrate (which yielded 0.31 gm., or 41%, of benzoic acid) and was crystallized from methanol–ethanol–benzene, from dioxane–water, and from acetone. The pure product, 0.11 gm. or 9%, was a white, microcrystalline solid melting at 244°. Found: C, 64.3, 64.5; H, 4.1, 4.2; N, 10.8%; mol. wt. (Rast), 423. Calc. for $C_{21}H_{15}N_3O_5$: C, 64.8; H, 3.9; N, 10.8%; mol. wt. 389.

(*c*) *Oxidation with Potassium Permanganate*

A mixture of 5.61 gm. (11.6 mM.) of the "disemicarbazone", 10 gm. (63 mM.) of potassium permanganate, 4 ml. (70 mM.) of glacial acetic acid, and 370 ml. of water was kept at 90° for 30 min. After removing the manganese dioxide, the weakly acid filtrate was concentrated to 250 ml. *in vacuo*, was adjusted to pH 2, and was continuously extracted with benzene. The residue from the extract, when fractionally crystallized from benzene–hexane, yielded 0.38 gm. (27%) of pure benzoic acid, and 0.24 gm. (11.5%) of benzoylglycolic acid melting correctly (7) at 111–112°. Found for the latter: C, 60.0; H, 4.8%*; neut. equiv., 179.7. Calc. for $C_9H_8O_4$: C, 60.0; H, 4.4%; neut. equiv., 180.

Dibenzoylkojic Acid "α-Monosemicarbazone"

A suspension of 3.05 gm. (6.33 mM.) of the "disemicarbazone" in 70 ml.

of glacial acetic acid was stirred at room temperature, while a concentrated aqueous solution of 10.8 gm. (157 mM.) of sodium nitrite was added very slowly during six hours. Stirring was discontinued one hour later, and next day the yellow-green solution was filtered from 0.3 gm. of the starting material. Dilution of the filtrate with an equal volume of cold water precipitated 2.03 gm. of a white solid melting at 173–174°. This solid contained several components, but only one could be isolated in a pure form by recrystallizing the mixture from benzene–methanol (1 vol. : 4 vol.). The product, 0.24 gm. (9%), was a white microcrystalline powder melting with decomposition at 212–213°, increased to 215° by recrystallizations from acetone–methanol. A mixed melting point determination with the original "disemicarbazone" (m.p. also 215°) was markedly depressed. Found: C, 59.6, 59.0; H, 4.7, 4.6; N, 10.1%. Calc. for $C_{21}H_{19}N_3O_7$: C, 59.3; H, 4.5; N, 9.9%.

Dibenzoylkojic Acid "β-Monosemicarbazone"

The preparation for the α-isomer was repeated with 7.2 gm. (104 mM.) of sodium nitrite instead of 10.8 gm., and with 60 ml. instead of 70 ml. of glacial acetic acid. The filtered liquor on dilution with 240 ml. of cold water deposited 2.41 gm. of a white solid decomposing at 166–170°. This product was extracted with 120 ml. of boiling methanol to remove a small amount of unchanged "disemicarbazone". The filtered extract, when diluted with 500 ml. of water, deposited 1.82 gm. (69%) of a white, microcrystalline solid whose decomposition point at 178–179° was not altered by recrystallization from benzene–methanol–ligroin. Found: C, 59.3, 59.2; H, 5.1, 4.9; N, 9.8%. Calc. for $C_{21}H_{19}N_3O_7$: C, 59.3; H, 4.5; N, 9.9%. A sample was recovered unchanged after its suspension in glacial acetic acid had been treated with an excess of aqueous sodium nitrite at room temperature.

Another sample, 0.60 gm. (1.4 mM.), was heated on the steam bath with 1.1 gm. (7 mM.) of potassium permanganate and 40 ml. of water for one and three-quarter hours. The reaction mixture, when worked up as already described for the oxidation of the "disemicarbazone", yielded 0.05 gm. (19.5%) of benzoylglycolic acid melting at 106–110°. Recrystallization raised the melting point to 111–112°, undepressed by admixture with the previous sample. The other product of the oxidation was benzoic acid, which was recrystallized until pure.

ACKNOWLEDGMENTS

One of us (A. B.) wishes to thank the National Research Council of Canada for a Studentship, and the Pulp and Paper Research Institute of Canada for a summer stipend. We acknowledge gratefully the determination of the infrared spectra of the dibenzoylkojic acid – benzoic acid adduct by Mr. A. W. Pross of Canadian Industries (1954) Limited, McMasterville, Que.; also a generous gift of kojic acid from the Corn Products Refining Company, Argo, Ill.

LONDON – VAN DER WAALS ATTRACTIVE FORCES BETWEEN GLASS SURFACES[1]

BY P. G. HOWE,[2,3] D. P. BENTON,[2] AND I. E. PUDDINGTON

ABSTRACT

The attractive force between a pyrex glass bead and plate has been measured using a sensitive pendulum-type apparatus. The force required for separation of the bead from the plate has been shown to be strongly time dependent, a phenomenon which appears not to have been reported previously for adhesions in gaseous media. The observed results have been shown to be consistent with the theoretical London – van der Waals interaction. The estimated value of the London force constant is compared with that obtained by other workers.

INTRODUCTION

Many workers have shown the existence of attractive forces between solid surfaces. Tomlinson (11) demonstrated the adhesion between quartz fibers and between equal glass spheres. Bradley (1) confirmed this adhesion between quartz spheres and improved the method to measure the adhesion between sodium pyroborate spheres and quartz spheres of unequal size. He also established experimentally the theoretical dependence of adhesion on the ratio of the bead diameters. McFarlane and Tabor (9) attempted to measure the interaction between a suspended glass bead and a glass plate by means of a pendulum-type apparatus. With this apparatus adhesions as low as 10^{-6} *g* could theoretically be measured but in clean dry air no adhesion was observed. Courtney-Pratt (3) found considerable adhesion when freshly cleaved mica sheets were placed in contact. Spaarnay and Overbeek (10) found the existence of long range attractive forces between highly polished parallel glass plates and that the calculated force constant was of the expected magnitude. Derjaguin (4) has also shown the existence of adhesion between various glasses but disagrees with the magnitude of those obtained by Spaarnay and Overbeek. In this paper the existence of time-dependent attractive forces between glass surfaces has been demonstrated. These have been attributed to London – van der Waals attractive forces and have been shown to be consistent with theoretical considerations.

EXPERIMENTAL

Measurements have been made of the adhesion between pyrex glass surfaces using various pendulum-type apparatuses, both *in vacuo* and in small pressures of nitrogen. In the main these apparatuses have consisted of a glass bead, about 1 mm. diameter, formed on the end of a very fine pyrex fiber which was suspended by sealing into a 25 mm. pyrex tube. Contact surfaces were variously a flame-polished glass plate, a convex surface drawn in from the wall of the container tube and approximately equivalent to a sphere of radius 25 mm., or the concave inner wall of the glass tube itself, preheated to the melting point of the glass. Both bead and contact surfaces were formed just prior to assembly and evacuation of the apparatus. The apparatus was then degassed at about 350°C. and mounted on an electrically driven slow-motion rotor arm. When not continuously attached to the vacuum line, the apparatus was sealed off or closed with a vacuum stopcock. Some tubes were coated externally with electrically conducting silver paint and effectively earthed.

The measurement of adhesion was carried out as follows. The bead was allowed to make contact with the plate for a certain time and then the deflection, α, of the bead suspension from the vertical at the break point was measured. As the fiber suspensions used were practically weightless compared with the weight of the bead, calculation of the adhesion was made assuming a rigid pivoted assembly, using the equation

$$F = mg.\sin\alpha \qquad [1]$$

where m is the weight of the bead.

The results obtained show that adhesion exists but that the interaction is strongly time dependent. Very large instantaneous adhesions were found with the freshly degassed apparatus. The time of contact required for maximum adhesion increased, while the maximum adhesion itself fell, as the initial hard vacuum decayed in the closed system to *ca.* 10^{-3} mm. The adhesion then fell off more slowly over a period of days until some reproducible lower maximum was obtained.

Fig. 1 shows the *typical* slow build-up of the adhesion which was consistently encountered. The decay of adhesion after separation of the bead from the plate was very rapid, as is also shown in Fig. 1. Measurement of this decay of adhesion was carried out as follows. After a required separation time a quick measurement of adhesion was made within the minimum time necessary to bring the bead up to the plate and rotate to find the angle of break. The contact time required for this operation was about 10 sec. and the residual adhesion in the decay curve is due to this short contact time. This is also shown in Fig. 2, which is essentially a detail from Fig. 1. Fig. 2 further shows the reproducibility of the adhesion build-up in successive determinations.

DISCUSSION

1. The time dependency is possibly determined by the viscous flow of the gaseous or adsorbed medium from the gap between the approaching bead and plate, since with the freshly degassed surfaces the adhesion is very large and

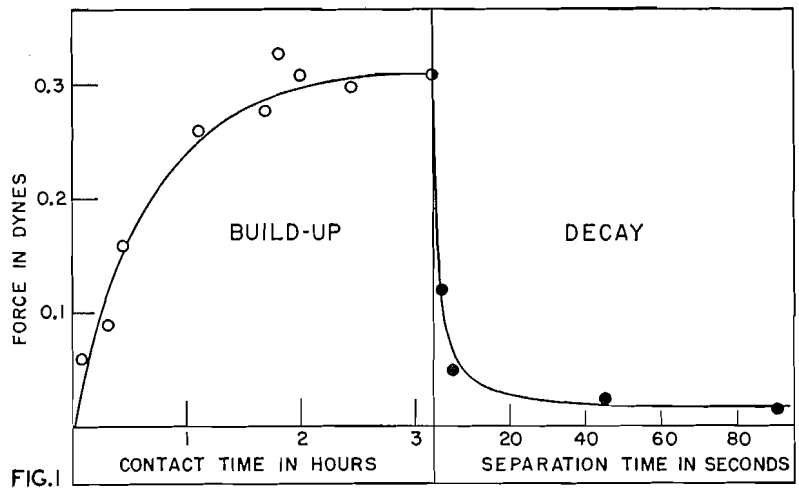

FIG. 1

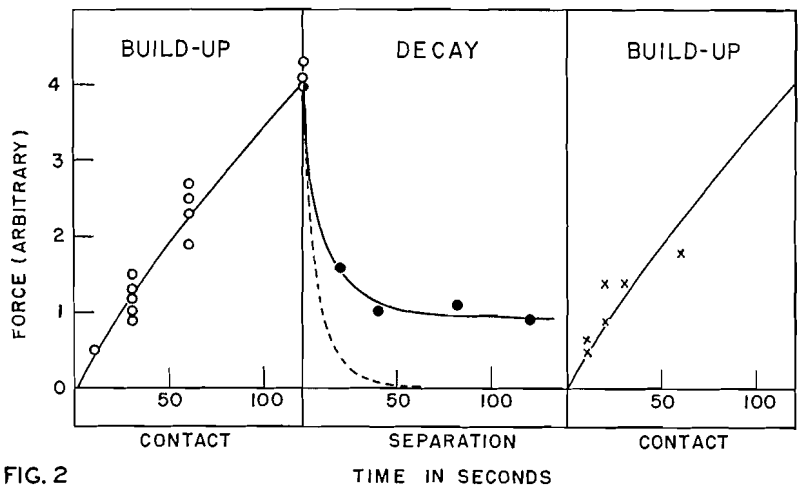

FIG. 2

FIG. 1. Adhesion build-up and decay for 0 7 mm. diameter bead and convex surface in decayed vacuum.

FIG. 2. Adhesion build-up and decay for 0.7 mm. diameter bead and convex surface in decayed vacuum. Residual adhesion of decay curve is due to short contact times required for force measurement.

instantaneous. If the movement over molecular distances of the bead towards the plate is responsible for the increase in adhesion with time, the time dependency of the decay may be explained by the reorientation of the molecules adsorbed on the surface. The initial rapid fall off in the maximum adhesion may be caused by this adsorption on the glass surface. The subsequent gradual fall off in the maximum adhesion might be attributed, in part, to the shock abrasion of the surfaces by repeated impact of the bead. Fig. 3 shows the decrease in the maximum adhesion over a period of several days in an apparatus containing 1 mm. of dry nitrogen. No very large adhesions were observed in atmospheres of nitrogen. The time required for the maximum adhesion

was very similar to that observed in a decayed vacuum although much greater than that required in freshly evacuated systems. This is consistent with the observed fall of the large maximum adhesions observed with freshly degassed and evacuated systems. The lower adhesions in atmospheres of nitrogen and the time dependence of the adhesion build-up might explain why McFarlane and Tabor (9) found no adhesion between glass surfaces in air. It is interesting to note that the adhesion kinetics reported in this paper are similar to those found by Derjaguin (4) for the interaction between quartz fibers in aqueous solution. The significance of this phenomenon in relation to the properties of suspensions is discussed elsewhere (7).

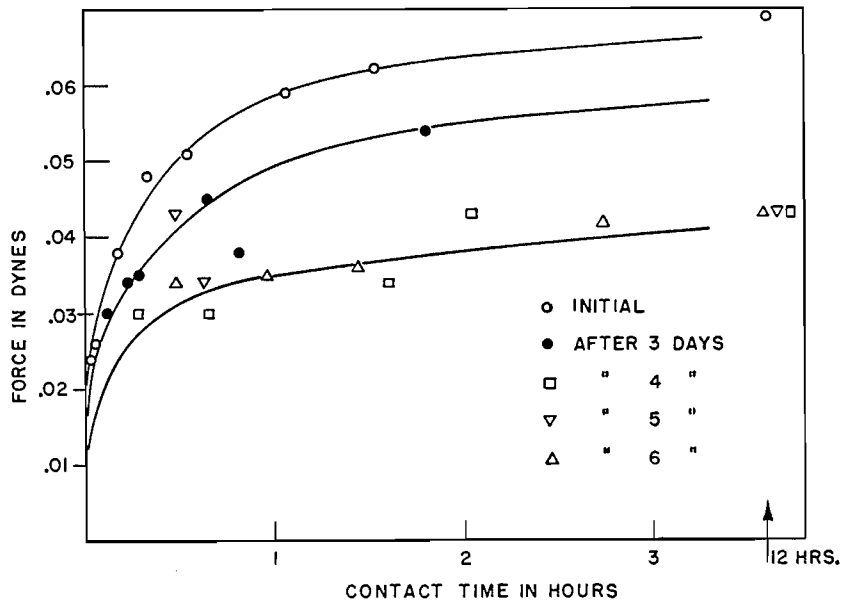

FIG. 3. Adhesion in 1 mm. nitrogen; 0.5 mm. diameter bead and convex surface.

In the course of the various experiments over a period of one year it was noted that the behavior of the bead was considerably affected by the induction of electrostatic charges. However, these decayed fairly rapidly and the consistent reproducibility of the adhesion and the adhesion kinetics points to the existence of attractive forces inherent in the system rather than spurious electrostatic charges. It seems unlikely that the mere 'contact' of the bead with the plate should induce electrostatic charge build-up. Also, the order of magnitude of the adhesion was found to be consistently the same in all experiments and with the various apparatuses used. In connection with this point it is interesting to refer to the behavior of glass spheres in anhydrous toluene (8). Agitation of the glass spheres in toluene apparently induces electrostatic charges which cause the beads to adhere to one another. Quite vigorous or prolonged agitation of the beads is required to produce agglomeration at room temperatures and the agglomerate collapses fairly rapidly in this temperature

region. Agitation of the beads alone, *in vacuo*, did not give any agglomeration, showing that the motion of the beads due to the supporting medium is important. In itself, this suggests that the contact of a bead with a plate is not sufficient to cause the build-up of an electrostatic attractive force. Furthermore, no indication of any increase in interparticle adhesion with time was obtained in the case of the uncharged sediments of glass spheres in various anhydrous liquids and with the glass beads *in vacuo*. If the observed time-dependent adhesion with the bead and the plate were electrostatic in origin, such an increase, of considerable magnitude, might be expected.

When the bead was brought into contact with the plate, it was allowed to rest under a small positive force. The application of larger positive forces did not seem to affect the observed adhesions. However, this was difficult to ascertain owing to the experimental difficulty of bringing the bead to the same position on the contact surface, since very small tangential forces would cause the bead to move in an arc, dictated by the fiber suspension, on the contact surface. Derjaguin (4) also observed the small dependence of the adhesion on the applied pressure in aqueous media.

McFarlane and Tabor (9) have shown that the elastic forces in the solid are important and that as the applied force is removed, contact points causing adhesion can break one by one. The measured adhesion is then the same as that without any applied load. In the above experiments it did not appear that elastic recovery prevented the measurement of adhesion. This is not surprising for two reasons; in the first place it is doubtful, except in the case of rigorously outgassed and freshly evacuated systems, whether the surfaces of the bead and plate in the above experiments ever were in true contact (continuous lattice formation) and secondly, elastic recovery at contact points implies an interaction between two irregular surfaces whereas in this case contact between the opposing lattices would be virtually at a single 'point' of molecular dimensions, if it occurred at all. It will be shown that the observed adhesion is consistent with the theoretical interaction expected for the close approach of the bead and the contact surface.

2. For the London – van der Waals force of interaction between a sphere and a plate Hamaker (5) obtains

$$F = AD/12d^2 \qquad [2]$$

where F is the force in dynes, $A = \pi^2 q^2 \lambda$, λ is the London constant, D is the diameter of the sphere in cm., d is the shortest distance of separation between the sphere and the plate in cm., and q is the number of atoms per cm^3.

This expression is not greatly affected by the curvature of the contact surface (the 'plate') as long as the radius of curvature of the plate is large compared with that of the bead. In the above experiments the curvature ratio was about 50 and any correction is of negligible importance, Fig. 4 shows the variation of F with d for a 1 mm. diameter bead, calculated from equation [2]. For a mean distance of close approach of 3–10 Å, which may be considered a reasonable range to assume for the approach between fused glass surfaces, it is seen that the attractive force would be in the vicinity of 10–100

dynes, taking the value of the A constant as 10^{-11} to 10^{-12} erg. This is consistent with the observation that the force of adhesion between freshly formed and rigorously degassed surfaces was well beyond the upper limit of force measurement of the apparatus which was about 1 dyne. The maximum adhesion measured with surfaces aged after evacuation and in atmospheres of nitrogen was generally of the order 0.1–0.2 dyne for beads of 1 mm. diameter. Taking the theoretical value of 10^{-12} for the force constant A, this corresponds

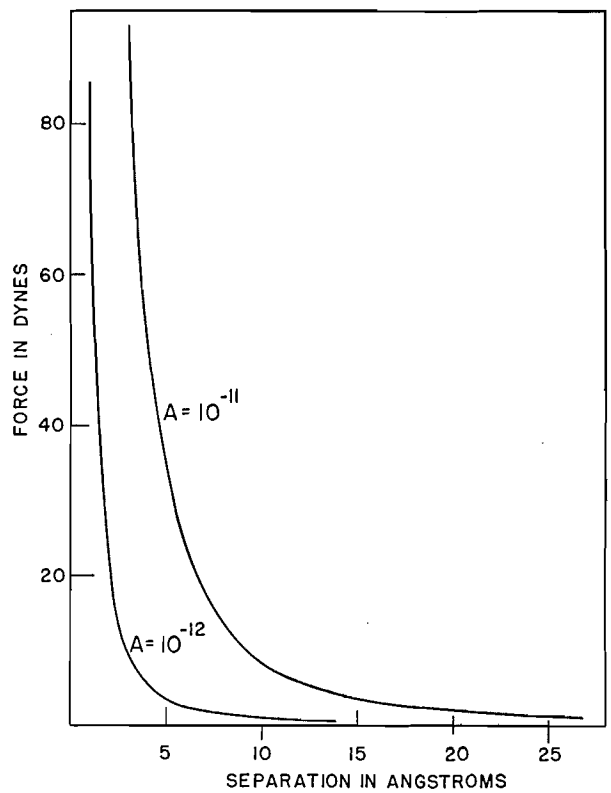

FIG. 4. Calculated interaction for 1 mm. diameter bead and plate.

to a distance of separation of 20–29 Å. This is a reasonable order for the effective separation in the presence of adsorbed foreign molecules in view of the separation considered *in vacuo*, and the fact that two solid surfaces are involved.

Table I shows the calculated variation in d, the closest distance of approach for perfect surfaces using the observed *maximum residual* forces of interaction. Using these values the selection of a value for the force constant A, which is consistent with the experimental evidence, will be considered. These residual forces were at least 10–100-fold less than the forces observed with freshly prepared and degassed systems *in vacuo*. This implies that the lower values of A, viz. 10^{-13} and 10^{-14}, can probably be eliminated since a 10–100-fold

TABLE I

CALCULATED SEPARATION BETWEEN 1 MM. DIAMETER BEAD AND PLATE FOR SELECTED VALUES OF THE A CONSTANT

A constant (ergs)	Separation d (Å)	
	F = 0.1 dyne	F = 0.2 dyne
10^{-10}	290	200
10^{-11}	91	65
10^{-12}	29	20
10^{-13}	9	7
10^{-14}	3	2

increase in the adhesion from the residual value would lead to a very unlikely value for the distance of closest approach, i.e., to within less than the diameter of an adsorbed gas molecule. Also, although fused glass surfaces are among the smoothest types of solid surfaces that can be obtained, surface undulations and discontinuities will possibly be of the order of 10–20 Å and this will tend to reduce the interaction. Calculated values of d will therefore tend to be too high, which favors the elimination of the lower values of the force constant.

For the residual adhesion it appears that the bead and the plate may be separated by adsorption products which prevent their approaching to within an atomic distance. It is unlikely that this adsorbed layer of gas could extend to over 50 Å from the surface of the solid, i.e., 10 or more molecular diameters. In view of this it is suggested that the values of 10^{-10} and 10^{-11} for A are too high. Adsorption studies in general indicate that after a few monolayers, adsorption energies are weak for physically adsorbed gases and approach normal bulk gaseous interactions. The observed results are therefore consistent with the adsorption of gaseous material and, with due allowance made for surface irregularities, the most favorable value of the A constant is about 10^{-12}, which agrees very well with the theoretical value.

3. The magnitude of the London – van der Waals interaction will depend on the value of the London constant, λ, which is included in the constant A. The direct experimental verification of the value of A is exceptionally difficult and the experimental results of different workers are conflicting. Table II shows the estimated values of A from the experimental data of other workers. These vary from about 10^{-10} to 10^{-14}, scattering about the theoretical estimate (2, 12) of 10^{-12} erg. For close approach between the surfaces a value of about 10^{-12} is general but Spaarnay and Overbeek (10) and Derjaguin (4), for wider distances of separation, give values which differ very considerably from one another. Unfortunately, the extreme sensitivity of the attraction to small changes of separation at close approach does not allow for a precise estimation of the force constant owing to the indeterminancy of the actual distance of separation, quite apart from other factors involved.

Derjaguin has suggested that the results of Spaarnay and Overbeek are too high owing to the inadequate removal of electrostatic mosaics from the glass surfaces. If this were the case it would seem surprising that the presence of water vapor or the coating of the glass plates with an evaporated silver layer

did not affect the measured interaction. It appears that the important question of the electrical neutrality of the surface, either on a molecular or on a macro scale, has not yet been settled. If a charge mosaic were capable of stable existence on such surfaces then it might be expected that such a phenomenon might also be a dominant factor in many types of suspensoidal systems. For glass type solids, the major part of the London interaction has been attributed to the highly polarizable oxygen atoms. In view of this, it is perhaps surprising that freshly sheared dispersions of paraffin wax in methanol coagulate spontaneously on standing. Vold (13) has offered an explanation of the interparticle adhesion in soap greases based on the polarizability of the oxygen atoms in the predominantly hydrocarbon fiber matrix. It is interesting to note, however, that comparable interparticle attraction apparently exists in polyethylene greases, in which the solid particles are totally hydrocarbon in composition and are embedded in a hydrocarbon liquid. This might suggest that such attractions are predominantly electrostatic in nature rather than London-type interactions. Alternatively, the application of the London additivity theorem to the interaction between solids might be inadequate, as suggested by Spaarnay and Overbeek, and much higher interactions than calculated from the London theory might be possible. Apart from the possibility of charged surface mosaics, the existence of induced like charges on two interacting glass-type surfaces might also be possible and thus account for the reduced interactions observed by Derjaguin. However, the present authors obtained reproducible adhesions in systems where there was no introduction of ionizing contaminants. The reproducibility of the observed adhesions suggests that the attractive force is an inherent property of the system and not due to electrostatic forces. The observed adhesion kinetics support this inference and are, in themselves, extremely important in the understanding and evaluation of colloidal and other aggregative phenomena.

THE MESOMORPHIC BEHAVIOR OF ANHYDROUS SOAPS

PART I. LIGHT TRANSMISSION BY ALKALI METAL STEARATES[1]

By D. P. Benton,[2] P. G. Howe,[2] and I. E. Puddington

ABSTRACT

The anhydrous salts of the long chain fatty acids are known to pass through a number of well-defined mesomorphic forms between the true crystalline solid and the isotropic liquid. The nature of some of these mesomorphic forms has been investigated by a study of their optical properties, electrical conductivity, density, and viscosity. In this paper, results obtained by an optical method are presented for phase transition temperatures of the alkali metal stearates and a number of sodium stearates having substituents in the hydrocarbon chain.

INTRODUCTION

The extensive and varied studies that have been made, in the past two or three decades, of the mesomorphic forms of salts of the long chain fatty acids have included a number of optical methods. The majority of the optical work has involved the use of hot stage microscopes; many photographs have been made of the different mesomorphic forms, particularly with the use of polarized light (10). The "hot wire" technique, used by Vold (7), has been very useful in the determination of phase transition temperatures. Relations between the transitions in different soaps have been investigated by Vold by a systematic microscopic study of the mesomorphic forms of the sodium salts of the *n*-fatty acids containing an even number of carbon atoms from C_6 to C_{22} (9) and also those of the series of alkali metal palmitates (11).

The optical methods have depended, in general, on the visual observation of change in appearance, usually by transmitted light, produced by the transition from one mesomorphic form to another. The experimental technique to be described here consists essentially of following the changes in intensity of light transmitted through the material under investigation, as a function of temperature, by means of a sensitive photometer. Besides confirming transitions which are observable to the eye without difficulty, this technique has enabled many less well defined changes from one mesomorphic form to another to be followed easily and speedily without camera work and without uncertainties caused by eye fatigue.

In this paper are given results obtained by the application of the light transmission technique to a study of the phase transitions in the alkali metal stearates and in a number of sodium stearates having substituents in the hydrocarbon chain. The density, viscosity, and electrical conductivity of these soaps have also been investigated in some detail and the results will be presented in subsequent papers in this series.

EXPERIMENTAL

Apparatus

The apparatus is shown diagrammatically in Fig. 1. The cell (*A*) consisted of a 3 in. length of precision molded Pyrex tubing, rectangular in cross-section,

[1]*Manuscript received March 24, 1955.*

supplied by H. S. Martin & Co. It was sealed at the lower end and fitted with a standard ground glass joint, for connection to the vacuum line, at the upper end. The internal dimensions of the cell were 10 mm.×2 mm. The cell fitted into a dural block furnace (*F*) which was bored so that light entering the tube (*B*) passed through the 2 mm. dimension of the cell. The block was

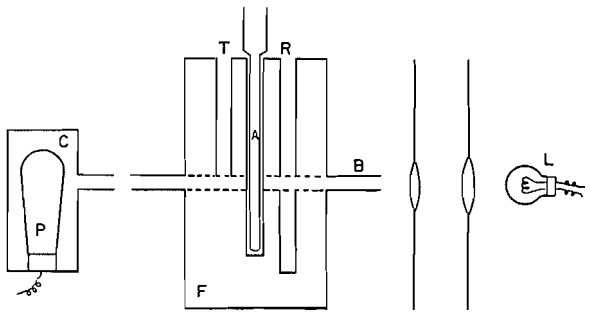

FIG. 1. Arrangement of apparatus (diagrammatic).

also bored to receive a thermocouple or thermometer at *T* and a mercury regulator at *R*. It was heated electrically by a Chromel winding and heavily lagged with asbestos. Temperature control was better than ±0.5°C. Light from an incandescent lamp (*L*) passed via a system of converging lenses through the tube (*B*) and was received by a phototube (*P*), mounted in the casing (*C*). The 12 volt lamp was usually run at 9 or 10 volts, this voltage being supplied from the mains, stabilized by a Sorenson regulator, and reduced by a Variac.

The maximum in the relative energy distribution curve for the lamp was in the wavelength region 7000–10,000 Å and the phototube selected was an RCA No. 917, giving maximum response in the region 7000–9000 Å. The phototube was operated in conjunction with a two-stage d-c. amplifier, this being a modification of a circuit appearing in Phototubes Form PT20R1 by RCA. The plate current of the second-stage amplification, a function of the light intensity and wavelength, was metered. A 1 ma. graphic meter was used, suitably shunted to give a recordable range of 0–20 ma. in the photoelectric current.

Preparation of Materials

The stearic acid used was the Eastman Kodak White Label material (m.p. 69–70°C.). 12-Hydroxystearic acid (m.p. 75°C.) was supplied by the Baker Castor Oil Co. 10-Methylstearic acid (tuberculostearic acid) (m.p. 26°C.) and 9-keto-10-methylstearic acid (m.p. 25°C.) were prepared by the method of Schmidt and Shirley (4). Phenylstearic acid was prepared from oleic acid by Friedel-Crafts reaction with benzene in presence of aluminum trichloride. This material was undoubtedly a mixture of the 9- and 10-phenylstearic acids.

The alkali metal salts (soaps) were prepared by titration of a hot solution of the acid in ethyl alcohol with an alcoholic solution of the appropriate alkali metal hydroxide, using phenolphthalein as indicator. The resultant gel (Na,

Rb, Cs stearates; Na 9-CO-10-Me stearate) or precipitate (Li, K stearates; Na 12-OH stearate; Na 10-Me stearate; Na phenyl stearate) was dried in an air oven at 105°C. In each case the soap was then fused under vacuum to remove last traces of water and alcohol. The opinion has been expressed, by Ralston (3) and Lawrence (1), that this treatment is insufficiently drastic to remove last traces of water associated with soaps. However, it has been shown (5) that the dilatometric behavior of sodium stearate prepared in the above manner is identical to that of sodium stearate prepared from sodium and stearic acid under anhydrous conditions. It would therefore seem most likely that fusion of the soap under vacuum will render it anhydrous.

Experimental Procedure

The soap was crushed and placed in the cell, which was then evacuated, and the temperature raised above the "final melting point" of the soap—this term being used to signify the temperature at which the soap becomes optically transparent. Nitrogen at a pressure of one atmosphere was then admitted to the cell. In the absence of this positive gas pressure slight degassing of the glass cell took place at higher temperatures and gas bubbles rising through the soap affected the measurement of the transmitted light intensity. This effect could be considerably reduced by prior degassing of the cell but was more conveniently eliminated by the presence of the nitrogen.

The temperature was then lowered in stages of about 5°C. and in each case time was allowed for the system to come to equilibrium, the criterion taken being a steady reading of the graphic meter for at least 15 min. Each substance investigated was run twice on a cooling curve and also checked on a heating curve. The equilibrium photoelectric current readings, being a measure of the intensity of light transmitted through the soap, were plotted as a function of temperature.

RESULTS AND DISCUSSION

The intensity of light transmitted through the 2 mm. thickness of soap decreased as cooling proceeded. A series of marked discontinuities occurred in the curve obtained by plotting the photoelectric current as a function of temperature. The results obtained are shown in Figs. 2 and 3. In these figures the degree of translucency of the soap, as measured by the photoelectric current, has been expressed as a percentage of the transparency of the liquid above the final melting point, i.e.,

$$\%\ \text{transmission at } T°\text{C.} = \frac{\text{photoelectric current at } T°\text{C.} \times 100}{\text{photoelectric current above final melting point.}}$$

While it is not presumed that the absolute values of the photoelectric current can have much significance in this experimental arrangement, the above function provides a convenient means of comparing the discontinuities in the change of translucency with temperature, for the different soaps. The temperatures at which these discontinuities appear have been found to be very accurately reproducible (virtually within 1°C.), both on cooling and on heating. The actual values of the photoelectric current were fairly reproducible on

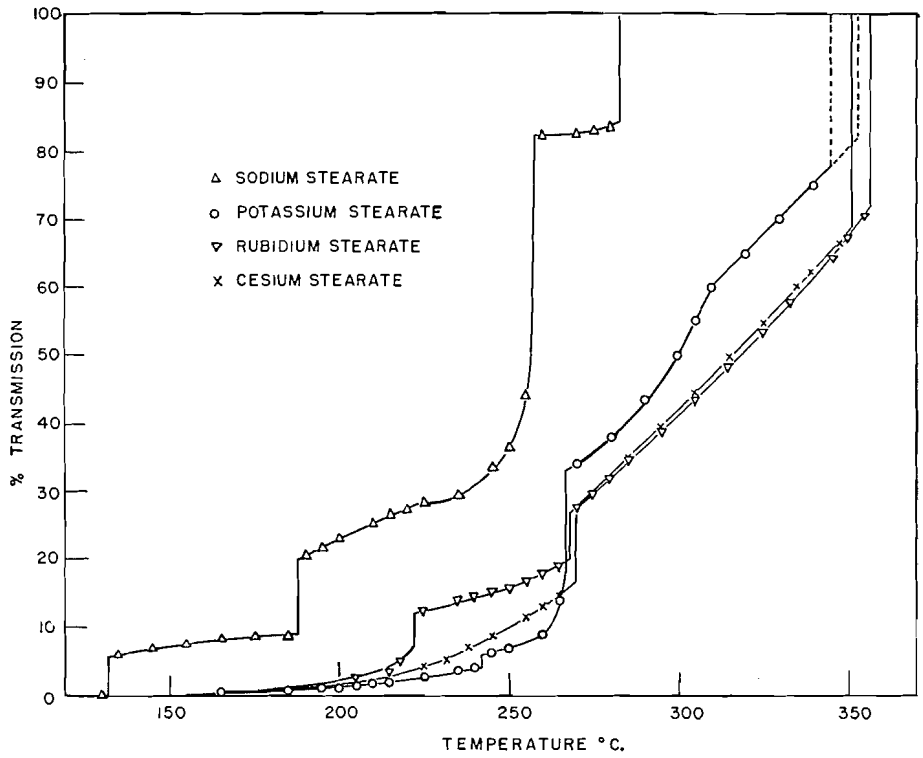

FIG. 2. Light transmission of alkali metal stearates as a function of temperature.

cooling curves but rather lower and less reproducible on heating curves, particularly at the lower temperatures. The reason for this is not perfectly clear but, in view of the excellent agreement between temperatures of discontinuities obtained on cooling and on heating, it would appear that supercooling is not responsible. One possible explanation may be that, on cooling from one phase to another where an appreciable density change is involved, microscopic cracking or vacuole formation may occur in the soap which will increase the light scattering and decrease the light transmission. On reheating it is to be expected that a hysteresis will exist in the closing of these cracks, leading to lower transmissions at any given temperature than those on cooling. Further, it is to be expected that the effect will be most marked in the lower temperature, more crystalline phases.

It should be mentioned here that one example of supercooling was observed in the case of lithium stearate. No results could be obtained for this soap below the temperature at which it melted to an optically clear liquid. The melting point was reproducible at 229°C. on heating. However, freezing occurred at temperatures between 229°C. and 218°C., depending on the rate of cooling. Below 229°C. the photoelectric current was irreproducible and no equilibrium was observed, even after two days had been allowed at each temperature.

A rather different phenomenon occurs in the case of potassium stearate

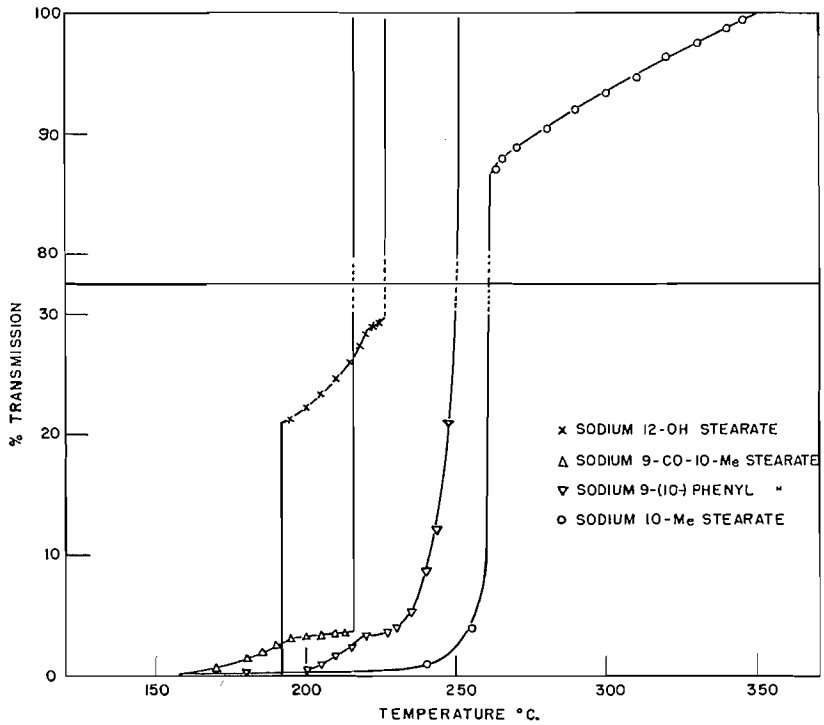

FIG. 3. Light transmission of some substituted sodium stearates as a function of temperature.

in the region of final melting. Between 345°C. and 353°C. two phases appear to be present, in stable equilibrium, and discrete lumps are visible to the naked eye. Above 353°C. the soap is optically clear and a maximum photoelectric current is obtained. Below 345°C. the homogeneous neat phase gives reproducible photoelectric current readings. Between these two temperatures, however, the reading depends on the position of the discrete lumps with respect to the optical path. For this reason, the final melting of potassium stearate is represented in two stages in Fig. 2.

A large non-equilibrium decrease in the intensity of transmitted light sometimes took place while a change was in progress. This was most probably caused by increased light scattering in the material while two phases were present.

A summary of the data obtained is given in Table II and comparison of the data for sodium stearate with those of Vold (8) and of Stross and Abrams (6) is given in Table I. It should be mentioned here that transition temperatures indicated by the optical method may not *necessarily* be true thermodynamic transition temperatures, since a change in translucency may be due to causes other than a phase transition. This may explain the discontinuity in the curve for sodium stearate at 188°C., which though doubtless a manifestation of the transformation from the superwaxy to the subneat phase is,

TABLE I

TRANSITION TEMPERATURES FOR SODIUM STEARATE

†Minor transitions.

nevertheless, 10–15° lower than the previously reported temperatures of this transition. However, in general and where comparable, the agreement between the present data and transition temperatures determined by observation of other properties is very close.

It is apparent from Figs. 2 and 3 that the present transition data may be divided into two types, i.e. those transitions where an abrupt change occurs in the intensity of the transmitted light and those manifested by a change of slope in the light transmission – temperature curves. It is believed that the temperatures at which these latter minor changes occur are very much more accurately determined by the present technique than by the usual microscopic methods.

The final melting points of the alkali metal stearates are seen to rise from lithium to rubidium and then fall slightly in the case of cesium. This parallels the behavior of the palmitates (11). For sodium stearate in the neat phase the light transmission is nearly constant throughout the range of existence but shows a very large decrease at the transition neat to subneat at 258°C. In potassium, rubidium, and cesium stearates it decreases steadily as the neat phase is cooled and shows a very much smaller abrupt decrease at the transition neat to subneat. A small, but very definite and reproducible change is indicated within the neat phase, at 310–315°C., in the case of potassium stearate. Below the neat–subneat transition, the behavior of potassium,

rubidium, and cesium stearates is less closely similar. Between this transition and 165°C., where all three soaps become opaque, potassium stearate shows a transition at 242°C., rubidium stearate at 222°C., and cesium stearate none at all. A corresponding variation in sodium stearate,within the subneat phase, is found at 220°C., confirming the observation of Powell and Puddington (2) from viscosity determinations.

Below 165°C. only sodium stearate retains any degree of translucence and shows a minor transition at this temperature. The soap finally becomes abruptly opaque at 132°C., the accepted transition from the waxy to the subwaxy phase.

Turning to a consideration of the results obtained for the sodium salts of the substituted stearic acids, it is found that, with the exception of sodium 10-methyl stearate, a very much greater decrease in intensity of light transmitted through these soaps takes place at the melting point. A very large decrease does, in fact, occur in the sodium 10-methyl stearate at 261°C. but this temperature is not the final melting point. Optically clear liquid does not exist below about 340–350°C. It has not been found possible to fix a definite temperature; the photoelectric current starts to decrease slowly at approximately 350°C. Between 350°C. and 261°C. this soap definitely possesses considerable rigidity and will not, for example, flow under its own weight. The introduction of the methyl group into sodium stearate thus considerably strengthens the structure. The introduction of the phenyl group weakens it, (sodium phenyl stearate m.p. 250°C.). The methyl group has approximately the same dimensions as the cross-sectional area of the hydrocarbon chain and its presence might conceivably allow these chains to interlock instead of standing end to end, as is considered the case in the unsubstituted stearates. Such interlocking would not only increase the interaction between chains but would also increase the interaction between polar carboxylic end groups, in successive polar planes, since these would be brought closer together. The very much larger phenyl group would be more likely to affect the lateral chain spacings to such a degree that the result may be a reduction of chain interaction and probably even of polar interaction if similar over-all packing is exhibited.

The introduction of the carbonyl group in the 9-CO-10-Me stearate lowers the melting point to 216°C. and the 12-OH stearate melts at 226°C. This effect caused by the introduction of a second distal polar group in the molecule is consistent with the behavior of compounds such as octadecane dicarboxylates, although the strength and position of the second polar groups in the above compound is insufficient to eliminate the mesomorphic properties.

It is interesting to note that small discontinuities of the same type as that shown by sodium stearate are apparent at 220°C. in the 12-OH stearate and the phenyl stearate. Furthermore the 12-OH stearate shows an abrupt decrease in transmitted light at 192°C. to be compared with that in sodium stearate at 188°C.

Vold (11) has pointed out that, with the exception of lithium soaps, the temperature of formation of neat soap is essentially constant, being very nearly independent both of the nature of the cation, in the series of palmitates,

and of the length of the hydrocarbon chain. This is also seen to be true for the stearates. Vold concludes that the forces of interaction between the chains are therefore all important and it is especially interesting in this connection to consider the results obtained here for the substituted stearates.

In the neat phase of the unsubstituted soaps some type of micellar structure would seem to be involved. This micellar structure may still be possible in the case of the sodium methyl stearate, accounting for the transition at 261°C., but the large phenyl group is likely not to allow its formation, by virtue of both entropic and polar interactions. Also it is difficult to imagine a stable micellar structure in the cases where a second distal polar group is present in the hydrocarbon chain. The subneat–neat transition is that at which the soaps become appreciably electrically conducting and a study of this property, in progress at the moment, seems likely to give useful information regarding the structure of soaps in the high temperature phases. The results of this work will be given in a later paper in this series.

ACKNOWLEDGMENTS

We are indebted to Mr. J. K. Waterman for photometer construction and to Dr. A. M. Eastham for preparation of the substituted stearic acids.

THE ACTION OF PYRIDINE ON DULCITOL HEXANITRATE[1]

By G. G. McKeown and L. D. Hayward

ABSTRACT

A pyridine solution of dulcitol hexanitrate evolved gas and became highly colored when warmed to 50°C.; dilution with water caused the precipitation of 67% of the theoretical amount of a dulcitol pentanitrate. The product was characterized as D,L-galactitol-1,2,4,5,6-pentanitrate by methylation to a monomethyl dulcitol pentanitrate, denitration of the latter, and periodate oxidation of the monomethyl dulcitol obtained. The hexitol derivatives were all obtained in a pure crystalline form. The significance of the data now available on the selective partial denitration by pyridine of hexitol hexanitrates is briefly discussed.

INTRODUCTION

In a previous research (5) it was shown that excess pyridine at 35°C. selectively removed the third (or equivalent fourth) nitrate group from D-mannitol hexanitrate to give D-mannitol-1,2,3,5,6-pentanitrate in 73% yield. This reaction was first described in 1903 by Wigner (14) who also reported a good yield of a mannitol pentanitrate from the action of alcoholic pyridine on mannitol hexanitrate. Wigner also nitrated dulcitol (I) to obtain a hexanitrate melting at "about 95°" (3, 4, 13) and found that alcoholic pyridine had almost no effect on this product even at the boiling point. Warming a solution of the dulcitol hexanitrate in pure pyridine, however, caused a reaction accompanied by evolution of a gas, and, on pouring the reaction mixture into water, Wigner obtained a crystalline product which "sintered at 71° and melted at about 75°" after three recrystallizations from aqueous alcohol. Analysis indicated this product to be a dulcitol pentanitrate.

In the present research Wigner's results were confirmed and the dulcitol pentanitrate was characterized as the racemic D- and L-galactitol-1,2,4,5,6-pentanitrate (III) by a series of reactions parallel to that previously described (5) for the characterization of D-mannitol-1,2,3,5,6-pentanitrate.

Dulcitol hexanitrate (D- or L-galactitol-1,2,3,4,5,6-hexanitrate) (II) was prepared in 92% yield by direct nitration of dulcitol (galactitol) (I) with nitric–sulphuric acid mixture, and the pure, crystalline, optically inactive compound melted at 98–99°C. and had the correct nitrate nitrogen content. Hydrogenolysis of a sample of the hexanitrate produced dulcitol quantitatively (5, 6). The hexanitrate dissolved readily in pure pyridine at 30°C. to give an initially colorless solution which became orange-colored in five minutes. No gas evolution was observed until the solution was warmed to 50°C., whereupon an exothermic reaction commenced, brown fumes were observed in the open vessel, and fine, colorless, needle-like crystals appeared on the inner walls of the flask above the solution. The vigorous reaction subsided within a few minutes and after 24 hr. the dark-red solution was poured into

[1]*Manuscript received May 30, 1955.*

water which caused the separation of crystalline dulcitol pentanitrate (III) in 63–72% yield. The pure pentanitrate melted at 85–86°, was optically inactive, and did not reduce Fehling's solution (13). Hydrogenolysis again gave a nearly quantitative yield of dulcitol thus proving that the pyridine caused no structural or configurational changes in the hexitol skeleton. The pentanitrate was stable to the further action of pyridine under conditions which caused the partial denitration of the hexanitrate.

V

II or III $\xrightarrow{H_2,\ Pd\text{–}C}$ I (quantitative) III + C_5H_5N ⟶ 94% recovery

V $\xrightarrow[H_2SO_4]{HNO_3}$ IV (75%) IV + C_5H_5N ⟶ 89% recovery

Methylation of the pentanitrate gave a 67% yield of a new methyl dulcitol pentanitrate (IV), m.p. 99–100°C., with correct methoxyl and nitrogen analyses and this compound was also stable to pyridine at room temperature. Catalytic hydrogenolysis of the methylated pentanitrate yielded a crystalline

monomethyl dulcitol (V) melting at 149–150°. A sample of (V) was renitrated with mixed acids at −10°C. to give a 75% yield of the original methyl dulcitol pentanitrate (IV).

A literature search revealed no previous report of monomethyl derivatives of dulcitol and, apart from an independent synthesis, periodate oxidation appeared to be the most reliable means of locating the position of the methyl group. Taking account of the meso configuration of dulcitol our monomethyl hexitol was one of three possible compounds: a racemate of (1) D- and L-1-*O*-methyl galactitol, (2) D- and L-2-*O*-methyl galactitol, or (3) D- and L-3-*O*-methyl galactitol. The theoretical behavior of these compounds toward periodate oxidation is summarized in Table I.

TABLE I

THEORETICAL PRODUCTS OF THE PERIODATE OXIDATION OF HEXITOL MONOMETHYL ETHERS

	Position of OCH_3 group	Periodate consumed (moles)	Oxidation products (moles)		
			HCHO	HCOOH	Other
Case 1	1 or 6*	4	1	3	CHO | CH_2OCH_3
Case 2	2 or 5*	3	1	2	CH_2OH | H—C—OCH_3 | CHO
Case 3	3 or 4*	3	2	1	CHO | H—C—OCH_3 | CHO

**Pairs of structural isomers although each compound has a unique configuration. Of the mannitol and iditol derivatives only one compound of the* D*-configuration and one of the* L*-configuration can exist in each case. For dulcitol and allitol derivatives the pair in each case is racemic.*

Oxidation of the monomethyl dulcitol with aqueous sodium periodate at room temperature showed a consumption of 4.9 moles of oxidant with the production of 2.1 moles of formic acid and 2.0 moles of formaldehyde per mole of methyl ether. Dulcitol under the same conditions gave the nearly theoretical values of consumption of oxidant (4.95 moles), formic acid (3.68 moles), and formaldehyde (1.98 moles). Comparison of the results for the monomethyl dulcitol with Table I showed Case 1 to be ruled out and that either Case 2 or Case 3 could have given these values if an additional oxidation requiring 2 moles of oxidant occurred with the concomitant formation of an extra mole of formaldehyde or of formic acid respectively. The rate of the periodate oxidation was therefore studied to determine the possibility of "overoxidation" at room temperature. The rates of oxidant consumption, and aldehyde and acid production at 23°C. for the monomethyl dulcitol (Fig. 1, Curves A, B, and C) indicated a rapid initial consumption of 3 moles of oxidant producing 2 moles of formaldehyde and approximately 1 mole of formic acid. The results at this stage conformed to Case 3. An hour later the aldehyde value was the same but the amount of

formic acid had increased to 2 moles and that of oxidant consumed to 5. A rate reaction run at 0°C. (Fig. 1, Curve D) in order to slow or halt the overoxidation clearly showed the rapid initial formation of 1 mole of formic acid followed by a slower secondary oxidation in which further quantities of

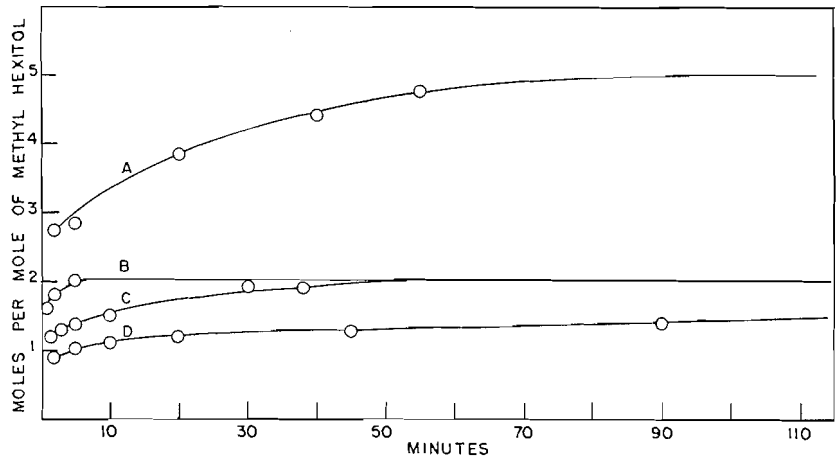

FIG. 1. Periodate oxidation of 3-*O*-methyl-D,L-galactitol.
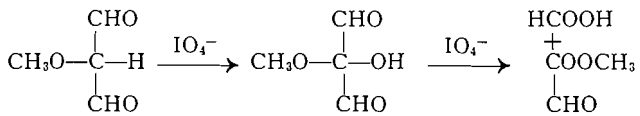
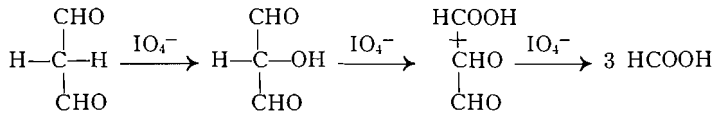
A: Periodate consumption at 23°C.
B: Formaldehyde production at 23°C.
C: Formic acid production at 23°C.
D: Formic acid production at 0°C.

acid were produced to the final total of 2.0 moles of acid at 11 hr. These data indicated Case 3 to be involved and that the dialdehyde formed (Table I) in the first stages of the oxidation was oxidized further to produce a mole of formic or other acid. A similar reaction of the dialdehyde of malonic acid



VI

(VII) was reported by Huebner, Ames, and Bubl (7) in which 3 moles of formic acid was produced with oxidant consumption of 3 moles. The methyl



VII

ester of glyoxylic acid (VI) presumably formed in Case 3 could be expected to be comparatively stable to further oxidation. The unique correlation of the periodate oxidation data was for the monomethyl dulcitol to be the racemate,

3-*O*-methyl-D- and L-galactitol (V), and hence the structures and configurations of the compounds (III) and (IV) which preceded it were also established.

The reactions of mannitol and dulcitol hexanitrates with pyridine were analogous and consisted in the replacement of a nitric acid ester group by hydrogen at the 3 (or equivalent 4) position in about 70% of the hexanitrate molecules. No inversion of configuration occurred at the asymmetric center attached to the nitrate group and it may therefore be assumed that the O—N bond was cleaved through some type of nucleophilic attack of pyridine on the nitrate nitrogen (1, 2).

The selectivity of the reaction for one particular nitrate group among six in each molecule is intriguing. To test the hypothesis that this group must occupy a unique spatial environment we plan to treat the nitrates of other polyols with pyridine. Urbanski and Kwiatkowska (12) reported partial denitration of sorbitol hexanitrate when it was heated with alcoholic pyridine; however, the viscous product was not characterized.

EXPERIMENTAL

Materials and Methods

Since dulcitol hexanitrate and its partially nitrated derivatives are explosives (11), the scale of the preparations was restricted to 5 gm. or less and all evaporations were under reduced pressure with bath temperatures not exceeding 50°C.

Pure dulcitol (galactitol (I)) (m.p. 187–188°, optically inactive) (8) when nitrated with fuming nitric and concentrated sulphuric acids at −10°C., as described by Bechamp (3) and Patterson and Todd (9), gave a 92% yield of the crystalline dulcitol hexanitrate (II). After recrystallization from aqueous ethanol the colorless, needle-like crystals of hexanitrate were optically inactive and melted at 98–99°C. (corr.). The melting point was not altered by further recrystallizations. Previous workers (3, 13, 14) reported a melting point of 95°C. Found: N (nitrometer), 18.4, 18.8%. Calc. for $C_6H_8(NO_3)_6$: N, 18.6%. Hydrogenolysis of 0.685 gm. of the hexanitrate over palladized charcoal at 20–30 p.s.i. and room temperature as previously described (5, 6) yielded 0.289 gm. of crude product. Recrystallization from aqueous ethanol gave thick, colorless crystals melting at 185–187°C. A mixed melting point with authentic dulcitol showed no depression.

The analytical procedures for nitrate nitrogen, methoxyl, and periodate oxidation products were previously described (5, 6, 10).

Action of Pyridine on Dulcitol Hexanitrate

A 500 ml. Erlenmyer flask containing 3.11 gm. of pure dry dulcitol hexanitrate was immersed in a water-bath at 30°C. The hexanitrate dissolved immediately on addition of 25 ml. of pyridine (B.D.H. analytical reagent grade) to form a clear, colorless solution which became orange-colored within five minutes. No further change was observed until the water-bath was heated to 50°C. when the solution rapidly evolved small bubbles of gas and fine, colorless crystal-needles appeared on the neck of the flask. After the first vigorous reaction had subsided, the now dark-red solution was allowed to stand at room temperature for 24 hr. and was then poured with stirring into

300 ml. of water. The colorless sirup which separated crystallized readily and was recovered on a glass filter, washed thoroughly with water, and dried to constant weight *in vacuo*; yield 1.81 gm. (65%). Yields obtained in similar denitrations were 63, 65, 69, and 72%. Recrystallization of the product from aqueous ethanol, ether – petroleum ether, or carbon tetrachloride yielded colorless needles of pure dulcitol pentanitrate (D,L-galactitol-1,2,4,5,6-pentanitrate) (III); m.p. 85–86°C., optically inactive, soluble in alcohol, ether, benzene, and chloroform, insoluble in water and petroleum ether. The pentanitrate did not reduce Fehling's solution (13, 14). Found: N (nitrometer), 16.9, 17.0%. Calc. for $C_6H_8(OH)(NO_3)_5$: N, 17.2%.

A sample of the dulcitol pentanitrate (0.63 gm.) when treated with pyridine (4.0 ml.) under the conditions which caused denitration of the hexanitrate produced no gas, although the solution became dark-red in color. Unchanged pentanitrate, 0.59 gm. (94%), was recovered when the solution was worked up as described above. A 0.240 gm. sample of dulcitol pentanitrate yielded 0.110 gm. (100%) of crude dulcitol when hydrogenolyzed as described for the hexanitrate. The pure product melted at 185–188°C. and caused no depression in the melting point of pure dulcitol.

Methyl Dulcitol Pentanitrate (*3-O-Methyl*-D,L-*galactitol-1,2,4,5,6-pentanitrate*) (*IV*)

Dulcitol pentanitrate, 0.730 gm., was dissolved in 11 ml. of methyl iodide and 4 ml. of methanol and treated with 5 gm. of Drierite and 5 gm. of freshly-prepared silver oxide. After being refluxed for nine hours the mixture was filtered and the solids washed with dry acetone. Evaporation of the filtrate and washings and recrystallization of the colorless solid residue from aqueous ethanol yielded 0.508 gm. (67%) of monomethyl dulcitol pentanitrate (3-*O*-methyl-D,L-galactitol-1,2,4,5,6-pentanitrate) (IV); m.p. 99–100°C., soluble in alcohol, ether, acetone, and dioxane, insoluble in water. Found: N, 16.6, 16.5%; OCH_3, 7.34, 7.37%. Calc. for $C_6H_8(OCH_3)(NO_3)_5$: N, 16.6%; OCH_3, 7.37%. A sample of the methylated dulcitol pentanitrate was recovered unchanged in 89% yield from a pyridine solution after two days at room temperature.

Monomethyl Dulcitol (*3-O-Methyl*-D,L-*galactitol*) (*V*)

Monomethyl dulcitol pentanitrate, 1.42 gm., dissolved in 30 ml. dioxane diluted with 45 ml. ethanol and 5 ml. of water was hydrogenated at room temperature over 1 gm. of palladized charcoal at 45 p.s.i. After one hour the pressure became constant and the solution was free of nitrate by the diphenylamine test. The catalyst was filtered off, and evaporation of the solution left a colorless crystalline product. Recrystallization from boiling absolute alcohol gave 0.552 gm. (83%) of thick, colorless crystals; m.p. 149–150°C. Recrystallization from isoamyl alcohol or from water yielded the same product. Found: OCH_3, 16.1, 16.0%. Calc. for $C_6H_8(OCH_3)(OH)_5$: OCH_3, 15.8%. The monomethyl dulcitol did not react with Fehling's solution or bromine water.

Nitration of a sample of the monomethyl dulcitol with sulphuric–nitric acid mixture gave a 75% yield of the original 3-*O*-methyl-D,L-galactitol-

1,2,4,5,6-pentanitrate, identified by a mixed melting point and methoxyl analysis. Found: OCH_3, 7.39, 7.20%.

Periodate Oxidation of Monomethyl Dulcitol (3-O-Methyl-D,L-galactitol) (V)

Forty to fifty milligram samples of the monomethyl dulcitol were oxidized with aqueous sodium periodate solution by procedures previously described (6) which revealed the amount of periodate consumed and the amounts of formic acid and formaldehyde formed. At room temperature the amounts of formic acid obtained per mole of methyl dulcitol were 1.20, 1.30, 1.38, 1.51, 1.91, 2.06, and 2.11 moles after 1.5, 3, 5, 10, 38, 130, and 900 min. respectively. At 960 min. 4.93 moles of periodate had been consumed and at 1020 min. the formaldehyde production was found to be 1.98 moles. In two other runs under the same conditions the consumption of 2.76, 2.83, 3.86, 4.43, and 4.77 moles of periodate at 2, 5, 20, 40, and 55 min. was observed while the molar production of formaldehyde amounted to 1.61, 1.81, 2.02, 1.92, and 1.98 after 1, 2, 5, 30, and 1020 min. Oxidation of pure dulcitol under the same conditions formed 3.53, 3.63, and 3.68 moles of formic acid after 5, 15, and 25 hr. At 25 hr. the periodate consumption was found to be 4.95 moles and formaldehyde production 1.98 moles.

An oxidation of methyl dulcitol conducted in an ice bath revealed formic acid production as 0.91, 1.04, 1.12, 1.20, 1.27, 1.40, 1.70, 2.06, and 2.11 moles after 2, 5, 10, 20, 45, 90, 300, 660, and 1440 min.

The data for the oxidation of the monomethyl dulcitol are plotted in Fig. 1; theoretical values for the different structural isomers are listed in Table I.

ACKNOWLEDGMENT

The authors wish to thank the National Research Council of Canada for Grant G249 which helped to defray the cost of this research. One of them (G.G.M.) also thanks the Standard Oil Company of British Columbia Limited for a Fellowship which enabled him to complete the work.

COEXISTENCE PHENOMENA IN THE CRITICAL REGION

III. COMPRESSIBILITY OF ETHYLENE AND XENON FROM LIGHT SCATTERING[1]

By F. E. Murray[2] and S. G. Mason

ABSTRACT

Turbidity measurements in the region immediately above the critical temperature are used to calculate values of $(\partial p/\partial v)_T$. These results show that $(\partial p/\partial v)_T$ is a continuously variable function of the density to within 0.02°C. above the critical temperature. The experiments indicate that there exists no region above T_c throughout which $(\partial p/\partial v)_T = 0$ in ethylene or xenon.

INTRODUCTION

In 1938 Mayer and Harrison (9, 10) concluded from a statistical treatment of a real gas that the phase transition at the critical point did not occur in the manner proposed by Andrews (1, 2). Their prediction of a "derby hat" region between two characteristic temperatures has stimulated a great deal of experimental work.

Maass (6) has summarized the evidence for the existence of anomalous behavior. Zimm (19), from a series of light-scattering measurements, concluded that the region predicted by McMillan and Mayer (8) did not exist in the case of a binary liquid system. From a theoretical viewpoint, Zimm (20) has discussed the probability of a single critical temperature. Weinberger and Schneider (16, 17) and Habgood and Schneider (4) found no evidence of a "derby hat" region in xenon. Other results observed in unstirred systems are of questionable value in settling this question, as it is doubtful if equilibrium can be attained without mechanical mixing. The experimental work described here was undertaken to obtain information regarding the validity of conclusions by Mayer and Harrison.

To account for the turbidity in the critical region of a pure gas, Smoluchowski (15) and Einstein (3) derived an equation from the theory of density fluctuations which may be written

$$[1] \qquad \frac{I_\theta}{I_0'} = \frac{A T \rho^3}{\lambda^4}\left[\frac{1+\cos^2\theta}{-(\partial p/\partial v)_T}\right].$$

Here I_θ is the intensity of the radiation scattered at angle θ from the incident beam, I_0' is the incident intensity, and λ the wavelength of the incident light beam. A is a constant for a particular gas and a fixed distance of observation, T is the absolute temperature, ρ is the density, and p and v are the pressure and specific volume of the fluid.

When the angular dependence of I_θ is given by the factor $(1+\cos^2\theta)$, the turbidity τ is related to the transversely scattered light by the equation

$$[2] \qquad \tau = b\, I_{90°}/I_0',$$

[1]*Manuscript received May 9, 1955.*

where b is a constant. Equations [1] and [2] may be combined to yield:

$$[3] \qquad \tau = \frac{BT\rho^3}{\lambda^4} \Big/ -\left(\frac{\partial p}{\partial v}\right)_T.$$

Equation [3] predicts that I_θ becomes infinite when $(\partial p/\partial v)_T = 0$, i.e. at the classical critical point. This result is obtained because the derivation predicts infinite density fluctuations at the critical point. Physically, it is of course impossible for I_θ to be infinite. In a modified treatment of the problem by Ornstein and Zernicke (12, 13), the density fluctuations at the critical point are infinite, but I_θ is kept finite owing to optical interference between wavelets scattered from different volume elements in the fluid.

In a more detailed analysis, which neglects optical interference, Rocard (14) derived the equation

$$[4] \qquad \tau = \frac{BT\rho^3}{\lambda^4} \Big/ \left(-\left(\frac{\partial p}{\partial v}\right)_T + c\right),$$

where c is a constant for any particular gas and light source.

In the development of Eq. [4], both the density fluctuations and the value of I_θ are kept finite when $(\partial p/\partial v)_T$ becomes zero. Klein and Tisza (5) have shown that both Eq. [3] and Eq. [4] as well as that of Ornstein and Zernicke follow from their work.

At constant λ and over a small temperature range, Eq. [4] may be rearranged to the form

$$[5] \qquad \tau^{-1} = \frac{K}{\rho^3}\left[-\left(\frac{\partial p}{\partial v}\right)_T + c\right],$$

where K is virtually constant.

From Eq. [5] it follows that

$$[6] \qquad -\left(\frac{\partial p}{\partial v}\right)_T = \frac{\rho^3\tau^{-1}}{K} - c.$$

If K and c are known, $(\partial p/\partial v)_T$ may be calculated using Eq. [6]. In any case, $(\partial p/\partial v)_T$ is a linear function of $\rho^3\tau^{-1}$ over the temperature range in which K may be considered constant. Equation [6] indicates that if $(\partial p/\partial v)_T$ becomes zero, $\rho^3\tau^{-1} = Kc$, i.e. $\rho^3\tau^{-1}$ should be constant within the "derby hat" region predicted by Mayer and Harrison (9, 10).

In this investigation, the turbidity τ was calculated from measurements of transmitted light using the relation (for 1 cm. light path in the fluid)

$$\tau = 2.30 \log(I_0'/I'),$$

where I' is the intensity of the transmitted beam.

A polychromatic light source was used to give high intensity illumination which could be measured with a 929 photocell. Since the total intensity of such a beam may be written as the sum of intensities at various wavelengths in the incident light, then the total intensity is

$$I_0' = \sum I_0'(\lambda),$$

where the sum is taken over all wavelengths in the spectrum of the incident beam. $I_0'(\lambda)$ is the incident intensity over a small wavelength interval. For the scattered intensity in a single wavelength interval, Rocard's equation predicts that

$$I_\theta(\lambda) = \frac{I_0'(\lambda)}{\lambda^4} AT\rho^3 \left[\frac{1+\cos^2\theta}{-(\partial p/\partial v)_T + c}\right].$$

For the total intensity scattered from the polychromatic beam at angle θ,

[7] $$\sum I_\theta(\lambda) = \sum \frac{I_0'(\lambda)}{\lambda^4} AT\rho^3 \left[\frac{1+\cos^2\theta}{-(\partial p/\partial v)_T + c}\right].$$

When both sides of [7] are divided by $\sum I_0'(\lambda)$, the intensity of transversely scattered light becomes

[8] $$\frac{I_{90°}}{I_0'} = \frac{AT\rho^3}{\sum I_0'(\lambda)} \sum \frac{I_0'(\lambda)}{\lambda^4} \left[\frac{1}{-(\partial p/\partial v)_T + c}\right].$$

Combining equations [2] and [8] yields

[9] $$\tau = \frac{BT\rho^3}{I_0'} \sum \frac{I_0'(\lambda)}{\lambda^4} \left[\frac{1}{-(\partial p/\partial v)_T + c}\right].$$

For any stable light source, where the distribution of $I_0'(\lambda)$ remains constant throughout the spectrum of the beam, $\sum I_0'(\lambda)/\lambda^4$ is constant and equation [9] may be written

[10] $$\tau = DT\rho^3/(-(\partial p/\partial v)_T + c)$$

or in a form similar to Eq. [6],

[11] $$-\left(\frac{\partial p}{\partial v}\right)_T = \frac{\rho^3 \tau^{-1}}{K'} + c.$$

Equation [11] is the form applicable to the following experimental results.

T_c is defined as the highest temperature (°C.) at which visible droplets form on slow cooling of the fluid; $\Delta T = (T - T_c)$ and may be positive or negative. The mean density $\bar{\rho}$ equals total mass of gas divided by volume of bomb.

EXPERIMENTAL

Apparatus

Except for modifications made to obtain transmission measurements, the apparatus was the same as that previously described (11). These modifications included the addition of a 929 photocell to the optical measuring assembly of Fig. 2 in Reference (11) to measure the intensity of the transmitted light. Except for a small round opening (about $\frac{1}{4}$ in. diameter) upon which the incident beam was aligned, the glass envelope of the photocell was painted black. The entire optical assembly could be moved to any desired level along the glass bomb.

The fluid sample was contained in a long (about 35 cm.) glass bomb (11). The bomb used in these experiments was sealed off at a point approximately

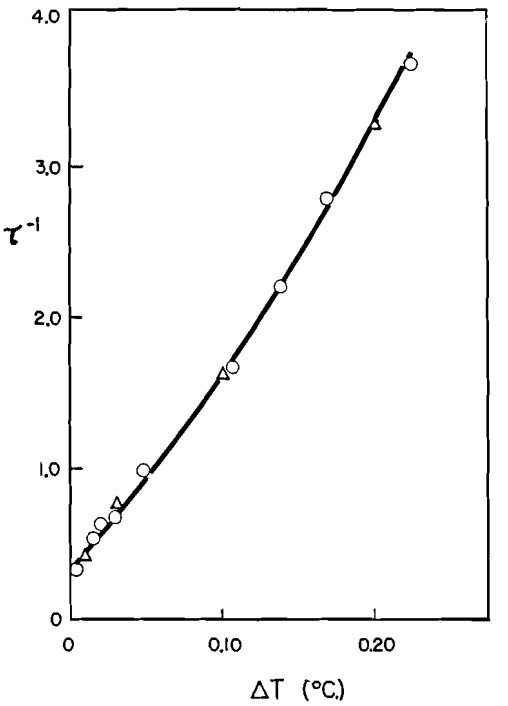

FIG. 1. Variation of τ^{-1} with $\Delta T = T - T_c$ at the density of maximum turbidity of xenon. The circles are measured values and the triangles values calculated from $(\partial p/\partial v)_{\min}$ values of Habgood and Schneider (4) using the Rocard equation.

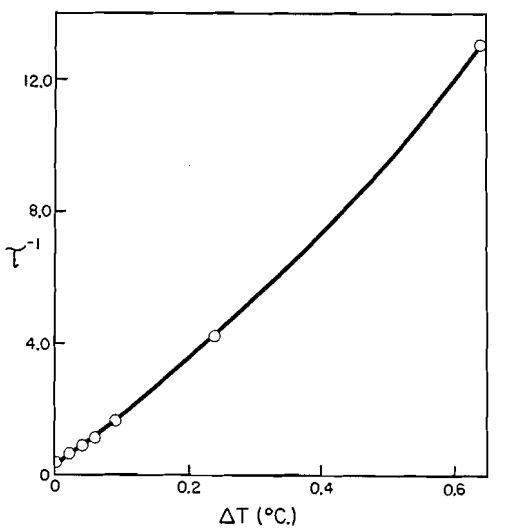

FIG. 2. Variation of τ^{-1} with ΔT at the density of maximum turbidity in ethylene.

10 cm. from the extreme top. This sealed-off portion was filled with methanol and was used at one fixed point to check and maintain a constant incident light intensity. The light source and 929 photocell combination had extremely good stability.

Procedures

The ethylene sample was Phillips research grade and contained 99.9 mole per cent ethylene before fractionation in the glass filling apparatus. The xenon was obtained from Linde Air Products and showed only the xenon spectrum when analyzed in a mass spectrometer. The xenon and ethylene samples were purified and distilled into the glass bomb in the manner previously described (11).

All transmission measurements were obtained immediately after vigorous stirring of the fluid and at one level near the center of the bomb. In this way,

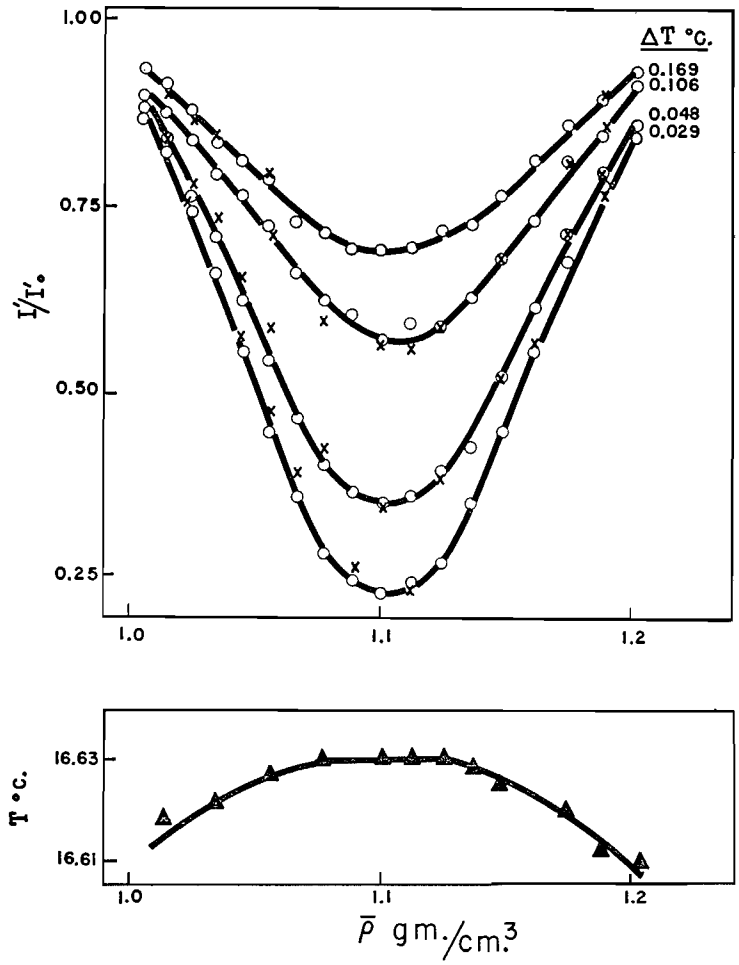

FIG. 3. Variation of transmittance with density along isothermals above T_c (upper curves) and liquid–vapor coexistence curve (lower curve) of xenon.

no appreciable time was allowed for establishment of a vertical density gradient and the density at the point of observation was virtually equal to the mean density. Under these conditions, the mean density $\bar{\rho}$ was used in the calculations from equation [11].

Points on the coexistence curves (lower parts of Figs. 3 and 5) were obtained by observing the first formation of visible droplets when the quiescent system was slowly cooled from above T_c as previously described (11, 18). The observed temperatures at any value of the average density were reproducible within ± 0.002°C. on a Beckmann thermometer.

RESULTS

Variation of Turbidity with Temperature

Xenon

Fig. 1 shows the variation of τ^{-1} with ΔT in xenon. All measurements were taken at the density of maximum turbidity ($\bar{\rho} = 1.100$ gm./cc.) and after the fluid had been efficiently stirred.

Using the equation

$$[12] \qquad \tau^{-1} = \frac{45.1}{\rho^3}\left[-\left(\frac{\partial p}{\partial v}\right)_T + 0.0059\right],$$

values of τ^{-1} were calculated from the $(\partial p/\partial \rho)_{\text{min}}$ data of Habgood and Schneider (4). K' and c in Eq. [12] were chosen to give best correspondence between these calculated values and those obtained from our transmission measurements.

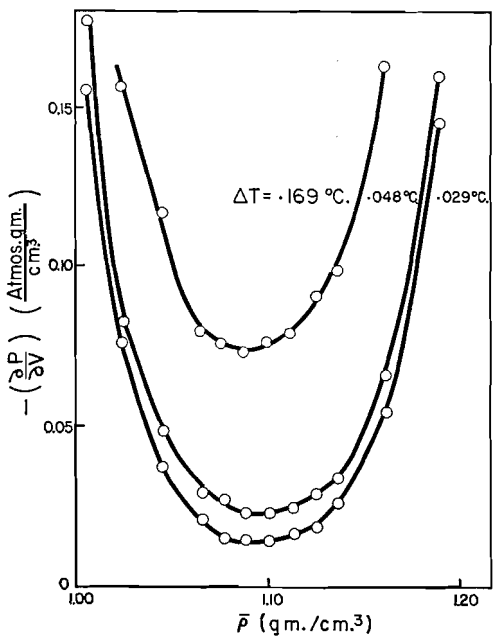

FIG. 4. Variation of $-(\partial p/\partial v)_T$ with density in xenon on isotherms immediately above T_c. Temperatures shown are values of ΔT.

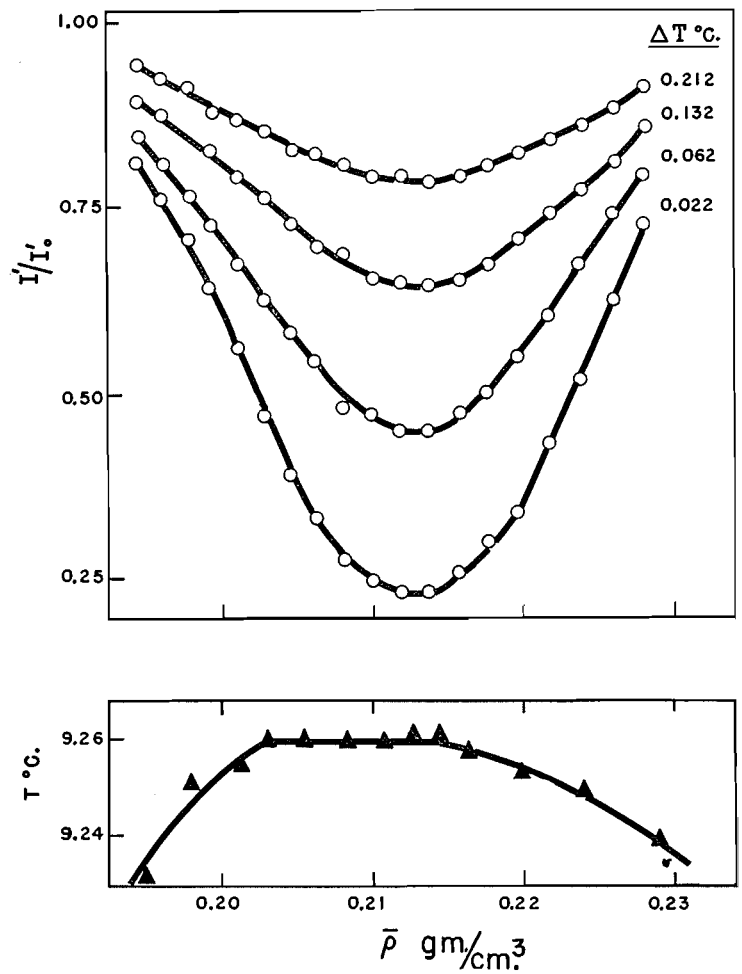

FIG. 5. Variation of transmittance with density along isothermals above T_c (upper curves) and liquid–vapor coexistence curve (lower curve) of ethylene.

Having, in this manner, established the values of K' and c for xenon, Eq. [12] was used to obtain $(\partial p/\partial v)_T$ from transmission measurements at other densities.

Ethylene

Fig. 2 shows values of τ^{-1} as a function of ΔT in ethylene. The curve obtained is almost identical with that obtained for xenon. The available PVT data on ethylene (7) are not sufficiently accurate for comparison of calculated and experimental values of τ^{-1}; consequently K' and c cannot be evaluated in this case.

Transmittance Isothermals

Figs. 3 and 5 show variation of transmittance with density in the systems xenon and ethylene and, in the lower portions, coexistence curves for these two

systems. The value of T_c observed for ethylene was 9.26±0.02°C. and that for xenon 16.63±0.02°C. The flat apexes on the coexistence curves have been attributed to gravity gradients by Weinberger and Schneider (17) and Mason *et al.* (11, 18).

The transmittance data are well fitted by continuous curves which show no indication of a discontinuity in τ.

Calculated $(\partial p/\partial v)_T$ *Isotherms*

Fig. 4 shows values of $(\partial p/\partial v)_T$ calculated from Eq. [12] at various densities in xenon.

Since K' and c of Eq. [11] could not be obtained for ethylene, $\tau^{-1}\rho^3$ is shown as a function of density in Fig. 6.

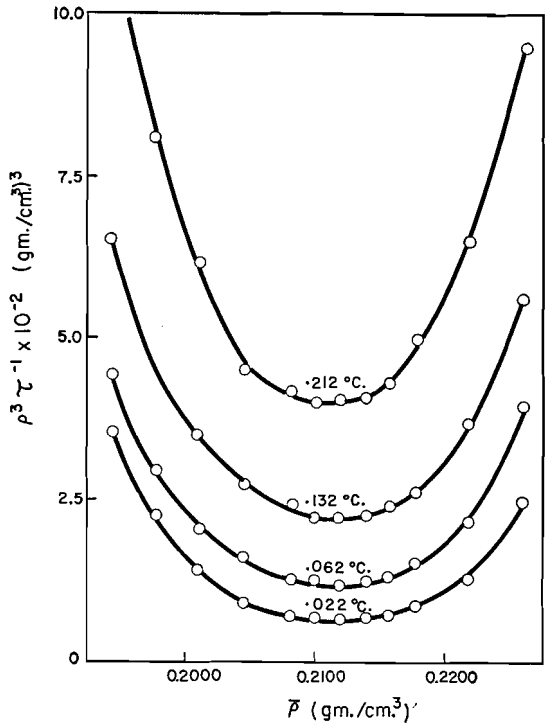

FIG. 6. Variation of $\rho^3\tau^{-1}$ with density in ethylene on isotherms immediately above T_c. Temperatures shown are values of ΔT.

CONCLUSIONS

The results of these experiments indicate that $(\partial p/\partial v)_T$ is a continuous function of the density and not equal to zero within 0.02°C. above T_c in ethylene and to within 0.03°C. above T_c in xenon.

Our results for xenon confirm the conclusion of Habgood and Schneider (4) based on PVT measurements. They are in disagreement with the conclusions of McIntosh, Dacey, and Maass (7) which were based on rather insensitive PVT data obtained for ethylene.

It appears that the "derby hat" region predicted by Mayer and Harrison

(9, 10) does not exist for the two systems studied. Other experiments, which are discussed in the following paper, indicate, however, that considerable molecular clustering may occur above T_c. This extensive molecular clustering is predicted by Mayer and Harrison (9, 10) at low values of $(\partial p/\partial v)_T$ and follows more rigorously from their theory than does the "derby hat" region.

COEXISTENCE PHENOMENA IN THE CRITICAL REGION

IV. TIME-DEPENDENT BEHAVIOR IN VERTICAL DISTRIBUTION OF THE CRITICAL OPALESCENCE IN ETHYLENE AND XENON[1]

By F. E. Murray[2] and S. G. Mason

ABSTRACT

The variation with height of the transmittance in the critical region at various heights in long columns of xenon and ethylene continued to change for several hours after stirring. This change with time is attributed to gravitational settling of large molecular clusters. Other experiments also indicate that a region in which extensive molecular clustering occurs is necessary for an adequate description of phase transitions in the critical region.

INTRODUCTION

In a previous paper (4), it was shown that vertical gradients in the intensity of scattered light occurred in the system ethane in the region of the critical temperature. These gradients in turbidity were destroyed by stirring and re-formed only after a considerable time lag. In the experiments to be described, these time lags were the subject of extensive study in the systems xenon and ethylene.

Mayer and Harrison (2, 3) considered a gas to be made up of a mixture of single molecules and molecular clusters formed by molecular attraction. The rate of change of pressure with volume for any gas is given, according to their work, by the relation

$$\left(\frac{\partial p}{\partial V}\right)_T = \frac{-kT}{V^2}\left(\sum_l l^2 V b_l Z^l\right)^{-1}. \qquad [1]$$

In this equation, l is the number of molecules in any cluster and the summation is taken over all values of l; b_l is the cluster integral for clusters of l molecules each; V is the average volume per molecule; and Z is defined by the relation

$$\sum l V b_l Z^l = 1.$$

When l in Eq. [1] is small, $(\partial p/\partial V)_T$ remains large, but when the large molecular clusters begin to form, l becomes large and $(\partial p/\partial V)_T$ becomes small as in the region of the critical point.

According to fluctuation theory, density deviations in small volume cells of a fluid give rise to critical opalescence. A large positive deviation in density results if the number of molecules in a volume cell is much greater than the average number in that volume. Such a deviation must bring the molecules close enough together to render important the intermolecular forces between them. In this way, a large positive deviation in density corresponds, from a physical viewpoint, to a mathematical cluster of the theory of Mayer and Harrison.

Since there is no essential conflict between fluctuation and cluster theory one can obtain an expression for the turbidity in a "cluster" gas using an equation derived by fluctuation treatment. For the turbidity τ of a gas, in terms of $(\partial p/\partial V)_T$, Rocard (6) derived an equation which we have (5) expressed in the form

$$[2] \qquad \tau = \frac{BT\rho^3}{\lambda^4}[c-(\partial p/\partial V)_T]^{-1}$$

where B and c are constants for given fluid and optical arrangements, T is the absolute temperature, and ρ and v are respectively the density and specific volume of the gas. Combining Eqs. [1] and [2] for a cluster gas yields

$$[3] \qquad \tau = \frac{BT\rho^3}{\lambda^4}\left[c+\frac{kT}{V^2}\left(\sum l^2 V b_l z^l\right)^{-1}\right]^{-1}.$$

Eq. [3] indicates that the high turbidity in the region above T_c is caused by the formation of numerous large molecular clusters.

The following symbols are used to denote experimental quantities:

T_c = the highest temperature at which visible aggregates form when the fluid is cooled slowly,
$\Delta T = (T-T_c)$,
I'/I_0' = the optical transmittance of the fluid,
$(t-t_0)$ = time elapsed since cessation of stirring,
$\bar{\rho}$ = mean density, i.e. total mass/total volume,
$\bar{\rho}_m$ = mean density at which maximum turbidity was observed,
x = distance measured downward from the top of the fluid column.

EXPERIMENTAL

The apparatus and procedures were identical to those described in previous papers (4, 5). The xenon and ethylene systems were the same as those already described (5).

RESULTS

Transmittance Gradients in Xenon

Figs, 1, 2, and 3 show typical vertical gradients of transmittance in xenon. Results in Fig. 1 were observed at an average density less than $\bar{\rho}_m$. Results in Fig. 2 were obtained at average densities very near to $\bar{\rho}_m$ such that the transmittance was a minimum near the center of the fluid column. Fig. 3 shows gradients in transmittance at a density greater than $\bar{\rho}_m$.

To obtain these results, the fluid was well stirred and after cessation of stirring, measurements were recorded when the transmittance at various levels in the bomb remained virtually constant with time. Similar results were obtained with ethylene.

Time Lags after Stirring

When the fluid was stirred, the transmittance gradients such as shown in Figs. 1, 2, and 3 were destroyed. These gradients re-formed gradually during a period of at least one hour.

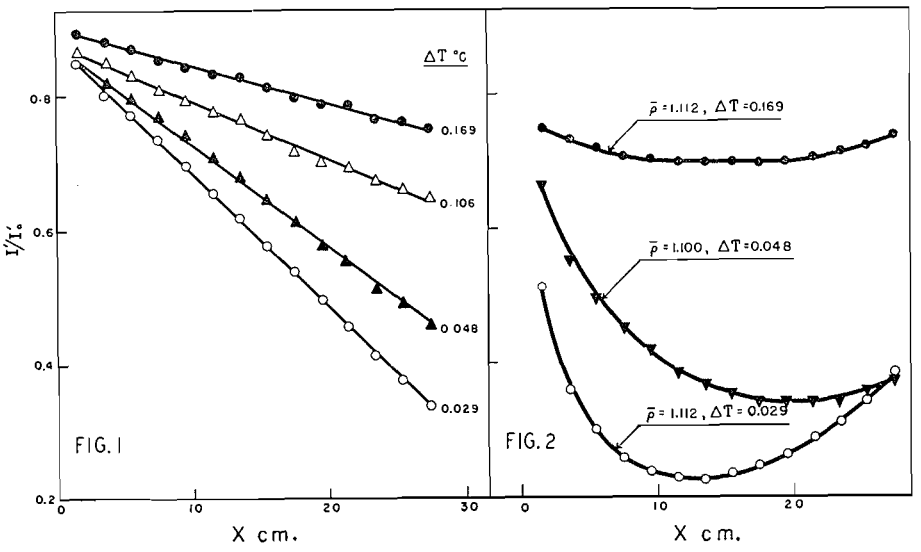

FIG. 1. Change in transmittance with distance (x) from top of vertical tube of xenon at various values of ΔT and at a mean density of 1.055 gm./cc., i.e. at $\bar{\rho} < \bar{\rho}_m$, $\bar{\rho}_m$ = 1.110 gm./cc.
FIG. 2. Transmittance–height curves in xenon at $\bar{\rho} = \bar{\rho}_m$ = 1.110 gm./cc.

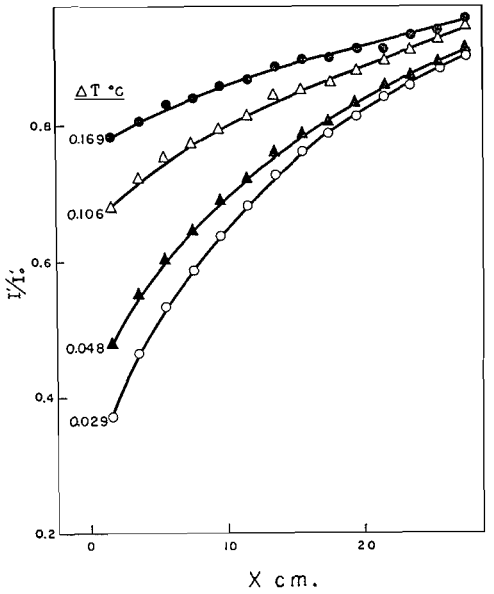

FIG. 3. Transmittance–height curves in xenon at $\bar{\rho}$ = 1.188 gm./cc., i.e. $\bar{\rho} > \bar{\rho}_m$.

Fig. 4 shows the change of transmittance with time after stirring in xenon. These diagrams typify results obtained from numerous observations. Similar behavior was observed in ethylene but the times to equilibrium were greater.

The upper diagram in Fig. 4 shows change of transmittance with time at a number of levels in the bomb, at ΔT = 0.048°C. and an average density less

than $\bar{\rho}_m$. The lower part of Fig. 4 shows results obtained at density greater than $\bar{\rho}_m$. These results illustrate the slow readjustment of the turbidity which appears visually to be due to a gravitational settling process.

Time Lags after a Turbidity Perturbation

When stirring in a fluid above T_c is stopped, rearrangement of material within the bomb takes place to establish the density gradients due to gravitational compression, which have been shown to exist (1, 4, 7, 8). The possibility of an extensive time lag in turbidity, not associated with redistribution of material, was investigated.

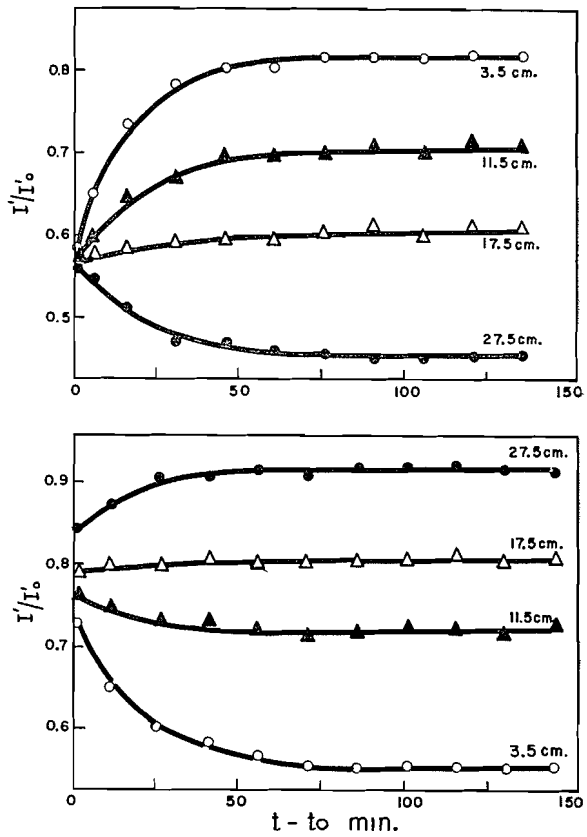

FIG. 4. Change in transmittance with time after cessation of stirring in xenon at $\bar{\rho}$ = 1.055 gm./cc., i.e. $\bar{\rho} < \bar{\rho}_m$ (upper diagram) and at $\bar{\rho}$ = 1.188 gm./cc., i.e. $\bar{\rho} > \bar{\rho}_m$ (lower diagram). Measurements made at various vertical heights indicated.

Xenon was allowed to attain vertical equilibrium, after stirring at $\bar{\rho}$ = 1.100 gm./cc. and ΔT = 0.048°C. The system was then rapidly compressed by means of the injector (4, 8) by a volume change of about 0.1%. This rapid compression caused a sharp increase in transmittance as shown in the lower part of Fig. 5. The transmittance was allowed to return to its precompression value and the system was rapidly expanded back to its original volume.

The rapid expansion caused a sharp decrease in transmittance. During the compression and expansion, the transmission was recorded continuously (at $x = 15.5$ cm.) on a Brush recording oscillograph.

Fig. 5 (lower part) shows a typical result of one of these experiments. The total perturbation by compression and expansion required slightly less than 1.5 min. In less than two minutes after the fluid was returned to its original volume, the turbidity had returned to its precompression value.

The upper portion of Fig. 5 shows the gradients observed at $\theta = 0$ min. (before the volume perturbation) and at $\theta = 10$ min. (after the volume

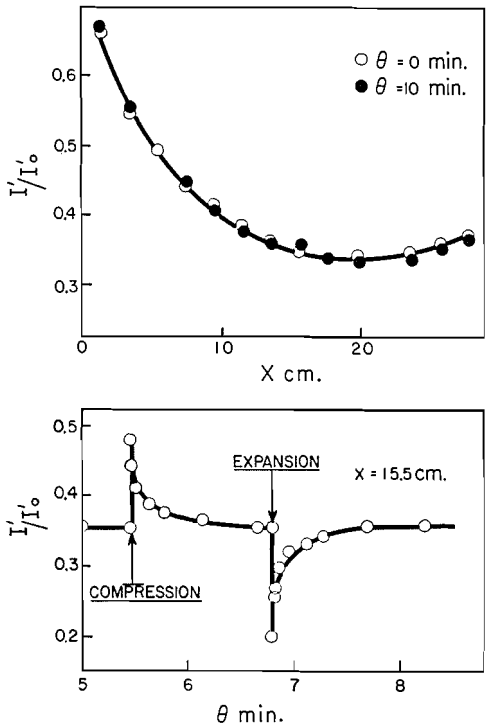

FIG. 5. The transmittance gradient in xenon immediately before (open circles) and after (solid circles) a rapid compression and expansion of xenon is shown in the upper curve. The lower curve shows the change in transmittance with time at $x = 15.5$ cm., $\bar{\rho} = \bar{\rho}_m = 1.100$ gm./cc., and $\Delta T = 0.048$°C.

perturbation). The total disturbance had no effect on the vertical transmittance gradient as shown by the coincidence of the open and closed circles.

From these results, it appears that the transmittance undergoes no protracted time lags when the vertical distribution of turbidity is not changing. Accordingly, the time lags after stirring must be associated with the slow redistribution of material in the gravitational field.

Miscellaneous Effects of Stirring

When a two phase system at $\bar{\rho} = \bar{\rho}_m$ is heated through T_c without stirring, the meniscus separating the two phases gradually becomes flat, but a visible

boundary persists over a positive interval of ΔT. A number of experiments were performed to show the result of stirring xenon after heating from below T_c without stirring. These experiments illustrate the increasing stability of a dispersion of the two phases as one approaches T_c from below. Above T_c, the two apparent phases are completely dispersible, by stirring, to a stable turbid fluid.

In the first of these experiments, xenon was heated, without stirring, from

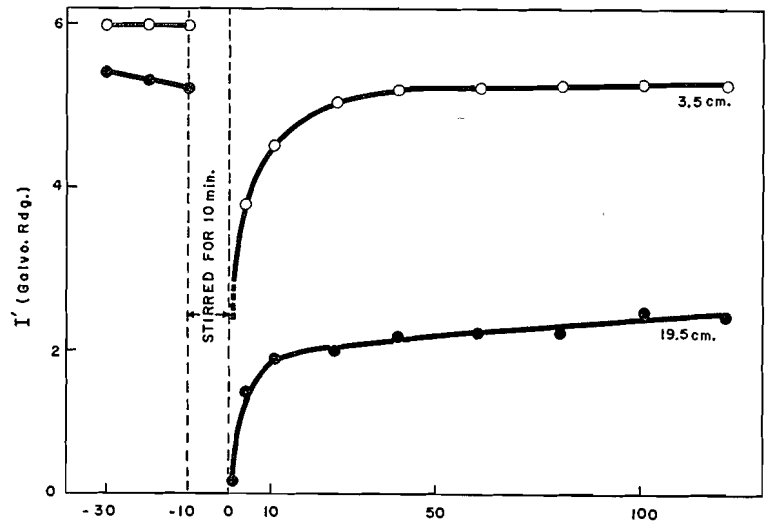

FIG. 6

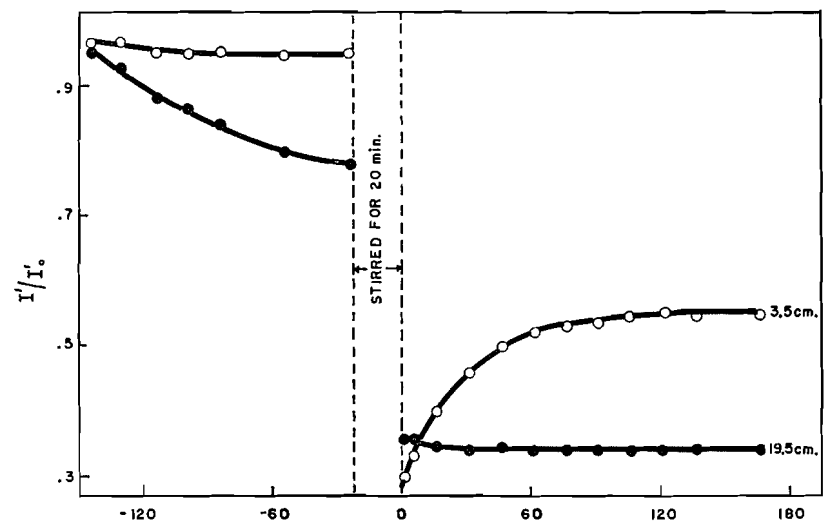

FIG.7

FIG. 6. Change in transmission readings before and after stirring xenon at $\bar{\rho} = \bar{\rho}_m = 1.100$ gm./cc. and $\Delta T = 0.027°C$.

FIG. 7. Change of transmittance before and after stirring xenon at $\bar{\rho} = \bar{\rho}_m$ and $\Delta T = 0.048°C$.

$\Delta T = -2$°C. and thermostatted at $\Delta T = -0.670$°C. No measurable change of transmission with time occurred at $\Delta T = -0.670$°C. and stirring was begun. Stirring caused complete mutual dispersion of the liquid and gas in the bomb. When stirring was stopped, the dispersion broke rapidly and the meniscus re-formed. There was no difference between transmission values observed before and after stirring.

As T_c was approached, the behavior of the dispersed system gradually changed. Fig. 6 shows the effect of stirring xenon, after heating without stirring from $\Delta T = -2$°C. to $\Delta T = -0.027$°C. Transmission readings, taken near the meniscus and near the top of the bomb, are shown as a function of $(t-t_0)$. When stirring was stopped, visible liquid droplets settled rapidly out of the gas phase to form a meniscus. This visible sedimentation was in progress during the observations at $(t-t_0) = 1$ and 4 min. At values of $(t-t_0)$ greater than five minutes, no discrete aggregates were visible above or below the meniscus and the opalescence which remained appeared visually to be identical in nature to that observed above T_c. At $(t-t_0) = 121$ min. a vertical gradient in transmission persisted throughout the fluid column.

In the experiment illustrated by Fig. 7, the xenon was heated from $\Delta T = -2$°C. through T_c, to $\Delta T = 0.048$°C. The fluid was thermostatted at this point. Before stirring, a clearly defined boundary persisted at the level $x = 20$ cm. During this time, the turbidity throughout the fluid column increased enormously. When stirring was stopped, the turbidity changed slowly throughout the bomb to reach an equilibrium distribution after about 90 min. The observed behavior resembled that which is seen when two liquid layers are dispersed by stirring to form a stable emulsion.

CONCLUSIONS

The experimental results discussed in this paper can be accounted for in terms of extensive molecular clustering in the region of T_c as was predicted by Mayer and Harrison (2, 3). The failure to observe any region within which $(\partial p/\partial V)_T$ remains zero (5) is not a serious contradiction of the more general cluster theory, but indicates that Mayer and Harrison (2, 3) may have made an erroneous assumption. This possibility is pointed out by Zimm (9) who contends that only one characteristic temperature is required to describe the phase change. In general, cluster theory, with the singular point modification of Zimm (9), seems best to describe the critical region.

TEMPERATURE COEFFICIENTS IN HYDROCARBON OXIDATION[1]

By Nan-chiang Wu Shu and J. Bardwell

ABSTRACT

The oxidation of gaseous butane has been investigated in the range 260°C. to 540°C. with reaction vessels differing greatly in surface to volume ratio. Increased surface area retards the reaction. The rate–temperature relation shows a maximum and a minimum. At low temperatures the rate is very sensitive to temperature, the apparent activation energy being greater than 100 kcal. The abnormal temperature coefficients are shown to arise in part from the differing response to temperature of the branching reactions and the initiation reactions, and in part from the occurrence of competing reactions.

The unusual effect of temperature on the rates of oxidation reactions has been pointed out by many investigators. Bodenstein (7) found that the oxidation of gaseous nitric oxide is slightly retarded by increased temperature. A similar but more pronounced effect, over a limited temperature range, was discovered by Pease in the oxidation of propane (18). Here the rate of reaction was found to pass through a maximum at 330°C. and then to decline, passing through a minimum at 380°C. The results of Pease were confirmed by Newitt and Thornes (16) and by Mulcahy (14). Anomalous temperature coefficients in oxidation reactions have been reported by others, for example by Beatty and Edgar with heptane (6), by Chamberlain and Walsh with diisopropyl ether (8), and by Bardwell and Hinshelwood with butanone (3, 4). The intervention of cool flames in hydrocarbon oxidation at certain temperatures and their disappearance at higher temperatures are related phenomena (3, 18).

When experiments are done at temperatures well below that at which a maximum occurs in the rate–temperature relation, it is frequently found that temperature now has an unusually large effect. The length of the induction period is particularly sensitive to changes of temperature. Aivazov and Neumann (1) reported that with pentane the apparent activation energy is in excess of 100 kcal. Abnormally high temperature coefficients have also been reported by Prettre (19) and by Mulcahy (14) with other hydrocarbons.

The oxidation of gaseous butane exhibits temperature effects similar to those cited for other fuels. In this paper these relations will be analyzed from the viewpoint of the theory of branching chains.

EXPERIMENTAL

Apparatus

The reaction vessel was supported vertically in a furnace and was connected to a manometer and an appropriate vacuum system. Close control of temperature was achieved by use of a "Merc-to-merc" thermoregulator and a Sunvic relay. The reactant gases were admitted separately to the vessel and the course of combustion was followed by pressure measurements.

Two reaction vessels were used, one with a low surface to volume ratio, the

[1]*Manuscript received May 17, 1955.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan. This work was supported by a grant from the National Research Council of Canada

other with a high ratio. Both vessels were made of clear silica and were cylindrical in shape, 6 cm. in external diameter and 9 cm. in length. The first vessel was empty; the second was packed with 25 silica tubes each of 0.6 cm. inside diameter. The surface to volume ratio of the packed vessel was therefore more than 10 times that of the empty vessel.

RESULTS

Analysis of Pressure–Time Curves

The autocatalytic character of the reaction between oxygen and gaseous hydrocarbons necessitates the use of some arbitrary criterion of reaction rate. Two such criteria have found extensive use in previous kinetic investigations (2, 9, 15):

(*a*) the maximum rate, ρ_{max}, i.e. the slope of the pressure–time curve at its inflection point,

(*b*) the reciprocal induction period, $1/\theta$, the induction period being the length of time between the entrance of the reactants to the vessel and the attainment of some defined rate, often the maximum rate.

Theoretical treatments of hydrocarbon oxidation, for example that of Semenov (21), have ascribed the autocatalytic nature of the reaction to a slow multiplication of reaction centers by chain branching of a degenerate type. In a reaction where chain branching occurs the number of chain centers x increases with time according to the equation

$$[1] \qquad dx/dt = B' + Ax.$$

B' is the rate of production of chain centers independent of the branching process, for example by direct interaction of fuel and oxygen. A is the branching factor. Insofar as it is permissible to consider A and B' constant in the early part of the reaction, equation [1] may be integrated to yield:

$$[2] \qquad x = (B'/A)(e^{At} - 1).$$

Thus chain centers multiply in an approximately exponential fashion, and reaction rate increases accordingly. If it is assumed that the observed rate of pressure increase dp/dt is a valid measure of reaction rate, the increase in pressure, Δp, will be proportional to $\int x dt$, i.e. proportional to:

$$(B'/A^2)(e^{At} - At - 1).$$

Combining the proportionality constant and B' to give a new term B, we obtain

$$[3] \qquad \Delta p = (B/A^2)(e^{At} - At - 1).$$

When At is considerably greater than unity the exponential term dominates and a plot of log Δp against time should be linear.

The oxidation of butane provides abundant confirmation of this prediction. Plots of log Δp against time show excellent linearity during the first third or so of the reaction; i.e. before the consumption of reactants becomes excessive. This is true both with the empty vessel and with the packed vessel, and with

wide variations of vessel temperature and reactant concentration. The precision with which the pressure–time data conform to the predicted exponential relation compares favorably with that observed in studies of the oxidation of other gaseous fuels (4, 21). For calculation it is convenient to neglect all but the exponential term in Eq. [3], i.e. to take

$$\Delta p = (B/A^2)e^{At}. \quad [4]$$

A is thus the slope of the linear portion of the plot of the natural logarithm of the pressure increase against time of reaction. B is calculated from the intercept and slope of this plot, and has the units of mm./min^2. B will henceforth be called the initiation factor, whereas A will be called the branching factor. The units of A are min^{-1}.

The use of Eq. [4] rather than the more exact Eq. [3] for estimating A and B introduces an approximation, the magnitude of which is exemplified by the following data for an experiment with the empty vessel at 270°C. using 100 mm. each of butane and oxygen. Here Δp increased from 5.8 mm. at 8 min. to 20.1 mm. at 10 min. Calculated values of A and B are given in Table I. The errors introduced by use of the approximate but much more convenient Eq. [4] are not serious for present purposes, since discrepancies are always in the same direction and are small compared with the alteration of A and B with temperature (see below).

Effect of Temperature on Maximum Rate and Reciprocal Induction Period

The general effect of temperature on oxidation rate with butane may be seen in Figs. 1–3, in which the logarithms of the usual criteria of reaction rate, ρ_{max} and $1/\theta$, are plotted against the reciprocal of the absolute temperature. Fig. 1 shows that with the empty vessel, the reciprocal induction period, $1/\theta$, passes through a maximum at about 350°C. and a minimum at about 430°C. The corresponding results for the maximum rate ρ_{max} are shown in Fig. 2. The curves resemble those in Fig. 1 in that the minima again occur at about 430°C. However, with the pressures used slow combustion gives way to cool flames over a considerable range of temperature and the curves for ρ_{max} are therefore not continuous.

When the packed vessel was used instead of the empty vessel, the reaction was considerably slower and cool flames appeared only in exceptional circumstances. Measurements of ρ_{max} and $1/\theta$ in the range 314°C. to 540°C. yielded the results shown in Fig. 3, which are qualitatively similar to those obtained using the empty vessel and lower pressures. The results also illustrate the two unusual temperature effects with which we are here principally concerned:

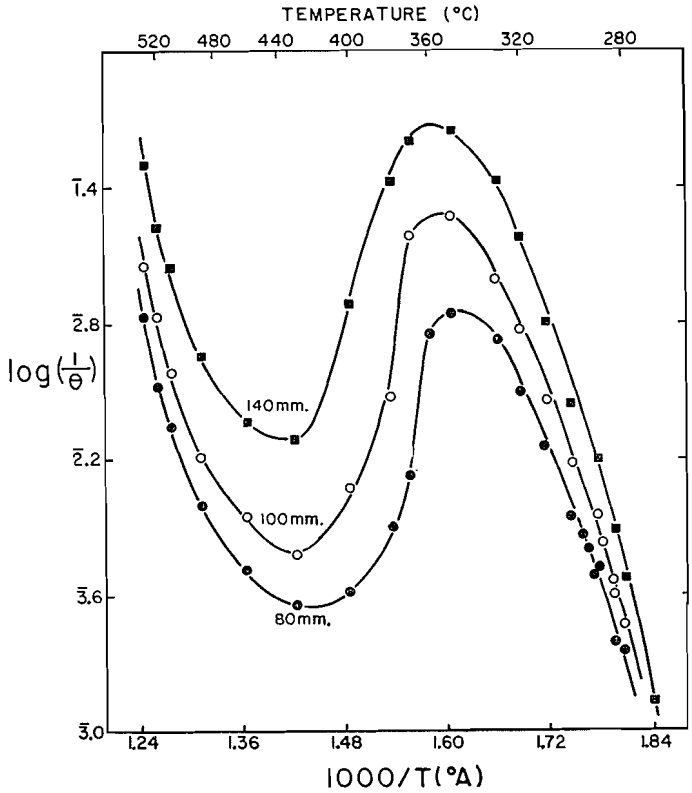

FIG. 1. Effect of temperature on the reciprocal induction period with equimolecular mixtures of butane and oxygen and an empty vessel 6 cm. in diameter. Total reactant pressure is shown.

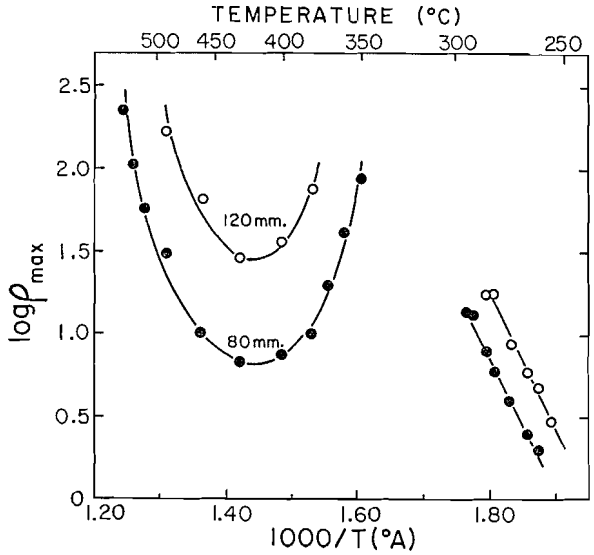

FIG. 2. Effect of temperature on the maximum rate of oxidation of butane with equimolecular mixtures of butane and oxygen and an empty vessel 6 cm. in diameter. Total reactant pressure is shown.

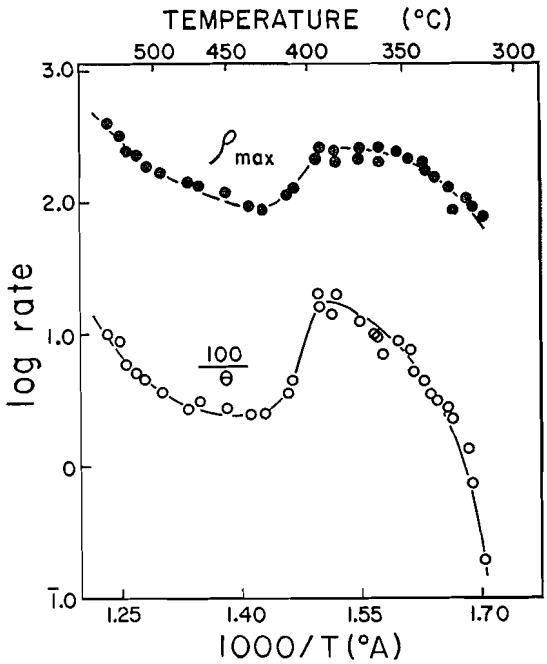

FIG. 3. Effect of temperature on the maximum rate of oxidation and on the reciprocal induction period using a packed vessel and equimolecular mixtures of butane and oxygen at a total pressure of 200 mm.

(*a*) The decline of reaction rate with rising temperature, which here occurs between 395°C. and 430°C. We shall henceforth refer to this negative effect of temperature as the anomalous temperature coefficient.

(*b*) The great sensitivity of the induction period to changes of temperature in the low temperature region. For example the data plotted in Fig. 3 show that on lowering the temperature from 324°C. to 314°C., the induction period increases from 50 sec. to 500 sec.

The Initiation Factor and the Branching Factor at Low Temperatures

Since the abnormal temperature coefficients noted above must arise from unusual sensitivity to temperature of the initiation factor, B, or of the branching factor, A, or of both, it is of interest to explore the effect of temperature on each of these factors. The exceptionally large temperature coefficient at low temperatures will be considered first.

When the pressure–time curves were analyzed by the method described above it was found that the initiation factor B was much more temperature-dependent than the branching factor A. For example, the results plotted in Fig. 3 in the temperature range 314°C. to 345°C. yield an apparent activation energy of 31 kcal. for A but a value of over 120 kcal. for B. In fact, the temperature coefficient of B becomes essentially infinite at about 314°C. with the pressure used.

The above relationships were investigated further in a series of experiments using 200 mm. each of butane and oxygen, again with the packed vessel. Convenient rates were obtained in the temperature range 260°C. to 305°C.

The results are shown in Fig. 4 and the calculated activation energies given in Table II. Of the four quantities plotted it is seen that the initiation factor B is by far the most sensitive to temperature, the values increasing by a factor of about 10^{13} for a temperature increase of 45°C. Considerable sensitivity to temperature is also shown by $1/\theta$, particularly in the range 260°C. to 270°C. In this 10-degree interval, $1/\theta$ increases by a factor of about five whereas ρ_{max} and A are approximately doubled. On the other hand B increases by a factor

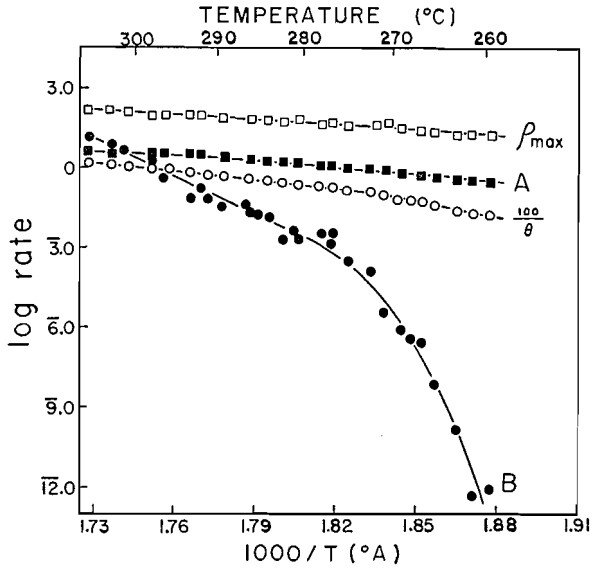

FIG. 4. Effect of temperature on maximum rate (ρ_{max}), reciprocal induction period ($100/\theta$), branching factor (A), and initiation factor (B) using a packed vessel and equimolecular mixtures of butane and oxygen at a total pressure of 400 mm.

of about 30 million. It may be concluded therefore that the large dependence of $1/\theta$ on temperature in this range is derived from the initiation factor rather than from the branching factor.

Experiments with the empty vessel gave results that confirmed the above conclusions for the packed vessel. For example, measurements in the temperature range 273°C. to 294°C. with 100 mm. each of butane and oxygen showed that the apparent activation energy of B was about 100 kcal. whereas that of A was about 68 kcal.

Temperature range (°C.)	Activation energy (kcal.)			
	ρ_{max}	$1/\theta$	A	B
275° to 305°C.	30	49	38	220
260° to 270°C.	41	93	46	1000

Limiting Pressure for Finite Induction Periods

The large variation of induction period with temperature appears to be related to the existence of pressure limits in hydrocarbon oxidation. Here we shall not be concerned with the pressure limits delineating the regions of occurrence of slow combustion, cool flames, ignition, etc., but only with the low-pressure limit which marks the transition from finite to infinite induction periods. The existence of such a limit has been clearly demonstrated by Malherbe and Walsh (13) who showed that a plot at constant temperature of induction period against pressure yielded an asymptote of a definite positive pressure. Below this pressure the induction period was of infinite duration. Using a vessel with an effective diameter intermediate between those employed in the present investigation, Malherbe and Walsh showed that the low-pressure limit increased with decreasing temperature (13).

Our measurements have in general confirmed the above conclusions and have shown, furthermore, that the low-pressure limit increases with increasing surface to volume ratio (see Fig. 5). The low-pressure limit, P_c, is readily

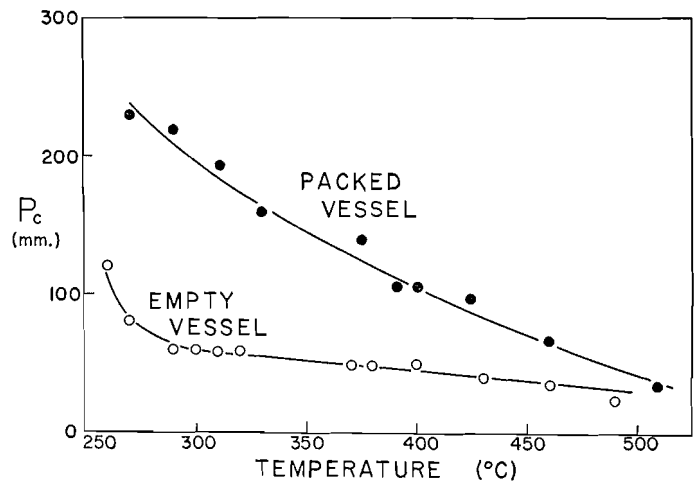

FIG. 5. Effect of temperature on the low-pressure limit. P_c is the total pressure of an equimolecular mixture of butane and oxygen at which the induction period becomes infinite.

determined by extrapolation of a plot of $1/\theta$ against pressure. Experiments with pressures slightly below this limit show that no perceptible reaction occurs even after many hours. Reaction can, however, be induced by the addition of a small amount of acetaldehyde (14) and it is of interest that the values of A and ρ_{max} then determined agree well with those obtained without acetaldehyde just above the pressure limit. Additions of acetaldehyde to reaction mixtures just above the low-pressure limit greatly increase B but have only a small effect on A. From these results it may be concluded that although favorable conditions for chain branching may still exist below the low-pressure limit the induction period is infinite because the effective rate of initiation is zero.

The Anomalous Temperature Coefficient

Attempts were made to analyze the sharp decline of reaction rate at about 400°C. by assessing the temperature coefficients of the branching factor and initiation factor. The empty vessel proved to be unsuitable for this purpose since the reaction rate was very high in the temperature range of interest (see Fig. 2). Even with the packed vessel where reaction was somewhat slower it was difficult to determine precise values of A and B over a considerable temperature range with any chosen constant pressure of reactants. The trends observed however are illustrated by the results given in Table III, which allow

TABLE III

EFFECT OF TEMPERATURE ON ρ_{max}, $1/\theta$, A, AND B IN THE REGION OF THE ANOMALOUS TEMPERATURE COEFFICIENT

Butane pressure: 70 mm.; oxygen pressure: 70 mm.

Temperature (°C.)	ρ_{max} (mm./min.)	$1/\theta$ (sec.$^{-1}$)	A (min.$^{-1}$)	B (mm./min.^{2})
368	83	0.030	8.9	6.7
382	20	0.0056	1.7	0.22

comparison of the behavior at 368°C. with that at 382°C. The latter temperature is approximately that for minimum reaction rate with the pressure employed. It is seen that here the sharp decline in ρ_{max} and $1/\theta$ is accompanied by substantial decreases in both A and B.

DISCUSSION

Temperature Coefficients

Although the experiments reported above have been confined to the oxidation of butane, comparison with other investigations shows that a wide range of temperature coefficient is a common property of the gas-phase oxidation of hydrocarbons (10, 12). Search for the origin of this behavior is considerably assisted by the exponential form of the pressure–time curve in butane oxidation, and by the opportunity thereby provided of estimating separately the branching rate and the initiation rate. It has been shown above that these two rates can differ greatly in their temperature dependence.

The large temperature coefficient of the induction period at low temperatures (Figs. 3 and 4) is apparently associated with the low-pressure limit (Fig. 5). Since this limit moves toward higher pressures as the temperature is lowered, it follows that when a series of experiments is done with constant pressures at successively lower temperatures the induction period will become infinite at (and below) some definite temperature. Comparison of Fig. 3 with Fig. 5 shows that it is just above this temperature that the induction period is most temperature-sensitive.

The Origin of the Low-pressure Limit

Malherbe and Walsh (13) have suggested that the low-pressure limit in hydrocarbon oxidation is similar in origin to that observed in the hydrogen–oxygen reaction, and represents the pressure above which the branching factor becomes positive and below which it is negative. Our results do not

support this explanation. Fig. 4 shows that the rapid lengthening of the induction period as the limit is approached, here by a decrease of temperature, is due to the approach to zero of the initiation factor B. It is also apparent from Fig. 4 and Table II that in this range the branching factor A is neither very small nor very temperature-sensitive. It seems very unlikely therefore that the branching factor would drop abruptly to zero when the temperature is lowered a few degrees more. The suggestion of Malherbe and Walsh also encounters difficulties in explaining the observed effect of adding small amounts of acetaldehyde along with the fuel and oxygen. As already noted, these additions to mixtures above the low-pressure limit greatly increase the initiation factor but have only a slight effect on the branching factor. The addition of acetaldehyde to mixtures just below the limit, i.e. where the induction period would normally be infinite, induces reaction which then displays a branching factor of substantial magnitude, and comparable to that observed just above the limit. These effects are not consistent with a vanishing of A at the limit but are quite in harmony with a vanishing of B.

The Anomalous Temperature Coefficient

It has been shown above that when the temperature approaches 400°C. the oxidation rate, as judged by either ρ_{max} or $1/\theta$, passes through a maximum and then declines. This behavior, as well as the resurgence of reaction at still higher temperatures, is similar to that reported in investigations of the combustion process with other paraffin hydrocarbons (18, 20). The customary interpretation is that at high temperatures the mechanism involves formaldehyde and relatively simple atoms and radicals, but that at lower temperatures complex molecules such as peroxides and higher aldehydes play an important part (11, 17). The decline of reaction rate with rising temperature at about 400°C. is taken as a sign of the decreasing importance of these compounds as combustion intermediates. Although the reactions responsible for this effect have not yet been firmly established, two reasonable possibilities exist:

(*a*) the combustion intermediate is wasted through its participation in reactions leading to inactive products (9, 20),

(*b*) the combustion intermediate is produced in smaller amounts because of pyrolytic destruction of one of its precursors in the chain sequence (22).

It has been shown in Table III that both the branching factor and the initiation factor are sharply reduced by a small rise of temperature in the region of the anomalous temperature coefficient. The decline of the initiation factor contributes to the lengthening of the induction period, but the decrease of the branching factor is more important since it affects both the induction period and the maximum rate, ρ_{max} (5).

Explanation by Competing Reactions

There remains the need for an explanation of the vanishing of the initiation factor and the branching factor at particular temperatures. For simplicity we may assume that a relatively stable combustion intermediate is formed which undergoes two modes of decomposition, one leading to its regeneration in increased quantity, the other leading to comparatively inert products. It may

be shown (5, 21) that when two such competing reactions occur the branching factor A is the difference of two terms, e.g. A_1-A_2. Each of these terms presumably increases with rising temperature, the rates of increase being determined by the respective activation energies E_1 and E_2. Now if $E_2 > E_1$, the variation of log (A_1-A_2) with $1/T$ will be as sketched in Fig. 6(*a*). At a sufficiently low temperature the apparent activation energy of the branching factor approaches that of A_1, but as the temperature is increased A_1-A_2 passes through a maximum and then falls off sharply. In this way the anomalous temperature coefficient at about 400°C. is accounted for, although the predicted vanishing of A is obscured by the intervention of the high-temperature mechanism of oxidation.

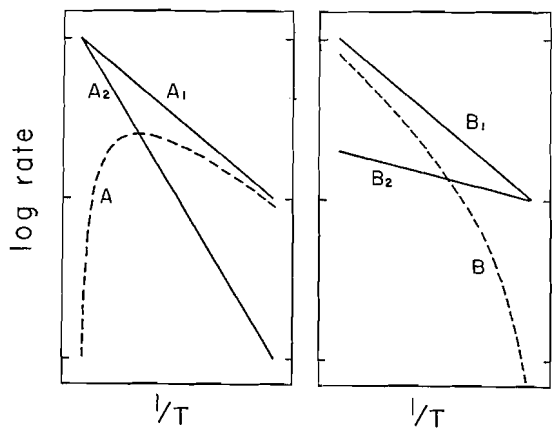

FIG. 6. Schematic diagrams explaining abnormal temperature coefficients.
Diagram (*a*), on left, $A = A_1-A_2$; activation energy of A_1 less than that of A_2.
Diagram (*b*), on right, $B = B_1-B_2$; activation energy of B_1 greater than that of B_2.

The extreme temperature-sensitivity of the initiation factor, B, at lower temperatures is explicable in a generally similar way. We may consider the measured initiation factor as being the difference of two terms, e.g. B_1-B_2, where B_2 represents inhibiting influences. If the activation energy of B_1 is greater than that of B_2 the variation of log (B_1-B_2) with $1/T$ will be as sketched in Fig. 6(*b*). The very large apparent activation energy of B (Table II) and the existence of a temperature below which the induction period is infinite (Fig. 5) are consistent with this diagram.

SYNTHESES OF A SERIES OF 15-KETOGLYCOLS AND 15-KETO FATTY ACIDS FROM USTILIC ACID[1]

By A. T. Crossley[2] and B. M. Craig

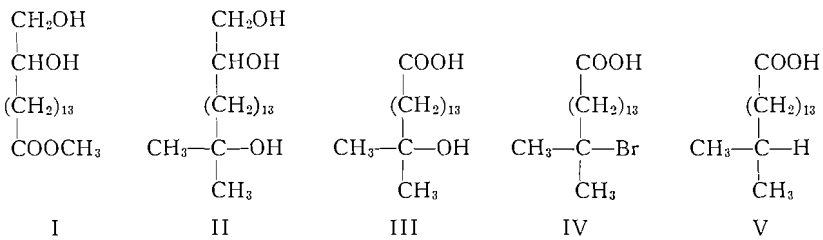
ABSTRACT

Reaction of the methyl ester of ustilic acid A (15,16-dihydroxypalmitic acid) with a methyl Grignard, oxidation of the glycol grouping, bromination, and hydrogenolysis produced 15-methylhexadecanoic acid. A series of 15-keto acids resulted from reaction of the amide of ustilic acid A with the appropriate Grignard reagent followed by oxidation of the glycol grouping. Infrared absorption characteristics of these compounds are described.

Ustilagic acid has been produced by fermentation using a culture of *Ustilago zeae* (2). Ustilic acid A (15,16-dihydroxypalmitic acid) and ustilic acid B (2,15,16-trihydroxypalmitic acid) are produced by hydrolysis of ustilagic acid (4). These acids are easily separated from the remainder of the hydrolysis products and from one another and are potentially available in large quantities.

The ustilic acids possess a carboxyl group at one end of the molecule and an easily oxidizable glycol grouping at the other end and as such should constitute valuable starting materials for the synthesis of various new and naturally occurring long chain compounds. The present investigation deals with the synthesis of 15-methylhexadecanoic acid and a series of 15-keto acids.

A number of methyl branched fatty acids which are primarily concerned with the wool fats have been synthesized by a number of workers (1, 3, 7, 8, 9). These syntheses have involved the preparation of appropriate fragments followed by chemical coupling or anodic syntheses. Weitkamp (9) prepared 15-methylhexadecanoic acid from a lower homologue and Stenhagen *et al.* synthesized the same acid (1). Ustilic acid A is a convenient starting material for the synthesis of this acid by the following series of reactions:



I II III IV V

Methyl ustilate A (I) was converted in almost theoretical yield into the tertiary alcohol II, m.p. 55.5–56.0° C., by using a large excess of methylmagnesium bromide. Reaction of methyl isopropylidene ustilate A with the Grignard reagent followed by removal of the isopropylidene grouping with

methanolic hydrochloric acid gave a very poor yield of II. Oxidation of II with chromic oxide in acetic acid at low temperature gave 15-methyl-15-hydroxyhexadecanoic acid III, m.p. 70.5–71.5° C., which yielded *p*-bromophenacyl derivative, m.p. 80.6–81.0° C. This oxidation was also carried out using lead tetraacetate and oxygen as described below. The hydroxy acid III was treated with hydrogen bromide in acetic acid to give the tertiary bromo derivative IV, m.p. 45–46° C., which, on treatment with hydrogen and Raney nickel in ethanolic sodium hydroxide, gave 15-methylhexadecanoic acid V, m.p. 60.7–61.3° C. (reported m.p. 59.3–59.9° C. (1) and 60.2° C. (9)).

The synthesis of a series of 15-keto acids was carried out by the series of reactions given below. To favor the formation of the ketoglycol rather than the tertiary alcohol derivative, the amide of ustilic acid A was used as a starting material in the Grignard reaction. The reaction of amides with Grignard reagents has been investigated by Whitmore *et al.* (10, 11). To increase solubility the isopropylidene derivative (VII) was used. Reaction of the latter with 1.1 moles of methylmagnesium bromide gave a poor yield of the ketone (VIII) (R = CH_3), m.p. 40.0–41.0° C., semicarbazone m.p. 123.5–124.0° C., but the yield was increased by the use of 100% excess of the Grignard reagent. A small amount of the tertiary alcohol formed was separated on alumina. The corresponding ethyl, propyl, and butyl homologues (VIII) were also prepared by using the appropriate Grignard reagents. These had melting points, respectively, of 37° C. (R = C_2H_5), 43° C. (R = C_3H_7), and 48.5° C. (R = C_4H_9). Removal of the isopropylidene group afforded the free ketoglycols (IX) which are described in Table I. Purification of the latter compounds was greatly facilitated by a treatment with warm alcoholic alkali before crystallization from benzene.

TABLE I

MELTING POINTS AND ELEMENTAL ANALYSIS OF KETOGLYCOLS AND KETO ACIDS

Compound	Formula	M.p., °C.	Found		Calculated	
			C (%)	H (%)	C (%)	H (%)
1,2-Dihydroxy-16-ketoheptadecane	$C_{17}H_{34}O_3$	83.0–83.7	71.34	12.07	71.28	11.96
1,2-Dihydroxy-16-ketooctadecane	$C_{18}H_{36}O_3$	93.8	72.43	11.48	72.44	11.51
1,2-Dihydroxy-16-ketononadecane	$C_{19}H_{38}O_3$	92.5	73.39	11.59	73.02	11.61
1,2-Dihydroxy-16-ketoeicosane	$C_{20}H_{40}O_3$	93.9	73.08	12.07	73.11	12.27
15-Ketohexadecanoic acid*	$C_{16}H_{30}O_3$	82.3	70.86	11.10	71.07	11.18
15-Ketoheptadecanoic acid	$C_{17}H_{32}O_3$	85.7–86.1	71.73	11.44	71.78	11.34
15-Ketooctadecanoic acid	$C_{18}H_{34}O_3$	83.4	72.44	11.51	72.43	11.48
15-Ketononadecanoic acid	$C_{19}H_{36}O_3$	85.7	73.39	11.59	73.03	11.61

**Semicarbazone, m.p. 129.6° C. (C, 62.57; H, 10.22; N, 12.82%. Calc. for $C_{17}H_{33}O_3N_3$: C, 62.35; H, 10.16; N, 12.83%.)*

These ketoglycols (IX) were converted to 15-keto fatty acids (X) by simultaneous oxidation with lead tetraacetate and oxygen at 50° C. according to the method of Mendel and Coops (6). The oxidation products were purified by distillation and crystallization from alcohol. The melting points of these four, hitherto unprepared, keto fatty acids are given in Table I.

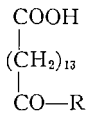
IX



X

Infrared absorption determinations were made on all the compounds with a Perkin-Elmer Model 21 instrument equipped with a sodium chloride prism, and the crystalline samples were mounted in KBr. The 15-methyl-15-hydroxy-hexadecanoic acid showed OH absorption bands at 3440 and 1152 cm.$^{-1}$, and also several poorly resolved bands between 1390 and 1300 cm.$^{-1}$ which might be caused by the $(CH_3)_2C$— group. The 15-methylhexadecanoic acid showed two clearly resolved bands at 1385 and 1365 cm.$^{-1}$ which are characteristic for branched methyl groups. These bands were absent in the spectrum of pure hexadecanoic acid. The 1,2-dihydroxy-15-keto compounds showed the expected hydroxyl band between 3400 and 3200 cm.$^{-1}$ and also two absorption bands at 1100 and 1082 cm.$^{-1}$ which could be assigned to a secondary and a primary hydroxyl group respectively. They also showed the ketonic carbonyl absorption between 1710 and 1705 cm.$^{-1}$. The corresponding 15-keto acids showed absorptions in the 1700 cm.$^{-1}$ and the 900–700 cm.$^{-1}$ regions characteristic for carboxylic acids. Resolutions of the carboxyl C=O and ketone C=O were achieved in the 1720–1700 cm.$^{-1}$ region for 15-ketohexadecanoic and 15-ketoheptadecanoic acids but not for 15-ketooctadecanoic and 15-keto-nonadecanoic acids. The C=O absorption band in the latter was much wider than for the corresponding 15-keto-1,2-dihydroxy-nonadecane and -eicosane.

EXPERIMENTAL

NOTE: All melting points are corrected and determinations have been made in each case in the usual manner and also on a heating stage microscope.

Separation of the Ustilic Acids

A ustilic acid mixture (158 gm.), prepared by hydrolysis of ustilagic acid (4), was shaken for four hours with 1 liter of dry acetone containing 1% sulphuric acid. A small amount of inorganic material remained insoluble and the solution was filtered into a separatory funnel containing 3 liters of ice-cold water. The solution was extracted with 1.6 liters of petroleum ether (b.p. 60–80° C.) and the mother liquor was extracted with a further 1 liter. The combined petroleum ether extracts were washed three times with water. A cold solution of 60 gm. of potassium hydroxide in 420 ml. of water was then added and after

one minute's shaking, 450 ml. of 40% aqueous ethanol was added and the aqueous layer run off. The petroleum ether extract was then washed with 500 ml. of 3% aqueous potassium hydroxide and three times with 30% aqueous ethanol. The five aqueous ethanol washings were combined and diluted with 1 liter of water and re-extracted with 400 ml. petroleum ether, the extract being added to the main bulk of petroleum ether solution. The aqueous extract was acidified with sulphuric acid and extracted with chloroform to yield 163 gm. of crude isopropylidene ustilic acid A which was recrystallized from acetone to m.p. 64–65° C. The petroleum extracts gave 12 gm. of diisopropylidene ustilate B, m.p. 42–43° C., reported m.p. 42.5–43° C. (5).

The proportions of the ustilic acids in the mixture have been found to vary slightly and the present mixture represents the highest proportion of ustilic acid A which has been found. The amount may fall to about 70% of the mixture of acids.

Methyl Isopropylidene Ustilate A

Isopropylidene ustilate A (154 gm.) was esterified with diazomethane in dry ether to yield 160 gm. of the crude product as outlined in the procedure of Lemieux (5). Two crystallizations from acetone at 4° C. gave the pure methyl ester, m.p. 46.3–46.7° C., reported m.p. 46–47° C. (5).

Methyl Ustilate A

Isopropylidene ustilic acid A (20 gm.) was boiled under reflux with 4% methanolic HCl for two hours as outlined by Lemieux (5). The solution was poured into water and extracted with chloroform to give 16.2 gm. of crude methyl ustilate A, which after three crystallizations from ethanol had m.p. 85.2–86.1° C., reported m.p. 85.5–86.0° C. (5).

1,2,16-Trihydroxy-16-methylheptadecane

Methyl ustilate A (10 gm.) in 200 ml. of dry ether was added during one hour, with rapid stirring, to 23.5 gm. of methylmagnesium iodide in 300 ml. of ether, the mixture being allowed to reflux continuously during the addition. The semisolid reaction mixture was boiled under reflux for 10 hr. and was then decomposed with water and acetic acid. The crude tertiary alcohol, 10.1 gm., m.p. 54.0–55.0° C., was extracted with chloroform. The 1,2,16-trihydroxy-16-methylheptadecane purified by one crystallization from acetone had a m.p. 55.5–56.0° C. Calc. for $C_{18}H_{38}O_3$: C, 71.50; H, 12.60%. Found: C, 71.33; H, 12.50%.

15-Hydroxy-15-methylhexadecanoic Acid

The above tertiary alcohol (5.0 gm.) was dissolved in 140 ml. of acetic acid containing 7.0 gm. of chromic oxide and the solution allowed to stand for 12 hr. at 3° C., when it was diluted with ice-cold water (1 liter) and extracted with benzene. The benzene solution was washed with water until neutral and the benzene evaporated. The crude hydroxy acid was then taken up in 100 ml. of ether and the ether washed twice with 5% aqueous potassium hydroxide, and twice with water. The combined washings were acidified with sulphuric acid and extracted with ether to yield 2.63 gm. of 15-hydroxy-15-methyl-

hexadecanoic acid, which was purified by three crystallizations from acetone and crystallized as colorless needles, m.p. 70.5–71.5° C. Calc. for $C_{17}H_{34}O_3$: C, 72.10; H, 11.95%. Found: C, 72.45%; H, 12.06%.

15-Bromo-15-methylhexadecanoic Acid

The hydroxy acid (1.39 gm.) was dissolved in 10 ml. of a 50% solution of hydrobromic acid in acetic acid and left for 14 hr. at 22° C. The solution was then diluted with 100 ml. of ice-cold water and the product extracted with benzene. Yield, 1.71 gm.; m.p. 45.0–46.5° C. Calc. for $C_{17}H_{33}O_2Br$: Br, 22.6%. Found: Br, 22.5%.

15-Methylhexadecanoic Acid

The 15-bromo-15-methylhexadecanoic acid (1.65 gm.) was dissolved in 25 ml. of ethanol, and 50 ml. of ethanol containing 5 ml. of 4 *N* sodium hydroxide added, together with a small amount of Raney nickel. The mixture was shaken with hydrogen under a pressure of 25 p.s.i. for 14 hr. at 25° C. The solution was filtered, poured into dilute sulphuric acid, and the product extracted with ether. Unexpectedly this material contained a large proportion of unsaturated material (iodine value 40) and it was therefore hydrogenated, in a similar medium to that previously used, but at a temperature of 80° C. and a pressure of 800 p.s.i. of hydrogen, for four hours. The product was saturated (iodine value 0), and was purified by distillation followed by three crystallizations from ethanol. The pure 15-methylhexadecanoic acid had m.p. 60.7–61.3° C. (reported m.p. 59.3–59.9° C. (1) and 60.2° C. (9)). Calc. for $C_{17}H_{34}O_2$: C, 75.56; H, 12.59%. Found: C, 75.45; H, 12.72%. The *p*-bromophenacyl derivative had a m.p. 83.1–83.6° C. Calc. for $C_{25}H_{39}O_3Br$: C, 64.23; H, 8.41; Br, 17.1%. Found: C, 63.61; H, 8.64; Br, 17.4%.

Isopropylidene Ustilamide A

Methyl isopropylidene ustilate A (70 gm.), together with 1500 gm. of a 25% (wt.) solution of ammonia in methanol (prepared and kept below 0° C.), was heated to 180° C. in a sealed bomb for six and one-half hours. The product was poured into 3000 ml. of ice-cold water and the precipitated amide filtered off and washed with 1000 ml. of cold water. This material was dried and then boiled with 500 ml. of ether, and the slurry cooled to 5° C. when it was filtered. The precipitate was washed with 300 ml. of cold ether. Thirteen grams of unchanged methyl isopropylidene ustilate A were recovered from the ethereal filtrate and 55 gm. of crude amide were obtained, which crystallized from methanol as colorless plates, m.p. 99.7–100.3° C. Calc. for $C_{19}H_{37}O_3N$: C, 69.67; H, 11.39; N, 4.15%. Found: C, 69.62; H, 11.32; N, 4.17%.

Reaction of Isopropylidene Ustilamide A with Grignard Reagents

A solution of methylmagnesium bromide was prepared by slow addition of 236 gm. of a 17% solution of methyl bromide in dry ether (prepared by passing methyl bromide gas into dry ether at 0° C.) to 10.0 gm. of magnesium in 300 ml. ether. The Grignard reagent was allowed to settle, decanted, and its strength determined by titration.

A solution of methylmagnesium bromide in 440 ml. ether containing 47.5 gm.

(1.9 times theoretical) of the reagent was added to a solution of 33.9 gm. of isopropylidene ustilamide A, dissolved in 1500 ml. of a mixture of equal volumes of dry benzene and dry ether, with stirring, the solution being allowed to reflux during the addition. The solution was heated under reflux for a further eight hours, and the product was isolated in the usual manner. It was then dissolved in 50 ml. of ether and a small amount of unchanged amide was filtered off. The crude ketone (32.79 gm.) was dissolved in a small amount of benzene, transferred to an alumina column (14 cm. × 5 cm.), and eluted with benzene. The material in the first 150 ml. of eluate (0.3 gm.) was discarded and the pure ketone (25.0 gm.) was isolated from the next 8000 ml. of eluate. The isopropylidene ether of 1,2-dihydroxy-16-ketoheptadecane had m.p. 40.0–40.5° C. Calc. for $C_{20}H_{38}O_3$: C, 74.12; H, 11.74%. Found: C, 73.9; H, 11.85%. Its semicarbazone had m.p. 123.5–124.0° C. Calc. for $C_{21}H_{41}O_3N_3$: C, 65.75; H, 10.77; N, 10.96%. Found: C, 65.79; H, 10.71; N, 11.00%. Three homologous ketones were prepared in a similar manner by using ethyl-, propyl-, and butyl-magnesium bromide Grignard reagents. These were purified by recrystallization and the melting points were respectively 37.0° C. (R = C_2H_5), 43.0° C. (R = C_3H_7), and 48.5° C. (R = C_4H_9).

1,2-Dihydroxy-16-ketoheptadecane

The 1,2-isopropylidene ether of 16-ketoheptadecane (8.0 gm.) was dissolved in 70 ml. of chloroform and the solution cooled to 5° C. Thirty milliliters of a 20% (wt.) solution of hydrochloric acid in 85% aqueous methanol was added and the solution allowed to stand at 20° C. for two hours. Water (100 ml.) was added and the product (m.p. 72–76° C.) extracted with chloroform. It was then dissolved in 50 ml. of 3% alcoholic potassium hydroxide solution and kept at 50° C. for 20 min. The solution was poured into 300 ml. of cold water and the methyl ketoglycol, 5.5 gm., m.p. 78–81° C., was filtered off and recrystallized three times from benzene, the pure product having m.p. 83.0–83.7° C. The products from the reaction of the ethyl, propyl, and butyl Grignards were treated in a similar manner to prepare the three other homologues whose constants are given in Table I.

15-Ketohexadecanoic Acid

Lead tetraacetate (300 mgm.) was dissolved in 25 ml. of dry benzene in a 50 ml. three-necked flask fitted with a stirrer, dropping funnel, and a condenser through which a glass tube passed and projected below the surface of the solution in the flask. 1,2-Dihydroxy-16-ketoheptadecane (500 mgm.) dissolved in 10 ml. of benzene (solution was maintained by the use of an infrared lamp) was added over a period of six hours from a dropping funnel. During addition the reaction mixture was stirred and maintained at a temperature of 50° C. and a stream of dried oxygen saturated with benzene was passed through the solution. At intervals of 45 min. 450 mgm. of lead tetraacetate was added to the solution. After the addition of ketoglycol was complete, the mixture was maintained at 50° C. with stirring for a further one and one-half hours, when 100 mgm. of ethylene glycol was added. After a further 10 min.

the warm solution was filtered and 10 ml. 30% acetic acid and then 100 ml. of water was added to the filtrate and the product extracted with benzene.

The benzene layer was washed once with water and the washings discarded. The keto acid was then extracted from the benzene layer by one washing with 50 ml. of 10% aqueous potassium hydroxide solution and two washes with water, disregarding emulsions formed owing to the rather low solubility of the potassium salt. The combined aqueous washings were acidified with sulphuric acid and extracted with benzene to yield 310 mgm. of the crude ketohexadecanoic acid. This was purified by conversion to its methyl ester, which was distilled and then reconverted to the free acid, which was crystallized four times from 95% methanol.

The ethyl, propyl, and butyl keto acids (Table I) were prepared similarly except that it was found unnecessary to convert to the methyl ester for the distillation of the crude product. The yield was found to decrease slightly as the molecular weight of the product increased.

ACKNOWLEDGMENT

The authors wish to express their thanks to J. A. Baignee for the microanalyses and to Miss Agnes Epp for the infrared studies.

THE REACTION OF 2-ALKYLTETRAHYDROPYRANS WITH ANILINE OVER ACTIVATED ALUMINA[1]

By H. P. Richards[2] and A. N. Bourns

ABSTRACT

The vapor-phase reaction over activated alumina of 2-ethyltetrahydropyran with aniline gave 1-phenyl-2-ethylpiperidine, 1-phenyl-2-propylpyrrolidine, N-phenyl-4-heptenylamine, and N-phenyl-5-heptenylamine. 2-Methyltetrahydropyran with aniline gave 1-phenyl-2-methylpiperidine, 1-phenyl-2-ethylpyrrolidine, N-phenyl-4-hexenylamine, and N-phenyl-5-hexenylamine. The structures of the cyclic amines were confirmed by independent syntheses. The unsaturated secondary amines were reduced to known N-alkylanilines and degraded by ozonolysis. A mechanism has been proposed to account for the formation of these products.

INTRODUCTION

In an earlier communication the results of an investigation of the reaction of tetrahydropyran with primary aromatic amines were reported (1). N-Arylpiperidines were formed in almost theoretical yields with aniline, *m*-toluidine, and *p*-toluidine, while a lower yield (65%) was obtained when *o*-toluidine was used as the amine component. The investigation has now been extended to the reaction of aniline with 2-ethyltetrahydropyran (I) and 2-methyltetrahydropyran (II). In contrast to the results obtained with the parent ether, the 2-alkyl homologues produced a mixture of amine products suggestive of a carbonium ion mechanism.

Reaction of 2-Ethyltetrahydropyran (I) with Aniline

Careful fractional distillation of the product formed by passing aniline and the cyclic ether, in a molar ratio of 2:1, over activated alumina at 300° C. gave three distinct fractions. These were identified as 1-phenyl-2-ethylpiperidine (III), 1-phenyl-2-propylpyrrolidine (IV), and a mixture (V) of N-phenyl-4-heptenylamine and N-phenyl-5-heptenylamine. The composition of the reaction product, the elemental analysis data, the boiling point and refractive index of each fraction, and the melting points of picrates prepared from the two cyclic amines are given in Table I.

TABLE I

PRODUCTS OF THE REACTION OF 2-ETHYLTETRAHYDROPYRAN WITH ANILINE

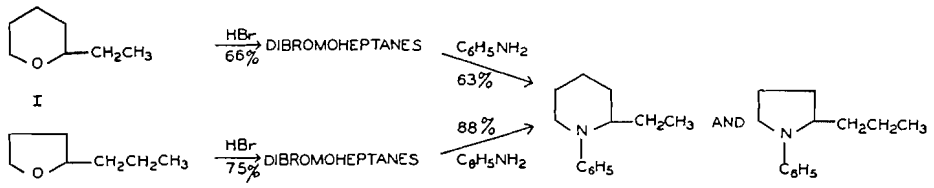
The identity of the cyclic amines was established through independent syntheses involving reaction of dibromoheptanes with aniline. The reaction sequence and composition of products are shown in the following reaction scheme:



I VI III IV

PRODUCT COMPOSITION		
FROM I	70%	30%
FROM VI	17%	83%

Treatment of 2-ethyltetrahydropyran (I) with hydrogen bromide converted it into dibromoheptanes, which on reaction with aniline gave a product 70% of which was shown to be identical with the lowest-boiling component (III) of the product of the catalytic reaction. The remaining 30% was identical with IV, the component of intermediate boiling point. On the other hand, conversion of 2-propyltetrahydrofuran (VI) to dibromoheptanes followed by reaction with aniline gave a product consisting of 17% III and 83% IV. In each sequence, ether → dibromide → amine, the major product was considered to be that resulting from direct substitution of oxygen by nitrogen without rearrangement, that is, the substituted piperidine from 2-ethyltetrahydropyran and the pyrrolidine from 2-propyltetrahydrofuran. This conclusion is based on the reasoning that if the major product of one sequence was that formed through a rearrangement, then this same compound would also have been the major product of the other sequence, since in this case it would have been formed directly without requiring a proton shift. Such clearly was not the case; the major product of one synthesis was the minor product of the other.* On the basis of these results, the lowest-boiling amine product of the catalytic reaction is considered to be 1-phenyl-2-ethylpiperidine; the component of intermediate boiling point, 1-phenyl-2-propylpyrrolidine.

The highest-boiling component (V) gave solid benzenesulphonamide derivatives, but these could not be recrystallized to constant melting point. Hydrogenation over Raney nickel converted V to N-heptylaniline. Ozonolysis of the benzoate of V produced volatile aldehydes identified as acetaldehyde and propionaldehyde by means of their 2,4-dinitrophenylhydrazones, which were separated chromatographically. The third component of the reaction of 2-ethyltetrahydropyran with aniline, therefore, consisted of a mixture of N-phenyl-4-heptenylamine and N-phenyl-5-heptenylamine. A separation of these unsaturated secondary amines was not attempted.

**The small amount of rearrangement occurring at the secondary carbon in these syntheses is considered more likely to occur in the reaction of the cyclic ethers with hydrogen bromide rather than in the subsequent reaction of the dibromide product with aniline.*

Reaction of 2-Methyltetrahydropyran with Aniline

Fractional distillation of the product formed by the reaction of 2-methyltetrahydropyran with aniline gave three distinct fractions identified as 1-phenyl-2-methylpiperidine (VII), 1-phenyl-2-ethylpyrrolidine (VIII), and a mixture (IX) of N-phenyl-4-hexenylaniline and N-phenyl-5-hexenylaniline. The composition of the product, the elemental analysis data, the boiling point and refractive index of each fraction, and the melting points of the picrates are shown in Table II.

TABLE II

PRODUCTS OF THE REACTION OF 2-METHYLTETRAHYDROPYRAN WITH ANILINE

No.	Compound	Mole %[a]	b.p., ° C. at 8 mm.	n_D^{20}	Analyses[b]			Picrate m.p., ° C.
					Carbon	Hydrogen	Nitrogen	
VII	1-Phenyl-2-methylpiperidine	42	113–114	1.5528	81.72	9.72	8.00	166.8–167.2
VIII	1-Phenyl-2-ethylpyrrolidine	27	125.5–126.5	1.5590	81.83	9.61	7.89	120.6–121.2
IX	N-Phenyl-4-hexenylamine and N-Phenyl-5-hexenylamine	31	131.5–132.5	1.5412	81.90	9.62	7.92	

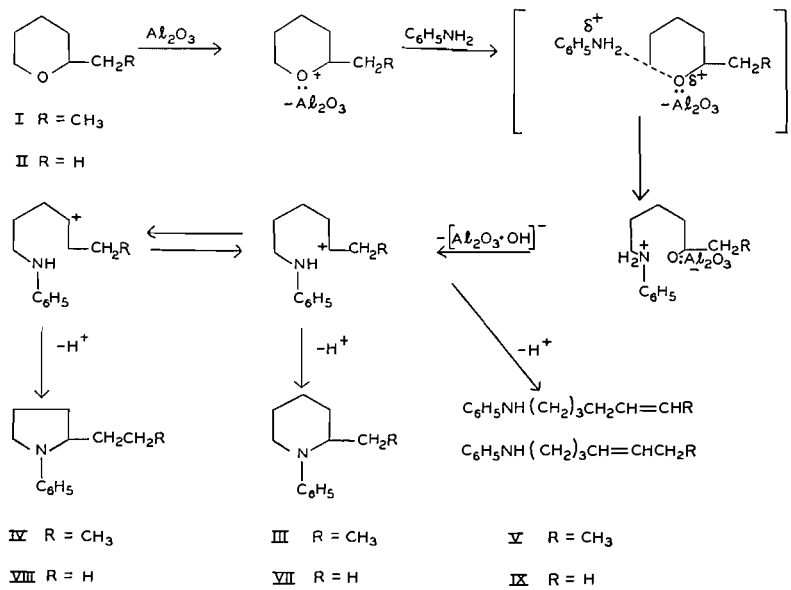
[a] *Based on a single run.*
[b] *Calculated for $C_{12}H_{17}N$, the molecular formula for all four compounds: C, 82.23; H, 9.78; N, 7.99.*

The identity of the two tertiary amines (VII and VIII) was established by an independent synthesis. 2-Methyltetrahydropyran was converted to dibromohexane, which on treatment with aniline gave a product 87% of which was identical with VII. The remaining 13% was identical with VIII. This result is entirely analogous to that obtained in the corresponding synthesis of 1-phenyl-2-ethylpiperidine (III) and 1-phenyl-2-propylpyrrolidine (IV), discussed in the preceding section. Furthermore, there is a similar relationship in boiling points, refractive indices, and picrate melting points of the isomeric tertiary amines in the two cases. (See Tables I and II.)

The highest-boiling component (IX) of the catalytic reaction was converted into N-hexylaniline on reduction over Raney nickel. Ozonolysis of the acetate of IX gave the volatile aldehydes, formaldehyde and acetaldehyde. It is therefore concluded that IX was a mixture of the two unsaturated secondary amines, N-phenyl-4-hexenylamine and N-phenyl-5-hexenylamine.

Reaction Mechanism Considerations

The reaction of aniline with tetrahydropyran, which involves the displacement of oxygen at two primary carbon centers, gives almost theoretical yields of 1-phenylpiperidine. In contrast, the corresponding reaction of 2-alkyltetrahydropyran, in which one of the two carbons joined to oxygen is secondary, gives a mixture of products suggestive of a process proceeding through an intermediate carbonium ion. The following mechanism is proposed:



The alumina, acting as a Lewis acid, accepts a pair of electrons from oxygen, thus weakening the two carbon–oxygen bonds of the ether molecule (13).* Bimolecular attack of aniline at the primary carbon is followed by proton transfer from nitrogen to oxygen and then by unimolecular dissociation of the oxygen – secondary carbon bond. The resulting 'carbonium ion' may (*a*) interact with nitrogen to form the substituted piperidine, (*b*) rearrange to give a new 'carbonium ion', which on ring closure yields the pyrrolidine, or (*c*) lose a proton from a carbon atom adjacent to the center of electron deficiency and produce an unsaturated secondary amine.

It is possible that the initial cleavage occurs at the secondary rather than at the primary carbon. However, the fact that the 2-alkyltetrahydropyrans appear to be somewhat less reactive than tetrahydropyran itself would suggest that the bimolecular displacement at primary carbon is more facile, and therefore is the initial cleavage step. It is worthy of note in this connection that reaction of hydrogen iodide with *n*-butyl *sec*-butyl ether has been shown to give *n*-butyl iodide and *sec*-butyl alcohol (7). Ether fission in this reaction would appear to involve bimolecular attack of iodide ion at the primary carbon atom.

Reference to the composition data given in Tables I and II shows that there is a very much greater tendency for unsaturated secondary amine formation in the reaction of 2-ethyltetrahydropyran. It is suggested that hyperconjugation is one factor responsible for this. Of the two unsaturated amines formed in each of the two systems, one possesses the partial structure $-CH_2CH{=}CHCH_3$. The second unsaturated amine found in the product from 2-methyltetrahydropyran has the partial structure $-CH_2CH{=}CH_2$, and

**Although this is undoubtedly an oversimplification of the catalytic function (14), it seems reasonable to assume that it is in this capacity that alumina performs its key role in dehydration reactions.*

in the product from 2-ethyltetrahydropyran, $—CH_2CH{=}CHCH_2CH_3$. Since hyperconjugative stabilization is greater in the latter, the reaction of the 'carbonium ion' giving this product should compete more effectively with the ring closure forming the substituted piperidine. Analogous effects of hyperconjugation in determining product proportions have been observed in the solvolysis of alkyl bromides (3) and of sulphonium salts (5).

Steric effects (2) also may play a role in determining product proportions in the two cyclic ether – aniline reactions. Ring closure at the carbonium ion center, $—CH_2CH_2\overset{+}{C}HCH_3$, giving the substituted piperidine from 2-methyltetrahydropyran should have a somewhat higher entropy of activation, and therefore greater reaction rate, than closure at the center, $—CH_2CH_2\overset{+}{C}HCH_2CH_3$, required to produce a piperidine from the 2-ethyl homologue. On the other hand, the two reactions giving the substituted pyrrolidines involve the two ions of partial structures $—CH_2\overset{+}{C}HCH_2CH_3$ and $—CH_2\overset{+}{C}HCH_2CH_2CH_3$. These would be expected to show smaller differences in rate, since the increase in steric requirements resulting from the substitution of *n*-propyl for ethyl at the seat of displacement is not as great as that resulting from substitution of ethyl for methyl. This relationship between the steric requirements of *n*-alkyl groups has been demonstrated in bimolecular substitution reactions (6), and it might be expected to show up in processes involving interaction of a bulky nucleophilic reagent with carbonium ion centers.

If now it is assumed that the interconversion of the isomeric carbonium ions is rapid compared to their conversion to stable products, then these steric considerations lead to the prediction that more substituted piperidine and less unsaturated amines should be formed from 2-methyltetrahydropyran than from the 2-ethyl homologue. Reference to Tables I and II shows this to be the case.

A further factor which would tend to favor piperidine formation at the expense of the pyrrolidine from the 2-methyl ether is the somewhat greater stability and, if equilibrium between the isomeric carbonium ions is approached, greater concentration of $—CH_2CH_2\overset{+}{C}HCH_3$ compared to $—CH_2\overset{+}{C}HCH_2CH_3$, since in the former an extra C—H bond is available for hyperconjugation. The fact that the pyrrolidine is favored in the reaction of the 2-ethyl compound might be taken to mean a greater inherent stability of the five-membered heterocyclic system.

EXPERIMENTAL*†

Catalysis Procedure

The catalysis procedure has been described in detail in an earlier communication (1). The cyclic ethers and aniline, mixed in a molar ratio 1:2, were vaporized in a preheater and the vapors passed through 200 ml. of pretreated (1) Alcoa Activated Alumina (Grade F-1, 4-8 mesh) at 300° C. The

**All melting points are corrected; boiling points are uncorrected.*

†The microanalyses were performed at the Research Laboratories, Dominion Rubber Company, Guelph, Ontario, by Mr. Ralph Mills.

feed rate was 60 ml. of mixed liquid reactants per hour. A run consisted of 100 ml. of mixed reactants, following a prerun of 40 ml. during which temperature and feed rate were given final adjustment.

The organic product was separated from a water phase, dried over sodium hydroxide, and very carefully fractionated in a 30-plate modified Podbielniak column (8). A small amount of low-boiling alkadienes and unreacted cyclic ether was removed at atmospheric pressure, while excess aniline and the amine reaction products were distilled at 8 mm. pressure. Composition of amine products, properties, and elemental analysis data are given in Tables I and II. Combined yields of the amine products, based on cyclic ether charged, were 60% from 2-ethyltetrahydropyran and 76% from 2-methyltetrahydropyran.

2-Ethyl- and 2-Methyl-tetrahydropyran

The cyclic ethers were prepared from dihydropyran by the method of Paul (9) and purified by fractional distillation. 2-Ethyltetrahydropyran, b.p. 126.8–127.1° C., n_D^{20} 1.4262, was obtained in 63.4% yield, and 2-methyltetrahydropyran, b.p. 101.5–101.8° C., n_D^{20} 1.4180, in 76% yield.

Synthesis of 1-Phenyl-2-ethylpiperidine (III) from 2-Ethyltetrahydropyran (I) via 1,5-Dibromoheptane

2-Ethyltetrahydropyran, 30.0 gm., was added slowly to a cold mixture of 340 gm. of 48% hydrobromic acid and 18 ml. of concentrated sulphuric acid. Following a three-hour refluxing period, the reaction mixture was steam distilled, and the organic phase of the distillate extracted with ether, washed with sodium carbonate solution, and dried over calcium chloride. Fractionation gave 44.4 gm. (66.3%) dibromide, b.p. 112–116° C. (12 mm.), n_D^{17} 1.5010–1.5025. On the basis of the composition of the product formed in the subsequent reaction with aniline, this product is considered to consist of 70% 1,5-dibromoheptane and 30% 1,4-dibromoheptane.

A solution of 38.5 gm. (0.15 mole) of the dibromide and 62.2 gm. (0.68 mole) of aniline was warmed on a steam bath until it had formed into a brown cake. The reaction mixture was dissolved in hydrochloric acid and the free amines liberated by addition of sodium hydroxide solution. The organic phase was extracted with ether and dried over sodium hydroxide. Careful fractionation gave 12.5 gm. (44%) of 1-phenyl-2-ethylpiperidine (III), b.p. 125.5–126.0° C. (8 mm.), n_D^{20} 1.5505, picrate m.p. 177.6–178.2° C., and 5.3 gm. (19%) of 1-phenyl-2-propylpyrrolidine (IV), b.p. 132–136° C. (8 mm.), n_D^{20} 1.5534, picrate m.p. 135.6–136.1° C. A mixture of the picrate of III with the picrate formed from the lowest-boiling fraction of the product of the 2-ethyltetrahydropyran–aniline reaction showed no depression in melting point. Similarly, the melting point of the picrate of IV was not depressed in admixture with the picrate of the intermediate fraction of the catalysis product.

Synthesis of 1-Phenyl-2-propylpyrrolidine (IV) from 2-Propyltetrahydrofuran (VI) via 1,4-Dibromoheptane

Thirty-six grams (0.315 mole) of 2-propyltetrahydrofuran, b.p. 130–133° C., n_D^{20} 1.4215, prepared by the method of Paul (10, 11) from furfural in an over-all

yield of 65%, was dissolved in an equal volume of glacial acetic acid. The solution was saturated with anhydrous hydrogen bromide and heated in a sealed tube at 120° C. for three hours. The product was steam distilled and the organic phase extracted with ether and dried over anhydrous sodium sulphate. Fractionation gave 61 gm. (75%) dibromide, b.p. 108–110° C. (8 mm.), n_D^{20} 1.5010–1.5015. The results of the subsequent reaction with aniline indicated that this product consisted of 83% 1,4-dibromoheptane and 17% 1,5-dibromoheptane.

The dibromide, 57.6 gm. (0.22 mole), was treated with 84.3 gm. (0.91 mole) of aniline and the product worked up as described in the preceding section. Careful fractionation gave 30.7 gm. (73%) of 1-phenyl-2-propylpyrrolidine (IV), b.p. 137–138° C. (8 mm.), n_D^{20} 1.5518, picrate m.p. 136.0–136.5° C., and 6.3 gm. (15%) of 1-phenyl-2-ethylpiperidine (III), b.p. 126–129° C. (8 mm.), n_D^{20} 1.5502, picrate m.p. 177.2–177.6° C. Mixed melting point determinations on the picrates of these compounds with the picrates of corresponding fractions obtained from the catalysis reaction showed no depression.

Reduction of Mixed N-Phenylheptenylamines (V) to N-Heptylaniline

A solution containing 6.5 gm. of the highest-boiling fraction from the 2-ethyltetrahydropyrananiline reaction in 100 ml. of ethanol was treated with hydrogen in the presence of Raney nickel at room temperature and 50 p.s.i. pressure. Distillation, following removal of the catalyst, gave 5.1 gm. (79%) of product, b.p. 163–169° C. (24 mm.), n_D^{20} 1.5188, *p*-bromobenzenesulphonamide derivative m.p. 117–118° C. A mixture of this derivative with *p*-bromobenzenesulphonamide prepared from authentic N-heptylaniline showed no depression in melting point.

Ozonolysis of N-Benzoyl-N-phenylheptenylamines

To a solution of 3.8 gm. (0.02 mole) of the mixed heptenylanilines in 38 ml. of dry pyridine and 76 ml. of dry benzene was added dropwise 4.8 gm. (0.034 mole) of benzoyl chloride at 60–70° C. After an additional 30 min. at this temperature, the product was worked up in the usual way. Distillation gave 4.6 gm. (78.4%) of a thick straw-colored oil, b.p. 163–173° C. (0.3 mm.).

A stream of ozone (5%) was passed into a solution of 3.2 gm. of the benzoyl derivative in 50 ml. of aldehyde-free propionic acid until ozonization was complete. The ozonide was decomposed by hydrogenolysis for 10 hr. over palladium on calcium carbonate at room temperature and 63 p.s.i. pressure. Following removal of the catalyst, the volatile carbonyl products were swept out of the gradually-heated propionic acid solution and collected in ethanol cooled to dry-ice temperatures. These were then converted to 2,4-dinitrophenylhydrazones in the usual way and separated chromatographically on a silicic acid – Super Cel column (12). The less strongly absorbed hydrazone, on recrystallization from ethanol, melted at 153.3–154.8° C. and gave no melting point depression when mixed with authentic propionaldehyde 2,4-dinitrophenylhydrazone. The more strongly absorbed derivative, also recrystallized from ethanol, melted at 166–167° C., and did not depress the melting point of authentic acetaldehyde 2,4-dinitrophenylhydrazone.

Synthesis of 1-Phenyl-2-methylpiperidine (VII) from 2-Methyltetrahydropyran (II) via 1,5-Dibromohexane

2-Methyltetrahydropyran, 18.0 gm. (0.18 mole), was dissolved in glacial acetic acid and treated with anhydrous hydrogen bromide at 120° C., following the procedure previously described for the reaction of hydrogen bromide with 2-propyltetrahydrofuran. Fractionation of the product gave 35.7 gm. (82%) dibromide, b.p. 100.0–102.3° C. (12 mm.), $n_D^{13.5}$ 1.5077. The composition of the product formed in the subsequent reaction with aniline indicated that the dibromide consisted of 87% 1,5-dibromohexane and 13% 1,4-dibromohexane.

The conversion of the dibromide to cyclic amines by reaction with aniline was carried out following the procedure previously described. From 34.5 gm. of the dibromide was obtained 16.9 gm. (80%) of 1-phenyl-2-methylpiperidine (VII), b.p. 110.8–113.0° C. (8 mm.), n_D^{13} 1.5560, picrate m.p. 167.4–168.4° C., and 2.4 gm. (12%) of 1-phenyl-2-ethylpyrrolidine (VIII), b.p. 117.5–118.5° C. (8 mm.), n_D^{14} 1.5631, picrate m.p. 118–119° C. The melting points were not depressed when these picrates were mixed with picrates from corresponding fractions obtained from the reaction of 2-methyltetrahydropyran with aniline.

Reduction of Mixed N-Phenylhexenylamines (IX) to N-Hexylaniline

A sample of the mixed amines dissolved in ethanol was reduced at room temperature and 43 p.s.i. pressure over Raney nickel. Distillation gave a product, b.p. 163–165° C. (30 mm.), n_D^{20} 1.5230, *m*-nitrobenzenesulphonamide m.p. 79.6–80.2° C., and *p*-toluenesulphonamide m.p. 67–68° C. The melting points of these sulphonamides agree closely with literature values for the corresponding derivatives of N-hexylaniline (4). The *p*-bromobenzenesulphonamide melted at 96.2–97.2° C.

Ozonolysis of N-Acetyl-N-phenylhexenylamines

A solution of 4.5 gm. (0.026 mole) of mixed amines (IX) dissolved in 10.6 ml. (0.10 mole) of acetic anhydride and 70.8 ml. of piperidine was refluxed for one and one-half hours. Dilute sulphuric acid was added and the organic phase extracted with ether, dried, and distilled to give 4.75 gm. (85%) of liquid product, b.p. 115–120° C. (0.5 mm.), n_D^{21} 1.5223.

A stream of ozone (5%) was passed into a solution of 2 gm. of N-acetyl-N-phenylhexenylamines in 50 ml. of purified glacial acetic acid until ozonization was complete. The ozonide was decomposed by hydrogenolysis over palladium on calcium carbonate. Following removal of the catalyst, nitrogen was passed through the solution while its temperature was gradually raised. The aldehyde first swept from the solution was converted into *p*-nitrophenylhydrazone and 2,4-dinitrophenylhydrazone derivatives, the melting points of which corresponded to derivatives of acetaldehyde. Mixed melting point determinations showed no depression. The sweep gas passing through the solution at the higher temperatures was led into ethanol cooled in dry-ice, dimedone added, and the resulting derivative recrystallized from ethanol. Its melting point

corresponded to that of the dimedone of formaldehyde, and a mixed melting point determination with authentic compound gave no depression.

2,3-DIHYDROBENZO(*f*)-1,4-OXATHIEPIN AND DERIVATIVES[1]

By Marshall Kulka

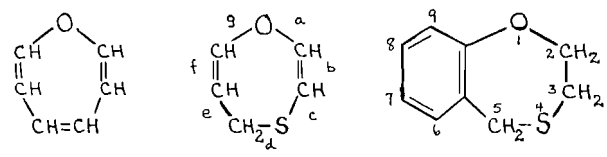
ABSTRACT

A method has been developed for the synthesis of a new heterocyclic system III. When 2-β-chloroethoxybenzyl chloride (XI) was heated with thiourea in alcohol solution, S-(2-β-chloroethoxybenzyl)isothiuronium chloride (XII) was formed which on cleavage with aqueous alkali in high dilution yielded 2,3-dihydrobenzo(*f*)-1,4-oxathiepin (III). Derivatives of III with substituents such as methyl, *t*-butyl, chlorine, and nitro in the 7 and 9 positions were prepared in high yields from the corresponding substituted 2-β-chloroethoxybenzyl chlorides. The presence of substituents in the position ortho to the chloroethoxy group of XII had no retarding effect on the cyclization to XIV.

During the synthesis of aralkyl mercaptans required as intermediates in a synthetic insecticide research program, a new heterocyclic system, III, was discovered. The name for this new system is derived from oxepin (I) and 1,4-oxathiepin (II). The fusion of a benzene ring in the *f* position of 1,4-oxathiepin (II), followed by saturation of the 2,3-double bond, results in the new system, (III), for which the name 2,3-dihydrobenzo(*f*)-1,4-oxathiepin is appropriate.

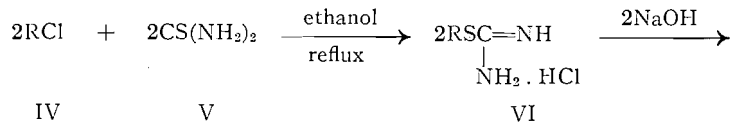
The thiourea method for the preparation of alkyl (12) and aralkyl (8) mercaptans (VII) comprises heating the alkyl or aralkyl halide (IV) with thiourea (V) in alcohol solution followed by alkaline cleavage of the resulting isothiuronium chloride (VI). Sodium chloride, water, and cyanoguanidine (VIII) are formed along with the mercaptan (VII). It is well known (1,9) that mercaptans react with alkyl halides (IX) in the presence of aqueous or alcoholic alkali to form sulphides (X).

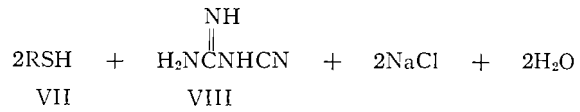
During the preparation of various benzyl mercaptans from the corresponding benzyl chlorides by the thiourea method, interest was aroused in regard to the behavior of 2-β-chloroethoxybenzyl chlorides (XI) in this reaction. Since phenyl 2-chloroethyl ether does not react with thiourea (V) under these conditions, the first product of the reaction between XI and V should be the S-(2-β-chloroethoxybenzyl)isothiuronium chloride (XII). This on treatment with alkali should yield the mercaptan XIII, which could theoretically undergo two reactions under these conditions. An intramolecular reaction would result in the 1,4-oxathiepin (XIV), while an intermolecular reaction would lead to the polymer (XV). Actually when an aqueous-alcoholic solution of S-(2-β-chloroethoxybenzyl)isothiuronium chloride (XII) was treated with excess sodium hydroxide in a small volume of hot water, the main product of

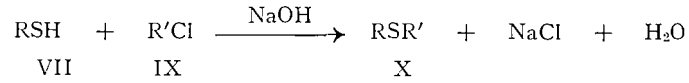


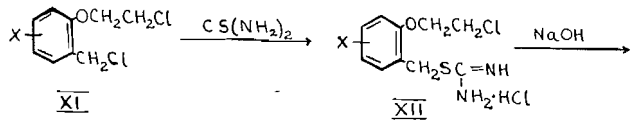
I II III

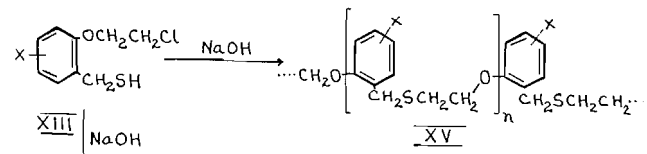
[1]*Manuscript received May 24, 1955.*
Contribution from the Dominion Rubber Company Limited Research Laboratories, Guelph, Ontario.

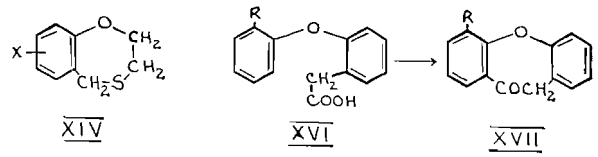


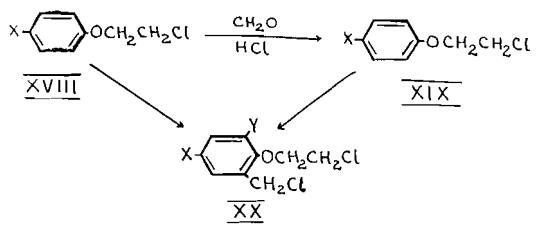


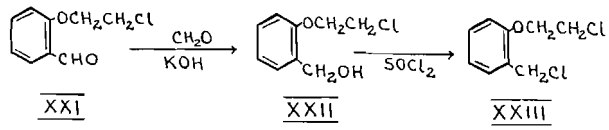




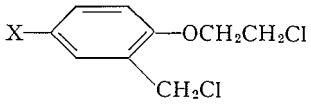








NOTE: The formula for compound XIX should read



the reaction was the benzene-insoluble polymer (XV). On the other hand when the aqueous-alcoholic solution of XII was added dropwise to excess sodium hydroxide in a large volume of hot water, a benzene-soluble compound was obtained in high yield. This compound possessed a boiling point slightly lower than the corresponding 2-β-chloroethoxybenzyl chloride (XI), it was free of chlorine and contained a neutral sulphur which oxidized easily to the sulphone. On the basis of these properties together with analytic figures and molecular weight it must be presumed to be the intramolecular reaction product XIV.

The thiourea method has been successfully applied to the synthesis of several 2,3-dihydrobenzo(*f*)-1,4-oxathiepins (XIV) substituted in the benzene ring (Table II). These were oxidized to the corresponding sulphones (Table III). The method appears to have wide scope which is governed only by the availability of the benzyl chlorides (XI). Difficulties were expected in the preparation of nitroderivatives of XIV in view of the facts that S-(3-nitro-4-methoxybenzyl)isothiuronium chloride on treatment with aqueous alkali yields only resinous materials and no mercaptan and that *p*-nitrobenzyl mercaptan is sensitive to hot alkali (1). However XII (X = NO_2) was easily converted to XIV (X = NO_2) (Table II). A number of 3-substituted-5-alkyl-2-β-chloroethoxybenzyl chlorides (XI, X = 3-Cl, 3-NO_2, and 3-*t*-butyl) were also easily converted to the 1,4-oxathiepins (XIV, X = 9-Cl, 9-NO_2, and 9-*t*-butyl) via the corresponding isothiuronium chlorides (XII) showing that 3-substituents in XII have no retarding effect on the cyclization to XIV. This is in direct contrast to the behavior of 2-phenoxyphenylacetic acids (XVI) where substituents in the *ortho* position (R) sterically hinder the cyclization to the dibenzoxepinones (XVII) (6).

The 4-substituted-2-β-chloroethoxybenzyl chlorides (XIX) required in this investigation were prepared by chloroethylation of the phenols with ethylene dichloride according to the method of Harris and Stewart (4) followed by chloromethylation of the resulting 2-chloroethyl phenyl ethers (XVIII). A few failures were experienced when *p*-nitrophenol, 2,4-di-*t*-butylphenol (11), and 2-hydroxy-5-methylacetophenone (10) reacted poorly or not at all with ethylene dichloride and when 2,4,5-trichlorophenyl 2-chloroethyl ether failed to chloromethylate. The introduction by usual methods of such groups as chlorine, nitro, and *t*-butyl into the 4-substituted-phenyl 2-chloroethyl ethers (XVIII) either before or after chloromethylation yielded additional 2-β-chloroethoxybenzyl chlorides (XX) required in this investigation. *o*-β-Chloroethoxybenzyl chloride (XXIII) was prepared from salicylaldehyde by chloroethylation and reduction (crossed Cannizzaro) of the resulting aldehyde (XXI) to the benzyl alcohol (XXII) followed by thionyl chloride treatment. This compound (XXIII) proved to be extremely unstable and had to be used immediately without purification in the preparation of the isothiuronium salt.

EXPERIMENTAL

2-β-Chloroethoxybenzaldehyde (XXI)

A reaction mixture of *o*-hydroxybenzaldehyde (100 gm.), ethylene dichloride (100 ml.), and potassium hydroxide (50 gm.) in water (100 ml.) was heated

under reflux for five days. The organic layer was separated, diluted with ethylene dichloride, washed with aqueous sodium hydroxide and with water, and the solvent removed. The residue was distilled, the fraction boiling at 163–164° (12 mm.) being collected; yield, 61 gm. or 40%. The distillate crystallized from benzene as white prisms melting at 38–39°. Anal. Calc. for $C_9H_9O_2Cl$: C, 58.53; H, 4.88. Found: C, 58.34; H, 4.71.

2-β-Chloroethoxybenzyl Alcohol (*XXII*)

To a stirred solution of 2-β-chloroethoxybenzaldehyde (20 gm.), ethanol (100 ml.), and 40% formaldehyde (40 ml.) was added dropwise 50% aqueous potassium hydroxide (50 ml.), the temperature being kept at 35–40° by cooling. The reaction mixture was stirred at 40° for two hours and then about half the ethanol was removed *in vacuo*. The residue was extracted with ether, the ether solution was washed with aqueous sodium bisulphite, and the solvent was removed. The residue distilled at b.p. (12 mm.) = 166–167° as a colorless liquid, $n_D^{20} = 1.550$, yield, 17 gm. or 85%. Anal. Calc. for $C_9H_{11}O_2Cl$: C, 57.90; H. 5.89. Found: C, 57.34, 57.60; H, 5.76, 5.90.

2-β-Chloroethoxybenzyl Chloride (*XXIII*)

To a solution of 2-β-chloroethoxybenzyl alcohol (12 gm.) in dry benzene (50 ml.) was added portionwise thionyl chloride (10 gm.), the temperature being kept below 35° by cooling. The reaction mixture was allowed to stand at room temperature for five hours during which time hydrogen chloride and sulphur dioxide were evolved. About two-thirds of the benzene was removed *in vacuo without heat application* and the purple solution was used directly in the formation of the isothiuronium salt (see below). The 2-β-chloroethoxybenzyl chloride is extremely unstable and polymerizes on standing or on warming.

2-β-Chloroethoxy-5-methylbenzyl Chloride (*XIX*, $X = CH_3$)

A reaction mixture of *p*-tolyl 2-chloroethyl ether (100 gm.) (4), ethylene dichloride (150 ml.), concentrated hydrochloric acid (300 ml.), water (15 ml.), and paraformaldehyde (22 gm.) was stirred and heated at 55–60° for 24 hr. The organic layer was separated, washed with water, with aqueous sodium bicarbonate, and with water. The solvent was removed and the residue was distilled, yielding a colorless liquid (111 gm. or 88%) boiling at 158–160° (12 mm.) and melting at 25–27°. Anal. Calc. for $C_{10}H_{12}OCl_2$: C, 54.80; H, 5.48. Found: C, 54.77, 54.59; H, 5.70, 5.33.

2-β-Chloroethoxy-5-t-butylbenzyl Chloride (*XIX*, $X = C(CH_3)_3$)

This was prepared in 50% yield as above from *p-t*-butylphenyl 2-chloroethyl ether (2). The colorless liquid boiled at 170–173° (12 mm.), $n_D^{20} = 1.533$. Anal. Calc. for $C_{13}H_{18}OCl_2$: C, 59.80; H, 6.90. Found: C, 59.43, 59.48; H, 6.53, 6.60.

2-β-Chloroethoxy-3,5-dichlorobenzyl Chloride (*XX*, $X = Y = Cl$)

The preparation of this compound required considerably more drastic conditions than those used for the preparation of 2-β-chloroethoxy-5-chlorobenzyl chloride (7).

A suspension of paraformaldehyde (25 gm.), zinc chloride (150 gm.), and acetic acid (400 ml.) was saturated with hydrogen chloride. To the resulting solution was added 2,4-dichlorophenyl 2-chloroethyl ether (100 gm.) (2) and the solution was heated at 90–95° for four days. About half of the acetic acid was distilled off *in vacuo* from the reaction mixture, and the residue was treated with dilute hydrochloric acid and extracted with benzene. The benzene solution was washed with water, with aqueous sodium bicarbonate, and with water and the solvent was removed. The residue was fractionally distilled, yielding fraction 1 (52 gm.) boiling at 150–175° (12 mm.) and fraction 2 (18 gm.) boiling at 175–185° (12 mm.). Fraction 2 could not be purified further so the crude material was used in the preparation of the isothiuronium salt (see below).

2-β-Chloroethoxy-5-nitrobenzyl Chloride (*XIX*, $X = NO_2$)

This was prepared in 35% yield of crude material by the chloromethylation of *p*-nitrophenyl 2-chloroethyl ether (5) employing a method similar to that above except that 30 gm. of zinc chloride was used instead of 150 gm. The yellow liquid boiled at 170–175° (1 mm.). In view of the fact that this contained a small amount of difficultly separable *p*-nitrophenyl 2-chloroethyl ether, the crude material was used directly in the preparation of the isothiuronium salt where purification was easier.

2-Chloro-4-t-butylphenyl 2-Chloroethyl Ether

Into a solution of *p-t*-butylphenyl 2-chloroethyl ether (71 gm.) (2), sodium acetate (35 gm.), and acetic acid (200 ml.), chlorine gas was passed until 24 gm. were absorbed, the temperature being maintained at 35–40° by cooling. After it had been left at room temperature for 15 min., the reaction mixture was poured into water and extracted with benzene. The benzene extract was washed with water and the solvent was removed. The residue was distilled and the fraction boiling at 160–163° (12 mm.) collected. The yield of the colorless distillate was 56 gm. or 75%, $n_D^{20} = 1.532$. Anal. Calc. for $C_{12}H_{16}OCl_2$: C, 58.30; H, 6.48. Found: C, 58.72, 58.21; H, 6.60, 6.46.

2-β-Chloroethoxy-3-chloro-5-t-butylbenzyl Chloride (*XX*, $X = C(CH_3)_3$, $Y = Cl$)

Into a suspension of paraformaldehyde (10 gm.), zinc chloride (30 gm.), and acetic acid (250 ml.), hydrogen chloride was passed until saturated. To this was added 2-chloro-4-*t*-butylphenyl 2-chloroethyl ether (44 gm.) and the resulting solution was heated at 80–90° for three days. About half of the acetic acid was distilled off *in vacuo* and the residue was treated with dilute hydrochloric acid and extracted with benzene. The benzene extract was washed with water, with aqueous sodium bicarbonate, and with water. The solvent was removed and the residue was distilled, yielding 32 gm. (60%) of a colorless liquid, $n_D^{20} = 1.539$, boiling at 180–185° (13 mm.). Anal. Calc. for $C_{13}H_{17}OCl_3$: C, 52.80; H, 5.75. Found: C, 53.31, 53.17; H, 5.88, 5.61.

2-β-Chloroethoxy-3-nitro-5-t-butylbenzyl Chloride (*XX*, $X = C(CH_3)_3$, $Y = NO_2$)

To a solution of 2-β-chloroethoxy-5-*t*-butylbenzyl chloride (12 gm.) (XIX) in acetic acid (25 ml.) and acetic anhydride (10 ml.) was added dropwise fuming nitric acid (4 ml.) with stirring, the temperature being kept at 25–30° by

cooling. After it was allowed to stand at room temperature for two hours, the reaction mixture was poured into water and the precipitated oil was extracted with benzene. The benzene extract was washed with water and the solvent removed. The residue on crystallization from methanol yielded 9.8 gm. (70%) of white prisms melting at 77–78°. Anal. Calc. for $C_{13}H_{17}NO_3Cl_2$: C, 50.98; H, 5.55. Found: C, 50.93; H, 5.55.

2-t-Butyl-4-methylphenyl 2-Chloroethyl Ether

To a solution of *p*-tolyl 2-chloroethyl ether (150 gm.) (4) in *t*-butyl chloride (400 ml.) was added aluminum chloride (3 gm.) in three 1-gm. portions with cooling and swirling until dissolved. Then the reaction mixture was heated under gentle reflux for three hours. Because of the continuous evolution of hydrogen chloride the internal temperature remained at 35–40° for the first two hours and rose gradually to 50° during the last hour of the reaction. The dark red solution was washed with cold dilute hydrochloric acid, with water, with aqueous sodium bicarbonate, and with water. After the excess *t*-butyl chloride was distilled off, the residue was fractionally distilled, the fraction (106 gm.) boiling at 140–160° (13 mm.) being collected. This partially solidified on cooling and rubbing with a little methanol and was crystallized from methanol. The white prisms melted at 35–37° and weighed 58 gm. (30%). Anal. Calc. for $C_{13}H_{19}OCl$: C, 68.87; H, 8.39. Found: C, 68.94, 69.26; H, 8.16, 8.37.

2-β-Chloroethoxy-3-t-butyl-5-methylbenzyl Chloride ($XX, X = CH_3, Y = C(CH_3)_3$)

A suspension of 2-*t*-butyl-4-methylphenyl 2-chloroethyl ether (30 gm.), paraformaldehyde (6 gm.), and acetic acid (150 ml.) was saturated with hydrogen chloride and then heated at 78–80° for 18 hr. Most of the acetic acid was removed *in vacuo*, and the residue was treated with water and extracted with benzene. The benzene solution was washed with water, with aqueous sodium bicarbonate, and with water and the solvent was removed. The residue was distilled and the fraction boiling at 172–177° (13 mm.) collected. The yield of the colorless liquid was 20 gm. or 60%, $n_D^{20} = 1.534$. Anal. Calc. for $C_{14}H_{20}OCl_2$: C, 61.09; H, 7.25. Found: C, 61.48; H, 7.38.

2,4,5-Trichlorophenyl 2-Chloroethyl Ether

This was prepared in 72% yield from 2,4,5-trichlorophenol and ethylene dichloride according to the method of Harris and Stewart (4). The white needles melted at 52–53°. Anal. Calc. for $C_8H_6OCl_4$: C, 36.92; H, 2.31. Found: C, 37.37; H, 2.47.

2-Acetyl-4-methylphenyl 2-Chloroethyl Ether

This was prepared in 10% yield from 2-hydroxy-5-methylacetophenone (10) and ethylene dichloride (4). The white prisms melted at 61–62°. Anal. Calc. for $C_{11}H_{13}O_2Cl$: C, 62.14; H, 6.12. Found: C, 62.72; H, 6.24.

Preparation of S-Benzylisothiuronium Chlorides (XII) (Table I)

To a solution of the 2-β-chloroethoxybenzyl chloride (20 gm.) in ethanol (50 ml.) was added about 20% excess thiourea and the reaction mixture was

heated under reflux for three hours. The ethanol was removed *in vacuo* from the solution and the residual sirup was treated with hot water (20 ml.) (about twice as much water was required by the nitro derivatives of XII). The resulting solution was then extracted with benzene in order to remove any impurities, which were present only when crude 2-β-chloroethoxybenzyl chloride was used, and the aqueous solution was allowed to cool. The S-(2-β-chloroethoxybenzyl)isothiuronium chloride precipitated and could be crystallized from water or alcohol. Although S-benzylisothiuronium chloride is known to exhibit dimorphism (3), this was not observed with those chlorides listed in Table I.

NOTES

THE CRYSTAL STRUCTURE OF THE ALIPHATIC DIBASIC ACID $C_4H_4O_6.2H_2O$[1]

By M. P. Gupta[2]

The aliphatic dibasic acid $C_4H_4O_6.2H_2O$ has variously been described as having either the *cis*- or the *trans*- configuration. Chemical evidence against or in favor of either of these configurations has been presented by Hartree (2). In a previous communication, however, the present author (1) was able to show conclusively from X-ray diffraction data that the molecule in the crystalline state must have the *trans*-configuration since it crystallized in the monoclinic system, class $2/m$, space group $P2_1/c$ with two molecules in the unit cell of dimensions

$$a = 6.40, \quad b = 13.03, \quad c = 5.34 \text{ Å}, \quad \beta = 126.5°.$$

Thus the molecules were, tentatively, confirmed as molecules of dihydroxyfumaric acid and not dihydroxymaleic acid. The present note describes the results of a Fourier analysis of the X-ray diffraction data obtained from the crystals of dihydroxyfumaric acid dihydrate.

Reflections in the $\{0kl\}$ and the $\{h0l\}$ zones were obtained from Weissenberg photographs using Cu unfiltered radiation, and the intensities were estimated visually. Patterson projections were calculated for both these zones. The $\{h0l\}$ projection showed clearly the molecules to be lying in a plane perpendicular to the a axis which was the best axis for clear resolution of the atoms. The first Fourier map showed the rough orientation of the molecule as well as the position of the water molecule and this was refined in successive stages; the last Fourier map obtained is shown in Fig. 1 below. The figure shows the molecule as projected on a plane perpendicular to the a axis. Only one molecule is outlined together with parts of the neighboring molecules. All the atoms in this projection are clearly resolved. The structure has been confirmed by the $\{h0l\}$ projection in which, however, there is serious overlap—only two atoms out of the six in the asymmetric unit are clearly resolved in this projection.

There is no hydrogen bonding in the COOH groups of the adjacent molecules which form an extensive chain running roughly parallel to the [102] axis, and as in oxalic acid dihydrate, the crystal structure is held together mainly by the water molecules. No pronounced departure from a completely planar molecule is expected. The crystal structure is being refined using three-dimensional data, and full details of the intramolecular and intermolecular distances will be published later.

The author wishes to thank Dr. W. H. Barnes for providing all facilities for this research in his laboratory.

THE ESTIMATION OF β-HYDROXY AMINO ACIDS BY A MICRODIFFUSION METHOD[1]

By L. Wiseblatt and W. B. McConnell

The periodic acid oxidation of β-hydroxy amino acids proceeds according to the following formula:

$$R—CHOH—CHNH_2—COOH \longrightarrow R—CHO + CHO—COOH + NH_3.$$

The reaction is rapid and quantitative and is used in analytical methods for determining serine and threonine (3, 5). It has also been used to estimate hydroxylysine, which occurs in a few proteins (6). Threonine yields acetaldehyde while serine and hydroxylysine give formaldehyde. Shinn and Nicolet (3) estimated threonine by aspirating the acetaldehyde into an excess of bisulphite, and Winnick (7) subsequently modified this to a microdiffusion method. Van Slyke, Hiller, and MacFadyen (6) have described a method for determining ammonia liberated by periodate oxidation (periodate ammonia) by aspirating it into boric acid and titrating in the usual way.

This communication describes a modified method for determining "periodate ammonia" which utilizes Conway Microdiffusion units (2).

To employ the method with protein hydrolyzates the following reagents are required:

1. Paraperiodic acid 0.5 *M* (114 gm. H_5IO_6 per liter).
2. Glycine solution (5% in *N* NaOH).
3. Potassium metaborate 5 *N* (410 gm. KBO_2 per liter).
4. Boric acid 2% containing 0.1% of bromcresol green – methyl red 2: 1.

One and one-half milliliters of boric acid solution are pipetted into the center well of a No. 1 Conway unit. One milliliter of sample solution, containing about 10 microequivalents of β-hydroxy amino acids, is added to the outer chamber. Immediately before the cell is sealed the following are added to the sample: 0.5 ml. periodic acid, 0.5 ml. glycine solution, 1.5 ml. potassium metaborate. After at least five hours at room temperature the contents of the center well are titrated with standard hydrochloric acid and the ammonia adsorbed is calculated. A control experiment with periodic acid omitted must be included to obtain a value for "preformed ammonia". Total ammonia less preformed ammonia is equal to periodate ammonia. Samples (10 microequivalents) of serine and threonine were analyzed as above. On individual determinations the percentage recoveries of the theoretical yield of ammonia were: serine—99.7, 100.4, 99.7, 100.1; threonine—99.5, 99.5, 100.3, 99.8. No interference from other common amino acids was found.

The total β-hydroxy amino acids in a protein hydrolyzate can be estimated in terms of periodate ammonia using the method outlined. If threonine is then estimated by Winnick's method (7) and "threonine ammonia" is subtracted from periodate ammonia, the difference should be a measure of serine content. Hydroxylysine glucosamine and ethanolamine give ammonia upon periodate oxidation and if present they would interfere with the estimation of serine.

[1]*Issued as N.R.C. No. 3692.*

Selected proteins were hydrolyzed for 20 hr. in refluxing 6 *N* hydrochloric acid. The hydrolyzates were freed from excess acid by repeated vacuum evaporation and dilution, made to suitable volumes, and 1-ml. aliquots were taken for "periodate ammonia" and threonine analyses. Aliquots were analyzed for total nitrogen by the micro-Kjeldahl method. Results are given in Table I.

A NEW TYPE OF OSMOMETER FOR AQUEOUS SOLUTIONS

BY J. L. GARDON[1] AND S. G. MASON

INTRODUCTION

Most osmometers for determining molecular weights of macromolecules have metal plate membrane supports and solvent-filled manometers. These units are not convenient for use in aqueous solutions, because the high surface tension causes air bubbles to be trapped at the metal surfaces and also leads to large capillarity errors in the manometer.

A NEW TYPE OF OSMOMETER FOR AQUEOUS SOLUTIONS

BY J. L. GARDON[1] AND S. G. MASON

INTRODUCTION

Most osmometers for determining molecular weights of macromolecules have metal plate membrane supports and solvent-filled manometers. These units are not convenient for use in aqueous solutions, because the high surface tension causes air bubbles to be trapped at the metal surfaces and also leads to large capillarity errors in the manometer.

[1]*Holder of the Anglo-Paper Research Fellowship and of a Studentship from the National Research Council of Canada. Present address: Industrial Cellulose Research Ltd., Hawkesbury, Ontario.*

The units described in this paper are inexpensive to construct, simple to operate, and have the following advantages:

(1) Measurements can be carried out reasonably fast, even with low porosity membranes, by making use of large membrane areas.

(2) In membranes as big as 200 sq. cm., membrane ballooning is eliminated.

(3) The membrane area per cc. half cell volume is 10 sq. cm., which compares favorably with other designs (2).

(4) The unit is transparent.

(5) Solutions can be changed readily without taking the unit apart.

The osmometer consists essentially of a cell and a manometer attachment. Two lucite disks and two rubber rings constitute the main body of the cell (Fig. 1). The membrane is clamped between two stainless steel screens and is

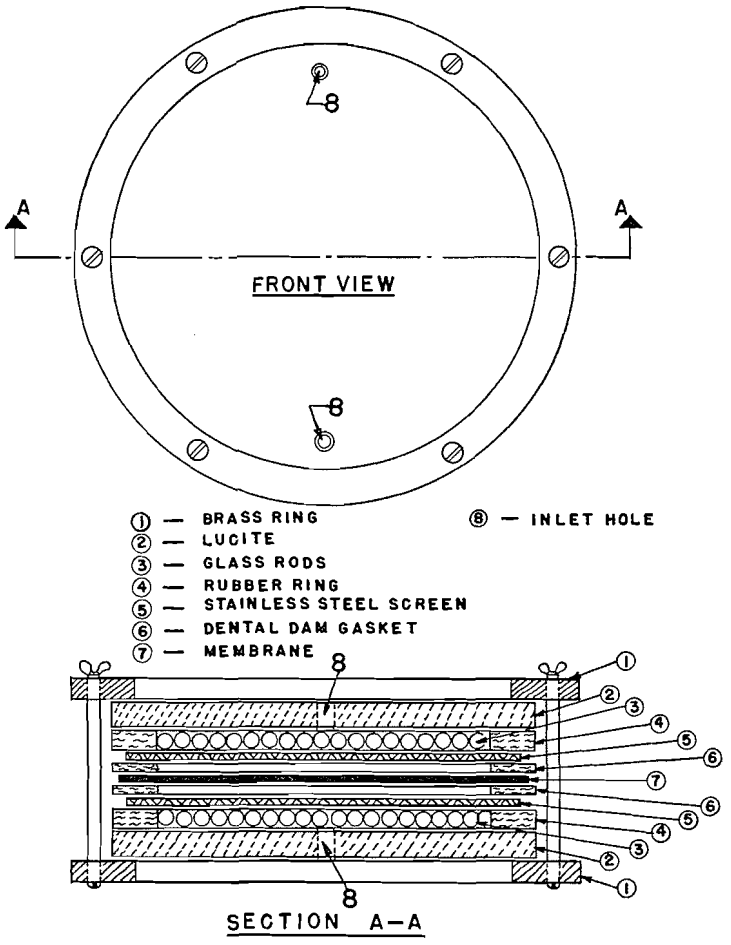

FIG. 1. Details of osmometer cell (exploded view).

supported by a layer of glass rods, closely packed parallel to one another in both cell compartments. The unit is sealed by means of the two rubber

rings mentioned above, which are compressed to the same thickness as the glass rods when the unit is assembled.

The osmotic pressure is measured in a capillary manometer which is connected to the solvent chamber. A syringe such as that from a glass syringe pipette acts as a levelling device.

All parts are individually clamped to a metal rod which forms the backbone of the unit.

CONSTRUCTION OF THE CELL

The stainless steel screens are placed between the rubber rings and the membrane. To avoid leakage through the screen meshes and to protect the membrane, two dental dam gaskets are placed between the screens and the membrane and the rubber rings are lubricated with silicone grease where they are in contact with the screens. As an additional precaution, Pyseal cement can be applied on the outside. If, for any reason, the use of silicone grease is to be avoided, four dental dam gaskets are used on each side of the screens, and Pyseal cement applied on the outside of the cell.

The components of three typical cells having active membrane areas of approximately 200, 60, and 20 sq. cm. are described in Table I. Standard

TABLE I

DIMENSIONS OF OSMOMETER CELL COMPONENTS

Active membrane area, sq. cm.	200	60	20
2 brass rings

Full diameter	17.5	11.5	6.5

pyrex rods with 3 mm. diameter are used as membrane supports. When these rods are initially packed into the cell, a 3 mm. clearance is left between them and the rubber rings to allow for expansion of the latter when the cell is tightened. The rods are vertical when the cell is in use.

There are two alternative methods of stabilizing the membrane and the stainless steel screen reinforcers.

(1) They can be supported by two disks of 12-mesh stainless steel screen instead of the glass rods. The diameters of these disks for the cells described in Table I are 14.5, 9.5, and 4.5 cm. The rubber rings for this design are cut

from sheets $\frac{1}{2}$ to 1 mm. thick, corresponding to the thickness of the 12-mesh screens.

(2) Disks of 5 mm. diameter, cut out of the same rubber sheet as used to prepare the body of the cell, can also be used as stabilizers. These disks are placed in pairs opposite to each other on both sides of the membrane, using two to three such pairs per 10 sq. cm. membrane area. This method does not provide as firm a membrane support as the two others and should be used only for small cells.

The cell is clamped to the metal rod backbone through two short metal rods pressed into drilled holes in one of the brass rings.

When the largest cell is assembled, there is a tendency for the lucite and consequently for the membrane to balloon, since the pressure is applied only at the edges of the lucite disks. This can be overcome by providing additional compression at the center of the disks by means of a suitable clamp which is independent of the brass rings.

The lucite disks are simply and tightly connected with the stopcocks and the glass parts leading to the manometer attachment by tygon tubing without any cement. This tubing, of 1.5 mm. wall thickness and 10 mm. outside diameter, is placed into 8 mm. bore holes in the lucite. To introduce the tubing into the smaller hole, a piece of end is cut off conically along the length and using the tongue thus formed, the tubing is pulled into the hole. The tongue is finally cut away.

The lucite disks are equipped with the connectors before the cell is assembled, and for this purpose, each lucite disk has two holes near the opposite ends of its vertical diameter.

THE MANOMETER

The design of the glass parts assembled with the cell is shown in Fig. 2 and, as can be seen, the cells can be changed without taking the manometer unit apart. The different glass parts are connected by spherical ground-glass joints of 12 mm. sphere diameter. These joints are lubricated with silicone grease and clamped together. The glass parts can also be connected by tygon tubing. All connecting capillaries have 1 mm. bore. To ensure a constant capillary rise effect, the measuring capillary (E) should be of uniform bore; it was found that the most satisfactory bore diameter was 0.3 ± 0.003 mm. The tubes (A) and (B) are 1 cm. in diameter and are cut from the same piece of tubing. The syringe is lubricated with silicone grease and its plunger is firmly wired to a levelling screw. The toluene–water interface is in the 1.5 cm. diameter bulb below the measuring capillary. The ground-glass joint (D) is lubricated with toluene-insoluble lubricant (e.g. Fisher's Nonaq Grease) and waterproofed by coating the outside with Pyseal cement. All stopcocks have 1 mm. bore.

OPERATION

The measuring capillary is attached to the unit after the other parts have been filled with water. The bulb (D) is then filled with toluene, the capillary is sealed in, the stopcock (C) is opened, and toluene is allowed to rise into the dry capillary.

The unit is filled with solution from a pipette which is connected to the stopcock (H) by rubber tubing. To change solutions, the solution chamber is emptied and rinsed several times with the new solution. If necessary the water in the solvent chamber can be changed without disturbing the toluene–water interface, through stopcocks (G) and (F).

The measurements are carried out slightly above room temperature in a water thermostat controlled to 0.001° C. Temperature equilibrium is established in the cell within 0.5 to 1.5 hr.

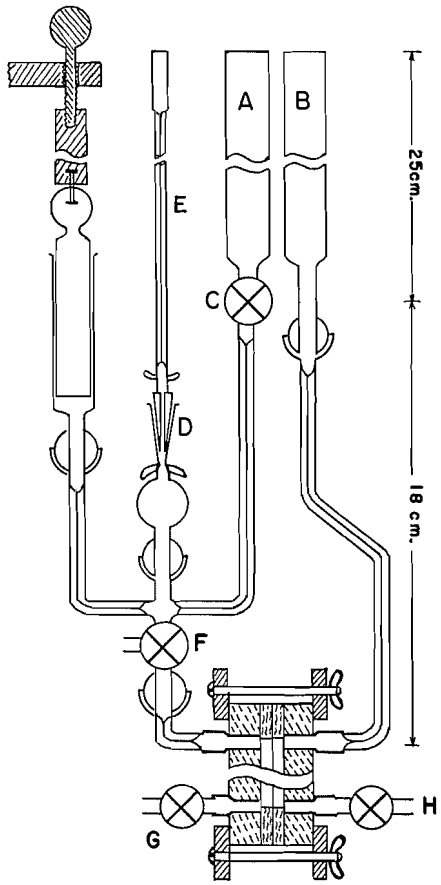

FIG. 2. Assembled osmometer unit showing details of the manometer system.

The readings are made on a scale with 0.5 mm. subdivisions behind the measuring capillary and are estimated to 0.01 cm. To avoid parallax, the scale is viewed through a cathetometer. The levels in tubes (A) and (B) are brought within 0.1 mm. of one another and the meniscus height in the measuring capillary is recorded. Stopcock (C) is then closed and the osmotic equilibrium is established by the half-sum method suggested by Fuoss and Mead (1). The difference between the original capillary meniscus reading and the one corresponding to the equilibrium is equal to the osmotic pressure

in centimeters toluene. No correction is necessary, since the density difference between water and the solution is negligible.

It is desirable to avoid excessive dilution of the solution by osmotic diffusion of solvent while the temperature equilibrium is being established. The measuring technique described above can be used only when the osmotic pressure of the solution is small, in our experience less than 3 cm. toluene. In the case of the larger osmotic pressures, it is preferable to adjust a level difference roughly corresponding to the expected osmotic pressure in tubes (A) and (B) when the instrument is being filled. Thus the driving pressure acting on the solvent is kept small until the actual measurement can be started. When temperature equilibrium is reached, stopcock (C) is closed and the osmotic equilibrium is established by the half-sum method. If the levels in tubes (A) and (B) are u and v respectively, and the meniscus levels in the capillary with stopcock (C) open and at equilibrium are w and z respectively, the osmotic pressure in gm./sq. cm. is given by

$$p = (v-u)d_{\text{solvent}}+(w-z)d_{\text{toluene}}$$

where d is the density.

The reproducibility of the capillary rise along the length of a 0.3 mm. bore capillary is ± 0.02 cm., if the precision of the bore is within 1%. If necessary, the accuracy can be improved by using larger capillaries; this however, can only be done at the expense of a longer time to osmotic equilibrium.

In addition, the accuracy of the measurements depends on the so-called "zero pressure", i.e. the finite apparent osmotic pressure existing when solutions of identical composition are placed on both sides of the membrane. In some instances, the solute may be adsorbed on the membrane thus leading to considerable difference in zero pressure before and after the measurement.

The speed of the measurements depends mainly upon the ratio of the capillary cross-section to membrane area. Using the small cell with 300 PT cellophane and the large cell with denitrated nitrocellulose and a capillary of 0.3 mm. bore, equilibrium osmotic pressures can be established to ± 0.02 cm. by the half-sum method within four hours after the temperature equilibrium is reached. This compares favorably with other designs of osmometer.

These units have been used for molecular weight determinations of fractionated samples of sodium ligninsulphonate; the results will be presented in a later communication.

CARBOHYDRATE THIOETHERS

1-DEOXY-1-THIOETHYL-D-FRUCTOSE[1]

BY SAMUEL B. BAKER

ABSTRACT

1-Deoxy-1-thioethyl-D-fructose was synthesized by two distinctly different methods. Less than the usual hindrance of the toluenesulphonyloxy group on the C-1 position in 2,3-4,5-diisopropylidene-1-*O*-*p*-toluenesulphonyl-D-fructose was found to occur in the presence of sodium ethanethiolate.

A previous (1) publication described the synthesis of a thioalkyl aldose, namely, 6-deoxy-6-thioethyl-D-galactose. Extension of this investigation into the ketose series resulted in the synthesis of 1-deoxy-1-thioethyl-D-fructose (III) by two distinctly different methods.

The first method employed 2,3-4,5-diisopropylidene-1-*O*-*p*-toluenesulphonyl-D-fructose (I). A solution of the latter substance in anhydrous N,N-dimethylformamide on treatment with freshly prepared sodium ethanethiolate yielded 2,3-4,5-diisopropylidene-1-deoxy-1-thioethyl-D-fructose (II), but only after heating at 100° for 30 hr. This latter reaction was exceedingly slow when compared with the reaction of sodium ethanethiolate and 1,2-3,4-diisopropylidene-6-*O*-*p*-toluenesulphonyl-D-galactose (I). The latter reaction was complete in two hours. The sluggishness of the ketose reaction is reminiscent of the nonreaction of the same fructose derivative with sodium iodide in acetone (4).

The second method of synthesis of III made use of so-called "glutose". This substance is essentially a mixture of fructose anhydrides (6, 7). Treatment of the amorphous "glutose" mixture with an excess of sodium ethanethiolate in anhydrous methanol yielded a small quantity of a substance that proved to be identical to that obtained from I.

EXPERIMENTAL

2,3-4,5-Diisopropylidene-D-fructose (3)

This substance was prepared according to the method of Glen, Myers, and Grant (3) with slight modification. A yield of 347 gm. (89%) was obtained from 270 gm. fructose. The melting point 96–97° and $[\alpha]_D^{22°}$ −32.6° (H_2O: *c*, 1.013) agreed with the constants reported in the literature (2) for 2,3-4,5-diisopropylidene-D-fructose.

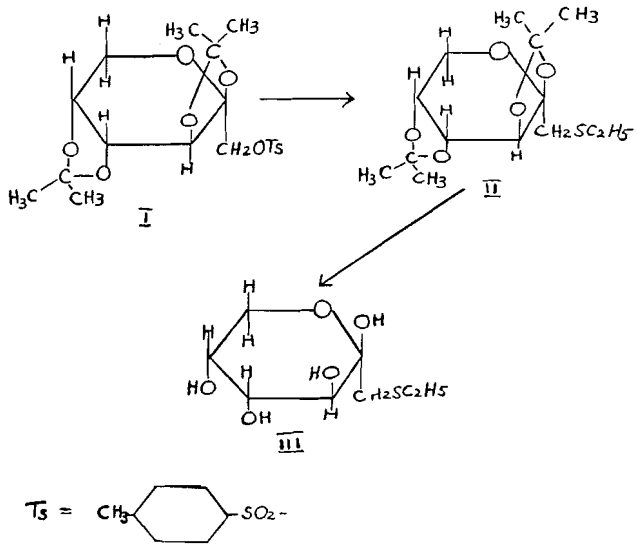
[1]*Manuscript received May 13, 1955.*
Contribution from the Division of Organic Chemistry, Research Institute, Montreal General Hospital, Montreal, Que.

*2,3-4,5-Diisopropylidene-1-O-p-toluenesulphonyl-*D*-fructose* (*I*) (*5*)

2,3-4,5-Diisopropylidene-D-fructose (179 gm.) was tosylated with *p*-toluenesulphonyl chloride (135 gm.) in anhydrous pyridine. The reaction mixture was treated in the usual manner and the crude air-dried product was recrystallized from methanol yielding 192 gm. (66%). A second recrystallization from aqueous ethanol gave m.p. 81–82° and $[\alpha]_D^{22°}$ −27.2° (ethanol: *c*, 2.693). The literature (5) reports m.p. 83° and $[\alpha]_D$ −27.1° (ethanol).

*2,3-4,5-Diisopropylidene-1-deoxy-1-thioethyl-*D*-fructose* (*II*)

2,3-4,5-Diisopropylidene-1-*O*-*p*-toluenesulphonyl-D-fructose (I) (97.5 gm.) and freshly prepared sodium ethanethiolate (35 gm.) were dissolved in hot N,N-dimethylformamide (275 cc.). The mixture was heated on the steam bath for 30 hr. and then added to cold water (3000 cc.). An oil separated and the mixture was extracted twice with ether. The ethereal solution was dried over



anhydrous sodium sulphate, filtered, and concentrated *in vacuo*. The residual sirup was then heated at 100° for six hours at 10 mm. pressure to remove any N,N-dimethylformamide. The main product was distilled at 96–100° and 0.04 mm. and the yield was 54.4 gm. (76%). A portion of the nearly colorless distillate was fractionally distilled through a 20 cm. Widmer column and practically all distilled at 107° and 0.07 mm. The constants were: $\eta_D^{26°}$ 1.4823 and $[\alpha]_D^{20°}$ −58.4° (chloroform: *c*, 9.4212). Anal.: Calc. for $C_{14}H_{24}SO_5$: C, 54.27; H, 7.89; S, 10.52. Found: C, 54.02; H, 7.93; S, 10.44.

*1-Deoxy-1-thioethyl-*D*-fructose* (*III*)

2,3-4,5-Diisopropylidene-1-deoxy-1-thioethyl-D-fructose (20 gm.) was added to 1 *N* sulphuric acid (1000 cc.). The mixture was stirred for 18 hr. at 50°, then cooled to room temperature and carefully neutralized with barium hydroxide – barium carbonate. The solution was not allowed to become alkaline

at any time. The barium sulphate and carbonate mixture was removed by filtration, the filter washed several times with hot water, and the combined filtrates and washings concentrated to a thick sirup *in vacuo* at 40°. The sirup, after it had been kept for three days in an evacuated desiccator over calcium chloride, crystallized. The hard mass was dissolved in a small volume of hot acetone and filtered. Slow cooling of the filtrate caused crystallization. The nearly pure product, having a melting point of 86–88°, was recrystallized once more from anhydrous acetone – ether mixture when the melting point was raised to 87.5–88.5° and it showed $[\alpha]_D^{22°}$ −71.3° → −62.8° (24 hr.) (water: *c*, 3.1548). Anal.: Calc. for $C_8H_{16}SO_5$: C, 42.85; H, 7.14; S, 14.29. Found: C, 42.66; H, 7.31; S, 14.3.

D-Glucose Phenylosazone from 1-Deoxy-1-thioethyl-D-fructose

1-Deoxy-1-thioethyl-D-fructose (2 gm.) was dissolved in water (20 cc.). Acetic acid (5 cc.) and redistilled phenylhydrazine (4 cc.) were added and the clear solution heated at 80° for 30 min. Ethanethiol was evolved and precipitation occurred. The reaction mixture was cooled to 20°, filtered, and the filter washed with cold water. The yield of air-dried material was 2.3 gm. (71%). A sample was recrystallized twice from hot dilute methanol and it melted at 205–207°. A mixed melting point determination with authentic D-glucose phenylosazone was 204–207°.

1-Deoxy-1-thioethyl-D-fructose from "Glutose" (6, 7)

Ethanethiol (40 cc.) was added to cold 0.7 *N* sodium methylate solution (500 cc.). "Glutose" (6, 7) (21 gm.) was added and the brown solution heated under reflux on the steam bath for two hours. The reaction mixture was cooled to 10°, neutralized carefully in the fume cabinet with 3 *N* hydrochloric acid, and then concentrated *in vacuo* at 30°. Final traces of water were removed by ethanol–benzene azeotropic distillation. The dry sirup was extracted with boiling anhydrous acetone and the filtrate was concentrated *in vacuo* to a thick sirup. The latter sirup was again extracted with hot acetone and the filtered solution was decolorized with activated charcoal. The yellow filtrate obtained was concentrated to approximately 50 cc., seeded with several crystals of 1-deoxy-1-thioethyl-D-fructose (III), and allowed to stand stoppered at room temperature for about three weeks. During this time crystallization occurred. The crystals were removed by filtration and the filter was washed with cold (0°) acetone. The crude product was twice recrystallized from acetone–ether and after drying it melted at 87–88.5°. The mixed melting point with 1-deoxy-1-thioethyl-D-fructose, obtained previously, was 86–88°. The yield was 0.36 gm.

Tetraacetyl-1-deoxy-1-thioethyl-D-fructose

1-Deoxy-1-thioethyl-D-fructose (5 gm.) was dissolved in anhydrous pyridine (25 cc.). The solution was cooled to −20° and acetic anhydride (25 cc.) was added. The reaction mixture was kept at −20° for one hour, allowed to stand at 22° for 22 hr., and finally added to cold water. The separated sirupy product did not crystallize and the aqueous mixture was extracted four times with ether (100 cc.). The combined ethereal solutions were washed with cold 2%

hydrochloric acid, water, and saturated potassium bicarbonate and then dried over anhydrous sodium sulphate. The ethereal solution, after filtration, was concentrated to dryness by slow evaporation in a desiccator and the sirupy mass solidified, in a yield of 5.9 gm. (68%). It was recrystallized twice from anhydrous ether and it melted at 133–134° and $[\alpha]_D^{22°}$ −47.6° (chloroform: *c*, 1.8492). Anal.: Calc. for $C_{16}H_{24}SO_9$: C, 48.98; H, 6.12; S, 8.19; CH_3CO, 43.9. Found: C, 48.60; H, 6.41; S, 8.2; CH_3CO, 43.74.

*Tetrabenzoyl-1-deoxy-1-thioethyl-*D*-fructose*

1-Deoxy-1-thioethyl-D-fructose (5 gm.) was dissolved in anhydrous pyridine (50 cc.). The mixture was cooled to −20° and benzoyl chloride (13 gm.) was added in one portion. The mixture was allowed to stand at −20° for two hours, then overnight at 22°. The reaction product was isolated as above and the resulting sirup was crystallized from methanol. The separated crystalline mass was recrystallized from hot methanol and the nearly pure product, 8.1 gm. (57%), after an additional recrystallization from a large volume of ether – petroleum ether (1: 1) melted at 103–104° and $[\alpha]_D^{22°}$ +61.9° (chloroform: *c*, 2.2844). Anal.: Calc. for $C_{36}H_{32}SO_9$: C, 67.5; H, 5.0; S, 5.0; C_6H_5CO, 65.62. Found: C, 67.34; H, 5.1; S, 4.96; C_6H_5CO, 65.6.

THE TERMINAL AMINO ACIDS OF WHEAT GLIADIN[1]

By L. K. Ramachandran[2] and W. B. McConnell

ABSTRACT

Wheat gliadin has been found by two different methods to contain three N-terminal histidine residues for each molecular weight of 27,000. Trace amounts of N-terminal aspartic acid, glutamic acid, alanine, valine, and serine were also detected in the preparation used. Hydrolysis in boiling hydrochloric acid partially destroyed the di-2,4-dinitrophenyl derivative of histidine. Losses of from 5% to 25% occurred depending upon the time and conditions of hydrolysis. Carboxypeptidase did not release free amino acids from wheat gliadin but qualitative evidence for the occurrence of C-terminal glutamic acid and C-terminal "leucine" was obtained.

It has been reported by Koroś (9) that wheat gliadin contains three free amino groups and that these belong to the three N-terminal histidine residues. Although doubt exists that gliadin is composed of a homogeneous and unique molecular species the observations of Koroś would point to the existence of at least one characteristic feature in gliadin. Because details of Koroś's work were unavailable independent experiments were done to determine the nature of the N-, and also of the C-, terminal amino acids of gliadin. Since the completion of the present work Koroś's results have been questioned (6) and it was reported that Sanger's method revealed one N-terminal tyrosine residue in gliadin from *Triticum durum*, and two N-terminal residues, one each of glutamic acid and tyrosine, in gliadin from *Triticum vulgare*; no N-terminal histidine was detected. Results recorded in the present communication support the earlier report (9) that histidine is the major N-terminal amino acid in gliadin. In addition, evidence presented indicates that glutamic acid and "leucine" occupy the C-terminal positions.

EXPERIMENTAL

Gliadin was prepared by the method of Blish and Sandstedt (4). The sample contained 17.64% nitrogen on a moisture and ash-free basis. The ninhydrin colorimetric procedure (8) and the Van Slyke nitrous acid method (11 min. reaction) indicated 3.18 and 3.32 free amino groups, respectively, for an assumed molecular weight of 27,000.

Identification of N-Terminal Groups Using 2,4-Dinitrofluorobenzene

DNP-gliadin was prepared using the reaction conditions described by Porter (14). Two grams of the protein and 2 gm. $NaHCO_3$ were suspended in 20 ml. water, 40 ml. of a 10% (w/v) solution of DNFB in ethanol were added, and the mixture was shaken for two hours at room temperature. The reaction mixture was exhaustively dialyzed against distilled water and the precipitated protein collected, washed, and dried (yield 2.0 gm.). It was calculated from

[1]*Manuscript received June 10, 1955.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1953–55.*

the amide nitrogen content (14) that 119.9 mgm. of DNP-gliadin corresponded to 100 mgm. of the original gliadin. Samples of DNP-gliadin (100 mgm.) were hydrolyzed in 10 ml. of boiling 5.7 *N* hydrochloric acid for four hours or for 24 hr. Another sample was hydrolyzed in 12 *N* acid in a sealed tube at 105° C. for 24 hr. (14). The DNP-amino acids in the hydrolyzates were fractionated into ether-soluble and acid-soluble materials and the fractions were chromatographed by each of three previously used methods (2, 3, 13).

DNP-histidine was the only amino acid derivative found in the acid-soluble fraction. Trace amounts of DNP-aspartic acid, glutamic acid, alanine, valine, and serine were detected in the ether-soluble material and, although gliadin contains at least two residues of lysine per molecule, no ϵ-DNP-lysine was found. The identity of the DNP-histidine was established by hydrolyzing it with concentrated ammonia (12) in a sealed tube and chromatographing the resulting amino acid on paper.

The yields of various 2,4-dinitrophenyl derivatives obtained from the treated gliadin are recorded in Table I. The calculations for the histidine are

TABLE I

YIELD OF DNP-DERIVATIVES FROM ACID HYDROLYZATES OF DNP-GLIADIN

Derivative	Yield: moles/27,000 gm.	
	4 hr. hydrolysis	24 hr. hydrolysis
Di-DNP-histidine (N-terminal histidine)	3.1	2.9
Other DNP-amino acids*	0.17	0.11
Dinitrophenol, dinitroaniline, etc.†	1.3	1.0

**Calculated as DNP-aspartic acid.*
†Calculated as dinitrophenol.

based on optical density measurements at 360 mμ and reference to the calibration curve for di-DNP-histidine. The DNP-amino acids found in traces are calculated as DNP-aspartic acid. Values for histidine are corrected for hydrolytic losses by increasing them by 25% (see below). It was also found that only 71% of the expected histidine derivative could be estimated in a dinitrophenylation of histidine done under the same conditions as employed with gliadin. To compensate for this low recovery in dinitrophenylation the yields of di-DNP-histidine were also multiplied by the factor 1.41. Because of the large corrections the results in Table I are only approximate. Chromatography on a silicic acid column was used to separate trace amounts of DNP-amino acids from the relatively large amounts of dintrophenol and dinitroaniline found in the ether-soluble fraction (11). No corrections have been applied for hydrolytic losses of the latter materials.

Effect of Acid Hydrolysis on Di-DNP-histidine

Di-DNP-histidine, with the reported physical constants (15), was prepared according to the method of Porter. Twenty-five milligrams was hydrolyzed with 20 ml. of 5.7 *N* HCl. The hydrolyzates were extracted with ether to remove artifacts like dinitroaniline and dinitrophenol, and the di-DNP-histidine

remaining in the acid phase was determined by spectrophotometry. For time intervals of 3.5, 6.5, and 24.0 hr. the destruction observed was 0.0, 5.0, and 12.0% respectively. When the same weight of the pure derivative was hydrolyzed in the presence of 40 mgm. gliadin the destruction observed was 25.0% for 24 hr. The latter figure has been used to correct for hydrolytic losses.

Application of the Edman Method (7) to N-Terminal Residue Identification

One gram gliadin was dissolved in 4 ml. 50% pyridine, the pH was adjusted to 8.6 with 0.1 *N* alkali, and 0.2 ml. of phenylisothiocyanate was added with vigorous stirring. The temperature was maintained at 40° C., and alkali was added as required to keep the pH at 8.6. When consumption of alkali ceased, the reaction mixture was extracted twice with benzene and the protein precipitated with acetone. The dry phenylthiocarbamyl protein was then suspended in 9 ml. of anyhydrous nitromethane containing 4% HCl by weight. After an hour of agitation, the material was filtered and washed with a few milliliters of the solvent. The combined filtrates were evaporated *in vacuo* to remove all traces of solvents and HCl. The residue was dissolved in EtOH. Absorption at 270 mμ indicated a content of 3.2 M. of phenylthiohydantoin per 27,000 gm. of the protein. Paper chromatography of the material (10) showed that PTH-histidine was the major component. Its identity was confirmed by barium hydroxide hydrolysis to the free amino acid. Stepwise degradation of the residual protein was carried out but during the second and third treatments an abnormally high yield of phenylthiohydantoin (of the order of five moles) was obtained. No detailed identification of the material was attempted, but paper chromatography of barium hydroxide hydrolyzates indicated the presence of several ninhydrin positive spots.

C-Terminal Residues of Gliadin

Action of carboxypeptidase on gliadin.—One-half gram of gliadin was suspended in 20 ml. water, the pH was adjusted to 7.7 with 0.2 *N* NaOH, and the mixture was incubated with 0.2 ml. of carboxypeptidase suspension (12.6 mgm./ml. Armour). In another experiment the same weight of protein was suspended in 20 ml. of 1% (w/v) sodium bicarbonate. No liberation of amino *N* could be detected by the Van Slyke method during a seven-hour period, and no free amino acids could be detected in the reaction mixture by paper chromatography. It was therefore concluded that the C-terminal amino acid residues in gliadin, if any, were not susceptible to hydrolysis by carboxypeptidase under the conditions used.

Application of the method of Schlack and Kumpf (1) to gliadin.—One gram of the protein was mixed with 0.3 gm. of pulverized anhydrous ammonium thiocyanate in 77 ml. of an AcOH: Ac_2O (9: 1) mixture, and the reaction mixture was stirred at 45° C. for four hours. At the end of this period 30 ml. of HCl was added dropwise with stirring and the material heated on a steam bath for one hour. The product was dried *in vacuo*, the residue dissolved in 60 ml. of 0.25 *M* phosphate (pH 6.5) and extracted five times with equal volumes of ethyl acetate. The combined extracts were washed once with an equal volume of water and dried, and the residue was hydrolyzed with 2.5 ml.

of 1.25 *N* $Ba(OH)_2$ at 140° C. in a sealed tube. The hydrolyzate was neutralized with carbon dioxide and heated for 10 min. on a steam bath to destroy carbamic acids. Aliquots of the suspension were examined by paper chromatography (BuOH–AcOH–H_2O, 4:1:5). The only amino acids detected were glutamic acid and "leucine". The amounts of these amino acids were estimated by ninhydrin colorimetry using a standard curve for the two amino acids obtained under the same conditions. One-half mole of glutamic acid and 0.45 mole of "leucine" were found for each 27,000 gm. gliadin. No corrections were applied.

Application of the lithium borohydride reduction method of Chibnall (5) indicated the presence of glutamic acid and "leucine" in C-terminal positions. Appreciable traces of other amino acids were also detected. Using a nine-fold excess of diazomethane for esterification of the protein and a 13-fold excess of $LiBH_4$ for the reduction in tetrahydrofuran, the total yield of α-amino alcohols was 0.654 mole per 27,000 gm. protein.

DISCUSSION

The present work supports the observations of Koroś (9) that gliadin of molecular weight 27,000 contains three free amino groups and that these belong to histidine. From this result, it was expected that three C-terminal amino acids could be detected. It was surprising, therefore, that carboxypeptidase did not liberate any free amino acids from the protein; particularly in view of the finding that leucine and glutamic acid were detected as C-terminal residues by the chemical method (1). Recoveries by the latter method are known to be very poor, and since only about 0.5 mole of C-terminal leucine and glutamic acid was found the data were not adequate for evaluation of the amounts of C-terminal leucine and C-terminal glutamic acid in gliadin. It is to be noted that Baptist and Bull (1) could not identify glutamic acid in glutathione or recover glutamic acid from glutamine by the Schlack and Kumpf method. The present identification of the C-terminal acids would therefore be tentative.

THE PREPARATION OF GUANIDINE FROM UREA, AMMONIUM CHLORIDE, ALUMINUM SULPHATE, AND AMMONIA UNDER PRESSURE[1]

By Jean L. Boivin

ABSTRACT

Guanidine has been synthesized by heating under ammonia pressure an intimate mixture of finely powdered urea, ammonium chloride, and aluminum sulphate. Good yields of guanidine as the hydrochloride salt have been obtained over a wide range of conditions. The mechanism of this synthesis is briefly discussed.

INTRODUCTION

If urea is heated under ammonia pressure, it is much more stable at high temperature because of the stabilizing effect of ammonia (1). The preparation of guanidine about to be described makes use of aluminum sulphate to assist the removal of water from the reaction. This starting material can be produced cheaply from bauxite, clay, and similar materials containing aluminum.

DESCRIPTION OF METHOD

By heating urea, ammonium chloride, and aluminum sulphate together under ammonia pressure at 300° C. for some time, yields of guanidine as high as 70% have been obtained. The reaction product was boiled with ammoniacal water in order to precipitate aluminum hydroxide (Diagram 1). The clear filtrate, which contained guanidine hydrochloride, ammonium sulphate, and unreacted urea and ammonium chloride, was evaporated to dryness. The residue was treated with liquid ammonia and the mixture filtered free from ammonium sulphate. By evaporation of the liquid ammonia solution, a residue was left containing guanidine hydrochloride together with unreacted urea and ammonium chloride. This crude guanidine hydrochloride was transformed into guanidine nitrate by treating its saturated aqueous solution with a quantity of ammonium nitrate equivalent to its guanidine content. After guanidine nitrate was removed the filtrate was evaporated to dryness and the residue heated to 250° C. This material was nearly pure ammonium chloride, suitable for use in a subsequent cycle.

The aluminum hydroxide and ammonium sulphate, individually isolated from the reaction products as indicated above, were heated together at 350° C. to regenerate aluminum sulphate (5) according to the following equation:

$$2Al(OH)_3+3(NH_4)_2SO_4 \rightarrow Al_2(SO_4)_3+6H_2O+6NH_3. \qquad [1]$$

The ammonia evolved during heating can be dried and returned to the reactor.

EFFECT OF TEMPERATURE

In order to explore the effect of the temperature of heating, mixtures consisting of equimolar quantities of urea and ammonium chloride and various

[1]*Manuscript received June 2, 1955.*
Contribution from the Organic Section of Canadian Armament Research and Development Establishment, Valcartier, Quebec. Issued as C.A.R.D.E. Report No. 50/51, 1951.

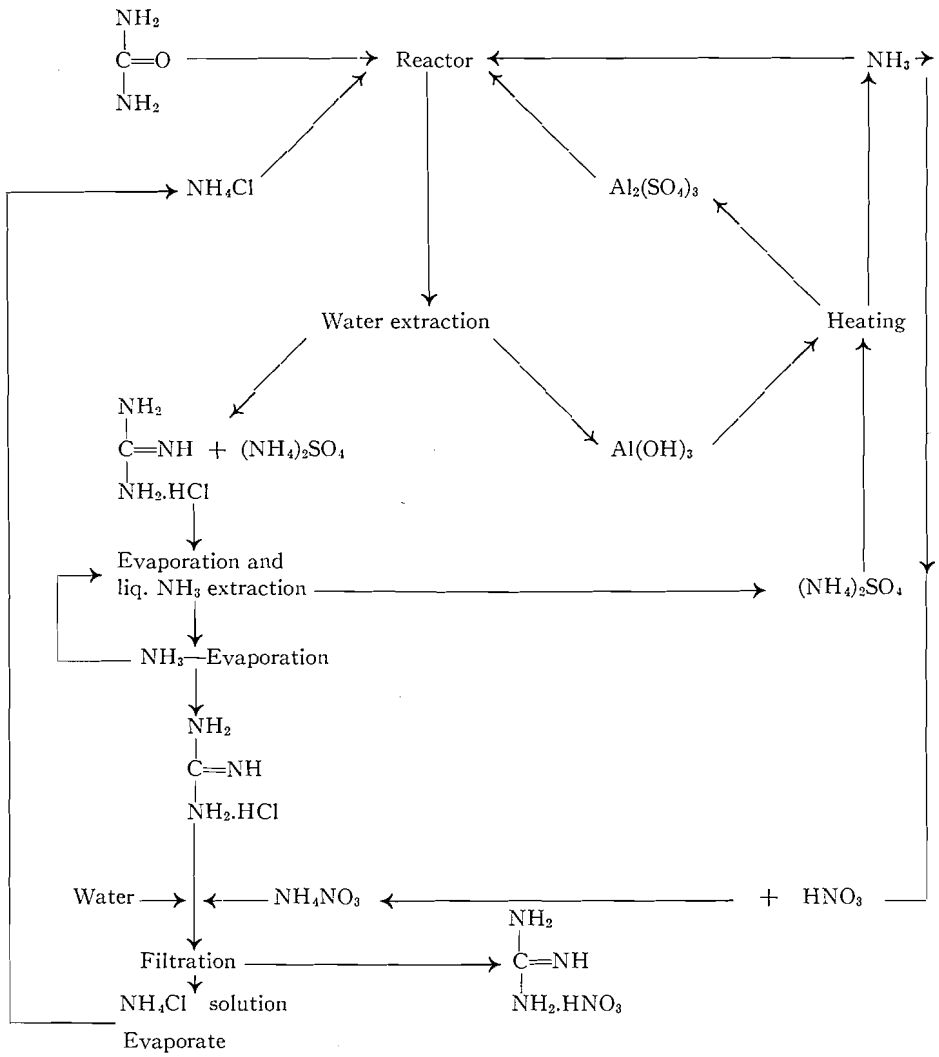

Diagram 1

amounts of aluminum sulphate were heated together under ammonia pressure. Table I shows the compositions of the mixtures and the conditions of the reaction. At high temperature, melamine is produced at the expense of guanidine. The yields of guanidine increase with temperature up to a maximum value, beyond which the formation of melamine becomes increasingly significant. The low yields shown here are ascribed to the fact that the ingredients were coarse and not thoroughly mixed. However, the table shows that increasing yields of guanidine were obtained with increasing amounts of aluminum sulphate.

TABLE I

EFFECT OF TEMPERATURE

Urea: 0.10 mole; NH_4Cl: 0.10 mole; time: 30 min.; pressure: 1000 p.s.i.g.

$Al_2(SO_4)_3$, mole	Temp., ° C.	Yield from urea, %	
		Guanidine	Melamine
0.0166	225	4	Nil
	250	10	Nil
	275	17	Nil
	300	36	10
	325	41	28
	350	29	35
0.033	250	14	Nil
	275	32	Nil
	300	45	Nil
	325	48	16
	350	38	20
0.05	225	Traces	Nil
	250	26	Nil
	275	40	Nil
	300	55	Nil
	325	63	37
	350	45	42

EFFECT OF CONCENTRATION OF UREA

By varying the molar quantities of urea added to a constant mixture of ammonium chloride and aluminum sulphate, as can be seen in Table II, the optimum yield was attained from equimolar amounts of urea and ammonium chloride. When urea was added in excess of this value, melamine was formed together with cyanuric acid.

TABLE II

EFFECT OF CONCENTRATION OF UREA

NH_4Cl: 0.10 mole; $Al_2(SO_4)_3$: 0.05 mole; temp.: 300° C.; time: 30 min.; pressure: 1000 p.s.i.g.

	Guanidine	Melamine
0.05	43	Nil
0.10	55	Nil
0.15	34	23
0.20	31	22
0.30	22	20

EFFECT OF CONCENTRATION OF AMMONIUM CHLORIDE

It has been found (Table III) that increasing quantities of ammonium chloride give increasing yields of guanidine, melamine being absent under these conditions. There is a great increase in yield as ammonium chloride increases from 0.05 mole to the stoichiometric amount of 0.10 mole. The better yields obtained here are attributed to thorough mixing of solid ingredients before reaction took place.

TABLE III

EFFECT OF AMMONIUM CHLORIDE

Urea: 0.10 mole; $Al_2(SO_4)_3$: 0.033 mole; temp.: 300° C.; time: 30 min.; pressure: 1000 p.s.i.g.

0.10	68
0.15	70
0.20	75
0.25	68
0.30	65

EFFECT OF TIME OF HEATING

This reaction is dependent on the period of heating (Table IV). It is more complete when the reaction time is longer. The yields increase with time and also with temperature.

TABLE IV

Urea: 0.10 mole; NH_4Cl: 0.10 mole; $Al_2(SO_4)_3$: 0.033 mole; pressure: 1000 p.s.i.g.

	90	64
	120	68
300	30	68
	45	70
	60	72
	90	79

EFFECT OF PRESSURE

The pressure factor is quite important in this reaction. There is evidence (Table V) that the yields are better at higher pressure. At atmospheric pressure, neither guanidine nor melamine was produced. At high pressure, yields were improved very significantly.

TABLE V

EFFECT OF PRESSURE

Urea: 0.10 mole; NH_4Cl: 0.10 mole; $Al_2(SO_4)_3$: 0.033 mole; temp.: 300° C.; time: 30 min.

200	37
400	57
1000	68
2000	72

MECHANISM OF THE REACTION

Although the mechanism of this reaction, involving four starting materials, is not fully understood, some suggestions may be offered as to the possible

intermediate compounds. In the absence of ammonium chloride, the heating of urea with aluminum sulphate and ammonia failed to give guanidine under the same conditions. Likewise, urea, ammonium chloride, and ammonia gave low yields of guanidine under these conditions of temperature and time; even with the long period of heating employed by Blair (1), these reactants gave only 23% guanidine. When both ammonium chloride and aluminum sulphate are present, however, yields as high as 75% can be obtained in a period of only an hour or so.

It is believed that in the presence of ammonia vapor, as in the present reaction, ammonium chloride and aluminum sulphate react as in the following reaction:

$$6NH_4Cl + Al_2(SO_4)_3 \longrightarrow 2AlCl_3 + 2(NH_4)_2SO_4. \qquad [2]$$

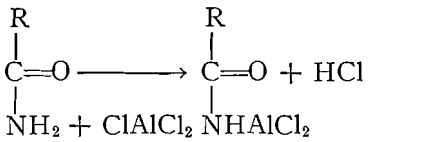
If then urea is present (6) and a small conversion to guanidine takes place, liberating water, the latter can react with aluminum chloride:

$$2AlCl_3 + 3H_2O \longrightarrow Al_2O_3 + 6HCl. \qquad [3]$$

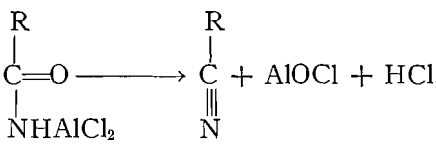
Accordingly, reaction is displaced towards the right, i.e. formation of guanidine is facilitated.

By analogy with the sulphamate synthesis of guanidine from urea (3) and also with the preparation of nitriles from amides by the action of sulphamates (2), it might be expected that an intermediate compound, comprising a substituted urea, could be involved.

Norris and Klemka (4) have shown that nitriles are obtained from amides and aluminum chloride through the formation of an intermediate compound, according to the following equation:

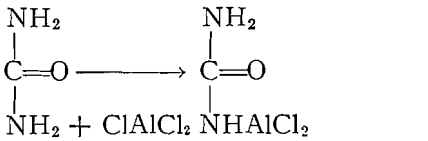


[4]

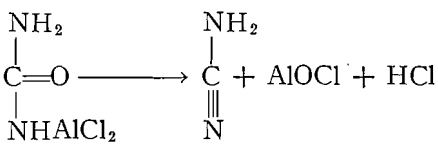


[5]

Urea, which is an amide, could react similarly giving cyanamide:



[6]



[7]

which under the actual condition should yield guanidine or melamine.

The above suggestions, though tentative, seem to offer an explanation of the observation that whereas neither ammonium chloride nor aluminum sulphate alone is effective, the two together produce a high yield of guanidine from urea and ammonia in a relatively short time of reaction.

It is believed that guanidine hydrochloride is formed from urea according to the following over-all equation:

$$3\,\underset{\underset{NH_2}{|}}{\overset{NH_2}{|}}C{=}O + 3NH_4Cl + Al_2(SO_4)_3 + 6NH_3 \rightarrow 3\,\underset{\underset{NH_2.HCl}{|}}{\overset{NH_2}{|}}C{=}NH + Al_2O_3 + 3(NH_4)_2SO_4. \qquad [8]$$

EXPERIMENTAL

Starting Materials

The urea used was commercial material previously dried at 110° C. Ammonium chloride used was Merck Reagent. Aluminum sulphate was the anhydrous material which had been heated at 500° C.

Procedure

An intimate mixture of finely powdered urea, ammonium chloride, and aluminum sulphate was placed in a glass liner. Enough ammonia (liquid) was added to the mixture to build the desired pressure. After the bomb was closed and the necessary connections were made, the reaction mixture was heated to the temperature of synthesis and in most cases vented to 1000 p.s.i.g. The period of heating was recorded from the time when the temperature of reaction was attained. After the mixture was cooled, the solid products were boiled with ammoniacal water. Aluminum hydroxide was filtered off and the filtrate was analyzed for guanidine and melamine contents.

Identification of Guanidine

(*A*) The picrate obtained from the solution presumed to contain guanidine was treated with an excess of dilute nitric acid and boiled. Then the mixture was exhaustively extracted with benzene to remove picric acid. By evaporation of the aqueous layer, a residue was obtained, m.p. 203–205° C. Recrystallizations from ethanol raised the melting point to 212–213° C. A mixed melting point with an authentic sample of guanidine nitrate was not depressed.

(*B*) A portion of the filtrate was evaporated to dryness and the residue dissolved in the minimum amount of water. Then ammonium nitrate was added, and the solution was heated to boiling and allowed to cool. Crystals separated out, m.p. 202–205° C. Recrystallizations from ethanol raised the melting point to 212–213° C.

SYNTHESIS OF γ-HYDROXYGLUTAMIC ACID (DIASTEREOMERIC MIXTURE)[1]

By Léo Benoiton and L. P. Bouthillier

ABSTRACT

γ-Hydroxyglutamic acid has been synthesized by two independent methods, namely the condensation of ethyl α-acetoxy-β-chloropropionate with diethyl acetamidomalonate, and the hydroxylation of glutamic acid. Chemical evidence is provided for the structure of the compound.

γ-Hydroxyglutamic acid has been proposed as an intermediate in the metabolism of hydroxyproline (3, 8). In 1941, Dakin (1) claimed to have prepared this dicarboxylic amino acid; however, the details of his synthesis were never published. As yet, there is no method available for the synthesis of this compound. We wish to report here the synthesis of γ-hydroxyglutamic acid by two independent methods.

For the first method, Fig. 1, ethyl α-acetoxy-β-chloropropionate (I) was condensed with diethyl acetamidomalonate (II) in the presence of sodium

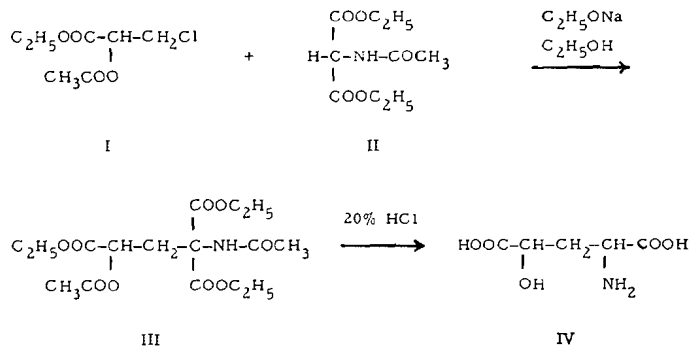

FIG. 1

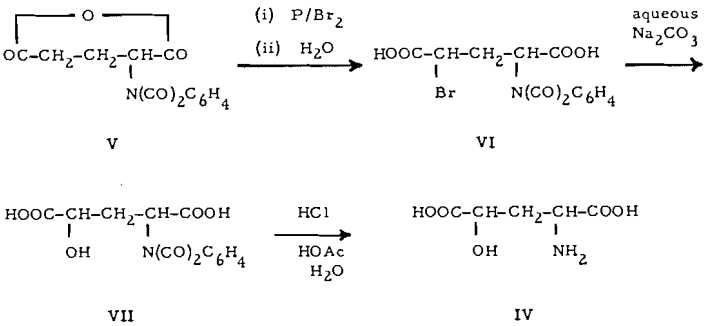
ethoxide to form diethyl α-acetamido-α-carbethoxy-γ-acetoxyglutarate (III) which on acid hydrolysis gave γ-hydroxyglutamic acid (IV). The free amino acid crystallized as the monohydrate from an aqueous solution at pH 2.5. The same product was obtained by condensing diethyl acetamidomalonate with ethyl α-acetoxyacrylate instead of ethyl α-acetoxy-β-chloropropionate in the presence of a catalytic amount of sodium; however the yield was not any better.

The structure of the compound was confirmed by the fact that it is resistant to periodate oxidation, oxidized to aspartic acid by potassium permanganate, and reduced to glutamic acid by hydriodic acid. The formation of aspartic acid and glutamic acid was demonstrated by paper chromatography in several solvents.

[1]*Manuscript received June 27, 1955.*
Contribution from the Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, Quebec.

For the second method, Fig. 2, N-phthaloyl-L-glutamic anhydride (V) was brominated and the γ-bromo-N-phthaloylglutamic acid (VI) thus obtained was hydroxylated to give γ-hydroxy-N-phthaloylglutamic acid (VII) which on hydrolysis gave γ-hydroxyglutamic acid (IV). The crystalline product obtained was contaminated with glutamic acid and could only be adequately purified by column chromatography. The pure amino acid coincided on paper



V VI VII IV

FIG. 2

chromatograms (Table I) with the γ-hydroxyglutamic acid prepared by the first method, and when submitted to the action of periodate, permanganate, and hydriodic acid, it gave results which were identical with those previously obtained.

EXPERIMENTAL*

1. *Preparation of γ-Hydroxyglutamic Acid*

(a) *Condensation of Ethyl α-Acetoxy-β-chloropropionate with Diethyl Acetamidomalonate*

To a solution containing 1.38 gm. (0.06 gm-atom) of sodium and 10.85 gm. (0.05 mole) of diethyl acetamidomalonate in 100 ml. of anhydrous alcohol was added dropwise 9.75 gm. (0.05 mole) of ethyl α-acetoxy-β-chloropropionate (4, 5). The reaction flask was placed on a mechanical shaker overnight and then the sodium chloride was removed by centrifugation and washed with alcohol. The combined supernatant and washings were freed of alcohol by distilling under reduced pressure and the remaining condensation product was refluxed for three hours in 100 ml. of 20% hydrochloric acid. The excess hydrochloric acid was removed by repeated distillation under reduced pressure and the residue was taken up with 25 ml. of water and decolorized with charcoal. The pH of the solution was adjusted to 2.5 with concentrated ammonia and the solution was cooled. The white crystalline mass obtained was filtered and recrystallized from water–alcohol. A further crop requiring several recrystallizations was obtained from the mother liquor by addition of alcohol. Total yield: 35%; m.p. 171–173° C. dec. Analysis for $C_5H_9NO_5 \cdot H_2O$: C, 33.89, 33.85; H, 6.23, 6.18; N, 7.81, 7.70. Calc.: C, 33.17; H, 6.12; N, 7.73.

When heated at 110° C. over phosphorus pentoxide *in vacuo*, the compound

**Analyses by the Geller Microanalytical Laboratories, Hackensack, N.J.; melting points by capillary method, uncorrected.*

loses two molecules of water to presumably give the lactam.* Analysis for $C_5H_7NO_4$: C, 42.23, 42.52; H, 4.78, 4.99; N, 9.80, 9.57. Calc.: C, 41.39; H, 4.86; N, 9.65.

(*b*) *Hydroxylation of* L-*Glutamic Acid*

N-Phthaloyl-L-glutamic anhydride was prepared by the method of Sheehan and Bolhofer (7). It was then brominated using a technique described by Eck and Marvel (2). Dry bromine, 146 gm., was added dropwise, with stirring, to a cooled mixture of 63 gm. of N-phthaloyl-L-glutamic anhydride and 9.4 gm. of red phosphorus. The mixture was then warmed on a water bath for six hours and the hot mixture was poured slowly into 500 ml. of water with vigorous stirring. The hydrolysis of the acyl bromide must be initiated by gentle warming, but it must then be controlled by cooling. The light yellow crystals obtained upon cooling were recrystallized from 500 ml. of hot water containing a few grams of bisulphite.

The product (35 gm.) was then refluxed in 250 ml. of 2 *N* sodium carbonate for three hours. The sodium ions were removed by adding sufficient Amberlite IR-120 to bring the pH down to 1, and the solution was concentrated under reduced pressure. The oily residue was refluxed for two hours in a mixture of 70 ml. of concentrated hydrochloric acid, 70 ml. of glacial acetic acid, and 70 ml. of water (6). The solution was cooled, the phthalic acid was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The residue was taken up with 25 ml. of water, filtered, and treated successively with silver carbonate, hydrogen sulphide, and charcoal. The solution was concentrated to 25 ml. and alcohol was added. The white crystals which formed (8 gm.) were chromatographed in two portions on an 8×50 cm. column of Dowex 50 (200 to 400 mesh) in the acid form using *N* hydrochloric acid as the eluting agent. The fractions containing the γ-hydroxyglutamic acid were combined and evaporated to dryness under reduced pressure. The residue was dissolved in 25 ml. of water and the solution was adjusted to pH 2.5 and cooled. The yield was 10% based on the N-phthaloylglutamic anhydride employed. The decomposition point observed was ill-defined (about 150°), being lower than the one reported above. This might well be due to a difference in the relative amounts of the optical isomers in the products obtained by the two methods. Analysis for $C_5H_9NO_5 \cdot H_2O$: C, 34.02, 34.13; H, 6.08, 6.05; N, 7.78, 7.61. Calc.: C, 33.17; H, 6.12; N, 7.73.

2. Characterization of γ-Hydroxyglutamic Acid

(*a*) *Paper Chromatography*

Five-microgram quantities of γ-hydroxyglutamic acid dissolved in water were chromatographed on Whatman No. 1 filter paper in several solvent systems using the ascending technique. The amino acid spots were revealed by spraying the chromatograms with a 0.1% solution of ninhydrin in *n*-butanol, and by heating them at 70° for 15 min. The results appear in Table I. The gray spots obtained in the last three solvents change to purple in 24 hr.

**The ninhydrin reaction was positive only after prolonged heating of the dehydrated product in the presence of the reagent.*

TABLE I

CHROMATOGRAPHY DATA

Solvent system	R_f	Color
Phenol–water (80: 20)	0.13	Purple
n-Butanol – acetic acid – water (60: 12: 28)	0.17 and 0.19	Pink and purple
Pyridine–water (65: 35)	0.53	Gray
n-Butanol–methanol–benzene–water (2: 4: 2: 2)	0.26	Gray
n-Butanol – 95% ethanol – ammonia (8: 1: 3)	0.02	Gray

In butanol – acetic acid – water, γ-hydroxyglutamic acid gives two overlapping spots of different colors. This is most probably due to the presence of two diastereoisomers.

(*b*) *Permanganate Oxidation*

A warm solution of 50 mgm. of γ-hydroxyglutamic acid in 50 ml. of 2 *N* sulphuric acid was titrated with a solution of potassium permanganate until no more reagent was consumed. The amino acids were extracted from the solution by shaking one hour with 5 gm. of Dowex 50 (20 to 50 mesh), and then displaced from the resin with 25 ml. of 5 *N* ammonium hydroxide (9). The eluate was evaporated to dryness, the residue was taken up with water, and aliquots of the solution were chromatographed. The only amino acid present in the solution coincided with aspartic acid in the five solvent systems described in Table I.

(*c*) *Reduction with Hydriodic Acid*

Forty milligrams of γ-hydroxyglutamic acid, 50 mgm. of red phosphorus, and 3 ml. of 57% hydriodic acid were heated in an evacuated sealed tube at 150° C. for eight hours. The mixture was diluted to 30 ml. with water and the amino acids were extracted from the reaction medium as in the previous experiment. Chromatograms of the resulting solution gave only one spot which coincided with glutamic acid in the same five solvents.

(*d*) *Periodate Oxidation*

A mixture of 10 mgm. of γ-hydroxyglutamic acid in 15 ml. of water, 10 ml. of 0.5 *M* sodium periodate, and 5 ml. of *M* sodium bicarbonate was allowed to stand for one hour. Chromatograms of the desalted solution, obtained as previously described, indicated a quantitative recovery of the original amino acid.

PHYSICOCHEMICAL STUDIES OF LIGNINSULPHONATES

I. PREPARATION AND PROPERTIES OF FRACTIONATED SAMPLES[1]

By J. L. Gardon[2] and S. G. Mason

ABSTRACT

High molecular weight ligninsulphonates were separated from other constituents of spent sulphite liquor by a method of dialysis allowing continuous removal of the dialyzates and their replacement by distilled water. The process was controlled by continuous analysis of the residue and dialyzate. The lower molecular weight ligninsulphonates in the dialyzates were separated from the carbohydrates by precipitating their barium salts with ethanol; four fractions corresponding to different times of dialysis were prepared in this manner. The ligninsulphonates in the dialyzed liquor were separated into four additional fractions by ultrafiltration through membranes of different pore sizes. The methoxyl, sulphur, and phenolic hydroxyl contents, neutralization equivalent weights, reducing powers, ultraviolet absorption spectra, diffusion coefficients, and number-average molecular weights of the eight fractions were determined. The molecular weights of the fractions range from 3700 to 58,000 but the integral molecular weight distribution curve indicates the presence of ligninsulphonates with molecular weights as high as 100,000.

INTRODUCTION

The dissolved solids in spent sulphite liquor consist largely of ligninsulphonates, and the remainder of sugars and acidic degradation products of cellulose and lignin. Various methods of separating ligninsulphonates from the other constituents have been used (2, 14) including precipitation, dialysis, and ion exchange. Attempts have also been made to fractionate the highly polydisperse ligninsulphonates according to their molecular weights by fractional dialysis (6, 32), fractional extraction of the free acids by propanol (31), fractional precipitation of the barium salts by ethanol (23) or acetone (25), countercurrent butanol extraction of free acids and amine salts in water (22), differential sorption on swollen ion-exchange resins (18), and fractionation by the different solubilities of various amine salts (4, 5, 19, 25).

It has been found that the methoxyl content of the fractions increases with decreasing diffusion coefficient (23), i.e. with increasing molecular weight, while the sulphur content of the fractions, with few exceptions (18), decreases with increasing methoxyl content.

Various attempts have been made to determine the molecular weights of ligninsulphonates. Cryoscopic and ebullioscopic methods (17, 30) yielded apparent molecular weights in the range of 1000 to 6000, but owing to electrolytic dissociation of the ligninsulphonates these values are probably low. Estimates of molecular weights have also been made from the diffusion coefficients (6, 7, 16) and from the dialysis rates (31) either by comparison of the ligninsulphonates with various test substances or by assuming that the ligninsulphonate molecules are spherical and non-solvated, and that the

relation between the molecular radius and the diffusion coefficient given by the Sutherland–Einstein equation applies.

Molecular weights ranging from 2000 to 20,000 have thus been obtained. These values agree in order of magnitude with the more precise values calculated by McCarthy (22) from diffusion and sedimentation constants, and by Olleman, Pennington, and Ritter (25, 28) from diffusion and viscosity data. McCarthy (22) obtained molecular weights ranging up to 100,000.

The ultimate aim of our work was to investigate some of the basic physicochemical properties of ligninsulphonates. For this purpose relatively large quantities of chemically well-defined ligninsulphonate fractions were prepared by a combination of fractional dialysis and ultrafiltration of a spent sulphite liquor concentrate. The flow sheet of this procedure is presented in Fig. 1.

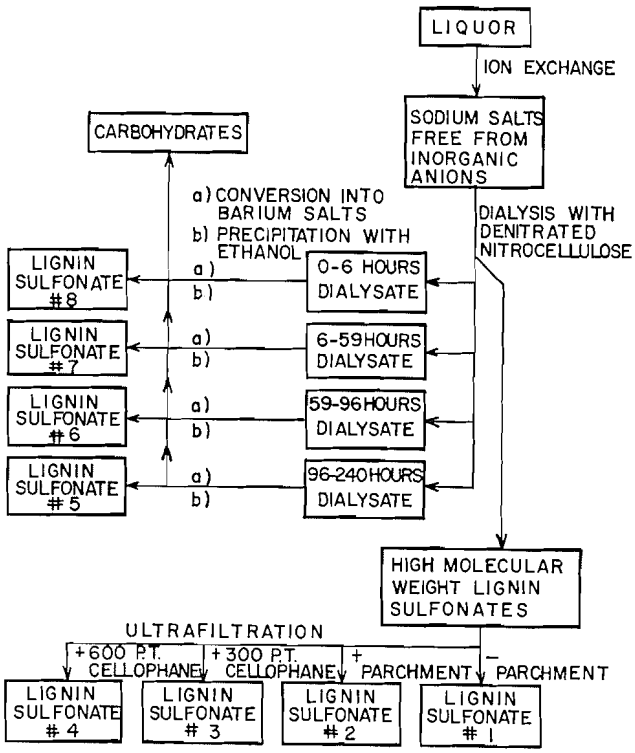

FIG. 1. Flow sheet for the fractionation of ligninsulphonates.

In this paper the fractionation techniques are described and the correlation between the analytical data and molecular weights of the samples is discussed. A number of other properties of the fractions are described in the following paper (10).

EXPERIMENTAL

Material

Spray-dried spent sulphite liquor marketed under the name of Lignosol B and supplied by Lignosol Chemicals Ltd. was used as the starting material.

The spent liquor was drawn from cooks of a mixture of balsam and spruce in approximately equal amounts.

About 700 gm. Lignosol was dissolved in 2 liters of water, filtered, passed through previously regenerated and well-washed Amberlite IR-4B (OH) anion- and IR-120 (H) cation-exchange resins to remove mineral acids and calcium respectively, and finally neutralized to pH 6.5 with sodium hydroxide. The resulting solution contained 633 gm. solids.

Fractionation

1. *Dialysis*

A Webcell Laboratory Model continuous countercurrent dialyzer (manufactured by Brosites Machine Corp., N.Y.) was used with denitrated nitrocellulose membranes. This dialyzer consists of 13 lucite rings, 17.5 cm. I.D. The membranes are clamped between these rings yielding seven water, and six solution chambers connected respectively in series through suitable channels. These channels were not used as it was found that the apparatus could be controlled better if the corresponding chambers worked in parallel. The design was accordingly altered by drilling holes in the top and bottom of each ring.

As shown in Fig. 2, the liquor was circulated from a reservoir through the dialyzer, with a continuous countercurrent flow of distilled water. A

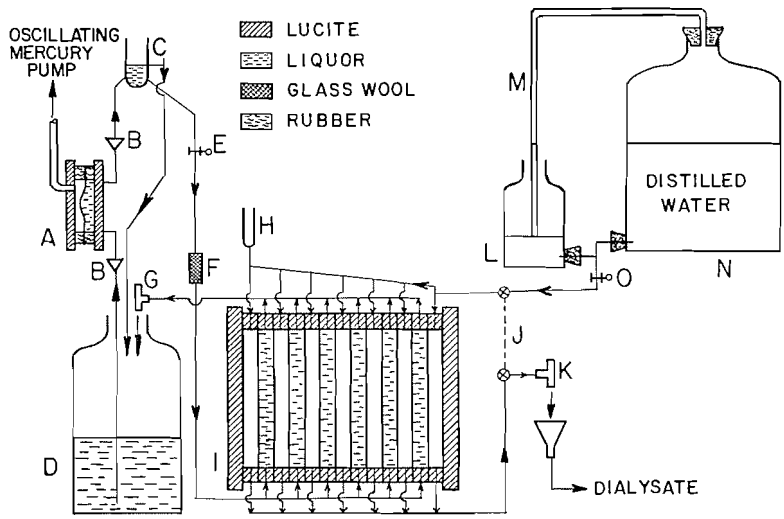

FIG. 2. The dialysis unit: (A) membrane pump, (B) valves, (C) liquor overflow, (D) liquor reservoir, (E) pinchcock to regulate liquor flow, (F) glass wool filter, (G) T tube, (H) air inlet, (I) dialysis cell, (J) bypass for initial filling of the water chambers, (K) T tube, (L) constant head device, (M) air inlet tube, (N) distilled water reservoir, (O) pinchcock to regulate water flow.

membrane pump (A) governed by an oscillating mercury pump was used for this purpose. The functioning of the pump is described in detail elsewhere (8).

To ensure steady flow the pump did not feed directly into the dialyzer, but passed through an overflow (C) and liquor flowed through the unit by gravity. The flow rate was regulated to 60 cc./min. by a pinchcock (E).

The distilled water came from a reservoir (N) and through a constant head device (L) at 3 cc./min. The free head of the water in the constant head device was maintained by the air inlet tube (M) which controlled the flow of air into and the flow of water from the reservoir (N). In this way the head of water was automatically maintained constant within 2 cm.

The volume of liquor was maintained between four and six liters. The volume increase due to osmosis amounted to about two liters per 12 hr.; this excess was periodically removed, neutralized with sodium hydroxide to avoid polymerization of the ligninsulphonic acids, concentrated by vacuum evaporation at 60°C., and reintroduced into the system.

To avoid growth of fungi during dialysis and the subsequent ultrafiltration, a small amount of toluene was added to the liquor.

The dialyzates produced every 12 hr. were handled as separate fractions. They were brought to pH 6.5 with sodium hydroxide or with cation-exchange resin as required. The content, reducing power, and neutralization equivalent weight of solids were determined. The reducing power of the solids in the residual liquor was calculated from these results by difference and checked by direct determination every 48 hr.

The dialysis was stopped after 19 days when the reducing power of the solids in both dialyzates and residual liquor became of the same order of magnitude (Fig. 3, curves F and G).

To separate the carbohydrates from the β-ligninsulphonates, i.e. the low molecular weight fractions, the barium salts were precipitated with ethanol as suggested by Erdtman (5). The dialyzates corresponding to 0 to 6, 6 to 59, 59 to 98, 98 to 240 hr. of dialysis were respectively combined to yield four separate fractions from which sodium was removed by cation exchange. The resulting free acids were neutralized with barium hydroxide, and the solutions were concentrated by vacuum evaporation at 60°C. to about 30% solid content and poured dropwise into four volumes of ethanol with vigorous stirring. The precipitates were twice dissolved in water and reprecipitated. The barium salts were passed through a cation exchanger and the free acids obtained were neutralized with sodium hydroxide and dried at 60°C. under vacuum, yielding fractions Nos. 5 to 8. The alcoholic mother liquors containing the carbohydrates were discarded; it should be noted, however, that in subsequent investigations it would be well worth while to study these constituents.

2. *Ultrafiltration*

Evidence presented later indicated that the residual liquor at the end of the dialysis contained pure ligninsulphonates. The residue was separated into four fractions (Nos. 1 to 4) by means of ultrafiltration using 600 P.T. cellophane, 300 P.T. cellophane, and No. 27 parchment membranes as supplied with the Webcell dialyzer.

It can be concluded from the results of the fractionation procedure that the

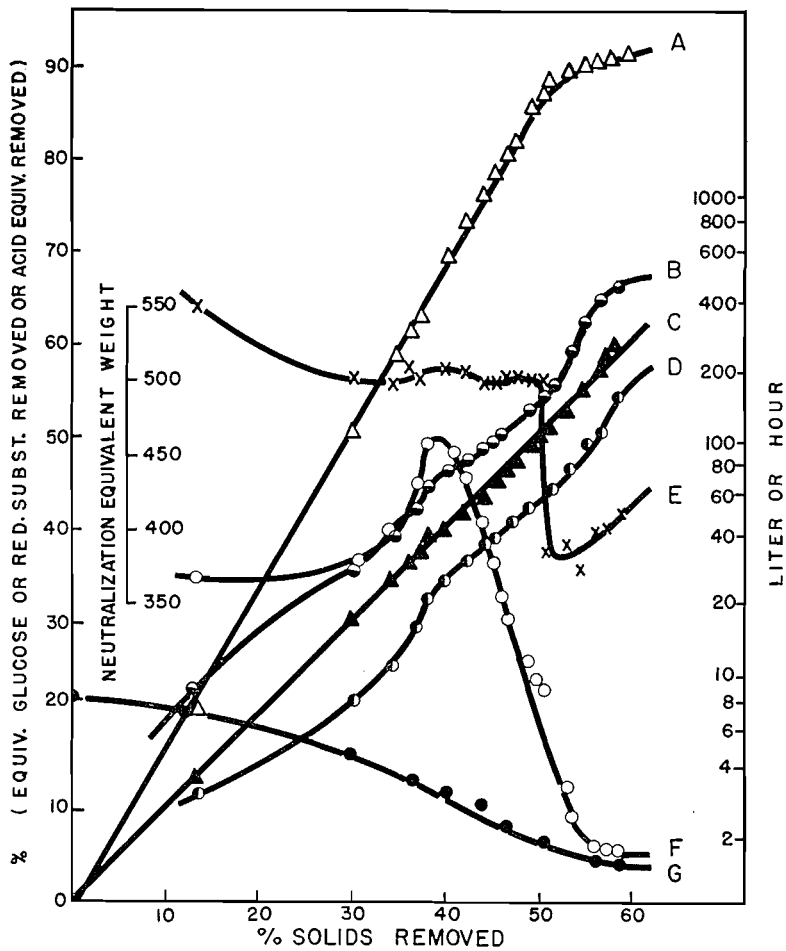

FIG. 3. Dialysis control diagrams showing per cent reducing substances removed (curve A), dialysis time (B), per cent acid equivalents removed (C), cumulative dialyzate volume (D), neutralization equivalent weight of the solids in the dialyzate (E), reducing power of the solids in the dialyzate (F), and reducing power of the solids in the dialyzed liquor (G).

denitrated nitrocellulose membranes used in dialysis have the smallest, and the parchment membranes the largest pore size.

The ultrafilter developed for the purpose of fractionating the lignin-sulphonates is described in detail in a separate publication (8); six ultrafilter cells each having a membrane area of 200 sq. cm. were used with cellophane and three with parchment membranes. The residual liquor was circulated in these cells and its volume was maintained constant at 1 liter. The ultrafiltration was stopped after 3, 7, and 12 days for the parchment, 300 P.T. cellophane, and 600 P.T. cellophane membranes respectively, the end points being determined as described later.

The ultrafiltrate of the 600 P.T. cellophane is fraction No. 4 and the fraction that did not pass the parchment is fraction No. 1. Before the solutions of the

different fractions were evaporated, they were adjusted to pH 6.5 by treatment with cation exchanger and addition of hydroxide as required.

All four of these fractions could be quantitatively precipitated with barium and alcohol.

Analytical Methods

To determine the neutralization equivalent weights, the sodium was removed by Amberlite IR-100 (H) cation exchanger and the free acid thus obtained was titrated with methyl red as indicator. Separate conductivity and pH titration experiments showed that all fractions have only one titration end point at pH 6.5. The titration curves were very similar to the ones presented by Peniston and McCarthy (26).

After the ligninsulphonates were oxidized with nitric acid the sulphur was determined as barium sulphate, as suggested by Yorston (34).

The methoxyl content was determined by the method of Peniston and Hibbert (27) adding red phosphorus, as suggested by Vjebock and Schwappach (33), instead of phenol to the hydriodic acid ligninsulphonate mixture.

The reducing power of the fraction was compared to that of glucose by means of Fehling solution and expressed as equivalent glucose, as described by Yorston (34).

Ultraviolet absorption spectra were measured in a Beckman Model DU spectrophotometer in pH 6 and pH 12 solutions with the buffers as blanks. It was shown that Beer's Law is valid for all fractions when ultraviolet light is used.

Diffusion Coefficients

The diffusion coefficients were evaluated in 0.5 *N* sodium chloride solution by the porous plate method (21, 24) in a modified apparatus described elsewhere (9). The diffusion cells were calibrated with 0.1 *N* potassium chloride, using Gordon's value (12) of 1.588 sq. cm./day for this solution. The ligninsulphonate concentrations were calculated by means of Beer's Law from the optical densities at 280 mμ.

Molecular Weights

The molecular weights were established from osmotic pressure measurements. To suppress dissociation 0.5 *N* aqueous sodium chloride was used as solvent. When necessary the results were corrected for membrane leakage as described in a separate paper (9). All data presented refer to neutral sodium salts.

RESULTS AND DISCUSSION

Dialysis

The main problem in fractionation of polydisperse materials by dialysis is to determine when the process is ended, since small amounts continue to diffuse through the membrane after long periods of dialysis. It was not possible to establish firm analytical criteria for the purity of ligninsulphonate fractions because their reducing power, sulphur content, neutralization equivalent weight, and methoxyl content change with the molecular weight. To complicate

matters further there are other acidic, reducing, sulphur-containing, and probably methoxyl-containing materials present in the liquor. These substances, mostly sugars and degradation products of cellulose and lignin, are believed, however, to have lower molecular weights than the bulk of the ligninsulphonates.

In Fig. 3 the control data of the dialysis are shown plotted against the cumulative percentage of the solids removed. Since the dialyzates contained materials with different diffusion rates, no theoretical relation could be derived for the time-dependence of the removal of the dialyzable solids. It was found that the concentration of the dialyzates was roughly inversely proportional to the dialysis time and cumulative dialyzate volume (Fig. 3, curves B and D).

The most significant curves are those of the reducing power of the solids in the dialyzate and in the residual liquor (curves *F* and *G*) and of the neutralization equivalent weights of the solids in the dialyzate (curve E). The following distinct stages of dialysis can be observed:

(1) The first 30% solids removed have a progressively increasing reducing power and decreasing neutralization equivalent weight as can be seen from curves F and G.

(2) In the next dialysis period 20% solids were removed. The reducing power of the solids in the dialyzate passed through a maximum while their neutralization equivalent weight remained constant.

(3) The reducing power and neutralization equivalent weight of the subsequent 2% solids removed decreased sharply and the neutralization equivalent weight passed through a minimum at 375. At this minimum the reducing power of the dialyzate was low, thus indicating that it contained little non-ionic sugar. Thus it is fair to assume that the previous dialyzates contained acids with neutralization equivalent of 375 and less.

(4) There is evidence that after the diffusion of 52% solids, the residual liquor consists of carbohydrate-free ligninsulphonates. This is indicated by the fact that the reducing power of the solids in the dialyzate and in the rest of the liquor is roughly the same and that, with increasing time of dialysis, the neutralization equivalent weight of the dialyzate increases; the neutralization equivalent weight of the ligninsulphonates increases with increasing molecular weight.

The reducing power of the diffusing and of the residual solids was roughly equal at the end of the dialysis indicating that the reducing power of the ligninsulphonates investigated was inherent and not due to impurities. In this connection the experiments of Peniston and McCarthy (26) are of interest. These authors plotted the reducing power of dialyzed ligninsulphonates, as obtained in a continuous countercurrent dialyzer, against the reciprocal of the time of dialysis and by extrapolating their data to a value corresponding to infinite time of dialysis concluded that really pure ligninsulphonates should not be reducing. The present experiments indicate that care must be taken in such an extrapolation. The curve G can be extrapolated to zero from the region of 30 to 52% solids removal but, on the other hand, it runs almost parallel to the horizontal axis.

Degree of Fractionation

Neither fractional dialysis nor ultrafiltration as employed allow absolute separation of the different molecular weight fractions; while this is self-evident in fractional dialysis, it needs further explanation for ultrafiltration.

The behavior of solutes in ultrafiltration depends on sizes of the molecules, and the membrane pores. Materials with relatively small molecules can pass through the membrane in unchanged concentration, intermediate molecular size materials pass through the membrane with a reduced concentration, and substances with relatively large molecules are retained by the membrane.

The concentration $c_i(t)$ of a fraction i in the solution after a period of ultrafiltration t can be calculated from an equation derived elsewhere (8):

$$c_i(t) = c_i(0).e^{-\gamma_i Kt/V_0}$$

where V_0 is the volume of the residual solution, constant under the experimental conditions, K is the volume of ultrafiltrate produced in unit time, and γ_i is the partition coefficient of the solute in question between the solutions in and outside of the membrane. To determine the time of ultrafiltration it was assumed that the solution to be filtered contained a component which could pass through the membrane in unchanged concentration, i.e. γ was unity. The values of V_0 and K were determined experimentally and the time necessary for the removal of 99.5% of this component was calculated. Consequently, besides really high molecular weight substances, a portion of the materials with $0 < \gamma_i < 1$ was left behind. Thus it is to be expected that there was some overlapping in the molecular weight distributions, even for higher fractions.

Despite the imperfections in the methods of fractionation, the fractions represent well-defined molecular weight ranges. In osmotic pressure measurements it was possible to follow the diffusion rates of fractions Nos. 2 to 6 continuously with time. Furthermore, in the diffusion coefficient determinations the diffusion times were varied up to threefold and it was found that the diffusion rates were independent of diffusion time; this indicates that the fractions cannot be very heterodisperse.

Analytical Data

It has already been mentioned that the dialysis method makes it probable that the four high molecular weight fractions are carbohydrate-free ligninsulphonates; further evidence is provided by the analytical data in Table I. The acid and sulphur contents are approximately equal, thus indicating that all acid groups are sulphonic. The reducing power of these fractions is low and the methoxyl content is high.

Some 60% of the total solids of the spent sulphite liquor from which the mineral acids were removed by ion exchange can be precipitated with ethanol as barium salts. It is, however, doubtful whether this technique in itself is adequate to separate the carbohydrates from the ligninsulphonates quantitatively. If not, there may be considerable impurities present in the low molecular weight fractions.

**Calculated from differential ultraviolet extinction coefficient (see text).*

Fractions 5 to 8 contain more acidic groups than calculated on the basis of their sulphur content. Freudenberg *et al.* (7) found similar analytical results and suggested that these were due to the presence of carboxyl groups in the ligninsulphonates. An alternative explanation is that the carboxyl groups belong to the contaminating carbohydrates.

The sulphur contents of the fractions increase with decreasing molecular weights up to fraction No. 5 and then decrease. This peculiar drop in sulphur contents after fraction No. 5 may be caused by the presence of sulphur-free impurities.

Even if the low molecular weight fractions are contaminated, there is no doubt that their bulk is made up of ligninsulphonates chemically similar to the higher fractions. The strongest evidence is furnished by ultraviolet absorption spectra.

It is well known that the ultraviolet absorption spectra of lignin preparations in neutral solution have maxima near 280 mμ and minima near 260 mμ. Not only do all of the fractions show the same pattern (Fig. 4, Table II) but

TABLE II

the ratio of the extinction coefficients (ϵ) at the maximum and minimum is approximately constant at 1.35 for all fractions. The only difference in the shapes of the curves is that the slopes in the lower wavelength region decrease with the molecular weights of the fractions. The ratios of extinctions at 245 and 260 mμ decrease from fraction No. 1 to fraction No. 8 (Table II).

The light-absorbing power decreases with the molecular weights of the fractions; this can be noticed by the visual observation of the color and is expressed quantitatively by the extinction coefficients for 0.1% solutions at 280 mμ (Table II). Nevertheless the ultraviolet light absorbing power per methoxyl bearing unit at 280 mμ is the same for all the fractions except the lowest, for which it is relatively high (Table II).

Aulin-Erdtman (1) found shifts in the characteristic ultraviolet spectra of lignin compounds when determined in neutral and in alkaline solutions, and attributed them to the ionization of the phenolic hydroxyl groups. The minima of the samples shifted from 263 to 266 mμ for the highest, and from 258 to 273 mμ for the lowest fraction. The values of λ_{max} decreased on the average by 1 mμ. The ratio $\epsilon_{max}/\epsilon_{min}$ was the same for all fractions, the mean value being 1.11, i.e. less than for neutral solutions.

Goldschmid (11) suggested that the phenolic hydroxyl contents of lignin

and analogous model compounds can be determined from the differential spectra of solutions with pH 6 and pH 12. These spectra were shown to have maxima around 250 and 300 mμ. With model substances Goldschmid determined the characteristic maximum extinction at 300 mμ ($\Delta\epsilon_{max}$) for 1 mole phenolic hydroxide per liter. According to this value the unknown phenolic hydroxyl content of a substance can be calculated from the following formula:

$$\%(\phi-OH) = (17/41)\ \Delta\epsilon_{max}.$$

The hydroxyl contents of the fractions (Table I) were determined from such differential spectra, characteristic data of which are shown in Table II and three of which are plotted in Fig. 5.

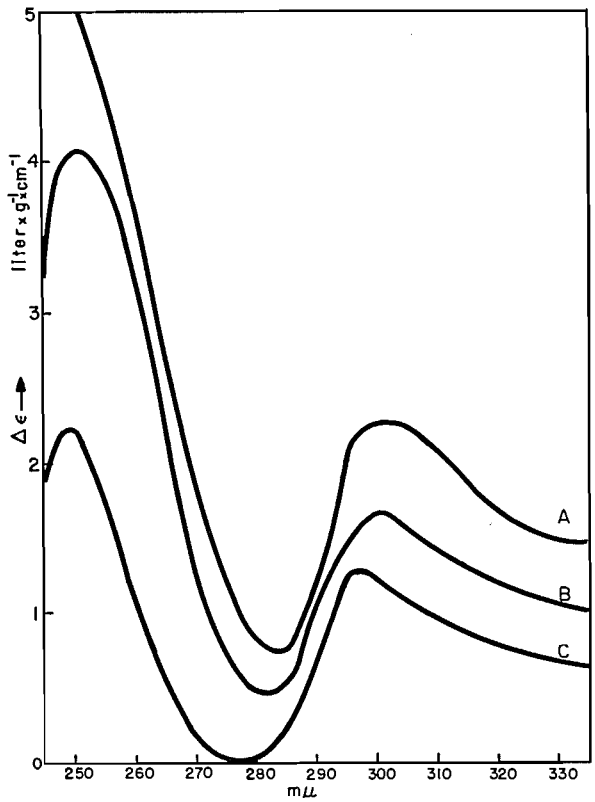

FIG. 5. Differential absorption spectra between solutions at pH 12 and pH 6; curve A: fraction No. 1, curve B: fraction No. 6, and curve C: fraction No. 8.

Molecular Weights

As described in a separate paper (9), molecular weights of all but the two lowest fractions were determined by the osmotic pressure method; these values are tabulated in Table II. When the logarithm of the molecular weight is plotted against the logarithm of the diffusion coefficient, the points corresponding to fractions Nos. 4, 5, and 6 fall on a straight line which can be extra-

polated to the measured diffusion coefficients of the lowest fractions, from which the molecular weights were calculated. It must be borne in mind that the ultraviolet extinction coefficients of the solutions were used to determine the concentrations in the diffusion experiments. Should the lower fractions be mixtures of ultraviolet light-absorbing ligninsulphonates and relatively transparent carbohydrates, the diffusion coefficients would be indicative of the ligninsulphonates alone.

In a homologous polymer series the following relation holds between the weight-average molecular weights M and diffusion coefficients D_1 (10):

$$D_1 = K\,M^{-b}$$

where b is a constant depending on the shape of the molecules and K is a constant characteristic for the homologous series. The error involved in using number-average molecular weights and the diffusion coefficients for estimating the molecular weights of the lowest ligninsulphonates should be small. As can be seen from the integral molecular weight distribution plot (Fig. 6) the degree of polydispersity of the fractions except the highest (No. 1) is relatively low. Hence there is only a slight difference between the weight-average and the number-average molecular weights.

The integral molecular weight distribution plot (Fig. 6) indicates that the

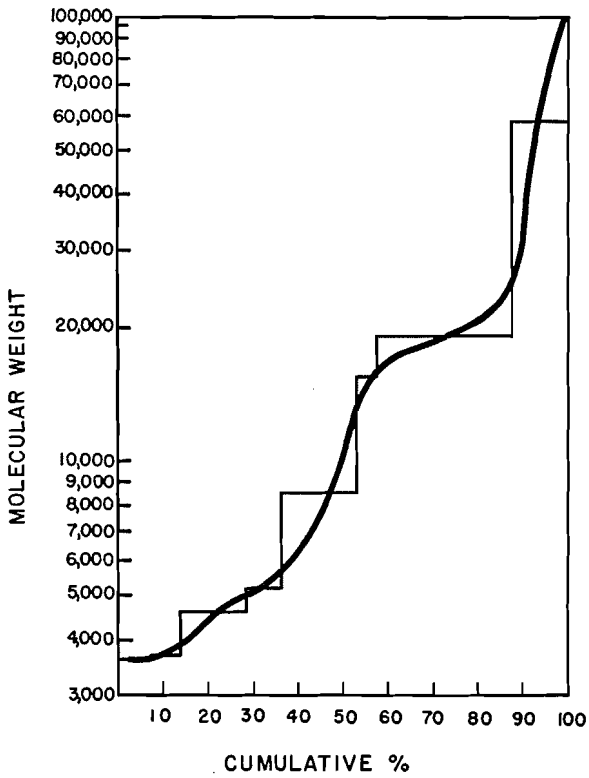

FIG. 6. Integral molecular weight distribution of the ligninsulphonates.

molecular weights of the ligninsulphonates investigated range from about 3700 to about 100,000. Around 30% of the material have molecular weights between 3700 and 5000 and also between 15,000 and 25,000.

It is beyond the scope of this paper to give a critical survey of the numerous attempts to determine the molecular weights of different lignin preparations. The accumulated data (2, 14) present a confusing picture because in the isolation of lignin or ligninsulphonates the original lignin in the wood can be considerably degraded or polymerized. Furthermore it is also possible that in the lower molecular weight region association may occur in the solutions (10); if this occurs the molecular weights obtained for the lower fractions would also be too high.

Nevertheless it is interesting to note that some investigators (3, 13, 20, 29) have found that lignin preparations isolated under mild conditions have molecular weights not lower than 3500 to 4000 which correspond well to the lower limit of the data presented here. According to Gralen (13) there is some indication that lignins with degrees of polymerization corresponding to the molecular weights 4000 and 8000 are the most stable. In the light of this, it is significant that 30% of our fractions have molecular weights in the 4000 range.

Considerably lower molecular weights of lignin, however, also have been reported (2, 15). Until a study is made of how the degree of polymerization of lignin is changed in the various isolation techniques it will be difficult to interpret the available data. Since the highest reported native lignin molecular weight is 27,000 (13), there is strong indication that during the sulphite cook at least part of the lignin becomes considerably polymerized.

PHYSICOCHEMICAL STUDIES OF LIGNINSULPHONATES

II. BEHAVIOR AS POLYELECTROLYTES[1]

By J. L. Gardon[2] and S. G. Mason

ABSTRACT

Conductivity, dyestuff adsorption, and viscosity measurements on aqueous solutions of fractionated ligninsulphonate samples having various molecular weights indicate that they behave as flexible polyelectrolytes. There is evidence that ligninsulphonates of molecular weight less than 5000 associate in solution in a manner analogous to micelle formation in colloidal electrolytes. From the variation of intrinsic viscosity with molecular weight, it may be concluded that the degree of molecular branching of the high molecular weight ligninsulphonates is greater than that of the low molecular weight fractions.

INTRODUCTION

In the pulping of wood by the sulphite process, large quantities of lignin-sulphonic acids and salts appear in the spent liquor. Relatively large amounts of ligninsulphonate concentrates are now used as dispersants and adhesives (16, 26), although the mechanisms underlying these applications are not understood. The purpose of the investigation outlined in this paper and in subsequent papers was to study some of the physicochemical properties of the material which may be relevant to these applications.

While the exact structure of ligninsulphonates is not known, it is believed (2, 14, 16) that they are built of guaiacyl–propyl units with the sulphonate groups attached to the aliphatic chains. This molecular structure and the results of the experiments described in this paper indicate that the lignin-sulphonates can be considered as substances consisting of flexible chain molecules with ionizable groups attached to them, i.e. they are polyelectrolytes.

Recently considerable research has been carried out on polyelectrolytes, general accounts of which are given by Fuoss (10, 11), Flory (8), and Kat-chalsky (20). The most important characteristic is that in solution the molecular shape depends upon the net electrical charge of the molecule. In the uncharged state the molecule curls up. If the ionic groups are dissociated, the polyelectrolyte molecule extends owing to the electrostatic repulsion between neighboring groups.

The degree of ionization of the polyelectrolyte depends on its concentration and also upon the presence of simple electrolytes in the solution. At low polyelectrolyte concentrations, the molecules occupy only a small part of the available space in the solution; this favors the escape of the counter-ions, e.g. the sodium ions of the ligninsulphonates, from polymer molecules, leaving the latter charged. The equilibrium between the counter-ions associated with the polymer molecules and in the part of the solvent free of polymer molecules, i.e. in the free space, is analogous to a Donnan-type equilibrium. Consequently

when the free space becomes smaller as the polyelectrolyte concentration is increased, the counter-ion concentration in this free space greatly increases, inhibiting further ionic dissociation. The polyelectrolyte molecules can also lose their charge, even at low concentrations, if the concentration of the counter-ions in the free space is increased by the addition of simple electrolytes containing the same counter-ion as the solution.

The dependence of the charge of the molecules of the polyelectrolyte on its concentration can be shown by conductivity measurements. As the molecules progressively lose their charge with increasing concentration, less and less current can be carried by each molecule. The specific conductivity/concentration (or reduced specific conductivity) decreases with increase of the square root of the concentration, but not linearly, as predicted by the Onsager equation for simple electrolytes. The corresponding plot is curved and is steep at low concentrations.

The flexible coiling of the molecules as they progressively lose their charge can be demonstrated by the dependence of the reduced viscosity (η_{sp}/c) on the concentration. As the effect of an extended molecule on the viscosity of the solution is greater than that of a molecular coil, the reduced viscosity of the polyelectrolyte decreases with increasing concentration. If, however, determinations are made of the viscosities of solutions containing different amounts of polyelectrolyte and always the same sufficiently large amount of simple electrolyte, the reduced viscosity of the polyelectrolyte, like the viscosity of uncharged polymers, increases linearly with concentration.

In the present paper, results of conductivity, dyestuff adsorption, and viscosity measurements carried out with ligninsulphonates of various molecular weights are presented. The method of preparation of these fractions, their analytical data, their diffusion coefficients D_1, and the determination of their molecular weights by osmotic pressure measurements are reported elsewhere (12, 13).

CONDUCTIVITY MEASUREMENTS

From the foregoing considerations variation of the reduced specific conductivity with concentration of ligninsulphonates may be expected to differ from that of simple electrolytes. This apparent anomaly has been observed but not adequately explained by a number of investigators (7, 22, 27, 30). The results obtained by Samec and Ribaric (30) and Koenig (22) did not conform with the pattern predicted for polyelectrolytes and, oddly enough, the reduced specific conductivity curves had maxima at very low concentrations.

The variation of the reduced specific conductivities of several sodium ligninsulphonate fractions with $\sqrt{c}$ at 25°C. is shown in Fig. 1. Curves A and B represent fractions having molecular weights of 58,000 and 19,200 respectively and are typical of polyelectrolytes. Curves C, D, and E obtained for fractions with molecular weights 5200, 3700, and 3650 show apparent breaks; these breaks may indicate association, as generally observed (1, 25) for colloidal electrolytes, but not for polyelectrolytes. The reduced specific conductivity vs. $\sqrt{c}$ plot for a colloidal electrolyte shows a sharp discontinuity at the critical micelle formation concentration. At lower colloidal electrolyte concentrations,

the plot is linear and descends slightly; at higher concentrations, it drops very markedly and quite often passes through a minimum (1, 25). The molecular weights of colloidal electrolytes, however, are in the range of several hundreds and about 20 to 200 molecules associate to form a micelle; abrupt changes are therefore shown in the properties at the critical concentration of micelle formation. Considerably higher molecular weights were found for the

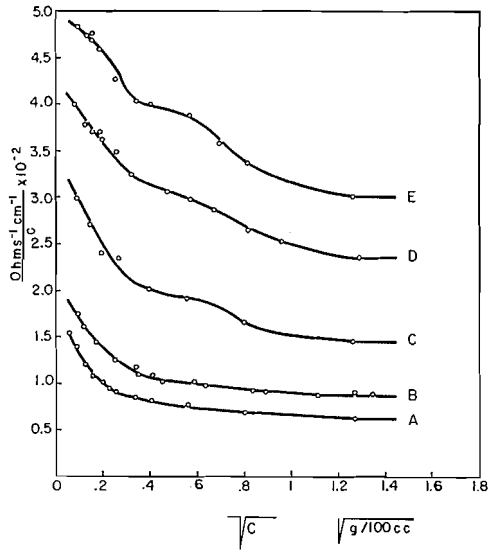

FIG. 1. Reduced specific conductivities of sodium ligninsulphonate fractions having molecular weights 58,000 (A), 19,200 (B), 4600 (C), 3700 (D), and 3650 (E).

ligninsulphonates investigated than for conventional colloidal electrolytes. Consequently it is improbable that aggregates consisting of a great number of ligninsulphonate molecules are formed. Hence the ligninsulphonate solutions do not show such sharp discontinuities as the solutions of colloidal electrolytes around the critical micelle formation concentration. The shape of curves C, D, and E may be considered as evidence that the low molecular weight ligninsulphonates are intermediate between polyelectrolytes and colloidal electrolytes. As will be shown, the reduced viscosity curves of all fractions and the dyestuff adsorption curves of all but the lowest molecular weight fraction were smooth. Hence the conductivity curves cannot be considered as absolute proof for association in the low molecular weight range; this matter requires further study.

DYESTUFF ADSORPTION MEASUREMENTS

It has been observed (15) that the optical absorption spectra of aqueous solutions of certain dyestuffs shift in the presence of micelles of colloidal electrolytes. According to Corrin and Harkins (4) this is due to adsorption or incorporation of the dyestuff on, or into, the micelle and to the different colors of the dyes in a polar medium, e.g. water, and in a non-polar medium,

as the non-charged micelle. They suggested the use of this phenomenon to detect the critical micelle formation concentration.

The influence of uncharged coiled polyelectrolyte molecules on the color of indicator dyes has not yet been investigated. The experiments here described indicate that, as was to be expected, they changed the absorption spectra of such dyes just as the micelles of the colloidal electrolytes.

Pinacyanole is blue when dissolved in pure water and green in the presence of uncharged aggregates (4). This cationic dyestuff was found to be suitable for experiments with ligninsulphonates. In Fig. 2 light-absorption curves of

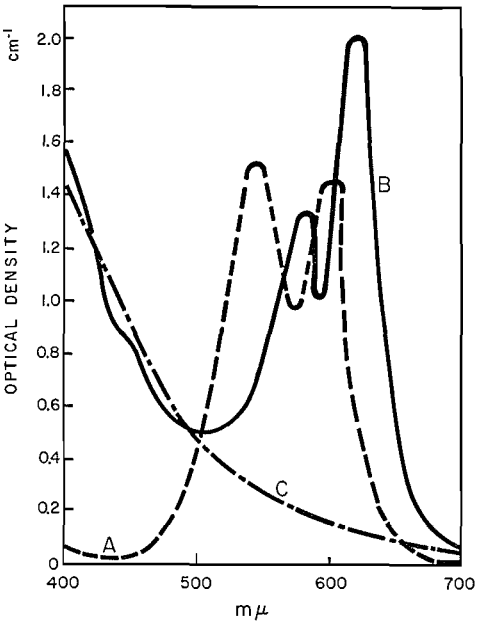

FIG. 2. Absorption curves of (A) 1.2 mgm./100 cc. pinacyanole, (B) 1.2 mgm./100 cc. pinacyanole and 0.5 gm./100 cc. ligninsulphonate (molecular weight 19,200), and (C) 0.5 gm./100 cc. ligninsulphonate.

solutions containing 1.2 mgm./100 cc. dye (A), the same amount of dye and 0.5 gm./100 cc. ligninsulphonate (B), and 0.5 gm./100 cc. ligninsulphonate alone (C) are shown. The maximum at 620 mμ in curve B is characteristic of the dyestuff – discharged aggregate complex, but the pure dyestuff solution also absorbs light at this wavelength appreciably. However, the light absorption of both pure dye and pure ligninsulphonate at 630 mμ wavelength is negligibly small. The optical density at 630 mμ can be considered as a measure of the amount of discharged aggregate – dye complex present in the solution.

The optical densities of solutions containing a fixed amount of dyestuff at various concentrations of ligninsulphonates, measured in a Beckman Model DU spectrophotometer at 630 mμ, are shown in Fig. 3.

As the molecules progressively lose their charge with increasing concentration, they adsorb increasing amounts of dyestuff. The high molecular weight

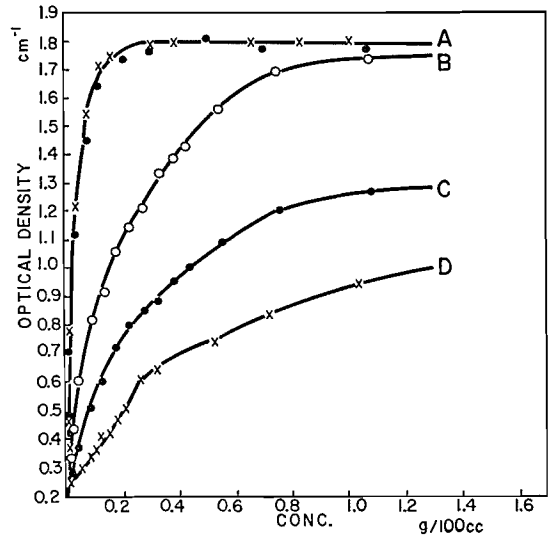

FIG. 3. Optical densities at 630 mμ of solutions containing 1.2 mgm./100 cc. pinacyanole and various amounts of ligninsulphonates. The molecular weights of the ligninsulphonates are 58,000 and 15,500 (A), 4500 (B), 3700 (C), and 3650 (D).

fractions adsorb all the dyestuff present in the solution at around 0.2% concentration. The shape of Curve A representing fractions with molecular weights 58,000 and 15,500 corresponds well to the pattern demonstrated by the conductivity and viscosity measurements.

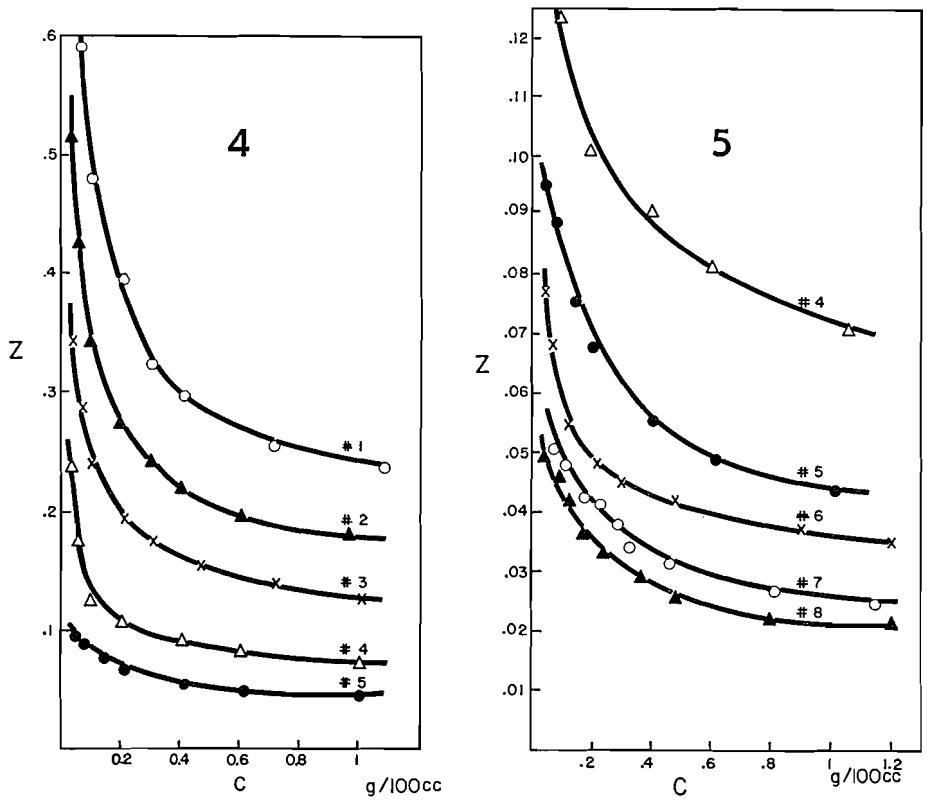
The curves B, C, and D indicate that the ability of the lower molecular weight fractions to adsorb dye is smaller than that of the high molecular weight fractions. The uncharged particles of the low molecular weight fractions are probably smaller than those of the high molecular weight fractions and, if they contain associated molecules, the number of the molecules per aggregate is probably small. The break in curve D may indicate that lowest molecular weight fractions associate in solution.

VISCOSITY MEASUREMENTS

The viscosities were determined at 25°C. in Ostwald–Cannon type (3) viscometers with flow times for water of about 400 sec. The kinetic energy corrections were negligible.

The dependence of the reduced viscosities of sodium ligninsulphonate fractions on concentration in distilled water is shown in Figs. 4 and 5. The shape of these curves is typical for polyelectrolytes; at low concentrations the reduced viscosities are high, as the molecules are extended, and at high concentrations they are low, as the molecules are coiled. The dependence of the reduced viscosities of the sodium ligninsulphonates does not follow the empirical equation of Fuoss (9):

$$[1] \qquad z = \eta_{sp}/c = [A/(1+B\sqrt{c})]+D.$$



FIGS. 4 and 5. Reduced viscosities z at various concentrations of sodium ligninsulphonates in water. The molecular weights of the number fractions are given in Table I.

In the above equation, z is the reduced viscosity, c the concentration, B a constant depending on the dielectric properties of the solvent, $(A+D)$ is the intrinsic viscosity of the polyelectrolyte when the molecules are extended, and D is a measure of the intrinsic viscosity of the randomly coiled molecules. According to this equation, the $1/(z-D)$ vs. $\sqrt{c}$ plot should be linear, but a linear plot could not be obtained for ligninsulphonates. If, however, the term $c^{\frac{1}{2}}$ was replaced by c^x in equation [1],

$$[2] \qquad z = [A/(1+Bc^x)]+D,$$

linear plots of $1/(z-D)$ vs. c^x were obtained for the three highest molecular weight fractions (Fig. 6). D was taken to be the reduced viscosity of a 4% solution; the error in doing so was very small as the reduced viscosities of solutions with concentrations higher than 2% were practically constant. The constant x was established by trial and error. With an approximate value of A, $\log[1/(z-D)-1/A]$ was plotted against $\log c$. The value of A was so chosen that this plot yielded a straight line, the slope of which was x. When D and x were known, the curves of Fig. 6 could be plotted. The intercepts on the vertical axes obtained by an analytical extrapolation were equal to $1/A$.

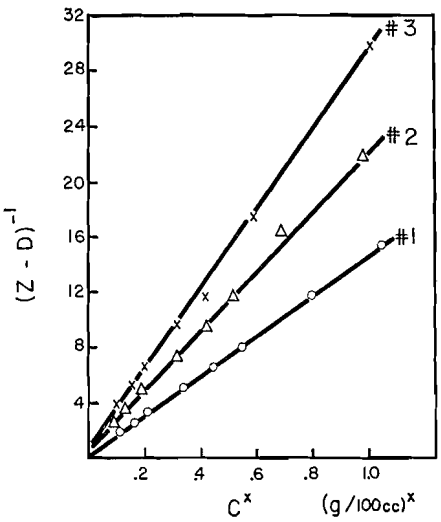


FIG. 6. $1/(z-D)$ vs. c^z plots for the three highest molecular weight fractions.

TABLE I

VISCOSITY DATA, DIFFUSION COEFFICIENTS, AND NUMBER-AVERAGE MOLECULAR WEIGHTS OF THE SODIUM LIGNINSULPHONATE FRACTIONS

		Fractions							
	Solvent	1	2	3	4	5	6	7	8
Molecular weight, gm.	0.5 *N* NaCl	58000	19200	15500	8500	5200	4600	3700	3650
Diffusion coefficient, cm./day	0.5 *N* NaCl	0.0314	0.0849	0.113	0.134	0.178	0.194	0.219	0.221
D, 100 cc./gm.	Water	0.172	0.134	0.0905	0.0563	0.0389	0.0328	0.0242	0.0211
$[\eta] = A+D$, 100 cc./gm.	Water	4–7	1.35–1.6	0.8–1.2	—	—	—	—	—
x	Water	0.71	0.73	0.78	—	—	—	—	—
$[\eta]$, 100 cc./gm.	2 *N* NaCl	0.0455	0.0425	0.0394	0.0262	0.0235	0.0220	0.0197	0.0190
k	2 N NaCl	4.9	5.0	5.42	6.00	4.75	4.15	4.6	4.6

Since this extrapolation was uncertain, the values of A thus obtained were not precise; values of $(A+D)$ are estimated to lie within the limits given in Table I. The values of x and D are also tabulated.

Equation [2] is empirical and does not have the theoretical significance of equation [1]. It is probable that the proportionality between $1/(z-D)$ and c^z is fortuitous and that the true equation describing the dependence of the reduced viscosity of the ligninsulphonates on their concentration is that of Schaefgen quoted by Katchalsky (20):

$$z = [A/(1+B\sqrt{c}+B'c)]+D.$$

The concentration dependence of the reduced viscosities of the other fractions cannot be expressed by equation [2]. Thus the intrinsic viscosities of the extended molecules could not be determined. The D values determined at a 4% concentration are given in Table I.

The reduced viscosities of the fractions in 2 N sodium chloride are shown in Fig. 7. The concentration dependence of the reduced viscosities can be

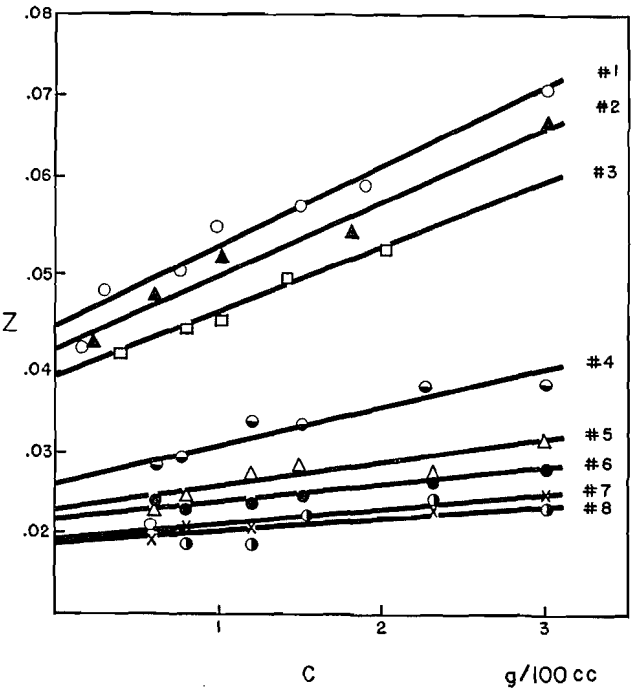

FIG. 7. Reduced viscosities at various concentrations of sodium ligninsulphonates in 2 N sodium chloride. The molecular weights of the various fractions are listed in Table I.

expressed by the equation of Simha (32) and Huggins (19) derived for non-charged interacting particles:

$$z = [\eta]+k[\eta]^2c+ \ldots \quad .$$

In this equation $[\eta]$ is the intrinsic viscosity and k is a constant characteristic for the homologous polymer series. Both $[\eta]$ and k are given for all fractions in Table I. As can be seen k changes between 4.2 and 6. Ligninsulphonates are approximately, but not truly, members of a homologous series and this may account for the variation of k.

RELATIONS BETWEEN INTRINSIC VISCOSITIES, DIFFUSION COEFFICIENTS, AND MOLECULAR WEIGHTS

According to the theories of Kuhn (23), Kirkwood and Riseman (21), and Debye and Bueche (5, 6), the constants a and b in the equations

$$[\eta] = K_2 M^a,$$
$$D_1 = K_1 M^{-b}$$

describing the dependence of the intrinsic viscosities $[\eta]$ and the diffusion coefficients D_1 on the molecular weights are both equal to unity, if the molecules are linear flexible chains, randomly coiled, and permeable to the solvent, and are equal to 0.5, if the randomly coiled flexible molecules are impermeable to the solvent. The constants K_1 and K_2 are characteristic of the homologous series. Kuhn and Kuhn (24) showed that these theories are also applicable to branched molecules if these chains are flexible and randomly coiled. The intrinsic viscosities of branched-chain molecular structures are lower than those of linear molecules of comparable size. Huggins (17, 18) has shown that $a = 2$ when the molecules behave as rigid rods.

It has been experimentally verified for a number of polyelectrolytes (20) that the values of a for the intrinsic viscosities $(A+D)$, corresponding to the extended molecules, approach 2 if the polyelectrolytes are linear, and are higher than unity but less than 2 if the polyelectrolytes are branched (31). As mentioned before, D is a measure of the intrinsic viscosity of a randomly coiled polyelectrolyte. Depending on the degree of ionization, D changes linearly with, or proportionally to the square root of, the molecular weight (20).

The diffusion coefficients, the D values, and the intrinsic viscosities in 2 N sodium chloride are plotted on a logarithmic scale against the number-average molecular weights of the ligninsulphonate fractions (Fig. 8). From the slopes

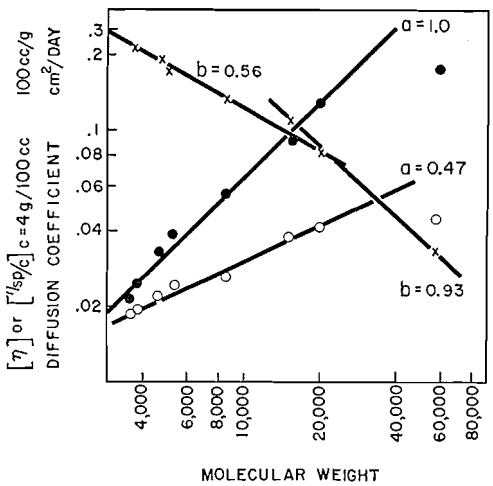

FIG. 8. Determination of constants a and b from reduced viscosities at 4% sodium ligninsulphonate in pure water (solid circles), intrinsic viscosities in 2 N sodium chloride (open circles), and diffusion coefficients in 0.5 N sodium chloride (crosses).

of these plots it can be concluded that $a = 1$ for the molecular weight dependence of D and 0.47 for the intrinsic viscosities in 2 N sodium chloride if the highest molecular weight fraction is disregarded. According to Debye (6)

the intrinsic viscosity is a measure of the true partial specific volume. As can be seen, the intrinsic viscosities in salt solution are smaller than the D values. Consequently in the sodium chloride solution, probably owing to the osmotic pressure of the sodium chloride, the coils are compressed, while in pure water the coils are expanded. The compressed coils are impermeable to water, the loose coils are permeable, and hence the values of a are in the range of 0.5 and 1 respectively.

Both the intrinsic viscosity in 2 N sodium chloride and the D value of fraction No. 1 are lower than predicted by the regularities described above. As shown in a previous communication (12), this fraction is more heterodisperse than the others and probably contains ligninsulphonates with molecular weights as high as 100,000. It is fair to assume that the higher the degree of polymerization, the greater the probability of branching during polymerization in the sulphite cook. If so, the reason for the relatively low D and low intrinsic viscosity of the highest molecular weight fractions is its higher degree of branching.

The diffusion coefficients were determined in 0.5 N sodium chloride (13). It seems that there are two b values describing the dependence of the diffusion coefficients on the molecular weight: $b = 0.56$ corresponds to all fractions but Nos. 1 and 3, while $b = 0.93$ corresponds to fractions Nos. 1, 2, and 3; this requires further investigation.

In connection with these experimental results, it is of interest to mention the work of Olleman, Pennington, and Ritter (28), who determined the diffusion coefficient, intrinsic viscosity, and partial specific volume of an ammonium ligninsulphonate in 1 N ammonium acetate solution. Using the Polson–Kuhn equation (29), they calculated the axial ratio to be 4.6. The weight-average molecular weight 21,000 calculated by them for a ligninsulphonate with 0.080 sq. cm./day diffusion coefficient compares favorably with the diffusion coefficient 0.0847 and number-average molecular weight 19,200 of fraction No. 2.

CONCLUSIONS

The results presented above lead to the conclusion that ligninsulphonates are flexible polyelectrolytes. At high concentrations of ligninsulphonates, and at low concentrations when sodium chloride is present, the molecules are coiled. At low ligninsulphonate concentrations and in the absence of sodium chloride the molecules become extended. There are indications that the low molecular weight fractions associate in solution and that the molecules of the highest molecular weight fraction are more branched than those of the other fractions. It is probable that the dispersive and adhesive properties of ligninsulphonates are due to their polyelectrolyte nature.

STUDIES ON ALUMINA CATALYSTS

IV. THE PRODUCTION OF DIETHYLANILINE BY CONDENSATION OF ETHANOL AND ETHYLANILINE[1]

By L. A. Munro and R. A. Washington

ABSTRACT

The condensation of ethanol and ethylaniline was studied using alumina catalysts at 300°C. The gel water of the alumina affects its catalytic activity. Maxima and minima in activity occur at gel water values corresponding to those previously found for the dehydration of ethanol and formic acid. There is no concurrent change in crystal structure of the alumina gel. The results suggest the initial dehydration of alcohol to ether followed by condensation of the ether and ethylaniline to give diethylaniline. It is concluded that the best and poorest spatial arrangement of 'active points' or adsorption spaces is established by the amount of residual gel water.

In general, heterogeneous catalysis is pictured as involving adsorption of the reactants on the surface of the catalyst with activation of the substrate followed by reaction and removal of the products. The patent literature gives ample evidence of the specific and distinctive behavior of catalysts differing in chemical nature, e.g. metals such as nickel for hydrogenation and hydrous oxides and phosphates for dehydration. Many workers have found that even in the same type of catalysts there are not only differences in over-all activity but also in specificity. It is to be expected that one or both of these qualities may be affected by the size and valence of the metallic element present, by alteration of the crystal lattice, and by changes in porosity or total surface.

Activation of a hydrous oxide consists in the removal of the major portion of the gel water by heating. The temperature used in activation is cited repeatedly as a criterion of activity. In the case of alumina catalysts for the production of ether "optimum activation temperatures" from 310° to 600°C. have been reported by various authors. Of fundamental importance is the degree of removal of gel water and the crystal structure of the colloidal fibrils with concurrent alteration of the surface.

It has been found that alumina catalysts prepared by different workers in this laboratory at intervals of several years showed maxima (or minima) in activity at the same gel water irrespective of the temperature of activation (1, 9, 10). Furthermore, in the dehydration of formic acid and the production of ether and ethylene from ethanol, these maxima and minima were not due to changes in crystal lattice (9).

The present paper reports a similar study of the effect of gel water on the condensation of ethanol and ethylaniline to give diethylaniline.

This investigation was not concerned with the determination of conditions of temperature and space velocity which would give 100% conversion of ethylaniline to diethylaniline. Conditions were chosen such that the production of diethylaniline would be sufficiently high that variations in yields could be readily measured, while side reactions such as the dehydration of the ethanol

[1]*Manuscript received June 17, 1955.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

to ether and ethylene would be depressed as much as possible. A reaction temperature of 300°C. was chosen. At this temperature no appreciable change in the activation of the catalyst would occur.

The apparatus was essentially similar to that used in the previous work (9) except that the catalyst tube was half filled with pyrex wool. This acted as the vaporization chamber for the reaction mixture (1 mole ethylaniline to 1.05 moles ethanol). Reagents were analar grade. The ethylaniline was redistilled at 10 mm. The refractive index of the product was 1.5422 (n_D^{20}). The product was also analyzed for total and tertiary amines by the method of Siggia, Hanna, and Kervenski (12). The results showed the ethylaniline to be free of tertiary amines, and to have a total amine content of 8.27×10^{-3} M./gm. If the figure given in the literature is accepted (8.24×10^{-3} M./gm.) this would indicate a purity of 99.4%. The absolute alcohol tested 99.8%. The catalysts were prepared from a combined batch of alumina gel as described previously (9). The air-dried gel contained 36.7% water.

Reaction products were collected in a cold receiver and gaseous products in a gasometer over saturated brine at atmospheric pressure. The liquid products were allowed to separate into aqueous and amine layers and these analyzed. Diethylaniline was determined by an adaptation of the colorimetric method of English (5) using a Klett-Summerson photometer. The standardization curve was prepared by using a series of samples containing known mixtures (by weight) of carefully purified mono- and di-ethylaniline.

Analysis of the gaseous products indicated almost pure ethylene. Ether was detected in the liquid products but the amounts were so small that they have been neglected in calculating the materials balance, which with one exception is over 90, the average being 96.3%.

The apparatus was swept out with nitrogen before and at the conclusion of each run. A blank run with the catalyst tube packed with pyrex wool gave no ethylene, ether, or diethylaniline at 300°C.

DISCUSSION OF RESULTS

The results of the experiments are summarized in Table I. In Fig. 1 is given a plot of the activity of the catalysts in the production of diethylaniline for gels differing in residual water. Included for comparison are curves from previous work on the decomposition of formic acid to carbon monoxide and water, using gels prepared from aluminum nitrate and chloride (9, Fig. 3). The points marked × on the second curve are per cent ethanol giving ether at

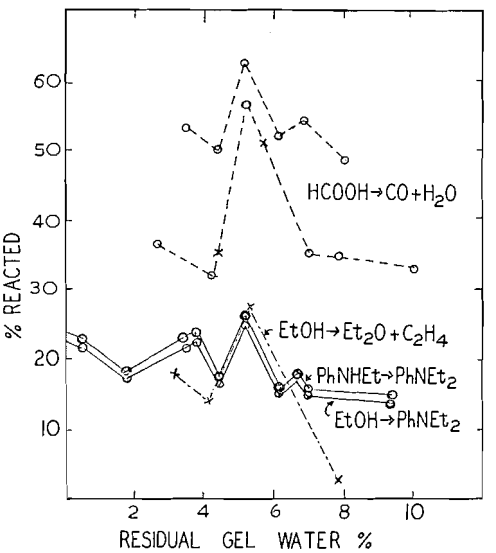

FIG. 1. The activity of catalysts differing in gel water.

250°C. (10). The bottom broken curve is for the production of both ether and ethylene at 318° (1).

It is apparent that alumina catalysts show a maximum in activity at 5.2% gel water. For the production of ethylene in the present work there is another maximum occurring between 2 and 4% gel water. This corresponds to the second maximum in the formic acid curve (9) and agrees with the position of the maximum in the ethylene to ether ratio (1, Fig. 1) although the latter differs from the point of maximum production of ethylene in the previous case.

That the activity of a catalyst may change with alteration in crystal lattice has been demonstrated by several workers (4, 8, 13). Taylor (14) and others (2, 6, 11) regard the catalytically active state of alumina as being due to the presence of gamma alumina having a cubic lattice A_0 7.90 (16), and consequently favor a method of preparation which is supposed to lead to the formation of this phase. Brown and Reid (3) however observed wide variations in the activity of their catalysts with slight variation in the method of preparation. Others have found no γ alumina in their most active catalyst (15).

The structural relations of the catalysts used in this work are shown in Figs. 2 and 3. In Fig. 2 X-ray patterns for catalysts M, N, I, and O, containing 7.0, 4.5, 3.5, and 1.8% residual water are obtained by plotting glancing angle as abscissa and intensity of the refracted beam as ordinate. No sharp peaks characteristic of crystalline samples were obtained. This indicates that the degree of crystallinity in all four samples was low, i.e. they were chiefly amorphous. Of these, catalysts M, N, and O exhibited low activity while catalyst I showed high activity. The patterns indicate no structural differences so that change in activity cannot be attributed to this factor.

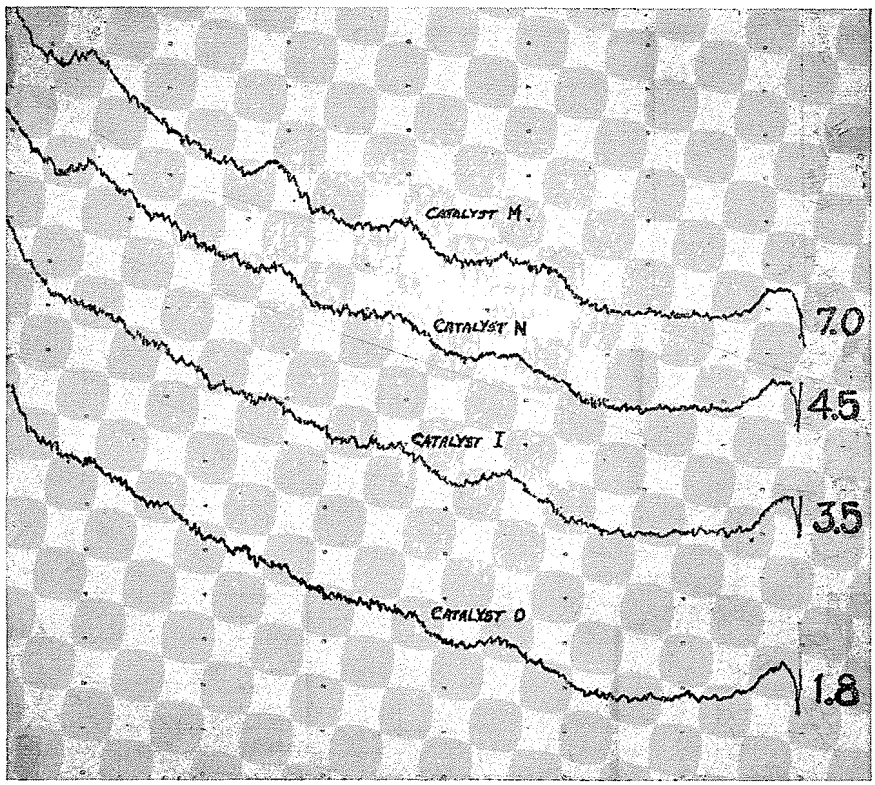

FIG. 2. X-ray diffraction patterns for catalysts containing 7.0, 4.5, 3.5, and 1.8% gel water. Catalyst I (3.5% water) had high activity, the others had low activity.

The X-ray photographs in Fig. 3 are for gels J, L, P, and Q, containing 3.8, 6.2, 5.2, and 0.0% gel water respectively. The first three obviously belong to the same type. The predominating structure appears to be that of Boehmite, with some gamma alumina. Catalysts J and P gave high activity, L much lower. These observations are similar to those made in the earlier work (9).

The catalyst containing zero water has a different structure. This catalyst also differs from that of zero water content used in the work cited above. The latter was prepared by blasting samples at 1200° resulting in conversion to alpha alumina or corundum. Such a catalyst showed a marked decrease in activity. In the present instance the anhydrous gel was obtained by activation in nitrogen at 550° which, according to Gregg and Sing (7), produces active gamma alumina. This is supported by its higher activity than the corundum sample and by the increase in activity over that of the gel containing 1.8% residual water.

Although an alumina catalyst containing 5.2% water had been found to be the best for the production of ether, both when ether alone is produced and when at higher temperatures ethylene and ether are formed, such a catalyst gave practically no ether in the present experiments. The very small amounts

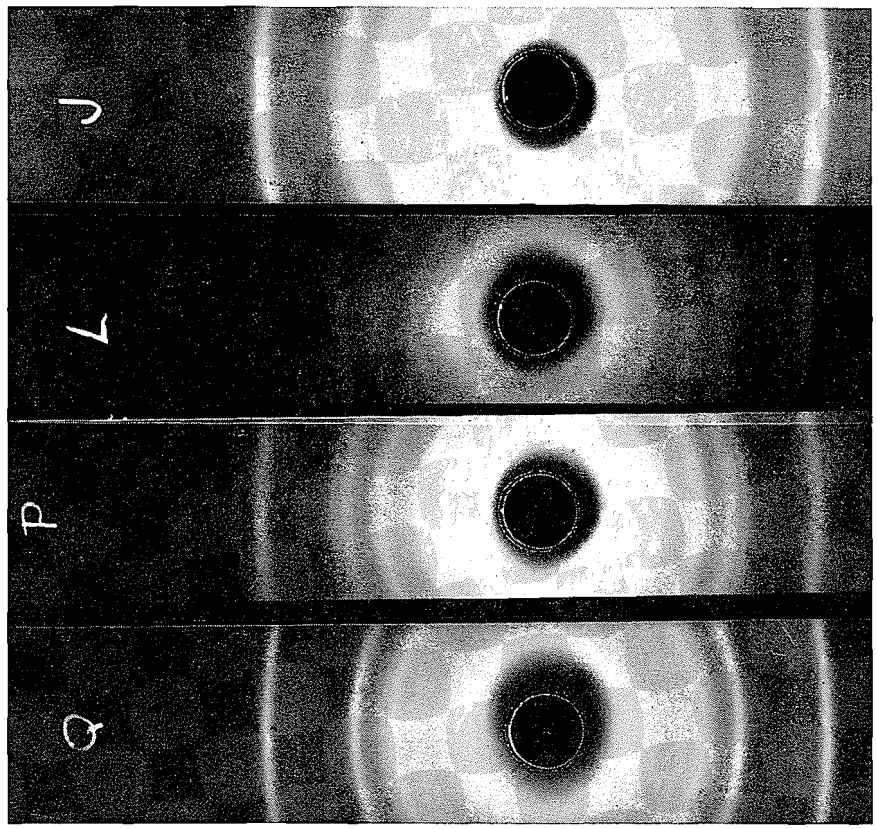

FIG. 3. X-ray photographs of catalysts containing 3.8, 6.2, 5.2, and 0% gel water.

of ether present in the reaction products can be explained if the reaction goes in two stages,

[1] $$2EtOH \rightarrow Et_2O + H_2O,$$

[2] $$Et_2O + PhNHEt \rightarrow PhNEt_2 + EtOH.$$

It was found that as the diethylaniline yield decreased the proportion of ethylene to diethylaniline decreased also. This would suggest that some of the ethylene was produced by decomposition of the reaction product, which might explain why maximum yields of ethylene were not obtained at the previously observed point on the activity – gel water curve.

SUMMARY AND CONCLUSION

From the above it may be concluded that while a change of surface geometry due to alteration of the crystal lattice can affect catalyst activity, the best and poorest surface condition of the catalyst may be established primarily by the extent to which constituent water is removed from the gel.

ACKNOWLEDGMENT

The authors wish to express their indebtedness to Dr. L. G. Berry, Department of Mineralogy, Queen's University, and to the management and staff of Aluminium Laboratories, Ltd., Arvida, for their assistance in obtaining X-ray diffraction patterns of the catalysts.

CONDUCTANCES OF AQUEOUS LITHIUM NITRATE SOLUTIONS AT 25.0°C. AND 110.0°C.[1]

By A. N. Campbell, G. H. Debus[2], and E. M. Kartzmark

ABSTRACT

The conductances, densities, and viscosities of aqueous solutions of lithium nitrate have been determined, at temperatures of 25.0° and 110.0°C., at concentrations up to 14 molar. The results have been compared with the conductances calculated by means of the Robinson–Stokes equation and good agreement found up to about 7 molar. A short discussion of the theoretical implications is given.

In pursuance of our work on the conductances of concentrated solutions we have determined those of lithium nitrate solutions at 25° and 110°C. up to a concentration of 14 molar, which represents saturation at 110°C. We have also determined the viscosities and thus we have been able to compare our results with those calculated from the Robinson and Stokes equation (9). The agreement is surprisingly good.

After we had commenced this work, we came upon a paper by Klotschko and Grigorjew (7), in which the authors appeared to have anticipated our work completely, in that they have determined the specific conductances, viscosities, and densities of aqueous lithium nitrate solutions at concentrations varying from 0.22 to 71.64 weight per cent and at temperatures of 25°, 75°, and 100°. In this article and elsewhere (8), the authors prefer the specific to the equivalent conductance as a basis of theoretical interpretation. They also seek to use the equilibrium diagram for the system lithium nitrate – water to interpret their results. For instance, they state (with approximate truth) that the composition at which the maximum specific conductance occurs is that of the eutectic at which ice and lithium nitrate trihydrate coexist. However, on plotting the experimental values of specific conductance obtained by Klotschko and Grigorjew against concentration, and comparing them with our own, we feel that they are too inaccurate to be of great value. For example, the specific conductance of their weakest solution (at 25°) would give a value of the equivalent conductance in excess of the limiting value, calculated as the sum of the ionic conductances.

EXPERIMENTAL

The lithium nitrate used was a Fisher "Certified Reagent". The principal impurity was described as "other alkalis 0.35%". The lithium nitrate was recrystallized from water and small samples ignited in platinum, immediately before weighing. The more dilute solutions were made up by direct weighing, while solutions which were supersaturated at room temperature were analyzed by the conductance of a weighed aliquot. All the details of conductance measurements have been previously described (3). Viscosity measurements

at 25° were made in a viscometer designed by Cannon and Fenske (2), while at 110° the simple apparatus of Fig. 1 was used. This apparatus was sealed after it had been filled, to prevent boiling and evaporation of the liquid; it was calibrated with water. Obviously, the total volume of liquid in the viscometer is not critical, so long as there is sufficient to fill the calibrated bulb. A number of different viscometers were used, having different capillary bores, in order to get a suitable flow time; this was never less than 30 sec. and, since time was measured with a stop-watch to one-fifth second, the accuracy of our viscosity determinations is better than one per cent, as far as this factor is concerned. As previously described (5) our high temperature density measure-

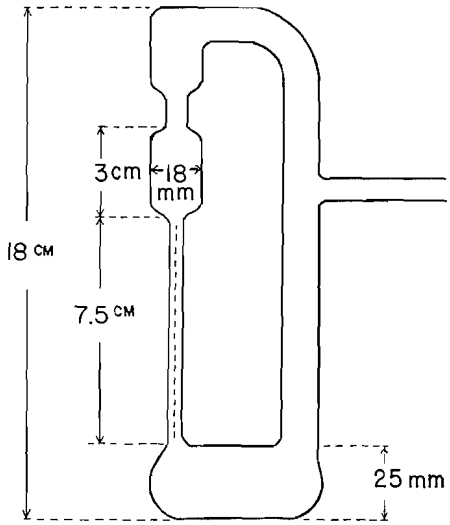

FIG. 1. Viscosity apparatus for high temperatures.

ments, carried out in a closed bomb, are probably not better than one in a thousand but this should not appreciably affect the viscosity. The apparatus (Fig. 1) could be rotated through 180°, while still in the thermostat, by means of a rack and pinion, and was automatically set in the same vertical position. The whole apparatus was placed in a tall thermostat filled with silicone. Temperature (at 110°) was maintained constant (using an Archimedean stirrer) within 0.1° which was sufficient for the purpose of our viscosity measurements. Temperature control for the conductance measurements was much better than this. For details of the high temperature conductance work, the paper by Campbell, Kartzmark, Bednas, and Herron (5) should be consulted.

EXPERIMENTAL RESULTS

The experimental results are contained in Table I, which is self-explanatory.

DISCUSSION OF RESULTS

As usual, the specific conductance is observed to pass through a maximum at about 5.337 molar at 25°, and 5.459 molar at 110°; the composition of the

maximum changes but little with temperature. The very low value (6.03 mhos) to which the equivalent conductance falls, at 25°, is remarkable. It should be noted that the last four figures at 25° represent supersaturated solutions, which are easy to obtain. Although no particular interest now attaches to the calculation, the values of $\Lambda\eta$ have been worked out and a glance at column 7 of Table I shows that, as usual, the product drops rapidly from 103 at 0.01 molar to 68 at 2.74 molar, after which it drops very slowly to 61.9 at 7.4 molar, and then rises slowly to 89.7 at 13.6 molar (all at 25°). Similar behavior is observed at 110°. If the Robinson–Stokes equation were valid throughout the concentration range, it is easy to see from the form of the equation that the product should decrease continuously. The concentration

at which the product actually starts to increase (about 7 M) is the concentration beyond which the Robinson–Stokes equation is no longer valid.

In order to calculate Λ by means of the Robinson–Stokes equation it is necessary to know Λ_0 and to know (or assume) å, the distance of closest approach. In order to obtain the (theoretical) constants (B, B_1, and B_2) of the Robinson–Stokes equation, it is also necessary to know the dielectric constant and viscosity of water. The dielectric constant of water is now known up to the critical temperature of water (1), while good values for the viscosity of water are available up to 125° (6). Hence, at 25°, the only doubtful parameter is the distance of closest approach of the ions. We have made two sets of calculations, using å = 4.5 Å and å = 5.0 Å. It will be observed that both values give rather good agreement up to 7 M, but å = 4.5 Å is the better value, on the whole. Observed and calculated results are graphed in Figs. 2 and 3. At 110° we had the usual difficulty of not knowing Λ_0. We have assumed

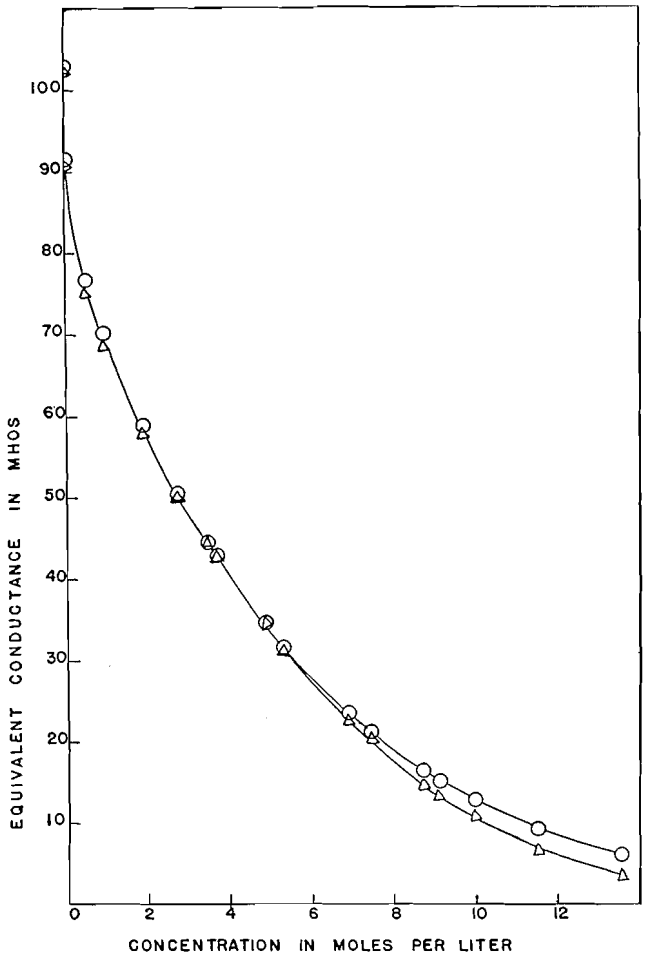

FIG. 2. ○ Experimental at 25°.
△ Calculated Λ_0 = 110.13, å = 4.5.

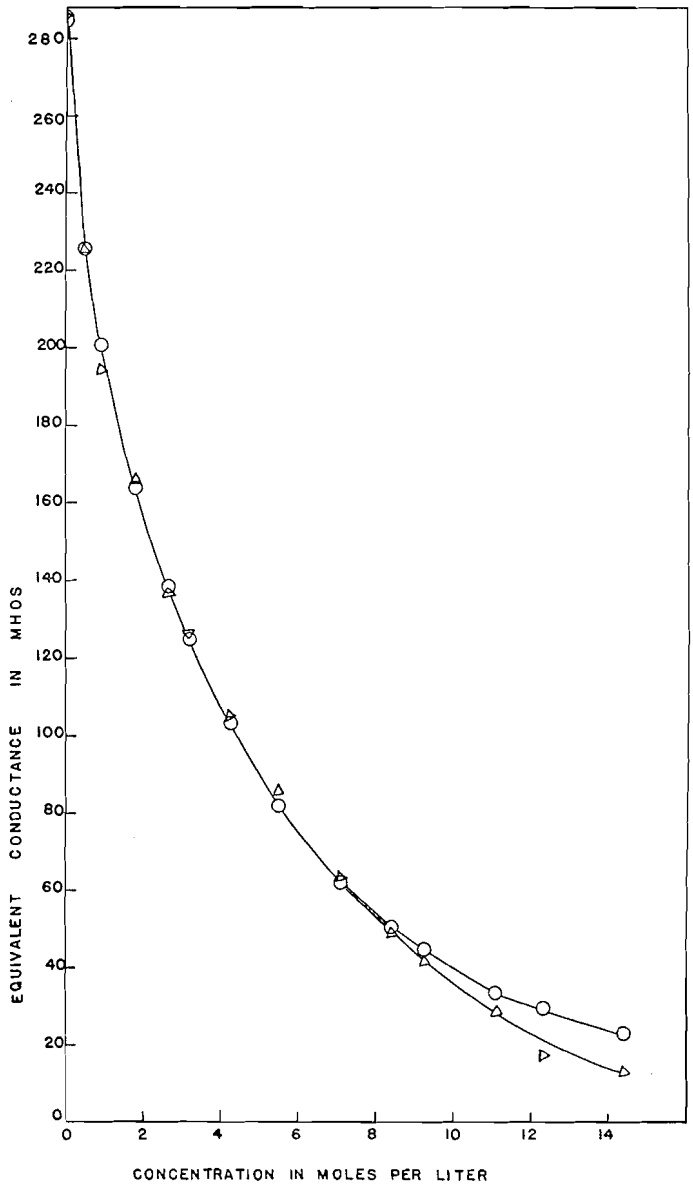

FIG. 3. ○ Experimental at 110°.
△ Calculated $\Lambda_0 = 360$, $\mathring{a} = 3.0$.

a value of $\Lambda_0 = 360$ mhos when using $\mathring{a} = 3.0$ Å, and of $\Lambda_0 = 356$ mhos when using $\mathring{a} = 3.5$ Å. Using the former set of values we obtain reasonably good agreement up to 4.2 *M*. Considering the uncertainty of Λ_0, better results can hardly be expected.

Despite the insistence of Stokes himself that $\mathring{a}$ must not be a temperature function, we have boldly used a much smaller value for $\mathring{a}$ at 110° than that

at 25° and for this we consider there may be justification. It is widely admitted that the lithium ion is highly and strongly hydrated. It seems reasonable to suppose, however, that the coordination number of hydration will decrease at higher temperatures and hence the distance of closest approach become smaller. Alternatively, if the coordination number does not change, or does not change very much, it may be that the attached water molecules may become more mobile at the higher temperature, and that they can then be pushed aside and thus allow the electrical centers of the ions to come closer together.

The agreement between calculated and observed equivalent conductances for lithium nitrate is so good, that it has not been necessary to resort to the hypothesis of ion-pair formation, though such an explanation has been offered to explain the fact that the calculated equivalent conductances are higher than the experimental values for silver nitrate and for ammonium nitrate. On the other hand, the agreement is good for ammonium chloride and potassium chloride (4). It seems reasonable to attribute ion-pair formation to the unsymmetrical form of the nitrate ion and therefore the Robinson–Stokes equation should be tested by further work on chlorides, etc.

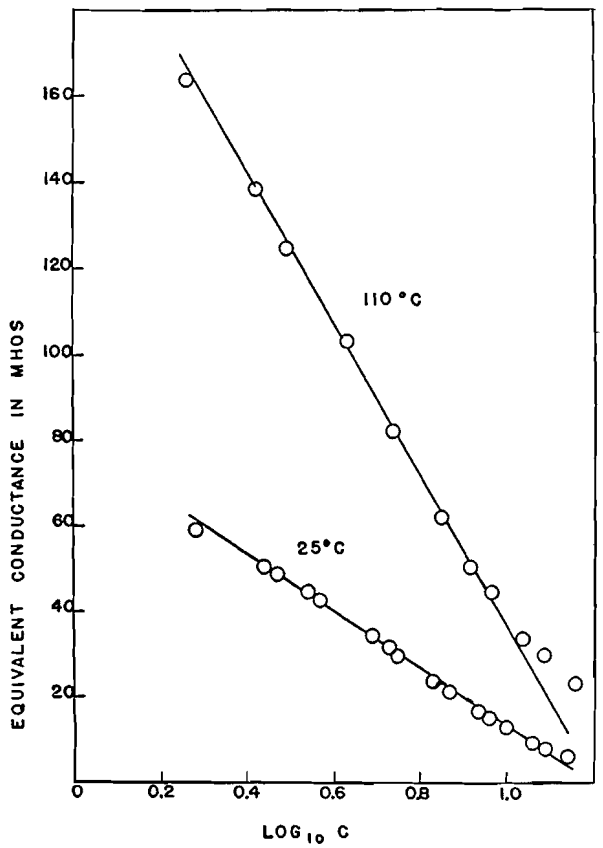

FIG. 4. Λ vs. log C.

We have elsewhere alluded to the fact that if equivalent conductance is plotted against the logarithm of the concentration, a straight line is obtained in the region of high concentration (5). The same effect is observed with lithium nitrate (Fig. 4), the straight line behavior beginning at about the concentration (say 5 to 7 molar) at which the Robinson–Stokes equation begins to break down. In the case of lithium nitrate, however, the straight line relation also breaks down at the very highest concentrations, where the lithium ion must be losing its water of hydration. If a coordination number of four is assigned to the lithium ion (Stokes believes it to be much higher than this) there must, at high concentrations, be insufficient water present to hydrate the ion. The lithium nitrate concentration corresponding to $Li^+.4H_2O$ is 49%; we have proceeded to a lithium nitrate concentration of 67% (by weight), which corresponds to less than $2H_2O$.

Finally, in the last two columns of the table of numerical results (Table I) the temperature coefficients of conductance and of viscosity have been obtained, assuming that both are straight line functions of temperature (they are not) between 25° and 110°. As usual, they are not equal and they behave in a somewhat erratic manner. The very high values of the temperature coefficient of viscosity in the region of high concentration (as high as 4.585 per degree) are, however, significant. These high values are in harmony with our belief that the lithium ion loses water of hydration at the higher temperature. This may also be true of the silver and ammonium ions but we see no reason to believe that these ions have any chemical or firmly bound water molecules. No doubt, all ions bind large numbers of water molecules in a more or less loose fashion, analogous to adsorption, but water of this kind will scarcely affect the distance of closest approach, or the viscosity, very much.

STEROIDS AND RELATED PRODUCTS. III. THE SYNTHESIS OF 17β-METHYL-17-ISODESOXYCORTICOSTERONE[1,2]

By Ch. R. Engel[3] and G. Just[4]

ABSTRACT

The synthesis of 17β-methyl-17-isodesoxycorticosterone, an epimer of the biologically active hormone homologue 17α-methyldesoxycorticosterone, is described.

In the first communication of this series (5) and in a second paper (7) syntheses of 17α-methyldesoxycorticosterone (IV), a biologically active homologue of the adrenal cortical hormone desoxycorticosterone (I), were reported. The present communication deals with the synthesis of 17β-methyl-17-isodesoxycorticosterone (XII), a new homologue of the "unnatural" 17-isodesoxycorticosterone (14).

The synthesis proceeded from methyl Δ^4-3-keto-17β-methyl-17-isoetienate (VI); this substance has previously been obtained (5) together with its 17 epimer V by a rearrangement of the Aston–Greenburg or Faworsky type (2, 6) of 21-chloroprogesterone (II*b*) or of a mixture of this compound with 21-tosyloxyprogesterone (II*a*), as well as by Oppenauer oxidation of methyl Δ^5-3β-hydroxy-17β-methyl-17-isoetienate (III), an intermediate in the synthesis of 17-β-methyl-17-isoprogesterone (8). The transformation of the not easily saponifiable keto ester VI to the keto acid VIII was carried out similarly to the experiments in the natural series (5). The alkaline sensitive α,β-unsaturated ketone was protected by the formation of the enol ethyl ether IX, the latter was heated at high temperatures in a sealed tube with methanolic potassium hydroxide, and, after acidification of the reaction product, the free acid VIII isolated in good yield.

We decided to transform the acid VIII to the diazoketone X through the acid chloride VII, to convert the diazoketone X to the chloroketone XI, and to substitute the highly inert chlorine atom of the latter by an acetoxy grouping (XII*a*), using the method described previously (5, 7). As reported earlier, the direct hydrolysis of the 17 epimer of the diazoketone X to the epimer of the ketol XII had been possible under well-defined conditions, but the ketol obtained was accompanied by appreciable amounts of the corresponding chloroketone (5).

In the series of experiments described in this paper the acid chloride VII was at first prepared from the sodium salt VIII*a* by the action of oxalyl chloride in the presence of pyridine, according to a method originated by Adams and Ulich (1) and developed in the field of steroid chemistry by Wilds and

Shunk (16, 17). The crude acid chloride prepared by this procedure was subjected to the action of diazomethane, under the experimental conditions employed in the 17 α-methyl series (5), and the resulting crude diazoketone X was treated with an excess of hydrogen chloride in ether–benzene (compare 7, 12, 15). The desired chloroketone XI was thus obtained but the yields in this series of reactions were unsatisfactory. Reichstein and co-workers (13) have lately experienced similar difficulties in obtaining in good yield Δ^4-3-keto-21-diazopregnene from Δ^4-3-ketoetienic acid, using Wild's experimental conditions (16, 17) for the preparation of the intermediate acid chloride. However, the Swiss authors obtained satisfactory results when subjecting the free acid to the action of oxalyl chloride without addition of pyridine, a procedure which had also been developed as a general method by Adams and Ulich (1). In a second series of experiments we therefore applied Reichstein's experimental conditions (10, 13); the crude acid thus obtained was then transformed to the chloroketone XI, as mentioned above. The yields in this series of reactions showed a marked increase over those obtained when using the acid chloride prepared from the sodium salt VIII*a*. The very inert chlorine atom of the chloroketone XI was replaced by an acetoxy grouping by the action of silver acetate in acetic anhydride – pyridine (compare 5, 7). The resulting 17β-methyl-17-isodesoxycorticosterone acetate (XII*a*) was hydrolyzed to the free 17β-methyl-17-isodesoxycorticosterone (XII) by the prolonged action of potassium bicarbonate in methanol–water at room temperature and in a nitrogen atmosphere. Acetic anhydride in pyridine reacetylated the free ketol XII to the acetate XII*a*.

Similar to the findings in the 17β-methyl-17-isoprogesterone series (8) and in the 17-isoprogesterone (3) and 17-isodesoxycorticosterone series (14), all the here-described 17β-methyl-17-isosteroids are more levorotatory than their stereoisomers with the "natural" configuration in position 17.

Using a modification of the bioassay described by Marcus *et al.* (11), 17β-methyl-17-isodesoxycorticosterone acetate was found to produce no sodium retention in adrenalectomized fasting rats, at dose levels up to 300 μgm. Desoxycorticosterone acetate showed marked activity in the same test at 6.25 μgm.[5] This lack of biological activity affecting the electrolyte metabolism is in contrast to the life maintaining action of 17α-methyldesoxycorticosterone acetate (7), and shows close analogy to the inactivity of 17-isodesoxycorticosterone acetate in the life maintenace test (14) and to the lack of progestational activity of 17β-methyl-17-isoprogesterone (8) and of 17-isoprogesterone (3).

EXPERIMENTAL[6,7,8]

Methyl $\Delta^{3,5}$-3-Ethoxy-17β-methyl-17-isoetiadienate (IX)

Following the procedure previously described by Julian and co-workers (9)

[5]*The biological tests were kindly carried out by Professor J. A. F. Stevenson, Department of Physiology, University of Western Ontario. Details of these experiments will be published elsewhere.*

[6]*All melting points were taken in evacuated capillaries and the temperatures corrected.*

[7]*The microanalyses were carried out by Mr. J. F. Alicino, Metuchen, N.J., to whom we wish to express our high appreciation.*

[8]*The aluminum oxide used in the chromatographic absorption was treated as described under footnote 31 of Reference (5). We wish to thank Messrs. Merck and Co., Montreal, for kindly providing us with their aluminum oxide for chromatography.*

and by Engel and Just (5), 1.633 gm. of ester VI, m.p. 152–154°, was transformed to its enol ethyl ether. The crude product afforded upon recrystallization from acetone–methanol, in the presence of a few drops of pyridine, 1.48 gm. of IX, m.p. 105–106°, and a second crop of 155 mgm., m.p. 100–106° (92.6%). A sample was recrystallized three times for analysis; shiny plates, m.p. 109–110°, $[\alpha]_D^{21}$ −132.8° (*c*, 0.982 in $CHCl_3$–pyridine). Anal. Calc. for $C_{24}H_{36}O_3$: C, 77.37; H, 9.74. Found: C, 77.20; H, 9.72.

Hydrolysis.—Following the experimental conditions described previously (5), 53 mgm. of enol ether IX was hydrolyzed with hydrochloric acid in methanol–water. Crystallization of the amorphous reaction product from acetone–hexane afforded 35 mgm. of the ester VI, m.p. 151–152.5° (71%). Further crystallization raised the melting point to 153–154°. The melting point was not depressed upon admixture of authentic ester VI.

The mother liquors from the recrystallizations of ether IX were subjected to a similar hydrolysis. Purification of the crude reaction product by chromatography and crystallization gave 33 mgm. of ester VI, m.p. 147–152°. Thus the total yield of ether IX from keto ester VI was raised to 94.5%.

Δ^4-3-Keto-17β-methyl-17-isoetienic Acid (VIII) from Enol Ether IX

In a sealed tube 1.636 gm. of enol ether IX was heated with 80 cc. of a 7% methanolic potassium hydroxide solution for 48 hr. at 168–170°. After cooling, the reaction mixture was poured into water and acidified with sulphuric acid. The chloroform extraction of the precipitate gave 1.663 gm. of crude acid, m.p. 203–207°, which afforded upon recrystallization from acetone 982 mgm. of long blades, m.p. 217–222° (62.6%). A sample was recrystallized four times for analysis; m.p. 223–225°, $[\alpha]_D^{24}$ 83.3° (*c*, 1.286 in $CHCl_3$). Anal. Calc. for $C_{21}H_{30}O_3$: C, 76.33; H, 9.15. Found: C, 76.60; H, 9.26.

Methylation of acid VIII.—Acid VIII (110 mgm.) was dissolved in absolute ether and methylated with an ethereal solution of diazomethane at 0° for 15 hr. The solvent was removed *in vacuo*. Chromatography of the resulting amorphous product (150 mgm.) on 5 gm. of aluminum oxide and recrystallization of the petroleum ether – benzene fractions from acetone–hexane yielded 79 mgm. of colorless needles, m.p. 150–152°, which gave no depression of melting point upon admixture of authentic ester VI.

Similar methylation of the mother liquors from the recrystallizations of acid VIII (545 mgm.) afforded 262 mgm. of ester VI, m.p. 144–152°. Considering this recovery of starting material, the yield of the saponification was 74.5%.

21-Chloro-17β-methyl-17-isoprogesterone (XI)

(*a*) *From the sodium salt of Δ^4-3-keto-17β-methyl-17-isoetienic acid (VIIIa).*—According to the procedure described previously (5, 16, 17), 1 gm. of acid VIII was transformed to its sodium salt, which after being dried for 10 hr. at 105° in a high vacuum was suspended in 21 cc. of absolute benzene containing seven drops of pyridine and treated with 10 cc. of oxalyl chloride at −15°; after 25 min. the temperature was raised to 25°, and after a further 15 min. the mixture was worked up in the usual manner. A solution of the product in 25 cc. of absolute benzene was slowly added, with vigorous stirring, to 33 cc.

of a 3.3% ethereal diazomethane solution at −15°. The mixture was kept seven hours at −5° and 90 min. at room temperature, and the excess solvents were removed *in vacuo*. To a suspension of this crude diazoketone in 50 cc. of absolute ether was added, with swirling, a solution of 876 mgm. of hydrogen chloride in 20 cc. of absolute ether. After 45 min., the reaction mixture was poured into water; the ether extraction of the precipitate gave 1.5 gm. of an oil which was chromatographed on 30 gm. of aluminum oxide. Recrystallization of the petroleum ether – benzene (4:1; 1:1; 1:4) and benzene elutions from acetone–hexane afforded 341 mgm. of the chloroketone, m.p. 175–180° (31%). A sample was recrystallized from acetone–hexane five times for analysis; colorless plates, m.p. 182.5°, $[\alpha]_D^{24}$ 43.2° (*c*, 1.02 in $CHCl_3$), λ_{max}^{EtOH} 239 mμ (log ε 4.2). Anal. Calc. for $C_{22}H_{31}O_2Cl$: C, 72.80; H, 8.61, Cl, 9.77. Found: C, 72.97; H, 8.81; Cl, 9.73.

(*b*) *From acid VIII.*—According to Reichstein's modification (10, 13) of Wilds' method (16, 17), 3.3 cc. of oxalyl chloride in 8.2 cc. of absolute benzene was added to a suspension of 660 mgm. of Δ^4-3-keto-17β-methyl-17-isoetienic acid (VIII), m.p. 221–222°, in 25 cc. of benzene at 0°. The acid went into solution after five minutes. The mixture was shaken for 45 min. at frequent intervals at room temperature. The excess solvents were removed *in vacuo* at 15° and the reaction product was dried with absolute benzene at 20°. The solution of the crude acid chloride VII in 18 cc. of absolute benzene was added slowly, with stirring and exclusion of moisture, to 26 cc. of a 1.8% ethereal diazomethane solution at −15°. The mixture was allowed to stand at 0° for 18 hr., then 30 min. at room temperature. The solvents were removed *in vacuo* at 15°. The crude diazoketone X was treated with 402 mgm. of hydrogen chloride in ether–benzene, as described above. The amorphous reaction product (950 mgm.) gave upon chromatography and recrystallizations 16 mgm. of methyl ester VI, m.p. 146–151°; 235 mgm. of 21-chloro-17β-methyl-17-isoprogesterone (XI), m.p. 178–181°; 83 mgm. of XI melting at 173–177° (43.9%); and 60 mgm. crude acid VIII. Methylation of the latter gave after chromatographic purification 40 mgm. of ester VI, m.p. 147–153°. Taking into account this recovery of acid, the yield of the chloride was 47.5%.

17β-Methyl-17-isodesoxycorticosterone Acetate (XIIa) from Chloroketone XI

To a solution of 560 mgm. of the chloroketone XI, m.p. 173–177°, in 7.7 cc. of acetic anhydride was added 1.8 gm. of silver acetate in 6.4 cc. of hot pyridine. The mixture was refluxed for 100 min. at 135–140° bath temperature in a nitrogen atmosphere. The usual working up gave 600 mgm. of a dark brown oil which was dissolved in 8 cc. of benzene and chromatographed on 20 gm. of aluminum oxide. Petroleum ether – benzene (1:4), benzene, and benzene–ether (95:5; 4:1) eluted 115 mgm. of fine needles, m.p. 140–154° (19.2%). A sample was recrystallized three times for analysis; m.p. 154.5–155.5°, $[\alpha]_D^{26}$ 33.2° (*c*, 1.11 in $CHCl_3$), λ_{max}^{EtOH} 241 mμ (log ε 4.24). Anal. Calc. for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87. Found: C, 74.62; H, 8.68.

17β-Methyl-17-isodesoxycorticosterone (XII)

To a solution of 83 mgm. of the acetate XII*a*, m.p. 150–153°, in 7.6 cc. of methanol was added 83 mgm. of potassium bicarbonate in 1.4 cc. of water.

The mixture was kept at room temperature in an atmosphere of nitrogen for four and one-half days. The usual working up afforded 72 mgm. (97.3%) of needles, m.p. 134–136°, giving a depression of the melting point upon admixture of the acetate XII*a*. The product was recrystallized three times for analysis; m.p. 137.5–138°, $[\alpha]_D^{22}$ 60.5° (*c*, 0.82 in $CHCl_3$), λ_{max}^{EtOH} 241 mμ (log ε 4.23). Anal. Calc. for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36. Found: C, 76.65; H, 9.23.

Acetylation.—Isodesoxycorticosterone XII (66 mgm.) was acetylated with 1 cc. of acetic anhydride in 2 cc. of pyridine and worked up in the usual way. The resulting product (79 mgm.) crystallized upon trituration with ether–hexane, m.p. 131–145°. The product was chromatographed on 3 gm. of aluminum oxide. Recrystallization of the petroleum ether – benzene (1:4), benzene, and benzene–ether (4:1) elutions from ether–hexane afforded 25 mgm. of the acetate XII*a*, m.p. 151–153°, and 20 mgm. melting at 145–148°. Admixture of authentic acetate XII*a* gave no depression of the melting point.

ACKNOWLEDGMENTS

We wish to express sincere thanks to Professor James A. F. Stevenson for the biological tests reported in this paper. We are very grateful to Dean J. B. Collip for his interest and encouragement during this study. We should also like to thank Professor J. A. Gunton for extending the facilities of his Department to this work.

CARBOHYDRATES OF SUNFLOWER HEADS[1]

By C. T. Bishop

ABSTRACT

Extractive-free, ash-free sunflower seed heads contained lignin (12.3%), pectin (27.5%), alkali-soluble polysaccharides (8.2%), and α-cellulose (52.0%). Pectin and polysaccharides were separated by successive extraction of the seed heads with ammonium oxalate – oxalic acid solution and 5% aqueous sodium hydroxide. The pectin was 37% esterified with methyl groups and yielded only galacturonic acid when hydrolyzed. The polysaccharides yielded, on hydrolysis, a mixture of neutral sugars and an aldobiouronic acid. The neutral sugars consisted of D-xylose (59.3%), D-glucose (23.5%), D-galactose (16.2%), and traces of arabinose and rhamnose. Fractionation of the polysaccharide acetate indicated that the three main sugars were constituents of three different polysaccharides. The aldobiouronic acid (1.53% of the polysaccharides) was shown to be 3-*O*-α-(D-glucopyruronosyl)-D-xylopyranose.

INTRODUCTION

Sunflowers are grown commercially in Southern Manitoba for the edible oils obtained from the seeds. The sunflower heads are not recovered after harvesting the seeds but are plowed back into the the ground and represent an agricultural waste of considerable importance. In 1948 Stoikoff (12) reported that sunflower seed heads gave good yields of pectin and suggested that they might become a commercial source for this product. Shewfelt (11) evaluated this possibility by studying the effect of isolation procedures on gelling properties of sunflower pectin. Highest yields of good-gelling preparations were obtained by extracting the sunflower seed heads with a hot dilute solution of ammonium oxalate – oxalic acid.

Pectin and polysaccharides are closely associated in plants and it has not been shown whether this association is chemical or physical (9). It has been difficult to isolate either of the two materials without concurrent degradation of the other. Polysaccharides are usually extracted by alkaline solutions which decompose pectin, and pectin is extracted by acidic solution which may hydrolyze the more labile polysaccharides (8).

This report deals with the effectiveness of the ammonium oxalate – oxalic acid extraction, developed by Shewfelt (11), for separating pectin from polysaccharides, and with the chemical composition and properties of these two products from sunflower seed heads.

Extraction Procedure

Diagram 1 shows the fractionation procedure used to separate the carbohydrate components of sunflower seed heads. Chromatography of Fraction 1 (mother liquors from precipitation of pectin) before and after hydrolysis showed the fraction to be free of sugars and proved that no degradation of the polysaccharides occurred during removal of the pectin. In a similar way, a hydrolyzate of Fraction 2 (pectin) was found to contain no sugars other than

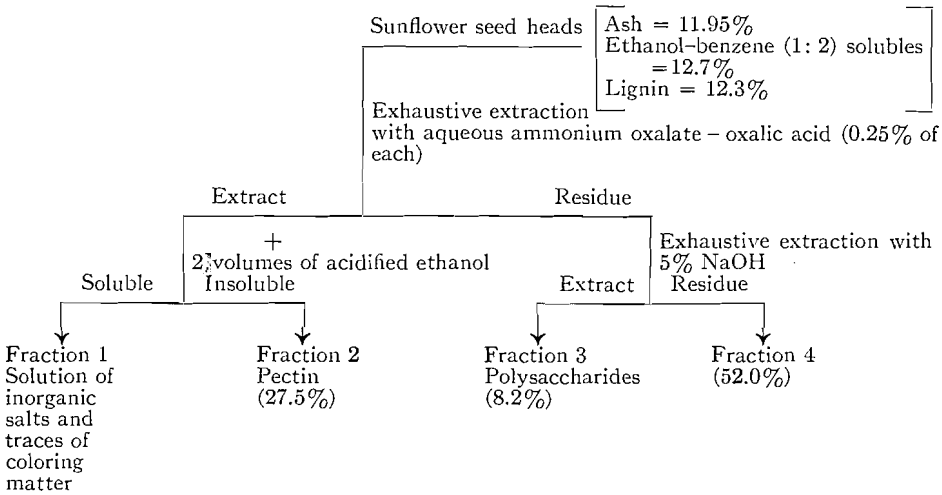
DIAGRAM 1

FRACTIONATION OF SUNFLOWER SEED HEADS*



**Lignin analysis and yields of fractions are on an ash-free, extractive-free basis.*

galacturonic acid, and therefore no polysaccharides were coextracted with the pectin. Complete removal of pectin by extraction with the ammonium oxalate – oxalic acid solution was confirmed by the absence of galacturonic acid in hydrolyzates of Fractions 3 (polysaccharides) and 4 (largely cellulose). These results showed that the pectin and polysaccharides of sunflower seed heads could be completely separated by first removing the pectin with a dilute solution of ammonium oxalate – oxalic acid. This procedure may prove useful in investigating carbohydrates of other plant materials when pectin interferes with the purification of polysaccharides.

Pectin

Sunflower pectin yielded only galacturonic acid on hydrolysis and was therefore devoid of contaminating polysaccharides. Ninety-seven per cent of the product was soluble in water, forming a clear 0.5% solution and having a specific rotation (+249°) in good agreement with that reported (+250°) by Luckett and Smith (10) for a highly purified sample of citrus pectin. Sunflower pectin, as isolated, contained 6% of methyl ester groups and was therefore only 37% esterified, fully esterified pectin requiring 16% of methyl ester groups. The pectin was fully esterified by diazomethane and then saponified, the difference in methoxyl contents corresponding to a uronic acid content of 95.6%. Oxidation of the pectin with nitric acid gave a 60% yield of mucic acid. Sunflower pectin was resistant to all attempts at methylation with (*a*) dimethyl sulphate and alkali, (*b*) diazomethane, (*c*) methyl iodide and silver oxide, and (*d*) thallous hydroxide and methyl iodide; hence no detailed structure could be determined. However, the properties and reactions described above were the same as those reported (8) for pectin from many other sources

and there seems little doubt that sunflower pectin has the same basic structure, i.e. D-galacturonic acid units joined by α, $1 \rightarrow 4$ glycosidic bonds.

Polysaccharides

Acid hydrolysis of the polysaccharides yielded an aldobiouronic acid (1.53%) and five neutral sugars: D-xylose (59.3%), D-glucose (23.5%), D-galactose (16.2%), arabinose (trace), and rhamnose (trace). The neutral sugars crystallized and were identified by melting points and rotations except for arabinose and rhamnose which were present in such small amounts that they could only be identified chromatographically.

Attempts were made to fractionate the polysaccharides to obtain a chemically homogeneous portion for structural studies. The polysaccharides gave a soluble and insoluble fraction with Fehling's solution, both containing all five monosaccharides in the same proportions.

The polysaccharide preparation was acetylated and fractionated by precipitation from chloroform solution with petroleum ether. Table I represents a

TABLE I

FRACTIONATION OF THE ACETATES OF POLYSACCHARIDES FROM SUNFLOWER HEADS

Fraction	Volume (ml.) of pet. ether per 400 ml. chloroform	Yield (gm.)	Rotation $[\alpha]_D^{25}$ (c = 1% in $CHCl_3$)	Constituent sugars*			
				Xylose	Glucose	Galactose	Arabinose

2	250	1.71	−32.6				
3	365	2.71	+37.3	70	20	10	Trace
4	440	0.70	+93.8				
5	640	2.84	+123.0	25	40	35	Nil

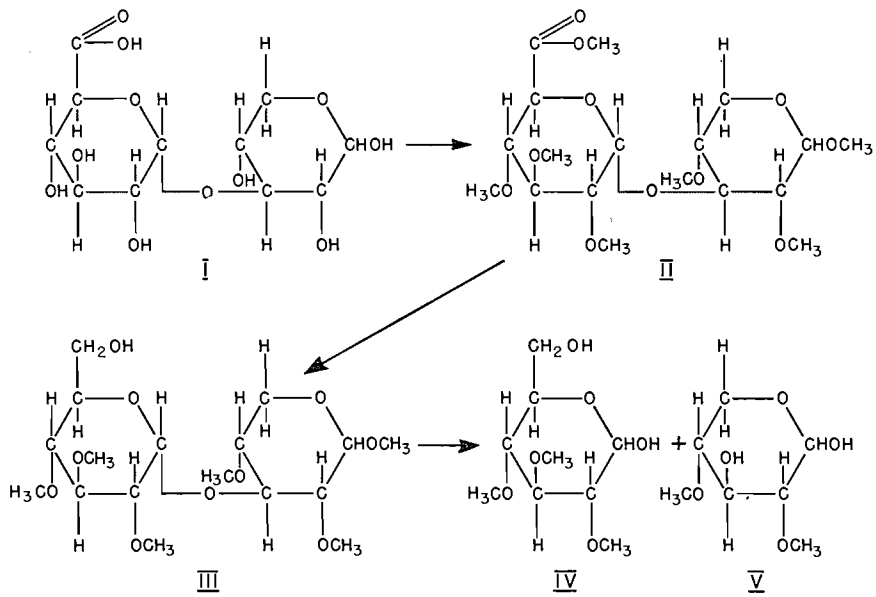
**No rhamnose could be found in any of the fractions. It may have been spread throughout all fractions in quantities too small for detection.*

fractionation of 10 gm. of this material. The differences in specific rotation indicated a mixture of chemically different polysaccharides and the change in a dextrorotatory direction corresponded with an increase in hexosan material and a decrease in pentosans. Naturally occurring xylans have high negative rotations, in the order of −90° to −110° after purification, and usually contain some arabinose units (13). It was probable, then, that the first two acetate fractions consisted of an arabo-xylan contaminated by some hexosan material. The results also showed that there was no constant ratio between any of the component monosaccharides, good evidence that the three main sugars were present in different polysaccharides: a levorotatory arabo-xylan, and a dextrorotatory glucosan and galactan. This is similar to results found by Gilles, Meredith, and Smith (7) who isolated three polysaccharides from barley gum: a levorotatory arabo-xylan and two polyglucosans, one dextrorotatory and the other levorotatory. However, the three polysaccharides of sunflower heads could not be completely separated either by repeating or by extending the fractionation, i.e. by further fractionation of each fraction. The difficulty in

separation was probably caused by similarities in molecular size of the components. Because of the dubiousness of interpreting results of methylation studies on a mixture of polysaccharides no further structural investigations were carried out.

Aldobiouronic Acid

The aldobiouronic acid (I), isolated from the hydrolyzate of the polysaccharides by ion exchange resins, had an acid equivalent of 318 (calculated 326) and yielded glucuronic acid and xylose when hydrolyzed. Its dextrorotatory specific rotation (+59.7°) indicated that the glycosidic linkage was in the α-configuration. This compound was methylated (II), reduced (III), and hydrolyzed to yield the partially methylated glucose (IV) and xylose (V) derivatives. The glucose fragment was identified as 2,3,4-tri-*O*-methyl-D-



glucopyranose (IV) by oxidation and esterification to the crystalline methyl ester of 2,3,4-tri-*O*-methyl-D-glucosaccharolactone. The xylose portion of the molecule was shown to be 2,4-di-*O*-methyl-D-xylopyranose (V) by conversion to the crystalline amide of 2,4-di-*O*-methyl-D-xylonic acid. These results proved that the aldobiouronic acid was 3-*O*-α-(D-glucopyruronosyl)-D-xylopyranose. This compound has also been isolated from xylans of pear cell wall (5) and wheat straw (1, 2).

EXPERIMENTAL

Chromatograms were run by the descending method using: (*A*) ethyl acetate – pyridine – water, 2:1:2; (*B*) ethyl acetate – acetic acid – water, 9:2:2; (*C*) butanol – acetic acid – water, 4:1:5; and (*D*) butanol – ethanol – water, 5:1:4. Sugars were detected on chromatograms by aniline oxalate or silver nitrate sprays. Evaporations were carried out under reduced pressure

at 40°C. or less. All melting points are corrected and rotations are equilibrium values.

Isolation of Pectin and Polysaccharides from Sunflower Heads

Sunflower seed heads (ash, 11.95%) were extracted exhaustively in a Soxhlet with ethanol–benzene, 1:2 (v/v). This procedure removed 12.7% as waxes and pigments. All analyses and yields that follow were calculated on an ash-free, extractive-free basis. Extractive-free sunflower heads (Klason-lignin, 12.3%) were stirred in an aqueous solution of ammonium oxalate – oxalic acid (0.25% of each) at 75°C. for one and one-half hours. A solid: liquid ratio of 1:22 was used. The extracts were removed by filtration through a linen cloth, and addition of two volumes of ethanol, acidified with 5 ml. of concentrated hydrochloric acid per liter, caused the formation of a gelatinous precipitate of pectin. The extraction procedure was repeated until no more ethanol-insoluble material was obtained, three extractions being required. The pH of the extracts varied from 3.6 to 4.0. The precipitated pectin (Fraction 2, Diagram 1) was filtered, with suction, on Whatman No. 1 paper, washed several times with ethanol and then with ether, and dried at 0.1 mm. over paraffin and phosphoric anhydride (yield, 27.5%). The alcoholic mother liquors (4 liters, Fraction 1, Diagram 1) from the pectin precipitation were evaporated to 250 ml. and examined by paper chromatography (solvent *A*). No sugars were detected. The solution was then made 2 *N* with respect to hydrochloric acid and was heated on a boiling water bath for six hours. The hydrolyzate was neutralized with Dowex-2 (carbonate form) and examined by chromatography as before. No sugars were found.

The pectin-free residue was stirred at room temperature in 5% aqueous sodium hydroxide using a solid: liquid ratio of 1:20. After 24 hr. the extract was removed by suction filtration through linen cloth and the residue was extracted three more times in the same way. The combined extracts were neutralized with acetic acid and dialyzed in cellophane against distilled water for 36 hr. The solution of non-dialyzable material was evaporated to one-quarter its volume and diluted with three volumes of 95% ethanol to precipitate the polysaccharides. The precipitate was removed by centrifuging, washed several times with ether, and finally dried at 0.1 mm. over paraffin and phosphoric anhydride (yield 8.2%, Fraction 3, Diagram 1).

The residue from the alkali extraction of the polysaccharides was washed successively with 10% aqueous acetic acid, water, and acetone before drying *in vacuo* over phosphoric anhydride (yield 52.0%, Fraction 4, Diagram 1). This fraction was not examined further but probably consisted largely of cellulose.

Pectin

Ninety-seven per cent of sunflower pectin was soluble in water, forming a clear solution having $[\alpha]_D^{25} = +249°$ ($c = 0.49$). The pectin as isolated had a methoxyl content of 6.0% which was completely removed by saponification with alkali showing that the methoxyl groups were present as methyl esters. Since the calculated methoxyl content for fully esterified pectin ($C_6H_7O_5$.-

$OCH_3)_n$ is 16.3%, sunflower pectin was only 36.8% esterified. A sample (1 gm.) of pectin was allowed to stand at 5°C. for seven days in an ethereal solution of diazomethane. The diazomethane solution was replaced from time to time as the yellow color faded. Evaporation of the ether left fully esterified sunflower pectin as a white powder (1.07 gm., MeO = 19.5%). This fully esterified, partially etherified pectin was shaken with *N* alcoholic sodium hydroxide for 24 hr. to saponify the ester groups. The de-esterified pectin was recovered by centrifuging and after being washed with ethanol, ether, and petroleum ether, it was dried *in vacuo*. This product (0.98 gm.) was a white powder having a methoxyl content of 3.9%. The saponification therefore reduced the methoxyl content by 15.6% corresponding to a uronic acid content of 95.6%. Pectin (1 gm.) was heated on a steam bath with nitric acid (10 ml., sp. gr. 1.2) until the volume was reduced by about two-thirds, and the solution was kept at room temperature for 10 hr. Crystals of mucic acid (0.65 gm.) were filtered and recrystallized from alkaline solution by acidification with hydrochloric acid. The crystals had a melting point and mixed melting point with mucic acid of 212–213°C. A sample (50 mgm.) of sunflower pectin was heated in a sealed tube at 110°C. for 17 hr. with 2.5% sulphuric acid (10 ml.). The hydrolyzate was neutralized with barium carbonate and the neutral solution freed of barium by Amberlite IR-120. When this solution was examined by chromatography, using glucuronic acid, galacturonic acid, xylose, arabinose, and glucose as reference sugars, only galacturonic acid could be found with solvents *A*, *B*, and *C*.

Pectin (40 gm.) was methylated 10 times with dimethyl sulphate and potassium hydroxide to a constant methoxyl content of 11.9% (calculated for $C_8H_{11}O_6K$, MeO = 25.6%). This product (8.4 gm.) was then converted to the thallium complex, which was methylated with methyl iodide. This procedure gave a product (2.1 gm., MeO = 34.5%) which was methylated twice more with Purdie's reagents to a constant methoxyl content of 38.5% (calculated for $C_6H_5O_3{\cdot}3OCH_3$, MeO = 42.6%). Fractionation of this material from acetone by precipitation with petroleum ether did not yield any fractions with a higher methoxyl content. When sunflower pectin was allowed to stand under ethereal diazomethane at 5°C. for several weeks, the methoxyl content was raised to 29%. Further methylations of this product with Purdie's reagents, by the thallium – methyl iodide method, and with dimethyl sulphate and alkali gave low yields of products with methoxyl contents no higher than 37%.

Polysaccharides

The polysaccharides (Fraction 3, Diagram 1) of sunflower heads were isolated as a light, tan powder having $[\alpha]_D^{25} = +110°$ (c = 2% in 4% sodium hydroxide). Hydrolysis of a small sample (50 mgm.) by heating with 2% sulphuric acid (3 ml.) at 97° for 10 hr. released xylose, glucose, galactose, glucuronic acid, and traces of arabinose and rhamnose. These sugars were detected by paper chromatography in solvents *A*, *B*, *C*, and *D* using known sugars as reference compounds. The polysaccharides, treated with Fehling's

solution (4), gave an insoluble copper complex, which was separated by filtration. Polysaccharide material isolated from both the precipitate and filtrate, after removal of copper salts by acidification and dialysis, yielded the same sugars on hydrolysis as the original polysaccharide preparation. The polysaccharides (43.6 gm.) were acetylated twice by the formamide – pyridine – acetic anhydride method (3). The acetate (59.3 gm.) was fractionated from chloroform solution by successive precipitation with petroleum ether (60–100°C.). Table I represents the fractionation of 10 gm. of the acetate by this method. Constituent sugars were estimated, after deacetylation of small aliquots (*ca.* 10 mgm.) of each fraction by alcoholic potassium hydroxide, by hydrolysis and quantitative paper chromatography (6). This fractionation was carefully repeated five times on the total acetate mixture and was extended by further fractionation of the individual fractions. The procedure was also carried out in reverse by extracting the acetate mixture with petroleum ether containing increasing amounts of chloroform. No improvement of the separation shown in Table I could be obtained.

Identification of Component Sugars

Deacetylated polysaccharides of sunflower heads (30.27 gm.) were heated on a boiling water bath in 2% sulphuric acid (500 ml.). After 10 hr. an insoluble residue (2.11 gm.) was filtered and the filtrate was heated again to constant rotation, $[\alpha]_D^{25} = +27.6°$. The hydrolyzate was brought to pH 3.0 with saturated barium hydroxide solution to remove a large amount of the sulphuric acid and was clarified by centrifuging. To remove barium, the centrifugate was passed through a column of Amberlite IR-120, which was then washed with water until the eluates gave a negative anthrone test. The eluates were evaporated to 500 ml. and passed through a column of Amberlite IR-4B to remove uronic acids (see below) and last traces of sulphuric acid. Evaporation of this eluate left a mixture of neutral sugars (25.05 gm.) which was shown by quantitative paper chromatography (solvent *A*) to consist of xylose (59%), glucose (23%), and galactose (16%). Arabinose and rhamnose were also present in trace quantities. A portion (1 gm.) of this mixture of sugars was separated by preparative paper chromatography to yield: D-xylose, m.p. 146–147°C., $[\alpha]_D^{25} = +19.5$ ($c = 3.18$ in water); D-glucose, m.p. 143–144.5°C., $[\alpha]_D^{25} = +54.0$ ($c = 1.11$ in water); and D-galactose, m.p. 165–166°C., $[\alpha]_D^{25} = +78.0$ ($c = 0.41$ in water). Since the quantities of arabinose and rhamnose were insufficient for isolation, these two sugars could only be identified as being chromatographically indistinguishable from arabinose and rhamnose in solvents *A*, *B*, *C*, and *D*.

Aldobiouronic Acid

The uronic acids were removed from the column of Amberlite IR-4B by elution with *N* sulphuric acid until an anthrone test was negative. The eluate was neutralized (pH 7.0) with saturated, aqueous barium hydroxide and inorganic barium salts were removed by filtration. The filtrate, evaporated to 200 ml., was passed through a column of Amberlite IR-120 to remove barium from the uronic acids. Evaporation of the eluate and examination by

chromatography revealed some xylose still mixed with the uronic acids. This mixture (1.40 gm.) was separated on a cellulose column, the xylose being eluted first with water-saturated butanol. Butanol – formic acid, 50: 1, then removed traces of glucuronic acid, and this was followed by elution with water, which removed the aldobiouronic acid. Evaporation of the aqueous eluate left the aldobiouronic acid as a thick yellow sirup (429.2 mgm.) having $[\alpha]_D^{25} = +59.7$ ($c = 7.5$ in water) and an acid equivalent, by titration, of 318 (calculated for $C_{11}H_{18}O_{11}$, 326). The aldobiouronic acid (400 mgm.) in water (5 ml.) was added to dimethyl sulphate (5 ml.) and the mixture was stirred vigorously at 0°C. during the dropwise addition of 30% aqueous sodium hydroxide (7.5 ml.) over a period of eight hours. The mixture was then stirred for an additional 18 hr. during which it was allowed to warm to room temperature. The mixture was again cooled to 0°C. followed by the addition of solid sodium hydroxide (4.5 gm. all at once), and dimethyl sulphate (5 ml., drop by drop, during six hours). After another 18 hr. of stirring the mixture was cooled, acidified with 10% sulphuric acid, and extracted continuously with chloroform for three days. The chloroform extract was dried over anhydrous magnesium sulphate and evaporated leaving a thick sirup (130.2 mgm.). This product was methylated three times with Purdie's reagents after which no hydroxyl groups were detectable by infrared analysis. This fully methylated product (130 mgm.) in dry ether (10 ml.) was added, drop by drop, to a stirred suspension of lithium aluminum hydride (0.5 gm.) in anhydrous ether (25 ml.). After addition was complete the mixture was heated under gentle reflux for three hours. Excess lithium aluminum hydride was destroyed by cautious addition of ethyl acetate and, after acidification with 10% sulphuric acid, the mixture was filtered. The filtrate was freed of organic solvents by evaporation and the residual aqueous solution (25 ml.) was extracted continuously with ether for 24 hr. Evaporation of the dried (sodium sulphate) ether extract left a sirup (92.1 mgm.) of which an infrared spectrum showed the absence of a carbonyl group, which was present before reduction, and the presence of a hydroxyl group, which had not been found in the unreduced product. The reduced product was hydrolyzed by heating for six hours on a boiling water bath with 1% hydrochloric acid (2 ml.). The hydrolysis could not be followed polarimetrically because the solution was too highly colored. The hydrolyzate was neutralized with Dowex-2 (carbonate form) and examination by chromatography (solvent *D*) revealed the presence of 2,4-di-*O*-methyl xylose and 2,3,4-tri-*O*-methyl glucose. These two compounds were separated by preparative paper chromatography (solvent *D*) and extracted from the papers with acetone. The extracts were evaporated to sirups, which were taken up in water and filtered through charcoal. Evaporation of these clarified solutions left 2,4-di-*O*-methyl-D-xylose (15.2 mgm., $[\alpha]_D^{25} = +25.5$ ($c = 1.52$ in water)) reported (15) $[\alpha]_D^{25} = +24.7$; and 2,3,4-tri-*O*-methyl-D-glucose (14.0 mgm., $[\alpha]_D^{25} = +65.7$ ($c = 1.4$ in water)) reported (14) $[\alpha]_D^{20} = +65°$.

The 2,4-di-*O*-methyl-D-xylose was taken up in water (2 ml.) to which 0.5 ml. of bromine was added. The mixture was stored in the dark at room temperature for 48 hr., after which excess bromine was removed by aeration. The

clear solution was neutralized with Dowex-2 (carbonate form) and the neutral solution was evaporated to dryness. The residue was dissolved in methanol (5 ml.) and anhydrous ammonia was passed through the solution for one-half hour. After it was stored at 5°C. for 18 hr., the solution was evaporated to dryness leaving a semicrystalline residue which was recrystallized from ethyl acetate to yield the amide of 2,4-di-*O*-methyl-D-xylonic acid, m.p. 98–99°C., reported (15) m.p. 98–100°C.

The 2,3,4-tri-*O*-methyl-D-glucose was oxidized by heating at 90°C. for three hours with nitric acid (5 ml., sp. gr. 1.2). Nitric acid was removed by repeated distillation with water and methanol and the residue was esterified by ethereal diazomethane. Evaporation of the ethereal solution left a residue, which was extracted with ether. Removal of the ether gave a sirup which crystallized completely after four days at room temperature. The crystals, after trituration and washing with cold ether, had m.p. 105–106°C., reported (14) for the methyl ester of 2,3,4-tri-*O*-methyl-D-glucosaccharolactone, m.p. 106–107°C.

ACKNOWLEDGMENTS

The author is indebted to Dr. A. L. Shewfelt, Department of Agriculture, Experimental Station, Morden, Manitoba, who provided the sunflower seed heads used in this work. The careful technical assistance of Mr. W. R. Rowsome is gratefully acknowledged as is also the assistance of Mr. F. Rollin, who carried out the infrared spectra.

THE VAPOR-PHASE PHOTOLYSIS OF ACETIC ACID[1]

By P. Ausloos[2] and E. W. R. Steacie

ABSTRACT

The photolysis of acetic acid (CH_3COOD) vapor has been investigated in the temperature range from room temperature to 285°C. Since CH_3D formation is independent of temperature, it is certain that the primary process

$$CH_3COOD + h\nu \rightarrow CH_3D + CO_2$$

occurs to the extent of about 10%. The results are complex and suggest that three other primary processes may occur, viz.

$$CH_3COOD + h\nu \rightarrow CH_3CO + OD$$
$$\rightarrow CH_3 + COOD$$
$$\rightarrow CH_3COO + D.$$

The abstraction reaction

$$CH_3 + CH_3COOD \rightarrow CH_4 + CH_2COOD$$

is of importance, and the results indicate that it has an activation energy of 10.2 kcal., and a steric factor of the order of 10^{-3}.

INTRODUCTION

The photolysis of acetic acid in the gas phase was first investigated by Farkas and Wansborough-Jones (5), who suggested the primary processes:

$$CH_3COOH + h\nu \rightarrow CH_4 + CO_2$$
$$(CH_3COOH)_2 + h\nu \rightarrow CH_4 + CO_2 + CH_3COOH$$
$$(CH_3COOH)_2 + h\nu \rightarrow C_2H_6 + CO_2 + CO + H_2O.$$

Burton (2) investigated the photolysis by mirror methods and suggested that radicals were formed by

$$CH_3COOH + h\nu \rightarrow CH_3 + COOH,$$

followed by

$$COOH \rightarrow CO_2 + H, \text{ etc.}$$

In later work (3) he rejected this mechanism and suggested that H-atoms but no CH_3 radicals were formed. He therefore proposed the primary step

$$CH_3COOH + h\nu \rightarrow CH_3COO + H.$$

Clusius and Schanzer (4) investigated the photolysis of CH_3COOD in the liquid phase, and concluded that two primary processes occur:

$$CH_3COOD + h\nu \rightarrow CH_3 + COOD$$
$$CH_3COOD + h\nu \rightarrow CH_3D + CO_2,$$

the first process being the more important. They suggested that CH_4, found in the methane fraction, could be accounted for by the abstraction reaction

$$CH_3 + CH_3COOD \rightarrow CH_4 + CH_2COOD.$$

In the present work the photolysis of CH_3COOD has been investigated in the vapor phase over a more extended temperature range.

EXPERIMENTAL

The apparatus has been described previously (1). A Hanovia S-500 medium pressure mercury arc was used as a light source. The full radiation was used

[1]*Manuscript received June 10, 1955.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1952–54.*

to obtain the maximum intensity. The intensity was varied by the use of calibrated screens. Two samples of CH_3COOD were used, containing respectively 20% and 15% CH_3COOH. The analysis of the products was done by taking off two fractions, one at −196°C., and one at −150°C. These were then analyzed by a mass spectrometer. No attempt was made to determine condensable reaction products.

One experiment was made with a Corning 7-54 filter, with a cutoff below 2400 Å. This gave a rate approximately one quarter the normal rate. Since the filter has a transmission of about 40% at 2537 Å and decreases sharply below this, it appears that the effective radiation was mainly in the range from 2400 Å to 2537 Å.

RESULTS AND DISCUSSION

The results are given in Table I. The main reaction products found were CO, CO_2, CH_4, CH_3D, and C_2H_6. At temperatures above 150°C. H_2 and HD were also present, and they constituted about 10% of the reaction products at temperatures above 250°C. Very small amounts of CH_2D_2 and C_2H_5D were also detected. The amounts of these products were always less than two per cent of the methane or ethane fraction, and their formation is probably due to the presence of small amounts of CH_2DCOOD in the starting material.

The Primary Process

The results in Table I indicate that for runs at constant intensity the rate of formation of CH_3D is constant within experimental error, and is independent of temperature in the range from 27 to 287°C. On the other hand, the rate of formation of CH_4 increases steadily with increasing temperature as might be expected if it is formed in a secondary reaction. This constitutes a definite proof of the occurrence of the primary process

$$CH_3COOD + h\nu \rightarrow CH_3D + CO_2. \qquad [I]$$

If runs 9, 12, and 15 are compared it can be seen that the rate of formation of CO decreases sharply below 100°C., while at higher temperatures (compare runs 2–7) it is nearly independent of temperature. This suggests that CH_3CO is formed in the primary process

$$CH_3COOD + h\nu \rightarrow CH_3CO + OD, \qquad [II]$$

and decomposes thermally.

A comparison of CH_3D with CO_2 shows that primary process [I] accounts only for about 10% of the CO_2 formed. Nevertheless the rate of CO_2 formation is nearly independent of temperature over the whole range. This excludes the formation of CO_2 by a secondary process unless it is one with a very low activation energy. There appear to be two possibilities:

(*a*) $$CH_3COOD + h\nu \rightarrow CH_3 + COOD \qquad [III]$$

followed by

$$COOD \rightarrow CO_2 + D. \qquad [1]$$

This will only account satisfactorily for CO_2 production if [1] is very fast, which appears to be the case (8). The analogous reaction

$$COOCH_3 \rightarrow CO_2+CH_3 \qquad [2]$$

is known to occur readily (7). Reaction [1] will be less exothermic than [2], but is probably feasible thermochemically.

(*b*) $$CH_3COOD+h\nu \rightarrow CH_3COO+D \qquad [IV]$$

followed by

$$CH_3CO_2 \rightarrow CH_3+CO_2. \qquad [3]$$

In solution the acetate radical appears to have considerable stability (6), which casts some doubt on the rapid formation of CO_2 by [3] at low temperatures.

Either mechanism involves the formation of D-atoms. Since no D_2 is formed, and H_2 and HD are only formed at higher temperatures, recombination is apparently negligible compared with the abstraction reaction

$$D+CH_3COOD \rightarrow HD+CH_2COOD. \qquad [4]$$

H_2 will be formed from the CH_3COOH present in the acetic acid. The quantity of H_2 is, however, rather large compared with that of HD, and the possibility of the loss of an H-atom from the methyl group in the primary process is not excluded.

In any case the very small amount of H_2 and HD relative to CO_2 shows that most H- or D-atoms disappear in some other way to form condensable products, such as HDO and D_2O. The independence of CH_3D formation with temperature rules out the reaction

$$CH_3+D \rightarrow CH_3D. \qquad [5]$$

It is also possible to explain the above results in a somewhat simpler way by postulating the occurrence of reactions such as

$$CH_3COOD^*+CH_3COOD \rightarrow CH_3CO_2+CH_3CO+D_2O$$

or

$$(CH_3COOD)_2+h\nu \rightarrow CH_3CO_2+CH_3CO+D_2O.$$

It should be noted that at 27°C. under the experimental conditions used about 90% of the acetic acid is in the form of double molecules. At 150°C., however, the number of double molecules is negligible for the pressures used in this work. It should be pointed out that processes [I], [II], and [III] are nearly independent of temperature. It may therefore be concluded that double molecules do not affect the primary processes.

The Abstraction Reaction

The fact that the formation of CH_3D is essentially independent of temperature, while that of CH_4 increases rapidly with increasing temperature, indicates that only H-atoms on the methyl group are involved in abstraction reactions to an appreciable extent, viz.

$$CH_3+CH_3COOD \rightarrow CH_4+CH_2COOD. \quad [6]$$

If this is the only way in which CH_4 is formed, and if all C_2H_6 results from recombination,

$$2CH_3 \rightarrow C_2H_6, \quad [7]$$

then $$R_{CH_4}/R^{\frac{1}{2}}_{C_2H_6}[A] = k_6/k_7^{\frac{1}{2}},$$

where R_{CH_4} and $R_{C_2H_6}$ are the rates of formation of the products indicated and A represents acetic acid. In applying this relationship it is necessary to correct the CH_4 for the small amount formed by a process analogous to [I] from the small amount of CH_3COOH present.

The results given in Table I show that $k_6/k_7^{\frac{1}{2}}$ is not appreciably affected by a variation of the intensity by a factor of 15. The corrected values of $k_6/k_7^{\frac{1}{2}}$ are given in Fig. 1 in the form of an Arrhenius plot. A good straight line is

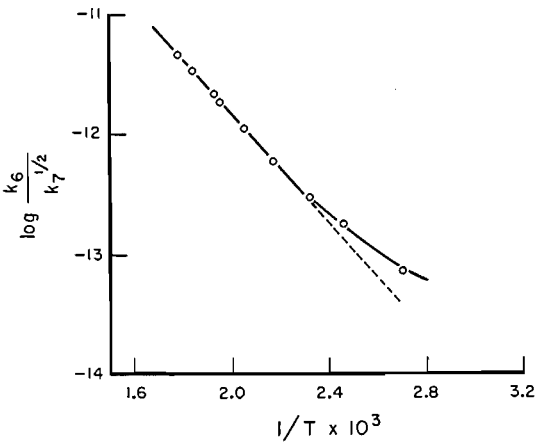

FIG. 1. Arrhenius plot of $k_6/k_7^{\frac{1}{2}}$.

obtained at higher temperatures with some curvature at low temperatures. The curvature may be connected with the presence of double molecules and wall reactions. The slope of the curve leads to a value of 10.2 kcal. for $E_6-\frac{1}{2}E_7 = E_7$. This is of the expected order of magnitude for such a reaction. The steric factor of reaction [7] is estimated to be $\sim 10^{-3}$.

Material Balance

On the basis of the above mechanism primary process [I] implies that

$$CH_3D = CO_2.$$

All other primary processes lead to $1CH_3$ for each CO_2 or CO formed. Hence it would be expected that

$$CO_2+CO-CH_3D = CH_4+2C_2H_6.$$

However, nothing has been said of the fate of the CH_2COOD radical formed

by abstraction. If it is assumed that this disappears only by recombination with methyl, then

$$(2CH_4+2C_2H_6)/(CO_2+CO-CH_3D) = 1. \qquad [A]$$

This ratio will be greater than unity if some CH_2COOD radicals disappear by dimerization, but will be low if CH_2COOD is formed by reaction [4] and is followed by the addition of methyl. A value of $[A]$ somewhat less than unity is therefore to be expected. Any other processes leading to condensable products with elimination of CO or CO_2 will also lower the ratio.

The last column of Table I gives values of the ratio $[A]$. There is considerable scatter, but it will be seen that from 80 to 90% of the methyls are accounted for, which seems quite satisfactory in the absence of a detailed knowledge of the condensable products.

REACTIONS OF ARYLSULPHONIC ESTERS

III. ON THE HYDROLYSIS OF METHYL *p*-METHYLBENZENESULPHONATE[1]

By R. E. Robertson

ABSTRACT

A study of the temperature dependence for the rate of hydrolysis of methyl *p*-methylbenzenesulphonate shows the specific heat of activation for this reaction in water to be 33.45±3 cal./mole degree. A comparison with the corresponding term for other methyl compounds reveals differences apparently characteristic of the anionic portion of the molecule. These differences are discussed in terms of specific solvation.

The possibility that the energy of activation for reactions in solution may be temperature dependent has been predicted and occasionally reported[2], but in general this property has been largely neglected. This is hardly surprising, since little interest was likely in such a derived quantity when the utility of the energy of activation was questionable (5, 6), especially since useful qualitative relationships, such as the S_N1–S_N2 classification, were more readily developed from a comparison of relative rates. Recently, Winstein, Grunwald, and Jones (16) and Swain and Scott (15) have suggested more quantitative classifications based on relative free energies. Such an approach, however, fails to take account of the many effects which result in compensating changes of energy and entropy. Nor will the substitution of the Arrhenius parameters or the equivalent energy and entropy of activation necessarily remove this objection unless it is known that the temperature dependence of the energy of activation is negligible.

Moelwyn-Hughes and co-workers (3, 10, 12) have shown that the specific heat of activation is by no means negligible for the hydrolysis of methyl halides and methyl nitrate. For these reactions ΔC_p[3] is not only large, but varies appreciably between the halides (10) and the nitrate, and may itself be temperature dependent. While it is probably too soon to assess the general significance of these results, and Moelwyn-Hughes has put forward two apparently unrelated hypotheses to account for the value he reports, it is clear that the magnitude of the ΔC_p term is such that it may not be neglected in any quantitative discussion relating structure and energy. In view of the prominent place given to ΔC_p values in discussion of the dissociation of weak acids, one may hope that the corresponding kinetic factor will prove a useful parameter in the quantitative study of reactions in solution.

Because of this possibility, a study was begun on the temperature dependence of the rate of hydrolysis for a series of benzenesulphonic esters. In this paper we report the results for methyl *p*-methylbenzenesulphonate.

$$dE_A/dT = C_{act} - C_{int} = \Delta C_p$$

EXPERIMENTAL DETAIL

Water

Distilled water flowed through an 80 cm. × 35 mm. Acid–Base Ion Exchange column at the rate of 500 cc. per min. The first 600–800 cc. was rejected and the subsequent delivery used to make up solutions and rinse cells.

Methyl p-Methylbenzenesulphonate

Eastman Kodak white label methyl *p*-methylbenzenesulphonate was fractionally frozen to give material melting at 28.0–28.1°C.

Toluenesulphonic Acid

Eastman Kodak white label grade was used without further purification.

The Conductance Bridge

The conductance bridge was built about a Tinsley No. 4896 Electrolytic Conductivity Bridge. The 1000 cycle supply was from a Model 200 AB Hewlett-Packard Oscillator. This was passed through a phase shifter, opposite phases being supplied to the bridge through an isolating transformer, and to the X input of the detecting oscilloscope (Dumont-304H).

The output from the bridge passed through an isolating transformer (GR, 578A), a band pass filter (General Radio, 830-R), and a GR Amplifier (1231 B) and thence to the Y input of the oscilloscope. The Wagner ground of the Tinsley bridge was modified by the introduction of a Leeds and Northrup Decade Resistor (No. 4755) in series with the variable resistance, and balance was observed on a second oscilloscope between the high side of the output of the bridge and ground. This separate balancing was of particular advantage in following fast reaction rates and simultaneous reactions. All wiring was with RG-62U low-loss shielded cable and the leads to the bridge from the cells were carefully shielded, observing the usual precautions.

The Conductance Cells

In control experiments the first order rate was shown to be independent of the design of the cell, provided the resistance was of the proper order. One important restriction was that with more insoluble esters (8), certain precautions had to be taken to avoid the effects of adsorption of appreciable amounts of ester on the glass walls. The obvious precautions of avoiding cells with high surface to volume ratios and further of adopting the Guggenheim method (4) of determining the rate were usually sufficient. Shiny platinum or gold-plated platinum electrodes proved satisfactory. Platinum gray or black electrodes gave evidence of adsorption at low concentrations. While the presence of air did not alter the rate, it was standard practice to partially evacuate the cells to avoid separation of gas on the electrodes at higher temperatures.

Temperatures were determined by a Leeds and Northrup Mueller Bridge and a platinum resistance thermometer calibrated by the Heat Section of these laboratories. Temperatures were controlled within limits of ±0.003°C. Time was determined by either an electric clock driven by current from our

Standard Frequency Laboratory or for shorter runs by a split second-hand stop watch which was checked against the standard time.

EXPERIMENTAL PROCEDURE

After the cells were cleaned with hot chromic acid and repeatedly washed with distilled water, they were filled with a solution of toluenesulphonic acid of the same concentration used as supporting electrolyte in the solution to be studied. A solution containing ester (0.2 gm./l.) and toluenesulphonic acid (0.2 gm./l.) was then prepared. The cells were filled with this solution, evacuated, and sealed off. The presence of backing electrolyte reduced the relative change in electrolyte concentration during a run, and created a more reproducible environment. It was customary to preheat the cells in a subsidiary bath to the temperature under study, to avoid disturbing the main thermostat.

Resistances were measured at times t_1, t_2, t_3, etc., and $t_1+\sigma$, $t_2+\sigma$, $t_3+\sigma$, etc., where $\sigma = 1$ to 2 half-lives, and the slope of the plot of $\log[1/(R_{t_i}+\sigma)-1/R_{t_i}]$ versus t_i gave the rate.

The use of this direct method involves the following approximation. Bolam and Hope (1) have shown that the equivalent conductance of benzenesulphonic acid in water is given by the equation

$$\Lambda = 383-(0.227_4\ \Lambda_0+59.79)\ \sqrt{c} \qquad [1]$$

which may be rewritten for any particular experiment as

$$M/R_x = C-0.38349\ C^{3/2} \qquad [2]$$

where M is a constant, characteristic of the system, and R_x is the measured resistance. If the concentration of backing electrolyte and ester is 1×10^{-3} molar at t_0 and hence 2×10^{-3} molar with respect to benzenesulphonic acid at t_∞ this will introduce a systematic positive error of approximately 1% in all the equivalent values. But the rate is derived from a difference of concentrations or (in the approximation) from the equivalent reciprocal ohms, so that the magnitude of this approximation is reduced to the order of 0.2%. The assumption that this argument applies equally at all temperatures and for similar strong acids does not seem unreasonable since the equivalent conductance of the proton is common to all. The application of this direct method was shown to give the same results, within the reproducibility possible, as those obtained using a calibration curve relating concentration and conductivity, and also was in agreement with values determined by our intermittent titration technique (13).

Precision

The errors introduced by fluctuations in temperature, time, and resistance readings were small compared to the errors arising as a result of what appears to be the adsorption of the ester on the glass walls of the cell. In Fig. 1 is shown a plot of the data for three typical runs done simultaneously. The resulting rates (37.04×10^{-5}, 37.14×10^{-5}, 36.72×10^{-5}) derived from these plots vary from the mean by 0.35% while the scatter of the points in

any run is estimated to be of the order of 0.1%. If care was taken that the concentration of ester did not fall below $5 \times 10^{-5}M$ during the run, this lack of reproducibility was reduced but probably not entirely eliminated by calculating rates by the Guggenheim method (4). With methyl esters this was easily achieved. With less soluble esters, errors from this source became the limiting factor. A further error for slow runs arose from what is generally called "glass-error" and rendered the data at 0° and 10°C. less reliable than the remainder.

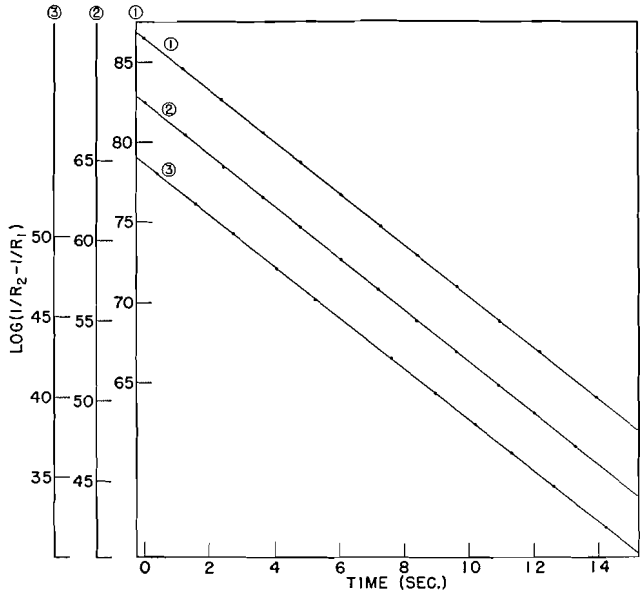

FIG. 1.

RESULTS

The initial concentrations of ester and the backing electrolyte were made up to 0.2 gm./l. in all experiments, and no attempt was made to explore salt effects (9), save for some preliminary experiments which indicated that a 10-fold increase in concentration of benzenesulphonic acid increased the rate by only a few per cent. Average rates corresponding to a series of temperatures are given in Table I, together with the average deviation from the mean, the number (n) of runs involved in the average, and the rate calculated from equation [4]. Prior to deriving such an equation by the direct application of the least mean squares to the data (average rates were used) it is advantageous to test the data for internal consistency by an adaptation of the graphical method of Everett and Wynne-Jones (2) based on equation [3],

$$[3] \qquad \Delta_{1,2}(T \log K)/\Delta_{1,2}(T) = (\Delta C_{p1,2}\, T \log T + B')/R\, \Delta_{1,2}(T),$$

by which these authors calculated the thermodynamic parameters from the ionization constants of weak acids, or more directly by the application of a plot of calculated E_A versus T such as was used by Moelwyn-Hughes (12). Our data

plotted according to equation [3] are shown in Fig. 2. Where $\Delta_{1,2}T \backsim 10°C.$, this plot provides a test of consistency, and on the basis of this test the data for 0° and 10°C. were omitted from the least mean square calculation. While the possibility that the systematic deviation noted in the rates for these temperatures may reflect some structural change in the solvent was considered, we believe that these data deviate from the remainder because of a larger glass-error resulting from the slowness of the runs. The slope of the curve in Fig. 2

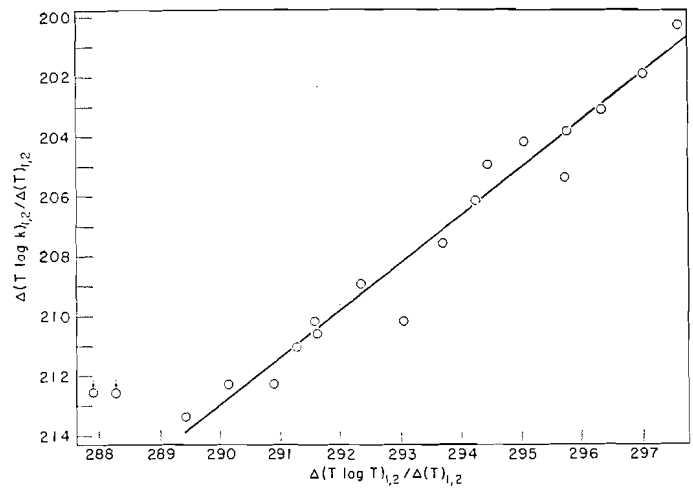

FIG. 2.

leads by the method of least mean squares to a value of ΔC_p of -33.9 ± 3 cal./deg. mole. The thermodynamic constants for equation [4] were then calculated by the method of least squares.[4]

[4]*See Hyne and Robertson. This issue.*

[4] $$\log_{10}k = (A/T)+B\log_{10}T+C$$

where $$A = -\Delta H_0/2.3026\,R = -7036.861,$$
$$B = \Delta C_p/R = -16.8385,$$
$$C = \Delta S_0 - C_p/2.3026\,R = 60.1695,$$
$$0°C. = 273.16°K. \text{ and } R = 1.9865,$$

[5] $$\Delta H_T = \Delta H_0+(-16.8385)RT.$$

Thermodynamic constants for the activation process at 298.16°C. are given in Table II.

TABLE II

THERMODYNAMIC CONSTANTS FOR THE ACTIVATION PROCESS AT 298.16°K.

ΔF = +6953.5 cal./mole
ΔH = −22220.4 cal./mole
ΔS = −51203 cal./mole deg.
ΔC_p = −33.45±3 cal./mole deg.

The error in ΔH is probably less than ±100 cal./mole. The random scatter of the points in Fig. 2 and the deviations between calculated and observed data in Table I show that the data are not sufficiently accurate to justify any claim for a change in ΔC_p with temperature in striking contrast to the results of Moelwyn-Hughes for the methyl halides (12).

DISCUSSION

In Table III, kinetic data are given for the hydrolysis of six methyl compounds. Large differences in the rates compared to that for methyl *p*-methylbenzenesulphonate are accompanied by corresponding changes in ΔH_T, but it is noted that the observed differences in this latter term would correspond to

rate differences from 2 to 700 times greater than actually found. It is interesting to note that the closest agreement on this basis (assuming constant entropy) is for the comparison with methyl fluoride, although the ratio of the rates is greater than 2000/1. The slope of the curve in Fig. 2 and the close agreement of the observed and calculated rates (Table I) leave no doubt that the activation energy for the hydrolysis of methyl *p*-methylbenzenesulphonate

changes with temperature in a systematic manner expressed by equation [5]. This change is of the same sign as, but of about one-half the magnitude of the values reported for the methyl halides in the lower temperature range, and there is no perceptible change in ΔC_p with temperature as was found for the halides.

Now it has long been recognized that the change in the bulk dielectric constant with temperature will lead to a corresponding change in the activation energy in the order of -13 cal./mole deg. for ionogenic reactions. It is clear that this factor will account neither for the magnitude of ΔC_p found for the above hydrolytic reactions, nor for the specific differences between compounds, nor would it be expected to lead to a difference in ΔC_p with temperature.

The fact that ΔC_p values for the hydrolysis of the methyl halides are roughly the same, in spite of widely differing bond strengths, led Moelwyn-Hughes to the conclusion that this coefficient is related to specific differences in the solvation of the reacting molecule. In view of the large difference between the sulphonate and the halides and to a lesser degree the nitrates, it seems probable that the specific solvation of the anionic part of the esters may play a major part in determining the value of this coefficient, and our explanation of the difference between the sulphonate ester and the corresponding halides is based on this postulate.

Reasoning on the basis of average specific heat values, Glew and Moelwyn-Hughes (3) calculate that the large and approximately equal ΔC_p values found for the hydrolysis of the methyl halides could be accounted for by the "freezing" of six water molecules (the freezing process for water involving a ΔC_p of -9 cal./mole deg.) about the transition state—the activation energy involving the breaking of water–water bonds. Such a model applied to the $\Delta C_p = -33$ cal./mole deg. found for the hydrolysis of methyl *p*-methylbenzenesulphonate would lead to a mechanism involving two water molecules reminiscent of the termolecular mechanism of Swain (14). If E_A is largely accounted for by the breaking of water–water bonds, as suggested in this hypothesis, the lower activation energy observed by us is not low enough to support such a hypothesis.

Qualitatively it is well known that the addition of a sulphonic group renders many organic molecules more soluble in water—an effect which points to strong interaction with the water of the initial state in hydrolysis of sulphonic esters. In attempting to account for the difference between the ΔC_p for the hydrolysis of the methyl halides and methyl *p*-methylbenzenesulphonate, in terms of solvation, it is reasonable to assume that the relative differences will be greater for the initial states where dipole–dipole interactions are weaker than for the transition states which involve partial charges. On this hypothesis, the lower value of ΔC_p reported for methyl *p*-methylbenzenesulphonate may be accounted for by assuming that the stronger solvation accompanying the initial state results in a smaller change in solvation on passing to the transition state as compared to the corresponding changes in solvation for the methyl halides. A similar explanation would also account for the lower value of ΔC_p

reported by McKinley-McKee and Moelwyn-Hughes (10) for the hydrolysis of methyl nitrate.

ACKNOWLEDGMENT

The author wishes to acknowledge the technical assistance of Mr. Allan Relf throughout this investigation. The advice of Dr. A. F. Dunn was very helpful in connection with modifying the bridge circuit.

ON THE TEMPERATURE DEPENDENCE OF THE REACTION VELOCITY[1]

By J. B. Hyne[2] and R. E. Robertson

ABSTRACT

The temperature dependence of the rates of three reactions in solution which the Arrhenius equation fails to express has been analyzed in terms of equations involving higher powers of the temperature and an improved fit of the experimental results obtained. The significance of the equations in terms of the thermodynamic parameters of the activation process is discussed.

There is a growing body of evidence to show that for important classes of reactions the Arrhenius equation fails to express fully the temperature dependence of reaction velocity. The Arrhenius equation assumes the activation energy to be temperature independent but this has not been fully tested in the majority of reactions in solution, since the temperature dependency has been derived from data over a limited temperature range with but an accuracy of a few per cent. With a few possible exceptions, such as in discussions of steric hindrance (3, 4), the activation energy has found little use save in converting rate data to a common temperature. Existing relationships between structure and the rate have been based on a comparison of rate data, the validity of such relations resting on the temperature independence of the Arrhenius parameters.

Both LaMer and Miller (15) and Moelwyn-Hughes and co-workers (8, 16, 17, 18), among others, have published results which indicate a marked temperature dependence of activation energy in particular systems. Neglect of such a measurable parameter at the present stage in the development of the kinetics of organic processes is not warranted and it is the object of this paper to present an analysis of kinetic data which considers the higher order temperature dependence of reaction velocity.

It must be recognized that the work of Harned *et al.* (11, 12), Everett and Wynne-Jones (7), and others (19, 23) on the analysis of acid and base dissociation constants as a function of temperature has already established a set of equations for the treatment of data for equilibrium systems. Accepting the assumption that the initial and transition states in a reaction are in equilibrium (5), such a system of equations may be applied to the analysis of rate–temperature data. The treatment of rate–temperature data in a manner analogous to the work on dissociation constants, however, presents problems peculiar to this field arising from difficulties attendant upon obtaining kinetic data of an accuracy comparable to e.m.f. data.

Refinement of the rate–temperature relationships for kinetic data would engender little interest were it not a necessary step in the long term problem of developing a more quantitative statement of the theory of the mechanism of reactions. A more immediate gain is the possibility that such refinement

[1]*Manuscript received June 16, 1955.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3721.
[2]*National Research Council Postdoctorate Fellow.*

will provide a parameter (14) which can be interpreted in a thermodynamic sense and will provide a means of obtaining quantitative measurement of the factors involved in solvation processes accompanying reactions in solution; heretofore, such problems in solvation have been dealt with on an empirical basis (10, 22) by the study of reactions in mixed solvents or as a function of the bulk dielectric constant of the system (1).

TYPES OF EQUATION

Skrabal (21) has set down the various types of equation which have been suggested as representing the temperature dependence of rate data. Harned and Robinson (12) in particular, however, have treated the problem of progressive refinement of equations relating the equilibrium constants of dissociation processes and temperature and it is upon this work that our analysis of kinetic data is based. The Arrhenius equation

$$\log k = (A/T)+B, \qquad [1]$$

where $A = -E_a/2.303R$, assumes that the activation energy, E_a, is temperature independent. If the activation energy, or heat content change of the activation process ΔH, is expressed as a power series in T,

$$\Delta H = a+bT+dT^2,$$

the expression for the temperature dependence of the rate becomes

$$\log k = (A/T)+B \log T+DT+C \qquad [2]$$

where the thermodynamic functions of the activation process are given by

$$\begin{aligned} \Delta H &= -2.303RA+BRT+2.303RDT^2, \\ \Delta C_p &= RB+2.303R(2DT), \\ \Delta S &= 2.303R(B \log T+2DT+C)+RB. \end{aligned}$$

Harned and Robinson (12) and Everett and Wynne-Jones (7) have simplified this four-constant equation and have obtained two three-constant equations which, within the limit of accuracy of the data available to them for analysis, were found to represent the temperature dependence of the log k function studied.

$$\log k = (A/T)+B \log T+C \text{ (Everett and Wynne-Jones)} \qquad [3]$$

where

$$\begin{aligned} \Delta H &= -R(2.303A-BT), \\ \Delta C_p &= BR, \\ \Delta S &= 2.303R(C+B \log T)+RB; \end{aligned}$$

$$\log k = (A/T)+DT+C \text{ (Harned and Robinson)} \qquad [4]$$

where

$$\begin{aligned} \Delta H &= -2.303R(A-DT^2), \\ \Delta C_p &= 2.303R(2DT), \\ \Delta S &= 2.303R(C+2DT). \end{aligned}$$

The progressive refinement implied in equations [1] to [4] is seen when the thermodynamic parameters are expressed in terms of the constants of the

equations. Equation [1] as stated previously assumes ΔH to be temperature independent; equation [3] assumes a linear dependence of ΔH on temperature leading to a specific heat of activation term ΔC_p, which is temperature independent; equation [4] expresses ΔC_p as directly proportional to the absolute temperature; equation [2], the general case of [3] and [4], requires ΔC_p to be a linear function of the temperature. It is on the basis of equations [1] to [4] that the results of Robertson for the hydrolysis of methyl *p*-methylbenzenesulphonate (20), of LaMer and Miller for the dealdolization of diacetone alcohol (15), and of Moelwyn-Hughes for the hydrolysis of methyl chloride (18) have been analyzed.

CALCULATION

In Fig. 1 are shown plots of the activation energy against temperature for the three systems analyzed in this work. The data were analyzed by means

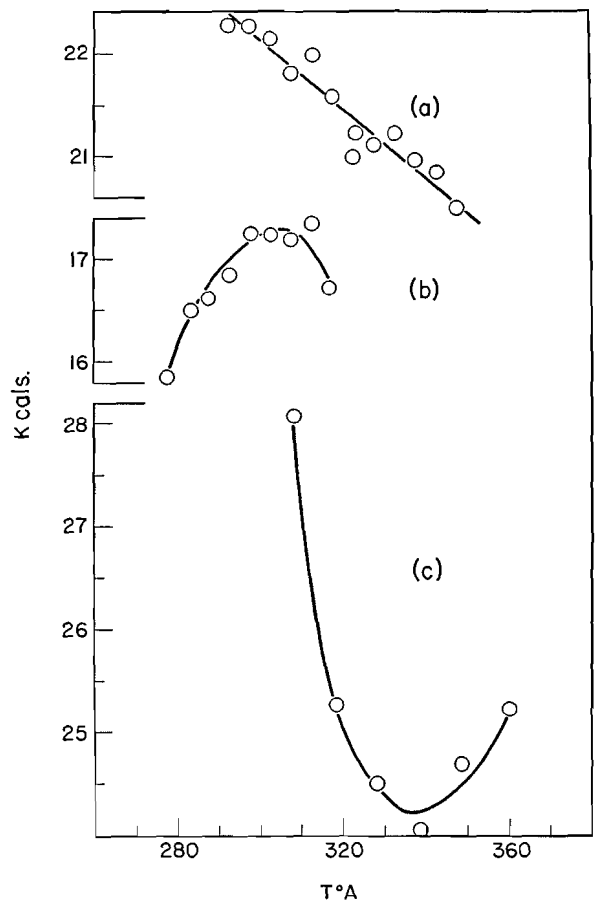

FIG. 1. Activation energy against temperature: (*a*) hydrolysis of methyl *p*-methylbenzenesulphonate; (*b*) dealdolization of diacetone alcohol; (*c*) hydrolysis of methyl chloride.

of the Arrhenius equation in the form [1′] using 10°C. temperature intervals, and the activation energies calculated for these intervals were associated with the mean temperature of the intervals:

$$[1'] \qquad \log(k_1/k_2) = E_a(T_1-T_2)/2.303R\ T_1T_2.$$

In the case of methyl *p*-methylbenzenesulphonate (Fig. 1(*a*)) the activation energy is a linear function of the temperature indicating a unique value of dE_a/dT over the temperature range studied, or in terms of thermodynamic parameters, a ΔC_p term which is temperature independent. In both the dealdolization of diacetone alcohol (Fig. 1(*b*)) and the hydrolysis of methyl chloride (Fig. 1(*c*)) the activation energy is a non-linear function of temperature indicating that the ΔC_p terms are temperature dependent. The curvature of the plot over the temperature range available is more marked in the case of methyl chloride than in that of diacetone alcohol hinting that the temperature dependence of the ΔC_p term is more complex in the former case. Such preliminary plots in the detailed analyses of rate–temperature data serve to indicate, in addition to the nature of the ΔC_p temperature dependence, any determinations which are not internally consistent with the other data since they will appear as deviating widely from the general trend of neighboring points. Calculation of the activation energy at intervals of less than 10°C. requires exceptionally accurate experimental data and is not necessary for preliminary plots such as in Fig. 1 when a temperature range of 40 to 50 degrees is available for study.

Figs. 2, 3, and 4 show, for the three systems studied, the deviations between observed and calculated log k values after the manner of Pitzer (19). The rate–temperature data for each system have been analyzed in terms of the various equations set down in the previous section until a minimum deviation between the observed log k value and that calculated from the equation fitted was obtained. The constants of the various equations were determined by a least mean square fit method applied directly to the data except in the case of the four-constant equation where an empirical graphical correction was applied to obtain the fourth constant C. The least mean square method used was that outlined by Goulden (9) using the method of Gauss Multipliers.

In work where rates of reaction of several systems are determined at a fixed series of temperatures the Gauss Multiplier method has much to recommend it since the Gauss Multipliers are dependent only on the temperature data and once calculated can be applied to any set of rate data determined for that particular set of temperatures.

In the design of experiments the extent of the temperature range studied is of considerable importance. In the application of the least mean square method to the results the inclusion of one determination at a temperature 10°C. outside the initially studied range (say 10° to 60°C.) is equivalent to increasing the number of determinations within the range by a factor of 1.7. The importance of determinations at the extremes of the temperature range has been pointed out previously (2) and great care is necessary in establishing the accuracy of these points.

DISCUSSION

Methyl p-Methylbenzenesulphonate

The failure of the Arrhenius equation [1*a*] to represent the data is clearly shown in Fig. 2, a systematic deviation between the observed and calculated log k values being observed. Analysis of the data in terms of equations [3*a*] and [4*a*] resulted in a random scatter of the deviation about the zero line in Fig. 2 showing that it is impossible to distinguish between the accuracy of fit of the two equations. Both equations take into consideration temperature dependence of the activation energy, i.e. they include a ΔC_p term, equation [3*a*] assuming ΔC_p to be temperature independent and [4*a*] requiring ΔC_p to be directly proportional to the absolute temperature. As Harned and Robinson (12) have pointed out, the fact that both equations fit the data equally well indicates that any temperature dependence of ΔC_p must be very small. The best fit of equations [3*a*] and [4*a*] also agrees with the linearity found in the E_a/T plot of Fig. 1(*a*).

Diacetone Alcohol

As in the methyl *p*-methylbenzenesulphonate system the failure of the Arrhenius equation [1*b*] is seen in Fig. 3. In this system, however, somewhat better agreement between observed and calculated log k values is found for equation [4*b*], where allowance is made for ΔC_p being directly proportional to the absolute temperature, compared with equation [3*b*], where the ΔC_p is assumed to be temperature independent. The preliminary plot of E_a against T established the non-linearity of the temperature dependence of E_a and hence the temperature dependence of the corresponding ΔC_p term. Inspection of the deviation curves in Fig. 3 shows that even the three-constant equation [4*b*], allowing temperature dependence of ΔC_p, does not give good agreement between the observed and calculated log k values especially at the limits of the temperature range employed. It does, however, provide evidence of the existence of data for a system exhibiting temperature dependence of ΔC_p.

Methyl Chloride

Fig. 4 again illustrates the failure of the Arrhenius equation [1*c*] to express the temperature dependence of the rate of hydrolysis of methyl chloride. In this system, however, although the two three-constant equations [3*c*] and [4*c*] give a better fit, the deviation between observed and calculated log k values is still systematic and not random. The four-constant equation [2*c*], which considers a linear dependence of ΔC_p on temperature (but not direct proportionality), gives a still better fit with all points except that at the lowest temperature. Furthermore, it should be noted that the coefficient of the log T term in [2*c*] has changed sign compared with that in the three-constant equation [3*c*] resulting in a change in sign of the ΔC_p term. The reason for this can be seen by considering the effect of neglecting the lowest temperature determination in Fig. 1(*c*) which will result in the slope of the best straight line through the points changing from negative to positive, and hence the change of sign of the ΔC_p. Investigation of the form of the systematic deviations between the observed and calculated values of log k for the methyl chloride system has shown that an improved over-all fit would require an equation involving at least a cubic term in T. Calculation of the constants of such an equation is an extremely laborious process and even with such an equation the physical significance of the coefficients of the higher powers of T could not be established on the basis of the present theory. The apparent complexity of the equation required to express the temperature dependence of rate in this case suggests the possibility that the hydrolysis of methyl chloride is not a simple reaction but is accompanied by a parallel reaction having a different activation energy (13). Moelwyn-Hughes does not consider this possibility in his presentation of the data although he offers several possible suggestions as explanations of the complex temperature dependence of the activation energy. Confirmation of the data, particularly at the extremes of the temperature range, is obviously desirable. The methyl chloride example is paralleled by the results for methyl bromide and methyl iodide also given by Moelwyn-Hughes (18) but not analyzed here.

The importance of choice of equation when the fit is not good is illustrated in Table I by a comparison of the ΔC_p terms calculated for the various systems

TABLE I

Equation	$\Delta C_p^{313.16}$ (cal./deg. mole)		
	Methyl *p*-methyl-benzenesulphonate	Diacetone alcohol	Methyl chloride
[3]	−33.5	−27.9	−44.2
[4]	−33.2	−37.1	−32.2
[2]			+10.4

from the corresponding coefficients of the equations used. For methyl *p*-methylbenzenesulphonate, where both equations [3*a*] and [4*a*] fit the data within the experimental error, the ΔC_p values are in excellent agreement. The diacetone alcohol system, where the fit is somewhat poorer, gives two

values of ΔC_p differing by 10 cal./deg.mole, while in the methyl chloride system, where the fit is poor even in the case of the four-constant equation [2*c*], the ΔC_p value calculated by the four-constant equation [2*c*] is of opposite sign to those evaluated from equations [3*c*] and [4*c*]. In no case, it should be noted, does the value of the ΔC_p determined by a least mean square method agree with the value quoted by Moelwyn-Hughes (17).

These systems suggest that kinetic data may well require more complex expressions to describe their temperature dependence than the corresponding dissociation constant temperature dependence relationships where Harned and Robinson (12) and Everett (6) found no evidence for discriminating between equations of the type [3] and [4]. Whether this apparent necessity for more complex equations to account for rate–temperature behavior is a reflection of a more complex activation process or is due to the fact that systems exhibiting complex temperature dependence of dissociation constants have not as yet been studied, is a question which only further work in both fields will answer.

ACKNOWLEDGMENTS

We gratefully acknowledge helpful advice of Mr. K. A. Brownlee and Mr. L. J. Savage, Committee on Statistics, University of Chicago, and of Mr. P. P. F. Clay, Section on Biometrics, of these laboratories.

SOME CORRELATIONS OF THE MOLECULAR STRUCTURE OF ORGANIC PHOSPHORUS COMPOUNDS WITH THEIR INFRARED SPECTRA[1]

By R. B. Harvey[2] and J. E. Mayhood[3]

ABSTRACT

The infrared spectra of fourteen organic esters of phosphorus containing dimethylamino groups, and two esters containing diethylamino groups have been examined over the region 5000 to 670 cm.$^{-1}$ (2 to 15 microns). Correlations have been obtained between absorption band frequencies and the presence of dialkylamino groups in the molecule as an aid to their identification in the spectra of phosphorus compounds. A number of compounds of the pyrophosphate type have been examined and absorption associated with the (P—O—P) linkage has been found in the 950 to 910 cm.$^{-1}$ (10.5 to 11.0 micron) region. Some criteria are proposed to distinguish absorption by the (P—O—P) linkage in this region.

INTRODUCTION

Some convenient method for the identification of compounds or of specific groupings present in compounds is desirable either from the standpoint of process or quality control in industrial application, or for the chemist in laboratory operations. Since the development of the theory of infrared spectra is not yet adequate to interpret the observations without accessory data except in the simplest cases, a system of correlations is required between known molecular configurations and absorption spectra. The present paper is concerned with such a series, characteristic of the dimethylamino (Me_2N) group in esters of phosphorus compounds. Some limited data are presented on absorption bands attributed to the (P—O—P) bond.

EXPERIMENTAL

A Perkin-Elmer Model 21 double beam recording spectrophotometer was used to obtain the spectra presented in Figs. 1 to 19. The particular instrument is set up to scan on a linear wavelength scale, but all references to absorption bands have been converted to wave numbers (cm.$^{-1}$). The absorption of energy was read in units of optical density or absorbance; the ordinate of the absorption curves in the figures is labelled "% transmission", the origin being 0% and the topmost index line being 100% transmission. Most of the samples were run as contact films; any exceptions to this are noted on the spectra concerned. Since many of the compounds are highly hygroscopic, care was taken to eliminate moisture both from the windows and from the cell surfaces coming into contact with the samples, and by preparing the samples in a dry box or under the beam of an infrared lamp. The presence of (OH) bands is usually a fairly good test of water that may have been present in the sample or that may have been picked up during sample preparation. Water bands in the majority of the spectra were of negligible importance. Spectra were obtained at room temperature.

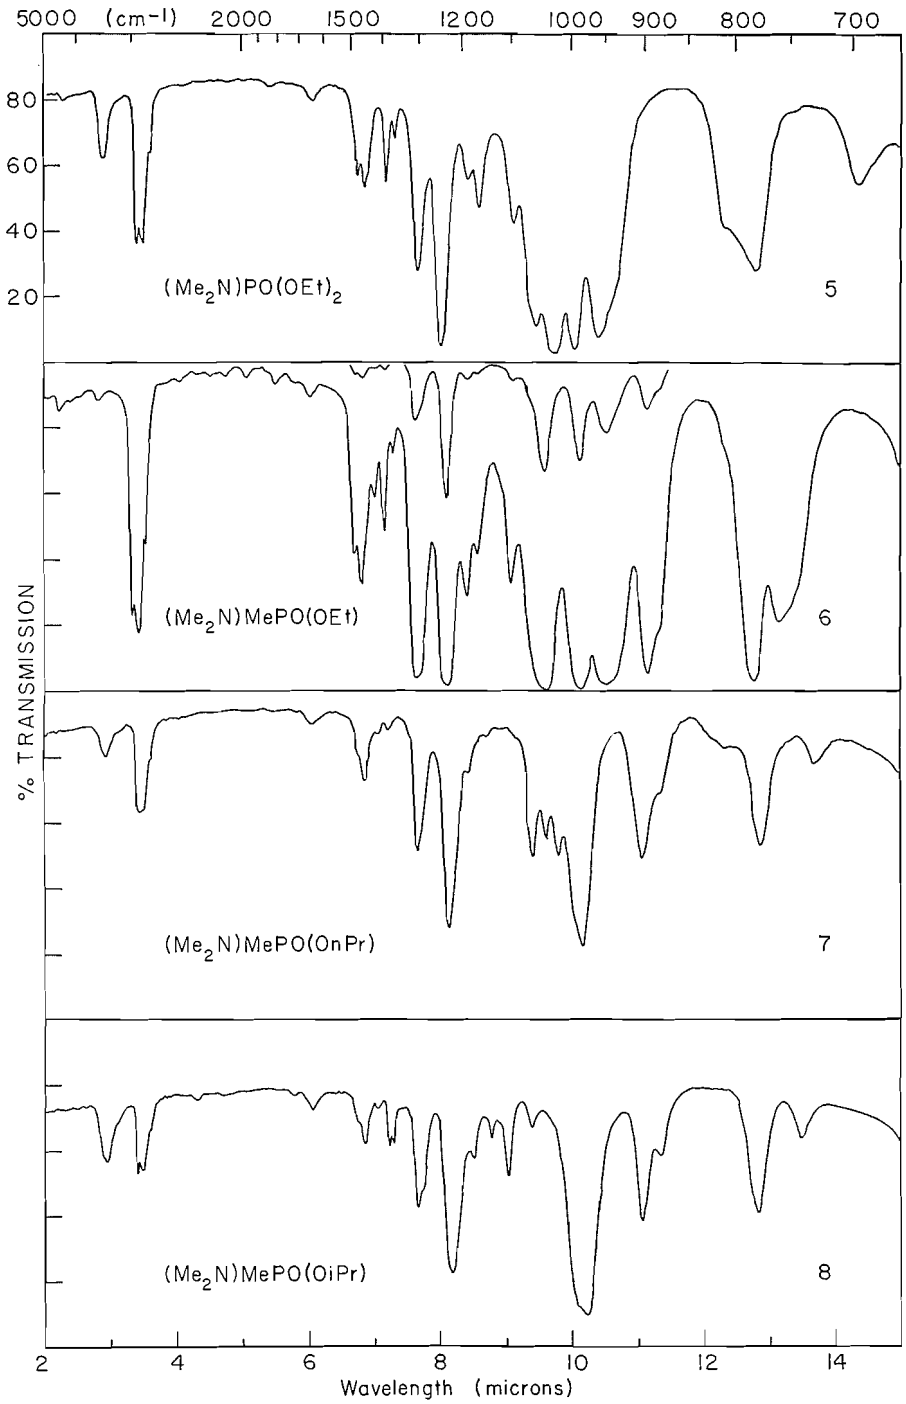
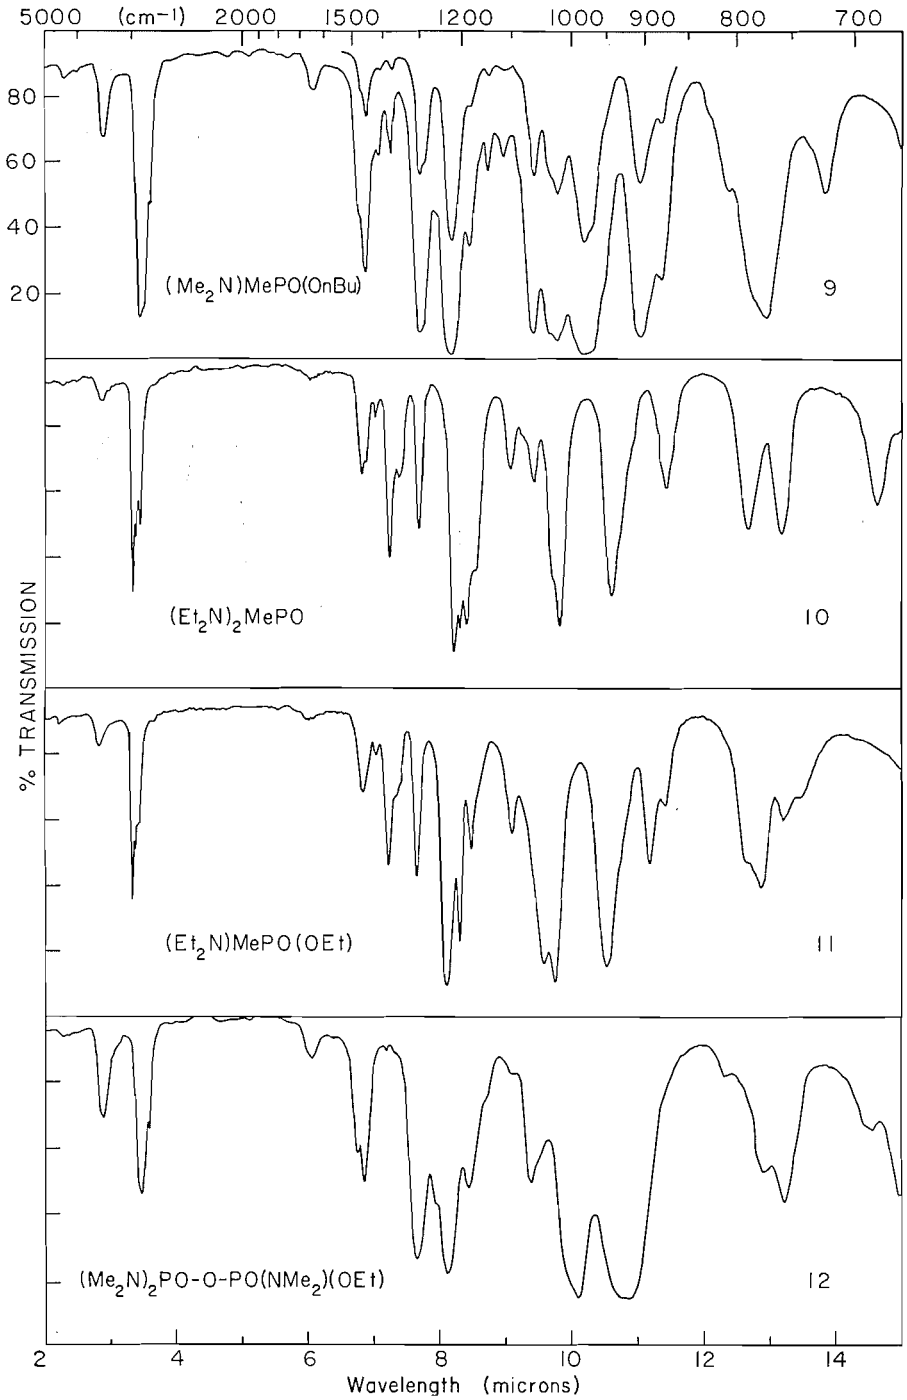
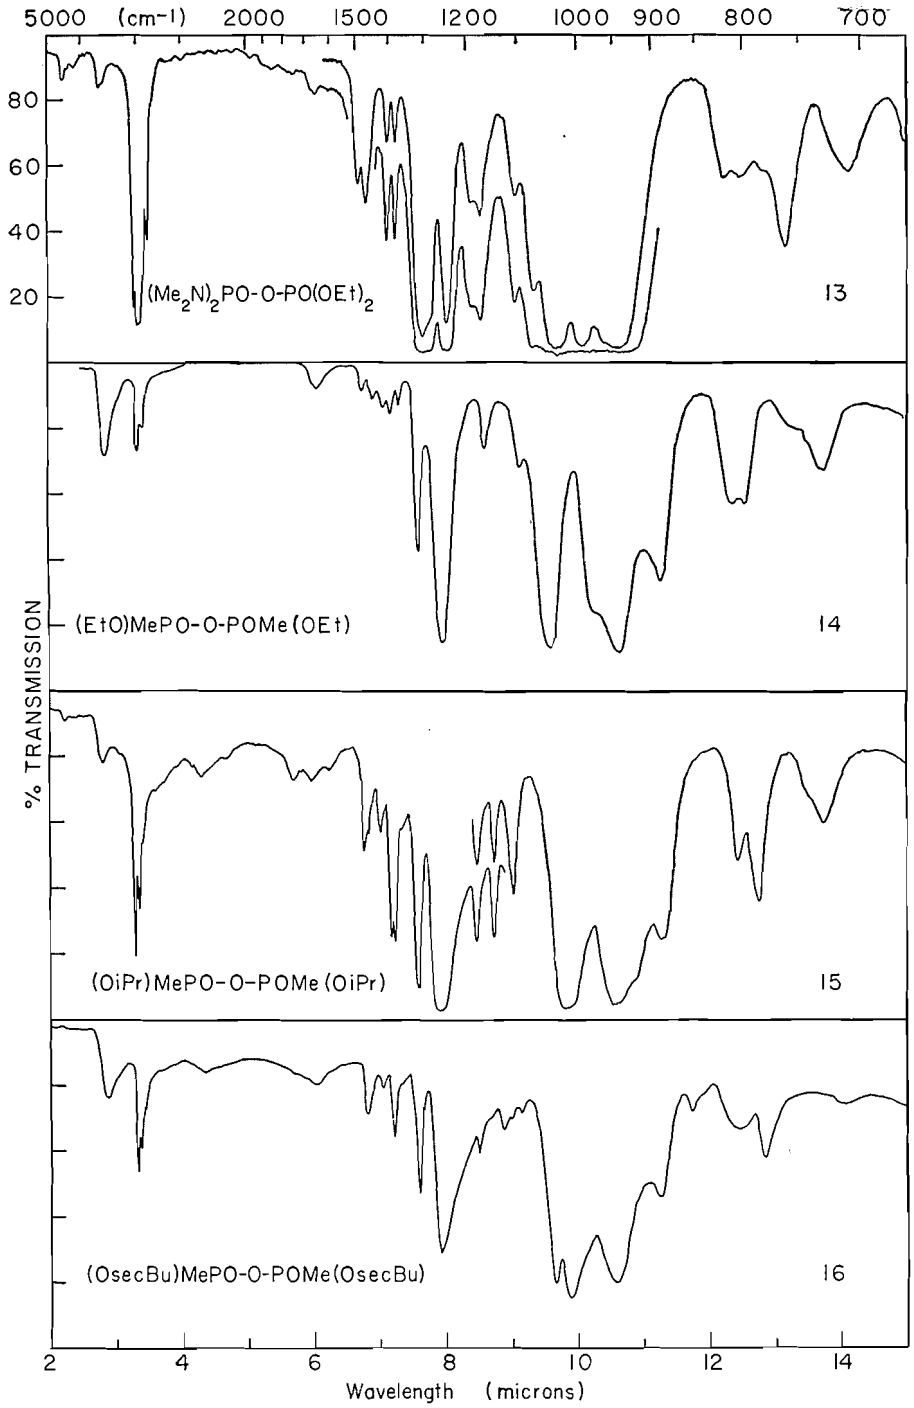


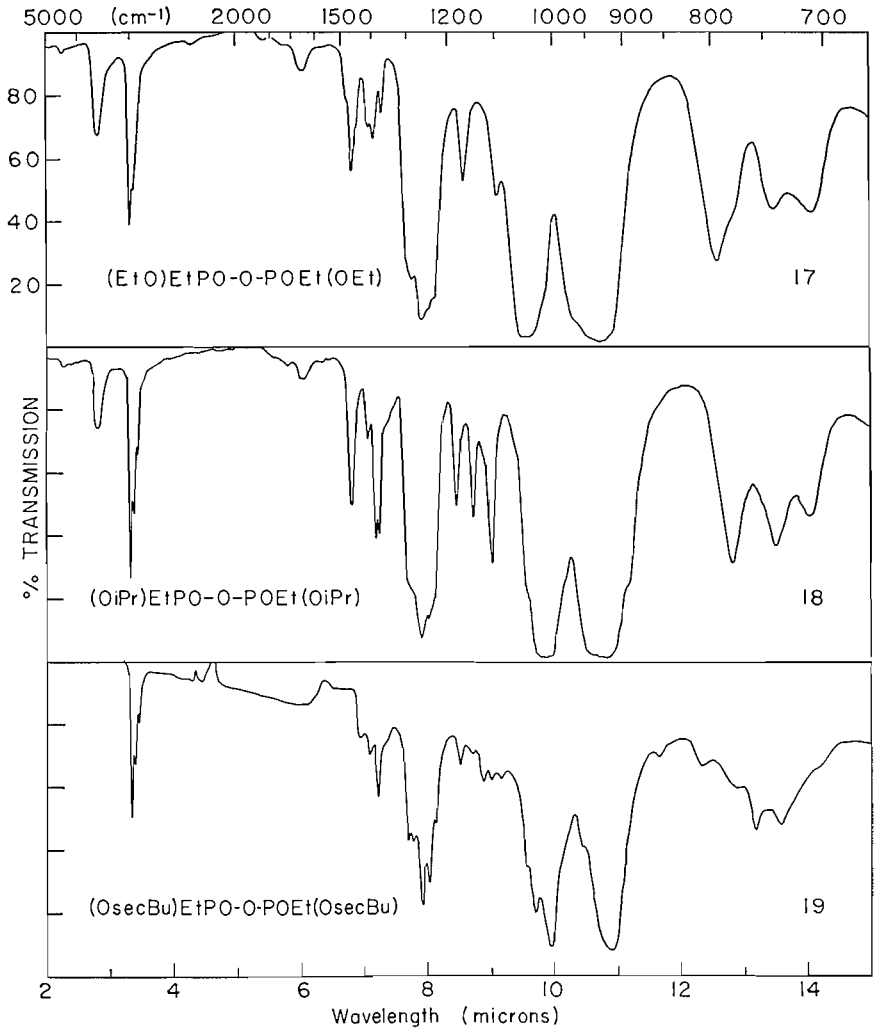
FIGS. 5 to 8.



FIGS. 9 to 12.



FIGS. 13 to 16.



FIGS. 17 to 19.

Most of the compounds whose spectra are presented were prepared through the co-operation of the Chemistry Section of the Suffield Experimental Station. Redistilled materials were used, and where possible, separate preparations of the same compound were examined for deviations in the spectrum. The spectrum of any compound of doubtful purity is marked. In Table I are listed compounds that we are concerned with in this paper, together with their boiling points and refractive indexes. Formulas are given for compounds to avoid confusion in the nomenclature.

RESULTS AND DISCUSSION

(*a*) *The Dimethylamino Grouping* (Me_2N)

Interest in the dimethylamino grouping,  , has arisen from the compound Schradan, in which all the ethoxy groups (EtO) of tetraethyl pyrophosphate have been replaced by dimethylamino groups. Many phosphonic acid esters containing the dimethylamino group have been synthesized and spectra have appeared in some publications. Bellamy and Beecher (2) and Colthup (4) have ascribed an absorption band at about 7.8 μ (1280 cm.$^{-1}$) to secondary aromatic amines. Holmstedt and Larrson (11) suggest that bands at 9.94 to 10.11 μ (1006 to 989 cm.$^{-1}$) and 13.7 to 14.25 μ (730 to 702 cm.$^{-1}$) are characteristic of dimethylamino compounds. They suggest the latter absorption may be the result of stretching vibrations of the (P—N) bond in the combination  ; the former they suggest may be associated with vibration in the (C—N) bond. Corbridge and Lowe (5) have calculated the absorption wavelength to be expected from a (P—N) stretching vibration by Gordy's relation (9) to be about 13.5 μ (740 cm.$^{-1}$). This is in agreement with their observation of a strong absorption near 14.3 μ (700 cm.$^{-1}$) in each of their phosphoramidates. Absorption in the 6.18 and 6.8 μ (1620 and 1470 cm.$^{-1}$) regions may be ascribed to zwitterion formation in this type of compound.

The spectra of 13 of the 16 compounds considered are presented here, 11 of them containing the dimethylamino group, and 2 containing the diethylamino group (see Figs. 1 to 13). Some characteristic absorption bands of the compounds are assembled in Table II. Compounds containing alkyl hydrocarbon groups usually exhibit absorption from 3130 to 2860 cm.$^{-1}$, which is the region attributed to the (C—H) stretching vibrations. Absorption arising from dimethylamino groups appears in a narrow band from 2850 to 2780 cm.$^{-1}$. The absorption band in this region is usually rather weak and may consist of a subsidiary peak or shoulder. The dimethylamino group appears to absorb at 2910 and 2890 cm.$^{-1}$ respectively in the two compounds.

Absorption in the region of 1470 cm.$^{-1}$ appears to be enhanced when dimethylamino groups are attached to phosphorus. A comparison of the spectra of compounds containing the dimethylamino group with the spectra of similar compounds without the group indicates a predominant absorption peak at 1460 to 1450 cm.$^{-1}$. Absorption is almost continuous over the region 1480 to 1430 cm.$^{-1}$ for the compound $[(Me_2N)(EtO)PO]_2O$. The two compounds containing diethylamino groups exhibit absorption in the region 1390 to 1350 cm.$^{-1}$, rather than at 1470 to 1450 cm.$^{-1}$, considerably greater than is normally observed for ethyl esters of phosphonic acids—compare for instance, the spectrum of tetraethyl pyrophosphate.

Compounds containing the methyl phosphoryl group (Me—P=O) exhibit a single sharp absorption band at about 1308 cm.$^{-1}$ with a width at half

The figures in brackets indicate the width of the absorption band at half the maximum height of the peak.

height ($\Delta\nu_{1/2}$,)* of about 16 cm.$^{-1}$. Absorption is shown in the region 1320 to 1280 cm.$^{-1}$ by compounds having a dimethylamino group, and if (Me—PO) and (Me_2N) groups both are present, the sharp absorption band of the former is obscured. Measurement of $\Delta\nu_{1/2}$ in such compounds gives values of 33 to 40 cm.$^{-1}$ (see Table II). In compounds that have no (Me—P) linkage, e.g. (Me_2N)PCl_2 and (Me_2N)$(OEt)_2PO$ the $\Delta\nu_{1/2}$ value is usually about 22 to 36 cm.$^{-1}$. In two pyrophosphate compounds, $[(Me_2N)(OEt)PO]_2O$ and $(Me_2N)_2PO—O—PO(OEt)_2$, the band is merged with other absorption bands in the region and does not appear as a discrete peak. The $\Delta\nu_{1/2}$ value for two compounds with diethylamino groups is 16 cm.$^{-1}$ and, since both compounds contain (Me—PO) groups, there appears to be no absorption contributed by the diethylamino group in the region 1320 to 1280 cm.$^{-1}$. From the results of the spectra examined it appears that absorption in the region 1320 to 1280 cm.$^{-1}$ is characteristic of dimethylamino groups in phosphonic acid esters, and it may be distinguished from absorption arising from (Me—PO) groups by the $\Delta\nu_{1/2}$ values: $\Delta\nu_{1/2}$ = 30 cm.$^{-1}$ for (Me_2N), 16 cm.$^{-1}$ for (Me—PO), and 35 cm.$^{-1}$ for both groups on the phosphorus atom. In some pyrophosphates the band may not be clearly separated from bands lying at slightly longer wavelengths (see the last two compounds of Table II).

The regions near 1190 cm.$^{-1}$ and 1064 cm.$^{-1}$ give rise to consistent absorption for all the compounds studied (see Table II). The maximum and minimum values of the 1190 cm.$^{-1}$ band are 1175 and 1192 cm.$^{-1}$, and of the 1064 cm.$^{-1}$ band, 1063 and 1070 cm.$^{-1}$ respectively. It may be noticed that all compounds give a discrete peak in the 1190 cm.$^{-1}$ region with the exception of $(Et_2N)_2MePO$ with two peaks, at 1192 and 1177 cm.$^{-1}$. There appears to be no certain method of determining the assignment here, but tentatively the 1192 cm.$^{-1}$ peak was chosen as being the more intense. In two pyrophosphates the 1064 cm.$^{-1}$ peak is merged with other absorption bands.

Absorption in the region 1050–950 cm.$^{-1}$ is frequently associated with the (P—O—C) linkage, suggested to arise more specifically from the P—O—(C) bond. Examination of the spectra of three compounds without this linkage, e.g., (Me_2N)PCl_2, (Me_2N)$POCl_2$, and (Me_2N)$_2POCl$, discloses a strong absorption band in the 1000 to 980 cm.$^{-1}$ region. A similar absorption band can be found in the remainder of the compounds, the minimum and maximum values of wavelength being 998 and 978 cm.$^{-1}$. The range of absorption is

*$\Delta\nu_{\frac{1}{2}}$ *is defined as the width of the absorption band in cm.*$^{-1}$ *at half the maximum optical density. D. A. Ramsay has derived an expression (J. Am. Chem. Soc. 74: 72. 1952)*

$$A = (K/cl)\log_e[(T_0)/(T)\nu_{max}] \times \Delta\nu_{\frac{1}{2}}^{a}$$

where $K \simeq \pi/2$ *for condition of slit width much smaller than band width at half intensity,*
c is the concentration of the solution in moles per liter,
l is the absorption path length,
$\log_e[(T_0)/(T)\nu_{max}]$ *is the apparent peak intensity of the band at the frequency* ν_{max},
$\Delta\nu_{\frac{1}{2}}^{a}$ *is the apparent half intensity width of the band.*
This formula permits comparisons of integrated band intensities at different parts of the spectrum. For the comparison of bands on a quantitative basis linear wavelength absorption curves are replotted on a linear wave number scale and the area under the curve determined. For comparison of absorption bands common to a series of a molecular species, values of $\Delta\lambda_{\frac{1}{2}}$ *(microns) may be substituted for* $\Delta\nu_{\frac{1}{2}}$ *(cm.*$^{-1}$*) without serious error for bands occurring over a narrow range of frequencies.*

rather narrow and the substitution of ethyl for methyl appears to shift the absorption band out of this region.

A calculation of the absorption frequency of the (P—N) stretching vibration from Gordy's rule gives a value of 735 cm.$^{-1}$ or 13.6 μ. Corbridge and Lowe (5) have observed strong absorption near 14.3 μ (700 cm.$^{-1}$). The position of this band may be expected to be variable depending on the characteristics of the other groups associated with the phosphorus atom. The assignment of specific bands to any linkage is uncertain since the region 770 to 670 cm.$^{-1}$ is usually associated with skeletal vibrations which may be strongly influenced by comparatively small structural changes. The last column of Table II suggests absorption bands which may arise out of (P—NMe_2) vibrations. In this column the absorption bands are designated as weak (w), medium (m), or strong (s).

An examination of the position of the absorption band arising from the (P=O) bond indicates a shift toward longer wavelengths when a dimethylamino or a diethylamino group is substituted into the molecule. The shift of the (P=O) band position is shown in Table III for several compounds.

TABLE III

EFFECT OF (Me_2N) GROUPS AND (Et_2N) GROUPS ON THE POSITION OF (P=O) ABSORPTION BAND POSITION (CM.$^{-1}$)

Compound	Number of (Me_2N) substituent groups

**The substituent group was (Et_2N) in place of (Me_2N).*

In all cases but the first, the shift of band position is greater on substitution of a second dialkylamino group into the molecule.

The effect of a substituted dimethylamino group on the magnitude of the band shift is greater than that of a diethylamino group for one set of compounds. A correlation between the substituent groups and the position of the (P=O) band has been put forward by several authors and elaborated in (1). The relationship is

$$\lambda(\mu)(P{=}O) = (39.96 - \sum x)/3.995$$

where $\lambda(\mu)$(P=O) is the expected wavelength for the phosphoryl absorption band in microns.

$\sum x$ is the sum of the "phosphoryl absorption shift constants" of the substitu-

ents attached to the phosphorus atom. Values are quoted for x for a wide range of atoms and radicals and a value of 3.0 is assigned to the (NR_2) group. Using this relationship the "phosphoryl absorption shift constants" for the dimethylamino and diethylamino groups have been calculated for the compounds in Table II. The values are 2.46±0.1 average deviation for the dimethylamino group (14 compounds), and 2.75±0.1 average deviation for the diethylamino group (2 compounds).

Absorption of radiation in the region of 3.4 μ (2940 cm.$^{-1}$) has been associated with (C—H) stretching vibrations (10, p. 195). The absorption bands observed in the region 2860 to 2780 cm.$^{-1}$ are probably attributable to (C—H) stretching in the dimethylamino group. The failure of diethylamino substituents to show absorption in this region is not clear since such absorption is present in the spectrum of diethylamine itself. Absorption in the region of 6.8 μ (1470 cm.$^{-1}$) is attributed to bending vibrations in the methyl group (6; 8; 10, p. 195). Absorption at 7.56 μ and 7.65 μ (1325 and 1308 cm.$^{-1}$) is associated with methyl symmetrical bending in Me_3PO (6). Absorption bands are observed in these two regions for compounds containing dimethylamino groups but they appear to be shifted when the substituent is diethylamino. Energy absorptions at 1190 cm.$^{-1}$ and 1064 cm.$^{-1}$ occur over rather narrow bands for a wide variety of substituents on the phosphorus atom and the vibration mode may not include the phosphorus atom itself. A calculation by Gordy's rule (9) suggests a wavelength of 8.5 μ (1178 cm.$^{-1}$) for the (C—N) stretching vibration and the bands at 8.4 μ and 9.4 μ (1190 cm.$^{-1}$ and 1064 cm.$^{-1}$) may arise out of the dialkylamino skeleton $\left(C\begin{smallmatrix}\diagup N\\ \diagdown N\end{smallmatrix}\right)$. This is supported by the fact that the wavelength varies only slightly from compound to compound, the band falls roughly in the same region as the (P)—O—C bands, and the terminal group may be ethyl or methyl without shifting the band position very much. The absorption band observed in the 1000 to 980 cm.$^{-1}$ region may involve the terminal methyl group since change of substituent from dimethylamino to diethylamino causes the band to be shifted from the region. The (P—N) stretching vibration should give rise to absorption near 13.6 μ (735 cm.$^{-1}$) according to Gordy's rule (9), but the assignment of specific bands in the 13 to 15 μ (770 to 670 cm.$^{-1}$) region to any linkage is uncertain, as the region is usually associated with skeletal vibrations, which may be strongly influenced by comparatively small structural changes.

In summary, the bands which appear to be specific for the dimethylamino group in phosphonic acid esters are 1330 to 1300 cm.$^{-1}$, 1000 to 980 cm.$^{-1}$, and possibly 2860 to 2780 cm.$^{-1}$. Other bands associated with the dimethylamino and diethylamino groups are 1470 to 1450 cm.$^{-1}$, 1190 cm.$^{-1}$, 1064 cm.$^{-1}$, and perhaps 770 to 670 cm.$^{-1}$, but in the absence of bands giving confirmation to assignments in the latter region, the added evidence is not strong. An additional bit of information may be derived from the position of the absorption band for the (P=O) bond which may be displaced toward longer wavelengths as much as 64 cm.$^{-1}$ when two substituent dimethylamino groups are put into the molecule.

(b) The Pyrophosphate Grouping (PO—O—PO)

Interest in the group of compounds of the Schradan type and in the pyrophosphates generally has led to an investigation of the possibility of distinguishing the (PO—O—PO) linkage from the point of view of recognition in unknowns, or of testing reaction products for the formation of the linkage. Holmstedt and Larrson (11) have suggested that the (P—O—P) linkage may give rise to absorption at about 14.1 μ (710 cm.$^{-1}$) on a basis of two derivatives of pyrophosphoric acid. Bergmann, Littauer, and Pinchas (3) have observed a band at 10.3 to 10.6 μ (970 to 944 cm.$^{-1}$) which they attribute to the (P—O—P) linkage. The band is not so apparent in the *n*-propyl and isopropyl esters and it is suggested that the wavelength is shifted so that the band cannot be distinguished from the 9.8 μ (1020 cm.$^{-1}$) absorption of the (P—O—C) linkage. Corbridge and Lowe (5) compared the (P—O—P) stretching vibration with the (Si—O—Si) stretching at 9.5–9.7 μ (1052 to 1031 cm.$^{-1}$) and the (P—O—C aliphatic) at 9.3–9.9 μ (1077 to 1010 cm.$^{-1}$). They observe that (P—O—P) stretching bands near 11 μ (910 cm.$^{-1}$) appear to shift toward longer wavelengths with increasing length of the (P—O—P) chain in the inorganic pyrophosphates they studied. Absorption in pyrophosphates is usually limited to a single band near 14.2 μ (704 cm.$^{-1}$), but this may become double in triphosphates and metaphosphates. They suggest that some bands observed near 14.2 μ (704 cm.$^{-1}$) may be due to (P—O) bending in the (P—O—P) link.

Some compounds prepared in these laboratories were examined in the 950 to 910 cm.$^{-1}$ and the 715 cm.$^{-1}$ regions of the spectrum and the results are given in Table IV, together with the characteristic absorptions from compounds of a similar type prepared by other workers (7). Since these compounds are limited to substituted pyrophosphates, the column labelled "Compound"

gives the four substituents in the molecule. Strong absorption is observed in the 950 to 910 cm.$^{-1}$ regions in all compounds except two, viz. $(MeO)_2$-PO—O—PO $(OMe)_2$ and P_4O_{10}. With respect to the former compound, Bergmann, Littauer, and Pinchas (3) comment that the behavior of the first member of a homologous series may not be characteristic of the series. The absorption bands occur over a range of 947 cm.$^{-1}$ maximum to 922 cm.$^{-1}$ minimum. From an examination of the spectra of compounds without the (P—O—P) linkage, it appears unlikely that confusion would occur with other bands, with the exception of that from the ethyl ester group (EtO—P) which usually occurs at 962 to 944 cm.$^{-1}$ with a shoulder at 944 to 926 cm.$^{-1}$. Examination of the height and of the width at half height ($\Delta\nu_{1/2}$) indicates that the (EtO—P) band has a value of $\Delta\nu_{1/2}$ = 32 to 40 cm.$^{-1}$ in five phosphonic acid esters. The value of $\Delta\nu_{1/2}$ for the pyrophosphate derivatives varies from 48 to 64 cm.$^{-1}$ (average 56 cm.$^{-1}$) with two compounds exhibiting peaks broadened so that continuous absorption occurs over the 1000 to 910 cm.$^{-1}$ region.

Absorption in the region 715 to 670 cm.$^{-1}$ is strong and well defined in only a few cases—Fig. 13, and for the compounds $(NMe_2)_2PO—O—PO(NMe_2)_2$, $(MeO)_2PO—O—PO(OMe)_2$, P_2O_5, and $(BuO)_2PO—O—PO(OBu)_2$. The range of wavelength is considerable, and absorption bands occurring at the limit of the range of the instrument are labelled "<670". P_2O_5 exhibits a well-defined absorption at 763 cm.$^{-1}$ and this shortening may correlate with the band at 1010 cm.$^{-1}$ instead of 950 to 910 cm.$^{-1}$. In general it would not appear reliable to attribute absorption bands in the 715 to 670 cm.$^{-1}$ region to the (P—O—P) linkage but they may be confirmatory in the presence of strong broad absorption at 950 to 910 cm.$^{-1}$.

Briefly, organic esters of phosphorus-containing compounds with a linkage (P—O—P) may best be distinguished by the presence of a strong broad absorption band in the spectral region 950 to 910 cm.$^{-1}$. The ethyl ester grouping (EtO—P) is most likely to be confused, but the width of the band at half intensity ($\Delta\nu_{1/2}$) for five esters with this grouping is not greater than 40 cm.$^{-1}$, while the average value of $\Delta\nu_{1/2}$ for the pyrophosphates considered is 56 cm.$^{-1}$. An additional absorption band at 715 to 670 cm.$^{-1}$ may furnish additional evidence, but it is confirmatory only.

The authors wish to thank the Chemistry Section of the Suffield Experimental Station for preparation of the compounds and for the analytical work, and Mr. E. A. Jackman for obtaining many of the spectra and preparing the figures for this paper.

THE ANALYSIS OF FLUOROCARBONS: USE OF INFRARED SPECTROPHOTOMETRY FOR THE ANALYSIS OF SMALL SAMPLES[1]

By P. B. Ayscough[2]

ABSTRACT

A method for the analysis of small quantities of mixtures of carbon tetrafluoride, hexafluoroethane, and fluoroform based on measurement of the intensity of infrared absorption bands is described. The relation between pressure and optical density for the main absorption bands of each gas was determined and used to calculate the composition of synthetic mixtures. These results were compared with those obtained by mass spectrometric analysis.

INTRODUCTION

Analytical procedures for handling small quantities of fluorocarbons are, as yet, largely undeveloped, though the physical and chemical properties of these compounds are well known. In order to make possible an examination of the reactions of trifluoromethyl radicals it was necessary to find an accurate and rapid method for the analysis of carbon tetrafluoride, hexafluoroethane, and fluoroform in quantities of 10 micromoles or less.

A summary of the various methods for analyzing fluorine compounds is to be found in Volume II of *Fluorine Chemistry* edited by J. H. Simons (Academic Press Inc., 1954). Procedures based on differences in vapor pressure or vapor density were shown to be of little value for analyzing these mixtures, and the chemical methods, such as pyrolysis over white-hot silica, combustion in moist hydrogen, and sodium fusion, give only values for the average carbon and fluorine content. Conventional oxidation methods cannot be used because of the high resistance to oxidation of fluorocarbons.

Mass-spectrometric analysis is one possible method since the mass spectra of most of the simple fluorine-containing compounds are known (2). However, a characteristic feature of the mass spectra of fluorocarbons is the almost complete absence of parent peaks and, for the straight-chain fluorocarbons, the preponderance of the mass 69 peak (CF_3^+). This means that the analysis depends on the magnitude of the relatively minor peaks which are frequently common to a large number of fluorocarbons. Carbon tetrafluoride is particularly difficult to estimate in this way because all of its peaks are shared by other fluorocarbons and it must be estimated from the residual 69 (CF_3^+) and 50 (CF_2^+) peaks.

Nevertheless, the method has been used successfully during the course of this work for the estimation of mixtures of carbon tetrafluoride, hexafluoroethane, and fluoroform in the presence of carbon monoxide and carbon dioxide. The results of a few analyses of test samples will be presented in a later section.

An examination of the infrared absorption spectra of carbon tetrafluoride,

hexafluoroethane, and fluoroform showed the presence of a number of strong well-defined bands in the region 1000–1500 cm.$^{-1}$ which might be used for analysis. It was shown experimentally that with the exception of carbon tetrafluoride these compounds obey Beer's law in this region and that for samples of 5–10 micromoles an accuracy of $\pm 5\%$ can be obtained. The results of experiments designed to determine the relation between intensity and pressure for these compounds are presented in this paper, together with the analysis of some test samples.

Although the spectra of higher fluorocarbons are more complex it is reasonable to suppose that this method can be extended to estimate mixtures of other fluorocarbons in the same way as it is applied to the estimation of complex mixtures of hydrocarbons.

EXPERIMENTAL

Apparatus

Optical density measurements were made using a Perkin-Elmer Model 21 double beam recording spectrophotometer with a sodium chloride prism. The optical cell used in conjunction with this instrument was made of pyrex with polished sodium chloride windows fixed with Benolite cement. The cell had a volume of 155 ml. and was fitted with a stopcock and ground glass joint for admitting the samples of gas. Silicone grease was used on all joints to reduce absorption of the gas. No absorption of gas on the walls of the vessel was observed. The pressure of gas in the optical cell was calculated by measuring the pressure of the sample in a calibrated gas burette and then allowing the gas to expand into the cell. A pressure of 1 mm. in the cell is given by about 8 micromoles of gas.

Materials

Samples of carbon tetrafluoride, hexafluoroethane, and fluoroform of unspecified purity were supplied by E.I. du Pont de Nemours and Co. Inc. to whom we are greatly indebted. The gases were purified by bulb to bulb distillation in the vacuum system, a small middle fraction being taken in each case for calibration purposes. The mass spectra and infrared absorption spectra of these samples were identical with those published previously (1, 2, 5–8) and they were therefore assumed to be pure.

RESULTS AND DISCUSSION

For the purpose of analysis the important spectral region is from 1000 to 1500 cm.$^{-1}$. Since the spectra have already been published, they will not be reproduced here. The only strong line in the carbon tetrafluoride spectrum is that at 1284 cm.$^{-1}$, which is well separated from the strongest absorption bands of hexafluoroethane (1253 cm.$^{-1}$) and fluoroform (1152 cm.$^{-1}$), so that it is possible to use the intensity of these bands as a measure of the partial pressure of each gas in a mixture. Weaker bands in the hexafluoroethane spectrum (1117 and 1123 cm.$^{-1}$) and in the fluoroform spectrum (1380 cm.$^{-1}$) might be used under conditions in which the other bands are too intense.

Measurements of peak optical density were made for each band, using the pure gases, and although some deviation from Beer's law is observed in the

case of carbon tetrafluoride and fluoroform this is not serious enough to affect the validity of the method. All measurements were made with comparable slit widths with no matching cell in the control beam of the spectrophotometer. The base lines were obtained with the cell evacuated and all measurements of optical density were made from these reference lines. Tables I–III and Figs. 1–3 indicate the results of these experiments.

Spectra of Mixtures

In order to check the accuracy of analyses using these absorption bands a number of mixtures were prepared. The absorption spectrum of each was observed under the same conditions as were used for the samples of pure materials, and from the peak heights the partial pressure of each was calculated and compared with the true values. There is very little overlap of absorption bands and it is necessary to apply a correction only in the case of the 1152 cm.$^{-1}$ band of fluoroform in the presence of hexafluoroethane. This correction becomes significant when C_2F_6/CF_3H is of the order of 5:1 or greater. The results of analyses of these test mixtures are shown in Table IV. It will be seen that there is good agreement between the values obtained in this way and those obtained by synthesis. In some cases the mixtures were also analyzed mass spectrometrically. The results of these analyses are added to the table for comparison.

Since the time this method of analysis was established, it has been used on numerous occasions in connection with a series of investigations of the reactions of trifluoromethyl radicals (3, 4). The mixtures have consisted, in general, of hexafluoroethane and fluoroform in the presence of small amounts of methane, ethane, and hexafluoroacetone. Small quantities of impurities such as these are of no importance since they do not absorb in the same region as the fluorocarbons. The only serious limitation so far observed is that resulting from pressure broadening of the fluoroform band in the presence of large amounts of hydrogen-containing material. Abnormally high results are obtained in this

way, and to overcome this difficulty new calibration curves have to be plotted for each total pressure. This is tedious, but under these conditions the mass-spectrometric method was equally unsatisfactory.

ACKNOWLEDGMENTS

The author is greatly indebted to Dr. R. N. Jones for the use of the infrared spectrophotometer and to Mr. R. Lauzon for its operation. Thanks are also due to Miss F. Gauthier for the mass-spectrometric analyses.

SOME MEASUREMENTS ON THE IRON (111) – THIOCYANATE SYSTEM IN AQUEOUS SOLUTION[1]

By M. W. Lister and D. E. Rivington

ABSTRACT

A spectrophotometric study of the ferric thiocyanate system is reported. The temperature and ionic strength of the solutions were carefully controlled, and suitable precautions were taken against fading. From the data, values of the equilibrium constant for the formation of $FeSCN^{++}$ from simple ions, and of the extinction coefficients of $FeSCN^{++}$ were obtained for different temperatures and ionic strengths, with results that differed somewhat from earlier values. The effect of varying acidity was also investigated. From more concentrated solutions, values for the equilibrium constants for the formation of $Fe(SCN)_2^+$ and $Fe(SCN)_3$ were obtained; it was not necessary to postulate higher complexes.

Many investigations have been made of aqueous solutions containing ferric and thiocyanate ions, starting with the original work of Gladstone (9) just over a hundred years ago. However it was only comparatively recently that Moeller (15) and, independently, Bent and French (3) showed that in dilute solution the color was due to the ion $FeSCN^{++}$. This put a new interpretation on the measurements made on this system, and as a result considerable further work was carried out (e.g. 6, 7, 10, 12, 18). This work mostly made use of the red color as a means of investigation, but some work was also done using solvent extraction (14), or electrochemical methods (15).

The present work was begun with the intention of using the red color of $FeSCN^{++}$ as a method of determining the concentration of free ferric ions in solution, and hence of evaluating the equilibrium constants of the dissociation of other complexes formed by ferric ions with other anions. This type of investigation was made by Lanford and Kiehl (13) for the ferric phosphate system. Although earlier work covered a fair range of conditions, it became apparent that in order to have an adequate picture of the system before adding other ions, it would be desirable to extend these measurements to cover systematically a range of temperature, hydrogen ion concentration, and ionic strength. These factors were therefore carefully controlled; temperature control, for instance, was provided by using absorption cells completely immersed in a thermostatted tank. The fading which occurs in these solutions had also to be taken into account, and it is believed conditions were found such that fading was negligible. It was also necessary to take into account the possible formation of the higher complexes, $Fe(SCN)_2^+$ and $Fe(SCN)_3$; and it was in fact possible to make a moderately accurate estimate of the extent to which these species were present, and so to determine their dissociation constants. In interpreting the experimental data, it is not necessary to assume that the extinction coefficients at various wave lengths were constant over a range of conditions; so that these experiments enable one to find the effect of temperature and ionic strength on the extinction coefficients. The effect of hydrogen ion concentration was

[1]*Manuscript received June 30, 1955.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

also examined, especially as regards the possible formation of the ion $FeOH^{++}$ and of undissociated thiocyanic acid. It is hoped therefore that the present work provides a reasonably critical and detailed account of the ferric thiocyanate system, and one which can be used in measuring the dissociation constants of other ferric complexes.

APPARATUS AND MATERIALS

Spectrophotometer

All optical measurements were made with the Beckmann Model DU Spectrophotometer. For normal slit widths in the wave length region used in this work (4000–5000 Å) this instrument uses a band of wave lengths about 10 Å wide (8). As earlier workers do not entirely agree about the position of the maximum absorption of $FeSCN^{++}$, the wave length scale was calibrated using the hydrogen and mercury spectra, and was found to agree within 3 Å (i.e. within experimental error) at the wave lengths of the well-established lines of these elements. The absorption cuvettes used were made of silica, and were of conventional design. The light path was usually 1 cm. and was calibrated to $\pm 0.1\%$. For shorter light paths silica inserts, 0.9 cm. thick, were put in to reduce the light path to 1 mm.

The chief modification that was made on the spectrophotometer was the introduction of thermostatting for the absorption cells. The cells were placed directly in the thermostatting water in a bakelite box fitted with silica windows. The box was light-tight except for the windows. The light beam passed through the water, which was circulated by a pump from a larger reservoir. This reservoir, which contained the usual constant temperature devices, was made of stainless steel, as were the attached pipes and valves, and was filled with distilled water to minimize absorption by impurities in the water. The flow rate through the box was about 1 liter/min., and the temperature could be easily maintained to 0.1°C.

Ferric Perchlorate

The G. Frederick Smith product was used without further purification. A stock solution of about 0.5 *M* was prepared and then analyzed for iron by ammonia precipitation, ignition, and weighing as Fe_2O_3. No check for free acid was made since a high concentration of perchloric acid was added to the mixtures in all the runs.

Perchloric Acid

The 72% reagent grade product supplied by G. Frederick Smith was diluted to give a 1 *M* stock solution which was standardized volumetrically.

Sodium Perchlorate

A 5 *M* stock solution was prepared from the G. Frederick Smith reagent grade sodium perchlorate by dissolving it in water and filtering. This solution gave no test for chloride. The concentration was determined by evaporating a known volume of solution to dryness, heating to 160°C. to break up the mono-

hydrate, and weighing the residue. A check showed that this method gave the same result as prolonged heating at 300°C. This solution produced the same results as one prepared by neutralizing a known amount of perchloric acid with reagent sodium hydroxide, and diluting to the required volume.

Sodium Thiocyanate

A 1 *M* stock solution was prepared from Baker's Analyzed product, and standardized against silver nitrate with ferric alum as indicator. Solutions of thiocyanate slowly decompose on standing to produce a flaky white precipitate. It was found that this trouble could be largely avoided by keeping the solutions in black storage bulbs in an atmosphere of nitrogen. When the solution was needed, it was driven out by a stream of nitrogen.

Benzyl Alcohol

Merck reagent grade benzyl alcohol was used, and was stored in an atmosphere of nitrogen.

Standard Ferric Solutions

It was desirable to prepare a ferric solution with its concentration accurately known in order to have an independent check on the various batches of ferric perchlorate that were prepared. For this purpose the usual iron standards such as ferrous ammonium sulphate were of no value since the sulphate interferes strongly with the ferric thiocyanate color. Consequently a length of clean iron wire was weighed to 0.1%, and heated with the required amount of perchloric acid and a small amount of ammonium nitrate to oxidize ferrous to ferric ions. After cooling, the product was diluted to a known volume and used to produce a ferric thiocyanate solution in the same way as other ferric perchlorate solutions. The intensity of the color was compared with that from the latter solutions, whose concentration could thereby be checked. The results agreed within experimental error with those obtained by precipitating ferric hydroxide.

EXPERIMENTAL

Stock solutions of ferric perchlorate, sodium thiocyanate, perchloric acid, and sodium perchlorate were made up of known strength. Mixtures of known amounts of these were made, and diluted to a known volume, and the color was measured by the spectrophotometer. The color was always measured against a reagent blank which did not contain thiocyanate. In runs where the iron concentration was low this was also omitted in the reagent blank, but at higher concentrations it was included.

It was discovered early in this part of the investigation that solutions with the ferric concentration around 0.1 *M* and thiocyanate around 10^{-4} *M* were subject to serious fading. This was apparently not the same fading reaction that interfered with the colorimetric determination of iron as reported, for example, by Peters, MacMasters, and French (17), and that was later the subject of a kinetic investigation by Betts and Dainton (4), since this latter reaction occurred in solutions of very high thiocyanate concentration and very

low ferric concentration—just the reverse of the present case. The explanation of this fading reaction that was arrived at was that the thiocyanate is oxidized by dissolved oxygen, probably with ferric ion acting as a carrier. This is not an unfamiliar role to assign to ferric and other transition element ions (see, for example, Ref. 1). Jeu and Alyea (11) give a list of substances in order of their ability to inhibit the oxidation of sulphite. From this list benzyl alcohol was selected as a substance with good inhibitory properties, but still not likely to form complexes with ferric ions. In both respects this proved to be a happy choice. The ability of benzyl alcohol to inhibit fading was observed in many solutions, even at 45°C. Qualitatively, an inhibited solution stored in a glass-stoppered volumetric flask was still decidedly red after 18 months, whereas a companion solution with no inhibitor faded completely in about 10 days.

In order to check the possible interference of benzyl alcohol in the color formation, a series of solutions were set up in which the ferric and thiocyanate concentrations were maintained constant throughout and increasing amounts of benzyl alcohol were added; the optical densities of the solutions were read. As seen from the results given in Table I the benzyl alcohol does not interfere to any significant extent.

TABLE I

EFFECT OF BENZYL ALCOHOL

Iron and thiocyanate: 0.001 M; $(H^+) = 0.2$ M; 25°C.; volume: 25 ml.

Drops of benzyl alcohol	0	1	2	4	8
Optical density (460 mμ)	0.496	0.498	0.496	0.493	0.499

In measuring the optical density on the spectrophotometer, no reading was accepted if it showed more than 0.001 change in density after the 'dark current' and blank absorption were checked. At least two, and usually three, readings were taken for each wave length; the density reading was first taken for each wave length used, and then the whole series repeated. It was found that about six drops of benzyl alcohol in 50 ml. of solution were sufficient to reduce fading so that this degree of reproducibility could be obtained.

The results obtained are given in Tables II–VI, and the interpretation of these results will be discussed in the next section. However there is one general comment that should be made first. The ionic strength of 1.2 which was used in many runs may seem unduly high. It was originally chosen to allow, firstly, a sufficient concentration of acid to be present to suppress the formation of $FeOH^{++}$; and, secondly, to allow for a fairly high concentration of ferric perchlorate in some runs. As it turned out this ionic strength was higher than was needed in most runs, but it was thought to be advisable to keep it constant throughout the whole series. In Table III results are given which show the effect of altering the ionic strength.

In all of these tables the optical densities have been reduced to the density per centimeter by dividing by the calibrated cell width.

TABLE II

VALUES OF OPTICAL DENSITY FOR 1 CM. LIGHT PATH

All measurements in this table at 25°C., 1.2 ionic strength, and $(H^+) = 0.2\ M$

DISCUSSION OF RESULTS

In the treatment of data of this sort it is usual to assume that a reaction such as

$$Fe^{+3}+SCN^{-} \rightleftharpoons FeSCN^{++}$$

conforms to a Mass Law expression

$$a_{FeSCN^{++}}/a_{Fe^{+3}}.a_{SCN^{-}} = K_0$$

where $a_{Fe^{+3}}$, etc., are the activities of the various substances. Indeed this is little more than a matter of definition, the real assumptions being that the activity coefficients are dependent only on temperature and ionic strength, and that they approach unity as the ionic strength approaches zero. In practice it is usually simpler to evaluate an apparent constant, K, defined by the concentrations; and then to observe the variation of K with ionic strength. K is in fact the equilibrium constant at a certain ionic strength and temperature, and most of the constants derived below are of this sort.

In evaluating K from optical densities, it is always assumed that the densities obey Beer's Law: $D = \epsilon.c$; where D is the density, ϵ is the extinction coefficient, and c is the concentration of the colored substance. ϵ is, of course, dependent on the wave length, and to a lesser extent on the ionic strength and temperature; but we assume that it is independent of c, if c is fairly small. In the present work the concentration of the colored ion was 10^{-3} M or less, so that it can be reasonably assumed that the colored ions are sufficiently far apart not to affect each other's extinction coefficient. The results in Tables II–V enable the effect of temperature and ionic strength on the extinction coefficient to be determined.

To obtain values of K and ϵ from optical densities somewhat similar methods are available, devised by Rabinowitch and Stockmayer (19), and by Frank and Oswalt (7). The relation of these two methods can be seen from the following, which provides a simpler derivation of Frank and Oswalt's equation. If a is the total ferric concentration (present either as Fe^{+3} or $FeSCN^{++}$), b is the total thiocyanate concentration, and x that of the complex, $FeSCN^{++}$, then:

$$x/[(a-x)(b-x)] = K.$$

As $x = D/\epsilon$, we can substitute and rearrange to get

$$ab/D = (a+b)/\epsilon + 1/\epsilon K - D/\epsilon^2.$$

If we ignore D/ϵ^2 as small compared to the other terms, we get Frank and Oswalt's equation. By plotting ab/D against $a+b$, ϵ and K can be evaluated. Rabinowitch and Stockmayer, in effect, take Frank and Oswalt's equation and divide by b to get

$$a/D = a/b\epsilon + 1/b\epsilon K + 1/\epsilon.$$

They assume that $1/\epsilon$ is small and can be neglected; and by plotting a/D against a for runs at constant b, they can evaluate ϵ and K. It can readily be checked that this is precisely equivalent to assuming that x is negligible compared with a in $(a-x)$ in the original Mass Law equation. This method is

simple to apply, and is sufficiently accurate provided a is appreciably larger than b. It cannot be applied to all mixtures, but it is easy to check whether it is applicable or not. Of course, if b is larger than a, an analogous equation can be derived by ignoring x with respect to b. The Frank and Oswalt equation was valid for all the conditions that were used; but, as it is more difficult to apply, it was only used when its use was unavoidable.

These equations of course assume that no other reactions occur. There are three complicating reactions that must be considered. These are: (i) hydrolysis of Fe^{+3} to $FeOH^{++}$, (ii) formation of thiocyanic acid molecules, and (iii) formation of higher complexes, notably $Fe(SCN)_2^+$. An estimate can be made of the extent to which the first two reactions interfere, and conditions chosen so that this interference is not serious and can be allowed for. The third reaction presumably does not occur at great dilutions; the equilibrium giving the higher complex can be measured by observing the deviations from the simple equations at higher thiocyanate concentrations. The effect of the first two reactions can be estimated as follows.

If K_h is the equilibrium constant for the reaction:

$$Fe^{+3}+2H_2O \rightleftharpoons FeOH^{++}+H_3O^+$$

defined as

$$K_h = (FeOH^{++}) \cdot (H^+)/(Fe^{+3}),$$

then the total iron concentration is given by

$$a = (Fe^{+3})+(FeOH^{++})+(FeSCN^{++})$$

and $a = (Fe^{+3}) \cdot \{1+K_h/(H^+)\}+(FeSCN^{++})$.

The Rabinowitch–Stockmayer equation is modified to

$$\frac{a}{D} = \frac{a}{b\epsilon}+\frac{1+K_h/(H^+)}{Kb\epsilon}.$$

Reported values of K_h are given in Table VII. As the extrapolation from low ionic strengths to an ionic strength of 1.2 is somewhat uncertain, the results given above in Table VI were obtained, which show the effect of varying the hydrogen ion concentration in ferric thiocyanate mixtures. These results also provide some evidence on the possible existence of the ion $Fe(OH)(SCN)^+$.

TABLE VII

LITERATURE VALUES OF K_h

All measurements are at 25°C.

K_h	Ionic strength	Method	Reference
0.006	Small	Potentiometric	5
0.0035	Small	Conductivity	12*a*
0.0028	0.05	Spectrophotometric	15*a*
0.0065	Small	Spectrophotometric	20

The interpretation of these results must also take into consideration the possibility of thiocyanic acid formation. If thiocyanic acid is formed the Rabinowitch–Stockmayer equation should be modified much as above:

$$\frac{a}{D} = \frac{a}{b\epsilon} + \frac{1+(H^+)/K_a}{Kb\epsilon}$$

where K_a is the ionization constant of thiocyanic acid. Values of K_a are none too certain, though it is known (15*b*) that thiocyanic acid is a strong acid. Recently Gorman and Connell (9*a*) reported that sodium thiocyanate exerts no discernible buffering action on solutions of perchloric acid. This is confirmed by the results of Table VI in the following way. If the Rabinowitch–Stockmayer equation, allowing for both the above side reactions, is written down:

$$\frac{a}{D} = \frac{a}{b\epsilon} + \frac{(1+K_h/(H^+)) \cdot (1+(H^+)/K_a)}{Kb\epsilon}$$

and is differentiated to find the point where D is a maximum as (H^+) varies, with a and b constant, we get

$$\frac{\partial D}{\partial (H^+)} = \frac{D^2}{ab\epsilon K}(K_h/(H^+)^2 - 1/K_a).$$

Hence the maximum occurs when $(H^+) = \sqrt{(K_h K_a)}$. The results in Table VI give no definite maximum, but D scarcely increases as (H^+) goes from 0.2 to 0.5, so possibly a maximum occurs at about $(H^+) = 0.5\ M$. The value of K_h (obtained below) at this ionic strength is 1.55×10^{-3}, so K_a is 160 or more. This value of K_a has, of course, no precise quantitative significance, except to show that thiocyanic acid is a strong enough acid for its formation to be ignored. It may be added that the same conclusion about the position of the maximum is reached if the full Mass Law equation is used.

If we turn now to the evaluation of K_h, the Mass Law equation gives:

$$1+K_h/(H^+) = \frac{K}{x}(a-x)(b-x) \cong K\left(\frac{ab}{x} - a - b\right).$$

Calling D_0 the limiting density at high (H^+), this can be rearranged to:

$$K_h = (H^+) \cdot \left(\frac{D_0}{D} - 1\right)(1+Ka+Kb).$$

Hence to evaluate K_h we must know K. Anticipating later conclusions we can take K as 130. This is not arguing in a circle, since K, as evaluated later, is only slightly dependent on K_h. To obtain (H^+), it is necessary to note that while most of the hydrogen ions come from the added perchloric acid, a little comes from the hydrolysis of the ferric ions. The simplest way to deal with this is by successive approximation, an approximate value of K_h being used to correct (H^+). Table VIII gives the results of this calculation of K_h, based on the experimental results of Table VI. The average value of K_h is 1.55×10^{-3}. To compare this with the literature values which are reported at zero ionic strength some form of extrapolation must be used. Bray and Hershey (5) used an empirical equation, which, if applied to the present data, makes K_h^0 equal to 5.6×10^{-3}. Siddall and Vosburgh (20) used a form of the extended Debye-Hückel equation; with this, K_h^0 comes out at 6.4×10^{-3}. As these are in reasonable agreement with the literature values, our assumptions about the

TABLE VIII

EVALUATION OF K_h

$(H^+)_{uncorr.}$, M	$(H^+)_{corr.}$, M	K_h, $\times 10^{-3}$
0.0175	0.01757	1.61
0.0100	0.01012	1.58
0.0075	0.00765	1.57
0.0050	0.00521	1.77
0.0025	0.00282	1.42
0.00175	0.00214	1.43
0.0010	0.00148	1.44

ions present are presumably correct; in particular it is unlikely that any large concentration of $Fe(SCN)(OH)^+$ is present. This can be checked however by the same type of calculation that will be used later to demonstrate the existence of $Fe(SCN)Cl^+$. When (H^+) falls below 0.005 M, slight, but fairly consistent, deviations occur between the calculated and observed densities. If it is assumed that this is due to the presence of $Fe(SCN)(OH)^+$, the hydrolysis constant of $FeSCN^{++}$ can be calculated. The results do not permit any great accuracy, and the values of the constant vary by $\pm 20\%$, the average being

$$k = \frac{(FeSCNOH^+) \cdot (H^+)}{(FeSCN^{++})} = 6.5(\pm 1) \times 10^{-5}.$$

This means that $FeSCN^{++}$ would be half hydrolyzed at a pH of 4.2, as compared with Fe^{+++} which is half hydrolyzed at a pH of 2.8 at this ionic strength. As is to be expected the larger ion with the smaller charge is hydrolyzed less readily. The extinction coefficient of $Fe(SCN)(OH)^+$ can also be very roughly evaluated, the results being:

λ	4400	4500	4600	4700	4800 Å
ϵ	5400	4500	4600	4500	3900

EVALUATION OF THE DISSOCIATION CONSTANT AND EXTINCTION COEFFICIENTS OF $FeSCN^{++}$

A plot of a/D against a at constant b of the results in Table II gives curves which are very nearly straight lines. This in itself is some evidence of the correctness of this method of treatment. The values of ϵ obtained by the method of least squares from the first two series of runs in Table II are given in Table IX. The two runs agree, with an average deviation of about 1%. This difference

TABLE IX

EVALUATION OF ϵ

ϵ (series 1)	2240	3430	3980	4360	4600	4670	4530	4260	3890	3470	2530
ϵ (series 2)	2270	3450	4010	4460	4670	4730	4590	4370	3940	3480	2530
λ, mμ	400	420	430	440	450	460	470	480	490	500	520

cannot be attributed to the approximations made in deriving the Rabinowitch–Stockmayer equation; it is probably due partly to errors in measuring D, and partly to errors in the concentrations, particularly the very dilute thiocyanate.

Reference to earlier measurements of the same quantity (7, 14) shows appreciable deviation from the present results, though as this earlier work was done

at room temperature part of the difference may be due to different temperatures. Frank and Oswalt's results would agree well with ours, if all their wave lengths were shifted 100 Å to the red. Macdonald reports results that are consistently about 6% higher than ours, and the reason for this inconsistency is not obvious.

Evaluation of K from these data gives the results in Table X. As can be seen there is some range in the values of K, even ignoring the extreme points.

TABLE X

EVALUATION OF K

Wave length used, mμ	K from series 1	K from series 2
400	119	107
420	124	136
430	125	132
440	125	117
450	126	127
460	123	127
470	128	131
480	129	120
490	128	131
500	123	136

This is not due to algebraic approximations, as calculation of a second order correction only decreases K by 0.2%. However some improvement in the method of calculation can be made if ϵ is known, as it can now be taken to be from Table IX. K can be calculated directly from

$$K = \frac{D/\epsilon}{(a-D/\epsilon)(b-D/\epsilon)}.$$

Before calculating K directly, a small correction should be applied to the values of ϵ, because, in any given solution, the value of ϵ at various wave lengths must be proportional to D. The relative values of D at various wave lengths are known from a considerable number of measurements. Accordingly the values taken for ϵ have been smoothed out slightly to agree with the relative values of D; the final result is as follows:

λ	4000	4200	4300	4400	4500	4600	4700	4800	4900	5000	5200 Å
ϵ	2230	3440	3990	4380	4630	4680	4560	4310	3920	3475	2530

This is really applying another test of mutual consistency to our ϵ values, and adjusting them accordingly; the maximum adjustment is 0.7%. Using these ϵ values we can calculate K, with the results given in Table XI. In each run an average K was extracted from all the density readings; some of the readings at the highest thiocyanate concentrations have not been included in the over-all average, because it is evident that higher complexes are becoming important. The final result, corrected for hydrolysis of Fe^{+3}, is $130(\pm 1)$.

Variation of Ionic Strength

The runs reported in Table III were made in order to determine the effect of ionic strength on the dissociation constant and on the extinction coefficients. It seemed likely that the effect of varying ionic strength on the extinction coefficients might be small, but it could not be assumed to be negligible. The extinction coefficients were accordingly measured at the lowest ionic strength used, namely 0.2. In these runs the total thiocyanate ranged from about 1% to 7% of the total iron; as this seemed rather a high amount for the Rabinowitch–Stockmayer equation to hold accurately, the values of ϵ were first calculated by least squares in the usual way, and then a second least squares calculation was made in which the total iron was corrected for the amount present as $FeSCN^{++}$. Finally some of the values were slightly adjusted, as before, to bring them into agreement with the actual absorption spectrum. The results, for an ionic strength of 0.2, were:

λ	4000	4200	4300	4400	4500	4600	4700	4800	4900	5000	5200 Å
ϵ	2280	3490	4030	4415	4625	4670	4530	4250	3875	3420	2480

The results differ from those at an ionic strength of 1.2 by an amount that is little more than the experimental error, but there is a consistent shift of the absorption band to shorter wave lengths at the lower ionic strength: in fact the two bands would virtually coincide if the band at 1.2 ionic strength were shifted 20 Å to the violet.

Since these extinction coefficients were so nearly the same, they were interpolated for runs at intermediate ionic strengths. From these values and the data of Table III, K was calculated to have the values given in Table XII. As before, the values of K drifted at higher thiocyanate concentrations, presumably owing to the formation of $Fe(SCN)_2^+$.

Although it is a long extrapolation from these results to K at zero ionic strength, it is perhaps worth while seeing how well they agree with the extended Debye-Hückel equation:

$$\log K = \log K_0 + \frac{A.\Delta z^2.\sqrt{\mu}}{1+aB\sqrt{\mu}} + C\mu$$

where K_0 is the dissociation constant at zero ionic strength; Δz^2 is the change in the squares of the ionic charges in the reaction, here equal to -6; and A, B, C, and a are constants. If we give A and B their usual values for water of 0.509 and 0.330×10^8, and, following Rabinowitch and Stockmayer (19)

TABLE XII

VALUES OF K AT VARIOUS IONIC STRENGTHS

(SCN^-), M	Ionic strength 0.8	0.5	0.3	0.2
0.00025	133	145	165	189
0.00050	133	146	168	191
0.00075	134	147	169	195
0.00100	134	146	169	192
0.00125	135	149	171	196
Mean	134	146	169	192

and Betts and Dainton (4), if we take a as 4.5×10^{-8} and C as 0.30, we find that our results make K_0 equal to 1070. The degree of fit is best seen by calculating K at various ionic strengths and comparing with experiment:

Ionic strength (μ)	0.2	0.3	0.5	0.8	1.2
K (calculated)	193	165	140	133	140
K (observed)	192	169	146	134	130

While this is not a striking agreement, it is probably as good as could be expected over such a wide range of ionic strengths, and it shows general agreement with the form of the equation.

Temperature Variation

Experiment shows that the optical densities of ferric thiocyanate mixtures are markedly temperature dependent. In general it must be assumed that this is due to changes in both ϵ and K. It is simplest to determine first the dependence of the extinction coefficients on temperature, since it is unlikely that they will change by any large amount. The results given in Table IV for 5°C. and 45°C. enable a determination of ϵ for these temperatures to be made by the Rabinowitch–Stockmayer method; the values so obtained are given in Table XIII. The values at 25°C. are included for comparison. As might be expected the absorption band is slightly narrower at lower temperatures, but this effect is quite small. The chief change is that the maximum extinction coefficient decreases by about $4\frac{1}{2}\%$ in going from 5°C. to 45°C.; the maximum also shifts slightly to longer wave lengths (about 4570 Å at 5°C. to 4620 Å at 45°C.).

Using these values of ϵ it is possible to calculate K as before. Another series of runs at various intermediate temperatures was also made, the data being also given in Table IV. ϵ was interpolated from the results in Table XIII, and the average values of K for various temperatures were as follows:

Temp.	5	10	15	20	25	30	35	40	45 °C.
K	155	147	139	134	130	126	122	119	118

TABLE XIII

EXTINCTION TEMPERATURES AT VARIOUS TEMPERATURES

λ, mμ	5°C.	25°C.	45°C.
400	2460	2230	2060
420	3550	3440	3230
430	4110	3990	3760
440	4530	4380	4170
450	4710	4630	4440
460	4750	4680	4550
470	4600	4560	4470
480	4320	4310	4260
490	3870	3920	3940
500	3390	3480	3540
520	2400	2530	2670

A plot of log K against $1/T$ gives a somewhat curved line. This is straightened slightly by converting the concentrations used in obtaining K to molal quantities, which are more strictly applicable to calculations of the partial molar heat change in the reaction. In doing this it was assumed that the coefficient of expansion of water was the same as that of the solutions. It is evident that the heat change is small: an average over the range of temperatures gives 0.8 kcal./gm-mol.; and the results suggest that it changes appreciably over the temperature range, which is not inconceivable as it is such a small quantity. However the accuracy of the results did not seem to warrant a more detailed evaluation. If K is converted to K_0 by means of the extended Debye-Hückel equation, making allowance for the variation of the constants in this equation with temperature, we get:

Temp.	5	25	45 °C.
K_0	1090	1070	1100

Hence the heat change at zero ionic strength seems to be virtually zero.

Investigations on Higher Complexes

In almost every investigation dealing with $FeSCN^{++}$ deviations have been found at higher thiocyanate concentrations which have been ascribed to higher complexes (e.g. 3, 7, 18). This explanation is certainly plausible, but direct evidence for it can only be obtained if the dissociation constants of the higher complexes can be evaluated and are found to remain constant. Let us call K_2 the dissociation constant of the second complex, defined by

$$K_2 = \frac{(Fe(SCN)_2^+)}{(FeSCN^{++}) \cdot (SCN^-)}.$$

K_3 will be a similar expression for $Fe(SCN)_3$. Some previous attempts have been made to determine K_2 (with which we are chiefly concerned), but the results have admittedly been very approximate (e.g. 14). Betts and Dainton (4) arrived at a value of 20 by a trial and error method to fit their kinetic data.

We can probably assume that, just as there is a region where only $FeSCN^{++}$ is important, so at somewhat higher concentrations only $FeSCN^{++}$ and $Fe(SCN)_2^+$ are important. The second complex introduces two new constants (K_2 and the second extinction coefficient), and one additional equation (the Mass Law equation for K_2). Because of the complexity of the system, attempts

were made to measure (SCN^-) or (Fe^{+3}) directly by electrochemical means. These were not successful, so the attempts will be only very briefly described.

A silver – silver thiocyanate electrode was prepared essentially by the method of Pearce and Smith (16). Two such electrodes, prepared together, were placed in the two compartments of a cell; one compartment was filled with a sodium thiocyanate solution and the other with an identical solution except for the addition of a known concentration of ferric ions. The two compartments were separated by a sintered glass plug in a narrow tube, and side-arms allowed the cell to be kept filled with nitrogen during a run. The electrodes were moved up and down continuously during a run. The cell was immersed in a water thermostat, and its e.m.f. was measured on a Leeds and Northrup K2 potentiometer. In trial runs, using different thiocyanate concentrations in the two compartments, the cell quickly settled down to give steady readings which varied by less than 0.1 millivolt in an hour. Unfortunately when ferric perchlorate was introduced, the results were never sufficiently steady to be useful. It was calculated that only an e.m.f. steady to less than 0.1 mv. would be useful; and it was found after considerable trial that the e.m.f. did not stay constant and reproducible to this accuracy. A ferrous–ferric cell and polarographic methods were also tried, but did not prove accurate enough.

Another type of attack was made on the same problem by adding some other ion in small amount which forms a compound with either ferric or thiocyanate ions, and measuring the effect of this on the optical density. If the dissociation constant of the complex so formed is known, we have enough information to calculate all the concentrations in the solution. Chloride was tried, since the dissociation constant of $FeCl^{++}$ is known; unfortunately there are definite indications that $Fe(SCN)Cl^+$ is also formed, and this vitiates the calculation. The behavior of mixtures of this sort will be reported in a later paper. Ions which form complexes with thiocyanate were also tried. Monovalent thallium gives TlSCN, whose dissociation constant has been measured by Bell and George (2), but this gave no absorption spectrum within the range of the spectrophotometer. Cobalt (11), chromium (111), and molybdenum (111) produce complex ions, but it was found that their absorption spectrum overlaps too much with that of Fe^{+3} or $FeSCN^{++}$. Nickel (11) and manganese (11) were tried, but gave no absorption that could be attributed to a thiocyanate complex.

Finally spectrophotometric measurements were made, as for $FeSCN^{++}$, and the results interpreted in a way that, it is believed, gives a good, though slightly approximate, value for K_2 and ϵ_2, the second extinction coefficient. The data are given in Table V. The upper limit to the thiocyanate concentration is set by the fading of the sort investigated by Betts and Dainton (4); this is a different reaction from that encountered earlier, which was retarded by benzyl alcohol. At high concentrations fading is due to the reduction of ferric to ferrous ions by thiocyanate. Hydrogen peroxide prevents this (or reoxidizes the ferrous ions) up to a thiocyanate concentration of about 0.2 M.

The results show the previously observed shift of the maximum to longer

wave lengths; and the densities are greater than if only $FeSCN^{++}$ had been formed. To interpret the results, we note that there are eight quantities that we need to know: these are the four concentrations of Fe^{+3}, SCN^-, $FeSCN^{++}$, and $Fe(SCN)_2^+$, and the four constants, namely K, K_2, ϵ, and ϵ_2. K and ϵ have, of course, already been measured. We have five equations available: the Mass Law expressions for K and K_2, the two mass balances for total iron and thiocyanate, and Beer's law. We can eliminate the four concentrations from these five equations, and obtain a single equation in K, K_2, ϵ, and ϵ_2. By varying the concentrations, and hence D, we can get this equation with various known numerical coefficients; from any two such equations we can evaluate K_2 and ϵ_2. Thus it is possible in theory to disentangle the constants directly, but the algebra is so cumbersome that a method of successive approximations was used. It was assumed as a first approximation that

$$\epsilon_2 = 2.\epsilon,$$

i.e. that the absorption of an ion is proportional to the number of thiocyanate radicals attached. If this is so, then

$$[i] \qquad (SCN^-) = b - D/\epsilon$$

where b, as before, is the total thiocyanate present. The mass balance for iron can be put in the form:

$$a = (Fe^{+3}).\{1+K(SCN^-)+K.K_2(SCN^-)^2\},$$

from which we get:

$$D\{1+K(SCN^-)+K.K_2(SCN^-)^2\}/a = \epsilon K(SCN^-)+\epsilon_2 K.K_2(SCN^-)^2.$$

K_2 was adjusted in the left-hand side of this equation, with the use also of the value of (SCN^-) from equation [i] above, until the values of $\epsilon_2 K.K_2$ showed minimum deviation. The best value of K_2 was $15(\pm 1)$. The values of K_2 were effectively constant as (SCN^-) varied from 10^{-2} to 10^{-1} molar. As an example of the constancy obtained, the average deviation of the values obtained at a wave length of 4600 Å over this range was 0.2×10^6 for $\epsilon_2 K.K_2$, while the average value of $\epsilon_2 K.K_2$ was 17.3×10^6. This is an average deviation of about 1%.

This average value makes ϵ_2 equal to 8900 at 4600 Å, so $\epsilon_2 = 1.90\epsilon$. The first approximation that $\epsilon_2 = 2.\epsilon$ is altered only 5% for the next approximation. If we substitute this new value of ϵ_2, K_2 is raised by 3%. This method is equivalent to calculating (SCN^-) from K and the approximate value of K_2. As little thiocyanate is used up in forming the second complex, (SCN^-) is very little altered by any error in K_2. If we know (SCN^-), we can substitute it in the equations and find ϵ_2 and K_2 directly. Doing this gave a value of K_2 only $\frac{1}{3}$% different from the second approximation, and a value of ϵ_2 of 9130 at 4600Å. This is probably the best approximate method. The final value for K_2 was $15\frac{1}{2}(\pm 1)$.

Values of ϵ_2 at other wave lengths were obtained in a similar manner. The results were:

λ	4200	4400	4500	4600	4700	4800	4900	5000 Å
ϵ_2	6550	8030	8700	9130	9740	9980	10080	9740

It is interesting to note that the absorption maximum is shifted towards the red to 4870 Å.

At very high thiocyanate concentrations the calculated values of K_2 start to drift upwards; this is due, doubtless, to appreciable amounts of $Fe(SCN)_3$ being formed. If we include this possibility in our equations, and assume that the extinction coefficient of $Fe(SCN)_3$ is three times that of $FeSCN^{++}$ (this is analogous to our first approximation for $Fe(SCN)_2^+$), the value of K_3 comes out close to 1. K_3 is here defined as

$$K_3 = \frac{(Fe(SCN)_3)}{(Fe(SCN)_2^+) \cdot (SCN^-)}.$$

This is necessarily very rough, but it was impossible to continue measurements to higher thiocyanate concentrations.

FERRIC SULPHATE COMPLEXES, AND TERNARY COMPLEXES WITH THIOCYANATE IONS[1]

By M. W. Lister and D. E. Rivington

ABSTRACT

A spectrophotometric study of solutions containing ferric and sulphate ions, and also ferric, sulphate, and thiocyanate ions, is reported. The measurements were made at constant temperature and ionic strength; the effect of varying acidity was also investigated. The data were interpreted with the help of the results of the first paper of this series. It is believed that the data show that $FeSO_4^+$ and $FeHSO_4^{++}$ ions are formed. Values are obtained for the equilibrium constants for their formation from simple ions, and for their extinction coefficients. At higher sulphate concentrations there is evidence for the appearance of $Fe(SO_4)_2^-$ and $FeSO_4.HSO_4$, and estimates are made of their equilibrium constants. When thiocyanate is also present, the data can best be interpreted by assuming that the complex $FeSO_4.SCN$ is formed, and at higher sulphate probably also $Fe(SO_4)_2SCN^{--}$. Values are obtained for the equilibrium constants for the formation of these species, and the results would indicate that mixed complexes of this type are formed as readily as 'simple' ones such as $Fe(SO_4)_2^-$.

INTRODUCTION

One of the possible methods for investigating the complexes of ferric ions is to use thiocyanate as an indicator ion. It is generally observed that the red color of a ferric thiocyanate solution fades as another ion is added which also forms a complex with ferric ions; and by suitable colorimetric measurements it should be possible to determine the equilibrium constant of the formation of this other complex. This method has been employed in a few investigations, e.g. by Lanford and Kiehl (6) using phosphate ions; and it was also used in effect by Bent and French (1) for chloride ions in their early paper on ferric thiocyanate. In the latter case the equilibrium constant of the reaction $Fe^{+++} + Cl^- \rightleftharpoons FeCl^{++}$, as obtained with the help of thiocyanate, differs from the result obtained directly without thiocyanate. This matter has been investigated by the present authors, and will be reported in another paper. The present paper reports work on the application of this method to ferric sulphate complexes. Investigations of the sulphate complexes have been described in two papers appearing since the present work was started, though in neither case was the thiocyanate ion used as indicator. The first paper by Sykes (9) reported measurements on the effect of sulphate ions on the kinetics of the reaction between ferric and iodide ions: Sykes concluded that the equilibrium constant for $FeSO_4^+$,

$$k_1 = (FeSO_4^+)/(Fe^{+++}) \cdot (SO_4^{--}),$$

had a value of 15,000 at zero ionic strength. He did not investigate the ion $FeHSO_4^{++}$. Whiteker and Davidson (10) in the second paper decided that $FeHSO_4^{++}$ did not occur in significant amounts because of the rather small differences produced in the absorption spectra of ferric sulphate systems by alteration of the hydrogen ion concentration. On this basis they evaluated

[1]*Manuscript received June 30, 1955.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

k_1 and found it to be 105 ± 15. The evidence against $FeHSO_4^{++}$ did not appear to be quite conclusive, and it was decided to investigate this particular matter in more detail. This was done directly on solutions of ferric and sulphate ions at different acidities. The alternative method of using thiocyanate as an indicator ion was also carefully examined, and it is believed that the results show that ternary complexes containing ferric, sulphate, and thiocyanate ions must be present. It is evident that similar work with other ions must also take into account the possible formation of ternary complexes.

APPARATUS AND MATERIALS

The extent of formation of the various complex ions was determined from the optical densities of the solutions as measured on a Beckmann DU spectrophotometer. The techniques used were generally the same as those used in the first paper of this series (7). The modification of the spectrophotometer and the methods of preparing the solutions were identical. The chemicals used were also the same, with the single addition of sulphuric acid, of which a stock solution was made by diluting the reagent grade acid.

EXPERIMENTAL RESULTS

As in the first paper of the series (7), runs were carried out at 25°C., and an ionic strength of 1.2, which was controlled by the addition of sodium perchlorate. Three series of runs were made. (i) Runs were made in which the ferric ion concentration was varied but the sulphate kept constant. The ferric ion was in considerable excess, so the results could be interpreted by the method devised by Rabinowitch and Stockmayer (8), though some extension of the method was necessary owing to the greater complexity of the sulphate systems.

Various runs were made at different hydrogen ion concentrations, so that the possible formation of $FeHSO_4^{++}$ could be investigated. The results are given in Table I. (ii) A short series of runs were made at higher sulphate and lower ferric ion concentrations, with varying hydrogen ion concentrations. The results throw some light on the formation of higher complexes, and are given in Table II. (iii) A series were made with constant (and low) ferric and thiocyanate ion concentrations, and with sulphate also present in a fairly wide range of concentrations. The acidity was kept constant. This series gave a comparison of the equilibrium constants obtained with and without thiocyanate. The results are given in Table III.

DISCUSSION OF RESULTS

A discussion of the results in Table I should perhaps be prefaced by saying that the optical densities in the table are relative to solutions of identical composition except that no sulphate has been added. Qualitatively an examination of the solutions containing sulphate shows an absorption band with a maximum at 3050 Å, which is absent without sulphate. However ferric perchlorate solutions are themselves beginning to absorb at this wave length, so the measurements were made at wave lengths from 3300 to 3600 Å, where ferric perchlorate scarcely absorbs at all. Hence there is no doubt that the absorption is really due to ferric sulphate complexes.

It is apparent from Table I that a high hydrogen ion concentration reduces the optical density of ferric sulphate solutions, but that the relative densities at different wave lengths are scarcely altered. Hence the effect of hydrogen ion is either just to remove absorbing ions (presumably $FeSO_4^+$), or to introduce other ions of similar spectrum (presumably $FeHSO_4^{++}$), or both. To explain the results it is necessary to consider various possible equilibria. It seemed reasonable to suppose that, under the conditions of the first run (0.001 *M* sulphate, 0.005 to 0.03 *M* iron, and varying acidity), the following equilibria might be important:

$$Fe^{+++} + SO_4^{--} \rightleftharpoons FeSO_4^+,$$
$$Fe^{+++} + HSO_4^- \rightleftharpoons FeHSO_4^{++},$$
$$H^+ + SO_4^{--} \rightleftharpoons HSO_4^-.$$

The acidity was high enough to suppress the formation of $FeOH^{++}$ to more than a small extent. It was thought unlikely that ions containing two iron atoms would be formed (e.g. $Fe_2SO_4^{++}$), chiefly because in general it never seems necessary to postulate such ions in fairly dilute aqueous solutions; so this possibility was ignored.

The results in Table I can be treated by an extension of the Rabinowitch and Stockmayer (8) method. This method assumes that only a negligible fraction of the iron is complexed, the concentrations being such that this is a reasonably good approximation. If we represent the concentrations of the various ions by the following symbols:

$$p = (Fe^{+++}), \quad q = (SO_4^{--}), \quad r = (HSO_4^-),$$
$$x = (FeSO_4^+), \quad y = (FeHSO_4^{++}), \quad s = (H^+),$$

and a = total iron present,
b = total sulphate present,
c = total acid put in, measured in hydrogen ion concentration;

then: $x/pq = k_1$ (equilibrium constant for $FeSO_4^+$),
$y/pr = k_m$ (equilibrium constant for $FeHSO_4^{++}$),
$sq/r = k_a$ (ionization constant for HSO_4^-);

and for the mass balances:

$$a = p+x+y,$$
$$b = q+r+x+y,$$
$$c = s+r+y.$$

For the optical density, D, we have:

$$D = \epsilon_1 x + \epsilon_m y,$$

where ϵ_1 is the extinction coefficient of $FeSO_4^+$,
and ϵ_m is the extinction coefficient of $FeHSO_4^{++}$.

As a first approximation we can write $a = p$, i.e. little iron is complexed, and $c = s$, as only a little sulphate is present, so the formation of bisulphate ions

will not significantly alter the hydrogen ion concentration. The first assumption is equivalent to that made by Rabinowitch and Stockmayer. We can now rapidly eliminate p, r, s, x, and y from the above equations, when we get:

$$b = q(1+c/k_a+k_1a+k_mca/k_a),$$
$$D = aq(\epsilon_1 k_1+\epsilon_m k_m c/k_a).$$

Finally, eliminating q, and rearranging, we get:

[i] $$\frac{D}{a}\left(1+\frac{c}{k_a}\right) = k_1(b\epsilon_1-D)+k_m(b\epsilon_m-D)\frac{c}{k_a}.$$

This means that at any given wave length a plot of D/a against D should give a straight line. The slope of this line is given by:

[ii] $$\frac{\partial(D/a)}{\partial D} = -\frac{(k_1k_a+k_mc)}{k_a+c}.$$

Applying this to the data of Table I, moderately straight lines result; the straightness is best at fairly high acidity and not too high total iron. Averaging the data for all wave lengths, we get the results given below.

c	0.5	0.2	0.1	0.05
Average slope	16.5	28.5	46.3	71.0
Range of slope	14.9–18.5	26.9–30.9	42.8–49.1	63.5–79.2

By 'slope' is meant $-\partial(D/a)/\partial D$. There was a tendency for the slope to increase at higher values of a; where this was noticeable the slope was taken from the best line for the earlier points. 'Range of slope' gives the range over different wave lengths: there was no observable trend with wave length.

To evaluate k_1 and k_m, we must first know k_a. Various values of this constant have been reported (see for example Harned and Owen (5)), but the most reliable value is probably that from a critical survey of the data made by Davies, Jones, and Monk (3). They conclude that at zero ionic strength $k_a = 0.010$. This value is close to the more careful early estimates (4). The value of this constant at the ionic strength used here is open to some doubt, but fortunately the results in the present paper provide some check on the figure chosen. If we use the extended form of the Debye-Hückel equation, for instance in the form proposed by Davies (2), we get $k_a = 0.038$ at an ionic strength of 1.2. This extrapolation is too long for us to be able to conclude more than that a value near 0.04 would be plausible. Young and Blatz (11) from Raman spectra obtain values for the concentrations of sulphate and bisulphate ions in solutions of sulphuric acid. Taking solutions of the same ionic strength, their results would make k_a lie between 0.04 and 0.05 at an ionic strength of 1.2. It therefore seems probable that k_a should be taken as near 0.04.

Referring back to equation [ii], if we call the slope S, then

$$S(1+k_a/c) = k_1 k_a/c+k_m.$$

Hence a plot of $S(1+k_a/c)$ against k_a/c should give a straight line. If this plot is made, the result is reasonably straight for $k_a = 0.03$ and 0.04, but is definitely

curved for $k_a = 0.02$ or 0.05. The present results are not accurate enough to give more than a very rough value of k_a, but they are consistent with a value in the range 0.03 to 0.04. The values of k_1 and k_m that are obtained are:

k_a	0.03	0.04
k_1	178	153
k_m	6.8	5.6

We can therefore conclude that at this ionic strength, $k_1 = 165(\pm 10)$ and $k_m = 6(\pm 1)$. It seems definite that k_m is not zero, and that the species $FeHSO_4^{++}$ is present. It is also possible to calculate the ionization constant of $FeHSO_4^{++}$ considered as an acid: $FeHSO_4^{++} \rightleftharpoons FeSO_4^{+} + H^{+}$. The ionization constant equals $k_m/k_1 k_a$, which comes out close to unity. This is at least a reasonable figure, since $FeHSO_4^{++}$ would probably be a stronger acid than HSO_4^{-}.

If we take these values of k_1 and k_m, we can substitute in equation [i], and get a number of equations in ϵ_1 and ϵ_m at any wave length. From any pair of these, ϵ_1 and ϵ_m can be obtained separately with the following results:

λ	3600	3500	3450	3400	3350	3300 Å
ϵ_1	270	440	560	690	810	970
ϵ_m	160	265	340	390	470	560

It is interesting to note that ϵ_m is always about three fifths of ϵ_1. These extinctions might be expected to run parallel, but there seems to be no obvious reason for this ratio.

If we look now at the results in Table II, at relatively high sulphate, a rough calculation shows that the densities do not agree adequately with the densities calculated from the assumptions made in treating Table I. This presumably means that other species are present; the most probable one is $Fe(SO_4)_2^{-}$, and possibly $Fe(SO_4)(HSO_4)$. The rigorous treatment of a mixture of this sort is not easy, but we can make simplifying assumptions. As the mixtures in Table II all contained 0.001 M total iron, and 0.05 M total sulphate, a plausible approximation is that:

$$b = q + r,$$

i.e. the sulphate is almost all present as SO_4^{--} or HSO_4^{-}. The total acid added is also much more than the total iron, so approximately:

$$c = s + r,$$

i.e. the acid hydrogen is present either as H^{+} or as HSO_4^{-}. These approximations, and the ionization constant of HSO_4^{-} ($k_a = sq/r$), enable us to calculate s, q, and r. If we suppose that $Fe(SO_4)_2^{-}$ is the only new ion formed, and call its concentration z, its extinction coefficient ϵ_2, and its equilibrium constant k_2, where

$$k_2 = \frac{[Fe(SO_4)_2^{-}]}{[Fe^{+3}][SO_4^{--}]^2} = z/pq^2,$$

then we have from the mass balance for iron:

$$a = p + x + y + z$$

and for the optical density:

$$D = \epsilon_1 x + \epsilon_m y + \epsilon_2 z.$$

Eliminating p, x, y, and z, the result is:

$$a(\epsilon_1 k_1 q + \epsilon_m k_m r + \epsilon_2 k_2 q^2) = D(1 + k_1 q + k_m r + k_2 q^2).$$

Hence from the data in Table II, we get a series of equations in the two unknowns ϵ_2 and k_2. This equation is, in fact, of the form:

$$\epsilon_2 = \alpha/k_2 + D/a$$

where α is a function of known quantities. Values of α and D/a were calculated, and then by combining them in pairs with the result at $c = 0.1$, the following values for k_2 were obtained:

	Wave length, Å				
c	3500	3450	3400	3350	3300
0.2	3.24	2.78	2.79	3.14	3.13×10^4
0.05	1.67	1.58	1.67	1.65	1.68×10^4
0.02	1.72	1.69	1.67	1.69	1.62×10^4

The results at $c = 0.05$ and 0.02 are fairly constant and make $k_2 = 16{,}600$ as an average. The values at $c = 0.2$ give a discrepancy, although this discrepancy is not as big as it looks, since a change of only about 0.02 in the density readings would bring these points also into line. However we are faced with the choice that (i) our general picture of these mixtures is wrong, and the results in Tables I and II must be reconciled by postulating some other ionic species; or (ii) some other new species is beginning to make its appearance at $c = 0.2$ (high acidity). One is naturally loath to reject the idea that $Fe(SO_4)_2^-$ ions are responsible for the deviations in the optical densities at high sulphate concentrations, since this is the obvious explanation. Hence it seems most probable that the explanation is that at $c = 0.2$ the new species $Fe(SO_4)(HSO_4)$ is beginning to appear. A rough calculation can be made of the amount of this species present on the assumption that its extinction coefficient is equal to that of $Fe(SO_4)_2^-$ (see below), which is probably at least roughly true. The optical density at $c = 0.2$ was calculated assuming no $Fe(SO_4)(HSO_4)$. The results at different wave lengths were moderately consistent: the calculated concentrations ranged from 2.7 to 3.7×10^{-5} with a mean of 3.3×10^{-5}. This makes the equilibrium constant for the reaction

$$Fe(SO_4)(HSO_4) \rightleftharpoons Fe^{+3} + SO_4^{--} + HSO_4^-,$$

defined as

$$k_x = \frac{[FeSO_4.HSO_4]}{[Fe^{+3}][SO_4^{--}][HSO_4^-]},$$

about 380 (perhaps ± 50). Considered as an acid the ionization constant of $FeSO_4.HSO_4$ would be about 1.7, which is not far from that for $FeHSO_4^{++}$.

The extinction coefficients of $Fe(SO_4)_2^-$ are readily calculated once k_2 is known; the results are:

λ	3500	3450	3400	3350	3300 Å
ϵ_2	560	700	860	1030	1170

These extinction coefficients are parallel to ϵ_1 and are about 1.25 times as large.

Summarizing this part, it seems fair to say that the picture presented is simple and fairly consistent, and it is unlikely that an equally satisfactory alternative explanation could be found. The results show that $FeSO_4^+$ is first formed (equilibrium constant 165, or 170 to two significant figures), and it seems impossible to interpret the effect of acid unless we also suppose that $FeHSO_4^{++}$ is also formed. At higher concentrations of sulphate $Fe(SO_4)_2^-$ is formed, and perhaps $FeSO_4.HSO_4$. The extinction coefficients of the three species $FeSO_4^+$, $FeHSO_4^{++}$, and $Fe(SO_4)_2^-$ run nearly parallel.

Table III reports the densities of solutions containing ferric, sulphate, and thiocyanate ions. The first point to decide is whether such solutions could be used to obtain the equilibrium constant for $FeSO_4^+$. A rough examination of the results showed that in fact they did not give the same value for k_1, at least assuming that the only complex ions present are $FeSO_4^+$, $FeSCN^{++}$, and $FeHSO_4^{++}$. We are therefore driven to supposing that mixed complex ions are formed, such as $FeSO_4.SCN$. This situation is found to be repeated in systems containing ferric, thiocyanate, and chloride or bromide ions. Examination of the results of Table III also show the following: (i) the relative densities at different wave lengths for any given sulphate concentration stay very much the same throughout; (ii) at any one wave length the density falls off as sulphate is added, and at first the fall in density is proportional to the sulphate added; and (iii) at higher sulphate concentrations the fall in density is less rapid than at first.

We can discover the extent to which $FeSO_4.SCN$ is formed from the following considerations. Let us use the same symbols for the concentrations of various species with the following additions:

$$(SCN^-) = n, \quad (FeSCN^{++}) = m, \quad (FeSO_4SCN) = j,$$

and let us write for the equilibrium constants:

$$\frac{(FeSCN^{++})}{(Fe^{+3})(SCN^-)} = k_t, \quad \frac{(FeSO_4.SCN)}{(Fe^{+3})(SO_4^{--})(SCN^-)} = k_j.$$

As these measurements were made at wave lengths from 4400 to 4800 Å where the simple sulphate complexes scarcely absorb, the optical density is given by

$$D = \epsilon_j j + \epsilon_t m$$

where ϵ_j and ϵ_t are the extinction coefficients of $FeSCN^{++}$ and $FeSO_4.SCN$. As before, let a, b, and c represent the total concentrations of iron, sulphate, and acid hydrogen, and in addition let d be the total concentration of thiocyanate. As c is much larger than a, we shall assume as before that $c = s + r$. Also, when b is small, it seems reasonable to assume that no ions containing

two sulphates have yet been formed. Thus the following nine species may be present: Fe^{+3}, SO_4^{--}, HSO_4^-, $FeSO_4^+$, $FeHSO_4^{++}$, SCN^-, $FeSCN^{++}$, $FeSO_4.SCN$, and H^+. There are five Mass Law equations:

$$k_a = sq/r, \quad k_1 = x/pq, \quad k_m = y/pr, \quad k_t = m/pn, \quad k_j = j/pnq;$$

and four equations for the mass balances:

$$\begin{aligned} a &= p+x+y+m+j, \\ b &= q+r+x+y+j, \\ c &= s+r, \\ d &= n+m+j; \end{aligned}$$

and the equation, given above, for the optical density. Hence, in theory, the nine concentrations can be eliminated, and values of all the constants obtained by combining a sufficient number of measurements. It is not difficult to eliminate x, y, m, j, s, and r to get

$$\begin{aligned} a &= p\left[1+k_1q+\frac{k_mcq}{k_a+q}+n(k_t+k_jq)\right], \\ b &= q\left[1+\frac{c}{k_a+q}+k_1p+\frac{k_mcp}{k_a+q}+k_jpn\right], \\ n &= p\left(1+k_1q+\frac{k_mcq}{k_a+q}\right), \\ D &= pn(\epsilon_t k_t+\epsilon_j k_j q). \end{aligned}$$

These equations also use the fact that in Table III, $a = d$. When b is small, so is q, and we can at first ignore q compared with k_a. If we also call $k_1+k_m\, c/k_a=\alpha$, these equations reduce to:

$$\begin{aligned} a &= p[1+\alpha q+n(k_t+k_j\, q)], \\ b &= q(1+c/k_a+\alpha p+k_j\, pn), \\ n &= p(1+\alpha q), \\ D &= pn(\epsilon_t\, k_t+\epsilon_j\, k_j\, q). \end{aligned}$$

Let p_0, n_0, and D_0 be the values of these quantities when $b = 0$. Then since $q_0 = 0$

$$\begin{aligned} a &= p_0(1+k_t\, n_0), \\ n_0 &= p_0, \\ D_0 &= p_0\, n_0\, \epsilon_t\, k_t. \end{aligned}$$

If we differentiate the above equations with respect to b, and suppose that $b = 0$, we get equations giving the initial slopes of the quantities p, q, n, and D as sulphate is added. The resulting equations (with a little rearrangement) are:

$$\left(\frac{\partial q}{\partial b}\right)_0 = \frac{1}{1+c/k_a+\alpha p_0+k_j{p_0}^2},$$

$$\left(\frac{\partial p}{\partial b}\right)_0 = -\frac{(a\alpha+k_j{p_0}^2)}{(1+2k_t p_0)}\left(\frac{\partial q}{\partial b}\right)_0,$$

$$\frac{1}{D_0}\left(\frac{\partial D}{\partial b}\right)_0 = \frac{2}{p_0}\left(\frac{\partial p}{\partial b}\right)_0+\left(\alpha+\frac{\epsilon_j k_j}{\epsilon_t k_t}\right)\left(\frac{\partial q}{\partial b}\right)_0.$$

As $(\partial D/\partial b)_0$ is known from the data, and as $(\partial q/\partial b)_0$ and $(\partial p/\partial b)_0$ could be eliminated, we have in effect at each wave length an equation containing the unknowns ϵ_j and k_j. Since the shape of the absorption curve is virtually unaltered by adding sulphate, ϵ_j is presumably proportional to ϵ_i; and from the nature of the species concerned it seems reasonable to take $\epsilon_j = \epsilon_i$ as a first approximation. This last approximation can be checked to some extent from the results as more sulphate is added; but the effect of other ions, notably $Fe(SO_4)_2^-$, makes the whole system so complicated that this confirmation is not at all strong.

The observed values of $(1/D_0)(\partial D/\partial b)_0$, taken over the range $b = 0$ to 0.01, are:

λ	4400	4500	4600	4700	4800 Å
$(1/D_0)(\partial D/\partial b)_0$	−14.0	−14.1	−14.2	−14.3	−14.9

Probably the best average is −14.2. Substituting this in the equations above the value of k_j comes out at 11,500. The magnitude of this constant is not unexpected; since, combining it with other known constants, it means that the reaction

$$FeSO_4^+ + SCN^- \rightleftharpoons FeSO_4.SCN$$

has an equilibrium constant of 70; and the reaction

$$FeSCN^{++} + SO_4^{--} \rightleftharpoons FeSO_4.SCN$$

has an equilibrium constant of about 90. No very great accuracy can be claimed for k_j, but it probably lies between 10,000 and 13,000.

As the sulphate is increased, the optical density falls off linearly at first and then less rapidly. If we calculate the concentrations of the various species, assuming that no new ions are formed and that $\epsilon_i = \epsilon_j$, the results make a plot of D against b deviate only quite slowly from a straight line (the fact that a straight line is maintained for a moderate distance is some evidence that our assumptions about the solutions containing sulphate up to about 0.01 M were right). The deviation from this straight line must mean that some new colored ion is appearing that is competing successfully against the ions $Fe(SO_4)_2^-$ and $FeSO_4.HSO_4$ which will now be present. This was checked in another way. At higher sulphate concentrations (>0.02) the fraction of sulphate used up in complexes will be so small that we can write approximately:

$$b = q + r.$$

As $c = s + r$, and $k_a = sq/r$, this enables us to find q, r, and s. Allowing now for the presence of $Fe(SO_4)_2^-$ and $FeSO_4HSO_4$, it is possible to calculate D in terms of q and known constants. The observed densities were greater than the calculated ones. As mentioned above, the calculated curve only departs very slowly from a straight line. The only plausible new colored (at 4600 Å) ion is $Fe(SO_4)_2.SCN^{--}$, and a rough estimate of the extent to which it might be present was made in the following way.

If we assume that the species $Fe(SO_4)_2^-$ and $FeSO_4.HSO_4$ may now also be present, but not $Fe(SO_4)_2.SCN^{--}$, the equations for the various concentrations can be reduced to the following:

$$a = p[f(q)+n(k_t+k_j q)],$$
$$n = p.f(q),$$
$$D = pn(\epsilon_t k_t+\epsilon_j k_j q),$$

where

$$f(q) = 1+\left(k_1+\frac{k_m c}{k_a+q}\right) q+k_2\left(1+\frac{k_a c}{k_i(k_a+q)}\right) q^2.$$

k_t is the ionization constant of $FeSO_4.HSO_4$ as an acid. If we assume as above that $\epsilon_t = \epsilon_j$, and call $D/\epsilon_t = X$, we get

$$(a-X)^2 = Xf(q)/(k_t+k_j q).$$

As q is known, X can be calculated. The results of this calculation can be compared with experiment as in Table IV. There is evidently a very slight

TABLE IV

VALUES OF 10^5 X

	Wave length							
b	440	450	460	470	480	Mean X_{obs}	X_{calc}	Difference
0.025	7.42	7.32	7.31	7.26	7.22	7.31	7.03	0.28
0.03	7.05	6.98	6.94	6.93	6.84	6.95	6.49	0.46
0.035	6.74	6.63	6.60	6.56	6.50	6.61	6.00	0.61
0.04	6.39	6.31	6.28	6.16	6.15	6.26	5.56	0.70
0.05	5.82	5.72	5.68	5.61	5.55	5.68	4.80	0.88

shift of the absorption spectrum to the violet, the maximum being shifted about 30 Å. However as points on both sides of the maximum have been used, it is probably legitimate to compare a mean value of X as observed with the calculated X. The difference is given in the last column, and this may tentatively be taken as the concentration of $Fe(SO_4)_2.SCN^{--}$. This involves the assumptions (i) that the extinction coefficient of $Fe(SO_4)_2.SCN^{--}$ is the same as that of $FeSCN^{++}$ at these wave lengths, and (ii) that the amount of $Fe(SO_4)_2.SCN^{--}$ present is not enough to throw out the calculations of the concentrations of the other ions present by any great amount. The first assumption is fairly reasonable from the formulae of the ions, but its only other justification is that it gives a plausible and moderately constant value of the equilibrium constant of this ion. The second assumption is at least nearly true, since even at $b = 0.05$ the concentration of ferric ions is about 24 times, and that of thiocyanate ions is 110 times as great as that of $Fe(SO_4)_2.SCN^{--}$. The relevant concentrations are given in Table V. The last column gives the

TABLE V

b	$(Fe(SO_4)_2SCN^{--})$, M	(Fe^{+3}), M	(SO_4^{--}), M	(SCN^-), M	k_w
0.025	0.28×10^{-5}	4.19×10^{-4}	4.37×10^{-3}	9.30×10^{-4}	3.76×10^5
0.03	0.46	3.63	5.34	9.35	4.75
0.035	0.61	3.15	6.35	9.40	5.12
0.04	0.70	2.74	7.40	9.44	4.95
0.05	0.88	2.09	9.61	9.52	4.79

equilibrium constant:

$$k_w = \frac{(Fe(SO_4)_2.SCN^{--})}{(Fe^{+3})(SO_4^{--})^2(SCN^-)}.$$

The values obtained for it are fairly consistent, and the last four values average 490,000. This means that the equilibrium constant for the attachment of a second sulphate to $FeSO_4.SCN$ is 43, and for the attachment of a thiocyanate ion to $Fe(SO_4)_2^-$ is 29. These values are reasonably similar to the corresponding values for attachment of sulphate and thiocyanate ions to other complex ferric ions; however the constants obtained will be reviewed after results with chloride and bromide have been reported. In conclusion it may be said that while no great accuracy can be claimed for these constants, it seems very improbable that any other selection of complex ions would have explained the results, and that part of the support for the present picture indeed comes from the relative sizes of these constants.

SOME FERRIC HALIDE COMPLEXES, AND TERNARY COMPLEXES WITH THIOCYANATE IONS[1]

By M. W. Lister and D. E. Rivington

ABSTRACT

A spectrophotometric study of solutions containing ferric and bromide ions; ferric, bromide, and thiocyanate ions; and ferric, chloride, and thiocyanate ions is reported. The measurements were made at constant temperature and ionic strength. The data were interpreted with the help of the results from the first paper of this series. The data show that $FeBr^{++}$ and $FeBr_2^+$ are formed, and values are obtained for the equilibrium constants for their formation from simple ions, and for the extinction coefficients of $FeBr^{++}$. When thiocyanate is also present, the data can best be interpreted by assuming that $FeSCNBr^+$ or $FeSCNCl^+$ is formed. At high chloride concentrations it seems necessary to postulate also $FeCl_2^+$ and $FeSCN.Cl_2$. Estimates are made for the equilibrium constants for the formation of all these species from simple ions. As with the corresponding sulphate complexes, there seems to be no particular reluctance to form mixed complexes such as $FeSCNCl^+$, as compared with the 'simple' complexes such as $FeCl_2^+$.

In the second paper of this series (3*b*), results were reported which showed that the color of ferric thiocyanate could only be used as a means of investigating complexes of ferric and sulphate ions, if allowance were made for the presence of species containing ferric, sulphate, and thiocyanate, such as $FeSO_4.SCN$. The present work deals with a similar investigation of solutions containing chloride or bromide ions, instead of sulphate. The intention was to make a critical examination of this method of investigating ferric complexes, and in particular to discover to what extent ternary complexes, such as $FeSCN.Cl^+$ or $FeSCN.Br^+$, were important. Rabinowitch and Stockmayer have already investigated solutions containing ferric and chloride or bromide ions, but not thiocyanate as well (6). They suggested that the discrepancy between their result for the equilibrium constant for the formation of $FeCl^{++}$, and the earlier results of Bent and French (1), who examined solutions made from ferric chloride and potassium thiocyanate, was due to the ion $FeSCN.Cl^+$. The present work attempts a more quantitative estimate of the formation of this ion, and of the analogous $FeSCN.Br^+$. It is believed that the results demonstrate the existence of these ions, and values for the equilibrium constants of their formation from simple ions have been obtained.

APPARATUS AND MATERIALS

All optical measurements were made with a Beckmann Model DU spectrophotometer, modified so that the temperature of the solutions could be controlled, as described in the first paper of this series (3*a*).

The reagents used were the same as described in this same paper, with the following additions.

Hydrochloric acid.—The concentrated reagent grade acid was diluted to give a stock solution of about 1 *M* concentration. This was standardized volumetrically against borax.

Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

Sodium chloride.—The reagent grade chemical was dissolved to give a stock solution of about 5 *M* concentration. This was standardized volumetrically against silver nitrate.

Sodium bromide.—A pure grade of sodium bromide was dissolved to give a 5 *M* stock solution, which was standardized by titration against silver nitrate.

The general technique used in making up and storing solutions, in preventing fading of the ferric thiocyanate color, and in measuring the optical densities was exactly the same as described in the first paper (3*a*). The mixtures in the present work contained ferric perchlorate, perchloric acid (to suppress hydrolysis), sodium perchlorate (to adjust the ionic strength), sodium thiocyanate, and sodium chloride or bromide.

EXPERIMENTAL RESULTS

It was first necessary to check that the ions $FeCl^{++}$ or $FeBr^{++}$ did not absorb light appreciably in the region of measurement which was 4400 to 4800 Å. Solutions containing 0.001 *M* ferric ions in 0.2 *M* perchloric acid and a large excess of sodium chloride (about 0.6 *M*) show a strong absorption band with a maximum at 3270 Å; however the absorption falls rapidly at longer wave lengths, and is negligible at 4400 Å. Similar measurements with bromide substituted for chloride show only a very slight absorption in the ultraviolet besides that due to ferric ions, but there is a long 'tail' extending into the visible with a very weak subsidiary maximum at about 4100 Å. Accordingly solutions containing ferric, bromide, and thiocyanate ions were measured against a 'reagent blank' which contained the same concentrations of the various ions except for thiocyanate. Some measurements were also made on ferric bromide solutions (without thiocyanate) in which case the reagent blank was simply a ferric perchlorate solution. These measurements with ferric, bromide, and thiocyanate solutions against this reagent blank require a slight correction which will be described later.

Effect of chloride ion.—In order to investigate the effect of chloride ion on the ferric thiocyanate equilibrium, a series of solutions having 0.001 *M* total iron, 0.00125 *M* total thiocyanate, 0.200 *M* hydrogen ions, an ionic strength of 1.2, and total chloride varying from zero to 1.2 *M* were prepared. The optical densities of these solutions at 25°C. were measured from 4400 to 4800 Å. The results are given in Table I.

Effect of bromide ion.—As the $FeBr^{++}$ complex has only been examined once before (6), it was thought worth while to check the value of its equilibrium constant. Accordingly measurements were made on solutions containing ferric perchlorate, perchloric acid, sodium perchlorate, and sodium bromide only, without thiocyanate. The results are given in Table II. The value of the dissociation constant of $FeBr^{++}$, and its extinction coefficients, will be deduced in the next section.

Solutions containing ferric, thiocyanate, and bromide ions were also examined. The results are given in Table III; as was mentioned above, these results are against a reagent blank of the same composition as the test solutions except that the thiocyanate is omitted.

DISCUSSION OF RESULTS

1. Solutions Containing Bromide

The results in Table II will be considered first as these are most simply dealt with. The method of Rabinowitch and Stockmayer (6) can be used to interpret these results. If we use the following symbols:

a = total ferric concentration,
b = total bromide concentration,
D = optical density,
ϵ = extinction coefficient of $FeBr^{++}$,
k = equilibrium constant of $FeBr^{++}$ = $(FeBr^{++})/(Fe^{+3})(Br^{-})$;

then Rabinowitch and Stockmayer show that

$$b/D = b/a\epsilon + 1/ka\epsilon$$

holds to a good approximation. In Table II, a is kept constant and b is varied; hence a plot of b/D against b should give a straight line from which k and ϵ can be evaluated. The results of Table II, when plotted in this way, do give reasonably straight lines; and by drawing lines by the method of least squares through the experimental points, we obtain the values of k and ϵ given in Table IV. The best average value of k is probably 0.61, as the result at 4500 Å

TABLE IV

VALUES OF k AND ϵ FOR $FeBr^{++}$

λ, mμ	ϵ	k
380	435	0.601
400	491	0.606
420	457	0.594
440	328	0.630
450	295	0.562
460	225	0.607

is somewhat divergent. This can be compared with the value of 0.5 obtained by Rabinowitch and Stockmayer. The values for the extinction coefficients make the absorption maximum close to 4050 Å, and the maximum extinction coefficient is about 495. This is lower than the value obtained by Rabinowitch and Stockmayer, but the reason for the discrepancy is not clear.

The equation given above assumes that $FeBr^{++}$ is the only complex formed. At high concentrations there is a slight but consistent deviation from the optical densities calculated on the above assumptions. This is presumably due to $FeBr_2^{+}$ being formed. If we call the equilibrium constant of this ion k_2, where $k_2 = (FeBr_2^{+})/(Fe^{+3})(Br^{-})^2$, and ϵ_2 is its extinction coefficient, and if we assume that at these high concentrations the concentration of free bromide is virtually equal to the total bromide, then

$$a(\epsilon\, k + \epsilon_2\, k_2\, b) = D(1/b + k + k_2 b).$$

This equation contains two unknowns, and so these can be evaluated from any two measurements at one wave length. Unfortunately a very small error

in the density can lead to a considerable error in the value of k_2. If we take the points at $b = 1.0$ and 0.7 as the two measurements to calculate k_2, we get the following values of k_2 from the measurements at various wave lengths:

λ	3800	4000	4200	4400	4500	4600 Å
k_2	0.17	0.18	0.24	0.43	0.07	0.19

An error of 0.001 in the density could give an error of 0.1 in k_2; so the most that can be said is that k_2 is probably close to 0.2. The values of ϵ_2 are not reliable enough to be worth reporting: they seemed to run parallel to ϵ, but to be unduly low.

Turning now to the results when both bromide and thiocyanate are present, we shall attempt to explain them on the assumption that the complex ions $FeBr^{++}$, $FeSCN^{++}$, and $FeSCN.Br^{+}$ are present, and at higher concentrations $FeBr_2^{+}$ also. A rough calculation showed that the observed densities did not agree with those calculated if only $FeBr^{++}$ and $FeSCN^{++}$ are formed, so that some other ion must be formed; we shall be justified in assuming that this is $FeSCN.Br^{+}$ if the results give a reasonably constant value for its equilibrium constant. It will readily be appreciated that this system leads to rather complicated expressions for the constants, so that some approximations have to be made. If the concentrations of the various species are indicated by the following letters: $(Fe^{+3}) = p$, $(SCN^{-}) = q$, $(FeSCN^{++}) = x$, $(Br^{-}) = r$, $(FeBr^{++}) = u$, $(FeSCN.Br^{+}) = z$, there are three equations for the equilibrium constants of the complex ions:

$$FeBr^{++} : k_a = u/pr,$$
$$FeSCN^{++} : k_1 = x/pq,$$
$$FeSCN.Br^{+} : k_m = z/pqr.$$

The total iron (a), total bromide (c), and total thiocyanate (b) in the solution lead to equations for the mass balances:

$$a = p+x+u+z,$$
$$b = q+x+z,$$
$$c = r+u+z.$$

Finally the observed density is given by

$$D' = \epsilon_1 x+\epsilon_m z+\text{correction},$$

where ϵ_1 and ϵ_m are the extinction coefficients of $FeSCN^{++}$ and $FeSCN.Br^{+}$. The correction is small owing to the fact that there is a slightly different amount of $FeBr^{++}$ in the reagent blank and in the test solution, as some of the ferric ions are used up forming $FeSCN^{++}$ in the test solution. This correction was evaluated from a rough value of k_m (and of course the other constants) in a way that will be described in a moment. There are thus seven equations and six concentrations, so that in theory the two unknown constants, ϵ_m and k_m, can be found from any two measurements.

The results in Table III are for solutions in which $a = b$, and the total bromide (c) is much larger than a or b. Therefore it seemed reasonable to put

$r = c$, as a good approximation. If D is the corrected optical density, given by

$$D = \epsilon_1 x + \epsilon_m z,$$

we can eliminate p, r, u, x, and z from the above equations to get:

[i] $$\frac{q^2(k_1+k_m c)}{1+k_a c} + q - a = 0,$$

[ii] $$q = \frac{D(1+k_a c)}{a(\epsilon_1 k_1 + \epsilon_m k_m c) - D(k_1 + k_m c)}.$$

These make use of the fact that, in these solutions, $a = b$.

Before dealing with these equations further, we must explain how D' was corrected to give D. The correction is evidently $\epsilon_a(u_0 - u)$, where ϵ_a is the extinction coefficient of $FeBr^{++}$ obtained above, and u_0 is the concentration of this ion when no thiocyanate is present. Putting $b = 0$, u_0 is readily obtained as

$$u_0 = k_a ca/(1+k_a c).$$

When thiocyanate is present, as $a = b$:

$$u = k_a cq/(1+k_a c);$$

and equation [i] can be converted into a quadratic in u:

$$u^2(k_1 + k_m c) + u.k_a c - [a(k_a c)^2/(1-k_a c)] = 0.$$

Very rough calculation showed that k_m was not far from 25, and this value was used to obtain u and hence $u_0 - u$. The values of $u_0 - u$ so obtained were

c	0.1	0.2	0.4	0.6	0.8	1.0
$u_0 - u$	0.62	1.05	1.82	2.40	2.73	3.03×10^{-5}

Hence as ϵ_a is known the correction can be calculated; it is always less than 0.015, usually much less, and not particularly sensitive to changes in k_m: hence the rough value of k_m was quite adequate here.

Before we turn to the main method used to determine k_m, a word should be said about applying the initial slope method, used for the mixed sulphate–thiocyanate complexes in the second paper of this series. This method assumed that the mixed complex (in that case $FeSO_4.SCN$) absorbed light to nearly the same extent as $FeSCN^{++}$, at least in the region of the main absorption band of the latter. However $FeBr^{++}$ also absorbs somewhat in the region where $FeSCN^{++}$ absorbs, (while $FeSO_4^+$ absorbs there scarcely at all), so it cannot be assumed that $FeSCN^{++}$ and $FeSCNBr^+$ have nearly the same extinction coefficient. Actually if this assumption is made, the equilibrium constant for $FeSCNBr^+$ comes out as 30, while (to anticipate) the most reliable value is probably 21. Accordingly a more laborious, but probably more accurate, method was used to evaluate k_m.

Equations [i] and [ii] above are the starting point of the method. q could be eliminated readily enough, but the resulting equation in ϵ_m and k_m is very cumbersome. A method of successive approximations was therefore used, as follows. First let us assume that $\epsilon_1 = \epsilon_m$; in spite of the considerations given

in the last paragraph, this is unlikely to be totally wrong, in view of the formulae of the ions concerned, and at the next approximation we can discard this assumption. If $\epsilon_1 = \epsilon_m$, equations [i] and [ii] can be readily combined, and reduced to

$$k_1+k_mc = \frac{(1+k_ac)D/\epsilon_1}{(a-D/\epsilon_1)^2}.$$

Hence a rough value of k_m can be obtained from each density reading, and with this value of k_m, q can be calculated from equation [i]; then everything in equation [ii] is known except ϵ_m, which can thus be evaluated to a first approximation. With these values of ϵ_m and k_m, improved values of q can be obtained from equation [ii], and then used in equation [i] to obtain improved values of k_m. In theory these approximations could be repeated; in effect we are adjusting k_m and ϵ_m until the two equations give the same values of q for each value of c, the total bromide concentration. However the first approximation $\epsilon_1 = \epsilon_m$ is actually a fairly good approximation so the process did not need to be carried very far.

Table V gives the results of the first approximation for k_m. Ignoring the rather deviant values at 4000 Å, k_m averages as 21.2. The first approximation for ϵ_m gives the values in Table VI. These values are not very constant, but it is easily seen that a relatively small change in D will give a considerable change in ϵ_m. The absorption band of $FeSCNBr^+$ is evidently similar to that of $FeSCN^{++}$ shifted somewhat to the red. If we use these mean values of ϵ_m from Table VI, we get as our next approximation for k_m the results in Table VII. The results in Table VII are more consistent but the average is little changed.

TABLE VII

VALUES OF k_m; SECOND APPROXIMATION

	Wave length, mμ					
c	400	420	440	450	460	470
0.1	(46.9)	29.4	24.9	26.1	23.1	26.7
0.2	21.3	17.2	22.8	22.7	24.9	25.1
0.3	19.5	22.3	21.7	18.7	19.9	19.2
0.4	24.3	19.7	20.7	21.5	21.9	22.2
0.5	23.2	19.1	19.1	20.2	18.3	20.1
0.6	19.3	19.8	18.0	18.0	19.2	19.2
0.7	19.7	—	16.4	17.9	16.8	17.6
Mean	21.2	21.2	20.5	20.75	20.6	21.45

The best value for k_m is 21, probably 21±2. The constancy of the values in Table VII seems to be sufficient to justify the initial assumption that the ion $FeSCNBr^+$ is indeed present. It is scarcely worth correcting the ϵ_m values further; however it was found that if k_m is reduced to 21.0, ϵ_m is raised by about ¾%. Therefore the best values of ϵ_m, rounded off to the nearest 50, are:

λ	4000	4200	4400	4500	4600	4700 Å
ϵ_m	1550	3200	4300	4650	5000	5150

At high bromide concentrations some deviation occurs, probably owing to the appearance of $FeBr_2^+$. An estimate of its effect can be made as follows. With the constants already known the densities at high bromide concentrations can be calculated; no systematic deviations from experiment were found until $[Br^-]$ is 0.7, but after this the observed densities were consistently higher. If we attribute this to $FeBr_2^+$, which removes some of the iron from possible equilibrium with $FeSCN^{++}$, the concentration of $FeBr_2^+$ can be calculated, and hence its equilibrium constant, k_2, which was defined earlier. The mean value of k_2 at various wave lengths was:

k_2	0.29	0.18	0.19	0.20	0.17
λ	4200	4400	4500	4600	4700 Å

This makes the mean value of k_2 about 0.2. This is a very rough calculation; but as the result agrees with the same constant obtained from solutions without thiocyanate, it seems plausible that this really is the cause of the deviation.

2. Solutions Containing Chloride

The first constant for the association of ferric ions with chloride ions has been measured before, e.g. Rabinowitch and Stockmayer (6), Bray and Hershey (2), Moeller (4), Olerup (5). These authors all used solutions which did not contain thiocyanate, and hence interference by ions such as $FeSCNCl^+$ could not occur. The best value for this constant, $K_1 = (FeCl^{++})/(Fe^{+3}) \cdot (Cl^-)$, under the conditions of the present experiments is probably 4.1. Both Rabinowitch and Stockmayer, and Moeller get results very close to this. Bent and French (1), using mixtures containing ferric, chloride, and thiocyanate ions, arrived at a value of 1.3; this difference is presumably due to $FeSCNCl^+$ ions. Our own results in Table I do not agree with the calculated densities, assuming that K_1 is 4.1 and no $FeSCNCl^+$ is present; hence we shall assume that $FeSCNCl^+$ really is present and attempt to evaluate its equilibrium constant.

Examination of Table I shows that as the chloride concentration is increased the densities at all wave lengths are reduced by the same fractional amount, at least to within the experimental error. Hence $FeSCNCl^+$ must have very nearly the same absorption spectrum as $FeSCN^{++}$; all the extinction coefficients of $FeSCNCl^+$ could be larger than those of $FeSCN^{++}$, but they would all have to be larger in the same ratio. It can also be seen that at any one wave length the densities fall off at first by an amount proportional to the chloride added. When the total chloride exceeds about 0.1 M, the fall slowly becomes less steep. The interpretation of the results was attempted by two methods: (i) as for the bromide solutions above, and (ii) as for the sulphate solutions, described in the second paper of this series. As a result of applying the first method, the values for ϵ_M, the extinction coefficient of $FeSCNCl^+$, which were obtained were all within 1% of those for $FeSCN^{++}$, which is within the experimental error. This is not surprising since $FeCl^{++}$ scarcely absorbs at all in this region. Since this is so, we can apply the second method, that is, the initial slope of the plot of D against total chloride as a means of determining k_M. Here k_M, the equilibrium constant for $FeSCNCl^+$, is defined as

$$k_M = (FeSCNCl^+)/(Fe^{+3}) \cdot (SCN^-) \cdot (Cl^-).$$

The evaluation of k_M is very similar to the method used for sulphate; but as here the concentrations of iron and thiocyanate are not equal, and as there is no complication from ions such as $FeHSO_4^{++}$, it is perhaps worth outlining the calculation. If we write for the concentrations:

$$(Fe^{+3}) = p, \quad (SCN^-) = q, \quad (FeSCN^{++}) = x,$$
$$(Cl^-) = r, \quad (FeCl^{++}) = u, \quad (FeSCNCl^+) = z,$$

we have from the Mass Law:

$$k_1 = x/pq, \quad K_1 = u/pr, \quad k_M = z/pqr,$$

where k_1, K_1, and k_M are the equilibrium constants for $FeSCN^{++}$, $FeCl^{++}$, and $FeSCNCl^+$ respectively. If a, b, and c are respectively the total concentrations of iron, thiocyanate, and chloride present, mass balances give:

$$a = p+x+u+z,$$
$$b = q+x+z,$$
$$c = r+u+z.$$

If ϵ_1 and ϵ_M are the extinction coefficients of $FeSCN^{++}$ and $FeSCNCl^+$, then

$$D = \epsilon_1 x + \epsilon_M z.$$

We shall assume for the reasons given above that $\epsilon_1 = \epsilon_M$. Eliminating x, u, and z:

$$a = p(1+k_1 q+K_1 r+k_M qr),$$
$$b = q(1+k_1 p+k_M pr),$$
$$c = r(1+K_1 p+k_M pq),$$
$$D = pq\ \epsilon_1(k_1+k_M r).$$

Differentiating these with respect to c, and (as we are interested in the initial slope) putting $c = r = 0$ in the result, we get

$$0 = \frac{\partial p}{\partial c}(1+k_1 q)+p\left(k_1\frac{\partial q}{\partial c}+K_1\frac{\partial r}{\partial c}+k_M q\frac{\partial r}{\partial c}\right),$$

$$0 = \frac{\partial q}{\partial c}(1+k_1 p)+q\left(k_1\frac{\partial p}{\partial c}+k_M p\frac{\partial r}{\partial c}\right),$$

$$1 = \frac{\partial r}{\partial c}(1+K_1 p+k_M pq),$$

$$\frac{\partial D}{\partial c} = \epsilon_1 k_1\left(p\frac{\partial q}{\partial c}+q\frac{\partial p}{\partial c}\right)+pq\epsilon_1 k_M\frac{\partial r}{\partial c}.$$

The initial concentrations, p_0 and q_0, are easily found as

$$a = p_0(1+k_1 q_0),$$
$$b = q_0(1+k_1 p_0).$$

D_0, the initial density, equals $\epsilon_1 k_1 p_0 q_0$. The equation in the initial slope of D reduces to

$$\frac{1}{D_0}\frac{\partial D}{\partial c} = \frac{1}{p_0}\frac{\partial p}{\partial c}+\frac{1}{q_0}\frac{\partial q}{\partial c}+\frac{k_M}{k_1}\frac{\partial r}{\partial c}.$$

Substituting for $\partial p/\partial c$, $\partial q/\partial c$, and $\partial r/\partial c$ from the equations above and simplifying, the result is finally:

$$\frac{1}{D_0}\frac{\partial D}{\partial c} = \frac{k_M/k_1-K_1}{(1+K_1 p_0+k_M p_0 q_0)(1+k_1 p_0+k_1 q_0)}.$$

The values of $(1/D_0)\,\partial D/\partial c$ at various wave lengths are

λ	4400	4500	4600	4700	4800 Å
$-(1/D_0)\partial D/\partial c$	1.62	1.59	1.62	1.62	1.67

The mean value is -1.62. With this and the values of a and b (and hence p_0 and q_0) from Table I, we get $k_M = 260$, to two significant figures. An error of about 1% in the slope would lead to about 1% error in k_M.

As the density falls off more gradually at high chloride concentrations it is evident that some other colored species must then have appeared. We can feel sure that $FeCl_2^+$ must be formed to some extent, and the new colored species is presumably $FeSCN.Cl_2$. As the position and shape of the absorption maximum does not change at high chloride concentration, it is reasonable to assume to a first approximation that the extinction coefficients of $FeSCNCl_2$ are roughly the same as those of $FeSCN^{++}$. With this assumption it is possible to evaluate the equilibrium constants of $FeCl_2^+$ and $FeSCNCl_2$. Let these constants be

$$k_2 = (FeCl_2^+)/(Fe^{+3})\,.\,(Cl^-)^2,$$
$$k_n = (FeSCNCl_2)/(Fe^{+3})\,.\,(SCN^-)\,.\,(Cl^-)^2.$$

When the chloride concentration is high, it must be nearly true that $c = r$. The equations given above for the Mass Law, etc., can then be reduced to:

$$X(1+K_1 c+k_2 c^2) = (a-X)(b-X)(k_1+k_M c+k_n c^2)$$

where $X = D/\epsilon_1$. The results of Table I give virtually the same values of X at all wave lengths for a given value of c. The average values of X are as follows (using the values of ϵ_1 given in the first paper in this series):

X	1.015	0.956	0.902	0.846	0.804	0.766	0.735	0.705	0.649	0.610	0.574	0.515	0.470×10^{-4}
c	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50	0.60	0.70	0.80	1.0	1.2

The equation above in X contains two unknowns, k_2 and k_n. It could be written in the form:

$$Ak_2 = B + k_n$$

where

$$A = X/(a-X)(b-X),$$

$$B = (1/c^2)\{k_1 + k_M c - A(1+K_1 c)\}.$$

The values of A and B obtained from the data are:

c	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50	0.60	0.70	0.80	1.0	1.2
A	98.4	91.6	85.5	79.3	74.8	70.7	67.4	64.3	58.6	54.6	51.1	45.3	41.0
B	484	409	370	363	333	309	284	265	240	212	193	164	143

A plot of A against B gives a reasonably straight line from $c = 0.3$ to 0.8. At lower c values the points are rather erratic, and the last two points drift away a little from the line. The fact that the plot is linear over a considerable length is some evidence that this is the correct explanation. The line makes $k_2 = 6.1$ and $k_n = 120$.

Finally it seems worth while to summarize all the constants evaluated for the complex ions considered in this work. The constants are the equilibrium constants for the formation of the complex ions from simple ions, written with the concentration of the complex ion on top. They are at the same ionic strength.

$FeSCN^{++}$	130;	$FeCl^{++}$	4.1;	$FeBr^{++}$	0.61;	$FeSO_4^+$	170;			
$Fe(SCN)_2^+$	1950;	$FeCl_2^+$	6.1;	$FeBr_2^+$	0.2;	$Fe(SO_4)_2^-$	17000;			
$FeSCNCl^+$	265;	$FeSCNBr^+$	21;	$FeSCN.SO_4$	12000;	$FeHSO_4^{++}$	6;			
$FeSCNCl_2$	120;			$FeSCN(SO_4)_2^{--}$	490000;	$FeHSO_4.SO_4$	380			

By dividing these constants, the constants for the attachment of further simple ions to the various complex ions can be obtained. As is to be expected, further ions are held less firmly than the first one attached; and generally speaking the numbers so obtained seem fairly consistent, or, at least, provide no obvious contradictions. The chief point to note is that the mixed ions, such as $FeSCNCl^+$, are formed as readily (or very nearly so) as those derived from only two simple ions, such as $FeBr_2^+$. This is perhaps slightly unexpected, but it is difficult to think of any reason why this should not be so.

THEORY OF THE TRANSIENT PHASE IN KINETICS, WITH SPECIAL REFERENCE TO ENZYME SYSTEMS[1]

By Keith J. Laidler[2]

ABSTRACT

The steady-state hypothesis is discussed for enzyme systems, and the conditions under which the steady-state equations will be valid over the main course of the reaction are obtained. It is shown that this is so if the substrate is in great excess, and also under several other circumstances. Equations are derived for the kinetic behavior during the transient phase of the reaction. Two-substrate systems, and the special case of catalase, are considered.

In the theoretical formulation of the rates of complex reactions in terms of the concentrations of reactants and other substances (e.g. inhibitors) it is customary to make use of the steady-state hypothesis. This hypothesis, according to which the rates of change of the concentrations of reaction intermediates can be neglected, is easily justified for systems in which the intermediates are present in much lower concentrations than the reactants. In enzyme systems, however, this condition is not necessarily satisfied, since in many instances the concentration of intermediate—the enzyme–substrate complex—is close to the total concentration of the enzyme.

The object of this paper is to examine the steady-state hypothesis as applied to simple enzyme systems, and to see under what conditions it may be expected to be valid. Consideration is also devoted to the question of the kinetics during the transient phase of the reaction—the period during which the steady-state concentration is being established. A single-substrate system is treated first, after which a two-substrate system is briefly considered.

Some of the kinetic equations obtained in this paper have previously been derived, particularly by Chance (3, 4, 5) and by Beers (1, 2), but the methods here employed are more general and permit application to a wider variety of cases.

THE SINGLE-SUBSTRATE SYSTEM

The single-substrate system, uncomplicated by the effects of activators and inhibitors, may be represented by the Michaelis-Menten scheme:

$$\underset{e_0-y}{\mathrm{E}} + \underset{s_0-y-p}{\mathrm{S}} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{y}{\mathrm{ES}} \xrightarrow{k_2} \underset{e_0-y}{\mathrm{E}} + \underset{p}{\mathrm{P}}.$$

Here E represents enzyme, S the substrate, P the product or products of reaction, and ES the binary complex between enzyme and substrate. If e_0 is the *total* concentration of enzyme (including that bound to substrate), s_0 the *initial total* concentration of substrate, p the amount of product at time t, and y the amount of complex at time t, the various concentrations at time t are as represented above. The rate equations are therefore

[2]*Present address: Department of Chemistry, The University of Ottawa, Ottawa, Canada.*

[1] $$dy/dt = k_1(e_0-y)(s_0-y-p)-\bar{k}y$$

and

[2] $$dp/dt = k_2y$$

where $\bar{k}$ is equal to $k_{-1}+k_2$.

Steady-state Treatment

The steady-state treatment involves setting dy/dt equal to zero in equation [1] and solving for y. The result is

[3] $$y=\left[\bar{k}+k_1(e_0+s_0-p)\pm[\bar{k}+k_1(e_0+s_0-p)]\left(1-\frac{4k_1^2e_0(s_0-p)}{[\bar{k}+k_1(e_0+s_0-p)]^2}\right)^{\frac{1}{2}}\right]\Big/ 2k_1.$$

In this solution the negative sign must be taken, as otherwise it becomes possible for y to be greater than e_0. In the event that

[4] $$[\bar{k}+k_1(e_0+s_0-p)]^2 \gg 4\,k_1^2e_0(s_0-p)$$

we can expand the square root and accept only the first term; the solution then reduces to

[5] $$y = \frac{k_1e_0(s_0-p)}{\bar{k}+k_1(e_0+s_0-p)}.$$

We may now enquire under what circumstances the condition [4] is satisfied. The inequality [4] transforms into

[6] $$\bar{k}^2+k_1^2[e_0^2+(s_0-p)^2]+2\bar{k}k_1(e_0+s_0-p) \gg 2k_1^2e_0(s_0-p)$$

or into

[7] $$\frac{\bar{k}^2}{2k_1^2e_0(s_0-p)}+\frac{e_0}{2(s_0-p)}+\frac{s_0-p}{2e_0}+\frac{\bar{k}(e_0+s_0-p)}{k_1e_0(s_0-p)} \gg 1.$$

This relationship can be true in various ways. Since p cannot be greater than s_0, it is evident that [7] is true if

[8] $$s_0 \gg e_0$$

or if

[9] $$e_0 \gg s_0.$$

It is also true if

[10] $$\bar{k} \gg k_1e_0$$

or if

[11] $$\bar{k} \gg k_1s_0.$$

The inequality [8] of course corresponds to a situation that usually exists in enzyme systems. However even if s_0 and e_0 are of comparable magnitudes equation [5] is valid provided that either [10] or [11] is true. If $s_0 \gg e_0$ equation [5] can be written as

[12] $$y = \frac{k_1e_0(s_0-p)}{\bar{k}+k_1(s_0-p)}$$

and the steady-state rate is then

$$[13] \qquad \frac{dp}{dt} = \frac{k_1 k_2 e_0 (s_0 - p)}{k + k_1 (s_0 - p)}.$$

The Maximum Concentration of Complex

It is unfortunately not possible to obtain an exact explicit solution of the differential equations [1] and [2]. It is possible, however, to arrive at some conclusions about the circumstances under which the steady-state assumption will be reasonably accurate.

For this purpose it is convenient to note that the relationships derived in the last section are satisfactory in giving the *maximum* concentration of complex, y_m, in terms of the concentration of product, p_m, present at the maximum. Thus if in equations [3], [5], [12], and [13] we replace y by y_m and p by p_m we obtain equations relating y_m and p_m which are independent of the steady-state assumption; the relationship

$$[14] \qquad y_m = \frac{k_1 e_0 (s_0 - p_m)}{k + k_1 (e_0 + s_0 - p_m)},$$

for example, is true provided that one of the four conditions [8], [9], [10], and [11] is satisfied. It is clear, therefore, that the steady-state equations are *exact* at the maximum. As the reaction proceeds the steady-state assumption predicts only a gradual diminution in y as p increases, and the exact theory predicts such a change during the later stages of the reaction. The steady-state assumption will, however, lead to error in the early stages of reaction, when the concentration of complex is building up, but if this occurs during the *very* early stages of the reaction the error will not be considerable over the main course of reaction.

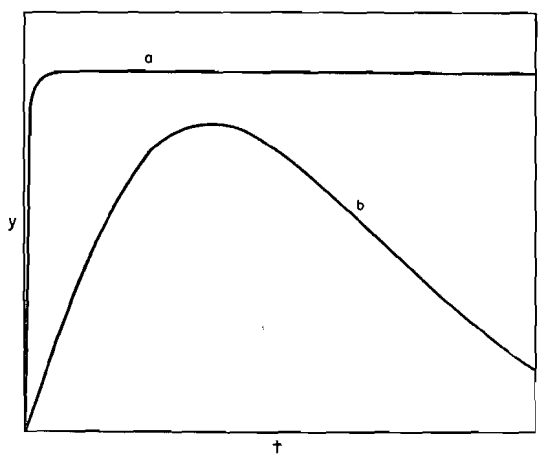

FIG. 1. Schematic curves showing concentration of enzyme–substrate complex vs. time. In curve *a* the steady state is established rapidly; in *b* the concentration of complex varies significantly throughout the course of reaction.

In view of this it is desirable to obtain an estimate of the time taken for the maximum concentration to be attained, in order to see whether it represents an appreciable fraction of the entire reaction. One may envisage two extreme cases, as represented in curves *a* and *b* of Fig. 1. In curve *a* the maximum is reached in the very early stages of the reaction, and in this case the steady-state treatment is satisfactory for the most part. In curve *b* on the other hand, the maximum is a fairly sharp one and the steady-state assumption is therefore unjustified.

The Transient Phase

A kinetic expression will now be obtained for the behavior during the transient phase. The equation will of necessity be an approximate one, but will be sufficiently correct to allow dependable conclusions to be drawn with regard to the circumstances under which the transient phase will constitute a small fraction of the half-life of the reaction.

In place of equation [1] we start with the approximate equation

$$dy/dt = k_1(e_0-y)(\bar{s}-y)-\bar{k}y. \qquad [15]$$

In this equation s_0-p has been replaced by $\bar{s}$, which is treated as constant; $\bar{s}$ may be regarded as the average concentration of the substrate during the transient phase. The circumstances under which this will be a close approximation are discussed later. Equation [15] integrates to

$$t = \frac{1}{\sqrt{Q}} \ln \frac{2ay+b-\sqrt{Q}}{2ay+b+\sqrt{Q}} + \text{constant} \qquad [16]$$

where

$$Q = b^2-4ac, \qquad [17]$$

$$a = k_1, \qquad [18]$$

$$b = -(k_1e_0+\bar{k}+k_1\bar{s}), \qquad [19]$$

$$c = k_1e_0\bar{s}. \qquad [20]$$

The boundary condition $t = 0$, $y = 0$ gives rise to

$$t = \frac{1}{\sqrt{Q}} \ln \frac{by+2c+y\sqrt{Q}}{by+2c-y\sqrt{Q}}. \qquad [21]$$

At the maximum

$$ay_m^2+by_m+c = 0, \qquad [22]$$

whence

$$y_m = (-b-\sqrt{Q})/2a. \qquad [23]$$

From equations [17] and [23] it can be shown that

$$\sqrt{Q} = -ay_m+(c/y_m), \qquad [24]$$

$$b = -ay_m-(c/y_m). \qquad [25]$$

The rate equation [21] therefore reduces as follows:

$$t = \frac{1}{\sqrt{Q}} \ln \frac{c - a y_m y}{c - c y / y_m} \quad [26]$$

$$= \frac{1}{\sqrt{Q}} \ln \frac{y_m - a y y_m^2 / c}{y_m - y} \quad [27]$$

$$= \frac{1}{[(k_1 e_0 + \bar{k} + k\bar{s})^2 - 4k_1^2 e_0 \bar{s}]^{\frac{1}{2}}} \ln \frac{y_m(1 + y y_m / e_0 \bar{s})}{y_m - y} \quad [28]$$

$$= \frac{y_m}{k_1 e_0 \bar{s} - k_1 y_m^2} \ln \frac{y_m(1 + y y_m / e_0 \bar{s})}{y_m - y}. \quad [29]$$

It is now possible to arrive at an estimate of the amount of product, p_m, that has been produced during the transient phase. The time that it takes for y to reach $0.99 y_m$ is given by (from equations [27] and [28])

$$\tau = \frac{1}{\sqrt{Q}} \ln 100 \left(1 + \frac{y y_m}{e_0 \bar{s}}\right). \quad [30]$$

Since y and y_m are necessarily less than the smaller of e_0 and $\bar{s}$ it follows that

$$\tau < (1/\sqrt{Q}) \ln 200 \quad [31]$$

$$< 5.3/\sqrt{Q}. \quad [32]$$

Since y is always less than y_m during the induction period, an *upper limit* to the rate of formation of product is therefore given by

$$dp/dt < k_2 y_m. \quad [33]$$

This integrates to

$$p < k_2 y_m t \quad [34]$$

since $p = 0$ when $t = 0$. An upper limit to the amount of product produced until $y = 0.99 y_m$ (and therefore essentially an upper limit to the amount of product produced in the transient phase) is therefore given by

$$p < 5.3\, k_2 y_m / \sqrt{Q}. \quad [35]$$

Using equations [17] and [23] this becomes

$$p < \frac{5.3 k_2}{2a} \left(-\frac{b}{\sqrt{Q}} - 1\right) \quad [36]$$

$$< \frac{5.3 k_2}{2k_1} \left(-\frac{b}{\sqrt{Q}} - 1\right), \quad [37]$$

$$\frac{p}{s_0} < \frac{5.3 k_2}{2k_1 s_0} \left[\frac{1}{\sqrt{(1 - 4ac/b^2)}} - 1\right]. \quad [38]$$

From this it follows that p/s_0 is small, i.e. that not much product has been produced during the transient phase, if

$$4ac \ll b^2. \quad [39]$$

The circumstances under which this is so were considered earlier, and are expressed by the inequalities [8]–[11] above. It may further be noted that b^2 is necessarily greater than $4ac$ (cf. [6] above), so that the term in the square brackets in [38] can never become very large; p/s_0 will therefore also be small if

$$k_1 s_0 \gg k_2. \qquad [40]$$

The conclusion that has been reached is therefore that the transient phase will be a relatively short one provided that one or more of the inequalities [8], [9], [10], [11], and [40] are satisfied. The situation is then as represented in curve *a* of Fig. 1. In any of these circumstances the kinetic equations derived in the present section for the transient phase will be obeyed with high accuracy since the approximation involved in equation [15] is justified *a posteriori*.

A Special Case: The Substrate Is Present in Great Excess

In view of the fact that in most enzyme systems the concentration of enzyme is very much less than that of the substrate it is now convenient to write down those relationships that are particularly applicable to this case. For this purpose the starred quantities, y^*, y_m^*, p^* will be used when the relationships between them only apply in the case that $s_0 \gg e_0$.

The value of y_m^* is given by (cf. equation [12])

$$y_m^* = \frac{k_1 e_0 s_0}{\bar{k}+k_1 s_0} \quad . \qquad [41]$$

During the induction period the rate equations are

$$dy^*/dt = k_1 s_0 (e_0 - y^*) - \bar{k} y^*, \qquad [42]$$

$$dp^*/dt = k_2 y^*. \qquad [43]$$

Since in equation [29] $k_1 y_m^{*2} \ll k_1 e_0 \bar{s}$ and $y y_m \ll e_0 \bar{s}$ (since y and y_m must be less than e_0, which is much less than $\bar{s}$), and $\bar{s}$ can be replaced by s_0, the kinetic law during the transient phase is

$$t = \frac{y_m^*}{k_1 e_0 s_0} \ln \frac{y_m^*}{y_m^* - y^*} \, . \qquad [44]$$

This may be written as

$$y^* = y_m^* [1 - \exp(-k_1 e_0 s_0 t / y_m^*)] \qquad [45]$$

and using equation [41] this becomes

$$y^* = \frac{k_1 e_0 s_0}{\bar{k}+k_1 s_0} [1 - \exp\{-(\bar{k}+k_1 s_0)t\}]. \qquad [46]$$

The variation of the concentration of product during the transient phase is obtained by using equation [43]:

$$\frac{dp^*}{dt} = \frac{k_1 k_2 e_0 s_0}{\bar{k}+k_1 s_0} [1 - \exp\{-(\bar{k}+k_1 s_0)t\}]. \qquad [47]$$

With the boundary condition $t = 0$, $p = 0$ this integrates to

$$[48] \qquad p^* = \frac{k_1k_2e_0s_0}{\bar{k}+k_1s_0}t+\frac{k_1k_2e_0s_0}{(\bar{k}+k_1s_0)^2}[\exp\{-(\bar{k}+k_1s_0)t\}-1].$$

When t is sufficiently large, i.e. at the maximum, the kinetics are seen to be first order. At lower times more complex behavior is observed. If t is sufficiently small that

$$[49] \qquad (\bar{k}+k_1s_0)t \ll 1$$

it is permissible to expand the exponential and accept only the first two terms; the result is

$$[50] \qquad p^* = \tfrac{1}{2}k_1k_2e_0s_0t^2.$$

This particular relationship has previously been given by Roughton (8).

Equations for the rate of disappearance of substrate during the transient phase can readily be obtained by making use of the fact that

$$[51] \qquad -ds/dt = (dp/dt)+(dy/dt).$$

Another result of interest is the time that it takes for the steady state to be established. Equation [32] gives the time that it takes for y to reach 0.99 y_m, and for the special case of $s_0 \gg e_0$ we obtain

$$[52] \qquad \tau \approx 5.3/(\bar{k}+k_1s_0).$$

It is of interest that this time is independent of the concentration of the enzyme. An experimental determination of the length of the induction period should therefore allow an estimate to be made of the magnitude of $\bar{k}+k_1s_0$, i.e. of $k_{-1}+k_2+k_1s_0$, and since k_2 and $k_1/(k_{-1}+k_2)$ can be determined by conventional kinetic methods the constants can be separated. Work along these lines has been carried out by Gutfreund (6). A more accurate, but experimentally more difficult, procedure for separating constants is to follow the rate of increase of y^* during the induction period; $\bar{k}+k_1s_0$ can then be determined using equation [46].

After y has attained the value of y_m the steady state is established, and the remaining course of the reaction is in accordance with equation [13]. This equation integrates to

$$[53] \qquad k_1k_2e_0 = \frac{1}{t}\ln\frac{s_0}{s_0-p}+\frac{k_1p}{\bar{k}t},$$

which is equivalent to the well-known Henri equation(7). The behavior is zero order as long as $k_1(s_0-p) \gg \bar{k}$ and first order when $\bar{k} \gg k_1(s_0-p)$.

The conclusion that has been reached in the present treatment is that as long as $s_0 \gg e_0$ the kinetic behavior can be closely represented by two sets of

equations, one referring to the transient phase and the other to the steady-state period. The situation is represented schematically in Fig. 2. Here the curve ABC corresponds to equation [46] for the transient phase, the value of y approaching $y_m{}^*$ asymptotically. The curve DBF, corresponding to equation [12], is that predicted by the steady-state theory. The treatment proposed in the present paper involves regarding ABF as representing the true course of the reaction. Strictly speaking it gives a discontinuity at B, but since y_m is very close to $y_m{}^*$ the error is evidently very slight.

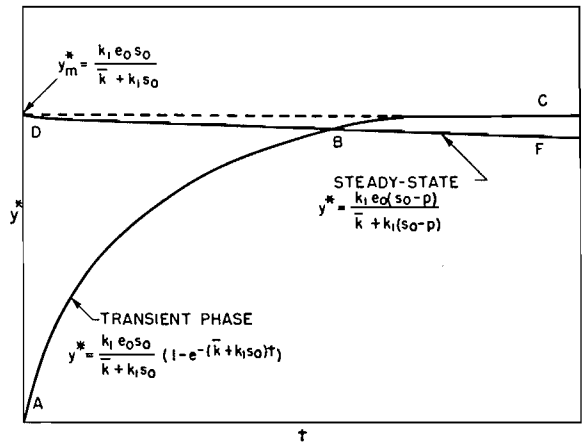

FIG. 2. Schematic curves showing complex concentration vs. time, for the case in which the substrate concentration is in great excess. The true course of the reaction is closely represented by ABF.

The above treatment at once leads to a useful graphical procedure for arriving at the variation of y with t in terms of known rate constants and initial conditions. The curve ABC can readily be plotted, and from equation [48] the amount of product at various times can be calculated. Curve DBF can then be constructed, and ABF will then represent the course of the reaction to a high approximation.

It may be noted that curves and equations of the same *form* as in Fig. 2 and the present section apply also if any of the conditions [9], [10], [11], and [40] apply. The constants appearing in the equations are, however, different for these cases, but may easily be written down by applying the methods of the present section.

The General Case

When none of the conditions [8], [9], [10], [11], and [40] applies it is no longer the case that only a small fraction of the substrate has been transformed into product by the time y has reached its maximum value. The situation is now more as represented in Fig. 3. The true curve, AGF, now deviates considerably from the transient-phase and steady-state curves in the region of

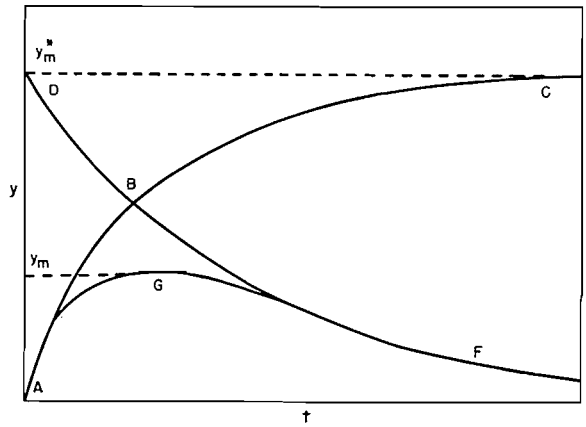

FIG. 3. Schematic curves showing complex concentration vs. time, for the case in which none of the inequalities [8], [9], [10], [11], and [40] is applicable.

the maximum, but corresponds at the beginning and end of the reaction. In the very early stages of the reaction equation [28] is valid and since y and p are small it may be written as

$$[54] \qquad t = \frac{1}{[(k_1e_0+\bar{k}+k_1s_0)^2-4k_1^2e_0s_0]^{\frac{1}{2}}} \ln \frac{y_m^*}{y_m^*-y}$$

or

$$[55] \qquad y = y_m^*(1-\exp\{-[(k_1e_0+\bar{k}+k_1s_0)^2-4k_1^2e_0s_0]t\})$$

where y_m^* is defined by equation [41]. This equation is of the same form as equation [46], and enables the function in the square brackets to be determined from the experimental results. A further separation of constants would, however, appear to be very difficult for this general case without the use of a differential analyzer.

TWO-SUBSTRATE SYSTEMS

A somewhat similar type of analysis can be applied to systems in which there are two substrates. The simplest kinetic scheme corresponding to this situation is the following:

$$\underset{e_0-y}{\mathrm{E}} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{y}{\mathrm{ES}}, \qquad \begin{matrix} \\ s_0-y-p \end{matrix}$$

$$\underset{y}{\mathrm{ES}} + \underset{r_0-p}{\mathrm{R}} \xrightarrow{k_2} \underset{e_0-y}{\mathrm{E}} + \underset{p}{\mathrm{P}}.$$

Here R, the second substrate, does not form a ternary complex ESR but reacts with ES to give products in a single step; the case of the ternary complex is considerably more difficult to work out. Examples of the above scheme are to be found in the peroxidatic reactions of peroxidase and catalase; in these reactions S is hydrogen peroxide and R an acceptor molecule.

The rate equations for this system are

[56] $$dy/dt = k_1(e_0-y)(s_0-y-p)-k_2(r_0-p)y-k_{-1}y,$$

and

[57] $$dp/dt = k_2y(r_0-p).$$

Steady-state Treatment

The general steady-state equation for this system is equation [3] with $\bar{k}$ replaced by $k_2(r_0-p)+k_{-1}$. In the event that any one of the conditions [8], [9], [10], and [11] holds the steady-state equation reduces to

[58] $$y = \frac{k_1e_0(s_0-p)}{k_{-1}+k_1(e_0+s_0-p)+k_2(r_0-p)}.$$

According to the steady-state treatment the concentration of y therefore starts at an initial value of

[59] $$y_0 = \frac{k_1e_0s_0}{k_{-1}+k_1(e_0+s_0)+k_2r_0}$$

when $t = 0$ and gradually diminishes as product accumulates.

The situation is again that steady-state conditions may, under certain circumstances, be expected to exist during the main course of the reaction. When this is the case a simple rate equation will apply to the early stages of the reaction, as will now be considered.

The Transient Phase

The procedure will again be to employ an approximate rate equation for the first part of the reaction, and to justify it *a posteriori* under certain circumstances.

The equation that will be used is

[60] $$dy/dt = k_1(e_0-y)(\bar{s}-y)-(k_2\bar{r}+k_{-1})y$$

where $\bar{s}$ and $\bar{r}$ are the average amounts of S and R during the transient phase. This equation is seen to be of the same form as equation [15], and the remainder of the argument is therefore exactly as previously except that $\bar{k}$ is now given the significance of $k_2\bar{r}+k_{-1}$. The general kinetic equation for the transient phase is now (cf. equation [28])

[61] $$t = \frac{1}{[(k_1e_0+k_1\bar{s}+k_2\bar{r}+k_{-1})^2-4k_1^2e_0s_0]^{\frac{1}{2}}} \ln \frac{y_m(1+yy_m/e_0\bar{s})}{y_m-y}$$

where y_m is as given previously (except that $\bar{k}$ is now $k_2\bar{r}+k_{-1}$). The conclusion is again that during the induction period only a very small amount of product is produced provided that one or more of the conditions [8], [9], [10], [11], and [40] are satisfied.

In the event that the two substrates are greatly in excess of the enzyme the rate equation during the induction period is (cf. equation [46])

[62] $$y^* = \frac{k_1e_0s_0}{k_{-1}+k_1s_0+k_2r_0}[1-\exp\{-(k_{-1}+k_1s_0+k_2r_0)t\}].$$

The course of the formation of product can then be readily obtained by proceeding as previously (equations [47]–[50]). Chance (3) has previously treated this type of situation using numerical methods.

THE CATALATIC REACTION

A slight variant of the above treatment is provided by the catalatic reaction —the decomposition of hydrogen peroxide catalyzed by the enzyme catalase. The reaction scheme is now (4)

$$\underset{e_0-y}{\mathrm{E}} + \underset{s_0-y-p}{\mathrm{S}} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} \underset{y}{\mathrm{X}},$$

$$\underset{y}{\mathrm{X}} + \underset{s_0-y-p}{\mathrm{S}} \overset{k_2}{\rightarrow} \underset{e_0-y}{\mathrm{E}} + \underset{p}{\mathrm{P}}.$$

The rate equations for this system are

$$[63] \qquad dy/dt = k_1(e_0-y)(s_0-y-p)-k_2y(s_0-y-p)-k_{-1}y,$$

$$[64] \qquad dp/dt = k_2y(s_0-y-p).$$

In the event that one of the conditions equivalent to [8], [9], [10], or [11] holds the steady-state equation reduces to

$$[65] \qquad y = \frac{k_1e_0(s_0-p)}{k_{-1}+(k_{-1}+k_2)(s_0-p)}.$$

Chance (4, 5) has shown that k_{-1} is exceedingly small so that almost invariably it is true that

$$[66] \qquad y = k_1e_0/(k_1+k_2).$$

The Transient Phase

In order to obtain an approximate expression for the transient phase the procedure will be, as above, to write equation [63] as

$$[67] \qquad dy/dt = k_1(e_0-y)(\bar{s}-y)-k_2y(\bar{s}-y)$$

where $\bar{s}$ is the average amount of free substrate during the transient phase. The solution of this is equations [16] and [21] above, but a, b, and c now have a slightly different significance, namely

$$[68] \qquad a = k_1+k_2,$$

$$[69] \qquad b = -(k_1e_0+k_1\bar{s}+k_2\bar{s})+k_1e_0\bar{s},$$

$$[70] \qquad c = k_1e_0\bar{s}.$$

The remainder of the treatment is then as given previously. It again follows that the transient phase will be short compared with the over-all duration of the reaction if, among other possibilities, $s_0 \gg e_0$.

For this case the final result for the kinetic equation during the transient phases is again found to be equation [44]. Such a result has previously been obtained, using another procedure, by Chance *et al.* (5) and by Beers and Sizer (2).

NOTES

A NEW TYPE OF ULTRAFILTER

By J. L. Gardon[1] and S. G. Mason

INTRODUCTION

Most ultrafilters (2, 3, 6) have perforated or porous plates as membrane supports, use membranes of small area, and to get appreciable rates of filtration are operated at relatively high pressures. The solution, being under pressure, cannot readily be stirred and, becoming increasingly concentrated on the membrane surface, has a tendency to block the membrane pores (1). Such ultrafilters are not suitable for handling large quantities of materials.

A simple and inexpensive method of supporting membranes which was developed by the authors for an osmometer cell and which inhibits ballooning in membranes as large as 200 sq. cm. in area is described elsewhere (4). In the present note we describe an ultrafiltration unit consisting of a number of slightly modified osmometer cells which has been used for the fractionation of ligninsulphonates (5).

Since the membrane area is large, the unit may be used at relatively low pressure differentials using water aspirators. It is fully automatic, simple to construct, leakproof, and allows thorough stirring of the liquid.

ULTRAFILTER CELLS

Each ultrafilter cell consists mainly of two lucite disks and two rubber rings (Fig. 1). The membrane is clamped between the rubber rings, reinforced with fine-mesh stainless steel screens, and supported on both sides by two layers of tightly packed glass beads. To avoid leakage at the edges of the screens, rings of dental dam rubber are placed between them and the membrane and between them and the rubber rings, forming the body of the cell. When the unit is compressed, the dental dam penetrates into the meshes of the screen reinforcers and seals the cell effectively. The necessary parts for a typical cell are described in Table I.

A simple leakproof connection between the glass parts and the lucite can be made without cement. For this purpose tygon tubing with 1.5 mm. wall thickness and 10 mm. O.D. is placed into 8 mm. bore holes in the lucite. To introduce the tubing into the hole the end of it is cut off conically along the length and pulled into the hole by the tongue thus formed, and the tongue is then cut away.

Each lucite disk is equipped with the connectors before assembling the cell. To prevent glass beads from dropping into the tygon tubing, a small piece of stainless steel screen is placed in the tubing.

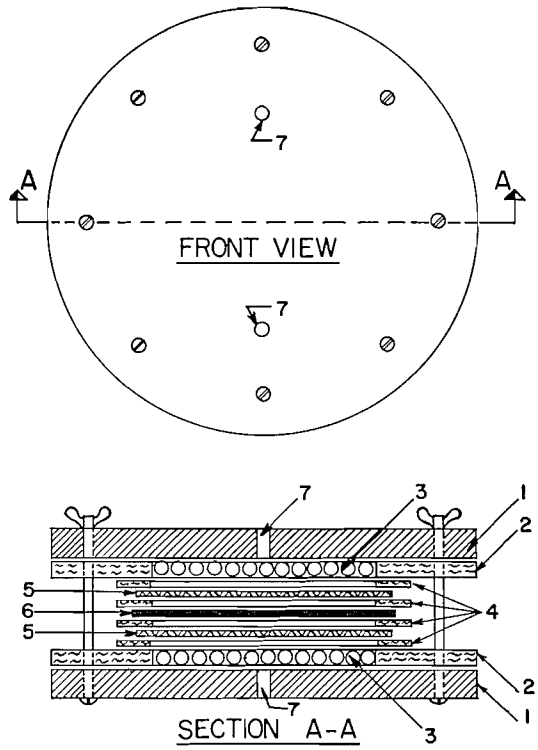

FIG. 1. Details of the ultrafilter cell: (1) lucite disks, (2) rubber rings, (3) glass beads, (4) dental dam gaskets, (5) stainless steel screens, (6) membrane, (7) inlet hole.

TABLE I

CELL COMPONENTS

1. 2 lucite disks
   - Diameter 25 cm.
   - Thickness 1 cm.
   - 8 holes with centers on a 23 cm. diameter circle concentric with the disks to accommodate the screws
   - 2 holes with centers on the same diameter 17.5 cm. apart—bore diameter 8 mm.
2. 8 rubber rings
   - Inside diameter 18 cm.
   - Outside diameter 25 cm.
   - Thickness 0.3 to 0.32 cm.
   - 8 holes drilled in identical positions as in the lucite for holding the screws
3. 4 dental dam gaskets
   - Inside diameter 18 cm.
   - Outside diameter 22 cm.
   - Thickness about 0.03 cm.
4. 2 stainless steel screens
   - Diameter 20 cm.
   - 125 mesh
5. 1 membrane
   - Diameter 21 cm.
6. Glass beads
   - Diameter 0.28 to 0.3 cm.
7. 8 screws, 8 wing nuts, 16 washers

THE CIRCULATING PUMP

Stirring in the cells is provided by circulating the solution from a reservoir. The pumping unit, shown in detail in Fig. 2, consists of a membrane pump (A) governed by an oscillating mercury pump (B).

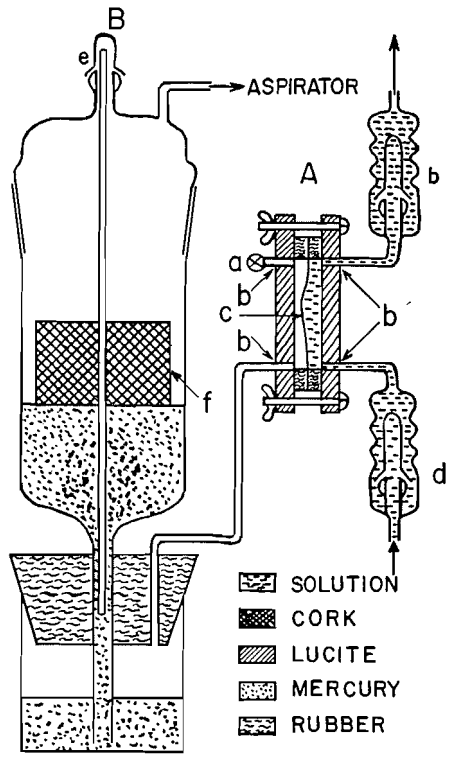

FIG. 2. Details of the circulating pump: (A) membrane pump, (a) stopcock, (b) inlet holes, (c) dental dam membrane, (d) valves, (B) oscillating mercury pump, (e) valve, (f) cork floater.

The construction of the membrane pump is similar to that of the ultrafilter cells. It is made up of two lucite disks of 12 cm. diameter, two rubber rings 5 mm. thick with 10 cm. outside diameter and 8 cm. inside diameter, and an elastic dental dam membrane disk (c) of 10 cm. diameter clamped between the rubber rings. To accommodate the screws, both lucite disks have four holes with centers on an 11 cm. diameter circle concentric with the disks and two 8 mm. bore holes (b), with centers 3.75 cm. from the center of the disk and on the same diameter, in which tygon tubing is placed in the same manner as described above. The membrane is made of two dental dam rubber sheets stuck together with silicone grease. This method of preparation gives the membrane a life of at least several months of continuous operation.

The two check valves (d) are made of spherical glass joints of 12 mm. diameter.

The oscillating mercury pump functions as follows. By applying vacuum in the upper chamber, mercury is sucked into it. The rising mercury raises the cork float (f) and thus opens valve (e). Consequently air enters into the upper chamber, the mercury level drops, valve (e) is closed, and a new pumping cycle starts. The lower chamber of this pump is connected with the membrane pump, and the membrane in the latter forcibly has to follow the movements of the mercury. In practice the oscillating mercury pump is put into

operation first, independently of the membrane pump, and stopcock (a) is closed afterwards. The difference in level between the mercury in the lower and upper chambers should alternate between 10 and 14 cm. The diameter in both the upper and lower chambers of the oscillating mercury pump is 7 cm. and the length of the pump is 25 cm. The valve (e) is made of a 12 mm. diameter spherical glass joint.

The capacity of this pumping unit is around 200 cc. per minute.

OPERATION

The assembled ultrafilter is shown in Fig. 3. The solution chambers of the different cells are connected in series and the solution is circulated from reservoir (C) to provide adequate stirring.

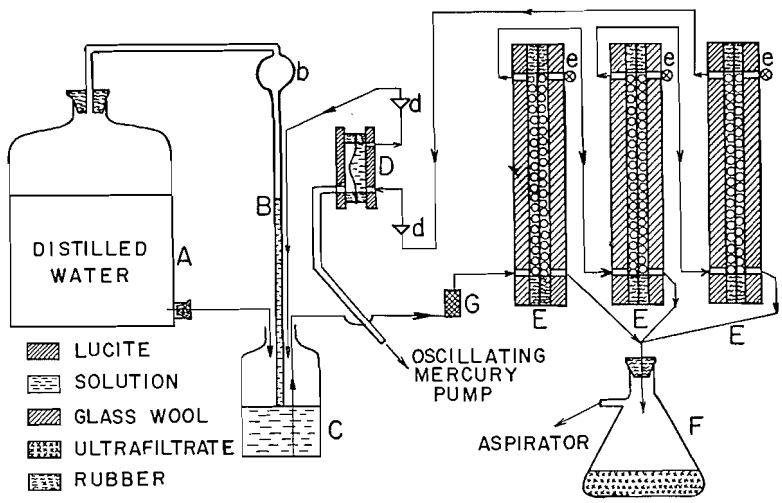

FIG. 3. The assembled ultrafiltration unit: (A) water reservoir, (B) constant head device, (b) solution trap, (C) solution reservoir, (D) membrane pump, (d) valves, (E) ultrafilter cells, (e) stopcocks, (F) suction flask, reservoir for ultrafiltrate, (G) glass wool filter.

The volume of the liquor is kept constant by the constant head device (B). If the level in reservoir (C) drops sufficiently to expose the end of the tube (B) to the air, air will enter into the distilled water container (A) and consequently water will flow into reservoir (C). The rising level in the reservoir closes tube (B) and thus stops the water flow. Trap (b) is needed to prevent the solution from entering the distilled water container.

The ultrafiltrate is fed into suction flask (F) by gravity.

Keeping the residual liquor at constant volume allows good control of the process. If V_0 is the volume of the residual liquor, K the volume of ultrafiltrate produced in unit time, $c(t)$ the concentration of the component to be removed, and $\gamma\, c(t)$ its concentration in the ultrafiltrate passing through the membrane at time t (γ is the partition coefficient between the solutions inside and outside

the membrane, $0 < \gamma < 1$), the following relation may be derived for the variation of $c(t)$ with time:

$$-V_0\,dc = \gamma\,K\,c(t)\,dt,$$

which on integration yields

$$c(t) = c(0).e^{-\gamma K t/V_0}.$$

By determining K, V_0, c_0, and several values of $c(t)$ at different time intervals, γ can be evaluated and the time necessary for the removal of any arbitrary portion of the component in question can be calculated.

The rate of ultrafiltration is readily varied by changing the number of cells in the unit.

THE REMOVAL OF FLUORIDE ION FROM AQUEOUS SOLUTION BY MAGNESIUM OXIDE

BY JOHN C. BARTLET AND ROSS A. CHAPMAN[1]

Venkateswarlu and Narayana Rao (1, 2, 3) reported that magnesium oxide takes up fluoride ion from hot solution, basic to phenolphthalein. Light magnesium oxide was reported to remove up to 20 μgm. of fluoride per mgm. of magnesium oxide. This procedure was used to reduce the fluoride content of water (1, 2) and as an aid in the determination of fluoride in tea (3).

In this laboratory, it was found that the removal of fluoride could be increased manyfold if the original solution was acidic. Table I shows the effect

of pH on the taking up of 1 mgm. of fluoride ion in 100 ml. of hot solution by 100 mgm. of magnesium oxide. The pH of the solutions was adjusted with sodium hydroxide or perchloric acid. The solution of pH 1.7 contained sufficient perchloric acid to dissolve approximately 40 mgm. of the original 100 mgm. of magnesium oxide added. From a hot solution at pH 1.7 containing 20 mgm. of fluoride as sodium fluoride in 100 ml., 100 mgm. of magnesium oxide took up 18.8 mgm. or 94% of the fluoride. This represents a removal of 188 μgm. of fluoride per mgm. of original magnesium oxide or 312 μgm. of fluoride per mgm. of magnesium oxide remaining in the solid phase.

The solid residue prepared under several different conditions with an excess of fluoride present was found to be of variable composition ranging from approximately the composition $2Mg(OH)_2 \cdot MgF_2$ to $4Mg(OH)_2 \cdot 3MgF_2$. These products were slightly soluble in hot water. Examination by the X-ray diffraction powder method showed that the products consisted of a mixture of $Mg(OH)_2$ and MgF_2 with no lines attributable to a new compound.

We wish to thank Dr. W. H. Barnes of the National Research Council of Canada who carried out the X-ray diffraction studies.

A SYNTHESIS OF L-ISOGLUTAMINE FROM γ-BENZYL GLUTAMATE

BY M. KRAML AND L. P. BOUTHILLIER

In the course of our studies on histidine metabolism (5) it became necessary to prepare some L-isoglutamine. Bergmann and Zervas (1) obtained the desired product by cleaving N-carbobenzyloxy-L-glutamic anhydride with anhydrous ammonia followed by catalytic hydrogenation to remove the carbobenzyloxy (CBZ) group. Recently, Chambers and Carpenter (3) achieved a similar synthesis by blocking the amino acid with the *p*-nitrobenzyloxycarbonyl group. Paper chromatography (3) has revealed that these methods, while favoring L-isoglutamine formation, invariably yield small amounts of L-glutamic acid and L-glutamine as contaminants. Swan and duVigneaud (6) have published the only unambiguous synthesis of L-isoglutamine. It consists in the preparation of N-*p*-toluenesulphonyl-L-glutamic acid, the conversion to N-tos-5-oxo-2-pyrrolidine-carboxyl chloride, the amidation to N-tos-5-oxo-2-pyrrolidine-carboxamide, the conversion to N-tos-L-isoglutamine, and the subsequent hydrogenation with sodium in liquid ammonia to give L-isoglutamine. We have found it more convenient to prepare L-isoglutamine by the amidation of N-CBZ-γ-benzyl-L-glutamate by the mixed anhydride procedure

Swan and duVigneaud (6) have published the only unambiguous synthesis of L-isoglutamine. It consists in the preparation of N-*p*-toluenesulphonyl-L-glutamic acid, the conversion to N-tos-5-oxo-2-pyrrolidine-carboxyl chloride, the amidation to N-tos-5-oxo-2-pyrrolidine-carboxamide, the conversion to N-tos-L-isoglutamine, and the subsequent hydrogenation with sodium in liquid ammonia to give L-isoglutamine. We have found it more convenient to prepare L-isoglutamine by the amidation of N-CBZ-γ-benzyl-L-glutamate by the mixed anhydride procedure

of Boissonnas (2), followed by catalytic hydrogenolysis of the resulting amide. The method is evidently unambiguous and L-isoglutamine is the only product formed. This was verified by paper chromatography in four solvent systems.

EXPERIMENTAL[1]

N-CBZ-γ-benzyl-L-glutamate

γ-Benzyl-L-glutamate, m.p. 168–169°, was condensed with carbobenzyloxy chloride in the presence of sodium bicarbonate as suggested by Hanby *et al.* (4). The N-CBZ-γ-benzyl-L-glutamate was crystallized from hot carbon tetrachloride, m.p. 77–78°. Calculated for $C_{20}H_{21}NO_6$, N: 3.77. Found N: 3.75.

N-CBZ-γ-benzyl-L-isoglutamine

N-CBZ-γ-benzyl-L-glutamate (32.8 mM.) was dissolved in 150 ml. of dioxane (redistilled from sodium) containing 7.80 ml. of tri-*n*-butylamine. The solution was cooled to 10° and 3.16 ml. of ethyl chlorocarbonate was added. The solution was shaken for 10 min. at 10° after which anhydrous ammonia was bubbled through for 15–30 min. The solution was evaporated to a white powder on a water bath at a temperature not exceeding 50°. The residue was suspended in 50 ml. of carbon tetrachloride and 50 ml. of water was added. The mixture was agitated vigorously and the N-CBZ-γ-benzyl-L-isoglutamine was filtered off and washed with cold water, carbon tetrachloride, and ether to remove any trace of starting material. The compound was recrystallized from hot ethanol, m.p. 126–127°, yield 80%. N-CBZ-γ-benzyl-L-isoglutamine has not been previously described in the chemical literature. Calculated for $C_{20}H_{22}N_2O_5$, C: 64.86; H: 5.96; N: 7.56. Found C: 65.16; H: 6.19; N: 7.52.

L-*Isoglutamine*

N-CBZ-γ-benzyl-L-isoglutamine (5 gm.) was dissolved in 100 ml. of 50% ethanol and hydrogenated for 12 hr. at room temperature and atmospheric pressure in the presence of palladium catalyst (5% Pd on calcium carbonate). The catalyst was filtered off and a trace of calcium ions was removed with oxalic acid. The solution was evaporated to dryness, the residue dissolved in a small amount of hot water, and the solution treated with charcoal. Alcohol was added to the cloud point and L-isoglutamine was recovered from the chilled solution as fine white crystals, m.p. 186–188°, yield 65%. Calculated for $C_5H_{10}N_2O_3$, N: 19.16. Found N: 18.94. Chambers and Carpenter (3) reported a melting point of 175–176°, whereas Swan and duVigneaud (6) found 186°. Chambers and Carpenter have reported $[\alpha]_D^{24}$ +19.4 to 20.5 (*c* 3, water) and Swan and duVigneaud, $[\alpha]_D^{21}$ +20.5° (*c* 6.1, water). We have measured $[\alpha]_D^{24}$ +20.0° (*c* 2.3, water). Paper chromatograms of our product revealed only one bluish-purple spot in each of the four solvent systems employed. The R_f in *n*-butanol – glacial acetic acid – water (15:3:7) was 0.28 and there was no

[1]*Analyses by the Geller Microanalytical Laboratories, Hackensack, New Jersey. All melting points were taken by the capillary method and are uncorrected.*

trace of L-glutamine (R_f 0.18); the R_f in phenol–water (4:1) was 0.56 and L-glutamic acid (R_f 0.30) was absent.

SOME FLUORINE SUBSTITUTED TOLANES[1]

BY C. S. ROONEY[2] AND A. N. BOURNS

ABSTRACT

p-Trifluoromethyltolane and *p*-fluorotolane have been synthesized by the action of sodium or potassium amide in liquid ammonia on *para*-substituted 1,1-diphenyl-2-bromoethylenes. The geometrical isomers of 1-(*p*-trifluoromethylphenyl)-1-phenyl-2-bromoethylene have been separated and their configurations assigned on the basis of dipole moment measurements. *p*-Trifluoromethyltolane has been converted to a dibromide, which on oxidation gave benzoic and *p*-trifluoromethylbenzoic acids. Both tolanes have been reduced to the correspondingly substituted 1,2-diphenylethanes.

INTRODUCTION AND DISCUSSION

The syntheses and some reactions of (*p*-trifluoromethylphenyl)phenylacetylene (*p*-trifluoromethyltolane) (I) and (*p*-fluorophenyl)phenylacetylene (*p*-fluorotolane) (II) are described. These compounds were prepared in the course of some work which was to have been preliminary to a carbon-tracer investigation of the rearrangement of 1,1-diaryl-2-haloethylenes to tolanes in the presence of strong base (5, 6). A related investigation of this reaction, using a different system, was completed recently in another laboratory (4) and for this reason our mechanism studies were discontinued.

1-(*p*-Trifluoromethylphenyl)-1-phenylethylene (III) was prepared by the interaction of acetophenone and *p*-trifluoromethylphenylmagnesium bromide, as well as from *p*-trifluoromethylbenzophenone (IV) and methylmagnesium iodide. Compound IV was synthesized by the action of antimony trifluoride on *p*-trichloromethylbenzophenone at an elevated temperature. Bromination of III, followed by dehydrobromination, yielded 1-(*p*-trifluoromethylphenyl)-1-phenyl-2-bromoethylene (V), which, by a combination of elution chromatography on alumina and fractional crystallization at low temperatures, was separated into two geometrical isomers. On the basis of dipole moment measurements, the crystalline isomer (VA) was assigned the *cis* configuration, and the other (VB), a liquid at room temperature, the *trans* configuration. Isomer VB could not be obtained completely free of its higher-melting, less-soluble isomer.

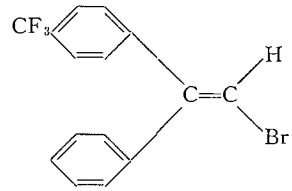
Compound VA



Compound VB

Compounds VA and VB on interaction with sodium or potassium amides in liquid ammonia solution both gave *p*-trifluoromethyltolane (I) in about 75% yield. Bromination of I yielded the dibromide VI, which on oxidation with chromic anhydride in acetic acid solution produced a mixture of benzoic and trifluoromethylbenzoic acids. Oxidation of I directly with potassium permanganate in acetone gave a low yield of these acids. Catalytic hydrogenation of compound I, using Raney nickel or Adam's catalyst at low pressure, produced 1-(*p*-trifluoromethylphenyl)-2-phenylethane (VII).

p-Fluorotolane (II) was prepared from 1-(*p*-fluorophenyl)-1-phenyl-2-bromoethylene (VIII) in a manner analogous to the synthesis of I. The bromo compound, VIII, prepared by the action of bromine on 1-(*p*-fluorophenyl)-1-phenylethylene, could not be crystallized, or separated into pure geometrical isomers by distillation or chromatography. Catalytic hydrogenation of II produced 1-(*p*-fluorophenyl)-2-phenylethane (IX).

EXPERIMENTAL*†

p-Trifluoromethylbenzophenone (IV)

p-Trichloromethylbenzophenone (10) (7.6 gm.) and 8.5 gm. of antimony trifluoride were mixed intimately and heated on a hot plate for 15 min. at a temperature sufficient to fuse the mixture. Water and benzene were added and 2.3 gm. of benzene-soluble material was isolated. Recrystallization from ethanol–water gave 1.53 gm., or 23% yield, melting at 116–118°C. Calc. for $C_{14}H_9OF_3$: C, 67.18; H, 3.63. Found: C, 67.24, 67.08; H, 3.75, 3.68.

1-(p-Trifluoromethylphenyl)-1-phenylethylene (III)

Method A

p-Bromobenzotrifluoride (9) (9.16 gm.) and 1.04 gm. of magnesium were allowed to react in 50 ml. of anhydrous diethyl ether. To the resulting red-colored Grignard reagent 4.88 gm. of acetophenone in 50 ml. of ether was added. The reaction mixture was worked up in the usual way. The resulting crude carbinol was dehydrated by heating at 150°C. in a nitrogen atmosphere for one and one-half hours. Distillation yielded 5.3 gm. of product (52.5% of theory), b.p. 78–79°C. at 0.1 mm., which crystallized. Recrystallization from methanol, or vacuum sublimation, gave the pure compound, m.p. 38–39°C.

**Melting points are corrected.*

†Carbon and hydrogen analyses were performed by Dr. F. G. Harcsar of McMaster University, and Miss G. Rotermann of the Dominion Rubber Company, Guelph, Ontario. Bromine analyses were carried out by the authors using the Carius combustion procedure.

Method B

p-Trifluoromethylbenzophenone (IV) (1.50 gm.) was added to an ether solution containing methylmagnesium iodide (0.22 gm. magnesium, 0.94 gm. methyl iodide) and the product was worked up as described under Method *A*. The yield of compound III, m.p. 38–39°C., was 1.12 gm. or 75% of theory. Calc. for $C_{15}H_{11}F_3$: C, 72.58; H, 4.47. Found: C, 71.82, 71.63; H, 4.98, 4.57.

Oxidation of compound III (0.068 gm.) with a solution containing 1.50 gm. of potassium permanganate, 10 ml. of acetone, and 7 ml. of water gave 0.043 gm. or a 76% yield of *p*-trifluoromethylbenzophenone.

1-(p-Trifluoromethylphenyl)-1-phenyl-2-bromoethylene (V)

Compound III (2.83 gm.) was brominated using bromine in acetic acid and the resulting dibromide dehydrobrominated by the procedure of Bergmann and Szmuszkowicz (2). On evaporation of the acetic acid solution, 3.78 gm., or 101% of theory, of a liquid product was isolated. After the product had been left overnight in the refrigerator, 1.54 gm. of crystalline solid (VA), m.p. 71–74°C., separated. This material was isolated by dissolving the surrounding liquid selectively in ethanol. The ethanol-soluble portion was chromatographed on an alumina* column using *n*-hexane as the developing solvent. A further 0.17 gm. of the solid isomer was obtained in this way, it being the last fraction removed from the column. Recrystallization of the combined solid product from ethanol gave pure VA, m.p. 74–75°C. The liquid fractions, which were eluted from the alumina column first, had n_D^{25} 1.5670–1.5690. When cooled to 0°C., or when cooled in ethanol solution to dry ice temperatures, these partially crystallized. Repeated chromatography, as well as fractional crystallization in ethanol solution, however, failed to give a sharply melting substance. What was probably the purest sample isolated had a melting point of 8–12°C., and n_D^{25} 1.5684. Anal. Calc. for $C_{15}H_{10}F_3Br$: C, 55.07; H, 3.08; Br, 24.4. Found: Solid isomer; C, 55.11, 55.11; H, 3.09; 3.07, Br, 25.9, 24.3. Liquid isomer; Br, 26.5, 24.8.

Dipole moment measurements determined using the resonance method (7) gave 3.46 D for the solid isomer (VA) and 2.26 D for the liquid product (VB). One therefore can assign with considerable certainty the *cis* (*p*-trifluoromethylphenyl and bromine *cis*) and *trans* configurations to the high- and low-melting isomers respectively. The moment of the liquid product was high for a pure compound of the *trans* configuration, indicating some contamination by the less soluble *cis* isomer.†

Oxidation of 0.072 gm. of compound VA in a solution containing 11 ml. of water, 15 ml. of acetone, 0.05 gm. of acetic acid, and 1.59 gm. of potassium permanganate yielded 0.045 gm. of *p*-trifluoromethylbenzophenone (81.5% yield).

**British Drug Houses chromatographic grade alumina, activated by heating for three hours with a Meeker burner, was used.*

†It is of interest that a larger-than-expected moment has also been observed (1) for the trans isomer of 1-(p-bromophenyl)-1-phenyl-2-bromoethylene, although in this case the compound appears to be free of its geometrical isomer (4). This would suggest that our liquid product was purer trans isomer than the dipole moment might imply.

p-Trifluoromethyltolane (I)

Compound VA, or VB, (0.61 gm.) in 15 ml. of diethyl ether was added to a liquid ammonia solution (70 ml.) containing 0.42 gm. of sodium amide. The mixture was evaporated to dryness after 15 min., 50 ml. of water added, and the insoluble product filtered. Recrystallization from ethanol–water, following vacuum sublimation, gave 0.135 gm., or 75% of theory, of the tolane melting at 104–105°C. Calc. for $C_{15}H_9F_3$: C, 73.17; H, 3.66. Found: C, 73.39, 73.38; H, 4.05, 4.02.

p-Trifluoromethyltolane Dibromide (VI)

To compound I (0.26 gm.), dissolved in 15 ml. of acetic acid, was added a slight excess of bromine in acetic acid and the solution heated at about 100°C. for 15 min. Following evaporation to 5 ml. and dilution with 20 ml. of water, 0.30 gm., or 72% of theory, of solid bromide was isolated, which after recrystallization from ethanol–water or isooctane melted at 159–161°C. Calc. for $C_{15}H_9F_3Br_2$: C, 44.30; H, 2.22; Br, 39.3. Found: C, 44.09, 43.86; H, 2.32, 2.22; Br, 37.0.

The dibromide VI (0.143 gm.) was added to a solution containing 0.40 gm. of chromic anhydride, 0.5 ml. of water, and 4 ml. of acetic acid. The mixture was heated at the boiling point for 15 min. and then 20 ml. of water was added. The precipitated solid (0.080 gm.) was filtered. A further 0.027 gm. was recovered from the filtrate by extraction with 60:40 benzene–ether. Extraction of the first product with 5% sodium hydroxide solution followed by acidification with dilute hydrochloric acid gave 0.046 gm. of acidic material. The combined solid products (0.073 gm.) were subjected to partition chromatography on a silicic acid column using methanol and isooctane as the stationary and mobile phases, respectively (8). The first compound removed from the column (0.038 gm.) melted at 218–220°C. and gave no depression when mixed with authentic *p*-trifluoromethylbenzoic acid. A later fraction gave 0.012 gm. of an acid whose melting point, 120–122°C., was unchanged in admixture with benzoic acid.

1-(p-Trifluoromethylphenyl)-2-phenylethane (VII)

Hydrogenation of compound I (1.33 gm.) in ethanol solution, using a Raney nickel catalyst at room temperature and 40 p.s.i., yielded 1.23 gm. of product (92% yield). Recrystallization from ethanol–water, or vacuum sublimation, gave the pure compound, m.p. 37.3–38.6°C. Calc. for $C_{15}H_{13}F_3$: C, 71.95; H, 5.23. Found: C, 71.77, 71.33; H, 5.15, 5.15.

1-(p-Fluorophenyl)-1-phenyl-2-bromoethylene (VIII)

This compound was prepared by bromination of 1-(*p*-fluorophenyl)-1-phenylethylene (X) (3) using the method of Bergmann and Szmuszkowicz (2). Compound X (21.2 gm.) gave 27.2 gm. (92% yield) of a product (VIII) boiling at 129–133°C. at 0.1 mm. Fractional distillation through a laboratory column *in vacuo* gave fractions with refractive indices varying from n_D^{25} 1.6131 to n_D^{25} 1.6162. Chromatography on an alumina column failed to give separation

into two distinct fractions. Calc. for $C_{14}H_{10}FBr$: C, 60.60; H, 3.61; Br, 28.8. Found: C, 59.97, 59.50; H, 3.59, 3.55; Br, 29.0, 28.4.

p-Fluorotolane (II)

Compound VIII (5.57 gm.) was added in ether solution to 100 ml. of liquid ammonia containing 2.5 gm. of potassium (as potassium amide) and the mixture was worked up as described for compound I. A crude solid (3.84 gm.) was isolated, which after recrystallization from ethanol–water weighed 3.01 gm. (75.5% yield) and melted at 109–110°C. Calc. for $C_{14}H_9F$: C, 85.71; H, 4.59. Found: C, 86.36, 86.29; H, 4.83, 4.68.

1-(p-Fluorophenyl)-2-phenylethane (IX)

Hydrogenation of compound II (0.128 gm.) with Raney nickel catalyst in ethanol solution at room temperature and 18 p.s.i. yielded 0.128 gm. of crude product, which after recrystallization from ethanol–water melted at 61–62.5°C. Calc. for $C_{14}H_{13}F$: C, 83.96; H, 6.50. Found: C, 83.16, 82.98; H, 6.49, 6.42.

THE ACTION OF SULPHURIC ACID ON GLIADIN: WITH SPECIAL REFERENCE TO THE N-PEPTIDYL→O-PEPTIDYL BOND REARRANGEMENT[1]

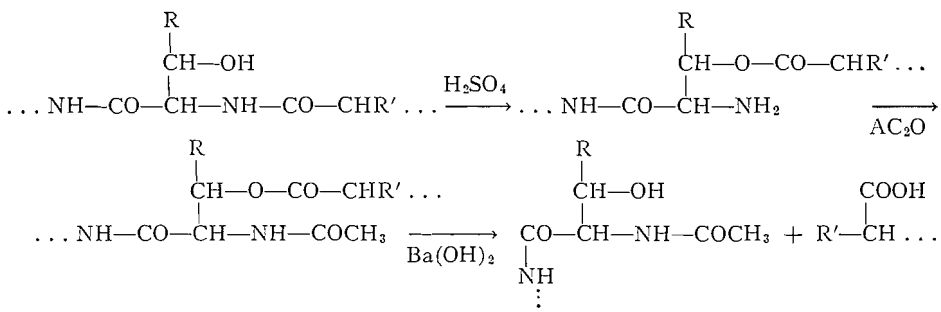
By L. K. Ramachandran[2] and W. B. McConnell

ABSTRACT

Treatment of gliadin with sulphuric acid transposes peptide bonds of serine from the amino to the hydroxyl group. Maximum transposition, 60–70% of the theoretical, occurs when the protein is treated with anhydrous sulphuric acid at 0°C. for 35 hr. No rearrangement was detected at threonine residues. Examination of the peptide material, obtained from the rearranged protein by Elliott's degradation method, indicates apparent "homogeneity". In an alternative scheme for the degradation, nitrous acid deamination of free amino groups was used. The resulting loss in serine content of the protein is direct evidence for the acyl migration of peptide bonds. Incorporation of sulphur and partial disappearance of several amino acids accompany the sulphuric acid treatment. The occurrence of these secondary reactions imposes limitations on the use of sulphuric acid as a reagent for the specific fission of peptide bonds.

INTRODUCTION

Attention has recently been directed towards methods which effect fragmentation of protein molecules in a predictable manner. Especially significant is Elliott's procedure for the cleavage of peptide bonds (7, 8, 9) at the amino groups of the β-hydroxyamino acids, serine and threonine. It is based on the strong acid-induced N-acyl→O-acyl transformations studied earlier by Bergmann, Brand, and Weinmann (2), Desnuelle and Casal (5), and Desnuelle and Bonjour (6), and is briefly outlined in the equations below:



This N-acyl→O-acyl migration might also occur where the ε-amino groups of δ hydroxylysine (26) are linked in a peptide bond.

The treatment of silk fibroin with 97.5% sulphuric acid for three days at 20°C. (8) caused rearrangement in only 66% of the serine residues, the major N-terminal residue detected by the dinitrofluorobenzene method (24) being serine. The non-reactivity of the other serine residues was thought to result

from factors like steric hindrance. With lysozyme (9) nearly all the serine groups and a third of the threonine residues participated in the reaction. The non-dialyzability of the lysozyme derivative and the absence of the Ehrlich test for tryptophan suggested that cross linking occurred through those residues. Wiseblatt and McConnell (37), who applied the method to wheat gluten, also observed the preferential release of serine amino groups and suggested that the product was highly cross linked.

In the present study the action of anhydrous sulphuric acid in effecting bond transposition in gliadin has been studied from the quantitative aspects of time of reaction and temperature, to determine suitable conditions for further degradation studies on wheat proteins. The gliadin fraction was chosen because of its discrete characteristics. The reactivity of the liberated amino groups towards nitrous acid was determined. This treatment would convert the N-terminal serine residues to glyceric acid. After saponification of the O-acyl bond, the reactivity of the terminal dihydric alcohol towards periodic acid was studied. The above alterations in Elliott's scheme avoid the necessity for protecting the free amino N with a substituent often difficult to remove without other alterations to the material.

An effort has also been made to detect changes in some of the amino acids, arising from sulphuric acid treatment of the protein. Uchino (33) reported that silk fibroin was stable towards sulphuric acid at 7–8°C. for 11 days, but that later there was slow liberation of amino groups. Reitz *et al.* (28) noted that although appreciable hydrolysis of γ-globulin occurred in one week at room temperature there was only 2–3% hydrolysis in 10 days at 4°C. Work on wool (11) indicated considerable non-ionic combination of sulphate ions with the amino groups to form sulphamates. With other proteins (28) it seemed possible to account for all bound sulphate on the basis of ester formation with aliphatic hydroxyl groups, formation of sulphonic acids, and formation of thiosulphates by reaction with the sulphydryl groups. Although some workers observe very little destruction of tryptophan, cystine, and serine (28) other reports (20) indicate appreciable alteration besides the sulphamate formation. When wool was treated with sulphuric acid at low temperatures 10% of the serine and 25% of the arginine was lost. Phenylalanine and tyrosine showed a decrease which, as with tryptophan, may be partly accounted for by sulphonation of the benzene ring.

EXPERIMENTAL

Analytical Methods

Total N was determined by the micro-Kjeldahl method with mercuric oxide catalyst. *Free amino groups* were estimated by the Van Slyke nitrous acid method and a ninhydrin colorimetric procedure (31).

The difference in free amino groups before and after treatment of the materials with pH 9.1 borate buffer for 12–16 hr. was taken as a measure of the *bond transposition* (8).

Standard methods were employed for determination of the following: *amide N* (24), *cystine* (16), *methionine* (13), *arginine* (21), *tryptophan* (10). *Tyrosine* was determined by the 1,2-nitrosonaphthol reaction (25, 34).

Total S was estimated by a combined micro-combustion and volumetric method (32) and *formaldehyde* by the chromotropic acid color reaction (23). The method of Rice, Keller, and Kirschner (30) was used for the identification of the aldehydes as the 2,4-dinitrophenylhydrazones.

Treatment of Gliadin with Sulphuric Acid

One gram of gliadin (N—17.64%, prepared by the method of Blish and Sandstedt (3)) and 10 ml. anhydrous sulphuric acid (prepared by addition of the calculated amount of oleum to 97.5% sulphuric acid) were shaken together for the required time at the temperature desired. The reaction mixture was then poured with stirring into 20 times its volume of cold ether and the precipitated material washed repeatedly with ether. The material was dissolved in the minimum volume of 60% (v/v) ethanol, transferred to a Visking cellophane bag, and dialyzed exhaustively against distilled water. The contents of the bag were lyophilized. The recovery of the products was close to 97% based on nitrogen analyses.

Degradation of the Sulphuric Acid Treated Gliadin

The material obtained above was *acetylated* at pH 5.0 using acetic anhydride (8) or *formylated* with a mixture of formic acid and acetic anhydride (35). *Deacylation* was effected by means of anhydrous MeOH – HCl (1.5 *M* in regard to HCl) under conditions used by Boissonnas and Preitner (4). *Saponification* of the O-acyl bond was achieved using 0.01 *N* NaOH or 0.02 *N* $Ba(OH)_2$ (8).

Deamination of Sulphuric Acid Treated Gliadin

Two methods were employed. In the first, the reaction mixture was treated at 0.5°C. with solid $NaNO_2$ (1 gm. for every gram of protein), added in small portions during 20 min. In the other method 0.5 gm. of the material in 30 ml. 50% acetic acid was treated at room temperature with 1 gm. $NaNO_2$ added in small portions during 20 min. with agitation. The reaction mixtures were exhaustively dialyzed against distilled water and lyophilized. The latter method gave products free of color.

Reaction of Terminal Amino Groups with 1-Fluoro-2,4-dinitrobenzene (DNFB)

Conditions for the reaction and hydrolysis of the products for the release of the dinitrophenyl amino acids were those recommended by Porter (24). Separation of the 2,4-dinitrophenol and 2,4-dinitroaniline from the amino acid derivatives was effected on a chloroform – silicic acid column (19). The dinitrophenyl amino acids were identified by paper chromatography (22) and determined quantitatively by spectrophotometry at 360 mμ (24).

RESULTS

To establish a basis for assessing the results the serine content of gliadin was determined (27) and found to be 4.9% by weight. Gliadin, of molecular weight 30,000, on cleavage of all peptide bonds attached to serine N should therefore yield material containing about 15 fragments with an average chain length of 15–16 residues and with 0.65% amino N (3.7% of total N)

due to exposed serine amino groups. The original gliadin contained 1.01% of the total N as free amino N.

Figs. 1, 2, and 3 contain results obtained for total amino N, amino N arising from bond transposition alone, and amino N other than that arising from bond transposition when samples of gliadin were treated with H_2SO_4 at

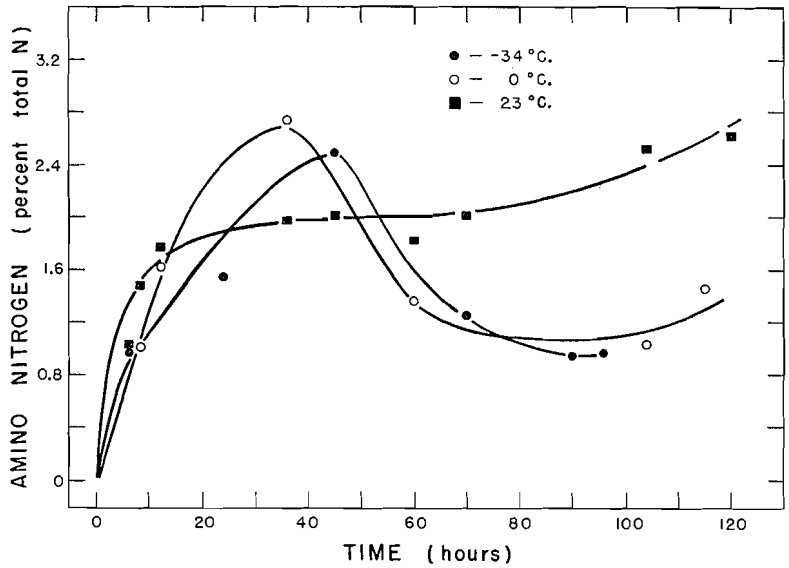

FIG. 1. Effect of time and temperature on free amino N released from gliadin by sulphuric acid.

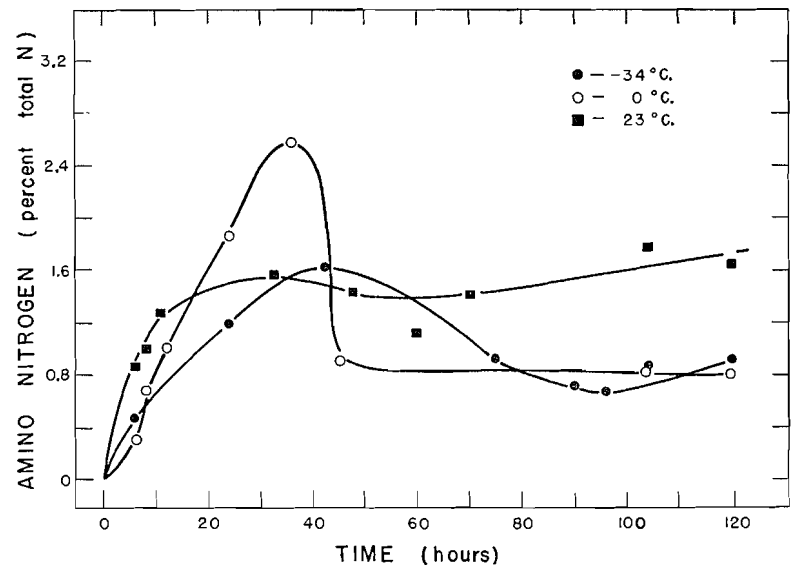

FIG. 2. Effect of time and temperature on the release of amino nitrogen by bond transposition alone during the sulphuric acid treatment of gliadin. Free amino nitrogen expected from a quantitative bond transposition at serine is 3.7% of total nitrogen.

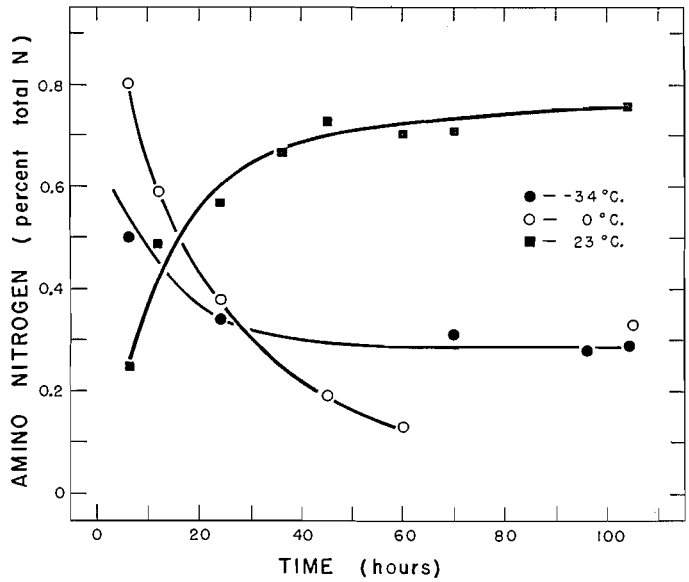

FIG. 3. Effect of time and temperature on amino nitrogen not arising from bond transposition during the sulphuric acid treatment of gliadin.

0°, 23°, and −34°C. for different lengths of time. The data were obtained on lyophilized products, isolated from the reaction mixtures, as described above.

The data indicate that in samples treated at 0°C. and −34°C. the total amino N increases during 35–45 hr. and thereafter falls to 50–65% of the maximum, remaining practically constant. At 23°C. amino groups increase rapidly for about 45 hr. after which there is a slow but continuous rise. Changes in amino N arising specifically from bond transposition follow the same pattern (Fig. 2). The pattern of changes in content of amino N other than those involved in the bond transposition is depicted in Fig. 3. In samples treated at −34° and 0°C. the values decrease gradually to a low value. Since the free amino N content of the original gliadin was measured to be 1.01% the initial decrease at 23°C. is relatively rapid but thereafter there is a progressive increase in free amino groups which may be the result of non-specific hydrolysis.

The difference between analytical values on duplicate preparations was of the order of 10%. The observed trends are therefore significant. The average deviation of the mean for determinations of amino N by the colorimetric method was ±1.5%.

Acylation and Saponification of the Treated Gliadin to Peptides

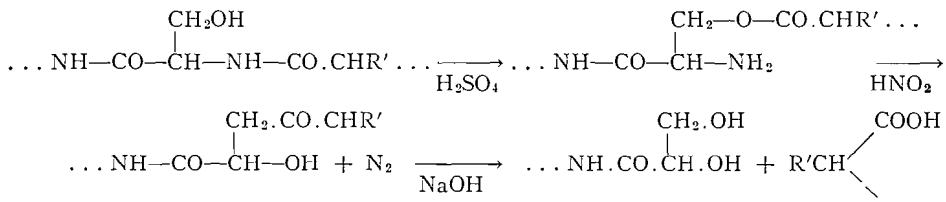
Two samples, one treated at 0°C. for 45 hr. and another treated at 23°C. for 60 hr. with sulphuric acid (0.312% and 0.221% of amino N, respectively, exposed by the bond shift), were subjected to acetylation, saponification, and deacetylation by methods referred to earlier. Material from saponification (after precipitation of barium either by passing in CO_2 at pH 6.5–7.0 or by

adding dilute sulphuric acid) had a high ash content which was retained even after the treatment with MeOH – HCl. To determine the serine end groups, the peptide samples obtained were oxidized with periodic acid. The amounts of formaldehyde obtained corresponded to 107.8 and 92.2% of the theoretical calculated from the amino N values for bond transposition.

The peptide samples were subjected to paper electrophoresis (Whatman 3 mm. 11×30 cm. sheet) using a pH 6.0 phthalate (0.05 *M*) buffer and 0.05 *N* acetic acid. The material was spotted along a line drawn across the middle of the sheet, which had been previously wetted with the electrolyte, and a potential of 220 v. was applied for a period of from two and one-half to three hours. No appreciable part of the material migrated toward either electrode so that although analyses indicated cleavage of the molecule at five to eight sites, no heterogeneity in the resulting material was demonstrable by paper electrophoresis. This observation is similar to results obtained in studies on gluten (37), where the suggestion was made that the material resulting from the treatments employed may consist of cross-linked polypeptide material of colloidal dimensions exhibiting marked homogeneity by physiochemical criteria. It was emphasized that the electrophoretic homogeneity may have resulted from polar groups introduced by the chemical treatments used. It thus appeared of some interest to avoid, at least, the steps of acylation and deacylation.

Deamination with Nitrous Acid and Saponification of the O-Peptide Bond

Some experiments were done therefore on deamination of the products from the sulphuric acid treatment. The reaction should convert the free amino groups to hydroxy groups and subsequent saponification should then yield a mixture of peptides with terminal glyceric acid. The reaction could be represented as follows:



Gliadin treated with sulphuric acid at 0°C. for 45 hr. was deaminated and saponified according to the above scheme of reactions. The isolated product was then oxidized with periodate (37) to determine terminal dihydric alcohols. Formaldehyde* equivalent to 105.5% of that calculated from bond transposition was recovered. The second method of deamination was applied to gliadin treated with sulphuric acid at 23°C. for 60 hr. The sample had a serine amino N value of 0.221% and total amino N 0.298%. After deamination the product had only 0.013% amino N, indicating destruction of 95.6% of the free amino

**Although the amounts of formaldehyde estimated in several samples examined were nearly equivalent to the bond transposition effected, the periodate consumed during the oxidation of the products was found to be several times higher than that expected. The sites in the protein-derivatives responsible for this reduction of periodate have not yet been determined.*

groups. Saponification with NaOH resulted in a product which on periodate oxidation yielded only a trace of periodate ammonia, indicating complete destruction of the serine amino groups. The formaldehyde produced during this oxidation corresponded to 112.8% of the calculated amount. The absence of acetaldehyde in the reaction mixture by the *p*-hydroxydiphenyl test indicated that no threonine residues were involved in the arrangement. This was confirmed when the aldehydes present were reacted with 2,4-dinitrophenylhydrazine and the hydrazones extracted and identified on paper chromatograms. Only one spot corresponding to formaldehyde was present.

The nitrous acid treated samples were hydrolyzed with 6 *N* HCl for 20 hr. as was a control sample of gliadin. The hydrolyzates were chromatographed in two dimensions (36) and the combined intensity of the ninhydrin spots due to serine and glycine was determined spectrophotometrically after extraction with 10% isopropanol. The values indicated that 80–90% of the serine determined as involved in the rearrangement had been destroyed by nitrous acid. However, application of both the dye test (17) and the biuret test (14) to electrophorograms of the two samples (deaminated H_2SO_4-treated gliadin, one at 0°C. for 45 hr. and the other at 23°C. for 60 hr.), prepared as described above, showed a single major component, which moved slowly towards the anode, but did not separate into differing fragments. Both the materials moved a distance of 2.3 cm. in three hours in 0.05 *N* acetic acid.

C-Terminal Groups of Degradation Products

Reaction of the degradation products with carboxypeptidase in a qualitative study indicated the following amino acids occupying C-terminal positions—tyrosine, "leucine",* valine, alanine, glutamic acid, and glycine. No amino acids were released when undegraded gliadin was treated with the enzyme, although application of the modified Schlack and Kumpf procedure (1) for C-terminal groups had indicated the presence of glutamic acid and "leucine" in less than molar amounts (unpublished results of the authors). It is thus possible that bond fission occurred at sites where serine is linked to the above amino acids.

Reaction of Exposed Amino Groups with DNFB

Gliadin was treated with sulphuric acid at 23°C. for four days, precipitated, acetylated, saponified, and then deacetylated with MeOH – HCl and the material fractionated roughly into MeOH – HCl soluble and insoluble fractions (37). The methanol insoluble sample (the amount of material recovered thus accounted for 25% of the nitrogen in the starting material) had very low amino N (0.137%) whereas the soluble fraction had a value of 0.490%. The free serine amino N was 0.082 and 0.183% respectively. The latter sample had a very high ash content and the formaldehyde values on periodate oxidation were abnormally high. It was considered desirable to determine the amount of free serine amino groups by condensing with DNFB and measuring the DNP-serine formed. The dinitrophenyl derivative was hydrolyzed and the DNP-amino acids in the ether extract and aqueous phase examined for their

**No differentiation has been made between leucine and isoleucine.*

identity by paper chromatography (22) after initial purification on silicic acid (19). DNP-serine was found in the ether phase and the aqueous phase contained DNP-histidine. The presence of DNP-histidine is to be expected since histidine occupies the N-terminal position in gliadin (15, unpublished data of the authors). The DNP-serine amounted to 10.65 μM. while the amount theoretically expected from the other analyses was 12.59 μM. Although the recovery for serine amino groups thus appeared to be nearly quantitative, the condensation with the other free amino groups, known to be present from ninhydrin amino N analysis, could not be detected.

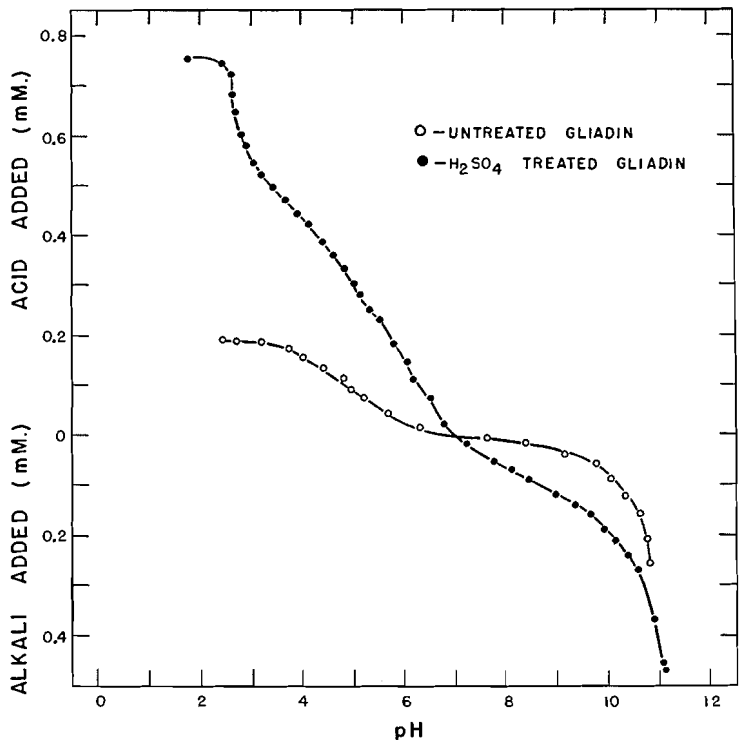


Fig. 4. Titration curve of gliadin before and after treatment with sulphuric acid.

The Effect of Sulphuric Acid Treatment on Some Amino Acid Residues

The titration curves of a sample of gliadin in 60% ethanol, before and after treatment with sulphuric acid at 23°C. for 70 hr., are indicated in Fig. 4. The shape of the curves suggests appreciable changes in the groups titrated in the pH region 2.5–8.5.

Table I contains the results of analyses for bound sulphate, amide N, arginine, methionine, and tyrosine. A single determination of tryptophan in the sample treated for 70 hr. at 23°C. indicated a decrease from 1.15 to 1.02%, of cystine from 2.35 to 1.85%, and of phenylalanine (12) from 5.45 to 4.72% on moisture and ash-free protein.

DISCUSSION

The results presented show that time of treatment is a factor of importance in the sulphuric-acid-induced acyl migration of peptide bonds in gliadin. Although this study of transposition as a function of time indicates the best conditions (40 hr. at 0°C.), the complete migration of peptide bonds was not obtained under any of the conditions. The shape of the curves in Fig. 3 suggests partial disappearance of amino N during acid treatment at the two lower temperatures, whereas at 23°C. a non-specific hydrolytic cleavage appears to be superimposed. Amino groups might undergo reaction to form sulphamates (11, 29) or be involved in other reactions. If some of the newly formed amino groups participate in such reactions under the conditions of treatment used, it would be impossible to detect or make use of a complete shift of the peptide bonds. Apparent incompleteness in the shift cannot be explained solely on the basis of factors like reactivity of the residues in the protein molecule. Elliott (9) suggested the occurrence of polymerization reactions involving tryptophan residues in the case of lysozyme, but quantitative fission at serine groups and at a third of the threonine residues had occurred. In silk fibroin the cleavage at serine residues was of the order of 66% (8). In gliadin the maximum observed is of the same order (Fig. 2). Thus the effective cleavage of these bonds seems to vary with different proteins.

The present observations indicate that problems arising in the blocking of amino groups and removal of the blocking agent later could be avoided by deamination and that, with gliadin, the removal of the amino groups by nitrous acid is quantitative. This treatment would however convert terminal serine residues to glyceric acid. In theory, this simplification in procedure could distinguish between serine residues rearranged in the first step and those encountered later. Samples of treated protein deaminated in this way showed a decrease in content of serine in the hydrolyzate, of the same order as involved in the bond rearrangement. This in effect constitutes direct evidence of a shift of peptide bonds attached to the serine N in gliadin. Desnuelle (see Ref. 9, p. 140) however has encountered difficulty with some proteins in dimethylating or deaminating the amino groups exposed by sulphuric acid.

The results obtained indicate the incorporation of considerable amounts of undetermined forms of sulphur into the protein during the treatment with acid. Extensive chemical modification of the original protein is also shown by the changes in the content of amide bonds, methionine (cf. 18), arginine, tyrosine, cystine, and phenylalanine. The tryptophan reaction was still strong in some of the products examined. Side reactions involving free amino groups in the sulphuric acid medium are indicated by the gradual diminution of non-serine amino N with time. This perhaps involves, amongst other possibilities, sulphamate formation. The differences observed in the titration curves of gliadin, before and after treatment, possibly result from rather extensive alterations.

The incomplete nature of the rearrangement and the chemical modification of several of the constituent amino acids in the protein severely limit the scope and usefulness of sulphuric acid as a reagent for the selective fission of peptide bonds. The results presented herein do nevertheless provide direct evidence for strong acid-induced acyl migration in gliadin and indicate that a fairly specific cleavage of peptide bonds can thereby be obtained. More satisfactory schemes for selective protein hydrolysis will probably be developed in the future but, for the present, degradation based upon the sulphuric-acid-induced bond transposition remains a useful tool in the study of proteins. Improved understanding of the various effects of sulphuric acid on proteins will lead to rational applications of the procedure and facilitate interpretation of the results.

THE REACTION OF ACTIVE NITROGEN WITH AZOMETHANE[1]

By D. A. Armstrong[2] and C. A. Winkler

ABSTRACT

The main products of the reaction between active nitrogen and azomethane were hydrogen cyanide and ethane. Traces of methane, ethylene, and acetylene were also formed, together with small amounts of an unstable product. Activation energies of about 0.5 ± 0.4 and 1.9 ± 0.3 kcal. per mole, with corresponding steric factors of 10^{-1} to 10^{-3} and 10^{-2} to 10^{-4}, were estimated for the reactions of active nitrogen with methyl radicals and azomethane respectively, on the assumption that atomic nitrogen is the reactive component of active nitrogen. Azomethane appeared to catalyze the deactivation of active nitrogen.

INTRODUCTION

Free alkyl radicals have been postulated as intermediates in many of the hydrocarbon – active nitrogen reactions studied in this laboratory, and it has been invariably assumed that they were very rapidly destroyed by reaction with active nitrogen. The present study represents an attempt to evaluate experimentally the kinetic characteristics of the methyl radical – active nitrogen reaction.

EXPERIMENTAL

The apparatus and analytical methods have been described in earlier papers (4). Two concentrations of active nitrogen, which differed by a factor of approximately ten, were used. For the higher concentration, molecular nitrogen at a flow rate of 9.75×10^{-5} mole/sec. was admitted to the condensed discharge. The lower concentration was obtained by reducing the flow of nitrogen to 3.53×10^{-6} mole/sec., while the pressure in the system was maintained at the previous value (*ca.* 1.0 mm.) by introducing argon into the discharge tube at a flow rate of 7.28×10^{-5} mole/sec. In two experiments on the hydrogen atom – azomethane reaction, a comparable hydrogen–argon mixture was passed through the discharge tube.

Three samples of azomethane were prepared from dimethylhydrazine by the method of Leitch* (11); these showed identical vapor pressure – temperature relations.

Reaction temperatures were measured with two copper–constantan thermocouples. One of these was situated directly below the hydrocarbon inlet tube in the center of the reaction vessel, while the other was located near the top of the vessel at the active nitrogen inlet.

RESULTS

A preliminary experiment with azomethane mixed with molecular nitrogen in approximately the proportions used in the subsequent studies of the active nitrogen reaction showed no significant thermal decomposition of azomethane under these flow conditions at 400°C. Also no decomposition was observed when argon alone was passed through the discharge tube and allowed to mix with azomethane in the reaction vessel.

The condensable products of the active nitrogen – azomethane reaction consisted mainly of hydrogen cyanide and ethane. Unreacted azomethane was also recovered. A Le Roy still (10) was used to separate the ethane fraction, which was subsequently analyzed with a mass spectrometer.*

The HCN content of the remaining fraction was estimated by absorption in KOH solution and titration with standard $AgNO_3$ solution (9). Unreacted azomethane was obtained by difference. The yields of HCN and C_2 hydrocarbons for three different temperatures, at each of the active nitrogen flow rates used, are shown in Fig. 1A, B, and C.

Analysis of the uncondensed gases from two experiments at the higher active nitrogen flow rate indicated that methane was produced only in small amounts in the azomethane – active nitrogen reaction and that the hydrogen production approximated to the HCN yield.

In all of the active nitrogen – azomethane experiments small amounts of methane and nitrogen (in roughly equal proportions as determined by mass spectrometer analysis of several samples) were evolved when the condensable products were evaporated from one vessel to another, and also during distillation in the Le Roy still. The evolution of these gases in the same proportion was also observed from the products of the two experiments with the hydrogen atom – azomethane reaction. These observations indicate that the formation of an unstable product in the active nitrogen – azomethane reaction is a result of secondary hydrogen atom – azomethane reactions. From the total amounts of methane and nitrogen formed by complete decomposition of the unstable product, it was possible to estimate its yield on the assumption that one molecule of the unstable material decomposed to one molecule of methane and one molecule of nitrogen. The data obtained from such estimates, together with the recovery of azomethane, have been plotted in Fig. 1D as a function of the azomethane flow rate for a number of experiments at the lower active nitrogen flow rate.

No products other than residual azomethane and hydrogen cyanide were detected in significant amounts by mass spectrometric analysis of the final fraction from two experiments at 45° and 177°C. with the lower active nitrogen concentration. The hydrogen cyanide yields calculated from these analyses agreed with those obtained by the chemical method mentioned previously.

At the lower temperatures material balances were within a few per cent of the theoretical. However, at higher temperatures the material balances were between 88 and 100% and some polymer formation was observed.

Experiments with ethylene and propylene at high temperatures and high flow rates, such that consumption of the active nitrogen should be complete (4), indicated a value of about $1.60 \pm 0.10 \times 10^{-5}$ mole/sec. for the higher active nitrogen flow rate (dotted line, Fig. 1A). Similar experiments with ethane and ethylene gave a value of $1.31 \pm 0.06 \times 10^{-6}$ mole/sec. for the lower flow rate.

Apart from the unstable product, the hydrogen atom – azomethane experiments yielded large quantities of ethane and a higher boiling fraction. Material

The authors are indebted to Dr. H. I. Schiff of this department for the mass spectrometer analyses.

balances, calculated on the assumption that the latter fraction was residual azomethane or dimethylhydrazine, were well over 100%, a feature in which the hydrogen atom – azomethane experiments differed from those with active nitrogen.

DISCUSSION

Although evidence has recently been obtained (3) to indicate the presence of more than one reactive species in active nitrogen, the identities of the species have not been established. As in most of the previous studies, therefore, the present results will be discussed on the assumption that atomic nitrogen is the only reactive species involved.

At the lower active nitrogen concentration the hydrogen cyanide production increased rapidly with azomethane flow rate, and attained a constant maximum value which was virtually independent of temperature. The close agreement between this maximum hydrogen cyanide yield and the corresponding yields from ethane and ethylene suggests that the hydrogen cyanide production from azomethane represents the complete consumption of the relatively small amount of active nitrogen available in these experiments.

On the other hand, the hydrogen cyanide production from azomethane at the higher active nitrogen flow rate never approached the value obtained with ethylene and propylene, although the constant yield observed for higher azomethane flow rates would again imply complete consumption of the available active nitrogen at 160° and 400°C.

The apparent loss of active nitrogen in the presence of azomethane might be due to catalyzed recombination of nitrogen atoms with azomethane as a third body; thus:

$$N+N+CH_3{-}N{=}N{-}CH_3 \rightarrow N_2+CH_3{-}N{=}N{-}CH_3{}^*. \qquad [1a]$$

This would be in competition with the reaction:

$$N+CH_3{-}N{=}N{-}CH_3 \rightarrow HCN+N_2+H_2+CH_3 \qquad [1b]$$

which appears to be the most reasonable process for the initial nitrogen atom attack on azomethane.

Both of these reactions are first order in respect of azomethane. A competition between them would thus explain the constant hydrogen cyanide production observed at azomethane flow rates in excess of the critical flow rate. A difference in activation energy would explain the increase in hydrogen cyanide production with temperature. Also, since the recombination reaction is second order in respect of the nitrogen atom concentration, a significant reduction in the concentration of this reactant should favor conversion of the active nitrogen to hydrogen cyanide, and the apparent difference in behavior at high and low active nitrogen concentrations can be explained.

It might be noted parenthetically that if excited or metastable nitrogen molecules, rather than atoms, were the major component of active nitrogen it would be difficult to account for this behavior, which has also been observed with other compounds (1, 2).*

**It is hoped that a general discussion of the behavior may be published shortly.*

Methyl radicals formed in the initial process may react with nitrogen atoms as follows:

$$N+CH_3 \rightarrow HCN+2H \quad [2a]$$

$$\rightarrow HCN+H_2 \quad [2b]$$

$$\rightarrow CN+H_2+H. \quad [2c]$$

Reaction [2*c*] is probably slightly endothermic; moreover if it were extensive, cyanogen might have been expected as a significant product. Although reaction [2*a*] is thermodynamically less favorable than [2*b*], it permits conservation of spin (1), while [2*b*] does not.

Ethane formation presumably occurred by the reaction:

$$CH_3+CH_3+M \rightarrow C_2H_6 \quad [3]$$

which seems to have a negligible activation energy and a steric factor close to unity (12).

Methane, ethylene, and acetylene are all minor products and were probably produced in relatively unimportant processes (for example methane might have been formed in reactions involving hydrogen abstraction by methyl radicals).

From the results of the present investigation and from previous studies of the hydrogen atom – azomethane reaction (5) it would seem that secondary hydrogen atom – azomethane reactions must have been relatively insignificant in the reaction of active nitrogen with azomethane. However, formation of the unstable product implies that a small concentration of atomic hydrogen was present in the system. This may be taken as evidence for the occurrence of reaction [2*a*]. Indeed it is possible to infer from the relative proportions of HCN, C_2H_6, and the unstable product that this reaction largely predominated over reaction [2*b*].

The chain characteristics observed in previous studies of the hydrogen atom – azomethane (5) indicated that hydrogen atom – azomethane complexes might be relatively stable. Since such complexes might decompose to yield methane and nitrogen in roughly equal proportions (and possibly other products which are condensable in liquid nitrogen) they might well be identical with the unstable product recovered in the present investigation.

By making certain simplifying assumptions it is possible to obtain estimates for the activation energies of reactions [1*b*] and [2] from the results of the experiments at the lower active nitrogen concentration where the occurrence of reaction [1*a*] could be neglected.

On the basis of the mechanism already outlined the equations required for these calculations may be formulated as follows:

$$N+AM \xrightarrow{k_1} HCN+H_2+N_2+CH_3 \quad [1b]$$

$$N+CH_3 \xrightarrow{k_2} HCN+2H \text{ (or } H_2) \quad [2]$$

$$CH_3+CH_3 \xrightarrow{k_3} C_2H_6 \quad [3]$$

$$d(\mathrm{HCN})/dt = k_1(\mathrm{AM})(\mathrm{N}) + k_2(\mathrm{Me})(\mathrm{N}) = R_1$$

$$d(\mathrm{Me})/dt = k_1(\mathrm{AM})(\mathrm{N}) - k_2(\mathrm{Me})(\mathrm{N}) - k_3(\mathrm{Me})^2$$

$$d(\mathrm{C_2H_6})/dt = \tfrac{1}{2}k_3(\mathrm{Me})^2 = R_2.$$

The usual steady state approximation for the methyl radical concentration gives:

$$\frac{k_2}{k_3^{\frac{1}{2}}} = \frac{(Q_1 - 2Q_2)}{2^{3/2} \cdot F_n \cdot Q_2^{\frac{1}{2}}} \times \frac{RT}{pV^{\frac{1}{2}}} \times (\text{total molar flow rate}) \qquad [\text{i}]$$

$$\frac{k_1 \cdot k_3^{\frac{1}{2}}}{k_2} = \frac{2^{\frac{1}{2}} \cdot (Q_1 + 2Q_2)}{(Q_1 - 2Q_2)} \times \frac{Q_2^{\frac{1}{2}}}{F_a} \times \frac{RT}{pV^{\frac{1}{2}}} \times (\text{total molar flow rate}) \qquad [\text{ii}]$$

$$k_1 = \frac{(Q_1 + 2Q_2)}{2 \cdot F_n \cdot F_a} \times \left(\frac{RT}{pV^{\frac{1}{2}}}\right)^2 \times (\text{total molar flow rate})^2 \qquad [\text{iii}]$$

F_a and F_n are the flow rates of azomethane and nitrogen atoms in the reaction zone, and Q_1 and Q_2 are the observed rates of production of hydrogen cyanide and ethane respectively.

Calculations were made for the higher azomethane flow rates, where the reaction flame was confined to the upper part of the reaction vessel and the reading of the upper thermocouple could be assumed to indicate the reaction temperature. With the assumption of completely turbulent flow in the reaction zone, F_a and F_n may be assigned steady-state values. As a rough approximation the values of F_a and F_n in the reaction zone were assumed to be equal and independent of temperature. A value of 1.30×10^{-6} mole/sec. (equal to the average hydrogen cyanide production) was therefore taken to represent both F_n and F_a.

The reaction volume V was assumed to remain constant over the temperature range studied and was estimated from the dimensions of the reaction flame to be about 50 cm^3. It was also necessary to assume negligible ethane consumption by the reaction:

$$\mathrm{N} + \mathrm{C_2H_6} \rightarrow \mathrm{HCN} + \mathrm{CH_3} + \mathrm{H_2}.$$

Collision diameters of 3.0, 3.5, and 5.5 Å for nitrogen atoms (4), methyl radicals (6), and azomethane (8) respectively were used in the calculation of the collision numbers and estimation of the steric factors.

The ratios $k_2/k_3^{\frac{1}{2}}$ calculated for the three different temperatures gave a value of 0.5 ± 0.4 kcal. per mole for $E_2 - \frac{1}{2}E_3$ and the ratio $P_2/P_3^{\frac{1}{2}}$ was found to be between 10^{-1} and 10^{-2}. Allowing for the possible decreases in P_3 at low pressures (7) a lower limit of 10^{-3} may be set for P_2. If secondary hydrogen atom – azomethane reactions, which led to the formation of methyl radicals or ethane, were responsible for some of the decomposition of the azomethane, the fraction of hydrogen cyanide formed in the methyl radical – active nitrogen reaction would be greater than indicated and the ratios $k_2/k_3^{\frac{1}{2}}$ and $P_2/P_3^{\frac{1}{2}}$ would be correspondingly greater. The values of the ratios $k_2/k_3^{\frac{1}{2}}$ and $P_2/P_3^{\frac{1}{2}}$ calculated above can thus be regarded as lower limits.

A value of 2.0 ± 0.3 kcal. with a corresponding steric factor between 10^{-2} and 10^{-4} was estimated for E_1 from the values of k_1 calculated by equation [iii] for the three temperatures. Relation [ii], which is independent of F_n, gave a value of 1.4 ± 0.3 kcal. for $E_1-E_2+\frac{1}{2}E_3$. This is consistent with the values of 2.0 ± 0.3 and 0.5 ± 0.4 kcal. per mole calculated for E_1 and $E_2-\frac{1}{2}E_3$ with the other two relations. These calculations indicate that the reaction of nitrogen atoms with azomethane was far more rapid than their reaction with saturated hydrocarbons and comparable in rate with their attack on unsaturated hydrocarbons.

DISINTEGRATION-RATE DETERMINATION BY 4π-COUNTING

PART III. ABSORPTION AND SCATTERING OF β RADIATION[1]

By B. D. Pate[2] and L. Yaffe

ABSTRACT

The "coincident discharges" in a 4π-counter have been examined and found to be due in the main to gas and wall back-scattering. This can be resolved into two components—scattering near to and far from the source. Curves have been obtained for the back-scattering of β radiation by the source-mounting film and for the absorption of the incident and back-scattered radiation. Back-scattering by the film is shown to be great enough to introduce a large error into the "sandwich" method which is currently in use for correcting for source-mount absorption.

INTRODUCTION

Previous publications in this series (37, 38, 39) have described experimental work aimed at improving the accuracy of absolute counting using a 4π-counter. In this paper additional experimental data are presented, which enable identification to be made of the agency giving rise to the discharges occurring coincidently in both half-counters, and examination to be effected of some of the scattering and absorption processes involved in using a 4π steradian geometrical arrangement.

The penetration of electronic radiation through matter is a complex phenomenon owing to the variety of processes by which interaction may occur (5). With an initially collimated beam of monoenergetic electrons, interaction with a layer of material up to a superficial density of a few hundred μgm./cm.^{2} occurs by means of a few scattering events per electron. This results in the beam spreading without too great an energy or intensity loss. With thicker layers, more scattering events per electron occur and a transition to "multiple scattering" takes place. With still thicker layers the electrons no longer have a preferred direction of motion and the process resembles diffusion. The number of electrons now emerging from the foil decreases with increasing foil thickness, i.e. absorption of the radiation occurs.

The single scattering of electrons has been treated theoretically (2, 33) and the multiple scattering has been treated in an approximate way (4). When the system is further complicated by an uncollimated β radiation with a continuous energy spectrum, a theoretical analysis is very difficult. Consequently the absorption and scattering of β radiation have only been described empirically, principally with counting geometries of less than 2π steradians.

The absorption process, of interest both as a source of error in disintegration-rate measurements and as an energy determination method, has been the subject of a voluminous literature (6, 17, 19, 20, 21, 27, 29, 41, 42). Our knowledge

[1]*Manuscript received July 11, 1955.*

[2]*Holder of a National Research Council Studentship.*

of the back-scattering of β radiation is largely due to experimental work performed in connection with disintegration-rate determinations using $\ll 2\pi$ geometry systems (12, 16, 22, 26, 50, 51).

Absorption measurements in a 4π-counting geometry are of interest for two reasons. First, the effects observed are due to absorption alone, and scattering effects which cause complications like maxima in absorption curves (15, 18, 34, 45) are virtually absent. Secondly, measurements in the absorber thickness range below a few hundred μgm./cm.^{2} (not hitherto reported), particularly with sources with minimal self-absorption, will provide absorption data regarding the lowest energy electrons in the β spectrum. The results given in an earlier paper in this series (39) and those of Suzor and Charpak (47, 48) indicate large absorption effects in this region.

Prior to the present investigation no detailed study of absorption effects in a 4π-counter has been reported. Measurements of the variation of total counter, half-counter, and coincidence counting rates have previously been made(25, 44, 47, 48). However these have all been done at a relatively high source-mount superficial density.

Previous observations of phenomena interpreted as due to back-scattering from a source mount in a 4π-counter have been reported (16, 25, 31). These were large compared with the corresponding effects in $\ll 2\pi$ geometries. The reason for this was attributed by Mann and Seliger (28) to a large contribution in the 4π geometry due to small-angle single-scattering.

"Coincidences in a 4π-counter" may be defined as events where both halves of the counter are discharged within the resolving time of the apparatus by a *single* disintegration. This is, of course, an entirely different phenomenon from that by which resolution losses occur at high counting rates, because the counter is unable to differentiate between *two successive* disintegrations. The "coincidences" obviously do not result in any error in the disintegration-rate determination.

This phenomenon was previously observed by Haxel and Houtermans (24), who ascribed it to conversion electrons emitted simultaneously with the β radiation of Rb^{87}. A fairly comprehensive study by Suzor and Charpak (13, 14, 46, 47, 48) pointed out three possible causes for these coincidences:

(i) Secondary electronic radiation resulting from interaction of the primary beta radiation with the source mount.

(ii) Electrons from the source, in addition to the β particle.

(iii) Very soft gamma radiation from the source.

Smith (44) interpreted his data for S^{35} on the basis of (ii) and (iii). However, Meyer-Schützmeister and Vincent (31) came to the conclusion that, in the case of S^{35} at least, the main cause was back-scattering of radiation by the counter gas and counter walls from one half-counter to the other. They considered that $<0.1\%$ of the effect observed could be attributed to inner bremsstrahlung electrons in the cases of S^{35} and P^{32}. This latter observation agrees with recent experimental work (8, 40) where inner bremsstrahlung electron emission was found to occur very much less frequently than reported by Bruner (11).

The first problem attempted in this paper is the identification of the phenomena leading to coincident discharges. Back-scattering and absorption curves, as observed in a 4π steradian counter geometry, are then obtained.

EXPERIMENTAL AND RESULTS

The counter and most of the associated equipment were the same as described earlier (38). The total counting rate N_T (with the two half-counter anodes connected in parallel) is related to the counting rates above (n_a) and below (n_b) the source mount and to the coincidence rate (n_c) by the relationship

$$N_T = n_a + n_b - n_c. \qquad [1]$$

n_c may be obtained by measuring N_T, and then n_a and n_b separately by disconnecting each anode in turn. n_c is then obtained by subtraction of two large quantities, which gives rise to a large statistical error. Alternatively, as in this work, one may use an electronic coincidence circuit which obtains the result directly.

The two counter anodes were connected to different high voltage supplies. The outputs were fed separately into Atomic Instrument Co. Ltd. 205-B Pre-Amplifiers, Atomic Energy of Canada AEP 1448 non-overloading amplifiers, and Marconi AEP 908 scalers. The output signals of the two amplifiers, taken after discrimination from the output of the multivibrator stage, were fed into an Atomic Energy of Canada AEP 1509 coincidence unit and thence to a third AEP 908 scaler. A block diagram of the equipment appears in Fig. 1.

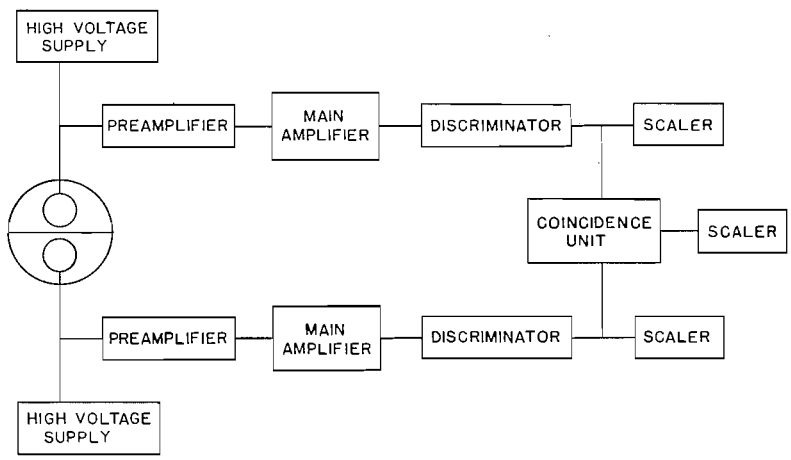

FIG. 1. Block diagram of electronic apparatus for coincidence experiments.

The two systems were shown to be matched using the threshold of the Ni^{63} plateau as a criterion.

The coincidence rates as measured were corrected for random coincidences. The rate at which random coincidences are recorded (N) when unrelated

sources of pulses occurring at rates of n_1 and n_2 are connected to the two inputs of the coincidence circuit is given by

$$N = n_1 n_2 t \quad [2]$$

where t is the effective resolution time of the circuit. The latter was determined to be 10.3 μsec. for a range of values for n_1 and n_2 (supplied by two independent proportional counters) and this value substituted into equation [2] was used to correct all subsequent data for random effects.

A disadvantage of measuring the coincidence rate directly, involving as it does an electrical separation of the two anode systems, is the appearance of positive pulses at the amplifier output, in addition to the usual negative pulses from the electron cascade. The amplitude of these positive pulses is observed to be a function of the diameter of aperture in the diaphragm separating the two half-counters, and of the polarization potential applied to the half-counter opposite to that in which they are produced. They are found to be in coincidence with negative pulses in the other half-counter, and to be nearly independent of the state of polarization of the hemisphere in which they are observed.

All the foregoing is consistent with this effect being due to induction of a positive pulse in one anode by the movement of the electron cascade away from it, towards the other. In normal counter operation, connection of the anodes in parallel eliminates the effect since the small positive pulse merely slightly reduces the amplitude of the negative pulse normally measured. In the coincidence experiments, the positive pulses are amplified but fail to trigger the discriminator circuit and so do not register. However, above 2.6 kv. polarization potential, the negative overshoot following the larger positive pulses begins to be effective in triggering the discriminator, and with the relatively long resolving time in use (10.3 μsec.), spurious coincidence counts are produced. In the experiments to be described below, conditions were always such that these spurious coincidences did not occur. The presence of these induced pulses of opposite sign, however, should always be considered in experiments where two halves of a 4π-counter are used separately.

The experimental results to be presented here fall into two main categories:

(*a*) The coincidence rate n_c was determined as a function of various diaphragm aperture sizes at a suitable polarization potential using β emitters with maximum energies covering the range 67 to 1700 kev. Methane, and argon +10% methane were the two counter filling gases used. In all cases but that of Ni^{63}, the sources were point sources prepared by evaporation of a carrier-free solution. For Ni^{63} the source was prepared as nickel dimethylglyoxime by a vacuum distillation method to be described in a forthcoming publication. Each source was prepared on a gold-coated VYNS film (5–10 μgm./cm.^{2}) which had been mounted over 5 cm. aperture. Measurements of n_a, n_b, n_c were made and N_T computed. A diaphragm with a smaller aperture was then placed over the film, and the measurements were repeated for a series of aperture sizes in this manner. The results of this series are plotted in Figs. 2 and 3. N_T was found to be independent of aperture size.

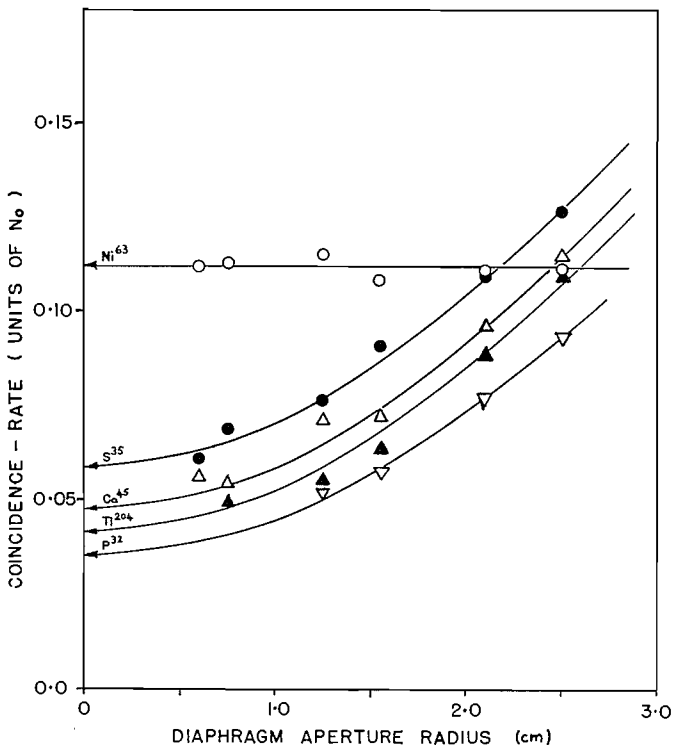

FIG. 2. Coincidence rate as a function of diaphragm aperture radius and beta end-point energy for methane counting gas.

(*b*) n_c, n_a, and n_b were measured for the same series of nuclides plus the α emitter Po^{210} as a function of source-mounting film-thickness with each of the counting gases mentioned. The aperture diameter remained constant at 2.5 cm. The sources were identical to those described previously. The results are shown in Fig. 4. In addition a thick source of Ni^{63} (2.6 mgm./cm.) was prepared. These curves show no features differing from those observed with the thin source, other than the expected additional absorption.

In all experiments at least 1000 coincidence events were recorded, giving a standard deviation of $\pm 3\%$.

In order to check on the operation of the counter with the greater mount thicknesses, the Ni^{63} characteristic was periodically checked. This at no time showed any unexpected features.

DISCUSSION

(*a*) *The Coincident Discharges*

The frequency of occurrence of the coincident discharges (as high as 20% of the disintegration-rate of pure β emitters even with very thin source mounts) allows one to eliminate many of the possible causes of this phenomenon. A low production probability, coupled in the relevant cases with a low counter response to photons, is sufficient to eliminate nuclear gamma radiation,

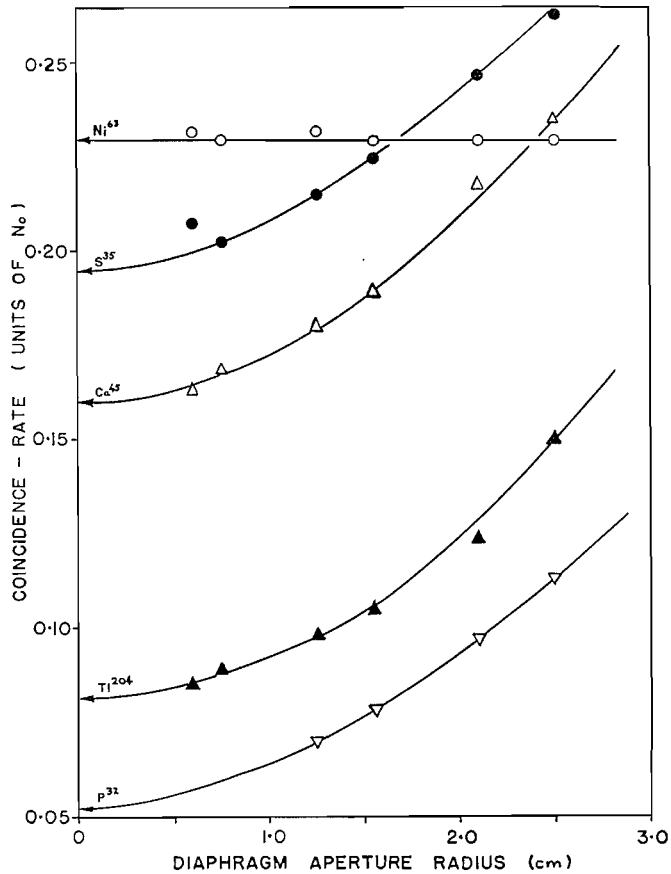

FIG. 3. Coincidence rate as a function of diaphragm aperture radius and beta end-point energy for argon + 10% methane counting gas.

conversion electrons, inner bremsstrahlung, and inner bremsstrahlung electrons (7, 9, 10, 35, 43, 49). Similarly bremsstrahlung production (3, 49) and secondary electron production (32, 33, 36) in the very thin film can be shown to be several orders of magnitude too low. Corresponding processes in the counter gas and walls may also be ruled out owing to absorption in the source-mount diaphragm and unfavorable geometrical conditions.

It appears that the only process of sufficient magnitude which could be responsible for a significant proportion of the coincidence events is back-scattering of radiation by the counter gas and counter walls into the other half-counter. (Back-scattering effects with $\ll 2\pi$ counters, e.g. end-window counters, have been shown to be of the necessary order of magnitude.) The rate of occurrence of coincidences due to scattering close to the source will be independent of the aperture diameter. That due to scattering further away from the source will increase with aperture diameter while that due to scattering at large distances will be proportional to the square of the aperture diameter.

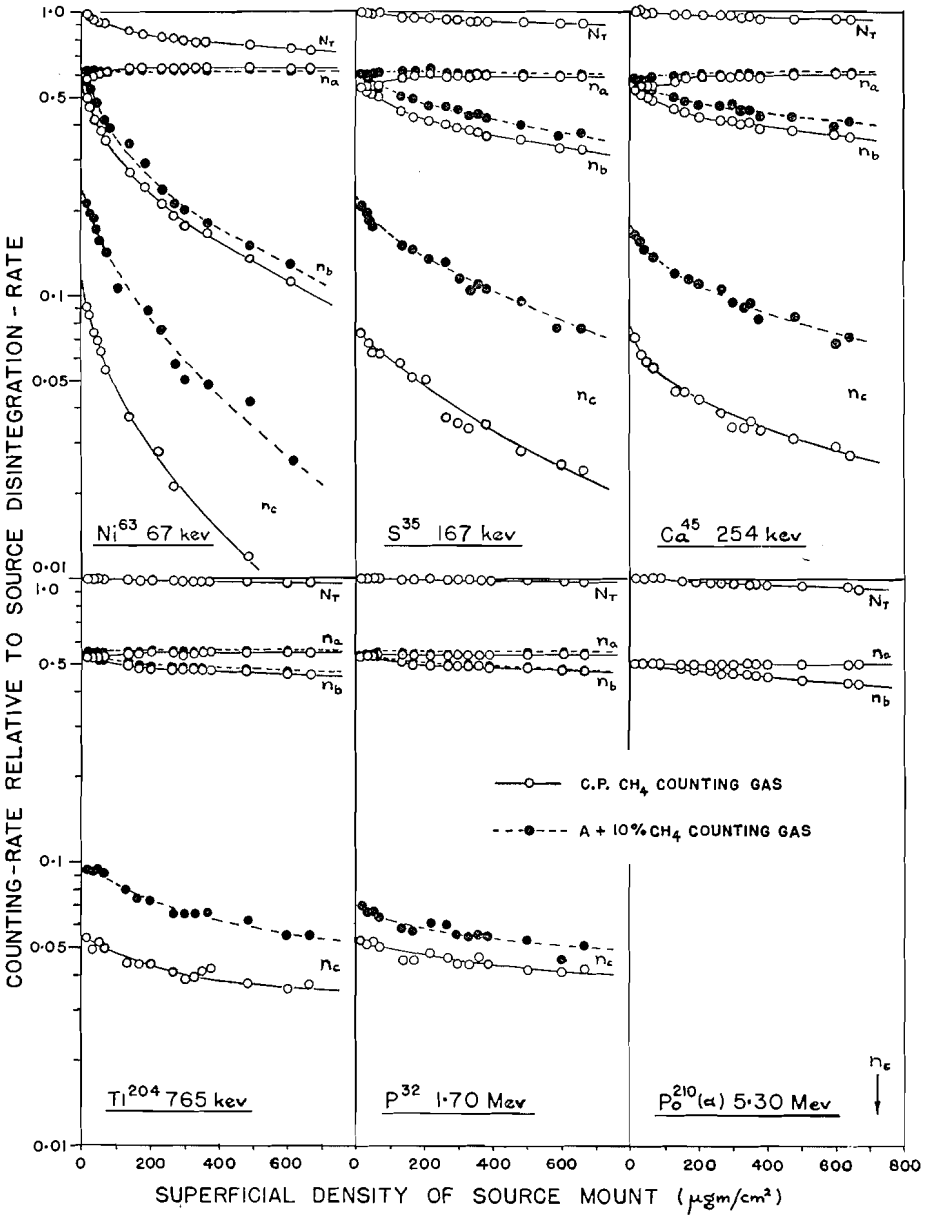

FIG. 4. Total counter, half-counter, and coincidence counting rates as a function of source-mount superficial density for beta emitters of increasing end-point energy and for Po^{210} alpha radiation for methane and argon+10% methane counting gases.

The contribution from either or both of these processes may be obtained from the data in Figs. 2 and 3. If the curves are extrapolated to $r = 0$, that part of the coincidence phenomenon which is independent of r can be separated. In Fig. 5 the values of n_c at $r = 0$ are plotted against the maximum energy of the β emitter. The values obtained for each counter gas lie on a smooth

curve and can be attributed to back-scattering from the gas in the neighborhood of the source. The relative positions of the curves for argon–methane ($\bar{Z} = 16$) and methane ($\bar{Z} = 2$) are consistent with the increased scattering expected (4) and observed by Yaffe and Justus (50) using material of higher atomic number. The form of the curves obtained here is similar to that observed by these authors for back-scattering from a constant thickness back-scatterer as a function of particle energy, if one neglects the fall-off they observed at very low energies. (This fall-off is undoubtedly due to preferential absorption of the back-scattered radiation in the counter window.)

The value of n_c for Ni^{63} is independent of aperture size as shown in Figs. 2 and 3. This is to be expected owing to the soft nature of this β radiation. An appreciable scattering will occur close to the source. Any other radiation will be absorbed by the counter gas.

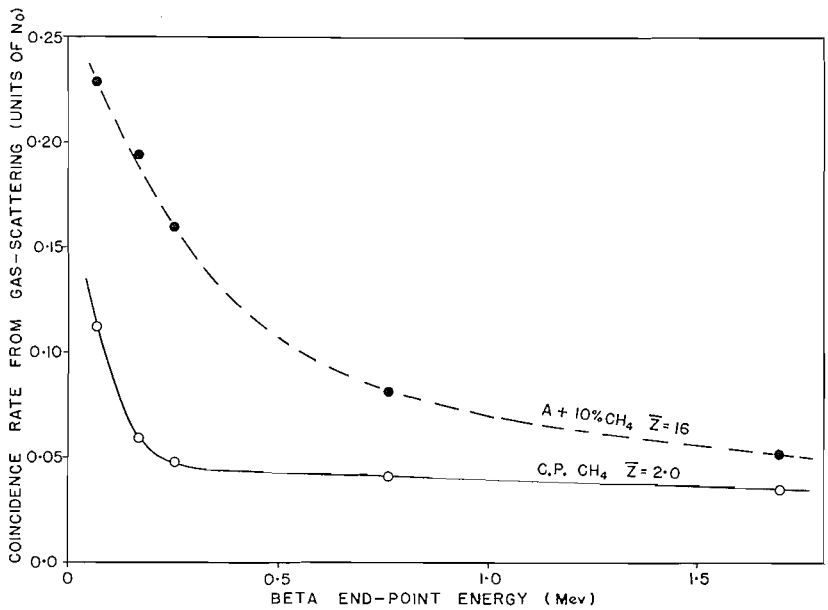

FIG. 5. Coincidence rate due to gas-scattering near the source, as a function of beta end-point energy for methane and argon+10% methane counting gases.

Measurements of Po^{210} α particles, as shown in Fig. 4, give values for n_c of less than 0.1% of the disintegration rate. This agrees with the foregoing interpretation since α radiation, for which the diffusion mechanism does not occur, can only back-scatter by large-angle single or plural scattering events, which are highly improbable. This value of 0.1% also serves as an upper limit enabling one to confirm that many of the processes suggested by other workers, e.g. secondary electron production by interaction with the source mount, are unimportant in this case.

Our conclusions regarding the origin of the coincidence phenomena agree with those of Hawkings (23), who studied the variation of coincidence rate with counting gas pressure using a S^{35} source.

(b) Absorption and Scattering of β Radiation by the Source-mounting Film

The curves shown in Fig. 4 can be resolved into the appropriate absorption and scattering components using methods somewhat similar to those used previously in calculations of this type (28, 44). Our treatment will however consider these components as functions of β particle energy and film thickness. One can assume a response probability of the counter of unity towards electrons and can neglect all processes involving the production of secondary electronic radiation as before. The relevant processes are absorption and elastic scattering in the source-mount film and back-scattering of electrons by the electron diffusion process near and far from the source.

During this part of the experiment the aperture diameter of the diaphragm between the two half-counters remained constant at 2.5 cm. If E is the maximum energy of the β radiation and d the film thickness, one can let

$p_1(E, d)$ = transmission of the film to the incident β radiation from the source,

$p_2(E, d)$ = the probability that β radiation originally emitted into the 2π steradian solid angle towards hemisphere A will be scattered by the film so as to enter the other hemisphere B,

$p_3(E)$ = the probability that the β radiation incident into either hemisphere is back-scattered by the counter gas at a distance small compared to the aperture diameter so as to enter the other hemisphere (one can neglect the small energy degradation by the film),

$p_4(E)$ = the probability that the β radiation incident into either hemisphere is back-scattered by the counter gas and/or counter walls at a distance comparable to or greater than the aperture diameter so as to enter the other hemisphere,

$p_5(E, d)$ = the transmission of the film to the back-scattered radiation arising from processes 3 and 4.

Other second-order effects may justifiably be neglected, e.g. wall scattering of back-scattered particles.

Using the above probabilities, the following expressions for the half-counter and coincidence counter rates are obtained where N_0 is the disintegration rate of the sample.

[3] $$n_a = \tfrac{1}{2}N_0[(1+p_2) + p_1 p_3 p_5 + p_1 p_4 p_5]$$

(incident + film scattering; near gas back-scattering from other hemisphere; far gas and wall back-scattering from other hemisphere)

[4] $$n_b = \tfrac{1}{2}N_0[(1-p_2)p_1+p_3 p_5+p_4 p_5]$$

[5] $$n_c = \tfrac{1}{2}N_0[p_3 p_5+p_1 p_3 p_5+p_1 p_4 p_5+p_4 p_5].$$

At $d = 0$, $p_5 = p_1 = 1$, and $p_2 = 0$,

$$n_{a_0} = n_{b_0} = \tfrac{1}{2}N_0[1+p_3+p_4],$$

and $$n_{c_0} = N_0[p_3+p_4].$$

Also $$N_T = n_a+n_b-n_c = \tfrac{1}{2}N_0[1+p_2+(1-p_2)p_1],$$

and at $d = 0$ $$N_T = N_0.$$

This agrees with the expectation that N_T will be independent of the factors governing the magnitude of the coincidence rate and differs from N_0 only owing to absorption in the film of that part of the radiation which escapes back-scattering. The values of n_a, n_b, and n_c can be obtained from Fig. 4. p_3 and p_4 are taken from Figs. 5 and 2 respectively. The unknown quantities p_1, p_2, and p_5 are obtained by substituting a series of values of E and d in equations [3], [4], and [5], and solving them simultaneously. The results are shown in Figs. 6 and 7.

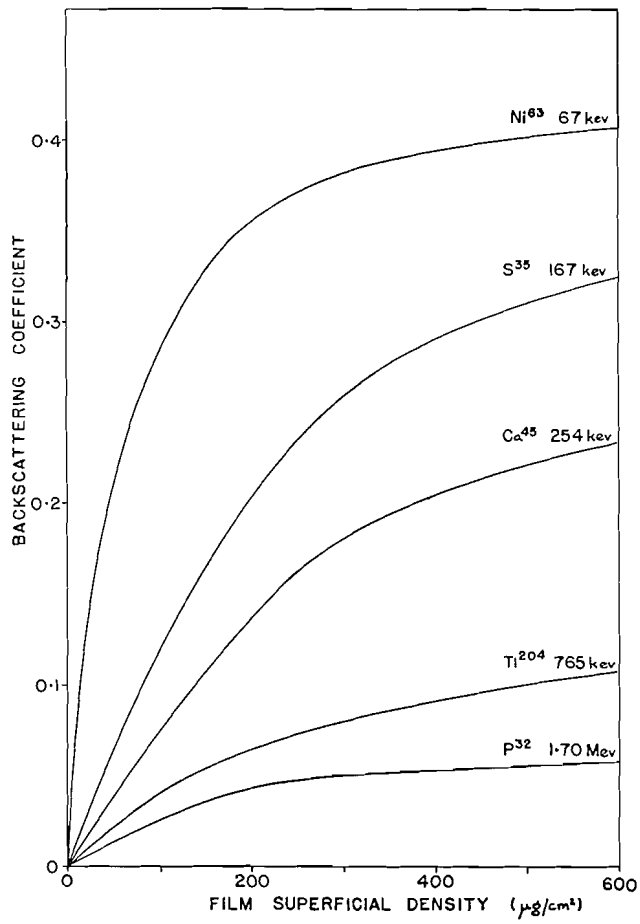

FIG. 6. Source-mount back-scattering coefficient (p_2) as a function of film superficial density for beta emitters of increasing end-point energy.

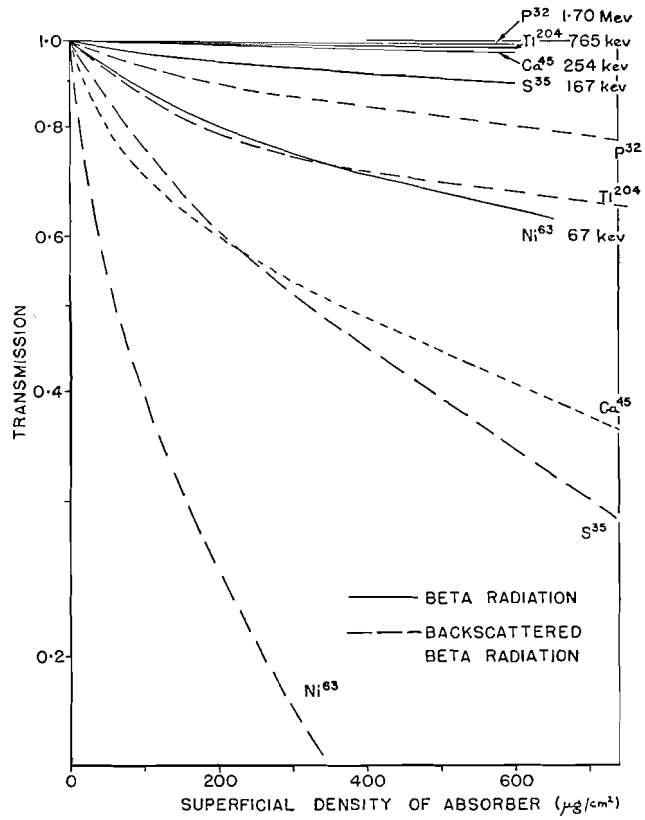

FIG. 7. Transmission of source mount to incident beta radiation (p_1) and to back-scattered beta radiation (p_5) as a function of film superficial density for beta emitters of increasing end-point energy.

Back-scattering of β Radiation from Thin Films

The curves of p_2, the film back-scattering coefficient, bear a superficial resemblance to the results of previous work using $\ll 2\pi$ counter systems. The magnitude of the effect observed here is much larger at low film thicknesses in agreement with the previous observations by other workers (14, 47, 48), who used much thicker films than we did. In contradistinction to the $<2\pi$ systems, back-scattering at a given mount thickness was found to be greatest for the lowest energy β emitter. This is consistent with the suggestion that the scattering effects observed here are due to single scattering events involving electrons incident at small angles to the film, rather than to the electron diffusion type of back-scattering. The Rutherford-type scattering of relativistic electrons by atoms, described for example by McKinley and Feshbach (30), will occur predominantly at very small angles, will fall off rapidly as the scattering angle increases, and will be greatest for small electron energies.

Absorption of Incident and Back-scattered Radiation

In Fig. 7 the absorption curves for the incident and the back-scattered β radiation are compared. The energy degradation of the back-scattered radi-

ation is found to be much greater than that observed in the $\ll 2\pi$ system. In the latter case a ratio of 0.4–0.8 for the ratio of half-thicknesses or ranges of the back-scattered to the incident radiation is found. In this work, for Ni^{63} for example, we find a half-thickness ratio of about 0.05. Our results, in agreement with those of Balfour (1), clearly indicate the existence of a large proportion of very low energy particles in the spectrum of the back-scattered radiation. This is observable because of the "windowless" nature of the counter.

(c) "Sandwich" Procedure for Correcting for Source-mount Absorption Losses

It was shown in an earlier publication (39) that the correction for source-mount absorption losses by the "sandwich" method leads to erroneous values being obtained for the source disintegration rate. Mann and Seliger (28) formulated the following expression for the fractional absorption τ in a film,

$$\frac{\tau}{2} = \frac{N_T - N_S}{2N_T - N_S},$$

where N_T and N_S are the counting rates observed for a source mounted on one film and in a "sandwich" respectively.

By inspection, using nomenclature as defined above, $N_S = N_0 . p_1$ and

$$\frac{\tau}{2} = \frac{(1-p_1)(1+p_2)}{2(1+p_2-p_1p_2)}.$$

If one assumes as Mann and Seliger have done that p_2, the back-scattering by the film, is negligible, then τ would equal $(1-p_1)$, the film absorption as expressed in our nomenclature. However one can see from Fig. 6 that p_2 cannot be neglected without introducing a fairly large error. Mann and Seliger assumed also that

$$N_T = N_0 - \tfrac{1}{2} N_0 . \tau,$$

i.e. that half the emitted radiation entered the film and a fraction of this would be absorbed. However this half is reduced by the back-scattered portion. This introduces an error in the opposite direction. Despite this fortuitous cancellation of errors, the "sandwich" process can only be considered as an approximation in disintegration-rate determinations.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council of Canada and Atomic Energy of Canada Ltd. for grants-in-aid. We would also like to express our appreciation to Dr. R. E. Bell for valuable discussions during the preparation of this manuscript. One of us (B. D. P.) wishes to thank N.R.C. for assistance in the form of a studentship.

A DIELECTRIC STUDY OF PLASTICIZED POLYVINYLIDENE CHLORIDE[1]

By B. L. Funt and T. H. Sutherland[2]

ABSTRACT

The electrical response of plasticized polyvinylidene chloride has been studied over a wide range of frequency, temperature, and plasticizer content. The dispersion region was shifted to lower temperatures at a given frequency on the addition of alpha chloronaphthalene as plasticizer, but remained practically unchanged with hexachlorobenzene as plasticizer. Comparison was made with mechanical measurements for plasticized vinylidene chloride copolymers and reasonable agreement between electrical and mechanical properties was found. Enthalpies and entropies for dielectric relaxation were calculated on the theory of absolute reaction rates and were compared with values for plasticized polyvinyl chloride. A calculation of plasticizer efficiency from electrical measurements was attempted on the basis of a method suggested by Dyson. An interesting empirical relationship between enthalpy and entropy of activation and plasticizer content in polyvinyl chloride and polyvinylidene chloride is presented.

Previous studies of the electrical response of plasticized polymers have contributed to the elucidation of the mechanism of interaction between a polar polymer and a plasticizer. In general the presence of a plasticizer serves to decrease the attractive forces between neighboring polymer chains and results in a softer and more pliable material. In a polar polymer, this increased freedom of molecular movement will be evident in a corresponding increase in the ability of polar groups to respond to an applied alternating electric field. The ease with which dipoles follow the impressed field can be measured by the characteristic Debye dispersion curves at a given temperature. Where a strong intermolecular attraction exists dielectric dispersion will occur at a relatively low frequency at which a sigmoidal change of dielectric constant with frequency and the appearance of a loss factor maximum will be exhibited. On the addition of plasticizer the dispersion region shifts to higher frequencies indicating a lower internal viscosity and a greater freedom of chain movement.

While the general features of plasticizer action and their investigation by dielectric methods were established by Fuoss (7, 8, 9, 10, 11, 12, 13, 14, 17) there has been considerable latitude in the quantitative interpretation of the data. Attempts have been made to relate plasticizer efficiency to size, shape, and polarity of the plasticizer molecule and to correlate electrical and mechanical properties (19). Although a relatively large number of investigations have been reported almost all of them have been confined to the study of plasticized polyvinyl chloride (2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 17). Consequently the validity and generality of many of the theoretical comparisons have rested on the experimental confirmation found with this polymer.

It therefore appeared advisable to initiate experimental work with other similar polar plasticized polymers in order to test some of the current views

of the dielectric interpretation of plasticizer action. Vinylidene chloride was selected for its chemical similarity to vinyl chloride.

APPARATUS

The electrical apparatus has been described previously (6, 18). In the current work a General Radio precision sample holder was used. The side plates were removed from the holder in order to permit its being thermostatted in an air thermostat maintained to ±0.05°C. A thermocouple was inserted in the housing of the sample holder to provide a further check of the sample temperature.

CHEMICALS

Polyvinylidene chloride (Saran A) of weight average molecular weight 10,000 and 100,000 was provided through the courtesy of the Dow Chemical Company.

Alpha chloronaphthalene, Eastman, reagent grade, was used as obtained. The lead stearate used was Wittco No. 10, and was not purified further.

The samples were prepared by treating the pulverized polymer in a 70:30 mixture of benzene and 2-butanone to which the plasticizer was added. After refluxing for four to five hours the samples were dried *in vacuo* for 24 hr. and then pressed into thin disks at a temperature of 135–165°C. and a pressure of 5000 lb./in^2.

After cooling, the samples were coated with aquadag and then placed into the sample holder.

RESULTS

The dielectric constant and loss factor of each sample was measured at frequencies of 50, 100, 300, 1000, 3000, 10,000, 30,000, and 100,000 cycles per second at temperature intervals of 5°C. throughout the dispersion range. The data are shown graphically in Figs. 1 to 6 for concentrations of 0 to 24.8% alpha chloronaphthalene plasticizer by weight.

The addition of a good plasticizer progressively decreases the temperature at which dispersion occurs at a given frequency. For instance, the maximum of the loss factor curve (f_{max}) changes by 35°C. from the unplasticized to the most plasticized sample at 3 kc. A plot of log f_{max} versus reciprocal temperature is expected to yield a straight line whose slope determines ΔH^*, the free enthalpy of activation. Such plots are shown in Fig. 7 for the data obtained at 3 kc. with alpha chloronaphthalene. Pronounced curvature is shown, particularly if the 100 kc. points are included. For the data in Table I the slopes were determined by the method of least squares, and weighting factors were used to compensate for the lower precision at the extremes of frequency. The relative weighting factors at each frequency were 50 c.p.s. (3), 100 c.p.s. (3), 300 c.p.s. (4), 1 kc. (4), 3 kc. (4), 10 kc. (4), 30 kc. (3), and 100 kc. (1). The curvature shown in the plots for activation energy is not new; a similar phenomenon is shown in Dyson's data for polyvinyl chloride (3).

The free energies, enthalpies, and entropies for dielectric relaxation were calculated by the method described by Kauzmann (16) and are also tabulated in Table I.

The data of Table I can be compared with similar data obtained from dielectric investigations of other polymer systems, and for plasticized polyvinyl chloride. For a given comparison the relative magnitudes of the enthalpies and entropies of activation are significant, and reflect freedom of movement of segments of the polymer chains.

It can be seen from Table I that for alpha chloronaphthalene, which is a relatively good plasticizer for polyvinylidene chloride, the dispersion region is shifted to lower temperatures with increasing plasticizer content. The enthalpy and entropy values are also lowered corresponding to increased freedom of segmental motion in the polymer chains. With hexachlorobenzene, however, the effect of plasticizer is very slight, the temperature range of the dispersion region remains unchanged, and the enthalpy and entropy values remain relatively constant even at plasticizer concentrations of 75% by weight. One must conclude that true plasticization is not occurring in this instance, and that a macro dispersion of plasticizer in polymer is being obtained.

The results with different unplasticized polymers are also shown in Table I. Polymer S-1 was a Dow Chemical Co. sample of weight average molecular weight 10,000 and S-2 was a similar sample of molecular weight 100,000. Sample P was obtained from S-1 on the addition of 1% by weight of lead stearate as a thermal stabilizer. Sample T was obtained by emulsion polymerization of vinylidene chloride under nitrogen at 25°C. using a persulphate activator, and was not fractionated.

The results obtained with these materials confirm the slight dependence of the position of the dispersion region on molecular weight. This is doubtless due to the segmental nature of the electrical response (16).

The mechanical properties of a vinylidene chloride 85% – vinyl chloride 15% copolymer have been reported by Havens (15). These data can be compared with the electrical results obtained in the present work. For this purpose we define temperature T_x obtained by extrapolation of the electrical data to a relaxation time τ of one second, where the relaxation time is defined as 2π times frequency of maximum absorption. The relaxation time of one second is comparable to that of a mechanical test, and is usually chosen where a comparison of electrical and mechanical properties is desired.

In Fig. 7 the flex temperatures determined by Havens and T_x values obtained in this work are plotted against plasticizer content for comparison. It is evident that quite good agreement is obtained.

A most detailed interpretation of data on plasticized polymers has been attempted by Dyson (3). If a typical relaxation mechanism involves n monomer units, then the enthalpy of activation, ΔH^*, is nM calories per mole where M is the attractive energy between two chains per monomer length. For vinylidene chloride M has been reported as 1890 cal. per unit (1). If there are r alternative configurations available in the excited state the n monomer units will have r^n configurations available and the entropy of activation can be expressed as

$$S^* = R \ln r^n$$

where R is the gas law constant.

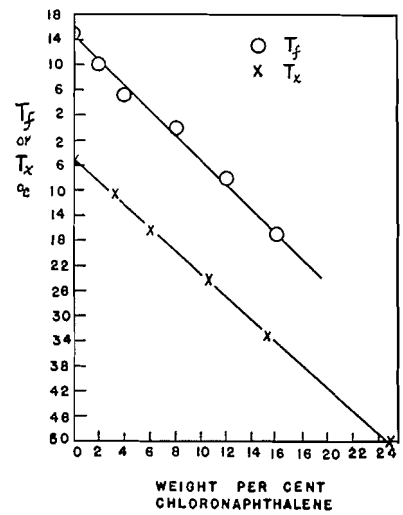

FIG. 7. Comparison of mechanical and electrical data.

Dyson has further elaborated his argument to include plasticized systems. He suggests that a plot of $1/\Delta H^*$ against volume fraction plasticizer should yield a straight line whose slope could be interpreted to indicate the tendency for plasticizer molecules to 'cluster'. The present data (and some of the data on polyvinyl chloride) do not yield a good linear relationship. Nevertheless the slope of the best line was taken and using the appropriate data a value for q of 6 was obtained for alpha chloronaphthalene, and a value approaching infinity for hexachlorobenzene. The significance of q on this picture is that it represents the number of plasticizer molecules in a cluster. One would interpret a large value of q as indicative of poor plasticizer action and a low value as giving high plasticizer efficiency. Corresponding values for polyvinyl chloride are 4.4 and 2.3 with tricresyl phosphate, 4.8 with diphenyl, and 1.7 with dioctyl phthalate, according to Dyson. These latter values would be reduced by the factor 1040/1520 if Bunn's recent values for cohesive energy (1) are used instead of those adopted by Dyson.

An interesting empirical relationship between plasticizer content and enthalpy and entropy of activation was discovered. It was found that on a logarithmic plot of enthalpy of activation against mole per cent polymer the data for all good plasticizers for a given polymer were found to fall on the same straight line. This is shown in Fig. 8 where the data of Fuoss for tetralin and diphenyl and of Daniels, Miller, and Busse for tricresyl phosphate as recalculated by Dyson (3), and of Fitzgerald and Miller (5) for dimethyl thianthrene plasticizers in polyvinyl chloride are shown. It should be noted that Dyson's treatment of enthalpy data yields different slopes for different plasticizers. The present empirical relationship shows agreement for all good plasticizers in a given polymer. Our data for polyvinylidene chloride plasticized with alpha chloronaphthalene are shown in Fig. 9. Again the agreement with a

linear relationship is reasonable, but the slope of the line is different for this polymer than for polyvinyl chloride.

SOME CALCULATIONS OF THE SURFACE ENERGY OF MAGNESIUM OXIDE[1]

By G. C. Benson and R. McIntosh[2]

ABSTRACT

Calculations of the surface energy of an undistorted {100} face of crystalline magnesium oxide have been made. An exponential form of the repulsive energy term was used, and the van der Waals attractive energy between dipoles was included, as in the Born–Mayer treatment of cohesive energy. Comparison with earlier work is made, and it is shown that results are markedly dependent upon the form of the repulsive potential term, the inclusion of the van der Waals term, and, indeed, the choice of coefficients of the van der Waals term. This is not the case so far as the calculated cohesive energies are concerned. The results indicate that a Born–Mayer model may be inadequate in the case of magnesium oxide, and that caution must be exercised before accepting surface energies arrived at by such calculations.

INTRODUCTION

In early theoretical calculations concerning the properties of ionic crystals the potential energy of interaction between ions was taken to be the sum of the coulombic and the repulsive terms. Originally the latter was represented through an inverse power law, but this was later replaced by an exponential form more in accord with a quantum mechanical consideration of the interaction between closed shells of electrons. A further refinement was the inclusion of terms for the van der Waals attraction between the ions. This model of an ionic crystal, usually referred to as the Born–Mayer model, has been quite successful in explaining the cohesive properties of the alkali halides and other ionic crystals. It has also been adopted in calculations of the surface energy of such crystals. In this case the theoretical problem is complicated by the asymmetrical field at the surface, which leads to polarization of the ions and distortion of the lattice near the surface. Consideration of these effects by Lennard-Jones and Dent (12) and Verwey (21) indicates that they will lead to a decrease of the surface energy below the value calculated for an undistorted crystal. Calculations due to Shuttleworth (18) show that although the van der Waals terms play a rather minor role in the cohesive energy of the alkali halides, they make a substantial contribution to the calculated surface energy of these crystals.

Unfortunately there are very few experimental data on which to base a judgment of the utility of the Born–Mayer theory in calculating surface energies. In the case of sodium chloride (3) the experimental evidence, though admittedly inconclusive, is that the surface energy is higher by a factor of two or three than the value obtained by the application of the Born–Mayer theory. The only other material for which data are available is magnesium oxide, for which Jura and Garland (10) have reported a surface energy of 1040 ergs per cm.^{2}, in good agreement with the only available theoretical value calculated

by Lennard-Jones and Taylor (13) some thirty years ago. Since in their calculation Lennard-Jones and Taylor employed the older form of repulsive potential (an inverse 10th power) and did not consider the van der Waals contribution, a reinvestigation of the problem is of some interest and is the purpose of the present communication.

METHOD OF COMPUTATION

According to the Born–Mayer (4) theory, the cohesive energy at 0°K. of a bivalent ionic crystal of sodium chloride type structure is given by

$$U = 1.7476 \times \frac{4\epsilon^2}{r_0} + \left[a_{+-}A_6' + \left(\frac{a_{++}+a_{--}}{2} \right) A_6'' \right] \frac{1}{r_0^6} - 6b[(e^{(r_+ + r_-)/\rho})\, e^{-r_0/\rho} + (1.5\, e^{2r_+/\rho} + 0.5\, e^{2r_-/\rho})\, e^{-\sqrt{2}\, r_0/\rho}].$$

In this equation zero point energy and van der Waals terms higher than those between dipoles have been omitted. The symbols employed are defined as follows:

r_0 is the nearest neighbor distance at 0°K.,

ϵ is the value of the electronic charge,

a_{++}, a_{--}, a_{+-} are van der Waals coefficients,

A_6', A_6'' are lattice sums tabulated by Jones and Ingham (9),

r_+, r_- are the Pauling radii of the ions,

b, ρ are the constants in the expression for the repulsive potential.

The corresponding expression for the surface energy of an undistorted {100} face of the crystal, that is, neglecting polarization of ions and changes of lattice spacing, is

$$\sigma = \frac{1}{2r_0^2}\left\{ 0.065246 \times \frac{4\epsilon^2}{r_0} + \left[a_{+-}B_6' + \left(\frac{a_{++}+a_{--}}{2} \right) B_6'' \right] \frac{1}{r_0^6} - b[(e^{(r_+ + r_-)/\rho})\, e^{-r_0/\rho} + 2(1.5\, e^{2r_+/\rho} + 0.5\, e^{2r_-/\rho})\, e^{-\sqrt{2}\, r_0/\rho}] \right\}$$

where B_6', B_6'' are lattice sums tabulated by Shuttleworth (18).

In applying these equations to magnesium oxide, difficulties arise in connection with the choice of the van der Waals coefficients and the constants in the term for the repulsion. Mayer and Maltbie (15) in their calculations of the cohesive energy employed $\rho = 0.345 \times 10^{-8}$ taken from previous work on the alkali halides. This choice was apparently dictated by the fact that the authors wished to deal with a series of alkaline earth oxides, and compressibility and other data necessary for a more direct adjustment of ρ were not available for the entire series. de Boer and Verwey (7) in repeating these calculations have also taken $\rho = 0.345 \times 10^{-8}$. Both groups of authors pointed out that this value of ρ is probably too small. In the present work, Bridgman's data for the compressibility and thermal expansion of magnesium oxide (5), together with a nearest neighbor spacing of 2.101_5 Å (22) at 30°C., have been used to calculate ρ and b in the manner outlined by Born and Mayer (4).

In treating the van der Waals term there is considerable uncertainty in the

choice of the "a" coefficients. Several possibilities have been considered, and thus this term is:

(a) Omitted.

(b) Evaluated from the London formula (14) using the ionization potential of Mg^{++} (1), the electron affinity of O^- in the crystal estimated from the edge of the ultraviolet absorption spectrum of the magnesium oxide crystal* (19), and the polarizabilities of the Mg^{++} (17) and O^{--} (20) ions.

(*c*) Evaluated from the Kirkwood–Müller formula (14), using, in addition to the polarizabilities referred to above, the diamagnetic susceptibilities of the ions calculated by Slater's method as has been recommended by Myers (16).

(*d*) Taken from the table compiled by Fowler (8).

See Table I for numerical values of these coefficients.

The particular choice made caused some variation of the constant ρ deduced from compressibility data. It should be noted that whatever method was utilized to obtain the van der Waals coefficients, the contribution to the cohesive energy obtained by us was greater than the values recorded by Mayer and Maltbie (15) and by de Boer and Verwey (7). We have not been able to ascertain the source of their values.

Results are recorded in Tables II and III. The choices made in dealing with the van der Waals term are indicated, as well as the parameters of the crystal which were employed. Both our computations and those of earlier workers have been summarized. Where individual terms are given which were not stated in the work of the original authors, these were evaluated by us from their publications.

DISCUSSION

Attention should be drawn to the range of values which may be obtained for the surface energy of magnesium oxide due both to the choice of the function employed for the energy of repulsion and to the values selected for the van der Waals attractive terms. These choices are of minor importance in the case of the cohesive energy, but are of extreme importance in the case of the surface energy.

The results raise the general question whether or not the use of the Born–Mayer model is justified to calculate the surface energy of ionic crystals, or whether the discrepant results are due to its inadequacy in the special case of magnesium oxide. Brill, Hermann, and Peters (6) have stated on the basis of X-ray measurements of electron density that magnesium oxide is not completely ionic in character in the solid state. They support their contention by reference to the work of de Boer and Verwey (7), in which the electron affinity of O is calculated for the series of alkaline earth oxides, by means of cohesive energies and the Born cycle. It is pointed out that the oxides of beryllium and magnesium have high values of the electron affinity when determined in this way. It should be noted, however, that these values are based upon the use of $\rho = 0.345 \times 10^{-8}$, which, as has been pointed out above, may lead to erroneous results. The experimental evidence must be recognized, however, and since de Boer and Verwey also point out that the bond in the gaseous magnesium oxide molecule is quite covalent in character, the treatment of the problem by a model assuming complete ionic character may not be justified. This does not, however, explain the wide variations in the computed values which are recorded in Table III. These arise from changes in the assumed values of the coefficients, changes which did not materially affect the cohesive energy. The results emphasize the sensitivity of calculated values of surface energy to the details of computation. They also suggest that the agreement between the Lennard-Jones and Taylor result and the experimental value of Jura and Garland may be fortuitous. The result obtained by Jura and Garland is of a preliminary nature as the authors have stressed (11) and the general procedure must be carefully assessed as Bauer (2) has emphasized. It would therefore seem that further experimental data are urgently required, and that some caution must be exercised in the use of calculated values until experimental results have been accumulated.

THE PREPARATION OF L-SORBOSE FROM 5-*KETO*-D-GLUCONIC ACID (L-SORBURONIC ACID)[1]

By J. K. N. Jones[2] and W. W. Reid[3]

ABSTRACT

L-Sorbose has been prepared from 5-*keto*-D-gluconic acid.

INTRODUCTION

The most convenient method of preparation of L-sorbose is undoubtedly from the biochemical oxidation of sorbitol (1). The purpose of this communication is to demonstrate how D-glucose can be converted to L-sorbose by purely chemical transformations. The starting product was the calcium salt of 5-*keto*-D-gluconic acid (L-sorburonic acid) which had been prepared by biochemical oxidation of D-glucose (4). Salts of this acid can be prepared by prolonged oxidation of D-glucose with bromine (3) or electrolytically (2). When the calcium salt was shaken with methanolic hydrogen chloride it dissolved with the formation of a mixture of products composed mainly of the methyl glycoside methyl ester of 5-*keto*-D-gluconic acid. The carbomethoxy group of this glycoside was reduced with sodium borohydride to the alcohol with the formation of methyl L-sorbofuranoside from which L-sorbose was prepared by hydrolysis.

Since the oxidation of sugars by bromine water to 5-*keto*hexonic acids is a general reaction (3) the interconversion of aldoses to ketoses with concomitant inversion of the chain of hydroxyl groups becomes possible.

EXPERIMENTAL

Solutions were evaporated under reduced pressure. Optical rotations were measured in water at 20°±2° (unless otherwise stated). Sugars were separated chromatographically in either (*a*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4, v/v) or (*b*) *n*-butanol–water–pyridine (18:3:3, v/v), and detected with the *p*-anisidine–hydrochloride spray.

Methyl 5-keto-D-Glucofuronic Acid Methyl Ester

The calcium salt of 5-*keto*-D-gluconic acid hydrate ($2\frac{1}{2}$, H_2O) (22 gm.) was suspended in methanol (500 ml.) and hydrochloric acid (d. 1.12, 20 ml.) added. The mixture was stirred overnight when a clear solution resulted. The pale yellow reaction mixture was heated at 40°C. for 24 hr., cooled, and then passed down columns of Amberlite resin 1R120 and 1R4B, which had been washed previously with dry methanol. The effluent was concentrated to a sirup (17 gm.) which was dissolved in acetone and filtered from insoluble material. The resultant methyl ester methyl glycoside was obtained as a pale yellow

non-reducing sirup (14.2 gm.) $[\alpha]_D$ −24° (*c*, 3.6 in MeOH). Found: OMe, 28.1%. Calc. for $C_8H_{14}O_7$: OMe, 27.9%. The product contained three components, detected chromatographically, which moved, relative to rhamnose (R_{RH}), at the rates 1.25, 1.59, and 1.98 (solvent (*b*)). They gave yellow orange spots with the *p*-anisidine spray. The fastest moving material was present in traces only. 5-*keto*-D-Gluconic acid had R_{RH} 0.95 in solvent (*a*).

Methyl L-*Sorbofuranoside and* L-*Sorbose*

The methyl ester methyl glycoside (2 gm.) was dissolved in water (10 ml.) and sodium borohydride (0.5 gm.) added. The solution became warm and changed color from pale yellow to pale green. After 24 hr., excess of acetic acid was added and the solution was deionized on Amberlite resins 1R120 and 1R4B. On concentration a sirup (1.28 gm.) remained which contained five components. These materials moved on the chromatogram relative to rhamnose at the rates 0.38, 0.91, 1.07, 1.87, and 2.12 (solvent (*b*)). The slowest moving component which reduced Fehling's solution was identified as sorbose, and results probably from the hydrolytic action of the acidic resin on the methyl furanoside. The components with R_{RH} 0.91 and 1.07 behaved like methyl sorbofuranoside whilst the fastest two components which were present in trace amounts only were not identified. The mixture was heated with *N* sulphuric acid for three hours at 100°C., cooled, neutralized ($BaCO_3$), and filtered. The filtrate on concentration gave crystalline L-sorbose, which was recrystallized from methanol. The product (0.71 gm.) had m.p. 165°C. not depressed on admixture with an authentic specimen, moved on the chromatogram at the same rate as sorbose, and had $[\alpha]_D$ −41° (*c*, 1.1). Found: C, 40.1; H, 6.9%. Calc. for $C_6H_{12}O_6$: C, 40.0, H, 6.7%.

MERCURY PHOTOSENSITIZED DECOMPOSITION OF ETHYLENE OXIDE[1]

By R. J. Cvetanović

ABSTRACT

Some aspects of the mercury photosensitized decomposition of ethylene oxide at room temperature have been reinvestigated. At least two, and probably more than two, distinct primary steps occur. The previously assumed major primary formation of hydrogen by a molecular process is shown to occur to a relatively small extent only. Hydrogen atoms play an important role in the process, as well as the following radicals: CH_3, CHO, CH_2CHO, and C_2H_5, and probably to a lesser extent also CH_2. The products formed are CO, H_2, C_2H_6, a little CH_2CO and C_2H_4, and large amounts of aldehydes. The presence of higher aldehydes has been demonstrated. While there is a general similarity to the other modes of decomposition of ethylene oxide, a unique and unambiguous solution of the complete reaction mechanism is at present not possible.

In a previous publication (5) an investigation of the reaction of oxygen atoms with ethylene has been reported. The primary step of the readily occurring reaction is believed to be a direct addition of the oxygen atom to the double bond in ethylene. Very little or no ethylene oxide is found, however, and a variety of products is formed instead, presumably as a result of further reactions of the initially produced energy rich molecule

$$C_2H_4+O \rightarrow C_2H_4O^* \qquad [1]$$
$$C_2H_4O^* \rightarrow \text{products.}$$

A support for this view is found in the similarity of the products formed in this process with those reported in the literature for the thermal, photolytic, and mercury photosensitized decomposition of ethylene oxide. All these processes appear to be quite complex and are difficult to treat in an unambiguous manner. While their courses cannot be expected to be identical, the over-all similarity suggests that a comparative study may yield useful information regarding the more important features of the respective mechanisms.

An investigation of the mercury photosensitized decomposition of ethylene oxide was reported in 1948 by Phibbs, Darwent, and Steacie (12). The observed products were CO, H_2, CH_3CHO, and a polymer, as well as smaller amounts of CH_4, HCHO, and of a fraction indicated as "C_2 hydrocarbons" but not further analyzed. It was postulated that initially an energy rich ethylene oxide molecule was formed and that it was capable of isomerizing to acetaldehyde or splitting in the following manner

$$C_2H_4O^* \rightarrow H_2+CO+CH_2. \qquad [2]$$

Only a small portion of the primary process was considered to proceed by the reaction

$$C_2H_4O+Hg^* \rightarrow C_2H_3O+H+Hg \qquad [3]$$

(Hg* refers to Hg $6(^3P_1)$ atoms). All the hydrogen is, therefore, supposed to

[1]*Manuscript received July 18, 1955.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 3741.

be formed by a molecular process and a very minor role is ascribed to hydrogen atoms.

Direct photolysis of ethylene oxide in the far ultraviolet was reported in 1950 by Gomer and Noyes (8). The products formed were CO, H_2, CH_4, C_2H_6, smaller amounts of HCHO and CH_3CHO, and almost certainly some C_2H_5CHO. The authors were led to assume for the primary step the reaction

$$C_2H_4O+h\nu \rightarrow CH_3+HCO \qquad [4]$$

followed by (or simultaneous with)

$$HCO \rightarrow H+CO. \qquad [5]$$

A considerable amount of work has been done on thermal decomposition of ethylene oxide. A recent investigation was conducted by Lossing, Ingold, and Tickner (10) who were able to observe directly by a mass spectrometer the products of the pyrolysis at 800 to 1000°C. They found CO, H_2, CH_4, C_2H_6, CH_2CO, and an abundant formation of methyl but no methylene radicals. Propane, formaldehyde, and acetaldehyde, reported previously at lower temperatures, were not formed. Mueller and Walters (11) found that at 400°C. acetaldehyde, ketene, and some formaldehyde were formed but not propionaldehyde, at least not in amounts comparable to those of acetaldehyde.

Both Lossing and his co-workers and Mueller and Walters find it necessary to ascribe an important role in the thermal decomposition of ethylene oxide to the primary splitting into CH_3 and HCO, analogous to the reactions [4] and [5] proposed by Gomer and Noyes, and to abandon the classical view of a primary formation of methylene radicals and formaldehyde. The well-known use of ethylene oxide as an excellent source of methyl radicals is thus made more easily understandable. In the reaction of oxygen atoms with ethylene the products formed (CO, paraffinic aldehydes, H_2, CH_4, C_2H_6, C_3H_8, and probably some CH_2CO) suggest a somewhat similar mode of decomposition of the initially formed intermediate. The mechanism proposed for the mercury photosensitized decomposition, on the other hand, is very different. The present work has been carried out, therefore, in order (1) to obtain further information on products formed in the mercury photosensitized decomposition of ethylene oxide, (2) to test the postulated molecular production of hydrogen and other features of the previously proposed mechanism, (3) to attempt to correlate the main features of this process with the other modes of decomposition of ethylene oxide, and (4) to attempt, by analogy, to formulate the more important of the secondary reactions following the addition of oxygen atoms to ethylene.

EXPERIMENTAL

The reaction was studied at room temperature using a conventional type of apparatus, including a cylindrical quartz reaction vessel (5 cm. in diameter, 10 cm. long). The apparatus and the analysis of products have been described in detail previously (3, 5).

Ethylene oxide was obtained from Matheson Co., Inc., ethylene was supplied by Ohio Chemicals Canada, Ltd., and butene-1 was a Phillips reagent grade

product. All the three reagents were further purified by repeated bulb to bulb distillation *in vacuo*. Deuterated ethylene oxide was kindly supplied by Dr. D. J. Worsfold of these laboratories.

The quantum yields of reaction products were determined relative to the formation of hydrogen by mercury photosensitized decomposition of 200 mm. of *n*-butane, and taking 0.50 for the value of ϕH_2, as found by Bywater and Steacie (1).

RESULTS

The pressure dependence of the quantum yields of formation of some of the products in the mercury sensitized decomposition of ethylene oxide is shown in Fig. 1. The trends in the H_2, CO, and CH_4 formation are in agree-

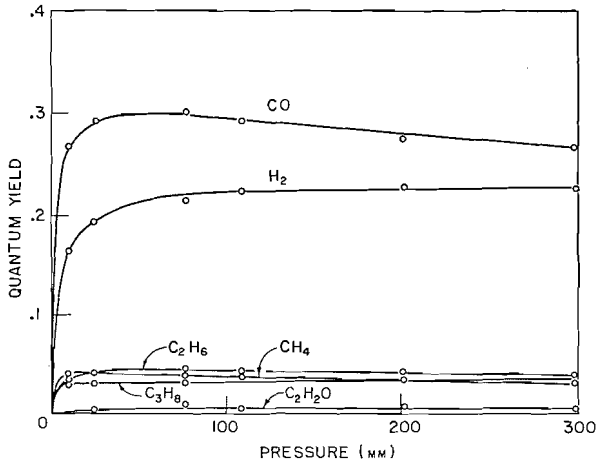

FIG. 1. Pressure dependence of the quantum yields of formation of some of the products in the mercury photosensitized decomposition of ethylene oxide (static experiments, exposure 90 min., mean $I_a = 3.27 \times 10^{15}$ quanta sec.$^{-1}$).

ment with those established by Phibbs, Darwent, and Steacie (12). The "C_2 fraction" reported by these authors is seen to consist mainly of C_2H_6 and C_3H_8. Small amounts of ketene (identified and estimated by mass spectrometer) are separated out with the propane. In addition very small amounts of C_4H_{10} are usually found with the propane and there is indication that traces of ethylene accompany ethane. In this series of experiments no determinations of aldehydes nor of ethylene oxide consumption were attempted. Determinations of these quantities were reported previously (12).

The effect of the addition of very small amounts of ethylene to ethylene oxide is shown in Table I for static (*A*) and circulating (*B*) experiments and for the latter also in Fig. 2. The inhibiting effect of ethylene is extremely pronounced; hydrogen production is strongly suppressed and to a somewhat smaller extent the production of carbon monoxide and methane. On the other hand, the amount of propane formed is much increased. The figures for ethane are uncertain since small amounts of this compound were determined

much the same as with ethylene. The following distinctions, however, are to be noted: propane is nearly completely suppressed, appreciable amounts of ethylene are produced, and appreciable quantities of less volatile substances ("room temperature fraction") are formed. By a combination of mass-spectrometer analysis and the removal of the aldehydes by polymerization on solid KOH, this fraction is found to be quite complex, being composed mainly

of higher paraffinic aldehydes (propanal to hexanal) and of higher paraffins (up to octane).

In order to establish in greater detail the effect of ethylene addition on the formation of various products, alternate experiments were performed with 100 mm. of ethylene oxide alone and 100 mm. of ethylene oxide with 3.45 mm. ethylene added. The time of exposure was varied and the results are given in Table III. In addition to the already indicated suppression of H_2, CO, and CH_4, and the increase of C_3H_8 production on addition of ethylene, it is also seen that ketene and especially aldehyde formation is much increased. Aldehyde was determined by infrared absorption measurement on the basis of calibrations with acetaldehyde (in the presence of analogous quantities of ethylene oxide). The quantities for aldehyde obtained in this manner are approximate because besides acetaldehyde its higher homologues appear to be present in quite appreciable quantities. This was evident from the details of the infrared absorption spectra and also from a partial separation, by the use of gas–liquid partition chromatography (2), of some higher aldehydes from the huge excess of ethylene oxide and their subsequent identification by mass spectrometer. A few determinations of HCHO were made in the manner described previously (5). Only very small amounts of this substance were found. There might have been, however, an appreciable loss of this compound by polymerization.

The inhibiting effects of C_2H_4 and C_4H_8-1 indicate that in the uninhibited reaction most of the hydrogen is formed through action of hydrogen atoms. In the inhibited reaction hydrogen production is not completely suppressed, suggesting that it may be formed by a molecular rather than an atomic process. In order to test this possibility several experiments were carried out with mixtures of C_2H_4O and C_2D_4O. The results are given in Table IV. In the uninhibited reaction (run 64) such mixtures form large amounts of HD, while in the inhibited reaction (runs 62 and 61) HD is suppressed to the level that appears when C_2D_4O is used in the absence of C_2H_4O (runs 63 and 65). In the inhibited reaction, therefore, hydrogen is formed by a molecular process. The interpretation of the ratios of the isotopic methanes formed is somewhat more difficult because the figures for CH_3D and CH_4 may be subject to large errors. The ratios CD_4 to CD_3H should, on the other hand, be accurate and the indications are that both in the inhibited and uninhibited reaction, methane is probably formed predominantly, but possibly not entirely, from free methyl radicals.

It is of interest also that there are pronounced isotopic effects in the rates of hydrogen formation, both the abstraction and the molecular formation of deuterium taking place less readily than those of hydrogen. This is in agreement with the observations of other workers in abstractions of the two isotopes of hydrogen and explains the fact that in the uninhibited decomposition of the 1:1 C_2D_4O–C_2H_4O mixture (run 64) the relative rate of HD formation is not as large as would be expected on probability grounds. An isotopic effect in a molecular reaction has recently been found in the mercury photosensitized decomposition of ethylene (6).

DISCUSSION

The quenching efficiency of ethylene is 10 times greater than that of ethylene oxide (4) and even for the largest ratios of ethylene to ethylene oxide used in the present experiments the fraction of the exciting radiation quenched by ethylene is small and cannot be responsible for the large inhibiting effects observed. It appears safe to conclude that the inhibition is due to the addition of H-atoms to ethylene or butene-1. In the former case the increased ethyl radical concentration leads to an increased propane formation, by combination with methyl radicals, which also leads to some decrease in methane formation. With butene-1 propane is not formed at all, but higher paraffins instead. The experiments with butene-1 show that quite appreciable amounts of ethylene are formed in the decomposition of ethylene oxide but, in the absence of excess butene, H-atoms add on to it readily; the ethyl radicals thus formed explain the production of propane in the "uninhibited" reaction.

An inspection of the magnitude of the inhibiting effect produced by ethylene and of the large consumption of this compound shows that large quantities of H-atoms are formed in the sensitized decomposition of ethylene oxide. This finding rules out the previously suggested (12) formation of hydrogen by a molecular process as the major primary step. The amounts of CH_4, C_2H_6, and C_3H_8 produced indicate that substantial quantities of methyl radicals are also formed. Formation of methane at room temperature by abstraction of hydrogen indicates that a relatively loosely bound hydrogen atom is available. All these considerations point to a primary step of the type suggested by Gomer and Noyes (8) for the direct photolysis: primary production of CH_3 and HCO radicals, the latter readily decomposing into H and CO. In order to explain the formation of higher aldehydes it is then necessary to assume also the occurrence of the reactions

$$R+HCO\ (+M) \rightarrow RCHO\ (+M) \qquad [6]$$

in addition to

$$R+HCO \rightarrow RH+CO \qquad [7]$$

and

$$H+HCO \rightarrow H_2+CO. \qquad [8]$$

The major features of the process are then qualitatively readily explainable. When ethylene is added, reaction [8] is suppressed and at the same time large quantities of C_2H_5 are formed which, through an increase in aldehyde formation, lead to more rapid removal of HCO radicals and therefore their decreased decomposition to yield CO. Thus, a drastic suppression of H_2, partial suppression of CO, and a large increase in aldehydes is observed. A slight pressure dependence of reaction [6] could explain the pressure dependence of CO formation. Alternately, there may be a slight collisional deactivation of an initially produced excited ethylene oxide molecule. The very slight increase in the yield of hydrogen with increasing pressure may be due to pressure dependence of reaction [5], as suggested by Horner, Style, and Summers (9).

It would appear, on the basis of the foregoing conceptions, that H-atoms undergo preferentially reaction [8], CH_3 radicals both reactions [6] and [7], and C_2H_5 and any higher radicals predominantly reaction [6]. These differences

may be due to different availability of degrees of freedom for a distribution of the heat of the reaction. It should be pointed out at the same time that a combination of CH_3 and CHO radicals to give acetaldehyde is, on the basis of the existing experimental information, indistinguishable from a direct primary isomerization to this compound without decomposition. The formation of higher aldehydes, on the other hand, would seem to require the occurrence of reactions [6].

While a primary split into CH_3 and CHO may explain in a qualitative way the major features of the process, it is evident that at least one more primary process has to be considered. The experiments with mixtures of C_2H_4O and C_2D_4O show that a small fraction of hydrogen is formed by a primary molecular process possibly by reaction [2] or by the similar reaction

$$C_2H_4O^* \rightarrow H_2+CH_2CO. \qquad [9]$$

It appears, therefore, to be reasonably certain that there are at least two primary processes. A primary molecular formation of methane, if it occurs at all, does not seem to be very important. A primary split into H-atoms and C_2H_3O radicals, (reaction [3]), on the other hand, is very likely in view of the seemingly largely saturated character of the ethylene oxide molecule. The properties of the C_2H_3O radicals have been investigated by Gomer and Noyes (8) and it appears that there is about equal probability of decomposition of these radicals into CH_3 and CO and of their stabilization by isomerization, presumably to CH_2CHO radicals. The latter could then lead to aldehyde formation. It can be seen that the qualitative consequences of such a primary step, followed by a number of feasible secondary reactions, are similar to those of a primary split into CH_3 and HCO. Attempts to exclude the latter primary step, however, lead to quantitative difficulties. Complete and unambiguous stoichiometric and kinetic treatment is at present impossible because of the lack of detailed quantitative information on the aldehydes formed and a very limited knowledge of the relative values of rate constants of the different reactions involved. Some conclusions, on the other hand, can be drawn from a comparative analysis of the various modes of decomposition of ethylene oxide.

The stoichiometry of the reaction of oxygen atoms with ethylene (5) can be approximately represented by

$$\begin{aligned} O+1.38\ C_2H_4 \rightarrow\ & .50\ CO+.15\ CH_3CHO+.20\ C_2H_5CHO+.05\ C_3H_7CHO \\ & +.03\ C_2H_4O+.04\ CH_2CO+.09\ H_2+.11\ CH_4 \\ & +.17\ C_2H_6+.17\ C_3H_8+.03\ (C_2H_4O\text{-polymer}). \end{aligned}$$

A stoichiometric balance of the likely processes involved can be written as follows:

$$O+C_2H_4 \rightarrow C_2H_4O^* \rightarrow \begin{cases} .03\ \text{polymer} \\ .03\ C_2H_4O \\ .05\ H_2+CH_2+CO \\ .04\ H_2+CH_2CO \\ .10\ H+C_2H_3O \\ .75\ CH_3+HCO \end{cases}$$

$$.10\ C_2H_3O \rightarrow .05\ CH_2CHO + .05\ CH_3 + .05\ CO$$
$$.05\ CH_2 + .05\ CH_3 \rightarrow .05\ C_2H_4 + .05\ H$$
$$.32\ CH_3 \rightarrow .16\ C_2H_6$$
$$.11\ CH_3 + .11\ HCO \rightarrow .11\ CH_4 + .11\ CO$$
$$.17\ CH_3 + .17\ C_2H_5 \rightarrow .17\ C_3H_8$$
$$.15\ CH_3 + .15\ HCO \rightarrow .15\ CH_3CHO$$
$$.28\ HCO \rightarrow .28\ H + .28\ CO$$
$$.43\ H + .43\ C_2H_4 \rightarrow .43\ C_2H_5$$
$$.20\ C_2H_5 + .20\ HCO \rightarrow .20\ C_2H_5CHO$$
$$.01\ C_2H_5 + .01\ HCO \rightarrow .01\ C_2H_6 + .01\ CO$$
$$.05\ C_2H_5 + .05\ CH_2CHO \rightarrow .05\ C_3H_7CHO.$$

The proposed scheme involves some simplifications and for some of the steps alternative reactions may be written. The small primary split into H and C_2H_3O, in particular, is suggested only in order to explain the formation of C_3H_7CHO and may prove to be unnecessary if this compound is found to arise by some other type of radical combination. Regardless of these uncertainties, in its main outline, the scheme appears feasible on the basis of the present knowledge. Considering the reactions

$$CH_3 + CH_3 \rightarrow C_2H_6 \qquad [10]$$
$$CH_3 + CHO \rightarrow CH_4 + CO \qquad [11]$$
$$CH_3 + CHO \rightarrow CH_3CHO \qquad [11']$$

and

$$CHO \rightarrow H + CO \qquad [5]$$

it is likely that reactions [11] and [11′] have each a collision efficiency of about 0.5. Assuming that (1) the collision efficiency of reaction [10] is unity and of reaction [11] 0.5, (2) the collision diameters of CH_3 and HCO have the same value of 3.5 Å, (3) the effective reaction volume is 10 cc., and (4) $k_5 = 10^{13} \exp(-E_5/RT)$, a value of 14.4 kcal./mole can be calculated for E_5 from the observed rate of reaction [10] and the ratio of the rates of reactions [5] and [11] as given in the foregoing stoichiometric balance (.28/.11). Even with an ample allowance for uncertainties in the assumptions made, E_5 remains within the range of the values for the same quantity quoted in the literature (13).

Inasmuch as the primary decomposition of ethylene oxide in the mercury photosensitized reaction follows the same course, the relative amounts of the products formed when ethylene is present should be very much the same as in the reaction of O-atoms with ethylene. A comparison of the rates of formation of all but some of the minor products detected is given in Table V. The figures given should be regarded as approximate since there is an appreciable uncertainty in some of the analytical results, particularly those for the total aldehydes and ketene. Nevertheless, it is clear that there is a broad similarity, as evidenced by the values reduced to equal CO production. There are also some important differences. In the mercury sensitized decomposition of ethylene oxide in the presence of ethylene less fragmentation products (CO, CH_4, C_2H_6, C_3H_8) and more aldehydes are formed, and also, relative to equal CO formation, there is less methane while propane remains about the same. These differences are qualitatively explainable by a decreased initial split into CH_3 and HCO and a considerably increased primary split

TABLE V

COMPARISON OF THE RATES OF FORMATION OF THE MAIN PRODUCTS IN THE MERCURY SENSITIZED DECOMPOSITION OF ETHYLENE OXIDE AND IN THE REACTION OF OXYGEN ATOMS WITH ETHYLENE (For ethylene oxide decomposition the rates are relative to the total number of moles of products containing oxygen, i.e., to the sum of CO, total aldehyde, and CH_2CO; the bracketed figures are relative to CO taken as 0.50. For the reaction of oxygen atoms with ethylene, the rates are expressed per oxygen atom consumed)

	CO	H_2	CH_4	C_2H_6	C_3H_8	CH_2CO	RCHO	C_2H_4
Ethylene oxide alone	.60	.46	.10	.10	.07	.03	.37	Small
Ethylene oxide $+C_2H_4$	.35 (.50)	.07 (.10)	.04 (.16)	.10 (.14)	.12 (.17)	.06 (.08)	.59 (.85)	Not detd.
Ethylene oxide $+C_4H_8$	.34 (.50)	.07 (.10)	.05 (.08)	.06 (.09)	.002 (.002)	.01 (.02)	.65 (.89)	.10 (.15)
O atoms $+C_2H_4$	.50	.09	.11	.17	.17	.04	.40	Not detd.

into H and C_2H_3O radicals. The CH_2CHO radicals, formed from C_2H_3O, could be visualized as being responsible for increased aldehyde formation by combination with free radicals. While this view seems to fit better all the experimental observations, it is also possible that the increased aldehyde formation could be due to a direct primary isomerization to acetaldehyde. An analysis of the material balance of the process, which could remove much of the ambiguity, is impossible until detailed and accurate determinations of the aldehydes formed are available.

An observation arising from the butene-1 inhibited experiments is that some ethylene is formed in the mercury sensitized decomposition of ethylene oxide. Two ways of formation of this compound appear possible: a primary split into C_2H_4 and an O-atom, or some reaction involving CH_2 radicals. In connection with the latter possibility it is of interest that some preliminary work of Gesser (7) indicates that C_2H_4 is formed in the reaction of CH_2 radicals with ethylene oxide.

The results of the experiments reported in the literature and in the present work indicate that there is a significant similarity between the different modes of decomposition of ethylene oxide: the thermal, photolytic, mercury photosensitized, and the decomposition of the energy rich molecule formed in the reaction of oxygen atoms with ethylene. The differences observed appear to be largely of a quantitative rather than a qualitative character and may be ascribed to a variation in the relative importance of the different primary processes and, in the case of thermal decomposition, also to a variation with temperature of the stability and the reactivity of the intermediate free radicals and atoms formed.

ACKNOWLEDGMENT

The author is thankful to Dr. A. W. Tickner for mass-spectrometer analyses, to Mrs. P. M. Schreiber and Mr. D. S. Russell for infrared analyses, and to Mr. L. C. Doyle for valuable technical assistance. A number of helpful suggestions made by Dr. E. W. R. Steacie are gratefully acknowledged.

SOLUBILITY CRITERIA FOR THE EXISTENCE OF HYDROXYAPATITE[1]

By J. S. Clark

ABSTRACT

The solubilities of synthetic basic calcium phosphate precipitates in carbon dioxide free aqueous systems were studied over a wide range of conditions. The pH of the suspensions and the calcium and phosphate concentrations in the solutions were determined both after precipitation and after dissolution of the solid phases. Solubility criteria applied to these measurements indicated that hydroxyapatite has a definite solubility product.

INTRODUCTION

Although hydroxyapatite is generally considered to be one of the stable basic calcium phosphates in nature, its existence as a compound with a fixed crystalline form and a unique solubility is controversial. Neumann and his co-workers (6, 7) considered the basic calcium phosphate system to be a solid phase of variable composition so that the principle of solubility product would not apply. In contrast to this opinion, the thermodynamic properties of crystalline hydroxyapatite have been reported by the Chemical Engineering Division of the TVA (8). Since in a previous paper solubility criteria were proposed as a means of establishing the existence of calcium phosphate compounds in soils (2), it was considered desirable to resolve the contrasting views on the solubility of hydroxyapatite in order to evaluate the validity of this approach. The object of the work reported here was to determine whether hydroxyapatite possesses a definite solubility product over a wide range of conditions.

EXPERIMENTAL

The solid phase calcium phosphates used for the solubility measurements were prepared by reacting dilute solutions of $Ca(OH)_2$ and H_3PO_4 at different temperatures for various periods of time while N_2 (CO_2 free) was passed through the systems. Following reaction at elevated temperatures, the flasks containing the suspensions were placed in a water bath at 25°C. for 96 hr. and the pH was measured with a glass electrode in the presence of N_2. The suspensions were filtered rapidly and phosphate and calcium determinations were made on the filtrates by the molybdenum blue (4) and the versene (1) methods, respectively. The activities of the ions were estimated by means of the Debye–Huckel equation (5).

In some cases, the precipitates were separated from the solutions and redispersed at 25°C. in CO_2-free water through which N_2 was passed. After 24 hr., the pH was measured and calcium and phosphate determinations were made on these suspensions in the manner described above.

RESULTS AND DISCUSSION

In preliminary experiments, it was found that reproducible solubilities could not be obtained in the presence of CO_2 even after reaction for long periods at relatively high temperatures. For this reason, a CO_2-free atmosphere was used in all experiments. In addition, it was found that, although satisfactory results were obtained by rapid mixing of the $Ca(OH)_2$ and H_3PO_4 solutions below a final pH of about 7.8, it was necessary to combine the reacting solutions slowly above this pH in order to obtain equilibrium.

The solubility measurements made on precipitates which had reacted at 90°C. for 120 hr. are reported in Table I, and those obtained by redispersing some of these precipitates in water are presented in Table II. The values for

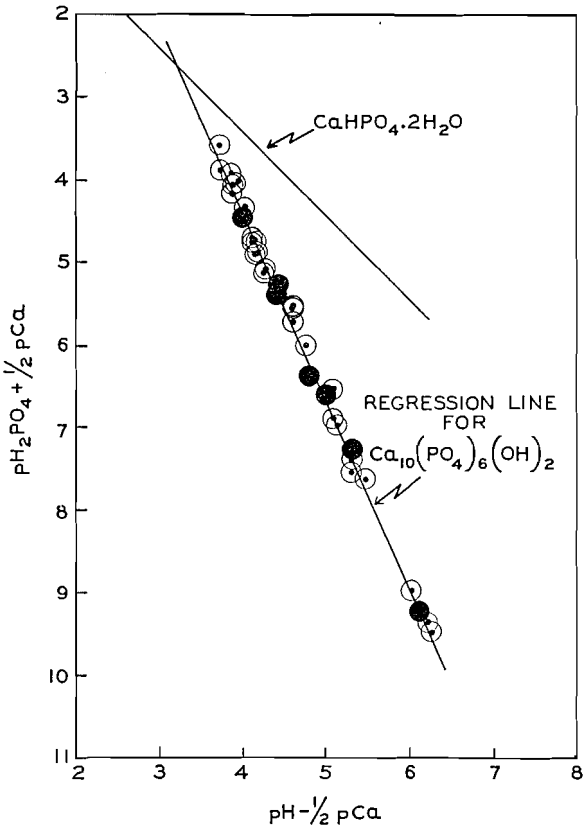

FIG. 1. Solubility diagram.
Legend: ⊙ Solubility measured after precipitation.
● Solubility measured after dissolution.

$pH-\frac{1}{2}pCa$ and $pH_2PO_4+\frac{1}{2}pCa$ in these tables are plotted on the solubility diagram in Fig. 1. Details with respect to the construction and interpretation of the diagram were presented in earlier publications (2, 3). The regression line relating $pH-\frac{1}{2}pCa$ and $pH_2PO_4+\frac{1}{2}pCa$ was calculated from the data and the corresponding value for the negative logarithm of the solubility product was 115.5. The slope of the regression line was similar to that for hydroxyapatite (actual slope 2.26 as compared with a theoretical value of 2.11) indicating that, although the calcium concentration varied from 10^{-3} to 10^{-6} M, the phosphate concentration from 10^{-3} to 10^{-6} M, and the pH from 5 to 9, hydroxyapatite possesses a definite solubility product.

To ascertain if heating to 90°C. for 120 hr. was sufficient to establish equilibrium, solubility measurements were made with precipitates that were prepared by reaction for 24 and 120 hr. at 40°C., 8 and 120 hr. at 60°C., and 4 and 120 hr. at 90°C. The solubilities, measured after equilibration at 25°C., are plotted on the enlarged section of the solubility diagram in Fig. 2. It is seen from Fig. 2 that increasing the reaction temperature decreased the solubilities

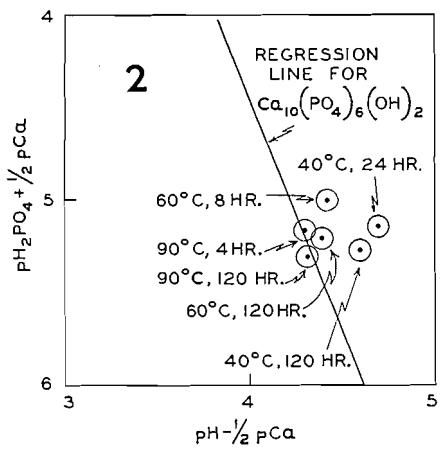

FIG. 2. The influence of reaction temperature and time of reaction at a given temperature on the solubility of hydroxyapatite.

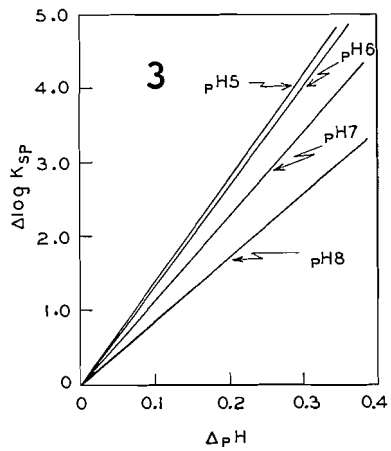

FIG. 3. The effect of errors in the measurement of pH on the calculated solubility product of hydroxyapatite.

of the precipitates. The solubilities were also decreased by increasing the length of the reaction period except at 90°C. The solubility after 4 hr. at 90°C. was as low as that after heating for 120 hr. at this temperature, and it is noted further that the solubility was only slightly higher after heating for 120 hr. at 60°C. Thus, heating for 120 hr. at 90°C. evidently was sufficient to produce stable conditions in these basic calcium phosphate systems.

As it was possible that the systems which had reacted at temperatures below 90°C. were in a state of supersaturation, the precipitates were separated from the solution and dispersed in water at 25°C. and the solubility measured 24 hr. later. The solubilities of precipitates formed at 90°C. were measured in this way and showed good agreement with the values obtained by precipitation (compare Tables I and II). On the other hand, after the solid phase of the system which had reacted for 24 hr. at 40°C. was redispersed in water the value obtained for $pH - \frac{1}{2}pCa$ was 5.14 and that for $pH_2PO_4 + \frac{1}{2}pCa$ was 6.10. Comparing these values with those for the corresponding precipitated system in Fig. 2, it is seen that the solubility did not decrease, indicating that the solution was not simply supersaturated. Similarly, when the other precipitates formed below 90°C. were redispersed in water, the solutions remained at the same degree of apparent supersaturation as in the original precipitated system. Increasing the reaction temperature and the length of the reaction period apparently served to age the precipitates producing better defined crystals with a lower solubility. Although the rate of precipitation and aging of hydroxyapatite is slow, its rate of dissolution is rapid since stable conditions were reached in 24 hr. when the precipitates were dispersed in water. These experiments on the dissolution of hydroxyapatite support the contention that a state of virtual equilibrium had been attained by heating to 90°C., and they indicate that the nature of the solid phase was not changed by heating.

In the light of these experiments on the effect of reaction time and temperature on the solubility of hydroxyapatite, it is improbable that the variability of the solubility products reported in the last columns of Tables I and II was caused by the failure to obtain stable conditions. The variability can be attributed to a great extent to the influence of analytical errors in the calculation of the solubility product where the ion activities are raised to such high exponents. As illustrated in Fig. 3, relatively small errors in pH may have a marked effect on the value of the calculated solubility product. Considering the effect of possible errors in the measurement of pH, the discrepancies observed in the pK_{sp} values do not appear serious.

In these unbuffered systems, errors in the measurement of pH coupled with errors in the determination of calcium and phosphate concentrations were probably sufficient to account for the observed differences in the values obtained for the solubility products. Further refinements in experimental technique would be necessary to obtain an accurate experimental value but these experiments were adequate to demonstrate that, within accountable errors, hydroxyapatite has a definite solubility product over a wide range of conditions.

PERIODATE–PERMANGANATE OXIDATIONS

I. OXIDATION OF OLEFINS[1]

By R. U. Lemieux[2] and E. von Rudloff[3]

ABSTRACT

It was discovered that olefinic double bonds are readily oxidized in an aqueous solution of periodate which contains only catalytic amounts of permanganate. The data suggest that in the effective pH range of 7 to 10 the permanganate is not reduced at once beyond the manganate state and that it is regenerated from this state by periodate action. Evidence was obtained that the main course of the oxidation of an olefin of type —CH=CH— involves first permanganate oxidation to hydroxyketones which are then rapidly cleaved by periodate to products which may subsequently be oxidized by the permanganate.

INTRODUCTION

The use of a mildly alkaline solution of periodate containing permanganate as a reagent for the detection of carbohydrates on paper chromatograms was described by Lemieux and Bauer (6). This communication deals with the ability of the reagent to oxidize olefins smoothly.

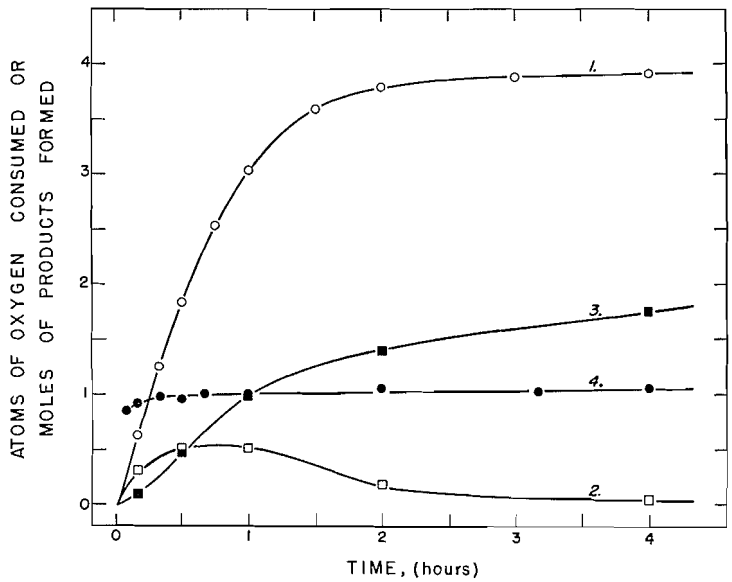

FIG. 1. Plot 1: Periodate (0.0197 *M*) – permanganate (0.00034 *M*) oxidation of oleic acid (0.0025 *M*) in the presence of potassium carbonate at pH 7.7 and 20°C. Contribution from the National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan. Issued as Paper No. 205 on the Uses of Plant Products and as N.R.C. No. 3742. Presented in part at the Second Western Regional Conference of the Chemical Institute of Canada, Vancouver, B.C., September 9–11, 1954.
[2]*Present address: Department of Chemistry, University of Ottawa, Ottawa, Ontario.*
[3]*National Research Council of Canada Postdoctorate Fellow, 1953–54.*

The data presented in Fig. 1 (plot 1) show that a reagent consisting of 0.0197 *M* periodate and 0.00034 *M* permanganate at pH 7.7 and 20°C. efficiently oxidized 0.0025 *M* oleate ion with the consumption of the amount of oxidant theoretically required to cleave the olefin to carboxylic acid.

$$\begin{matrix} -CH \\ \| \\ -CH \end{matrix} + 4[O] \longrightarrow 2\,-COOH$$

The fact that after 20 hours' reaction time these conditions gave a product from which azelaic and pelargonic acids were isolated in quantitative yields shows that the oxidation was specific for the olefinic linkage. Periodate alone did not oxidize the olefin. Therefore, the ability of the reagent to bring about complete cleavage of the olefin must depend on an ability of the periodate ions to regenerate permanganate from its reduced state. We have observed that the addition of sodium *meta*-periodate to an alkaline solution of manganate ion (11) resulted in the immediate formation of permanganate ion. This observation provided a satisfactory explanation for the regeneration of the permanganate in the above periodate–permanganate oxidation since Drummond and Waters (2) have recently produced evidence that olefins and other organic compounds do not reduce permanganate at once beyond the manganate stage. This conclusion was supported by the effect of pH on the ability of the reagent to oxidize substances stable toward periodate. The data presented in Fig. 2 show that, in acidic media, the oxidation of mesityl oxide did not go to completion and that the extent of oxidation was least when the pH was lowest. The cessa-

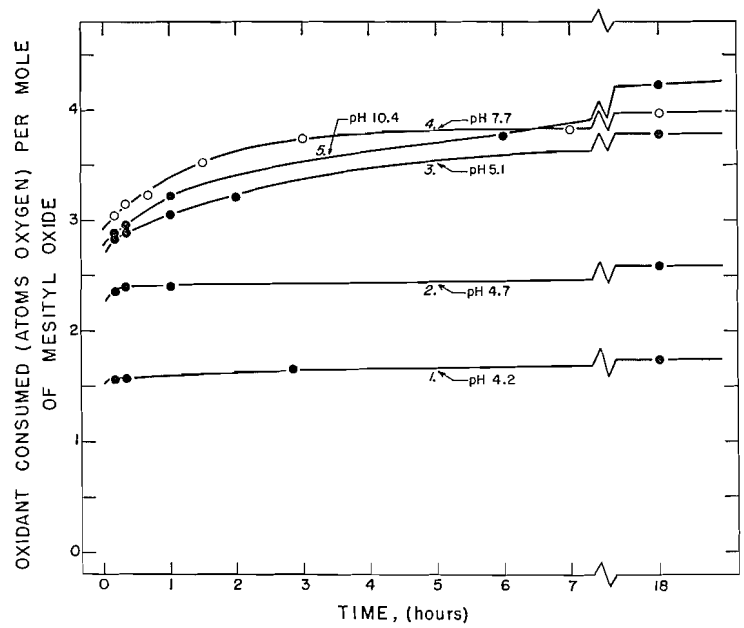

FIG. 2. Experimental rates for the oxidation of mesityl oxide (0.0025 *M*) at 20°C. Relative molar concentrations: mesityl oxide, 1; sodium *meta*-periodate, 7.9; potassium permanganate, 0.13; potassium carbonate, 0 (plot 1), 0.125 (plot 2), 0.25 (plot 3), 1 (plot 4), 10 (plot 5).

tion of oxidation was accompanied by precipitation of manganese dioxide. It is well known that manganate ions disproportionate into manganese dioxide and permanganate ions in acidic media. Since periodate does not oxidize manganese dioxide to permanganate in alkaline media, the oxidations which had ceased to operate in acidic media did not resume when the solution was rendered alkaline. The periodate oxidation of α-glycols usually becomes very slow in strongly alkaline media (1, 10). Since this is a step in the periodate–permanganate oxidation of olefins, high pH's are not favorable. Furthermore, strongly alkaline media lead to disappearance of the typical permanganate color. Therefore, it was concluded that the most favorable pH range for the periodate–permanganate reagent is from 7 to 10.

Permanganate has been widely used to hydroxylate olefins. Treatment of oleic acid with an alkaline solution of permanganate yields racemic *erythro*-9,10-dihydroxystearic acid (3, 5). The reaction results in a green solution containing manganate ion. However, when the oxidation is carried out near neutrality and an excess of permanganate is avoided, the main product is a mixture of 9-keto-10-hydroxy and 9-hydroxy-10-keto-stearic acids (3). 9,10-Dihydroxystearic acid is formed only in smaller amounts. Since King (3) was unable to prepare the ketohydroxy acids by a similar oxidation of the 9,10-dihydroxy acid, it was evident that the mechanism of the permanganate oxidation of olefins is strongly dependent on pH.

The periodate–permanganate oxidation of oleate ion described in Fig. 1 was carried out at pH 7.7, i.e. in the pH range where the main product of the permanganate oxidation of oleate ion is the mixture of ketohydroxy acids. If this product was also intermediate in the periodate–permanganate oxidation, then it could be concluded that the initial stages of the periodate–permanganate oxidation involve true permanganate oxidation. Direct evidence that the ketohydroxy acids were in fact intermediates was obtained by oxidizing oleate ion (0.0025 M) at pH 7.7 using a relatively high concentration of permanganate (0.000806 M) to speed up the initial stage of the reaction and only a relatively small amount of periodate (0.00106 M). The reaction was stopped by the addition of bisulphite at the first indication that the permanganate was not being regenerated as evidenced by the appearance of manganese dioxide. This procedure restricted the reaction to the conditions which prevail in periodate–permanganate oxidation. The product contained the mixture of ketohydroxystearic acids in near quantitative yield based on the amount of periodate added. Elaidic acid was also in part converted to the ketohydroxystearic acids and 10-undecenoic acid was oxidized in part to 10-keto-11-hydroxyundecanoic acid under similar reaction conditions. Since 9,10-epoxystearic acid was not oxidized under these conditions, the intermediate formation of epoxides was ruled out.

Furthermore, the periodate–permanganate oxidation of ethylene resulted in the formation of only about one mole of formaldehyde on the consumption of oxidant equivalent to four oxygen atoms. Had ethylene glycol alone been produced in the first stage of the reaction, a consumption of oxidant equivalent to only two oxygen atoms would have yielded two moles of formaldehyde. Therefore, it seems clear that the periodate–permanganate oxidation of an

olefin in the pH range 7 to 8 has a strong tendency to proceed by way of an acyloin. It is noteworthy in this respect that the permanganate oxidation under near neutral conditions may prove to be a useful means for converting certain olefins to acyloins.

The products isolated after different reaction times in the course of the oxidation of oleate ion under the conditions described in Fig. 1 were analyzed for their aldehyde and carboxylic acid contents. The results, plotted in Fig. 1 (plots 2 and 3), form a picture of the reaction sequences involved in terms of the isolable products. Since periodate alone rapidly oxidized the 9,10-dihydroxy and ketohydroxystearic acids (plot 4), the concentration of these substances must always have been relatively small. The fact that the amount of aldehyde passed through a maximum at 0.52 mole per gram ion of oleate ion oxidized supports the above conclusion that the ketohydroxystearic acids were intermediates in the over-all reaction.

Thus, in terms of the isolable organic products, the periodate–permanganate oxidation can be considered to take place in three stages. The first stage appears to be a complex sequence of reactions which involve permanganate ion in one-electron exchanges leading, near neutrality, mainly to hydroxyketone. The rapid periodate cleavage of the hydroxyketone (and any diol which may have been formed) can be considered as the second stage. This property of the periodate–permanganate reagent is undoubtedly that mainly responsible for the high specificity of the over-all reaction. The oxidation of the products formed in the periodate cleavage through permanganate action can be considered as the third stage. It is noteworthy that the fact that the reagent requires only mildy alkaline conditions is conducive to the oxidation of an aldehyde without degradation.

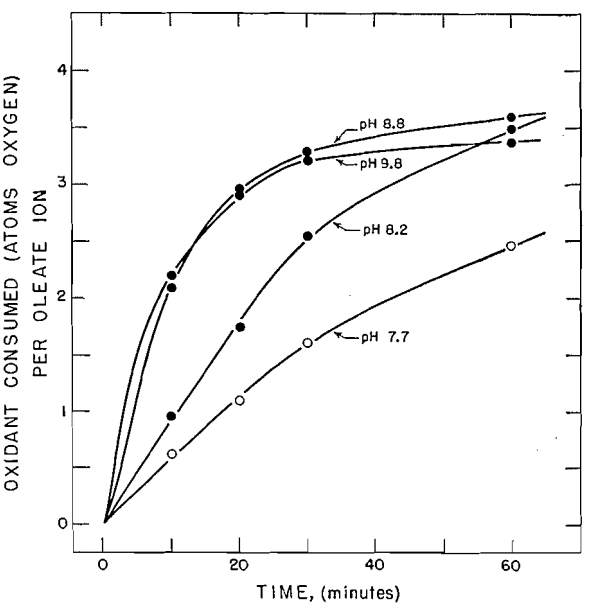

FIG. 3. Effect at 20°C. of pH on the rate of periodate (0.02 *M*) – permanganate (0.00034 *M*) oxidation of oleate (0.0025 *M*).

Although the periodate–permanganate reagent is limited in application to the oxidation of compounds which are soluble in slightly alkaline media, the high yields obtained and the convenience of operation render it likely that the reagent will find application for degradative and analytical purposes. Thus, for example, the oxidation of 10-undecenoic acid gave sebacic acid and formaldehyde in excellent yield. The fact that formaldehyde resisted oxidation suggests the use of the reagent for determining terminal methylene groups (7). The oxidation of mesityl oxide at pH 7.7 gave a quantitative yield of acetone. This result forms a convenient basis for the determination of terminal isopropylidene groups and will be described in a later communication (12).

In view of these possible uses for the reagent, a study was made of the effect of certain variables on the rate of reaction using oleate ion as substrate. The data plotted in Fig. 3 show that the rate of the over-all reaction increases with increase in pH. The effect of temperature on the rate of reaction is illustrated in Fig. 4. The plots of Fig. 5 show clearly that permanganate is involved in the rate controlling stages. The results presented in Fig. 6 show that an increase in the periodate ion concentration has a retarding effect on rate of reaction. This interesting effect was not to be expected. Nevertheless, these results serve as further evidence that in these oxidations the steps which involve periodate ion are fast as compared to those which involve permanganate ion. It should be noted in this respect that the periodate cleavage of glycols is strongly dependent on pH in basic media with the rate of reaction decreasing with increasing pH (1, 10). This fact may account for the slower rate of the second stage of periodate–permanganate oxidation of oleate ion on going from pH 8.8 to 9.8 (see Fig. 3).

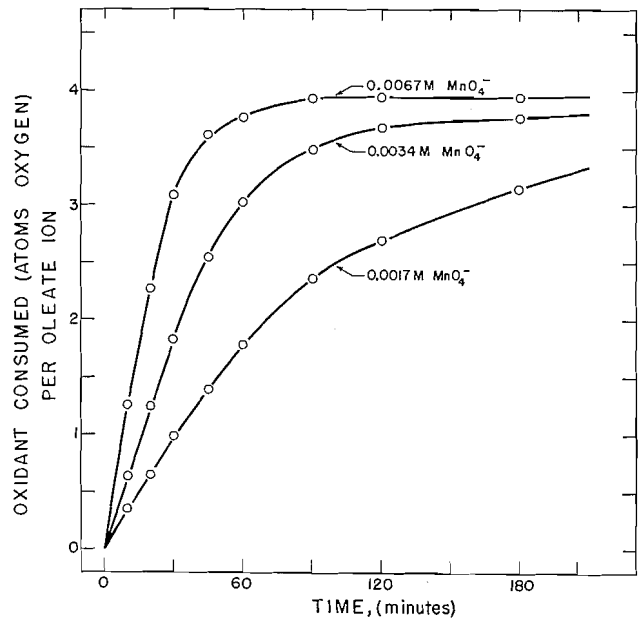

FIG. 5. Effect of the permanganate concentration on the rate of periodate–permanganate oxidation of oleate using the conditions of Fig. 1, plot 1, except for the permanganate concentration.

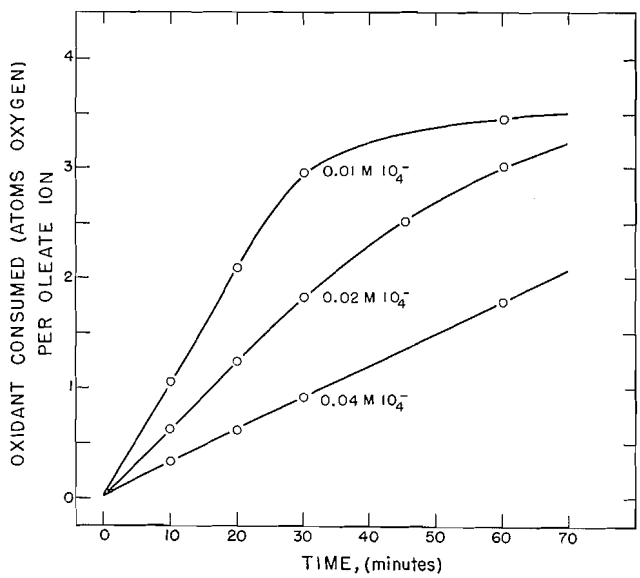

FIG. 6. Effect of the periodate concentration on the rate of periodate–permanganate oxidation of oleate using the conditions of Fig. 1, plot 1, except for the periodate concentration.

EXPERIMENTAL

Methods

The following procedure was used to follow the rates of oxidation. The required amounts of olefin and potassium carbonate were dissolved in water and the solution was made up to 100 ml. The periodate–permanganate reagent was made up freshly before use by mixing the required amounts of standard solutions of sodium *meta*-periodate and potassium permanganate and diluting to 100 ml. At zero time, 5-ml. volumes of the two solutions at the desired temperature were mixed in a glass-stoppered flask. The reaction was stopped by rapidly adding about 0.5 gm. sodium bicarbonate, a measured volume of standard arsenite solution, and a few crystals of potassium iodide. After this solution was left for at least 10 min., the excess arsenite was determined by slow titration of the stirred solution with standard iodine solution to the starch end point. The difference between the titers for a run and a reagent blank was taken as equivalent to the oxidant consumed. The pH values reported were measured soon after the reaction mixture was made up. In some experiments, potassium hydroxide was added to achieve the desired pH. The following procedure was used to determine the amounts of aldehyde and acid present in the reaction mixture (see Fig. 1). After a given reaction time, the oxidant was destroyed and the solution rendered strongly acid by the addition of an excess arsenite solution and 10% sulphuric acid. The resulting mixture was extracted continuously with ether. The extract was filtered and concentrated to a small volume. The acid content in the residue was determined by titration with standard methanolic sodium hydroxide to the phenolphthalein end point. The aldehyde content was determined by the hydroxylamine procedure of Siggia (13).

Runs with mixtures of heptanal, azelaic acid, and oleic acid showed the method reliable to within ±2% for the acid content and to within ±10% for the aldehyde content. Formaldehyde was determined colorimetrically using chromotropic acid (4, 7). The acetone liberated in the oxidation of mesityl oxide was removed from the oxidation mixture by distillation and determined by iodometric titration (9).

Oxidations of Oleic Acid

A reaction mixture, 400 ml., which contained initially 0.2824 gm. (1 mM.) of pure oleic acid, 3 mM. of potassium carbonate, 8 mM. sodium *meta*-periodate, and 0.134 mM. potassium permanganate was kept at 20°C. for 20 hr. The solution was rendered strongly acid by addition of 10% sulphuric acid and extracted with ether. The extraction yielded 0.354 gm. of material which on trituration with petroleum ether gave 161 mgm. of an oil with neutral equivalent 164. The oxidation would theoretically yield 0.158 gm. of pelargonic acid and 0.188 gm. of azelaic acid. The oil was distilled *in vacuo* and then gave a hydrazide of m.p. 93.5–94.5°C. (undepressed by pelargonic acid hydrazide m.p. 94–95°C. (8)). The residue from the trituration melted at 102–104.5°C. (undepressed by azelaic acid m.p. 106.5–107.5°C.) and was pure azelaic acid after recrystallization first from water and then from ethyl acetate.

A reaction mixture, 200 ml., was made up at 20°C. which contained 0.1412 gm. (0.5 mM.) oleic acid, 1.5 mM. potassium carbonate, 0.162 mM. potassium permanganate, and 0.2 mM. sodium *meta*-periodate. The initial pH was 7.7. Discoloration of the permanganate began in about three minutes and a large excess of sodium bisulphite was immediately added. The precipitate which formed on acidification was filtered off and triturated with cold petroleum ether to yield 35 mgm. of a substance, which was recrystallized from petroleum ether. The melting point, 60–62°C., of the material, 31 mgm., was not depressed by the mixture of ketohydroxystearic acids, m.p. 62–63.5°C., prepared by the method of King (3).

Almost exactly the same result was obtained when elaidic acid, m.p. 42.5–43.5°C., was oxidized under the above conditions except that the low solubility of the elaidate ion required that the reaction mixture be 2.5 times more dilute.

Oxidations of 10-Undecenoic Acid

10-Undecenoic acid was oxidized in the manner described above for oleic acid (Fig. 1, plot 1). Commercial undecenoic acid was distilled *in vacuo* to give a product of about 96% purity (iodine value 132); 0.190 gm. of the distilled acid yielded 0.192 gm. petroleum ether insoluble material, m.p. 126–131°C. Recrystallization from water and ethyl acetate yielded a product of m.p. 131–132.5°C. (undepressed by sebacic acid, m.p. 132–133°C.). The yield of formaldehyde was 73% (7).

The following procedure for preparing 10,11-dihydroxyundecanoic acid is similar to that described by Lapworth and Mottram (5) for the preparation of 9,10-*erythro*-dihydroxystearic acid. 10-Undecenoic acid, 0.68 gm., was dissolved with 1 gm. sodium hydroxide in 100 ml. of water and the solution was diluted to 800 ml. with ice-cold water. A 1% solution of potassium permanganate, 80 ml., was added with stirring. The mixture immediately changed in color to a dark green and was decolorized with sodium bisulphite after five minutes' reaction time. The solution was concentrated to 150 ml., made strongly acid with sulphuric acid, and extracted with ether. Evaporation of the dried ether extract to small volume led to the deposition of 0.50 gm. of a crystalline solid, m.p. 72–78°C. The material was recrystallized alternately from ethyl acetate and water to yield a substance, m.p. 67–69°C. Upon rapid recrystallization from acetone at −20 to −30°C. an acid was obtained, m.p. 83–84°C., which was undepressed in admixture with and possessed the same infrared spectrum as 10,11-dihydroxyundecanoic acid (m.p. 83–85°C.) prepared by the method of Swern *et al.* (14). The high and low melting forms could be readily interconverted by crystallization and both gave a *p*-bromophenacyl ester of m.p. 105–106°C. The material gave a negative 2,4-dinitrophenylhydrazine test, consumed oxidant equivalent to two atoms of oxygen on periodate–permanganate oxidation (as described above) with the formation of a mole of formaldehyde, and possessed the neutral equivalent (218) expected for 10,11-dihydroxyundecanoic acid (calc. 218.29).

10-Undecenoic acid (0.924 gm., 5 mM.) and potassium carbonate (5 mM.) were dissolved in 500 ml. of ice-cold water. An ice-cold solution of 5 mM.

potassium permanganate and 10 mM. sodium *meta*-periodate in 500 ml. water was added with stirring. After one minute, an excess of sodium bisulphite was added. The solution was concentrated to about 200 ml., cooled to about 2°C., and made strongly acid with cold 10% sulphuric acid. After the mixture had stood in the cold for 15 to 20 min., the precipitate was collected and dried, m.p. 83–89°C. Recrystallization from chloroform raised the melting point to 89–94°C. The following observations established the substance to be substantially pure 10-keto-11-hydroxyundecanoic acid. The infrared spectrum showed two bands in the carbonyl region and the material gave a positive 2,4-dinitrophenylhydrazine test. The material, neutral equivalent 220, liberated 1 mole of formaldehyde on periodate oxidation with the liberation, by titration, of 0.84 equivalent of acid per mole of periodate consumed. In a separate experiment, periodate oxidation gave a quantitative yield of crude sebacic acid, m.p. 119–129°C.; after two recrystallizations the compound had m.p. 130–132°C.

Oxidation of Ethylene

Ethylene, about 0.13 mM., was admitted to 200 ml. of solution containing 0.034 mM. potassium permanganate, 1.97 mM. sodium *meta*-periodate, and 0.25 mM. potassium carbonate kept in a nitrogen atmosphere. Highly erratic results were obtained when the reaction was performed in air. These results were probably due to the ability of permanganate to catalyze autoxidation (15). After it was shaken for 18 hr., the solution, pH 7.6, was analyzed as described above for oxidant content and for formaldehyde (7). Since the consumption of oxidant equivalent to 0.402 milliatoms of oxygen resulted in the formation of only 0.11 mM. formaldehyde, it is apparent that glycollic aldehyde is the first product of the reaction. It was established (7) that formaldehyde is oxidized only very slowly under these conditions.

ACKNOWLEDGMENTS

The authors wish to express their gratefulness to Dr. B. M. Craig who kindly supplied the oleic and 9,10-epoxystearic acids and to Miss Agnes Epp for the infrared-spectrographic measurements.

PERIODATE–PERMANGANATE OXIDATIONS

II. DETERMINATION OF TERMINAL METHYLENE GROUPS[1]

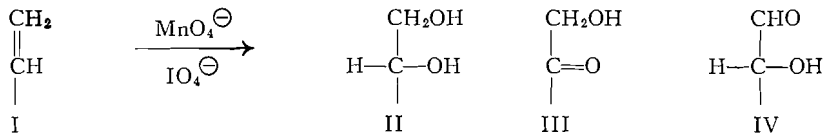
By R. U. Lemieux[2] and E. von Rudloff[3]

ABSTRACT

The periodate–permanganate oxidation of a terminal methylene ($CH_2{=}C<$) group can be made to produce formaldehyde in high although not quantitative yield. Since the yields compare favorably with those obtained by ozonolysis, the reagent can serve as the basis for a convenient micromethod for the estimation of terminal methylene groups. The less than theoretical yields of formaldehyde are believed mainly due to the conversion of the olefin in part to α-hydroxyaldehyde in the initial stage of the reaction.

INTRODUCTION

Results were reported in our first communication in this series (12) which indicated that the periodate–permanganate oxidation of a terminal methylene group (I) produces, simultaneously, in the first stage of the reaction, glycol (II), ketol (III), and hydroxyaldehyde (IV). Subsequent periodate oxidation of these substances produces formaldehyde from II and III but not from IV. Glycol formation did not appear extensive in weakly alkaline media since the oxidation of ethylene gave very nearly one mole of formaldehyde. However, oxidation of 10-undecenoic acid gave a 73% yield of formaldehyde (12). It was therefore evident that the ketol formation can be the preferred route and since the oxidant attacked formaldehyde only very slowly, it was apparent that the reagent deserved attention as a means for the semiquantitative estimation of terminal methylene groups.



We now wish to report on evidence that any attempt to obtain a maximum yield of formaldehyde in the periodate–permanganate oxidation of a terminal methylene group should consider: (*a*) the effect of pH on the reaction route, (*b*) the effect of pH on the rate of the periodate oxidation of glycols and acyloins, (*c*) the effect of pH on the rate of the permanganate oxidation of formaldehyde, and (*d*) the solubility of the compound in aqueous media.

Evidence has been obtained (12) that hydroxylation of the olefin is favored at a pH of 9–10 with acyloin formation predominating at a slightly lower pH. On this basis, it would appear desirable to operate at a high pH. However, the periodate–permanganate reagent does not operate above about pH 10 (12). Also, even at pH 10, the periodate oxidation of glycols is relatively slow (3, 14).

Furthermore, as seen in Fig. 1, formaldehyde is oxidized fairly rapidly at pH 10. Therefore, it is evident that should the pH of the media be maintained at a pH about 10, loss of formaldehyde would result from the oxidation of the formaldehyde and degradation of the glycol by the permanganate. Also, the use of alkaline media can be expected to give rise to formaldehyde from the enol

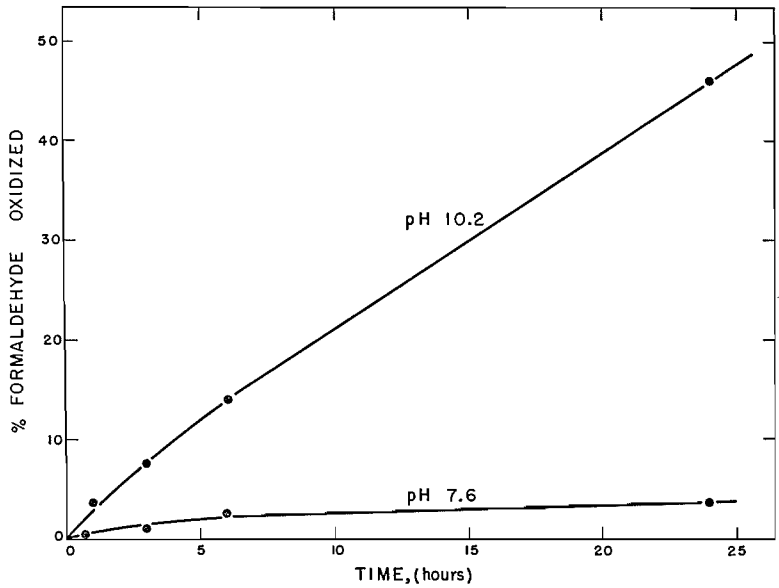

FIG. 1. Effect of pH on the rate of the oxidation of formaldehyde by the periodate–permanganate reagent.

form of methyl ketones thus complicating the results. On the other hand, the maintenance of the medium at near neutrality can be expected to result in the formation of appreciable amounts of hydroxyaldehyde. As a compromise to these conflicting effects, it was decided to carry out the oxidation for a short period of time at pH 10 and then to adjust the pH to near neutrality for completion of the reaction. The data listed in Table I show that this expedient gave in most cases a much improved yield of formaldehyde over that obtained when near neutral conditions were maintained throughout the reaction.

The yields of formaldehyde listed in Table I were determined colorimetrically using the chromotropic acid reagent according to the procedure of Lambert and Neish (10). The formaldehyde can also be determined by precipitation as the methone derivative (10, 13). In this case, larger samples are required and it is best to isolate the formaldehyde by distillation of the acidified reaction mixture before carrying out the precipitation. The present procedure should prove of value since it is easier to use than the standard methods of ozonolysis (4, 5), obviates the need of an expensive ozonizer, appears to provide higher yields of formaldehyde in many instances (see Table I), and may prove to be more reliable (6, 9, 15). The latter point is of importance since the detection of a terminal methylene group by infrared spectral analysis (2) must

be checked by chemical means. The method in its present form is restricted in scope by the fact that water is used as solvent. This limitation is not great, however, since only extremely low concentrations are required.

EXPERIMENTAL

The following procedures were used to determine the data listed in Table I and plotted in Fig. 1.

The compound, 0.005 mM., was dissolved in 5 ml. (or less) water contained in a 25 ml. volumetric flask. A quantity of 0.1 *N* potassium carbonate solution was then added to give the final solution a pH of 7 to 7.6. At zero time, 10 ml. of a solution of 0.02 *M* sodium *meta*-periodate and 1 ml. of 0.005 *M* potassium permanganate solution were added. The solution was made up to volume. Aliquots, 5 ml., were then transferred to 10 ml. volumetric flasks and after the desired time intervals, 15, 30, and 60 min., the reaction was stopped by the addition of 2 ml. of 1 *M* sodium arsenite solution and 2 ml. of 2 *N* sulphuric acid to a flask. The resulting solutions were then analyzed for their formaldehyde contents as described below, following the procedure of Lambert and Neish (10).

When it was desired to carry out the oxidation at higher pH's, 0.1 *N* potassium hydroxide was added to the solution before the addition of the oxidant. If it was desired to lower the pH back to near neutrality after a given period

of oxidation, an equivalent amount of hydrochloric acid was added before the solution was made up to volume. The data listed in Table I for pH about 10 with return to pH about 7 were obtained by adding 5 ml. of 0.1 *N* potassium hydroxide solution followed by 5 ml. of 0.1 *N* hydrochloric acid after about one minute's reaction time.

After the oxidation had been stopped, the solutions were allowed to stand for about 15 min., made up to volume (10 ml.), and 1-ml. aliquots were transferred to 25 × 200 mm. test tubes. Chromotropic acid reagent (1 gm. chromotropic acid in 100 ml. water, filtered and the filtrate made up to 500 ml. with 2:1 v/v concentrated sulphuric acid – water mixture), 10 ml., was added and the mixtures heated in a boiling water bath for 30 min. After the contents were cooled to room temperature, they were transferred to cuvettes for measurement of the per cent transmission at 570 mμ when compared to a reagent blank. Erythritol was used as standard for the production of known amounts of formaldehyde (2 moles of formaldehyde per mole of erythritol) in the setting up of a standard curve.

ACKNOWLEDGMENT

The authors are indebted to Dr. O. E. Edwards who supplied the alkaloids listed in Table I.

PERIODATE–PERMANGANATE OXIDATIONS

III. DETERMINATION OF ISOPROPYLIDENE GROUPS[1]

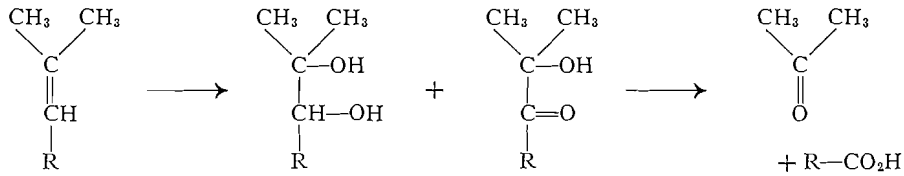
By E. von Rudloff

ABSTRACT

The reaction of the periodate–permanganate reagent with olefinic double bonds was applied to the determination of isopropylidene groups. The oxidation of compounds containing such groups gave a quantitative yield of acetone which could be readily determined by known iodometric and colorimetric procedures. Use of aqueous solutions of pyridine or dioxane as solvent permitted analysis of water-insoluble compounds. The colorimetric determination of acetone was then preferred. This method also allowed a simultaneous estimation of terminal methylene groups. The content of isopropylidene groups of commercial samples of three terpenes of the geraniol type was determined.

INTRODUCTION

The oxidation of olefinic double bonds with the periodate–permanganate reagent was described in part I of this series (2). From the general characteristics of this reaction the oxidation of an isopropylidene group would be expected to proceed as follows at pH 7–8:



each isopropylidene group yielding one molecule of acetone. At neutrality the acetone formed by the oxidation of mesityl oxide did not appear to react further with the reagent (2). The yield of acetone could, therefore, be used as a convenient measure of isopropylidene groups in general. In conjunction with the semiquantitative estimation of terminal methylene groups, described in part II (3), such a procedure should also make it possible to distinguish readily between these two positions of unsaturation, which would be of special interest in the study of terpenes and resin acids.

RESULTS AND DISCUSSION

In preliminary experiments the effect of pH on the stability of acetone in the oxidation mixture was determined. Table I shows the amount of oxidant consumed when acetone was oxidized at varying pH values with five times the amount of oxidant used in the standard procedure (2).

Since the hydroxylation and cleavage steps are relatively fast reactions (2), it is safe to assume that the amount of acetone lost owing to oxidation will be insignificant at a pH below 8.0.

Acetone can be conveniently determined both iodometrically (5) and colori-

metrically (7). In the former method the acetone was distilled from an alkaline solution after the excess oxidant had been destroyed with sodium arsenite solution. This method could not, however, be used when volatile compounds were present which react with iodine or alkaline iodine solution, unless these were removed by prior oxidation. The colorimetric method proved to be less accurate (the error was $\pm 2\%$), but it had the advantage that aliquots could be used directly from the reduced reaction mixture. In addition, the color reaction is more specific and no interference was obtained when formaldehyde was present in concentrations more than twice that of acetone.

Water-soluble Compounds

From experiments using mesityl oxide as test substance the following conclusions were drawn:

(1) The amount of oxidant should be at least twice the theoretical amount required for complete oxidation as deduced from the above reaction scheme.

(2) Increasing the amount of permanganate in the periodate–permanganate reagent increases the rate of reaction (2), but too high a permanganate concentration results in a more rapid oxidation of the acetone formed.

(3) If other volatile compounds, such as aldehydes, are formed during the oxidation, these may be removed from the distillate by dichromate oxidation (4) in acidic medium at room temperature. Acetone itself is not oxidized under these conditions, but a second distillation step is then introduced into the procedure. As an alternative, the more convenient, though slightly less accurate, colorimetric determination of acetone may be used.

Under optimum conditions the yield of acetone was 95 to 96% of the theoretical. This represented a practically quantitative result, since the sample of mesityl oxide used gave after oxidation a yield of about 2% formaldehyde, indicating the presence of 2 to 3% of the isomer having the double bond in the 4,5-position. The presence of this isomer in mesityl oxide has been reported before (1).

Because of the possible interference with the iodometric determination by volatile reaction products or unreacted starting material from the oxidation of mesityl oxide, 3-methyl-2-butenoic acid appeared to be a more satisfactory test substance and was consequently prepared by hypochlorite oxidation of mesityl oxide (6). On oxidation this acid would be expected to yield acetone, oxalic acid, and carbonic acid, with glyoxylic acid and formic acid as intermediates. The only distillable product at any stage of the periodate–permanganate oxidation from an alkaline reaction mixture would therefore be acetone.

The rate of oxidation of 3-methyl-2-butenoic acid was similar to that of mesityl oxide, e.g. at pH 7 the amount of oxidant consumed was equivalent to 2.08, 3.09, 3.65, and 3.88 oxygen atoms after 0.05, 0.5, 3, and 70 hr. respectively. A formaldehyde determination indicated the presence of up to 2% of the Δ^3-isomer. The yield of acetone was determined iodometrically after different reaction times (from 5 to 360 min. at 5 to 10 min. intervals) with the reagent containing the normal and twice and four times the normal amount of potassium permanganate. A practically quantitative yield was obtained (98.8, 98.8, and 98.4 $\pm$0.4% respectively) within one hour of reaction time, and this yield did not appear to drop during a further period of two hours.

Water-insoluble Compounds

When the above procedure was applied to terpenes of the geraniol group, difficulty was encountered because of their insolubility. A study was therefore made of certain organic solvents which, when added to the aqueous reaction mixture, would increase the solubility sufficiently without interfering with the periodate–permanganate oxidation. Of the solvents tested only pyridine and dioxane proved suitable. Reagent blanks containing these solvents, especially dioxane, consumed appreciable amounts of iodine in excess of the aqueous reagent blank (Table II), but the oxidation of mesityl oxide appeared to be little altered in rate and degree by their presence (Table III). When pyridine

was used the pH of the reaction mixture was 8.4 and the addition of potassium carbonate was therefore omitted. The reaction mixture containing 25% dioxane decolorized overnight and the reaction stopped. This may have been due to the regeneration of permanganate by periodate being slowed down to a critical value. When 30% or more solvent was used, this phenomenon was

noticed at an earlier stage. However, the early part of the reaction involving the formation of acetone is relatively fast and a quantitative yield of acetone could still be obtained.

Difficulties were experienced when the iodometric method for determining acetone was used since most of the solvent distilled over with the acetone. With dioxane the error introduced was not large, but when pyridine was used the procedure had to be modified by introducing a second distillation step. After the acetone and pyridine from the first distillation was collected, excess 10% sulphuric acid (20–25 ml.) was added and the acetone was redistilled. Although the results obtained by this modification were satisfactory, the procedure was cumbersome and the colorimetric method was preferred. The latter method gave results similar to those with aqueous solutions as long as the reagent blank and reference samples contained the same amount of solvent.

3-Methyl-2-butenoic acid was oxidized in the different solvent systems under the usual conditions, and aliquots were analyzed colorimetrically after various reaction times. The time required to reach a maximum yield of acetone was different for each medium, but the maximum values were maintained for 5 to 10 min. After this period the yield dropped somewhat faster than would be expected from the rate of oxidation of the acetone (in an aqueous medium) alone. The results obtained were:

(1) in aqueous solution = 99% of theoretical (maximum after 10 min.),
(2) solution containing 25% pyridine = 100% (maximum after 30 min.),
(3) solution containing 25% dioxane = 99% (maximum after 20 min.).

The foregoing results show that the procedures outlined should be of value in both structure determination and routine analysis, especially since as little as 0.01 mM. of a substance was sufficient for quantitative results. The use of the reagent for determining the position of double bonds in unsaturated fatty acids and related compounds will be the subject of a future communication.

Application to Terpenes

The method was applied to the analysis of three commercial samples of terpenes. Each compound gave the maximum yield of acetone (see Table IV)

TABLE IV

YIELDS OF ACETONE* FROM TERPENES
Per cent of the theoretical

Medium	Terpene		
	Geraniol	Citronellol	Citronellal

already after 5 to 10 min. These results show that in each of the terpenes the isomer having the isopropylidene grouping is the major component. The same

reaction mixtures were also analyzed for their content of formaldehyde resulting from the presence of terminal methylene groups. The maximum yields for geraniol, citronellol, and citronellal were 43%, 4%, and 8.5% respectively.

EXPERIMENTAL

Apparatus

The condenser was constructed of capillary glass-tubing surrounded by an ordinary cooling jacket. The tubing extended into the receiver so that the distillate was collected under 10 to 15 ml. of water. The receiver was surrounded by ice water. The connection to the distillation flask was through a standard glass joint.

The colorimetric measurements were carried out with a Coleman electrophotometer (Junior 6A).

Reagents

Analytical grade reagents and solvents were used. Mesityl oxide (Eastman Kodak) was redistilled through a Podbielniak fractionating column. Pyridine and dioxane were further purified by treating with weak alkaline permanganate solution for 16 hr. at room temperature and redistilling over solid potassium hydroxide after the excess permanganate had been reduced.

3-Methyl-2-butenoic acid was synthesized by hypochlorite oxidation of mesityl oxide (6) and was purified by recrystallization from water and light petroleum, m.p. 67–68°C. (reported m.p. 66–67.5°C.); neutralization equivalent found 100.7, calc. 100.1. The terpenes were of technical or practical grade (Eastman Kodak) and were not purified further.

Periodate–Permanganate Oxidant

The stock solution of the oxidant contained 20.980 gm. (98.33 mM.) sodium *meta*-periodate and 167 ml. 0.01 *M* (1.67 mM.) potassium permanganate per liter. In experiments using two or four times the concentration of permanganate, the amount of periodate was reduced in order to maintain the total concentration of oxidant at 100 mM. per liter.

Standard Procedure of Oxidation

The substance to be oxidized, 0.5 mM., was dissolved in distilled water, or where necessary, in the required amount of organic solvent, and the solution was made up to 100 ml. with distilled water. To 50 ml. of this solution sufficient potassium carbonate was added (about 25 mgm. for a neutral substance) to give the final reaction mixture a pH of 7.2 to 7.5. To this solution 20 ml. stock oxidant solution was added with shaking, the time of addition being noted, and the solution was quickly made up to 100 ml. Aliquots of 10 ml. were analyzed at the desired time intervals by the method described in part I (2).

Periodate–Permanganate Oxidation and Iodometric Acetone Determination

Aliquots of 10 ml. of the oxidation mixture were placed in 100 ml. flasks having ground glass joints. At the required time interval the oxidation was stopped by adding to each aliquot 1 ml. 1 *M* sodium arsenite, 1 ml. 2 *N* NaOH, and 10 to 15 ml. water. About half the volume of this solution was distilled,

the distillate being collected in 10 to 15 ml. ice-cooled water. Five milliliters 2 *N* sodium hydroxide and 5.0 ml. 0.1 *N* iodine solution were added to the distillate and this solution was allowed to stand out of contact with direct sunlight for 10 to 15 min. Five milliliters 10% sulphuric acid was then added and the liberated iodine was titrated with 0.025 *N* sodium thiosulphate to the starch end point. When dioxane was present 10–15 ml. sulphuric acid had to be added. When pyridine was present the distillate was treated with excess 10% sulphuric acid (approx. 20 ml.) and redistilled. In this way the iodometric determination could be carried out without interference from the pyridine.

Periodate–Permanganate Oxidation and Colorimetric Acetone Determination

The solution of the compound to be oxidized, 2.0 ml., was pipetted into a 25 ml. volumetric flask and 2.0 ml. 0.1 *N* potassium carbonate, 10 ml. water, and 8.0 ml. stock oxidant solution were added. The solution was made up to 25 ml. after noting the time when the oxidant was added. Aliquots of 5.0 ml. of this reaction mixture were pipetted into 10 ml. volumetric flasks and after 5, 10, 20, or 30 min. reaction time 2.0 ml. 1 *M* sodium arsenite and 2.0 ml. 2 *N* sulphuric acid were added. The solutions were allowed to stand for 15 to 30 min., when 0.4 ml. 10 *N* sodium hydroxide (enough to neutralize the solution) was added to each sample, and these were then made up to 10 ml. These solutions could be kept for several hours before colorimetric analysis. Aliquots of 2.0 ml. of each sample were pipetted into a 25 × 200 mm. test tube and 3.0 ml. distilled water was added. When all samples, reagent blanks, and reference standards were thus prepared, 4.0 ml. 10 *N* sodium hydroxide was added with a syringe and finally, with mixing, 1.0 ml. of salicylic aldehyde solution. The salicylic aldehyde solution (1 volume of the aldehyde and 4 volumes ethanol) was used within five to six hours after preparation. The test tubes were immediately placed in a water-bath at 50°C., kept at 45–50°C. for 20 min. and then at room temperature for 30 min. The contents were transferred to 19 mm. cuvettes for immediate measurement of the percentage transmission at 530 mμ as compared to a reagent blank.

Formaldehyde Determinations

Aliquots of 1.0 ml. from the reaction mixture in the 10 ml. volumetric flasks could be used directly and these were analyzed as described in part II (3).

OZONOLYSIS OF 1-SUBSTITUTED CYCLOOLEFINS[1]

By D. G. M. Diaper[2]

ABSTRACT

Extension of an aliphatic chain by five, six, or seven carbon atoms may be achieved by adding to it a 5-, 6-, or 7-membered olefinic alicycle and subsequently breaking the double bond. Addition of the ring is achieved by a Grignard reaction between an alkylmagnesium bromide and a cyclic ketone, and the resulting 1-alkylcycloolefin is opened by ozonolysis. The end product is a 5-, 6-, or 7-keto acid.

Methods for extension of the aliphatic chain fall into two main groups; those in which one or two carbon atoms are added, and those in which the starting material and added fragment are of comparable chain length. To the former class belong the familiar cyanide and malonic ester syntheses. These are regarded as inferior in long-chain work because end products and starting materials have similar chain-lengths (and thus similar physical properties) and are difficult to separate from each other. Methods of the latter class include the Robinson (5), Noller and Adams (4), and Blaise (1) syntheses, in which a large increment is added in one step and end product is easily separated from relatively short-chain starting materials. These methods suffer from the limited accessibility of such necessary chain-extending reagents as ω-bromo, -cyano, or -aldehydo esters or ω-carbalkoxy acid halides.

Extension using an alicyclic fragment which is subsequently opened to become part of the chain is a tempting approach. Fieser and Smuszkovicz (2) showed that 1-substituted cycloalkanols (from cycloalkanones and a Grignard reagent) may be oxidized to keto acids by chromic acid at 30° in the presence of large amounts of anhydrous acetic acid. Kelkar, Phalnikar, and Bhide (3) encountered difficulty in an attempt to make a keto acid from a 1-alkylcyclohexene by strong oxidation. Schneider and Spielman (7) concluded that chromic acid oxidation of a 1-alkylcyclohexene was inferior to the alkylzinc synthesis of a keto acid. In all investigations there was evidence of concurrent reactions. If linkages other than those intended are attacked, as may well happen when oxidizing agents of poor selectivity are employed, the same problem of separation of end product from lower homologues may be encountered.

In the present investigation, opening of the alicyclic system was achieved by ozonolysis and the resulting keto aldehydes were oxidized by performic acid to the corresponding keto acids. These are "clean" reagents of high specificity and the end products in all cases were nearly white and reasonably pure. A prerequisite for success of the synthesis is unambiguity of location of the olefinic linkage. Wallach (10) has shown that, in general, dehydration of a 1-alkylcyclohexanol gives the olefin with the cyclic rather than the semicyclic double bond. During ozonolysis of the olefins of this investigation, no evidence of alkylidenecycloalkanes was encountered.

The use of cyclohexanone is illustrated above in the extension of a chain by six carbon atoms giving a 6-keto acid. It is also found that a 5-keto acid may be obtained from cyclopentanone and a 7-keto acid from cycloheptanone. Yields in the two-step synthesis are indicated in Tables I and II.

Losses in the synthesis of 1-alkylcycloolefins are attributable (cf. 6, 8) to two main causes, "coupling" of the Grignard reagent giving a paraffin hydrocarbon and reduction of the cyclic ketone giving an olefin and cycloalkanol. "Coupling" appears to be more serious when higher alkyl halides are employed, and reduction appears to be favored by branching of the Grignard reagent and by increase in the size of the alicycle. It was found to be least in the reaction involving phenylmagnesium bromide.

EXPERIMENTAL

Synthesis of 1-Substituted Cycloolefins

The procedure outlined below in the synthesis of 1-*n*-butylcyclohexene from cyclohexanone and *n*-butylmagnesium bromide is typical for all olefins listed in Table I (cf. Signaigo and Cramer (8)). Cyclohexanone (47 gm., 0.48 mole) was added during eight and one-half hours to the Grignard reagent from *n*-butyl bromide (71 gm., 0.52 mole) and magnesium (12 gm., 0.50 mole) in 200 cc. of dry ether, cooled with solid carbon dioxide to maintain an internal temperature of −40 to −20°C. Next day, the mixture was added to ice and hydrochloric acid in excess, and the ethereal solution was washed with water, three times with a saturated aqueous solution of sodium bisulphite (to remove cyclohexanone), and with potassium carbonate solution before it was dried over sodium sulphate. The product, a tertiary alcohol, was not purified, but used directly in the next stage.

Dehydration of 1-*n*-butylcyclohexanol was achieved by heating with iodine (0.2 gm., cf. 11) at reflux in an apparatus provided with a water separator. The theoretical quantity of water was collected in one and one-half hours, and the liquid remaining was fractionally distilled through a 15 cm. Widmer column. To avoid overheating during dehydration of higher tertiary alcohols it was found desirable to add xylene as a diluent. 1-*n*-Butylcyclohexene (26 gm., 40%) boiled at 71–73° at 17 mm. and had n_D^{20} 1.4592. On standing in air, the liquid darkened somewhat, became more viscous, and had a higher refractive index. This was taken to indicate polymerization, and the olefin was utilized as soon as possible in the next step.

Oxidation of 1-Substituted Cycloolefins to Keto Acids

The general procedure employed is described here for the case in which 1-*n*-butylcyclohexene was converted, by ozonolysis, to 6-ketodecanal, and this aldehyde was oxidized to the corresponding acid by performic acid, generated *in situ*. A slow stream of oxygen containing approximately 6% of ozone was passed into 1-*n*-butylcyclohexene (20 gm., 0.15 mole) in acetic acid (20 cc.) until a test sample failed to decolorize bromine and for 10 min. afterward. A technique similar to that of Noller and Adams (4) was used to decompose the ozonide as follows: The viscous solution was diluted with an equal volume of ether, cooled in ice, and treated cautiously with several cubic centimeters of water and 1 gm. (0.01 mole) of zinc dust. There ensued a violent reaction after an induction period, and next day the solution was filtered and separated. The ether solution was washed with water, and then 20 cc. of hydrogen peroxide (30%, 0.2 mole), 25 cc. of formic acid (90%), and 1 gm. of ammonium acetate were added. After 24 hr. at room temperature the mixture was diluted with ether and water and separated. The ethereal layer was shaken with several portions of aqueous ferrous sulphate until free from peroxides, and the acidic product was freed from neutral impurities using potassium carbonate solution in the usual manner. After removal of ether, 6-ketodecanoic acid was recrystallized from petroleum ether; the yield was 61–68% in several runs and the acid melted at 46–47°.

A simplification of the oxidation procedure was made possible by the obser-

vations that formic acid may replace acetic acid as an ozonization solvent and that performic acid oxidation appears to be unaffected by the presence of zinc salts. In the modified procedure, 21 gm. of 1-*n*-butylcyclohexene in an equal volume of formic acid was treated with ozonized oxygen as before except that care was necessary in using the bromine test as the formic acid gradually decolorized bromine. After treatment with zinc, water, and ether, the reaction mixture was filtered but not washed before treatment with a further 20-cc. portion of formic acid and 20 cc. of 30% hydrogen peroxide. The yield of keto acid was 16.5 gm. (58%).

A neutral fraction was obtained in varying quantity after performic acid oxidation of 6-ketodecanal. It was shown to contain unchanged aldehyde, as a second treatment with performic acid gave some 6-ketodecanoic acid. There remained, however, a residual neutral fraction, corresponding to 10–15% of the starting material, which was not an aldehyde and showed evidence of unsaturation. This material will be further studied.

Ozonolysis of 1-Phenylcyclohexene

A modified procedure was employed in the ozonolysis of the aromatic hydrocarbon 1-phenylcyclohexene. By a technique similar to that of Dawson (9) this substance was ozonized in ethyl acetate at −70° under conditions designed to avoid over-ozonization with attack of the benzene nucleus. Following catalytic hydrogenation of the ozonide, the ethyl acetate solution containing 5-benzoylpentanal was treated with performic acid as previously described. From 11.4 gm. of starting material, the yield of 5-benzoylpentanoic acid was 10.3 gm. (69%), melting at 75°.

Undecenyl Bromide

1-Bromoundec-10-ene (undecenyl bromide) made by the action of phosphorus tribromide upon the corresponding alcohol must be freed from unchanged alcohol before use in the Grignard reaction. This cannot be achieved by distillation, as the two compounds have similar boiling points. The crude bromide (80 gm.) was taken up in dry ether (150 cc.) and treated with 20 gm. of phosphorus pentoxide. Next day, a further 20-gm. portion of phosphorus pentoxide was added, and the mixture was frequently shaken during the next four hours and then decanted into 250 cc. of 50% aqueous methanol. Concentrated aqueous ammonia was quickly added until the mixture was alkaline to phenolphthalein, and after it was washed with a similar portion of aqueous-methanolic ammonia and with water, the ether solution was dried and distilled.

NOUVELLES SYNTHÈSES DE L'ACIDE GLUTARIQUE, DE LA GLUTARIMIDE ET DE L'ACIDE GLUTAMIQUE

PRÉPARATION DE LA N-BROMOGLUTARIMIDE[1]

PAR GÉRARD PARIS, ROGER GAUDRY ET LOUIS BERLINGUET

RÉSUMÉ

La monoamide de l'acide glutarique a été obtenue par condensation du cyanure de potassium avec la γ-butyrolactone, suivie de neutralisation et d'hydrolyse partielle du sel de potassium du nitrile intermédiaire. Cette monoamide a été facilement hydrolysée pour donner quantitativement l'acide glutarique. La glutarimide a été obtenue avec un excellent rendement, en cyclisant par chauffage, la monoamide de l'acide glutarique. L'ester éthylique monobromé de l'acide glutarique, préparé à partir de l'acide glutarique, a été condensé avec la phtalimide de potassium par chauffage dans la diméthylformamide. L'hydrolyse de ce dérivé phtalimidé a donné l'acide glutamique avec un bon rendement. La N-bromoglutarimide a été préparée à partir de la glutarimide par bromuration en présence d'hydroxyde de potassium. Cette N-bromoglutarimide s'est comportée, dans les quelques essais effectués à date, comme un bon agent de bromuration, comparable à la N-bromosuccinimide.

Les synthèses de l'acide glutarique et de la glutarimide sont assez nombreuses. On s'est servi comme produits de départ de l'acide L-glutamique naturel (6), du dicyanure de triméthylène (16, 21), de la cyclopentanone (14), de la δ-hydroxyvaléraldéhyde (3) de l'acrylonitrile et des esters β-cétomaloniques (17), du dihydropyranne (8), et enfin de la pipéridine (27).

Les produits de départ des principales synthèses de l'acide glutamique sont aussi nombreux: acide lévulique (25), acide β-aldéhydopropionique (12), acide α-cétoglutarique (13, 15, 24), ester acylaminomalonique (7, 9, 22).

Toutefois peu de ces synthèses sont pratiques, soit à cause des faibles rendements, soit à cause de la rareté relative des produits de départ.

Récemment Pichat, Baret et Audinot (18) ont montré que la β-méthylbutyrolactone s'ouvrait facilement en présence de cyanure de potassium à une température de 280°C. pour donner le sel de potassium du mononitrile correspondant. Ce sel de potassium leur a permis d'obtenir avec d'excellents rendements l'acide β-méthylglutarique et la β-méthylglutarimide.

Dans le but d'élaborer une synthèse simple et facile de l'acide glutarique et de la glutarimide, nous avons repris cette synthèse et l'avons appliquée à la γ-butyrolactone, produit facilement accessible.

La γ-butyrolactone a été condensée avec le cyanure de potassium à 190°C. Le sel de potassium du mononitrile formé n'a pas été isolé mais immédiatement neutralisé par l'acide chlorhydrique concentré, soit à une température de 25°C. pour donner la monoamide de l'acide glutarique avec un rendement de 80%, soit à 0°C. pour donner le mononitrile de l'acide glutarique avec un rendement de 65%. Par hydrolyse de ces deux derniers produits, l'acide glutarique a été obtenu avec un rendement quantitatif dans le cas de la monoamide et un rendement de 80% dans le cas du mononitrile.

[1]*Manuscrit reçu le 25 juillet, 1955.*
Contribution du Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Québec.

La glutarimide est formée avec un rendement de 84% par cyclisation de la monoamide de l'acide glutarique à une température de 210°C.

Cette synthèse permettait de préparer facilement et avec d'excellents rendements l'acide glutarique et la glutarimide. Ces deux produits intermédiaires ont été utilisés pour de nouvelles synthèses de l'acide glutamique et de la N-bromoglutarimide.

Dans une nouvelle synthèse de l'acide glutamique, nous avons d'abord préparé le diester éthylique monobromé de l'acide glutarique suivant la méthode décrite par Ingold (11). Ce diester fut condensé avec la phtalimide de potassium. Le produit de condensation fut hydrolysé pour donner l'acide glutamique avec un rendement total de 50%, calculé à partir de l'acide glutarique.

La N-bromoglutarimide a été préparée à partir de la glutarimide suivant une méthode de synthèse identique à celle de la N-bromosuccinimide. Le rendement brut en N-bromoglutarimide est de 62%.

La N-bromoglutarimide ainsi préparée semble se comporter dans les essais effectués à date comme un bon agent de bromuration. C'est ainsi que nous avons bromé l'acétanilide, la triéthylamine. Nous avons oxydé l'alanine et finalement, nous avons effectué la bromuration allylique du méthylcrotonate. Les rendements obtenus se comparent avantageusement avec ceux décrits pour la N-bromosuccinimide.

PARTIE EXPÉRIMENTALE

Monoamide de l'acide glutarique

On ajoute du cyanure de potassium (17 g., 0.26 mole) à de la γ-butyrolactone (20.9 g., 0.24 mole) et on agite mécaniquement. On élève rapidement la température du mélange et on la maintient à 190°C. pendant trois heures après quoi on refroidit la solution. Le solide formé est repris à l'eau (50 ml.) et neutralisé avec un équivalent d'acide chlorhydrique (ou d'acide sulfurique concentré) à une température de 25°C. On ajoute un léger excès d'acide chlorhydrique (19.5 ml. en tout) et on laisse reposer quelque temps. On extrait la monoamide à l'éther. L'éther est séché sur du sulfate de sodium anhydre, puis évaporé à sec sous pression réduite. L'huile résiduelle brunâtre pèse 25.5 g. Rendement brut: 80%.

Par distillation fractionnée de cette huile, on obtient la monoamide contaminée par un peu de la glutarimide formée par chauffage lors de la distillation, lequel mélange distille à 150–155°C. sous 4.5 mm. La monoamide pure est extraite à l'éther. Point de solidification 14–15°C., $n_{20} = 1.450$. Calculé pour $C_5H_9O_3N$: N, 10.69%. Trouvé: N, 10.60%.

Acide glutarique

(*a*) *À partir de la monoamide*

On dissout la monoamide brute (5 g., 0.038 mole) dans 50 ml. d'eau et on ajoute 50 ml. d'acide chlorhydrique concentré. Le mélange est chauffé à reflux pendant une heure. On évapore la solution à sec sous pression réduite. On dissout le résidu dans l'eau chaude et on le décolore au noir animal. L'eau

est évaporée sous pression réduite. Par recristallisation du chloroforme bouillant, on obtient l'acide glutarique, débarrassé du chlorure d'ammonium insoluble. Le rendement est quantitatif: 5.02 g. P. f. 98–99°C. Litt: 97.5°C. (16).

(*b*) *À partir du mononitrile*

Le mononitrile (5 g., 0.04 mole) est hydrolysé de la même façon sauf que la durée de l'hydrolyse est portée de une à trois heures. Rendement: 4.67 g., 80%. P. f. 98–99°C. Litt: 97.5°C. (16).

Mononitrile de l'acide glutarique

La neutralisation lente à 0°C. avec un équivalent d'acide chlorhydrique concentré (19 ml.) du produit de condensation obtenu en traitant la γ-butyrolactone (16.5 g., 0.19 mole) par le cyanure de potassium (13 g., 0.20 mole) donne le mononitrile correspondant. On extrait le nitrile à l'éther lequel est séché sur du sulfate de sodium anhydre, puis évaporé à sec sous pression réduite. Le nitrile ainsi obtenu est recristallisé d'un petit volume d'éther pour enlever les traces de monoamide présente laquelle est beaucoup plus soluble. Rendement: 14.1 g., 65% P. f. 41–42°C. Litt: 45°C. (5). Calculé pour $C_5H_7O_2N$: N, 12.39%. Trouvé: N, 12.42%.

Glutarimide

(*a*) *À partir de la monoamide*

Dans un ballon de 50 ml. à un col surmonté d'un réfrigérant à air, on place la monoamide brute (5 g., 0.04 mole). On élève rapidement la température et on la maintient à 210–215°C. pendant trois heures. La solution est refroidie, après quoi on dissout le résidu dans l'eau chaude et on le décolore au noir animal. L'eau est évaporée sous pression réduite. Le résidu est recristallisé de l'alcool éthylique. Rendement 3.6 g., 84%. P. f. 154°C. Litt: 154.5°C. (27). Calculé pour $C_5H_7O_2N$: N, 12.38%. Trouvé: N, 12.39%.

(*b*) *À partir de l'acide glutarique*

Le chauffage de l'acide glutarique en présence d'ammoniaque concentré suivant la méthode habituelle (1) donne la glutarimide avec un bon rendement quoique le rendement total, calculé à partir de la γ-butyrolactone, soit inférieur à celui obtenu en passant par la monoamide.

Diester éthylique de l'acide 2-bromoglutarique

Le diester éthylique de l'acide 2-bromoglutarique est préparé à partir de l'acide glutarique par traitement au chlorure de thionyle, bromuration et réaction avec l'alcool éthylique, suivant la méthode décrite par Ingold (11). Le rendement a toutefois été augmenté de 50% à 80–85% en effectuant la bromuration avec l'aide de rayons ultraviolets.

Acide glutamique

Dans un ballon à trois cols, muni d'un agitateur et d'un réfrigérant surmonté d'un tube de chlorure de calcium, on ajoute de la phtalimide de potassium (18 g., 0.097 mole) à un mélange du diester éthylique de l'acide 2-bromoglutarique (25 g., 0.094 mole) et de 100 ml. de diméthylformamide. On agite une heure à la température d'ébullition de la diméthylformamide (152–154°C.).

La solution est refroidie. On filtre le précipité de bromure de potassium (9.5 g., théorie 11.1 g.). On évapore la solution à sec sous pression réduite et on ajoute de l'acide chlorhydrique concentré. On chauffe à reflux pendant 15 h. puis on évapore à sec. On reprend à l'eau et, après refroidissement, on filtre l'acide phtalique (15.5 g., théorie 16.1 g.) La solution est concentrée à faible volume, amenée à un pH de 3.2 au moyen de NaOH 10%, et placée à la glacière pendant plusieurs heures. Une première fraction (8.5 g.) précipite. Au bout de plusieurs jours on obtient une seconde fraction (2 g.). Rendement brut en acide glutamique: 10.5 g., 76%. Après recristallisation de l'acide aminé de l'alcool et de l'eau le p. f. est de 180–185°C. Litt.: 198°C. (26). Calculé pour $C_5H_9O_4N$: N, 9.52%. Trouvé: N, 9.48%. L'acide glutamique fut identifié par chromatographie sur papier ascendante et circulaire avec la pyridine à 80% comme solvant: R_f 0.21. De plus l'acide glutamique, étant un acide aminé monoaminé dicarboxylique, a été analysé par électrophorèse sur papier (pH 8.6, 4 ma., 200 volts). La bande obtenue après révélation à la ninhydrine correspondait exactement avec celles d'échantillons commerciaux d'acide glutamique.

L'acide glutamique fut aussi préparé à partir du diester éthylique monobromé de l'acide glutarique en présence d'ammoniaque sous pression. La présence de sels d'ammonium interfère toutefois dans l'isolement de l'acide libre.

N-Bromoglutarimide

On ajoute avec agitation rapide de la glutarimide (5 g., 0.044 mole) à une solution d'hydroxyde de potassium (2.78 g. de KOH dans 10 cc. d'eau) maintenue à −5°C. Au bout d'une minute, on ajoute rapidement et en une seule addition 7.1 g. de brome. Le solide formé (5.3 g., 62%) est filtré, lavé à l'eau froide, et recristallisé immédiatement de l'eau chaude. Rendement de la N-bromoglutarimide: 4.4 g., 52%; p.f. 185–190°C. d. Calculé pour $C_5H_6O_2NBr$: C, 31.40%; H, 3.14%; N, 7.13%; Br, 41.62%. Trouvé: C, 28.60%; H, 3.02%; N, 6.30%; Br, 44.08%. On peut aussi recristalliser la N-bromoglutarimide de l'acide acétique glacial.

Lorsqu'on solubilise la glutarimide dans une solution d'hydroxyde de potassium au lieu d'une solution d'hydroxyde de sodium, la N-bromoglutarimide obtenue est plus pure et plus facile à recristalliser, quoique les rendements obtenus lors de la bromuration soient inférieurs.

Réactions effectuées à l'aide de la N-bromoglutarimide

(*a*) *p-Bromoacétanilide*

La méthode est identique à celle décrite par Buu-Hoi' (4) pour la N-bromosuccinimide. Le résidu obtenu est recristallisé d'un mélange d'alcool et d'eau. Le rendement en *p*-bromoacétanilide est quantitatif. P. f. 167°C. Litt: 167°C. (10). Calculé pour C_8H_8ONBr: N, 6.5%; Br, 37.4%. Trouvé: N, 6.5%; Br, 37.5%.

(*b*) *Bromhydrate de la triéthylamine*

La méthode est la même que celle décrite par Braude et Waight (2) pour la N-bromosuccinimide. On ajoute en faibles portions de la N-bromoglutarimide à une solution de triéthylamine dans du tétrachlorure de carbone

refroidie à 0°C. Le solvant est évaporé. La glutarimide est extraite à l'acétone. Le bromhydrate fond à 245°C. Litt: 245–246°C. (2).

(*c*) *Dérivé 2,4-dinitrophénylhydrazone de l'acétaldéhyde, obtenu à partir de l'alanine*

La méthode est la même que celle décrite par Schönberg et collaborateurs (23) pour la N-bromosuccinimide. On ajoute de la N-bromoglutarimide à une solution aqueuse d'alanine. Après 10 min., on refroidit la solution et on ajoute du chlorhydrate de la 2,4-dinitrophenylhydrazine. Après recristallisation de l'alcool le dérivé fond à 146°C. Litt: 147°C. (19).

(*d*) *γ-Bromométhylcrotonate*

La méthode est la même que celle décrite par Ziegler et collaborateurs (28) pour la N-bromosuccinimide. On ajoute de la N-bromoglutarimide à un grand excès de méthylcrotonate et on chauffe à reflux pendant une heure. La solution est ensuite refroidie et la glutarimide formée est filtrée. Le γ-bromométhylcrotonate distille à 65°–68°C. sous 4.5 mm. $n_{20} = 1.495$. Litt: $n_{19} = 1.498$ (20).

REMERCIEMENTS

Les auteurs sont heureux de remercier le Conseil National des Recherches du Canada pour l'octroi à l'un d'eux (G. P.) d'une bourse qui a permis la réalisation de ce travail.

NOTES

A QUARTZ SPIRAL-TORSION MICROBALANCE*

By W. Bushuk† and C. A. Winkler

During a study of the adsorption of vapors and gases on porous powders with a Gulbransen type (1) torsion balance it was found that the instrument (at least the particular one available) lacked stability over a range of pressures and temperatures. A McBain–Bakr (2) quartz spiral balance had the necessary stability but had inadequate load capacity for a spiral with sufficient sensitivity. This note describes a null-point microbalance in which a torsion wire supports the load and the increase in weight during adsorption is determined with a highly sensitive quartz spiral.

A practically self-explanatory schematic diagram of the complete balance assembly is shown in Fig. 1. It has been found an advantage to have suitable

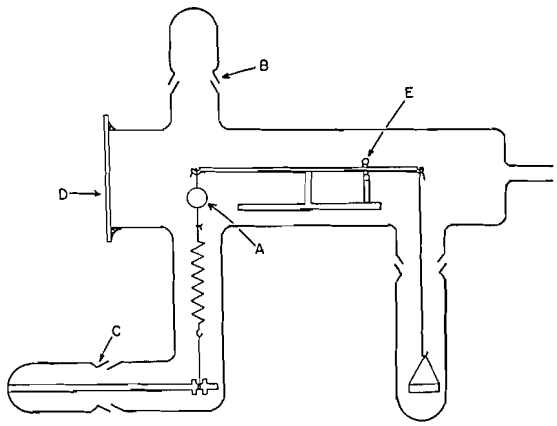

Fig. 1.

arrests (E) on the balance frame to limit the movement of the beam and thereby reduce the possibility of damage to the beam or the spiral. The quartz spiral is attached, as shown, from a hook on the counterpoise, A, at the opposite end of the beam from which the sample is suspended. Access to the balance may be had through B. The tension in the spiral is varied by winding or unwinding a very thin silk thread, which hangs from the lower end of the spiral, on a glass rod fitted through a ground glass joint C. Increase in weight during adsorption is determined from the extension of the spiral necessary to bring the beam to a null-point in the field of a microscope focused through the window D.

This type of balance has the calibration characteristics of the spiral‡

THE VISCOSITIES OF AMMONIUM NITRATE SOLUTIONS AT 180°C.

BY A. N. CAMPBELL AND G. H. DEBUS*

Because of our interest in the Robinson–Stokes conductance equation (4), which requires a knowledge of the viscosity in order to calculate the equivalent conductance for any given concentration, we have determined the viscosities, at 180°C., of ammonium nitrate solutions ranging in concentration from 0.80% by weight up to 100% (molten salt). The conductances of these solutions had previously been determined in this laboratory (2). After obtaining the viscosities, however, we realized that not even a reasonable guess could be made at the value of Λ_0, the limiting conductance, at 180°. Elsewhere, we have made such guesses for temperatures of 35°, 95°, and even 110°C. (1) but the more the temperature is removed from 25°C., the only temperature at which Λ_0 is known experimentally, the greater the uncertainty. We therefore feel that our viscosity figures should be published at this time.

It is apparent that, if as much importance is attached to the Robinson–Stokes equation by others as by us, this must result in a stimulation of work in the dilute region at temperatures other than 25°C. The data might then be profitably treated by Stokes' simplified equation (3) to obtain Λ_0. A rigorous test of the Robinson–Stokes equation could then be made at temperatures other than 25°, since good data on conductances of concentrated solutions are beginning to accumulate.

EXPERIMENTAL

The method used has been described elsewhere (1). We express our results to the third decimal, the third decimal being uncertain. The viscosity is given as relative viscosity only, since the absolute viscosity of water is not known with great accuracy at 180.0°C.

RESULTS

The results are contained in Table I.

THE DETERMINATION OF HYDROGEN CHLORIDE IN TITANIUM TETRACHLORIDE*

BY T. R. INGRAHAM†

INTRODUCTION

Titanium tetrachloride, as prepared by the chlorination of titanium oxide in the presence of carbon, generally contains appreciable quantities of dissolved hydrogen chloride. The hydrogen chloride may form during the chlorination owing to the presence of moisture or hydrocarbons. Unlike the other impurities present (Cl_2, $COCl_2$, $VOCl_3$, $SiCl_4$, etc.) it is not completely eliminated during subsequent purification procedures. Also, since titanium tetrachloride is strongly hydroscopic, additional amounts of hydrogen chloride form and contaminate the product during handling in moist air.

When titanium tetrachloride is reduced to metallic titanium, the presence of HCl causes embrittlement of the metal due to hydrogen absorption. Hence,

THE DETERMINATION OF HYDROGEN CHLORIDE IN TITANIUM TETRACHLORIDE*

BY T. R. INGRAHAM†

INTRODUCTION

Titanium tetrachloride, as prepared by the chlorination of titanium oxide in the presence of carbon, generally contains appreciable quantities of dissolved hydrogen chloride. The hydrogen chloride may form during the chlorination owing to the presence of moisture or hydrocarbons. Unlike the other impurities present (Cl_2, $COCl_2$, $VOCl_3$, $SiCl_4$, etc.) it is not completely eliminated during subsequent purification procedures. Also, since titanium tetrachloride is strongly hydroscopic, additional amounts of hydrogen chloride form and contaminate the product during handling in moist air.

When titanium tetrachloride is reduced to metallic titanium, the presence of HCl causes embrittlement of the metal due to hydrogen absorption. Hence,

**Published by permission of the Acting Deputy Minister, Department of Mines and Technical Surveys, Ottawa, Canada.*
†Metallurgist, Extractive Metallurgy Section, Division of Mineral Dressing and Process Metallurgy, Mines Branch, Ottawa, Canada.

to control the embrittlement due to hydrogen, it is necessary to have a convenient analytical method for determining the amount of HCl dissolved in $TiCl_4$ and for following its removal by vacuum distillation. With the exception of an infrared spectroscopic determination recently published by the U.S. Bureau of Standards (1), little attention appears to have been given to this determination.

EXPERIMENTAL

Apparatus

Since the freezing points of HCl and $TiCl_4$ differ widely (−112°C. and −30°C. respectively), and since it was found that HCl was readily liberated from cold $TiCl_4$ solutions under vacuum, a method was developed to measure the pressure developed by a known volume of HCl liberated from $TiCl_4$ solutions. The apparatus is shown diagrammatically in Fig. 1.

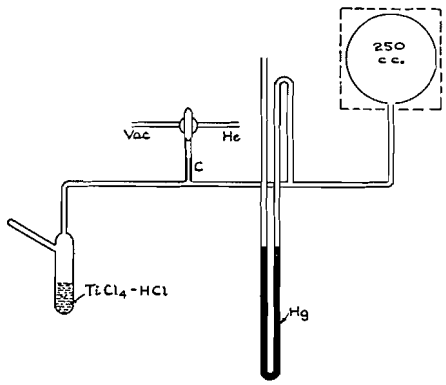

FIG. 1. Apparatus for determining HCl in $TiCl_4$.

The apparatus was constructed entirely of pyrex glass. Stopcocks were greased with Dow-Silicone stopcock grease. It was found that under the experimental conditions used in HCl determinations, no protection was required for the mercury in the manometer, or its alternative, a McLeod Gage. Volumes of all sections of the apparatus were determined before assembly by filling with water.

Procedure

The apparatus was thoroughly evacuated and flushed, using a mechanical pump and helium. With the apparatus at atmospheric pressure, an entry was blown into the $TiCl_4$ bulb and a specified (25.0 ml.) quantity of $TiCl_4$ admitted by pipette against a gentle countercurrent of helium. Helium was chosen because of its low condensation temperature. The apparatus was then resealed, the $TiCl_4$ sample frozen with liquid air, and the helium evacuated from the apparatus. As a precaution against attack of the stopcock grease by HCl, the capillary section C was then sealed, thus isolating the system.

When the liquid air was removed from the $TiCl_4$ container, the $TiCl_4$ melted slowly with a visible liberation of gas. When the $TiCl_4$ had melted completely, but had not been heated sufficiently to develop an appreciable

vapor pressure, it was refrozen with a slurry of CO_2 in a CCl_4–$CHCl_3$ mixture. This reduced the vapor pressure of $TiCl_4$ in the system to a very small value but did not alter the pressure developed by the HCl.

RESULTS

From the pressure of HCl developed in the system, and the known volume of the system, the quantity of HCl originally dissolved in the $TiCl_4$ was calculated assuming the Ideal Gas Law.

It was found that no change took place in the original pressure when the $TiCl_4$ was repeatedly refrozen and remelted. It was also shown that once a sample had been degassed by this procedure, the removal of HCl was virtually complete, as indicated by a zero HCl content when the determination was repeated on the same sample. Repeat determinations on previously degassed samples also showed that the helium used did not dissolve in or become mechanically trapped in the $TiCl_4$ during the determination.

Examination of the evolved gas with an infrared spectroscope has shown that HCl was the only constituent present.

The following results were obtained from triplicate samples of reagent grade $TiCl_4$:

Sample	% HCl
1	0.032%
2	0.034%
3	0.030%

When a sample of $TiCl_4$ at room temperature had been saturated with HCl at atmospheric pressure, it was found to contain 0.117% HCl.

CONCLUSIONS

The proposed method yields reproducible results for HCl within the range usually found in $TiCl_4$ (less than 0.1%).

THE ACTION OF PYRIDINE ON D-MANNITOL HEXANITRATE[1]

BY J. R. BROWN AND L. D. HAYWARD

ABSTRACT

From a 0.368*M* solution of D-mannitol hexanitrate in pyridine at 30±5°C. a gas consisting of nitric oxide, nitrous oxide, and nitrogen was evolved and D-mannitol-1,2,4,5,6-pentanitrate and pyridinium nitrate were recovered after dilution with water. The amount and composition of the gas mixture were sensitive to traces of moisture in the pyridine. Establishment of a material balance for the reaction indicated that approximately two moles of pyridine suffered ring cleavage while 0.25 mole of hexanitrate was completely denitrated and 0.75 mole of pentanitrate was formed. Some features of the mechanism of the denitration reaction are discussed.

In earlier papers it was shown that pyridine caused selective partial denitration of dulcitol (22) and D-mannitol (18) hexanitrates; the corresponding pentanitrates were recovered in 67–73% yield and identified as the 3-hydroxy derivatives in each case. Elrick and collaborators have recently confirmed these results with D-mannitol hexanitrate and have also shown that treatment with an aqueous acetone solution of ammonium carbonate gave a similar yield of the same D-mannitol pentanitrate (11).

The pyridine denitration amounted to the replacement of nitronium ion by a proton at the oxygen atom of carbon 3 in the hexitol hexanitrates since no racemization or inversion of the asymmetric centers occurred. In the present research the nonhexitol products of the reaction of pyridine with D-mannitol hexanitrate were explored in an attempt to reveal further details of this unusual selective reaction (32).

Pure D-mannitol hexanitrate dissolved readily in pyridine in a molar ratio of 1:34 to give an initially colorless solution which rapidly turned yellow and then deep red while external cooling was required during the first hour to maintain the temperature below 35°C. When the reaction was carried out in an open vessel (Runs F and G), small bubbles of gas rapidly rose through the solution and a red-brown vapor collected in the upper part of the flask. After the solution was left for 24 hr. at room temperature a thin film of colorless crystals was observed on the inner walls of the flask above the solution. This material was collected and identified as pyridinium nitrate. In other runs (A to E), contact with the atmosphere was avoided during the reaction and the temperature maintained at 30±2°C. by combining the reactants in the

Toricellian vacuum of a water-cooled du Pont nitrometer, and in these cases the gas evolved was colorless and no crystals of pyridinium nitrate appeared.

The volume of the gas evolved in the nitrometer was measured at intervals, corrected for the vapor pressure of pyridine (34), and plotted against time (Fig. 1, Runs A and B). Extrapolation of the nearly linear, later portion of these rate plots to zero time indicated the production of about 1.33 moles of gas per mole of hexanitrate in the initial vigorous reaction. The addition of small amounts of water to the pyridine considerably reduced the amount of

Chemical (20) and mass-spectrometric (17) methods for determining nitrous oxide, nitric oxide, and nitrogen in admixture have but recently been reported; the procedure developed in the present case appeared to be new and although probably less accurate, was considerably more straightforward than the above. Nitric oxide was determined in the evolved gas by mixing it with an excess of pure oxygen and exposing the mixture to a fine stream of mercury droplets until it became colorless and constant in volume. Previous reports of this reaction (10, 23, 24) were qualitative in nature; our experiments with samples of the pure gases showed the reaction to be quantitative and to be represented by the following equation at room temperature:

$$NO_{(g)}+O_{2(g)}+Hg_{(l)} \rightarrow HgNO_{3(s)}.$$

After removal of the nitric oxide the remaining gas was analyzed for nitrous oxide, carbon dioxide, and the known excess of oxygen in an Orsat apparatus (28) and for nitrogen by gas-density measurements on the nonabsorbable residual gas (19, 28). Appropriate corrections were made for the pyridine vapor and its coabsorption with the nitrous oxide. The over-all accuracy of the method was assessed at 1.5% with known samples of the individual gases.

Crystalline D-mannitol-1,2,4,5,6-pentanitrate was recovered from the pyridine solutions as previously described (18) when these were diluted with water; the yields obtained at different reaction times are shown in Table II.

[a] *Water was added to the pyridine before reaction, see Table I.*
[b] *The reaction mixture was exposed to air (18).*

An orange-brown, partially crystalline residue, 42% of the weight of the hexanitrate used, was obtained by careful evaporation of an aliquot of the yellow aqueous filtrate, and crystalline pyridinium nitrate (31% of the residue) was isolated from this solid by adsorption of the colored material on charcoal. Paper chromatography of the aqueous filtrate indicated about 14 components to be present, but no clear-cut separation of these substances could be achieved by fractional crystallization, solvent partition, dialysis, adsorption chromatography on silica gel, or by treatment with an anion exchange resin. Attempts

to separate pyridine quantitatively from the residue by precipitation from acetic acid solution as the perchlorate salt (4) or from aqueous solution as the copper thiocyanate complex (30) were unsuccessful and nitrogen analyses for nitrate were hampered by the presence of pyridine.

Potentiometric titration of aliquots of the aqueous pyridine filtrate first with alkali and then with acid revealed the concentration of *bound* and of *free* pyridine. The accuracy of this method was assessed as 1.1% with suitable aqueous solutions containing pyridine and pyridinium nitrate. *Bound* pyridine was recorded as equivalent to nitrate ion and the sum of *bound* and *free* pyridine as unreacted pyridine. These assumptions were supported by the actual isolation of 0.41 mole of pyridinium nitrate per mole of hexanitrate and by the agreement between the pH values measured potentiometrically at the beginning of the titration (7.57) and at the equivalence points (10.1, 4.2) and those calculated from the apparent ionization constant (pK_b 7.82) (26) measured in the known solution (initial pH, 7.55; calculated at equivalence points: 10.0, 3.3). A summary of the analyses of the four-hour runs C, D, and E is given in Table III.

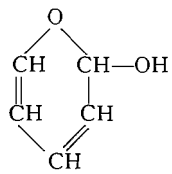
[a]*Corrected for losses in manipulations.*
[b]*Including nitrous oxide dissolved in the pyridine (29).*

As shown in Table III the total nitrogen and oxygen content of the reactants was accounted for, within the experimental error, as mannitol pentanitrate, nitrogen, nitrogen oxides, nitrate ion, and unreacted pyridine. The mannitol hexanitrate not represented by the pentanitrate recovered, an average of 0.25 mole, was therefore completely denitrated in the aqueous solution. One mole

of hexanitrate yielded on the average 0.75 mole of pentanitrate while approximately 2.0 moles of pyridine disappeared. That some of this pyridine suffered ring cleavage in the initial vigorous reaction was certain since, in Runs A, B, and C, the total nitrogen content of the pentanitrate and gases isolated, excluding that of nitrate ion and pyridine, exceeded the nitrogen content of the original amount of hexanitrate by 0.88, 1.19, and 1.03 gm-atoms per mole respectively. In Runs D and E these figures were substantially lowered (0.45 and -0.35) by the presence of water in the pyridine. The material balance calculated for the three runs (Table III) indicated that the unidentified, water-soluble, and dialyzable products were probably nitrogen-free and approximated to the composition $C_xH_x(OH)_y$ of a mixture of unsaturated aldehydes and alcohols of low molecular weight. A possible major component was glutaconaldehyde (I and II), $C_5H_6O_2$, which has been shown by Zincke and others (5, 13, 14, 36, 37) to be formed by ring opening of pyridine under salt-forming and oxidizing conditions and to have indicator properties, existing in basic media as the dark red enolate ion (I) and in acid solution as

$\bar{O}$—CH=CH—CH=CH—CHO+H^+ OHC—CH_2—CH=CH—CHO

I or



II

the yellow-brown dialdehyde (II). The aqueous pyridine denitration solutions showed a reversible change in color from pale yellow to orange with alteration of pH from 4 to 10, but attempts to isolate the dianilide of glutaconaldehyde (12) were unsuccessful and were hampered by the presence of pyridinium nitrate. Evaporation of the aqueous pyridine solution in the presence of excess potassium hydroxide left a dark, tarry, pyridine-free substance. Steam distillation of an alkaline solution of glutaconaldehyde was shown by Baumgarten and Glatzel (6) to cause decomposition of the dialdehyde to acetaldehyde, formic acid, crotonaldehyde, and other fragments.

Since several reaction products, amounting to 4 to 5% of the carbon and hydrogen content of the reactants, remained unidentified, the over-all mechanism for the denitration reaction was not obvious; some salient features of the reaction, however, were indicated:

(*a*) The source of the proton substituted for nitronium ion in the nitryloxy-fission (3) appeared to be traces of active hydrogen remaining in the pyridine after distillation from barium oxide. Nitronium ion substitution on carbon atoms of the pyridine nucleus was ruled out as the source of the proton since pyridine has been shown to stubbornly resist such substitution (16, 27). Tanberg (33) showed that samples of pyridine distilled from barium oxide

contained 0.013 to 0.028% by weight active hydrogen and Zerewitinoff (35) considered that this active hydrogen might have been present as dihydropyridine formed in the drying operation. The yield of pentranitrate obtained in Run C would require 0.028% active hydrogen to be retained in the pyridine; in Runs A and B the pyridine was exposed to the moist laboratory air for shorter periods of time and the yield of pentanitrate was lowered (Table II). Addition of small amounts of water (0.17 and 0.34% by weight) in Runs D and E considerably reduced the amounts of gas evolved but only slightly increased the yield of pentanitrate.

(*b*) Nitrogen cleaved from the pyridine ring in the anhydrous reaction appeared in part in the gaseous form, the proportion so evolved decreased with increasing moisture content although the amount of pyridine ring-opened was only slightly reduced by added water. Freytag (14, 15) showed that hygroscopically absorbed moisture reacted with pyridine to form pyridinium hydroxide which subsequently suffered ring opening, slowly in the dark, more rapidly in sunlight and in the presence of nitrate ion, to give the colored ammonium salt of the enolic glutaconaldehyde (I), "photopyridine". Lane (21) has reported colored polymeric material to be formed in addition to pyridinium nitrate and alkenes when pyridine was treated with some simple alkyl secondary and tertiary nitrate esters at reflux temperature.

(*c*) Nitrogen dioxide, if released from the hexanitrate, could be expected to form first an addition compound with the pyridine of the type described by Spencer (31) and others (1, 9) and this complex would then undergo oxidation–reduction reactions (9) to give the gaseous products observed.

(*d*) The 0.25 mole of hexanitrate not recovered in the form of pentanitrate was rendered soluble in water and, from the nitrogen balance (Table III), was probably denitrated to a tetranitrate stage in the first vigorous reaction with dried pyridine and then completely saponified during the titration of the aqueous pyridine solution with 0.2 *N* alkali.

It is of interest that in the partial denitration of other polynitrates (19, 28) the presence of free hydroxylamine in the pyridine inhibited the color formation, caused the evolution of gaseous nitrogen only, and increased the rate of reaction. The formation of the colorless dioxime of glutaconaldehyde (7) might account for the very slow development of color in those reactions.

EXPERIMENTAL

Materials and Methods

Pure D-mannitol-1,2,3,4,5,6-hexanitrate was prepared as described previously (18). The usual precautions (18, 19, 22) were observed in handling this high explosive and its derivatives.

Analytical reagent grade pyridine supplied by the British Drug Houses was dried by distilling over anhydrous barium oxide with care to avoid exposure to moist air.

Gas Evolved from D-*Mannitol Hexanitrate and Pyridine*

Pure, finely divided mannitol hexanitrate, 2.500 gm., was placed in the cup

of the reaction vessel of a du Pont nitrometer which was fitted with a thermometer well and water-cooling jacket and connected to two gas burettes by a three-way stopcock. The nitrate was quickly washed into the reaction chamber with pyridine, 15.0 ml., with care to prevent the entry of air, and the volume and temperature of the colorless gas evolved were noted at two to four minute intervals. The rate plots with the most carefully dried pyridine were closely grouped (Fig. 1, Runs A and B) and were corrected for the vapor pressure of pyridine (34). Similar experiments were carried out with pyridine to which water had been added from a graduated pipette (Fig. 1, Runs D and E) and with pyridine previously exposed to the moist air of the laboratory for three minutes before use (Fig. 1, Run C).

Admission of air or oxygen to a sample of the evolved gas caused the immediate appearance of red-brown nitrogen dioxide indicating nitric oxide to be present. The brown gas reacted slowly with the surface of the confining mercury forming a gray to white powder. When a continually renewed, fresh surface of mercury was exposed to the gas mixture by adjusting the mercury levelling bulbs so that a fine stream of mercury droplets flowed through it, the color of the gas disappeared and the residual volume became constant in about two hours at room temperature. To test the value of this reaction as a means of determining nitric oxide, 16.20 ml. of nitric oxide was generated by the nitrometer reaction from pure potassium nitrate and mixed with 16.40 ml. of dry oxygen (99.0% soluble in alkaline pyrogallol) at 757.0 mm. and 20.5°C. The mercury stream was passed through this mixture and the residual volume of colorless gas was 0.30 ml. after two hours indicating that the reaction was 99.4% complete. The grayish white powder trapped by the mercury against the walls of the gas burette partially dissolved in water to give an acid solution. It dissolved readily in dilute nitric acid and appeared to be mercurous nitrate (23, Vol. 4, p. 987).

After four hours' reaction time the pyridine denitration solution was removed from the nitrometer chamber which was flushed with pyridine (3.00 ml.) and then with water (10 ml.) and dried with acetone. Dry oxygen, approximately one half the volume of the evolved gas, was then admitted through the chamber to the burette and the mixed gases were treated with mercury as before. The volume of the colorless residual gas became constant in about two hours and the gas was then analyzed in an Orsat apparatus equipped with pipettes containing 95% ethanol, 40% potassium hydroxide, and alkaline pyrogallol solutions for absorption of nitrous oxide (28), ethanol vapor and carbon dioxide, and oxygen respectively. The percentage of nitrous oxide was given by $aV_2/V_1-p\ 100/P$, of nitrogen by bV_2/V_1, and of nitric oxide by $100-(a+b)V_2/V_1$, where a and b were respectively the percentage of the mercury-and-oxygen-treated gas absorbed by ethanol and 40% potassium hydroxide, and the percentage of the nonabsorbable gas. V_1 was the volume of the gas before admission of oxygen, V_2 the volume of the gas after treatment with oxygen and mercury, p the vapor pressure of pyridine (34), and P the atmospheric pressure. The nonabsorbable gas was found to have a molecular weight of 29.1 ± 0.5 (average of six experiments) by the method of Daniels,

Mathews, and Williams (8) and was assumed to be nitrogen (19, 28); any carbon monoxide present in the evolved gas would have been oxidized at room temperature to the dioxide by the nitrogen dioxide. In the analysis of the oxygen-and-mercury-treated gas a repass through the ethanol pipette established that the loss in volume of the gas ($<1.5\%$) on passage through the potassium hydroxide solution was probably due to absorption of ethanol vapor and not to acid gases. The results of these analyses are shown in Table I. A sample of commercial nitrous oxide was found to be 98.5% soluble in 95% ethanol, the absorption requiring 90 min.

Isolation of D-*Mannitol*-1,2,4,5,6-*pentanitrate*

The reaction mixture removed from the nitrometer was poured into water, 200 ml., contained in a ground-glass stoppered flask. The pyridine and water washings were added and after the solution had stood for two hours the precipitation of solid material was complete. The crystalline, nearly colorless product was recovered on a fritted glass crucible, washed thoroughly with water, and dried *in vacuo*. After two recrystallizations from aqueous ethanol the pure D-mannitol-1,2,4,5,6-pentanitrate melted correctly at 81–82°C. (11, 18). This melting point was not altered by further recrystallization from carbon tetrachloride. The specific rotation in alcohol was $+47.7°$ (c, 4.426).* The yields of crude pentanitrate obtained at several different reaction times with dried and moist pyridine are given in Table II.

The Aqueous Pyridine Solution from the Denitration Reaction

The combined filtrate and washings from the denitration of 5.00 gm. of hexanitrate (Run F) were evaporated to dryness *in vacuo*. The solid, odorless, orange-brown residue contained some crystals and weighed 2.61 gm. From Run G 2.1 gm. of the residue was similarly obtained. This material was readily soluble in water, methanol, ethanol, and acetic acid and to the extent of about 75% in boiling acetone. It was slightly soluble in ether, benzene, and petroleum ether.

A portion of the solid residue, 0.78 gm., dissolved in 50 ml. of water was heated to boiling with 1 gm. of activated charcoal and filtered through Kieselguhr. Evaporation of the slightly yellow filtrate and recrystallization of the residual product from acetone gave 0.24 gm. of colorless, odorless needles melting at 115.0–116.2°. The substance was pyridinium nitrate since it immediately produced a strong odor of pyridine on contact with caustic solution and did not depress the melting point (115.5–117.2°) of authentic pyridinium nitrate prepared from pyridine and yellow fuming nitric acid (2, 25). Crude pyridinium nitrate, 0.12 gm., was also recovered in Run G from the inner walls of the reaction flask which had been exposed to the laboratory atmosphere during the denitration. Further small amounts of pyridinium nitrate were obtained by fractional crystallization of an acetone extract of the residue.

Other attempts to fractionally crystallize or partition the residue with a variety of solvents gave only highly colored amorphous products. A sample of the residue (*ca.* 5 mgm.) was chromatographed on paper for 24 hr. by the

*An incorrect value of $+43.6°$ was reported earlier (18).

descending technique with butanol–water–ethanol–ammonia (40: 49: 10: 1) as irrigating solvent. The dried chromatogram was inspected under ultraviolet light, which revealed 14 distinct spots ranging in color from pink to blue with R_f values from 0.02 to 0.90. D-Mannitol pentanitrate and pyridinium nitrate did not fluoresce under the same conditions. Adsorption chromatography of the acetone extract of 0.8 gm. of residue on a column of unactivated silica gel (80–115) mesh, 1.3×52 cm.) with acetone followed by methanol as eluting solvents gave six separate fractions detected by diphenylamine reagent, each of which was amorphous and yellow to orange in color and was not investigated further.

To 0.62 gm. of pyridinium nitrate dissolved in 10 ml. of glacial acetic acid was added a 1 *N* solution of perchloric acid in acetic acid until precipitation of the colorless pyridinium perchlorate (14) was complete. The dried precipitate (0.75 gm.) represented 98% of the pyridinium nitrate. An attempt to precipitate pyridinium perchlorate from a glacial acetic acid solution of the residue (0.70 gm.) gave a dark colored solid product (0.73 gm.) which was not investigated further. Dialysis against water of a solution of 0.80 gm. of the residue in 100 ml. of water contained in a cellophane bag caused all but 0.01 mgm. of the residue to move into the dialyzing liquid in 24 hr. The brown product from the evaporated dialyzate could not be crystallized. Amberlite I-R-45 anion exchange resin, 20 gm., completely removed nitrate ion (diphenylamine test) from a solution of 1 gm. of pyridinium nitrate in 100 ml. of water. When 0.68 gm. of the residue was treated in a similar manner with the exchange resin, and the treated solution was evaporated to dryness, 0.11 gm. of a hard, amorphous, dark brown solid remained which gave a paper chromatogram similar to that of the untreated residue, but showing only nine separate spots under ultraviolet light.

A portion of the residue, 1.31 gm., was dissolved in anhydrous methanol, 50 ml., treated with sodium hydroxide pellets, 0.4 gm., and warmed with stirring on the steam bath for five minutes. When all the hydroxide had dissolved the solution became turbid and a fine brown precipitate separated while the solution gave off a distinct odor of pyridine. Concentrated hydrochloric acid (1.70 ml.; d., 1.18) was then added with stirring and the solution once more became clear and yellow in color. Aniline, 2.00 ml., was added and the solution gradually became deep cherry-red in color. Evaporation of the solution left a large amount of colorless crystalline product covered with a sticky, deep-red sirup which could not be induced to crystallize. N-(2,4-Dinitro-)-phenylpyridinium hydrochloride in ethanol solution gave an immediate precipitate of the dianilide hydrochloride of glutaconaldehyde (12) as cherry-red needles (44% of theory) when treated with hydrochloric acid and aniline under the same conditions.

Titrimetric Estimation of Pyridine and Nitrate in the Reaction Products

Twenty-five-milliliter aliquots of a 250 ml. aqueous solution containing 1.340 gm. of pyridinium nitrate and 18.2 gm. of pyridine were titrated first with 0.2 *N* potassium hydroxide solution for estimation of nitrate ion and then

with 0.6 *N* sulphuric acid for estimation of total pyridine (*free* pyridine added plus *bound* pyridine released from the pyridinium nitrate). The end points, detected with a Beckman model G pH-meter, occurred at pH 10.23 for the alkali titration and at pH 4.13 for the acid titration and had a sharpness of about 0.16 pH units per 0.20 ml. at the maxima. Found: pyridinium nitrate, 0.134, 0.135 gm. (100.3%); pyridine, 1.81, 1.81 gm. (99.5%).

Each filtrate from the isolation of D-mannitol pentanitrate in Runs C, D, and E was combined with the water washings and made up to 250 ml. and aliquots of these solutions were titrated by the above procedure. The value from the alkali titration was recorded as nitrate ion concentration and that from the acid titration as concentration of unreacted pyridine in Table III. Losses of pyridine in the manipulations were estimated at 1.1% by carrying out the procedure of denitration with a pyridine blank.

Evaporation of 25-ml. aliquots of the denitration solutions from Runs C, D, and E after addition of a measured excess of potassium hydroxide left 0.097, 0.046, and 0.102 gm. of dark amorphous residues respectively.

ACKNOWLEDGMENT

INTENSITY IN THE RAMAN EFFECT

IV. RAMAN INTENSITY SUM RULES AND FREQUENCY ASSIGNMENTS FOR CH_3CN, CD_3CN, CH_3CCl_3, AND CD_3CCl_3 [1]

By J. C. Evans[2] and H. J. Bernstein

ABSTRACT

The standard intensities of the Raman bands of CH_3CN, CD_3CN, CH_3CCl_3, and CD_3CCl_3 have been obtained for the liquids with a photoelectric, grating spectrometer. The intensity sum rules for isotopic homologues are valid within the experimental error. The infrared spectra of CD_3CN and CD_3CCl_3 have been obtained in the liquid phase and in the vapor phase. A definitive assignment of $\nu_{11}(e)$ has been made for methyl chloroform.

In Paper III (1) of this series the theoretical rules relating the intensities of vibrational Raman bands in isotopic molecules were applied to benzene and its deuterium substituted homologues. Within the experimental uncertainty the rules were found to be valid. Further intensity data have been obtained and tests of the rules have been made for CH_3CN and CD_3CN and for CH_3CCl_3 and CD_3CCl_3.

The vibrational spectra of the two deuterium substituted molecules have not been reported previously, but methyl cyanide (10, 11) and methyl chloroform (8) have been studied extensively. However, there are available only qualitative values for the depolarization ratios of the Raman bands of CH_3CN (3) and only 10 of the 12 fundamental modes of CH_3CCl_3 are well-established. Of the two remaining modes one is inactive in both Raman and infrared, while the other has been assigned differently by various authors (8). The Raman spectrum of CD_3CCl_3 enabled this last difficulty to be resolved.

EXPERIMENTAL

The CH_3CN and CH_3CCl_3 were Eastman Kodak samples; they were fractionally distilled. The methods of preparing the deuterium substituted compounds will be described: CD_3CN (6), CD_3CCl_3 (7).

A White, grating Raman spectrometer with photoelectric recording (12) and a Perkin Elmer model 112 double pass spectrometer were used to record the spectra. Depolarization ratio measurements were made (5) and corrected for convergence error (9). Standard intensities of scattering per molecule referred to the 458 cm.$^{-1}$ band of CCl_4 were obtained (2).

The observed Raman spectra and the corrected depolarization ratios for CH_3CN and CD_3CN are summarized in Table I, and the infrared data for CD_3CN are given in Table II. Figs. 1 and 2 illustrate the spectra. The doubtful Raman band reported at 1124 cm.$^{-1}$ in previous investigations on CH_3CN was not observed here. In CD_3CN, ν_1, ν_2, $2\nu_3$, and $2\nu_6$ appear to be in Fermi reson-

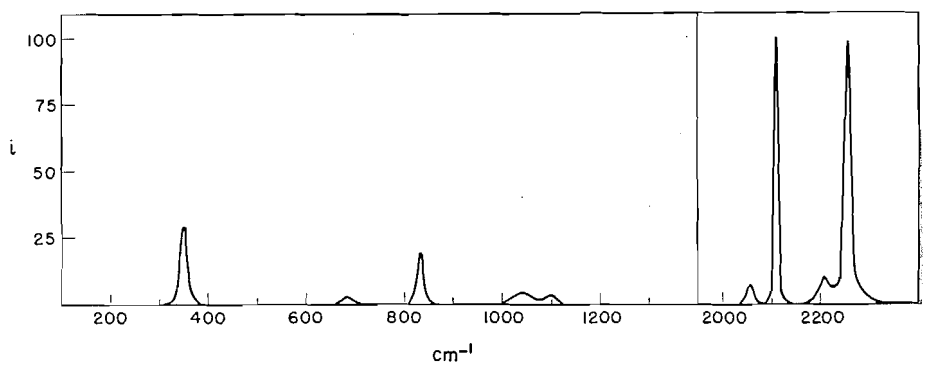

FIG. 1. The observed Raman spectrum of CD_3CN. The intensity of the band with greatest peak height is 100. Slits were 6.5 cm.$^{-1}$ in the 3000 cm.$^{-1}$ region and 7.5 cm.$^{-1}$ in the region 0–1600 cm^{-1}.

ance. Several minor features in the infrared spectrum of CD_3CN remain to be explained. The band at 1375 cm.$^{-1}$ in the vapor was not observed in the liquid spectrum while the band at 2692 cm.$^{-1}$ in the liquid has no simple explanation. The band at 1246 cm.$^{-1}$ in the vapor and one of the two bands at 1266 and 1282 cm.$^{-1}$ in the liquid seem to correspond to $4\nu_8$. (Some support for this assignment is that ν_8 also shifts to higher wave number from vapor to liquid.) The assignments of the fundamentals and of the other observed bands are straightforward.

**Liquid phase data were used in computing the frequencies in the last column of this table and Table III.*

The Raman and infrared data for CD_3CCl_3 are collected in Table III and are illustrated in Figs. 3 and 4. Corresponding to the band at 343 cm.$^{-1}$ in the liquid phase spectrum of CH_3CCl_3, there are in CD_3CCl_3 two bands, 335 (a_1) and 315 (e). This latter band is the controversial e-type mode which in CH_3CCl_3 must be at 343 cm.$^{-1}$ in the liquid and at 350 cm.$^{-1}$ in the vapor. Pitzer and Hollenberg's suggestion (8) (which is based on the observed combination tones in the far infrared) that the 350 cm.$^{-1}$ band in CH_3CCl_3 vapor is composed of an a_1 type and an e-type band is therefore confirmed.

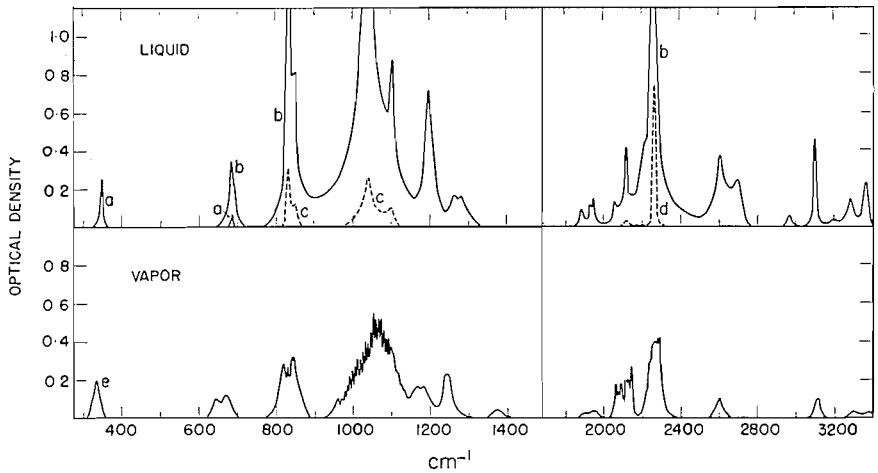

FIG. 2. The infrared spectrum of CD_3CN.
Liquid: *a*, capillary film; *b*, 0.1 mm. film; *c*, another capillary film; *d*, another capillary film.
Vapor: *e*, 6 cm. cell at 60°C.; vapor pressure ~370 mm. The remainder of the spectrum was obtained with a 1 meter cell at 20°C.; vapor pressure ~70 mm.

In CD_3CCl_3, $2\nu_8$, and $\nu_2+\nu_3$, which are presumably in Fermi resonance with ν_1, appear in the liquid spectra but are absent from the infrared vapor spectrum. This may be due to the removal or reduction of Fermi resonance by the separation of levels which are influenced differently by intermolecular interaction. The band at 2280 cm.$^{-1}$ in the liquid, assigned as $2\nu_2$, is also absent from the spectrum of the vapor.

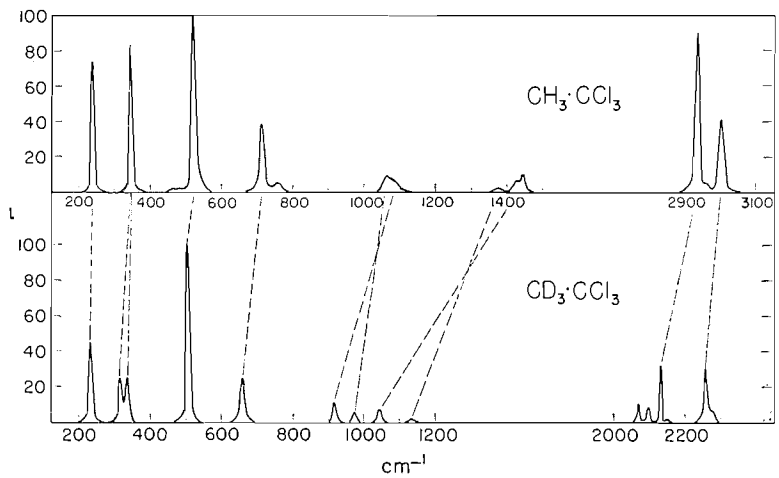

FIG. 3. The observed Raman spectra of CH_3CCl_3 and CD_3CCl_3. In each spectrum the band with greatest peak height is 100; the two scales are therefore not identical. Slits were 5 $cm.^{-1}$ in the 3000 $cm.^{-1}$ region and 6.5 $cm.^{-1}$ in the region 0–1600 cm^{-1}.

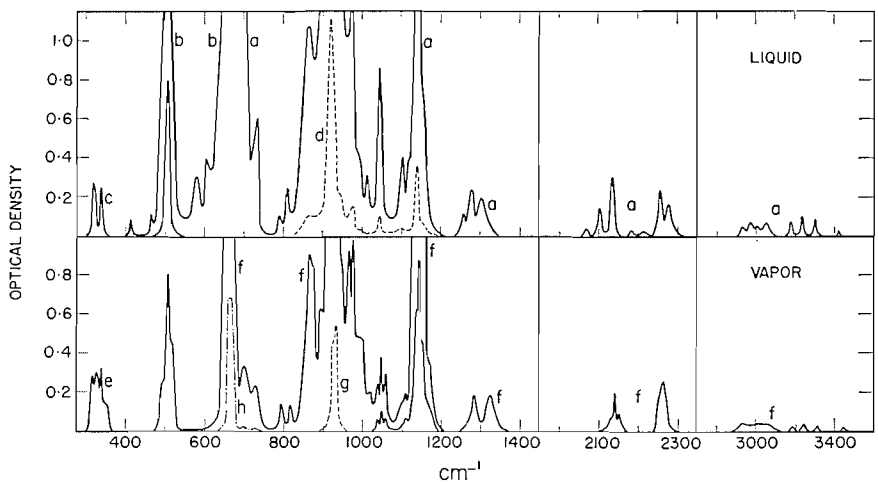

FIG. 4. The infrared spectrum of CD_3CCl_3.
Liquid: *a*, 0.1 mm. film; *b*, 0.24 mm. film; *c*, capillary film; *d*, another capillary film.
Vapor: *e*, 6 cm. cell at 60°C.; vapor pressure ~500 mm. *f*, 1 meter cell at 20°C.; vapor pressure ~90 mm. *g* and *h*, 1 meter cell at 20°C. with lower pressures of vapor. Slits were 8, 4, 5, 3, 2, 3, and 1.5 $cm.^{-1}$ in the regions 3000, 2000, 1400, 1100, 900, 700, and 400 $cm.^{-1}$ respectively.

The theoretical product rule ratios* for both pairs of molecules have been calculated and, in Table IV, these values are compared with the observed ratios. The agreement is satisfactory.

**Dimensions for calculating moments of inertia: CH_3CN and CD_3CN; C—H and C—D = 1.09 Å, C—C = 1.46 Å, C≡N = 1.16 Å, angles tetrahedral (Kessler et al. Phys. Rev. 79:54. 1950). CH_3CCl_3 and CD_3CCl_3: C—H and C—D = 1.09 Å, C—C = 1.53 Å, C—Cl = 1.76 Å, angles tetrahedral.*

	e	0.375	0.371

RAMAN INTENSITIES

Crawford's (4) $\sum^F$ rule relating the intensities of the vibrational Raman bands of isotopic molecules may be written in the form

$$[1] \qquad \sum_a \frac{I_{1a}}{K_{1a}\Delta\nu_{1a}} = \sum_a \frac{I_{2a}}{K_{2a}\Delta\nu_{2a}}$$

if the conditions of irradiation and observation are the same for the isotopic molecules. Here, subscripts 1 and 2 refer to the two isotopic species; I_{1a} is the intensity of the "a"th fundamental of Raman shift $\Delta\nu_{1a}$ in isotopic molecule 1, and

$$K_{1a} = (\nu - \Delta\nu_{1a})^4(1-e^{-1.44\Delta\nu_{1a}/T})^{-1}$$

where ν is 22,938 cm.$^{-1}$, the frequency of the exciting line, and T is the absolute temperature. The assumptions made in deriving the rule are: (*a*) isotopic substitution does not change the force constants of the most general quadratic potential function, (*b*) nor does it change the polarizability and anisotropy derivatives with respect to the internal coordinates, and, (*c*) anharmonicity effects may be neglected. Assumption (*b*) is very nearly true if there is no rotation which changes the equilibrium polarizability of the molecule in the species of vibration considered. The a_1 species of CH_3CN and CH_3CCl_3 are of this type.

Written in terms of standard intensities S (1), the rule is

$$[2] \qquad \sum_a \frac{S_{1a}}{(\Delta\nu_{1a})^2} = \sum_a \frac{S_{2a}}{(\Delta\nu_{2a})^2}.$$

Although the rule was derived for the vapor phase it has been applied here to liquid phase intensities since it is expected that intermolecular interaction effects are the same for isotopic molecules.

The rule has been applied in both forms given by equations [1] and [2], and the results for the a_1 modes of CH_3CN and CD_3CN are given in Table V. There are several cases of Fermi resonance and in each case the total intensity of fundamental and overtone or combination tone was taken. Correction for overlapping of ν_2 by $\nu_5(e)$ was also necessary for CD_3CN. These bands are coincident so that the usual method of drawing symmetrical contours which is

at 2258 cm.$^{-1}$ in CD_3CN to leave $\bar{S}_{\nu_2}$. Apart from being without basis, this assumption is complicated by the fact that ν_1 and ν_2 in CD_3CN may be in Fermi resonance. Unfortunately, ν_2 makes a large contribution to the total sum and introduces a large uncertainty, probably in excess of $\pm 5\%$, to this sum. For CH_3CN conditions are more favorable, and the estimated uncertainty in the total sum is $\pm 5\%$. Within $\pm 8\%$ the sums are the same.

The results for CH_3CCl_3 and CD_3CCl_3 are presented in Table VI. One case of Fermi resonance involving ν_1 in CD_3CCl_3 arises here, but a more serious uncertainty is introduced by the coincidence of ν_5 and ν_{11} in CH_3CCl_3. The ratio $\bar{S}_{\nu_5}/\bar{S}_{\nu_{11}}$ was assumed to be the same for the two molecules ($\bar{S}_{\nu_5}+\bar{S}_{\nu_{11}}$ was observed to be the same and a comparison of the depolarization ratios of the three observed bands suggests that the assumption is not unreasonable). It is again unfortunate that the overlapped band makes an important contribution to the sum, but a comparison of the total sums shows that within $\pm 6\%$ they are the same.

The experimental data for the *e*-type modes of CH_3CN and CD_3CN are given in Table VII and the data for CH_3CCl_3 and CD_3CCl_3 are collected in Table VIII. Here the intensity sum rules are not expected to be valid since

molecular rotations which change the equilibrium polarizability occur. The quantities in equations [1] and [2] were however determined and are:

For CH_3CN and CD_3CN		
Equation [1]:	L.H.S. 30.2	R.H.S. 36.3
Equation [2]:	L.H.S. 5.76	R.H.S. 7.52
and for CH_3CCl_3 and CD_3CCl_3		
Equation [1]:	L.H.S. 132	R.H.S. 130
Equation [2]:	L.H.S. 49.2	R.H.S. 50.1

In each case, the deuterium substituted compound is on the right-hand side. The sum rule seems to be obeyed better for the *e*-type modes of the two methyl chloroform molecules than for the *e*-type modes of the two methyl cyanide molecules. This is proably due to the fact that the *e*-type rotational frequency changes less upon deuterium substitution in methyl chloroform than it does in methyl cyanide.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. L. C. Leitch and Mr. J. Francis for preparing the samples of CD_3CN and CD_3CCl_3, and to Mrs. C. A. Hunt for assistance in reducing the spectra.

THE EFFECT OF ADDITION AGENTS ON CATHODE POLARIZATION DURING ELECTRODEPOSITION OF COPPER AT SINGLE CRYSTAL COPPER CATHODES[1]

By K. Ekler[2] and C. A. Winkler

ABSTRACT

The polarization–time relations for the initial (P_i), maximum (P_{max}), and pseudo-steady-state (P_s) polarizations on copper single crystals in the absence and presence of gelatin and gelatin plus chloride ion were found to depend upon crystal orientation. The P_i and P_{max} in the absence of gelatin, the P_i in its presence, and the static potentials were all similarly related to the reticular density. The P_i increased, and the time to maximum polarization (t_{max}) decreased, with increase of current density; the relations between these quantities showed marked differences for the different crystals. The variation with reticular density of P_i and P_{max} in the absence of addition agents and of P_i in its presence probably represents differences in activation overpotential at the various crystal faces. The adsorption of gelatin on different crystal faces was also found to be markedly different. Polarization in the presence of gelatin was decreased by small amounts of chloride ion; a linear relation for all the crystals used was obtained by plotting the increase in polarization caused by gelatin against the decrease caused by 2 mgm./liter chloride ion in the presence of gelatin. In the absence of addition agent, change of acid concentration from 50 to 200 gm./liter had no effect on P_i and addition of chloride ion had no effect on P_s at single crystal cathodes.

INTRODUCTION

A number of papers from this laboratory have discussed the changes in cathode polarization at polycrystalline cathodes during electrodeposition of copper from acid copper sulphate electrolyte containing addition agents. Since the earliest of these studies (4), it has been of interest to examine the behavior with single crystal copper cathodes under similar conditions. Ample evidence exists that significantly different lattice energies are associated with different crystal faces of a single crystal, and such differences might be expected to influence not only the adsorption of an addition agent, hence the polarization in its presence, but perhaps also the polarization values in the absence of addition agent. The present paper represents a re-examination with single crystal cathodes of the more prominent features found previously to characterize the polarization behavior with polycrystalline cathodes.

EXPERIMENTAL AND RESULTS

Crystals $1\frac{1}{2}$ in. $\times$ $\frac{1}{2}$ in. $\times$ $\frac{1}{4}$ in. were purchased from Horizons Inc., Cleveland, Ohio. Their orientations were specified to be (111), (100), (110), (211), (410), and (322), referred to the longitudinal axis.

The interplanar spacings shown in Table I were calculated from the relation (3):

$$d = s/\sqrt{(h^2+k^2+l^2)}$$

where h, k, and l are the Miller indices and s is a term which for a face centered

[1]*Manuscript received July 28, 1955.*

cubic lattice, e.g. copper, is equal to 0.5 if one or two indices are odd; otherwise it is unity.

It should be noted that although two lattice planes of different Miller indices may have the same interplanar distances, e.g. (410) and (322), hence the same reticular densities (2), examination of a space lattice model readily revealed that the environment of a given atom in the two cases is quite different.

The polarization measurements were made in a modified Haring cell as described previously (4).

Prior to every experiment after the first one with a given crystal, deposited copper was carefully removed with a succession of files of decreasing roughness. A special guide was designed to ensure uniform removal of the deposit and thus preserve the original orientation of the crystal face. A rectangular groove was milled along a 10 in. brass bar to accommodate interchangeable files, while the crystal to be ground was placed in a slot milled into a brass block 2 in. long. When the block was inverted over the bar, and allowed to slide on it, the deposit of copper was removed while retaining parallelism of the crystal faces as indicated by micrometer measurements. The crystal was ground finally on metallographic papers 0 to 4/0 after which it was transferred to a suitable holder and all of the crystal surface coated with paraffin wax except the face under examination. The dimensions of the exposed area were determined with a table cathetometer so that the current could be adjusted to the desired apparent current density for the next operation of electropolishing. Chemical etching did not allow reproducible polarization values to be obtained.

The electropolishing bath consisted of 42.5% orthophosphoric acid (6). To minimize gassing, a copper cathode of area approximately 20 times that of the crystal was used. The potential between the electrodes was 4 volts and the spacing approximately three and one-half inches. The crystal was anodically polished for eight minutes at a starting current density of 12 amp./dm^2. An increase of polishing time to 20 min. gave identical results. Pitting of the surface was largely avoided by dislodging gas-bubbles as soon as their formation was detected.

After it had been electropolished, the crystal was rinsed with distilled water and immediately placed in a Haring cell containing electrolyte in presence of air at 25$\pm$0.1°C. Unless otherwise stated the electrolyte contained 125 gm./liter Merck's reagent grade copper sulphate pentahydrate and 100 gm./liter Baker's C.P. sulphuric acid in freshly distilled water. It was not stirred during polarization measurements.

Potentials were measured with a recording potentiometer (Brush Development Co., Cleveland, Ohio, Recorder BL 201, DC-Amplifier BL 932) and a potentiometer (Tinsley, Type 3184 D).

A reproducibility within $\pm$5 millivolts was required and generally obtained without difficulty.

For all experiments in the absence of addition agents the cathode was allowed to remain in contact with the electrolyte for 10 min. before starting

electrolysis. An increase of this immersion time to 30 min. gave identical polarization values. When addition agent was present in the electrolyte the immersion time was 15 min. An increase from 15 to 120 min. did not show any detectable polarization changes.

(*i*) *No Addition Agent Present*

The polarization–time relations for the various crystals at 2 amp./dm.^{2} are shown in Fig. 1. From the original tracings of these curves on the recording

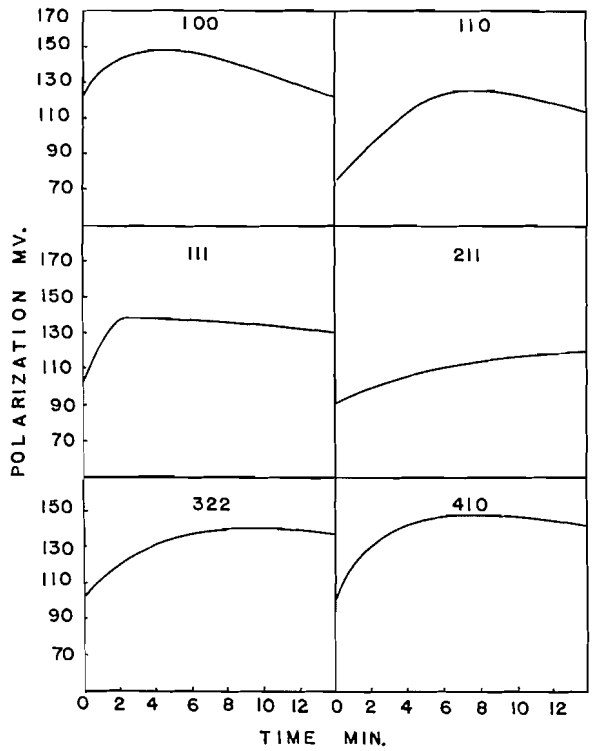

FIG. 1. Polarization–time relations at single crystal cathodes.

potentiometer, values of the initial (P_i) and maximum (P_{max}) polarization respectively were obtained and are recorded for the six crystals in Table I.*

The relative static potentials of the crystals are also shown in the table. To obtain these values, each crystal was immersed in the standard electrolyte in the presence of air and the electrode potential measured relative to a capillary probe filled with the same electrolyte in contact with a calomel half-cell through a closed, ungreased stopcock. Potential measurements were taken every five minutes until a steady state was obtained after 70 to 120 min.

The initial polarization and times required to attain the maximum polarization values for current densities from 0.2 to 4.0 amp./dm.^{2} are summarized

**While various quantities may be graphically represented in relation to the d-values, it should be noted that d is not a "running parameter", hence such plots are of doubtful significance.*

TABLE I

INITIAL (P_i) AND MAXIMUM (P_{max}) POLARIZATION VALUES, AND STATIC POTENTIALS, AT SINGLE CRYSTAL CATHODES IN THE ABSENCE OF ADDITION AGENT

Crystal (Miller indices)	Interplanar distance (d)* (Å)	P_i (mv.)	P_{max} (mv.)	Static potential (mv.)
(111)	0.5774	102	132	84
(100)	0.5000	120	148	90
(110)	0.3536	78	123	83
(211)	0.2041	90	118	69
(410)	0.1213	99	140	77
(322)	0.1213	101	147	80

in Fig. 2. (For clarity the curves for only four crystals are shown; the other two are similar.) The latter quantity for a given crystal shifted systematically to lower values as the current density was increased.

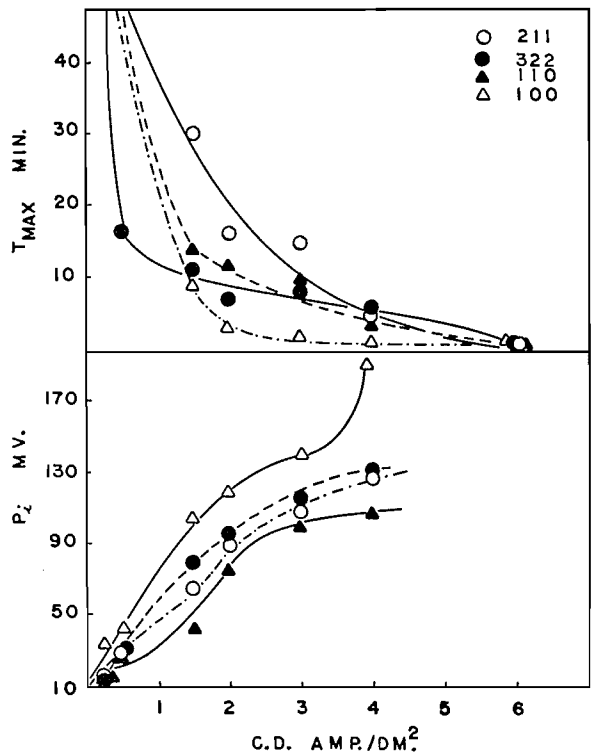

FIG. 2. Variation with current density of initial polarization (P_i) and time to maximum polarization (t_{max}).

The concentration polarization for the (100) face at 2 amp./dm.^{2} was determined with an oscilloscope (11) (Dumont 304H) and was found to be 17 ± 2 mv. This is comparable with the value (20 mv.) observed for polycrystalline copper under similar conditions.

An attempt was made to study perpetuation of the base structure at 0.5 and 0.2 amp./dm^2. The deposition was interrupted after 10 min. and the polarization allowed to dissipate. The current was then turned on again and the second recorded pattern compared with the original. It was noted that at 0.5 amp./dm.^{2} only the (111) face seemed to repeat the original pattern; all the other crystals gave somewhat higher initial polarization values in the second pattern. At 0.2 amp./dm.^{2} the values of the initial pattern appeared to be repeated in the second pattern only with the (111) and (410) crystal faces.

At 2 amp./dm.^{2} microscopic examination of the deposits showed islands of varying reflectivity, indicative of polycrystallinity after deposition times of three minutes or less.

Change of the sulphuric acid concentration of the electrolyte from 50 to 200 gm./liter resulted in no pronounced or systematic changes of polarization, as indicated by the following values:

Acid conc. (gm./l.)	Polarization values for crystal faces					
	(110)		(111)		(410)	
	P_i	P_{max}	P_i	P_{max}	P_i	P_{max}

D: Relation between steady-state polarization at a single crystal cathode and chloride content of the electrolyte in the presence of gelatin.

(ii) Addition Agent Present

An experiment in the presence of addition agent was usually made following an experiment in the standard electrolyte, after removing the previous copper deposit and preparing the crystal anew by electropolishing.

In the presence of gelatin (25 mgm./liter), the single crystal cathodes gave polarization–time curves similar to those observed previously (9) with polycrystalline cathodes (Fig. 3A). The initial polarizations (P_i) for the six crystals varied from 265 to 365 mv., while the steady-state polarization (P_s)* showed a variation with orientation ranging from 200 to 270 mv. The curve relating initial polarization (P_i) to gelatin concentration was similar in shape for the six crystals (Brush oscillograph). Typical of the behavior is the plot shown in Fig. 3C, for the (100) crystal. However the polarization values for a given amount of gelatin differed for the different crystal faces, as shown in Table II.

TABLE II

RELATION BETWEEN INITIAL POLARIZATION AND GELATIN CONTENT OF THE ELECTROLYTE

Gelatin conc. (mgm./l.)	Initial polarization (mv.)					
	(111)	(100)	(110)	(211)	(322)	(410)
0	105	120	75	90	101	102
2	164	205	178	207	190	255

10	254	335	260	266	274	290
25	271	365	265	274	290	350
50	284	370	287	292	296	356
200	304	387	290	300	307	366
Adsorption (%) from electrolyte containing 1.5 mgm./l. gelatin	18	38	7	7	25	21
Interplanar spacing (d-value)	0.5774	0.5000	0.3536	0.2041	0.1213	0.1213

It is interesting to note that P_i changes with interplanar spacing in a similar manner for all the systems, including that which contained no gelatin.

The dependence of P_i on d-value in the presence of gelatin prompted an attempt to determine the relative extents of adsorption of gelatin on the six crystals. A calibration curve was first established, to relate P_s measured at a *polycrystalline* cathode (which had been given a steady-state surface) to the gelatin concentration in the electrolyte (up to 2 mgm./liter). Electrolyte containing 1.5 mgm./liter gelatin and a polycrystalline cathode with a steady-state surface were then placed in the Haring cell and the single crystal of copper, with known area exposed, was immersed during one hour with constant agitation but no passage of current, to permit adsorption of gelatin on the crystal. The crystal and stirrer were then removed from the cell and the value of P_s in the gelatin-depleted electrolyte determined. The corresponding gelatin

**This really corresponds only to a pseudo steady state for the short deposition times involved. Had deposition been continued for a sufficiently long time, it is probable that the true steady-state values would all have been similar at the eventual polycrystalline surfaces.*

concentration remaining in the electrolyte could then be obtained from the calibration curve, and the extent of adsorption of gelatin calculated. Adsorption of gelatin on the cell walls and polycrystalline cathode was eliminated as a factor by allowing the cell to stand with the appropriate electrolyte for 10 min. before each experiment, after which fresh electrolyte was introduced. All conditions used in establishing the calibration curve were reproduced as precisely as possible in the adsorption experiments; the only difference was immersion of the single crystal in the latter. The procedure gave values for adsorption on a given crystal that were reproducible within $\pm 4\%$. The relative extents of adsorption at the different crystal surfaces are shown in Table II. It will be noted that the variation of per cent adsorption with d-value parallels rather closely corresponding changes in P_i.

When chloride (2 mgm./liter) was added to the electrolyte in the absence of gelatin the polarization behavior was substantially the same as that in the standard electrolyte. This was true for immersion times of 1 to 30 min. With polycrystalline cathodes the addition of chloride to the electrolyte had little effect with the immersion time of one minute but caused about 15 mv. increase in polarization when the immersion time was increased to 30 min.

The results reported so far were obtained on the six crystals of known orientation. A second group of crystals available in this investigation consisted of 25 crystals, each 3 in. $\times \frac{1}{4}$ in. $\times \frac{1}{4}$ in., grown from melts of spectroscopically pure copper without benefit of seed crystal.* As a consequence the Miller indices of most of these crystals were quite complex and not suitable for estimation of interplanar distances.

With these single crystals, as with the ones previously used, the addition of chloride (2 mgm./liter) to electrolyte containing gelatin (25 mgm./liter) had a pronounced effect on P_s, though not on P_{max} (cf. Figs. 3A and 3B as typical). There appeared to be no significant effect of immersion time (up to 120 min.) on P_{max} or P_s in such systems. Experiments with two of the single crystals showed that the relation between P_s and chloride concentration (Fig. 3D) in the presence of gelatin (25 mgm./liter) was similar to that observed with polycrystalline cathodes.

When all the available data† for the various crystals were considered, it was found that the decrease in P_s caused by the chloride in the presence of gelatin ($-\Delta P_{Cl}$) was correlated with the increase in P_s caused by the gelatin alone (ΔP_{gel}) (Fig. 4A; line drawn by least squares).

In the above experiments, a given amount of chloride appeared capable of nullifying polarization increments which differed because of different cathode surfaces. This suggested that a similar study be made in which the polarization increments at a given cathode face were varied by addition of different amounts of gelatin. For this purpose, steady-state *polycrystalline* cathodes were used (5) and the behavior was examined not only with a constant amount of chloride (2 mgm./liter) (broken line, Fig. 4B) but with the amount of chloride deter-

*We are indebted to Mr. C. Cupp, Department of Metallurgy, University of Toronto, for preparing these crystals and determining their orientations.

†*With most of the crystals data were obtained for two orientations corresponding to two faces of the crystal at right angles.*

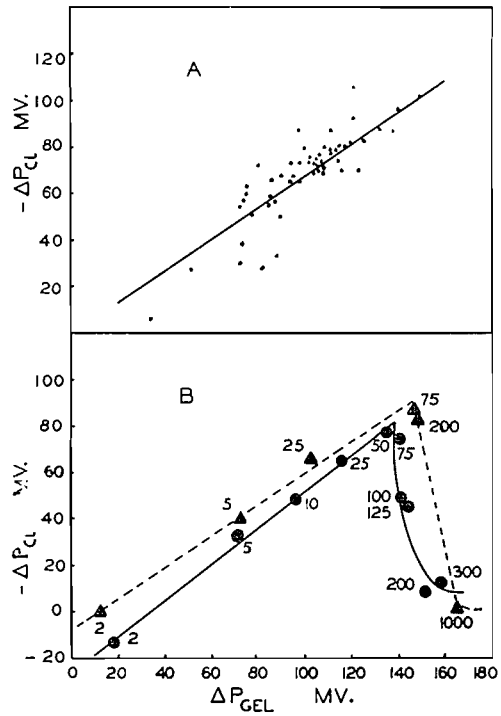

FIG. 4. Relation between decrease ($-\Delta P_{Cl}$) in steady-state polarization caused by chloride in the presence of gelatin and the increase (ΔP_{gel}) in steady-state polarization caused by gelatin alone.

Top: Single crystal cathodes, with 25 mgm./liter gelatin, 2 mgm./liter chloride.

Bottom: Polycrystalline cathodes with amounts of gelatin (mgm./liter) shown on figure.

mined experimentally (8) that gave the minimum polarization for each gelatin concentration (full line, Fig. 4B).

When the effect of chloride (2 mgm./liter) in the presence of gelatin (25 mgm./liter) was examined for the six crystals of known orientation, the values of $-\Delta P_{Cl}$ were found to relate in much the same way as P_i to the d-values for these crystals.

DISCUSSION

The results of the present study in the absence and presence of addition agents demonstrate rather marked differences in behavior of the cathode polarization with the changes in crystal orientations and changes from single- to poly-crystallinity. A polycrystalline metal surface consists of an array of crystal faces of diverse orientations, edges, corners, and boundaries. Each type of orientation has its characteristic arrangement of atoms which influences the surface free energy of the crystal face. The properties of the polycrystalline surface therefore depend upon the properties of these individual parts. In some cases, e.g. cold rolled metal, there may be a preponderance of certain

preferred orientations and the properties of the surface therefore may be weighted in one direction or the other.

(*i*) *No Addition Agent Present*

The initial polarization on electropolished *polycrystalline* copper, in the absence of addition agent, lies between the values for single crystals; this is reasonable because of the composite nature of the former. The value, 85 mv., is biased towards the lower values for the crystals investigated. This might be attributed to a preponderance of certain orientations on the rolled polycrystalline copper cathodes. The static potential for the polycrystalline cathode, 73.7 mv., is similarly related to the static potentials of the crystals, probably for a like reason.

The maxima observed in the polarization–time relations for the six crystals of specified orientations indicate that opposing processes are involved in the polarization changes. It seems reasonable that these processes might be:

(*a*) Increase of total polarization due to build-up of concentration and hydrogen-ion interference polarizations.

(*b*) Increase of polarization due to deposition of nuclei of orientations different from that of the base crystal, such that discharge of atoms requires a higher activation polarization than on the original base matrix.

(*c*) Decrease of total polarization due to increase of true surface area of the cathode, hence decrease of true current density.

The pseudo-steady-state value might be expected when the single crystal base eventually becomes overgrown with nuclei of diverse orientations to such an extent that the increase of true surface area, with the attendant decrease of true current density, hence of polarization, finally predominates.

As expected, t_{max} decreased systematically with an increase in current density, owing in all probability to increased rate of nucleation with consequent increase in rate of surface roughening.

The values of the initial polarization, i.e. in the absence of significant concentration polarization, must contain an activation overpotential and presumably also an ohmic component due to hydrogen ion interference. In the present study, no effect of increased acid concentration on this initial polarization at three different crystal cathodes was observed in the range of 50 to 200 [illegible]gm./liter acid. On the other hand, with polycrystalline cathodes, a linear increase of polarization with acid concentration was previously observed in this laboratory (10). The extent of the increase was the same in the absence and presence of addition agent (cystine), and the opinion was expressed that adsorption of hydrogen ion was probably not involved. However, there seems no alternative to assuming optimal adsorption of hydrogen ion on the single crystal cathodes over the range of acid concentrations studied, to account for the absence of an acid effect with these cathodes. The behavior with polycrystalline cathodes might then be ascribed to an adsorption which is less than optimal, if it is further assumed that the adsorption–concentration relations for hydrogen ion and cystine are comparable in the ranges of concentrations concerned.

If, as seems reasonable, the contribution to the polarization at single crystal cathodes due to hydrogen ion is comparable with or less than that at polycrystalline cathodes (30), the *differences* in the hydrogen ion effect at the different single crystals would be less, probably much less than 30 mv., and the observed differences in P_i may be taken to reflect mainly differences in activation overpotentials at different crystal faces.

The differences in P_{max} might also be due largely to differences in activation overvoltage for the different crystal orientations, but it must be remembered that by the time P_{max} occurs, the single crystal surface might have undergone considerable change due to the formation of nuclei with orientations other than that of the crystal base.

The variation of P_i and P_{max} with d-value for the crystal might reasonably be expected to reflect changes in the surface free energy, which in turn should presumably be associated with the different static potentials of the crystals. In general, the P_i and P_{max} values appear to be related to the reticular density in much the same way as the static potentials. However, there is not a linear relation between either P_i or P_{max} and the static potentials when all the data are considered. It would appear therefore that polarization is not determined solely by the surface lattice energy. It is interesting to note, however, that the plot of P_i-values against static potentials may be considered to yield a roughly linear relation for five of the six crystals used; the P_i value for the (110) face only seems to deviate to an unacceptable extent from the relation. For the dynamic conditions that prevail in polarization measurements, it seems likely that the spatial distribution and density of atoms in the lattice may play a part which is not reflected in the contribution of these factors to a thermodynamic quantity such as the static potential.

(*ii*) *Addition Agent Present*

A satisfactory explanation of the P_i–time pattern observed in the presence of gelatin seems to be possible along the lines suggested by Parsons and Winkler (9). The rise in polarization to the early maximum is readily explained by cataphoretic migration of cuprous–gelatin complexes to the cathode when the circuit is completed, thus increasing the amount of addition agent on the cathode with consequent increase of polarization. Simultaneously, slight depletion of the gelatin in the immediate neighborhood of the cathode must occur. When deposition is initiated, new copper surface is laid down (either with growth of the existing crystal or as new nuclei) in an environment of electrolyte partially depleted of gelatin, such that adsorption of gelatin on the newly formed surface is hindered and the true current density decreases with increase in extent of cathode area free from addition agent. The polarization therefore tends to decrease again, and a maximum is observed in the polarization–time curve. Eventually, of course, the supply of gelatin at the cathode face is replenished by convection and the polarization passes through a minimum to a steady-state value. The effect of immersion time on the polarization pattern with polycrystalline electrodes was attributed to corrosion which would serve to expose different crystal faces and change the true surface area until

a steady state was reached. The absence of any effect of immersion time when single crystals were used may reasonably be attributed to the absence of such change in true surface area due to corrosion.

The value of P_i in the presence of gelatin consists probably of an activation overpotential, an ohmic component due to adsorbed cuprous–gelatin complexes, and possibly some component due to hydrogen ion interference. The observation that the presence of gelatin makes no substantial change in the relation between d-value and P_i suggests that the activation overpotential in the presence and absence of gelatin is the same, and corresponds to the deposition of aquo-complexes in both cases, while the ohmic and hydrogen ion components of the polarization are practically constant for the different crystals. This latter condition, in turn, would probably prevail if all the crystals were almost completely covered by adsorbed cuprous–gelatin complexes.

The effect of chloride ion in reducing the polarization is readily explained by assuming that the chloride ion acts as an electron bridge as suggested by Heyrovsky (7). Consideration of Fig. 4B indicates that a limit is reached, perhaps when the cathode becomes so heavily overladen with adsorbed complexes that access of the chloride ion to effective positions is virtually precluded. This view would gain support from the polarization – gelatin concentration curve, from which it would appear that a plateau, presumably corresponding to essentially complete coverage of the cathode by gelatin or its copper complexes, occurs in the neighborhood of 75 mgm./liter gelatin.

In the presence of gelatin plus 2 mgm./liter chloride the polarization gradually decreased from P_i to P_s with no minimum in the polarization–time curve. This behavior seems reasonable enough since, after the maximum is passed and new surface is laid down in the presence of chloride ion, any tendency for polarization to increase again because of adsorption of complexes should be offset by the facilitated electron transfer effected by the chloride ion. Hence, as deposition continues and the polycrystalline character of the cathode surface is increased, the polarization should merely decrease to that corresponding to deposition on a polycrystalline surface in the presence of gelatin plus chloride.

With single crystals, 2 mgm./liter chloride ion (no gelatin present) had no effect on the pseudo-steady-state polarization, whereas with polycrystalline cathodes the steady-state polarization was increased about 15 mv. (8). Adamek has suggested that this increase be associated with migration of atoms into lattice positions following their deposition in out-of-lattice positions in the presence of chloride by the dismutation reaction (1)

$$2Cu^{+} = Cu + Cu^{++}.$$

Failure to observe the increase with single crystals might be expected on this basis, since deposition on the single crystals until the pseudo steady state was established presumably consisted largely of nucleus formation, with limited crystal growth, and dismutation could occur freely on the crystal face without subsequent migration of atoms into an established lattice.

THE TERTIARYBUTYLBENZENES

III. THE SYNTHESIS OF 2,4,6-TRI-*t*-BUTYLBENZOIC ACID AND THE DISSOCIATION OF DI- AND TRI-*t*-BUTYLBENZOIC ACIDS[1]

By Eileen E. Betts[2] and L. Ross C. Barclay

ABSTRACT

2,4,6-Tri-*t*-butylbromobenzene, m.p. 177–177.5°, was prepared by the bromination of 1,3,5-tri-*t*-butylbenzene in the presence of silver nitrate. The reaction of 2,4,6-tri-*t*-butylbromobenzene and *n*-butyllithium gave 2,4,6-tri-*t*-butylphenyllithium, which on carbonation yielded 2,4,6-tri-*t*-butylbenzoic acid, m.p. 297°. A solution of this acid in fuming sulphuric acid yielded a methyl ester, m.p. 96–98°, when it was poured into absolute methanol. Similar treatment of 1,4-di-*t*-butylbenzene with bromine gave 2,5-di-*t*-butylbromobenzene, which on reaction with *n*-butyllithium and subsequent carbonation gave 2,5-di-*t*-butylbenzoic acid. The reaction of 1,3,5-tri-*t*-butylbenzene with acetyl chloride in the presence of aluminum chloride gave a liquid ketone, and hypohalide oxidation of this ketone yielded 3,5-tri-*t*-butylbenzoic acid. The ultraviolet absorption spectra of the two bromo compounds and the three acids were measured and are discussed. The considerable acid-weakening effect in 2,4,6-tri-*t*-butylbenzoic acid is attributed to steric hindrance to the formation of the carboxylate anion.

We have been interested in the synthesis of derivatives of 1,3,5-tri-*t*-butylbenzene required in a study of the influence of two bulky ortho *t*-butyl groups on aromatic functional groups. The present communication describes the synthesis of 2,4,6-tri-*t*-butylbenzoic acid. As a preliminary study of steric hindrance in such a structure, the ultraviolet spectrum and apparent dissociation constant of this acid are measured and compared with those of 3,5-di-*t*-butyl- and 2,5-di-*t*-butyl-benzoic acids.

1,3,5-Tri-*t*-butylbenzene, prepared by the alkylation of 1,4-di-*t*-butylbenzene with *t*-butyl chloride (1), was brominated with bromine in the presence of silver nitrate by a procedure similar to the one used by Derbyshire and Waters (7) for the bromination of chloro- and bromo-benzenes. The 2,4,6-tri-*t*-butylbromobenzene prepared by this method was identical with 2,4,6-tri-*t*-butylbromobenzene prepared by the Sandmeyer reaction on 2,4,6-tri-*t*-butylaniline. Attempts to react 2,4,6-tri-*t*-butylbromobenzene with magnesium were unsuccessful.

2,5-Di-*t*-butylbromobenzene was prepared by the addition of bromine to 1,4-di-*t*-butylbenzene in the presence of silver nitrate. The procedure of Thiec (15) was used to prepare 2,5-di-*t*-butylbenzoic acid from 2,5-di-*t*-butylbromobenzene by refluxing with *n*-butyllithium and carbonation of the resulting 2,5-di-*t*-butylphenyllithium. Similar treatment of 2,4,6-tri-*t*-butylbromobenzene with *n*-butyllithium gave 2,4,6-tri-*t*-butylphenyllithium, which on hydrolysis gave 1,3,5-tri-*t*-butylbenzene or on carbonation gave 2,4,6-tri-*t*-butylbenzoic acid, m.p. 297°. The methyl ester, m.p. 96–98°, of 2,4,6-tri-*t*-butylbenzoic acid was prepared from the acid by the procedure of Newman (11).

The reaction of 1,3,5-tri-*t*-butylbenzene with acetyl chloride in the presence of aluminum chloride for two hours at room temperature gave a brown liquid ketone, 3,5-di-*t*-butylacetophenone, whose 2,4-dinitrophenylhydrazone melted at 212–214°. Hypohalide oxidation of this ketone gave an acid, 3,5-di-*t*-butylbenzoic acid, m.p. 173–174°. Carpenter and Easter (6) report 3,5-di-*t*-butylbenzoic acid, m.p. 169.5–170.5°, by oxidation of a hydrocarbon described as 3,4-di-*t*-butyltoluene by Capeller (5), but given the 1,3,5 configuration by Schlatter (14). No conclusive evidence has been given for the structure of this acid. Brown (4) has shown that inherent strain in an *o*-di-*t*-butyl configuration makes the existence of such a structure highly improbable. On this basis, and from comparison of the absorption spectrum and ionization constant with those of 2,5-di-*t*-butylbenzoic acid, we have assigned the structure 3,5-di-*t*-butylbenzoic acid. This product requires a replacement of a *t*-butyl group by an acetyl group during the Friedel-Crafts acetylation of 1,3,5-tri-*t*-butylbenzene. This result is analogous to the anomalous acetylations obtained by Nightingale and Hucker (12) where *p*-di-*t*-butylbenzene yielded *p*-*t*-butylacetophenone.

The ultraviolet absorption spectra of 2,4,6-tri-*t*-butylbromobenzene and 2,5-di-*t*-butylbromobenzene (Fig. 1), and of 2,4,6-tri-*t*-butylbenzoic, 2,5-di-*t*-butylbenzoic, and 3,5-di-*t*-butylbenzoic acids (Fig. 2) were measured in cyclohexane with a Beckman DU spectrophotometer. In Fig. 1, 2,5-di-*t*-butyl-

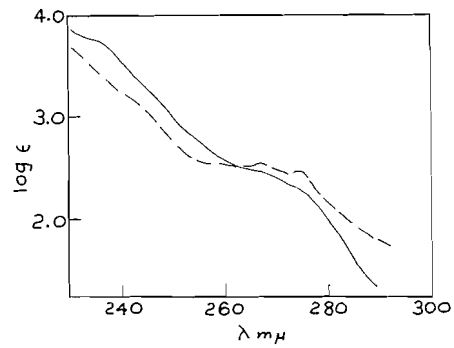

FIG. 1. Ultraviolet spectra in cyclohexane:
— — 2,5-di-*t*-butylbromobenzene (b.p. 150° (12–13 mm.));
—— 2,4,6-tri-*t*-butylbromobenzene (m.p. 177–177.5°).

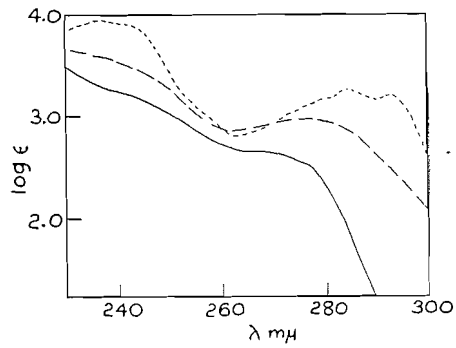

FIG. 2. Ultraviolet spectra in cyclohexane:
—— 2,4,6-tri-*t*-butylbenzoic acid (m.p. 297°);
— — 2,5-di-*t*-butylbenzoic acid (m.p. 128°);
- - - - 3,5-di-*t*-butylbenzoic acid (m.p. 173–174°).

bromobenzene shows slight absorption at 2750 and 2670 Å, while 2,4,6-tri-*t*-butylbromobenzene has no bands. The presence of the second *t*-butyl group ortho to the bromine in 2,4,6-tri-*t*-butylbromobenzene evidently blots out resonance interaction between the bromine and the benzene ring. A similar effect of the bulky *t*-butyl groups is more noticeable in the spectra of the *t*-butylbenzoic acids (Fig. 2). In the case of the di-*t*-butylbenzoic acids a shift of

a *t*-butyl group from a meta position, as in 3,5-di-*t*-butylbenzoic acid, to a position ortho to the carboxyl group removes the K-band near 2360 Å. In addition, the benzenoid "fine structure" absorption of 3,5-di-*t*-butylbenzoic acid (2800–2950 Å) is replaced by weaker general absorption at 2700 Å. When two *o*-*t*-butyl groups are present this effect is very pronounced—so much so that 2,4,6-tri-*t*-butylbenzoic acid has no characteristic absorption maxima, only rising absorption towards shorter wave lengths.

The relative dissociation constants of benzoic, 2,5-di-*t*-butylbenzoic, 3,5-di-*t*-butylbenzoic, and 2,4,6-tri-*t*-butylbenzoic acids (Table I) were measured by potentiometric titration in 50% methanol–water using a Beckman pH meter, with a glass electrode and a calomel reference electrode. The results for benzoic acid agree well with that of pK_a 5.15 obtained by Bright and Briscoe (3) but not with the value of 5.62 recently obtained by Hammond and Hogle (9). Other workers (8) have used aqueous dioxane media. Although our procedure yielded reliable comparative pK_a values the necessity for some standard technique is apparent.

TABLE I

Acid	pK_a ($\frac{1}{4}$ point)	pK_a ($\frac{1}{2}$ point)	pK_a ($\frac{3}{4}$ point)
Benzoic	5.19	5.21	5.20
2,5-Di-*t*-butylbenzoic	5.03	5.05	5.05
3,5-Di-*t*-butylbenzoic	5.78	5.80	5.84
2,4,6-Tri-*t*-butylbenzoic		6.25	

A number of effects can be brought into play in the steric effect of ortho-substituted benzene derivatives. These effects have been discussed by Ingold (10) and recently summarized by Hammond and Hogle (9). Ingold explains that aromatic conjugation weakens a benzoic acid and that the often-observed acid-strengthening effect in *o*-substituted benzoic acids is due to a twisting of the carboxyl group from the plane of the benzene ring. In the case of 2,5-di-*t*-butylbenzoic acid this acid-strengthening effect is greater than the hindering effect of one *t*-butyl group to the formation of the anion and the acid-weakening effect of electron-repelling *t*-butyl groups. The latter effect is important in 3,5-di-*t*-butylbenzoic acid where there is a considerable rise in the pK_a value. 2,4,6-Tri-*t*-butylbenzoic acid is a much weaker acid than benzoic. We attribute this to the controlling hindering effect of two *o*-*t*-butyl groups which decrease the stability of the carboxylate ion.

EXPERIMENTAL[3]

2,4,6-Tri-t-butylbromobenzene

(*a*) *By Direct Bromination*

1,3,5-Tri-*t*-butylbenzene, m.p. 74° (2.46 gm., 0.01 mole), was dissolved in

[3]*Melting points are uncorrected.*

30 ml. of glacial acetic acid in a 100 ml. round-bottom flask. To this solution was added 0.60 ml. (a slight excess of 0.01 mole) of bromine, solutions of 5 ml. of concentrated nitric acid in 10 ml. of water and of 1.7 gm. of silver nitrate in 5 ml. of water, the addition of the last solution taking one half-hour. Another 20 ml. of glacial acetic acid was added and the reaction mixture heated on the steam cone for an hour with occasional shaking, a loose cork being placed in the mouth of the flask to prevent excess escape of bromine. At the end of the hour most of the bromine color had disappeared and the oil which had appeared on the solution when it was first heated had solidified. The hot reaction mixture was poured into 200 ml. of water, a little sodium sulphite added to destroy excess bromine, and then 5% sodium hydroxide until the solution was approximately neutral. The cooled solution was extracted three times with ether, the ether extracts washed with water, and most of the ether removed by distillation. The yellow solid, which separated from the residue on cooling, was collected on a filter paper, water was added to the filtrate and more product was collected (total yield 1.7 gm., 50%). After four recrystallizations from ethanol, the shining white plates melted at 177–177.5°. In a subsequent bromination the yield was 67%. Anal. Found: C, 66.52, 66.57; H, 9.09, 8.86; Br, 24.51, 24.40. Calc. for $C_{18}H_{29}Br$: C, 66.46; H, 8.98; Br, 24.57.

(*b*) *By the Sandmeyer Reaction*

1,3,5-Tri-*t*-butylbenzene was nitrated by the addition of 6.1 gm. of fuming nitric acid (sp. gr. 1.5) to 22 gm. of the hydrocarbon dissolved in a solution of 30.5 ml. of acetic acid and 23.6 ml. of acetic anhydride. The yellow precipitate, 2,4,6-tri-*t*-butylnitrobenzene, which was isolated 45 min. later by filtration, melted at 204–206° after recrystallization from petroleum ether (yield 80%).

2,4,6-Tri-*t*-butylaniline, m.p. 146–148°, was prepared by the reduction of 2,4,6-tri-*t*-butylnitrobenzene using the procedure of Bartlett and co-workers (2).

Three grams of 2,4,6-tri-*t*-butylaniline was added to 30 ml. of glacial acetic acid, 15 gm. of 48% hydrobromic acid was then added, the suspension warmed until solution was complete and then cooled with stirring to 0°. The slow addition of a solution of 1.5 gm. of sodium nitrite in 7.5 ml. of water caused the formation of a yellow precipitate. This was added to a solution of 5 gm. of cuprous bromide in 30 gm. of 48% hydrobromic acid. After it was left for two hours at room temperature, the purple reaction mixture was heated on the steam cone for 30 min., cooled, water added until the reaction mixture was yellow, then concentrated hydrochloric acid until it was clear. The organic layer, which was a semisolid mass on the bottom of the flask, was removed, washed with water, and placed on a filter paper. A yellow oil was drawn off with suction, leaving colorless needles, m.p. 100–176° (wt. 0.370 gm.). After two recrystallizations from ethanol the reaction product, in the form of shining plates, melted at 177.5–178° and did not depress the melting point of the 2,4,6-tri-*t*-butylbromobenzene prepared by direct bromination. The ultraviolet absorption spectra of the two samples were identical.

Attempts to react 2,4,6-tri-*t*-butylbromobenzene with magnesium or sodium in absolute ether failed.

2,5-Di-t-butylbromobenzene

2,5-Di-*t*-butylbromobenzene was prepared by the addition of bromine to 5.7 gm. (0.03 moles) of 1,4-di-*t*-butylbenzene using the same procedure as for the direct bromination of 1,3,5-tri-*t*-butylbenzene. The reaction mixture was heated for eight hours on the steam cone and the product was distilled *in vacuo* to give 1.7 gm. (21% yield) of 2,5-di-*t*-butylbromobenzene, a yellow liquid (b.p. 150° at 12–13 mm.).

2,5-Di-t-butylbenzoic Acid

An approximately 0.1 molar *n*-butyllithium solution was prepared by the procedure given in *Organic Reactions* (13).

2,5-Di-*t*-butylbromobenzene (1 gm.), 5 ml. of the *n*-butyllithium solution, and 10 ml. of absolute ether were refluxed in an atmosphere of dry nitrogen for 40 min. Dry carbon dioxide was passed over the surface of the reaction mixture for four hours at room temperature. Dilute sodium hydroxide was added to the reaction mixture, the resulting solution warmed, and the aqueous layer filtered. Acidification of the filtrate with hydrochloric acid gave a precipitate which, after standing overnight, was collected on a filter paper (0.25 gm., about 35% yield). The 2,5-di-*t*-butylbenzoic acid after repeated recrystallizations from ethanol–water melted at 128° (lit. (15), 128°). Anal. Neutralization equivalent found: 237. Calc. for 2,5-di-*t*-butylbenzoic acid: 234.

The Synthesis of 2,4,6-Tri-t-butylbenzoic Acid

2,4,6-Tri-*t*-butylbromobenzene (1.4 gm.), 12 ml. of 0.1 molar *n*-butyllithium solution, and 25 ml. of absolute ether were refluxed together for one hour. Hydrolysis of a small amount of the reaction mixture with 10% hydrochloric acid gave a white crystalline product, which did not depress the melting point of authentic 1,3,5-tri-*t*-butylbenzene.

Dry carbon dioxide was passed over the reaction mixture for three hours. Sodium hydroxide (10%) was then added, the resulting solution warmed, filtered, and the filtrate acidified with hydrochloric acid. The mixture was allowed to stand overnight, then filtered (0.5 gm., 40% yield). The 2,4,6-tri-*t*-butylbenzoic acid, which crystallized from petroleum ether in thick white needles, melted at 297°. In a subsequent preparation a 60% yield was obtained. Anal. Found: C, 78.83, 78.75; H, 10.40, 10.53; N.E., 296, 292. Calc. for tributylbenzoic acid: C, 78.57; H, 10.41; N.E., 290.

2,4,6-Tri-*t*-butylbenzoic acid (0.1 gm.) was dissolved in 2.5 ml. of fuming sulphuric acid and after several minutes this solution was added slowly to 25 ml. of absolute methanol. Most of the methanol was removed under reduced pressure, 6 ml. of water added, and the remaining methanol removed, leaving a white precipitate. Water (100 ml.) was added to the residue and the solid methyl ester of 2,4,6-tri-*t*-butylbenzoic acid was isolated by filtration, washed with water, dried, and recrystallized from ethanol, m.p. 96–98° (yield 0.08 gm., about 80%).

When 0.01 gm. of the methyl ester of 2,4,6-tri-*t*-butylbenzoic acid was dissolved in fuming sulphuric acid and the resulting solution added to ice, the starting acid was regenerated.

3,5-Di-t-butylbenzoic Acid

A 500 ml. three-neck flask was fitted with a dropping funnel, stirrer, and gas trap. Aluminum chloride (7.3 gm.) and 10 ml. of carbon disulphide were placed in the flask and cooled with ice–salt to −10°. A solution of 15.6 gm. of 1,3,5-tri-*t*-butylbenzene in 8.5 gm. of acetyl chloride was added with stirring over a 45 min. period. The reaction mixture was then allowed to warm to room temperature and after two hours it was decomposed by adding it to water. The organic layer was separated and the solvent removed by evaporation, leaving a semisolid reaction product. This was cooled to −10° and filtered immediately. The white solid (0.4 gm.) thus isolated after recrystallization from ethanol melted at 69–72°. A mixed melting point with authentic 1,3,5-tri-*t*-butylbenzene showed this to be the starting material.

The filtrate from the filtration of the reaction product was a brown liquid, 3,5-di-*t*-butylacetophenone (wt. 4.2 gm.). The 2,4-dinitrophenylhydrazone of the ketone was prepared and after recrystallization from ethanol the derivative melted at 212–214°.

One gram of 3,5-di-*t*-butylacetophenone was dissolved in 20 ml. of dioxane, 10 ml. of 10% sodium hydroxide added, then iodine – potassium iodide solution until the dark color of iodine remained for over five minutes at 60°. The dark color was removed by the addition of a little 10% sodium hydroxide, water was then added until no more cloudiness appeared, and after 15 min. the solution was filtered and the filtrate acidified. The precipitate, which formed in the filtrate on standing overnight, was isolated by filtration. After two recrystallizations from ethanol–water the 3,5-di-*t*-butylbenzoic acid melted at 173–174°. Carpenter and Easter (6) report 169.5–170.5° as the melting point of their 3,5-di-*t*-butylbenzoic acid prepared by the oxidation of 3,5-di-*t*-butyltoluene. Anal. Found: N.E., 234. Calc. for dibutylbenzoic acid: N.E., 234.

Measurement of the Ionization Constants

The ionization constants (Table I) were measured by the method of Hammond and Hogle (9) in 50 volume % methanol–water solution at 21° using a Beckman pH meter with calomel and glass electrodes, standardized against buffer solutions of pH 4 and 10. About 0.01 meq. of the acid was dissolved in 10 ml. of 50% methanol and titrated with 0.0095 *N* methanolic NaOH. In the case of 2,4,6-tri-*t*-butylbenzoic acid, a saturated solution of the acid in 50% methanol was used.

HEAT OF HYDROLYSIS OF URANIUM (IV) IN PERCHLORIC ACID SOLUTIONS[1]

By R. H. Betts

ABSTRACT

The heat of hydrolysis of uranium (IV) in perchloric acid solution has been measured by a spectrophotometric technique. A value of 10.7±1 kcal. per mole was obtained, in good agreement with a previous value determined by a calorimetric method. The entropy of association of uranium (IV) with hydroxyl ion is +52 e.u.

INTRODUCTION

In a kinetic study of the oxidation of uranium (IV) by iron (III) (1), a value was required for the heat of hydrolysis of uranium (IV). This quantity, ΔH, is related to the temperature variation of the hydrolysis constant K for reaction [1] according to $d(\ln K)/dT = \Delta H/RT^2$.

$$U^{4+} + H_2O \rightleftharpoons UOH^{3+} + H^+ \qquad [1]$$

The hydrolysis constant K is defined by:

$$(UOH^{3+})(H^+)/(U^{4+}) = K, \qquad [2]$$

where the brackets indicate concentrations in gram-ions per liter.

A value of 11 kcal./mole has been reported for ΔH (2). This result is based on the difference between the measured heats of solution of solid uranium tetrachloride in 0.5 M perchloric acid and in water. The accuracy of the value obtained by this method depends on the assumptions that:

(i) UOH^{3+} is the only species of uranium (IV) in very dilute acid solutions,
(ii) U^{4+} is the only uranium species in 0.5 M perchloric acid solution, and
(iii) chloride ion does not form complex ions with uranium (IV).

However, Kraus and Nelson (3) have shown in a careful study of equilibrium [1] at 25°C. that none of these assumptions is strictly correct. Further, the precision of the value of 11 kcal./mole depends on a single measurement of the heat evolved when uranium tetrachloride is dissolved in water (2).

In the present work, the value of ΔH has been calculated more directly from measurement of the hydrolysis constant K as a function of temperature. The method used depends on measurement of the changes in optical density of partially hydrolyzed uranium (IV) solutions with temperature, and is based on the technique described in Reference (3). The principle of the method may be summarized.

The optical density D for a 1-cm. thickness of solution containing U^{4+} and UOH^{3+} as the only light-absorbing species is

$$D = (U^{4+})E_4 + (UOH^{3+})E_3, \qquad [3]$$

where E_3 and E_4 are the extinction coefficients of UOH^{3+} and U^{4+}, respectively,

[1]*Manuscript received August 4, 1955.*
Contribution from the Chemistry and Metallurgy Division, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 235.

for the wave length used. If the total concentration of uranium (IV) is a molar, then the hydrolysis constant K is given by:

$$K = (H^+)(E_4 - E_{obs})/(E_{obs} - E_3), \quad [4]$$

where E_{obs} = observed extinction coefficient
$= D/a$.

It follows from equation [4] that if E_4 and E_3 are known, measurements of E_{obs} and (H^+) permit the calculation of K. Kraus and Nelson (3) have shown that their data at 648 mμ (the wave length at the maximum of a characteristic U^{4+} absorption peak) are best described by $E_4 = 60.0$ and $E_3 = 6.1$, independent of ionic strength.

The principal assumption made in the application of this method to the present work is that the activity coefficient terms, which are implicit in the definition of the hydrolysis constant by equation [2], are unaffected by changes in temperature between 15.2°C. and 24.7°C. The assumption, although not strictly correct, is frequently made in other studies of similar equilibria (see, for example, Reference (4)). A second assumption is that the extinction coefficients E_3 and E_4 are temperature-independent. Further discussion bearing on this latter assumption is given below.

EXPERIMENTAL

Solutions of U^{IV} of the desired concentration and acidity were prepared by dilution of weighed portions of a stock solution 0.0787 M in U^{IV}, 1.010 M in perchloric acid. Other details of the preparation and analysis of the solutions are given elsewhere (1).

Two series of experiments have been made. (i) The first set were carried out with 2.44 M perchloric acid. At this concentration of acid, the hydrolysis of U^{4+} is very largely suppressed ($K \sim 0.01$ at 25°C. (3)). Such measurements served therefore to fix the value of E_4, the extinction coefficient of U^{4+}. (ii) The second set of experiments, made with 0.104 M perchloric acid, provided the values of E_{obs} required for the calculation of K as a function of temperature.

The optical measurements were made with a Beckman DU spectrophotometer. The instrument was adapted to permit control of the temperature of solutions in the cell compartment to ±0.05°C. in the temperature range used here. The optical density at 648 mμ was read vs. a blank cell containing either 0.10 M or 2.44 M perchloric acid. The two 1-cm. cells used were matched to ±0.1% transmission at this wave length.

The optical density for solutions 2.44 M in perchloric acid showed no tendency to drift with time. However a slight decrease with time was noted for the solutions 0.104 M in perchloric acid, presumably as a result of slow air oxidation of U^{IV} which is known to occur more readily in solutions of low acidity. For these samples, the readings of optical density vs. time were extrapolated back to the time of preparation of the samples. These extrapolated values never differed by more than 0.5% from the optical density first recorded.

RESULTS AND DISCUSSION

Tables I and II give the relevant data for solutions 2.44 M and 0.104 M in

perchloric acid. The excellent agreement of our value of 59.9±0.05 for E_4 at 25°C. with the value of 60.0 (3) is to be noted (Table I). However, the apparent dependence of E_4 on temperature (−0.2% per degree) shown in Table I is unexpected. To account for this relatively large change in the optical density on the basis of hydrolysis alone, it would be necessary to assume that the true value of E_4 is 63 or 64, and that $K = 0.14$ at 25°C. Such a value of K is 10 to 15 times higher than one would expect from the careful work of Kraus and Nelson. A more reasonable explanation is that K is indeed of the order of 0.01 at 25°C., and that the extinction coefficient of U^{4+} is temperature dependent. This uncertainty in interpretation fortunately does not appreciably alter the value of ΔH calculated from the experimental results. (See below.)

Table III gives the values of the hydrolysis constants calculated from the experimental results by means of equation [4]. Since $E_{obs} \gg E_3$, an error of ±20% in E_3 has only a small effect on ΔH, and the Kraus and Nelson value of 6.1 (3) has therefore been accepted for this constant. Because of the uncertainty regarding possible variations of E_4 with temperature, K has been calculated using three sets of values for E_4. The second and third columns of Table III give the values of K based on $E_4 = 64$ and 63 respectively. In the last column are shown values of K deduced on the basis that E_4 is temperature-dependent. In this case, the appropriate value of E_4 for each temperature is given in Table I. The values of ΔH listed in Table III were calculated from a plot of

TABLE III

VALUES FOR THE EQUILIBRIUM CONSTANT AND ΔH FOR HYDROLYSIS OF URANIUM (IV)

Temp., °C.	K*	K†	K‡
24.7	0.0810	0.0778	0.0680
20.4	0.0619	0.0591	0.0519

log K vs. $1/T$°K. (Fig. 1). The values of ΔH obtained from these three sets of values of K are identical within experimental error, i.e., 10.7 ± 1.0 kcal./mole.

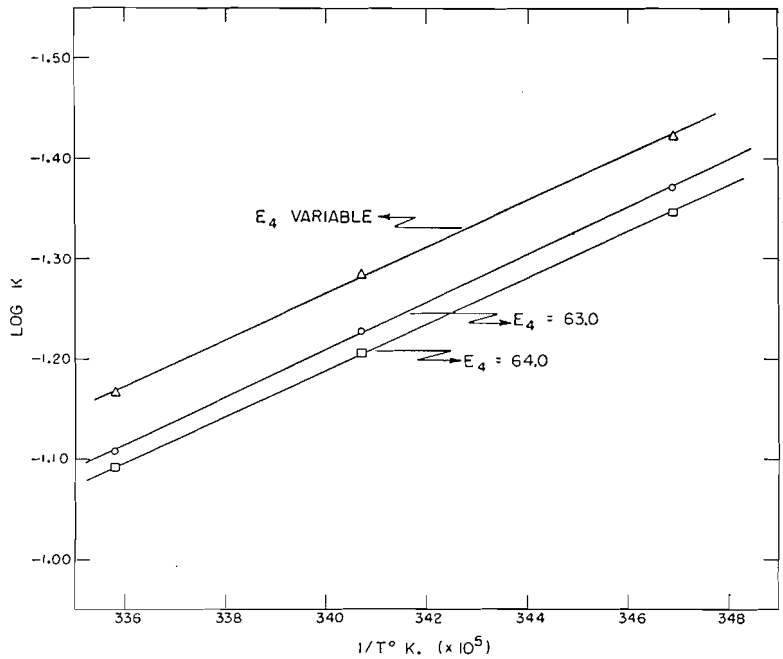

FIG. 1. Dependence of the hydrolysis constant on temperature (Table III).

The agreement of this result with that found earlier (2) is striking, in view of the completely different experimental methods employed; however the almost exact coincidence of the two values must be regarded as fortuitous.*

Table III shows that K is about 0.075 at 24.7°C., the exact value depending on the value of E_4 assumed. For comparison, the Kraus and Nelson result (3) is 0.05 at 25°C., for ionic strength 0.19. This agreement is as good as can be

*NOTE ADDED IN PROOF: *In a paper published after completion of present manuscript, Kraus and Nelson (J. Am. Chem. Soc. 77:3721. 1955) report* $\Delta H = 11.7$ *kcal./mole for heat of hydrolysis of uranium (IV) in perchlorate media, in agreement with value obtained in present work.*

expected, since in the present study, uranium (IV) perchlorate contributes almost 50% of the total ionic strength at $\mu = 0.19$, whereas the value of 0.05 applied to solutions in which sodium perchlorate and perchloric acid were the principal electrolytic components.

The entropy of association of U^{4+} with a hydroxyl ion can now be estimated. For this purpose the hydrolysis constant at zero ionic strength, K_a, must be used— 0.21 ± 0.02 at 25°C. (3). Using the relation $\Delta F^\circ = -RT \ln K_a$, and $\Delta F^\circ = \Delta H^\circ - T\Delta S^\circ$, ΔS° and ΔF° at 25°C. are found to be +33 e.u. and +0.92 kcal./mole, respectively. These values refer to reaction [1] above. This result may be combined with the dissociation equilibrium of water (4) to derive the thermodynamic constants for the association reaction proper:

	ΔF°, kcal.	ΔH°, kcal.	ΔS°, e.u.
$U^{4+}_{aq} + H_2O \rightarrow UOH^{3+}_{aq} + H^+_{aq}$	+0.9	+11.0	+33
$H^+_{aq} + OH^-_{aq} \rightarrow H_2O$	−19.1	−13.5	+19
$U^{4+}_{aq} + OH^-_{aq} \rightarrow UOH^{3+}_{aq}$	−18.2	−2.5	+52

The large positive value of ΔS° for the association reaction is in qualitative agreement with the suggestion of Rabinowitch and Stockmayer (4), viz., the partial neutralization of charge which occurs releases water molecules from the hydration shells around the separated ions, and thereby increases the disorder (and hence the entropy) of the system as a whole.

KINETICS OF THE OXIDATION OF URANIUM (IV) BY IRON (III) IN AQUEOUS SOLUTIONS OF PERCHLORIC ACID[1]

By R. H. Betts

ABSTRACT

The kinetics of oxidation of uranium (IV) by iron (III) in aqueous solutions of perchloric acid have been investigated at four temperatures between 3.1°C. and 24.8°C. The reaction was followed by measurement of the amount of ferrous ion formed. For the conditions $(H^+) = 0.1$–$1.0\ M$, ionic strength = 1.02, $(Fe^{III}) = 10^{-4}$–$10^{-5}\ M$, and $(U^{IV}) = 10^{-4}$–$10^{-5}\ M$, the observed rate law is $d(Fe^{2+})/dt = -2d(U^{IV})/dt$

$$= 2(U^{IV})(Fe^{III})\left[\frac{K'(H^+)+K''}{(H^+)^2+(K_1+K_2)(H^+)+K_1K_2}\right] \text{ mole/liter/sec.}$$

K_1 and K_2 are the first hydrolysis constants for Fe^{3+} and U^{4+}, respectively, and K' and K'' are pseudo rate constants. At 24.8°C., $K' = 2.98$ sec.$^{-1}$, and $K'' = 10.6$ mole liter^{-1} sec^{-1}. The corresponding temperature coefficients are $\Delta H' = 22.5$ kcal./mole and $\Delta H'' = 24.2$ kcal./mole. The kinetics of the process are consistent with a mechanism which involves, as a rate-controlling step, electron transfer between hydrolyzed ions.

INTRODUCTION

Oxidation–reduction reactions between cations in aqueous solution have been thought until recently to proceed very rapidly, and the term "instantaneous" has frequently been used to characterize their rates. However recent studies with radioactive tracers have shown that even such elementary reactions as electron transfer between iron (II) and iron (III), or between Ce (III) and Ce (IV), do not proceed instantaneously (18, 8). Such results have reawakened interest in the whole subject of both isotopic and nonisotopic electron transfer reactions between cations in solution. Some kinetic information is now available relating to the reactions between the nonisotopic pairs Sn (II) – Fe (III) (5), Tl (III) – Fe (II) (2), and Np (IV) – Fe (III) (10). Several review articles have recently appeared in which the current status of theory and experiment have been summarized for both isotopic and nonisotopic electron transfer reactions (1, 14, 19). The proceedings of a symposium held in 1954 on this subject have also been published (12).

As a further example of this type of reaction, the present paper describes experiments relating to the kinetics of the oxidation of uranium (IV) by iron (III) in aqueous acidic media. Perchloric acid and sodium perchlorate were chosen as the principal electrolytes, since amongst the common inorganic anions, perchlorate has the least tendency to form ion-pairs with cations. To bring the rate of reaction into a range suitable for study, it has been necessary to work with solutions 10^{-4} to $10^{-5}\ M$ in uranium (IV) and iron (III).

The course of the reaction has been followed by measurement of the rate of formation of iron (II). Such measurements, in conjunction with a knowledge of the stoichiometry of the reaction, were sufficient to enable a kinetic analysis of the results to be made. It would have been useful, as confirmatory evidence,

[1]*Manuscript received August 4, 1955.*
Contribution from the Chemistry and Metallurgy Division of Atomic Energy of Canada, Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 236.

to measure also the rate of disappearance of uranium (IV). However no method could be devised which was specific for uranium (IV) at the low concentrations involved.

EXPERIMENTAL

A. Reagents

Doubly distilled water was used in the preparation of all reagents and in all experiments in the present investigation.

Uranyl perchlorate was prepared by dissolving reagent grade uranium trioxide in an excess of standard perchloric acid. An aqueous solution of uranium (IV) perchlorate was prepared from this solution by electrolytic reduction of the uranium at a mercury cathode in a two compartment cell. The uranium (IV) content was determined by titration with standard potassium permanganate.

Sodium perchlorate, which was used to adjust the ionic strength of solutions as required, was prepared from reagent grade stock by two recrystallizations from water.

A stock solution of iron (III) perchlorate was prepared by methods described previously (4). Solutions of iron (II) perchlorate, which were required for standardization of the analytical procedures used in the kinetic experiments, were made by dissolving iron (II) ammonium sulphate in 1.0 *M* perchloric acid, and were standardized against potassium permanganate.

All other chemicals used were reagent grade, and were not further purified.

B. Procedure

Unless indicated otherwise, all experiments were made with solutions of ionic strength 1.02.

The kinetic experiments were carried out in glass-stoppered flasks which were suspended in a water bath at the desired temperature. All of the reagents except uranium (IV) were added to the flask, after which the required amount of this reactant was added carefully by micropipette. The reaction was started by inverting the flask, and mixing thoroughly the added uranium (IV) with the rest of the solution.

The course of the reaction was followed by measurement of the amount of iron (II) formed as a function of time. For this purpose, 4 to 5 ml. samples were withdrawn at measured times, and run rapidly into a mixture which stopped the reaction, and which also served as a means for analysis of ferrous ion formed (see below). Generally eight samples were taken during each experiment, together with two more when the reaction had gone to completion. The purpose of the last two samples was to give an independent measure of the initial concentration of either uranium (IV) or iron (III), depending on which of these two was in excess initially. In most of the experiments, iron (III) was in large excess over uranium (IV), and hence the final measurement of ferrous ion formed was used as a measure of the initial concentration of uranium (IV) ion. Confirmatory evidence regarding the validity of this procedure is given later.

The quenching mixture referred to above consisted of 5 ml. of an aqueous

solution of *o*-phenanthroline; it contained also an equimolar mixture of ammonium fluoride and ammonium acetate in sufficient quantity to raise the pH of the final reaction mixture to 4.0. At this pH, *o*-phenanthroline reacts immediately with ferrous ion to form the highly colored complex $Fe(o\text{-phen})_3^{++}$. The concentration of this complex was determined by measurement of the optical density at 511 mμ of portions of the quenched mixture with a Beckman DU spectrophotometer. The exact dilution of the reacting mixture by the quenching solution was calculated from the weight of the latter before and after addition of the sample for analysis.

The analytical scheme was calibrated by addition of known amounts of iron (II) perchlorate to solutions similar to those used in the kinetic studies. A small blank was observed which depended on the total amount of iron (III) present. This was taken into account as required. The presence of either uranium (IV) or uranium (VI) had no measurable effect on the analysis. Separate experiments showed that the quenching agent did not induce the oxidation of uranium (IV) by iron (III); it was also shown that ferrous ion has no tendency to form in quenched solutions containing both uranium (IV) and iron (III).

The detailed mechanism of the quenching action of this mixture is not completely understood. However, the omission of ammonium fluoride from the mixture completely destroys the quenching action; it is probable therefore that the reaction is stopped by fluoride ion complexing of the reactants at pH 4.0.

C. Experimental Results

(*i*) *Stoichiometry of the Reaction*

Table I presents the data for seven experiments relating to the stoichiometry of the reaction. The initial concentrations of reactants in each experiment were calculated from the amounts of standardized stock solutions used. In column four is given the final concentrations of iron (II) found when the reaction had gone to completion. Each value in this column is based on at least two concordant analyses which were made on samples taken several hours apart. Values of iron (II) concentrations given in column five are those calculated according to

TABLE I

STOICHIOMETRY OF THE REACTION

Run No.	$(U^{IV})_0$, $M \times 10^5$	$(Fe^{III})_0$, $M \times 10^5$	Fe^{2+}, $M \times 10^5$	
			Found	Calc.
1	3.75	52.4	7.30	7.50
3	3.72	21.1	7.26	7.44
4	3.63	10.60	7.04	7.26
5	9.10	10.65	10.57	10.65
6	9.10	5.41	5.41	5.41
7	18.20	2.26	2.27	2.26
8	36.20	1.21	1.22	1.21

$$2Fe^{III} + U^{IV} = 2Fe^{II} + U^{VI}. \quad [1]$$

The slight differences between the corresponding values in columns four and

five of Table I are not greater than the combined probable errors involved; it is concluded therefore that Equation [1] represents the stoichiometry of the reaction.

(*ii*) *Kinetic Order of the Reaction*

Experiments which were made to deduce the kinetic order of the reaction are summarized in Table II. These experiments were carried out at a perchloric acid concentration of 1.021 *M*, at 24.8°C. The second order rate constant k_0 shown in the last column of Table II is defined by Equation [2]:

$$\frac{+d(\mathrm{Fe^{II}})}{dt} = \frac{-d(\mathrm{Fe^{III}})}{dt} = \frac{-2d(\mathrm{U^{IV}})}{dt} = 2\,k_0\,(\mathrm{U^{IV}})(\mathrm{Fe^{III}}). \qquad [2]$$

The constant k_0 was calculated from the results in the following way. If $(\mathrm{U^{IV}})_0$ and $(\mathrm{Fe^{III}})_0$ represent the total concentrations of these species at time zero,

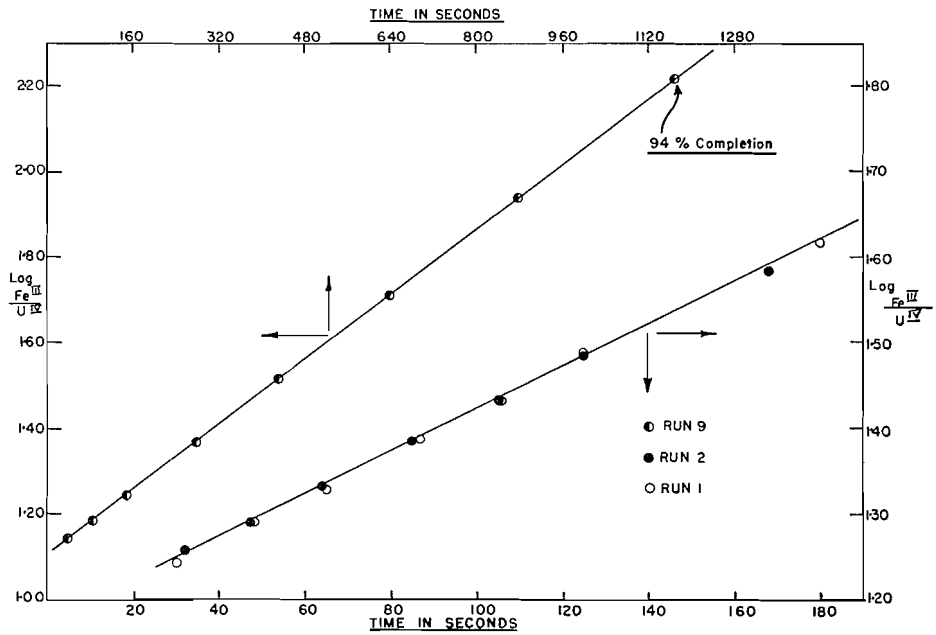

FIG. 1. Plot illustrating second order behavior of the reaction.

and if $(\mathrm{Fe^{II}})_t$ is the concentration of iron (II) measured at time t, then the corresponding concentrations of reactants are given by:

$$(\mathrm{U^{IV}}) = (\mathrm{U^{IV}})_0 - 0.5(\mathrm{Fe^{II}})_t, \qquad [3]$$

$$(\mathrm{Fe^{III}}) = (\mathrm{Fe^{III}})_0 - (\mathrm{Fe^{II}})_t. \qquad [4]$$

Substitution of Equations [3] and [4] into [2] and integration in terms of $(\mathrm{Fe^{II}})$ leads to

$$k_0 t = \frac{2.303}{(\mathrm{Fe^{III}})_0 - 2(\mathrm{U^{IV}})_0} \log \frac{(\mathrm{Fe^{III}})}{(\mathrm{U^{IV}})} + B, \qquad [5]$$

where B is an integration constant related to the (arbitrary) initial concen-

trations of uranium (IV) and iron (III). Equation [5] implies that a plot of log $(Fe^{III})/(U^{IV})$ vs. t should give a straight line if the reaction is of first order in both iron (III) and uranium (IV). Fig. 1 shows such plots for the data of Runs 1, 2, and 9 of Table II. In these cases, and for all experiments in this study, such plots gave good straight lines up to at least 80% completion of the reaction. Table II shows also that the value of k_0 deduced from the slope of these plots is unaffected by a 30-fold variation in $(U^{IV})_0$, and a 40-fold variation in $(Fe^{III})_0$. We conclude therefore that at constant hydrogen-ion concentration, the reaction is first order with respect to both uranium (IV) and iron (III).

TABLE II

VALUES OF SECOND ORDER RATE CONSTANT AT 24.8°C. $(HClO_4) = 1.021\ M$; $\mu = 1.02$

Run No.	$(Fe^{III})_0$, $M \times 10^5$	$(U^{IV})_0$, $M \times 10^5$	k_0 (mole^{-1} liter^1 sec.$^{-1}$)
1	52.4	3.75	12.9
2	52.4	3.72	12.9
3	21.1	3.72	12.7
4	10.6	3.63	12.2
5	10.6	9.10	11.9
6	5.41	9.10	10.8
7	2.26	18.2	11.5
8	1.21	36.2	13.2
9	21.1	1.69	12.4
10	21.1	3.13	12.6

Fig. 1 also gives some idea of the reproducibility of the kinetic experiments. Evidently the slope of the log $(Fe^{III})/(U^{IV})$ vs. t plot can be reproduced to $\pm 2\%$. However the derived rate constant is not known with this precision, since it also depends on the difference $(Fe^{III})_0 - 2(U^{IV})_0$. Judging from the spread of results in Table II, an over-all uncertainty of ± 4–5% is associated with the rate constants obtained in this work.

(iii) Dependence of the Rate on Hydrogen-ion Concentration

Table III summarizes the results for experiments at varying concentrations of hydrogen ion, for each of four temperatures. The ionic strength of each solution was maintained at 1.02 by addition of sodium perchlorate as required. For each run a good straight line was observed when log $(Fe^{III})/(U^{IV})$ was plotted vs. t. From the slope of such plots, the corresponding second order rate constants shown in Table III were calculated.

TABLE III

VALUES OF SECOND ORDER RATE CONSTANT k_0 AS A FUNCTION OF ACIDITY AND TEMPERATURE

Temp., °C.	$HClO_4$, M					
	1.021	0.821	0.6167	0.4125	0.2083	0.1045
24.8	12.3*	19.2	30.7	64.7	233	—
16.8	4.16	6.57	10.4	21.8	74	304
7.8	1.17	1.81	2.92	6.15	22.4	80
3.1	0.54	0.82	1.36	3.01	10.3	33.6

**Average of 10 values listed in Table II.*
The units of k_0 are mole^{-1}. liter^{+1}. sec^{-1}.

The apparent order of the reaction with respect to hydrogen ion at each temperature has been calculated from these results by using the following empirical rate expression:

$$\text{Rate} = 2k'[H^+]^n\,[U^{IV}][Fe^{III}]. \qquad [6]$$

In Equation [6], $k'[H^+]^n$ is to be identified with k_0 for each experiment. The value of n can therefore be deduced from a plot of log $[H^+]$ vs. log k_0 for each temperature. These plots are shown in Fig. 2, from which it was found that n

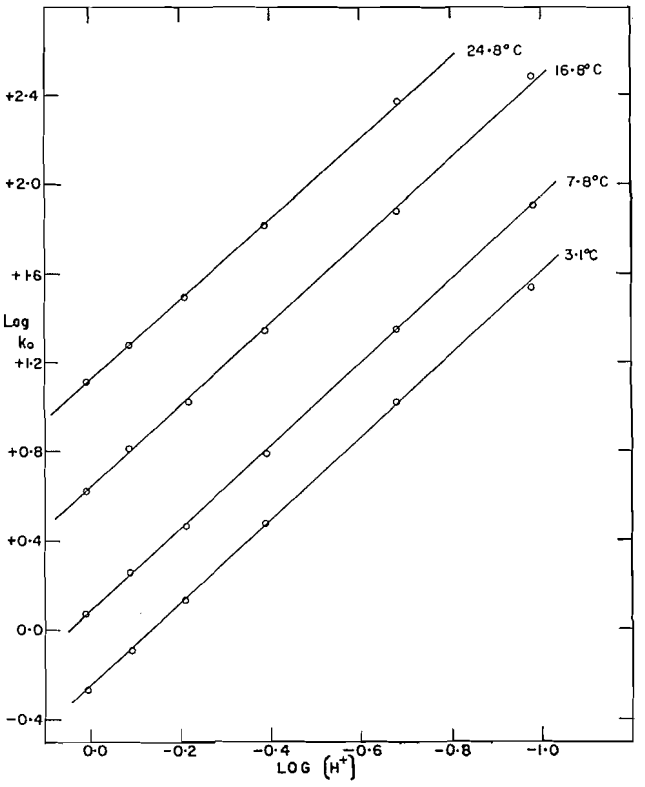

FIG. 2. Variation of the observed rate constant k_0 with temperature and acidity.

has a value of -1.81 ± 0.02, independent of temperature. This result implies that the rate of oxidation of uranium (IV) by iron (III) is dependent on very nearly the inverse second power of the hydrogen-ion concentration.

(*iv*) *Effect of Ionic Strength on the Reaction*

A few experiments were made to determine the effect of an inert electrolyte (sodium perchlorate) on the rate of the reaction. The results of these experiments are summarized in Table IV. Evidently, the rate of the reaction increases slowly with ionic strength in the region $\mu = 0.4$ to $\mu = 1.02$.

TABLE IV

EFFECT OF IONIC STRENGTH ON RATE OF REACTION AT 5°C.

0.405	0.819	4.06
0.609	1.023	4.35

DISCUSSION

Stoichiometry and Kinetic Order of the Reaction

The kinetic order of the reaction at constant acidity and the stoichiometry of the process are most simply accounted for by the following scheme:

$$U^{IV} + Fe^{III} \xrightarrow{k_0} U^{V} + Fe^{II}, \text{ slow and rate-controlling,} \quad [7]$$

$$U^{V} + Fe^{III} \rightarrow U^{VI} + Fe^{II}, \text{ fast.} \quad [8]$$

U^V represents an undetermined form of pentavalent uranium (11). These equations have not been balanced with respect to hydrogen ion, nor are the ionic configurations of the reactants specified. These aspects are discussed further below. Assuming that $d(U^V)/dt = 0$, this scheme leads directly to the observed rate expression (Equation [2] above). The factor 2 in Equation [2] arises from the fact that for every Fe(II) formed in Reaction [7], a second Fe(II) is formed by Reaction [8].*

The absence of terms like $(U^{IV})^2$ or $(Fe^{III})^2$ in the empirical rate expression rules out any significant contribution from dimeric ions, e.g., $(FeOHFe)^{+5}$; this ion is known to be present at very low concentration in aqueous solutions of ferric salts (9, 15).

Effect of Hydrogen-ion Concentration

The appearance of the nonintegral order $[H^+]^{-1.81}$ in the rate expression suggests that at least two paths involving hydrolyzed ions contribute to the slow stage of the reaction. The slight departure of this exponent from -2.00 points to the principal path as one involving two hydroxyl groups, with some minor participation from reactions involving only one hydroxyl group.

The principal hydrolyzed species present in solution are $FeOH^{2+}$ and UOH^{3+} (15, 17, 13), which exist in equilibrium with the parent fully hydrated ions according to:

$$Fe^{3+} + H_2O \rightleftharpoons FeOH^{2+} + H^+; \qquad K_1 = (FeOH^{2+})(H^+)/(Fe^{3+}), \quad [9]$$

$$U^{4+} + H_2O \rightleftharpoons UOH^{3+} + H^+; \qquad K_2 = (UOH^{3+})(H^+)/(U^{4+}). \quad [10]$$

The doubly hydrolyzed ion $Fe(OH)_2^+$ is also present at very low concentration (8, 9, 16, 17):

$$Fe^{3+} + 2H_2O \overset{K_3}{\rightleftharpoons} Fe(OH)_2^+ + 2H^+. \quad [11]$$

**A rapid disappearance of U^V by disproportionation according to: $2U^V \rightarrow U^{VI} + U^{IV}$ would also satisfy the observed stoichiometry and kinetic order. This reaction is known to be rapid in solutions of high acidity (11). However the low concentration of U^V makes it unlikely that this mechanism would compete favorably with Reaction [8] above.*

Although there is no quantitative information available, it is reasonable to assume, by analogy with the chemistry of iron (III), that the ion $U(OH)_2^{++}$ also is present at very low concentration:

$$U^{4+}+2H_2O \overset{K_4}{\rightleftharpoons} U(OH)_2^{++}+2H^+. \qquad [12]$$

The rate-controlling step (Equation [7] above) may therefore consist of the following competitive reactions:

$$Fe^{3+}+UOH^{3+} \xrightarrow{k_1} Fe^{2+}+U^{V}, \qquad [13]$$

$$U^{4+}+FeOH^{2+} \xrightarrow{k_2} Fe^{2+}+U^{V}, \qquad [14]$$

$$UOH^{3+}+FeOH^{2+} \xrightarrow{k_3} Fe^{2+}+U^{V}, \qquad [15]$$

$$Fe(OH)_2^{+}+U^{4+} \xrightarrow{k_4} Fe^{2+}+U^{V}, \qquad [16]$$

$$U(OH)_2^{++}+Fe^{3+} \xrightarrow{k_5} Fe^{2+}+U^{V}. \qquad [17]$$

Reactions [13] and [14] involve one hydroxyl group and are of course kinetically indistinguishable. The remaining reactions, which involve two hydroxyl groups, are also kinetically equivalent. These two groups of processes are referred to below as the 1-OH and the 2-OH processes, respectively.*

The following rate expression is derived on the basis of these postulated reactions:

$$\frac{d(Fe^{2+})}{dt} = 2\,(U^{IV})(Fe^{III})\,\frac{K'(H^+)+K''}{(H^+)^2+(K_1+K_2)(H^+)+K_1K_2}. \qquad [18]$$

Equation [18] is based on the assumption that the concentrations of the species $U(OH)_2^{++}$ and $Fe(OH)_2^{+}$ are negligible in comparison to the total concentration of uranium (IV) and iron (III). In this equation:

$$K' = k_1K_2+k_2K_1, \qquad [19]$$

$$K'' = k_3K_1K_2+k_4K_3+k_5K_4. \qquad [20]$$

Equation [18] describes the variation of the observed rate constant k_0 with acidity (Table III) provided:

$$k_0 = \frac{K'(H^+)+K''}{(H^+)^2+(K_1+K_2)(H^+)+K_1K_2}. \qquad [21]$$

If the denominator on the right-hand side of Equation [21] is represented by D, then

$$k_0D = K'[H^+]+K''. \qquad [22]$$

The left-hand side of Equation [22] can be calculated from the results in Table III together with a knowledge of the hydrolysis constants K_1 and K_2. The appropriate values of K_1 and K_2 for each temperature were calculated from

**In reactions [13] to [17] the products have been written as Fe^{2+} and U^{V}; if, as is probable, uranium (V) exists in solution as UO_2^{+}, one or more rapid hydrolyses may take place following electron transfer between the reactant ions indicated in the L.H.S. of these equations. It is not possible to specify the exact sequence of these hydrolytic reactions, nor for the present purpose, is it necessary.*

data in the literature (17, 15, 3, 6, 13), and are given in Table V. A test of Equation [22] can therefore be made, since a plot of k_0D vs. $[H^+]$ should give a straight line, with a finite intercept. Fig. 3 shows the data from the present

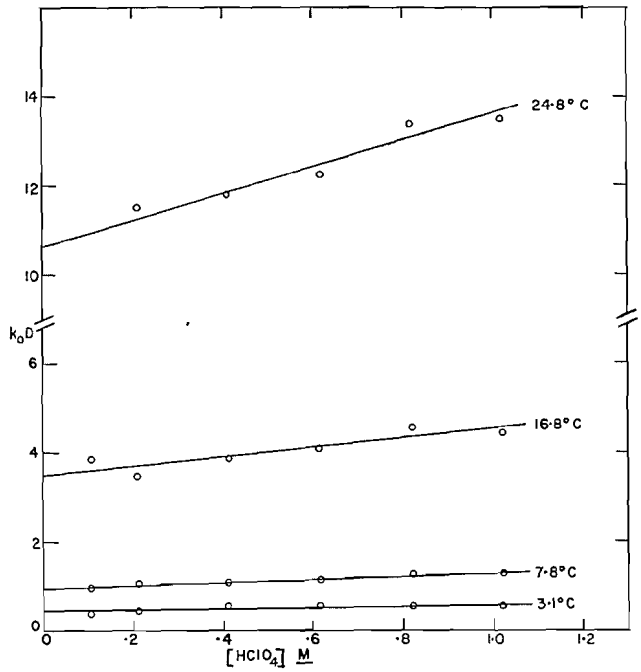

FIG. 3. Application of Equation [22] to the experimental results.

work treated in this manner. Within experimental error, Equation [22] describes the results at each temperature, and lends support to the suggestion that a duality of mechanism is involved in the rate-controlling step of the process.

TABLE V

VALUES OF THE HYDROLYSIS CONSTANTS K_1 AND K_2

Temp., °C.	K_1, mole liter^{-1} ($\times 10^3$)	K_2, mole liter^{-1} ($\times 10^3$)
3.1	0.311	6.8
7.8	0.452	9.4
16.8	0.85	17.0
24.8	1.59	27.8
25.0	1.61*	28.2†

*Value at 25.0°C. from Ref. (15), for μ = 1.02.
†Value at 25.°0C. from Ref. (13), for μ = 1.02.
Values at other temperatures calculated from
ΔH_1 = 12.3 kcal./mole (17)
and ΔH_2 = 10.6 kcal./mole (3)
according to $d \ln K/dt = \Delta H/RT^2$.
K_1 and K_2 are defined by Equations [9] and [10] in the text.

Values of the constants K' and K'' at each temperature can be obtained from the slopes and intercepts, respectively, of the lines in Fig. 3. These values

are given in Table VI. The variation of these pseudo rate constants with temperature is shown in Fig. 4, in which are plotted log K' or log K'' vs. $1/T$°K.

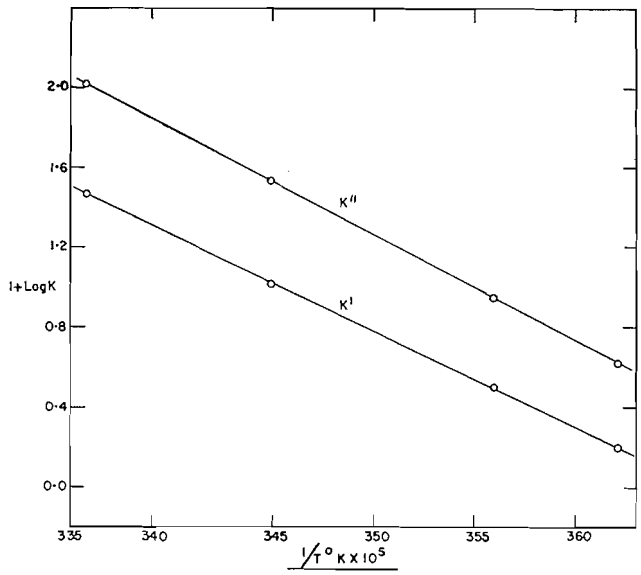

FIG. 4. Variation of the pseudo rate constants K' and K'' with temperature.

From the slopes of these lines, values of the corresponding temperature coefficients $\Delta H'$ and $\Delta H''$ were found to be 22.5 and 24.5 kcal./mole, respectively. These ΔH terms may be thought of as the apparent energies of activation for the 1-OH and 2-OH processes.

TABLE VI

VALUES OF THE PSEUDO RATE CONSTANTS K' AND K''

Temp., °C.	K' (sec.$^{-1}$)	K'' (mole liter^{-1} sec.$^{-1}$)
3.1	0.158	0.420
7.8	0.320	0.936
16.8	1.05	3.48
24.8	2.98	10.6

K' and K'' are defined by Equations [19] and [20] in the text.

The relative contributions of the 1-OH and 2-OH processes can be assessed from the values of K' and K''. For example, at 24.8°C., in 1.021 M perchloric acid, the mechanisms involving two hydroxyl groups make up 78% of the total reaction.

The positive identification of the constants K' and K'' with the rate constants for the individual processes shown in Equations [13] to [17] cannot of course be made with any certainty. This is evident from Equations [19] and [20] which define K' and K''. However, two points emerge from a more detailed examination of the results.

(i) A possible assumption would be that since $Fe(OH)_2^+$ and $U(OH)_2^{++}$ are present in very low concentration, they contribute nothing to the reaction, i.e., k_4 and $k_5 = 0$. The apparent energy of activation $\Delta H''$ for the 2-OH process would then be:

$$\Delta H'' = 24.2 \text{ kcal.} = E_3 + \Delta H_1 + \Delta H_2, \qquad [23]$$

where ΔH_1 = heat of hydrolysis of iron (III),
ΔH_2 = heat of hydrolysis of uranium (IV),
and E_3 = true energy of activation for the electron transfer reaction between UOH^{3+} and $FeOH^{2+}$ (Reaction [15] above).
Since $\Delta H_1 = +12.3$ kcal./mole (17) and $\Delta H_2 = +10.6$ kcal./mole (3, 6), then E_3 could not be more than 1 or 2 kcal./mole. This is an extraordinarily low value for the activation energy of an electron transfer reaction between cations in solution (19). It is suggested therefore that the main contribution to the 2-OH process is *not* that indicated by Reaction [15], and that Reactions [16] and [17], involving $Fe(OH)_2^+$ and $U(OH)_2^{++}$, are the principal contributors to the 2-OH process.

This admittedly qualitative method of distinguishing between kinetically equivalent paths cannot be extended to the other 2-OH processes, since we have insufficient knowledge of the thermodynamics of formation of either $U(OH)_2^{++}$ or $Fe(OH)_2^+$.

(ii) We finally consider the relation between K' and the individual rate constants k_1 and k_2 for the 1-OH processes. The *maximum* values of these rate constants can be calculated from the experimental results in the following way:

(*a*) If $k_2 = 0$, the whole of the 1-OH contribution is carried by Reaction [13]:

$$UOH^{3+} + Fe^{3+} \xrightarrow{k_1}, \text{ and } k_{1(\max)} = K'/K_2.$$

(*b*) Similarly, if $k_1 = 0$, then $k_{2(\max)} = K'/K_1$.

Table VII gives the maximum values for k_1 and k_2 derived in this way, together with the corresponding energy and entropy of activation terms (E_{act} and $\Delta S^{\ddagger}$, respectively). The E_{act} terms in Table VII were calculated from the value of $\Delta H'$ and either ΔH_1 or ΔH_2, in a manner similar to that shown in Equation [23]. Values of $\Delta S^{\ddagger}$ were calculated from the data in columns two and three of Table VII by reaction rate theory (7).

TABLE VII

MAXIMUM VALUES OF RATE CONSTANTS k_1 AND k_2 AT 25°C.

Condition assumed	Rate constant, mole^{+1} liter^{-1} sec.$^{-1}$	E_{act}, kcal./mole	$\Delta S^{\ddagger}$, e.u./mole
$k_2 = 0$ $k_1 = K'/K_2$	107	11.9	−11.2
$k_1 = 0$ $k_2 = K'/K_1$	1860	10.2	−11.3

Perhaps the most significant feature of the results in Table VII is that E_{act} for either process is ~10 to 12 kcal./mole. Most of the simple cationic electron transfer reactions which have been examined in any detail yield values between 8 and 11 kcal./mole for this factor (19).

CONCLUSION

The principal conclusion of the present work is that the rate of reaction between iron (III) and uranium (IV) is controlled by the concentration of hydrolyzed forms of the reactants. Two independent paths appear to be present, the predominant one involving two hydroxyl groups. The experimental evidence suggests, but does not prove, that the reactions $Fe(OH)_2^+ + U^{4+} \rightarrow$ and $Fe^{3+} + U(OH)_2^{2+} \rightarrow$ predominate over the kinetically equivalent 2-OH path involving $FeOH^{2+}$ and UOH^{3+}. The energy of activation for the 1-OH path is in qualitative agreement with other data for similar systems, and in this respect the result is unexceptionable.

The marked reactivity of hydrolyzed species in this system has also been observed in the other studies already cited. For example, the oxidation of neptunium (IV) by iron (III) requires the participation by three hydroxyl groups (10). Also, the conclusions we have reached regarding the presence of two concurrent paths for reaction find a counterpart in several other systems. Thus, the isotopic electron transfer reaction between iron (II) and iron (III) proceeds in perchlorate media via the pairs Fe^{2+}–Fe^{3+} and Fe^{2+}–$FeOH^{2+}$; the rate constant for the reaction involving $FeOH^{2+}$ is about 1000-fold greater than that for the reaction between the fully hydrated ions (18).

THE VIBRATIONAL SPECTRA OF CH_2=CHCl AND CH_2=CDCl[1]

By J. C. Evans[2] and H. J. Bernstein

ABSTRACT

The infrared and Raman spectra of CH_2=CDCl and the Raman spectrum of CH_2=CHCl have been obtained and depolarization ratios of the Raman bands have been measured. The spectra of the two molecules have been correlated.

While the vibrational assignment of vinyl chloride has been satisfactorily made with the aid of the observed envelopes of the infrared absorption bands (8), the vibrational spectrum of CH_2=CDCl has not previously been examined. Since a sample of the latter compound was available in this laboratory, its vibrational spectrum was examined and correlated with that of vinyl chloride. Furthermore, since previous Raman studies (6) did not include depolarization measurements, the Raman spectrum of vinyl chloride was obtained and depolarization ratios measured.

EXPERIMENTAL

Samples of both compounds were provided by Mr. J. Francis and Dr. L. C. Leitch. A commercial sample (Matheson Co.) of vinyl chloride was distilled. The preparation of the deuterium substituted compound will be described (3). This sample contained a small amount of vinyl chloride which was detected spectroscopically.

The spectra were obtained with a Perkin-Elmer Model 112 double pass infrared spectrometer and a White, grating Raman spectrometer with photoelectric recording (9), using 4358 Hg as exciting line. The infrared spectrum of CH_2=CDCl in the vapor phase was measured using LiF, CaF_2, NaCl, and CsBr optics and the Raman spectra of both compounds in the liquid phase were obtained at $-100°C. \pm 5°C.$ A low temperature cell, in which the sample tube was cooled by a controlled stream of air passed through liquid nitrogen, was used. The cooled central part of the cell was surrounded by an evacuated jacket which in turn was surrounded by an outer jacket containing saturated aqueous sodium nitrite solution. The filter and the low temperature inhibited polymerization of the samples. Depolarization measurements were made by wrapping polaroid film around the entire cell, first with its axis parallel to the length of the sample tube and then at right angles (2). The observed ratios were corrected for convergence (7).

The Raman and infrared data for the two molecules are collected in Tables I and II. The Raman spectra are reproduced in Fig. 1, and Fig. 2 illustrates the infrared spectrum of CH_2=CDCl.

TELLER–REDLICH PRODUCT RULE RATIOS FOR CH_2=CHCl AND CH_2=CDCl

Species	a'	a''
Observed ratio	0.518	0.812
Theoretical ratio	0.516	0.807

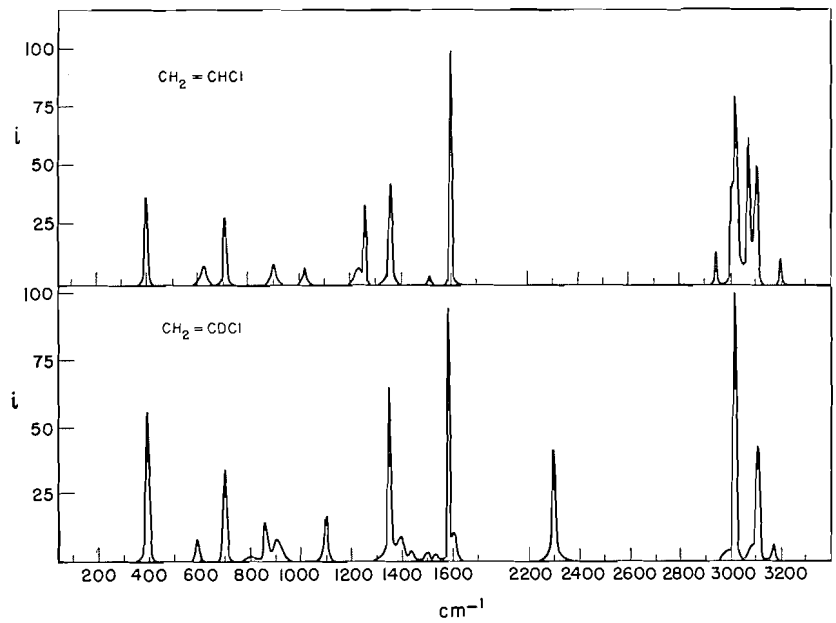

FIG. 1. Raman spectra of CH_2=CHCl and CH_2=CDCl in the liquid state. Temp. −100°C. ±5°C. Volume of sample 6 ml. Slit widths: ~7.5 cm.$^{-1}$ between 300 and 1600 cm.$^{-1}$; ~6.5 cm.$^{-1}$ in 3000 cm.$^{-1}$ region. The scales are different in the two spectra. In each case the band with highest peak is 100.

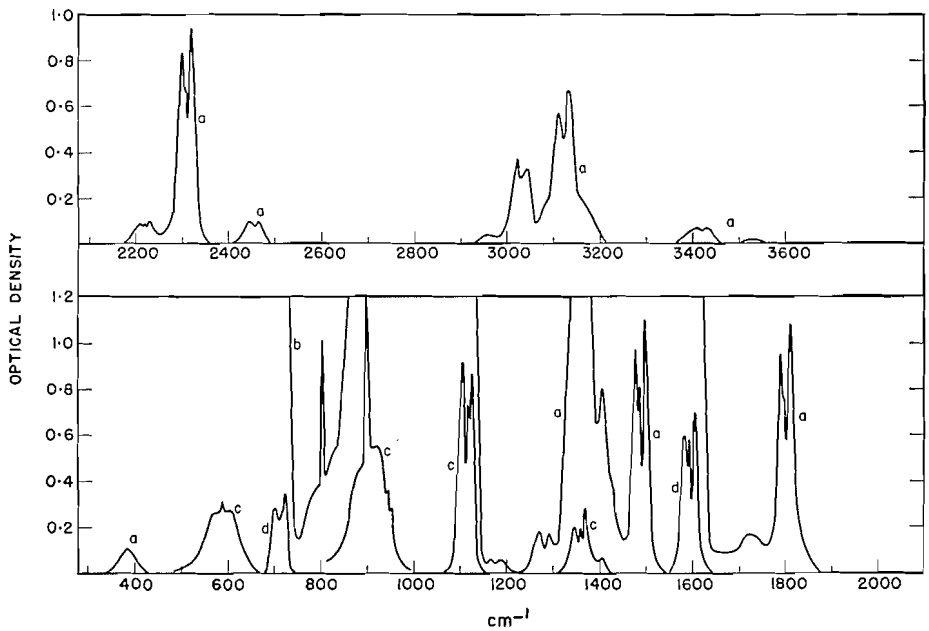

FIG. 2. Infrared spectrum of CH_2=CDCl in the vapor state. 10 cm. cell at 20°C. Vapor pressures: *a*, 760 mm.; *b*, 370 mm.; *c*, 75 mm.; *d*, 19 mm. Slit widths: 8, 3, 3, 4, 3, 3, and 2 cm.$^{-1}$ in the regions 3000, 2000, 1600, 1300, 1000, 700, and 400 cm.$^{-1}$ respectively.

DISCUSSION

Both molecules have the same symmetry, Cs, (5) and all twelve modes of each should be infrared and Raman active. The nine planar modes, species a', and the three out-of-plane modes, species a'', should give rise to polarized and depolarized Raman bands respectively.

Little need be said about the Raman spectrum of CH_2=CHCl. The depolarization ratios confirmed the assignment, based on the observed envelopes of the infrared bands of the vapor, which was made by Thompson and Torkington (8). The a'' mode at 942.5 cm.$^{-1}$ in the infrared was not observed in the Raman spectrum.

For CH_2=CDCl the bands were readily separated into the a' and a'' species by means of the depolarization ratios in the Raman spectrum and the vapor band contours in the infrared. The molecule approximates to a symmetric rotator* with moments of inertia C = 18.7; and $A = B = 149 \times 10^{-40}$ gm. cm.^{2}. The a'' modes are essentially perpendicular modes and should give rise to infrared bands with strong central peaks. The three bands with such a structure correspond to three depolarized Raman bands. The PR separation calculated using Gerhard and Dennison's formula (4) for parallel bands of a symmetric rotator with moments of inertia of 18.7 and 149.5 is approximately 20 cm^{-1}. Most of the infrared bands have a triplet structure with two strong outer peaks separated by ~20 cm.$^{-1}$, and a very weak central peak. The fundamental modes were readily identified. One mode, the a' mode at 861 cm.$^{-1}$ in the Raman, was not observed in the infrared spectrum probably because it was obscured by the strong a'' band at 900 cm^{-1}.

The agreement between the theoretical and observed product rule ratios was satisfactory. The results are collected in Table III.

When a correlation of the fundamentals of CH_2=CHCl and CH_2=CDCl is attempted using the approximate descriptions of the modes given in Table I, it is apparent that an unexpected change has occurred. Two bands, that arising from the in-plane rocking mode of the CH group (1274 cm.$^{-1}$) and that arising from the in-plane rocking mode of the CH_2 group (1026 cm.$^{-1}$), have shown major changes upon deuterium substitution. The explanation for the large change ($>\sqrt{2}$) in the former band's position and the anomalous increase in frequency of the latter must presumably be looked for in the coupling, in CH_2=CDCl, of vibrational modes which, in CH_2=CHCl, are well separated, thus allowing only a small interaction. A closely similar situation occurs in the corresponding bromo compounds where the following tentative assignment was made (1):

	CH_2=CHBr	CH_2=CDBr
CH_2 rocking	1006	1091
CH, CD rocking	1256	841

More data are available for the bromo compounds where all the possible hydrogen–deuterium homologues of vinyl bromide have been examined (1).

Using the dimensions (5): C—Cl = 1.73 Å, C=C = 1.33 Å, C—H = 1.08 Å, C—C—Cl = 122°, C—C—H = 120°, the moments of inertia were calculated to be:

$$I_A = 18.7,\ I_B = 140.2,\ I_C = 158.9 \times 10^{-40}\ gm.\ cm^2.$$

Comparison of the spectra of CD_2=$CHBr$ and CD_2=$CDBr$ shows that the CD rocking mode lies just below 1000 cm^{-1}. Deuterium substitution at the CH_2 group has only a relatively small effect upon the CH rocking mode as is shown by the band positions in CH_2=$CHBr$ (1256 $cm.^{-1}$) and in CD_2=$CHBr$ (1239 $cm.^{-1}$). So it is not unreasonable to assume that the CH_2 rocking mode will also be relatively unaffected by deuterium substitution at the other carbon atom. On this basis, both the CH_2 rocking and the CD rocking modes in CH_2=$CDBr$ would be expected near 1000 cm^{-1}. It is probable that strong coupling of the modes occurs, giving rise to two new vibrational levels at 841 $cm.^{-1}$ and 1091 cm^{-1}. These modes cannot therefore be described simply as CH_2 rocking and CD rocking.

For the two vinyl chlorides the argument is the same; only the band positions differ. The remaining a' modes in the two molecules may readily be correlated in accordance with the approximate descriptions in Table I.

One of the a'' modes, the torsional mode, is easily identified in both molecules but the correlation of the other two out-of-plane modes is uncertain. In CH_2=$CHCl$ they are about 40 $cm.^{-1}$ apart while in CH_2=$CDCl$ the separation is increased to about 100 cm^{-1}.

THE MESOMORPHIC BEHAVIOR OF ANHYDROUS SOAPS

PART II. DENSITIES OF ALKALI METAL STEARATES[1]

By D. P. Benton,[2] P. G. Howe,[2] R. Farnand, and I. E. Puddington

ABSTRACT

The densities of the series of alkali metal stearates and of a number of sodium stearates having substituents in the hydrocarbon chain have been measured over a temperature range of 25–380°C. Discontinuities in the density–temperature relationships indicate the transitions between the various mesomorphic forms in which these soaps exist and the results are compared with transition data obtained by an optical method, described in Part I of this series. Mesomorphism is found to be much less pronounced in the substituted stearates examined than in the normal soaps.

INTRODUCTION

In the extensive and varied studies that have been made of the mesomorphic behavior of salts of the long chain fatty acids, dilatometric measurements have been found particularly useful, since many of the thermal transformations between successive phases are accompanied by conspicuous changes in specific volume (2, 4, 5, 7, 8).

This paper presents the results of a study of the density–temperature relationships of the series of alkali metal stearates and of a number of sodium stearates having substituents in the hydrocarbon chain. The work parallels the previously reported transition data, obtained by an optical method, for the same soaps (1). To facilitate comparison of the data for the different soaps and for use in connection with electrical conductivity and viscosity data, to be presented in subsequent papers in this series, the density measurements have been made on an absolute basis.

EXPERIMENTAL

The sources of materials and methods of preparation of the soaps used in this work were as described previously (1). J-shaped, weight dilatometers were used. A weighed quantity of soap, previously fused under vacuum to remove last traces of water and alcohol (1), was introduced to the dilatometer before sealing to the capillary. The apparatus was then evacuated to a pressure not exceeding 10^{-5} mm. Hg, at a temperature above the final melting point of the soap and, after cooling, mercury was admitted to fill the dilatometer. A 2 meter length of 0.5 mm. diam. capillary was sealed to the capillary outlet and the dilatometer was set in an air thermostat so that the long capillary protruded vertically. The thermostat consisted of heavily lagged, hollow dural block which was heated electrically and controlled by a well-distributed mercury regulator. Calibrated complete immersion thermometers were used within the air bath and temperature control was better than ±0.5°C. over the range 25–355°C.

The upper ends of the capillaries were bent over and dipped below the

[2]*National Research Council Postdoctorate Fellow, 1953–55.*

surface of mercury in small weighing bottles. The weights of mercury expelled from the dilatometers as the temperature was raised were determined at 5–10° intervals. Not more than two determinations were made per day, thus allowing a time found to ensure attainment of equilibrium values. The use of the 2 meter length of capillary gave a total pressure of about four atmospheres on a soap sample and appeared to prevent vacuole formation within the sample on cooling (6). Using this device, reproducible values of the weight of mercury expelled at a given temperature were obtained in every case on passing through the cycle of melting to isotropic liquid and cooling to room temperature.

After completion of the above measurements, the capillary was broken at the point of exit from the thermostat and the dilatometer, containing soap and mercury, was weighed. The dilatometer was then emptied, cleaned, and weighed and finally weighed when completely filled with mercury. The density of a soap at temperature T was calculated using the equation

$$\text{density of soap at temp. } T = W_s/[W_0/\rho_t - (W_M - W_T)/\rho_T]$$

where W_s = weight of soap, W_0 = weight of mercury required to fill dilatometer at temperature t, W_M = weight of mercury in dilatometer with soap at temperature t, W_T = weight of mercury expelled at temperature T ($W_T = 0$ when $t = T$), ρ_t and ρ_T = densities of mercury at t and T. The assumptions thus made are that the expansion of the glass dilatometer and the expansion of the small quantity of mercury in the capillary outside the thermostat are negligible.

In order to check the accuracy of the absolute density values, some subsidiary measurements were made in the higher temperature regions, by means of a different experimental method. A small glass bulb, of approximately 0.25 ml. capacity, was formed at the end of a uniform, calibrated 2 mm. capillary and the bulb calibrated. This container was baked out at 380°C. under vacuum, let down under dry nitrogen, and the required amount of soap weighed in. The apparatus was evacuated, the soap melted, and dry nitrogen introduced into the tube above the soap. An amount of soap was used so that, at about the melting point, the meniscus lay somewhere near the center of the capillary. The apparatus was mounted in a dural block furnace, fitted with a glass covered viewing slot. The slot was illuminated at one side and readings of the height of the meniscus made with a telescopic cathetometer through the other, after equilibration at various temperatures. An etched ring on the capillary tube, used for the volume calibration, was used as a reference point for readings. Measurements below the final melting points of the soaps could only be made in some cases where the soap–glass adhesion was sufficiently low. However, this method provided a check on the values obtained at the highest temperatures with the mercury dilatometers and allowed observations to be extended to about 380°C.

RESULTS AND DISCUSSION

Results for the series of alkali metal stearates are shown graphically in Fig.1. The curve for lithium stearate shows only three transitions, at 229°, 176°, and

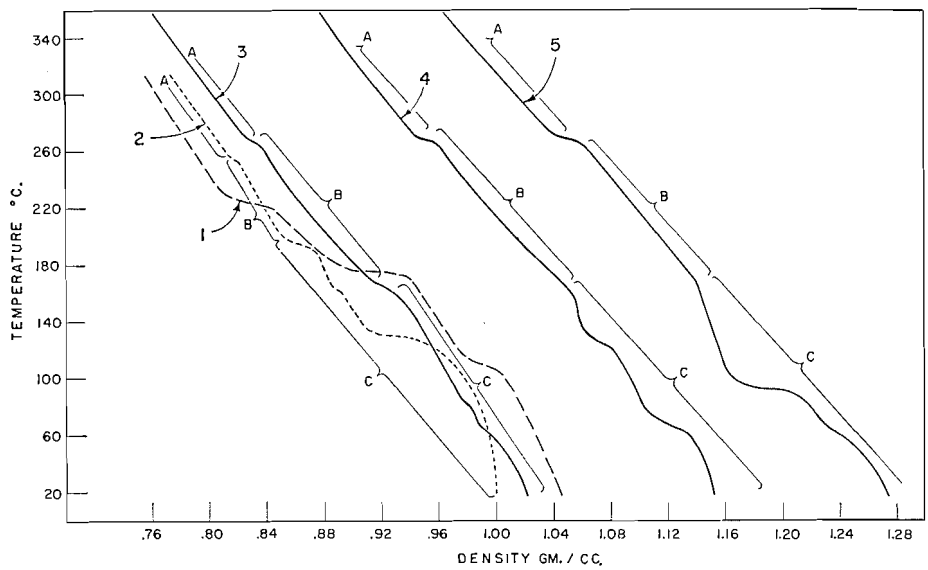

FIG. 1. Densities of alkali metal stearates. 1. Lithium stearate. 2. Sodium stearate. 3. Potassium stearate. 4. Rubidium stearate. 5. Cesium stearate.

115°C. This is similar to the behavior of lithium palmitate (8), which exhibits transitions at 223°, 190°, and 103°C. Supercooling occurred at the final melting point, cf. Part I (1).

The density–temperature curves for the four other alkali metal stearates may each be divided into three major portions, viz., the linear region A, the second linear region B, and the remaining region C.

(1) The linear region A. These regions contain the neat phase and isotropic liquid in each case. The temperatures at the terminations of regions A agree closely with the subneat–neat transition temperatures for the four soaps, determined by the optical method (1). The final melting points of these four soaps are not manifested by sufficiently substantial discontinuities in the density–temperature relationships to produce noticeable deviations from linearity in the graphs.

(2) The linear region B. The next break in the curve for sodium stearate occurs at 190–200°C. This is doubtless a manifestation of the transition which caused a major discontinuity in the light transmission – temperature curve for this soap at 188°C. (1) and ascribed to the change from the subneat to the superwaxy phase. The corresponding terminations of the linear regions in potassium, rubidium, and cesium stearates occur at 160–165°C., 160°C., and about 170°C. respectively. It is noteworthy that these are close to the temperatures at which these soaps were found to become opaque (1). It is suggested that these changes indicate transitions in potassium, rubidium, and cesium stearates corresponding to the subneat–superwaxy transition in sodium stearate.

The regions B would thus represent the subneat phases of this series of soaps. We may note that the optical studies (1) indicated minor transitions within

the subneat phases at 220°, 242°, and 222°C. for sodium, potassium, and rubidium stearates respectively. However, it would appear from dilatometric measurements that no radical changes in molecular packing occur within this region.

(3) The region C. The curve, in region C, for sodium stearate is seen to show an irregularity at about 165°C., corresponding to the discontinuity found by light transmission (1) at this temperature. At 132°C., the temperature ascribed to the transition waxy–subwaxy soap (7), a large density change commences and proceeds in an apparently continuous manner to that of the room temperature crystalline soap. The continuous nature of the density–temperature relationship for sodium stearate in this range, 25–132°C., has been observed previously (2, 6) in spite of very considerable precautions to ensure attainment of equilibrium values, although it has been shown by differential thermal analysis (7) that at least two thermal transitions, at approximately 90° and 117°C., do in fact occur.

The curves in region C for potassium, rubidium, and cesium stearates are seen to be basically of similar form to that for sodium stearate. However, by consideration of the property of density alone, a choice of possible interpretation into corresponding phases is afforded. The lowest temperature regions at 25–70°C., 25–75°C., and 25–70°C., in the curves for potassium, rubidium, and cesium stearates respectively, may correspond to the 25–132°C. region for sodium stearate. In this case the discontinuities at 90°, 130°, and 100°C. presumably would correspond to that at 165°C. in sodium stearate. On the other hand, the regions 25–90°, 25–130°, and 25–100°C. in potassium, rubidium, and cesium stearates may correspond, as a whole, to the 25–132°C. region in sodium stearate. If this is the case, then discontinuities within these regions might correspond to the transitions in sodium stearate that become apparent by reason of their heats of transition.

Consideration of the behavior of the soaps in dispersion in oil is of interest in this connection. The transition at 117°C. in sodium stearate is close to the temperature at which an unsheared dispersion in oil, of this soap, precipitates soap on cooling from a higher temperature or, conversely, close to the swelling temperature of the soap in oil (3). Loosening of the interactions in the hydrocarbon tail–tail planes of the soap lattice is believed to be involved at this temperature. Although observation of the like phenomenon with potassium, rubidium, and cesium stearates is rendered more difficult, by virtue of the greater difficulty of their initial dispersion by application of heat alone, comparable precipitation of these soaps appears to occur at about 70°C. This observation would appear to favor the second of the alternative interpretations postulated above. However, X-ray studies in the temperature ranges in question may be desirable before a choice is made between the two interpretations.

To supplement the graphical presentation of the density data, the numerical values within some of the phase ranges are given in Table I. This table also shows the density values for the isotropic liquids determined by the supplementary experimental method. Agreement between results obtained by the two methods is within 0–2%.

The molecular volumes of the series of alkali metal stearates, as functions of temperature, are shown graphically in Fig. 2. It is seen that the magnitudes of

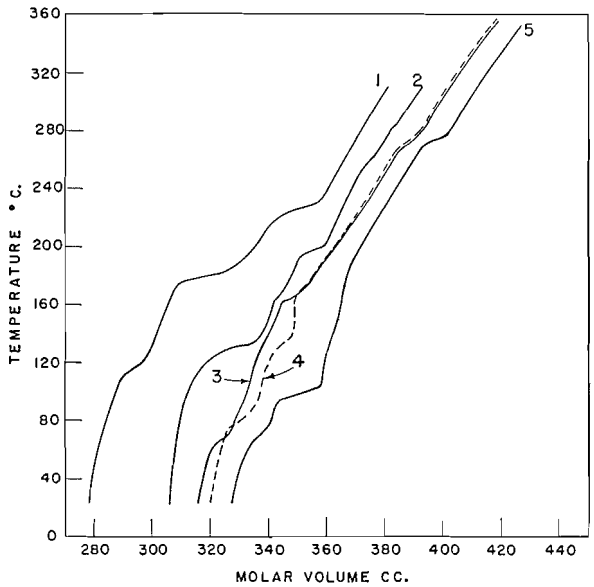

FIG. 2. Molecular volumes of alkali metal stearates. 1. Lithium stearate. 2. Sodium stearate. 3. Potassium stearate. 4. Rubidium stearate. 5. Cesium stearate.

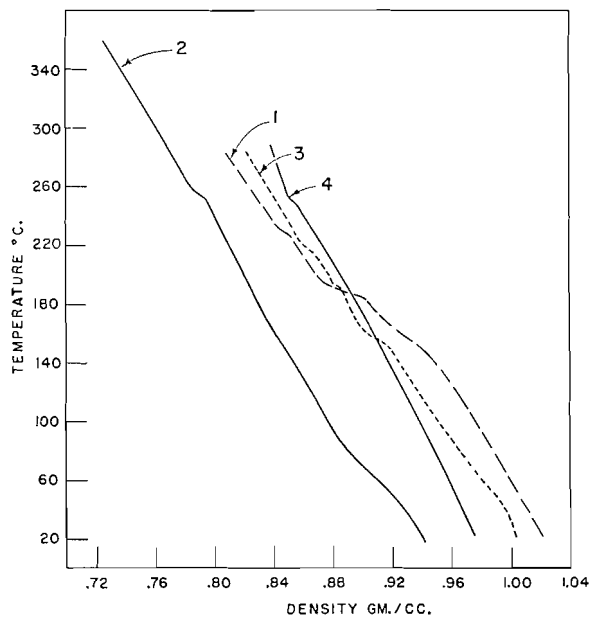

FIG. 3. Densities of substituted sodium stearates. 1. Sodium 12-hydroxy stearate. 2. Sodium 10-methyl stearate. 3. Sodium 9-keto 10-methyl stearate. 4. Sodium 9(10)-phenyl stearate.

this property increase from lithium stearate to cesium stearate, although the values for potassium and rubidium stearates in the subneat and neat phases and in the isotropic liquid are virtually identical.

Results of density determinations for the substituted sodium stearates are shown graphically in Fig. 3. It is apparent that the introduction of these substituent groups into the hydrocarbon chain of sodium stearate has greatly reduced the gross discontinuities in the density–temperature relationship. In the case of the phenyl stearate this relationship is virtually linear. A definite specific volume change is indicated at the final melting point, 250°C., of this soap.

The curves for sodium 9-CO-10-Me stearate and sodium 10-Me stearate also show only small departures from linearity. In the former case small discontinuities provide support for the minor transitions at 195° and 160°C. and the final melting point at 216°C. (1). The 10-Me stearate shows several slight deviations from a linear relationship at the lower temperature regions but the most conspicuous discontinuous specific volume change occurs at 255–260°C., in good agreement with the temperature at which this soap exhibited the major change in translucency (1).

The density–temperature curve for sodium 12-OH stearate is less linear than those for the other substituted soaps. Definite discontinuities occur at 185–195°C., and 225–230°C., again conforming with the results obtained by the light transmission technique (1).

Table II gives some numerical density data for the substituted stearates.

TABLE II

Soap	Temp.	Density
Sodium 10-Me stearate	25–255°	0.94–0.79
	265–355°	0.78–0.73

	235–280°	0.84–0.81

Fig. 4 shows the molecular volumes of the substituted stearates plotted as a function of temperature. Progressive increase in molecular volume is exhibited as the size of the substituent group is increased. It is to be noted that the size of the substituent hydrocarbon group is indicated to be of primary importance in the effect on the nature of the crystal packing. Perhaps surprisingly, the further introduction of the polar keto grouping into the 10-methyl stearate does not substantially affect the molecular volume. Also, on comparing the

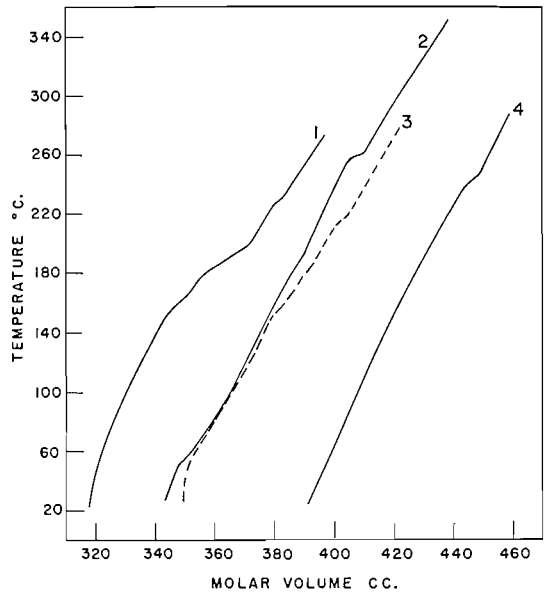

FIG. 4. Molecular volumes of substituted sodium stearates. 1. Sodium 12-hydroxy stearate. 2. Sodium 10-methyl stearate. 3. Sodium 9-keto 10-methyl stearate. 4. Sodium 9(10)-phenyl stearate.

molecular volume curves for sodium stearate and sodium 12-OH stearate, it is found that the effect of the polar hydroxyl group is less pronounced than that of the hydrocarbon substituents.

The density–temperature relationships of these substituted stearates indicate that the relative balance of polar and van der Waals interactions has been modified to a great degree and the stepwise structural changes of the normal soap, on heating, reduced in number or virtually eliminated. These substituted soaps appear to be very useful in grease preparation and likely to give lubricating materials with much more uniform behavior, over a range of operating temperatures, than those prepared with normal soaps.

THE POLAROGRAPHY OF MALEIC HYDRAZIDE[1]

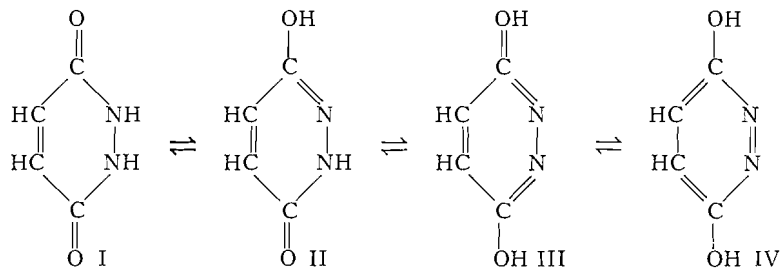
By D. M. Miller

ABSTRACT

Maleic hydrazide was found to be similar to maleic acid in its polarographic behavior. Two pairs of double waves are produced, one in the region around pH 5.9 and the other around 8.2. The theory that the double waves are a result of the reduction of the undissociated acid followed by that of its anion at a higher negative potential appears to explain the first of these double waves but fails to explain the second.

INTRODUCTION

The polarographic behavior of maleic hydrazide (MH) was studied with the intention of using the polarographic method to follow some of the reactions of MH. It was also hoped that some information concerning the tautomeric



forms of MH might be obtained. The pyridazine ring in structures III and IV should make these forms highly aromatic with a possible similarity to hydroquinone. No anodic wave was found in the voltage range available to the dropping mercury electrode however, but a well-defined cathodic wave was produced. This cathodic wave is probably the result of the reduction of the carbon–carbon double bond of structure I. MH might then be expected to be polarographically analogous to maleic acid (MA), and since no information on the polarography of MH appears to have been published, reference will be made to the work on MA.

Elving and Teitelbaum (4) obtained waves for MA over the pH range of 0.7 to 12, and found a complicated relationship between $E_{\frac{1}{2}}$ and pH. A double wave occurred in the region of pH 5.9 but with increase in buffer concentration to one molar the two waves merged. The double wave was considered to be the result of insufficient buffering and all subsequent work was done at a buffer concentration of one molar. Elving and Rosenthal (3) reinvestigated MA using buffer concentrations ranging from 0.1 to 1.0 M and confirmed the existence of the double wave. These waves did not appear to be normal however, showing characteristics attributed to adsorption and kinetic control. A value of 4 was found for the polarographic constant $I_d = i_d/Cm^{2/3}t^{1/6}$ for the first wave

[1]*Manuscript received July 22, 1955.*
Contribution 57, Science Service Laboratory, Canada Department of Agriculture, University Sub Post Office, London, Ontario.

in the pH range 0 to 4. As the pH increased beyond this range however I_d decreased reaching 0 at pH 6.5. I_d for the second wave increased as the first decreased, becoming equal to it at pH 6, and then passing through a maximum at pH 7 became 0 at pH 10. Similar results were found with fumaric acid.

Double waves having equal heights at pH 5.8 were reported for pyruvic acid by Müller and Baumberger (6), while Brdicka (1) showed that phenolglyoxylic acid produced a double wave but its ethyl ester and ethyl pyruvate produced only single waves. This would indicate that the two waves are a result of the reduction of the free acid followed by the reduction of its anion at a more negative potential, a theory which received quantitative treatment by Brdicka and Wiesner (2) for monobasic acids and by Hanus and Brdicka (5) for dibasic acids. It was shown (2) that the pH at which the double waves are of equal height could occur several pH units higher than the pK_a for the acid, provided the formation of the free acid from its anion is fast enough.

EXPERIMENTAL

Polarograms were obtained with a Sargent Model XXI Recording Polarograph. Applied e.m.f. and pH measurements were made with a Beckman Model "G" pH meter. A saturated calomel electrode was used as reference in an H-cell maintained at 25±0.05°C. The resistance of all solutions was measured by an a-c. bridge and correction for *IR* drop applied where necessary. Reagent grade chemicals were used as supplied except for the MH which was recrystallized from water. All polarograms were obtained on solutions of 5.0×10^{-4} *M* with respect to MH except where otherwise noted.

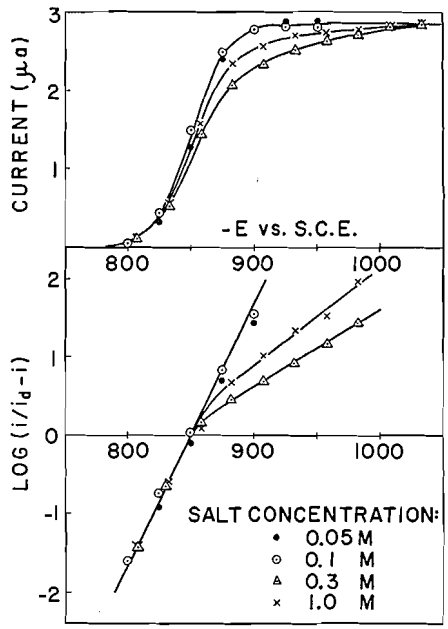


FIG. 1. Top: Polarographic curves of MH in 0.01 *M* HCl with KCl added to give indicated salt concentration ($-E$ in mv.).
Bottom: Log $i/(i_d-i)$ vs. $-E$ for above.

RESULTS

The effect of salt concentration on the polarographic waves was first investigated. Fig. 1 shows the results of increasing the salt concentration of a solution of MH in 0.01 *M* HCl (pH 2.19) from 0.05 *M* to 1.0 *M* using KCl. The top of Fig. 1 shows the polarograms and the bottom the log $i/(i_d-i)$ vs. $-E$ plot. Both plainly show distortion at salt concentrations in excess of 0.1 *M*. Similar results were obtained with other buffer solutions whether KCl or the buffer itself was used to increase the salt concentration. In some cases $E_{\frac{1}{2}}$ was also found to be altered. As a result of these findings all subsequent polarograms were made on solutions of approximately 0.1 *M* with respect to the salt component. A list of the buffer systems used is given in Table I. Elving and

11.70	0.1 *M* KCl and 0.01 *M* KOH

Rosenthal (3) reported anomalous results from the use of acetate buffer and since similar difficulties were encountered in this work it was decided to avoid the use of acetate using pyridine in its place. The polarograms obtained for MH over the pH range 1.2 to 11.7 are shown in the top of Fig. 2. Three distinct waves are apparent. The first wave (I), existing at the lowest pH, exhibits a constant height up to about pH 5, beyond which it gradually decreases being replaced by a second wave (II) which is in turn replaced at higher pH by a third wave (III).

A plot of log $i/(i_d-i)$ vs. $-E$ for each of these waves is shown in the lower section of Fig. 2. Where double waves occur, a separate plot is made for each wave. In all cases the straight line plots obtained indicate that the waves are of normal shape. One anomaly is apparent, however, in that the theoretical number of electrons ($n = 2$) involved in the electrode reaction, as obtained from the slope of these plots, is only realized in the lowest pH range. The slope of the remaining lines indicates a change to one electron (see column six, Table II) which must be fictitious since no reduction in I_d occurs simultaneously.

The half wave potentials ($-E_{\frac{1}{2}}$) and polarographic constants (I_d) of the three waves are given in Table II and plotted against pH in Fig. 3. The curves for I_d vs. pH (top of Fig. 3) show a striking similarity to those of Elving and Rosenthal for MA, the addition of the third wave (III) being the only essential

difference. It should be noted that in both cases curves start at I_d equal to 4 at pH 0 and that the crossover point of curves I and II occurs at pH 5.9. The $-E_{\frac{1}{2}}$ vs. pH plots for waves I and II (bottom of Fig. 3) are generally similar to those for MA. Both show a straight line portion for wave I at low pH but tend to become parallel to the pH axis as the crossover point is approached, while wave II appears more or less sigmoid.

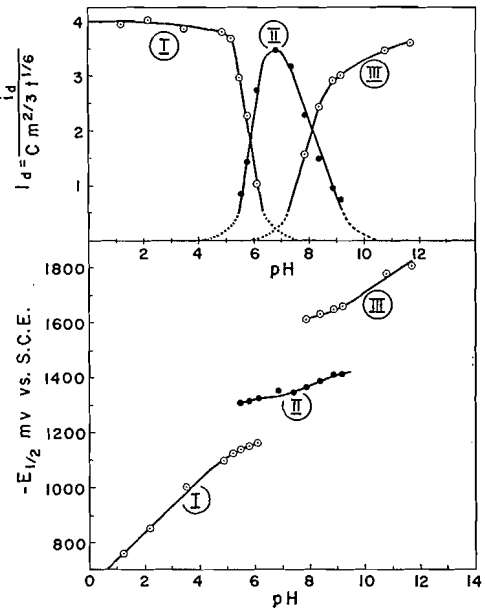

FIG. 3. Top: Polarographic constant I_d of MH vs. pH.
Bottom: Half wave potential of MH vs. pH.

The three curves for MH could be the result of the existence of three species. According to the theory of Brdicka *et al.* these species should be the free acid, its singly charged anion, and its doubly charged anion. There must therefore be two pK_a values for MH, the first being less than 5.9 (the first crossover point) and the second less than 8.2 (the second crossover point). An attempt to determine these by titration with NaOH gave a value of pK_{a1} equal to 5.67 but no value for pK_{a2} was found although the titration was carried to pH 12. The ultraviolet spectra of MH were then recorded at various pH values between 0.92 and 12.10. Two changes occurred with increasing pH as shown in Fig. 4. The height of the peak at 217 mμ (A in Fig. 4) increased and the position of the peak at 300 mμ shifted to 330 mμ (B in Fig. 4). These changes were plotted against pH in the usual way giving for pK_{a1} a value of 5.61 from A and 5.65 from B. No change in the spectra was noticeable from pH 7 to 12. Thus the second ionization constant, if it existed, must be greater than 12.

A test for the constancy of I_d with change in MH concentration was made and the values of I_d resulting are shown in Table III. For any given pH there appears to be little change in I_d for either waves I or II over the concentration range 0.5 to 2.0 mM.

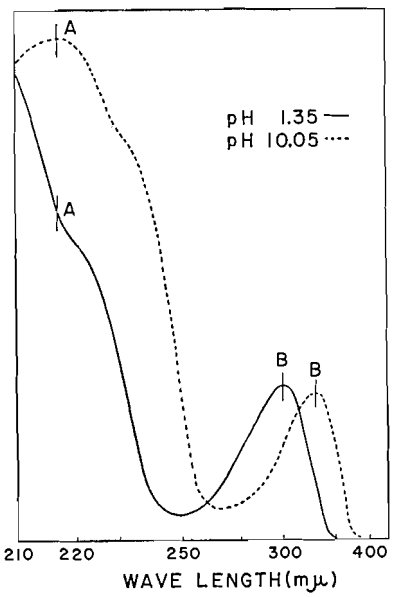

FIG. 4. Ultraviolet absorption curve for MH.

DISCUSSION

The polarography of MH presents two main anomalies:

1. The apparent number of electrons (n) involved in the electrode process changes from two at low pH to one as the pH increases (Table II). This may be the result of a two step reduction, one step of which becomes irreversible as the pH increases.

2. Two sets of double waves are produced. The first of these may be explained using the concept of Brdicka *et al.* Treating MH as a monobasic acid HA, we may write:

$$HA \rightleftharpoons H^+ + A^- \text{ and } K_a = [H^+][A^-]/[HA].$$

The total concentration of MH is given by

$$C = [HA]_B + [A^-]_B$$

where $[HA]_B$ and $[A^-]_B$ represent concentrations in the bulk of the solution. From these expressions it follows that

[1] $$[HA]_B = C[H^+]/([H^+]+K_a),$$

[2] $$[A^-]_B = C K_a/([H^+]+K_a).$$

At potentials such that the diffusion current of the first wave alone has been reached, all HA molecules, but no A^- ions, arriving at the electrode are reduced immediately and the following processes occur:

$$\begin{array}{lll} (HA)_B \xrightarrow{R} & (HA)_0 \longrightarrow & (HR) \\ & \uparrow k & \\ (A^-)_B \xrightarrow{R} & (A^-)_0 & \end{array}$$

where $(MA)_B$ and $(A^-)_B$ represent the species in the bulk of the solution and $(HA)_0$ and $(A^-)_0$ those at the electrode interface, R is the diffusion rate constant which is assumed to be approximately the same for HA and A^-, k is the rate constant for the association, and HR the reduced form of HA. In a well-buffered solution the hydrogen ion concentration can be assumed to be the same in the bulk and at the interface; thus if i_d is the diffusion current and Q a factor converting it to the proper units, the following steady state equations may be written:

[3] $$d[HA]/dt = R[HA]_B + k[A^-]_0[H^+] - Qi_d = 0,$$

[4] $$d[A^-]/dt = R([A^-]_B - [A^-]_0) - k[A^-]_0[H^+] = 0.$$

If i_d^0 is the diffusion current measured at large $[H^+]$ (i.e. pH = 0) so that $[A^-]_B$ is essentially 0, then

[5] $$Qi_d^0 = RC.$$

From expressions [1] to [5] it can be shown that the ratio of the rate constants for association to that for diffusion is:

[6] $$\frac{k}{R} = \frac{K_a[i_d/(i_d^0 - i_d)] - [H^+]}{[H^+]^2 + K_a[H^+]}.$$

Expression [6] may be checked by substituting $K_a = 2.24 \times 10^{-5}$ moles liters^{-1}, $i_d^0 = 2.83$ μa., and the appropriate values of i_d and $[H^+]$ into [6] to obtain k/R which should be constant over a wide range of hydrogen ion concentrations. The results obtained in this way follow:

$[H^+]$	k/R
1.29×10^{-5} M	1.3×10^5 liters moles^{-1}
6.17×10^{-6}	2.6×10^5
3.09×10^{-6}	1.9×10^5
1.59×10^{-6}	2.2×10^5
6.17×10^{-7}	0.8×10^5

Although the ratio shows some variation, probably due to errors in pH measurements to which expression [6] is sensitive, there is no definite trend with change in pH; thus a value of 2×10^5 liters moles^{-1} can be taken for k/R.

By substituting $i_d = \frac{1}{2}i_d^0$ into equation [6] the dependence of the hydrogen ion concentration at the crossover point ($[H^+]_{\frac{1}{2}}$) on the other factors is given by the expression

$$[7] \qquad k/R = K_a - [H^+]_{\frac{1}{2}}/([H^+]_{\frac{1}{2}}^2 + K_a[H^+]_{\frac{1}{2}}).$$

This equation is similar to the one obtained by Brdicka and Wiesner for similar conditions ($i_+ = i_-$ in their paper). It must be emphasized that since R is a complex function of diffusion and reaction rates, no absolute values of k can be obtained from the above form of the equation. It does give a fairly adequate qualitative picture, however, showing that the crossover point is not only a function of K_a but is dependent also on the relative rates of the diffusion and recombination processes.

On the basis of the above theory the second crossover point would occur when the reduction rate of the singly and doubly charged anions is equal. The second ionization constant, however, was found to be less than 10^{-12}, which is so much lower than $[H^+]_{\frac{1}{2}}$ that substitution in [7] would result in a negative value for k/R. This is of course meaningless, and the above theory must be discarded as an explanation of the second set of double waves. Elving and Teitelbaum (4) reported a double wave in the case of the diethyl esters of maleic and fumaric acids at a higher pH than for the acids themselves. This would indicate that the second set of waves cannot be attributed to normally ionized species but to some other pH dependent feature of the reduction. An explanation of these waves would most likely be found in a study of the mechanism of the electrode reaction. It would also seem advisable to reinvestigate the polarography of all acids giving a double wave, as well as their esters, under conditions similar to those used in this work, with the view to determining which compounds give a second set of double waves at higher pH. The methyl esters of MH are being investigated to this end.

THE REACTION OF HYDROGEN ATOMS WITH METHYL CYANIDE[1]

By W. Forst[2] and C. A. Winkler

ABSTRACT

Hydrogen atoms produced in a discharge tube were found to react with methyl cyanide to produce hydrogen cyanide as the main product, together with smaller amounts of methane and ethane. The proposed mechanism involves the formation of hydrogen cyanide and a methyl radical in the initial step; methane and ethane are attributed to secondary reactions of the methyl radicals.

INTRODUCTION

The reaction of hydrogen atoms with methyl cyanide seems never to have been studied. A limited investigation of it has been made, partly for its intrinsic interest, and partly to provide information about the possible significance of hydrogen atom reactions during the reaction of active nitrogen with methyl cyanide, which will be reported in a later communication.

EXPERIMENTAL

The apparatus was essentially identical with that used for active nitrogen studies in this laboratory (1, 5) except for the methyl cyanide feed system. Methyl cyanide was stored as a liquid in a wide flat-bottomed bulb immersed in a thermostat regulated at 20.25 ± 0.05°C., and the vapor drawn directly from the liquid surface. The methyl cyanide flow rate was varied by placing jets of different sizes in a flowmeter.

The molecular hydrogen flow rate was 7.95×10^{-5} mole/sec., corresponding to an operating pressure of 0.95 mm. Hg in the system.

Methyl cyanide, "chemically pure", was purchased from Brickman and Company and thoroughly dehydrated by one distillation over calcium chloride, followed by six distillations over P_2O_5 (13), and a final distillation over freshly fused potassium carbonate (9).

The condensable products of the reaction were distilled into a low temperature still of the type described by LeRoy (8). The C_2 fraction was distilled off at −140°C. and by mass-spectrometric analysis* was found to contain only ethane. The remainder of the products were distilled into an absorber containing $N/2$ KOH immersed in liquid air. After the solution had melted, the cyanide was determined by titration with silver nitrate (6). Three experiments were made in which the products were analyzed for cyanogen by the method due to Rhodes (11); the result in each case was negative. Samples of non-condensable products were withdrawn from the hydrogen stream by a Toepler pump and analyzed on the mass spectrometer. They contained only methane,

in addition to excess hydrogen. There were traces of a white solid on the walls of the tube leading from the reaction vessel into the first trap.

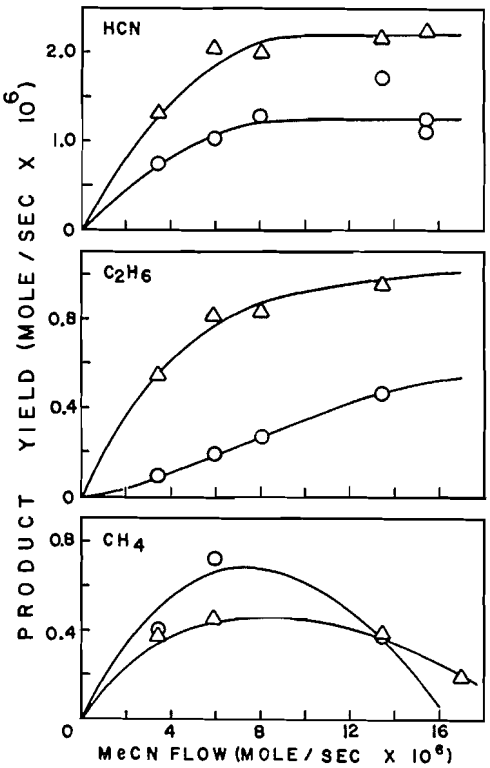

FIG. 1. Yields of hydrogen cyanide, ethane, and methane as functions of methyl cyanide flow rate.
Circles: 107°C. Triangles: 237°C.

The yields of hydrogen cyanide, ethane, and methane at 107° and 237°C. are plotted in Fig. 1 as functions of the methyl cyanide flow rate.

DISCUSSION

The initial attack of a hydrogen atom on the methyl cyanide molecule can be represented in three ways:

$$H+CH_3CN \rightarrow CH_4+CN-2 \text{ kcal.} \quad [1]$$

$$H+CH_3CN \rightarrow H_2+CH_2CN+3 \text{ kcal.} \quad [2]$$

$$H+CH_3CN \rightarrow HCN+CH_3+10 \text{ kcal.} \quad [3]$$

The heats of reaction in each case were calculated from heats of formation given in Reference (10). The heat of formation of the CH_2CN radical was estimated at about -70 kcal., and the heat of formation of the CN radical was taken as -93 kcal. (2, 10).

If reaction [1] occurs to an appreciable extent, some of the cyanide radicals formed in [1] should, at least at low MeCN flow rates, recombine to cyanogen. Since HCN but no cyanogen was found, every cyanide radical formed in [1] would have to be removed quantitatively by reactions leading ultimately to hydrogen cyanide. Moreover, with reaction [1] as initial step, there should be one molecule of methane produced for every cyanide radical disappearing. Fig. 1 shows that no such relation exists between the formation of HCN and CH_4. It would also be difficult to account for the presence of ethane in the products on this basis. Hence reaction [1] must be ruled out as a possible primary step.

If reaction [2] is the initial step, it is difficult to visualize how methane, ethane, and hydrogen cyanide could arise by further reactions of the cyanomethyl radicals produced. While it is true that recombination of the CH_2CN radicals to succinonitrile would account for the white deposit observed on the walls of the reaction vessel, this cannot be taken as proof that reaction [2] occurs, since CH_2CN radicals may also be formed in the reaction

$$CH_3+CH_3CN \rightarrow CH_4+CH_2CN$$

which is known to occur (12). While reaction [2] does not appear to be attractive for the primary step, the present experiments do not permit its importance to be assessed directly.

If reactions [1] and [2] are considered unimportant, and the primary step is assumed to be reaction [3], methane and ethane would have to arise by subsequent reactions of methyl radicals, and at any flow rate of methyl cyanide the following relation between the products of the reaction should exist:

$$2(\text{moles of ethane})+(\text{moles of methane}) = (\text{moles of HCN}).$$

Inspection of Fig. 1 shows that this is approximately true, within the relatively large experimental error. This agreement may, perhaps, be taken as evidence that, compared with reaction [3], reaction [2] does not occur to an appreciable extent.

The two curves in Fig. 1 representing the production of hydrogen cyanide as a function of methyl cyanide flow rate show that above a flow rate of about 8×10^{-6} mole/sec. MeCN, further increase in MeCN flow rate does not increase the production of hydrogen cyanide. A reasonable explanation of this behavior seems to be that the available supply of hydrogen atoms becomes exhausted.

If the flat portion of each curve represents complete consumption of all the available hydrogen atoms, there is reason to expect that the plateau should be higher at the lower temperature, since presumably more hydrogen atoms should be available at the lower temperature owing to a decreased number of collisions (in the gas phase and at the wall) leading to their recombination. From the relative positions of the two plateaus in Fig. 1, the experimental results seem to imply that the opposite is true. On the basis of a detailed mathematical treatment, it will be shown in a later communication that the change of plateau values with temperature could be accounted for on the assumption that

methyl cyanide acts as an efficient third body in the recombination of hydrogen atoms.

There are four obvious possibilities for secondary reactions of methyl radicals:

$$CH_3+H \rightarrow CH_4 \quad [4]$$

$$CH_3+CH_3 \rightarrow C_2H_6 \quad [5]$$

$$CH_3+H_2 \rightarrow CH_4+H \quad [6]$$

$$CH_3CN+CH_3 \rightarrow CH_4+CH_2CN. \quad [7]$$

Reactions [4] and [5] have low activation energies, and both probably require a third body. Reactions [6] and [7] are both known to have activation energies of the order of 10 kcal. (14, 15). On the basis of this information, reactions [4] and [5] should be equally likely at 107°C. and 237°C., with reactions [6] and [7] becoming important only at the higher temperature. This conclusion appears to be borne out by the pattern of methane production shown in Fig. 1. At 107°C. the amount of methane formed rises with increasing methyl cyanide flow rate up to a maximum which corresponds roughly to the point where complete consumption of hydrogen atoms occurs, and then drops off sharply as the methyl cyanide flow rate is increased further. This suggests a strong dependence of methane production on hydrogen atom supply, and consequently reaction [4] must be responsible for a major part of the methane produced at this temperature. At 237°C. the decrease of methane production at MeCN flow rates corresponding to complete consumption of hydrogen atoms is less pronounced than at 107°C., and this may be taken as evidence that at this temperature reactions [6] and [7]—in addition to reaction [4]—contribute significantly to the formation of methane, as expected.

It is difficult to assess the relative importance of reactions [6] and [7]. It will be noted however that in reaction [6] a hydrogen atom is formed for each molecule of methane produced. If reaction [6] were the only important methane-producing step at high MeCN flow rates, a chain reaction could conceivably be set up in conjunction with reaction [3], resulting in continued increase of hydrogen cyanide yield at high MeCN flow rates. Since the hydrogen cyanide production curve (Fig. 1) reaches a flat plateau (within experimental error), it is very improbable that at high flow rates appreciable amounts of methane are produced in reaction [6].

There can be little doubt that ethane is due to recombination of methyl radicals, and by reference to the discussion of methane production the only other important reaction competing at both temperatures for methyl radicals at low MeCN flow rates should be reaction [4]. The fact that production of ethane increases markedly with a rise in temperature would then seem to be a matter of methyl radical concentration. The increased amount of reaction at 237°C. increases $[CH_3]$ relative to its value at 107°C., and this should profoundly affect the rate of formation of ethane, which depends on the second power of $[CH_3]$. The rate of formation of methane (reaction [4]) should also increase, though to a lesser extent.

Actually, a decline in the yield of methane is observed at 237°C., and this appears to be attributable to a decrease in hydrogen atom concentration. At low MeCN flow rates, only relatively few hydrogen atoms are removed in reactions [3] and [4], and in third order recombination with methyl cyanide as the third body. As a result, under these conditions, an appreciable part of the hydrogen atoms will recombine by $H–H_2$ collisions and at the wall, and, as mentioned, such recombination can be expected to exhibit a positive temperature coefficient. It appears that at 237°C. this hydrogen atom recombination is much more pronounced than at 107°C., to the extent that it may offset the effect of the temperature increase on $[CH_3]$, hence on the rate of formation of methane, and lead to a reduced yield of methane at the higher temperature.

The reaction of hydrogen atoms with methyl cyanide appears to be essentially similar to the reactions of methyl halides with hydrogen atoms (3, 4, 7). This is perhaps not surprising since in many inorganic reactions the cyanide group exhibits a strong resemblance to the halogens.

THE PREPARATION OF *o*- AND *p*-ACETAMINOBENZALDEHYDES[1]

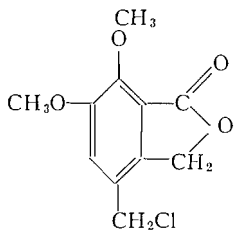
By J. J. Brown[2] and R. K. Brown

ABSTRACT

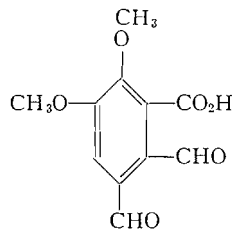
Treatment of N,N-diacetyl-*o*-toluidine with N-bromosuccinimide followed by hydrolysis of the intermediate dibromo compound gave *o*-acetaminobenzaldehyde. The reaction was applied successfully to N,N-diacetyl-*p*-toluidine, N,N-diacetyl-4-chloro-*o*-toluidine, 2,4-bis(diacetamino)toluene, and 4-acetoxy-N,N-diacetyl-*o*-toluidine.

Both *o*- and *p*-acetaminobenzaldehyde were required for synthetic work in this laboratory. These compounds have been prepared in the usual way by the acetylation (6, 7) of *o*- and *p*-aminobenzaldehyde. However, the methods described in the literature for the preparation of *o*-aminobenzaldehyde by the reduction of *o*-nitrobenzaldehyde with ferrous sulphate and ammonia (15) and for *p*-aminobenzaldehyde by the action of sodium polysulphide upon *p*-nitrotoluene (3) are tedious, and the products must be used immediately in order to avoid self-condensation.

A direct preparation of *o*- and *p*-acetaminobenzaldehyde was suggested by the hydrolysis of N,N-diacetyl-*p*-toluidine (16) using aqueous sodium carbonate which gave a quantitative yield of *p*-acetotoluidide, and also by the work of Brown and Newbold (2) who used N-bromosuccinimide to oxidize 4-chloromethylmeconin(I) to 3-formylopianic acid (II).



I



II

We found that treatment of N,N-diacetyl-*p*-toluidine with two moles of N-bromosuccinimide in carbon tetrachloride, followed by aqueous sodium carbonate hydrolysis without isolation of the intermediate bromo compound, gave *p*-acetaminobenzaldehyde in 70% yield. Similarly, N,N-diacetyl-*o*-toluidine (16) gave *o*-acetaminobenzaldehyde in 66% yield.

The reaction was investigated further with respect to certain 4-substituted N,N-diacetyl-*o*-toluidines prepared by prolonged refluxing of the toluidine or its acetyl derivative in acetic anhydride. N,N-Diacetyl-4-chloro-*o*-toluidine, 2,4-bis(diacetamino)toluene, and 4-acetoxy-N,N-diacetyl-*o*-toluidine when

[1]*Manuscript received August 29, 1955.*

[2]*National Research Council of Canada Postdoctoral Fellow, 1954–1955. Present address: The Converse Memorial Laboratory, Harvard University, Cambridge 38, Mass., U.S.A.*

treated with N-bromosuccinimide as above gave 2-acetamino-4-chlorobenzaldehyde (69%), 2,4-bis(acetamino)benzaldehyde (79%), and 2-acetamino-4-hydroxybenzaldehyde (70%) respectively.

The reaction was also applied to N,N-diacetyl-4-nitro-*o*-toluidine but the acetaminobenzaldehyde could not be isolated from the reaction mixture.

EXPERIMENTAL

Brominations using N-bromosuccinimide were carried out with irradiation from a Westinghouse Sunlamp (type R.S.-275 Watt) placed close to the flask.

p-Acetotoluidide

N,N-Diacetyl-*p*-toluidine (5 gm.) was treated with anhydrous sodium carbonate (10 gm.) and water (100 ml.) on the steam bath for one hour. Partial solution took place, and the solid which separated on cooling was crystallized from benzene to give *p*-acetotoluidide as blades, m.p. and mixed m.p. 149–150°.

p-Acetaminobenzaldehyde

A solution of N,N-diacetyl-*p*-toluidine (5 gm.) in carbon tetrachloride (100 ml.) containing 10.3 gm. of N-bromosuccinimide was heated under reflux on the steam bath for one hour. The filtered solution was evaporated under reduced pressure, and the residual red oil was heated with anhydrous sodium carbonate (10 gm.) in water (100 ml.) for one hour on the steam bath. The solution was decanted from a small amount of tar, extracted with ether (3×100 ml.), and the combined extracts were dried with sodium sulphate. Removal of solvent under reduced pressure gave a yellow solid which was crystallized from benzene – light petroleum (b.p. 30–60°) to give *p*-acetaminobenzaldehyde as needles (3 gm., 70%), m.p. 152–153° (lit.(7) 154.5–155°). Oxime, m.p. 206–207° (lit.(7) 205–206°). Calc. for $C_9H_9O_2N$: C, 66.2; H, 5.6. Found: C, 66.4; 5.5%.

o-Acetaminobenzaldehyde

N,N-Diacetyl-*o*-toluidine (5 gm.) was brominated as above, with the reflux time extended to eight hours. After hydrolysis of the product, the dried (Na_2SO_4) ethereal extract was evaporated to a dark red oil which was extracted thoroughly with boiling light petroleum (b.p. 30–60°). The extract was reduced to a small volume and placed in the refrigerator for one hour when *o*-acetaminobenzaldehyde separated as needles (2.8 gm., 66%), m.p. 68–70°. A specimen recrystallized from light petroleum (b.p. 30–60°) melted at 70–71° (lit. (6) 70–71°). Found: C, 66.6; H, 5.6%. Oxime, m.p. 193–194° (lit.(1) 194°).

N,N-Diacetyl-4-chloro-o-toluidine

4-Chloro-*o*-toluidine was prepared in good yield by the method of Hodgson and Moore (8). Twenty grams of 4-chloro-*o*-toluidine in acetic anhydride (50 ml.) was heated under reflux for 17 hr. The cooled solution was diluted with water (200 ml.) and the brown oil which separated was extracted with ether (3×50 ml.). The combined ethereal extracts were washed with water (2×50 ml.), 10% sodium bicarbonate solution (3×50 ml.), and water (50 ml.) and then dried (Na_2SO_4). The red oil obtained on removal of the solvent under reduced pressure was distilled to give N,N-diacetyl-4-chloro-*o*-toluidine as a

colorless oil which rapidly crystallized as needles (24 gm.), m.p. 40–42°, b.p. 154° at 8.5 mm. Calc. for $C_{11}H_{12}O_2NCl$: C, 58.5; H, 5.4. Found: C, 58.6; H, 5.6%.

2-Acetamino-4-chlorobenzaldehyde

N,N-Diacetyl-4-chloro-*o*-toluidine (5 gm.), N-bromosuccinimide (9 gm.), and carbon tetrachloride (100 ml.) were heated under reflux on the steam bath for three hours. The filtered solution when evaporated gave a yellow solid which was heated under reflux for 30 min. with a solution of anhydrous sodium carbonate (10 gm.) in water (50 ml.). The cooled reaction mixture was extracted with chloroform (3×50 ml.) and the combined chloroform extracts were dried (Na_2SO_4). Evaporation of solvent under reduced pressure, followed by crystallization of the yellow solid from aqueous ethanol, gave 2-acetamino-4-chlorobenzaldehyde as yellow blades (3 gm., 69%), m.p. 124–125°. Calc. for $C_9H_8O_2NCl$: C, 54.7; H, 4.1. Found: C, 54.7; H, 4.1%. The oxime crystallized from aqueous ethanol as needles, m.p. 215–216°. Calc. for $C_9H_9O_2N_2Cl$: C, 50.9; H, 4.3. Found: C, 50.8; H, 4.4%.

2-Acetamino-4-chlorobenzaldehyde was hydrolyzed to 2-amino-4-chlorobenzaldehyde by heating the former compound (1 gm.) with sodium hydroxide solution (40 ml., 2 *N*) and methanol (20 ml.) on the steam bath for 15 min. with occasional shaking. The solution was decanted from a small amount of tar, cooled, and extracted with ether (3×30 ml.). The combined ethereal extracts were washed with water (30 ml.), dried (Na_2SO_4), and evaporated to a yellow oil which soon solidified. Crystallization from aqueous ethanol gave 2-amino-4-chlorobenzaldehyde as needles (550 mgm.), m.p. 86–87°. Calc. for C_7H_6ONCl: C, 54.0; H, 3.9. Found: C, 53.8; H, 3.8%. Sachs and Sichel (14) give a melting point of 86° for the same compound obtained by reduction of 4-chloro-2-nitrobenzaldehyde using titanous chloride.

2,4-Bis(diacetamino)toluene

2,4-Bis(acetamino)toluene was prepared from 2,4-diaminotoluene (11) by the method of Lumière and Barbier (10). The compound melted at 219–223° (lit.(9) 223°). 2,4-Bis(acetamino)toluene (40 gm.) and acetic anhydride (200 ml.) were heated under reflux for 17 hr. The acetic anhydride was removed under reduced pressure and water (50 ml.) was added to the residue which was then extracted with chloroform (3×50 ml.). The combined chloroform extracts were washed with water (50 ml.), 10% sodium bicarbonate solution (50 ml.), and water (50 ml.) and then dried (Na_2SO_4). Removal of the solvent under reduced pressure gave a dark brown oil which solidified on standing. The solid, which was filtered with the aid of some ether and then washed with a small amount of ether, crystallized from benzene – light petroleum (b.p. 30–60°) to give 2,4-bis(diacetamino)toluene as prisms (20 gm.), m.p. 109–110°. Calc. for $C_{15}H_{18}O_4N_2$: C, 62.0; H, 6.25. Found: C, 62.2; H, 6.4%.

2,4-Bis(acetamino)benzaldehyde

2,4-Bis(diacetamino)toluene (5 gm.), N-bromosuccinimide (6.75 gm.), and carbon tetrachloride (100 ml.) were heated under reflux on the steam bath for

three hours. Evaporation of the solvent after filtration gave a yellow oil which was heated on the steam bath for 15 min. with a solution of anhydrous sodium carbonate (10 gm.) in water (50 ml.). The solid which separated on cooling was collected and crystallized from ethanol to give 2,4-bis(acetamino)benzaldehyde as plates (3 gm., 79%), m.p. 233–235°. Calc. for $C_{11}H_{12}O_3N_2$: C, 60.0; H, 5.5. Found: C, 59.8; H, 5.5%. Sachs and Kempf (13) give m.p. 235.5° for the compound obtained by treating the product of the ammonium sulphide reduction of 2,4-dinitrobenzaldehyde with acetic anhydride. The phenylhydrazone melted at 252–254° (lit.(13) 246–252°).

2-Amino-p-cresol (Me = 1)

2-Nitro-*p*-toluidine, prepared in excellent yield by the method of Cohen and Dakin (4) for 4-nitro-*o*-toluidine, was converted into 2-nitro-*p*-cresol (17). Sodium dithionite (50 gm.) was added in small portions, with stirring, to 2-nitro-*p*-cresol (5 gm.) in a solution of potassium hydroxide (12 gm.) in water (100 ml.). After 15 min. at room temperature, the solution was acidified to Congo red with hydrochloric acid (d., 1.16) and heated on the steam bath to remove sulphur dioxide. The filtered solution was neutralized with 10% sodium bicarbonate, extracted with ether (4×100 ml.), and the combined ethereal extracts were washed with water (100 ml.) and dried (Na_2SO_4). Evaporation of solvent under reduced pressure yielded 2-amino-*p*-cresol as a brown solid (3 gm.), m.p. 147–150°. Copisarow (5) reports a melting point of 157–159° for the compound obtained by sodium sulphide reduction of 2-nitro-*p*-cresol.

4-Acetoxy-N,N-diacetyl-o-toluidine

2-Amino-*p*-cresol (5 gm.) and acetic anhydride (20 ml.) were heated under reflux for 17 hr. The cooled solution was diluted with water (100 ml.) and the product was isolated with ether as before. Removal of solvent gave a red oil which was extracted with boiling light petroleum (b.p. 30–60°). The solvent was reduced in volume and the remaining solution cooled in a refrigerator for one hour. The 4-acetoxy-N,N-diacetyl-*o*-toluidine separated as needles (4 gm.), m.p. 72–73°. Calc. for $C_{13}H_{15}O_4N$: C, 62.6; H, 6.1. Found: C, 62.4; H, 6.2%.

2-Acetamino-4-hydroxybenzaldehyde

4-Acetoxy-N,N-diacetyl-*o*-toluidine (2 gm.) and N-bromosuccinimide (3.15 gm.) in carbon tetrachloride (30 ml.) were heated under reflux for two and one-half hours on the steam bath. The yellow oil, obtained by evaporation of the filtered solvent, was heated on the steam bath for 30 min. with a solution of anhydrous sodium carbonate (4 gm.) in water (25 ml.). The solution was acidified with acetic acid and extracted with ether (5×50 ml.). The dried solution (Na_2SO_4), freed of solvent under reduced pressure, gave 2-acetamino-4-hydroxybenzaldehyde as a light brown solid. Crystallization from aqueous ethanol gave needles (1 gm., 70%) melting at 238–239°. Calc. for $C_9H_9O_3N$: C, 60.3; H, 5.1. Found: C, 60.2; H, 5.4%. The oxime crystallized from water as needles, m.p. 215° (decomp.). Calc. for $C_9H_{10}O_3N_2$: C, 55.7; H, 5.2. Found: C, 55.5; H, 5.5%.

N,N-Diacetyl-4-nitro-o-toluidine

4-Nitro-*o*-toluidine (20 gm.) (prepared according to Cohen and Dakin (4)) in acetic anhydride (50 ml.) was heated under reflux for 17 hr. The cooled solution was diluted with water (200 ml.) and the product, a dark red oil, was isolated with chloroform. The oil was dissolved in a few milliliters of benzene and the 4-nitro-*o*-acetotoluidide (5 gm.) which separated was filtered off, m.p. 151–153° (lit.(12) 150–151°). Evaporation of the filtrate gave a dark oil which soon solidified. Crystallization from benzene – light petroleum (b.p. 30–60°) gave N,N-diacetyl-4-nitro-*o*-toluidine as prisms (16 gm.), m.p. 81–83°. Calc. for $C_{11}H_{12}O_4N_2$: C, 55.9; H, 5.1. Found: C, 56.1; H, 5.2%.

DEGRADATION OF D-GLUCOSE-1-C^{14} TO TRIOSE-REDUCTONE-C^{14} [1]

By H. F. Bauer and Carol Teed

ABSTRACT

Triose-reductone-C^{14} was obtained by treating D-glucose-1-C^{14} with sodium hydroxide in the presence of lead acetate at elevated temperatures. Carbon atoms four, five, and six, as well as carbon atoms one, two, and three, of the D-glucose molecule are shown to contribute to the triose-reductone yield. The formation of triose-reductone was found not to be accompanied by glycerol formation. Mechanisms for fragmentation of reducing sugars are discussed in the light of these findings.

INTRODUCTION

Triose-reductone, often called "glucoreductone" or "reductone", was discovered and isolated in a crystalline state by Euler and Martius (6) when they treated D-glucose with strong solutions of sodium hydroxide. It was subsequently shown that many reducing sugars yield triose-reductone under the same conditions but the methods for its isolation have been modified only slightly and D-glucose still remains the only practical source. By analogy with the ascorbic acids triose-reductone was assigned an α-carbonyl-α-enediol structure (I). This structure, though still widely accepted, cannot account for all of the observed properties of reductone and a resonance hybrid (II) has been suggested recently (12) as a more adequate alternative.

It was the object of this work to gain information about the mechanisms of decomposition of a hexose molecule to three-carbon fragments, especially triose-reductone, under the influence of alkali.

Two main mechanisms have been suggested for this disintegration. The older of these, postulated by Nef (10), involves an alkali-induced 1,2-enediol formation followed by a migration of the double bond via the 2- and 3-ketose to yield a 3,4-enediol. Fragmentation at the double bond was then assumed to result in the formation of two molecules of glyceraldehyde, which in turn could undergo a Lobry de Bruyn – Alberda van Ekenstein rearrangement to dihydroxyacetone or be enolized and oxidized to give triose-reductone. However, the step involving cleavage at the double bond has made this mechanism no longer acceptable since it was shown that the bond energy of a carbon–carbon double bond is much higher than of a single bond and that cleavage of a carbon chain occurs preferentially in α,β-position to a double bond (11, 14).

The other theory, first suggested by Evans and co-workers (1, 2), avoids the shortcomings of Nef's mechanism. Again a 1,2-enediolate ion (III) initiates the degradation reaction. The formation of triose-reductone and elucidation of its structure as an enediol have actually served as evidence for the existence of a 1,2-enediol (2) and other evidence can also be cited (7, 13), although the enediolic forms of the common reducing sugars themselves have never been

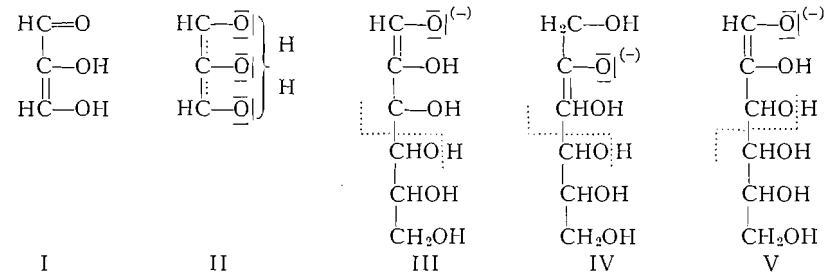
isolated. The 2-ketose formed via the 1,2-enediolate can still undergo 2,3-enolization (IV) (16). The fragmentation to three-carbon fragments is then thought to occur by a reverse aldolization of the 1,2- or 2,3-enediolate between C-3 and C-4. The possibility of formation of a 3,4- and 4,5-enediolate to explain epimerizations observed on C-4 and C-5 is today regarded as very unlikely and the epimerizations are explained by a recombination of three-carbon fragments (18). A fragmentation as indicated in III and IV would lead to two molecules of triose, one being in an enolized form. Oxidation of the triose could then give rise to triose-reductone, a possibility that is suggested by the formation of triose-reductone by the action of alkali on dihydroxyacetone (17). According to Euler (3) a fragmentation as indicated by V would lead, however, directly from D-glucose to one molecule of triose-reductone and one molecule of glycerol.



I II III IV V

The use of carbon-14 tracer techniques in recent studies of the action of alkali on carbohydrates (9, 15) has provided a deeper understanding of some aspects of the degradation reactions. It appeared, therefore, that preparation of triose-reductone from carbon-14 labelled sugars might likewise yield information suitable for evaluating the mechanisms discussed above. D-Glucose-1-C^{14} was dissolved in water and heated in a stream of nitrogen in the presence of lead acetate and small amounts of potassium cyanide (4, 6) and cupric acetate (5). Sodium hydroxide was then added and after the desired reaction time the mixture was neutralized with acetic acid. The triose-reductone lead salt was analyzed for its lead content and decomposed with the calculated amount of phosphoric acid. The purification was simplified and the yield of pure material increased by the finding that the triose-reductone obtained from the decomposition sublimes easily *in vacuo*. To determine the C^{14} content of the triose-reductone the compound was combusted to carbon dioxide, which was either analyzed as such in a gas phase counter, or counted as barium carbonate at infinite thickness in a gas flow counter (Table I).

TABLE I

CONTRIBUTION OF THE CARBON ATOMS OF D-GLUCOSE TO THE YIELD OF TRIOSE-REDUCTONE

Activity in mμc./mM. CO_2		Contribution by	
D-Glucose-1-C^{14}	Triose-reductone-C^{14}	C-1+C-2+C-3	C-4+C-5+C-6
38.9	42.8	55.1%	44.9%
70.5	74.2	52.6%	47.4%

From the results of these analyses and by examining the mother liquors it could be shown that:

(*a*) Carbons 4, 5, and 6 of the D-glucose molecule as well as carbons 1, 2, and 3 contribute to the triose-reductone formation.

(*b*) The contribution of the bottom half of D-glucose to the yield of triose-reductone nearly equals that of the top half.

(*c*) No glycerol is formed from D-glucose in the degradation by alkali.

These findings strongly suggest that a fragmentation according to Euler (4) is not possible and that triose-reductone is a secondary reaction product derived from a three-carbon compound possibly by a fragmentation according to III and IV with triose-enediol as an intermediate. The small deficiency of triose-reductone formed from the bottom half of D-glucose might best be explained by the fact that the glyceraldehyde formed on the reverse aldolization has first to be converted to its enediolate before being oxidized to triose-reductone. Since enolization is not an instantaneous reaction (13), the top half of the molecule, already present as enediolate before fragmentation, is therefore converted to triose-reductone at a slightly faster rate. It was noted above that formation of triose-reductone has been taken as evidence for the existence of a 1,2-enediolate (III) in an alkaline solution of a hexose (2). However, since the compound is also derived from the bottom half of the molecule, its formation may not necessarily serve as a direct proof of this postulate.

EXPERIMENTAL

Triose-reductone-C^{14} from D-*Glucose-1-C^{14}*

D-Glucose-1-C^{14}, 25 gm., was dissolved in 375 ml. of water. Lead acetate, 13.5 gm., potassium cyanide, 3 mgm., and copper acetate (5), 50 mgm., were added and the solution was heated in a stream of nitrogen to 92°C. Sodium hydroxide, 8.5 gm. in 25 ml. of water, was added and the mixture was shaken for two to three minutes. It was then acidified with glacial acetic acid, 4 ml., and quickly cooled. The lead salt of triose-reductone-C^{14}, 12.5 gm., was isolated by centrifuging, washed in succession with water, acetone, and ether, and dried *in vacuo*. The lead content of the salt was 58.8%. The lead salt was suspended in dry acetone, 50 ml., and phosphoric acid, 4.5 ml. of 85% acid, was added and the mixture was shaken for 30 min. at room temperature. The lead phosphate was filtered off and the acetone solution was concentrated *in vacuo* and cooled to −15°C. The crude crystals obtained on filtration were sublimed at 5μ pressure and a bath temperature of 60–80°C. to yield 0.85 gm. of pure triose-reductone-C^{14}, m.p. 153°C.

For determination of their radioactivity the samples of D-glucose-1-C^{14} and triose-reductone-C^{14} were combusted in an apparatus used for carbon–hydrogen microdeterminations. The carbon dioxide was converted to barium carbonate, which was plated by filtration on paper disks and counted at infinite thickness. A parallel determination was always carried out by combusting a sample with Van Slyke solution and measuring the activity of the carbon dioxide in a gas phase counter. The results obtained are listed in Table I.

In calculating the contribution of the different carbon atoms of D-glucose to the formation of triose-reductone, the following considerations were made: the maximum activity possible for triose-reductone is twice the activity of the hexose, and this value is attained through direct conversion of only carbons 1, 2, and 3 to reductone. In experiment 1, for example, the maximum theoretical value is 38.9×2, or 77.8 mμc./mM. CO_2. The activity of the derived reductone was 42.8 mμc./mM. CO_2. Hence carbons 1, 2, and 3 of D-glucose contributed $(42.5/77.8) \times 100$, or 55.1% of the yield of the reductone. Dilution of the activity of the reductone from the maximum to the observed value was due, therefore, to the contribution of carbons 4, 5, and 6 (44.9%).

Large Scale Preparation of Triose-reductone

In general the preparation was carried out as described for the triose-reductone-C^{14}. For the fragmentation of kilogram quantities of D-glucose it was advantageous to heat the solution by blowing in steam and to add the sodium hydroxide when the D-glucose solution had reached 87–88°C. Addition at higher temperatures was dangerous since the reaction mixture tended to boil vigorously. After neutralization the solution was cooled with crushed ice, 2–3 kgm., and the triose-reductone lead salt isolated by allowing it to settle and decanting the supernatant. The salt was washed in succession with water, acetone, and ether, always allowing the salt to settle and decanting the supernatant. This procedure required several hours but resulted in a purer lead salt since a cake obtained on filtration could not be washed efficiently. The crude triose-reductone isolated from the lead salt was sublimed in 20–30 gm. batches. One thousand grams of D-glucose yielded 32–35 gm. of pure triose-reductone.

Determination of Glycerol in the Reaction Mixture of D-Glucose with Alkali

D-Glucose, 25 gm., treated as described for D-glucose-1-C^{14}, yielded a dark brown solution after the lead salt of triose-reductone was filtered off. This solution was concentrated *in vacuo* to a thin sirup and extracted continuously with ethyl acetate. The ethyl acetate extract and the original sirup were examined for the presence of glycerol (8). None could be detected. Addition of known amounts of glycerol to the sirup showed that the limit of identification (5γ) and the limit of concentration (1:10,000) of glycerol was the same in the presence of sugars as in pure glycerol solutions.

LIGHT ABSORPTION STUDIES

PART II. ULTRAVIOLET ABSORPTION SPECTRA OF SUBSTITUTED BENZOIC ACIDS AND PHENYL BENZOATES[1]

By W. F. Forbes and M. B. Sheratte

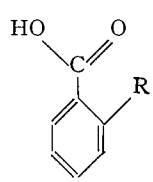
ABSTRACT

The spectra of a number of substituted benzoic acids, acetanilides, and phenyl benzoates are discussed in terms of the electronic and steric effects of substituents.

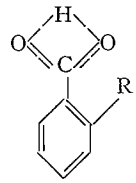
INTRODUCTION

The absorption band observed in the 230 mμ region of the absorption spectrum, and designated by Moser and Kohlenberg (12) as the B-band, is of interest in the *ortho*-substituted benzoic acids, since the usual explanation of the steric effect due to an *ortho*-substituent must be modified in order to account for the observed spectra.

The formula of benzoic acid may be written in two forms, one possessing an intact carboxyl group (type IA), the other a hydrogen-bridged structure (type IB). On steric considerations alone, neither form accounts satisfactorily



IA



IB

for all of the *ortho*-substituted benzoic acid spectra (see Table I). For example, supposing *o*-toluic acid exists as structure IA (R = Me), no unusual loss of intensity should be apparent since a similar conformation may be shown to be relatively insensitive to steric effects involving excited states only in *o*-methylacetophenone (8), where the OH group of IA is replaced by a methyl group. In *o*-toluic acid, however, there is observed a pronounced hypsochromic shift accompanied by almost complete loss of intensity of absorption as compared to *p*-toluic acid. Similarly, if IB (R = Me) alone were the correct configuration, and one *ortho*-methyl substituent was to produce a twist in the carbon–carbon linkage sufficient to accommodate the substituent, a second methyl substituent in the other *ortho*-position would not be expected to bring about much further change in the observed spectrum. However, in 2,6-dimethylbenzoic acid the band in this region has disappeared completely (12).

Hence it may be concluded that the observed changes in the B-band of the spectra of substituted benzoic acids are primarily due to the *electrical* effects of substituents, which is not unexpected since an isolated C=O group is known

[1]*Manuscript received August 9, 1955.*
Contribution from the Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland.

to be relatively small. Thus only very bulky substituents in the *ortho*-position would be expected to make steric overlap the primary factor in the observed changes of the spectra.

Electrical effects may be divided into *inductive* effects, and *mesomeric* (or resonance) effects. Bearing in mind the geometrically small hydroxyl group in benzoic acids, the *inductive* effect would be of greater importance in the *ortho*-position. Mesomeric effects are generally considered to be of equal importance in *ortho*- and *para*-positions. Of the substituents discussed here, methyl groups have a positive inductive effect (i.e. they repel electrons) while nitro, hydroxyl, and methoxyl groups, and halogens exert a negative inductive effect, the halogens being in the order F > Cl > Br > I. Only the nitro group exerts a negative mesomeric effect, while all the other groups referred to exert a positive mesomeric effect; the positive mesomeric effect of the halogens is in the order I > Br > Cl > F.

ULTRAVIOLET ABSORPTION SPECTRA

Para-substituted Benzoic Acids

Table I shows that all *para*-substituted benzoic acids, with the exception of *p*-nitrobenzoic acid, exhibit pronounced bathochromic shifts accompanied by enhanced intensity of absorption which are both approximately parallel to the *mesomeric* effect of the substituent, for example I > Br > Cl > F. The *inductive* effect in *para*-halogen compounds appears to be of secondary importance, since both the bathochromic shifts and the observed intensities of absorption may be correlated with the *mesomeric* effect, but not with the *inductive* effect of the substituent. In the above-mentioned example, the latter would suggest, in both bathochromic shifts and intensities, an order F > Cl > Br > I. In this connection the reported value of the absorption maximum for *p*-bromobenzoic acid (12), i.e. λ_{max} 240 mμ, ϵ = 12,500, appeared to us to be slightly inaccurate with respect to the intensity at maximal absorption and a careful redetermination gave a value of ϵ = 16,000 at 238.5 mμ, the wave-length of

maximal absorption. This value of $\epsilon = 16{,}000$, as expected, lies between the values for the intensities at wave-length of maximal absorption of *p*-chlorobenzoic acid ($\epsilon = 15{,}000$) and *p*-iodobenzoic acid ($\epsilon = 17{,}000$) (see Table I).

p-Nitrobenzoic acid, because of the negative *mesomeric* effect of the nitro group, does not exhibit any enhanced intensity of absorption, and the spectrum resembles that of nitrobenzene itself (see below).

Meta-substituted Benzoic Acids

For *meta*-substituted benzoic acids, according to the above hypothesis, the *inductive* effect increases in importance, owing to the greater proximity of the heteroatoms and the more effective transmission of the electron release (or *mesomeric* effect) to the *ortho*- and *para*-positions. This will normally prevent the *mesomeric* effect of the substituent from making its contribution, and the molecular spectrum resembles that of the unsubstituted benzoic acid, but with a slightly decreased absorption intensity owing to the adverse *inductive* effect. Appreciable changes in the location of maximal absorption are observed only for *m*-iodo- and *m*-nitro-benzoic acid, and this may be ascribed to the characteristic behavior of iodo atoms and nitro groups. In the iodobenzoic acids the interaction of the carboxyl group and the iodo atom is readily apparent. The *meta*-compound, compared to the *para*-compound, exhibits appreciable loss of intensity of absorption together with a pronounced change in the location of maximal absorption. This is of interest since in that region 2-iododiphenyl also exhibits a similar unusual absorption band—for a compound containing an iodophenyl group—which becomes apparent under conditions of slight steric strain (7). In the nitrobenzoic acids, the carboxyl groups, from an electrical point of view, appear to be of relatively little consequence. The spectrum of *p*-nitrobenzoic acid is altered as might have been expected from steric considerations, namely the *meta*-compound exhibits an hypsochromic shift accompanied by loss of intensity of absorption, and neither spectrum is radically different from that of nitrobenzene which was found to absorb maximally at 258 mμ, $\epsilon = 8500$. A fuller discussion of these effects, together with a semiquantitative examination of various theoretical formulas to account for these effects, will be the subject of a separate communication.

A similar explanation, that is in terms of steric factors, holds for the spectra of toluic acids, in which the *inductive* effect of the substituent is small. This steric effect becomes readily apparent in *increasing* magnitude *ortho* > *meta* > *para*. The increased sensitivity of benzoic acids to steric effects, compared with acetophenones, is ascribed to the more appreciable concentration of electrons *in the excited state* of the benzoic acid in the carboxyl group as compared with the acetyl group, and/or less double bond character in the carbon–carbon linkage. Thus the hindrance occurs chiefly in the excited state, which, as has previously been pointed out (8), explains the observation that the steric effect consists chiefly of decreased absorption intensity rather than of a pronounced hypsochromic shift of the band. The intermediate steric effect of the methyl group in the *meta*-position may be accounted for by the known but-

tressing effect of a methyl group in that position (3), that is the methyl group exerting a buttressing effect on the *ortho*-hydrogen atom which in turn sterically interacts with the carboxyl group.

The spectrum of benzoic acid may now also be correlated with other spectra in accordance with the above hypothesis. Benzoic acid absorbs maximally with smaller intensity of absorption than acetophenone and this may again be ascribed to steric inhibition of resonance *in the excited state* due to the *ortho*-hydrogen atoms. Both acetophenone and benzoic acid from dipole moment and X-ray crystallographic data (both of which measure ground state contributions only) appear to be planar, or nearly planar, in the ground state (4, 5, 14), which corroborates the postulated hindrance in the excited state. The steric hindrance in benzoic acid would therefore be expected to give rise to reduced absorption intensity and a slight hypsochromic shift. However, the ground state of benzoic acid is more stabilized by resonance forms than that of acetophenone, because the replacement of the methyl group in acetophenone, or the hydrogen atom in benzaldehyde, by the hydroxyl group of benzoic acid aids the setting up of polar excited states because of the negative *inductive* effect of the hydroxyl group; thus the energy level of the ground state of benzoic acid is reduced relative to that of acetophenone, and this together with the relative *increase* in the energy level of the excited state of benzoic acid with respect to acetophenone gives rise to a considerably greater energy difference in benzoic acid between the ground state and the excited state. Thus benzoic acid absorbs maximally at much shorter wave-length and lower intensity (227 mμ, ϵ = 11,000) than either acetophenone (240 mμ, ϵ = 12,500) or benzaldehyde (244 mμ, ϵ = 13,000).

Ortho-substituted Benzoic Acids

Although as Moser and Kohlenberg (12) point out—from evidence involving comparisons with van der Waals radii—shifts in the wave-lengths of the B-band should not be assigned only to steric interference with coplanarity, the conclusion that the recorded values of maximal absorption of the *ortho*-substituted benzoic acids can best be rationalized by consideration of the steric factors involved appears to us irrefutable. Also van der Waals radii are rather unsatisfactory as a measure of *intra*molecular interference properties of atoms, particularly for groups containing heteroatoms whose electronegativity largely differs from that of the carbon atom. Heteroatoms may give rise to appreciable *mesomeric* and *inductive* effects, the latter especially affecting any semiquantitative interpretation of the values.

Toluic acids have already been discussed. It is supposed that both benzoic and *o*-toluic acid and possibly also 2,6-dimethylbenzoic acid are near-planar in the ground state, but the permitted planar or near-planar excited states are sharply reduced in the order benzoic acid > *ortho*-toluic acid > 2,6-dimethylbenzoic acid.

All the other above-mentioned *ortho*-substituted benzoic acids also show the expected hypsochromic shift of the absorption maxima accompanied by loss of intensity of absorption compared with the corresponding *para*-substituted compound.

Acetanilides

Applying this hypothesis to the recently investigated ultraviolet absorption spectra of acetanilides (15; see Table II) it is seen that the data correspond with the generalizations made. Thus acetanilide itself, to which the steric

TABLE II

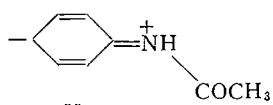
considerations referred to under benzoic acid do not apply, absorbs maximally in a similar manner to acetophenone, because of transitions involving polar excited states of type II (13). In *para*-substituted acetanilides, the shifts in the locations of maximal absorption and intensity changes again generally



II

correspond to the *mesomeric* effect of the substituents, for example I > Br > Cl > F. The *para*-nitro group gives rise to a pronounced hypsochromic shift because of the negative *mesomeric* effect of the nitro group and interaction with the $NHCOCH_3$ group (compare Table I for the spectrum of *p*-nitrobenzoic acid, where there appears to be no interaction).

For *meta*-substituted acetanilides, because of the *ortho–para* directive properties of the $NHCOCH_3$ group, that is its powerful electron-releasing properties, the spectra will even more resemble that of the unsubstituted acetanilide than was the case for *meta*-substituted benzoic acids. An exception is provided by the *m*-nitroacetanilide where the combination of a negative *inductive* effect together with the negative *mesomeric* effect of the nitro group appears to stabilize excited states of type II, thus giving rise to considerably increased intensity of absorption. Steric effects also become noticeable in some of the compounds, particularly where the substituent is large, such as in *m*-bromo- or *m*-iodo-acetanilide (see Table II). The nitroacetanilides as described above are of special interest. The negative *mesomeric* effect of the nitro group lessens the electron density of all ring carbon atoms, but the

ortho- and *para*-positions are deactivated almost exclusively, leaving the *meta*-position with the greatest concentration of electrons. Thus the *meta*-nitro compound exhibits the largest absorption intensity. It is tentatively proposed that in *o*-nitroacetanilide the steric hindrance of the *ortho*-substituents inhibits the deactivation mechanism and thus the spectrum of the *ortho*-compound reverts to a spectrum where the opposing *mesomeric* effect of the nitro group is less noticeable (see Table II).

In the other *ortho*-substituted acetanilides, steric effects play their expected part. This steric *ortho*-effect is generally strikingly similar to that observed in substituted benzoic acids and thus lends additional support to the proposed polar excited states of type II; comparison of Tables I and II indicates this, as for instance the halogen-substituted compounds, where the combination of *mesomeric*, *inductive* and steric effects gives rise to similar spectra. Discussing *ortho*-substituted acetanilides, Ungnade (15) states that there are no steric effects in *o*-methoxyacetanilide, but we believe that a steric effect hypothesis accounts more satisfactorily for the observed spectrum. Ungnade argues that although the primary band of *o*-methoxyacetanilide is somewhat less intense than that of the *meta*-isomer, the order of intensities is reversed for the secondary bands and the wave-lengths of corresponding bands in the *ortho-* and *meta*-isomers are virtually identical. In our view, the *ortho*-compound exhibits a typical steric effect of a type which has been discussed fully elsewhere (3, 4, 8), in which the location of maximal absorption remains approximately the same, while the intensity of absorption is reduced. This effect becomes readily apparent if the *ortho*-compound is compared with the corresponding *para*-compound rather than with the *meta*-compound. This seems justified, since it has been shown in the study of acetophenones (4, 8) that the former comparison has greater validity. We would propose a similar steric effect for the anisidine spectra referred to by Ungnade (15). Further, since it has been shown in a number of other examples (12, 8) that the secondary band is not apparently affected by steric interference of resonance, we would not expect the secondary band to exhibit a corresponding steric effect.

Aromatic Esters

In the light of these hypotheses an examination of the spectra reported by Cilento (6) and the extension of this work to a number of other esters appeared to be of interest. The spectrum of phenyl benzoate we explain as follows: The spectrum of benzoic acid compared to acetophenone has been correlated by the *inductive* effect of the hydroxyl group and by consideration of steric factors operative largely in the excited state of benzoic acid. This steric effect in benzoic acid, postulated to be due to a concentration of electrons in the carboxyl group, is reduced somewhat in phenyl benzoate since the phenyl group attached to the oxygen atom (henceforth referred to as ring B in accordance with Cilento's nomenclature) is an electron-attracting group. It therefore removes some of the electrons responsible for the steric effect, and hence transitions to excited states of type III are aided, accounting for the increased intensity of absorption and the slight bathochromic shift. The value for the observed absorption intensity, however, also includes some absorption

TABLE III

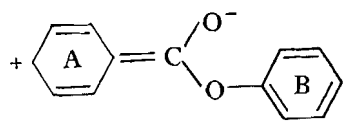
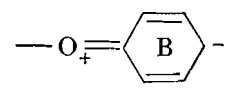
due to ring B, that is, due to transitions involving excited states of type IV. In agreement with Cilento we ascribe bands to transitions involving either ring A or ring B, although both bands will be influenced by the neighboring ring.



III



IV

From Tables I and III it is seen that substituents in ring A produce changes as might be expected from a consideration of the corresponding benzoic acid spectra. Since the *para*-substituent on account of its *mesomeric* effect will also influence the electron density in the carboxyl group, the change due

to the introduction of the B-ring phenyl group will also be affected. However, in most cases, these additional changes from the benzoic acids to the corresponding phenyl esters are similar and roughly the same as between benzoic acid and phenyl benzoate, that is, a wave-length shift $\Delta\lambda$ of about 3 mμ and intensity increase $\Delta\epsilon$ of approximately 4000. The greatest change is observed in the *para*-methoxy compound ($\Delta\lambda_{max}$ 12 mμ, $\Delta\epsilon$ = 8000) which may be ascribed to a combination of favorable *mesomeric* and *inductive* effects stabilizing resonance forms of type III. The smallest change occurs in the *para*-nitro compound ($\Delta\lambda_{max}$ 1 mμ), presumably because of the negative *mesomeric* effect of the nitro group.

With a view to investigating the conjugation of the non-bonding *p*-electrons of the oxygen atom and the π-electrons of the B-ring, which Cilento considers to be rather weak, we may consider a number of compounds in which this conjugation might manifest itself. Taking phenyl *p*-anisate as an example where conditions favoring this conjugation already exist, we should expect the introduction of a *para*-nitro group in the B-ring to enhance this effect; the nitro group by withdrawing electrons from the B-ring should stabilize polar excited states of type III. This in fact occurs, and a further bathochromic shift relative to phenyl *p*-anisate accompanied by increased intensity of absorption is observed. Cilento (6) classifies this band separately, but this seems to us to be unnecessary, since we believe it to be due to what is essentially the same type of transition. Introduction of a *para*-nitro group in the B-ring generally would be expected to give rise to a similar effect, and a second example is in fact provided by *p*-nitrophenyl *p*-nitrobenzoate where this change is again observed on comparison with the parent compound, that is phenyl *p*-nitrobenzoate. In these compounds the B-band is not apparent since its maximal absorption closely approximates that of the A-band (see Table III). This was confirmed by determining the maximal absorption of *p*-nitrophenyl cyclohexanecarboxylate, which as expected absorbs maximally in the same region (λ_{max} 268 mμ, ϵ = 10,000). Occasionally the ester spectra exhibit the absorption due to the B-ring as maximal absorption, but often this occurs as an inflection. It seems to us unfortunate that Cilento does not record these inflections, that is the submerged maxima, in his table (6), even though the absorption in that region includes some absorption due to the secondary band of ring A.

Reversing the substituents in the above examples has the expected effect. A *para*-methoxy group in the B-ring, because of its *mesomeric* effect, causes a slight hypsochromic shift relative to phenyl benzoate. This is ascribed to the increased electron-availability in the carboxyl group, which enhances the steric effect in that area. The intensity of absorption does not exhibit the expected decrease, since the increased intensity of absorption due to ring B outweighs the supposed decrease accompanying the hypsochromic shift. An analogous effect is observed in *p*-anisyl *p*-anisate relative to phenyl *p*-anisate and in *p*-anisyl *p*-nitrobenzoate relative to phenyl *p*-nitrobenzoate (see Table III). In B-ring *para*-halogen substituted compounds an intermediate effect is observed; the *para*-substituent does bring about a bathochromic shift, which, however, is smaller than that observed for a *para*-nitro substituent in ring B

(see Table III for the spectra of *p*-chlorophenyl *p*-chlorobenzoate and *p*-iodophenyl *p*-iodobenzoate compared to those of phenyl *p*-chlorobenzoate and phenyl *p*-iodobenzoate respectively). This is readily explained by the intermediate *mesomeric* effects in these compounds.

Meta-methoxy substituents in the B-ring produce a low-intensity band in the 270–280 mμ region. This band is not appreciably influenced by an unsubstituted A-ring as may be seen from the similar B-ring absorption bands in the spectra of *m*-anisyl benzoate and *m*-anisyl cyclohexanecarboxylate. Substituents in the A-ring, however, again give rise to the preferential absorption of the A-ring band (see Table III for the spectra of *m*-anisyl *p*-anisate and *m*-anisyl *p*-nitrobenzoate) which masks the low-intensity absorption due to the B-band.

Finally a number of other B-ring substituted esters are listed in Table III. Sometimes the absorption due to the B-ring is negligible, and the absorption due to the A-ring almost completely predominates as in *p*-chlorophenyl or *p*-iodophenyl benzoates; compounds like *p*-nitrophenyl benzoate, on the other hand, serve as examples where the two bands are of almost the same intensity.

EXPERIMENTAL

The ultraviolet absorption spectra were determined in duplicate by standard methods using a Unicam SP 500 spectrophotometer as described in Part I (8).

Melting points are uncorrected; analyses were carried out in the microanalytical laboratory (Mr. F. H. Oliver) of the Department of Organic Chemistry, Imperial College, London, England, and in the microanalytical laboratory (Mr. A. Bernhardt) of the Max-Planck Institut für Kohlenforschung, Mülheim, Ruhr, Germany.

Benzoic Acids

The commercially available compounds were crystallized to constant melting point and intensity of absorption. *o*-Fluoro-, *m*-fluoro-, *p*-bromo-, and *m*-nitro-benzoic acids were obtained by the oxidation with permanganate of the appropriate toluene according to the method described by Vogel (16). *p*-Bromobenzoic acid had melting point 251–253° (Heilbron and Bunbury (10) give melting point 251–253°). Anal.: Calc. for $C_7H_5O_2Br$: Br, 39.75%. Found: Br, 40.1%. Light absorptions in ethanol: see Table I.

Phenyl Benzoates

The esters were prepared by standard methods. Solid esters were crystallized from methanol or aqueous methanol to constant melting point and intensity of absorption; liquid esters were distilled to constant refractive index and intensity of absorption.

Phenyl benzoate crystallized as prisms, melting point 70° (Heilbron and Bunbury (10) give melting point 71°); phenyl *p*-chlorobenzoate crystallized as plates, melting point 100° (Birkenbach and Meisenheimer (2) give melting point 100°); *phenyl p-iodobenzoate* crystallized as plates, melting point 133°.

Anal.: Calc. for $C_{13}H_9O_2I$: C, 48.2; H, 2.8; I, 39.15%. Found: C, 47.9; H, 2.6; I, 39.0%. *p*-Chlorophenyl *p*-chlorobenzoate crystallized as plates, melting point 71° (Birkenbach and Meisenheimer (2) give melting point 71°); *p-iodophenyl p-iodobenzoate* crystallized as plates, melting point 148°. Anal.: Calc. for $C_{13}H_8O_2I_2$: C, 34.7; H, 1.8; I, 56.4%. Found: C, 34.7; H, 2.1; I, 56.1%. *m-Anisyl benzoate* distilled at 163°, 3 mm., n_D^{27} 1.5751. Anal.: Calc. for $C_{14}H_{12}O_3$: C, 73.7; H, 5.3%. Found: C, 73.9; H, 5.5%. *m-Anisyl p-anisate* crystallized as prisms, melting point 102°. Anal.: Calc. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.5%. Found: C, 69.95; H, 5.7%. *m-Anisyl p-nitrobenzoate* crystallized as needles, melting point 126°. Anal.: Calc. for $C_{14}H_{11}O_5N$: C, 61.5; H, 4.1; N, 5.1%. Found: C, 61.4; H, 4.3; N, 4.9%. *p*-Chlorophenyl benzoate crystallized as needles, melting point 87° (Autenrieth and Müllinghaus (1) give melting point 86°); *p*-iodophenyl benzoate crystallized as needles, melting point 119° (Willgerodt and Wiegand (17) give melting point 118.5–119.5°).

The light absorption properties of the above-described compounds are recorded in Table III.

Phenyl Cyclohexanecarboxylates

Cyclohexanecarboxylic acid was prepared from cyclohexyl chloride according to the method of Gilman and Zoellner (9) and distilled at 179°, 17 mm.; n_D^{30} 1.4620 as a colorless liquid, which solidified on standing to a solid, melting point 28° (Hiers and Adams (11) give boiling point 105°, 4 mm.; n_D^{38} 1.4520; melting point 29–30°). The esters were prepared in the above-described manner.

Phenyl cyclohexanecarboxylate distilled at 129°, 3 mm.; n_D^{27} 1.5107. Anal.: Calc. for $C_{13}H_{16}O_2$: C, 76.4; H, 7.9%. Found: C, 76.5; H, 8.0%. *p-Nitrophenyl cyclohexanecarboxylate* crystallized as needles, melting point 53.5°. Anal.: Calc. for $C_{13}H_{15}O_4N$: C, 62.6; H, 6.1; N, 5.6%. Found: C, 62.3; H, 5.9; N, 5.7%. *p-Anisyl cyclohexanecarboxylate* crystallized as needles, melting point 64°. Anal.: Calc. for $C_{14}H_{18}O_3$: C, 71.8; H, 7.7%. Found: C, 71.5; H, 7.8%. *m-Anisyl cyclohexanecarboxylate* distilled at 80°, 3 mm.; n_D^{28} 1.5460. Anal.: Calc. for $C_{14}H_{18}O_3$: C, 71.8; H, 7.7%. Found: C, 72.0; H, 7.9%.

The light absorption properties in ethanol of the above-described compounds are recorded in Table III.

PHOTOLYSIS OF DIETHYL KETONE AT LOW PRESSURES: THE PRESSURE DEPENDENCY OF THE COMBINATION OF ETHYL RADICALS[1]

By R. K. Brinton[2] and E. W. R. Steacie

ABSTRACT

The photolysis of diethyl ketone has been investigated in the pressure range 0.01–30 mm. at 100°, 150°, 200°, and 250° with a variation in absorbed intensity of 1000-fold. Over this wide variation in experimental conditions the kinetics of the reaction show excellent agreement with the mechanism of Kutschke, Wijnen, and Steacie. Under conditions where the production of ethylene by decomposition of the pentanonyl radical was negligible (high light intensity and low ketone pressure), the ratio of the rate of ethylene formed to the rate of butane produced was determined to be 0.12 independent of the temperature. These data indicate that both the disproportionation and combination of ethyl radicals are homogeneous and pressure independent to as low as 0.01 mm. pressure. In addition it is probable that the two reactions are the result of different reaction intermediates as was postulated by Wijnen and Steacie. The abstraction reaction

$$C_2H_5+C_2H_5COC_2H_5 \rightarrow C_2H_6+C_2H_4COC_2H_5$$

showed definite heterogeneous character at low pressures similar to the analogous reaction of methyl radicals with acetone studied by Ausloos and Steacie.

INTRODUCTION

The absolute values of the rate constant for the combination of methyl radicals as determined in several independent investigations (2, 5, 10, 11) have differed significantly. Recent papers by Dodd and Steacie (3) and Kistiakowsky and Roberts (7) treat this reaction by a pressure dependent mechanism,

$$2CH_3 \leftrightharpoons C_2H_6^*$$

$$C_2H_6^*+M \rightarrow C_2H_6+M,$$

in an attempt to reconcile these apparent discrepancies. Both studies were made on the photolysis of acetone at low pressures whereby it is possible to compare the rate of ethane formation by combination to the rate of methane formed by the abstraction mechanism,

$$CH_3+CH_3COCH_3 \rightarrow CH_4+CH_2COCH_3.$$

The magnitude of the pressure effects on the relative rates of methane and ethane production can be explained for the most part by such a mechanism, but the lower pressure experiments of Dodd and Steacie indicate other anomalies which are strongly surface dependent. These latter effects have been verified by similar low pressure experiments of Ausloos and Steacie (1).

This paper reports on a similar investigation of the pressure dependency of the combination of ethyl radicals formed in the photolysis of diethyl ketone. It was expected that the experimental difficulties would be somewhat greater than in the acetone photolysis since, presumably, the more complex ethyl

[1]*Manuscript received August 26, 1955.*

[2]*On leave from Department of Chemistry, University of California, Davis, California, U.S.A.*

radicals would not show the effect of third body deactivation for the combination reaction at such high pressures as observed for methyl radicals. On the other hand the disproportionation reaction of ethyl radicals into ethylene and ethane seemed to offer a more reliable comparison reaction than the abstraction reaction which most certainly is partly heterogeneous at low pressures in the case of the acetone photolysis.

EXPERIMENTAL

The photolysis apparatus was similar to that of Dodd and Steacie (3). A majority of the experiments were conducted in a cylindrical silica cell of 3.9 cm. diameter and 100 cm. length (volume = 1210 cm.^{3}, surface = 1260 cm.^{2}). Another cell of similar dimensions but having two concentrically mounted inner silica tubes (volume = 1040 cm.^{3}, surface = 3580 cm.^{2}) was used in a series of photolyses at 200° in order to evaluate the effect of increased surface and shorter diffusion distance. The method of temperature control of the cells was identical to that used by the above workers. It was possible to maintain the temperature along the cell's length to ±1°. No correction was made for that part of the reaction taking place at the cooler end windows since these cold zones represent a rather small fraction of the total reaction volume.

The light which completely filled the reaction cell in all experiments was a well-collimated beam from a B.T.H. ME/D 250 watt high pressure mercury arc operated on a regulated d-c. supply. A Corning 9-53 filter and the long wave length absorption limit of diethyl ketone limited the absorption region to λλ2800–3200 Å. A plane aluminized mirror was used at the back cell window to increase the light intensity in some of the photolyses and neutral density filters of chromel deposited on silica plates were used to decrease the intensity in other cases.

The per cent decomposition of diethyl ketone was limited in most of the experiments to 0.5 to 4%. However it was necessary to exceed this amount in those photolyses at pressures less than 0.1 mm. pressure and some decompositions were as much as 20%. In all cases the concentration of diethyl ketone used in the various calculations was the average over the run. A supplementary volume of 15 liters was used in conjunction with the photolysis cell in the photolyses under 1 mm. pressure. This additional gas supply was circulated through the reaction cell at frequent intervals during the photolysis by a mercury diffusion pump. Circulation was not carried out during irradiation since the pumping caused considerable pressure differentials within the cell system. Measurement of diethyl ketone pressure was made by a McLeod gauge.

The analytical vacuum system and the diethyl ketone circulation system employed mercury cutoffs throughout, thus eliminating possible errors due to the absorption of diethyl ketone and reaction products in stopcock grease. Photolysis products were separated by use of a Ward–LeRoy still (9) into three fractions: (*a*) CO fraction (volatile at −210°), (*b*) C_2 fraction (volatile at −175°), (*c*) C_4 fraction (volatile at −115°). These three fractions were analyzed mass spectrometrically. Fraction (*a*) was essentially pure CO. Analysis showed <0.2% CH_4 to be present. Fraction (*b*) contained C_2H_6, C_2H_4, and

traces of C_3H_8, C_3H_6, and CO_2. Fraction (*c*) was predominantly C_4H_{10} with small amounts of butene and propene in experiments carried out at high temperature and low intensity.

Eastman Kodak Company diethyl ketone was dried with anhydrous $CaSO_4$ and fractionated in a 15 plate column. Small portions of the fraction boiling from 100.8° to 101.0° (uncorrected) used as a main supply were thoroughly outgassed before each trial in the vacuum system. The perfluorodimethyl cyclohexane obtained from Halogen Chemicals Inc., Columbia, S.C., was distilled and degassed *in vacuo*.

EXPERIMENTAL RESULTS

In all about 90 runs were made at four different temperatures. The pertinent data for the experiments conducted on diethyl ketone alone are shown in Table I; those shown in Table III refer to the photolyses made in the presence of added perfluorodimethyl cyclohexane, C_8F_{16}.

DISCUSSION

The Photolysis Mechanism

Recently a detailed study of the photolysis of diethyl ketone has been made

by Kutschke, Wijnen, and Steacie (8). They explained their results on the basis of the following mechanism—

[1] $$C_2H_5COC_2H_5+h\nu \xrightarrow{\phi I_a} 2C_2H_5+CO$$

[2] $$2C_2H_5 \xrightarrow{k_2} C_4H_{10}$$

[3] $$2C_2H_5 \xrightarrow{k_3} C_2H_4+C_2H_6$$

[4] $$C_2H_5+C_2H_5COC_2H_5 \xrightarrow{k_4} C_2H_6+C_2H_4COC_2H_5$$

[5] $$C_2H_5+C_2H_4COC_2H_5 \xrightarrow{k_5} C_4H_9COC_2H_5$$

[6] $$2C_2H_4COC_2H_5 \xrightarrow{k_6} [C_2H_4COC_2H_5]_2$$

[7] $$C_2H_4COC_2H_5 \xrightarrow{k_7} C_2H_4+C_2H_5+CO$$

If the rate of formation of a product, P, is expressed by R_P and the concentration of diethyl ketone by [D] the following expression may be derived.[3]

$$\log(R^{ab}_{C_2H_6}/R_{C_4H_{10}}) = \log(k_4/k_2^{\frac{1}{2}})+\log([D]/R^{\frac{1}{2}}_{C_4H_{10}})$$

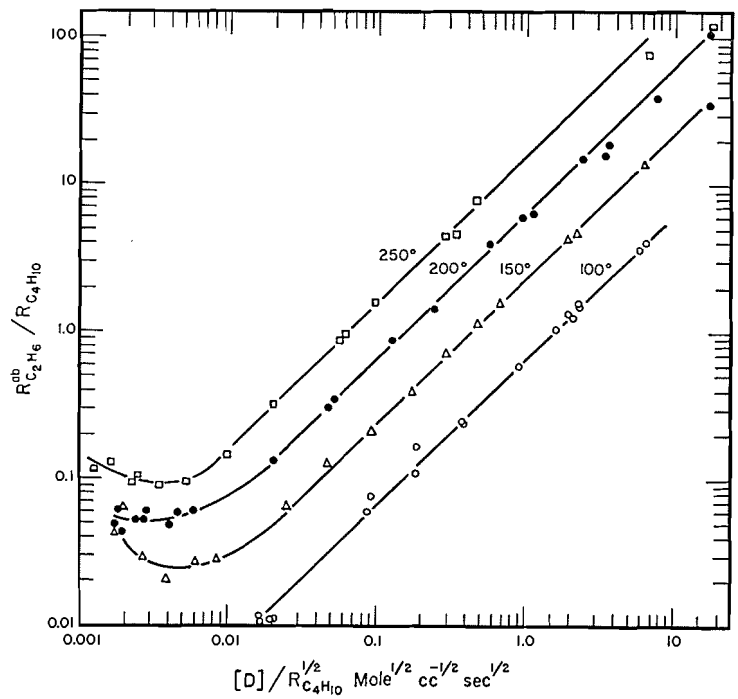

FIG. 1. Plot of $\log R^{ab}_{C_2H_6}/R_{C_4H_{10}}$ vs. $\log [D]/R^{\frac{1}{2}}_{C_4H_{10}}$.

[3] *$R^{ab}_{C_2H_6}$ represents the rate of ethane formation by the abstraction reaction [4] to differentiate it from $R^{dp}_{C_2H_6}$, the rate of ethane formed by the disproportionation reaction [3]. This quantity was calculated from the expression $R^{ab}_{C_2H_6} = R^{total}_{C_2H_6} - 0.12\ R_{C_4H_{10}}$ assuming tacitly that the ratio $k_3/k_2 = 0.12$, independent of experimental conditions. Justification for this procedure is given in the subsequent discussion. $R^{ab}_{C_2H_6}$ is greater than $\Delta R_{C_2} = R^{total}_{C_2H_6} - R^{total}_{C_2H_4}$, the rate calculated by Kutschke, Wijnen, and Steacie, by the amount of the additional ethylene produced by the decomposition of the pentanonyl radical, $C_2H_4COC_2H_5$, in reaction [7]. In most cases, however, the difference between $R^{ab}_{C_2H_6}$ and ΔR_{C_2} is small.*

The results of the present investigation are shown in Fig. 1 as a plot of $\log R^{ab}_{C_2H_6}/R_{C_4H_{10}}$ vs. $\log [D]/R^{\frac{1}{2}}_{C_4H_{10}}$. Data at the four temperatures cover the pressure range 0.01–30 mm. and represent a variation in absorbed intensity of more than 1000-fold. The series of straight lines of unit slope fit the experimental points well except at the low and high extremes of the variables. Deviations in the low region which occur at pressures under *ca.* 0.4 mm. are treated in detail in a later section; those in the high region are most pronounced at high [D] and low absorbed intensity and are apparent at the two higher temperatures only. A reasonable explanation of these latter anomalies has not been formulated but it is possible that some mode of butane formation in addition to reaction [2] is becoming significant under these conditions. This reaction seemingly must be of the type

$$R + C_2H_5COC_2H_5 \rightarrow C_4H_{10} + \text{other products}$$

where R represents some radical present in the system. Production of detectable amounts of 2-butene and a pentene (2-pentene probably) accompanying the extra amounts of butane could well be the result of the same or a closely related mechanism.

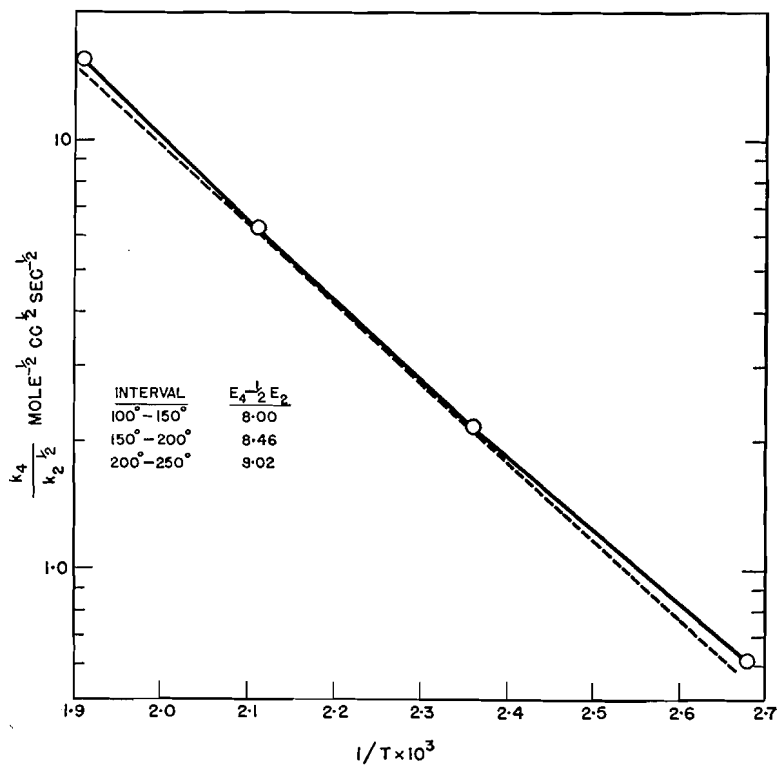

FIG. 2. Arrhenius plot of $k_4/k_2^{\frac{1}{2}}$.

Fig. 2 shows values of $\log k_4/k_2^{\frac{1}{2}}$ calculated from the straight line portions of the curves of Fig. 1 plotted vs. $1/T$. The line connecting the four points shows a

curvature so the values of $E_4-\frac{1}{2}E_2$ were calculated for each of the three intervals. These activation energies are all higher than the $E_4-\frac{1}{2}E_2 = 7.4$ kcal./mole reported by Kutschke, Wijnen, and Steacie. Reasons for these differences are not altogether clear but it may be pointed out that almost all of their experiments were conducted at ketone pressures greater than 10 mm. In this region it has been indicated that the values of $k_4/k_2^{\frac{1}{2}}$ tend to be too small at higher temperatures, and hence a calculated activation energy would be low in value. The curvature, although not large, seems to be real and is perhaps the consequence of the diethyl ketone molecules having both a primary and secondary hydrogen atom available for the abstraction process. Activation energies of these two processes would be expected to differ by several kcal./mole (13) and lead to a curvature of the type observed.

No attempt was made in the course of the study to analyze for the products of reactions [5] and [6], ethyl butyl ketone and bipentanonyl respectively. However, it is possible to calculate the rate of production of these two substances by a consideration of the balance of the radicals involved,

$$R_{CO}-R^{p}_{C_2H_4} = R_{C_4H_{10}}+R^{dp}_{C_2H_4}+R_{C_2H_5COC_4H_9}+R_{(C_2H_4COC_2H_5)_2}$$

(total radical balance)

$$R^{ab}_{C_2H_6} = R_{C_2H_5COC_4H_9}+2R_{(C_2H_4COC_2H_5)_2}+R^{p}_{C_2H_4}$$

(pentanonyl radical balance).

Then

$$\frac{R_{C_2H_5COC_4H_9}[D]}{R^{\frac{1}{2}}_{(C_2H_4COC_2H_5)_2}R^{ab}_{C_2H_6}} = \frac{k_5}{k_6^{\frac{1}{2}}k_4} \text{ and } \frac{R_{C_2H_5COC_4H_9}}{R^{\frac{1}{2}}_{(C_2H_4COC_2H_5)_2}R^{\frac{1}{2}}_{C_4H_{10}}} = \frac{k_5}{k_6^{\frac{1}{2}}k_2^{\frac{1}{2}}}.$$

Ratios of rates shown in the latter two equations have been calculated for those experiments at the three higher temperatures in which the amount of ethylene formed by reaction [7] was large enough to justify such a procedure. These ratios shown in the second and third columns of Table II have a good

TABLE II

MECHANISM VALIDITY OF THE DIETHYL KETONE PHOTOLYSIS

	$k_5/k_6^{\frac{1}{2}}k_4$, mole$^{\frac{1}{2}}$ cm.$^{-3/2}$ sec$^{\frac{1}{2}}$.	$k_5/k_6^{\frac{1}{2}}k_2^{\frac{1}{2}}$
150° (6 runs)	0.666±0.136	1.50±0.30
200° (10 runs)	0.311±0.061	1.61±0.35
250° (4 runs)	0.135±0.029	1.92±0.35
	$E_4-E_5+\frac{1}{2}E_6 = 7.1$ kcal./mole	
	$E_5-\frac{1}{2}E_6-\frac{1}{2}E_2 \sim 1$ kcal./mole	

precision at each temperature considering the indirect nature of the calculations involved. In addition $E_4-E_5+\frac{1}{2}E_6 = 7.1$ kcal./mole estimated from the second column ratios compares well with $E_4-\frac{1}{2}E_2 \backsim 8.0$ kcal./mole determined directly while $E_5-\frac{1}{2}E_6-\frac{1}{2}E_2$ from the third column data is about zero.

Since E_2, E_5, and E_6 are activation energies of radical–radical combination reactions and are probably near zero, the agreement of the calculated values with those predicted by analogy to other similar mechanisms is excellent. The above treatment gives strong evidence that only the seven reactions enumerated by Kutschke, Wijnen, and Steacie are required to describe the photolysis of diethyl ketone adequately in the temperature range 150°–250°. The actual magnitude of the derived quantities must be accepted with some reservation because of the type of operations necessary in making the calculations.

The Formation of Ethylene

The ratio $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$ at temperatures under 150° was shown by Kutschke, Wijnen, and Steacie to be about constant at ∽0.1. However, at higher temperatures, and especially at high diethyl ketone concentrations and low absorbed intensities, this ratio increased. It was this latter evidence that led them to add reaction [7] to the mechanism of Dorfman and Sheldon (4). In the present study the absorbed intensity and ketone concentration have been varied over a much wider range and the essentials of this study are shown in Fig. 3 where $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$ is plotted vs. R_{CO}.[4] It is evident that $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$ tends toward a constant value of about 0.11–0.12 as the absorbed intensity is

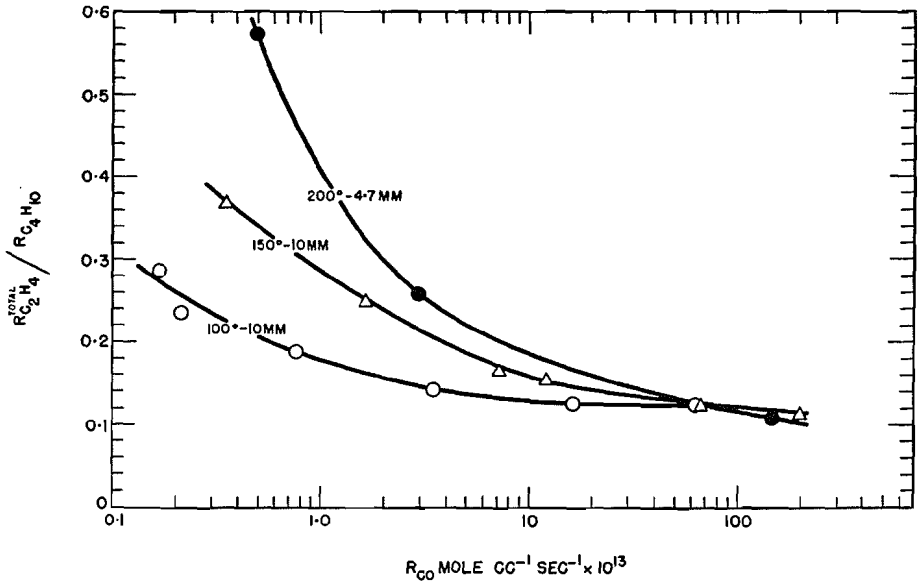

FIG. 3. Plot of $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$ vs. R_{CO}.

[4]*The quantum yield of diethyl ketone was carefully determined by Dorfman and Sheldon (4) at 60° and 120°. They found* $\Phi_{CO} = 1.0$ *within experimental error and consequently wrote reaction [1] as given previously. Thus it would seem that even at 60° any propionyl radical formed by* $C_2H_5COC_2H_5 \xrightarrow{h\nu} C_2H_5 + C_2H_5CO$ *would decompose before appreciable participation in other reactions causing its disappearance. At higher temperatures reactions [4] and [7] constitute a chain mechanism for CO production. However, a calculation from the data of Table I shows that no more than ca. 13% of the total CO is formed by reaction [7] in even the most unfavorable case at 250°. For this reason* R_{CO} *may be taken as a good approximation of the absorbed intensity.*

increased. For a given intensity the deviation from this value is greater at higher temperatures, and, although not indicated in Fig. 3, for fixed temperature and intensity a higher pressure is accompanied by greater deviations. The values of relatively few of the ratios are shown in Fig. 3 but those of all the photolyses follow the generalizations just given in a very regular manner as may be verified by simple calculations from Table I. At 250° the ratio was never lower than about 0.13 even in the very low pressure region. In fact at constant maximum *incident* intensity the minimum of 0.131 was at $[D] = 0.0345 \times 10^{-7}$ mole cm.$^{-3}$; both higher and lower concentrations produced a larger ratio. It is probable that the lower absorbed intensities due to the smaller percentage absorption at the concentrations below $[D] = 0.0345 \times 10^{-7}$ more than offset the effects of the lower concentrations of diethyl ketone tending to decrease the value of $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$. Limits on the intensity imposed by the B.T.H. lamp prevented a real test of this latter explanation.

The evidence given in the preceding sections indicates rather clearly that the disproportionation of ethyl radicals in the photolysis of diethyl ketone in the 3000 Å region is essentially independent of experimental conditions of temperature, intensity, and pressure over a very wide range. The variation in $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$ seems well explained by the production of extra ethylene formed by pentanonyl radical decomposition, reaction [7]. Calculation of $R^{\text{dp}}_{C_2H_4} = 0.12\ R_{C_4H_{10}}$ made earlier in the paper is justified on the basis of such a mechanism. The apparent value of the disproportionation to combination for other systems, especially in the photolysis of diethyl mercury, differs markedly from this value. Discussions of these other determinations are given by Ivin, Wijnen, and Steacie (6) and LeRoy and co-workers (12), and it appears that all recent evidence is in agreement with $k_3/k_2 = 0.12$–0.15.

The Combination of Ethyl Radicals. Third Body Effects

The influence of a third body effect on the combination of ethyl radicals in the photolysis process is conveniently demonstrated by comparing the rate of the combination reaction to the rate of some other reaction occurring simultaneously. This comparison reaction must not be dependent on such a third body deactivation. Both Dodd and Steacie (3) and Kistiakowsky and Roberts (7) used the methyl radical abstraction of a hydrogen atom from acetone for this purpose. An analogous treatment in the case of the diethyl ketone photolysis leads to the equations,

$$2C_2H_5 \xrightarrow{k_a} C_4H_{10}^*$$

$$C_4H_{10}^* \xrightarrow{k_b} 2C_2H_5$$

$$M + C_4H_{10}^* \xrightarrow{k_c} C_4H_{10} + M$$

$$R_{C_4H_{10}} = \frac{k_a[M]}{k_b/k_c + [M]}[C_2H_5]^2$$

$$[M] \gg k_b/k_c, \quad R_{C_4H_{10}} = k_a[C_2H_5]^2;$$

$$[M] \ll k_b/k_c, \quad R_{C_4H_{10}} = \frac{k_a k_c}{k_b}[M][C_2H_5]^2.$$

Thus if [M] is limited to diethyl ketone as a third body, the formation of butane should be independent of [D] above some low pressure. By using the

rate of ethane formation by the abstraction reaction [4], $R^{ab}_{C_2H_6} = k_4[C_2H_5][D]$, as a measure of the ethyl radical concentration, equations [I] and [II],

$$\frac{R^{ab}_{C_2H_6}}{R^{\frac{1}{2}}_{C_4H_{10}}[D]} = \frac{k_4}{k_a^{\frac{1}{2}}}\left[1+\frac{k_b}{k_c[D]}\right]^{\frac{1}{2}}, \qquad [I]$$

$$\frac{R^{ab}_{C_2H_6}}{R^{\frac{1}{2}}_{C_4H_{10}}[D]^{\frac{1}{2}}} = \frac{k_4}{k_a^{\frac{1}{2}}}\left[\frac{k_b}{k_c}+[D]\right]^{\frac{1}{2}}, \qquad [II]$$

may be derived. At a single temperature the first of these expressions should approach a constant value with increasing [D] while the latter should tend toward constancy at low [D] values. These two functions are plotted vs. [D] in Figs. 4 and 5. The curves of Fig. 4 follow in a general way the predicted

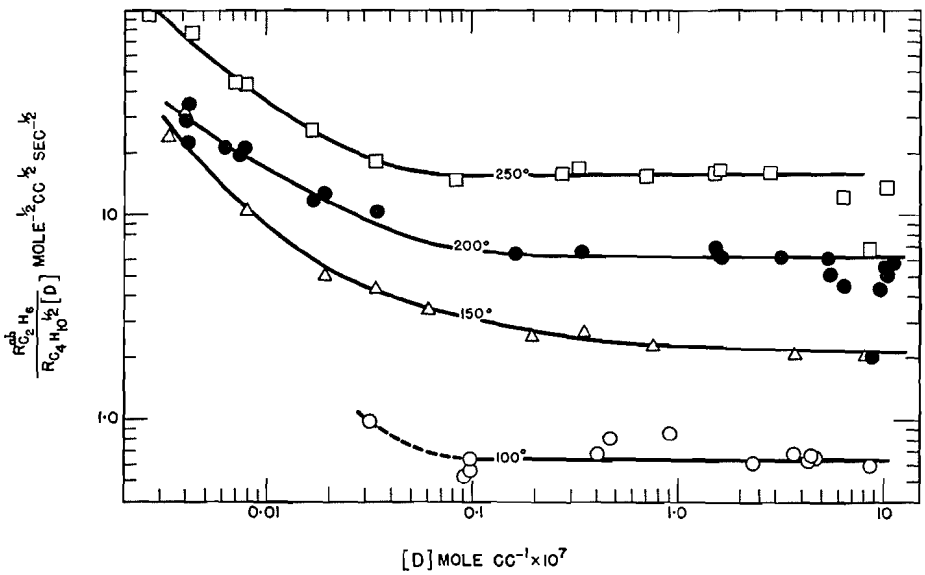

FIG. 4. Plot of $R^{ab}_{C_2H_6}/R^{\frac{1}{2}}_{C_4H_{10}}[D]$ vs. [D].

trend except for the experiments at the highest pressures in which the absorbed intensity was low. A possible explanation of this deviation has been given previously. The curves of Fig. 5 all show a decided increase in the low pressure region where they should be essentially constant if they were to behave as predicted by equation [II]. The dotted curve of Fig. 5 indicates that the data obtained at 200° in the cell with the increased surface area deviate to a still greater extent. It is evident that some heterogeneous reaction is affecting the variables of equations [I] and [II] in the low pressure region. How much of the total defect in the low pressure values of equation [I] from the high pressure value of $R^{ab}_{C_2H_6}/R^{\frac{1}{2}}_{C_4H_{10}}[D]$ is due to surface effects and how much is due to a third body deactivation anomaly is difficult to assess by this treatment. It seems significant that the minima in the curves of Fig. 5 occur at lower pressures (*ca.* 0.1 mm.) than do the corresponding ones (0.5–2 mm.) for the photo-

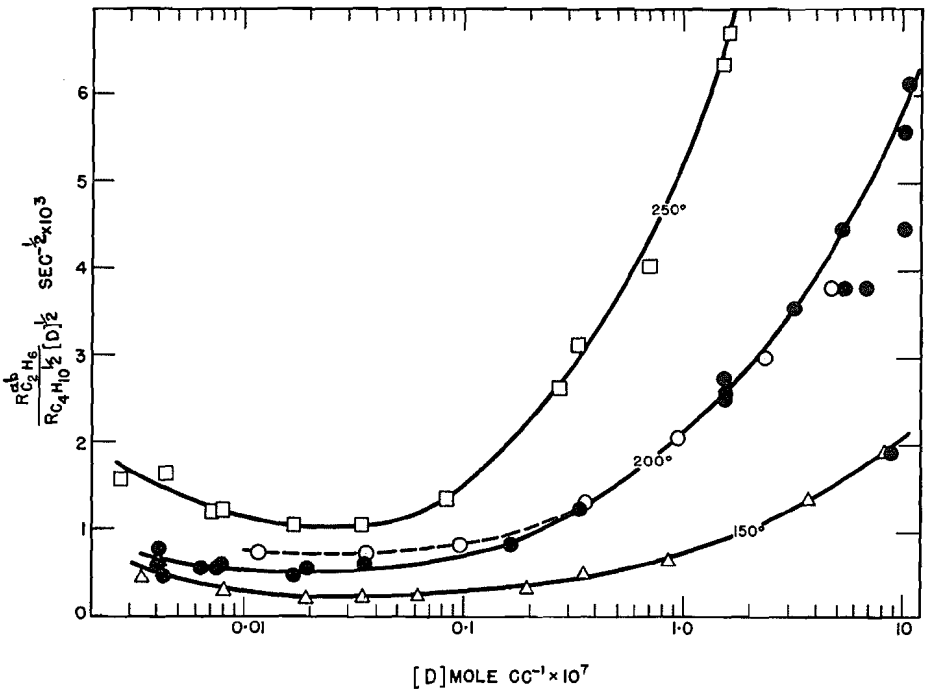

FIG. 5. Plot of $R^{ab}_{C_2H_6}/R^{\frac{1}{2}}_{C_4H_{10}}[D]^{\frac{1}{2}}$ vs. [D].

lysis of acetone given by Ausloos and Steacie (1). Since the influence of a heterogeneous reaction should not be appreciably different for the two ketones, the minima at lower pressures in the case of diethyl ketone could well indicate a much smaller third body effect.

A less complex and seemingly more meaningful treatment of the third body effect in the case of diethyl ketone is to compare the rate of disproportionation to the rate of combination. Although the reactants are identical in the two reactions it will be assumed that the two reaction intermediates differ and that the complex for the disproportionation reaction is not influenced by a third body effect. The disproportionation scheme will be

$$2C_2H_5 \xrightarrow{k_\alpha} C_4H_{10}^{**}$$

$$C_4H_{10}^{**} \xrightarrow{k_\beta} 2C_2H_5 \qquad R^{dp}_{C_2H_4} = [k_\alpha k_\gamma/(k_\beta+k_\gamma)]\,[C_2H_5]^2$$

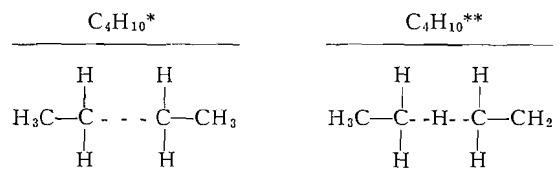
$$C_4H_{10}^{**} \xrightarrow{k_\gamma} C_2H_4+C_2H_6$$

If this latter rate is combined with the expression already derived for the third body mechanism for butane formation, the rate of disproportionation to combination becomes

$$\frac{R^{dp}_{C_2H_4}}{R_{C_4H_{10}}} = \frac{k_\alpha k_\gamma/(k_\beta+k_\gamma)}{k_a k_c[D]/(k_b+k_c[D])}.$$

Since it has been found that this ratio is 0.12 independent of experimental conditions, it must be true that $[M]k_c \gg k_b$ or that the combination reaction is not showing a dependency on a third body deactivation down to pressures as low as 0.01 mm.

It is necessary to substantiate the two postulates made in the previous discussion: (*a*) the reaction intermediates of the disproportionation and combination reactions differ, and (*b*) the disproportionation complex will not be third body dependent. The two complexes may be represented as



These same complexes were postulated by Wijnen and Steacie (14) to explain the composition of the various deuterated ethylenes formed in the photolysis of 2,2′4,4′ tetradeuterodiethyl ketone. Their evidence strongly supports a "head to head" intermediate for the combination and a "head to toe" intermediate for the disproportionation.

A consideration of the possible fates of the two complexes and the energetics involved leads to the conclusion that they should have very different response to a collisional deactivation. The combination of two ethyl radicals to form C_4H_{10}* produces a molecule essentially of the butane configuration which is "hot" by about 80 kcal./mole compared to the final butane product. If the possibilities of H atom rearrangements are ruled out as seems to be the case from Wijnen and Steacie's results (14), the only possible reactions available for C_4H_{10}* are deactivation by collision and dissociation into the original ethyl radicals. The C_4H_{10}** complex, on the other hand, cannot be deactivated to a stable molecule without an H atom shift. In addition the complex is not as "hot" as is C_4H_{10}* when it is compared to its end products, C_2H_4 and C_2H_6 ($2C_2H_5 \rightarrow C_2H_4+C_2H_6$, $\Delta H = -59$ kcal./mole). Most important, however, is the ability of the two product fragments of almost equal mass to distribute this excess energy between them so that the 30 kcal./mole carried by each product is far below that necessary to decompose either the ethylene or ethane.

A further test of the role of a third body was attempted by adding perfluorodimethyl cyclohexane to the reaction system. This gas was chosen because (*a*) its physical characteristics allowed an easy separation from the products of the photolysis, (*b*) it was transparent to the radiation used in the photolysis, (*c*) it was inert to the various radicals formed in the photolysis, and (*d*) the data of Dodd and Steacie indicated that its efficiency as a third body was quite high. Runs were made at 200° and 250° using essentially constant intensity and ketone concentration but with varying amounts of C_8F_{16} added. Experimental data and various calculated parameters for these runs are given in Table III. The most significant and unexpected result of the experiments was the increase in $R^{\text{total}}_{C_2H_4}/R_{C_4H_{10}}$ with an increase in C_8F_{16} concentration. Inas-

much as the formation of butane would not be expected to be made less favorable by an added gas, the increase in the ratio must be attributed to an enhanced C_2H_4 formation. It seems likely that the unimolecular pentanonyl radical decomposition, reaction [7], is in its pressure dependent region at 0.02 mm. of diethyl ketone. Addition of C_8F_{16} must aid in the deactivation of the pentanonyl reaction complex thus increasing the C_2H_4 formation.

Values of $R^{ab}_{C_2H_6}/R^{\frac{1}{2}}_{C_4H_{10}}[D]$ in the last column of Table III, although not constant to a high degree of precision, show no trend with increasing C_8F_{16} concentration. The poorer agreement between the values is compatible with the difficulty of analyzing for the photolysis products contained in the very large amounts of added C_8F_{16}. The lack of any appreciable effect of even high C_8F_{16} concentrations on $R^{ab}_{C_2H_6}/R^{\frac{1}{2}}_{C_4H_{10}}[D]$ may substantiate the independence of the ethyl radical combination to pressure. Unfortunately this latter evidence is complicated by the unevaluated effect of the added gas on the heterogeneous formation of ethane. It might be expected that the greater gas concentration would reduce the rate of radical diffusion to the wall and in addition perhaps reduce the concentration of adsorbed substrate. Since both these effects would tend to decrease the heterogeneous ethane formation it is surprising that the values in the last column of Table III do not decrease at the high C_8F_{16} concentrations.

NOTE

A FURTHER OBSERVATION ON THE BIOGENESIS OF HYOSCYAMINE[1]

By Léo Marion and Alan F. Thomas[2]

It has been shown previously that in mature *Datura stramonium* plants putrescine is not involved in the formation of either hyoscine or hyoscyamine (3), and that ornithine is a precursor of hyoscyamine but not of hyoscine (7, 8). This fact has been interpreted as implying a different mode of formation for the two alkaloids (8), although the conclusion that hyoscine is no longer synthesized in the mature plant, while hyoscyamine is, is equally plausible (cf. 12).

In all cases of nitrogen methylation in plants studied so far methionine has always been found to act as a precursor of the methyl groups (1, 2, 4, 9) although formate and choline did not always perform that role (4, 9). Therefore, it appeared legitimate to assume that in *D. stramonium* methionine would perform the same function. On feeding C^{14}-methyl-labelled methionine to mature *D. stramonium*, both hyoscyamine and hyoscine should be radioactive because of the presence of an $N—C^{14}H_3$ group in each, if both alkaloids were still being synthesized, albeit by different pathways. On the other hand, were hyoscine no longer synthesized at the time of the experiment, then only the hyoscyamine should be radioactive.

It has now been found that when C^{14}-methyl-labelled methionine was fed to the mature plant and the alkaloids isolated, only the hyoscyamine but not the hyoscine was radioactive. There seems to be little doubt, therefore, that as stated by Trautner (12) hyoscine is formed at a comparatively early stage in the development of the plant, after which hyoscyamine is formed exclusively. Although it is possible that hyoscine could be synthesized from a different precursor, the fact that this base is no longer produced in the mature plant accounts for the failure of ornithine-2-C^{14} to give rise at this stage to radioactive hyoscine (7, 8).

Very recently, in a study of the metabolism of glycine-2-C^{14} in vigorously growing *D. ferox*, Evans and Partridge (6) found that both hyoscine and meteloidine were radioactive, but also they observed that the labelling of the alkaloids varied significantly with the state of maturity of the plant.

In reporting the results of previous experiments on feeding ornithine-2-C^{14} to *D. stramonium*, the radioactivity of the amino acid fraction obtained from the plant extract was assumed to be due to the presence of excess labelled ornithine (8). Examination of this fraction has now revealed that it contained practically no ornithine, and hence the radioactivity of this fraction must be attributed to other amino acids arising from the metabolism of ornithine.

EXPERIMENTAL

dl-C^{14}-Methionine prepared from *dl*-homocysteine according to the method of Melville, Rachele, and Keller (10) had an activity of 1.07×10^7 counts per

min. per mgm. (1.59×10^9 counts per min. per millimole); and 74 mgm. was fed to a mature *D. stramonium* plant as described previously (3). The methionine was rapidly taken up by the plant, over 90% having been absorbed in four days at which time it was harvested. The radioactivity then was distributed as follows in counts per min. per mgm. (before drying): roots, 1000; leaves, 9; seeds, 4. The whole plant was dried at 100° in an oven for 48 hr., and the crude alkaloids isolated as described already (8). To the crude mixture of alkaloids 250 mgm. each of hyoscine and hyoscyamine was added and the mixture was dissolved in ether. The total activity of the crude solution at this stage was 6.34×10^6 counts per min. (i.e. *ca.* 1% of the total activity administered). Separation of the alkaloids was effected by chromatography on a kieselguhr column as described by Evans and Partridge (5) since the method previously used (8, 11) was found to be unreliable. The alkaloids were purified finally by recrystallization of the aurichlorides to constant activity. Hyoscyamine was found to have an activity of 5.8×10^4 counts per min. per millimole, while that of hyoscine, although faintly positive at first, had dropped to zero after three recrystallizations from water.

The N-methyl group was eliminated from the hyoscyamine in a Herzig-Meyer determination, the reaction being carried out as described by Dubeck and Kirkwood (4) up to the precipitation of the tetramethylammonium reineckate. The precipitate was dissolved in acetone and chromatographed on alumina which retained the impurities while the tetramethylammonium reineckate passed through the column. The solution was concentrated under reduced pressure at room temperature and diluted with water. The salt crystallized as pale pink leaflets, m.p. 288–289° (decomp.). Its activity was 5.4×10^4 counts per min. per millimole.

As reported previously (8), *D. stramonium* fed with C^{14}-labelled ornithine yielded when extracted, besides labelled hyoscyamine, a radioactive amino acid fraction. This fraction has now been examined further by two-dimensional paper chromatography. It was found to contain mainly the following free amino acids: asparagine, glycine, alanine, proline (trace), methionine, and aspartic acid. Neither ornithine nor glutamic acid was present in appreciable concentration.
